In a first assay (treatment A1), the extraction process was performed following the MERCOSUR Regulations [22], which indicate that distilled water should be used as food-simulating liquid for plastic containers to be used with milk. The regulation also indicates that the samples tested have to complete a final contact surface of 600 cm^2. For this reason, three new baby bottles filled up to 250 mL were used in each experiment. They were filled with boiling distilled water and kept in contact at 100 °C at atmospheric pressure for 30 min. The extract was cooled at room temperature, completed to volume with distilled water (for loss due to evaporation), and then a 300-mL aliquot was mixed with 2.0 mL of 30:70 methanol:water. Four sorbent beads were put in contact with this mixture in a stainless steel basket under convection for 1 h. The beads were then dried with tissue paper and put in contact with 4.0 mL of 60:40 isopropanol:methanol in a tube with cap under agitation at 30 °C in a thermostated bath to extract BPA for HPLC analysis. For recovery experiments the water extract was spiked with BPA standard by replacing 2.0 mL of 30:70 methanol:water by 2.0 mL of 0.400 mg L^{-1} BPA standard in the same solvent and thus making a 2.65 μg L^{-1} BPA spike (final concentration of 0.200 mg L^{-1} in the alcoholic extract). The analysis of the sample with and without the BPA spike was carried out in triplicate.

A blank was carried out with 300 mL of distilled water instead of the extract.

The beads were washed three times with 4.0 mL of 60:40 isopropanol:methanol for reutilization.

A comparison of the retention behaviour of BPA was made with Oasis HLB cartridges of 200 mg (60 μm particle size, purchased from Waters) after pretreatment with methanol and pure water. A 300-mL aliquot of the extract and another sample of distilled water spiked with 1.67 μg L^{-1} of BPA were, respectively loaded on the solid phase column at 3 mL min^{-1}. Each sample was eluted with 4.0 mL of 60:40 isopropanol:methanol. The analyses of both the extract and the water spiked with BPA were carried out in triplicate.

Then three used baby bottles were rinsed with distilled water and the extraction procedure was repeated (treatment A2). They were then subjected to 10 cycles of simulated use by boiling for 10 min in tap water and washing with a brush, after which the migration assay was repeated (treatment A3).

In order to validate the method, other treatments and liquids were used on new baby bottles. Tap water 1 from the laboratory with pH 6.9 and 59 mg L^{-1} of total alkalinity was kept in contact with the bottles for 10 min at 100 °C in treatment B. Tap water 2 with pH 7.6 and 499 mg L^{-1} of total alkalinity was kept in contact with the bottles for 10 min at 100 °C in treatment C, and the sample was diluted 5-fold with recently distilled water (pH 7.0) for preconcentration. A blank was carried out with 300 mL of each tap water instead of the extract, and BPA was not detected.

In treatment D, distilled water was kept in contact with new bottles for 30 min at 100 °C and was then spiked with 1.2 μg L^{-1} (8.0 nmol L^{-1}) methylparaben, 1.2 μg L^{-1} (6.9 nmol L^{-1}) propylparaben, 5.3 μg L^{-1} (57 nmol L^{-1}) phenol and 0.2 μg L^{-1} (1 nmol L^{-1}) diethyl phthalate.

In treatments B, C and D, the analysis of each sample was carried out in triplicate. The recovery figures for a 2.65 μg L^{-1} BPA spike were obtained in triplicate in treatments C and D.

3. Results and discussion

3.1. Characterization of the poly(EGDE–MAA–2MIH$^+$)–DS complex

Fig. 1 exhibits the FTIR spectra for the polyampholyte, SDS and the polyampholyte–DS complex. The results show a clear evidence of dodecyl sulfate (DS) adsorption on the surface of the poly(EGDE–MAA–2MIH$^+$). The polymer bands previously reported [16] were: 1730 cm^{-1} (carbonyl symmetric stretching); 1570 cm^{-1} (carboxylate asymmetric stretching); 1640 (C=C and/or C=N stretching vibrations), 750 and 670 cm^{-1} (2-methylimidazole ring stretching); 1450 cm^{-1} (C=C and/or C=N stretching vibrations

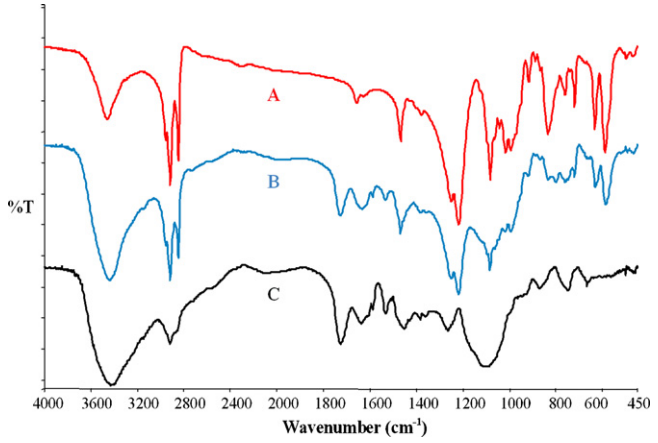

Fig. 1. FTIR spectra for SDS (A), the poly(EGDE–MAA–2MIH$^+$)–DS complex (B) and poly(EGDE–MAA–2MIH$^+$) (C).

and ether groups); 1100 cm^{-1} (ether groups); 2930 cm^{-1} (C–H) and 3435 cm^{-1} (O–H). The main signals for SDS were: 1469 and 1220 cm^{-1} (SO_2 stretching); 1253 and 1185 cm^{-1} (asymmetric and symmetric stretching of $ROSO_3Na$); 837 and 760 cm^{-1} (asymmetric and symmetric stretching of S–O–C); 635 and 591 cm^{-1} (SO_3 flexion).

In the FTIR spectrum of the polyampholyte–DS complex strong bands related to DS appeared at 2950, 1230, 635 and 591 cm^{-1}, and the bands associated with the polyampholyte network were weaker.

The ^{13}C CP-MAS signals for SDS were assigned tentatively according to the results reported by Ferruglio and co-workers in solution [23], and those for the polyampholyte were assigned as previously reported [18] (Fig. 2). The solid-state results indicate that important changes in the chemical environment occurred upon sorption with the DS surfactant. Fig. 3 clearly shows the effects on the chemical shifts associated with the carbons 3–9 of the DS molecule and for the signals of the carbons near the positive sites of the disubstituted imidazole ring in the polymer (C3, C4 and C6).

The thermogravimetric curves (TG and DTG) for the polymer and the polyampholyte–DS complex are shown in Fig. 4. The thermal

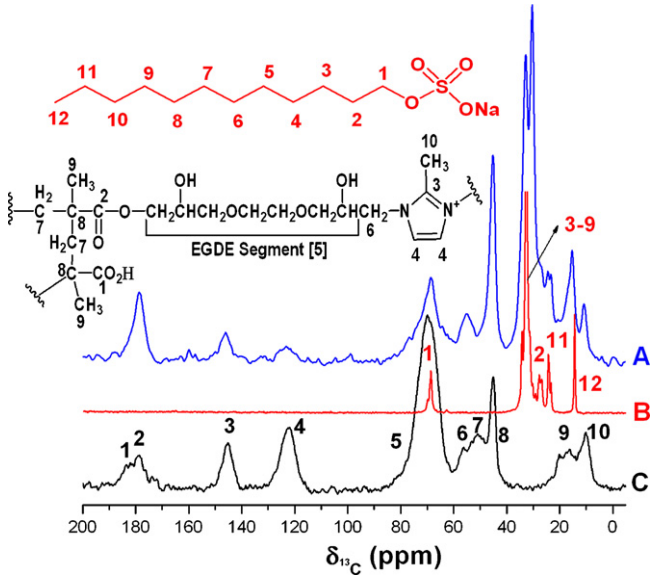

Fig. 2. Solid-state ^{13}C spectra for the poly(EGDE–MAA–2MIH$^+$)–DS complex (A), SDS (B) and poly(EGDE–MAA–2MI) (C). Operating frequency: 75.46 MHz. Spinning rate: 10 kHz.

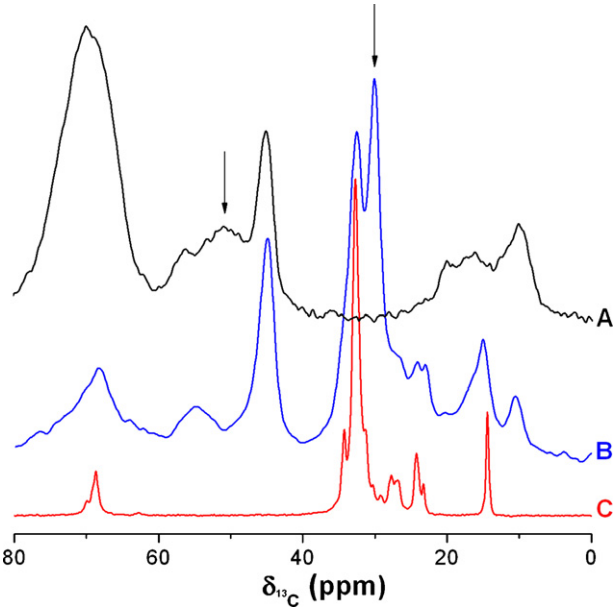

Fig. 3. Changes in the ^{13}C chemical shift for poly(EGDE–MAA–2MI) (A), the poly(EGDE–MAA–2MIH$^+$)–DS complex (B) and SDS (C).

behaviour of this kind of polymer matrixes has been previously studied [18]. The results showed an initial loss of weight due to the evaporation of water in the complex. Also, the anionic surfactant interacted electrostatically and hydrophobically through the $ROSO_3^-$ group and the hydrocarbon chain with the polymer backbone, respectively. The most important interaction was located between the positive charges of the imidazolium units and the disubstituted imidazole ring of the matrix with the negative domain of the DS [18,24]. That association produced the low thermal stability of the complex against the polyampholyte matrix and partial degradation of the DS molecules, as a consequence of the disruption in the electronic density in the polymer backbone with the concomitant weakness of the chemical bonds [18].

The scanning electron microscopy (SEM) images exhibit the modifications produced by the DS adsorption on the polyampholyte particles. This coverage had left rows of macropores with an average diameter of 85 nm, sharing the same direction over a restricted region (Fig. 5).

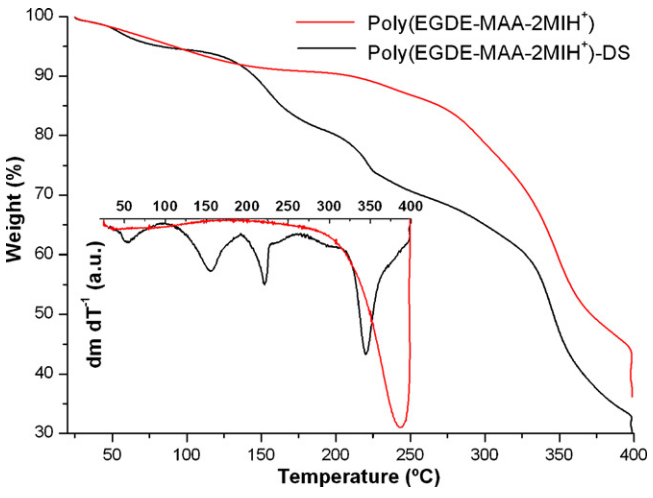

Fig. 4. TG and DTG curves for poly(EGDE–MAA–2MI) and the poly(EGDE–MAA–2MIH$^+$)–DS complex. Heating rate: 10 °C min^{-1}. Operating under nitrogen flux. Sample size: 10 mg.

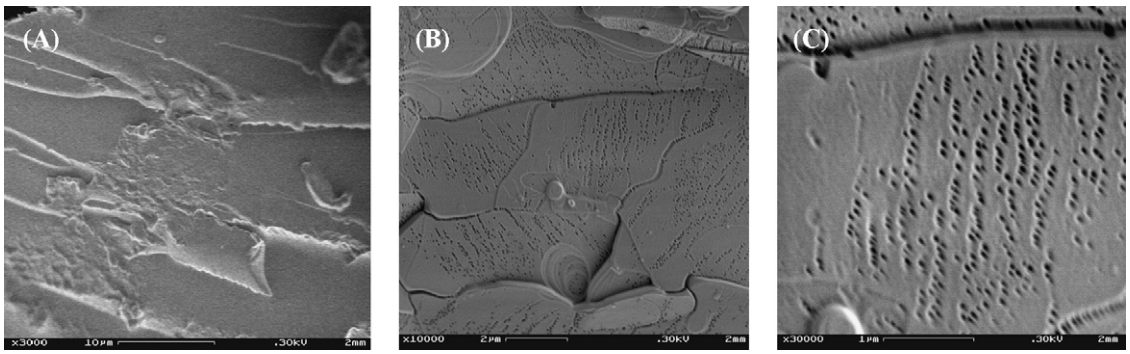

Fig. 5. SEM images for poly(EGDE–MAA–2MIH$^+$) (A), the poly(EGDE–MAA–2MIH$^+$)–DS complex (B) and the poly(EGDE–MAA–2MIH$^+$)–DS complex with magnification (C). Acceleration voltage: 0.3 kV.

The average nanopore width and the equivalent specific surface area obtained from the nitrogen adsorption isotherm were 36.8 Å and 3.04 $m^2\,g^{-1}$, respectively (the value for the polymer without DS is 0.6 $m^2\,g^{-1}$). These results were consistent with an increase in the specific surface area as a consequence of the increase in the hydrophobic segments from the interaction with DS.

3.2. Surfactant uptake

Kinetics and equilibrium studies were carried out with SDBS instead of SDS.

The results of the kinetics studies indicated that the binding equilibrium was reached in 5 min under forced convection at 20 °C.

The binding isotherm of dodecyl benzenesulfonate (DBS) to poly(EGDE–MAA–2MIH$^+$) is exhibited in Fig. 6. The experimental data fitted properly with Langmuir model with a regression coefficient (R) of 0.9911, a maximum loading capacity estimated in 1.5 ± 0.2 mmol g^{-1} (0.54 ± 0.07 g DBS g^{-1}) and a dissociation constant of $2.1 \pm 0.5 \times 10^{-3}$. This well-known model is based on the interaction of a ligand and a finite number of active sites available on the sorbent surface. In this case the nature of the interaction is mainly electrostatic: the ligand provides a negative charge and the polyampholyte presents regions of positive charge in protoned 2-methylimidazole terminal residues together with fixed positive charges in disubstituted 2-methylimidazole [16,17]. A hydrophobic interaction between the hydrocarbon chain of DS and the polymer backbone may take place to a lesser extent.

Even if the initial concentration of SDBS in the experiment in most of the experimental points of the isotherm was above the CMC, the interaction with the polymer was well described by Langmuir model, involving the uptake of one DBS molecule per site.

Then, a second binding experiment was performed as described in Section 2.2, using high amounts of SDS and SBDS. The elemental analysis of poly(EGDE–MAA–2MIH$^+$)–DS gave 4.992% of sulfur, equivalent to 1.557 mmol DS per gram of complex and 2.653 mmol DS per gram of polyampholyte. In the same way, 0.66 g of DBS (1.9 mmol) per gram of polyampholyte were adsorbed in this experiment, an amount higher than the binding predicted by Langmuir model. These results led us to conclude that some degree of aggregation took place, as expected for the interaction of polymers with surfactants [21]. Here, the concentration of the surfactant was far above the CMC, so an equilibrium between free micelles and the micelles bound to the polyampholyte must be taken into account.

3.3. Studies of interaction between the complex and bisphenol-A (BPA)

Poly(EGDE–MAA–2MIH$^+$)–DS was prepared following the procedure described in Section 2.2. Under that treatment, the polyampholyte was assumed to adsorb individual DS molecules to a larger extent and DS micelles.

The results of the kinetic experiments of BPA uptake are presented in Fig. 7. These results fit well with a first-order empiric model (R, 0.9962):

$$[\mathrm{BPA}] = [\mathrm{BPA}]_\infty + [\mathrm{BPA}]_b \times e^{-k \times t} \quad (1)$$

where $[\mathrm{BPA}]_\infty$ is the free amount in equilibrium, $[\mathrm{BPA}]_b$ the total amount of BPA withdrawn from the solution by sorption

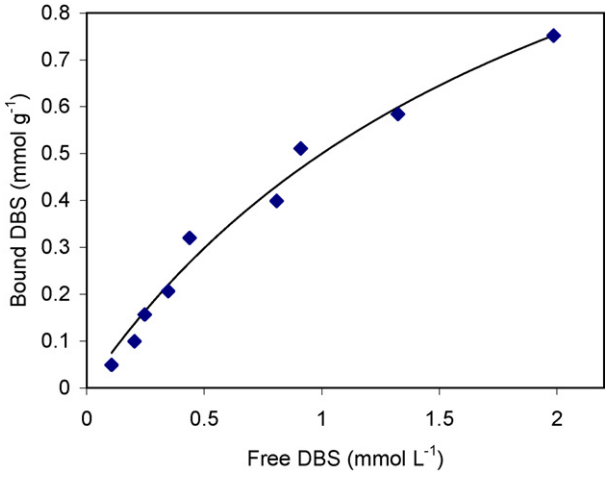

Fig. 6. Adsorption isotherm of DBS to poly(EGDE–MAA–2MIH$^+$). DBS concentration range: 0.2–8.0 mmol L^{-1}. Temperature: 20.0 ± 0.5 °C.

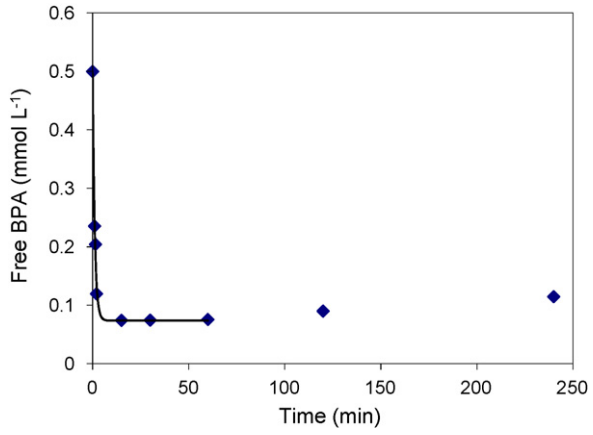

Fig. 7. Concentration of BPA for the solution in contact with poly(EGDE–MAA–2MIH$^+$)–DS as a function of time. Weight of the complex: 50 mg. Initial BPA concentration: 114 mg L^{-1} (500 μmol L^{-1}); solution volume: 125 mL; medium: 10:90 methanol:water.

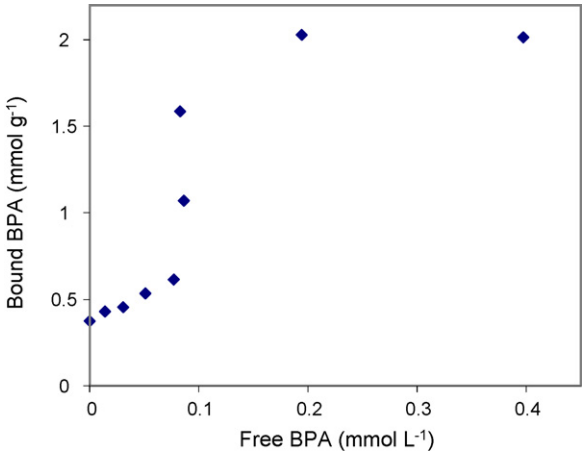

Fig. 8. Sorption isotherm of BPA to poly(EGDE–MAA–2MIH$^+$)–DS. Weight of the complex: 40 mg. BPA concentration range: 75–800 μmol L^{-1}; sample volume: 200 mL; medium: 10:90 methanol:water. Temperature: 20.0 ± 0.5 °C.

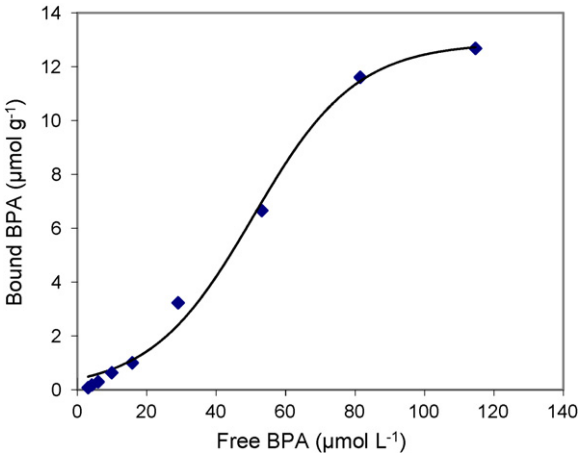

Fig. 9. Adsorption isotherm of BPA to poly(EGDE–MAA–2MIH$^+$). Polymer weight: 200 mg. BPA concentration range: 3.7–216 μmol L^{-1}; aqueous sample volume: 25 mL. Temperature: 20.0 ± 0.5 °C.

to the matrix, and k the pseudo first-order kinetic constant for the decrease in BPA in solution. The estimated parameters were: $[BPA]_\infty$: 7.38×10^{-5} mol L^{-1} (σ_{n-1}: 9.4×10^{-6}); $[BPA]_b$: 4.26×10^{-4} mol L^{-1} (σ_{n-1}: 1.9×10^{-5}); k: 0.929 min^{-1} (σ_{n-1}: 0.081).

This model properly describes the behaviour of this system for the first hour of contact between the matrix and the BPA solution. After this, a slow increase in BPA in solution was observed and attributed to the desorption of DS micelles from the polyampholyte surface. The contact time for BPA preconcentration on the polyampholyte–DS complex surface was then set in 60 min.

The results for BPA binding equilibrium gave a type-H4 isotherm (Fig. 8) in the classification of Giles et al. [25]. In this case the solute has such high affinity for the matrix that it was completely bound or there was no free measurable amount in equilibrium in diluted solutions (below 0.1 mmol L^{-1}). The first plateau corresponds to the formation of the first "monolayer". One possible mechanism for solute–sorbent interaction is hydrogen bonding between hydroxyl groups from BPA and the hydroxyl and carboxylic groups on the polyampholyte surface, forming isolated clusters of BPA molecules on the most active sites. Another possible mechanism of sorption is the partition of BPA into the hydrophobic environment of the hydrocarbon chains electrostatically bound to the polyampholyte. These simultaneous mechanisms would account for the complete solute uptake at low concentration levels. Electrostatic attraction is discarded under this experimental condition since BPA is expected to be neutral.

At total BPA concentrations above 0.2 mmol L^{-1} there was a sharp increase in sorption, indicating a complete saturation of the active surface of the polymer. In this second step, the solute molecules could be partitioned in the DS micelles sorbed on the polymer, and hydrogen bonding between BPA molecules on the sorbent could also be considered. The amount of BPA bound in the first step was 0.450 mmol g^{-1} (103 mg), and that in the second step 2.02 mmol g^{-1} (461 mg), representing a significantly high loading capacity for this new matrix as compared with other sorbents [14,15,26]. Then, in conditions of saturation, 2.02 mmol BPA can be bound to a gram of complex that contains 2.653 mmol of DS.

These results were compared with the isotherm for BPA adsorption on the polyampholyte without DS (Fig. 9). In this case, a sigmoidal or S-type isotherm was obtained with an R of 0.9975 for non-linear regression. This indicates cooperative adsorption, meaning that at low concentrations of BPA the interaction is weak but the adsorption becomes easier as the concentration of BPA increases. This behaviour is expected when the solute molecule is adsorbed as a single unit (not a micelle), has a moderate degree of intermolecular attraction by π–π interaction (which determines a vertical orientation in a regular arrangement), and presents strong competition with water for active sites on the surface of the polyampholyte [25]. In this case, BPA probably interacts by hydrogen bonding with carboxylic groups and the hydroxyl groups on the network resulting from the epoxide opening. Hydrogen bonding between BPA molecules could contribute to sorption at high solute concentrations.

The modification of the polyampholyte surface with DS significantly improved the uptake of BPA. The maximum binding capacity of the complex (2.02 mmol g^{-1}) was 160 times higher than the value observed for the polyampholyte (12.9 ± 0.5 μmol g^{-1}). When the concentration of BPA was lower than 100 μmol L^{-1}, a complete uptake of BPA on the complex was observed.

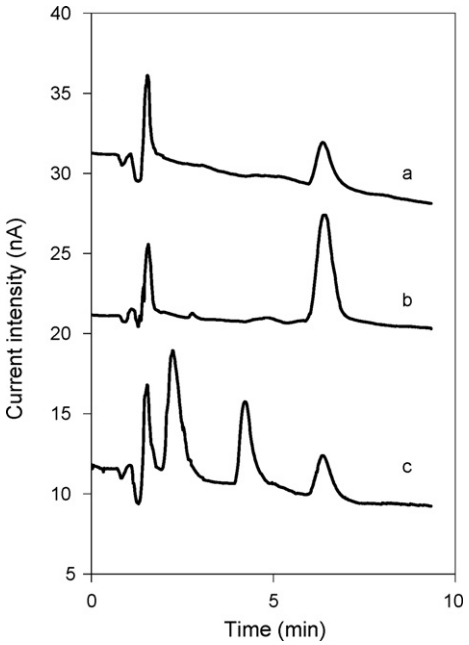

Fig. 10. Chromatograms of the sample in treatment A1 (a), the sample in treatment A1 with spiking of 0.200 mg L^{-1} BPA (final concentration in alcoholic extract) (b) and the sample in treatment D (c). Mobile phase: 55:45 methanol:aqueous solution of 10 mmol L^{-1} KNO_3 and 0.25 mmol L^{-1} H_2SO_4. Injection volume: 20 μL. Flow rate: 0.8 mL min^{-1}. Electrode potential: +1 V vs. Ag/AgCl.

Table 1
BPA concentration in extracts from baby bottles.

Sample treatment for extraction of BPA	BPA in extracts ($\mu g\,L^{-1}$)	Recovery[a] (%)
(A1) Distilled water at 100 °C for 30 min	1.70 (σ_{n-1}: 0.09)	96 (σ_{n-1}: 4)
(A2) Second sequence (after rinsing)	0.52	–
(A3) Third sequence (after 10 cycles of boiling for 10 min with tap water 1 and brushing)	3.6	–
(B) Tap water 1 at 100 °C for 10 min	3.7 (σ_{n-1}: 0.1)	–
(C) Tap water 2 at 100 °C for 10 min	9.1 (σ_{n-1}: 0.2)	95 (σ_{n-1}: 5)
(D) Distilled water at 100 °C for 30 min, and then spiking with other pollutants	1.7 (σ_{n-1}: 0.1)	98 (σ_{n-1}: 5)

[a] Recovery from a 2.65 $\mu g\,L^{-1}$ BPA spike.

3.4. Preconcentration and analysis of BPA released from baby bottles

The HPLC-ED system presented linearity for BPA tested in a concentration range up to 0.500 mg L^{-1} with a sensitivity of 667 nCoulombs L mg^{-1} (σ_{n-1}: 10) and a correlation coefficient of 0.9986. The repeatability of the technique was also good as the relative standard deviation for the standard BPA replicates of each concentration level was less than 4%.

The instrumental detection and quantification limits of the technique were 10 and 35 $\mu g\,L^{-1}$, respectively, and the preconcentration step allowed lowering the limits of the method to 0.14 and to 0.46 $\mu g\,L^{-1}$, respectively.

The new material was used as solid phase for preconcentration of BPA released by polycarbonate baby bottles to food-simulating liquids. The extraction sorbent was prepared by including poly(EGDE–MAA–2MIH$^+$)–DS in agarose gel as described in Section 2.6. Several sample treatments were carried out.

The first migration assay was performed following the MERCOSUR Regulations [22], using distilled water at 100 °C for 30 min as food simulant for milk (treatment A1). The BPA in the simulant was preconcentrated on the new sorbent and released to the alcoholic mixture for analysis by HPLC-ED. Fig. 10 shows the chromatogram of the sample (a) and the sample spiked with BPA in a final concentration of 0.200 mg L^{-1} (b). The retention time for BPA was 5.6 min and the released BPA was 2.1 ng cm^{-2} (σ_{n-1}: 0.1) using the new phase, and 2.3 ng cm^{-2} (σ_{n-1}: 0.1) using Oasis HLB phase for preconcentration. The amounts were in the same order as the results obtained by evaporation of the simulant liquid as strategy for preconcentration [27], and lower than the SML established by the Mercosur (4.8 $\mu g\,cm^{-2}$) [22] or the SML established by the EU Commission (750 ng cm^{-2}).

Table 1 presents the concentrations of BPA found in the food simulants and the recoveries for the 2.65 $\mu g\,L^{-1}$ BPA spike (final concentration of 0.200 mg L^{-1} in the alcoholic extract). The recovery of BPA with treatment A1 was 96% (σ_{n-1}: 4) with the new sorbent for a 2.65 $\mu g\,L^{-1}$ BPA spike, and 97% (σ_{n-1}: 4) with Oasis HLB for a 1.67 $\mu g\,L^{-1}$ BPA spike, indicating that the performance of the new matrix is good in comparison with the best sorbent [1,12].

The particularly high loading capacity of this new phase allowed the detection of released BPA by an amperometric technique with a relatively high LoD (10 $\mu g\,L^{-1}$) [1].

The sorbent beads were reused twice with new baby bottles and the relative difference between each replicate and the mean value found for BPA was lower than 7%.

The release of BPA into hot distilled water diminished in a successive test [28] as observed with treatment A2 (Table 1). Then, with treatment A3, the same polycarbonate baby bottles were subjected to simulated use by boiling in tap water and brushing in order to create scratches on the inner surface and increase the wettability of the wall. This fact could have contributed to the deposit of residual limescale which further dissolved in the food stimulant and promoted the degradation of the polymer [29,30]. Table 1 exhibits the release of 3.6 $\mu g\,L^{-1}$ BPA from these aged baby bottles into distilled water kept at 100 °C for 30 min.

Biedermann-Brem and Grob [30] found that hot water at high pH degraded the polycarbonate causing an increase in the amount of the released BPA. In treatments B and C we used tap water of different pH and alkalinity as food simulants. Tap water 1 was kept boiling in the bottle for 10 min, the pH rose from 6.9 to 7.3 and 3.7 $\mu g\,L^{-1}$ of BPA were released after 10 min. With tap water 2, the pH rose from 7.6 to 8.1 by loss of carbon dioxide causing the hydrolysis of polycarbonate and the release of 9.1 $\mu g\,L^{-1}$ of BPA, as expected [30].

In treatment D, we repeated the migration test on new bottles with distilled water at 100 °C for 30 min, and then four organic pollutants (phenol, methylparaben, propylparaben and diethyl phthalate) were added to the water extract prior to the preconcentration step. Parabens are a homologous series of hydroxybenzoic acid esterified at the C-4 position used as an antimicrobial in foods, beverages, pharmaceuticals and cosmetics [31]. Phenol is usually present in polluted water samples. The phenolic compounds were uptaken together with BPA on the new phase and later detected electrochemically. Fig. 10 exhibits their signals in chromatogram c; phenol had a retention time of 1.4 min and parabens coeluted at 3.4 min. Diethyl phthalate is a plasticizer designed to increase the durability and flexibility of plastics. Since plasticizers are not chemically bound to the polymer they can leach from the plastic into the environment [32]. Even if diethyl phthalate was expected to be preconcentrated on the new adsorbent, it is not electroactive and was not detected at +1 V vs. Ag/AgCl. The preconcentration of BPA on the sorbents tested was not affected by the presence of other structurally similar compounds in the matrix at the same concentration level. The concentration of BPA released to the simulant in treatment D did not differ from treatment A1 and the recovery figures were optimal.

4. Conclusions

The surface of a synthetic polyampholyte was modified with a surfactant in order to change its chemical and physical properties. The new material, which combines hydrophobic domains with hydrophilic functionality, was exhaustively characterized by spectroscopic and microscopic techniques.

BPA was chosen as a model molecule of intermediate polarity to evaluate the efficiency of this matrix as a solid phase for extraction. The sorption of this analyte was significantly improved by the presence of a surfactant and was complete at low concentration levels. The particularly high loading capacity of this new phase allowed the detection of released BPA by an amperometric technique with a relatively high LoD. The new complex was tested with different food simulants (distilled water, tap water and a model solution containing phenolic pollutants and a plasticizer) and the recovery figures were optimal. The use of this encapsulated sorbent was simple, not expensive and adequate for this application.

ABSTRACT

The design and characterization of a new organic–inorganic hybrid composite material for glucose electrochemical sensing are described. This material is based on the entrapment of both gold nanoparticles (AuNPs) and glucose oxidase, which was chosen as a model, into a sol–gel matrix. The addition of spectroscopic grade graphite to this system, which confers conductivity, leads to the development of a material particularly attractive for electrochemical biosensor fabrication. The characterization of the hybrid composite material was performed using atomic force microscopy and scanning electron microscopy techniques. This composite material was applied to the determination of glucose in presence of hydroxymethylferrocene as a redox mediator. The system exhibits a clear electrocatalytic activity towards glucose, allowing its determination at 250 mV vs Ag/AgCl. The performance of the resulting enzyme biosensor was evaluated in terms of sensitivity, detection limit, linear response range, stability and accuracy. Finally, the enhancement of the analytical response of the resulting biosensor induced by the presence of gold nanoparticles was evaluated by comparison with a similar organic–inorganic hybrid composite material without AuNPs.

1. Introduction

Development of sensors based on enzyme immobilization onto transducer surfaces has become one of the most promising research areas in the field of bionanotechnology, mainly due to its potential applications in the development of analytical devices. In general, the retention of the enzymatic activity after the immobilization process is one of the most important issues in this field. The interaction between the enzyme and the solid surface can induce conformational changes in the adsorbed enzymes. The alteration of the three-dimensional conformation leads to a diminution of the catalytic activity and hinders the enzyme functionality.

During the last years, numerous works have been published concerning the use of the silica sol–gel technology as a strategy to preserve the catalytic activity of enzymes after the immobilization step [1–4]. In this sense, the polymeric network generated by sol–gel technology can be used as an adequate matrix [5,6] in which several compounds, including biological material, can be encapsulated through physical entrapment rather than by covalent bonding leading to a non aggressive approach. Particularly, the sol–gel network provides a biocompatible environment for enzyme protection exhibiting additional advantages such as simplicity of preparation, chemical inertness, high stability, physical rigidity, renewable surface and tuneable properties. The final properties of the sol–gel matrix play a key role in the biosensor performance and can be easily controlled by varying some parameters such as the precursor or the preparation conditions (pH, ratio of compounds, etc). Various precursors have been reported in the literature for the preparation of the sol–gel network, but among them the most used for enzyme encapsulation are oxysilanes such as methyltrimethoxysilane (MTMOS), tetramethoxysilane (TMOS), 3-aminopropyltriethoxysilane (APTOS) and tetraethoxysilane (TEOS) [7–12].

Recently, the integration of nanomaterials into (bio)sensors has become an attractive method for improving the properties of the resulting analytical device. From a practical point of view, gold nanoparticles (AuNPs) are widely used due to their interesting physicochemical properties, which are essentially different to those of bulk gold [13]. In particular, several works have demonstrated that AuNPs exhibit highly attractive catalytic properties toward several compounds in solution indicating an enhancement of the electrical communication with the electrode surface [14,15]. Other key properties of AuNPs are their large surface area in

conjunction with an excellent biocompatibility. Both characteristics make this nanomaterial suitable to immobilize biomolecules, particularly enzymes, allowing the retention of the biological activity for a long period of time. Since the recognition of the use of nanoparticles is a versatile strategy for biomolecules immobilization [16], a great interest has been addressed to the development of biosensors based on AuNPs as a strategy of improving the biosensor performance [17].

In the present work we describe the preparation and characterization of a new organic–inorganic hybrid composite material from a three-dimensional silica polymer network, obtained by means of the sol–gel technology using tetraethoxysilane as precursor. This matrix provides an excellent network allowing the encapsulation of gold nanoparticles (AuNPs), a conductive material (graphite powder, C) and a biosensing molecule such as glucose oxidase (GOx), chosen as a model since it is a stable, inexpensive and well-studied enzyme. Moreover, GOx presents a wide range of applications in many fields such as biofuell cells [18] or clinical glucose determination [7,9,19,20]. The resulting hybrid materials were characterized by means of scanning electron microscopy (SEM) and atomic force microscopy (AFM) techniques. Both techniques allow obtaining information about not only the morphological properties of the surface but also about its compactness degree, homogeneity, rigidity and roughness. Finally, the analytical parameters of the resulting integrated glucose biosensor were studied.

2. Experimental

2.1. Reagents

Glucose oxidase (GOx, EC 1.1.3.4 from *Aspergillus niger*), lyophilized powder containing 15,200 U/g solid, was obtained from the Sigma Chemical Co. (St. Louis, MO). D-(+)-Glucose (99.5%) and Colloidal Gold (AuNPs, 20 nm particle size) were also purchased from Sigma Chemical Co. Tetraethoxysilane (TEOS), hydroxymethylferrocene (HMF, 97%) and polyethylene glycol (PEG, MW 400) were provided from Aldrich. Ultra pure spectroscopic graphite powder (C, particle size 50–50.3 μm) was from United Carbon Products Co. Inc. (Bay City, MI, USA). Other chemicals used in this work, such as sodium phosphate, acetaminophen, uric acid and ascorbic acid were reagent grade quality and used as received without additional purification steps. Sodium phosphate was employed for the preparation of buffer solutions (0.1 M, pH 7.0). Water was purified with a Millipore Milli-Q-System. All solutions were prepared just prior to use.

2.2. Experimental techniques

2.2.1. Scanning electron microscopy measurements

The scanning electron microscope was an ISI (DS-130C) operating at 40 kV. Measurements were carried out under high vacuum conditions.

2.2.2. Atomic force microscopy measurements

The atomic force microscope was a Nanoscope IIIa from Digital Instruments (DI, Santa Barbara, CA) used with D and J scanners (maximal scan range of ~14 μm and ~125 μm, respectively). Measurements were carried out in tapping-mode using Si cantilevers from Veeco. The samples were imaged with different cantilevers in order to ensure that the imaged structures were not due to tip artefacts. All measurements were carried out under ambient conditions.

2.2.3. Electrochemical measurements

All electrochemical measurements were performed on an Ecochemie Autolab PGSTAT12 system (Utrecht, The Netherlands). Experiments were carried out in an electrochemical cell with standard Teflon cover. All potentials are reported against a Ag/AgCl (Metrohm, 3.0 M KCl) reference electrode. The auxiliary electrode was a platinum wire and TEOS/GOx/C or TEOS/GOx/AuNPs/C composite electrodes were used as the working electrode. Cyclic voltammetry (CV) was the electrochemical technique applied to study the response of the composite electrodes in the presence of HMF (which acts as soluble mediator) and in the presence or absence of glucose. Solutions were deaerated with nitrogen gas before use, and the gas flow was kept over the solutions during experiments. Instrumental parameters were as follows: potential range from −0.1 V to 0.5 V and scan rate 10 mV s^{-1}.

2.3. Procedures

2.3.1. Sol–gel solution preparation

The sol–gel solution was prepared mixing 1.6 mL of TEOS with 1.0 mL of water and 200 μL of 0.1 M HCl. This solution was sonicated using an Ultrasons bath (P-Selecta) for 15 min at room temperature and stored overnight at 4 °C.

2.3.2. Activation of the graphite powder

The graphite powder used in the electrode preparation was previously activated by washing it with acetone, then with a mixture of HCl and HNO_3 (1:3) and finally with distilled water. The resulting paste was subsequently dried during 4 h at 400 °C [21].

2.3.3. Preparation of the biosensing organic–inorganic hybrid composite material

Two different kinds of biosensing organic–inorganic hybrid composite materials were prepared depending on the compounds encapsulated into the sol–gel three-dimensional network. The biosensing composite material denoted as TEOS/GOx/C was obtained by mixing 0.6 mL of the sol–gel solution with 0.4 g of graphite powder previously modified with enzyme. To obtain the glucose oxidase modified graphite, an amount of the conditioned graphite powder was mixed with GOx in phosphate buffer solution (PBS, pH 7) to adsorb the enzyme on the powder's surface after solvent evaporation (80 mg of GOx/0.5 g of graphite). This enzyme-modified graphite powder was allowed to dry for a week into a desiccator before being mixed with the sol–gel solution. The biosensing composite material including gold nanoparticles, denoted as TEOS/GOx/AuNPs/C, was prepared in a similar way, but using the gold colloidal solution (AuNPs, 20 nm average particle size) instead of water in the sol–gel solution preparation.

2.3.4. Electrode preparation procedure

The preparation of the electrode can be summarized as follows: 0.5 mL of the sol–gel solution was mixed with 0.4 g of graphite powder previously conditioned. The resulting inorganic composite material was packaged firmly into a glass body (15 mm large × 2 mm i.d.), leaving a little empty cavity (3 mm large × 2 mm i.d.) in one of the extremes. This was allowed to dry for five days at room temperature to achieve an adequate consistency. Subsequently, the little empty cavity was filled up tightly with the corresponding biosensing organic–inorganic hybrid composite material, leaving a little extra mixture sticking out of the tip to make easy the ulterior polishing step. Finally, a 0.5 mm diameter copper wire was inserted to the opposite extreme using silver tincture to establish the electrical contact and ensure the adhesion. The final electrode was allowed to dry for one day at room temperature and the surface was polished to remove any extra composite material, rinsed thoroughly with ultra pure water.

Before electrochemical measurements were made, electrode surfaces were conditioned by immersion during 2 h into 1 mM HMF

solution in PBS. This treatment avoids a posterior increment of the signal due to a mediator's adsorption.

3. Results and discussion

3.1. Optimization of parameters

As mentioned above, the first step involved in the preparation of the biosensing organic–inorganic hybrid composite material consists in a polymeric network generation by sol–gel technology, in which all the components integrating the biosensor will be subsequently encapsulated. The final properties of the resulting three-dimensional matrix depend strongly on both the chemical structure of the oxysilane precursor and the composition of the sol–gel solution. In this sense, two different silicon alcoxides (MTMOS and TEOS) were evaluated in order to study their influence on the final sol–gel properties. Among them, TEOS was selected as the most adequate because its use as precursor allows obtaining homogeneous sol–gel solutions without phase separation, relative short gelation times and adequate viscosity. Likewise, several volume ratios TEOS:H_2O were tested concluding that the optimal volume ratio TEOS:H_2O to reach the above requirements was 1.6:1.0. Under these conditions, the sol–gel process results in a homogeneous and transparent solution only under acid conditions using 200 μL of 0.1 M HCl as catalyser and ultrasonic agitation during 15 min. The obtained sol–gel solution is kept overnight at 4 °C and subsequently used to prepare the TEOS/GOx/C and TEOS/GOx/AuNPs/C composite electrodes. This preparation consists in thoroughly hand-mixing of the sol–gel solution with spectrographic graphite powder that is then allowed to gelify and to dry [21]. Different relations between graphite and sol–gel solution, unmodified and modified with GOx, were tested in order to obtain a uniform and suitable paste for its posterior packaging into the adequate electrode body. The optimal relation found were 0.4 g of graphite and 0.5 mL of sol–gel solution (0.8%, w/v), since the use of different ratios, 0.7% (w/v) and 0.5% (w/v), gives rise to a resulting paste whose consistency is not adequate for packaging into the glass tube. In the case of graphite modified with the enzyme, it was necessary to increase the volume of sol–gel solution up to 0.6 mL to ensure a good compactness, which is provided by the silicate continuum, without the necessity of any organic binder. The resulting composite material was packaged firmly into an electrode body. Among the diverse materials evaluated as candidates for electrode body, -plastic, Teflon and glass-, the last one was selected as the best material since, when the electrode body is filled up tightly with the sol–gel–graphite paste, the sol–gel solution bonds to the glass body, which results in an hermetic structure that only has contact with solutions through the electrode surface.

As mentioned above, gold nanoparticles are of extreme current interest since they have proved to be highly conductive (fast electron transfer) nanomaterials. In the preparation of TEOS/GOx/AuNPs/C composite electrodes, two different methods were used to achieve the objective of AuNPs incorporation in the composite: adsorption on graphite microparticles after solvent evaporation or direct incorporation in sol–gel precursors. In this case, although both methods were effective, the last one was selected because of its simplicity.

On the other hand, according to several authors, polyethylene glycol (PEG) enhances the hydrophilic character and permeability of the composite while reducing the sol–gel shrinkage over time [3,22]. After soaking in aqueous solution it forms microchannels within the composite because PEG leaches from the electrode. Thanks to the formation of these microchannels, PEG could be considered as "diffusion enhancer" of the analyte giving a higher current response [23,24]. In this sense, a volume of 250 μL of 10% (v/v) PEG was added to the sol–gel precursors but in this case, the AFM assays (discussed below) did not show significant structural differences between the two types of composites (in absence and in presence of PEG). As a consequence, PEG was not added to the sol–gel precursors.

3.2. Morphological characterization

As mentioned above, AFM and SEM techniques are very useful tools to obtain information about the morphological properties of the resulting surface obtained after each step involved in the ceramic composite electrodes preparation. The first step, the sol–gel formation, involves hydrolysis and polycondensation reactions leading to a SiO_2 lattice. Both the composition of the sol–gel mixture and the chemical structure of the precursor have a great influence on the morphological characteristics of the resulting surface, in particular roughness and size of pores. Fig. 1A shows a SEM image of a 40 μm × 40 μm sol–gel area, prepared as described above, which results to be rather flat and almost featureless. Fig. 1B and C shows AFM images taken on one of these flat areas. From these data a surface roughness in the 0.3–0.7 nm range is obtained, confirming the flatness of the surface. The higher resolution image displayed in Fig. 1C reveals a nanoporous surface with a typical external pore diameter of ~10 nm. The size and distribution of pores in the resulting sol–gel matrix is a relevant factor for enzyme encapsulation [25]. The pore diameter value obtained from the higher resolution AFM image confirms that the sol–gel preparation methodology leads to size pore diameters that will be not wide enough to allow the enzyme leakage, but adequate to facilitate the substrate permeation. As mentioned above, the influence of PEG addition to the sol–gel precursor on the final surface morphology was also evaluated by AFM (data not shown). In this case, the AFM measurements show that both preparation procedures (in absence and in presence of PEG) of the sol–gel lattice lead to a similar morphology of the resulting surface.

The addition of graphite powder to the sol–gel solution allows us to obtain a material (TEOS/C) that consists of a robust silica backbone entrapping interconnected carbon microparticles, which impart electronic conductivity to the material. As can be observed in Fig. 2A, it can be concluded that the addition of the graphite powder to the sol–gel solution causes a dramatic change on the micro-morphology of the surface. Large grains (between 25 μm and 50 μm of size) are observed on the surface, which correspond to those also observed by SEM on the raw graphite powder (data not shown). This rough morphology turns difficult the AFM measurements. It should be noted that the samples analyzed in this work were not specifically prepared for AFM characterization but they were the real surfaces generated by the sol–gel process. Notwithstanding, it is possible to carry out AFM analysis on restricted areas provided that special care is addressed to preserve the cantilever condition, particularly the tip size and shape during the imaging process. Under these conditions, images as that shown in Fig. 2B can be obtained. This figure shows micro and nanocrystalline flat graphite regions on top of one of the large grains observed in the SEM image. On one of these regions, we were able to obtain atomic resolution AFM images (Fig. 2C). The characteristic 0.25 nm graphite hexagonal lattice periodicity is clearly observed [26]. As mentioned above, we have essayed different ratios between graphite powder and sol–gel solution (0.8%, 0.7% and 0.5% (w/v)) to obtain the TEOS/C material. Subsequently, we have performed AFM measurements of the resulting composites. AFM images corresponding to TEOS/C material obtained by using graphite powder/sol–gel solution ratios of 0.7% and 0.5% (w/v) (data not shown) are similar than that presented in Fig. 2C for a 0.8% (w/v) ratio. Therefore, it can be concluded that a moderate change in the graphite powder/sol–gel solution ratio did not affect the final morphological characteristics of the resulting composite material.

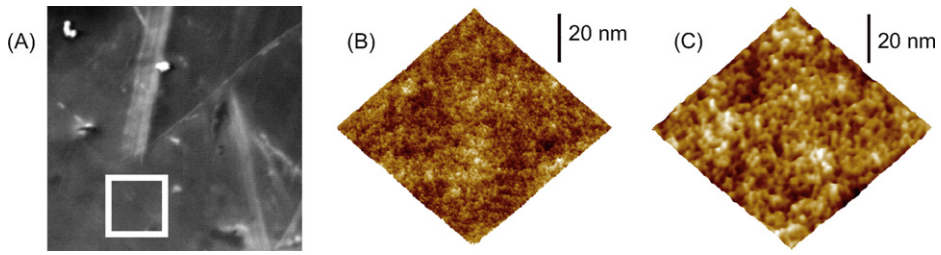

Fig. 1. (A) 40 μm × 40 μm SEM image of the sol–gel surface. (B) 7.5 μm × 7.5 μm and (C) 420 nm × 420 nm AFM images taken on a flat region as that marked in (A).

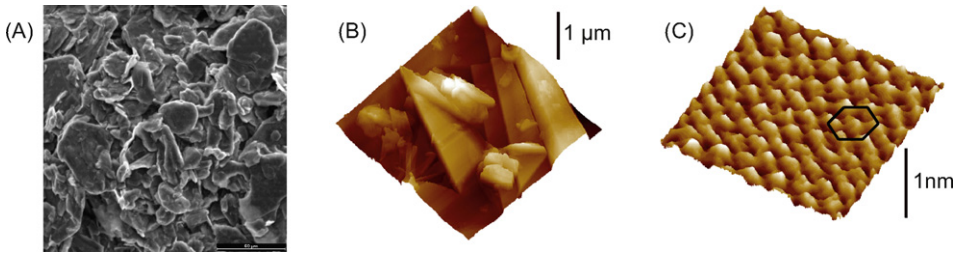

Fig. 2. (A) 150 μm × 150 μm SEM image of the TEOS/C surface. (B) 7.5 μm × 7.5 μm AFM image taken on a large grain. (C) 1.7 nm × 1.7 nm atomic resolution AFM image taken on a flat region of figure (B). The hexagonal graphite lattice, with a lateral side of 0.25 nm, is marked.

The presence of the enzyme (TEOS/GOx/C) implies a further change in the surface morphology of the sample at the micrometer scale (Fig. 3A) since it is formed by flat platelets delimited by deep crevices. Fig. 3B is an AFM image on two neighboring platelets separated by a deep groove in the middle of the image. At this scale, the platelet surface is rough and it is formed by rounded structures (Fig. 3C) that correspond to the globular GOx enzymes and aggregates covering the electrode surface. The measured lateral dimension of the smallest globular structures (14–16 nm) is in good agreement with the typical dimensions of GOx (6.0 nm × 5.2 nm × 7.7 nm) reported in the literature [27] taking into account tip widening effects due to the tip geometry and applied force. It is worth noting that AFM studies of the inner part of such sample, which was previously fractured, did show also globular structures. This fact indicates that the enzyme was successfully incorporated into the hybrid sol–gel matrix proving that the resulting sol–gel matrix is a good material for enzyme loading.

Finally, in order to assess the influence of the nanoparticles addition on the electrode nano-morphology we have compared the images obtained for the TEOS/GOx/AuNPs/C system (Fig. 4) with those obtained for the TEOS/GOx/C system (Fig. 3). From this comparison it is clear that both systems are analogous at the micron (Figs. 3A and 4A) and nano (Figs. 3B–C and 4B–C) scales.

3.3. Electrochemical performance of the glucose biosensor

Glucose biosensor is based on glucose oxidase, which in presence of oxygen catalyzes the oxidation of glucose into gluconolactone and hydrogen peroxide. The activity of the immobilized GOx can be electrochemically detected by monitoring the H_2O_2 produced in the enzymatic reaction. Accordingly, we have obtained the cyclic voltammetric response from −0.1 V to +0.8 V at 10 mV/s for the TEOS/GOx/AuNPs/C electrode in a 0.1 M pH 7.0 phosphate buffer solution containing 10 mM of hydrogen peroxide in order to test whether this strategy is adequate to glucose determination. The resulting cyclic voltammetric response (data not shown) exhibits an irreversible anodic wave with a peak potential at about +0.7 V. Therefore, the determination of glucose in real samples, such as blood, by direct oxidation of the hydrogen peroxide generated in the enzymatic reaction do not represent an adequate strategy because it can be affected by potential interfering species present in the sample, which could also be oxidized at the high potential required for H_2O_2 amperometric detection. In order to minimize the contribution of interfering substances to the glucose biosensor response, one of the most important approaches reported in the literature is based on the replacement of the natural electron acceptor (O_2) by an artificial mediator such as polyneutral red [11], celestin blue [20], or prussian blue [28,29]. Based on our previous experience with other oxidases [30], we have studied the ability of the hydroxymethylferrocene (HMF) to act as a redox mediator in solution. Fig. 5 (curve a) shows the cyclic voltammetric response from −0.1 V to +0.5 V at 10 mV/s for the TEOS/GOx/AuNPs/C electrode in a 0.1 M pH 7.0 phosphate buffer solution containing 1.0 mM of HMF in the absence of glucose. The redox response of the ferrocene/ferrocinium process in aqueous media is observed. Addition of glucose to a final concentration of 2.0 mM (curve b) leads to an enhancement of the anodic peak current concomitant with a decrease of the cathodic peak current consistent with a clear elec-

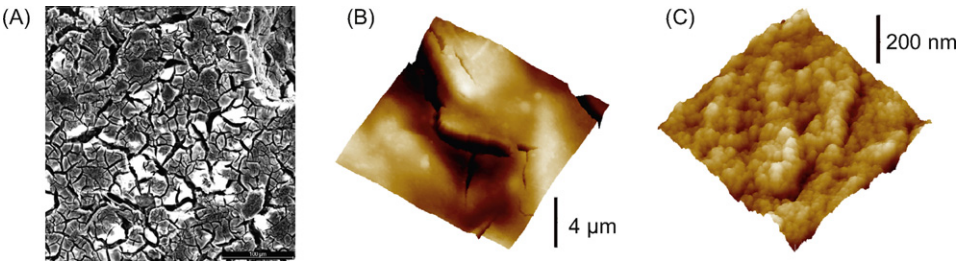

Fig. 3. (A) 350 μm × 350 μm SEM image of the TEOS/GOx/C surface. (B) 7.5 μm × 7.5 μm and (C) 1.0 μm × 1.0 μm AFM images taken on a platelet region.

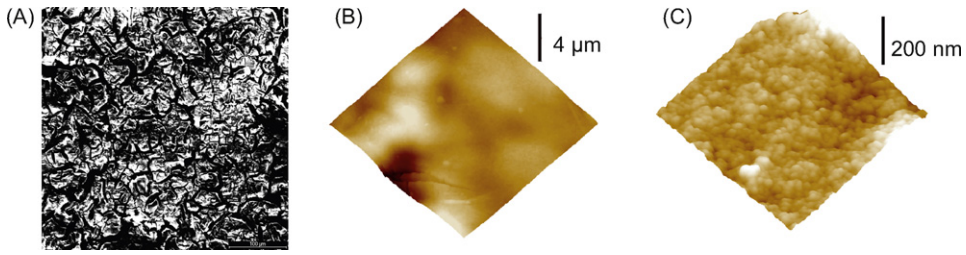

Fig. 4. (A) 350 μm × 350 μm SEM image of the TEOS/GOx/AuNPs/C surface. (B) 7.5 μm × 7.5 μm and (C) 1.0 μm × 1.0 μm AFM images taken on a platelet region.

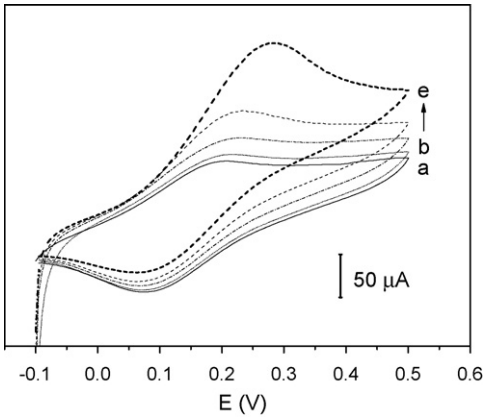

Fig. 5. (A) Cyclic voltammetric response at 10 mV/s for a TEOS/GOx/AuNPs/C composite electrode in a deareated solution of 1.0 mM HMF in 0.1 M phosphate buffer (pH 7.0) as a function of glucose concentration: (a) 0.0 mM, (b) 2.0 mM, (c) 7.0 mM, (d) 25 mM, (e) 55 mM.

trocatalytic effect. Fig. 5 (curves c–e) shows the increment of the magnitude of the catalytic current as a consequence of increasing the amount of glucose (final concentrations of 7 mM, 25 mM and 55 mM, respectively).

In order to ascertain the influence of the AuNPs on the enhancement of the analytical response of the designed organic–inorganic hybrid composite material, we have also obtained the voltammetric response (data not shown) of a similar composite material containing GOx but free of gold nanoparticles (TEOS/GOx/C). As one would expect, in this case the catalytic wave obtained after addition of 2.0 mM of glucose is smaller and less defined than that obtained when gold nanoparticles are present. Fig. 6 depicts typical calibration curves, in which catalytic current obtained from CV measurements was plotted vs glucose concentration for (A) TEOS/C, (B) TEOS/GOx/C and (C) TEOS/GOx/AuNPs/C ceramic carbon electrodes, respectively. Catalytic current was obtained by subtracting the current response in the absence of glucose to the response in the presence of glucose at a potential of +0.25 V. As one would expect, the response obtained (in the same conditions) for a hybrid composite material without enzyme (TEOS/C) is completely different. In this case, upon addition of glucose no catalytic waves are observed, confirming both the role of the enzyme in the catalytic response to substrate and the biocompatibility of the developed hybrid sol–gel material for immobilization of enzymes that retain their activity in a large extent. The analytical properties – linear response, sensitivity and detection limit – of both TEOS/GOx/C and TEOS/GOx/AuNPs/C biosensors were obtained from the linear part of the current vs glucose concentration plot. As shown in Fig. 6, the calibration plots were linear over a wide concentration range, 1–20 mM and 0.5–55 mM for TEOS/GOx/C and TEOS/GOx/AuNPs/C biosensors, respectively. The sensitivity values, calculated from the slope of the plot, were of 1.73 μA mM^{-1} and 2.43 μA mM^{-1}, respectively. The detection limit, calculated as the ratio between three times the standard deviation of background current and the sensitivity, was 1.9 mM for TEOS/GOx/C and 1.3 mM for TEOS/GOx/AuNPs/C. Since the normal glucose concentration in blood is in the 4.4–6.6 mM range [31], the detection limit obtained for the TEOS/GOx/AuNPs/C biosensor is medically useful for glucose level monitoring in blood. The accuracy of both TEOS/GOx/C and TEOS/GOx/AuNPs/C biosensors was evaluated from the relative standard deviation (R.S.D.) of eight different measurements of a 5 mM glucose concentration with the same biosensor. The R.S.D. values were 1.1% and 0.5%, respectively. As can be seen in Table 1, most of the analytical properties corresponding to both TEOS/GOx/C and TEOS/AuNPs/GOx/C are comparable or even better than results reported in the literature for similar sol–gel-based glucose biosensors [9,11,28,29,32–36]. The storage stability was also investigated by measuring the magnitude of the current response for a 10 mM glucose concentration every 5 days during a period of 30 days, keeping the biosensor stored at 4 °C between measurements. When the biosensor is reused, a gradual decay in the signal is observed, leading to a loss of 50% of the initial response after 30 days. Moreover, the developed biosensor exhibited a high degree of robustness since changes in the experimental conditions such as temperature, pH and electrolyte concentration do not critically affect its response.

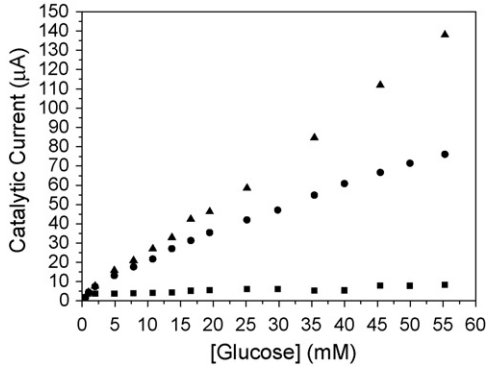

Fig. 6. Catalytic current vs glucose concentration for the following composite electrodes: (■) TEOS/C, (●) TEOS/GOx/C and (▲) TEOS/GOx/AuNPs/C. Data were obtained from cyclic voltammetric measurements at 10 mV/s in a deareated solution of 1.0 mM HMF in 0.1 M phosphate buffer (pH 7.0) for increasing glucose concentration.

In order to test the utility of the developed biosensors in the determination of glucose present in a real sample, we have carried out an exhaustive study of the influence of the more usual potential interferences. In this sense, we have obtained the biosensor response to 5 mM of glucose in absence and presence of several substances, which can be usually present in blood samples, such as acetaminophen (0.1 mM), ascorbic acid (0.1 mM) and uric acid (0.2 mM). While the presence of acetaminophen has a negligible effect to the biosensor response, addition of ascorbic acid or uric acid (both of them easily oxidized at electrodes) results in an increase of the catalytic current of 6% and 7%, respectively. These results, comparable or even better than other reported in the literature for similar biosensors [7,28,32,37], suggest that the developed

Table 1

Biosensor	Sensitivity ($\mu A\,mM^{-1}$)	Linear range (mM)	Applied potential (V)	Accuracy (R.S.D.)
TEOS/GOx/C (present work)	1.73	1–20	+0.25	1.1% ($n=8$)

device can be successfully used to measure glucose concentrations in presence of possible interfering substances.

In the light of the results obtained concerning the performance of both TEOS/GOx/C and TEOS/AuNPs/GOx/C biosensors (summarized in Table 1), it is clear that addition of gold nanoparticles to the hybrid composite material improves the analytical properties of the resulting biosensor, particularly sensitivity, linear range concentration and accuracy. This improvement is a consequence of the advantages obtained through the combined use of gold nanoparticles and a biocompatible organic–inorganic hybrid material with a porous and open framework.

4. Conclusions

In this paper, we develop a novel organic–inorganic hybrid composite material for glucose electrochemical sensing based on integration of a biosensig element (GOx), nanomaterials (AuNPs) and graphite powder (C) into a sol–gel matrix. This composite material combines the advantages induced from both the silica matrix, which enables the incorporation of the other elements while keeping the enzymatic activity of the assembly, and the presence of nanostructures, which enhances the electroactive area. As a consequence, the resulting biosensor TEOS/AuNPs/GOx/C exhibits a wider linear range concentration, higher sensitivity and higher accuracy, when compared with a similar composite containing GOx but free of AuNPs (TEOS/GOx/C). Taking into account the good performance of the resulting biosensor, this approach is a promising route for designing a wide range of biosensors.

ABSTRACT

Based on direct hapten coated format a competitive indirect enzyme-linked immunosorbent assay (ciELISA) for bisphenol A (BPA) was developed. Polystyrene surface was modified by 3-Aminopropyltriethoxysilane (APTES) to produce amino groups after H_2SO_4/HNO_3-pre-treatment. 4,4-bis (4-hydroxyphenyl) valeric acid (BVA) which is analogue of BPA, was successfully immobilized on the surface of microtiter plates by N,N′-dicyclohexylcarbodiimide (DCC) method. The essential steps of the assay were optimized, especially blocking procedure which is key step to prevent unspecific binding of antibody. The results indicated that compared with hapten-protein coated format (IC_{50} = 176.67 ng ml^{-1}, LOD = 15.90 ng ml^{-1}), the direct hapten coated format (IC_{50} = 23.50 ng ml^{-1}, LOD = 0.27 ng ml^{-1}) could improve assay sensitivity and the detection ranges were 2.30 ng∼157.60 ng ml^{-1} with good signal reproducibility (P value > 0.05) after careful optimization of assay conditions. Tap water samples and seawater samples were spiked with a known amount of BPA and measured by ciELISA. The average recoveries were between 70 and 142%. As far as we are aware this is the most sensitive ELISA for BPA yet reported.

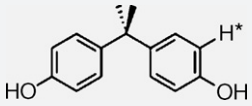
1. Introduction

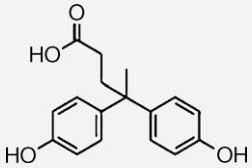
In recent years, the issues of environmental endocrine disruptors (EEDs) have attracted more and more public attention. Bisphenol A (BPA) (Table 1) which is widely used for the production of plastics, belongs to EEDs. Since Krishnan firstly reported that BPA had weak estrogenic property [1], many studies have verified its effect on animals and human beings [2,3]. Thus, it is urgent to develop highly sensitive, selective, large-scale and rapid analytical methods to routinely monitor BPA level in the environment.

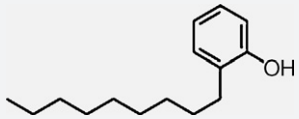
Enzyme-linked immunosorbent assays (ELISAs) have been developed and used widely to detect EEDs [4–6] due to their fast, portable and cheap characteristics.

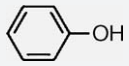
Competitive ELISAs are always employed to determine EEDs because most of EEDs are low-molecular-weight compounds (hapten) without multi-epitopes compared with macromolecules.

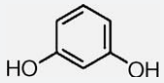
In competitive ELISAs there are two assay formats—the antibody-immobilized-format and the antigen-immobilized-format [7].











In the antibody-immobilized-format antibody was coated on polystyrene surface by passive adsorption owing to intermolecular attraction forces (hydrophobic interactions). However, most of the antibodies were denatured in this process. Butler determined that over 90% of monoclonal antibodies and about 75% of polyclonal antibodies against fluorescein could not recognize hapten upon adsorption onto polystyrene surfaces [8]. Moreover, it is difficult to prepare hapten–enzyme conjugate because enzyme has fewer coupling site than albumins and the conjugation could deactivate enzyme.

Hapten–protein conjugate was always used as coating protein in the antigen-immobilized-format. Based on hydrophobic interactions hapten–protein was immobilized on polystyrene surfaces. However, the immobilization must involve significant conformational changes to create large-scale hydrophobic contacts. Conformational change would influence hapten presentation for the reason that low-molecular-weight compounds with small size could be easily screened by macromolecular. On the other hand, the reaction between hapten and protein was not always reproducible, which is unfavorable to make assay standardization.

Table 1
Cross-reactivities of the inhibition assays with selected compounds.

Compounds	Structure	Cross-reactivity (%)
Bisphenol A		100
BVA		75
Nonylphenol		<0.1
Phenol		<0.1
Resorcinol		<0.1

These drawbacks could be avoided by the new format—direct hapten linkage to the polystyrene surface. The polystyrene surface without reactive groups could be modified by silane coupling agents to produce various functional groups such as hydroxyl, amino, carbonyl, carboxyl, etc. Functional silane compounds are available from a number of commercial sources, which include Gelest, Aldrich, and others. There are some commonly used silane agents such as carboxyethylsilanetriol, 3-aminopropyltriethoxysilane (APTES), 3-glycidoxypropyltrimethoxysilane (GOPTS), isocyanatopropyltriethoxysilane (ICPTES), *N*-(trimethoxysilylpropyl)ethylenediamine triacetic acid (TMS-EDTA) etc. In our study, we developed an efficient and convenient method to modify the polystyrene surface by APTES to produce reactive amino group. One commercially available reagent, 4,4-bis(4-hydroxyphenyl) valeric acid (BVA) (Table 1) which is analogue of BPA, was used to link to modified surface based on DCC method. The results revealed that direct hapten coated format showed higher degree of assay sensitivity than hapten–protein format.

2. Experimental

2.1. Materials

APTES, BPA, BVA, GOPTS, native bovine serum albumin (nBSA), and ovalbumin (OVA) were purchased from Sigma (St. Louis, MO, USA). *N*,*N*′-Dicyclohexylcarbodiimide (DCC) and *N*-hydroxysuccinimide (NHS) were obtained from Pierce (Rockford, IL, USA). Goat anti-mouse IgG–HRP conjugate was from Sino-American Biotechnology Company (Beijing, China). Dimethylformamide (DMF) and other organic solvents were purchased from Sino-pharm Chemical Reagent Company (Shanghai, China). The anti-BPA monoclonal antibody was a kind gift from Dr. Gerardo R. Marchesini and Prof. Willem Haasnoot (RIKILT-Institute of Food-Safety, P.O. Box 230, 6700 AE Wageningen, The Netherlands).

2.2. Hapten–protein conjugates preparation

Preparation of Hapten–BSA conjugates for coating protein was carried out by the previous method [9] with some modifications. The coupling reaction was performed at pH 7.4 according to the following procedure. NHS (10 mg in 750 μl DMF) was mixed with DCC (20 mg in 750 μl DMF) and BVA (10 mg in 500 μl DMF) for 24 h at 25 °C. Of this mixture, 200 μl was added drop wise to 2 ml of a BSA solution (10 mg ml^{-1} in 0.1 M PBS buffer at pH 7.4). After 2 h incubation at 25 °C, the products were dialyzed against PBS for 72 h and the solution was lyophilized. Then the white crystal obtained was stored at −20 °C.

2.3. Direct hapten immobilization on polystyrene surface modified by APTES

Direct hapten immobilization followed by the method [10] with some modifications. The reaction mechanism of direct hapten immobilization on polystyrene surface modified by APTES is shown in Fig. 1. In brief, plates were first treated with 47% (v/v) HNO_3 in concentrated H_2SO_4 for 30 min at room temperature to generate $-NO_2$ groups on polystyrene surface. Then each well was treated with 250 μl 5% aqueous APTES solution at pH 5.5 by incubating at room temperature (RT) for 2 h. After washing wells two times with double distilled water (DDW), the plates reacted at 70 °C for 2 h to stabilize thin monolayer of APTES on polystyrene microtiter plates and incubated overnight at 4 °C. The unbound amines were blocked with 0.2 M formaldehyde by incubating the plates for 2 h at 37 °C.

Protein–hapten conjugates (BVA–BSA) coated on the surface of microtiter plate by adding 100 μl conjugate (50 ng ml^{-1} in carbonate buffer) per well and incubating overnight at 4 °C. To solve non-specific adsorption problem, plates were treated with blocking buffer (0.1 mol/l phosphate buffered saline, pH 7.4, containing 0.05% Tween 20, 1.0% BSA, 0.5% casein, 0.01% sodium azide) at 37 °C for 2 h and washed three times with washing solution (0.1 mol/l phosphate buffered saline, pH 7.4, containing 0.05% Tween 20, PBST) for further reaction.

2.4. Competitive inhibition ELISA protocol

The procedure of competitive inhibition ELISA was similar to routine methods [11] with some modifications. Briefly, treated plate was washed three times with washing solution for each well and decanted. Then 50 μl of antibody against BPA (1/6000) in antibody dilution buffer (0.1 mol/l phosphate buffered saline, pH 7.4, containing 0.05% Tween 20, 0.1% BSA, 0.01% sodium azide) and 50 μl various concentrations (10^{-2}, 10^{-1}, 10^{0}, 10^{1}, 10^{2}, 10^{3}, 10^{4} ng ml^{-1}) of analytes were added to each well and incubated at 37 °C for 2 h. After washing five times, 100 μl of goat anti-mouse IgG–HRP conjugate (1/2000) in secondary antibody dilution buffer (0.1 mol/l phosphate buffered saline, pH 7.4, containing 0.05% Tween 20, 1.0% BSA, 0.01% sodium azide) was added into each well and incubated at 37 °C for 1 h. Then 100 μl of 3,3′,5,5′-tetramethylbenzidine (TMB) substrate was added after washing the plate six times and incubated at 37 °C for 15 min. The reaction was terminated by the addition of 2 mol l^{-1} sulfuric acid. Absorbance at 450 nm was determined in a Multiskan MK3 ELISA reader (Thermo, China).

2.5. Immunoassay sensitivity and specificity

Briefly, after the polystyrene plates were coated by BVA–BSA and blocked with our blocking buffer, 50 μl of antibody against BPA (1/8000) in antibody dilution buffer (0.1 mol/l phosphate buffered saline, pH 7.4, containing 0.05% Tween 20, 0.1% BSA, 0.01% sodium azide) and 50 μl various concentrations (10^{-2}, 10^{-1}, 10^{0}, 10^{1}, 10^{2}, 10^{3}, 10^{4} ng ml^{-1}) of analytes were added to each well and incubated at 37 °C for 1 h. The subsequent steps were as described in Section 2.4.

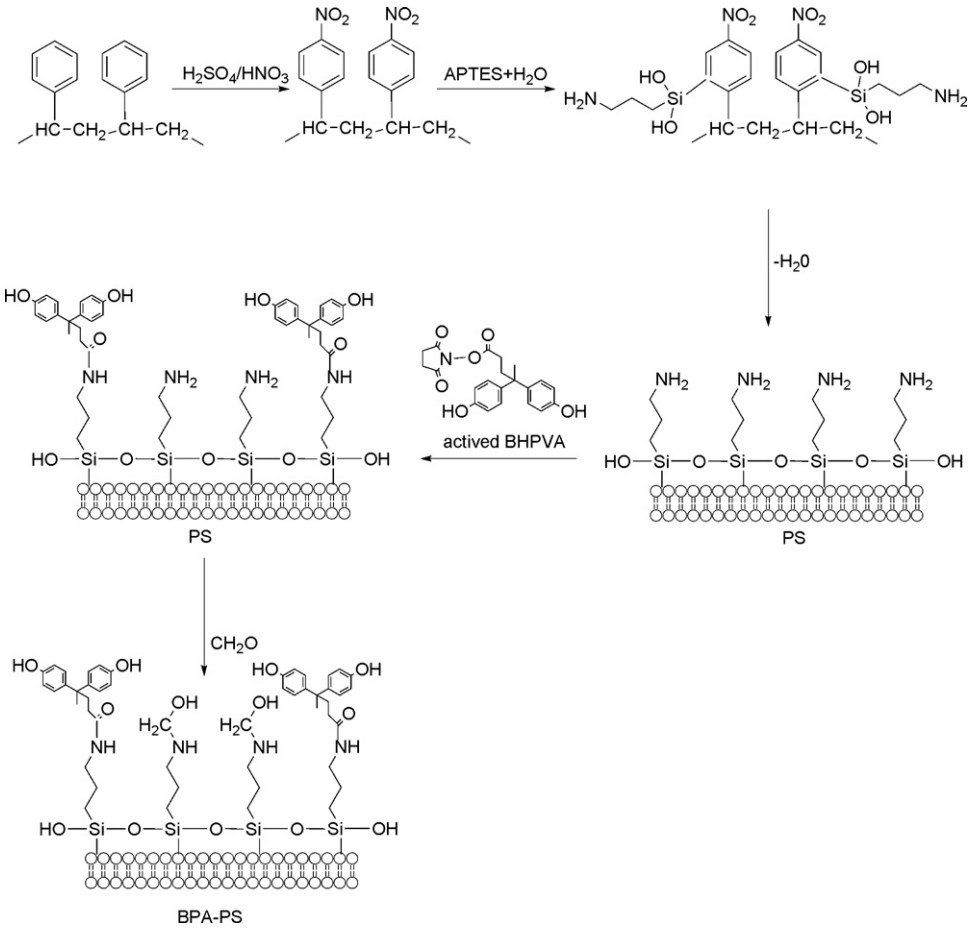

Fig. 1. Reaction mechanism of direct immobilization of BHPVA on PS surface modified with APTES.

Data analysis was performed using normalized assay signals % B/B_0 using the following formula:

$$\%\frac{B}{B_0} = 100 \times \frac{A - A_{ex}}{A_0 - A_{ex}}$$

where A is the absorbance of hapten at standard concentration; A_0 the absorbance at zero hapten concentration; and A_{ex} is the absorbance at excessive hapten concentration surface.

IC_{50} value was the half maximal (50%) inhibitory concentration of a substance and was determined in the competitive experiment described above. The cross-reactivity values were calculated according to the formula: $\frac{IC_{50\,hapten}\,(ngml^{-1})}{IC_{50\,BPA\,analogs}\,(ngml^{-1})} \times 100\%$

2.6. Matrix effect studies

Different natural water samples (tap water (Tianjin city), seawater (Tianjin coast)) were collected and used to assess the performance of the indirect ELISA method.

3. Results and discussion

3.1. Determination of BVA–BSA conjugates by UV spectrophotometer and mass spectrum

From UV–vis spectra (Fig. 2), we could observe that BVA–BSA conjugates had maximum absorption peak wavelength in 279 nm which is similar with BSA. Furthermore, the results also indicated that the absorption peak strength of BVA–BSA (1 mg ml^{-1}) in 279 nm was stronger than BSA (1 mg ml^{-1}) in same wavelength. This might result from BVA in the conjugate since BVA has maximum absorption peak wavelength at 277 nm.

MW of BVA–BSA was 71,127 determined by mass spectrum as shown in Fig. 3 and the coupling ratio was found to be 15:1.

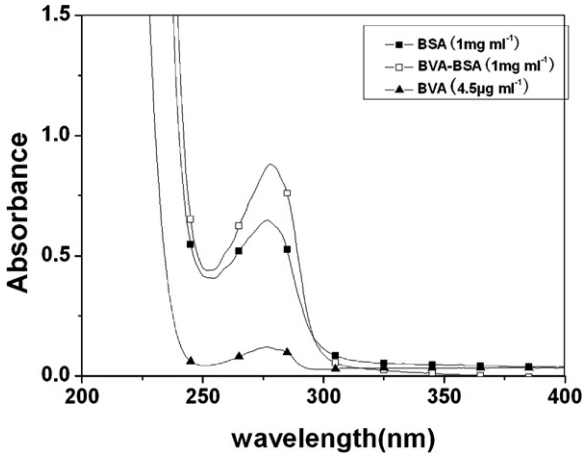

Fig. 2. The UV–vis spectra of 4.5 μg/ml BVA, 1.0 mg/ml BPA-BSA and 1.0 mg/ml BVA–BSA in 10% methanol solution.

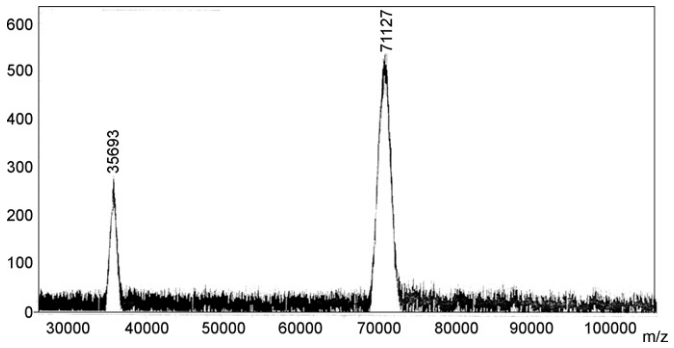

Fig. 3. Mass spectrograms of BVA–BSA.

3.2. Detection of specificity of antibodies by indirect competitive ELISA

In this study, cross-reactivities (CR) of two phenolic compounds (BPA, BVA) and three simple phenolic compounds (phenol, nonylphenol, resorcinol) were evaluated for competitive inhibition ELISA and were calculated as CR (%) = ($IC_{50\ BPA}$)/($IC_{50\ BPA\ analogs}$) × 100. From the result (Table 1), it could be clearly seen that the cross reactions of BPA and BVA were 100% and 75%, respectively, while the cross reactions of the other three compounds were all much lower than 1%. The common part of the structure of BPA and BVA is the two phenolic rings bridged through a carbon atom. Thus we believed that the produced antibody specifically recognized such a bisphenolic group. Interestingly BPA showed higher affinity than BVA with antibody. The results may be due to the influence of carboxy group of BVA on the antigen–antibody reaction.

3.3. Optimization of the essential steps of the assay

100 μl activated BVA solution at serial concentrations (40, 80, 160, 320, 640, 1280, 2560, 5120 nmol ml^{-1}) was added into each well with modified by APTES and incubated overnight at 4 °C. It could be clearly seen that with increasing of concentration of activated BVA solution OD_{450} value increases. The result indicated that the hapten was successfully immobilized on the polystyrene surface with modified by APTES.

To prevent the antibody from unspecific binding to the surface a blocking step is required. In hapten–protein format, blocking buffer (0.1 mol/l phosphate buffered saline, pH 7.4, containing 0.05% Tween 20, 1.0% BSA, 0.5% casein, 0.01% sodium azide) was added into well to block blank site on the surface before competition step. Our results (Fig. 4) showed that compared with blocking buffer without casein (IC_{50} = 206.34 ng ml^{-1}), assay with our blocking buffer (IC_{50} = 176.67 ng ml^{-1}) could improve assays sensitivity. However, BSA/OVA pre-treatment was not effective to prevent unspecific binding of the antibody in direct hapten coated format. Different blocking reagents were tested for their effectiveness–BSA, OVA, skimmed milk, trehalose. All were unable to prevent unspecific binding of the secondary antibody. Our study found that unspecific binding problem could be effectually solved only while the primary antibody and the secondary antibody were diluted in PBS + 0.1% BSA (W/V).

Chequerboard titration has been used for selecting an optimum of antigen–antibody reaction. Fig. 5 showed the chequerboard titration results for the antibody. From the result the titers of the antibody were found to be 1:6000, and the optimal concentration for activated BVA was 640 nmol/ml. Furthermore, it was interesting to note that with increasing coating hapten concentration A_0 signals showed a drop beyond 640 nmol/ml. Previous studies [12–14] also described a similar phenomenon. The extraordinary

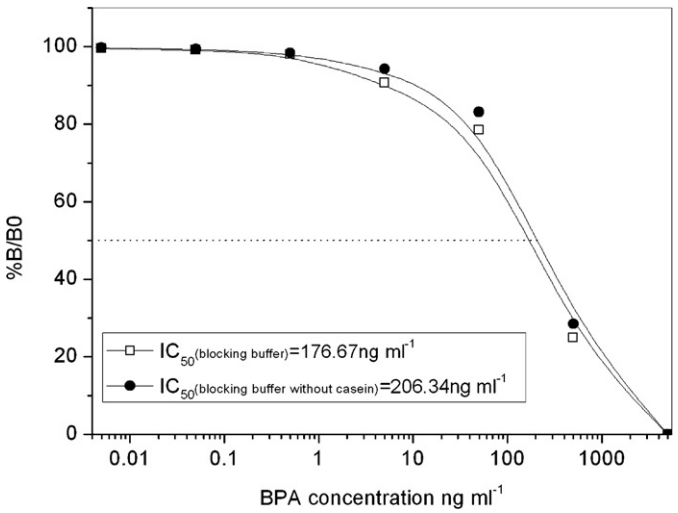

Fig. 4. Effect of different blocking buffers on ELISA sensitivity (IC_{50}).

results may be due to steric effects which could influence reaction between the primary antibody and surface-immobilized hapten. Steric effects arise from the fact that each atom with a molecule occupies a certain amount of space. If atoms are brought too close together, there is an associated cost in energy duo to overlapping electron clouds, and this may affect the molecule preferred shape (conformation) and reactivity. Based on steric effects theory, we proposed an explanation of decreasing A_0 signals beyond 640 nmol ml^{-1} that excessive surface-immobilized hapten would involve its conformational changes which was unfavorable to make the primary antibody recognize hapten. On the other hand, a change of the binding mechanism from univalent to bivalent might also be a factor. Thus in our study we chose 640 nmol/ml or below as coating hapten concentration.

3.4. Immunoassay sensitivity

The procedure of indirect competitive ELISA (icELISA) was similar to that mentioned in Section 2.4 with some modifications. Briefly, after the polystyrene plates were coated and blocked as described in Section 2.3, 50 μl of suitable diluent antibodies (1/3000) were added to each well and then 50 μl of serial concentrations (10^{-2}, 10^{-1}, 10^{0}, 10^{1}, 10^{2}, 10^{3}, 10^{4} ng ml^{-1}) of BPA

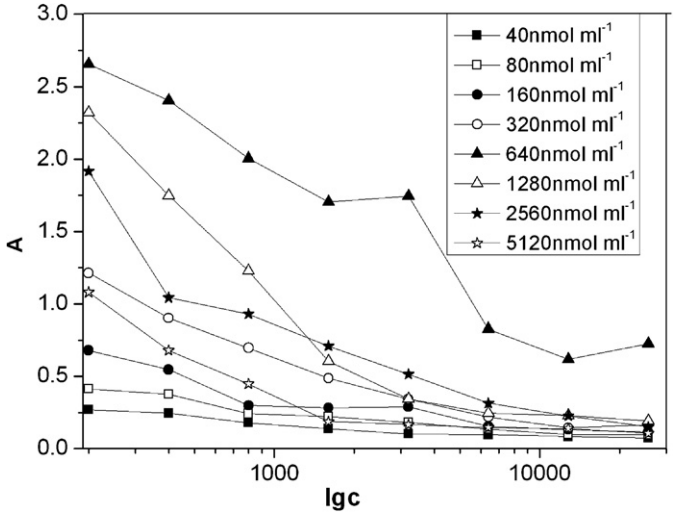

Fig. 5. The results of chequerboard titration.

Table 2
Parameters of optimized ELISA for two formats.

Format	Equation	R^2	IC_{50} (ng ml^{-1})	LOD (ng ml^{-1})	Working range (ng ml^{-1})
Hapten coated	$y = 445{,}077 + 97.6935/(1 + (x/32.7328)^{0.69812})$	0.993	23.50	0.27	2.30–157.60
Hapten–protein BSA	$y = -4.93161 + 103.31184/(1 + (x/201.77856)^{0.95583})$	0.997	176.67	15.90	4068–1289.70

Table 3
Based on direct hapten coated ELISA and hapten–protein coated ELISA the recovery has been determined by spiking BPA in PBS, tap water and seawater.

Format	Compels added (ng ml^{-1})	Seawater			Tap water			PBS		
		Found (ng ml^{-1})	% recovery	CV%	Found (ng ml^{-1})	% recovery	CV%	Found (ng ml^{-1})	% recovery	CV%
BVA coated	250	332	132	3.9	290	116	6.7	312	124	7.6
	50	57	114	12.3	43	96	8.4	53	106	9.7

	25	31	124	5.4	20	80	3.4	29	110	12.9

in 10% methanol solution were added and incubated at 37 °C for 1 h. The subsequent steps were as described in Section 2.4. However, there were some gaps between direct hapten coated format and hapten–protein coated format. First, in hapten–protein coated format blocking buffer was used to prevent the antibody from unspecific binding to the surface before competition step. In our study we found that the blocking procedure mentioned above was not effective to prevent unspecific binding of the antibody in direct hapten coated format. The antibody (include the primary antibody and the secondary antibody) solution diluted in PBS + 0.1% BSA could effectively decrease $A_{background}$ for direct hapten coated format. Second, hapten–antibody reaction time was extended to 2 h in direct hapten coated format compared with hapten–protein coated format. The explanations for this were that hapten–protein coated format was favorable to hapten presentation due to BSA or OVA with the large specific surface area as carrier protein.

Based on two types of coated formats, competitive ELISA was performed at optimum antibody concentration of 0.6 μg ml^{-1} (direct hapten coated format) and 0.15 μg ml^{-1} (hapten–protein coated format). From the results (Fig. 6; Table 2), we could observe that for hapten–protein coated format the IC_{50} values (50% B/B_0) and the limit of detection for BPA were approx. 176.67 and 15.90 ng ml^{-1}, respectively. However, immunoassay sensitivity and the limit of detection were up to 23.50 and 0.27 ng ml^{-1} with the direct hapten coated for BPA. As far as we are aware this is the most sensitive ELISA for BPA yet reported.

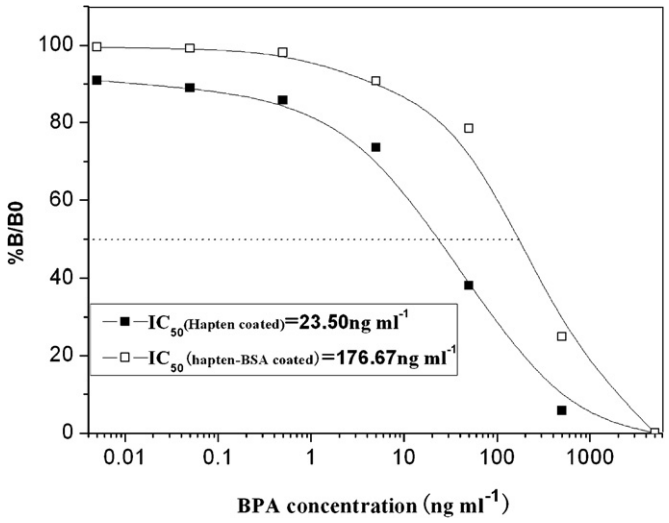

Fig. 6. The competitive inhibition curve of antibody against BPA.

Hapten–protein conjugate was always used as coating protein in the antigen-immobilized-format. Based on hydrophobic interactions hapten–protein was immobilized on polystyrene surfaces. However, the immobilization must involve significant conformational changes to create large-scale hydrophobic contacts. Conformational change would influence hapten presentation for the reason that low-molecular-weight compounds with small size could be easily screened by macromolecular. On the other hand, the reaction between hapten and protein was not always reproducible perhaps for above reasons, which is unfavorable to make assay standardization.

In competitive ELISAs hapten–protein was always used as coating protein to determine low-molecular-weight compounds (hapten). However, hapten–protein coated format had some drawbacks. First, the reaction between hapten and protein always involved severe precipitation for the reason that hydrophobic hapten would screen hydrophilic group (–COOH or $–NH_3$) of carrier protein in the reaction. Second, even when performing at same reaction condition, conjugation was not always reproducible which is unfavorable to make assay standardization. The explanation might be that different coupling ratios of hapten–protein conjugate would make different hapten densities on the polystyrene surfaces, and consequently different assay sensitivities. Finally, based on hydrophobic interactions hapten–protein was adsorbed on polystyrene surfaces. However, the immobilization must involve significant conformational changes to create large-scale hydrophobic contacts. As a result, Conformational change would influence hapten presentation because low-molecular-weight compounds with small size could be easily screened by macromolecular.

3.5. Matrix effect studies and assay validation

No significant matrix effect was observed when the ELISA was applied to measure the spiked tap water samples. But for seawater samples, a 1:10 dilution with PBS was necessary to obtain quantitative recoveries. As a result, the LODs for seawater shifted to 159 (hapten–protein coated format) and 2.7 ng ml^{-1} (direct hapten coated format). The recovery results were shown in Table 3.

4. Conclusions

In conclusion, this paper described a simple and efficient method to directly immobilize hapten with carboxy group on the polystyrene surface of microtiter plates.

Compared with hapten–protein coated format, immunoassay sensitivity increased seven folds up to 23.50 ng ml^{-1} with the direct hapten coated for BPA after careful optimization of assay con-

ditions. Tap water samples and Seawater samples were spiked with known amount of bisphenol A and measured by the competitive ELISA. Recoveries were between 70% and 142%. On the other hand, general applicability was important advantage for this format. Based on DCC method, we could immobilize hapten with carboxy group on the APTES layer. In further study various types of organo-siloxane layers with different functional groups could be constructed on the polystyrene surface of microtiter plates using Silane Coupling Agents such as GOPTS, ICPTES, etc. Thus, reactive polystyrene surface could be employed to fix different hapten by different conjugate techniques.

Antioxidants
Oranges and tomatoes
Capillary zone electrophoresis
Amperometric detection

ABSTRACT

In the paper, a new kind of vitamin B_{12} (acquo-cobalamine) chemically modified electrode was fabricated and applied in capillary zone electrophoresis coupled with amperometric detection (CZE-AD) for simultaneous determination of six antioxidants in fruits and vegetables. The catalytic electrochemical properties of the chemically modified electrode could obviously enhance oxidation peak heights responses by about five times to glutathione, ascorbic acid, vanillic acid, chlorogenic acid, salicylic acid, and caffeic acid compared with common carbon disk electrode. Furthermore, the effects of working electrode potential, pH and concentration of running buffer, separation voltage and injection time on CZE-AD were investigated. Under the optimum conditions, the six analytes could be completely separated and detected in a borate–phosphate buffer (pH 8.4) within 15 min. Their linear ranges were from 2.5×10^{-7} to 1.0×10^{-4} mol L^{-1} and the detection limits were as low as 10^{-8} mol L^{-1} magnitude ($S/N = 3$). The proposed method has been successfully employed to monitor the six analytes in practical samples with recoveries in the range 96.0–106.0% and RSDs less than 5.0%. Above results demonstrate that capillary zone electrophoresis coupled with electrochemical detection using vitamin B_{12} modified electrode as detector is of convenient preparation, high sensitivity, good repeatability, and could be used in the rapid determination of practical samples.

1. Introduction

Free radicals are very unstable molecules arising physiologically during cellular aerobic metabolism, and their harmful effects for human health have been more and more concerned in recent years [1]. They react quickly with other compounds, causing chain reactions. Once the process starts, it can cascade, finally results in disruption of a living cell or in molecular and cellular DNA damage. So, free radicals have been indicated as probable pathogenesis determinants of many degenerative and chronic diseases that develop with age, such as cancer, cardiovascular disease, cataract, and immunity system dysfunctions [2]. For their potential role in preventing such diseases, natural compounds with antioxidant activity have attracted the attention of researchers and nutritionists. Estimation of the antioxidant contents is becoming, in fact, an evaluation parameter for the nutritional quality of foods.

A large number of fresh fruits and vegetables are primary sources of antioxidants. Oranges and tomatoes, two kinds of them, contribute to the daily intake of a significant amount of antioxidants [3]. They contain different classes of substances with antioxidant properties, such as ascorbic acid, phenolics, glutathione, etc. It is well known that ascorbic acid is a soluble vitamin widely present in oranges and tomatoes, which is commonly used to supplement inadequate dietary intake for antioxidants [4–6], and widely used for the prevention and treatment of common cold, mental illness, infertility, and in some clinical manifestations of HIV infections [7]. The major phenolics in oranges and tomatoes are vanillic acid, chlorogenic acid, salicylic acid, caffeic acid, etc. These phenolic compounds are located in the lipid–water interface of the membrane because of their lipophilic–hydrophilic structure. This location allows them to scavenge free radicals inside and outside the cell. Glutathione, which is also found to exist in both oranges and tomatoes, is a physiologically significant aqueous antioxidant, capable of scavenging reactive oxygen and nitrogen species which is thought to contribute to induce many diseases including cancer, heart attack, stroke, arthritis [8,9].

The most widely used method for the analysis of antioxidants in plants and fruits is high-performance liquid chromatography (HPLC) with photodiode array (PDA) detection [10–13]. HPLC coupled with mass spectrometric detection for analyzing polyphenols in plant extracts and food has also been explored [14]. However,

HPLC has some shortcomings including time-consuming sample pretreatment and short column lifetime. Owing to its advantages of short-analysis time, small-consuming sample, simple-experiment operation, and high separation efficiency [15], capillary zone electrophoresis (CZE) has been increasingly recognized as an important analytical separation technique for charged compounds and partially charged organics. In combination with electrochemical detection (ED), CZE-ED offers high sensitivity, good selectivity, free derivatization, and low cost for the analytes. However, the success in the electrochemical detection is strongly dependent on the choice of the working electrode materials. Different electrodes, such as carbon, sol–gel, platinum, gold, nickel, etc. have been used for different analytes [16–20]. In the past few years, there has been an explosion of research activity in the area of chemically modified electrodes. This area of research has attracted such interest because the chemical modification electrodes with redox active thin films, offer significant advantages in the design and development of electro-catalyst, enhance the sensitivity and extend further the applicability of capillary electrophoresis with electrochemical detection.

Vitamin B_{12} is a naturally cobalt (III) corrin complex or aquocob(III)alamine. Its electrochemical property has been studied extensively by many authors, including polarographie studies [21] and cyclic voltammetry [22]. These studies have demonstrated that vitamin B_{12} exhibits a rich redox chemistry centred on the cobalt atom. Vitamin B_{12a} (with Co (III)) can be reduced reversibly to vitamin B_{12r} (having Co (II)), and be further reduced to give vitamin B_{12s} that contains Co (I). Zagal's group has reported that vitamin B_{12} adsorbs on ordinary pyrolytic graphite (OPG) electrodes to investigate oxygen reduction kinetics, and the active for the electro-oxidation of cysteine and glutathione [23–25]. Therefore, immobilization of vitamin B_{12} on an electrode is a potential method for developing novel chemical conversion devices to improve further the detection sensitivity in some trace analysis.

In this regard, we are now investigating the method of immobilizing the vitamin B_{12} on an electrode by electropolymerization and manage to provide an easy and feasible method to improve the detection limits of ascorbic acid, phenolics, and glutathione in fruits and vegetables. It is found that under the optimum conditions, the six main antioxidants in vegetables and fruits could be completely separated and detected in a borate–phosphate buffer (pH 8.4) within 15 min. Their linear ranges were from 2.5×10^{-7} to 1.0×10^{-4} mol L^{-1} and the detection limits were as low as 10^{-7} or 10^{-8} mol L^{-1} magnitude ($S/N = 3$). Furthermore, the proposed method has been successfully employed to monitor the six analytes in practical samples with recoveries in the range 96.0–106.0% and RSDs less than 5.0%. Above results demonstrated that capillary zone electrophoresis coupled with electrochemical detection using vitamin B_{12} modified electrode as detector was of convenient preparation, high sensitivity, good repeatability, and could be used in the rapid determination of practical samples. It is possible to get new insights in the quality control of foods.

2. Experimental

2.1. Apparatus

The CZE-AD system was laboratory-built [26,27]. Electrophoresis was driven by a high-voltage power supply (±30 kV, Shanghai Institute of Nuclear Research, Shanghai, China). The high-voltage end of the system was housed in a plexiglas box equipped with an interlock for operator safety. Separations were performed in a fused silica capillary (Polymicro Technologies, Phoenix, AZ, USA) with 25 μm I.D., 360 μm O.D. and 70 cm long. Potential control and current output were achieved with a CH-2 amperometric detector (Jiangsu Electrochemical Analytical Instrumental Factory, China). Electropherograms were recorded by use of a chart recorder (Shanghai Dahua Instrument Factory, China). Electrochemical experiments were carried out with a CHI 830b electrochemical analyzer (CHInstruments, Austin, TX, USA). A three-electrode system was used, a vitamin B_{12} modified working electrode, a saturated calomel reference electrode (SCE), and a platinum wire counter electrode.

2.2. Reagents

Glutathione and ascorbic acid were obtained from First Chemical Reagent Factory (Shanghai, China). Vanillic acid, chlorogenic acid, salicylic acid, and caffeic acid were purchased from Shanghai Leechdom Inspection Agency (Shanghai, China) without further purification. Tomatoes and oranges were purchased from a local supermarket. All the other chemicals including carrier electrolytes were of analytical reagent grade. Doubly distilled water was used throughout the experiments.

The six standard analytes were accurately weighed and dissolved in anhydrous ethanol to furnish 1.0 mmol L^{-1} stock solutions of each; these were stored in the dark at 4 °C. Before CZE experiment they were diluted with the pH 8.4 borate–phosphate buffer. All solutions were filtered through 0.22 μm polypropylene acrodisc syringe filter (Xinya Purification Instrument Factory, Shanghai, China) and degassed by agitation in an ultrasonic bath for 5 min to remove bubbles.

2.3. Procedures

2.3.1. Preparation of modified electrodes

First, the working electrode was constructed by inserting 300 μm diameter carbon disk into a disposable polypropylene pipette tip with 3–5 mm protruding out and then sealing with epoxy glue (GC Electronics, Rockford, IL). Electrical contact was established via a copper wire, which was threaded into the opposite end of the electrolyte body. To smooth the resulting relatively rough surface, it was further subjected to sequential polishing on a polishing cloth covered with alumina powder of 1.0, 0.3 and 0.05 mm particle size (Buehler, USA) for 5, 10 and 20 min, respectively. To remove any adherent Al_2O_3 particles the electrode surface was rinsed thoroughly with doubly distilled water and cleaned in an ultrasonic bath for 5 min. Finally, the electrode was pretreated electrochemically by scanning in a 0.1 Na_2HPO_4/NaOH buffer solution (pH 12.0) between −1.2 and 0.6 V versus SCE until five subsequent scans were identical.

Then, the vitamin B_{12} electrochemically modified electrode was prepared by electropolymerization, and it was achieved by repetitive cycling of the electrode between −0.6 and 1.6 V at 0.05 V s^{-1} in a 1.0×10^{-3} mol L^{-1} dichloromethane solution of vitamin B_{12} and 0.1 mol L^{-1} tetrabutylammonium tetrafluoroborate. The growth of the film was observed by monitoring the increase in the charge attributed to the reversible redox couple of the metal centre Co (III)/(II) located at −0.85 V [28].

The modified working electrode was arranged in a wall-jet configuration in which the modified carbon disk electrode was inserted into the cathode compartment of the CE instrument and then positioned up against the capillary outlet as close as possible. In this configuration, the CE effluent impinged directly onto the disk-shaped electrode and then flowed radially outward across its surface.

2.3.2. Cyclic voltammetry experiments

Cyclic voltammetry (CV) was used to investigate the current responses of six analytes (glutathione, ascorbic acid, vanillic acid, chlorogenic acid, salicylic acid, and caffeic acid) on the modified

working electrodes in borate–phosphate solutions (pH 8.4). The scan rate was 50 mV s^{-1}.

2.3.3. CZE experiments

Before each run in CZE experiments, the capillary was sequentially rinsed with a self-made washing system, with 0.1 mol L^{-1} hydrochloric acid, doubly distilled water, 0.1 mol L^{-1} sodium hydroxide, doubly distilled water, 5 min for each and running buffer for 10 min, which was necessary for obtaining a reproducible electroosmotic flow (EOF). CZE was performed at the separation voltage of 17 kV with 0.05 mol L^{-1} borate–0.10 mol L^{-1} phosphate mixture solution (pH 8.4) as running buffer. The potential applied to the working electrode was 0.85 V (versus SCE). Samples were electrokinetically injected at 17 kV for 10 s. All experiments were carried out at room temperature. Currents were allowed to reach a stable baseline prior to doing experiments.

2.4. Sample preparation

One kind of orange and two kinds of tomatoes were obtained from local supermarket. The orange of Sunkist brand was planted in America, and the two kinds of tomatoes were nontransgenic and transgenic (cherry-tomato), respectively. A precisely weighed quantity of the samples was dissolved in 10 mL of anhydrous ethanol and sonicated for 30 min, then filtered through a cellulose filter and thereafter stored at 4 °C. The stock solution was diluted three times with 0.05 mol L^{-1} borate–0.10 mol L^{-1} phosphate buffer (pH 8.4) and filtered with 0.22 μm polypropylene acrodisc syringe filter, then sonicated before the analysis of CZE-AD.

3. Results and discussion

3.1. Electrochemistry experiments

Cyclic voltammetry was employed to investigate the electrochemical characteristics of the six anlytes at the modified electrode. As an example, Fig. 1 shows cyclic voltammograms of 50 μM chlorogenic acid in the borate–phosphate buffer solution at the bare carbon electrode (curve a) and vitamin B_{12} modified electrode (curve b), respectively. It could be seen that there was weak oxidation peak current response at about 0.2 V at the bare carbon disk electrode, while at the modified electrode, the oxidation currents

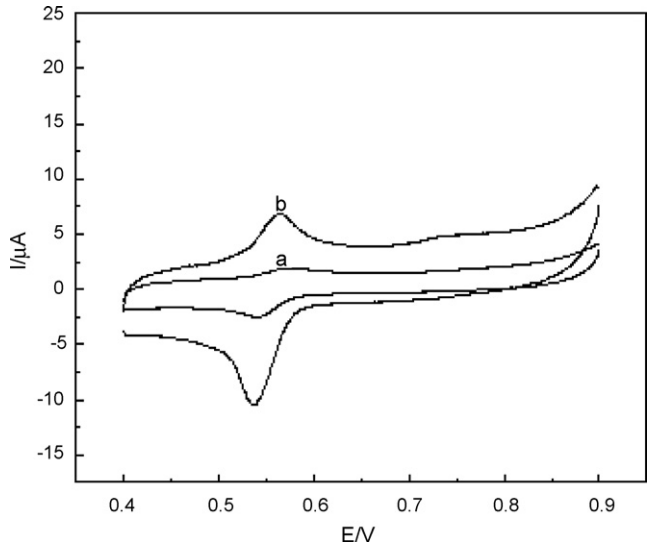

Fig. 1. Cyclic voltammetry of borate–phosphate buffer solution (pH 8.4) in the presence of 1.0×10^{-5} mol L^{-1} chlorogenic acid at (a) bare carbon disk electrode, (b) vitamin B_{12} modified electrode. Scan rate, 50 mV/s.

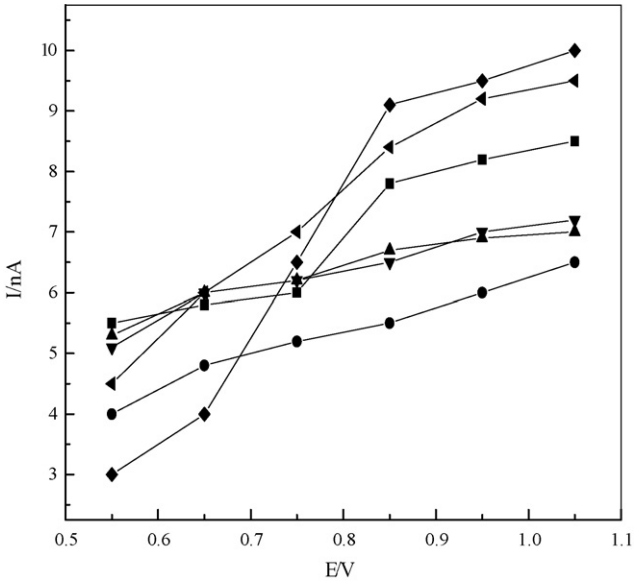

Fig. 2. Hydrodynamic voltammograms with a concentration of 2.0×10^{-5} mol L^{-1} glutathione (■), 1.0×10^{-5} mol L^{-1} ascorbic acid (●), 1.0×10^{-5} mol L^{-1} vanillic acid (▲), 2.0×10^{-5} mol L^{-1} chlorogenic acid (▼), 1.0×10^{-5} mol L^{-1} salicylic acid (♦), and 1.0×10^{-5} mol L^{-1} caffeic acid (◄), under the optimal CZE-AD conditions.

responses increased evidently about five times. The phenomenon can be explained by that vitamin B_{12}, the macrocyclic cobalt complexes, decreased the over potential with high current efficiency, since the cobalt complex can afford the ability to the analytes oxidation by Co(I), Co(II) and Co(III) surface states [29,30]. Analogous electrochemical behaviours were seen for other five investigated analytes. The modified electrode was chosen as working electrode for the study of capillary zone electrophoresis performance.

3.2. Effect of the detection potential

In amperometric detection, the potential applied to the working electrode directly affects the sensitivity, detection limit and stability of this method. Fig. 2 illustrates the hydrodynamic voltammograms (HDVs) for the six analytes at the modified working electrode. The curves were recorded step by step over the +0.55 to +1.05 V range, using a separation voltage of 17 kV. It was found that the current responses of these analytes increased with the applied potential increasing and got leveling at about +0.95 V. However, when applied potential was greater than +0.85 V (versus SCE), both the baseline noise and the background current increased, resulting in an unstable baseline, which was a disadvantage for sensitive and stable detection. Therefore, the applied potential of +0.85 V (versus SCE) was selected as the most suitable detection potential in this experiment, where the background current was not too high and the *S*/*N* ratio was the highest.

3.3. Optimization of capillary electrophoresis conditions

3.3.1. Effect of buffer pH and concentration

In order to improve the resolution and sensitivity, borate, phosphate, borate–phosphate mixture were employed as running buffer in this CZE separation respectively, and the best result was got with borate–phosphate mixture buffer.

The effects of pH and concentration of the buffer on the electrophoretical separation of the six analytes were evaluated in order to select the optimum separation conditions. The pH dependence of the migration time was investigated in the pH range of 5.0–10.0. When the running buffer pH increased, the resolution of

all compounds was improved. It was clear that when pH was 8.4, the six analytes could be separated completely. However, the peak height was low and the peak shape became poorer at pH value above 8.4. Therefore, pH 8.4 was chosen as the running buffer in considering of the peak height, resolution and the analytical time in the experiments.

Besides the pH value, the running buffer concentration is also an important parameter. The effect of the concentration of borate–phosphate mixture buffer was investigated. Several different concentrations of the buffer (0.05, 0.10, 0.20, 0.30, 0.40, 0.50, 0.60, 0.70 mol L^{-1} of borate mixed with 0.10, 0.20, 0.30, 0.40, 0.50, 0.60, 0.70, 0.80 mol L^{-1} of phosphate, respectively) were tested in order to choose the best one. The results showed that with the increase of the concentration of borate–phosphate buffer, the separation efficiency was much better. However, higher buffer concentrations also have negative effects on the detection limit, because the peak height of six analytes decreased and the effect of Joule heating became more pronounced. So 0.05 mol L^{-1} borate −0.10 mol L^{-1} phosphate buffer (pH 8.4) was finally chosen as the optimum running buffer concentration in this work, on the basis of the peak height, resolution, analysis time, and buffer capacity.

3.3.2. Effect of the separation voltage and injection time

The separation efficiency of CZE was investigated within the separation voltage range from 10 to 22 kV. The migration time of the analytes was significantly shortened and their corresponding current peaks were sharpened as the separation voltage was increased. However, if the separation voltage was higher than 18 kV, more Joule heat was produced because of the higher current inside the capillary, which caused peak broadening and reduced separation efficiency. As a compromise, 17 kV was selected as the optimum separation voltage in the experiments. Moreover, in order to make the process stable and obtain the best separation results, the same high-voltage was chosen for separation and injection.

Electrokinetic injection was used in the CZE experiment. The effect of injection time was investigated by selecting different injection time (4, 6, 8, 10 and 12 s at a voltage of 17 kV). It was found that when the injection time was prolonged, the peak height increased correspondingly. However, the current response peaks of the analytes were obviously broadened if the injection time was more than 12 s. So, 10 s was selected as the injection time in the experiments and satisfactory results were obtained under these conditions.

3.4. Analytical performance

Through the experiments above, the optimum conditions of CZE-AD for determining glutathione, ascorbic acid, vanillic acid, chlorogenic acid, salicylic acid, and caffeic acid were detection potential 0.85 V (versus SCE), separation voltage 17 kV, electrokinetic injection time 10 s (voltage 17 kV) and 0.05 mol L^{-1} borate–0.10 mol L^{-1} phosphate running buffer (pH 8.4). Fig. 3 shows the electropherograms of a standard six analytes mixture solution under the optimum conditions. It was clear that a very good base-lined separation was achieved for the six analytes within 15 min.

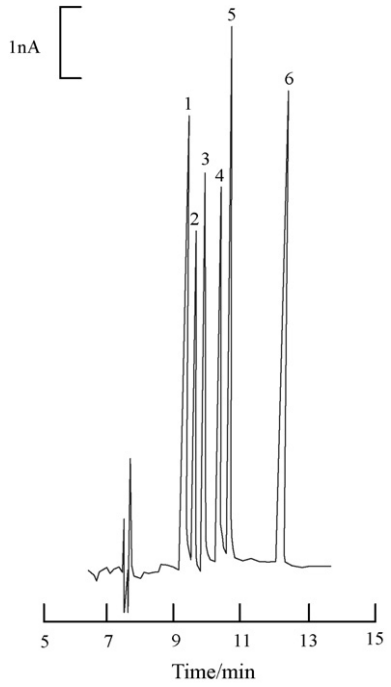

Fig. 3. Electropherograms of a standard solution containing 2.0×10^{-5} mol L^{-1} glutathione, 1.0×10^{-5} mol L^{-1} ascorbic acid, 1.0×10^{-5} mol L^{-1} vanillic acid, 2.0×10^{-5} mol L^{-1} chlorogenic acid, 1.0×10^{-5} mol L^{-1} salicylic acid, and 1.0×10^{-5} mol L^{-1} caffeic acid by CZE-AD at the vitamin B_{12} modified working electrode under the optimal conditions of detection potential 0.85 V (versus SCE), separation voltage 17 kV, electrokinetic injection time 10 s (voltage 17 kV) and 0.05 mol L^{-1} borate–0.10 mol L^{-1} phosphate running buffer (pH 8.4): (1) glutathione, (2) ascorbic acid, (3) vanillic acid, (4) chlorogenic acid, (5) salicylic acid, and (6) caffeic acid.

3.5. Repeatability, linearity and detection limits

A standard mixture solution was used to determine the repeatability of the current response and migration time under the optimum conditions in this experiment. The relative standard deviations (RSDs) of peak height and migration time are 2% and 3% for glutathione, 3% and 4% for ascorbic acid, 4% and 2% for vanillic acid, 3% and 4% for chlorogenic acid, 2% and 2% for salicylic acid, and 3% and 2% for caffeic acid, respectively. After the analysis was repeated five times under the same conditions, the peak signals only decreased slightly, which demonstrated that this method was of good repeatability.

A series of standard mixture solutions of glutathione, ascorbic acid, vanillic acid, chlorogenic acid, salicylic acid, and caffeic acid ranging from 2.5×10^{-7} to 1.0×10^{-4} mol L^{-1} were tested to determine the linearity of this detection method. Table 1 summarizes the regression equation, correlation coefficient and detection limit according to the 3 sb/m criterion [31], where m is the slope of the calibration curve and sb the standard deviation. Their detection limits were 2.9×10^{-7}, 2.2×10^{-7}, 1.6×10^{-7}, 3.9×10^{-7}, 7.5×10^{-8}, and 7.8×10^{-8} mol L^{-1}, respectively, which are lower than using a carbon disc working electrode. Table 2 compared

Table 1
The regression equations and the detection limits of glutathione, ascorbic acid, vanillic acid, chlorogenic acid, salicylic acid and caffeic acid.

Analytes	Concentration range (10^{-6} mol L^{-1})	Regression equation C (10^{-3} mol L^{-1}); I (nA)	Correlation coefficient	Detection limit (10^{-6} mol L^{-1})
Glutathione	1.0–100.0	$I = 388C - 0.018$	0.9998	0.29
Ascorbic acid	0.5–100.0	$I = 546C - 0.113$	0.9973	0.22
Vanillic acid	0.5–100.0	$I = 675C - 0.079$	0.9996	0.16
Chlorogenic acid	1.0–100.0	$I = 299C + 0.096$	0.9968	0.39
Salicylic acid	0.25–50.0	$I = 965C - 0.051$	0.9995	0.075
Caffeic acid	0.25–50.0	$I = 957C + 0.018$	0.9992	0.078

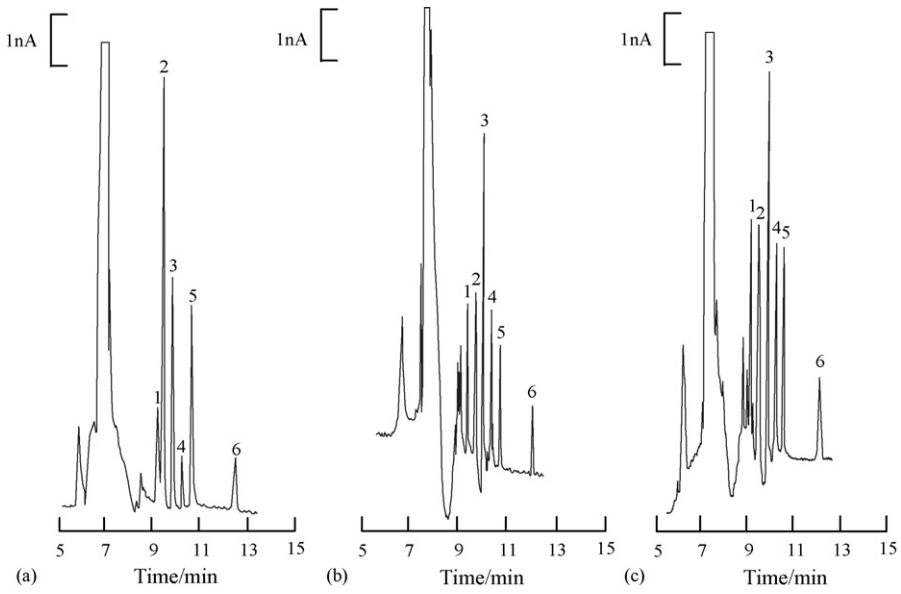

Fig. 4. Electropherograms of 10 mg orange was dissolved and extracted by 1 mL^{-1} anhydrous ethanol solutions at modified electrode under the optimal CZE-AD conditions: (a) Sunkist orange, (b) nontransgenic tomato, (c) transgenic tomato (cherry-tomato): (1) glutathione, (2) ascorbic acid, (3) vanillic acid, (4) chlorogenic acid, (5) salicylic acid, and (6) caffeic acid.

Table 2
The contrast of the six analytes detection limits in this experiment with the relevant reported in the literatures.

Analytes	Detection limit[a] (10^{-6} mol L^{-1})	Detection limit[b] (10^{-6} mol L^{-1})
Glutathione	0.29	2.5 [32]
Ascorbic acid	0.22	1.0 [33]
Vanillic acid	0.16	1.5 [34]
Chlorogenic acid	0.39	1.5 [35]
Salicylic acid	0.075	0.16 [36]

[b] Detection limits of the six analytes in the relevant literatures.

different detection limits of the six analytes with reported in the relevant literatures [32–37]. The results demonstrate that the vitamin B_{12} modified working electrode is suitable for the detection of the six analytes, allowing a reproducible and more sensitive quantification of mixtures containing the six analytes.

3.6. Sample analysis

In order to demonstrate the practical application of the modified electrode by present analytical method, the determination of active ingredients in Sunkist orange and tomatoes practical samples was conducted by CZE-AD at the modified electrode under the selected optimum conditions. Typical electropherograms of the samples are shown in Fig. 4. By comparing the migration time of analytes with the electropherogram of the standard mixture solution and standard addition approach was used for further demonstration. The results showed that the active ingredients were (1) glutathione, (2) ascorbic acid, (3) vanillic acid, (4) chlorogenic acid, (5) salicylic acid, and (6) caffeic acid, indeed. The prolonged migration time of some analytes can be explained that in the practical samples, some organic acids such as citric acid, malic acid, tartaric acid, etc. are contained, which might influence the migration time of the active ingredients. From the sample electropherograms, it can be found that large amount of ascorbic acid in Sunkist orange (Fig. 4a), while large amount of phenolics compounds in tomato

Table 3
Determination results of the recoveries for this method in orange and tomatoes sample ($n = 5$).

Samples	Active ingredients	Original amount (10^{-5} mol L^{-1})	Added (10^{-5} mol L^{-1})	Found (10^{-5} mol L^{-1})	Recovery (%)	RSDs (%)
Orange	Glutathione	0.54	1.0	1.58	104.0	3.6
	Ascorbic acid	1.61	1.0	2.59	98.0	3.2
	Vanillic acid	0.73	1.0	1.78	105.0	4.2
	Chlorogenic acid	0.47	1.0	1.50	103.0	3.8
	Salicylic acid	0.48	1.0	1.45	97.0	3.9
	Caffeic acid	0.11	1.0	1.09	98.0	3.3
Tomato	Glutathione	0.90	1.0	1.92	102.0	4.5
	Ascorbic acid	0.72	1.0	1.70	98.0	4.1
	Vanillic acid	0.52	1.0	1.48	96.0	4.6
	Chlorogenic acid	1.17	1.0	2.20	103.0	3.9
	Salicylic acid	0.36	1.0	1.40	104.0	3.2
	Caffeic acid	0.14	1.0	1.12	98.0	4.4
Cherry-tomato	Glutathione	0.70	1.0	1.65	95.0	4.5
	Ascorbic acid	0.60	1.0	1.62	102.0	4.7
	Vanillic acid	0.95	1.0	2.01	106.0	3.8
	Chlorogenic acid	0.99	1.0	1.95	96.0	4.2
	Salicylic acid	0.28	1.0	1.25	97.0	3.9
	Caffeic acid	0.10	1.0	1.15	105.0	4.1

and cherry-tomato (Fig. 4b and c). Therefore, in order to maintain physical well being, it is necessary for us to intake them every day. Accurate amounts of glutathione, ascorbic acid, vanillic acid, chlorogenic acid, salicylic acid, and caffeic acid were added to the sample solutions, and the recovery values were obtained using their peak height from the calibration curve under the same conditions. The average recoveries and RSDs for the six analytes are listed in Table 3. The results indicate that this method is accurate for the analytes.

4. Conclusion

This work demonstrates that the modified vitamin B_{12} electrode showed excellent catalytic activity towards the antioxidants of glutathione, ascorbic acid, vanillic acid, chlorogenic acid, salicylic acid, and caffeic acid and can be used as amperometric detector for capillary zone electrophoresis to detect simultaneously. The results show that this method is of high separation efficiency, short-analysis time, and convenience of analysis. Under the optimum conditions, the six analytes are separated completely within 15 min and good linearity, repeatability and recovery results are obtained. Their detection limits are low to 10^{-8} mol L^{-1}, which are lower than using a carbon disc working electrode. From the present study, it can be concluded that the modified vitamin B_{12} electrode successfully employed in capillary zone electrophoresis provides a new methodology for the CZE-AD.

Mediator
Glucose biosensor

ABSTRACT

A novel amperometric glucose sensor based on inclusion complex of mono-6-thio-β-cyclodextrin/ferrocene capped on gold nanoparticles (GNPs/CD–Fc) and glucose oxidase (GOD) was described. The inclusion complex of mono-6-thio-β-cyclodextrin/ferrocene capped on gold nanoparticles played an effective role of an electron shuttle and allowed the detection of glucose at 0.25 V (versus SCE), with dramatically reduced interference from easily oxidizable constituents. The sensor (GNPs/CD–Fc/GOD) showed a relatively fast response time (5 s), low detection limit (15 μM, S/N = 3), and high sensitivity (ca. 18.2 mA M^{-1} cm^{-2}) with a linear range of 0.08–11.5 mM of glucose. The excellent sensitivity was possibly attributed to the presence of the GNPs/CD–Fc film that can provide a convenient electron tunneling between the protein and the electrode. In addition, the biosensor demonstrated high anti-interference ability, stability and natural life. The good stability and natural life can be attributed to the following two aspects: on the one hand, the fabrication process was mild and no damage was made on the enzyme molecule, on the other hand, the GNPs possessed good biocompatibility that could retain the bioactivity of the enzyme molecules immobilized on the electrode.

1. Introduction

Amperometric enzyme electrodes possess the advantages of combining the specificity of the enzyme for recognizing particular target molecules with the direct transduction of the rate of reaction into the current [1]. Enzyme electrodes, particularly the glucose electrode, have been subject to numerous studies devoted to their optimization for both biomedical and bioprocess control applications [2]. For glucose sensors, this enzyme is well-studied, inexpensive, stable and particularly applied in clinical and chemical analysis [3]. Nevertheless, there is need to improve the sensitivity and stability of glucose sensors due to the great demand for blood glucose measurements in control and treatment of diabetes. Recently, Adam Heller and Ben Feldman have given a wonderful review about electrochemical glucose sensors and their applications in diabetes management [4].

The oxidase-based amperometric biosensors previously relied on the immobilization of oxidase enzymes on the surface of various electrodes. However, electron transfer efficiency of redox enzymes is poor in the absence of mediator, because enzyme active sites are deeply embedded inside the protein. The sensitivity of resulted biosensors can be significantly improved by the immobilization of mediators in the matrices [5–9]. Among the different mediators described in the literature, ferrocene (Fc) and its derivatives, first reported by Cass et al. [5], have proved to be the most efficient electron transfers for the GOx enzymatic reaction. There are a lot of cases about ferrocene (Fc) and its derivatives introduced to enzyme biosensor as the mediator [10–16]. However, leakage has been a main problem for the entrapment of mediators due to their low molecular weight in polymer matrices [8]. In order to prevent the leakage of mediator, mediator can be linked covalently with polymer or with high molecular weight compounds before immobilization on the surface of electrode [8,17]. Gorton et al. [18] studied ferrocene-containing siloxane polymer modified electrode surface with a poly (ester-sulfuric acid) cation-exchanger to improve the stability of the mediator. Another alternative method is to synthesize a few Fc derivatives with specific functional groups [19,20], but the preparation methods are complicated. For instance, Jönsson et al. [19] used hydroxymethyl Fc and anthracene carboxylic acid to synthesize anthracene substituted ferrocene.

The other alternative method to increase the stability of Fc and its derivatives is the formation of inclusion complex with cyclodextrin (CD), a class of torpidly shaped cycloamyloses with a hydrophilic outer surface and a hydrophobic inner cavity, which makes the dissolubility of Fc decrease. Several investigations have been made to study the characterization of interacting Fc–CD

doi:10.1016/j.talanta.2009.07.068

system and their roles [21–23]. Liu et al. [21] developed the sensitive biosensor for glucose by immobilizing glucose oxidase in β-cyclodextrin via cross-linking and by including ferrocene in the cavities of dextrin polymer via host–guest reaction. Zhang et al. [22] successfully used ferrocene with β-cyclodextrin to prepare β-CD/Fc inclusion complex modified carbon paste electrode. The water-soluble inclusion complex of 1,1-dimethylferrocene with (2-hydroxypropyl)-β-CD has been used in bioelectrocatalysis [23].

Recently, nanomaterials, such as gold (Au) [24–27] and magnetic nanoparticles have attracted much interest in the construction of biosensors due to their unique chemical and physical properties. Gold nanoparticles, in particular, have been widely used to construct biosensors because of their excellent ability to immobilize biomolecules and at the same time retain the biocatalytic activities of those biomolecules. In this paper, gold nanoparticles were capped by inclusion complex between mono-6-thio-β-cyclodextrin and ferrocene through –SH, which resulted into stable fixation of ferrocene on the surface of gold nanoparticles. Then, the glucose biosensors were constructed by using GNPs/CD–Fc as the building block. The composite nanoparticles showed excellent efficiency of electron transfer between the GOD and the electrode for the electrocatalysis of glucose.

2. Experimental

2.1. Reagents

Glucose oxidase (GOD) (EC1.1.3.4, Type VII-S, 108 U/mg) from *Aspergillus niger* was purchased from Amresco. Ferrocene was obtained from the Shanghai Chemical Reagent Pharmaceutical Factory. Hydrogen tetrachloroaurate tetrahydrate ($HAuCl_4{\cdot}4H_2O$) and sodium borohydride ($NaBH_4$) were purchased from Shanghai Chemical Reagents Company. Mono-6-thio-β-cyclodextrin was synthesized according to the literature [28]. Other reagents used in this paper were of analytical grade and used as commercially available. Double distilled and sterilized water was used to prepare all solution.

2.2. Apparatus

The film of GNPs/CD–Fc/GOD was characterized by scanning electron microscope (SEM). SEM was taken by Philips XL-30ESEM operating at an accelerating voltage of 20 kV. The morphology and size of GNPs/CD–Fc after adding glucose oxidase aqueous solution were investigated on a Philips TECNAI-12 transmission electron microscope (TEM) instrument operated at an accelerating voltage of 120 kV. Images of GOD in GNPs/CD–Fc organized assemblies were observed by TEM after negative staining with sodium phosphotungstate. All electrochemical experiments were carried out with a CHI660c electrochemical workstation (Chenghua, Shanghai) with a three-electrode cell. A platinum disk electrode (diameter: 1 mm) was used as a working electrode. The reference electrode was a saturated calomel electrode (SCE). All potentials reported in this paper were against SCE. A platinum wire was used as the counter electrode. All measurements were carried out in a thermostated cell at 25 °C. The aqueous electrolyte solutions were prepared in 0.1 M PBS buffers (Na_2HPO_4–NaH_2PO_4) in which the pH was measured as 7.0 using a PHs-25 pH-meter (Leizi Instrumental Factory, Shanghai). Electrolytic solutions were purged with highly purified nitrogen for at least 20 min prior to the series of experiments.

2.3. Construction of the GNPs/CD–Fc/GOD modified electrode

Firstly, the inclusion complex was synthesized. Mono-6-deoxy-6-(*p*-tolylsulfonyl)-β-cyclodextrin (β-CD–SH) (0.5 g) and Fc (1.6 g) were dissolved by 20 mL DMF in a 100 mL conical flask. Then, the solution should be stirred continually at least 24 h at room temperature. Finally, 20 mL ethanol was added into the solution. Immediately, a great deal of yellow crystal precipitate was occurred, which was the inclusion complex of Fc with β-CD–SH. The solubility of inclusion complex was weak in ethanol. The inclusion complex was obtained by filtrating and washed with ethanol and water for three times in turn, respectively, to clean the residual guest and host monomers. Then it was dried in a vacuum oven at 50 °C for 24 h.

Secondly, CD–Fc capped gold nanoparticles were prepared by the reduction of $AuCl_4^-$ with a similar method described before [28]. $NaBH_4$ and CD–Fc were dissolved in 10 mL of DMF, and $HAuCl_4$ in 10 mL of DMF was quickly added into the mixture of $NaBH_4$ and CD–Fc. The molar ratio of [CD–Fc]/[$HAuCl_4$] was 1:1. After 24 h stirring at room temperature, the precipitate was collected by centrifugation and washed with 25 mL of DMF for three times and then with 25 mL ethanol/water (9:1 in volume) for four times. At last, the precipitate, GNPs/CD–Fc, was dried at 60 °C in a vacuum oven for 24 h and characterized by TEM.

Finally, the working electrode (diameter: 1 mm) was polished to a mirror with 0.05 μm alumina aqueous slurry and rinsed with water in an ultrasonic cleaning bath before use. GOD was also dissolved in deionized and decarbonated water with a concentration of 5 mg mL^{-1}. The colloidal suspension of GNPs/CD–Fc (1 mg mL^{-1}) was prepared by dispersing GNPs/CD–Fc in deionized and decarbonated water. A defined amount of the aqueous mixture (GOD and GNPs/CD–Fc) was spread on the surface of the platinum disk electrode. The coating was dried in air at room temperature. Finally, the film was equilibrated under stirring for about 20 min in a phosphate buffer solution in order to allow hydrogel formation and remove unadsorbed enzyme. All electrodes were stored in PBS at 4 °C.

3. Results and discussion

3.1. Characterization of the GNPs/CD–Fc/GOD films

Fig. 1 shows SEM images of GNPs/CD–Fc film and GNPs/CD–Fc/GOD composite film. From Fig. 1A, GNPs/CD–Fc was found to form the three-dimensional island structure of film. However, when enzyme was absorbed onto GNPs/CD–Fc, the composite film was multi-layer and multi-pore structure which indicated that the composite film was highly porous in nature (Fig. 1B). At larger magnification in Fig. 1C, the distribution of the enzyme on the composite film can be clearly observed. The enzyme congregated and formed global congregation (diameter: 100–500 nm). The multi-layer and multi-pore structure of the GNPs/CD–Fc/GOD composite film would be of benefit to the fast electron shuttle among enzyme, mediator and substrate.

The morphology of GOD and GNPs/CD–Fc in aqueous solution may be obtained by TEM images. The image of GNPs/CD–Fc was shown in Fig. 2A. Because there were enough –SH to cap on the surface of the gold nanoparticles, stable gold nanoparticles with uniform distribution were obtained. However, when GOD was added into the solution of GNPs/CD–Fc, the gold nanoparticles were congregated and formed abnormal structure shown as in Fig. 2B. Because the morphology of biomacromolecules cannot be observed directly by TEM, specimen must be negative staining with heavy metal salt to increase contrast. Therefore, in order to observe the morphology of GOD, the specimen was negative staining with sodium phosphotungstate for 60 s. Fig. 2C showed that a mass of GOD were congregated together and a lot of gold nanoparticles were deeply embed into the congeries. The electron transfer between the redox center of GOD and electrode would be effectively promoted through the combination mode between GOD and GNPs/CD–Fc.

3.2. *Electrocatalytic oxidation of glucose at biosensor of GNPs/CD–Fc/GOD*

The GNPs/CD–Fc modified platinum electrode was cycled continuously in the potential range of −0.1 to 0.5 V (versus SCE) in 0.1 M PBS buffers. The current finally reached a steady state after 10 cycles. From Fig. 3A, there were well-defined anodic and cathodic peaks with the mean potential $\Delta E = (E_{pa} - E_{pc})$ at 75 mV (curve a in Fig. 3A). It corresponded to the reversible single electron oxidation of Fc to Fc^+, which indicated that the electrochemistry reaction was close to quasi-reversible state. Next, at the same condition, cyclic voltammogram of the enzyme electrode was carried out. In Fig. 3A, curve b showed well-defined anodic and cathodic peaks. Under the same conditions, neither glucose nor glucose oxidase showed any observable electrochemistry, so the peaks were still attributed to the redox reaction of Fc. Compared with the voltammogram of GNPs/CD–Fc modified platinum electrode, the anodic peaks shifted from 0.194 to 0.258 V and the ΔE increased 30 mV. When GOD was

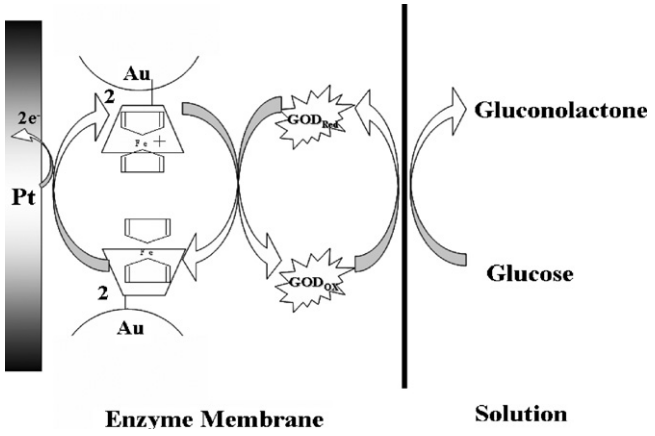

Fig. 4. Schematic illustration of sensing mechanism for electrocatalytic glucose on the GNPs/CD–Fc/GOD modified platinum electrode surface.

immobilized in the composite film, protein molecule blocked the charge transfer, which led to the positive shift of anodic peak and the value of ΔE increase. The phenomenon about the shifting of E_p upon immobilization of GOD was also observed in ferrocene-containing Nafion film [29]. At the same time, the current of anodic peak was larger than that of cathodic peak. The phenomenon was also observed in ferrocene-containing Nafion film. Upon the addition of glucose to the test solution, a very strong catalytic effect was observed: a dramatic increase in the oxidation current that was simultaneous with a gradual decrease of the reduction current (curves b–g in Fig. 3B). The decrease of the cathodic current was attributed to the reduction of oxidized form of Fc (Fc^+) by the reduced form of the enzyme (GODred), which was more efficient than the electro-reduction of the former at the base electrode. The oxidation wave was enhanced, since the reduced form of the mediator (Fc) was regenerated and then reoxidized at the base electrode. In this case, the mechanism of electron transfer from glucose to mediator was known to be of the "ping-pong" type which was shown in Fig. 4.

3.3. Optimization of experimental variables

In order to optimize the performance of the glucose biosensor based on GNPs/CD–Fc/GOD modified electrode, various experimental variables affecting the amperometric determination of glucose, such as the concentration ratio of GNPs/CD–Fc and GOD, GOD loading and pH of the solution, were investigated.

3.3.1. Influence of GOD loading

First, the effect of concentration ratio of GNPs/CD–Fc and GOD was studied. The response currents reached the maximum when the mass ratio of GOD and GNPs/CD–Fc was 1:5. The effect of GOD loading activity on the response characteristics of GNPs/CD–Fc/GOD modified electrode was examined in the presence of 1.0 mM glucose. The results showed that the current increased with the enzyme loading and the response currents reached the maximum when the GOD loading located at 12.7 $\mu g\,mm^{-2}$. However, when the GOD loading continuously increased, the current gradually decreased, which was due to the increasing resistance of the biomembrane. Furthermore, it is well known that enzyme denaturation often causes a considerable reduction in loss of biosensor response. Considering the response stability of the GNPs/CD–Fc/GOD biosensor, GOD loading for each test strip was set at 12.7 $\mu g\,mm^{-2}$ in this study.

3.3.2. Influence of pH

The value of pH is known to be one of the most important factors affecting the enzyme activity and stability, and hence the performance of enzyme electrodes. Lukachova et al. [29] also stated that pH values between 5.5 and 7 should be considered as being more appropriate for biosensors application, since most oxidases have pH optima in the neutral pH region. Thus, effects of pH on the current of the biosensor were determined in the range of pH 5–9 in the presence of glucose (1.0 mM). The results show that the highest response current can be obtained at pH 7. The pH value of the highest activity for GOD is 5.5 as reported by the supplier. In the case, the optimal pH value is larger than that for GOD highest activity (ca. pH 5.5), which is attributed to the presence of GNPs/CD–Fc, which may change the microenvironment of the enzyme and the surface charge distribution of the enzyme [30]. The experiment result also shows that the current sharply decreases at higher pH values. Wilson and Turner [31] ever reported that catalytic activity of GOD was rapidly lost below 2 or above 8 for pH. This result suggested that GNPs/CD–Fc addition may have no benefit to preventing GOD from alkaline inactivation. Moreover, the physiological pH value of blood is known to be near 7. As a consequence, pH 7 was selected for evaluating the performance of the glucose biosensor based on the GNPs/CD–Fc/GOD modified electrode.

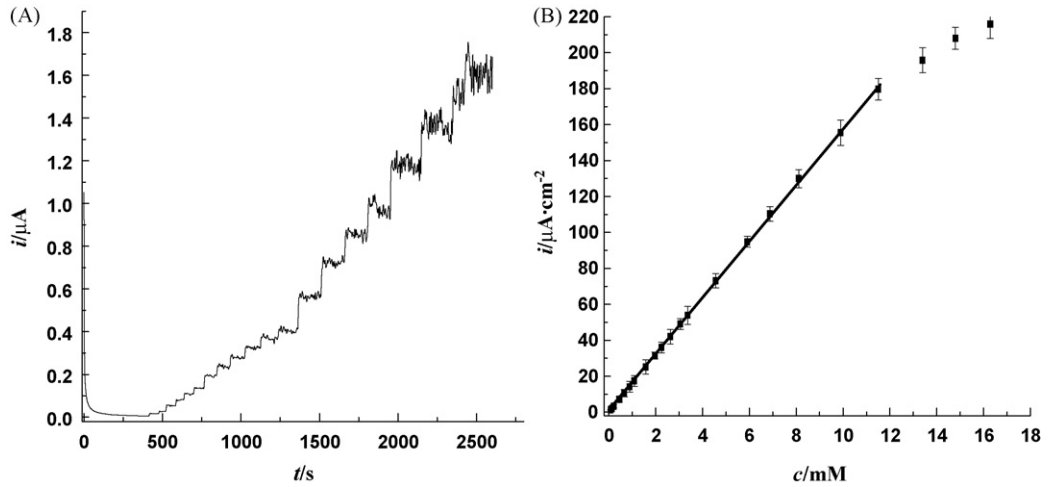

Fig. 5. (A) The i–t plot of GNPs/CD–Fc/GOD electrode response for glucose, under the optimum conditions; (B) Calibration curves of GNPs/CD–Fc/GOD for glucose, under the optimum conditions (0.1 M phosphate buffer solution with pH 7.0, at 25 °C, E_{app} = 0.25 V).

3.4. Performance of the chronoamperometric glucose biosensors

The electrocatalytic oxidation of glucose at GNPs/CD–Fc/GOD modified platinum electrode was also studied by amperometry. The potential of 0.25 V (versus SCE) was chosen as the applied potential for the amperometric determination of glucose. Fig. 5A showed the typical response curves for the GNPs/CD–Fc/GOD modified platinum electrode on successive injections of glucose to the stirring PBS at pH 7.0. Fig. 5B showed the corresponding linear range of the calibration curve obtained via the GNPs/CD–Fc/GOD modified platinum electrode. A clearly defined oxidation current proportional to the concentration of glucose was observed. The biosensor achieved 95% of the steady-state current within 5 s, with a linear range of 8×10^{-5} to 11.5×10^{-3} M. This kind of biosensor had a low detection limit of 1.5×10^{-5} M based on S/N = 3 and a high sensitivity of 18.2 mA M^{-1} cm^{-2}. The high sensitivity of the enzyme electrode can be attributed to the excellent adsorption ability, high electrocatalytic activity and good biocompatibility of the GNPs/CD–Fc composite nanoparticles. The apparent Michaelis–Menten constant (K_M) can be obtained by the analysis of the slope and the intercept of the plot of the reciprocals of the steady-state current versus glucose concentration. K_M value for GNPs/CD–Fc/GOD modified platinum electrode was 6.42 mM.

3.5. Effects of the interferences on the response of mediated enzyme biosensors

Generally, the influence of the presence of easily oxidizable endogenous and exogenous interferences was examined at their physiological normal levels on the biosensor response to glucose as reported in literature [32,33]. However, the normal concentration of these interferences (0.1 mM for ascorbic acid, 0.5 mM for uric acid, 0.2 mM for dopamine, 0.05 mM for *p*-acetaminophenol, and 0.02 mM for L-cysteine) was rather low compared with that of glucose (5.6 mM). The experiment results were shown in Table 1. Except for uric acid, the influences of ascorbic acid, dopamine, *p*-acetamidophenol and L-cysteine were quite weak. This was ascribed to the efficiency of the electrocatalytic process in the whole structure of the GNPs/CD–Fc composite film and also to the value of the low operating potential of 0.25 V versus SCE.

3.6. Reproducibility and stability of GNPs/CD–Fc/GOD biosensors

The reproducibility of biosensor was estimated by five GNPs/CD–Fc/GOD electrodes, which were prepared under the same condition and used to detect the current response of 1 mM glucose. The results revealed that the biosensors possessed satisfying reproducibility with a relative standard deviation (RSD) of 5.87% for 50 successive measurements (each sensor was performed 50 measurements). The storage stability of enzymatic biosensor in storage conditions (phosphate buffer of pH 7.0 at 4 °C) was investigated in the same phosphate buffer solution containing 1.0 mM glucose. In the storage stability test, 5 measurements of each biosensor were performed in each day during the period of the 30 days. The corresponding result showed that 82% response current was still retained after 30 days. The good stability can be attributed to the following aspects. Firstly, the fabrication process was mild and no damage was made on the enzyme molecule. Secondly, the GNPs possessed good biocompatibility that can retain the bioactivity of the enzyme molecules immobilized on the electrode. Finally, GOD can be immobilized efficiently on the film, which maintained a porous environment likely to impart fast mass transport issues into the composite film and thereby good sensitivity to the biosensor.

Table 1
Influence of interfering compounds on the response of GNPs/CD–Fc/GOD electrode.

Interfering compound	Physiological concentration (mM)	$(i_{G+I} - i_G)/i_G$ (%)
Ascorbic acid	0.1	3
Uric acid	0.5	18
3-Hydroxytyramine hydrochloride	0.2	5
p-Acetamidophenol	0.05	4
L-Cysteine	0.02	1.5

i_G: current response to 5.6 mM glucose; i_{G+I}: current response to 5.6 mM glucose in presence of interfering compound.

Table 2
Glucose content determination in serum sample.

Samples	Content determined by local hospital (mM)	Content determined by current method (average of five times) (mM)	Relative error (%)
1	4.17	4.35	−4.1
2	6.19	5.97	+3.7
3	4.88	4.99	−2.2
4	5.83	5.67	+2.8
5	4.26	4.43	−3.8

3.7. Real sample analysis

Human plasma samples were assayed to demonstrate the practical use of the GNPs/CD–Fc/GOD electrode. Fresh plasma samples were first analyzed in the local hospital with Olympus AU2700 biochemistry analyzer (Japan). The samples were then reassayed with the GNPs/CD–Fc/GOD electrode. A plasma sample (0.5 mL) was added into 5 mL PBS (pH 7.0), and the response was obtained at +0.25 V. The contents of glucose in blood can then be calculated from the calibration curve. The results, which were shown in Table 2, were satisfactory and agreed closely with those measured by the biochemical analyzer done by local hospital, indicating that the fabricated glucose biosensor had practical potential.

4. Conclusions

GOD can be effectively immobilized on GNPs/CD–Fc modified electrode. The immobilized GOD maintained its bioactivity and native structure. Fc was fitted on the surface of GNPs through inclusion complex with CD. This construction of the GNPs/CD–Fc/GOD modified electrode can decrease the leakage of mediator and improve the reproducibility and stability of GNPs/CD–Fc/GOD biosensors. From the cyclic voltammetry and amperometric measurements, the entrapped Fc was demonstrated to be redox active and function as electron shuttling agent between GOD and electrode. The use of artificial electron mediators to shuttle electrons from the redox center of the enzyme to the surface of the working electrode can effectively reduce the operating potential (0.25 V) and hence enhance selectivity and sensitivity.

Molecularly imprinted polymers
Dairy products
Solid-phase extraction

ABSTRACT

In this paper, a highly selective sample cleanup procedure combining molecular imprinting and solid-phase extraction (MI-SPE) was developed for the isolation of melamine in dairy products. The molecularly imprinted polymer (MIP) was prepared using melamine as the template molecule, methacrylic acid as the functional monomer and ethylene glycol dimethacrylate as the cross-linking monomer. The melamine imprinted polymer was used as selective sorbent for the solid-phase extraction of melamine from dairy products. An off-line MI-SPE method followed by high-performance liquid chromatography with diode-array detection for the detection of melamine was also established. The mean recoveries of melamine from ultra-heat treatment (UHT) milk and milk powders were 92.9–98.0% and 91.6–102.8%, respectively. Good linearity was obtained from 0.5 μM to 10 μM ($r > 0.999$) with a quantitation limit of 0.5 μmol/L (0.06 ppm) which was sufficient to analyse melamine at the maximum level permitted by U.S. Food and Drug Administration (1 ppm) in dairy products. It was demonstrated that the proposed MI-SPE-HPLC method could be applied to direct determination of melamine in dairy products.

1. Introduction

Melamine, known as tripolycyanamide, is an industrial chemical in the production of melamine resins, which are used in laminates, glues, adhesives, and plastics. Melamine can be found at ppm levels in food and beverages due to migration from melamine-containing resins [1], or as a metabolite product of cyromazine, an insecticide used on animals and crops [2]. When added to milk intentionally, melamine can increase the nitrogen concentration, which suggests a false increase in protein concentration (by Kjeldahl method [3]). Though, low level melamine does not pose any danger to humans, intentional adulteration by a high melamine level can induce renal failure and even death in humans especially babies and children. Therefore, a reliable method is needed to determine melamine residues in food and particularly in dairy products for children.

High-performance liquid chromatography (HPLC) [4–8] particularly reversed-phase liquid chromatography (RPLC), gas chromatography [9,10] and capillary electrophoresis (CE) [11,12] have been developed for the analysis of melamine in different matrices. In view of the complexity of the bio-matrix, pretreatment in order to concentrate and purify melamine for analysis should be executed. Solid-phase extraction (SPE) is an extraction method that uses a solid phase and a liquid phase to isolate one, or one type, of analyte from a solution. SPE is usually used to cleanup a sample before using a chromatographic or other analytical method to quantitate the amount of analyte(s) in the sample. One of the main disadvantages of the classical SPE sorbents (C_8, C_{18}, etc.) is low selectivity. New sorbents such as molecular imprinting polymers (MIPs) and immunosorbents were increasingly developed to meet the need of selectivity. Coupling MIPs with SPE is possible to combine the advantages of both molecular recognition and traditional separation methods. Thus, molecularly imprinted solid-phase extraction (MI-SPE) presents the high specificity, selectivity and sensitivity of the molecular recognition mechanism and the high resolving power of separation methods [13].

In the present work, melamine imprinted polymer was prepared through bulk polymerization method using melamine as template molecule, methacrylic acid (MAA) as the functional monomer and ethylene glycol dimethacrylate (EGDMA) as the cross-linking agent. The obtained imprinted polymer showed high affinity to melamine and was successfully applied as special SPE sorbent for selective extraction of melamine from dairy products. The method had been validated and applied to determine melamine from dairy products with satisfactory results. To our knowledge, this work represents

the first attempt of using MIPs as selective SPE sorbents for the determination of melamine in dairy products.

2. Experimental

2.1. Materials

Methacrylic acid (MAA), ethylene glycol dimethacrylate (EGDMA) were purchased from Alfa and distilled to remove the polymerization inhibitor before use. Azobis(isobutyronitrile) (AIBN) was the product of Sinopharm Chemical Reagent Beijing Co., Ltd. (Beijing, China) and was recrystallized prior to use. Acetonitrile and methanol are all of HPLC grade and from Merck. All water used was obtained from a Millipore Milli-Q purification system. UHT milk and milk powders were purchased from a local supermarket.

A 1.0×10^{-3} mol/L melamine (Sigma) stock solution was prepared in methanol and placed in the dark. More dilute standards were prepared by appropriate dilution.

2.2. HPLC and ESI-TOF/MS conditions

HPLC analysis was performed on an Agilent 1100 series HPLC system containing a G1322A Vacuum Degasser, a G1312A Binary Pump, a G1313A ALS Autosampler, a G1316A Column Compartment, and a G1315B diode-array detector. Separation was carried out on a Luna HILIC (hydrophilic interaction liquid chromatography) column (250 mm × 4.6-mm-i.d., particle size 5 μm, Phenomenex Inc., USA). The column thermostat was set at room temperature. The mobile phase was water–acetonitrile (10:90, v/v) containing 0.01 mol/L ammonium acetate, and its flow rate was set at 1.0 mL/min.

ESI-TOF/MS analysis was performed on a 6210 time-of-flight mass spectrometer (Agilent, USA) equipped with an electrospray ionization (ESI) interface. The mass spectrometer conditions were optimized for melamine detection as follows. The collision induced dissociation (CID) voltage was set at 100 V. A spray voltage of 4.0 kV was employed and the velocity of drying gas was 10.0 L/min. The temperature of the heated transfer capillary was 340 °C. The mass spectrometer was scanned from m/z 100 to 300 in full scan mode.

2.3. Preparation of MIP

MIP was prepared using bulk polymerization method by dissolving 0.5 mmol of melamine, 6 mmol of functional monomer MAA, 30 mmol of cross-linker EGDMA in 5 mL of ethanol and 1.5 mL of water in a 20 mL borosilicate glass bottle, equipped with a rubber cap. This mixture was stirred over night at 50 °C for the formation of a complex of imprint molecule and monomers. After added 0.25 mmol of AIBN, the solution was saturated with dry nitrogen for 5 min and the bottle was placed in a thermostated oil bath at 60 °C for 24 h. After polymerization, the polymer was ground with a mortar and pestle, and sieved between 200 mesh and 400 mesh screens to give particles with size dimensions between 37 μm and 74 μm and then repeatedly suspended in acetone to remove the small particles. The product was extracted with ethanol containing 10% acetic acid using a Soxhlet apparatus for 48 h. Then the product was washed with ethanol for three times and dried under vacuum at room temperature.

The non-imprinted polymer (NIP) particles were prepared and washed using the same recipe but without the addition of the template melamine.

2.4. Steady-state binding studies

An amount of 10 mg of the bulk polymer particles was weighed and put into a 4 mL vial. Then 2 mL of melamine solution with known concentration was mixed with the polymer. The mixture was slightly shaken on a horizontal shaker for 5 h at room temperature and then filtered. Final melamine concentrations were determined by HPLC using UV detection at 240 nm. The amount of melamine bound to the polymer was calculated by subtracting the amount of free melamine from the initial amount added to the mixture.

2.5. Preparation of MI-SPE column

MI-SPE column was prepared by packing the dry MIP (100 mg) in a 1.0 mL glass syringe (2 cm × 0.9 cm i.d.). The syringe tube was thoroughly cleaned and dried, and attached with two sieve plates at the bottom end and the top end, respectively. Prior to loading the sample, the MI-SPE column was washed with water containing 5% acetic acid to remove residual melamine from the synthetic procedure, until melamine could not be detected in the filtrate.

2.6. Sample preparation

Five milliliters of UHT milk was transferred to a 30 mL centrifuge tube. Then, 10 mL of acetonitrile was added, and this tube was thoroughly shaken for 1 min to achieve proteins precipitation. After centrifugation at 10,000 rpm for 3 min, the buttermilk was spiked with melamine.

5 g of milk powder was mixed with 15 mL of MeOH, and stirred to a homogeneous status with a glass rod and then ultrasonicated for 10 min at room temperature. The mixture was centrifuged at 10,000 rpm for 3 min, and the supernatant was collected and spiked with melamine.

2.7. SPE for melamine standard solutions

Before loading analyte, the MI-SPE column was previously conditioned with 2 mL of deionized water and methanol, successively. After melamine standard solutions at different concentrations were passed through the columns at a flow rate of 0.25 mL/min, the columns were washed with 2 mL of water and 2 mL of methanol at the same flow rate. The analyte retained on the sorbent was eluted with 3 mL methanol containing 5% ammonium hydroxide. The eluent was evaporated to dryness under vacuum at 25 °C, and

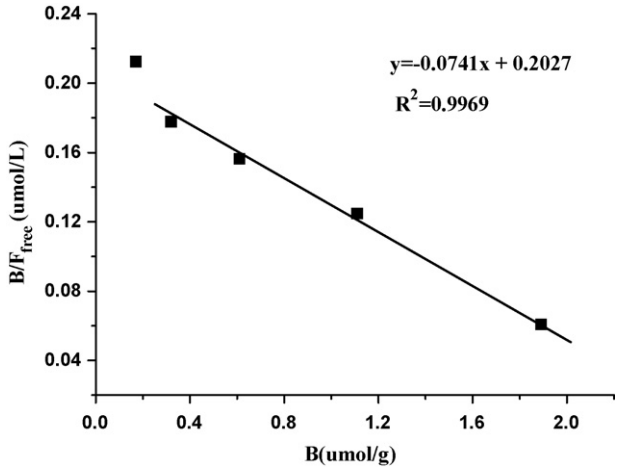

Fig. 2. Scatchard plot over 2.5–50 μmol/L (0.3–6 ppm) concentration range. Curve-fitting gives a dissociation constant K_d of 13.5 μmol/L with a saturation capacity of 2.74 μmol/g.

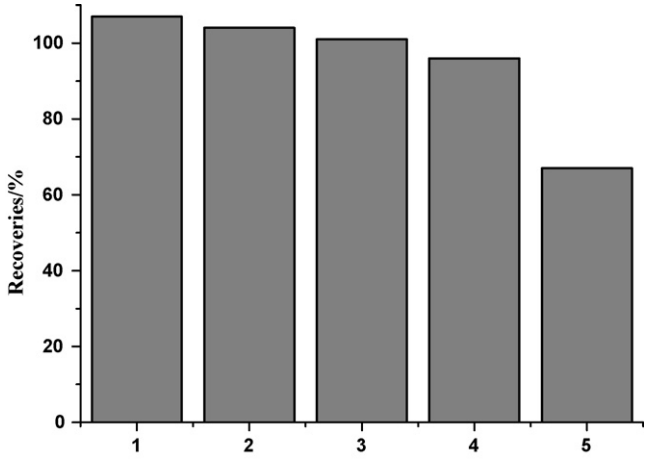

Fig. 3. The recoveries of melamine in standard solutions with an enrichment factor of 5.

the residue was reconstituted into 1 mL of mobile phase for further HPLC analysis.

2.8. SPE for spiked UHT milk and milk powders

To validate the performance of MI-SPE for the bio-matrix, the MIP and corresponding NIP were packed individually into cartridges to compare their efficiency of extracting melamine from UHT milk and infant formula. 5 mL of the dairy products sample spiked at 1 μmol/L (0.12 ppm) of melamine was passed through the MI-SPE (or NI-SPE) column as described above. Finally, the elution fractions were dried under a gentle nitrogen stream, the residues were reconstituted with methanol to final volume of 1 mL for subsequent HPLC analysis and extraction recoveries were calculated using the constructed calibration curve, respectively.

3. Results and discussion

3.1. Preparation of MIPs

Melamine is an organic base and a trimer of cyanamide, with a 1,3,5-triazine skeleton. The melamine imprinted polymer has not been synthesized though several MIPs for triazine herbicides have been prepared [14]. In order to synthesis melamine MIP, MIPs prepared in non-polar solvents, polar solvents and mixed medium with different molar ratios between template and functional monomer were investigated in our experiment, while the molar ratio of monomer to cross-linker was selected at 1:5 to ensure the formation of defined recognition sites with polymers [15]. Due to solubility limitations of melamine, melamine imprinted polymer could not be synthesized successfully in non-polar solvents. Coupled with restrictions of mechanical strength of the MIPs, only the melamine MIP prepared in the ethanol–water system with the molar ratio between template and functional monomer at 1:12 was successful (data not shown).

3.2. Evaluated the recognition efficiency of MIP

After MIP and NIP synthesis, equilibrium binding experiments were performed at room temperature with MIP and NIP. Fig. 1 shows experimental binding isotherms of MIP (and NIP) amount versus melamine concentrations. In the 2.5–50 μmol/L (0.3–6 ppm) melamine concentration range, the MIP exhibits a higher capacity for melamine than the NIP. The weak adsorption of template on NIP is due to non-specific interaction with the polymer matrix.

The data of the static absorption experiment were further processed with the Scatchard equation to estimate the binding parameters of the MIPs. Scatchard plot was constructed by plotting the ratios of bound amount to free melamine concentration against the bound concentration. As shown in Fig. 2, one straight line fitting the Scatchard equation, $B/F = (B_{max} - B)/K_d$, can be drawn, and gave two typical binding parameters. A dissociation constant (13.5 μmol/L) and a maximum number of binding sites (2.74 μmol/g) for MIP were calculated from the Scatchard

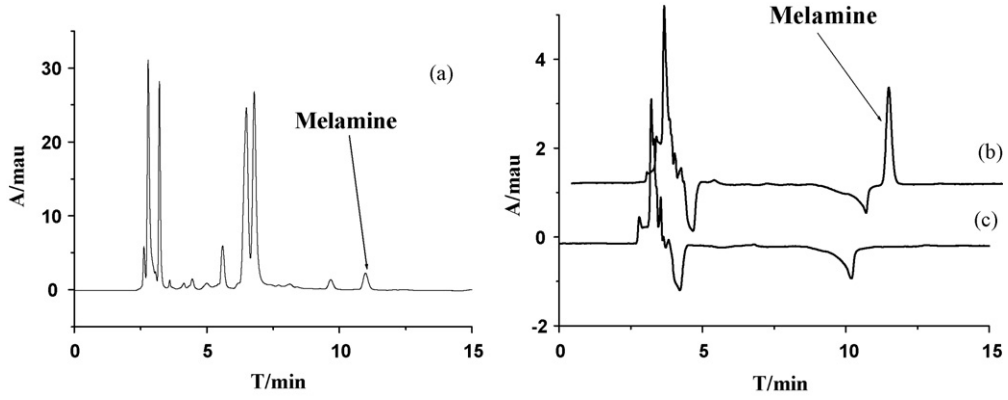

Fig. 4. HPLC chromatograms of (a) UHT milk extract after addition of 5 μmol/L (0.6 ppm) of melamine and after extraction of the UHT milk extract containing 1 μmol/L (0.12 ppm) melamine on MIP-SPE column (b) and NIP-SPE column (c).

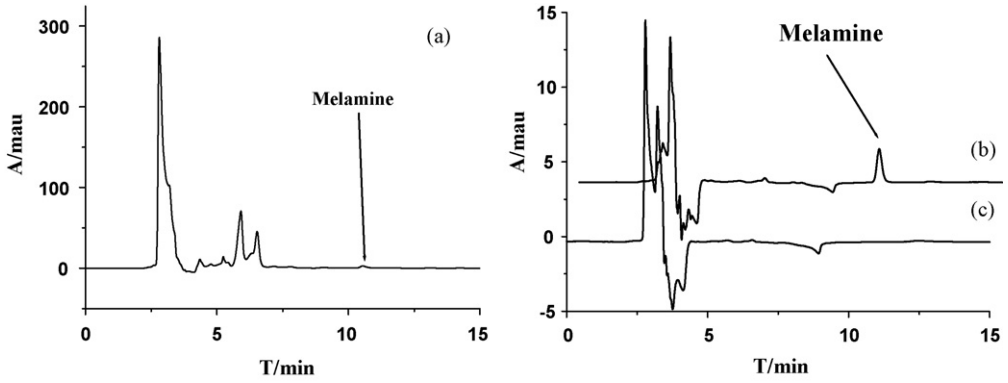

Fig. 5. HPLC chromatograms of (a) milk powder extract after addition of 5 μmol/L (0.6 ppm) of melamine and after extraction of the milk powder extract containing 1 μmol/L (0.12 ppm) melamine MIP-SPE column (b) and NIP-SPE column (c).

equation. Meanwhile a dissociation constant (107.5 μmol/L) and a maximum number of binding sites (2.54 μmol/g) for NIP were calculated from the NIP binding data. A large dissociation constant means low affinity to the target. When compared to NIP, the MIP has similar binding capacity but higher affinity to melamine. The difference in melamine binding affinity to the MIP and blank polymer clearly indicates the role of the imprinting process in the formation of specific binding sites.

3.3. SPE for melamine standard solutions

The recoveries of melamine in standard solutions were calculated and plotted in Fig. 3. It is clear that MI-SPE columns have good recoveries for melamine at different concentrations except for high concentration. A standard calibration curve for melamine analysis was constructed, which was linear ($R^2 > 0.999$) over the concentration range from 0.5 μM to 10 μM with a quantitative limit of 0.5 μmol/L (0.06 ppm). Thus, this method could be used to detect some polluted dairy products samples.

3.4. SPE for spiked UHT milk

To validate the performance of MI-SPE for the bio-matrix, the MIP and corresponding NIP were packed individually into cartridges to compare their efficiency of extracting melamine from UHT milk. Fig. 4a is the HPLC chromatogram of buttermilk of

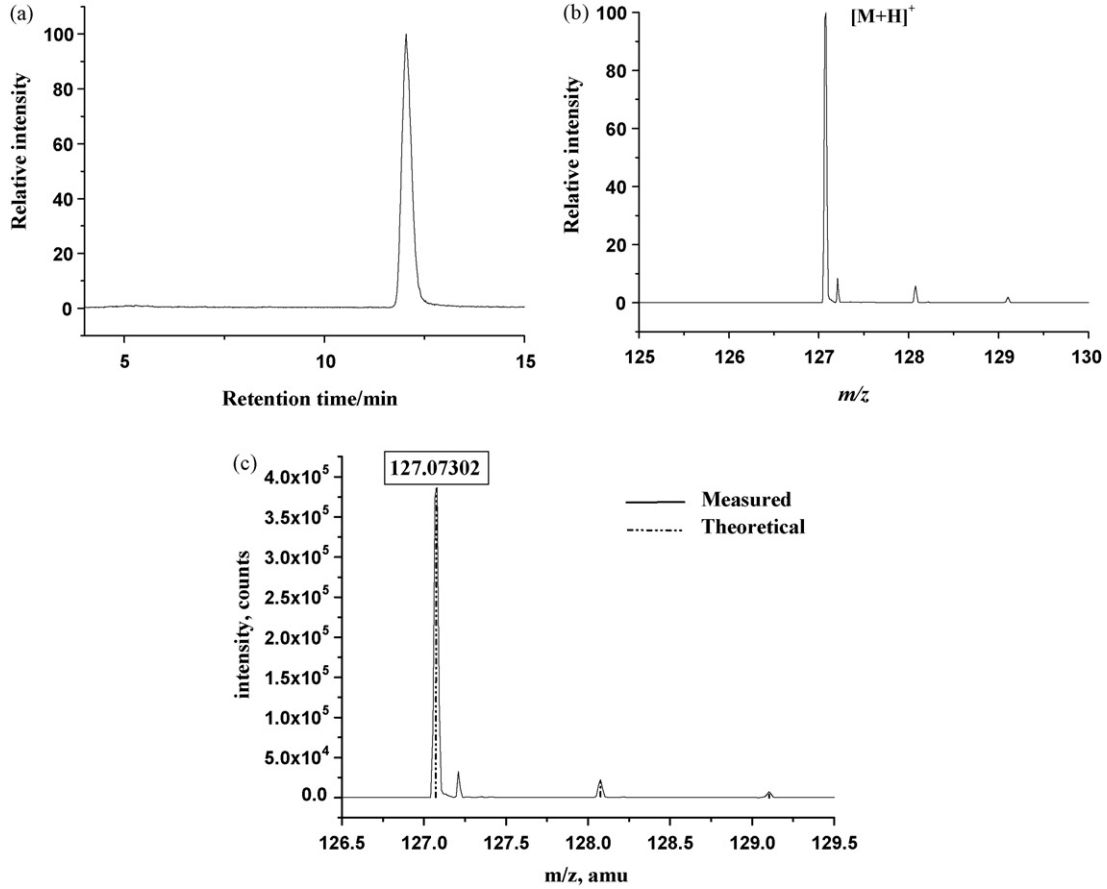

Fig. 6. The extracted ion chromatogram (EIC, a) of the elution fraction from milk powders; MS spectra (b) of the peak at 12 min in the positive mode; Observed mass ($[M+H]^+$) of melamine and its isotopics compared with calculated isotopics (c).

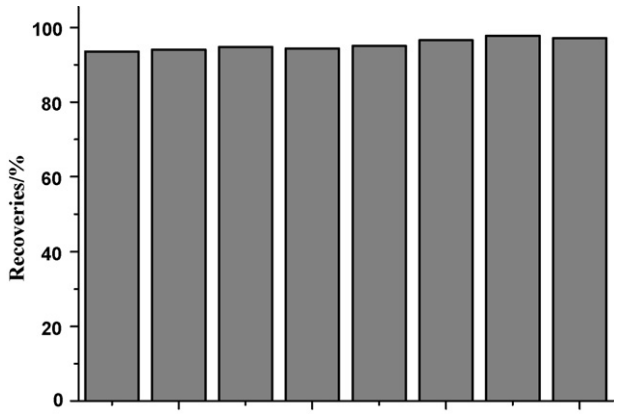

Fig. 7. Regeneration property experiment of the MI-SPE column (repeat 8 times).

UHT milk after addition of 5 μmol/L (0.6 ppm) of melamine, in which the complexity of the UHT milk matrix background is evident. The extraction on MIP column can successfully cleanup the UHT milk matrix, thus allowing the extraction of melamine with high selectivity (Fig. 4b). The result showed that the recovery of 1 μmol/L (0.12 ppm) melamine in UHT milk was 95.3 ± 1.1% (n = 3). Contrary to this, NIP column showed no such selectivity (Fig. 4c).

3.5. SPE for spiked milk powders

Milk powder constitutes a very complex matrix (Fig. 5a). The extraction on MIP column can successfully cleanup the milk powder matrix, thus allowing the extraction of melamine with high selectivity (Fig. 5b). The recovery of 1 μmol/L melamine in milk powder was also high enough for real sample analysis (95.2 ± 7.9%, n = 3). The high percentage recovery indicate that no interferences from milk powder that might be found in different formulations, which evaluates the high efficiency of extraction procedure.

Hence MIP offers itself as a simple and straightforward technique for the direct analysis of melamine in dairy products without lengthy sample cleanup.

3.6. Identification of melamine by HPLC-ESI-TOF/MS

In order to confirm the extraction of melamine on MIP column, ESI-TOF/MS analysis was performed on a 6210 time-of-flight mass spectrometer equipped with an ESI interface. The extracted ion chromatogram (EIC, 127–127.2 m/z) and MS spectra of peak at 12.05 min of the elution fraction from milk powder is shown in Fig. 6. The peak at 12.05 min observed on total ion chromatogram (TIC, not shown) was attributed to m/z 127 (EIC), meanwhile was not found from blank. Positive mass spectra of peak at 12.05 min showed its molecular ion peaks, $[M+H]^+$:m/z 127.1, in agreement with the molecular weight of melamine being 126. The typical isotopic pattern of the melamine was calculated by the isotope calculator and was found to be consistent (including position and intensity) with the pattern obtained from the main distribution in the spectrum (Fig. 6c). This provides a direct evidence for the extraction of melamine on MIP column.

3.7. Reproducibility of the MI-SPE column

Regeneration property is one of the important advantages of MIPs. MIPs can be used again to adsorb the interested analyte after regeneration. In order to reuse the polymers after each extraction, a short regeneration step was performed by washing with 3 mL of water: acetic acid (95:5, v/v). The results (see Fig. 7) showed that the MIP could be used many times and maintained their adsorption capacity at an almost constant value. This confirmed the reliability and efficacy of the proposed method for the analysis of melamine residues in real samples.

4. Conclusion

The melamine imprinted polymer was prepared by bulk polymerization using MAA and EGDMA as the functional monomer and cross-linker, respectively. The obtained MIP showed good selectivity and affinity for melamine. Accordingly, a method was successfully developed for analysis of melamine in dairy products by using the obtained MIP as the SPE sorbent coupled with HPLC. The high recoveries and satisfied precisions for analyte proved that the proposed method was valid for the analysis of melamine in different matrixes (UHT milk, infant formula). The limit of quantitation of the proposed method was 0.5 μmol/L (0.06 ppm), which is below the maximum residue limits established by U.S. FDA.

ABSTRACT

Adrenal was believed to affect the prostate tumor tissue growth by its secretion of adrenal androgens. However, the mechanisms regulating these effects were not fully understood. In this work, a sensitive and specific method for the determination of 15 steroids in blood via gas chromatography–mass spectrometry in selective ion storage detection mode was established to evaluate the impact of emasculation on adrenal steroids metabolism. Steroids were isolated by solid-phase extraction using Oasis HLB cartridge, and then derivated with heptafluorobutyric anhydride before analysis. The limits of detection were between 0.15 and 1.0 ng/mL and limits of quantification were between 0.62 and 2.6 ng/mL. The recoveries of steroids were above 83%, and both the intra-day and inter-day precisions (RSD%) were lower than 8%. Pregnenolone, progesterone, 17α-hydroxyprogesterone (17αP), 17α-hydroxypregnenolone (17αH), dehydroepiandrosterone (DHEA), estrone, 17β-estradiol, dihydrotestosterone (DHT), testosterone (T), 4-androstenedione (4-A), 1,4-androstadiene-3,17-dione, 11-deoxycortisol, 11-deoxycorticosterone, cortisol and aldosterone were quantified in 156 major male SD rats at 0, 1, 2, 4, 7 days, 2, 4, 6, 8, 10, 12, 14, and 16 weeks following emasculation. T and DHT decreased by 86.2% and 73.4%, respectively in the first 7 days following emasculation, but adrenal androgens (DHEA, 4-A) stabled at the normal level accordingly. Adrenal androgens and their precursors (17αH, 17αP) increased from the 2nd week along with the increase of androgens and the decrease of mineralocorticoids. These facts revealed that adrenal possibly enhanced its function of producing adrenal androgens from the 2nd week responding to the low androgens level induced by emasculation.

1. Introduction

Recently, Prostate cancer (PCa) is a focused issue in men's health especially in the Europe and USA [1]. Based on the androgen dependence of prostate growth, medical and/or surgical emasculation was the main therapy for PCa, but it failed when the PCa became so-called androgen independent procedure [2]. Though the initial decrease of androgens levels responding to the androgen-deprivation therapy (ADT) was inspiring, those in blood and PCa tissue still increased after a period of time [3]. It was believed that adrenal played a role in the procedure because it was another important gland for steroids production [4]. In normal, adrenal produced corticoids and adrenal androgens, but not androgens and estrogens. However, the adrenal androgen, dehydroepiandrosterone (DHEA) and 4-androstenedione (4-A), could be converted to testosterone (T) and dihydrotestosterone (DHT) in periphery tissue, such as prostate [4]. In addition, it was reported that the adrenal tumor induced by emasculation was able to function as gonad [5]. Therefore, the evaluation of adrenal function after emasculation was valuable for the clinical PCa therapy. Based on the androgen metabolic pathway, the most important markers for evaluating adrenal function responding to emasculation were DHEA and 4-A. Meanwhile, the whole steroid metabolic pathway in adrenal also should be taken into consideration.

For steroids quantitation, immunoassays [6] and gas chromatography with mass spectrometry (GC–MS) [7] were the most preferred methods. Immunoassays were especially suitable for the screening of a large amount of samples for a few kinds of substances with great sensitivity, while GC–MS was superior in the screening of limited samples for a multiplicity of substances. Gas chromatography with mass spectrometry detection was widely used in the detection of steroids owing to its sensitivity and selectivity [8]. In order to endow GC with the detectability of steroids, and to further improve sensitivity and selectivity, target analytes had always been

Table 1
Analysis parameters for 15 steroids.

Compounds	Retention time (min)	Fragments (amu)	Calibration curve	r^2	Linear range (ng/mL)
Ald	17.45	542, 483[a], 105	$Y = 142.4X + 42.58$	0.9999	0.62–100
T	21.06	467, 451[a], 320	$Y = 59.57X - 56.21$	0.9982	1.4–180
E_2	21.43	468, 451[a], 237	$Y = 210.7X - 125.1$	0.9973	1.30–170
1,4-A	21.71	480[a]	$Y = 93.66X + 98.77$	0.9977	1.00–120
4-A	22.62	482[a], 467	$Y = 40.09X - 27.25$	0.9973	1.8–230
DHEA	22.72	270[a], 255, 199	$Y = 54.58X - 59.50$	0.9973	0.81–100
E_1	22.95	466, 422[a], 410	$Y = 20.82X - 63.62$	0.9971	2.6–130
DHT	24.10	414[a], 399	$Y = 21.32X - 18.25$	0.9989	1.8–230
17αH	24.73	528, 510, 467[a]	$Y = 266.4X + 41.78$	0.9998	1.7–220
17αP	24.76	526, 508, 465[a]	$Y = 305.0X + 82.15$	0.9984	1.8–230
Pr	27.02	510[a], 425, 296	$Y = 293.4X - 55.70$	0.9999	1.6–210
P	27.02	512, 298[a], 283	$Y = 198.2X - 22.62$	0.9997	1.8–230
RS	27.98	465[a], 369	$Y = 169.0X - 35.48$	0.9992	1.2–160
C	28.18	463[a], 169	$Y = 83.85X + 267.6$	0.9999	1.0–160
H	30.27	523, 491, 355[a]	$Y = 80.71X + 58.77$	0.9980	1.2–150

In the calibration curve, Y means the peak-area, and X means the compound concentration.
[a] Means the quantitative fragment ion of each compound.

derivatized. N,O-bis(trimethylsilyl)trifluoroacetamide (BSTFA) [9], N-methyl-N-(trimethylsilyl trifluoroacetamide) (MSTFA) [10,11] and heptafluorobutyric anhydride (HFBA) [11–14] were the preferred derivatization agents which had been used to react with the hydroxyl or keto functional groups in steroids. Scherer et al. [15] reported a method for the determination of T in human hair by GC–MS, proposing that the derivatization with HFBA gave rise to high mass increments thus diminishing background noise and that these derivatives tended to have shorter retention times than those of O-methoxime/trimethylsilyl (MO–TMS) ethers. Recently, solid-phase micro extract technology (SPME) combined with GC–MS was used in the determination of some anabolic steroids which could be analyzed without derivation [16]. Since Oasis HLB (hydrophilic–lipophilic balance) solid-phase extraction (SPE) cartridge was widely employed for its efficacy in steroids' extraction [17–20], Oasis HLB SPE cartridge was adopted in sample preparation.

Based on the art research, there were some reports on the study of specific steroids hormones classes such as androgens [9,17,21], estrogens [19,22], corticoids [23] and progestogens [24], but we found few reports on the simultaneous determination of the above four classes of steroids hormones. In this study, a sensitive method was established for the simultaneous determination of 15 steroids derivated with HFBA in rat's blood at 0, 1, 2, 4, 7 days, 2, 4, 6, 8, 10, 12, 14, and 16 weeks following emasculation, aiming to evaluate the impact of emasculation on adrenal function. Significant changes of steroids metabolism in adrenal occurred from the 2nd week to 4th week following emasculation when adrenal androgen levels were elevated and mineralocorticoid levels were decreased. These facts revealed that the enhancement of adrenal androgens' production was possibly due to the adrenal's compensation for the low androgen levels induced by emasculation, which should be paid more attention to in PCa patients undergoing surgical and/or medical emasculation.

2. Materials and methods

2.1. Animals

156 male Sprague–Dawley (SD) rats, weighing 250 ± 10 g, were housed at 21–23 °C with a relative humidity of 50–55%. They were maintained under a 12 h:12 h light:dark regime and fed commercial rat food and water. The experiment was performed in the animal research laboratory at Peking University. All experi-

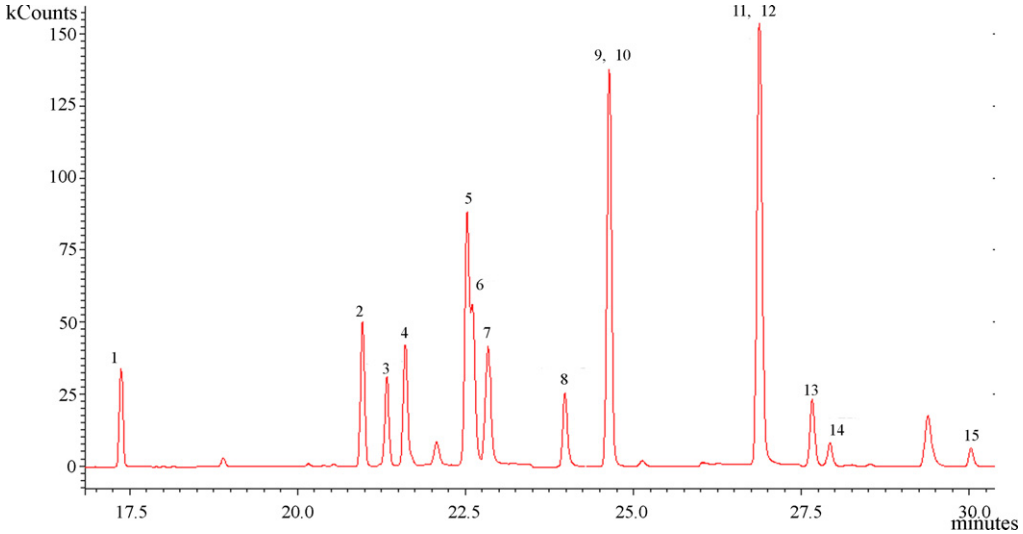

Fig. 1. Gas chromatography of 15 steroids. 15 Steroids were detected via mass spectrometry in selected ion storage mode after been derivated by heptafluorobutyric anhydride: (1) aldosterone; (2) testosterone; (3) 17β-estradiol; (4) 1,4-androstadiene-3,17-dione; (5) 4-androstenedione; (6) dehydroepiandrosterone; (7) estrone; (8) dihydrotestosterone; (9) 17α-hydroxypregnenolone; (10) 17α-hydroxyprogesterone; (11) progesterone; (12) pregnenolone; (13) 11-deoxycortisol; (14) cortisol; (15) 11-deoxycorticosterone.

mental protocols were approved by the Institutional Animal Care Committee.

156 rats were divided into 13 groups. Each group stood for one time point. Adrenal tissues were retained before emasculation, and at 1, 2, 4, 7 days, 2, 4, 8, 10, 12, 14, and 16 weeks after emasculation. All adrenal tissues were taken at 8–10 a.m.

2.2. Chemical and reagents

Pregnenolone (P, 98%), progesterone (Pr, cell culture tested), 17α-hydroxyprogesterone (17αP, 95%), 17α-hydroxypregnenolone (17αH, 95%), dehydroepiandrosterone (DHEA, 99%), 1,4-androstadiene-3,17-dione (1,4-A, 98%), 11-deoxycortisol (RS, 98%), 11-deoxycorticosterone (H, 99%), cortisol (C, 99.8%), aldosterone (Ald, 98%), estrone (E_1, 98%), and 17β-estradiol (E_2, 98%) were purchased from Sigma (St.

Loius, MO, USA), dihydrotestosterone (DHT, 99%) was purchased from TCI-EP (Tokyo, Japan), testosterone (T, 99%) and 4-androstenedione (4-A, 99%), heptafluorobutyric anhydride (HFBA, 99%) were purchased from ACROS (Geel, Belgium). SPE cartridge (Oasis HLB, 3 mL) was purchased from Waters (Milford, Mass, USA), and HPLC-grade methanol and hexane were purchased from Fisher (Fair Lawn, NJ, USA). DI water was generated by the MilliQ system (Millipore, Bedford, MA, USA).

2.3. Apparatus

The GC–MS experiment was performed on a Varian CP-3800 series gas-chromatograph with mass spectrometric detector Saturn 2200. GC condition was as follows: splitless injection mode; 5% phenyl methyl siloxane; 95% dimethylpolysiloxane capillary column [Varian, VF-5m, 30 m × 0.25 mm (i.d.); 0.25 μm film thickness]; injection port temperature, 280 °C; carrier gas, helium; flow rate, 1 mL/min; column temperature, 95 °C, hold 6 min, then increased to 210 °C at 30 °C/min, increased to 250 °C at 2 °C/min, and then increased to 290 °C at 10 °C/min, hold 5 min. Mass spectrometry was in SIS (select ion storage) mode, ion trap temperature, 200 °C; transfer line temperature, 270 °C; multiplier temperature, 40 °C.

2.4. Sample preparation

Samples were stored in liquid nitrogen, thawed prior to analysis. Before analysis, 200 μL of serum was mixed with 400 μL of methanol for deproteinization, thoroughly vortex-mixed and cen-

trifuged at 1500 × *g* for 30 min, kept the supernatant, discarded the pellet, then 500 μL DI water was added to the supernatant. The supernatant was then loaded with the flow rate of 2–3 drops/s onto the SPE cartridge which has been activated by 1 mL methanol, 1 mL H_2O, 1 mL methanol–H_2O (v:v = 1:1), and then extraction was performed with 2 mL 50% methanol/water, 1 mL 100% methanol in turn with the flow rate of 3–4 drops/s. Collected methanol wash-off liquor was evaporated with gentle nitrogen at 60 °C, and then mixed with 200 μL of acetone to resolute the pellet, added 40 μL HFBA to the solution. The reaction took place at 60 °C for 60 min, then evaporated with gentle nitrogen at 60 °C after the reaction, added 100 μL hexane to resolute the pellet and 2 μL was injected for analysis.

2.5. Standards and controls

Stock solutions of 0.5 mg/mL of each analyte were prepared in methanol. These stock solutions were mixed and diluted to give a series of stock solutions of all analytes.

3. Results and discussion

3.1. Method validation

3.1.1. Retention times and specificity

The retention times of 15 steroids were shown in Table 1. Though retention times of 4-A and DHEA, 17αH and 17αP, Pr and P were nearly the same, based on the fragmentation difference, high specificity was achieved in the select ion storage (SIS) mode employed in this quantitative method. An unknown 467 amu fragment was also detected at 21 min near the retention time of testosterone, thus 451 but not 467 amu was chosen as the quantitative ion of testosterone. The gas chromatography of 15 steroids was shown in Fig. 1.

3.1.2. Mass spectra

The main fragments of 15 steroids in full-scan EI (electronic ionization) mode were shown in Table 1. The molecular ions of 13 steroids derivated by HFBA were detected except DHEA and H. DHEA–HFBA was prone to lose a molecule of HFBA to obtain a strong 270 amu fragmentation, and H was suspected to react with three molecular HFBA to obtain a 918 amu H-$(HFBA)_3$ which exceeded the 650 amu maximum mass range of GC–MS. Fragments were mostly resulted from the cleavage of the D ring, especially at the 17 carbon connecting a side chain. For HFBA mostly reacted with the 3-hydroxyl group, the A ring cleavage was to lose HFBA. The B and C rings were split to obtain some low molecular ions at C7-8, C9-10, and C12–13, C8-14, respectively. The mechanism of fragmentation was illustrated in Fig. 2.

3.1.3. Optimized reaction condition

Reaction conditions such as volume of HFBA (10–90 μL), reaction time (30–90 min) and reaction temperature (25–75 °C) were tested. Recoveries of steroid would be better along with the increase of HFBA volume (<60 μL), reaction time (<60 min) and reaction temperature (<60 °C). But excessive HFBA volume, too long reaction time, and too high reaction temperature would also induce side reaction to reduce steroid recoveries. In this study, that samples reacting with 60 μL HFBA at 60 °C for 60 min was the optimized condition.

3.1.4. Calibration and sensitivity

The linear regression analysis was constructed by plotting the peak-area of analytes versus analyte concentration (ng/mL). The retention time, main fragments, regression equation of these curves, square of correlation coefficients (*r*), and linear range for each steroid were shown in Table 1. Signals 3 and 10 times higher than the peak noise were considered as the limit of detection (LOD) and quantification (LOQ) for all the 15 steroids. The LOQ were ranging from 0.62 to 2.6 ng/mL, and the LOD were ranging from 0.15 to 1.0 ng/mL.

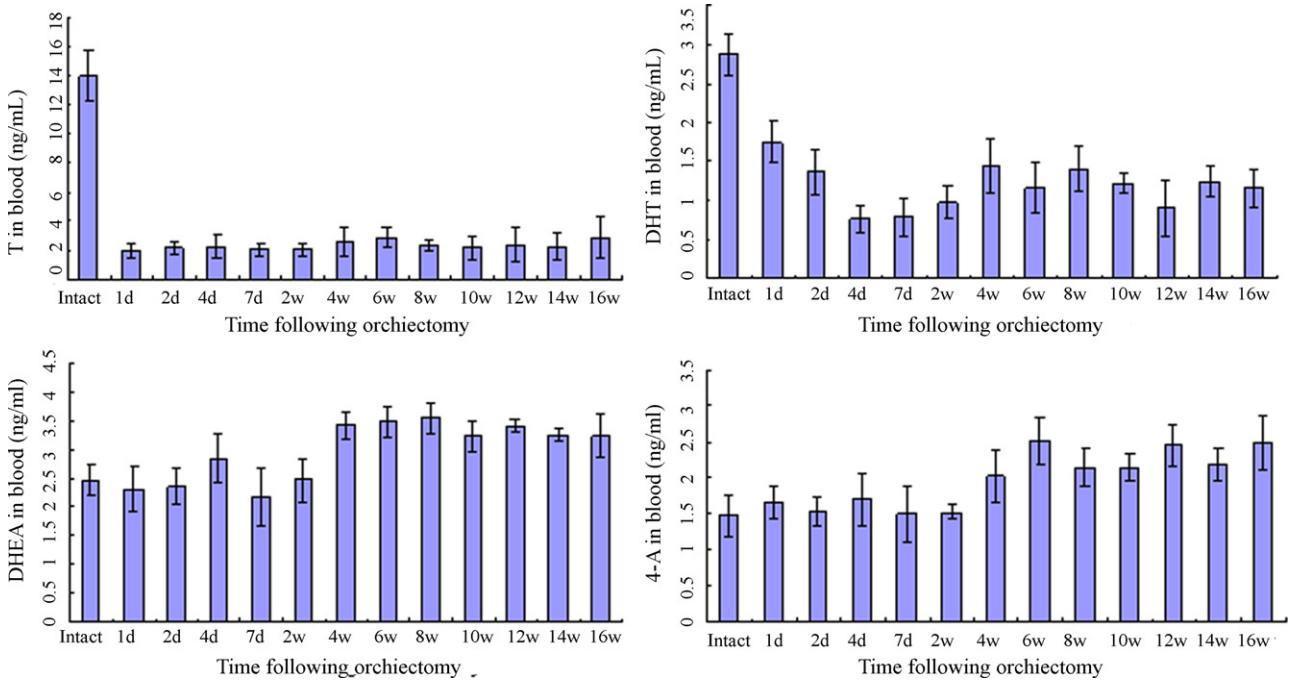

Fig. 3. Androgens and adrenal androgens levels in blood before and after emasculation. Androgens were decreased more than 70% while adrenal androgens (DHEA and 4-A) were nearly remain the same as normal level in the first 7 days following emasculation. But both androgens and adrenal androgens were rising from the 2nd week following emasculation.

3.1.5. Recoveries and stability

The extraction recoveries were determined at three concentration levels. The recoveries ranged from 83% to 107%, and the results were shown in Table 2. The background response in blank sample was subtracted.

The stability of 15 steroids was evaluated by determining a sample repeatedly at 0 h, 6 h, 12 h, 24 h with a RSD <7% ($n = 3$), which showed that the derivatives of these steroids had a good stability within 24 h.

3.1.6. Accuracy and precision

A total of 12 mL normal rat serum sample was divided into 60 portions as 200 μL each. All these portions were detected throughout 3 days, 18 portions per day. Then the intra-assay variation and the inter-assay variation of the method were determined, whose RSD% were both below 10%. We determined the extraction recovery by measuring a blank serum sample and the same serum sample enriched with synthetic compounds at three concentration levels. Results were shown in Tables 2 and 3.

3.2. Steroids in blood of castrated rat

Androgens, adrenal androgens, and progestogens were quantified, but estrogens, cortisol, 11-dehydrocortisol and 1,4-androstadiene-3,17-dione were under the limit of determination in blood of castrated rat.

3.2.1. Androgens in blood of castrated rat

After emasculation, T levels in blood descended dramatically from a normal level of 14.02 ± 1.78 to 1.96 ± 0.52 ng/mL, whose descending extent was about 86.2% ($p < 0.05$). Despite the initial drastic drop, T levels were stable ranging from 2.02 ± 0.43 to 2.19 ± 0.81 ng/mL during the first 2 weeks, while a gentle increase occurred from the 4th to 16th week, where the T levels were about 15.1–20.3% of normal manner. A successive descent of DHT levels occurred in the first 4 days, whose descending extent was about 73.4% at the 4th day compared to normal level ($p < 0.05$). From the 4th to 16th week, DHT levels were higher than that of the 2nd week ($p < 0.05$), ranging from 1.27 ± 0.13 to 1.59 ± 0.19 ng/mL which were about 72.9–90.9% of normal level. Since androgen was mainly produced by gonad, emasculation could reduce androgen level in blood immediately as it took place. The increase from the 4th week after emasculation implied emasculation was not a lasting effective way to reduce androgen level [3]. In addition, for adrenal was the primary gland for steroids production after emasculation, androgens after the 4th week were supposed to be adrenal source [4].

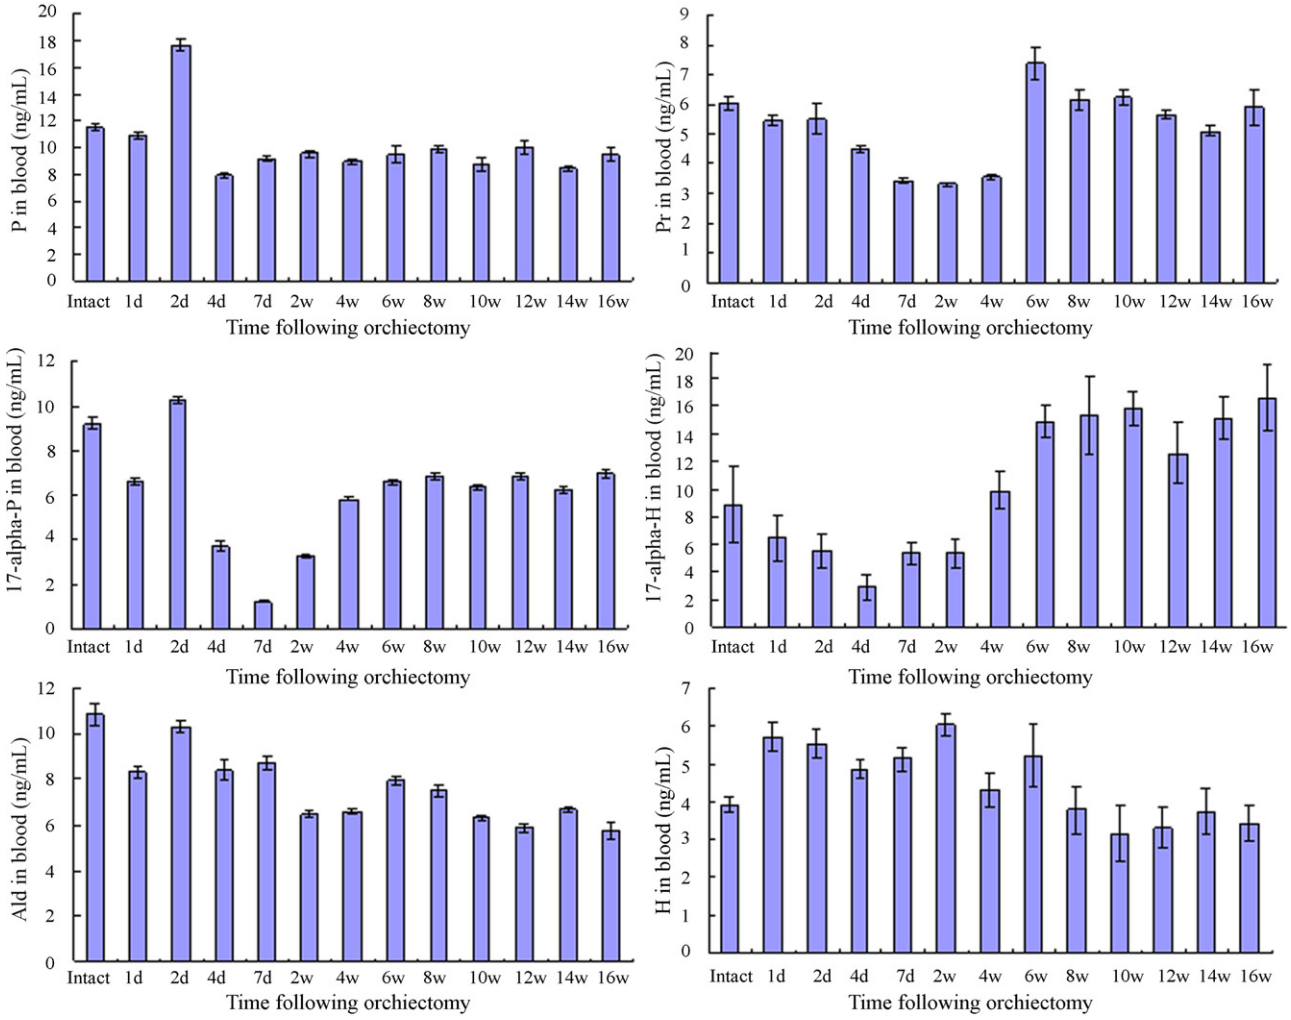

Fig. 4. Progestogens and corticoids levels in blood before and after emasculation. Progestogens decreased in the first 7 days to 2 weeks after emasculation, but then initiated a increasing procedure. Aldosterone decrease slightly in the first 7 days, but dramatically from the 2nd week, while 11-deoxycorticosterone (H) was above than normal till the 6th week, then a decrease initiated.

3.2.2. Adrenal androgens in blood of castrated rat

There was no obvious change of DHEA in the first 2 weeks with concentrations ranging from 2.15 ± 0.50 to 2.84 ± 0.43 ng/mL. It then escalated from the 4th to the 16th week compared to the 2nd week, ranging from 3.23 ± 0.27 to 3.54 ± 0.28 ng/mL which were 31.7–44.4% higher than the normal manner ($p < 0.05$). Similar to DHEA, 4-A levels were stable in the first 2 weeks. Compared to the normal level 1.47 ± 0.30 ng/mL, there was no significant difference of 4-A in the first 2 weeks ranging from 1.50 ± 0.38 to 1.70 ± 0.38 ng/mL. After 4 weeks, the concentrations of 4-A were higher than the normal manner by about 37.7%–70.5% ($p < 0.05$), ranging from 2.02 ± 0.36 to 2.51 ± 0.33 ng/mL. DHEA and 4-A which could be converted to androgens in periphery tissue were considered as adrenal androgens [4]. The increase of both of them from the 4th week was possibly a result of enhanced expression of CYP17 in adrenal induced by emasculation [25–27] (Fig. 3).

3.2.3. Progestogens and mineralocorticoids in blood of castrated rat

P stabled at concentrations lower than normal level except for the 2nd day. A successive descending occurred for Pr in the first 7 days, and stabled at half of the normal level from the 7th day to 4th week, but increased since the 6th week ranging from 8.41 ± 0.21 to 9.87 ± 0.32 ng/mL, 72.9–86.2% of normal level. 17αP descended successively till the 7th day at 1.20 ± 0.02 ng/mL, 13.1% of normal level, and then ascended till the 6th week to stable at 6.20 ± 0.14 to 6.96 ± 0.17 ng/mL, 67.5–75.8% of normal level. Nearly the same as 17αP, 17αH descended successively till the 4th day at 2.87 ± 0.95 ng/mL, 32.5% of normal level, and then ascended till the 6th week to stable at 12.5 ± 2.2 to 16.5 ± 2.4 ng/mL, 141–186% of normal level. Ald descended significantly from the 2nd week ($p < 0.05$), and H was above normal level at 3.92 ± 0.20 ng/mL before the 6th week ($p < 0.05$) ranging from 4.30 ± 0.43 to 6.03 ± 0.27 ng/mL, and descended till lower than normal level from the 8th week ranging from 3.17 ± 0.72 to 3.79 ± 0.62 ng/mL (Fig. 4). That 17αP and 17αH increased along with their metabolites DHEA and 4-A from the 2nd week implied that the enhancement of DHEA and 4-A production possibly occurred, while the decrease of Ald and H from the 2nd week implied that the production of mineral corticoids was weakened in adrenal responding to emasculation.

3.2.4. Impact of emasculation on adrenal

Despite androgen-deprivation therapy being the standard treatment of advanced prostatic cancer, the effect of emasculation on adrenal was poorly understood. For adrenal androgens was believed to be important in the prostate cancer therapy, we need to illuminate the changes of adrenal source androgens after emasculation.

Both T and DHT decreased significantly after emasculation, but DHEA and 4-A were stable in the first 2 weeks. These four hormones increased at the 4th week, and stabled since the 6th week. DHEA and 4-A, which could be converted to T and DHT in periphery tissue, were thought to be the primary source of androgens after emasculation. In addition, the levels of DHEA and 4-A were above normal from the 4th week, while the levels of 17αP and 17αH, precursors of DHEA and 4-A, respectively, both increased from the 2nd week and stabled since the 6th week. As DHEA and 4-A were mainly produced by adrenal, the increase of the both and their precursors from the 2nd week suggested that adrenal enhanced its production of adrenal androgens, presumably leading to the decrease of mineralocorticoids. Based on these facts, adrenal was suggested to increase adrenal androgens production and decrease aldosterone production from the 2nd week responding to the low androgens level induced by emasculation, which possibly resulted in the increase of DHT and T from the 4th week.

4. Conclusion

Different from the current study which usually focused on several specific analytes among steroids classes, the present study established a GC–MS method for the simultaneous determination of as many as 15 analytes covering 4 classes of endogenous steroids hormones such as androgens, estrogens, corticoids and progestogens. The utilization of HLB solid-phase extraction in the pretreatment of biological samples had significant merits in improving the recoveries, reducing the treatment time and also avoiding the usage of some solvents for liquid–liquid extraction such as ethyl acetate and chloroform. The method was applied to the study of evaluating adrenal function after emasculation. In the first 7 days after emasculation, androgens decreased dramatically but adrenal androgens stabled. Adrenal androgens and their precursor increased from the 2nd week along with the decrease of mineralocorticoids and the increase of androgens. These facts revealed that adrenal possibly enhanced its function of producing adrenal androgens which could further influence the androgens level. More efforts should be made to investigate these steroids in adrenal tissue after emasculation to illuminate the differentiate process of adrenal function.

ABSTRACT

HPLC with UV and acidified potassium permanganate chemiluminescence detection, combined with multivariate data analysis techniques, were used for the geographical classification of some Australian red (Cabernet Sauvignon) and white (Chardonnay) wines from two regions (Coonawarra and Geelong). Identification of the wine constituents prominent in the chromatography was performed by mass spectrometry. Principal components analysis and linear discriminant analysis were used to classify the wines according to region of production. Separation between regions was achieved with both detection systems and key components leading to discrimination of the wines were identified. Using two principal components, linear discriminant analysis with UV detection correctly classified 100% of the Chardonnay wines and, overall 91% of the Cabernet Sauvignon wines. With acidified potassium permanganate chemiluminescence detection, 75% of the Chardonnay wines and 94% of the Cabernet Sauvignon wines were correctly classified using two factors.

1. Introduction

There is increasing interest from consumers for food products from known geographical origins, and product pricing is often related to region or country of origin. Considerable research has been devoted to applications of analytical science for food authentication and quality assurance with a number of reviews appearing in recent years [1–3]. Modern analytical techniques including spectroscopic [4–9], chromatographic [10–11], mass spectrometry [11–13], sensor [14] and isotopic methods [12,15] have been used for the determination of food authenticity. Combining these analytical methodologies with appropriate chemometric analysis offers the most promising approach for distinguishing geographic origin of foods [16].

In particular, classification of wines according to their denomination of origin has received considerable attention in the scientific literature and has been performed by elemental metals analysis using atomic absorption and atomic emission spectrometry and isotopic analysis [12,17]. Molecular spectroscopic techniques have also been extensively studied for wine analysis and classification, with UV–vis spectroscopy being employed in a number of publications. Urbano et al. have reported the use of UV–vis spectroscopy with pattern recognition methods as an inexpensive screening method for differentiation and classification of Spanish wines [4]. Principal components analysis (PCA) and modelling (SIMCA) were used for exploratory data analysis and development of classification models respectively. Acevedo et al. [5] examined the classification of Spanish red and white wines using UV–vis spectrophotometric analysis and novel classification methods such as support vector machines as a means of achieving improved classification rates. Liu et al. employed visible–near infrared (NIR) spectroscopies in an attempt to classify Spanish and Australian Tempranillo red wines as well as commercial Riesling wines from Australia, New Zealand, France and Germany [6,7]. PCA, linear discriminant analysis (LDA), partial least squares discriminant analysis (PLSDA), and stepwise linear discriminant analysis were examined as classification tools. The results clearly demonstrated that visible–NIR spectra contain information that when used with chemometrics allows discrimination between wines from different countries. The feasibility of visible–NIR spectroscopy for discriminating Australian white wines (Chardonnay and Riesling) of different varietal origin using PCA, principal components regression and PLSDA has also been reported [8]. Although successful classification models were developed, the authors recommended caution in extending the techniques to other wine varieties. The varietal discrimination of Australian wines by means of mid-infrared spectroscopy has been described by Bevin et al. [9]. Three red wine varieties (Cabernet Sauvignon, Shiraz and Merlot) and four white wine varieties (Chardonnay, Riesling, Sauvignon Blanc and Viognier) from different Australian wine regions were

doi:10.1016/j.talanta.2009.08.001

successfully discriminated according to variety using LDA. Chemometrics with mass spectrometric analysis is exemplified by the work of Cozzolino et al. using an electronic nose with PCA and PLSDA to classify Australian wines [13]. Isotopic ratios determined by SNIF-NMR and mass spectrometry methods have been used in combination with chemometric methods for the detection of wine chaptalisation and differentiation of wines according to the geographical origin [18].

Much of the molecular spectroscopy work involves non-specific analytes. Greater specificity is afforded when some form of separation science is involved in the procedure, and hyphenated techniques have proved successful for classification of wines. Ballabio et al. performed classification of wine samples using dynamic headspace gas chromatography mass spectrometry [19] and Brescia et al. have examined high-performance ion chromatography exclusion, ICP optical emission spectrometry and NMR measurements [20]. Phenolic compounds are important components in wines and have been successfully employed for characterising commercial wines [1,21]. Rodriguez-Delgado et al. have studied the phenolic profiles attributable to 15 polyphenols in 55 samples of red wine using HPLC with UV and fluorescence detection [22]. Good differentiation among the wines examined according to production region was achieved using PCA and LDA. With the aid of HPLC–MS, La-torre et al. classified Marsala wines according to their polyphenol and carbohydrate levels using discriminant analysis [23]. The results showed that the wines were correctly classified according to their phenolic and sugar content. Heberger et al. employed ion-exchange chromatography with PCA and LDA to classify Hungarian wines according to wine-making technology, geographic origin, grape variety, and year of vintage based on free amino acid and biogenic amine contents [24].

Due to the selective conditions attainable with individual reactions, chemiluminescence detection has been shown to be effective in the direct determination of a range of analytes in complex matrices. Acidified potassium permanganate [25], tris(2,2′-bipyridyl)ruthenium(II) [26] and luminol [27] chemiluminescence detection systems have been used to monitor a variety of analytes in wine that have been shown to be significant for geographical discrimination such as proline, polyphenols including resveratrol, and sulfite.

In this study we report for the first time the use of HPLC with both UV detection and chemiluminescence detection of the eluent stream for differentiation and classification of some Australian red and white wine varieties with multivariate data analysis techniques. Identification of the components significantly attributing to separation and classification has been undertaken using mass spectrometry.

2. Experimental

2.1. Samples

Finished high-quality Cabernet Sauvignon ($n = 34$) and Chardonnay ($n = 22$) wines were collected from the Geelong (Cabernet Sauvignon, $n = 10$, Chardonnay, $n = 11$) and Coonawarra (Cabernet Sauvignon, $n = 24$, Chardonnay, $n = 11$) wine regions of Australia from the 2003 (Cabernet Sauvignon, $n = 15$, Chardonnay, $n = 9$) and 2004 (Cabernet Sauvignon, $n = 19$, Chardonnay, $n = 13$) vintages with a total of 21 different wineries involved in the study. The wine samples were placed in centrifuge tubes and stored at −18 °C until required. Before analysis the samples were thawed and visually examined to confirm no precipitation, for example of tartaric acid, had formed and then equilibrated at room temperature and mixed thoroughly, using a vortex mixer, prior to filtering through a 0.45 μm nylon membrane filter (Acrodisc PSF syringe filters; Pall Australia, Vic., Australia). All wines were sampled in duplicate, providing for a total of 112 wine analyses.

2.2. Chromatographic analysis

Chromatographic runs were performed using a Hewlett Packard 1100 series liquid chromatograph equipped with a quaternary pump, solvent degasser, diode-array detector (DAD) and autosampler (Agilent Technologies, Forest Hill, Vic., Australia). The HPLC was fitted with a Chromolith Performance RP-18e 100 mm × 4.6 mm column, a 5 mm monolithic guard column (Merck, Kilsyth, Vic., Australia). The eluent from the DAD (254 nm) was then merged with a chemiluminescent reagent prior to the chemiluminescence detector [25]. Thus the column eluent was propelled sequentially through each detector. Control of the HPLC pump, DAD, and data acquisition from the chemiluminescence detector was achieved using Hewlett Packard Chemstation Software (Agilent Technologies). Wines were analysed by injecting 20 μL aliquots of the samples and separated at a flow rate of 3 mL min^{-1}. Solvent composition of 3% methanol in an aqueous solution of trifluoroacetic acid (0.1%, v/v) was increased to 30% methanol over 12 min, which was then raised to 70% methanol for a further 10 min. These conditions were based on an earlier study reported by Adcock et al. [28]. Duplicate runs were performed on all samples.

2.3. Mass spectrometry

The characterisation of the prominent wine constituents was obtained with the aid of high-resolution mass spectrometry. In order to gain an optimum signal in negative ion mode the chromatography was repeated without trifluoroacetic acid. Since the 3 mL min^{-1} flow rate is too fast for the formation of a stable electrospray, the sample stream was split 50% post chromatographic separation with a portion sent to the mass spectrometer. A 6210 MSDTOF mass spectrometer (Agilent Technologies) was used with the following conditions: drying gas, nitrogen (7 mL min^{-1}, 350 °C); nebulizer gas, nitrogen (16 psi); capillary voltage, 4.4 kV; vaporizer temperature, 350 °C; and cone voltage, 60 V.

2.4. Chemicals

HPLC grade methanol was obtained from BDH (Poole, UK). All mobile phases were filtered through a 0.45 μm nylon membrane filter. The permanganate chemiluminescence reagent was made by dissolving potassium permanganate (5×10^{-4} M, Ajax; Auburn, Australia) in a 1% (w/v) sodium polyphosphate (Sigma–Aldrich; Castle Hill, NSW, Australia) solution and the pH adjusted to 2.0 using sulfuric acid (Rhone-Poulenc; Melbourne, Australia).

2.5. Multivariate data analysis

All data manipulation and analysis algorithms were implemented in-house using Matlab (V 7.4, Mathworks Inc., USA) and the PLS Toolbox (V 4.0.2 Eigenvector Research Inc., USA).

Pre-processing involved removing the solvent peak, aligning, binning and normalising the data. Alignment was performed using correlation optimised warping (COW) [29–31]. The algorithm is a piecewise or segmented data pre-processing method aimed at aligning a sample data vector towards a reference vector by piecewise linear stretching and compression. The reference vector is selected by finding the sample with the maximum cumulative product of the correlation coefficients. COW requires two user input parameters, the segment length and slack size, which are selected in order to optimise the overall correlation between the sample and reference. Alignment is achieved by dividing the sample and

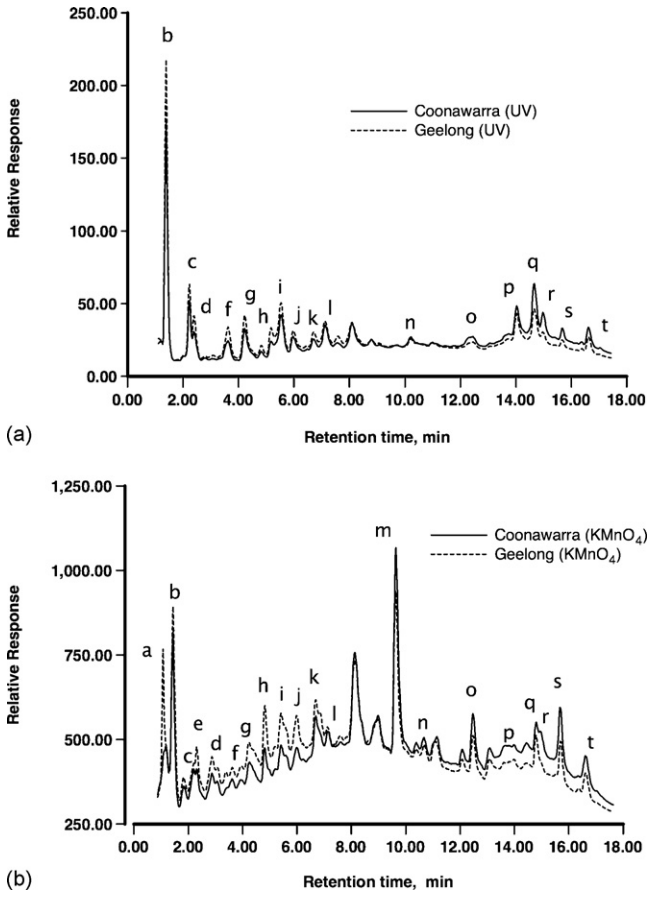

Fig. 2. The average chromatogram for Cabernet Sauvignon wines from the Coonawarra and Geelong regions using (a) UV detection and (b) potassium permanganate chemiluminescence detection. Peak assignments are provided in Table 1.

reference data into segments and warping each section by stretching and compressing within the designated slack range [30,31]. The multivariate data analysis methods employed were PCA and LDA. PCA was applied to mean-centred data and was used to reduce the dimensionality of the data and gain visual insight into possible grouping of the samples according to geographic origin. LDA assumes class data follow a multivariate normal distribution and seeks to maximise the ratio of between class variance and minimise the ratio of within class variance in order to select the boundary that achieves maximum separation between the two groups [16]. LDA was performed on the first two PCs and the classification model was developed and validated using the 'leave-one-out cross-validation' method.

3. Results and discussion

The characteristic chromatograms for Chardonnay and Cabernet Sauvignon produced with 254 nm UV detection and acidified potassium permanganate from the two wine growing regions are shown in Figs. 1 and 2. Peak assignments and analyte identification were achieved by mass spectrometry, as discussed previously and summarised in Table 1. Variation can be observed between the wine varieties from the two regions. In general the intensity of the chromatographic peaks is higher between 0 and 8 min for the Geelong region with the Coonawarra wines presenting a greater intensity for the peaks after 8 min. Based on the reversed-phase chromatography employed this may indicate that the Geelong wines contain higher concentrations of smaller water–soluble phenols and fewer less soluble polyphenolic tannins than those from Coonawarra. When comparing the average Chardonnay and Cabernet Sauvignon UV chromatograms (Figs. 1a and 2a) the Cabernet Sauvignon contain greater quantities of polyphenols as indicated by the greater

relative intensity of peaks later in the separation. This difference is not observed when comparing the acidified potassium permanganate chromatograms of Chardonnay and Cabernet Sauvignon (Figs. 1b and 2b). It has been found that polyphenols elicit a greater response than simple phenols with chemiluminescent detection. Chemiluminescence is more sensitive to polyphenols [32] than the smaller phenols as demonstrated by the observed response to myricetin (peak *m*), the peak of which is barely discernable with UV detection. Myricetin contains many hydroxy moieties making it an ideal candidate for reactivity with acidified potassium permanganate. The chemical structure of myricetin is similar to that of quercetin (myricetin has an extra hydroxyl moiety) that has been shown to have an exceptionally high response with permanganate chemiluminescence [25].

PCA was performed on the UV and acidified potassium permanganate data from both Chardonnay and Cabernet Sauvignon samples. The scores plots for the first two PCs are presented in Figs. 3 and 4. The percent variance explained by each component is noted on each axis, and these results show clustering of the wines according to production region. Details of the vintage (2003 and 2004) are also shown. It is evident that under the analytical conditions employed here that vintage plays no role in the classification.

Discrimination between the Geelong and Coonawarra regions was obtained using PCA–LDA and Table 2 summarises the LDA results for the Chardonnay and Cabernet Sauvignon wines as so-called confusion matrices. The tables present the true class identities in rows and the predicted classes in columns. The diagonal elements represent misclassified samples. The tables also present the accuracy of the classifier as the percentage of correctly classified samples in a given class compared to the total number of

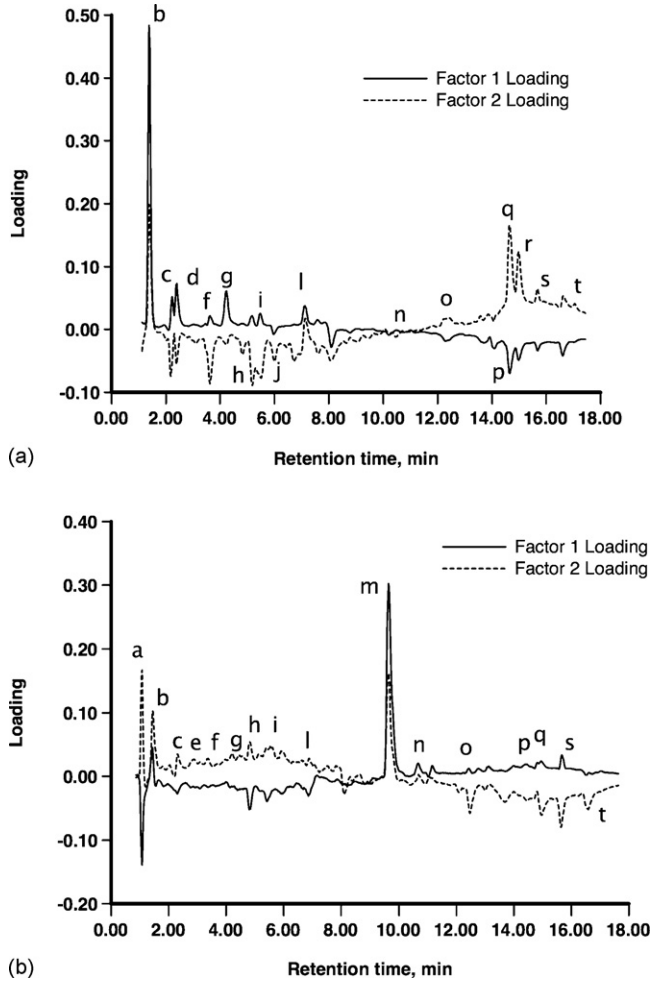

Fig. 5. The loadings (Factor 1 solid line and Factor 2 dashed line) associated with the first two principal components from the Chardonnay wines using (a) UV detection and (b) potassium permanganate chemiluminescence detection. Peak assignments are provided in Table 1.

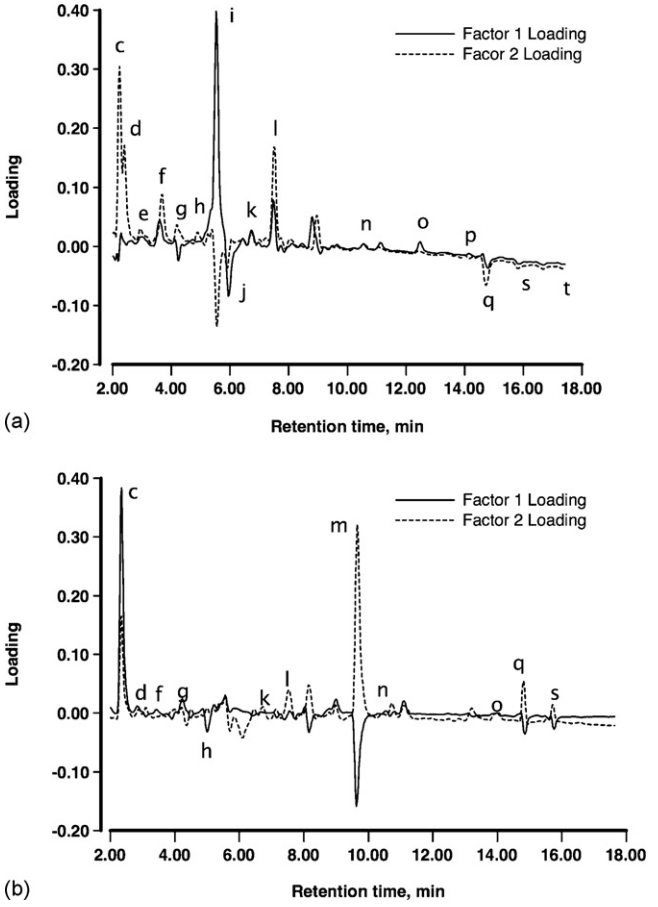

Fig. 6. The loadings (Factor 1 solid line and Factor 2 dashed line) associated with the first two principal components from the Cabernet Sauvignon wines using (a) UV detection and (b) potassium permanganate chemiluminescence detection. Peak assignments are provided in Table 1.

samples in that class. The overall accuracy of the classifier is also presented. Using two PCs, the UV data was able to correctly classify 100% of the Coonawarra and Geelong Chardonnays. while the acidified potassium permanganate was able to correctly classify 86% and 64% respectively. For the Cabernet Sauvignon the acidified potassium permanganate afforded marginally better discrimination, correctly identifying overall 94% compared with 91% for the UV.

The Chardonnay UV loadings data (Fig. 5a) show that the main species responsible for geographic discrimination are the simple phenolic acids, coumaric acid (peak *i*) and gallic acid (peak *c*), and epicatechin (peak *l*). The concentrations of these species are known, and have been shown to vary according to geographic origin [33]. Arvanitoyannis et al. have also shown that coumaric acid is a significant marker in chemical profiling of variety and ageing of wines [1]. Coumaric acid is a volatile phenol that can contribute to the aroma of wine and is a key component in the development of wine by yeast [34]. The loadings data for the acidified potassium permanganate (Fig. 5b) also highlights gallic acid (peak *c*) as a key marker compound and, along with myricetin (peak *m*), serves to discriminate the Chardonnay wines. Although myricetin is more commonly associated with red wines [35] its high sensitivity using chemiluminescent detection enables it to play a significant role here.

The Cabernet Sauvignon UV loadings data (Fig. 6a) identifies tartaric acid (peak *b*) and resveratrol (peak *q*) as significant marker compounds for identification of geographic origin. Tartaric acid is one of the most common acids found in red wine and is a key component responsible for the acidity of wine. Resveratrol concentrations in wine have been shown to vary considerably between regions, with significantly less resveratrol present in wines from warmer climates, such as Australia [36].

As found with the Chardonnay samples, the Cabernet Sauvignon acidified potassium permanganate loadings (Fig. 6b) highlight myricetin (peak *m*), cinnamic acid (peak *a*) and tartaric acid (peak *b*) as significant compounds in the classification of these red wines.

4. Conclusion

Acidified potassium permanganate chemiluminescence and UV detection systems when combined with HPLC were both found to be suitable for the geographical determination of some Australian wines. The UV detection highlighted that coumaric acid, gallic acid, and epicatechin were important for geographical determination of Chardonnay, whereas tartaric acid and resveratrol were found to be important for Cabernet Sauvignon samples. The acidic potassium permanganate detection showed that for both Chardonnay and Cabernet Sauvignon, the major constituents responsible for geographical determination, were differing concentrations of myricetin, cinnamic acid and tartaric acid.

Using two principal components, linear discriminant analysis with UV detection it was possible to correctly classify 100% of the

Chardonnay samples and 91% of the Cabernet Sauvignon samples, compared with acidified potassium permanganate chemiluminescence detection that afforded the correct classification of 75% of the Chardonnay samples and 94% of the Cabernet Sauvignon samples.

Acknowledgments

The authors would like to thank the following wineries for their generous donations of wines for analysis: Punters Corner Wines, Wynns Coonawarra Estate, Brand's of Coonawarra, Balnaves of Coonawarra, Wingara Wine Group, Hollick Wines Pty. Ltd., Rymill Winery, Majella Wines, Di Giorgio Family Wines Pty. Ltd., Flint's of Coonawarra, Redman Wines, Leconfield, Moorabool Estate, Provenance Wines, Scotchmans Hill, Bannockburn Vineyards, Pettavel Pty. Ltd., Eagles Rise, Clyde Park Vineyard, and Lethbridge Wines.

ABSTRACT

A fast and simple method for the analysis of polybrominated diphenyl ethers (PBDEs) in fish samples was developed using a one-step extraction and clean-up by means of pressurized liquid extraction (PLE) combined with gas chromatography–ion trap tandem mass spectrometry (GC–ITMS–MS). The selective PLE method provided to obtain ready-to-analyse extracts without any additional clean-up step, using a sorbent as fat retainer inside the PLE cell. Several PLE operating conditions, such as solvent type, extraction temperature and time, number of cycles and type of fat retainer, were studied. Using Florisil as fat retainer, maximum recoveries of PBDEs (83–108%) with minimum presence of matrix-interfering compounds were obtained using a mixture of n-hexane:dichloromethane 90:10 (v/v) as solvent, an extraction temperature of 100 °C and a static extraction time of 5 min in combination with three static cycles. Quality parameters of the method were established using standards and fish samples. Limits of detection and quantification ranged from 10 to 34 pg g^{-1} wet weight and between 34 and 68 pg g^{-1} wet weight, respectively. In addition, good linearity (between 1 and 500 ng ml^{-1}) and high precision (RSD % < 15%) were achieved. The method was validated using the standard reference material SRM-1945 (whale blubber) and was then applied to the analysis of PBDEs in fish samples.

1. Introduction

Polybrominated diphenyl ethers (PBDEs) are a class of chemicals extensively used as flame retardant additives in a wide variety of commercial and industrial products [1,2]. They are released into the environment both during the production, use and recycling of products containing PBDEs, and during disposal in domestic waste, landfill, and incineration [3–5]. The presence of PBDEs in the environment is a cause of concern due to their persistence, lipophilic character and the ease with which they bioaccumulate in wildlife and humans through the food web [6]. They have been detected as environmental contaminants with widespread global distribution [7] in both biotic and abiotic matrices [8,9], and they accumulate in serum [10,11], adipose tissue [11,12] and human breast milk [13,14]. Due to the significant bioaccumulation of PBDEs in animals and humans, their detection in increasing concentrations during the last decade, and the adverse health effects reported (e.g., reproductive toxicity, endocrine disruption, and neurodevelopment effect in animals) [15–18], the use of Penta-BDE and Octa-BDE technical mixtures in consumer products have been regulated in Europe since 2004 [19]. In addition, restrictions in electrical and electronic equipment that contains these compounds became effective in 2006 [20].

Since an important human exposure route of PBDEs is through the diet, recent studies on PBDE levels in food [21–24] have demonstrated that fish consumption significantly contributed to the total human exposure. Due to these findings, efforts have been undertaken to develop reliable methods to analyse these compounds in biota samples. PBDEs are currently analysed using similar methods to those applied for polychlorinated biphenyls (PCBs) and other persistent organic pollutants [9]. These methods generally involve the extraction of the analytes from biological matrices using Soxhlet [25,26] or sonication with apolar solvents [27]. Alternative extraction techniques, such as pressurized liquid extraction (PLE) [28–30], microwave assisted extraction (MAE) [31], SFE [32] and matrix solid-phase dispersion (MSPD) [33,34], have also been used. All these extraction methods often require extensive clean-up procedures after extraction to remove matrix-interfering compounds and are usually time-consuming. In order to reduce the handling time, simultaneous PLE extraction and clean-up have been developed for the analysis of persistent organic pollutants such as polychlorinated biphenyls (PCBs) [35,36], polychlorinated dibenzo-*p*-dioxins and dibenzofurans (PCDD/Fs) [37,38], polychloronaphtalenes (PCNs) [39,40] and also PBDEs [41–44] in environmental samples. For fish samples, only two PLE methods

using alumina as fat retainer have been proposed for the analysis of PBDEs [43,44].

Gas chromatography coupled to mass spectrometry (GC–MS) is the technique commonly used for the determination of PBDEs [9,45,46]. Negative chemical ionisation (NCI) is the most popular ionisation mode for determination of these compounds by low resolution MS. This technique provides higher sensitivity than that of electron ionisation (EI) but is less selective, since only bromine ions are monitored. In addition, less accuracy in quantification is obtained since isotope dilution cannot be used. GC–HRMS in EI mode provides the most selective and sensitive method for the determination of these compounds [22,29,47,48] and it is recommended by the U.S. EPA for the analysis of PBDEs [49]. Nevertheless, since this technique is relatively expensive and requires skilled personnel and heavy maintenance to ensure proper functioning, low resolution mass spectrometry is preferred. Gas chromatography coupled to ion trap mass spectrometry working in tandem mode (GC–ITMS–MS) has shown to be a low-cost, rapid and reliable alternative to HRMS for the analysis of PBDEs in environmental and biological samples [13–15,50–54].

The aim of this study was to develop a simple and rapid PLE method in combination with gas chromatography coupled to GC–ITMS–MS for the analysis of PBDEs at low concentrations in fish samples. A one-step extraction and clean-up method was optimized in order to reduce the analysis time and solvent consumption. For this purpose, several fat retainers were studied and PLE parameters were optimized. In addition, MS–MS working conditions that provided maximum sensitivity and selectivity for the analysis of PBDEs were established. To validate the whole analytical method, a certified reference material was analysed. In addition, the method developed was used for the analysis of PBDEs in fish samples.

2. Experimental

2.1. Chemicals and standards

A standard solution of PBDEs (BDE-LMS, Lake Michigan Study) containing the BDE congeners 28, 47, 66, 85, 99, 100, 138, 153 and 154 at a concentration of 10 μg/ml in nonane was purchased from AccuStandard (New Haven, USA). For quantification, a standard solution of isotopically $^{13}C_{12}$-labelled BDEs 47, 99 and 153 (BDE-MXA), supplied by Wellington Laboratories (Guelph, Canada), at 5 μg ml^{-1} of each congener was used as internal standard. In addition, a standard solution of isotopically $^{13}C_{12}$-labelled BDE 139 at a concentration of 5 μg ml^{-1} (Wellington Labs) was used as syringe standard for recovery determination. Seven calibration standard solutions containing a mixture of the nine PBDE congeners at concentrations ranging from 2 to 400 ng ml^{-1} and the isotopically labelled internal standards for recovery and quantification at 100 ng ml^{-1} were prepared by dilution of the corresponding standard stock solutions in isooctane.

Dichloromethane and isooctane of Pestanal grade were purchased from Riedel-de Haën (Sigma–Aldrich Laborchemikalie, Seelze, Germany) and n-hexane of residue analysis grade was obtained from Fluka Chemie (Bucks, Switzerland). Hydromatrix was supplied by Varian (Palo Alto, USA) and glass fibre filters for the extracting cell came from Dionex Corp. (Sunnyvale, CA). Sulphuric acid (95–97%), sodium hydroxide and anhydrous sodium sulphate (purity > 99%) of residue analysis grade were obtained from Merck (Darmstadt, Germany). Florisil (0.15–0.25 mm) of residue analysis grade, silica gel (Gel 60) and aluminium oxide 90 active neutral (activity stage I) of chromatographic analysis quality were also obtained from Merck (Darmstadt, Germany). Before use, the silica gel and Florisil were baked at 600 °C for 10 h, while the alumina was activated at 300 °C for 10 h. Silica gel modified with sulphuric acid (44%, w/w) was prepared by slowly adding an appropriate amount of sulphuric acid to the activated silica at room temperature. All glass materials were cleaned with AP-13 Extran alkaline soap (Merck, Darmstadt, Germany) for 24 h, rinsed consecutively with Milli-Q water (Millipore Corp., Bedford, MA) and acetone, and dried overnight.

2.2. Samples and sample preparation

Fish samples (trout, salmon and horse mackerel) were purchased from a local supermarket and were selected for the analysis of PBDEs since they cover a wide range of lipid content and are among the fish products most frequently found in the Spanish diet [55]. Trout and salmon were of aquaculture origin, while horse mackerel were caught in the Mediterranean Sea. Each fish was washed and the non-edible parts were removed to obtain clean tissues. The muscle tissue was triturated, homogenized, frozen and lyophilized for 2 days. Then, the dried tissue was ground in a glass mortar to a fine powder, and stored in glass vials in dark at 4 °C before analysis.

A standard reference material, SRM-1945 (whale bubbler), obtained from the National Institute of Standards and Technology (NIST, Boulder, Colo, USA) was used to validate the whole method (on-line PLE/clean-up and GC/ITMS–MS) for PBDE analysis.

2.3. GC–MS instrumentation

A Trace GC 2000 Series gas chromatograph (ThermoFisher, Milan, Italy) coupled to a GCQ-Polaris (ThermoFisher, Austin, TX, USA) ion trap mass spectrometer equipped with an AS2000 autosampler was used for PBDE determination. The chromatographic separation of these compounds was performed using a DB-5MS (5% phenyl, 95% methyl polysiloxane) fused-silica capillary column (J&W Scientific, Folsom, USA) 30 m × 0.25 mm I.D., 0.25 μm of film thickness. The oven temperature was programmed from 90 °C (held for 1 min) to 200 °C at 15 °C min^{-1} and then to 280 °C at 2 °C min^{-1} and finally to 310 °C at 15 °C min^{-1} (held for 20 min). Helium was used as carrier gas at a constant flow-rate of 1 ml min^{-1} held by electronic pressure control at 90 °C. Injector temperature was kept at 280 °C and 1 μl of samples and standards was injected in the splitless injection mode (1 min). The MS operating conditions were the following: electron ionisation mode using automatic gain control (AGC) with electron energy of 70 eV and an emission current of 250 μA. The ion source and transfer line temperatures were kept at 200 °C and 280 °C, respectively. The instrument was tuned using perfluorotributylamine (FC-43) according to the manufacturer's recommendations in order to achieve the highest sensitivity. Electron multiplier voltage was set to 1450 V (10^5 gain) by automatic tuning. In MS–MS mode, for native and $^{13}C_{12}$-labelled PBDEs the most intense ion of the molecular and the $[M-2Br]^{+\bullet}$ cluster ions of each homologue group were investigated as precursor ion. After optimization, the $[M+4]^{+\bullet}$ ion of each homologue group was selected as precursor ion, except for tri-BDEs and hexa-BDEs where the $[M+2]^{+\bullet}$ and $[M+6]^{+\bullet}$ ions, respectively were selected (Table 1). For quantitative purposes, the product ions corresponding to the loss of two ^{79}Br atoms and one ^{79}Br and one ^{81}Br atoms of native and $^{13}C_{12}$-labelled compounds were monitored. After optimization, the resonance excitation voltages, which produce the maximal yield in the abundance of the corresponding product ions for all the compounds, was 1.20 V (Table 1). Other optimum MS–MS parameters were the following: maximum excitation energy, q_z, 0.3; isolation window of precursor ion, 2 m/z; isolation time, 10 ms; excitation time, 15 ms. The MS–MS acquisition method was time-programmed in five segments to determine tri- to hexa-PBDEs. Xcalibur version 2.0 software was used for data acquisition and

Table 1
MS–MS transitions selected and excitation voltage for each homologue group of PBDEs in GC–ITMS–MS method.

Homologue	Congener	Time window (min)	Transition $[M]^{+\bullet} \rightarrow [M-2Br]^{+\bullet}$				Transition $[M-2Br]^{+\bullet} \rightarrow [M-2Br\text{-}COBr]^{+}$

processing of the results. Quantification of PBDEs was carried out by isotope dilution using $^{13}C_{12}$-labelled PBDE congeners as internal standards.

2.4. PLE extraction and clean-up

The simultaneous extraction and clean-up of the lyophilized fish samples was performed on an ASE 100 Accelerated Solvent Extractor System (Dionex, Sunnyvale, CA). Before PLE extraction, an adequate amount of the isotopically $^{13}C_{12}$-labelled PBDEs (BDE-MXA) was added to 0.5 g of the freeze-dried fish sample, which was left overnight at room temperature to equilibrate. The sample was then mixed with sodium sulphate at a fish/Na_2SO_4 ratio of 1:20 (w/w) in a mortar until a homogenous mixture was obtained. Florisil (20 g) and alumina were tested as fat retainer material. The extraction cell was loaded by inserting a glass fibre filter into the cell outlets, followed by the fat retainer and the sample, using Hydromatrix to fill up the dead volume of the extraction cell. After sealing the cell with the top cell cap, the extraction cell was placed in the ASE system. Fish samples were extracted at 100 °C with a solvent mixture of n-hexane:dichloromethane (95:5, v/v) and working at a pressure of 1500 psi, a flush volume of 100% and a purge time of 290 s for a 100 ml PLE cell. Further details about the optimization of the extraction parameters are described in Section 3. The final extracts were then rotary evaporated to approximately 2 ml adding 100 μL of isooctane as a keeper. Afterwards, the final extract was carefully concentrated under a gentle nitrogen stream up to 25 μL and analysed by GC–ITMS–MS after adding an adequate amount of $^{13}C_{12}$-BDE 139 as internal standard.

The fat content of fish was determined gravimetrically by evaporation of the extract obtained from a PLE process (without fat retainer) of an additional sub-sample (2.5 g of freeze-dried fish). A solvent mixture of n-hexane:dichloromethane (1:1, v/v) was used. The percentage of fat determined for the fish samples (wet weight) was as follows: 0.68% for trout, 2.1% for horse mackerel and 16.9% for salmon.

2.5. Quality control criteria

A daily isomer-specific GC separation test, sensitivity test and calibration test were carried out. Procedural blanks (both instrumental and method) were routinely performed during the analysis, and quality control fish samples were periodically analysed in order to ensure that the analytical method was maintained under control. A salmon sample with non-detectable amounts of the PBDEs spiked at 1 ng g^{-1} ww was used as quality control sample. The certified reference material SRM-1945 was used for validation.

3. Results and discussion

3.1. Optimization of MS–MS conditions

Different MS–MS working conditions and strategies on the selection of the precursor and product ions have been proposed for the analysis of PBDEs, even using similar instruments. Therefore, experiments conducted to determine the optimum MS–MS parameters, especially those depending on the instrument for achieving the best sensitivity and selectivity in the PBDE analysis, were carried out. Before optimization, the precursor ions and the corresponding transitions were selected. Some authors [51,53,56] propose the use of $[M-2Br]^{+\bullet}$ ions as precursors since they are the most abundant ions on the EI-MS spectra for most tetra- to octa-BDEs, except for non-ortho-substituted congeners, BDE-35, BDE-37, BDE-77 and BDE-126, for which the $[M]^{+\bullet}$ cluster ions are predominant [57,58]. Selecting $[M-2Br]^{+\bullet}$ as precursor ions, the most abundant product ions obtained after CID collision correspond to the loss of COBr• ($[M-2Br-COBr]^{+}$) while $[M-3Br]^{+}$ and $[M-4Br]^{+\bullet}$ fragment ions were obtained at lower abundance. Other authors propose the use of $[M]^{+\bullet}$ ions instead of $[M-2Br]^{+\bullet}$ as precursor ions [11,12,52,54,59]. In this case, the fragment ions corresponding to the loss of two bromine atoms from the molecular cluster ions were selected as product ions. To determine the precursor ion which provides the best sensitivity on the MS–MS analysis, the performance of both strategies was examined. Table 1 shows the precursor and product ions selected for each transition studied. For this purpose, MS–MS parameters such as excitation voltage, excitation time, excitation energy and isolation mass window, were optimized for each CID transition evaluated. The effect of each parameter upon the MS–MS process was studied varying only one of the parameters while keeping the others constant. For these experiments, a standard mixture of native and $^{13}C_{12}$-isotopically labelled PBDE congeners (100 ng g^{-1}) was used. The best results were obtained using an excitation time of 15 ms and a mass isolation window of 2 m/z. The effect of the excitation voltage on the product ion yield was also studied and Table 1 shows the optimum values for both MS–MS transitions. The influence of the excitation energy (q_z parameter) on the fragmentation yield and the stabilization of the product ions was studied at three q_z levels, 0.225 (low), 0.300 (medium) and 0.450 (high). Maximum abundances of the product ions were observed at the medium q_z value (0.30) using both $[M]^{+\bullet}$ and $[M-2Br]^{+\bullet}$ as precursor ions. Fig. 1 shows the abun-

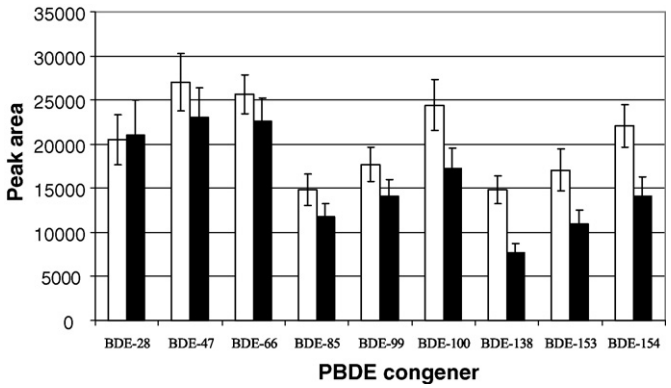

Fig. 1. Peak area of the product ions corresponding to the $[M]^{+\bullet}$ (white bars) and $[M-2Br]^{+\bullet}$ ions (black bars) selected as precursor ions. Error bars correspond to the standard deviation ($n = 7$).

dances of the product ions expressed as peak area ($n = 7$) obtained from the two precursor ions $[M]^{+\bullet}$ and $[M-2Br]^{+\bullet}$. As can be seen, the use of the most abundant ion of the molecular cluster ion of each homologue group as the precursor ion provided the highest response on the product ions for PBDE congeners, mainly for higher brominated ones (hexa-BDEs). Therefore, the $[M]^{+\bullet} \rightarrow [M-2Br]^{+\bullet}$ transitions are recommended for achieving maximum sensitivity for PBDEs analysis. Potential interferences on the determination of PBDEs by GC–ITMS/MS were also evaluated. The presence of several chlorinated compounds in the PBDE extracts could interfere on the isolation of precursor ions of PBDEs, but due to the transition selected any effect on the response of the product ions occurred. Other interfering compounds present in biotic samples such as polybrominated biphenyls (PBBs) did not cause any interference on the PBDE quantification because the contribution on the selected precursor ions of PBDEs is negligible (0.00002% of the most intense peak of the molecular or $[M-2Br]^{+\bullet}$ cluster ions). Methoxylated tetra-PDEs (MeO-tetr-BDEs) have also been reported as potential interfering compounds of $^{13}C_{12}$-penta-BDEs, but the fragments corresponding to the loss of CH_3Br from MeO-tetra-BDE congeners only interfere with the $[M+4-2Br]^{+\bullet}$ of $^{13}C_{12}$-penta-BDEs and these ions were not selected in our study. In addition, the molecular ions of hexabromocyclododecane (HBCD) could also interfere to hexa-BDE congeners, but these ions are not present in the EI spectrum of HBCD.

Instrumental quality parameters of the GC–ITMS–MS method were determined using standard solutions. To study the linearity, seven-point calibration standard solutions ranging from 5 to 400 ng ml^{-1} for native PBDEs and containing isotopically $^{13}C_{12}$-labelled PBDE congeners at a concentration of 100 ng ml^{-1} were used. Good linearity in the concentration range was obtained for all the compounds, with correlation coefficients (r) higher than 0.9990. Limits of detection (LODs), defined as the concentration that produces a signal to noise ratio (S/N) greater than 3, were determined experimentally using standard solutions at low concentrations (2.0 ng ml^{-1}). Under these conditions, instrumental LODs ranged from 0.8 to 2.5 pg injected. For run-to-run and day-to-day precisions, a standard mixture of PBDE congeners at a concentration of 20.0 ng ml^{-1} were analysed in quintuplicate on 1 day and on 3 days, respectively. Good run-to-run and day-to-day precisions were achieved with RSDs (%) between 4% and 9% and from 6% to 10%, respectively.

3.2. Simultaneous PLE extraction and clean-up

In order to set up a PLE method to simultaneously perform in-cell extraction and purification, several sorbents as fat retainers were evaluated. Preliminary studies were carried out using an off-line method based on a PLE extraction followed by a clean-up step with sorbents, such as Florisil, silica modified with sulphuric acid and alumina, often used in conventional analytical methodology for the clean-up of a wide range of environmental and biological samples [9]. For this purpose, 1 g of a lyophilized salmon sample spiked with the target PBDE congeners at a concentration of 5 ng g^{-1} dry weight (0.3 ng g^{-1} wet weight) and the $^{13}C_{12}$-labelled PBDEs (BDE-MXA) was used. The spiked sample was kept overnight at room temperature to equilibrate before PLE extraction and then mixed with anhydrous sodium sulphate (10 g) and Hydromatrix (around 4 g). Extraction was carried out using PLE (34-ml cell) without fat retainer. The extraction was carried out at 100 °C using hexane:dichloromethane 1:1 (v/v) as extraction solvent and applying 3 static cycles of 5 min each and a flush volume of 100% (90 s of purge). To clean-up of the PLE extracts, glass columns filled with different amounts of the sorbents (30 g of modified silica, 20 g of Florisil and 20 g of alumina) were studied. n-Hexane and several mixtures of n-hexane:dichlorometane (9:1, 8:2 and 7:3, v/v) were tested as elution solvents. Using modified silica, acceptable recoveries of the target compounds were obtained using n-hexane:dichlorometane 7:3 (v/v), but the presence of lipids and fat degradation products in the final extract was detected (Fig. 2A), causing a high variability in the GC–ITMS–MS determination (RSD % > 40%). Both Florisil and alumina using a mixture of hexane:dichloromethane 95:5 (v/v) allowed to obtain extracts clean enough for GC–ITMS–MS determination of the target compounds, achieving recoveries between 85% and 95%. Therefore, these sorbents were selected as potential fat retainers for the simultaneous extraction and clean-up in-cell method. Fig. 2B shows the GC-MS chromatogram of a salmon sample spiked with the target compounds where the lipid content was completely removed using Florisil.

The next step in the optimization process was to incorporate the fat retainer into the extraction cell in order to evaluate the capability of PLE for the analysis of the target compounds. Experiments were conducted to select the most adequate fat retainer with the aim of obtaining the maximum efficiency for the extraction of PBDEs with the minimum presence of interfering compounds. The efficiency of alumina and Florisil as fat retainers was tested using a similar amount of sorbent (10 g) in a 100 ml PLE cell, using 0.5 g of freeze-dried fish sample (a salmon spiked at 5 ng g^{-1} dry weight), an extraction temperature of 100 °C, a solvent mixture of n-hexane:dichloromethane 95:5 (v/v) and 2 static cycles of 10 min each (flush volume of 100%). At these conditions, recoveries obtained for all PBDE congeners and for each sorbent ranged from 65% to 85%, but a high variability on the results (RSD % > 30%) was obtained using alumina, even using higher amounts of sorbent (>10 g). The poor precision achieved with alumina could be attributed to the incomplete lipid removal that drastically affected the GC–ITMS–MS response. In contrast, when Florisil was used, an important improvement on the precision was obtained. Although alumina has been reported as fat retainer for on-line PLE extraction [9], it has always been used in GC–NCI–MS, which seems to be less affected than GC–ITMS–MS by lipid contamination. Therefore, Florisil was selected as fat retainer for the simultaneous extraction/clean-up in-cell of fish samples.

Several PLE parameters such as the amount of fat retainer, type of extraction solvent, number of extraction cycles, extraction temperature and static extraction time were optimized. For this, different amounts of Florisil were used, from 10 to 25 g, maintaining constant the other PLE parameters (n-hexane:dichloromethane 95:5 (v/v), 2 static cycle of 10 min). As a result, 25 g of Florisil were selected because this material provided the highest cleanness of the extract with a relatively high recovery of the analytes. We then examined the influence of the static extraction time (from 3 to 10 min), the number of cycles (between 2 and 4 cycles) and the

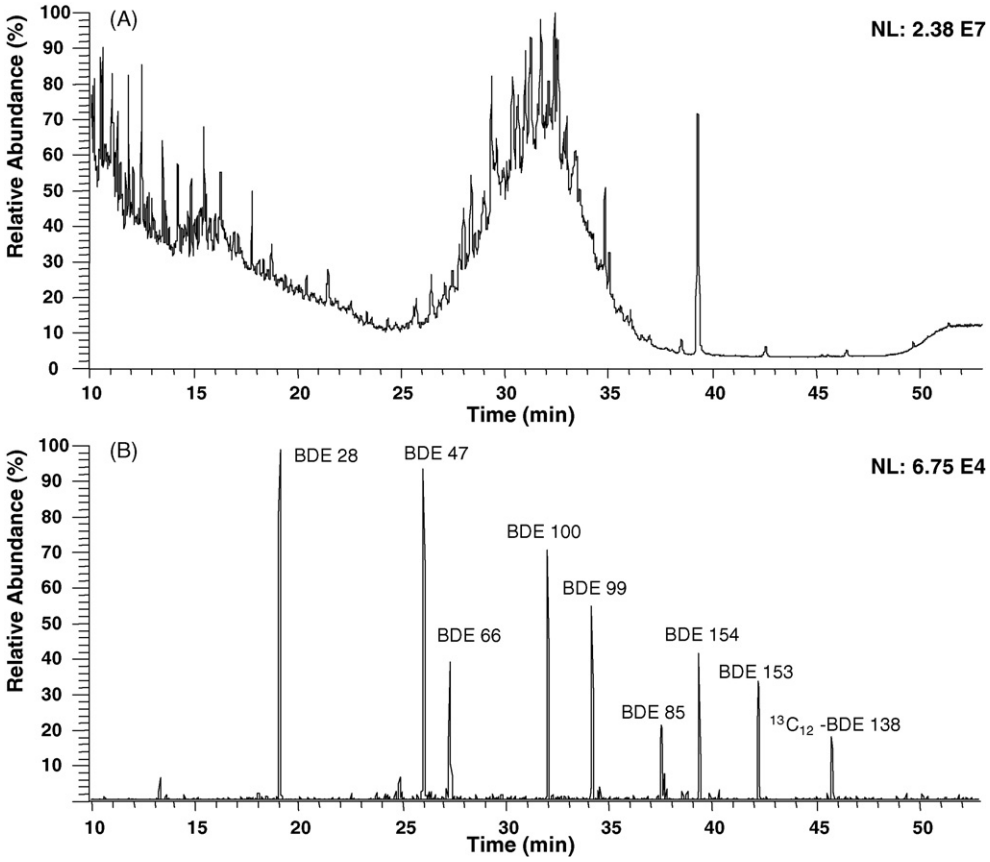

Fig. 2. GC–MS chromatogram (TIC) obtained in full-scan mode of a spiked salmon sample (0.3 ng g^{-1} ww) after simultaneous PLE extraction and purification with (A) silica modified with sulphuric acid, and (B) Florisil.

extraction temperature (at 50 °C and 100 °C) on the recovery of the analytes. For all experiments, a flush volume of 100% and a purge time of 290 s were used. After optimization, the best results were obtained using an extraction temperature of 100 °C and a static extraction time of 5 min in combination with 3 static cycles. Finally, we examined the effect of the composition of the extraction solvent on the recovery of the analytes. Several solvent mixtures of n-hexane:dichloromethane (95:5, 90:10, 80:20, 70:30 and 60:40, v/v) were tested using the optimized PLE parameters above mentioned. Generally, a rise in the proportion of dichloromethane in the extraction solvent increased the recovery of the target compounds. Solvent mixtures with percentages of dichloromethane higher than 30% provided coloured extracts with high lipid content. For the other mixtures, similar recoveries of the PBDE congeners were obtained, but the amount of lipids extracted increased with the percentage of dichloromethane. For this reason, the mixture n-hexane:dichloromethane 90:10 (v/v) was selected as optimum extraction solvent. Table 2 shows the recoveries (%) obtained for the spiked salmon samples using 25 g of Florisil as fat retainer under the optimized PLE conditions. High extraction efficiencies were obtained, with recoveries ranging between 83% and 108%.

Limits of detection and quantification of the simultaneous extraction and clean-up in-cell combined with GC–ITMS–MS determination were estimated using fish samples with low concentration levels. The LODs ranged from 10 to 34 ng g^{-1} wet weight, depending on the compound, while the LOQ of the method ranged between 34 and 68 pg g^{-1} wet weight. These results are in agreement with those reported in the literature for fish samples [9]. In order to evaluate the accuracy of the whole developed method, a whale blubber standard reference material, NIST SRM-1945, was

analysed. Triplicate analyses were carried out following the on-line PLE and GC–ITMS–MS method developed. The results obtained agreed with the certified values of the material (Table 2), achieving relative standard deviations lower than 13%. These results show that the proposed method can be considered as an attractive alternative method for the analysis of PBDEs in fish samples.

3.3. Analysis of PBDEs in fish samples

The proposed method was used for the determination of PBDEs at low concentrations in several fish samples (trout, horse mackerel and salmon) which cover a wide range of lipid content. Table 3 shows the PBDE concentration mean values obtained with their corresponding relative standard deviation (%). As an example, Fig. 3 shows the GC–ITMS–MS chromatograms obtained for a horse mackerel sample from the Mediterranean Sea. As can be seen, high selectivity and good signal-to-noise ratio were obtained using the proposed method. Concentration of the PBDE congeners ranged from 0.95 to 16.9 ng g^{-1} wet weight for trout, from 0.39 to 91.3 ng g^{-1} wet weight for horse mackerel and between 2.5 and 46.6 ng g^{-1} wet weight for salmon, with relative standard deviations (RSD %) ranging from 9% to 15% (Table 3). Total PBDE levels expressed as a sum of the nine PBDE congeners were respectively 45.0 ng g^{-1} ww, 144.3 ng g^{-1} ww and 82.3 ng g^{-1} ww for trout, horse mackerel and salmon. In all samples, the BDE-47 was the predominant congener followed by BDE-99 and BDE-100, which are the primary components of the commonly used Penta-BDE formulation. Generally, the results obtained in this study are consistent with data published in the literature for similar fish species. For instance, PBDE levels found in trout from the Laurentian Great Lakes (27–95 ng g^{-1} ww) [47] and four Swiss Lakes (1.6–7.4 ng g^{-1} ww) [60] are in agreement with those obtained in this work. Nevertheless, reported levels of PBDEs in horse mackerel from several markets in Fukuoka (Japan) (473.6 ng g^{-1} ww) were fourfold higher than those determined in this paper. For salmon, PBDE levels found in this work were similar to those reported for similar samples [61–63] and can be considered as fish samples with a medium contamination level.

4. Conclusion

A fast, simple and accurate on-line PLE extraction/clean-up method combined with GC–ITMS–MS has been proposed for the analysis of PBDEs in fish samples at low concentration levels. The use of Florisil as fat retainer in the PLE cell provided quantitative recoveries of PBDEs and extracts ready to GC–ITMS–MS determination. In contrast, the use of alumina did not provide extracts clean enough for PBDE determination and important variations in the results were obtained. Using the proposed on-line PLE procedure, a considerable reduction in the extraction time (around 30 min) and solvent consumption (100 ml) was obtained compared with conventional or PLE methods that employ an off-line clean-up. In addition, the accurate optimization of GC–ITMS–MS conditions allowed maximum sensitivity and selectivity on the PBDE determination. The whole method provided low limits of detection (10–34 pg g^{-1} wet weight) and good precisions (lower than 15%). Therefore, the PLE method combined with GC–ITMS–MS can be proposed for the analysis of PBDEs at low concentration levels in fish samples.

ABSTRACT

A simple, fast and accurate procedure is proposed for the determination of antimony in certified sediment reference materials using direct solid sampling high-resolution continuum source electrothermal atomic absorption spectrometry and iridium as a permanent modifier. The less sensitive resonance line at 231.147 nm has been used in order to allow the introduction of larger sample mass. Six certified reference materials, one river, one estuarine and four marine sediments have been analyzed. The use of iridium as a permanent modifier caused an increase of 30% in sensitivity and stabilized antimony in the sediment to a pyrolysis temperature of 1100 °C. Significant background absorption with pronounced rotational fine structure was observed at the optimum atomization temperature of 2100 °C, which coincided with the analyte atomic absorption in time. This background was found to be due to the electron excitation spectra of mostly the SiO and in part the PO molecules, and could be eliminated by applying a least-squares background correction algorithm. A characteristic mass of 28 pg Sb was obtained, and the limit of detection (3σ, $n=10$) was 0.02 $\mu g\,g^{-1}$, calculated for 0.2 mg of sample. The results obtained for six certified reference materials with concentrations between 0.40 and $11.6 \pm 2.6\ \mu g\,g^{-1}$ Sb were in agreement with the certified values according to a Student's *t*-test for a 95% confidence level, using aqueous standards for calibration. The precision, expressed as relative standard deviation, ranged between 7% and 17% ($n=5$).

1. Introduction

In contrast to other toxic elements, such as arsenic, cadmium, lead or mercury, antimony came into the focus of environmental and health concern only less than a decade ago, maybe because no big environmental accident, such as the Minamata disaster in Japan or the arsenic poisoning in Bangladesh, was associated to antimony intoxication. Antimony and many of its compounds are toxic, bio-accumulative and persistent in the environment and its behavior and transport depend on its chemical form [1–3]. Antimony is generally more toxic than lead due to its higher solubility in lipids, which increases the potential for biological uptake and bio-accumulation. Its presence in the environment is due to natural processes and anthropogenic activities [4–6]. Antimony is increasingly being used in the semiconductor industry, in a wide variety of alloys and as a flame retardant [7,8]. Industries such as smelters, coal-fired plants and refuse incinerators can release relatively high amounts of antimony in the air. When released to air, antimony can attach itself to very small particles and may stay in the atmosphere for many days and be transported over long distances. In soil, antimony is strongly associated with particles containing iron, manganese or aluminum. In water it usually adheres to sediments [9].

The determination of trace elements in sediment is particularly difficult because of the complexity of the matrix. The total analyte concentration can only be determined after a fusion with sodium carbonate [10], lithium tetraborate [11] or lithium metaborate [12–14], or after acid digestion in the presence of hydrofluoric acid and frequently also perchloric acid [15,16]. These digestion procedures are relatively time-consuming and certainly not without problems. The high reagent concentration requires regular blank controls to be performed, and frequently the calibration solutions have to be matched to the matrix content. Moreover

doi:10.1016/j.talanta.2009.08.004

the high salt concentration can lead to interferences in the final determination. Digestions in hydrofluoric or perchloric acid are dangerous, and next to silicon, which should be removed in this manner, a number of elements, including antimony, form volatile fluorides which might be lost during sample preparation.

Owing to these problems, instead of a total digestion or fusion, it is common in environmental analysis to use a leaching with *aqua regia* [17,18]. This method is based on the assumption that heavy metals that are so strongly bound to the mineral matrix that they do not go into solution under these conditions will also not be taken up by plants and cannot be dissolved by water or bacteria. Even if this assumption might be true for many elements and matrices, such an extraction cannot replace a determination of the total content of an analyte in all situations. In addition, the resulting matrix can cause serious interferences in most spectrometric techniques unless the solutions are strongly diluted, which is often not possible in trace element determinations, or the analyte is extracted, which is another time-consuming procedure.

Due to the difficulties of bringing environmental samples, such as sediments, into solution and due to the complexity of the resulting solutions, which might need additional treatment before they can be analyzed, direct solid sampling (SS) using electrothermal atomic absorption spectrometry with a graphite tube furnace (GF AAS) might be an attractive alternative [19]. However, the complex and refractory matrix of sediments might also cause problems in SS-GF AAS. Although non-spectral interferences can usually be controlled using the Stabilized Temperature Platform Furnace (STPF) concept [20], spectral interferences and the limited background correction capability of conventional line source atomic absorption spectrometers might be the major obstacle in the application of this technique [21]. The introduction of high-resolution continuum source AAS (HR-CS AAS) has brought about a significant change in this direction due to its unsurpassed background correction capabilities [22]. It has been demonstrated that a number of trace elements in a wide variety of complex sample matrices can be determined by SS-HR-CS GF AAS using aqueous standards for calibration, i.e., without any interference [23].

Chemical modifiers are routinely used in GF AAS as part of the STPF concept in order to thermally stabilize volatile analytes and enable the use of higher pyrolysis temperatures to remove the majority of the matrix prior to the atomization stage [24]. In SS-GF AAS the addition of a modifier in solution over the solid sample prior to every determination obviously complicates the procedure. Permanent chemical modifiers, which are usually applied as kind of a surface coating on the SS platform, have therefore been investigated intensively and have been shown to stabilize the analyte in a similar way as when it is applied in solution [25–29]. The mechanism of operation is believed to be a migration of the analyte to the modifier in the pyrolysis stage, as it has been demonstrated that the analyte is released from the sample well below its melting point [30]. Platinum group metals, mainly those with high melting points, i.e., Rh, Ru and Ir, have typically been used as permanent modifiers for the stabilization of volatile elements. The use of permanent modifiers also reduces blank values, as the modifier is purified during its thermal deposition, resulting in better limits of detection and quantification [17].

The goal of this work has been to develop a fast routine procedure for the determination of total antimony in sediments using SS-HR-CS GF AAS. The visibility of the spectral environment at high resolution in HR-CS AAS has also been used as a diagnostic tool in order to investigate spectral interferences that might impede the determination of antimony in sediment using conventional line source GF AAS. The investigation of permanent chemical modifiers has been included in the study for obvious reasons in order to simplify the procedure.

2. Experimental part

2.1. Instrumentation

All experiments were carried out with a prototype high-resolution continuum source atomic absorption spectrometer, built at ISAS Berlin, based on an AAS 6 Vario (Analytik Jena AG, Jena, Germany), from which the entire optical compartment, including detector and associated controls, was removed and replaced by a double monochromator, similar to that described by Heitmann et al. [31]. This monochromator consists of a pre-dispersing prism monochromator and an echelle grating monochromator, both in Littrow mounting, resulting in a spectral resolution of $\lambda/\lambda\Delta \approx 140\,000$. A xenon short-arc lamp XBO 301 (GLE, Berlin, Germany) with a nominal power of 300 W, operating in a *hot-spot* mode, was used as the continuum radiation source. A UV-sensitive charge coupled device (CCD) detector, model S7031-0906 (Hamamatsu Photonics, Japan), with 512×58 pixels operating in full vertical binning mode was used, resulting in a spectral bandwidth per pixel of about 2 pm at 231.147 nm. 200 pixels are used for analytical purposes, which corresponds to a spectral environment of about ±0.20 nm around the center pixel. Details of this equipment and its specific features have been described previously [22,32]. Atomic absorption has been measured at the secondary resonance line of antimony at 231.147 nm, which is about a factor of 2.4 less sensitive than the primary resonance line at 217.581 nm. Three pixels have been used for signal evaluation, corresponding to a spectral interval of ~6 pm, as the best signal-to-noise ratio has been obtained under these conditions. The absorbance values obtained this way are denominated Peak Volume Selected Absorbance (PVSA, $A_{\Sigma 3,\mathrm{int}}$), i.e., the integrated absorbance summated over three pixels [33]. The integrated absorbance values obtained with direct solid sampling have been normalized for 1.0 mg of sample, as it is impossible and unnecessary to weigh always the same sample mass.

The conventional transversely heated graphite tube atomizer supplied by Analytik Jena together with the AAS 6 Vario has been used throughout. All experiments were carried out using pyrolytically coated SS graphite tubes without a dosing hole (Analytik Jena, Part No. 07-8130325) and SS graphite platforms (Analytik Jena, Part No. 407-A81.312). Samples were weighed on a M2P microbalance (Sartorius, Göttingen, Germany) directly onto the SS platforms and inserted into the graphite tube using a pre-adjusted pair of tweezers, which is part of the SSA 5 accessory for manual SS (Analytik Jena). Argon 99.996% (White Martins, São Paulo, Brazil) was used as purge and protective gas. The temperature program adopted for aqueous standards (calibration) and for solid samples is shown in Table 1. In all figures in which time-resolved absorbance is shown,

Table 1
Graphite furnace temperature program for the determination of Sb in sediment samples by SS-HR-CS GF AAS using Ir as a permanent modifier.

Program stage	Temperature (°C)	Ramp (°C s^{-1})	Hold (s)
Drying 1	90	10	10
Drying 2	130	5	5
Pyrolysis	1100	50	15
Auto Zero[a]	1100	0	1
Atomization[a]	2100	3000	7
Cleaning	2500	1000	5

[a] Purge gas (argon) flow rate 2 L min^{-1} in all stages, except during Auto Zero and atomization, where the gas flow was interrupted.

Table 2
Graphite furnace temperature program for the deposition of iridium as a permanent modifier on the SS graphite platform.

Step	Temperature (°C)	Ramp (°C s^{-1})	Hold (s)
1	130	10	40
2	160	10	50
3	1000	20	25
4	1400	100	5
5	2000	100	5

recording starts with the 'Auto Zero' stage, i.e., 1 s prior to the atomization stage.

2.2. Reagents and samples

Analytical grade reagents were used throughout. The nitric acid 65% (Merck, Germany), used to prepare aqueous calibration standards, was further purified by sub-boiling distillation in a quartz apparatus (Kürner Analysentechnik, Rosenheim, Germany). Distilled, deionized water with a resistivity of 18 MΩ cm from a Milli-Q water purification system (Millipore, Bedford, MA, USA) was used for the preparation of aqueous calibration standards. The antimony stock solution was prepared from Sb_2O_3 (SPEX, Edison, NJ, USA). Iridium stock solution with 1000 mg L^{-1} Ir in 1 mol L^{-1} nitric acid (Fluka, Buchs, Switzerland) was used as provided for coating of the platform.

The following certified reference materials (CRM) were used for validation of the method: NIST SRM 8704 (Buffalo River Sediment), NIST SRM 2702 (Inorganics in Marine Sediment), NIST SRM 2703 (Sediment for Solid Sampling Analytical Techniques) and NIST SRM 1646a (Esturine Sediment) (all from National Institute of Standards and Technology, Gaithersburg, MD, USA); Marine Sediment MESS-3, HISS-1 and PACS-2 from National Research Council of Canada (NRCC, Ottawa, Canada).

2.3. Procedure

Iridium was thermally deposited onto the platform surface using 10 repetitive injections of 40 μL of the 1000 mg L^{-1} Ir stock solution as described previously [34]. After each injection, the temperature program shown in Table 2 was applied. One coating has been sufficient for the lifetime of a SS platform. For the determination of Sb, sediment samples were ground in an agate mortar and passed through a polyester sieve for particle size <50 μm. Aliquots containing between 0.02 and 1.1 mg were weighed directly onto the SS platforms and inserted into the graphite tube with the SSA 5 accessory. Calibration solutions (20 μL) were injected manually onto the SS platforms using a micro-pipette. The analysis of one sample including five repetitive weighings and determinations takes less than 10 min, making possible the analysis of about 50 samples per working day.

3. Results and discussion

3.1. Pyrolysis and atomization temperatures

All method development and optimization experiments were carried out using an aqueous standard and NIST SRM 8704 (Buffalo River Sediment). Fig. 1 shows the pyrolysis curves obtained for the sediment CRM (Fig. 1a) and the aqueous standard (Fig. 1b) without a modifier and with iridium as a permanent modifier. Without a modifier antimony is partially lost above 800 °C from the aqueous standard and above 900 °C from the sediment CRM. In the presence of the permanent modifier a pyrolysis of 1100 °C can be used for the sediment, and an even higher pyrolysis temperature would be possible for the aqueous standard. A pyrolysis temperature of 1100 °C has been selected for all further experiments. The atomization temperature has been optimized in a similar way considering sensitivity and signal shape, and a temperature of 2100 °C has finally been selected.

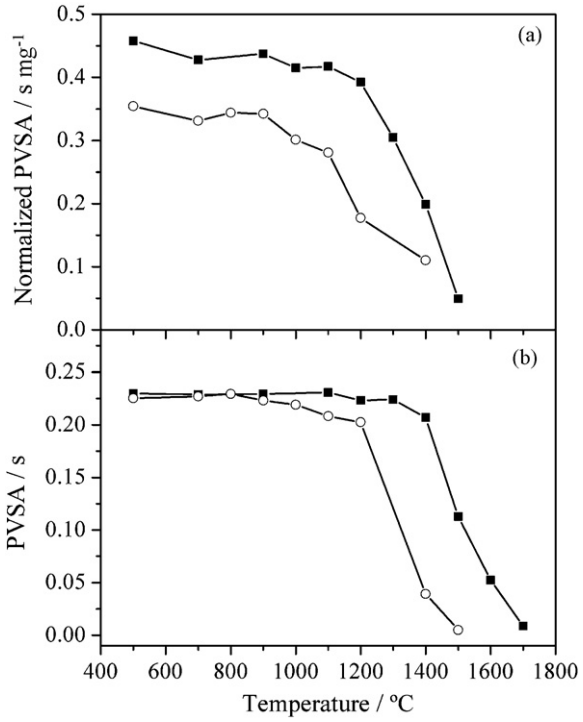

Fig. 1. Pyrolysis curves for Sb –○– without modifier and –■– with 400 μg Ir as permanent modifier; atomization temperature: 2100 °C; (a) NIST SRM 8704 (Buffalo River Sediment), PVSA ($A_{\Sigma 3,int}$) normalized for 1 mg of sample; (b) aqueous standard containing 1.3 ng Sb in 0.5% (v/v) HNO_3.

3.2. Background absorption and background correction

In HR-CS AAS 'continuous' background absorption, i.e., background absorption that does not exhibit any fine structure within the spectral range that is probed by the detector, such as radiation scattering or molecular absorption due to dissociation continua or polyatomic molecules, is corrected automatically and simultaneously with the measurement of atomic absorption using correction pixels. After this correction only discontinuous absorption, such as atomic absorption and molecular absorption due to diatomic molecules, which exhibits pronounced fine structure that can be resolved by the spectrometer, is displayed by the equipment.

The time- and wavelength-resolved absorption spectrum obtained for NIST SRM 8704 (Buffalo River Sediment) in the vicinity of the antimony line at 231.147 nm after automatic correction for continuous background is shown in Fig. 2. The Sb atomic absorption line and a secondary absorption line of Fe at 231.31 nm are marked with arrows; all the other lines are part of an electronic transition spectrum of one or more diatomic molecule(s) with pronounced rotational fine structure. There are actually three different phases within the time frame of the atomization stage. The first one is the appearance of very sharp peaks of a rotational fine structure at the onset of the atomization stage; the second set of molecular bands appears more or less together with the atomic absorption of Sb (and Fe), but does not return to the baseline; instead, towards the end of the atomization cycle, the molecular absorption increases rapidly to relatively high absorbance values. Due to the post-processing capability of the spectrometer it is possible to analyze the recorded spectrum after it has been stored in the computer in order to iden-

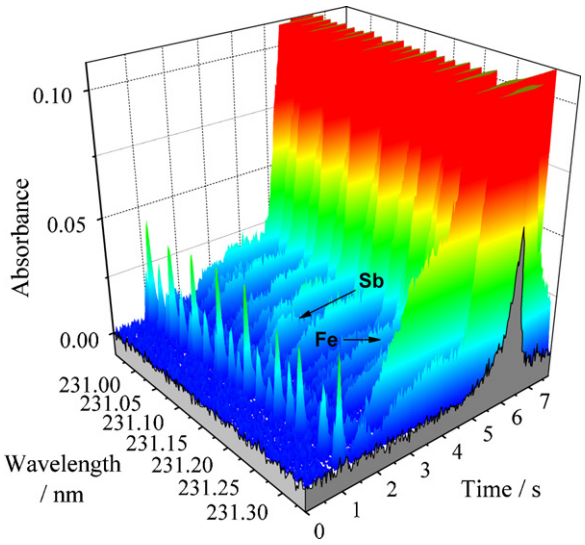

Fig. 2. Time- and wavelength-resolved absorbance spectrum recorded for NIST SRM 8704 (Buffalo River Sediment) in the vicinity of the Sb line at 231.147 nm after automatic correction for continuous background absorption; T_{pyr} = 1100 °C; T_{at} = 2100 °C; Ir as permanent modifier.

tify the molecular structures and to correct them using reference spectra and a least-squares algorithm [22].

Fig. 3a–c shows the three phases as wavelength-resolved absorbance spectra integrated over three time intervals, i.e., from 0 to 1.4 s, which are the first 0.4 s of the atomization stage, as signal recording starts with the Auto Zero stage (Fig. 3a); from 1.4 to

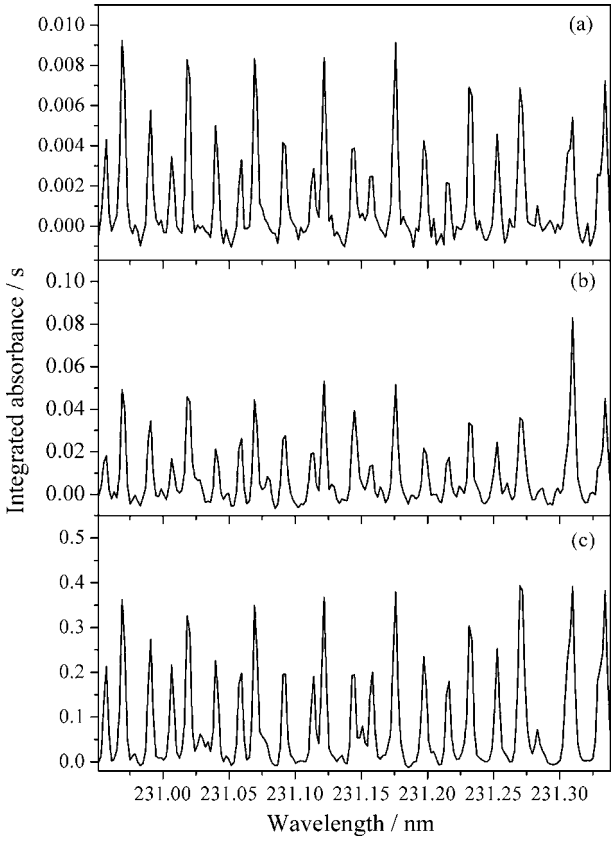

Fig. 3. Wavelength-resolved integrated absorbance spectrum in the vicinity of the Sb line at 231.147 nm for 0.092 mg of NIST SRM 8704 (Buffalo River Sediment); Ir as permanent modifier; T_{pyr} = 1100 °C; T_{at} = 2100 °C; (a) integration limits 0.0–1.4 s; (b) integration limits 1.4–4.2 s; (c) integration limits 4.2–7.0 s.

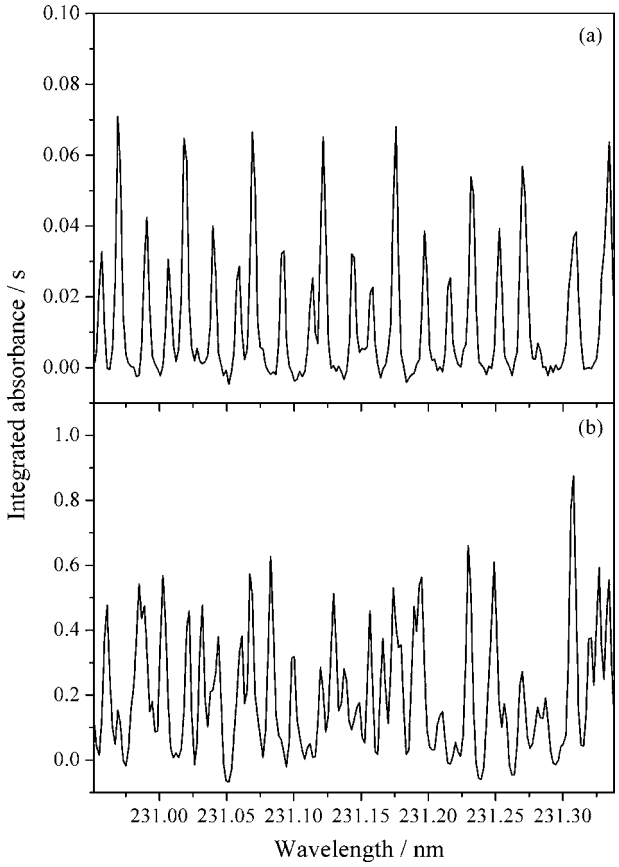

Fig. 4. Wavelength-resolved integrated absorbance spectrum in the vicinity of the Sb line at 231.147 nm; Ir as permanent modifier; T_{pyr} = 1100 °C; T_{at} = 2100 °C; (a) 0.116 mg of silica; (b) 150 μg P as $NH_4H_2PO_4$.

4.2 s, which is the period in time when the Sb atomic absorption signal appears (Fig. 3b); and from 4.2 to 7.0 s, which is the period after the Sb absorption signal returned to the baseline and the molecular absorption reaches fairly high levels (Fig. 3c). Although the spectra appear to be similar, they are not exactly identical. For this reason two reference spectra have been recorded, one for the silicon monoxide SiO, using pure silica (SiO_2), and one for the phosphorus monoxide PO, using ammonium dihydrogen phosphate ($NH_4H_2PO_4$), which are shown in Fig. 4a and b, respectively. The spectrum recorded for HISS-1 CRM, which has a very low antimony content (information value: 0.13 μg g^{-1}), has also been used for correction purposes in some cases, but is not shown here, as it is almost identical to that of SiO (Fig. 4a).

The spectrum shown in Fig. 3a, which appears at the onset of the atomization stage, has been identified as being exclusively due to SiO, and could be corrected to the baseline using the reference spectrum in Fig. 4a and least-squares background correction (LSBC). This is actually surprising, as this means that there is a silicon-containing compound in the sediment that is significantly more volatile than antimony, i.e., it cannot be mineral SiO_2; this early SiO absorption spectrum has been observed in all investigated sediment CRM. The molecular structures of the spectrum shown in Fig. 3b, which actually comprises the main atomization stage, could be removed reasonably well using LSBC and the spectrum of HISS-1 or SiO as reference spectrum; however, as can be seen in Fig. 5a, besides the atomic absorption peaks of antimony and iron, there are some irregularities in the baseline, indicating some correction problems, most likely due to a small amount of another diatomic molecule. Nevertheless, as these minor irregularities did not affect the analytical line, and were less than ±0.01 s in integrated absorbance,

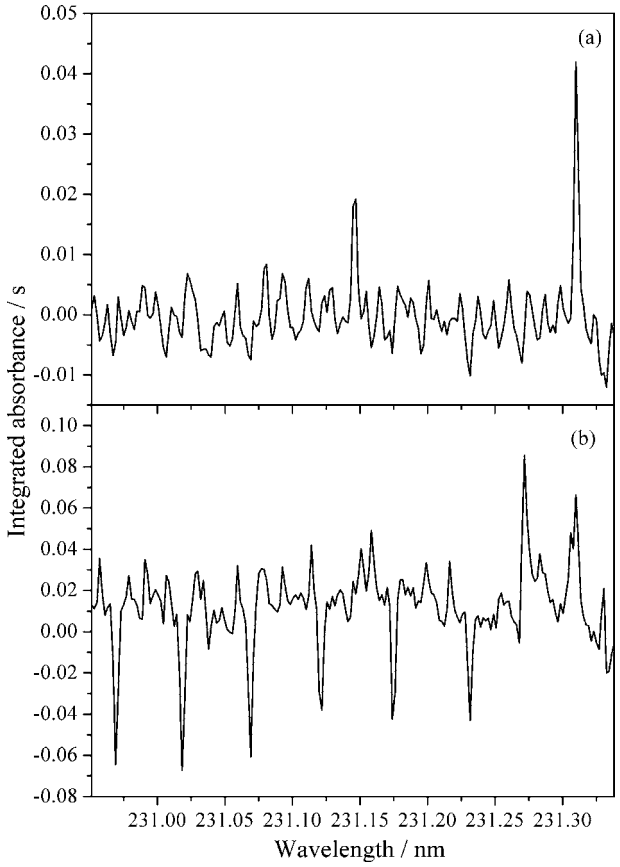

Fig. 5. Wavelength-resolved integrated absorbance spectrum in the vicinity of the Sb line at 231.147 nm for 0.092 mg of NIST SRM 8704 (Buffalo River Sediment) using HISS-1 CRM as reference spectrum for LSBC; Ir as permanent modifier; T_{pyr} = 1100 °C; T_{at} = 2100 °C; (a) integration limits 1.4–4.2 s; (b) integration limits 4.2–7.0 s.

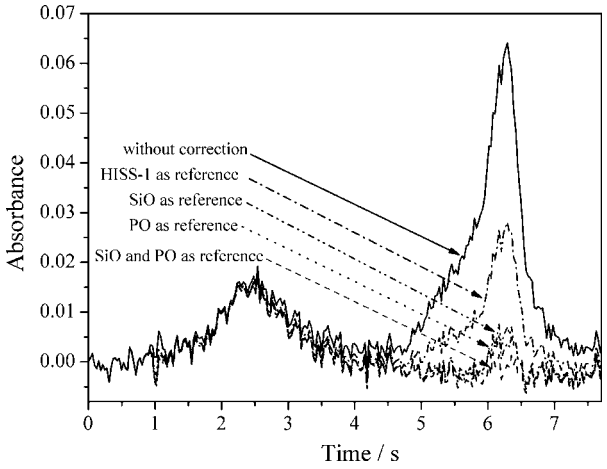

Fig. 6. Superimposed transient signals recorded at 231.147 nm for NIST SRM 8704 (Buffalo River Sediment) without LSBC (black line) and using the spectrum of HISS-1, SiO, PO, and SiO + PO, as reference for LSBC.

they have not been further investigated. The third section of the absorption spectrum, which is shown in Fig. 3c, is of no analytical interest, as it occurs in time after the atomization of antimony, but it might be of diagnostic interest in order to find out the source of this molecular absorption. A first attempt to correct for this molecular absorption using the spectrum of HISS-1 as a reference failed at least in part, as can be seen in Fig. 5b. There was a baseline offset of about 0.015 s in integrated absorbance, and pronounced negative peaks that coincided with the strongest absorption lines of SiO. The explanation for this phenomenon is straight-forward when we compare Fig. 3c with a maximum absorbance of about 0.4 s and Fig. 4a, where the maximum absorbance only reaches values of about 0.07 s. The intensity ratio between the strongest and the less intense absorption peaks in Fig. 4a is roughly 2:1, whereas in Fig. 3c it is less, indicating that the absorbance of the strongest peaks is already in the non-linear range, a task that cannot be solved by a least-squares algorithm.

This situation has therefore been investigated in more detail, primarily in the environment of the analytical line. Fig. 6 shows the absorbance signal over time recorded at the central pixel at 231.147 nm for the NIST SRM 8704 (Buffalo River Sediment) using different reference spectra for correction. Without LSBC there appears a strong molecular absorption after the antimony signal, which can only be corrected in part using the spectrum of HISS-1 CRM. The correction is much better using the reference spectrum of SiO, but there is still a residual signal that could only be corrected using the reference spectrum of PO in addition to that of SiO. This also explains why the spectrum of the HISS-1 CRM could not be used successfully for LSBC, at least not in this time interval. Whenever more than one molecule is contributing to such a spectrum, the reference spectra and the LSBC have to be applied sequentially for each molecule, unless the ratio between the two molecules is known and can be simulated in the reference spectrum, which is impossible in real sample analysis.

Obviously, this correction appears to be of no importance for the analyte signal, which returns to the baseline before the molecular absorption becomes significant. However, Fig. 6 only shows the situation at the central pixel, whereas the best S/N ratio is obtained using PVSA over three pixels; the results obtained for NIST SRM 8704 using this evaluation technique are shown in Table 3. It is obvious that a wrong result is obtained without using LSBC, as one of the rotational lines of the SiO molecular absorption is already overlapping significantly with the wing of the antimony absorption line. On the other hand there is little difference in the final result if HISS-1 is used for correction or SiO alone or together with PO, indicating the robustness of the method. The use of PO alone for LSBC does not give a satisfactory result, showing that this molecule has no significant contribution to the absorption spectrum during the first 4.2 s of the atomization stage. The fact that some correction has been achieved even with PO as the reference spectrum is due to some similarity of this spectrum with that of SiO (see Fig. 4a and b). The LSBC has therefore been in part successful to correct for the effect of SiO on the integrated absorbance of Sb using the spectrum of PO, although the final result is not within the confidence interval.

As a result of these investigations it would be of advantage to shorten the atomization stage to about 4 s in order to avoid the strong molecular absorption at the end of the atomization stage and remove these matrix components during the cleaning stage. A typical time- and wavelength-resolved absorbance spectrum recorded under these conditions, using LSBC for SiO and PO is shown in Fig. 7.

Table 3
Results obtained for antimony in NIST SRM 8704 (Buffalo River Sediment) (certified value: 3.07 ± 0.32 μg g^{-1} Sb) using different reference spectra for LSBC; integration interval: 0.5–4.5 s; T_{pyr} = 1100 °C; T_{at} = 2100 °C; Ir as permanent modifier.

Reference spectrum	Found value (μg g^{-1})[a]	Recovery (%)[b]
Without LSBC	4.61 ± 1.37	150 ± 35
HISS-1	2.96 ± 0.29	96 ± 9
SiO	2.77 ± 0.42	90 ± 14
PO	3.58 ± 0.86	117 ± 28
SiO + PO	2.81 ± 0.46	91 ± 15

[a] Average of five determinations ± confidence interval (at the 95% level).
[b] Recovery factor = (found value/certified value) × 100 ± confidence interval.

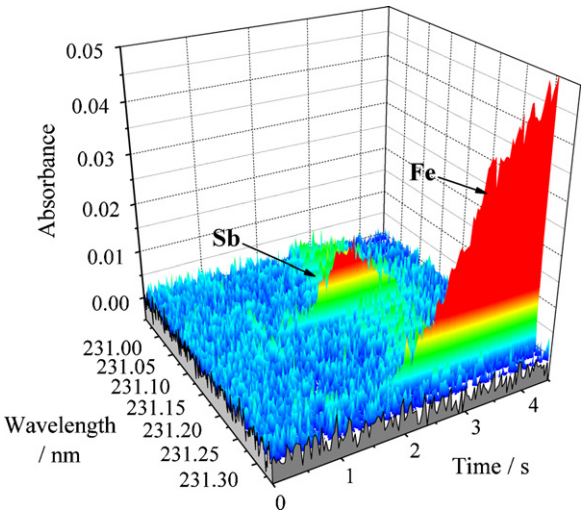

Fig. 7. Time- and wavelength-resolved absorbance spectrum recorded for 0.092 mg of NIST SRM 8704 (Buffalo River Sediment) in the vicinity of the Sb line at 231.147 nm after correction for continuous and discontinuous background absorption using the reference spectra of SiO and PO for LSBC; Ir as permanent modifier; T_{pyr} = 1100 °C; T_{at} = 2100 °C; integration interval: 0–4.5 s.

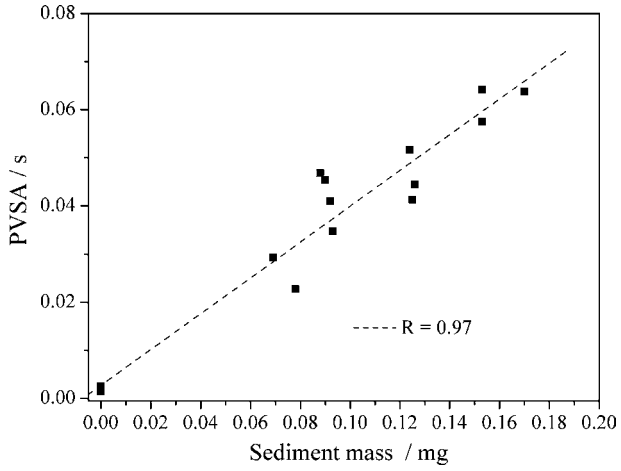

Fig. 8. Correlation between the sediment mass (NIST SRM 8704, Buffalo River Sediment) introduced into the graphite furnace and the PVSA ($A_{\Sigma 3,int}$); T_{pyr} = 1100 °C; T_{at} = 2100 °C; Ir as permanent modifier.

In essence only the analyte signal and the atomic absorption due to Fe are visible under these conditions.

3.3. Figures of merit

The limit of detection (LOD) has been calculated as three times the standard deviation of 10 measurements of a blank divided by the slope of the calibration curve; in SS-GF AAS the blank measurements are usually carried out according to the "zero mass response" technique [35], introducing repeatedly an SS platform containing only the modifier and running a full atomization cycle. The limit of quantification (LOQ) is based on the same measurements, using 10 times the standard deviation of the blank readings. The LOD and LOQ were determined as 0.02 and 0.07 μg g^{-1} Sb, respectively, based on a sample mass of 0.2 mg introduced into the furnace. A larger sample mass could obviously be introduced, resulting in even lower LOD and LOQ; however this was not found necessary for the present investigation. The characteristic mass (m_0), defined as the mass of the analyte that produces a PVSA of 0.0044 s, has been determined as m_0 = 28 pg Sb. There is no literature data available for the characteristic mass for the secondary Sb line at 231.147 nm used in this work. The characteristic mass at the main resonance line for Sb at 217.58 nm using line source AAS is around m_0 = 20 pg, and the secondary line used in this work is about a factor of 2.4 less sensitive than the primary resonance line [24], which would result in a characteristic mass of about 48 pg; it is quite typical for HR-CS AAS that the sensitivity obtained with PVSA is better than that obtained with line source AAS. A calibration curve established using a blank and six calibration solutions in the concentration range 5–50 μg L^{-1} Sb (mass range: 100–1000 pg Sb) in 0.007 mol L^{-1} HNO_3, using the conditions described in Section 2 gave the linear relationship:

$$A_{\Sigma 3,int} = 1.55 \times 10^{-4} m + 0.00002 \quad (R = 0.9998),$$

where $A_{\Sigma 3,int}$ is the PVSA, i.e., the integrated absorbance summated over three pixels, and m is the analyte mass.

3.4. Accuracy, precision and analytical application

The correlation between the sediment mass introduced into the graphite furnace and the integrated absorbance (PVSA, $A_{\Sigma 3,int}$) for NIST SRM 8704 is shown in Fig. 8. The sample mass has been varied in the range from 0.069 ± 0.001 to 0.170 ± 0.001 mg; each measurement point corresponds to an individual sample weighing and measurement, and is hence an indication for the precision of the entire procedure, which will be discussed in some more detail later. The good linear correlation shows that at least up to about 0.2 mg of sediment sample can be introduced and measured with the proposed procedure.

Six sediment CRM (one river, one estuarine and four marine sediments) have been analyzed; each concentration value was obtained as the mean of five individual weighings and measurements, using a calibration curve established with aqueous standards for quantification. The results are shown in Table 4 together with the calculated recovery and uncertainty (95% confidence interval). There is no statistically significant difference between the results obtained with the proposed method and the certified or informed values based on a Student's t-test ($t_{calculated}$ = 0.93; t_{value} = 2.57, n = 6). These results show that the determination of antimony in sediment using SS-HR-CS GF AAS can be carried out with calibration against aqueous standards.

The precision, expressed as relative standard deviation (% RSD), ranged between 7% and 17%, which are typical values for the direct analysis of solid samples. Although these values should not be over-interpreted, it might be interesting to note that the highest imprecision has been obtained for the sample with the highest antimony content, and the best precision for a sample with about an order of magnitude lower antimony content. As smaller sample masses are usually introduced into the furnace for samples with high analyte content, this difference in precision might be

Table 4
Results obtained for the determination of antimony in sediment samples using SS-HR-CS GF AAS and calibration against aqueous standards; T_{pyr} = 1100 °C; T_{at} = 2100 °C; Ir as permanent modifier.

CRM	Certified value (μg g^{-1})	Found value (μg g^{-1})[a]	Recovery (%)[b]
NIST SRM 8704	3.07 ± 0.32	2.96 ± 0.29	96 ± 9
PACS-2	11.6 ± 2.6	12.6 ± 2.0	109 ± 17

[b] Recovery factor = (found value/certified value) × 100 ± confidence interval.
[c] Informed value, not certified.

directly related to the sample mass and the natural inhomogeneity of samples such as sediments. Another interesting comparison is that between NIST SRM 2702 and 2703, which are actually the same CRM, with the only difference that the latter one is ground to smaller particle size. The fact that the same imprecision has been obtained for both CRM might suggest that particle size is not of decisive importance for SS-GF AAS, as was proposed by others previously [36].

4. Conclusion

A simple, fast and reliable method for the determination of antimony in sediment has been developed using direct solid sampling HR-CS GF AAS and calibration against aqueous standards, i.e., without interference. As the spectral environment of the analytical line becomes visible at high resolution with this technique, it is possible to draw some conclusion about the performance of conventional line source AAS in the analysis of these samples. Spectrometers with deuterium or similar continuum source background correction are unable to cope with this background, which appears in time together with the analyte signal; as this kind of correction system makes an average of the background over the spectral band pass, background correction errors are inevitable. The same is true for Smith–Hieftje background correction, which measures the background on both sides of the analytical line, which is in this case obviously not the same as on the analytical line. To which extent Zeeman-effect background correction could deal with this spectral situation is difficult to predict; however, it is known that the narrow rotational lines of various diatomic molecules also exhibit Zeeman splitting. This would mean that the background measured with magnetic field is not identical to that without magnetic field, which would result in a correction error. The extent of this error could obviously only be determined by experiment. Nevertheless, the background correction systems available with HR-CS AAS are far superior to those available for line source AAS, and it might be expected that a variety of other trace elements could be determined in sediment and similar materials without interference using this technique. In addition, with modern equipment, in contrast to the prototype used in this work, full automation of direct solid sampling analysis is possible, which is obviously of importance for routine analysis.

ABSTRACT

An optical fiber biosensor has been developed for the determination of catecholamines (dopamine, norepinephrine and epinephrine) based on the recognition capacity of the enzyme laccase. In this study, a glass tube constituted by a fused silica fiber coated with a film of polystyrene/divinylbenzene resin (PS/DVB) was used for catecholamines separation. Firstly, the analyzer was tested for calibration and its analytical performance for catecholamines detection was compared with a classical analytical method, namely high performance liquid chromatography-electrochemical detector (HPLC-ED). The developed analytical device shows a high potential for catecholamines quantification with a detection limit of 2.1, 2.6 and 3.4 pg mL^{-1} for dopamine, norepinephrine and epinephrine, respectively. The analytical sensitivity, inferred from the slope of the calibration curves established for a range of concentrations between 5 and 125 pg mL^{-1}, was found to be 0.344, 0.252 and 0.140 dB/pg mL^{-1} for dopamine, norepinephrine and epinephrine, respectively. Furthermore, catecholamines speciation with the PS/DVB fiber was completely achieved in 3 min. The analytical performance of the reported sensor was also evaluated and found adequate for catecholamines determination in human urine and plasma samples.

1. Introduction

Biosensors constitute an expanding field of analytical devices for the detection of analytes and other parameters of biological interest, which usually combines a biological component with a physic-chemical transducer.

Optical fiber (OF) biosensors are analytical devices in which the OF serves as a transduction element, showing several analytical advantages due to their high analytical sensitivity, fast response, large geometrical versatility, possibility of continuous monitoring of many chemical parameters, low cost, lightweight associated to small size, and high degree of miniaturization. These advantages make them an excellent alternative to laboratory-scale analytical methods and highly competitive in non-invasive clinical applications.

The use of the enzyme laccase as recognition element towards the development of biosensors for catecholamines determination has received a great deal of attention from several research groups [1–7]. Although some analytical devices have been reported for catecholamines determination which combines the enzymatic recognition with the OF technology, such as for example, an OF biosensor for epinephrine determination based on immobilized laccase catalysis and fluorescence quenching [7], they have not shown yet an adequate analytical selectivity and sensitivity.

Catecholamines, namely dopamine, norepinephrine and epinephrine, play an important role in the central nervous system as neurotransmitters or hormones, and they also affect the regulation of blood pressure, heart rate and lipolysis [4,8]. The determination of catecholamines in different human fluids, such as plasma and urine, is of great interest in medical diagnostics, especially for patients suffering from Parkinson's disease or Phaeochromocytoma and stress. An early and accurate determination of the catecholamines concentration in urine and plasma could prevent unnecessary drug treatment.

This work aimed at the development of an optical fiber biosensor for screening of catecholamines (dopamine, norepinephrine and epinephrine) based on a sensitive cladding of laccase. The OF biosensor, named LacOF biosensor, is composed of a miniaturized column for catecholamines separation, a biocomponent enzymatic cladding of laccase, and an OF component with associated electronics. The results obtained by applying the LacOF biosensor to the analysis of human urine and plasma were compared to those

obtained by a methodology based on high performance liquid chromatography coupled to an electrochemical detector (HPLC-ED).

2. Experimental

2.1. Development of the LacOF biosensor

2.1.1. Preparation of the optical fiber (OF) and deposition of the enzymatic cladding

A directional 50:50 Y optical coupler was prepared from a single-mode optical fiber (OF) with core and cladding diameters of 9 and 125 μm, respectively. The OF was mechanically uncladded, immersed in dichloromethane in order to remove the protective cladding, and cleaved in a length of 15 mm with a Cleaver V6 (Future Instrument, Spain) precision fiber cleaver. The sensitive coating (enzymatic cladding) was deposited onto the cleaved ended surface of the fiber following the dip-coating technique. The uncladded OF section was dipped into an alginate/enzyme suspension, followed by the immersion into a 0.2 M calcium chloride ($CaCl_2$) solution. The suspension of alginate and laccase of *Trametes versicolor* a white-rot fungus (E.C.1.10.3.2) (22.4 U mg^{-1}), was prepared mixing 400 U mL^{-1} of laccase, with a 3% (w/v) alginic acid solution salt from brown algae and kept stored at 4 °C.

2.1.2. Assemblage of the optical fiber biosensor and the underlying analytical principles

Fig. 1 shows the schematics of the whole LacOF biosensor detection system, including enzymatic cladding at the OF surface which provides the analytical principle underlying this biosensor.

The developed biosensor is constituted by two main components. The first analytical component aiming at the separation of the three catecholamines, includes a pump, a mobile phase, an injection cell (IC), and a glass tube (GT) which contains a fused silica fiber coated with a polystyrene/divinylbenzene resin (50–100 mesh particles size). The second component aiming at the detection of the catecholamines is constituted by an analytical tube (AT) containing the sensitized OF section, an optical coupler (OC), a photodetector (OZ Optics, Spain) and a laser diode (OZ Optics, working in the infrared region (λ = 1550 nm)). The connections between the following system elements: IC-GT; GT-AT and AT-OF, were made of Teflon. The various components of the sensor, excluding the mobile phase, the pump and the laptop were appropriately located inside a home-made aluminum box (height: 14.0 cm, width: 17.7 cm and length: 25.1 cm), providing the analytical system with a very compact design.

The catecholamines standards and samples are injected with a micro-syringe (Hamilton) at the top of a glass cell (injection cell) which are then carried by a constant flow (0.75 mL min^{-1}) of mobile phase to the glass tube and finally reach the analytical tube. The mobile phase consisted of 5% acetronitrile, 0.025 M sodium phosphate, 0.025 M citric acid, 0.001 M heptane and sulphonic acid pH 2.85, being its flow rate controlled by a mass flowmeter (Supelco, Spain).

Fig. 1b shows a schematic design of the OF surface coated with an enzymatic cladding and the oxidation of the catecholamine (epinephrine) by the enzyme (laccase) to the respective aminoquinone (adrenoquinone). The linkage of catecholamines to the enzyme changes the refractive index of the sensitive cladding (laccase incorporated in an alginate matrix) causing changes of the reflected optical power, which are independent of the produced quinone. The optical power changes are measured as the analytical signal by the photodetector and data acquisition and processing performed by a computer (PC) with home-made software.

2.2. Application of a HPLC-ED methodology

The HPLC-ED methodology was carried out in an Aliance 2695 HPLC system (Waters, USA) with a PLRP-S 100 Å 5 μm, 150 mm × 4.6 mm I.D. reversed-phase analytical column (from Polymer Laboratories Inc., USA). The detection of catecholamines was attained by a Waters 2465 electrochemical detector with a glassy working electrode set at 750 mV to a salt-bridge Ag/AgCl reference electrode. The mobile phase at a constant flow rate of 0.75 mL min^{-1} consisted of 5% acetonitrile, 0.025 M sodium phosphate, 0.025 M citric acid, 0.001 M heptane and sulphonic acid pH 2.85, as in the case of the OF system.

2.3. Preparation of standards mixtures of catecholamines

The standard solutions of mixtures of the three catecholamines were prepared in phosphate-citrate buffer pH 5.5 and used for calibration studies, performing five replicates of the various standard concentrations (5, 35, 65, 95 and 125 pg mL^{-1}) of each catecholamine. All reagents used were analytical grade from Sigma–Aldrich and used without further purification.

2.4. Preparation and analysis of human urine and plasma samples

Urine and blood samples were obtained from healthy volunteers in a certificated laboratory of clinical analysis. Blood samples were stored in glass tubes containing EDTA as the anticoagulant, and then

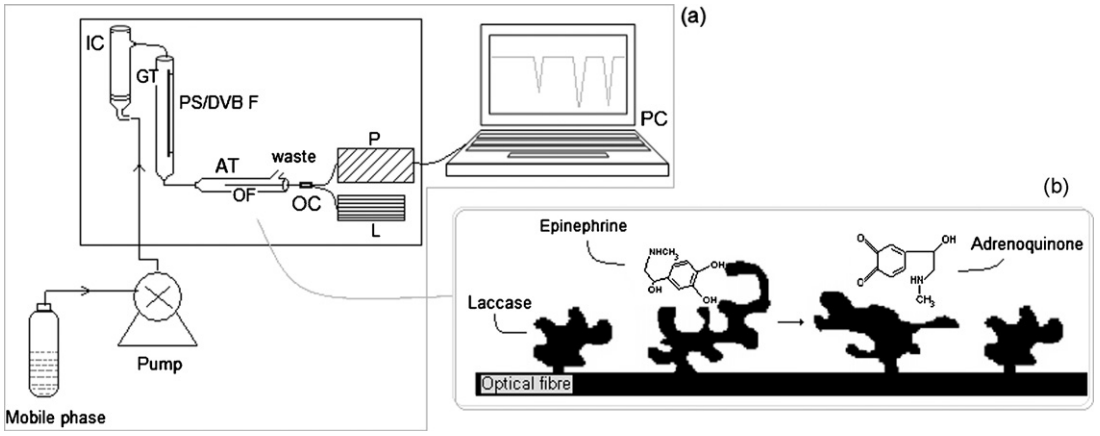

Fig. 1. (a) Schematic configuration of the experimental layout (AT – analytical tube; GT – glass tube; IC – injection cell; L – laser; OC – optical coupler; OF – optical fiber; P – photodetector; PC – laptop for data acquisition and processing; PS/DVB F – styrene/divinylbenzene fiber) and (b) schematics of the enzymatic reaction occurring at the OF surface coated with laccase.

centrifuged at 1400 × *g* for 15 min; the supernatant, i.e. plasma, was then transferred to polypropylene test tubes. Urine and plasma samples were stored at −18 °C until further processing for each of the analytical methodologies implemented in this work (LacOF biosensor and HPLC-ED). The preparation of the samples of urine (2.4.1) and plasma (2.4.2) was carried out by solid phase extraction (SPE) and performed according to Janichy-Deverts et al. [9] and Mercolini et al. [10] procedures, respectively. After the extraction procedure, the obtained solutions were analyzed by LacOF biosensor and HPLC-ED; quantification of the catecholamines in urine and plasma samples was attained by linear regression of the calibration data, performing five repeated measurements for each sample analyzed, exactly in the same way as in the calibration studies. The samples were numbered from 1 to 5 and the same number in urine and plasma analysis means that the sample has the same subject as source.

2.4.1. *Preparation of urine samples*

Prior to extraction by SPE the thawed samples were centrifuged at 10,000 × *g* for 3 min and diluted with ultra-pure water (SG Water, Germany). Aliquots of 3 mL of the diluted sample were mixed with 5 mL of dilution reagent (30 mM ammonium acetate, 2.7 mM EDTA; pH 7.5) and 100 μL of 0.5 M NaOH. Each prepared sample was adjusted to a pH value of approximately 6.5 with 0.5 M of NaOH. The extraction of catecholamines of urine samples was performed by SPE column filled with Bio-Rex 70 cation exchange resin (50–100 mesh) previously washed with dilution reagent and ultra-pure water. Elution of the analytes was achieved by 6 mL of 3.6 mM ammonium pentaborate following a procedure developed by Janichy-Deverts et al. [9].

2.4.2. *Preparation of plasma samples*

The plasma samples were extracted by SPE on Waters (Milford, Mass., USA) Oasis MAX cartridges (30 mg, 1 mL). The SPE cartridges were preconditioned and activated with 2× 1 mL of carbonate buffer (200 mM Na_2CO_3, pH 9.0) and 2× 1 mL of methanol prior to loading with plasma sample. After that, the cartridges were then washed with 2× 1 mL of carbonate buffer and vacuum dried. Elution of the analytes was achieved with 1 mL of 5% acetic acid in methanol. The eluate was dried using a rotary evaporator and the residue was re-dissolved in 150 μL of mobile phase for analysis.

3. Results and discussion

Fig. 2 shows the optical power changes obtained during the process of preparation of the LacOF biosensor for determination of different amounts of catecholamines. Fig. 2a shows the sensor response for 35 and 95 pg mL^{-1} of dopamine, norepinephrine and epinephrine and Fig. 2b reports the calibration curves obtained for the three catecholamines tested, with estimates of slope and intercept with their respective standard deviation.

The maximum amplitude of the optical power variation recorded before the injection of dopamine, norepinephrine and epinephrine (baseline) was approximately 0.01 dB, which was about 1% of the minimum analytical signal obtained during the lower concentration of catecholamines tested (0.9 dB for 5 pg mL^{-1} of epinephrine).

The total analytical time was found to be around 3 min for the three completely separated catecholamines detected as shown in Fig. 3a.

This analytical system shows a high statistical degree of linearity for the calibration model used, as it can be inferred from the r^2 and respective *p* values also shown in Fig. 2b. The intensity and therefore the sensitivity (measured as the slope of the calibration curve) of the analytical signal obtained for dopamine was higher than the ones obtained for norepinephrine and even for epinephrine.

The results obtained during the calibration process also revealed that the detection capacity of the developed sensor system reaches

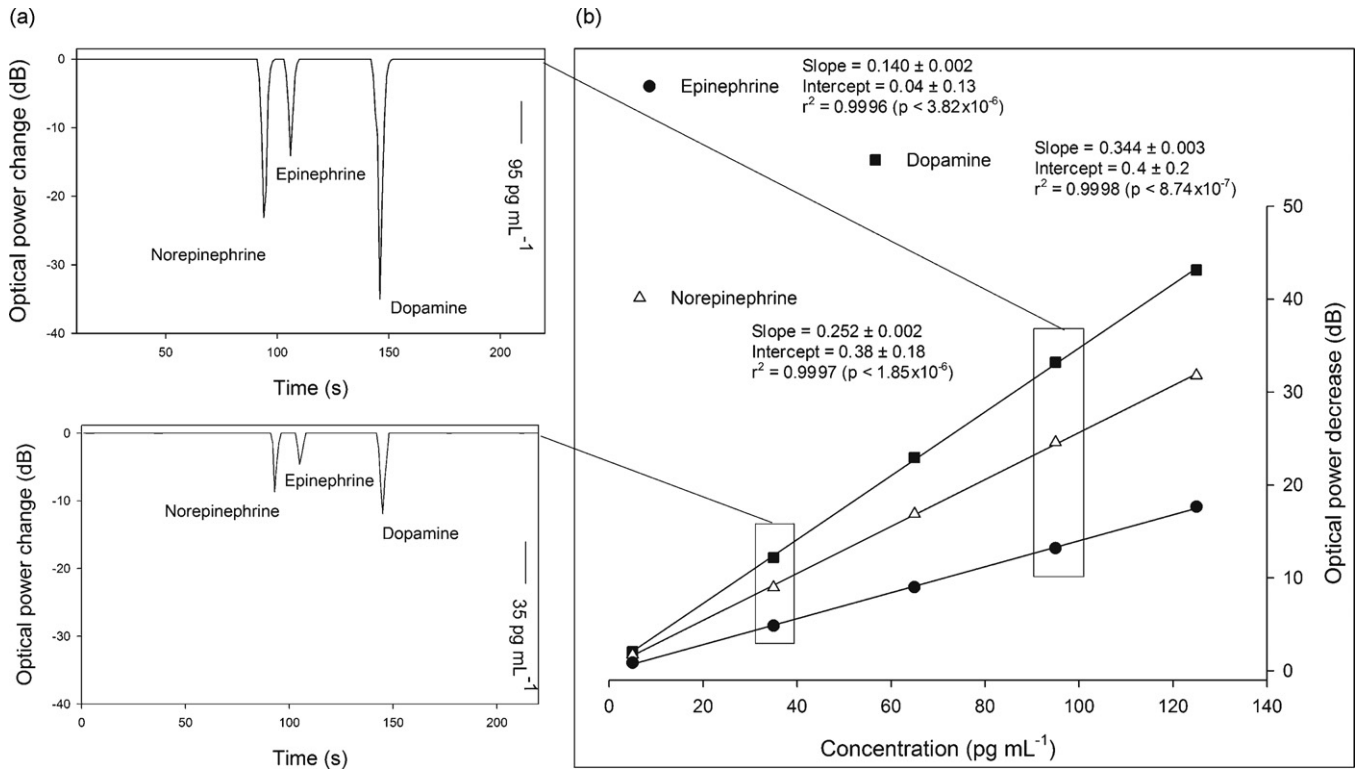

Fig. 2. LacOF biosensor response for different amounts of catecholamines, namely, dopamine, norepinephrine, and epinephrine: (a) example of the biosensor profile obtained for 35 and 95 pg mL^{-1} of catecholamines; (b) calibration of the LacOF biosensor with amounts of catecholamine in a range between 5 and 125 pg mL^{-1}.

80	79.9 ± 0.2	79.6 ± 4.1	79.9 ± 0.3	79.9 ± 2.5	79.8 ± 0.7	79.7 ± 3.7
90	90.1 ± 0.2	89.4 ± 5.8	90.1 ± 0.3	90.1 ± 2.8	90.2 ± 0.5	90.1 ± 3.5
100	99.9 ± 0.4	99.5 ± 5.8	100 ± 0.6	100.3 ± 6.9	99.9 ± 1.1	99.7 ± 7.5

a plateau in terms of maximum capacity of detection for concentrations of catecholamines higher than about 130 $pg\,mL^{-1}$, with a decrease of the analytical performance of the LacOF biosensor for concentrations above that value.

Since the linkage of the catecholamine to the enzyme is the most relevant factor for the analytical signal generation, the differences in the analytical sensitivities obtained with the developed LacOF sensor are mainly due to the differences in the affinity of laccase to each of the catecholamines under study. Therefore, the highest analytical sensitivity obtained for dopamine could be attributed to the high affinity of the enzyme to this catecholamine, with consequent increase of the optical power change amplitude.

The detection limits obtained for the three catecholamines analyzed, based on three times the residual standard deviation [11] for both LacOF biosensor and HPLC-ED method were, respectively, 2.1 and 5.1 $pg\,mL^{-1}$ for dopamine, 2.6 and 4.5 $pg\,mL^{-1}$ for norepinephrine and 3.4 and 4.5 $pg\,mL^{-1}$ for epinephrine. These values show that the detection limits for both analytical methodologies have the same order of magnitude.

A set of experiments has been carried out for the assessment of the sensor system stability; thus five repeated measurements of catecholamines (35 $pg\,mL^{-1}$) have been performed during different weeks of 2 months of operation with the same system. The developed biosensor showed a relative standard deviation of the performed measurements of less than 5%, suggesting an adequate degree of stability of the analytical system. However, additional studies regarding the monitoring of the LacOF device behavior for periods of operation longer than 2 months showed a slightly analytical signal degradation after the 13th week of the device operation. This observation was not find to be of special concern, since the sensors head (OF section coated with the enzymatic matrix) can be easily replaced, after 12 weeks, avoiding any losses of the analytical signal or decrease of performance caused by extensive utilization for longer periods of the developed LacOF based biosensor.

The analytical performance of the LacOF biosensor was also compared with HPLC-ED method: 10 different concentrations (10, 20, 30, 40, 50, 60, 70, 80, 90 and 100 $pg\,mL^{-1}$) of a standard mixture of catecholamines were injected, five times each, using both methods in order to test the performance of the developed sensor against the HPLC-ED method. The obtained results are displayed in Table 1.

The ANOVA of the results shows that there is no statistically significant difference ($p = 0.431$, 0.832 and 0.704, for dopamine, norepinephrine and epinephrine, respectively) for the effects of differences in the two methods. However, and as expected, there is a significant statistic difference ($p < 0.001$) between the different levels of the concentrations.

The analytical error, measured as the residual standard deviation of both LacOF biosensor and HPLC-ED, varied between 1.9 and 2.5 $pg\,mL^{-1}$.

The ANOVA can also be confirmed with a regression analysis of the results obtained with the two analytical systems during the determination of different amounts of catecholamines ranging from 10 to 100 $pg\,mL^{-1}$. Assuming the null hypothesis (same sensitivity, i.e. slope equals 1 and no systematic errors, i.e. intercept equals to 0) for the results obtained with both methods the slope, the intercept, r^2 and p of the regression line, of each of the data sets were calculated and included in Table 2.

For all the three catecholamines analyzed the regression line has an intercept not significantly different of zero and a slope not significantly different of 1. The values above mentioned and a correlation coefficient of approximately 1, allows concluding that the results obtained with the two analytical systems cannot be statistically differentiated, as already inferred from the ANOVA.

Both analytical methodologies were also applied to samples of human urine and plasma, for assessing comparatively the concentrations of catecholamines. Figs. 3 and 4 depict the results obtained in the analysis of five samples of human urine and plasma, respec-

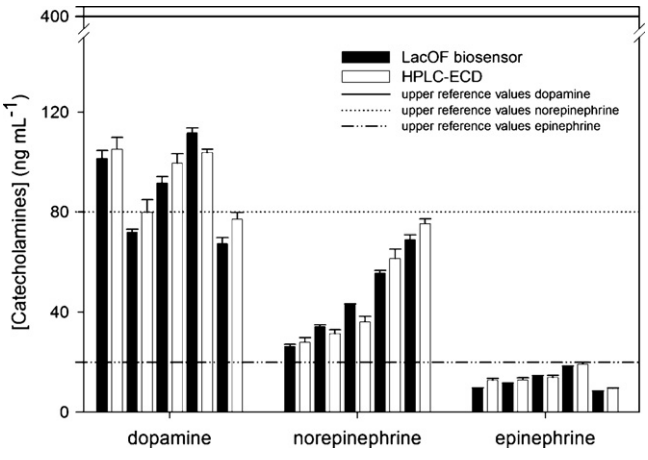

Fig. 3. Results obtained for catecholamines determination of five actual samples of human urine by LacOF biosensor and HPLC-ED methods.

Table 2
Analytical parameters obtained for the comparison of the results obtained with the LacOF biosensor and HPLC-ED method for determination of catecholamines.

	Intercept	Slope	Coefficient of determination (r^2)
Dopamine	0.0 ± 0.1	1.0 ± 0.1	0.99997 ($p < 3.48 \times 10^{-17}$)
Norepinephrine	0.1 ± 0.1	0.998 ± 0.002	0.99998 ($p < 1.15 \times 10^{-17}$)
Epinephrine	0.1 ± 0.1	1.001 ± 0.002	0.99997 ($p < 2.88 \times 10^{-17}$)

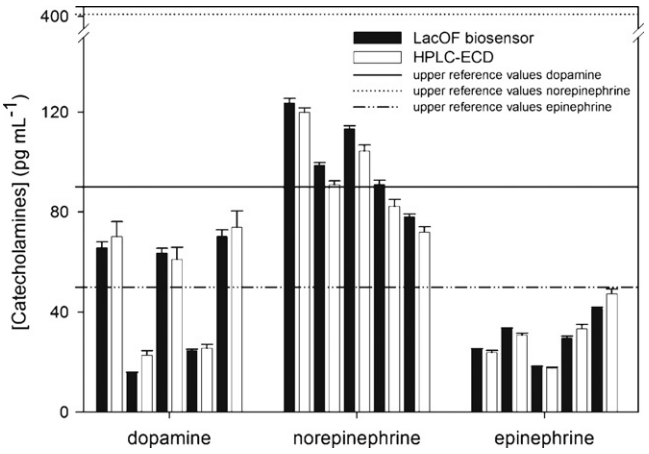

Fig. 4. Results obtained of catecholamines determination for five actual samples of human plasma with five replicates by LacOF biosensor and HPLC-ED methods.

tively by both the LacOF biosensor and the HPLC-ED method for dopamine, norepinephrine and epinephrine.

The levels of catecholamines found in the urine samples analyzed do not exceed the values accepted as normal for these compounds, according to Moyer et al. [12] studies: <400 μg 24 h^{-1} for dopamine; <80 μg 24 h^{-1} for norepinephrine; and <20 μg 24 h^{-1} for epinephrine.

The concentration obtained for dopamine, norepinephrine and epinephrine in plasma are also below the normal values, according to Peaston and Weinkove [13] studies: 0.01–0.475 nmol L^{-1} for dopamine; 0.71–4.02 nmol L^{-1} for norepinephrine; and 0.01–0.328 nmol L^{-1} for epinephrine.

The comparison of the means of the five samples analyzed by the biosensor and the HPLC-ED method, showed that there is no statistically significant difference between the results obtained by the two analytical systems in both urine ($p = 0.460$, 0.868 and 0.848 for dopamine, norepinephrine and epinephrine, respectively) and plasma ($p = 0.970$, 0.995 and 0.889 for dopamine, norepinephrine and epinephrine, respectively).

In order to test the developed biosensor for interferences that could be present in the biological matrices (urine and plasma), the effects of normetanephrine and metanephrine used as example of interferences compounds, on the analytical signal were also evaluated. Each compound tested produces a peak, but in a different analytical time window of the compounds of interest, therefore none of the above mentioned compounds exhibit any interference in the analytical signal. The obtained results allow concluding that the adjustment of the time window could be used for avoiding other potential interferences, as a consequence it is also possible to infer that the developed biosensor could be also applied to determine of a large variety of analytes.

4. Conclusions

An optical fiber biosensor has been successfully developed for determining the concentration of dopamine, norepinephrine and epinephrine. The reported analytical system showed a high analytical signal and a linear response between 5 and 125 pg mL^{-1}, allowing the determination of catecholamines with detection limit less than 3.4 pg mL^{-1}. In addition, the new and compact design of the developed LacOF analytical system has obvious analytical advantages, constituting an excellent alternative to the more classical methods for catecholamines detection.

Acknowledgments

This work has been developed under the scope of the FCT (Portugal) funded research project PTDC/QUI/70970/2006: "Development of a new Optical Fiber Biosensor for Determination of Catecholamines (CATSENSOR)". A Ph.D. grant (SFRH/BD/44175/2008) awarded to Filipe D.P. Ferreira is also gratefully acknowledged.

ABSTRACT

A new petentiometric method to determine peroxide hydrogen and glucose had been studied. This method had been applied on the petentiometric determination of peroxide hydrogen and glucose in the total ionic strength adjustment buffer (TISAB) (pH 7.5) solution with the glassy electrode modified by the calix[4]arene. The glassy carbon electrode covered with the calix[4]arene depended on the H_2O_2 concentration in the range of log[H_2O_2] from −3.3 to −1.2 in the solution of TISAB (pH 7.5) with nearly Nernstian slope of about 65.6 ± 3 mV and the detection limit of peroxide hydrogen was 4.0×10^{-5} mol L^{-1}. The glassy carbon electrode covered with the calix[4]arene depended on the glucose concentration in the range of log[glucose] from −3.6 to −2.8 in the solution of TISAB (pH 7.5) with nearly Nernstian slope of about 50.2 ± 2 mV and the detection limit of glucose was 2.0×10^{-5} mol L^{-1}. The electrode had the good selectivity, sensitivity, stability and repeatability.

1. Introduction

Chemically modified electrodes [1,2] as useful analytical tools have been widely used in different research fields since more analytical possibilities [3–5] have been offered by electrode manufacture. However, only a few analytical applications have employed chemically modified electrodes as potentiometric sensors [6–8], and the preparation of these potentiometric sensors often suffer from the complicated preparation process of the based electrodes and are time-consuming.

Recent years have witnessed a wide application of electroconducting polymers in the solid state ion-selective electrodes [9,10]. The incorporation of conducting polymer into the surface coating of the ion-selective sensor simplifies its manufacture. The thickness, conductivity and charge of the surface layer obtained in electropolymerization are easily controlled by the electrolysis parameters and reaction media content. This makes it possible to change the operational characteristics and analytical performance of the sensors in accordance with the particular tasks of their application. Due to these advantages, the application of electroconductive polymers offers broad opportunities for developing ion-selective electrodes, which is of great importance in chemical, environmental and clinical analysis.

Generally, the electropolymerized polymer is used either as a solid redox mediator between the transducer and ion-exchangeable component or as an immobilization matrix entrapping the components with intrinsic ionic/electron conductivity. In accordance with this, the sensor potential changes either with the redox potential of the electroconductive polymer or with the number of charged complexes formed by a neutral carrier and guest species on the surface.

Neutral carriers on the calix[4]arene platform are intensively investigated to obtain selective and sensitive recognition response toward various analytes. Simple and cost-effective synthesis, variety of substitutes introduced into the lower and upper rims as well as complication abilities toward inorganic [11–13] and organic [14,15] ions have made calix[4]arenes promising components of ion-selective membranes and solid-contact sensors. Most calix[4]arene-based sensors have been developed for selective detection of alkali and alkali-earth metals.

Hydrogen peroxide (H_2O_2) is a very important intermediate in environmental and biological reactions. The monitoring of H_2O_2 with a reliable, rapid and economical method is of great significance for numerous processes. Several analytical techniques have been employed for its determination [16,17], including the manganese dioxide-modified CPE amperometric sensor [18], but most suffer from interference, complex instrumentation and expensive reagents [19–21]. The potentiometric analytical method has turned out to be more suitable for the determination of many analytes since it possesses advantages such as rapid, simple instrumentation and a widely linear range. But until now, to the best of our knowledge, a potentiometric method for the determination of H_2O_2 has been not reported except Xingwang Zheng and Zhihui Guo had detected H_2O_2 with

the potentiometric method by MnO_2-doped carbon paste electrode [22].

In this paper, a new GCE-based electrode was prepared by electrodepositing the calix[4]arene on the glassy carbon electrode and it was found that this GCE-based electrode presented the Nernstian response for H_2O_2. Based on this observation, a new potentiometric sensor for the determination of H_2O_2 was proposed and the pH of the support solution together with some factors which affected the analytical performance of this sensor such as the thickness of the film was studied. At the same time, the possible response mechanism of the sensor was discussed. This sensor had been used to detect H_2O_2 in antisepsis water samples and it had manifested some advantages such as simple instrumentation, simple preparation procedures, good stability and reproducibility.

2. Experimental

2.1. Apparatus

The potentials were measured with a PXD-2 ION-meter (JiangShu Jiangfen Electroanalytical Instrument Ltd., China). The reference electrode was a saturated calomel electrode (SCE) and the total ionic strength adjustment buffer (TISAB) solution was stirred with a Teflon-coated magnetic bar during measurement on the JB-1 magnetic force stirrer (Shanghai Leici Instrument Plant, China). The electrochemical cell used can be represented by the calix[4]arene film-modified glassy carbon electrode/sample solution (pH 7.5, TISAB solution)/SCE.

Electrochemical measurements were performed on a CHI 660A Electrochemical Workstation (CH Instruments, USA). A conventional three-electrode system was used throughout the experiments. The working electrode was a GCE (3.0 mm in diameter); the auxiliary electrode was a platinum wire and a saturated calomel electrode was used as the reference. All potentials in this paper refer to this reference electrode. Cyclic voltammetric experiments were carried out with a scan rate of 100 mV s^{-1}, unless otherwise stated.

Atomic force microscopy (AFM) images of the films were collected on a multimode Nanoscope III scanning probe microscopy (Veeco Company, USA) in the tapping mode. A microfabricated silicon cantilever with a bending spring constant of 20–80 N m^{-1} and a resonance frequency of 229–287 kHz was used to collect the images at a scan rate of 1.0 Hz in air.

Electrochemical impedance spectroscopy (EIS) was performed in 1.0×10^{-3} mol L^{-1} $K_3Fe(CN)_6/K_4Fe(CN)_6$ (1/1) mixture with 0.10 mol L^{-1} KCl as supporting electrolyte, using an alternating current voltage of 5 mV within the frequency range of 0.1–1E6(1,000,000) Hz by Autolab Electrochemistry Instruments (Autolab, Eco Chemie, The Netherlands). Prior to modification of the calix[4]arene, a bare GCE was polished successively with 0.3 μm and 0.05 μm Al_2O_3 slurry on silk. Then, it was rinsed with double-distilled water and sonicated subsequently in a 1:1 aqueous HNO_3 solution (volume ratio of water to HNO_3 = 1:1), acetone, and doubly distilled water. After being cleaned, the electrode was immersed in 0.5 mol L^{-1} H_2SO_4 and was activated by cyclic potential scanning from 0.5 V to 1.6 V at 100 mV s^{-1} until the stable cyclic voltammograms were obtained in order to increase the concentration of the electroactive points. Electrochemical modification of the activated GCE was performed by cyclic voltammetry in 0.1 mol L^{-1} tetrabutylammonium perchlorate containing 7.0×10^{-4} mol L^{-1} calix[4]arenein with a potential range of −0.2 V to +0.8 V at a scan rate of 100 mV s^{-1} for 20 cyclic times. After the electropolymerization, the modified electrode was rinsed thoroughly with distilled water for further application.

2.2. Reagents

All reagents (such as $K_3Fe(CN)_6$, $K_4Fe(CN)_6$, KCl, acetone, citrate sodium, NaH_2PO_4, Na_2HPO_4, H_3PO_4, $NaNO_3$, and NaOH) were of analytical-reagent grade or better and water doubly distilled in a fused-silica apparatus was used throughout the experiment. A stock solution of H_2O_2 (0.100 mol L^{-1}) was prepared by diluting 5.5 mL of 30% (v/v) H_2O_2 (Shanghai Chemical Reagents Plant) to 500 mL with water. The solution was standardized by titration with potassium permanganate. Test standard solutions were prepared daily by appropriate dilution of the stock solution. A TISAB solution ($I \approx 1.23$) was prepared by dissolving 58.3 g of citrate sodium and 85 g $NaNO_3$ in 1 L water.

Tetrabutylammonium perchlorate (TBAP) was purchased from BeiJing Ouhe Technology Co. Ltd. And the stock solution of 0.1 mol L^{-1} tetrabutylammonium perchlorate was prepared by directly dissolving it in double-distilled water and then stored in a refrigerator at 4 °C. The calix[4]arene was synthesized by literature [23] (methyl resorcin calix[4]arene azobenzol sulfonate sodium) and the structure of it was shown in Fig. 1 and the stock solution of 0.01 mol L^{-1} calix[4]arene was prepared by directly solving it in doubly distilled water and then stored in a refrigerator at 4 °C.

Glucose oxidase (from Aspergillus niger, EC 1.1.3.4, 210 U/mg) and b-D-(II)-glucose were obtained from Sigma.

2.3. Construction of the sensor

Voltammograms of 7.0×10^{-4} mol L^{-1} calix[4]arene in 0.1 mol L^{-1} TBAP on the GCE was shown in Fig. 2. With a continuous increase of the number of cycles, anodic peaks appeared at potentials about +0.3 V and trended to be stable after 20 cycles, reflecting the continuous growth of the polymer film and the saturation of polymerization. These facts implied that calix[4]arene membrane was deposited on the surface of GCE by electropolymerization. After electropolymerization, the modified electrode was carefully rinsed with doubly distilled water and then kept at room temperature. The GCE modified by calix[4]arene was immerged in the solution of 0.1% glutaraldehyde for 40 min and then dipped in 0.1 g L^{-1} of the glucose oxidase (GOD) for 2 h. Finally, the modified electrode was carefully rinsed with doubly distilled water and then stored in a refrigerator at 4 °C. Thus the electrode used to determine the glucose was prepared.

Before using the modified GCE for potentiometric measurements, the electrode was preconditioned in TISAB solution for 2 h until a steady potential response was obtained.

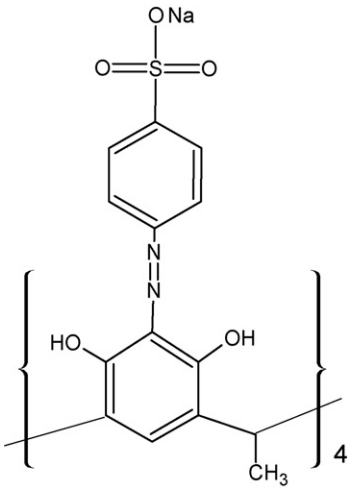

Fig. 1. The structure of the calix[4]arene.

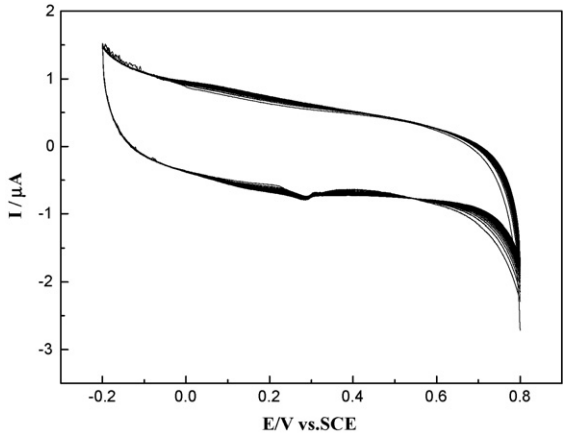

Fig. 2. Cyclic voltammograms of polymerization of calix[4]arene (7.0×10^{-4} mol L^{-1}) on a bare glassy carbon electrode in the potential range from −0.2 V to 0.8 V at a scan rate of 100 mV s^{-1}.

2.4. EMF measurement and selectivity

The electrode potential was measured in 10 mL TISAB solution by adding sample or standard hydrogen peroxide solutions continually with stirring at room temperature, and potentiometric measurement of the steady-state response was carried out in the usual manner. After each measurement, the H_2O_2 sensor was washed free of residual H_2O_2 and pH buffer solution with water until a stable blank potential was obtained. The glucose determination was carried through by the same method mentioned above. The selectivity coefficients of the electrode for H_2O_2 and the glucose with respect to other ions were quantified by the mixed solution method.

3. Results and discussion

3.1. Impedance characterization of the calix[4]arene film-modified GCE

The bare GCE and the calix[4]arene modified GCE was characterized by EIS (shown in Fig. 3). From Fig. 3a–e, we could see that the redox process of the $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ ions showed a lower electron transfer resistance at a bare GCE(Fig. 3, curve a) than that at the calix[4]arene modified GCE. When a bare GCE was electropolymerized with calix[4]arene for different cyclic times, the

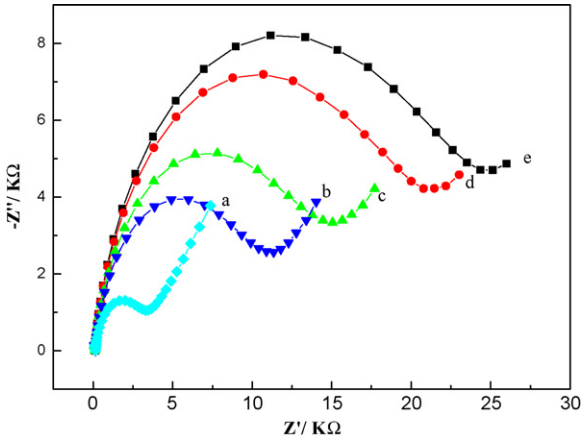

Fig. 3. Nyquist plots in impedance measurements of electrodes: (a) a bare GCE; (b–e) the calix[4]arene film-modified GCEs with different electropolymerization cyclic times. Cyclic times: (b) 10; (c) 20; (d) 30; (e) 40.

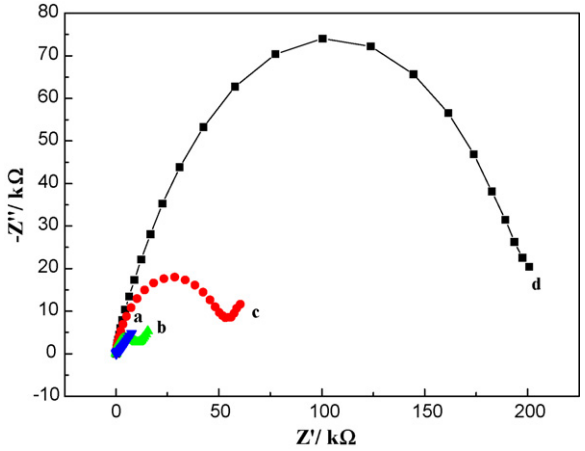

Fig. 4. Nyquist plots in impedance measurements of electrodes: (a) a bare GCE; (b) the calix[4]arene film-modified GCE; (c) the calix[4]arene film-modified GCE modified by glutaraldehyde again; (d) the calix[4]arene film-modified GCE modified by GOD again.

electron transfer resistance increased significantly along with the increasing scan cycles. Fig. 4 showed the impedance characterization of different conditions of the same GCE. Curves a–d respectively represented the impedance of the bare GCE, this GCE modified by calix[4]arene, this modified GCE after immersing in glutaraldehyde and this GCE then dipped in the glucose oxidase. It indicated that the glutaraldehyde and the glucose oxidase were modified on the GCE successfully.

3.2. The AFM characteristic of the modified GCE

The formation and morphology of the calix[4]arene modified GCE were characterized by AFM in air (shown in Fig. 5). The AFM images showed that the bare GCE surface was relatively smoother. After modification with the calix[4]arene, the surface morphology became very rough. This result demonstrated that the calix[4]arene film with mesoporous morphology was deposited on the GCE surface.

3.3. Effect of the thickness on the property of the modified GCE

The different thickness modified GCE were obtained by scanning different cycles and then the modified GCE was applied on the potentiometric detection of H_2O_2. The results (shown in Table 1) showed that the GCE modified 20 cycles enjoyed such superiorities as the wide range of potentiometric response, the good linear relation, the low detection limit and the response slope was 65.6 mV/log[H_2O_2], which was close to Nernstian response.

3.4. Effect of pH on the response

The potentiometric determination was performed in the TISAB of the different pH. The results showed that while the pH changed in the range of 3.0–11.0, the potential response slope descended, the response range increased and the detection limit increased with the rise of pH. These results might be related to the response of calix[4]arene modified GCE to the pH variation in this range and the results could be seen in Table 2. Simultaneity, the potentiometric response of H_2O_2 (10^{-2} mol L^{-1}) and the glucose (10^{-3} mol L^{-1}) were tested in buffer solution of different pH. The results were shown in Figs. 6 and 7. From Fig. 6 we could see that the potential response decreased with the increased of pH. Fig. 7 showed that the potential response of glucose was similar with the poten-

Table 1
Effect of the thickness on the property of the modified GCE.

Modified cycles	Linear range, mol L^{-1}	Response slope, mV/log[H_2O_2]	Correlation coefficient	Detection limit, mol L^{-1}	Stability, d	Response, time/s
10	5.5×10^{-4} to 1.2×10^{-2}	79.2	0.978	3.5×10^{-5}	7	180
20	5.5×10^{-4} to 6.3×10^{-2}	65.6	0.998	4.0×10^{-5}	60	240
30	5.5×10^{-4} to 3.7×10^{-2}	47.1	0.988	4.2×10^{-5}	30	420
40	1.8×10^{-3} to 2.5×10^{-2}	64.1	0.994	2.0×10^{-4}	30	600

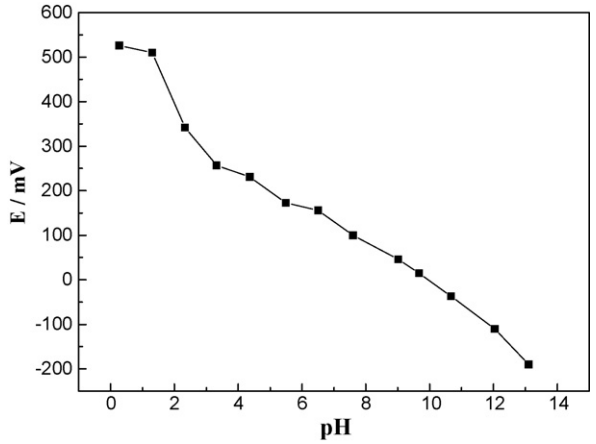

Fig. 6. The potentiometric response of 10^{-2} mol L^{-1} H_2O_2 in buffer solution of different pH.

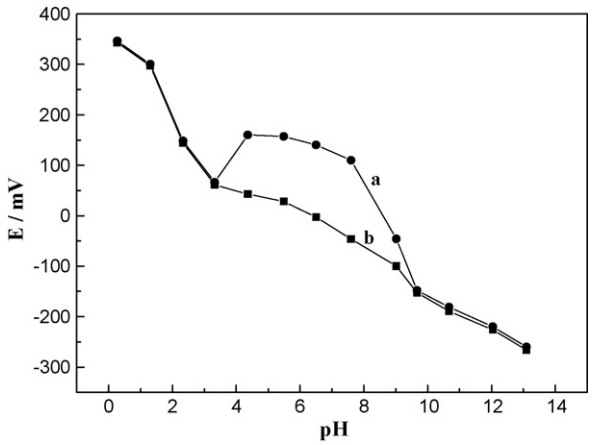

Fig. 7. The potentiometric response of 10^{-3} mol L^{-1} glucose in the buffer solution of different pH (a) and the potentiometric response of different pH (b).

tial response of pH when pH >9.5 or pH <3. For pH values in the range 4–8, the potential response of glucose was almost constant. The results might be related to that the glucose oxidase was inactive in alkali and strong acid solution. Considering different factors, TISAB (pH 7.5) solution was selected for the further experiments in detection of H_2O_2 and glucose.

3.5. Electrode response

A typical calibration curve of the electrode response for 2.2×10^{-4} to 0.32 mol L^{-1} H_2O_2 (shown in Fig. 8a) showed that the linear range of electrode response was 5.5×10^{-4} to 6.3×10^{-2} mol L^{-1} H_2O_2 and the electrode gave near-Nernstian response of 65.6 mV/log[H_2O_2] and a detection limit of 4.0×10^{-5} mol L^{-1} H_2O_2. In addition, the calibration curve of the electrode response to glucose showed that the linear range of electrode response was 2.5×10^{-4} to 1.6×10^{-3} mol L^{-1} and the electrode gave a near-Nernstian response of 50.2 mV/log[glucose] (shown in Fig. 8b) and the detection limit of 2.0×10^{-5} mol L^{-1} glucose.

3.6. Selectivity of the electrode

The selectivity of the sensor was evaluated by the mixed solution method. The results were presented in Table 3 and showed that the sensor offered a good selectivity for H_2O_2 and the glucose, and of many potentially interfering ionic species, only SCN^- interfered in the determination of H_2O_2 and the glucose.

Table 2
Effect of pH on the response.

pH	Linear range, mol L^{-1}	response slope, mV/log[H_2O_2]	detection limit, mol L^{-1}
3	3.2×10^{-3} to 3.6×10^{-2}	72.5	8.0×10^{-5}
5	1.5×10^{-3} to 4.5×10^{-2}	70.8	1.0×10^{-4}

Values of selectivity coefficient for modified electrode.

Interfering ions	K (H_2O_2, j)	K (glucose, j)
Sb^{3+} (0.1 mol L^{-1})	2.9×10^{-3}	1.8×10^{-3}
Bi^{3+} (0.1 mol L^{-1})	1.8×10^{-3}	2.3×10^{-3}
Ca^{2+}(0.1 mol L^{-1})	1.2×10^{-4}	2.1×10^{-4}
Mg^{2+} (0.1 mol L^{-1})	5.4×10^{-4}	3.6×10^{-4}
K^{+}(0.1 mol L^{-1})	1.0×10^{-4}	2.1×10^{-4}
Hg^{2+}(0.02 mol L^{-1})	1.6×10^{-3}	4.2×10^{-3}
Pb^{2+} (0.02 mol L^{-1})	1.0×10^{-2}	3.0×10^{-2}
Cu^{2+}(0.1 mol L^{-1})	3.0×10^{-3}	6.1×10^{-3}
$C_2O_4^{2-}$ (0.1 mol L^{-1})	9.2×10^{-2}	7.8×10^{-2}
SO_4^{2-} (0.1 mol L^{-1})	4.1×10^{-3}	1.7×10^{-3}
Cl^{-} (0.2 mol L^{-1})	1.0×10^{-4}	2.0×10^{-4}
Br^{-} (0.1 mol L^{-1})	4.0×10^{-3}	5.0×10^{-3}
SCN^{-} (0.1 mol L^{-1})	1	1.5
Dopamine (0.01 mol L^{-1})	6.6×10^{-2}	2.6×10^{-2}
Ascorbic acid (0.01 mol L^{-1})	8.2×10^{-2}	2.4×10^{-2}
Citric acid ion (0.1 mol L^{-1})	5.0×10^{-4}	4.1×10^{-4}
Uric acid (0.1 mol L^{-1})	3.6×10^{-3}	2.2×10^{-3}

3.7. The performance of the sensor

3.7.1. The response time

When the hydrogen peroxide concentration was above 2.0×10^{-3} mol L^{-1}, the response time was shorter than 3 min; when the H_2O_2 concentration was lower than 2.0×10^{-3} mol L^{-1}, the response time turned to be 5 min. The response time of glucose detection was 5 min.

3.7.2. The repeatability of the sensor

The repeatability of the sensor was examined using the reference method [24]. The results are shown in Table 4 and reveal that the sensor had a good repeatability for the determination of H_2O_2 and glucose.

Table 4
Results of examination of the sensors reproducibility.

Number of repeats for determination of H_2O_2/glucose	6.0×10^{-4} mol L^{-1} H_2O_2/glucose	1.0×10^{-3} mol L^{-1} H_2O_2/glucose
1	84/128 (mV)	96/139 (mV)
2	83/129 (mV)	98/138 (mV)
3	84/131 (mV)	99/136 (mV)
4	81/128 (mV)	97/137 (mV)
Average value	83/129 (mV)	97.5/137.5 (mV)
RSD (%)	1.7/1.1	1.3/0.9

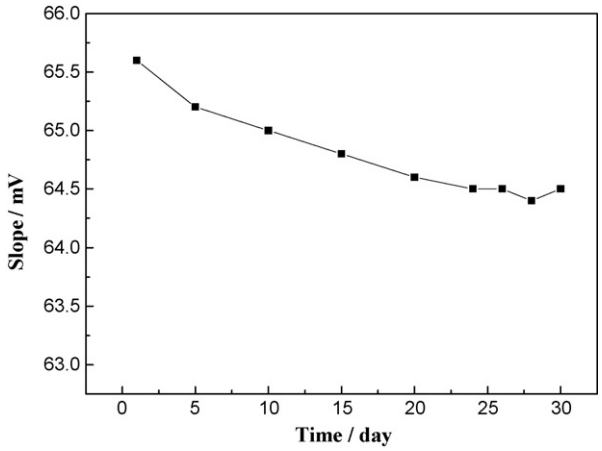

Fig. 9. Effect of the usage time of the sensor.

3.7.3. The life time of the sensor

After the new sensor had been conditioned for a given time, it showed a stable response for H_2O_2 when it was used continually for 30 days; the response slope and linear range of the sensor for H_2O_2 kept from any obvious varieties (shown in Fig. 9). The sensor appeared the poor stability and long response time after it was continually used over such a long time as 40 days; at the same time, the response linear range of the sensor for H_2O_2 was also poor.

3.8. Discussion on the possible response mechanism of the sensor

When the sensor was conditioned in 0.10 mol L^{-1} TISAB solution, the electromotive force (EMF) increased with time at first and then gave a constant response over a long time. While a few of H_2O_2 presented in the testing buffer solution, the response of this sensor was faster than that in blank testing buffer solution. Based on those experimental phenomena and the literature of the calix[4]arene petentiometric response mechanism to some molecule such as methanol [25], dopamine [26], p-methylphenol [27], sugars [28], carbon dioxide [29] and ions such as Ag^{+} [30], we proposed the possible response mechanism was that the calix[4]arene formed the host–guest complex with H_2O_2 by the hydrogen bond between H_2O_2 and hydroxybenzene of the calix[4]arene. Since the content of calix[4]arene modified on the electrode was limited, when the concentration of H_2O_2 increased to a certain value, all calix[4]arene on the electrode surface formed the complex with H_2O_2, and consequently, the potential became a constant(shown in Fig. 8a). However, the sensor regained its EMF response after it was washed by distilled water and measurement solution (TISAB) and used again.

3.9. The sample analysis and recovery test

By using standard addition method, the recoveries of ten H_2O_2 samples with concentrations from 5.5×10^{-4} mol L^{-1} to 4.9×10^{-2} mol L^{-1} were obtained. The recovery was satisfactory in the range of 96.2–103.5% and average recovery was 97.8% (RSD = 4%, n = 7).

The utility of this sensor was checked by using it for the quantitative determination of H_2O_2 in antisepsis water sample and compared the result (3.2%) with that of the titration with potassium permanganate (3.5%). The result clearly showed that the proposed method performed exceptionally well in the determination of H_2O_2 in samples.

Similarly, the recoveries of ten glucose samples with concentrations from 1.6×10^{-4} mol L^{-1} to 1.2×10^{-3} mol L^{-1} were achieved

Table 5
Results of the analysis of the blood samples with different glucose concentrations.

Blood samples	Clinical assay result, mol L^{-1}	Test result, mol L^{-1}	Deviation, mol L^{-1}
Sample1	8.7×10^{-3}	8.4×10^{-3}	-0.3×10^{-3}
Sample2	8.9×10^{-3}	8.8×10^{-3}	-0.1×10^{-3}
Sample3	9.0×10^{-3}	8.8×10^{-3}	-0.2×10^{-3}

by using standard addition method. The recovery was also satisfactory in the range of 97.2–102.5% and average recovery was 96.8% (RSD = 3.6%, $n = 7$). The sensor was used to quantify glucose on blood sample collected from diabetic patients of Affiliated Hospital of Yangzhou University by the standard addition method and the results shown in Table 5. The results obtained with sensor are in good agreement with reference values obtained with a yellow springs blood sugar analyzer (YSI Model 2300).

4. Conclusion

A novel peroxide hydrogen and glucose sensor with good sensitivity, selectivity, stability and reproducibility and anti-interferent ability was constructed by an electrochemical deposition method. Glucose oxidase was immobilized on the modified glassy carbon electrodes by dipping in the solution of the glucose oxidase (GOD) after immerged in the solution of glutaraldehyde. The method is simple and easy to control. The interference of ascorbic and uric acid could be avoided. The presence of the calix[4]arene film increased the stability of the sensor.

Ultrasonic nebulization extraction
Gas chromatography (GC)

ABSTRACT

Ultrasonic nebulization extraction (UNE) coupled with on-line gas chromatography (GC) was proposed for the determination of *trans*-anethole in fruits of *Illicium verum* Hook. f. and *Foeniculum vulgare* Mill. The extraction was performed in a common self-made extraction system. In the UNE the analyte was transferred and enriched from the solid sample to gas phase. The sample gas containing analyte obtained by UNE was introduced into the sampling loop with the purging gas (N_2). And then the sample gas in the sampling loop was introduced into the GC column. Several experimental parameters of on-line UNE-GC, including sampling time, flow rate of purging gas, standstill time and temperature of tubing, were optimized. The calibration curve ranging from 0.05 to 1.5 mg g^{-1} for determining the *trans*-anethole was obtained. The recoveries for determining *trans*-anethole are between 99.2% and 111.2% and RSDs are less than 8.3% when the UNE was applied. The analytes can rapidly be extracted and transferred from the solid sample to gas phase. The analytes in the gas phase are easier to be introduced into GC system than those in the solid and liquid phase. Compared with off-line systems, the proposed on-line system is more suitable to detect volatile compounds.

1. Introduction

Fruits of *Illicium verum* Hook. f. and *Foeniculum vulgare* Mill. are widely used as cooking spices and medicinal materials. The essential oils are the active components in fruits of the two kinds of plants. Many investigations about their antimicrobial and insecticidal behaviors have been reported [1–4]. In the essential oils, *trans*-anethole is the major component. The *trans*-anethole is one of the common rough materials and reaction solvent in the chemical industry. For example, alkylanisole derivatives producing from *trans*-anethole are valuable intermediates for the manufacture of pharmaceuticals, antioxidant, etc. [5]. Anisaldehyde producing from *trans*-anethole is an important chemical and chemical intermediate in the pharmaceutical, perfumery and agrichemical industry [6].

Several methods, such as hydrodistillation (HD) which is the state standard method of China [1,7,8], ultrasonic-assisted extraction (UAE) [9,10] and microwave-assisted extraction (MAE) [11–13], were usually applied to the extraction of the volatile compounds from spices. Recently, these methods coupled with some enrichment techniques, e.g. solid-phase extraction (SPE) [14,15], solid-phase microextraction (SPME) [16,17], and single-drop microextraction (SDME) [18,19], were applied to the extraction and determination of the volatile and semivolatile compounds on-line.

The ultrasonic nebulization extraction (UNE) was first studied by our group in the extraction of quercetin from *Rhizoma Alpiniae Officina-rum* [20] and Anthraquinones from *Rheum palmatum* L. [21]. These experiments confirmed that the UNE is a feasible and alternative method for extraction of effective constituents from plant samples. But the UNE was not applied to the extraction of volatile compounds. It can be seen from literature [21] that the high frequency ultrasonic wave (1.7 MHz) can result in "ultrasonic fountain" and aerosol at the same time. In the UNE process, the volatile compounds in the spices were transferred from the spices to the extraction solvent and then to gas phase. Namely, the UNE method is different from other conventional extraction methods, analyses can rapidly be extracted, transferred and enriched from the solid sample to gas phase.

The purge and trap (P&T) method [22–26] is used to transfer the volatile compounds from a liquid or solid matrix to gas phase by an inert gas flow and has been applied to the analysis of water [22], soil [23], body fluids [24], and so on [25,26]. It is a simple and fast method to detect the volatile and semivolatile compounds in liquid. But for the solid sample, it needed pre-extraction off-line, which made operation steps increase.

In this paper, a novel on-line analytical method combined the UNE and purge technique was used to detect *trans*-anethole in

fruits of *I. verum* Hook. f. and *F. vulgare* Mill. It has both advantages of UNE and on-line analysis. Compared with off-line systems, the on-line UNE coupled with GC technique has several advantages: (1) minimal sample contamination, (2) ideal method for the labile samples, (3) reduction of manual operation, (4) more inexpensive settings-up, (5) reduction of analyzing time, (6) the possibility for a totally automated analytical system. In addition, compared with P&T, the proposed method is suitable to analyze solid sample. And the UNE coupled with many enrichment techniques (SPE, SPME, SDME and so on) can improve the sensitivity.

2. Experimental

2.1. Chemicals and sample preparation

Three kinds of fruits of *I. verum* Hook. f. (named as Sample 1, 2 and 3) and three kinds of fruits of *F. vulgare* Mill. (named as Sample 4, 5 and 6) were purchased from Changchun, Jilin Province, China. The fruits of *I. verum* Hook. f. and *F. vulgare* Mill. were crushed by high-speed disintegrator (FW-100 Test Instrument Co., Ltd., Tianjin, China) at 24,000 rpm, and the powders obtained were passed through 80 mesh sieve and stored in the desiccators.

The standard of *trans*-anethole was purchased from Acros Company (NJ, USA). The naphthalene was used as internal standard and purchased from Beijing Chemical Factory (Beijing, China). Both analyte and internal standard were dissolved in n-hexane to obtain stock solution. These solutions were stored in the dark glass bottles at 4 °C. Pure water was obtained by using Milli-Q water purification system (Millipore Co., USA). The other reagents purchased from Beijing Chemical Factory (Beijing, China) are all of analytical grade.

2.2. Instruments and apparatus

The on-line UNE-GC system was assembled in our laboratory. A schematic diagram of the system is shown in Fig. 1. An ultrasonic humidifier (Beijing Branson Ultrasound Co. Ltd., China) working at 1.7 MHz with maximum output power of 35 W was employed as the ultrasonic source. A self-made glass flask (100 mL, ID 10 cm) was used as extraction vessel. There were three ports on this vessel. One of the ports on the bottom of the vessel has the same size as the piezocrystal and was sealed by PVC film. Other accessories, such as an injection valve (Nanda Analysis Instrument Graduate School, Nanjing, China), a sampling loop (1 mL) and a few stainless steel tubes, were used to fabricate the on-line system. A filtering column consisting of a stainless steel cylinder (2 cm × 3 mm i.d.) packed with glass wool was closed by screws at either end. A thermocouple sensor (XMTD-2001 Xinghua AOTE temperature Instrument Co., Xinghua, China) connected with a heating tape was used to measure the temperature. In addition, an ultrasonic generator (KQ2200E Kunshan Ultrasonic Instrument Co. Ltd., Kunshan, China) with 150 W of output power and 40 kHz of frequency was used in UAE.

The extract was analyzed by GC (Hewlett Packard computerized system comprising a 4890 gas chromatograph) with a HP-1 column (30.0 m × 250 μm × 0.32 μm film thickness). Nitrogen was used as the carrier gas at a flow rate of 4 mL min^{-1}.

2.3. Extraction procedures

2.3.1. On-line UNE-GC

In sequence 1 (Fig. 1a), the mixture of 0.1 g of sample and 15 mL of n-hexane, which was referred to as the extract, was put into extraction vessel and the nebulizer was switched in. During this

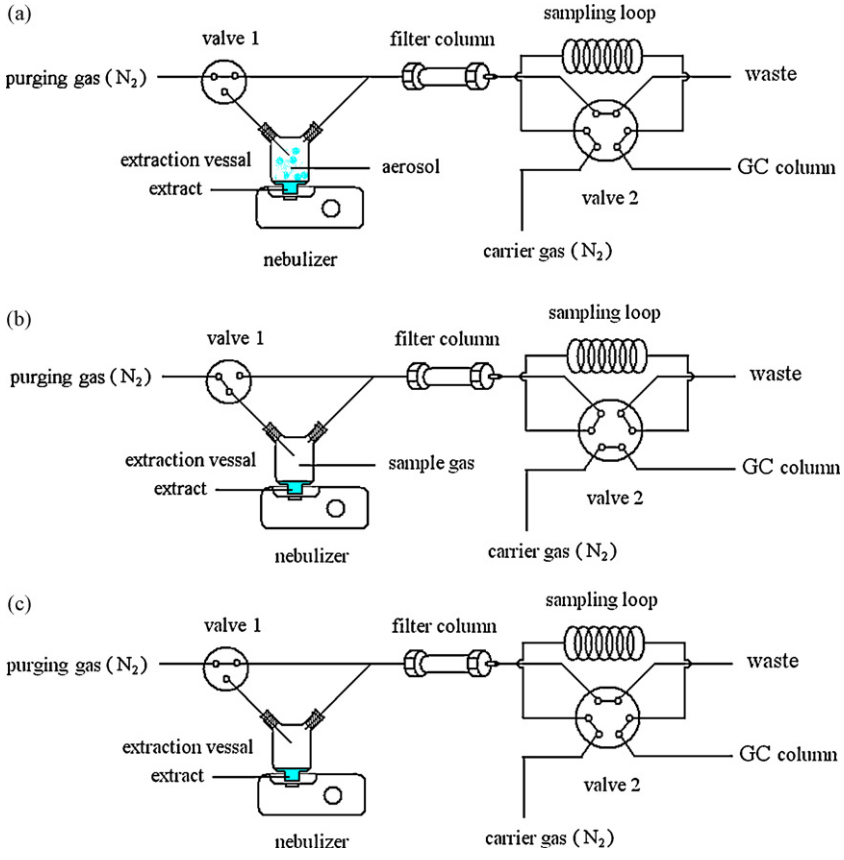

Fig. 1. On-line UNE system. (a) Extraction, (b) sampling and (c) injection.

sequence, the extraction vessel was full of aerosol. The valve 1 was in extraction position and valve 2 in sampling position. 5 min later, the nebulizer was switched off. The nebulizer was at a standstill for a certain standstill time. The aerosol in the headspace of extraction vessel will drop into the extract located in the bottom of extraction vessel. In sequence 2 (Fig. 1b), the valve 1 was in injection position, and valve 2 was also in sampling position. The purging gas (N_2) (270 mL min^{-1}) was passed through the extraction vessel for a certain purging time and the sampling loop was fill with the sample gas containing analyte. In sequence 3 (Fig. 1c), the valve 1 was in extraction position and valve 2 was in injection position. The sample gas in sampling loop was introduced into GC column and analyzed. The tubing in the UNE system was wrapped by a heating tape except the extraction vessel, and the temperature of heating tape was controlled at 80 °C.

In the method, the volatile compounds in the spices were transferred from solid phase (spices) to liquid phase (extraction solvent) because of the UNE extraction, and then transferred from liquid phase to gas phase due to the gas–liquid equilibrium. The focused energy of UNE makes the extraction solvent and sample powders spurt from the bottom of the extraction vessel, which looks like a fountain. Thank to the "ultrasonic fountain", the sample powders can be spurted from the bottom of the extraction vessel and suspended in the headspace in the aerosol and then dropped into the bottom of the extraction vessel. In this process, because the collision between extraction solvent and sample powder occurred frequently and the extraction solvent around the sample powder was renewed rapidly, the extraction efficiency of the analytes was enhanced. In the other hand, a lot of aerosols, which are small in size, were produced in UNE. The transfer the analytes from the aerosols into the gas phase is easy because the surface area of aerosols is large [27] and the interface between gas and liquid is frequently renewed. The gas–liquid distribution equilibrium of analytes was rapidly reached. So the total amount of the volatile compounds in gas phase increased at a certain time.

2.3.2. Off-line UNE

0.10 g of sample powder and 15 mL of n-hexane were added into the extraction vessel. The optimized UNE conditions were as follows: extraction solvent was 15 mL of n-hexane; ultrasonic power was 35 W; extraction time was 5 min. The extract was filtered with 0.45 μm micropore filter membrane and then analyzed by GC.

2.3.3. UAE

The comparison between conventional UAE with on-line UNE was carried out to evaluate the extraction efficiencies of different methods. 0.10 g of sample powders and 15 mL of n-hexane were added into the extraction vessel. After UAE for 5 min, the resulting suspension was filtered through a 0.45 μm micropore filter membrane. And 0.3 μL extract was injected into the GC system for analysis.

2.3.4. HD

According to Chinese Pharmacopoeia [1], 20 g of sample and 300 mL of water were put into a 500 mL flask and heated by heating jacket at 100 °C for 4 h. The essential oil was collected, dried with anhydrous sodium sulphate and then stored at 4 °C until analyzed.

2.3.5. Gas chromatography

The operating conditions were as follows: nitrogen carrier gas flow rate 4.0 mL min^{-1}; split ratio 1:10; injection and detection temperature 260 °C; oven temperature progress from 60 °C (holding for 3 min) to 240 °C at the rate of 5 °C min^{-1}. The injection volume is 0.3 μL in off-line methods. The flame ionization detector was used and its temperature was 260 °C.

3. Results and discussion

3.1. Optimization of on-line UNE-GC

Some parameters can affect the performances of on-line UNE-GC, such as purging time, flow rate of purging gas, standstill time and temperature of tubing. When one parameter was changed, other parameters were fixed at their optimal values.

3.1.1. Effect of purging time

The effect of purging time on peak area of *trans*-anethole is shown in Fig. 2. It can be seen that the peak area increases with the increase of purging time from 10 s to 20 s, does not significantly changes from 20 s to 60 s and slightly decreases from 60 s to 120 s. When purging time was shorter than 20 s, the analyte concentration in the sample gas in the extraction vessel and the sampling loop was not identical, and concentration of analyte in sampling loop was lower than that in the extraction vessel. On the contrary, the concentration of analyte in extraction vessel was diluted when purging time was longer than 60 s. Remarkably, the precision was not satisfactory when the purge time was 10 s. So 20 s was chosen finally to be purging time in this work.

3.1.2. Effect of flow rate of purging gas

The effect of flow rate of purging gas ranging from 70 to 630 mL min^{-1} on the peak areas was examined, and the result is shown in Fig. 3. It can be seen that the peak area of *trans*-anethole increases at first, but then decreases when the flow rate of purging gas is higher than 270 mL min^{-1}. The flow rate of purging gas was measured by soap film flowmeter in waste vent. At low flow rate, small amount of analyte was introduced into the sampling loop. On the contrary, the overhigh flow rate will dilute the sample gas in extraction vessel. So, the flow rate of purging gas was chosen finally to be 270 mL min^{-1}.

3.1.3. Effect of standstill time

In the UNE extraction process, the sample powders of small diameter will spurt from extract, suspend in the headspace and exist in the aerosol. Under the gravitational effect those powders fall into the extract after a period of time. This circulating process is beneficial to the renewal of the solvent on the surface of sample powders and the extraction efficiency can be enhanced. If the nebulization stopped, the sample powders would gradually drop into the

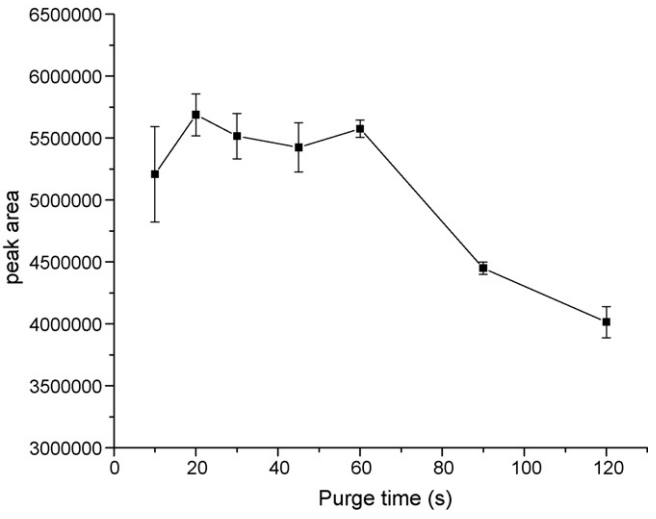

Fig. 2. Influence of the purging time. Flow rate of purging gas, 270 mL min^{-1}; standstill time, 5 min; temperature of tubing, 80 °C.

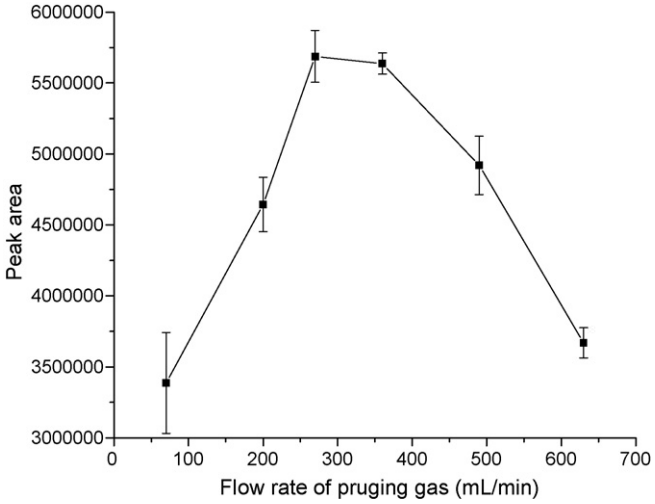

Fig. 3. Influence of the flow rate of purging gas. Purging time, 20 s; standstill time, 5 min; temperature of tubing, 80 °C.

extract along with the aerosol. The concentration of volatile compounds was highest in the headspace of extraction vessel when the nebulization stopped. If the sampling was performed immediately, a large quantity of aerosol was introduced into the sampling loop in which the solution droplet can form and block the tubing. So, the sampling was performed after a period of standstill. The effect of standstill time of 0, 1, 3, 5, 8 and 10 min was tested, respectively. When the standstill time was longer than 5 min, a large quantity of aerosol containing sample powders would drop into the extract, which was observed by the naked eye. The results are shown in Fig. 4. It can be seen that the extraction yield of *trans*-anethole decreases with the increase of the standstill time. If the standstill time is too long, the *trans*-anethole in gas phase would loss, which results in the decrease of concentration of *trans*-anethole in sample gas. So the standstill time of 5 min was selected in the work.

3.1.4. Effect of temperature of tubing

The effect of tubing temperature from 20 to 120 °C on the peak area was evaluated, and the result is shown in Fig. 5. It can be seen that the peak area increases obviously along with the increase

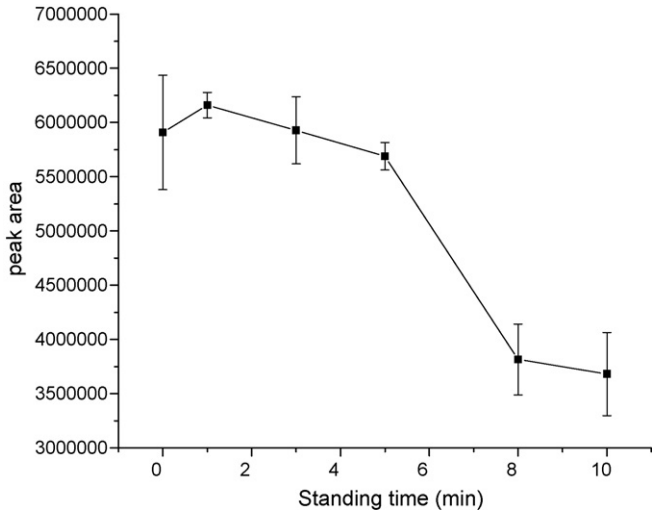

Fig. 4. Influence of the standstill time. Purging time, 20 s; flow rate of purging gas, 270 mL min^{-1}; temperature of tubing, 80 °C.

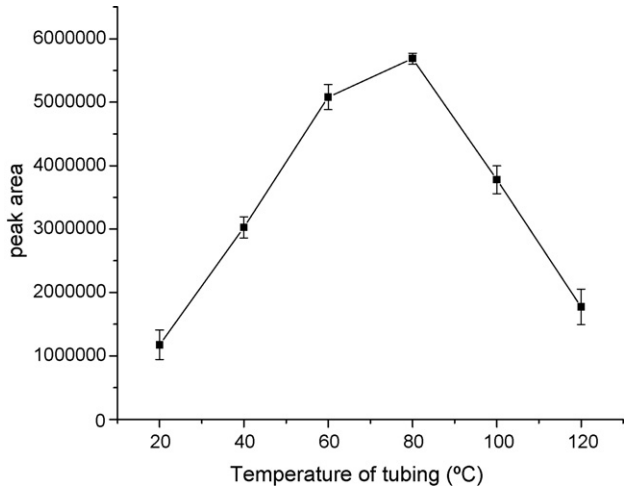

Fig. 5. Influence of the temperature of tubing. Purging time, 20 s; flow rate of purging gas, 270 mL min^{-1}; standstill time, 5 min.

of temperature from 20 to 80 °C, whereas it decreases when the temperature is higher than 80 °C. Before the sample gas was introduced into GC column the main component in the gas phase and the aerosol was n-hexane whose boiling point was 68.7 °C. At the 270 mL min^{-1} of flow rate, small amount of aerosol in sampling gas was introduced into the sampling loop. When the temperature is lower than 68.7 °C, n-hexane can precipitate on the wall of tubing. Therefore, the analyte transferred to the sampling loop lost. If the temperature was too high the small amount of aerosol which was transferred to the sampling loop will vaporize and then the volume of sample gas was expanded and the concentration of analyte in sample gas decreases. Finally, the temperature of tubing was chosen to be 80 °C in this work.

3.2. Evaluation of the method

3.2.1. Standard curve and limit of quantification

In the work, *trans*-anethole was determined by on-line and off-line UNE-GC. The working standard solutions of *trans*-anethole at the concentrations ranging from 0.05 to 1.5 mg mL^{-1} were prepared. The linear equations for on-line and off-line UNE-GC are $A = 0.01574 + 4.05186C$ and $A = -0.3107 + 2.50664C$ and limits of quantification (LOQs) are 0.020 and 0.017 mg g^{-1}, respectively. The LOQs were determined as the lowest concentration that yielded a signal-to-noise (S/N) ratio of 10.

3.2.2. Enrichment effect of UNE

In the UNE process, the frequency of acoustic vibration is about 1.7 MHz. When the vibration was transmitted through the solvent, "ultrasonic fountain" and aerosol would occur. If the analyte has good volatility, its concentration in gas phase obtained by UNE is higher than that obtained by stirring extraction. The reasons may be that compared with the stirring extraction, the transfer rate of volatile compounds from liquid to gas phase is more rapid and gas–liquid equilibrium is more rapidly reached when the UNE is applied. Compared with the conventional stirring extraction, the UNE process also can be viewed as an enrichment step. In order to evaluate the enrichment effect of UNE, the stirring method without nebulization was applied. In the two experiments, the standard solution at concentration of 0.2 mg mL^{-1} was added into the 15 mL n-hexane in extraction vessel. In the UNE, both the nebulization and the standstill time was 5 min; while in the stirring method, the stirring time was 10 min. The resulting sample gas in extraction vessel was introduced into GC for analysis. The results indicted that the concentration of the analyte obtained by the UNE was 5 times

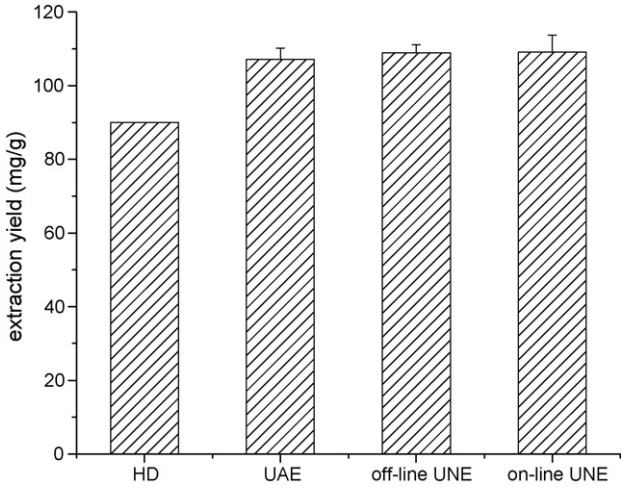

Fig. 7. Comparison of different extraction methods.

higher than that obtained by stirring method. It was obvious that enrichment effect of UNE was significant.

3.2.3. Sample analysis

The *trans*-anethole in fruits of *I. verum* Hook. f. and *F. vulgare* Mill. obtained from different cultivated areas was determined by on-line and off-line UNE-GC, respectively. The chromatograms of standard solution and extracts obtained by on-line UNE-GC and off-line UNE-GC are shown in Fig. 6. The contents of *trans*-anethole obtained by on-line and off-line UNE-GC are shown in Table 1. From Table 1, it can be seen that the contents of *trans*-anethole in fruits of *I. verum* Hook. f. and *F. vulgare* Mill. obtained by on-line are very similar. The results demonstrate proposed method can be applied to the real sample analysis with good accuracy. But, it was worth to notice that there were significant differences in the contents of *trans*-anethole belong to different samples, which was perhaps due to the different cultivated areas and picking periods. The contents of *trans*-anethole in the samples collected from different areas were compared applying of variance. For this purpose, the Student's t test was applied. The statistical analysis indicated that there are significant differences among contents of *trans*-anethole in the samples collected from different area. The difference between sample 5 and 6 was significant ($P < 0.01$) and the differences between the other samples were very significant ($P < 0.001$). In addition, the RSDs and recoveries obtained by on-line UNE-GC are 3.3–7.0% and 99.2–111.2%, respectively. The results also indicate the on-line UNE-GC can be applied to the determination of *trans*-anethole in fruits of *I. verum* Hook. f. and *F. vulgare* Mill. with good precision and accuracy.

3.3. Comparison of HD, UAE, off-line UNE and on-line UNE

In order to evaluate the extraction efficiency of proposed method, HD and UAE were applied to extract *trans*-anethole from sample 1. The extraction yields obtained by different methods are shown in Fig. 7. Correspondingly, the extraction yield obtained by HD is the lowest. So, compared with HD, the extraction yield obtained by on-line UNE-GC is higher, but shorter extraction time was required and lower energy was consumed. Furthermore, the extraction yield obtained by proposed method is in agreement with those obtained by UAE and off-line UNE-GC, which indicates that on-line UNE-GC is a feasible method for extracting volatile compounds from spices. In addition, it is worth to notice that on-line UNE-GC is also a gentle and enjoyable method without any noise.

4. Conclusion

In this study, UNE coupled with on-line GC detection was applied to determining *trans*-anethole in fruits of *I. verum* Hook. f. and *F. vulgare* Mill. The experimental conditions for on-line UNE-GC were examined and optimized. On-line UNE-GC was then compared with HD, UNE and off-line UNE-GC. The extraction yield obtained by on-line UNE-GC was obviously higher than those obtained by conventional HD, and RSD and recovery obtained by

the proposed method are also satisfactory. Therefore, it can be concluded that on-line UNE-GC is a simple, labor saving, sensitive, novel and feasible method for extracting and determining the constituents in essential oil from spices. If the UNE coupled with many enrichment techniques (SPE, SPME, SDME and so on), the sensitivity of the proposed method would be improved.

ABSTRACT

In order to solidify the electrochemiluminescence (ECL) luminophor tris(2,2′-bipyridyl) ruthenium(II) ($[Ru(bpy)_3]^{2+}$) onto the electrode surfaces robustly, the negative charged heteropolyacids (HPAs) moieties were utilized to attract and bond cations $[Ru(bpy)_3]^{2+}$ via an adsorption method. The compositions and microstructures of the hybrid complexes were characterized by elemental analysis (EDS), spectroscopic techniques (UV–vis, FTIR) and field-emission scanning electron microscopy (FE-SEM). The electrochemical and ECL behaviors of the $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$ hybrid complex contained in the solid film of the nanocomposites formed on the electrode surfaces were also studied. It was found that the corresponding solid membranes exhibited a diffusion-controlled voltammetric feature and excellent electrochemiluminescence behaviors. Hence potential prospects as new electrochemiluminescent materials for application in electroanalytical detection are envisioned.

1. Introduction

Nowadays, electrogenerated chemiluminescence (ECL) has been paid considerable attention due to its inherent advantages such as low background signal, simple optical setup, and versatility [1–3]. Among various ECL reagents, $[Ru(bpy)_3]^{2+}$ is selected and studied most extensively because of its superior properties including excellent stability, and good efficiency in aqueous solution [4]. Compared with those solution-phase ECL procedures, the immobilization of $[Ru(bpy)_3]^{2+}$ on electrode surfaces can provide several advantages such as reducing the consumption of expensive reagents, enhancing ECL signal, and simplifying experimental design [5–7]. Thus increasing attention has been paid to immobilize $[Ru(bpy)_3]^{2+}$ on electrode surfaces [8–12]. Some of the above-mentioned methods possess a fast response and good stability, but the synthesis processes are complicated and arduous. Therefore, developing a simple method to stably and sensitively modify the electrodes is quite urgent. Recently, Wang et al. prepared a series of ion conductors via adsorption between cationic $[Ru(bpy)_3]^{2+}$ and anionic $PtCl_6^{2-}$, $AuCl_6^{2-}$ or citric-capped AuNPs [13–15]. The prepared ion conductors have been utilized in ECL detection and exhibited good stability. The method proposed by Wang et al. is relatively simple and the generated sensors exhibit fast responses and excellent ECL behaviors. However, the high prices of the precursors have hindered their potential practical utilizations. Therefore, developing an economical and simple method to solidify $[Ru(bpy)_3]^{2+}$ on the electrodes becomes an urgent task.

Heteropolyacids (HPAs) of Keggion structure is a family of complexes with the general formula $[X_yM_zO_m]^{n-}$ (where M represents Mo, W, V, etc. and X represents P, Si, As, etc.), presenting excellent properties such as stability and availability depending on the counter-ion, quite small size and very high electronic density [16]. Most importantly, they have good ability to form very stable membranes [17,18]. Thus, they are usually used as the charged anionic moieties to attract and bond multiply cations in assembled films [19,20]. Although a few reports about multilayer films such as $[Os(bpy)_3]^{2+}/[P_2Mo_{18}O_{62}]^{6-}$ and $[Ru(bpy)_3]^{2+}/[Si_2Mo_{18}O_{62}]^{4-}$ have been reported [21–23], these studies mainly focused on the properties of transition metal ions and their electrochemistry. Few studies reported the synthesis of $[Ru(bpy)_3]^{2+}/[X_yM_zO_m]^{n-}$ via a precipitation reaction followed by a simple mixing method and their corresponding ECL properties.

In this research, a direct mixing method was introduced to construct a series of $[Ru(bpy)_3]^{2+}/[X_yM_zO_m]^{n-}$ hybrid films, which is simple and economical. To our knowledge, it is the first attempt to prepare robust $[Ru(bpy)_3]^{2+}$ nanocomposites containing HPAs via a precipitation reaction by adsorption. In addition, electrochemical and ECL behaviors of the $[Ru(bpy)_3]^{2+}$ hybrid membranes on ITO electrodes are investigated. Good stability and high sensitivity in solid-state ECL detection are observed. All the merits above of

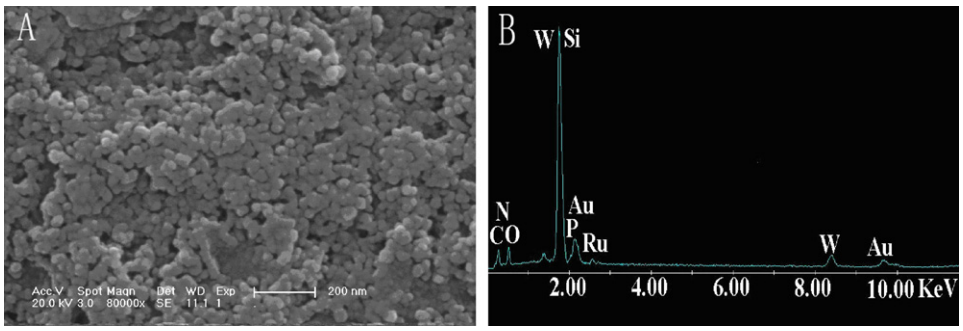

Fig. 1. The FE-SEM image of the aggregates and (B) the corresponding EDS of 100 μL 0.20 mM PTA and 1 mL 0.030 mM $[Ru(bpy)_3]^{2+}$ solution.

the $[Ru(bpy)_3]^{2+}/[X_yM_zO_m]^{n-}$ hybrid films indicate great potential applications in electroanalysis.

2. Experimental

2.1. Reagents

PTA ($H_3PW_{12}O_{40}\cdot nH_2O$) was purchased from Fluka. $Ru(bpy)_3Cl_2\cdot 6H_2O$ and 2-(dibutylamino)ethanol (DBAE) were obtained from Aldrich. $Na_2H_9PW_{12}O_{42}$, $H_4SiW_{12}O_{40}\cdot nH_2O$, and other chemicals and reagents were of analytical grade, and all the reagents were used as received without further purification.

2.2. Instruments and characterizations

The field-emission scanning electron microscopy (FE-SEM) measurements were carried out on a PHILIPS XL-30 ESEM with an accelerating voltage of 20 kV. The silicon slides were used as substrates for the FE-SEM experiments. Energy-dispersed spectrum (EDS) analysis was performed using an EDAX system. UV–visible (UV–vis) absorption spectra were detected from a Cary 50 UV-vis spectrometer (Varian, USA). Fourier transform infrared (FTIR) spectra were recorded on a FTIR spectrometer (Nicolet 520, USA) using the KBr wafer technique. Electrochemical experiments were carried out with a CHI 832 (Shanghai, China). In our three-electrode system, the ITO or nanocomposite-coated ITO electrodes were selected as working electrodes. Ag/AgCl (saturated KCl) was chosen as a reference electrode, and a platinum foil was employed as a counter electrode. The ECL signals were recorded by an MPI-A chemiluminescence analyzer (Xi'An Remax Science & Technology Company, Xi'An, China). The photomultiplier tube was biased at 800 V. It was worthwhile mentioning that all the work electrodes used in our experiment were set at a fixed area by carrying out in the place of the reservoir with a defined area (Ø, 3 mm).

2.3. Procedures

2.3.1. $[Ru(bpy)_3]^{2+}$ nanocomposites containing HPAs preparation

In a typical experiment, 100 μL of 0.2 mM $[PW_{12}O_{40}]^{3-}$ was diluted to 1 mL aqueous solution first, and then 1 mL of 0.03 mM $[Ru(bpy)_3]^{2+}$ aqueous solution (3:2 molar ratio of $[Ru(bpy)_3]^{2+}$ to $[PW_{12}O_{40}]^{3-}$) was added into the resulting solution under vigorous stirring to mix them uniformly. After the addition, the stirring was stopped and the resulting solution was kept at room temperature. Several minutes later, a large amount of precipitates were produced. The resulting precipitates were collected by centrifugation, washed several times with water, and then suspended in water for the further experiments and characterizations.

2.3.2. Sensors fabrication

Sensors were fabricated by sonicating and rinsing indium tin oxide (ITO) electrodes clearly, and then a 10 μL aliquot of as-prepared suspension was coated on the ITO electrode and allowed to dry at room temperature. Finally some completely dry brown $[Ru(bpy)_3]^{2+}/[X_yM_zO_m]^{n-}$ composite films on ITO electrodes were obtained. When not in use, the films were kept under in dry state at room temperature.

3. Results and discussion

3.1. SEM characterizations

Fig. 1A showed the typical SEM of the resulting precipitates of sample $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$. It was clear that the precipitates consisted of a large quantity of spherical shape nanocomposites in a relative uniform size range. It was worthwhile to mention that the formed structure was robust enough to undergo an ultrasonication for about 15 min using a sonifier with 100 W. The chemical composition of the precipitates was further determined by the EDS. As shown in Fig. 1B, the peaks of Ru, P, W, C, O, and N elements were observed (other peaks such as Si and Au elements originated from the substrate), demonstrating the precipitates formed by the proposed method consist of $[Ru(bpy)_3]^{2+}$ and $[PW_{12}O_{40}]^{3-}$. The quantitative elemental analysis was conducted to determine the stoichiometry. It was observed that the atom number ratio of Ru and W in the as-formed nanocomposites was 10.19:79.27, which was consistent with the 3:2 reaction molar ratio of $[Ru(bpy)_3]^{2+}$ to $[PW_{12}O_{40}]^{3-}$. Based on these observations, it was concluded that these structures were produced via the interaction between $[PW_{12}O_{40}]^{3-}$ and $[Ru(bpy)_3]^{2+}$. Control experiments by mixing $[Ru(bpy)_3]^{2+}$ and other negative charged polyoxometalates ($Na_2H_9P(W_2O_7)_6$ or HPAs ($H_4SiW_{12}O_{40}\cdot nH_2O$) were also investigated, and the similar hybrids were obtained (Supporting Information, Fig. S1). In comparison, $[Ru(bpy)_3]^{2+}$ with other anions (SO_4^{2-}, PO_4^{3-}) were also mixed. It was found that the solution was still clear and none of any precipitates occurred. Considering the positive charge of $[Ru(bpy)_3]^{2+}$ ions and the negative charge of $[X_yM_zO_m]^{n-}$ groups, the electrostatic attractions between these two complexes may impulse these hybrid composites formation, and the unique properties of HPAs such as counter-ion, small size and very high electronic density might play an important role in the hybrids fabrication.

The effects of the reactant molar ratio on the morphologies and stoichiometry compositions of these hybrid complexes were examined. If the concentration of $[Ru(bpy)_3]^{2+}$ and $[PW_{12}O_{40}]^{3-}$ were set, the quantity of the precipitates increased with the quantity of $[Ru(bpy)_3]^{2+}$ and $[PW_{12}O_{40}]^{3-}$. However, similar morphologies and same stoichiometry compositions were obtained for them, and similar results were obtained for $Na_2H_9P(W_2O_7)_6$ and

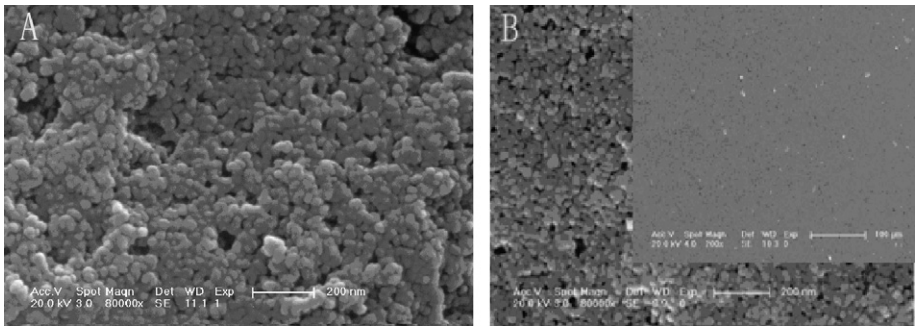

Fig. 2. SEM images of the precipitates were obtained at (A) fivefold, (B) one-fifth the concentration of Fig. 1 sample and (inset of (B)) SEM image of the resulting aggregates $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$ formed film on an ITO substrate.

$H_4SiW_{12}O_{40}{\cdot}nH_2O$ (data not shown here). The results showed that the original molar ratios had no significant effects on the morphologies and stoichiometry compositions of the hybrid complexes. Fig. 2 showed typical SEM images of other two samples obtained at different concentrations of reactants under the otherwise identical conditions. When the concentrations of both $[Ru(bpy)_3]^{2+}$ and $[PW_{12}O_{40}]^{3-}$ were increased to fivefold, the size of precipitates slightly increased (Fig. 2A). When the concentrations of both $[Ru(bpy)_3]^{2+}$ and $[PW_{12}O_{40}]^{3-}$ were decreased to one-fifth, the resulting precipitates exhibited more uniform spherical morphologies in a narrower size distribution of about 20 nm (Fig. 2B). Their small sizes and uniform distributions may favor the membrane fabrication on various substrates. Hence, the one-fifth concentration of the sample was utilized to do the next experiment. The inset of Fig. 2B showed a SEM image of the aggregates formed film on an ITO substrate, indicating that the aggregates formed a fairly smooth and quite uniform film on the substrate. No cracks were observed. This suggested that the PTA had good ability to form films [19,20]. The thickness of the composite films was also determined by FE-SEM, and the mean thickness was 800 nm.

3.2. Spectra study of the $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$ hybrid nanocomposites

As the $[Ru(bpy)_3]^{2+}$ ions had characteristic absorption in the UV–vis region, the UV–vis absorption spectra of the $[Ru(bpy)_3]^{2+}$ aqueous solution and their hybrid complexes were collected and compared. For free $[Ru(bpy)_3]^{2+}$ solution, two obvious peaks appeared at about 286.0 and 454.0 nm (Fig. 3A, curve a), which were assigned to ligand-centered transitions and metal-to-ligand charge transfer (MLCT), respectively [2]. For the $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$ hybrid complexes, the similar absorption peaks were found except an red-shift phenomena from 286.0, 454.0 to 293.0 and 465.0 nm respectively (curve b). The red shift of 7–9 nm for every absorption peak further demonstrated the strong electrostatic interaction between $[Ru(bpy)_3]^{2+}$ and negatively charged $[PW_{12}O_{40}]^{3-}$ [2,4]. UV–vis spectroscopy of other hybrids $[Ru(bpy)_3]^{2+}/[H_9P(W_2O_7)_6]^{2-}$ and $[Ru(bpy)_3]^{2+}/[SiW_{12}O_{40}]^{4-}$ were also obtained (Supporting Information, Fig. S2). These curves also exhibited red-shift phenomena compared with that of free $Ru(bpy)_3Cl_2$.

The FTIR spectra were shown in Fig. 3B, and the results were listed in Table 1. Free $[Ru(bpy)_3]^{2+}$ (curve b) and $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$ (curve c) exhibited several absorption peaks located in the range of 1400–1650 cm^{-1} corresponding to the characteristic of 2,2′-bpy [24]. The peaks at 1081 and 1012 cm^{-1} might be attributed to the P–O stretches and the W=O stretches respectively. The bands at 879 and 792 cm^{-1} were assigned to the edge shared (W–Ob–W) and corner-shared octahedral of Keggin unit (W–Oc–W) compared to the pure PTA (curve a). The

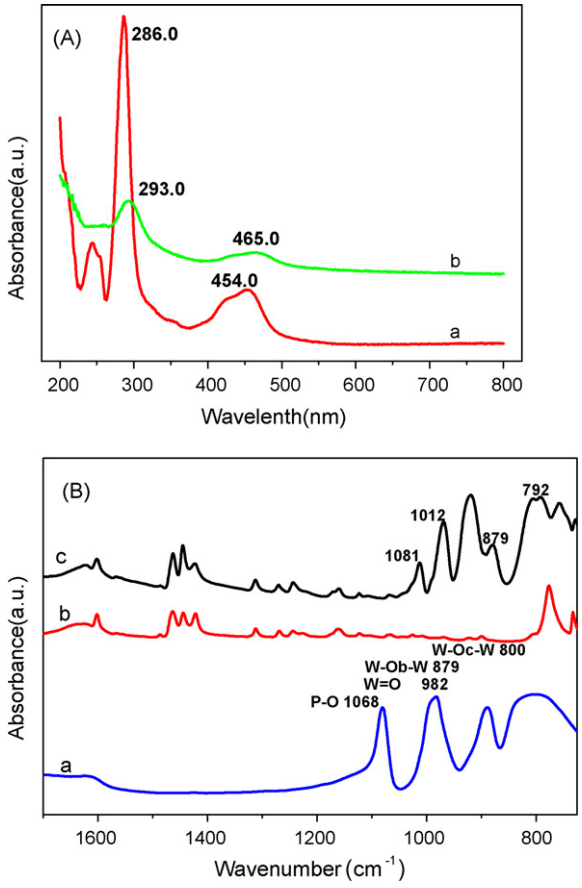

Fig. 3. (A) UV–vis absorbance spectra of (curve a) free $[Ru(bpy)_3]^{2+}$ and (curve b) $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$ in aqueous solution, (B) FTIR spectra of (curve a) pure PTA, (curve b) $[Ru(bpy)_3]^{2+}$ and (curve c) $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$.

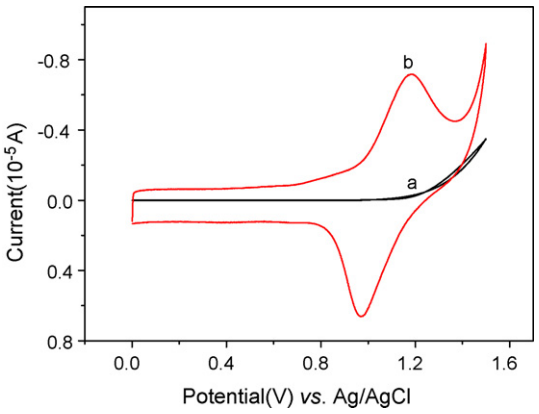

Fig. 4. CVs of (curve a) bare and (curve b) $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$-coated ITO electrodes in 100 mM PBS at scan rate of 100 mV s^{-1}.

P–O and the W=O band stretches appeared at higher wavenumbers indicating an interaction of PTA with $[Ru(bpy)_3]^{2+}$ to form the hybrids robustly [25,26]. The FTIR results for the precipitates of $[Ru(bpy)_3]^{2+}$ between $[H_9P(W_2O_7)_6]^{2-}$ and $[SiW_{12}O_{40}]^{4-}$ were also confirmed the formation of $[Ru(bpy)_3]^{2+}/[H_9P(W_2O_7)_6]^{2-}$ and $[Ru(bpy)_3]^{2+}/[SiW_{12}O_{40}]^{4-}$ hybrids (Supporting Information, Fig. S3). These spectra indicated that $[Ru(bpy)_3]^{2+}$ were successfully immobilized in the hybrids via the electrostatic interaction using the simple mixing method.

3.3. Electrochemistry investigation of the $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$ hybrid nanocomposites

Cyclic voltammograms (CVs) of the hybrid nanocomposite $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$ suspension on ITO electrodes were recorded. Fig. 4 showed a pair of redox waves appeared at 1.18 V, which was attributed to the one-electron redox reaction of $[Ru(bpy)_3]^{2+}$ [15]. Furthermore, it was found that the anode peak currents were proportional to the square roots of scan rates ($V^{1/2}$) in the range of 100–500 mV s^{-1} (data not shown here), indicating that the $[Ru(bpy)_3]^{2+}$ components contained in the nanocomposite film on the electrode surfaces underwent a diffusion-controlled process [15]. Therefore, it may be expected that the resulting hybrid material is an ion conductor with redox-active sites. The effects of pH on the electrode responses and the formal redox potential were studied. It was found that the shifts of the anodic and the cathodic peaks towards negative potentials with the increase of the solution pH (from 4 to 10), but the separation between oxidation and reduction peaks remains constant during the displacement.

3.4. ECL behaviors and linear range

The effect of the quantity of hybrid complexes $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$ on the DBAE ECL responses was investigated. It was found that the concentration and amount of $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$ on the ITO surfaces determine the thickness of the film, and hence influence the ECL responses of DBAE. The responses increased gradually with the increase of the film thickness. However, the film becomes too thick, and blocks electron transfer when the original concentration of $[Ru(bpy)_3]^{2+}$ exceeds 0.06 mM and the amount of $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$ dispersion exceeds 10 μL. Therefore, the 0.06 mM $[Ru(bpy)_3]^{2+}$ and 10 μL dispersion were chosen in our experiment. Fig. 5A showed the ECL intensity-potential curve of the hybrid nanocomposite $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$ suspension-coated ITO containing 4.0×10^{-5} M DBAE. The highest ECL occurred near 1.18 V, which was consistent with the oxidation of the $[Ru(bpy)_3]^{2+}$ [15]. The wide

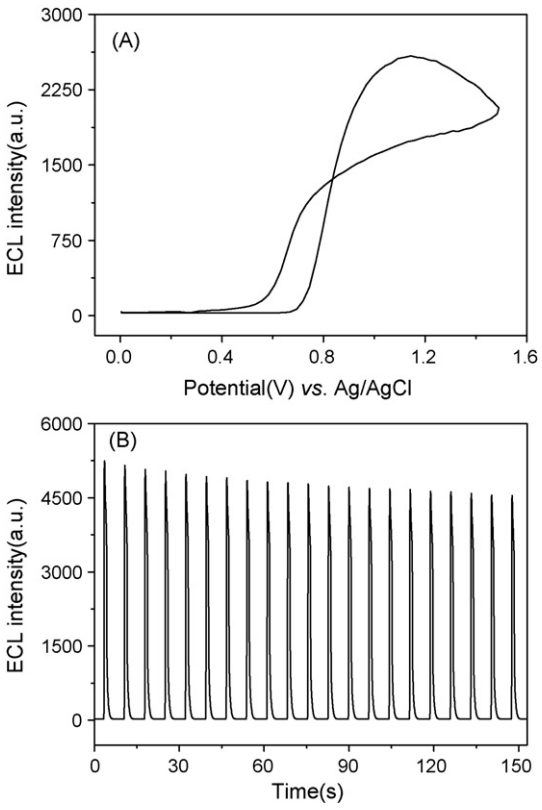

Fig. 5. (A) ECL intensity–potential curve and (B) ECL intensity–time curve of $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$-coated ITO containing 4.0×10^{-5} M DBAE under continuous cyclic voltammetry for 21 cycles in PBS with the scan rate of 500 mV s^{-1}.

linear range for DBAE detection from 6.0×10^{-9} to 8.0×10^{-3} M ($R = 0.98$) with the detection limit of 1.33×10^{-10} M (S/N = 3) was obtained. The $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$ nanocomposite-coated ITO electrodes also showed excellent reproducibility and stability towards DBAE detection. Fig. 5B showed the ECL intensity–time curve with 4.0×10^{-5} M DBAE under continuous potential scanning for 21 cycles, and the relative average deviation was 4.38%. The reduced ECL intensity in a span is possibly because of the fact that partial of the structure of $[Ru(bpy)_3]^{2+}/[PW_{12}O_{40}]^{3-}$ became loose and the $Ru(bpy)_3{}^{2+}$ began to leach out of the hybrid film. However, in previous report using the AuNPs to immobilize $Ru(bpy)_3{}^{2+}$, the relative average deviation of the biosensor was 2.77% only after continuous potential scanning for five cycles [13]. Most importantly, there was no additional formed film materials added in our experiments. The electrode had good ECL stability and kept over 85% its initial intensity within 2 weeks. The results indicated that the $[Ru(bpy)_3]^{2+}$ components contained HPAs nanocomposite films on the electrode surfaces were very stable. Note that the other two samples, $[Ru(bpy)_3]^{2+}/[H_9P(W_2O_7)_6]^{2-}$ and $[Ru(bpy)_3]^{2+}/[SiW_{12}O_{40}]^{4-}$, also exhibited good ECL behaviors (Supporting Information in Fig. S4).

4. Conclusions

In summary, the nanocomposites containing $[Ru(bpy)_3]^{2+}$ and HPAs have been successfully synthesized via a simple directly mixing method. Because of the good ability to form membranes of HPAs, the $[Ru(bpy)_3]^{2+}/[X_yM_zO_m]^{n-}$ nanocomposites have been robustly formed on the ITO electrode surfaces. The nanocomposite-coated ITO electrodes exhibited excellent and stable ECL behaviors. Due to their simpleness, universalness and low price, potential

applications for solid-state ECL detection in capillary electrophoresis (CE) or a CE microchip could be envisioned.

ABSTRACT

In this article, a new ligandless dispersive liquid–liquid microextraction method has been developed for preconcentration of trace quantities of silver as a prior step to its determination by flame atomic absorption spectrometry. In the proposed approach, carbon tetrachloride and ethanol were used as extraction and dispersive solvents. Several factors that may be affected on the extraction process, like, extraction solvent, disperser solvent, the volume of extraction and disperser solvent, pH of the aqueous solution and extraction time were optimized. Under the optimal conditions, the calibration curve was linear in the range of 5.0 ng mL^{-1} to 2.0 μg mL^{-1} of silver with $R^2 = 0.9995$ ($n = 9$) and detection limit based on three times the standard deviation of the blank ($3S_b$) was 1.2 ng mL^{-1} in original solution. The relative standard deviation for eight replicate determination of 0.5 μg mL^{-1} silver was ±1.5%. The high efficiency of dispersive liquid–liquid microextraction to carry out the determination of silver in complex matrices was demonstrated. The proposed method has been applied for determination of trace amount of silver in standard and water samples with satisfactory results.

1. Introduction

The widespread use of silver compounds and silver-containing procedures in industry, medicine, jewellery, cloud seeding and in the disinfection of drinking water has resulted in an increasing silver content of environmental samples. Silver impregnated filters are used in water disinfection, while silver concentrations up to 200 μg L^{-1} is permitted for antimicrobial activities for human health [1]. Silver often presented as an impurity in Cu, Zn, As and Sb ores and thus it is possible to be entered into the environment from industrial wastes [2,3]. Bowen [4] suggested that silver may pose a potential risk as a water pollutant, because of the lack of recycling of mined silver. Also, recent information about the interaction of silver with essential nutrients, especially selenium, copper and vitamins E and B_{12}, has focused attention on its potential toxicity [1]. Consequently, determination of trace amounts of silver is important for many areas of chemical analysis.

Several atomic spectrometric techniques such as flame and electrothermal atomic absorption spectrometry (FAAS and ETAAS) [5–8], inductively coupled plasma atomic emission spectrometry (ICP-AES) [9] and inductively coupled plasma mass spectrometry (ICP-MS) [10–13] have been proposed for the determination of silver in different environmental samples. However, aforementioned methods except to FAAS involve a greater cost and increased instrumentation complexity, limiting its widespread application to routine analytical works. FAAS is still being used because it combines a fast analysis time, a relative simplicity and a cheaper cost. All of these features have been responsible for its broad utilization in the determination of trace elements in different samples. Although the development of modern analytical instruments provides a great enhancement in analysis, in many cases the available analytical instrumentation does not demonstrate enough sensitivity for the analysis of natural samples [14]. Nevertheless, the detection of metal trace elements in aqueous samples is difficult due to various factors, particularly their low concentration and the matrix effects [15]. Several methods have been reported for the separation and preconcentration of metal ions, such as coprecipitation [16,17], liquid–liquid extraction (LLE) [18,19], solid-phase extraction (SPE) [20–22] and cloud point extraction (CPE) [23–25], but the disadvantages such as time-consuming, unsatisfactory enrichment factors, large organic solvents and secondary wastes, limit their applications. In recent years, liquid-phase microextraction (LPME) has been developed as a solvent-minimized sample pretreatment procedure because it is inexpensive and has a minimal exposure to toxic organic solvents [26]. However, LPME method suffers from some disadvantages such as the fast stirring would

doi:10.1016/j.talanta.2009.08.009

tend to format air bubble [27], time-consuming and equilibrium could not be attained after a long time in most cases [28]. In order to overcome the problems, a novel modality of LPME termed as dispersive liquid–liquid microextraction (DLLME), was proposed recently [29].

DLLME is based on a ternary component solvent system like homogeneous liquid–liquid extraction and cloud point extraction. In this method, the appropriate mixture of extraction solvent and dispersive solvent is injected into an aqueous sample rapidly by a syringe, and a cloudy solution is formed. The analyte in the sample is extracted into the fine droplets of extraction solvent. After extraction, phase separation is performed by centrifugation. The advantages of the DLLME method are simplicity of operation, rapidity, low cost, high recovery, and enrichment factors. This method has been applied for the determination of trace organic pollutants and metal ions in the environmental samples [30–35].

The aim of this work is at combining DLLME with FAAS and proposes a new method for separation, preconcentration and determination trace amounts of silver in water and standard samples. In this work, DLLME as separation method and FAAS as analytical method were selected for preconcentration and determination of silver.

2. Experimental

2.1. Instrumentation

A SensAA GBC atomic absorption spectrometer equipped with deuterium background correction and silver hollow cathode lamp was used for absorbance measurements at wavelength of 328.1 nm according to instrument instruction. The instrumental parameters were adjusted according to the manufacturer's recommendations. A Metrohm 692 pH meter was used for pH measurements.

2.2. Reagents and solutions

All chemicals were of analytical-reagent grade and all solutions were prepared with deionized water. The laboratory glassware was kept overnight in a 1.4 mol L^{-1} HNO_3 solution. Before using, all of the glassware were washed with deionized water and dried. A stock solution of silver at a concentration of 1000.0 μg mL^{-1} was prepared by dissolving appropriate amounts of $AgNO_3$ (Merck, Darmstadt, Germany) in deionized water containing 1 mL concentrated nitric acid (Merck) and stored in the dark. The working reference solutions were obtained daily by stepwise dilution from stock solution with deionized water. A solution of 1% NaCl (Merck) was prepared by dissolving of 1 g of NaCl in 100 mL of deionized water. The solutions of alkali metal salts (1%) and various metal salts (0.1%) were used to study the interference of anions and cations, respectively.

2.3. Dispersive liquid–liquid microextraction procedure

An aliquot of 8.0 mL water samples or standard solutions were placed in a screw cap glass test tube with conic bottom and 1 mL of 0.1 mol L^{-1} phosphate buffer (pH 5.0) and 1 mL of NaCl 1% (w/v) were sequentially added to it. Then, 0.5 mL of ethanol (disperser solvent) containing 15.0 μL of carbon tetrachloride (extraction solvent) was injected rapidly into the sample solution. Then, the solution was centrifuged at 4000 rpm for 5 min, and the dispersed fine droplets of CCl_4 were deposited at the bottom of conical test tube. The sediment phase was removed and 0.50 mL of dimethylformamid (DMF) was added to it. The final solution was aspirated directly into the flame of AAS against the blank prepared in the same manner without the addition of metal ions.

2.4. Sample preparation

Tow certified reference material furnished by the Nippon Keikinzoku Kogyo (NKK) No. 916 and No. 920 Aluminum Alloy has been analyzed. Approximately 0.10 g of these materials were weighed accurately into a Teflon cup and dissolved in concentrated nitric acid (~10 mL) with heating on a water bath. The solutions were cooled, and pH was adjusted to 5 by NaOH and was diluted to 100.0 mL with deionized water in a calibrated flask. Then, 8.0 mL of the sample solution was taken individually and silver ion was determined by the general procedure.

X-ray photographic films were washed with distilled water and were cut into small pieces after drying in an oven at 40 °C for 20 min. Then, 5 mL of aqueous nitric acid (4 mol L^{-1}) was added to 0.01 g of film. The mixture was filtered and solution was diluted to 100.0 mL and pH adjusted to 5 by NaOH. An aliquot of the sample solution was taken and silver ion was determined by the general procedure.

Water samples were collected in acid leached polyethylene bottles. The only pretreatment was acidification to pH 2 with nitric acid, which was performed immediately after collection, in order to prevent adsorption of the metal ions on the flask walls. The samples were filtered before analyses through a cellulose membrane of 0.45 μm pore size (Millipore).

3. Results and discussion

In this study, combination of DLLME with FAAS was developed for determination trace amounts of silver. It is based on microextraction of silver chloride with using of ethanol as dispersive solvent and carbon tetrachloride as extraction solvent. At first, phosphate buffer and NaCl solution were added to silver solution. In this step, silver reacted with chloride ion for AgCl formation, then the aqueous, dispersive and extraction solvents were mixed and a cloudy solution was formed. After formation of cloudy solution, AgCl diffuses into the extraction solvent quickly, because of the infinitely large surface area between extraction solvent and the aqueous phase. Then, the solution was centrifuged and the dispersed fine droplets of CCl_4 were deposited at the bottom of conical test tube. The sediment phase was removed and DMF was added to it. The final solution was aspirated directly into the flame of AAS.

3.1. Selection of disperser solvent

The disperser solvent must be miscible in extraction solvent (organic phase) and also sample solution (aqueous phase). Therefore, acetone, methanol, ethanol and tetrahydrofuran were tested. The effect of these solvents on the extraction efficiency of DLLME was investigated using 1.0 mL of each solvent containing 15.0 μL of CCl_4 as the extraction solvent. The maximum extraction efficiency of DLLME was obtained by using ethanol as a disperser solvent. That is due to the high compatibility of ethanol with aqueous solution than other solvents. Therefore, ethanol was selected for further experiments.

3.2. Effect of the disperser solvent volume

The volume of the disperser solvent is one of the important factors to be considered in DLLME. At lower volumes of the disperser, tiny droplet formation may not be effective. Additionally, the lack of ethanol availability for partitioning into CCl_4 phase may occur. Both phenomena will decrease the extraction efficiency. When the volume of the dispersive solvent is an increased, two competitive processes may occur. One is the increase in the solubility of the analytes in the aqueous phase leading to diminished partition of the polar compounds into CCl_4 droplets. On the contrary, an increased volume of the partitioned ethanol phase into CCl_4 phase leads to

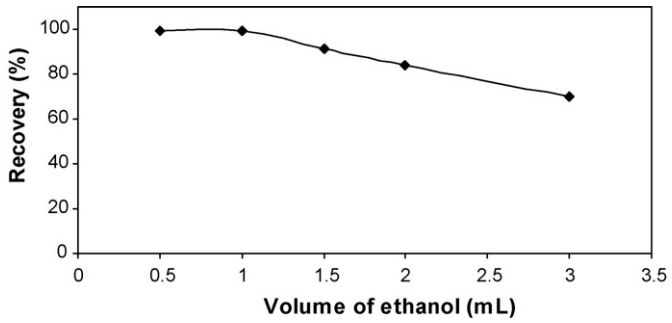

Fig. 1. Effect of the disperser solvent volume (ethanol) on the ligandless DLLME extraction. *Conditions*: Ag(I), 5.0 μg; buffer, 1 mL; NaCl 1% (w/v), 1 mL; and CCl_4, 15.0 μL.

increase in the extraction efficiency. Hence it was necessary to evaluate the volume effect of dispersive solvent. For this, a fixed amount of organic extractant (15.0 μL CCl_4) was dissolved in an increasing volume of the disperser ranging 0.5–3.0 mL. The results are presented in Fig. 1. It was observed that the extraction efficiency was constant up to 1.0 mL and then extraction efficiency was decreased for increasing volume of ethanol (1.0–3.0 mL). Finally, 0.5 mL ethanol was chosen as the optimum volume.

3.3. Selection of the extraction solvent

Choosing the most suitable extraction solvent is of primary importance to achieve good selectivity of the target compounds. This solvent must be immiscible with water and the solubility of analytes in this solvent in organic phase should be higher than the donor phase to promote the extraction of the analytes and in the case of DLLME, the density of the extraction organic solvent must be higher than water [36,37]. Dichloromethane (CH_2Cl_2), chloroform ($CHCl_3$), 1,2-dicholorobenzene (1,2-DCB) and carbon tetrachloride (CCl_4) were studied as extraction solvent. A series of sample solution were studied by using 0.5 mL of ethanol and 15.0 μL of different kind of extraction solvents. Three replicate tests were performed for each of these solvents under the same conditions. The results showed that, extraction efficiency of CCl_4 is higher than CH_2Cl_2, $CHCl_3$ and 1, 2-DCB. Therefore, CCl_4 was selected as extraction solvent for subsequent experiments.

3.4. Effect of the organic extraction volume

To study the effect of volume the extraction solvent, a series of solutions containing increasing volumes of CCl_4 (15.0–90.0 μL) dissolved in a fixed volume of ethanol were subjected to DLLME. The results are shown in Fig. 2. It was observed that the extraction efficiency was constant up to 30.0 μL and then extraction efficiency was decreased for increasing volume of CCl_4 (30.0–90.0 μL). A small

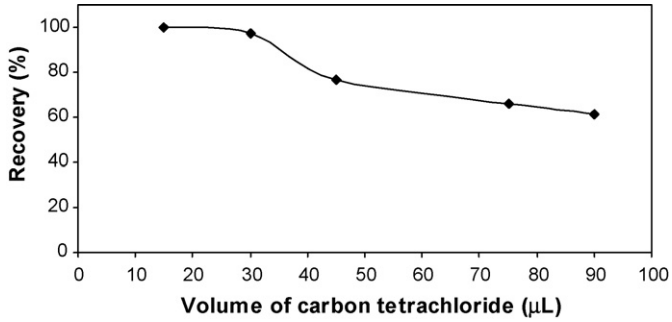

Fig. 2. Effect of the extraction solvent volume (CCl_4) on the ligandless DLLME extraction. Conditions were the same as Fig. 1.

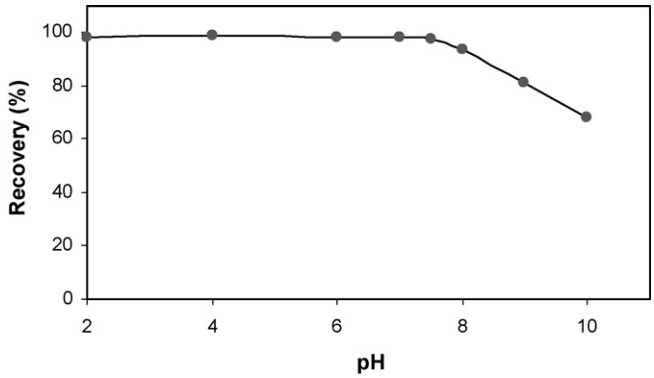

Fig. 3. Effect the pH of sample solution on the ligandless DLLME extraction of silver. Conditions were the same as Fig. 1.

decrease in efficiency was observed above 30.0 μL probably due to the decrease in the ratio between the dispersive and the extractant solvent. The decreased ratio lowers the number of droplets formation available for extraction thereby lowering the extraction efficiency. Based on these observations, 15.0 μL CCl_4 was used for further experiments.

3.5. Effect of pH

The effect of pH to the extraction systems was investigated in the range of 2–10 and keeping other variable constant. The results demonstrated in Fig. 3 reveals that the recovery is nearly constant in the pH range of 2.0–7.5. Accordingly, a pH approximately of 5 was selected for further experiments.

3.6. Effect of chloride concentration

The influence of the chloride concentration on the recovery of silver ion was studied in the range of 0.05–1% (w/v). The results are shown in Fig. 4. The recovery was increased by increasing the chloride concentration up to 0.3%. A further excess of 0.3% would cause a decrease in extraction. Therefore, the chloride concentration of 0.1% was selected for further experiments.

3.7. Effect of the extraction time

In DLLME, the extraction time is defined as interval time between the injection of the disperser and extraction solvents and the starting of centrifuge. The effect of extraction time was examined in the range of 10 s to 30 min with the constant experimental conditions. The obtained results showed that the extraction time was no significant influence on the signal of silver. Therefore, the DLLME method was time-independent, which was the most

Cd^{2+}	400	95

Conditions were the same as Fig. 1.

important advantage of this technique. In this method, the most time-consuming step was the centrifuging of sample solution in the extraction procedure. The process took about 5 min.

3.8. Effect of foreign ions

In view of the high selectivity provided by flame atomic absorption spectrometry, the only interference may be attributed to the separation step. Interferences studied were those related to the separation step, cations that may react with chloride or species that may react with analytes and decrease the extraction efficiency. To perform this study, interference ions in different interference-to-analyte ratios were added to a solution containing 5.0 μg of Ag(I) and were subjected to the recommended procedure. Table 1 shows the tolerance limits of the interference ions (error ±5%). The results demonstrate that the presence of large amounts of species commonly present in water samples have no significant effect on the DLLME of silver.

3.9. Calibration, precision and detection limit

Repeatability, linearity, correlation coefficient and detection limit were investigated under the optimized experimental conditions. For a sample volume of 8.0 mL, the calibration graph exhibited linearity over the range of 5.0 ng mL^{-1} to 2.0 μg mL^{-1} with a correlation coefficient of 0.9995 ($A = 0.46C + 0.007$). Eight replicate determination of 0.5 μg mL^{-1} silver gave a mean absorbance of 0.236 with relative standard deviation ±1.5%. Detection limit was 1.2 ng mL^{-1} for Ag(I) based on three times of blank standard deviation.

3.10. Accuracy of the method

The accuracy of the proposed method has been studied by adding silver ion in Nippon Keikinzoku Kogyo (NKK) No. 916 and No. 920 Aluminum Alloy. Results are given in Table 2 and were shown good recovery for silver ion. Therefore, the proposed method was shown good accuracy.

3.11. Analysis of water samples

The proposed procedure has been applied to the determination of silver content in different water samples. The results are given in Table 3.

The recovery of silver from water samples spiked with Ag(I) were also studied. The results were tabulated in Table 3. According this table, the added silver ion can be quantitatively recovered from the water samples by the proposed procedure.

These results demonstrate the applicability of the procedure for silver determination in water samples. The recovery of silver

added to the samples demonstrates the efficiency of the proposed method.

4. Conclusion

This work has been demonstrated combination of ligandless DLLME with flame atomic absorption spectrometry provides a novel route for trace determination of silver in water samples. The main benefits of the ligandless DLLME methodology were: minimum use of toxic organic solvent, simplicity, low cost, enhancement of sensitivity, and rapid analysis time.

A comparison of the represented method with the other reported methods [38–40] was shown in Table 4. As shown in Table 4, the detection limit of the proposed method is comparable to those in reported methods.

ABSTRACT

Simple and sensitive synchronous fluorimetric, and second derivative synchronous fluorometric methods were developed for the validated and simultaneous determination of sulpiride (SLP) and its alkaline degradation product (DSLP). The method is based on measuring the synchronous fluorescence of both the drug and its degradation product in borate buffer of pH 8 at $\Delta\lambda$ of 45 nm. The peak amplitude (^{2}D) was measured at 295.5 and 342 nm for SLP and DSLP, respectively. The different experimental parameters affecting the synchronous fluorescence intensity of both compounds were studied and optimized. The fluorescence–concentration plots were rectilinear over the range of 0.05–1.0 and 2–10 μg mL^{-1} for SLP and DSLP, respectively. The limits of detection (LOD) were 0.02 and 0.4 μg mL^{-1} and quantification limits (LOQs) were 0.05 and 1.2 μg mL^{-1} for SLP and DSLP, respectively. The proposed methods were successfully applied to commercial capsules and tablets. Statistical comparison of the results with those of the official method revealed good agreement and proved that there were no significant difference in the accuracy and precision between the two methods, respectively. The method was utilized to study the kinetics of the alkaline induced degradation of the drug. The application was further extended to include the *in vivo* and *in vitro* determination of sulpiride. The mean % recoveries (n = 3) were 100.22 ± 2.04 and 92.00 ± 3.00 for spiked and real human plasma, respectively.

1. Introduction

Sulpiride (SLP); 2-methoxy-*N*-((1-propylpyrrolidin-2-yl) methyl)-5-sulphamoyl benzamide (Fig. 1) is the most widely prescribed anti-psychotic drug. It is a selective dopamine D2 antagonist with antidepressant activities [1]. It has found widespread clinical applications for the treatment of acute and chronic schizophrenia as well as similar mental disorders such as hallucination [1].

The British Pharmacopoeia (BP) recommended non-aqueous titration method for the determination of SLP in its pure form, using perchloric acid as a titrant and glacial acetic acid as a solvent. For its dosage forms, the BP recommended a spectrophotometric method based on measuring its absorbance in 0.1 M NaOH at 291 nm [2]. Several methods have been reported for the determination of SLP in pharmaceutical preparations and biological fluids. These methods include: spectrophotometry [3], HPLC [4–8], capillary electrophoresis [9,10] and adsorptive stripping voltammetry [11].

A spectrofluorimetric method was reported for the determination of SLP in spiked human urine. It involved the incorporation of excitation–emission matrix (EEM) fluorescence and second-order calibration methodologies based on the alternating fitting residue (AFR) and self-weighted alternating trilinear decomposition (SWATLD) algorithms [12].

To the best of our knowledge, nothing has been reported concerning determination of SLP in presence of its alkaline degradation product (DSLP). For this reason our target was to study the application of second derivative synchronous fluorescence spectroscopic (SDSFS) technique for the simultaneous determination of SLP and DSLP. The present study describes a novel spectrofluorimetric method with enhanced sensitivity, specificity and good separation for the simultaneous determination of SLP and DSLP without prior separation step.

The proposed spectrofluorimetric method is more simple and more sensitive than the reported method [12].

Synchronous fluorescence spectroscopy (SFS) provided narrow and sharp spectrum contrast to broad fluorescence emission/excitation spectra obtained in conventional fluorescence measurement [13].

Synchronous fluorescence spectroscopy (SFS) can further be classified according to scanning modes of monochromators into constant-wavelength, variety-angle and constant-energy. At present study, constant-wavelength method, that is to maintain a constant difference between the emission and excitation wavelengths, is used.

doi:10.1016/j.talanta.2009.08.007

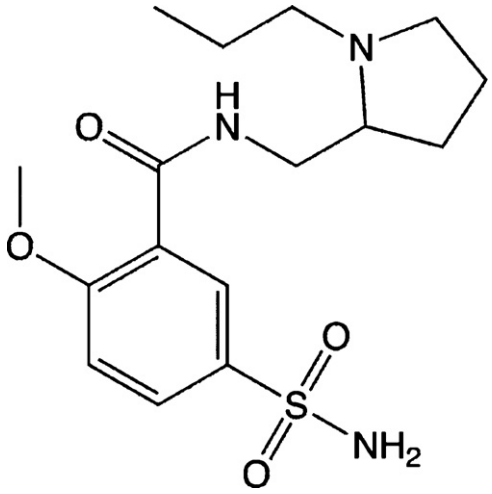

Fig. 1. Chemical structure of sulpiride.

The combination of SFS and derivatives is more advantageous than differentiation of the conventional emission spectrum in terms of sensitivity, because the amplitude of the derivative signal is inversely proportional to the bandwidth of the original spectrum [14]. Derivative synchronous fluorometric (DSF) technique is the most widely used in pharmaceutical analysis of several mixtures in their co-formulated dosage forms and biological fluids such as metoclopramide/pyridoxine [15], cinnarzine/nicergoline and cinnarzine/domperidone [16,17].

2. Experimental

2.1. Apparatus

The fluorescence spectra and measurements were recorded using a PerkinElmer model LS 45 luminescence spectrometer, equipped with a 150 W Xenon arc lamp, grating excitation and emission monochromators and a PerkinElmer recorder. Slit widths for both monochromators were set at 10 nm. A 1-cm quartz cell was used. Derivative spectra were evaluated using Fluorescence Data Manger (FLDM) software. FL WINLAB, Version 4.00.02, copyright 2001, PerkinElmer, Inc., UK. $\Delta\lambda$ of 45 nm was chosen as it resulted in two distinct peaks with good regular shapes and reduced the spectral interference caused by each compound in the mixture.

A pH meter (Model pHS-3C, Shanghai Leici Instruments, China) was used for pH adjustment.

2.2. Materials and reagents

All reagents and solvents were of Analytical Reagent grade.

Sulpiride pure sample was obtained from Sigma (St. Louis, Mo, USA) and used as received. Dogmatil® capsules each containing 50 mg SLP, batch # 3051022 (product of Memphis Chemical Co. For Pharmaceutical and Chemical Industries, Cairo, Egypt. Topmode® capsules each containing 50 mg SLP, batch # 14296 and Topmode® tablets each labelled to contain 200 mg SLP, batch # 61089 (products of Delta Pharm for Pharmaceutical Industries, Cairo, Egypt). All were obtained from local Pharmacy. Methanol (Merck, Darmstadt, Germany). Borate buffer (0.2 mol L^{-1}, pH 6–11). Acetate buffer (0.2 mol L^{-1}, pH 3.6–5.6). Sodium hydroxide and hydrochloric acid (BDH, UK), 2 mol L^{-1} aqueous solutions. Plasma samples were obtained from Mansoura University Hospital, Blood Bank, Mansoura, Egypt, and were kept frozen until use after gentle thawing.

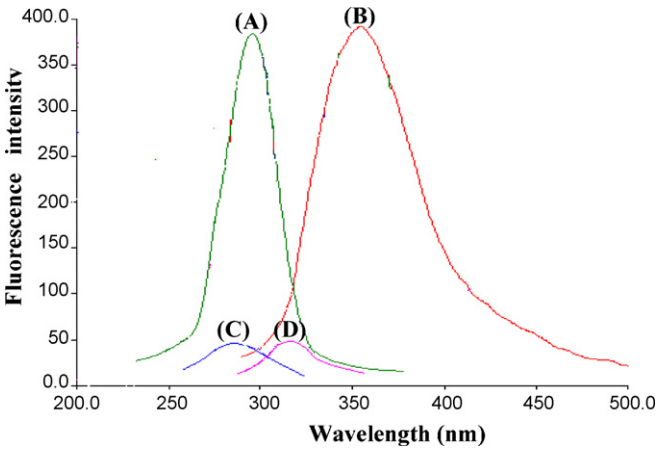

Fig. 2. Excitation and emission fluorescence spectra of: (A and B) SLP (1.0 μg mL^{-1}) and (C and D) DSLP (1.0 μg mL^{-1}).

2.3. Preparation of standard solution

2.3.1. Preparation of stock standard solution

Stock solution of SLP was prepared by dissolving 20.0 mg in 100 mL of methanol and was further diluted with the same solvent as appropriate. The standard solutions were stable for 10 days when kept in the refrigerator.

2.3.2. Preparation of alkaline degradation product

Methanolic SLP solution containing 400 μg mL^{-1} was mixed with 20 mL of 2 mol L^{-1} NaOH in a small flask, heated under refluxed in a boiling water bath for 2 h. The solution was cooled, neutralized with 2 mol L^{-1} HCl and transferred to 50 mL volumetric flask and diluted to the mark with methanol. This solution was further diluted with the same solvent as appropriate to obtain the working standard solutions.

2.4. Construction of calibration graph

Aliquots of SLP and DSLP standard solutions covering the working concentration ranges were transferred into a series of 10 mL volumetric flasks. Two milliliters of borate buffer (pH 8.0) were added, and the solution was completed to the volume with distilled water. The synchronous fluorescence spectra of the solutions were recorded by scanning both monochromators at a constant-wavelength difference, $\Delta\lambda$ of 45 nm and scan rate of 600 nm min^{-1} using 10 nm excitation and emission windows. The second derivative fluorescence spectra of SLP and DSLP were derived from the normal synchronous spectra using FLDM software. For best resolution and smoothing, the number of points used were 99 for deriving the second derivative spectra. The fluorescence intensities of the second derivative spectra were estimated at 295.5 and 342 nm for SLP and DSLP, respectively. A blank experiment was carried out simultaneously. The peak amplitude of the second derivative technique was plotted *versus* final concentration (μg mL^{-1}) to get the calibration graphs. Alternatively, the corresponding regression equations were derived.

2.5. Procedure for the synthetic mixture

Aliquots of SLP with DSLP standard solutions in different ratios were transferred into a series of 10 mL volumetric flasks. Two milliliters of borate buffer (pH 8.0) were added, and completed to the volume with distilled water and mixed well. The procedure described under Section 2.4 was performed.

2.6. Procedure for commercial capsules and tablets

The contents of 10 capsules were emptied and mixed well. For tablets, 20 tablets were weighed and pulverized well. A weighed quantity of the powdered capsules or tablets equivalent to 20.0 mg of SLP was transferred into a small conical flask and extracted with 3 × 30 mL of methanol. The extract was filtered into a 100 mL volumetric flask. The conical flask was washed with few mLs of methanol. The washings were passed into the same volumetric flask and completed to the volume with the same solvent. Aliquots covering the working concentration range were transferred into a series of 10 mL volumetric flasks. The procedure described under Section 2.4 was applied. The nominal content of the capsules or tablets was determined either from the previously plotted calibration graph or using the corresponding regression equation.

2.7. Procedure for spiked human plasma

One ml aliquots of plasma were transferred into a series of centrifuge tubes. Aliquots of sulpiride working solution were added so that their final concentration is in the range of 0.05-0.15 μg mL^{-1}. 0.1 mL of 1 mol L^{-1} NaOH was added. The samples were mixed well using a vortex mixer, then extracted with 3 × 3 mL of ethylacetate/dichloromethane (5:1, v/v) by centrifugation for 5 min at 3500 rpm. The organic layer was transferred into an evaporating dish and evaporated till dryness. The residue was reconstituted in 3 mL of methanol. The procedure described under Section 2.4 was followed. The nominal content of the drug was determined from the previously plotted calibration graph or using the corresponding regression equation.

2.8. Procedure for real human plasma

Sulpiride (50 mg/capsule) was orally administered to a healthy fasting volunteer (male, 40 years old). Five milliliters of blood sample was withdrawn after 4 h, 4 mL of citrate solution was added, and centrifuged at 3500 rpm for 15 min to get about 3 mL of plasma. The "procedure for spiked human plasma" was applied. The nominal content of SLP in plasma was determined adopting the following equation [18]:

$$\text{Recovery}_{\text{“}in\ vivo\text{”}} = \text{Delivery}_{\text{“}in\ vivo\text{”}} \times \text{Recovery}_{\text{“}in\ vitro\text{”}}/\text{Delivery}_{\text{“}in\ vitro\text{”}}$$

$$\text{The \% recovery for sulpiride in real human plasma} = \frac{\text{concentration of the drug in real plasma} \times \text{\% recovery in spiked plasma}}{\text{concentration of the drug in spiked plasma}}$$

3. Results and discussion

Both sulpiride and its alkaline degradation product exhibit native fluorescence at 350 and 317 nm, after excitation at 295 and 288 nm, respectively, as shown in Fig. 2.

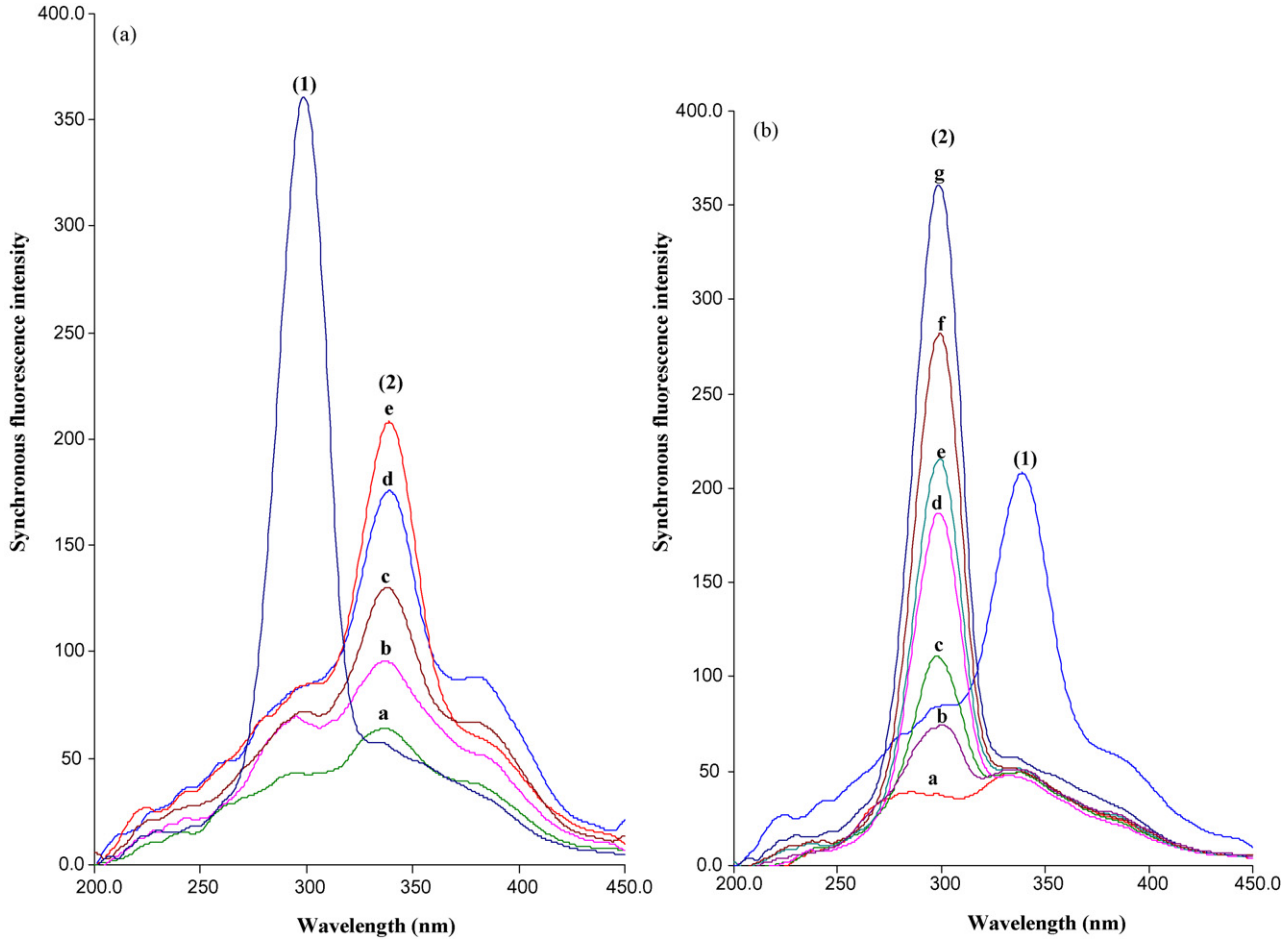

Fig. 3. (a) Synchronous fluorescence spectra of: (1) SLP (1 μg mL^{-1}) at 299 nm and (2) (a–e) of DSLP (2, 4, 6, 8 and 10 μg mL^{-1}) at 336 nm. (b) Synchronous fluorescence spectra of: (1) DSLP (10 μg mL^{-1}) at 336 nm and (2) (a–g) of SLP (0.1, 0.2, 0.3, 0.5, 0.6, 0.7 and 1 μg mL^{-1}) at 299 nm.

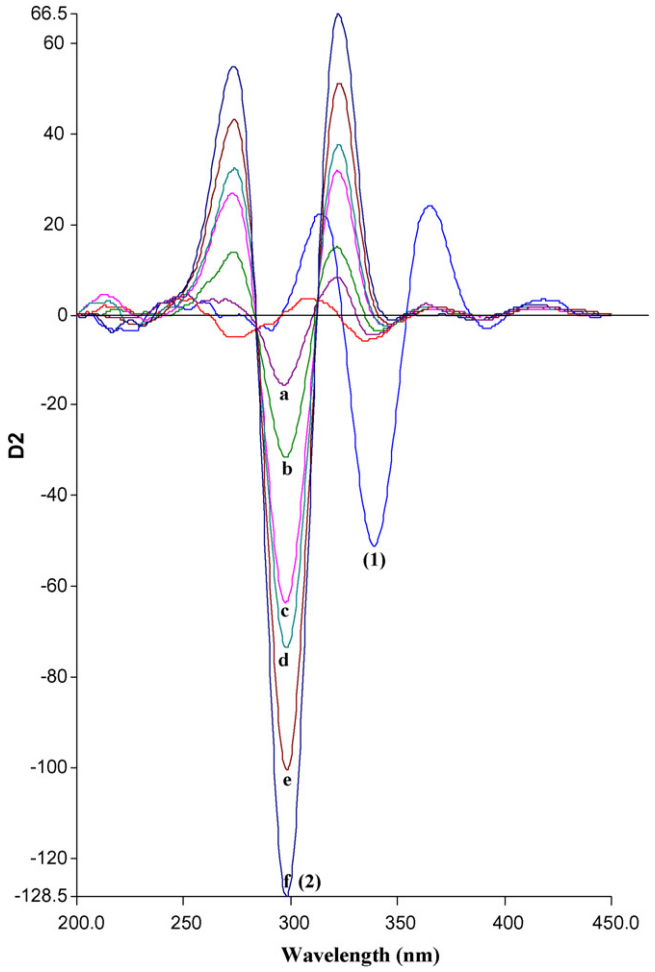

Fig. 4. Second derivative synchronous fluorescence spectra of: (1) DSLP (10 μg mL^{-1}) at 342 nm and (2) (a–f) of SLP (0. 1, 0.2, 0.5, 0.6, 0.8 and 1 μg mL^{-1}) at 295.5 nm.

Fig. 3(a) and (b) shows the synchronous fluorescence spectra of SLP at 299 and different concentrations of DSLP at 336 nm and SF spectra of different concentrations of SLP at 299 nm and DSLP at 336 nm, respectively. It is clear that, there is strong overlapping between the two spectra. This led us to adopt second derivative synchronous fluorescence spectroscopy (SDSFS) technique for the simultaneous determination of the two compounds. The fluorescence spectra of SLP and DSLP were well separated with a zero-crossing point for each compound. Under the described experimental conditions, the two peaks appeared at 295.5 for SLP (Fig. 4) and 342 nm for DSLP (Fig. 5).

The different experimental parameters affecting the fluorescence of the studied compounds were carefully studied and optimized. Such factors were changed individually while others were kept constant. These factors included $\Delta\lambda$ selection, pH, type of diluting solvent and stability time.

3.1. Effect of pH

The influence of pH on the synchronous fluorescence intensity of the studied compound and its degradation product was studied. Different salts were used to prepare the various kinds of buffers covering the whole pH range, such as 0.1 M HCl of pH 1.0, acetate buffer, borate buffer and 0.1 M NaOH. The results showed that, the synchronous fluorescence intensity of SLP increased with the increase of pH up to 7.8, then remained constant up to pH 8.2, after which the fluorescence intensity decreased gradually.

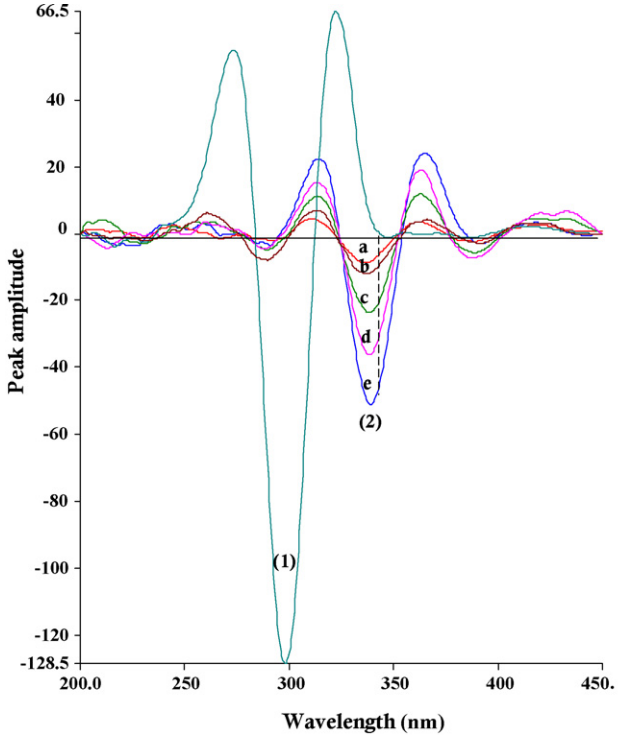

Fig. 5. Second derivative synchronous fluorescence spectra of (1) SLP (1 μg mL^{-1}) at 295.5 nm and (2) (a–f) of DSLP (2, 4, 6, 8 and 10 μg mL^{-1}) at 342 nm.

3.2. Effect of diluting solvent

Dilution with different solvents such as water, methanol, isopropanol, dimethyl sulphoxide (DMSO), tetrahydrofurane (THF) and dimethyl formamide (DMF) was attempted. Each of DMSO, THF and DMF decreased the fluorescence intensities of SLP, since they initiated intersystem crossing process (similar to heavy atom effect) [19]. On the other hand, the fluorescence intensities of SLP and DSLP were higher in water compared to other solvents. Moreover, its use adds another advantage of the method. The results are summarized in Table 1. In water, the fluorescence readings were stable for up to 2 h as revealed in Table 1.

Table 1
Effect of solvents and time on the synchronous fluorescence intensity of sulpiride (1 μg mL^{-1}).

Parameter	Synchronous fluorescence intensity
1: Effect of solvents	
Water	377

Slope	121.9	4.1
Intercept	0.017	−0.13
Limit of detection (LOD) ($\mu g\,mL^{-1}$)	0.02	0.4
Limit of quantification (LOQ) ($\mu g\,mL^{-1}$)	0.05	1.2
$S_{y/x}$: standard deviation of the residuals	0.26	0.53
S_a: standard deviation of the intercept	0.64	0.49
S_b: standard deviation of the slope	0.280	0.074
% RSD = relative standard deviation	1.24	1.93
% Error = % RSD/$\sqrt{n}$	0.47	0.86

3.3. Analytical performance

The fluorescence–concentration plots for the studied compounds by SDSFS were linear over the concentration ranges of 0.05–1.0 and 2–10 $\mu g\,mL^{-1}$ for SLP and DSLP, respectively (Table 2). Linear regression analysis of the data gave the following equations:

For SLP:. . .. . .

$$^2D = 0.017 + 121.9C \quad (r = 0.9999)$$

For DSLP:. . .. . .

$$^2D = -0.13 + 4.1C \quad (r = 0.9994)$$

where ^2D is the peak amplitude in the second derivative synchronous fluorescence mode, C is the concentration of the drug ($\mu g\,mL^{-1}$).

LOQ and LOD were calculated according to ICH Q2B recommendations [20]. The values of LOD and LOQ for SLP and DSLP by SDSFS method are abridged in Table 2.LOQ and LOD were calculated according to the following equation [20]:

$$LOQ = 10\sigma/S$$

$$LOD = 3.3\sigma/S$$

S is the slope and σ is the standard deviation of the intercept of regression line of the calibration curve.

The proposed method was evaluated by studying the accuracy as percent relative error and precision as percent relative standard deviation. The results are abridged in Table 2.

Statistical analysis of the results obtained by the proposed and the official methods [2] using Student's t-test and variance ratio F-test [21] shows no significant difference between the performance of the two methods regarding the accuracy and precision, respectively as shown in Table 3.

3.4. Analysis of mixture of SLP and DSLP

The proposed method was applied to the simultaneous determination of SLP and DSLP in synthetic mixtures containing different concentrations of both compounds in different ratios (Table 4). The concentrations of both compounds in the synthetic mixture were calculated according to the linear regression equation. The results indicate the accuracy of the proposed method as shown in Table 4.

3.5. Validation of the method

The proposed method was tested for linearity, specificity, accuracy and precision. Linear regression equations using the proposed method were obtained. The regression plots showed a linear dependence of peak amplitudes on drug concentration over the range

cited in Table 2. Statistical evaluation of the regression lines for SLP and DSLP, respectively, regarding standard deviation of the residual ($S_{y/x}$), standard deviation of the intercept (S_a) and standard deviation of the slope (S_b) is given in Table 2. The small value of the figures point out to low scattering of the points around the calibration curve and thus indicating the high accuracy and high precision of the method.

3.5.1. Precision

The intra-day precision was evaluated through replicate analysis of different concentrations of SLP (0.2–0.6 $\mu g\,mL^{-1}$) both in raw material and in dosage forms. Each sample was analyzed three successive times. The precision expressed by % RSD values were fairly acceptable. The results are summarized in Table 5.

Similarly, the inter-day precision was evaluated through replicate analysis of the same samples on three successive days. The results obtained are abridged in Table 5.

3.5.2. Accuracy

The accuracy of the proposed method was evaluated by analyzing standard solutions of the studied drug and the results were favorably compared with those obtained using the British Pharmacopoeia method [2].

The robustness of the proposed method is demonstrated by the constancy of the fluorescence intensity with the deliberated changes in the experimental parameters such as pH, 8.0 ± 0.2. This minor change that may take place during the experimental operation did not greatly affect the fluorescence intensity SLP and DSLP, respectively.

3.6. Validation of the method as applied to pharmaceutical preparations

The proposed method was applied to the determination of the studied drug in its commercial tablets and capsules. The selectivity of the method was investigated by observing any interference encountered from the common excipients, such as starch, lactose, magnesium stearate and avisil. These excipients did not interfere with the proposed method. The results were compared with those obtained using the BP method [2]. Statistical analysis of the results [21] obtained using Student's *t*-test and variance ratio *F*-test revealed no significant difference between the performance of the two methods regarding the accuracy and precision, respectively (Table 3).

3.7. Application to plasma samples

The high sensitivity of the proposed method allowed the determination of SLP in biological fluids by SDSFS technique. Sulpiride is absorbed from gastro-intestinal tract. Following oral ingestion of a single oral dose of 50 mg of SLP, a peak plasma concentration of 0.03–0.60 $mg\,L^{-1}$ (mean 0.18 $mg\,L^{-1}$) is attained in about 4–7 h [22]. This value lies within the working concentration range of the proposed method. The method involved extraction with ethylacetate/dichloromethane (5: 1, v/v). The extraction procedure described by Huang et al. [23] was adopted. The proposed method applied to spiked human plasma was tested for linearity, specificity, accuracy and precision, respectively.

The second derivative signal of SLP–concentration plot in spiked human plasma was applied over the working concentration. Linear regression analysis of the results gave the following equation:

$$^2D = -0.203 + 98.70C \quad (r = 0.999) \quad \text{for SLP}$$

Second derivative synchronous fluorescence spectroscopy (SDSFS) is specific for the determination of SLP at 295.5 nm. The proposed method was applied to human plasma by studying the accuracy as percent relative error and precision as percent relative standard deviation. The results are abridged in Table 6.

Intra-day precision was evaluated through replicate analysis of plasma samples spiked with different concentrations of the drug (0.05–0.15 $\mu g\,mL^{-1}$). The mean percentage recoveries based on the average of three separate determinations were 100.22 ± 2.04 and 92.00 ± 3.00 for spiked and real human plasma, respectively (Table 6).

Table 5
Validation of the proposed method to the determination of sulpiride using SDSF mode.

0.60	100.09 ± 1.73	1.73	0.75

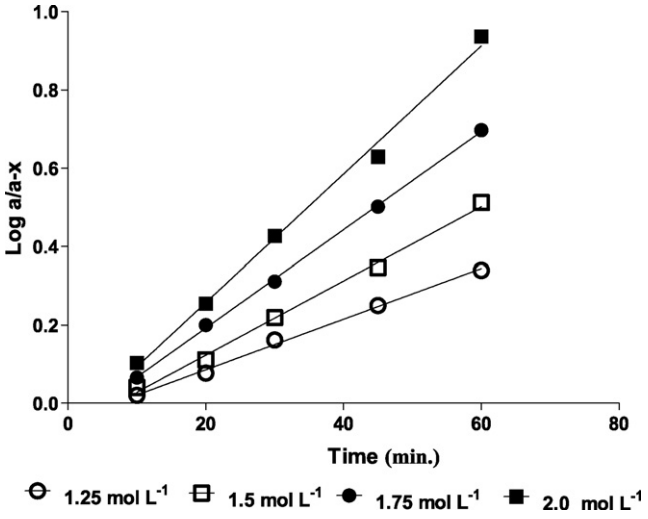
Inter-day precision was performed through replicate analysis of plasma samples spiked with 0.10 $\mu g\,mL^{-1}$ SLP on three successive days and the results are abridged in Table 6.

3.8. Degradation kinetics Study

The alkaline treatment of sulpiride with 2 mol L^{-1} NaOH was accompanied by a gradual decrease in the synchronous fluorescence intensity. Upon heating in a boiling water bath for 2 h complete degradation of the drug occurred as revealed by complete disappearance of the synchronous fluorescence spectrum of the drug at 299 nm and the appearance of a new fluorescence spectrum peak at 336 nm. The degradation was found to be temperature dependent (Fig. 6). The apparent first order degradation rate constant and half-life time at each temperature were calculated (Table 7). By plotting log K_{obs} values *versus* $1/T$, Arrhenius plot was obtained. The activation energy E_a was calculated and was found to be 7.57 K Cal mol^{-1} (Table 7).

3.8.1. Pathway of degradation

Upon heating sulpiride in alkaline medium, it undergoes complete degradation. Being an amide, SLP is proposed to be decomposed to the corresponding carboxylic acid (sodium salt) (A) and the primary amine (B). Also, the sulphonamide group is probably hydrolysed to the corresponding sulphonic acid (sodium salt) (A) and ammonia. Compound B is non-fluorescent as it is devoid of conjugation and chromophores. So the entire study is devoted to compound (A). The proposal of the alkaline degradation pathway is postulated in the following Scheme 1.



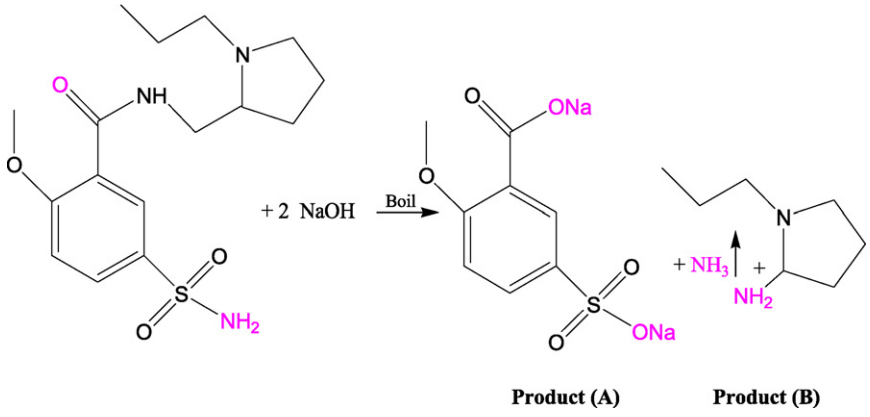


Fig. 6. Semilogarithmic plot of sulpiride (20 $\mu g\,mL^{-1}$) *versus* different heating times using different molarities of NaOH: 1.25 mol L^{-1} NaOH, 1.5 mol L^{-1} NaOH, 1.75 mol L^{-1} NaOH and 2 mol L^{-1} NaOH.

Table 6
Application of the proposed method for the determination of sulpiride in spiked and real human plasma.

Sample	Amount added ($\mu g\,mL^{-1}$)	Amount found ($\mu g\,mL^{-1}$)	Recovery (%)

Table 7
Effect of temperature on the kinetic parameters of the degradation of sulpiride.

Temperature (°C)	K (min^{-1})	$t_{1/2}$ (min)	E_a (K Cal. mol L^{-1} K)
70	0.016	45	6.55
80	0.021	34	6.99
90	0.027	26	9.16
100	0.038	18	X' = 7.57

4. Conclusion

The present study described a fully validated and novel second derivative synchronous spectrofluorimetric method for the simultaneous determination of sulpiride and its degradation product with enhanced sensitivity and specificity. The proposed method do not require elaborate treatment for the sample or tedious procedure for the extraction. As well as, the method is sensitive enough for the analysis of lower concentration of sulpiride as low as 0.05 $\mu g\,mL^{-1}$. Furthermore, the proposed method is a good analytical tool for the determination and monitoring of sulpiride in spiked and real human plasma.

Protein separation

ABSTRACT

In this work, biomimetic technique was proposed for the first time to prepare chromatographic packings (2HAp-ZM) for protein separation. By mimicking the mineralization procedures in vivo, this type of matrix with hydroxyapatite (HAp) coating and zirconia–magnesia (ZM) composite core was fabricated. Systematic characterizations, including scanning electron microscopy (SEM), X-ray photoelectron spectroscopy (XPS), X-ray diffraction (XRD) and specific surface area analysis, were carried out to investigate the properties of the material. Results showed that the surface of 2HAp-ZM was composed of bead-like, amorphous or nanocrystalline HAp. The specific surface area, total pore volume, and average pore diameter of the resultant material were 25 m^2/g, 0.09 cm^3/g, and 14 nm, respectively. Furthermore, 2HAp-ZM exhibited good mechanical stability through repeated testing and its application as stationary phases for protein separation was then studied. Five model proteins (bovine serum albumin, trypsin, lysozyme, ribonuclease A, and cytochrome *c*) were successfully separated on 2HAp-ZM. Finally, the mass recovery of protein and the dynamic loading capacity were studied; the results were calculated to be no less than 93% and 80 μg/mL of blank column volume, respectively.

1. Introduction

Protein separation has been attracting increasing interests with the development of biology and physiology in recent years. High-performance liquid chromatography (HPLC) is by far the most widely utilized technique in this field; its performance is mainly based on the packing materials [1]. In this case, some common criteria have been proposed to dictate the selection of chromatographic media for protein separation in a previous review [2], which are summarized as: (a) chemically and physically stable to withstand regeneration and cleaning procedures; (b) good mechanical strength to allow high flows; (c) not containing groups that bind proteins non-specifically; (d) easy to be derived to allow the introduction of functional groups for interactive chromatography applications; (e) good control of particle size and pore size; (f) high selectivity and loading capacity; (g) low cost. However, it is often not possible to reconcile all the criteria, and therefore compromises have to be searched and further development of the stationary phases is required for their application to protein separation.

During the past decades, continuous efforts have been devoted to improve the stationary phases for protein chromatography by the employment of new packing materials. Zirconia (ZrO_2) was introduced as a competitive alternative to the traditional silica with enhanced chemical, thermal or mechanical stability [3]. This advantage made it can be cleaned and sterilized using hot acids and bases to remove irreversibly adsorbed proteins [4–6]. Furthermore, this oxide showed ligand-exchange behavior due to the presence of Lewis acid sites at its surface, which could interact with Lewis bases, such as fluoride, phosphate ions or carboxylic acids, and also with the carboxyl groups of proteins. Hence, protein separation was able to be achieved using a mobile phase containing strong Lewis base at well defined concentrations [7,8] or on a strong Lewis base-modified ZrO_2 [9–14]. Unfortunately, its selectivity and loading capacity were relatively limited, owing to the single modal mechanism of separation and lower surface area, respectively [9,10].

Hydroxyapatite [HAp: $Ca_{10}(PO_4)_6(OH)_2$] was another promising medium for protein separation. It had unique bioaffinity and biocompatibility, which could adsorb and desorb biomolecules such as proteins and nucleic acids without denaturation [15–17]. Its underlying mechanism of separation was multimodal [1,18–23]: cation exchange took place at PO_4^{3-} (P) sites; anion exchange as well as ligand exchange took place at Ca^{2+} (C) sites. Nevertheless, the original crystalline HAp was too fragile to withstand high packing pressure and flow rates [2]. One way to solve this problem was the preparation of ceramic HAp, which was sintered into a spherical particle with large pores [24]. The other was the fabrication of HAp-based composites. Majumder and Ramesh [25] suspended phosphorylated silica in 2 M $CaCl_2$ solution and then in 1 M phosphate buffer to obtain a HAp substitute, which could be employed for open column LC as well as for HPLC purpose. Though it was

successfully used in the purification of topoisomerase I and II from wheat germ, no detailed information on its morphological features or stability were reported. Later on, Honda et al. [26,27] reported two kinds of HAp-coated composite particles, which were made of orthodox fragile HAp (or cattle bone powder) and polyethylene beads by the dry impact blending method. Irreversible adsorption of proteins onto the columns was observed during the chromatographic running.

Considering the inherent properties of the packing materials listed above, we aimed at preparing a type of matrix that consisted of a HAp surface and a ZrO_2-based core for protein chromatography. Through integrating unique bioaffinity and biocompatibility, and excellent thermal and mechanical stability as a whole, this stationary phase was expected to provide better separation efficiency and larger application scale. Thus, it is of great importance to select an appropriate method to achieve this objective.

Biological systems are a rich source of ideas for individuals concerned with the synthesis of new materials and processes [28], from which the biomimetic technique was derived and developed. The biomimetic technique was a low-cost and facile process to coat implants (usually used in orthopedic surgery) with calcium phosphate [29–34]. It was performed by soaking substrates under mild pH and temperature conditions into simulated body fluid (SBF) solutions that have a similar inorganic content as human blood plasma [35]. Once the apatite nuclei formed on the surface of the substrate, they could spontaneously grow by consuming the calcium and phosphate ions from the fluid [36]. It was worthwhile to point out that the functional groups on the surface of the substrate were important to induce the nucleation of apatite [37]. Wen et al. [38] reported that HAp could deposit and grow on oxide layers of titanium in a modified SBF solution (supersaturated calcification solution, SCS), indicating TiO_2 were favorable to induce apatite formation in the body environment. Fortunately, ZrO_2 possessed the similar surface chemical properties as TiO_2 [39], which inspired us that biomimetic technique would be a feasible pathway to prepare HAp-coated zirconia–magnesia (a ZrO_2-based composite) as stationary phase for protein chromatography.

In the present work, HAp-coated zirconia–magnesia (ZM) microspheres were prepared via biomimetic technique by incubating the substrates in SCS and applied to the separation of proteins with HPLC. This was, to the best of our knowledge, the first demonstration of using biomimetic technique to fabricate chromatographic packings for biological analysis. Five proteins, i.e. bovine serum albumin, trypsin, lysozyme, ribonuclease A, and cytochrome *c*, were employed as model analytes to evaluate the separation performance of the resultant materials. Enhanced separation efficiency and dynamic loading capacity, as well as improved mechanical stability, were observed when compared with unmodified ZM and HAp, respectively.

2. Experimental

2.1. Chemicals and materials

ZM microspheres (8–10 μm) were synthesized by sol–gel method in our laboratory [40]. Tiselius type HAp, NaCl, KCl, anhydrous Na_2HPO_4 (NaP), $CaCl_2$, HCl, trihydroxymethylaminomethane (Tris), anhydrous K_2HPO_4 (KP) and H_3PO_4 were purchased from Shanghai General Chemical Reagent Factory (Shanghai, China). Lysozyme was purchased from Shanghai Bio Life Science & Technology (Shanghai, China). Trypsin was purchased from Amresco (Solon, OH, USA). Bovine serum albumin (BSA), ribonuclease A (RNase A), cytochrome *c* (Cyt *c*), ovalbumin and α_1-acid glycoprotein (AGP) were purchased from Sigma (St. Louis, MO, USA). Double-distilled water was used for all experiments.

2.2. Preparation of SCS

The SCS was prepared according to the method described by Kokubo et al. [41] with a little modification. NaCl, KCl, anhydrous NaP and $CaCl_2$ were dissolved one by one in distilled water, the concentrations of each ion were listed as follows: $[Na^+] = 136.8$ mM, $[K^+] = 3.71$ mM, $[Cl^-] = 144.5$ mM, $[Ca^{2+}] = 3.10$ mM, and $[HPO_4^{2-}] = 1.86$ mM. The SCS was buffered at pH 7.4 with HCl and Tris at 36.5 °C. After preparation, it was preserved at 5–10 °C in a refrigerator, and was used within 30 days.

2.3. Preparation of the HAp-coated ZM microspheres

The preparation of HAp-coated ZM was composed of four successive steps: activation, pre-calcification, incubation, and calcination.

ZM microspheres were firstly dispersed in 1 M NaOH at room temperature overnight, then washed to neutral and dried at 160 °C for 8 h. Pre-calcification treatment was then performed by immersing the activated ZM in 0.5 M NaP solution at 100 °C for 12 h, followed by suspending them in freshly prepared saturated $Ca(OH)_2$ solution for 2 h. The particles were thoroughly rinsed with distilled water and dried at 120 °C. Afterwards, the pretreated ZM were soaked in SCS in a 36.5 °C water bath to produce HAp coatings on their surfaces. The SCS was replaced every 2 days. In this study, all the HAp-coated ZM were denoted as HAp-ZM, ZM obtained after one incubation in SCS were denoted as 1HAp-ZM, after two incubations in SCS were denoted as 2HAp-ZM, and so forth. Finally, the calcination procedure was carried out by heating at a rate of 0.5 °C/min to 600 °C and holding for 2 h to age the HAp coating.

2.4. Instrumentation

Surface morphology of the particles was displayed by a QUANTA-200 scanning electron microscopy (SEM) system (FEI, Eindhoven, the Netherlands). Ca/P ratios of the HAp coatings were determined by an XSAM800 X-ray photoelectron spectroscopy (XPS) system (Kratos, Manchester, UK), with Mg Kα radiation as the exciting source. Crystal structure of HAp-ZM was determined with an XRD-6000 X-ray diffraction (XRD) system (Shimadzu, Kyoto, Japan) using Cu Kα radiation and a rotating anode operating at 40 kV and 30 mA. Specific surface area, pore volume, and pore size were measured by nitrogen sorption at 77 K using a SA3100 Plus surface area analyzer (Beckman, Fullerton, CA, USA).

2.5. Chromatographic conditions

Unmodified ZM and 2HAp-ZM were both slurry-packed into 150 mm × 4.6 mm I.D. stainless steel columns with 0.3 M sodium phosphate buffer (pH 6.8) at 6000 psi.

All chromatographic measurements were carried out at room temperature on an Agilent 1100 HPLC system (Agilent Technologies, Palo Alto, CA, USA) including a Rheodyne Model 7125 injector with a 20 μL loop, a quaternary pump, a micro-vacuum degasser and a diode array detector (DAD). Separation of proteins was performed at a flow rate of 1 mL/min. The gradient elution was firstly water for 3 min, and then transferred to 300 mM, pH 6.8 NaP buffer in 1 min, delayed for 12 min, at last transferred to 500 mM, pH 6.8 KP buffer in 1 min, and delayed for 18 min. The eluent was monitored at 220 nm. When investigating the dynamic loading capacity of the 2HAp-ZM stationary phase, 1 mL injection loop was used.

2.6. Protein recovery studies

The protein mass recovery was measured according to a previously reported method [9,10], by comparing the amount of protein

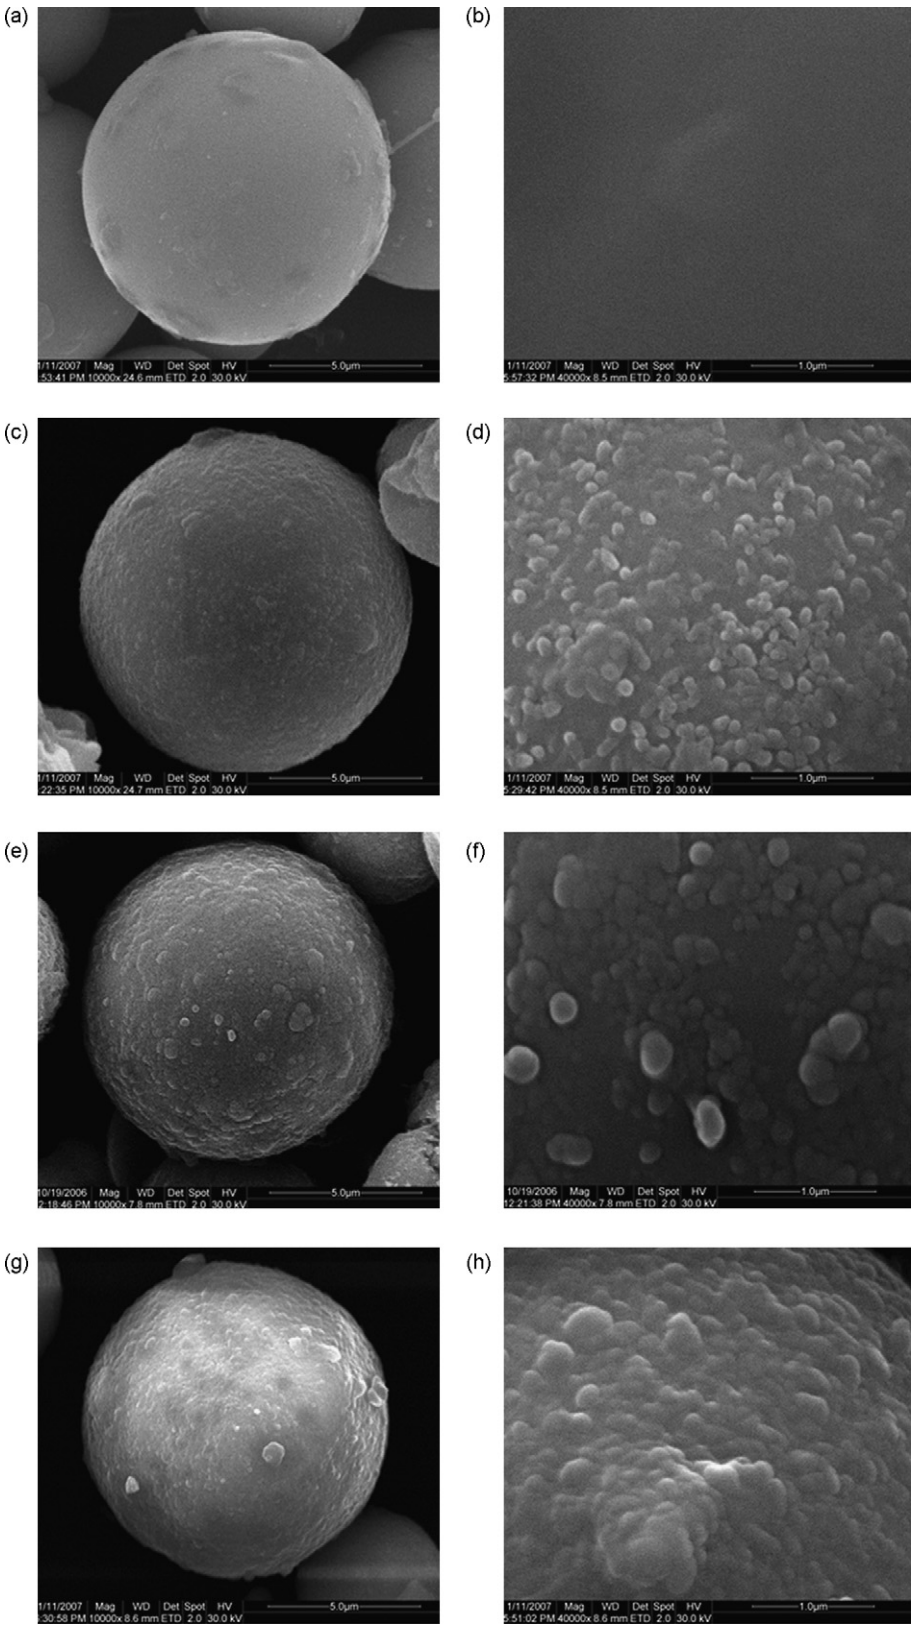

Fig. 1. Typical SEM photographs of unmodified ZM and HAp-ZM: (a), (b) unmodified ZM; (c), (d) pre-calcified ZM; (e), (f) 2HAp-ZM; (g), (h) 10HAp-ZM.

collected in a control experiment in which the column was replaced with a zero dead volume pipe to that obtained with the column in place. The mass recovery was calculated as follows:

$$\text{mass recovery\%} = \frac{\text{area (column)}}{\text{area (pipe)}} \times 100\%$$

The proteins were eluted isocratically, and the analysis was repeated three times for each protein.

3. Results and discussion

By definition, biomimetic technique for HAp deposition is the mimic formation of inorganic compounds in vivo (biomineralization). Its mechanism is complicated and the process is time-consuming. Hence, pre-calcification was proposed to accelerate the precipitation rate of HAp [38]. In this procedure, phosphate anions and calcium cation were adsorbed onto ZM surface one after the other; and a nonstoichiometric calcium phosphate was formed. When the pre-calcified ZM were immersed in SCS, some components are released from the material into the fluid and, thereby, increase the ionic activity product of the apatite, which can accelerate apatite formation. Additionally, SCS rather than SBF was utilized in this study because the former one provided higher concentration of phosphate and calcium ions, which could consequently speed up the deposition rate of apatite [42].

3.1. Characterization of the HAp-ZM

Direct observation of the surface morphology of unmodified ZM and HAp-ZM is provided by the SEM micrographs illustrated in Fig. 1. Fig. 1b shows a smooth surface of unmodified ZM, and Fig. 1d, f and h shows the modified surfaces of ZM after pre-calcification, 2 and 10 repetitions of incubation in SCS, respectively. It can be seen that rod-like nanoparticles are formed on the substrate after pre-calcification (Fig. 1d), which is speculated to be composed of nonstoichiometric calcium phosphate. After repeating the immersion in SCS, the rod-like nanoparticles grow more and bigger (bead-like, Fig. 1f) gradually, and finally a dense and uniform HAp coating emerged via attraction and attachment of the nanoparticles (Fig. 1h).

The composition of HAp coating on the surfaces of ZM was characterized by XPS. Results are shown in Fig. 2. It can be found that considerable amount of Ca and P elements has existed on ZM after 4 days immersing in SCS. Increasing the immersion time, tiny differences in peak area of Ca, P and Zr are observed between 2HAp-ZM and 10HAp-ZM. This means that a HAp coating was basically formed at the stage of 2HAp-ZM; long immersion time was avoided because of the introduction of pre-calcification treatment, which stimulates the apatite nucleation and accelerates the growth rate of the HAp layer. Furthermore, the Ca/P ratio of the resultant coating is calculated to be 1.59, close to the Ca/P ratio of HAp 1.66. Therefore, we considered that this coating was mainly composed of HAp and 2HAp-ZM was selected for the following experiments.

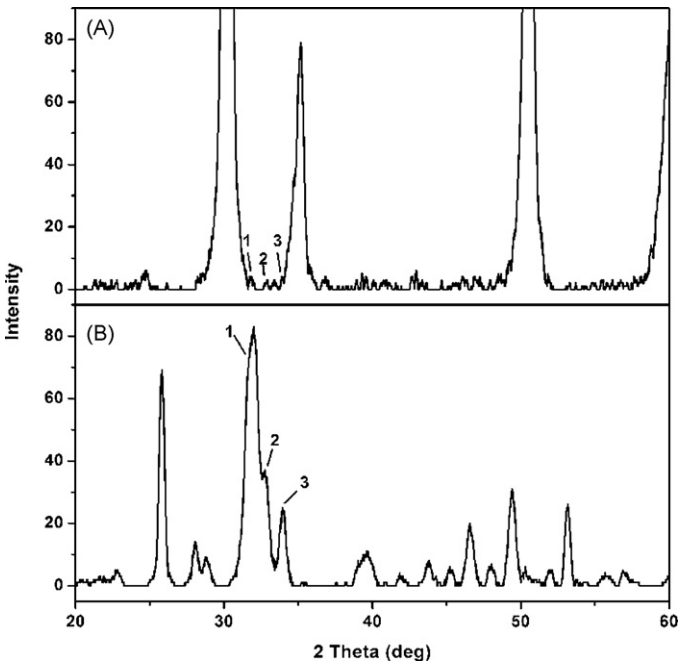

Fig. 3. XRD patterns of (A) HAp and (B) 10HAp-ZM. Peaks (1–3) around 32–34° were ascribed to the diffraction of 2 1 1, 3 0 0 and 2 0 2 planes of HAp crystal. The strong peaks in (B) were engendered by the ZM matrix.

The X-ray diffraction patterns of 2HAp-ZM were displayed in Fig. 3 in comparison with that of Tiselius type HAp. Only small typical peaks (around 32° and 34°), which are ascribed to the diffraction of 2 1 1, 3 0 0 and 2 0 2 planes of HAp crystal, are observed, suggesting the poor crystallinity of the HAp on 2HAp-ZM. Combined with the SEM photos, we can suppose that the coating is composed of an amorphous or nanocrystalline apatite. This phenomenon is consistent with the previously reported results [36,43].

The specific surface area, total pore volume, and average pore diameter of 2HAp-ZM are 25 m^2/g, 0.09 cm^3/g, and 14 nm, respectively, calculated using the standard BET method.

3.2. Chromatography of proteins

The feasibility of the HAp-coated ZM used as HPLC stationary phase for protein chromatography was evaluated using BSA, trypsin, lysozyme, RNase A and Cyt *c* as model analytes. The physical and chemical properties of these proteins are listed in Table 1.

It is reported that there are two types of interaction site on HAp. An acidic protein, such as BSA, mainly interacts with the C sites, while a basic protein, such as lysozyme, mainly interacts with the P sites [27]. Hence, both acidic and basic proteins were able to be resolved within a single run of HPLC on the basis of multimodal mechanism of separation [49]. In this study, five proteins were successfully separated on the 2HAp-ZM stationary phases in gradient elution mode using pH 6.8 phosphate buffer as mobile phase, as shown in Fig. 4. Compared to the unmodified ZM, on which lysozyme and RNase A were eluted in one peak without sufficient resolution, it can be concluded that the HAp coating is

Table 1
Properties of proteins investigated in this study.

Protein	Source	MW	pI[a]	R_s[b] (nm)

[e] Ref. [47].
[f] Ref. [48].

effective to improve the selectivity of 2HAp-ZM, mainly resulting from its unique bioaffinity toward biomolecules. Compared to a commercial HAp packing [27], although the retention of basic proteins on 2HAp-ZM is comparable, the retention of acidic proteins varies. BSA as well as other acidic proteins (ovalbumin and α_1-acid glycoprotein) has been tested on this column under different chromatographic conditions. Unfortunately, they were all hardly retained even eluted with pure water as mobile phase. Comparing the Stocks radii of acidic and basic proteins in our study (Table 1), the relatively small pore size of the stationary phases may be one possible explanation. Another explanation may be the electrostatic repulsion between the negatively charged Zr–OH on the uncoated matrices and the acidic proteins, which were also negatively charged at pH 6.8.

The dependence of protein retention on pH values was also investigated on 2HAp-ZM. Three pH values (pH 6.0, 6.8 and 7.8) were employed; lower or higher pH was avoided in view of its chemical instability at acidic conditions and lack of selectivity at basic conditions. Results are shown in Fig. 5. Retention increases with decreasing pH for all proteins except BSA, implying that cation exchange provides significant contributions to the retention of basic proteins. Higher pH of the mobile phase may deprotonate the proteins. Accordingly, basic proteins, which were less positively charged at higher pH, are less retained on 2HAp-ZM via weaker cation exchange interaction.

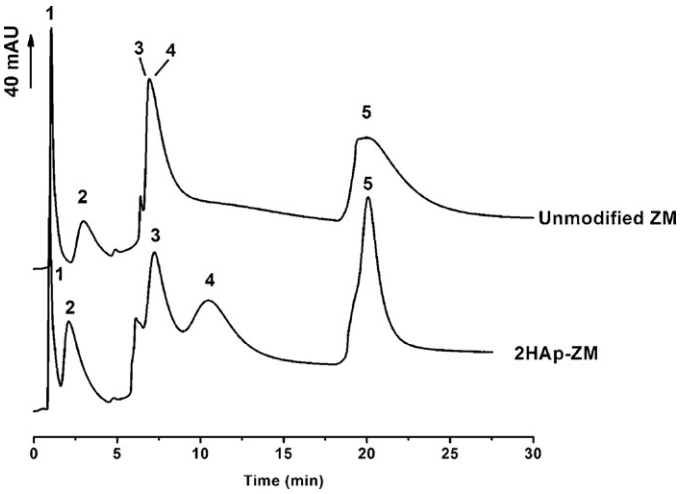

Fig. 4. Separation of five model proteins on unmodified ZM and 2HAp-ZM. Chromatographic conditions: NaP–KP buffer at pH 6.8, 1 mL/min, the gradient of mobile phase was outlined in Section 2.5; detection at 220 nm. Peaks: 1 = BSA; 2 = trypsin; 3 = RNase A; 4 = lysozyme; 5 = Cyt *c*.

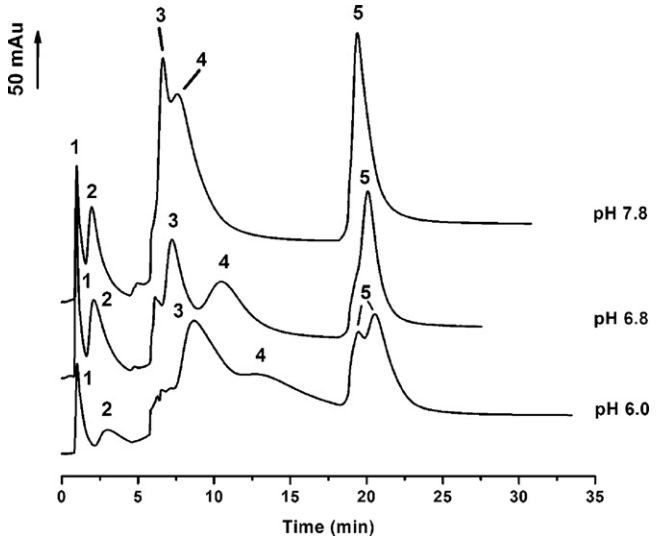

Fig. 5. Separation of five model proteins at three pH values on 2HAp-ZM column. Other conditions were the same as those in Fig. 4. Two forms of Cyt *c* (oxidized and reduced) were separated on at pH 6.0.

3.3. Stability

Mechanical stability is a crucial criterion for stationary phase of HPLC, and also the primary objective for us to prepare the HAp-coated ZM. The backpressure as well as the separation performance was thus monitored on 2HAp-ZM throughout the whole experiment. It was demonstrated that this particle could withstand the packing pressure (approximately 6000 psi) and allow the use of high flow rate of mobile phase (1 mL/min). Moreover, during the 3-month experiment, the backpressure of 2HAp-ZM column remained stable; and the separation performance was also preserved, as shown in Fig. 6.

3.4. Protein recovery and loading capacity

The goal of this work was to synthesize a viable support for protein chromatography. To be well suited for this application,

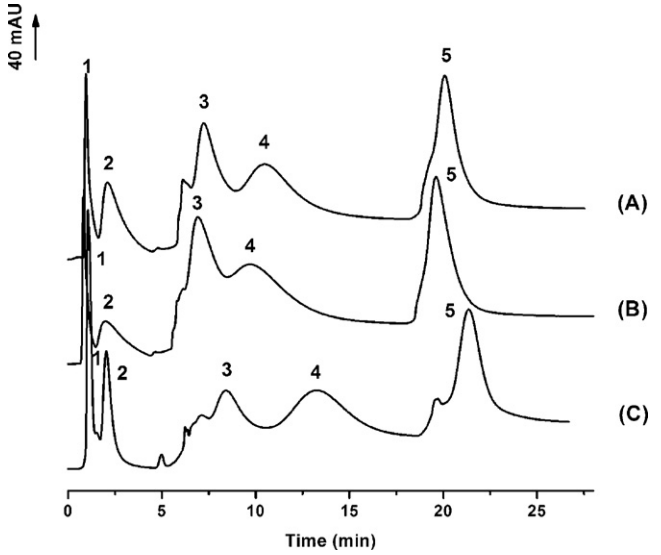

Fig. 6. Chromatograms of proteins on 2HAp-ZM column at different times: (A) once in the experiment; (B) 3 months later (approximately 100 injections had been operated within this period); (C) 6 months later (stored in refrigerator at about 4 °C). Other conditions were the same as those in Fig. 4.

Table 2
Protein recovery study on 2HAp-ZM column.

Protein	Mobile phase	% Recovery ($n = 3$)
BSA	5 mM NaP buffer, pH 6.0	99.7 ± 3.1
Trypsin	5 mM NaP buffer, pH 6.8	93.3 ± 3.5
Lysozyme	150 mM NaP buffer, pH 6.8	102.6 ± 0.9
RNase A	300 mM NaP buffer, pH 7.8	97.0 ± 3.7
Cyt *c*	500 mM KP buffer, pH 6.8	100.2 ± 1.1

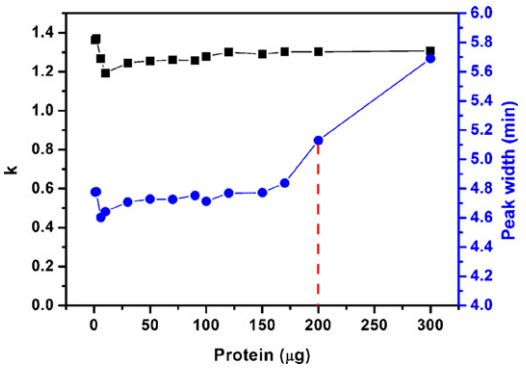

Fig. 7. Study of loading capacity of the 2HAp-ZM column. Experimental conditions: isocratic elution with 150 mM NaP mobile phase at pH 6.8; 1 mL/min; detection at 220 nm. Symbols: (■) capacity factor; (●) peak width.

very high recoveries are essential. Therefore, protein recovery was studied on 2HAp-ZM with results listed in Table 2. In order to ensure accurate peak integration, mobile phases were deliberately selected to obtain reasonable retention time and suitable peak width [6]. It can be found that the 2HAp-ZM column gave good recovery for all tested proteins, with the average recovery higher than 93%, indicating little irreversible adsorption of proteins.

The dynamic loading capacity of the 2HAp-ZM column was investigated by monitoring the column performance with increasing sample quantity. It is reported that the retention time and peak width will remain constant when the sample quantities are below the loading capacity of the column, while overloading will cause a decrease in retention time and an increase in peak width [9]. Lysozyme was chosen as a tested sample, and the results are shown in Fig. 7. The peak width is somewhat more sensitive to sample loading than the capacity factor. The dynamic loading capacity of the 2HAp-ZM-600 column was estimated to be about 80 μg/mL of blank column volume, based on the amount of sample which caused a 10% increase in peak width. This is higher than those reported for fluoride- and phosphate-modified zirconia (60 μg/mL) [9,10], but lower than that of a particular high-performance hydroxyapatite support (120 μg/mL) [50].

4. Conclusions

In this paper, biomimetic technique was demonstrated to be a low-cost and facile approach to prepare biocompatible and stable column packings (2HAp-ZM) for protein chromatography. Systematic characterization showed that bead-like HAp was successfully deposited on the surface of zirconia–magnesia microspheres after pre-calcification and 4 days incubation in SCS. Using this material as stationary phase, improved separation efficiency, resulting from the unique selectivity of HAp coating, was confirmed by the separation of lysozyme and RNase A (their physical and chemical properties were similar) in comparison with an unmodified ZM column. And following experiments also indicated that 2HAp-ZM exhibited good mechanical stability, relatively high recovery, and acceptable dynamic loading capacity, which made it a promising HPLC support in the separation of proteins or other biomolecules, but there remained much to be understood and optimized before routine use.

PLS
Noise frequency spectrum

ABSTRACT

Near infrared spectroscopy (NIR) contains excessive background noise and weak analytical signals caused by near infrared overtones and combinations. That makes it difficult to achieve quantitative determinations of low concentration samples by NIR. A simple chemometric approach has been established to modify the noise frequency spectrum to improve NIR determinations. The proposed method is to multiply one Savitzky–Golay filtered NIR spectrum with another reference spectrum added with thermal noises before the other Savitzky–Golay filter. Since Savitzky–Golay filter is a kind of low-pass filter and cannot eliminate low frequency components of NIR spectrum, using one step or two consecutive Savitzky–Golay filter procedures cannot improve the determination of NIR greatly. Meanwhile, significant improvement is achieved via the Savitzky–Golay filtered NIR spectrum processed with the multiplication alteration before the other Savitzky–Golay filter. The frequency range of the modified noise spectrum shifts toward higher frequency regime via multiplication operation. So the second Savitzky–Golay filter is able to provide better filtering efficiency to obtain satisfied result. The improvement of NIR determination with tailoring noise frequency spectrum technique was demonstrated by both simulated dataset and two measured NIR spectral datasets. It is expected that noise frequency spectrum technique will be adopted mostly in applications where quantitative determination of low concentration sample is crucial.

1. Introduction

Near-infrared (NIR) spectroscopy is a powerful analytical technique used in various industrial sectors, e.g. the agricultural [1–3], petrochemical [4,5], textile [6,7], medical diagnostics and pharmaceutical [8–10]. Due to its fast, accurate and non-destructive analytical characters, NIR spectroscopy is considered as a replacement of the traditional chemical analysis in some sense. NIR spectra consist of near infrared overtones and combinations thereof, making interpretation of the results complicated. Thus, multivariate analysis (MVA) such as principal-component regression (PCR) and partial least-squares regression (PLS) come to be crucial in translating the large amount of spectral data into useful information, mainly for predictive purposes [11]. The performance of above methods was affected by spectral interferences, including background and noise. The interference of background and noise not only worsen the precision of prediction, but also complicate the multivariate models, which usually leads to over fitting of the calibration [12,13]. Therefore, usually the first step of a multivariate calibration based on NIR spectra data is to preprocess the data for the purpose of removing interference. However, the diverse sources of background and noise make it a hard task to eliminate them completely. There are several methods presented for eliminating varying background and noise of data [14–22], but they usually require more sophisticated software procedures and sometimes tedious trials in their computational procedures.

Recently, the applications of noise frequency spectrum modification to eliminate the noise have been used in analytical technologies to improve the LC-MS/MS determinations [23,24]. This simple chemometric technique multiplies one match-filtered or low-pass filtered chromatogram with another artificial chromatogram of similar peak features containing only thermal noises. The noise on the modified chromatogram can be more efficiently removed with the second filtering procedure via the multiplication procedures which can smear the bandwidth-limited noise frequency spectrum of a filtered chromatogram to a wider range [23]. However, you will find it is difficult to perform the cross-correlation of a NIR spectrum with a simulated spectrum during the matched filtering if you are trying to use this method to remove the noise on NIR spectral signal, because the weak signal of NIR always submerged in a wide background.

In this paper, we develop an improved noise frequency spectrum modification to remove the noise of NIR spectra. This simple chemometric technique is to multiply one Savitzky–Golay filtered NIR spectrum with another Savitzky–Golay filtered NIR spectrum of reference substance added with thermal noise before the other

Savitzky–Golay filter. For illustration, we use simulated spectra that exemplify how noise frequency spectrum modification technique eliminates the background noise and improves the NIR determinations. We also used the spectra of water samples and plasma samples to validate the presented method.

2. Theory and algorithm

2.1. Savitzky–Golay filter

The Savitzky–Golay (SG) filter is a type of low-pass digital filter that was proposed in 1960s [25] as a good smoothing and differentiating technique for spectral use [26–30]. Their simple smoother has become an almost universal method to improve the signal-to-noise ratio of any kind of signal [31,32]. Since the algorithm is well-known, it will not be explained in detail in this paper. More information can be found in the literatures [25,33,34].

2.2. Multiplication

The signal process using multiplication method is originated from the sequential paired covariance (SPC) [35] and applied to improve signal-to-noise ratio of liquid chromatography-tandem mass spectrometry peaks using noise frequency spectrum modification between two consecutive matched-filtering procedures [23,24]. The simulated NIR spectrum $sp(\lambda)$ is the summation of a smooth peak $s(\lambda)$ and noise $n(\lambda)$. The features of $s(\lambda)$ are estimated from those of Savitzky–Golay filtered NIR spectrum $SGf(\lambda)$. When the Savitzky–Golay filtered NIR spectrum $SGf(\lambda)$ is multiplied by $sp(\lambda)$, the expansion can be expressed as Eq. (2) [23],

$$SGf(\lambda)sp(\lambda) = SGf(\lambda)s(\lambda) + SGf(\lambda)n(\lambda) \quad (2)$$

The first term $SGf(\lambda)s(\lambda)$ maintains the NIR signal peak because the features of $SGf(\lambda)$ are similar to these of $s(\lambda)$. Therefore, the tailored noise spectrum of the above multiplication product is mainly contributed by the second term $SGf(\lambda)n(\lambda)$. The Fourier transform of the product $SGf(\lambda)n(\lambda)$ to frequency domain is proportional to the convolution of two spectra $SGF(\nu)$ and $N(\nu)$, which are the Fourier transforms of $SGf(\lambda)$ and $n(\lambda)$, respectively [23,36],

$$F\left\{SGf(\lambda)n(\lambda)\right\} = \int [SGf(\lambda)n(\lambda)]\, e^{-i\omega\lambda} d\lambda = \frac{1}{2\pi} \int SGF(\nu)N(\omega-\nu)d\nu \quad (3)$$

The Fourier transform of a Savitzky–Golay filtered spectrum $SGF(\nu)$ only contains low-frequency components due to Savitzky–Golay filter works as a low-pass filter. $SGF(\nu)$ is estimated as an exponential-decay profile in Fig. 1A. The profile of $N(\nu)$, the Fourier transform of random noises $n(\lambda)$, is a flat line in Fig. 1B. As shown in Fig. 1C, although $SGF(\nu)$ falls to zero quickly as the frequency gets higher, the convolution of $SGF(\nu)$ with a flat line $N(\nu)$ results in a wider frequency spectrum. Therefore, on the modified spectrum, its noise spectrum is shifted toward higher frequency regime. Since the noise spectrum is no longer squeezed at the low-frequency regime, therefore the second Savitzky–Golay filter efficiently removes more noises to obtain higher signal-to-noise ratio spectrum. The baseline of the final NIR spectrum was therefore not fluctuated or shifted due to the low-frequency components on the noise spectrum of the conditioned spectrum remain suppressed.

2.3. Signal processing procedures

NIR spectra of sample and reference substance are firstly processed with Savitzky–Golay filter procedure. As illustrated in Eq. (4), the Savitzky–Golay filter of the sample NIR spectrum of total length k points Sample(Λ_i) is calculated.

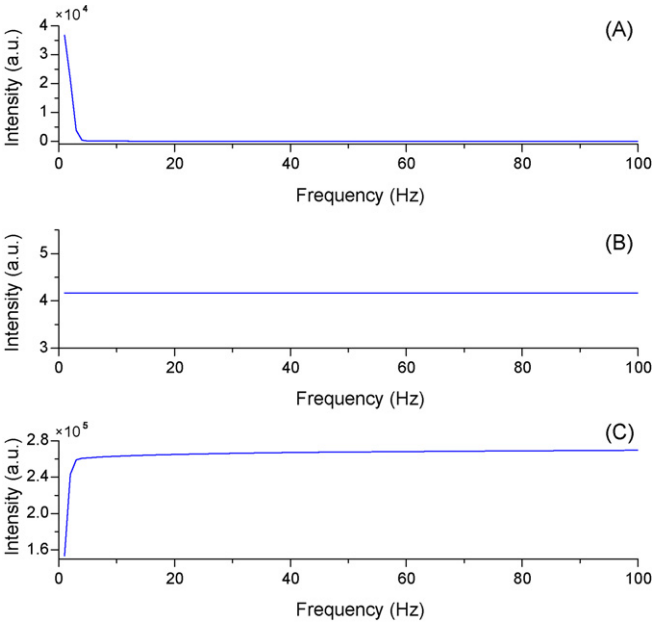

Fig. 1. (A) The simulated frequency spectrum of one Savitzky–Golay filtered NIR spectrum. (B) The simulated frequency spectrum of the thermal noise. (C) The convolution results of the spectra in parts A and B.

$$SGF_1(\Lambda_i) = \frac{1}{N}\sum_{j=-m}^{m} w_j \mathrm{Sample}(\Lambda_{i+j}); \quad i = 0,\ 1,\ 2,\ \ldots,\ k \quad (4)$$

Where N is the number of convoluting integers and m is the number of neighboring points. $SGF_1(\Lambda_i)$ represents Savitzky–Golay filtered spectrum of sample NIR spectrum and (Λ_i) is the ith wavenumber points.

The Savitzky–Golay filter of the reference substance NIR spectrum of total length k points $ref(\Lambda_i)$ is also calculated.

$$SGref(\Lambda_i) = \frac{1}{N}\sum_{j=-m}^{m} w_j ref(\Lambda_{i+j}); \quad i = 0, 1, 2, \ldots, k \quad (5)$$

Where $SGref(\Lambda_i)$ represents Savitzky–Golay filtered spectrum of the reference substance NIR spectrum.

The multiplication product result of the filtered sample spectrum with another reference spectrum, which contains the one Savitzky–Golay filtered reference substance spectrum added with additional thermal noises, is obtained.

$$MP(\Lambda_i) = SGF_1(\Lambda_i)[SGref(\Lambda_i) + N(\Lambda_i)] \quad (6)$$

Where the term $MP(\Lambda_i)$ represents the multiplication operation result. The term $N(\Lambda_i)$ represents the random noises added on the Savitzky–Golay filtered reference substance spectrum $SGref(\Lambda_i)$. The noises $N(\Lambda_i)$ are generated with a random number generator of normal distribution function with zero mean. The variance of this distribution function is estimated by the root mean square (RMS) of noise in sample NIR spectrum. As illustrated in Eq. (6), the modified spectrum $MP(\Lambda_i)$ will no longer contain only low-frequency noise when the Savitzky–Golay filtered spectrum $SGF_1(\Lambda_i)$ with only low-frequency noises is multiplied with a reference spectrum containing random noise $N(\Lambda_i)$. The noise frequency spectrum range of $MP(\Lambda_i)$ becomes wider via this modification.

Eq. (7) shows that each point on the modified spectrum $MP(\lambda)$ is then divided by the summation of its corresponding point on the Savitzky–Golay filtered reference substance spectrum $SGref(\lambda)$ and

Table 1
The parameters of the simulated NIR spectra dataset.

Parameters	Background	Analytical signal
Sample spectra		
x_0	925	1601
σ	371	14
A	Random	Proportional to concentrations
Reference spectrum		
x_0	925	1601
σ	371	14
A	3	3

the average intensity of noises $\langle N \rangle$ to adjust the exaggerated peak intensity.

$$AMP(\Lambda_i) = \frac{MP(\Lambda_i)}{SGref(\Lambda_i) + \langle N \rangle} \quad (7)$$

Where $AMP(\Lambda_i)$ indicates the adjusted result. The noise frequency range of $AMP(\Lambda_i)$ should be similar to that of $MP(\Lambda_i)$ because Eq. (7) only results in intensity adjustment.

The adjusted spectrum is processed with the second Savitzky–Golay filter procedures to obtain the final results.

$$SGF_2(\Lambda_i) = \frac{1}{N}\sum_{j=-m}^{m} w_j AMP(\Lambda_{i+j}); \quad i = 0, 1, 2, \ldots, k \quad (8)$$

Where $AMP(\Lambda_i)$ is the adjusted result of $MP(\Lambda_i)$. Because $AMP(\Lambda_i)$ also contains high frequency noises, the second Savitzky–Golay filter is able to accomplish efficient noise reduction.

When the sample signal spectrum Sample(Λ_i) in Eq. (4) is multiplied by a factor k, the same multiplication k will appear in the final results $SGF_2(\Lambda_i)$ in Eq. (8). So these filtering procedures are able to maintain the signal intensity linearity.

3. Experimental section

3.1. Simulated dataset

The simulated data mimicked common NIR spectral data with excessive background. A simulated sample spectrum was obtained by adding a background (a broader Gaussian peak), an analytical signal (a narrower Gaussian peak), and normal distributed noise. The Gaussian peaks were generated by

$$x_i = A \exp\left[-\frac{(x_i - x_0)^2}{2\sigma^2}\right] \quad (9)$$

Where A is the height at the centre, x_0 is the position of the centre and σ is the standard deviation of the Gaussian peak, and 4σ is the peak width.

A simulated dataset with 42 samples were used in this paper. In total, there are about 2203 points in each simulated NIR spectrum. The parameters x_0, σ and A of background and analytical signal in simulated sample spectra and reference substance spectrum are shown in Table 1. The peak heights A of simulated sample spectra are proportional to concentrations for analytical signal, whereas the peak heights for background are random. The simulated sample spectra and reference substance spectrum are shown in Fig. 2 and Fig. 3(B), respectively.

3.2. Measured dataset

3.2.1. Water samples

Fifty samples of chlorpyrifos in drinking water with concentration range from 1 to 125 ng/ml were prepared. All samples were measured using a multipurpose Fourier transform NIR (FT-NIR) spectrometer (MPA, Bruker Optics, Inc., Ettlingen, Germany)

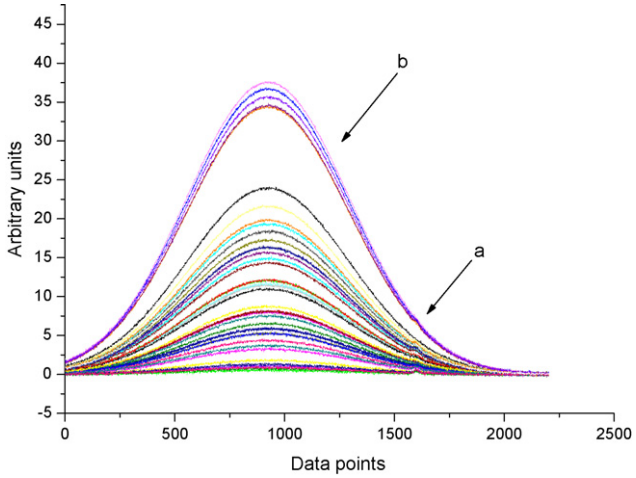

Fig. 2. The simulated NIR spectra. (a) The simulated analytical signal; (b) The simulated background.

equipped with a PbS detector and a fiber optic probe. OPUS/IDENT (version 5.0) multivariate statistical qualitative analysis software (Bruker Optics, Inc.) was used for spectral data collection and transformation. Each spectrum represented the average of 64 scans at a resolution of 16 cm^{-1}, over the wave number of 12,500 to 4000 cm^{-1}. Each sample was scanned three times. The average spectrum of each sample was used for further analysis.

3.2.2. Plasma samples

Plasma samples were from 19 healthy Chinese male volunteers received an oral dosage of 300 mg acyclovir capsule [37]. The sample set was split randomly into separate training and test sets that spanned nearly identical concentration ranges, containing 60 and 20 samples, respectively.

High performance liquid chromatography based procedures were employed to determinate the concentration of samples used for PLS model. The flow-rate was set at 1.0 ml/min and the effluent was monitored by UV detector at 254 nm. The mobile phase was acetonitrile–water containing 5 mmol/l perchloric acid, (pH 2.0; 4:96, v/v). All the analyses were performed at an ambient temperature.

Forty microliters H_3PO_4 solution (20%, v/v) was added to 500 μl plasma. Vortex mixed for 1 min, and then added 400 μl perchloric acid to the mixture. After vortex mixing for 3 min, the last mixture was then centrifuged for 10 min at 16000 rpm. After centrifugation, 20 μl of the clear supernatant was injected into the LC system. The area values of the chromatographic peaks were used to calculate the concentrations of samples from standard curve.

An appropriate amount of sample was transferred to quartz cell with a 1 mm optical path (NIR).The FT-NIR spectrum was recorded from 12500 to 4000 cm^{-1} using a nominal resolution of 8 cm^{-1}, accumulating 64 scans per spectrum and air was used as reference (empty sample holder). Each sample was scanned in triplicate (repack) and the spectra were averaged for chemometric analysis.

3.3. Computation

The algorithm described in this paper was implemented in Matlab (The Mathworks, Inc., Natick, MA, USA). PLS calibrations were derived using the PLS algorithm included in OPUS (Version 5.0, Bruker Optics, Inc.).

4. Results and discussion

4.1. Analysis of simulated dataset

The simulated data mimicked typical NIR spectral data with excessive background and weak analytical signal. The peak heights and widths of the background are obviously larger than those of the analytical signals (Fig. 2). Forty-two samples were randomly divided into two datasets, 28 in calibration set and the others in validation set. All spectra were preprocessed by proposed noise frequency spectrum modification between two consecutive filtering procedures as described in the flowchart of Fig. 3. Fig. 3(A) shows one simulated NIR spectrum obtained by adding a background (a broader Gaussian peak, $A = 40$), an analytical signal (a narrower Gaussian peak, $A = 0.01$), and normal distributed noise. The analytical signal was embedded completely in excessive background noise. Fig. 3(B) shows the simulated reference substance spectra obtained by adding a small background ($A = 3$), an analytical signal of certain intensity ($A = 3$) and some tiny normal distributed noise. Fig. 3(C) and(D) were Savitzky–Golay filtered spectra of simulated sample spectrum Fig. 3(A) and reference spectra Fig. 3(B), respectively. As mentioned above, Savitzky–Golay filter works as a low-pass filter. The frequency spectrum imbedded in Fig. 3(C) shows almost no high frequency components. The remaining low-frequency noises cannot be eliminated with the second Savitzky–Golay filter or any other types of low-pass filter. Fig. 3(E) shows the results of the multiplication product of sample spectrum in Fig. 3(C) with reference substance spectrum in Fig. 3(D) added with certain intensity thermal noise. Fig. 3(F) shows the intensity-adjusted results of spectra in Fig. 3(E). The appearance of noises in Fig. 3(F) shows more high frequency components and is significantly different from that in Fig. 3 (C). The multiplication of two spectra at the signal space is in equivalence to the convolution between the two frequency spaces of these spectra. When the remaining low-frequency noises on the Savitzky–Golay filtered spectrum are multiplied by the random noises on the simulated spectra, the noise spectrum of this multiplication product no longer contains only low-frequency components. The range of noise spectrum becomes wider. The imbedded graphs in Fig. 3(E) and (F) show the frequency spectra of these two spectra, respectively. Like the previous discussion, when the noise spectrum of conditioned spectra is shifted toward the higher frequency range, the second Savitzky–Golay filter procedures are able to eliminate noise more efficiently. Fig. 3(G) shows the final result of the second Savitzky–Golay filter product of spectrum in Fig. 3(F).

After all NIR spectra being preprocessed by noise spectrum modification technique, a PLS model of analytical signals was built. The results are shown in Table 2. Table 2 shows the R^2 of the calibration set, the root mean square error of cross validation (RMSECV), the R^2 of the validation set and the root mean square error of prediction (RMSEP) were obtained in each preprocess method of simulated NIR spectra. Without preprocess method of noise frequency spectrum modification between two consecutive Savitzky–Golay filtering procedures, the RMSEP was 0.139 and the R^2 of the validation set was only 94.74. The results showed that the RMSEP was decreased to 0.0931 and R^2 of validation set was increased to 97.63. The prediction of PLS model should be improved. But after correcting with conventional preprocess method provided by OPUS software, such as constant offset elimination, straight line subtraction, vector normalization, min-max

normalization, multiplicative scattering correction, first derivative and second derivative, poor results were obtained. It was clear that the proposed noise frequency spectrum modification technique can be used to eliminate excessive background and spectra noise for improve NIR determination.

The final result of spectrum processed by noise spectrum modification technique can be affected by the parameters of Savitzky–Golay filter. The commonly used setup of Savitzky–Golay filter consists of an interleaving polynomial function of length of about 5–29 data points and polynomial degree *n*. The effectiveness of the various functions was tested in this study. The tested length of the interleaving function varied from 5 to 29 data points and a polynomial degree from 3 to 7. Fig. 4 shows the results of PLS model with different parameters of Savitzky–Golay filter. The result shows the optimum value of RMSECV and RMSEP were obtained simultaneously with polynomial degree *n* was 4 and data points of interleaving function was 17.

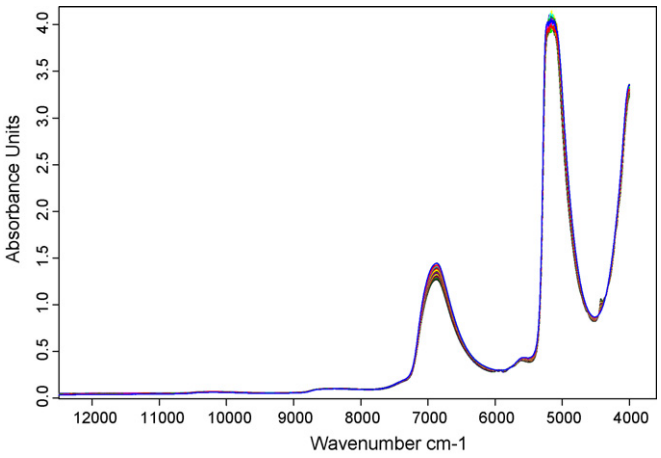

Fig. 5. The NIR spectra of chlorpyrifos water samples.

4.2. Analysis of measured datasets

4.2.1. Water samples

In order to test the efficiency of noise frequency spectrum modification technique in practice, the method was tested by measured NIR spectral data on chlorpyrifos water solution. Half of the samples were used in the calibration set and the others in the validation set. Fig. 5 shows that the absorbance peaks of the O–H bond at 6944 and 5155 cm^{-1} are very large, which peaks are mainly attributed to water. While the absorbance of the low concentration of chlorpyri-

fos was so weak that no clear absorbance peaks can be found in the spectra. Building a PLS model of chlorpyrifos would be a challenging work.

Fig. 6(A) shows the representative NIR spectrum of chlorpyrifos water solution. The signal-to-noise ratio of the spectrum was 19.49 (estimated by OPUS software). The absorbance peaks of chlorpyrifos were submerged in excessive background of H_2O. Fig. 6(B) shows the NIR spectrum of chlorpyrifos powder (reference substance). The representative absorbance peaks of chlorpyrifos were at regions 6102–5446 cm^{-1} and 4600–4000 cm^{-1}. The intensity-adjusted result of the multiplication product of Savitzky–Golay filtered sample spectrum with Savitzky–Golay filtered reference spectrum was showed in Fig. 6(C). The embedded graph in Fig. 6(C) shows the enlarged spectrum at with region 6102–5446 cm^{-1}. This region in Fig. 6(C) is significantly different from Fig. 6(A). The high frequency noise shifted from low frequency using noise frequency spectrum modification technique can be eliminated with the second Savitzky–Golay filter to obtain better improvement of spectral characteristics. The final processed spectrum of chlorpyrifos water solution was shown in Fig. 6(D). The signal-to-noise ratio of the processed spectrum was improved to 24.96.

A PLS model of chlorpyrifos was built after all spectra being preprocessed by noise frequency spectrum modification technique. The results were shown in Table 3. The results suggested that without data preprocess, poor results were obtained. Slightly better or even worse results were obtained by the classical data preprocess methods provided by OPUS software, such as constant offset elimination, straight line subtraction, vector normalization, min-max normalization, multiplicative scattering correction, first derivative and second derivative. The best results were obtained by the proposed noise frequency spectrum modification technique, as shown in the simulated datasets. Table 4 illustrates the results of chlorpyrifos water solution NIR spectra processed by one or two consecutive Savitzky–Golay filter procedures with and without performing additional multiplication modification steps before the second Savitzky–Golay filtering computation. Compared to original PLS without spectra preprocess, RMSECV and RMSEP of PLS model with noise frequency spectrum modification steps decreased from 3.06 and 3.49 to 1.69 and 2.37, respectively, and the corresponding R^2 of calibration set and validation set increased from 99.29 and 99 to 99.78 and 99.54, respectively.

The parameters of Savitzky–Golay filter were also optimized by the same way as in the simulated datasets. The optimum value of RMSECV and RMSEP were obtained simultaneously with polynomial degree n was 3 and data points of interleaving function was 9.

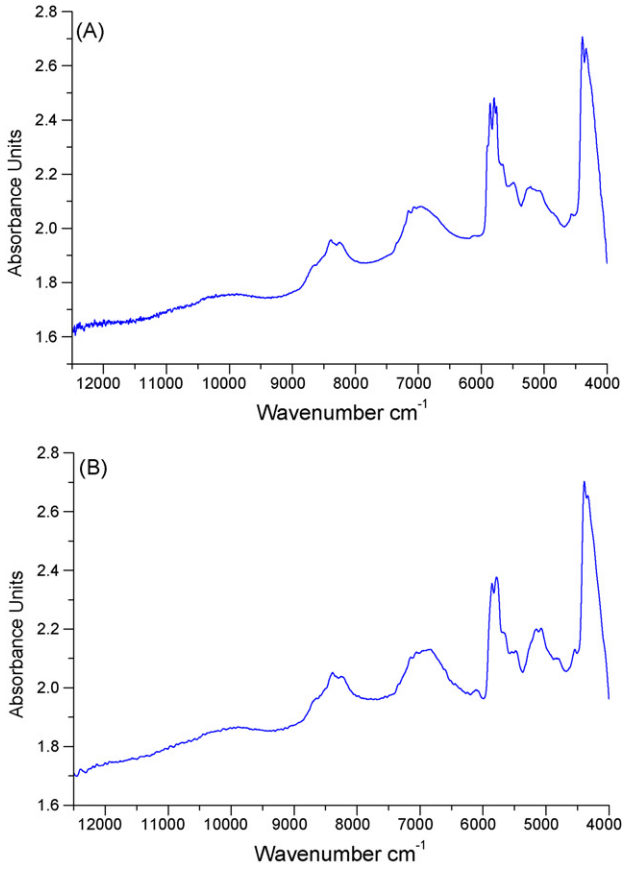

Fig. 7. (A) The NIR spectrum of acyclovir plasma sample at concentration 1.92 μg/ml.
(B) The final NIR spectrum via processing (A) with noise frequency spectrum modification technique.

Table 5
The results of the PLS model of the acyclovir plasma sample NIR spectra dataset processed with different preprocess methods.

Process method	Calibration set		Validation set	
	RMSECV	R^2	RMSEP	R^2
No process	0.283	78.01	0.848	74.63
Constant offset elimination	0.202	88.73	0.422	85.51
Straight line subtraction	0.381	74.72	1.24	69.44
Vector normalization	0.161	91.68	0.25	90.29
Min-max normalization	0.217	87.04	0.329	86.85
Multiplicative scattering correction	0.241	84.06	0.233	84.82
First derivative	0.257	82.45	0.513	80.38
Second derivative	0.159	92.19	0.301	91.87
Multiplication modification between two Savitzky–Golay filters	0.13	94.77	0.213	94.16

4.2.2. Plasma samples

The proposed method was also validated by treating plasma samples. Fig. 7(A) shows a representative NIR spectrum of acyclovir plasma sample and the signal-to-noise ratio of the spectrum was 19.35. All spectra of plasma samples were preprocessed by noise frequency spectrum modification technique. The optimized polynomial degree n and data points of interleaving function were 3 and 17, respectively. Fig. 7(B) shows the final processed spectrum of acyclovir plasma sample and the signal-to-noise ratio of the processed spectrum was improved to 22.91. A PLS model of acyclovir was built after all spectra being preprocessed by the proposed method. The results were shown in Table 5. The optimum value of RMSECV and RMSEP were 0.13 and 0.213, respectively, and the corresponding R^2 of calibration set and validation set were 94.77 and 94.16, respectively. It was obvious that the best results were obtained by the proposed noise frequency spectrum modification technique.

5. Conclusion

Within non-destructive analytical technology, NIR spectroscopy has been found to be an effective technique for the determination of solid, semisolid, fluid, and vapor sample. However, NIR spectra consist of excessive background, weaker analytical signal and thermal noise making interpretation of the analysis and modeling results complicated. On both simulated and measured NIR case studies, we have shown that the recent tailoring noise frequency spectrum technique provides an intrinsic improvement for the interpretation of NIR data. This is achieved through multiplying one Savitzky–Golay filtered NIR spectrum containing only low-frequency noises with another reference spectrum containing thermal noises. The conditioned spectrum is processed with the second Savitzky–Golay filter to obtain much better RMSECV and RMSEP than the corresponding value using two Savitzky–Golay filters without noise conditioning. This noise-tailoring technique can shift the low-frequency noise spectrum of Savitzky–Golay filtered spectrum toward the higher frequency range. As a result, the noises on the conditioned spectrum can be removed more efficiently using the second Savitzky–Golay filter. Our study proves that this noise-modification technique is able to improve PLS model using Savitzky–Golay filter to process NIR spectrum, which typically contain many background. Furthermore, it is simple to develop software works to implement this noise tailoring technique. Potentially, this noise-modification technique can be also used between any two low-pass filters to eliminate low-frequency noises to improve NIR determination.

ABSTRACT

An automatic sampling device, i.e., process sampling module (PSM), connected with a purge and trap–GC–FID system has been developed for real-time monitoring of VOCs in wastewater. The system was designed to simultaneously monitor 17 compounds, including one polar compound, i.e., acetone, and 16 non-polar compounds. The trapping tube is packed with two adsorbents, Carbopack B and Carbosieve III, to trap target compounds. For the purpose of in situ monitoring, the flush valve of the sampling tube is composed of two two-way valves and a time controller to prevent absorption interference of the residue. The optimal conditions for the analytical system include a 12 min purge time at a temperature of 60 °C, and 4 min of desorption time with a desorption temperature of 260 °C. Good chromatograms have been obtained with the analytical system even if a cryogenic device and de-misting were not used. The relative standards deviation (RSD) of the system is between 2% and 13.4%, and accuracies between 0.3 and 23.5% have been achieved. The detection limits of the method range from 0.32 to 2.39 ppb. In this system, the four parts, i.e., PSM, P&T, GC, and FID, were simple, reliable and rugged. Also, the interface of these four parts was simple and dependable.

1. Introduction

Volatile organic compounds (VOCs) are persistent, toxic, and carcinogenic or mutagenic, and they have adverse effects on human health, even at very low concentrations [1–3]. At industrial or accidental spill sites, VOCs can accumulate in ground water up to concentrations of several hundred mg L^{-1} [1], and VOCs in indoor environments are as worrisome as those in the outdoors [4]. For example, many consumer products found around the house, such as cleaning solvents, paints, and wood preservatives in certain furniture all emit VOC compounds, which may contribute to sick building syndrome [5,6]. Consequently, the spread of VOCs in our surroundings is a serious environmental concern, and monitoring of VOCs is critical. VOCs occur in numerous products including fuels, solvents, paints, adhesives and deodorants. Other sources include combustion exhaust and electronic manufacture processes. VOCs may also exist in the air due to the evaporation of organic solvents in water or soil [7]. Due to low concentrations of VOCs in water, and their volatility, they are not often found in concentrations above a few μg L^{-1} in surface water; hence, their quantification is a big challenge. Therefore, measurement of VOCs usually requires preconcentration prior to detection in order to get reliable and satisfactory results. It is widely known that VOCs may be lost during sampling, preservation, shipping, and storage greatly affecting the resulting data. Therefore, in situ and automatic sampling/sample preparation techniques are quite important for their quantification.

For the determination of VOCs in waste water, static headspace (HS) techniques [8], dynamic HS [9–11], liquid–liquid extraction [2], membrane [12,13], solid-phase extraction, and solid-phase micro-extraction (SPME) [14–20] and many other methods [21] are used as sample preparation techniques. Purge and trap extraction (PTE) has been successfully applied in the separation and preconcentration of a variety of VOCs from different matrices [22,23]. By coupling with various detection modes, PTE has been widely used to quantify the amount of VOCs in drinking water, seawater [24], industrial wastewater [22], rainwater, blood, urine, mud [25], food [26–28] and beverages [29]. Recently, PTE has been adopted for the long-term monitoring of VOC content in surface water [30,31]. In addition, Chen and Her [32] proposed applying the purge and trap system for continuous analysis of flowing samples, e.g., halocarbons can be measured effectively in the low-flow samples.

Naphthalene	1.99	7.86	0.32	0.998

HsinChu High Technology Park (HTP) is located in a populated area. The factories inside this park produce large amounts of organic substances due to their unique and necessary processes. Although these organic substances have been treated before released by a wastewater treatment plant, their concentrations need to be closely monitored, using a simple, fast, instantaneous and automatic method. The process sampling module (PSM) is an appropriate apparatus; sampling times for PSM are programmable through the GC's timed events control. By collecting a fixed volume sample of a sample stream upon command from the analytical system, the PSM eliminates the need for labor intensive, repeated manual sampling. The collected sample is subsequently transferred to the purge and trap apparatus for concentration and then is analyzed by the appropriate analytical systems, e.g., GC, GC/MS, etc.

The objectives of this work were twofold: first, simplification of the sampling apparatus and second, determination of the relationship between the concentration of VOCs and their time variations. One way to simplify would be to omit the SPME which is expensive and complicated when coupled with GC. To that end the design and applicability of PSM combined with P&T followed by GC–FID was investigated in the analysis of 17 VOCs, e.g., chloroform, toluene, naphthalene, methylene chloride, trichloroethylene, bromodichloromethane, tetrachloroethylene and acetone (Table 1), in waste water taken from the effluent released by the waste water treatment plant in HTP.

2. Experimental

2.1. Chemicals

All chemicals and reagents used in this study (the standard solutions were 5000 $\mu g\,L^{-1}$ in concentration) were obtained from Supelco (Supelco Individual Calibration Standards).

2.2. Apparatus and procedure

2.2.1. Automatic sampling system and procedure

The process sampling module (PSM) (an automatic sampling device) was commercially available (OI Analytical, College Station, TX) and was composed of a signal-receiving circuit board, a six-way valve, and a Teflon tube with volume of 5 mL and a caliber of 1/8″ in connected with a set of time controllers for sampling time control. The pushing gas was high-purity nitrogen. When the pre-set sampling time was completed, the time controllers delivered a signal to the circuit board, hence, the six-way valve return to its original place as that in the status of rinsing, and was ready for the next task. In this study, the sampling time was set at 8 min. If the sampling time is not long enough, the amount of water sample in the 5-ml Teflon tube cannot completely reach the purge and trap device, resulting in sample loss.

2.2.2. Purge and trap system and procedure

An O.I. analytical purge and trap concentrator (model 4560), GC (model 6890, Hewlett-Packard, Avondale, MA, USA) with fused-silica column (OV-624, 75 m × 0.25 mm i.d.) equipped with a flame ionization detector (FID) was used for the measurement of VOCs. Helium (99.9995%) was used as it carries gas at constant head column pressure. Temperature programming of the GC and data acquisition were begun simultaneously. Chromatographic separations were carried out using a temperature program, i.e., the temperature was held constant at 36 °C for 14 min, then linearly increased to 180 °C at 8 °C/min for 2 min, and finally increased to 210 °C at 15 °C/min for 2 min. Flow rate of the helium was set at 0.9 mL min^{-1}.

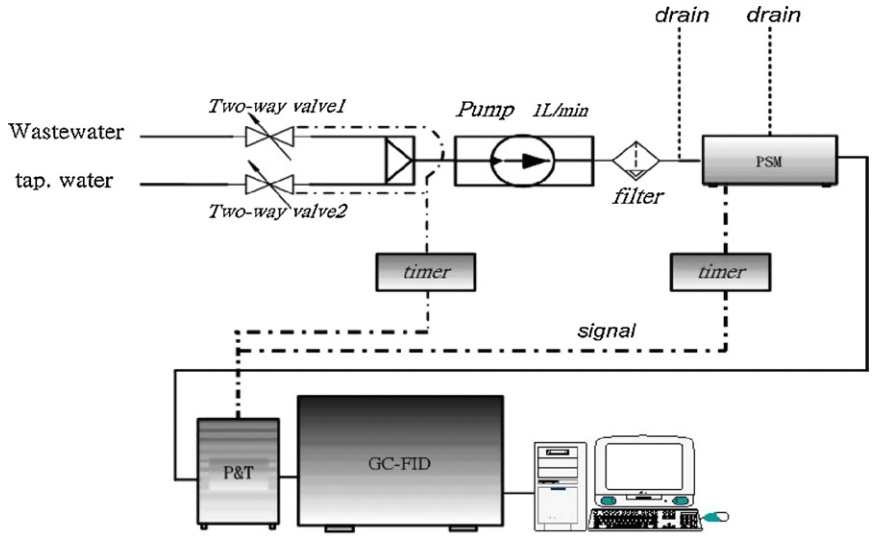

Fig. 1. Schematic diagram of the PSM–P&T–GC–FID system.

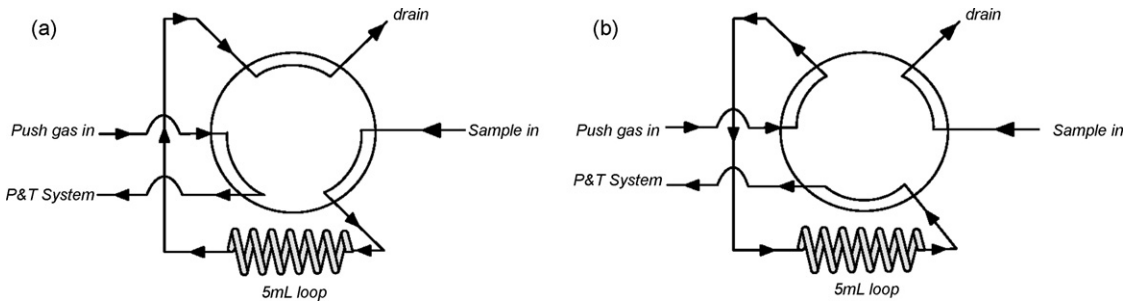

Fig. 2. Flow direction diagram of the PSM when (a) rinsing and (b) sampling.

2.2.3. Sampling tube and flush system

In this study, time controllers, a medium flux piston pump, silicosteel tube and two sets of two-way valves were assembled to form the sampling tube and tube flush system. Fig. 1 presents the schematic diagram of the complete automated PSM–P&T–GC–FID system. The inlet of the piston pump was connected via a three-way tie-in, and the outlet, working as the water sample flow port and the PSM sampling port, was also connected via a three-way tie-in. The water-in (flushing) tube was connected with a common PE tube. Fig. 2 describes the flow direction of PSM.

2.2.4. Trap tube

The stainless steel desorption tube used in this setup consisted of 0.25 g Carbopack B and 0.05 g Carbosieve III (Supelco Ltd.) separated by glass wool. The two head portions of the tube were also filled with glass wool and sealed by Swagelok fittings. The filled trap tube was formed into a U-shape for conditioning in the P&T system.

2.3. Calibration curve

The calibration curve for VOCs was established with seven different concentrations, i.e., 5, 10, 15, 20, 25, 30, 35 $\mu g\,L^{-1}$, and for acetone, the concentrations were 60, 100, 120, 160, 180, 220, and 240 $\mu g\,L^{-1}$.

3. Results and discussion

3.1. Automatic sampling (PSM) and flush systems

3.1.1. Feasibility of PSM

In this work, to verify the performance of this system, the response evaluation of the PSM was compared with that of the Archon auto-sampler (Varian). The Archon auto-sampler was specially designed for lab use, and it consisted of 51 sample trays to accept water or soil samples, providing easy loading and refrigeration. Water samples containing 5 ppb of benzene, toluene or m,p-xylene, individually, were used separately in both the PSM and the Archon auto-sampler to investigate the feasibility of PSM. As can be seen in Fig. 3, the response from the PSM system was excellent, i.e., over 90% of those of the Archon auto-sampler.

3.1.2. Stability of the flushing system

To understand the stability of the in situ operation, i.e., why the pollutants did not accumulate or remain in the tube as sewage samples continuously passed through the tube, the tube flush system was installed for continuous monitoring. Before sample collection, the container was rinsed with a real water sample. When the rinse time was longer than 30 s, the peak area remained stable with a fluctuation of only $\pm 3\sigma$ (Fig. 4). The rinse time before sampling was set at more than 5 min to ensure that the sampling tube was fully rinsed by the real water sample. Fig. 5 shows the effects of flushing

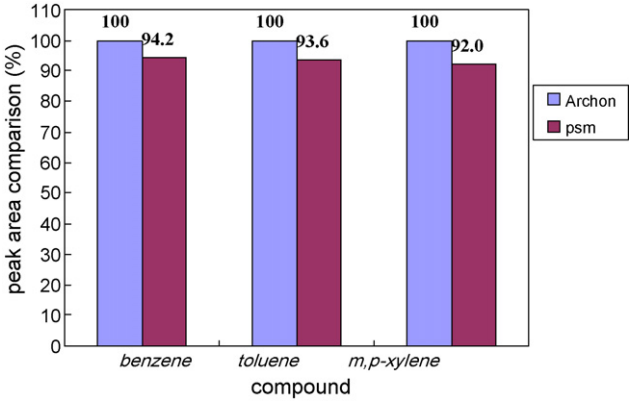

Fig. 3. Comparison of the response from PSM system and from Archon auto-sampler.

a 35 ppb BTX standard and blank sample. After flushing for 20 min, no residual sample remained to influence the next analytical result.

3.1.3. Accuracy, precision and detection limit

Results in Table 1 show the performance of the system that we developed. The data show that the *r*-squared (r^2) values of the calibration curve for all target compounds were greater than 0.990. Among them, methylene chloride, trichloroethylene, toluene, and tetrachloroethylene yielded values of 0.999; acetone and chloroform values were 0.993 and 0.994, respectively. The data show that this method is feasible for analyzing these 17 compounds. The method detection limit (MDL) of the polar compound acetone was 9.07 ppb, and the MDLs for the other target compounds ranged from 0.32 to 2.39 ppb. The accuracy value is defined as the difference between the numerical value of the concentration and the known theoretical concentration divided by the theoretical value, and is written as a percentage.

For our system, we used a calibration curve of the lowest concentration to test the accuracy. The results indicate that only

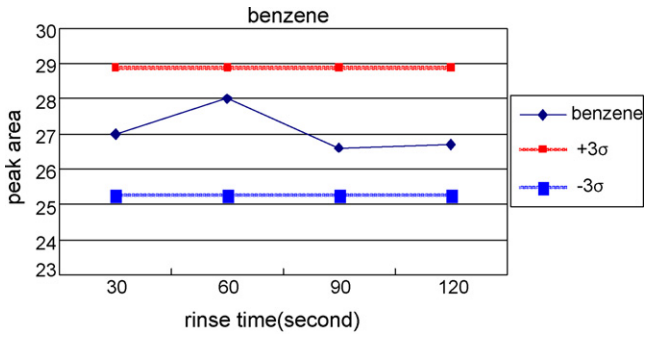

Fig. 4. Relationship between the rinse time and peak area (benzene, 5 ppb).

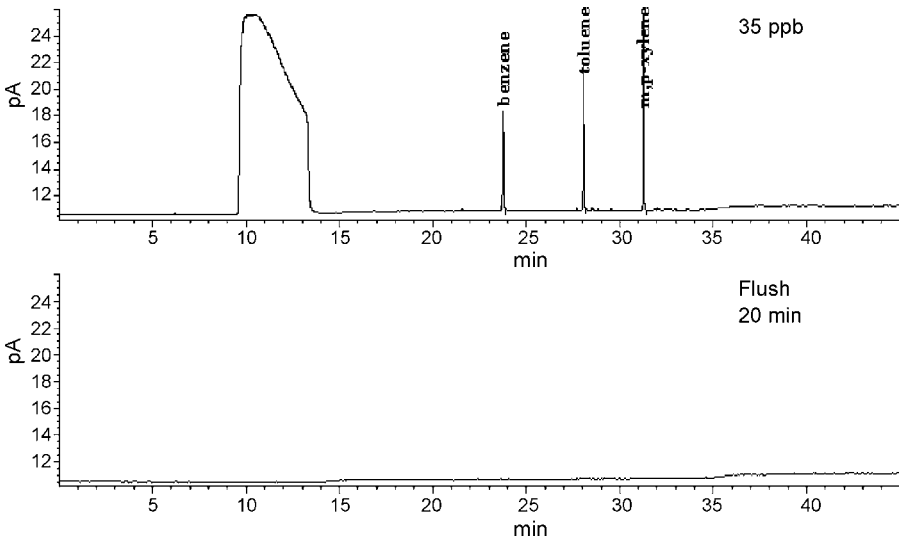

Fig. 5. Diagram of the flushing effect.

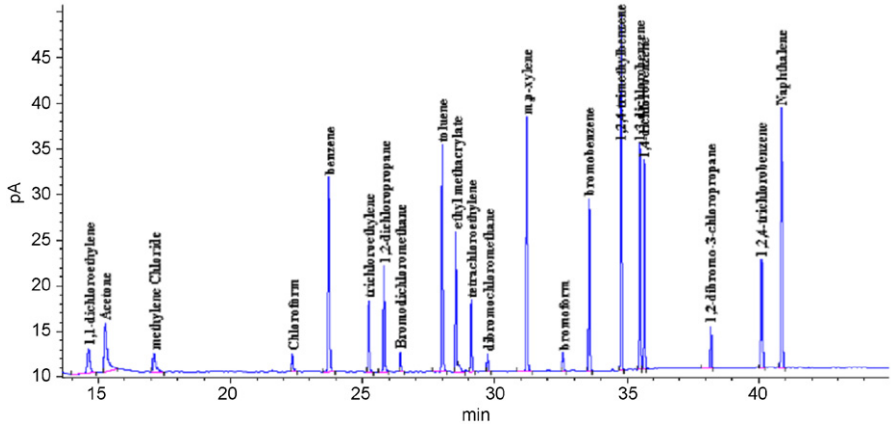

Fig. 6. Chromatogram of standards as measured by laboratory-made automated system.

chloroform reached an accuracy of 23.5%, which was close to the theoretical limit of 30%. The accuracies of the other compounds were all lower than 20%. The average accuracy value was 9.6%, and all 17 VOCs were completely separated in 41 min (Fig. 6). Based on the results of continual analysis of seven calibration curves of the compounds with the lowest concentration at 5 ppb (acetone = 60 ppb), the standard deviation was calculated. The precision of 1,1-dichloroethylene and methylene chloride was around 13%, and the rest of the compounds were within 10%. The average precision value was 7%. The above mentioned results suggest that this method is consistent in repetition.

3.2. *In situ application to environmental wastewater samples*

Once the validity of the proposed method was determined, real wastewaters were collected for long-term in situ VOCs analysis to estimate the capability of this system. A continuous 36 h test was carried out near the wastewater treatment plant. Water samples were collected every 2 or 3 h from a sampling site near the sewage treatment plant in high-tech industry park. A graph of the concentration tendency of acetone is shown in Fig. 7. The graph shows that from 9:30 p.m. of day 1 to 11:00 a.m. of day 3, the highest concentration peak was 1270.42 ppb. From 7:00 to 10:00 p.m. of

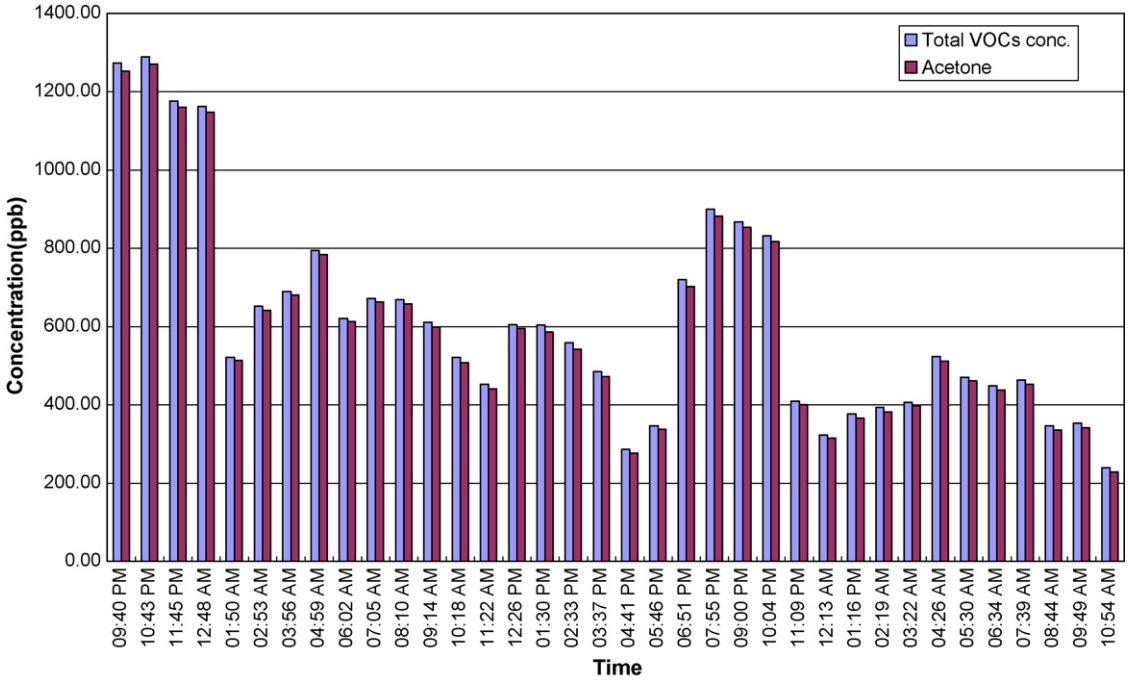

Fig. 7. Hourly concentration variations of acetone and total VOC determined by the laboratory-made automated system. The period of in situ monitoring was 36 h.

the second day, the highest concentration peak was 882.14 ppb. This second concentration peak was considerably lower than the first one. Except for these two relatively high peaks, the concentrations in the other time periods showed a tendency to decline. The average concentration was 601 ppb. In situ monitoring continued for 54 h (from 12:30 a.m. of day 1 to 4:05 p.m. of day 3) in the same location after a 36 h in situ experiment (as shown in Fig. 8). The peaks with higher VOC concentrations (526, 532 and 390 ppb) appeared individually at 5:55 a.m., 1:45 p.m. and 5:00 a.m. of day 1, respectively. In day 2, another peak reflecting a concentration of 308.29 ppb appeared at 10:45 p.m. During the entire period of in situ monitoring, a total of six different VOCs were detected: acetone, chloroform, trichloroethylene, toluene, 1,4-dichlorobenzene and naphthalene. The average concentration for the total VOCs was 220 ppb. In both in situ monitoring results, the concentration of acetone was higher than the concentrations of other VOCs in the chromatograms.

3.3. Comparison between this system and Archon system

To compare the results between the laboratory-made system and the commercial Archon system, wastewater samples were col-

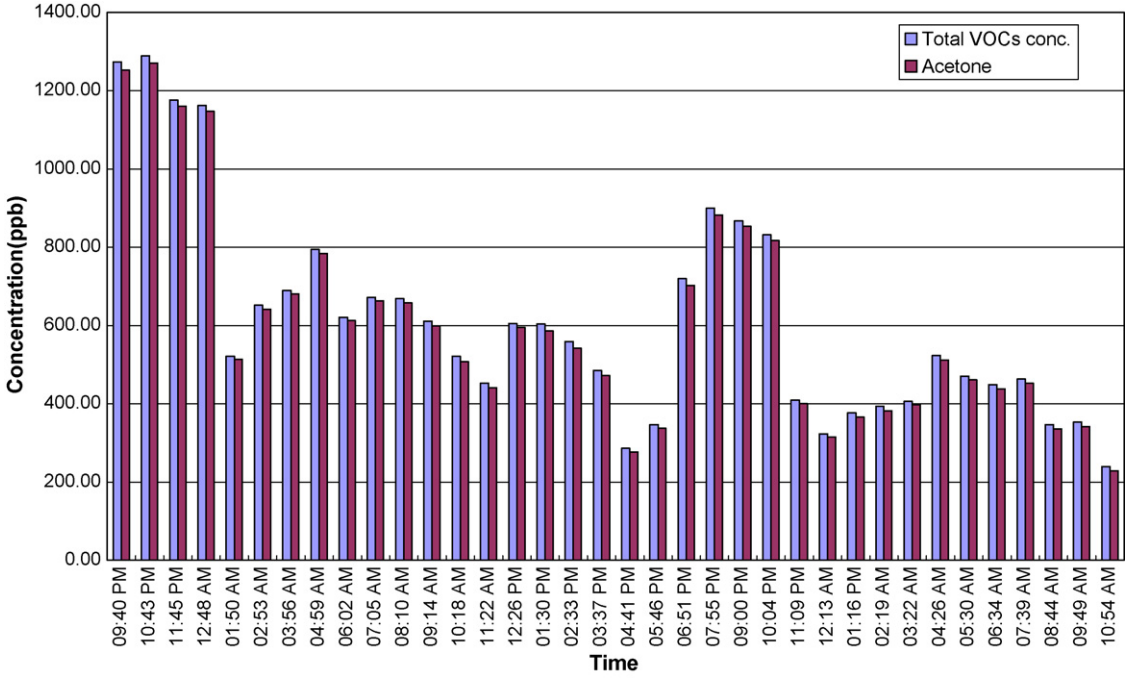

Fig. 8. Hourly concentration variations of acetone and total VOC determined by the laboratory-made automated system. The period of in situ monitoring was 54 h.

lected for advanced study by both systems. The sampling sites were the same, and the sampling times were at 1:50, 9:40, 10:52 a.m., and 3:37 p.m. during a 36 h in situ monitoring experiment. The VOCs under study were acetone, chloroform, trichloroethylene, toluene, 1,4-dichlorobenzene, and naphthalene. The wastewater samples were analyzed immediately by both systems, and the results are presented in Table 2. As can be seen in Table 2, there are very slight differences between these two systems in the four different sampling times, and all the differences are less than 4%. Because acetone was the major organic solvent used for cleaning electronic parts, its extremely high concentration in the effluent measured by both systems is reasonable.

4. Conclusion

This study demonstrates the feasibility of this laboratory-made in situ continual PSM–purge and trap–GC–FID system when using real water samples. The cycle time can be reduced to an hour (including the tube washing time), resulting in a maximum frequency of 24 samples day^{-1}. Detection limits of 17 VOCs were at ppb levels, and the suitability of the system for on-line monitoring of VOCs in wastewater was proven excellent after extended continuous in situ monitoring of wastewater from the treatment plant. The RSDs of the system were between 2 and 13.4%, and accuracies between 0.3 and 23.5% were achieved. The detection limits of the method ranged from 0.32 to 2.39 ppb. In this system, the four parts, i.e., PSM, P&T, GC, and FID, were simple, reliable and rugged. Also, the interface of these four parts was simple and dependable. In the future, it can be applied in instant monitoring of environmental pollution. Based on these data, we are able to measure pollutant activity immediately in order to reduce damage to our environment.

ABSTRACT

The rapidly increasing demand for cultured fish as a food resource requires simple, effective methods for controlling fish health in culture conditions. Plasma total cholesterol levels are significantly related to fish mortality following bacterial challenge, and are thus a good indicator of the general health of fish. We developed a wireless biosensor system to continuously monitor the total cholesterol concentration in fish (Nile tilapia, *Oreochromis niloticus*). The biosensor was constructed with Pt–Ir wire (φ0.178 mm) as the working electrode and Ag/AgCl paste as the reference electrode. Cholesterol oxidase and cholesterol esterase were immobilized on the working electrode using glutaraldehyde. The sensor output was linear and strongly correlated with the cholesterol level ($R = 0.9970$) in the range of 2.65–403 mg dl^{-1}. This range covers the range of total cholesterol levels in fish. To avoid blood coagulation and proteins coalescing on the sensor, we implanted the sensor in the fluid under the scleral surface of the eyeball (EISF). The EISF is presumed to reflect the levels of most blood components and does not include the substances contained in blood that inhibit sensor measurement. Total cholesterol concentrations in blood and EISF were strongly correlated ($R = 0.8818$, $n = 72$) in the blood total cholesterol range of 74–480 mg dl^{-1}. Therefore, we used EISF as an alternative to blood and performed continuous *in vivo*-monitoring of the total cholesterol concentration in fish. We also investigated the application of the calibration method and wireless monitoring system. These applications enabled us to securely monitor total cholesterol levels in free-swimming fish in an aquarium for over 40 h. Thus, our newly developed sensor provided a rapid and convenient method for real-time monitoring of total cholesterol concentrations in free-swimming fish.

1. Introduction

There is growing concern that many resources, such as food and energy, are in limited supply and may eventually run out. Fisheries are also at a crisis point because of increased worldwide consumption, over-fishing, and regulatory demands. The demand for fishery products will eventually exceed supply. The development of aquaculture is expected to resolve this problem, providing society with a sustainable food supply. Aquaculture, however, must still overcome many issues before it can be regarded as a mainstream method of fish production. In particular, aquafarms are plagued by fish disease. Due to overcrowded farming conditions, the diseases quickly spread through the water to other fish. Dead or diseased fish have no value as food and aquafarmers thus sustain considerable financial hardship. Although antibiotics are effective, their use affects the risk of exposing the consumer to residual drug. Therefore, a method to maintain fish health without using drugs is in high demand. Several blood tests have been developed for monitoring fish health [1]. For example, plasma total cholesterol concentration is significantly related to fish mortality following bacterial and viral challenge, and unhealthy fish have below normal plasma total cholesterol concentrations [2]. Therefore, plasma total cholesterol concentration is a good indicator of the general health of fish. Currently, in aquaculture, plasma total cholesterol concentration is measured using a colorimetric determination method. This method, however, is complicated, costly, and time-consuming. Therefore, a simple, cost-effective, and convenient system for monitoring fish health is needed.

Electrochemical technology, especially biosensor technology, is potentially useful for solving this problem. Many types of

biosensors for measuring blood components, such as glucose [3], cholesterol [4,5], and lactic acid [6] have been developed. In 1982, Karube et al. [7] developed a sensor system comprising an immobilized enzyme and an oxygen electrode. Since then, various sensors have been developed based on the same principle and that implemented innovations such as the use of a hydrogen peroxide electrode [8], quartz crystal [9], silicate sol–gel [10], and Langmuir–Blodgett films [11]. Sensors for measuring total cholesterol concentration in the blood have also been developed [12,13], but these sensor systems do not provide continuous measurement.

We have developed enzyme sensor systems for measuring total cholesterol and glucose concentration in fish blood. These sensor systems are based on flow injection analysis [14], which allows for rapid and convenient measurement of total cholesterol and glucose, but separate procedures are required for collecting the blood samples for testing. Moreover, the flow injection analysis system is large and complicated compared with a batch-type measurement system. To miniaturize and simplify the sensor system for measuring blood components in fish, we developed a needle-type enzyme sensor comprising a needle-type hollow container, an immobilized enzyme membrane, and a fiber optic probe coated with ruthenium complexes [15]. In this system, direct insertion of the sensor into the caudal vein allows for rapid and convenient measurements of blood glucose concentrations, but continuous long-term measuring is difficult because the sensor output is decreased by blood coagulation and coalescing protein (e.g., albumin, γ-globulin) deposits on the sensor. Methods for continuous *in vivo*-monitoring of glucose concentrations in human and other mammals have been studied, focusing on measurements of glucose in interstitial fluid (ISF) [16,17]. ISF is the biologic fluid present between the blood vessels and cells. The reason for selecting ISF for the sampling site is that ISF is presumed to reflect the concentration of most blood components and does not include the substances in blood that hamper sensor measurement. We focused on the fluid under the scleral surface of the eyeball (EISF) in fish as a site for collecting ISF and developed a needle-type enzyme sensor to wirelessly monitor fish glucose levels [18]. The sensor system was constructed using a platinum–iridium (Pt–Ir) Ag/AgCl electrode, controlled potentiostat, electric wave sensor, and personal computer. The sensor was inserted into the external layer of the fish (Nile tilapia, *Oreochromis niloticus*) eyeball. Real-time glucose monitoring was performed using the sensor system. Glucose concentrations reflecting those in fish blood could be monitored in free-swimming fish.

The present paper describes the development of a rapid and convenient method for real-time monitoring of cholesterol concentrations in fish, as follows; (1) investigating the relationship between EISF and blood total cholesterol levels in fish, (2) determining the characteristics of the needle-type cholesterol biosensor, (3) developing a wireless system for monitoring total cholesterol levels under free-swimming conditions in an aquarium.

2. Experimental

2.1. Reagents

Cholesterol esterase (EC 232-808-6, 2.8 U mg^{-1}), cholesterol oxidase (EC 232-842-1, 2.4 U mg^{-1}), and nonaethylene glycol monododecyl ether were purchased from Sigma–Aldrich (St. Louis, MO). Bovine serum albumin, cholesterol oleate, 2-phenoxy ethanol, and 5% nafion dispersion solution were purchased from Wako Pure Chemical Industries (Tokyo, Japan). Standard solutions of cholesterol ester were prepared by first dissolving cholesterol oleate in nonaethylene glycol monododecyl ether and then in 0.1 M phosphate buffered saline (PBS). Approximately 3 g of nonaethylene glycol monododecyl ether was added to 100 mg cholesterol oleate. The solution was then stirred until it became clear and colorless at 60 °C and 600 rpm. PBS (pH 8.0) was added to bring the solution to the desired volume, and the solution was stirred again until it became clear and colorless. A fresh standard solution was prepared for each experiment.

2.2. Total cholesterol analysis for evaluating the relationship between total cholesterol concentration in blood and EISF

2.2.1. Collection and analysis of the sample

We used Nile tilapia (*O. niloticus*) as the test fish, cultured at Tokyo University of Marine Science & Technology. Total cholesterol concentrations between blood and EISF were measured. Each fish (body weight; ca. 100–300 g, body length; ca. 15–25 cm) was netted from the preserve and anesthetized with 400 ppm 2-phenoxy ethanol by bath exposure. Blood samples were collected from the caudal vein along the backbone by inserting a heparinized syringe fitted with a 23G needle (0.65 mm × 25 mm) into the basal anal fin. The blood samples (100–200 μl) were then centrifuged (550 × *g*) for 10 min to separate the plasma. EISF samples were collected by inserting a syringe fitted with a 27G needle (0.40 mm × 19 mm) into the sclera of the eyeball. To minimize measurement error, the collection procedure never lasted more than 10 min per fish. Each collected sample was transferred to a test tube and stored at −80 °C until analysis.

Total cholesterol concentrations were determined by an enzymatic colorimetric method (E-test, Wako Pure Chemical Industries, Tokyo, Japan). Each sample (20 μl) was mixed with 3 ml buffer solution (pH 6.1) containing enzymes (cholesterol esterase, cholesterol oxidase, horseradish peroxidase) and a color-producing reagent. Total cholesterol was hydrolyzed and then oxidized to produce 4-cholesten-3-one and hydrogen peroxide. The hydrogen peroxide reacted with 4-aminoantipyrine and D-amino acid oxidases to produce a blue color (600 nm). Total cholesterol concentrations were measured using a UV/Vis spectrophotometer (JASCO Co., Tokyo, Japan).

2.2.2. Temporal change of total cholesterol concentration between blood and EISF in individual fish over days

We evaluated whether the temporal changes in total cholesterol concentrations in the blood were reflected by changes in the total cholesterol concentration in EISF in individual fish. The testing system comprised a 45-L plastic tank (50 cm × 30 cm × 30 cm). During the test, the water temperature was maintained at 30 °C with continuous aeration and recirculation through a biologic filter. The photoperiod, provided by a fluorescent light, was set to be on from 10:00 to 20:00. Blood and EISF samples were collected at 12:00 daily, as described above. The testing period spanned 30 days and the fish were fed on days 7 and 15.

2.2.3. Correlation of total cholesterol concentration between blood and EISF in randomly selected fish

We evaluated whether there were differences in the relationship between total cholesterol concentration in the blood and EISF in individual fish. Our stock population consisted of 72 adults Nile tilapia (ca. 100–300 g). The fish were randomly selected, netted from the tank, and blood and EISF were collected by the methods described above.

2.3. Needle-type total cholesterol sensor

2.3.1. Preparation of hydrogen peroxide electrode

The sensor was constructed using a 15-mm Teflon-coated platinum/iridium (Pt–Ir) wire (φ0.178 mm), 10-mm copper wire (φ0.1 mm), Ag/AgCl coating paste (BAS, Tokyo, Japan), and two copper lead wires (Fig. 1). The sensor was composed by two electrodes (working electrode and reference electrode/counter

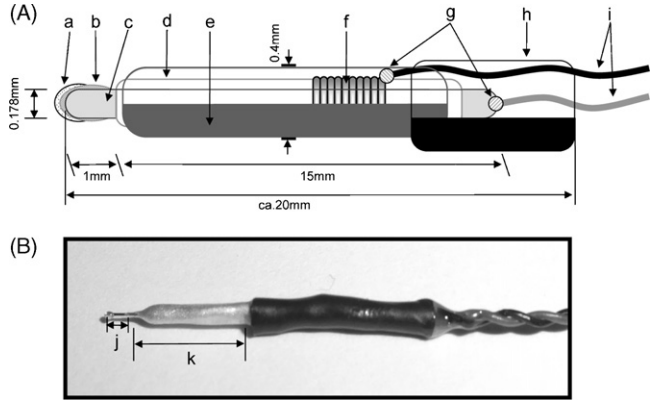

Fig. 1. Diagram (A) and photograph (B) of needle-type total cholesterol sensor. (A): (a) enzyme membrane, (b) nafion, (c) platinum/iridium, (d) Teflon-coat, (e) Ag/AgCl paste, (f) copper wire, (g) connection, (h) heat-shrink tubing, (i) lead wire, (B): (j) working electrode (Pt–Ir) and (k) reference electrode/counter electrode (Ag/AgCl).

electrode) because of less invasive for biological body. Thus, a material electric potential of which is relatively stable was used as reference electrode/counter electrode. The Teflon-coated Pt–Ir wire was stripped of 1.0-mm Teflon to expose the Pt–Ir wire as a sensing cavity (working electrode). The copper wire was wound around the Teflon-coated surface as extended line of lead wire. Then, the copper wire was coated with the Ag/AgCl paste and used as a reference electrode/counter electrode. After soldering each lead wire to either the Pt–Ir or the copper wire, each connection was covered with heat-shrink tubing and epoxy adhesive.

2.3.2. Enzyme immobilization on the working electrode

First, a 5% nafion dispersion solution (10 μl) was applied to the working electrode to prevent noise induced by oxidized substances in the EISF. Then, the enzyme membrane was immobilized on the tip of the working electrode. An enzyme solution containing cholesterol oxidase (8.4×10^{-4} units), cholesterol esterase (3.36×10^{-4} units), and 20 mg bovine serum albumin dissolved in 1.0 ml of 0.1 M PBS (pH 7.8) was applied to the tip of the working electrode and the enzymes were immobilized by a cross-linking reaction using 25% glutaraldehyde (20 μl) for 6 h. This immobilization method was repeated 2 times per electrode.

2.4. Amperometric total cholesterol measurement

The enzyme sensor was connected to a multichannel potentiostat (Pinnacle Technology Inc, Lawrence, KS) attached to a personal computer (DELL Dimension 4700C, Round Rock, TX) via either a USB 2.0 or RS232C port. Then, a 650-mV potential (vs. Ag/AgCl) was applied to the Pt–Ir working electrode using the potentiostat. Amperometric total cholesterol measurement was then performed based on the following 3 reactions that occurred on the surface of the working electrode.

$$\text{Cholesterolesters---(cholesterolesterase)} \rightarrow \text{cholesterol} + \text{fattyacid} \quad (1)$$

$$\text{Cholesterol} + O_2\text{--(cholesteroloxidase)} \rightarrow \text{4-cholesten-3-one} + H_2O_2 \quad (2)$$

$$H_2O_2\text{--(electrocatalyticoxidation)} \rightarrow O_2 + 2H^+ + 2e^- \quad (3)$$

Reaction (3) produced an electric output current that was recorded via the computer-controlled data acquisition software (Pinnacle Acquisition Laboratory).The sensor was placed in 50 ml of 0.1 M PBS (pH 8.0). After the output current stabilized, a 1.0-ml aliquot of the 1000 mg dl^{-1} cholesterol oleate standard solution was added to the 0.1 M PBS. After the output current again stabilized, another 1.0-ml aliquot of the cholesterol standard solution was added. This procedure was repeated until 20 aliquots had been added. The sensor output current was measured after each addition of cholesterol and the background current was subtracted from the response current. Because cholesterol generally exists as a cholesterol ester, cholesterol oleate was used for the cholesterol standard.

2.5. Total cholesterol monitoring in fish

2.5.1. Wired sensor system for continuous total cholesterol monitoring

Sensor implantation and fixation were performed after anaesthetizing fish with 400 ppm 2-phenoxy ethanol. A small hole was created in the sclera using a 20G catheter (φ1.10 mm) consisting of an outer Teflon layer and inner puncture needle (22G, 23 mm, Serflow™ Terumo, Tokyo, Japan). The inner puncture needle was then removed, and the excess exposed catheter on the skin was trimmed off. The sensor was then inserted into the scleral ISF, immersing the working and reference electrodes of the sensor in the EISF. The sensor was then fixed in place using a biomedical adhesive (Aronalpha-A Sankyo, Toagosei, Tokyo, Japan). The adhesive was applied around the insertion point to fill the hole and the sensor was stapled to the fish's body. After implantation and fixation, the sensor was connected to a multichannel potentiostat. Monitoring of total cholesterol was performed after the background current of the sensor became stable. During monitoring, EISF from the contralateral eyeball was collected periodically using a syringe fitted with a 27G needle (0.40 mm × 19 mm) to compare the obtained sensor response to the actual total cholesterol concentration. To prevent the fish from moving while collecting the EISF sample, the fish was transferred to a 7.5-L water tank containing 200 ppm of 2-phenoxy ethanol as a light-anesthetic agent. The fish was held in place using a string to simplify the EISF sample collection process.

2.5.2. In vivo calibration

Continuous estimation of total cholesterol in EISF was performed using one-point or two-point *in vivo* calibration methods [19–21]. The one-point calibration method is represented by the following formula:

$$\text{TC}(t) = \frac{I(t)}{S}$$

The sensor sensitivity (S), expressed in nA/(mg dl^{-1}), was determined from a single total cholesterol measurement in EISF as the ratio between the concomitant sensor output current (I; expressed in nA) and the total cholesterol (TC) concentration. Subsequently, the TC concentration was estimated based on the sensor output current (I).

First, the sensor output current was measured until it stabilized after the sensor was implanted into the sclera. An EISF sample was obtained from the other sclera using a syringe fitted with a 27G needle. TC concentration in EISF was determined by an enzymatic colorimetric method. These parameters (I, TC) were used as the calibration reference.

The two-point calibration method is represented by the following formula:

$$\text{TC}(t) = \frac{I(t) - I_0}{S}.$$

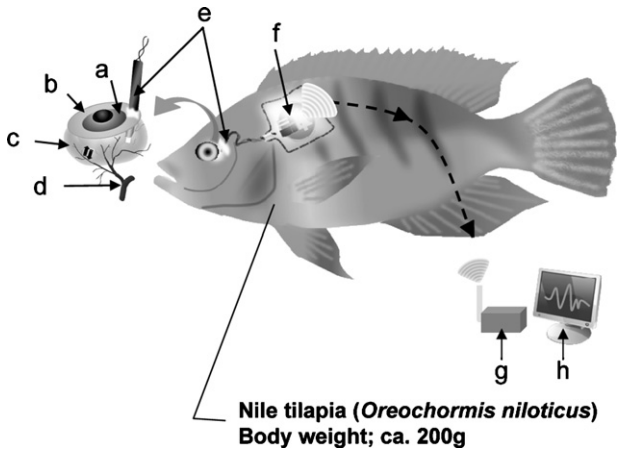

Fig. 2. Schematic diagram of the wireless monitoring system for fish (Nile tilapia). (a) Eyeball, (b) sclera, (c) EISF, (d) blood vessel, (e) needle-type total cholesterol sensor, (f) wireless potentiostat, (g) receiver and (h) personal computer.

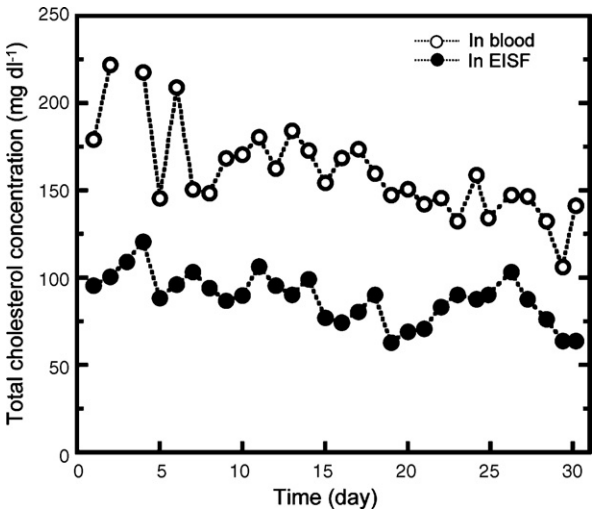

Fig. 3. Representative plot of total cholesterol concentration in the blood and EISF in an individual fish over 30 days. Total cholesterol concentration in blood was plotted as white circles and that in EISF was plotted as a black circles.

The formula consists of the sensor sensitivity (S) and the intercept I_0 of the sensor output. Parameters (S) and (I_0) were calculated from the change of total cholesterol concentration in EISF from TC_1 to TC_2, the change in the sensor current I from I_1 to I_2: $S = (I_2 - I_1)/(TC_2 - TC_1)$, followed by calculation of I_0 using the following formula: $I_0 = I_1 - (S \times TC_1)$.

2.5.3. *Wireless sensor system for total cholesterol monitoring under free-swimming conditions*

A schematic diagram of the wireless monitoring system is shown in Fig. 2. Sensor implantation and fixation were performed according to the same method used for the wired monitoring. The sensor was connected to a wireless potentiostat (3102BP, Pinnacle Technology, Inc) and covered with a waterproof polypropylene sheet. The waterproofed wireless potentiostat was attached to the dorsal and pectoral fins of the fish using nylon thread. The signal of the sensor output current signal was sent to a receiver (3100RX, Pinnacle Technology Inc) using a radio wavelength of 916.5 MHz. The fish were then transferred to a water tank (40 cm × 24 cm × 50 cm). During the monitoring, EISF samples from the contralateral eyeball were collected periodically from fish anesthetized with 400 ppm 2-phenoxy ethanol to prevent noise signals due to fish movement. After collecting the EISF, the water dissolved 2-phenoxy ethanol in tank was changed with new one. During the experiment, the water was maintained at 30 °C, aerated, and filtered. Continuous monitoring of total cholesterol was performed after the sensor output current became stable.

3. Results and discussion

3.1. *Comparison of total cholesterol between blood and EISF*

It is difficult to perform continuous monitoring of blood components using a biosensor because the sensor output decreases over time due to blood coagulation and protein coalescing on the sensor. We investigated the correlation between total cholesterol concentrations in blood and EISF. Changes in cholesterol levels in individual fish over time were measured to assess whether fluctuations of cholesterol concentrations in the blood were reflected by changes in cholesterol concentrations in the EISF. We examined the correlation between total cholesterol concentration in blood and in EISF over 30 days in a fish. The temporal changes in total cholesterol concentration in a single representative fish are shown in Fig. 3. The fluctuations of the total cholesterol concentrations in the blood and EISF over 30 days were significantly correlated. Additionally, two specific properties of EISF were discovered by comparing the two temporal cholesterol concentration profiles. First, total cholesterol concentration in EISF was approximately half that in blood. Second, the kinetics of the changes in EISF cholesterol concentrations were dependent on the valence of the change; increases in the blood concentration were slowly reflected by increases in the EISF concentration, whereas decreases in blood concentration were rapidly reflected by decreases in the EISF concentration. This difference in kinetics likely reflects the fact that the EISF cholesterol concentration is a product of cholesterol moving into the EISF along a concentration gradient and cholesterol being removed from the EISF by the cells, which depends on the requirements of the cells for cholesterol. An increase in cholesterol availability can lead to a rapid increase in cell demand. In addition, the amount demanded by the cell has an established minimum. Thus, total cholesterol concentration in EISF was reflected by blood concentrations, especially when the total cholesterol concentration in the blood decreased.

We next examined interindividual variations in the relationship between blood and EISF cholesterol concentrations at a single time point. The tilapia were captured randomly from the water tank ($n = 72$), and both blood and EISF samples were obtained. Total cholesterol concentration in EISF was strongly correlated ($R = 0.8818$) with blood total cholesterol in the range of 74–480 mg dl^{-1} (Fig. 4), thus indicating that the EISF is a useful alternative to blood collection for measuring total cholesterol. In general, in the aquafarm setting, blood tests are performed once a day. Although there is a small time-lag between total cholesterol concentration in the blood and that in the EISF, total cholesterol concentration in the EISF generally reflects the total cholesterol concentration in the blood. Thus, sampling the EISF to determine total cholesterol levels should be a good indicator of fish health.

3.2. *Characteristics of the needle-type total cholesterol biosensor*

Fig. 5 shows a relationship between output current and cholesterol oleate concentration. Cholesterol oleate, which is a kind of esterified cholesterol, was prepared as standard sample of total cholesterol. Good linearity was observed in the concentration range of 2.65–403 mg dl^{-1} (correlation coefficient: 0.9970). The mean total cholesterol concentration in the blood of Nile tilapia is 140.35 mg dl^{-1} [22] and the concentration in the EISF is usually lower than that in blood (Fig. 3). Thus, the physiologic cholesterol

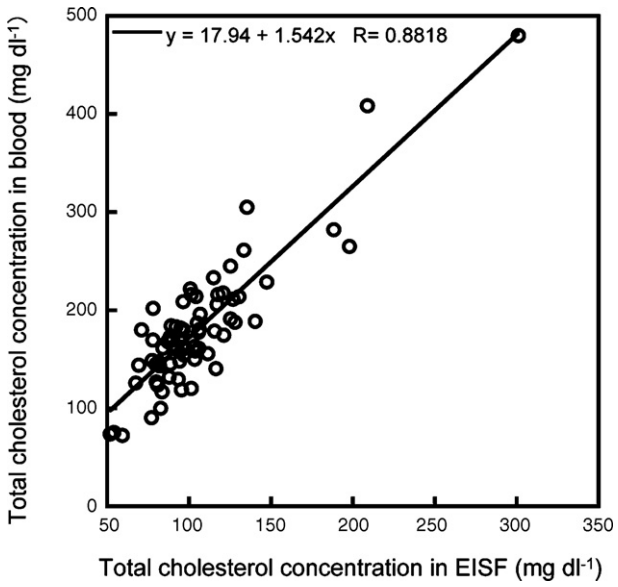

Fig. 4. Correlation of total cholesterol concentration in blood and EISF in randomly selected fish ($n = 72$, 74–480 mg dl^{-1}).

concentrations in EISF are well within the linear range of the sensor.

As the sensor comprises a biologic catalyst (enzyme), the response can vary depending on the pH and temperature of the solutions in which the immobilized enzyme is placed. The effects of pH and temperature on the sensor induced current for a 100 mg dl^{-1} standard solution are shown in Fig. 6. The sensor current gradually increased in the range of pH 5.5–6.5 and rapidly decreased at pH greater than 6.5 (Fig. 6 A). The EISF pH in Nile tilapia is 8.0 [23]. Although pH affects enzyme activity, even at pH 8.0 the sensor induced enough current to detect changes in the total cholesterol concentration. Temperature also has important effects on enzyme activity. For temperatures ranging from 10 to 40 °C, the sensor current increased rapidly up to 30 °C and then became nearly constant (Fig. 6 B). Above 40 °C, the current

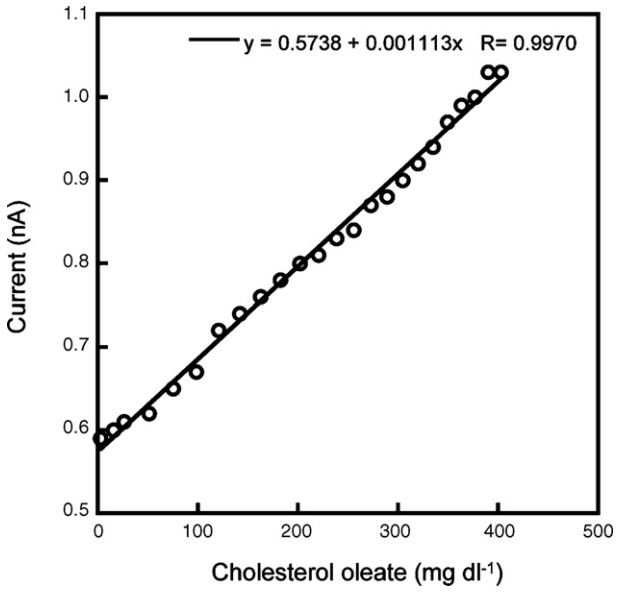

Fig. 5. Relationship between sensor output current and cholesterol oleate concentration (range of cholesterol oleate concentration 2.65–403 mg dl^{-1}). The measurement was performed by sequential addition of 100 mg dl^{-1} cholesterol oleate standard solution in pH 8.0, 30 °C PBS under a +650 mV potential (vs. Ag/AgCl).

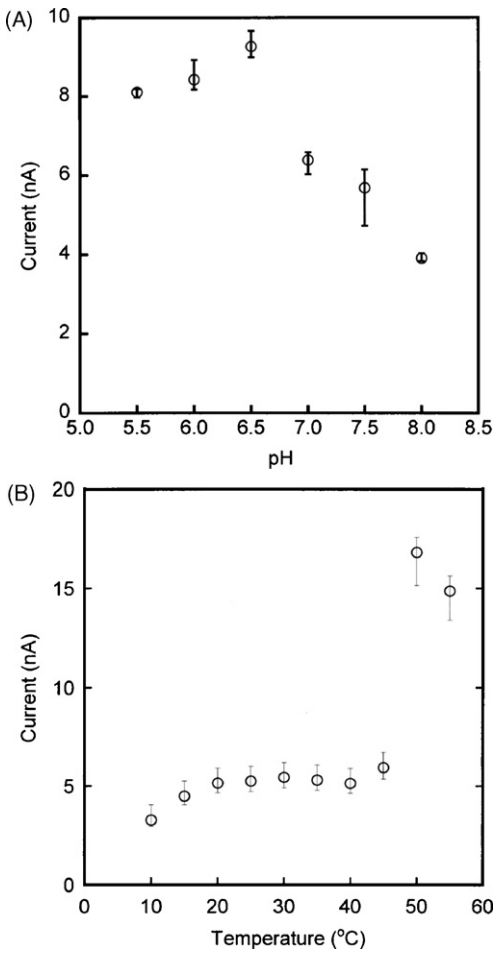

Fig. 6. Typical effects of pH (A) and temperature (B) on the total cholesterol sensor response in PBS. In (A) the temperature was 30 °C, in (B) the pH was 8.0. The measurements were performed using 100 mg dl^{-1} cholesterol oleate standard solution under a +650 mV potential (vs. Ag/AgCl).

increased rapidly again and reached the maximum output. At temperatures above 40 °C, however, the signal was very noisy and the output current was not stable. EISF is assumed to be at the same temperature as the environmental water temperature since the internal body fluid temperature of fish is influenced by its environment. The water temperature used for rearing Nile tilapia is in the range of 15–30 °C. Thus, the sensor induces sufficient output current under typical EISF temperature conditions and can be applied to *in vivo*-measurements.

The reproducibility of sensor measurements is shown in Table 1. The reproducibility of the measurements was demonstrated by immersing a single sensor in 100 mg dl^{-1} standard solution (30 °C).

Table 1
Reproducibility of total cholesterol measurements using the cholesterol biosensor ($n = 20$).

Electrode no.	Relative standard deviation (RSD %)
1	4.02
2	2.40
3	2.68
4	9.37
5	4.45
Mean ± SD	4.58 ± 2.52

The measurement was performed using 100 mg dl^{-1} cholesterol oleate in PBS, pH 8.0, 30 °C under a +650 mV potential (vs. Ag/AgCl).
Absolute response value for five sensors: 2.97–6.49 nA.

Each of five enzyme sensors was tested 20 times. The relative standard deviation (RSD %) was used to evaluate the reproducibility because of lot-dependent variability in the sensor output current. The RSD was 4.58 ± 2.52% in the absolute response values for five sensors was from 2.97 to 6.49 nA. The low RSD values indicated that the sensor can be used to determine total cholesterol concentrations with satisfactory precision. Therefore, the sensors have excellent reproducibility for measuring total cholesterol, and can be applied to continuous measurement of total cholesterol concentration *in vivo* with stable and accurate results.

3.3. Continuous cholesterol monitoring using the wired enzyme sensor system

We performed continuous total cholesterol monitoring in Nile tilapia using a wired sensor system. The fish were immobilized in the water tank to minimize experimental error while collecting the EISF samples. After sensor implantation in the EISF, the fish were not touched until the output current became stable (approximately 240 min). The total cholesterol concentration was then continuously monitored for 230 min. The time course of the total cholesterol concentration in EISF and the sensor output current were similar. In fact, the correlation coefficient between the actual total cholesterol concentration and sensor output current was 0.8961 ($n = 6$), confirming the corresponding relationship between them.

Sensor-calibrated cholesterol concentrations were estimated using either a one-point or two-point calibration method. The one-point calibration method used the calibration value (TC_1, I_1) in which TC_1 was the total cholesterol concentration in EISF (165 mg dl^{-1}) and I_1 was the subsequently obtained sensor output current (5.05 nA). The two-point calibration method used the first parameter (I_1; 5.05 nA, TC_1; 165 mg dl^{-1}) and the total cholesterol concentration in EISF and sensor output current obtained 90 min after sensor implantation (I_2; 4.53 nA, TC_2; 157 mg dl^{-1}). The relationship between the actual concentration and calibrated curve of the sensor is shown in Fig. 7. The two-point calibration method appeared to be more accurate than the one-point calibration method for determining the actual cholesterol concentration.

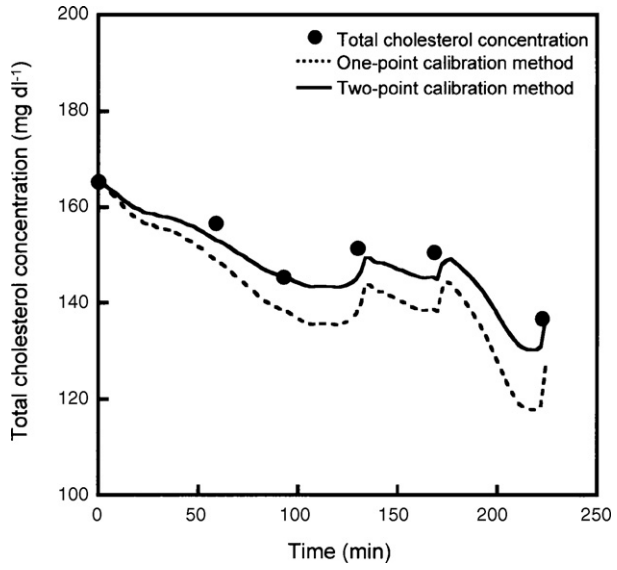

Fig. 7. The relationship between total cholesterol concentration in EISF and the calibrated sensor response. Total cholesterol concentrations were plotted as black circles, the calibrated response using the one-point calibration was plotted as the broken line, and the calibrated response using the two-point calibration was plotted as the solid line.

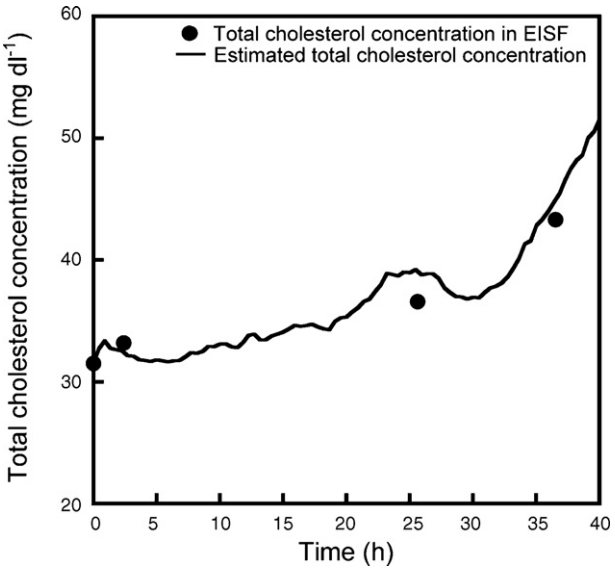

Fig. 8. The change in estimated total cholesterol concentrations in the wireless monitoring system. Total cholesterol concentrations in EISF at 0 and 90 (min), plotted as black circles, were used in the two-point calibration method.

To judge this relationship objectively, we compared the range of error between the actual and estimated cholesterol concentration values. The range of error was calculated as the mean value of the difference between the estimated value and the actual value for all 6 time points. The results indicated that the error for the two-point calibration method was lower (−1.18 mg dl^{-1}) than that for the one-point calibration method (−13.11 mg dl^{-1}). Therefore, the two-point calibration method should be used to measure total cholesterol concentration in fish. These findings confirm that the needle-type sensor monitoring system can be used for real-time measuring of total cholesterol concentration in fish.

3.4. Total cholesterol monitoring using the wireless enzyme sensor system under free-swimming conditions

We applied the sensor system to wirelessly monitor total cholesterol concentrations in free-swimming fish in an aquarium. Nile tilapia was anesthetized with 400 ppm 2-phenoxy ethanol, and then the wireless sensor system was attached. The fish were transferred to a 50-L fish water tank containing no anesthetic. The time courses of the output current of the sensor and sensor-calibrated total cholesterol levels are shown in Fig. 8. The two-point calibration method was adopted using the first measurement (I_1; 3.65 nA, TC_1; 31.5 mg dl^{-1}) and a second measurement obtained 90 min later (I_2; 3.79 nA, TC_2; 3.32 mg dl^{-1}). Wireless monitoring was continued for over 40 h and the results indicated that this system can be used for short-term measurement of total cholesterol in free-swimming fish. Actually, the calibration curve showed actual concentration of total cholesterol in EISF well. The estimated total cholesterol levels that were monitored for 40 h were within the range of standard values for Nile tilapia. The point of notice is that periodical calibration will be essential for practical chronic monitoring, which range for several weeks or a month, of total cholesterol levels. The results of wireless monitoring showed potential of the sensor as ubiquitous tool for aqua farm.

4. Conclusion

The present findings confirm that a needle-type enzyme biosensor-based monitoring system can be used to continuously

measure total cholesterol concentrations in fish. We used EISF as an alternative to blood and investigated the relationship between total cholesterol concentration in the blood and EISF. The total cholesterol concentration in EISF strongly correlated with that in blood. We prepared a needle-type enzyme sensor for measuring total cholesterol in fish. The sensor size was ca. 0.4 mm width × 20 mm length and provided a rapid response, good linearity, and good reproducibility. Continuous *in vivo*-monitoring was performed when the sensor was implanted under the scleral surface of the fish eyeball. The changes in the cholesterol concentrations in EISF and those in the sensor output current were similar. We investigated two steps for practical application; (1) establishing an accurate calibration method and (2) application of a wireless monitoring system. The two-point calibration method was more effective than the one-point calibration method for calculating the actual cholesterol concentration. Additionally, the wireless monitoring system enabled us to securely monitor total cholesterol levels in free-swimming fish in an aquarium. The wireless monitoring system detected changes in total cholesterol concentration and thus the ability of the fish to fight disease. Several issues, however, remain. One is determining how to protect the sensor output response from changes in the *in-vivo* environment of the fish, such as those due to changes in temperature and dissolved oxygen in EISF. Another is that the monitoring space must be enlarged so that the free-swimming fish can be placed in larger tanks that are typically used for aquaculture. Future improvements should address these issues. This system will contribute to monitoring fish health in aquaculture.

ABSTRACT

Symphytum officinale L. (comfrey) is a medicinal plant commonly used in decoctions and aliments. Besides therapeutic bioactive compounds present in the herb, it is found to contain hepatotoxic pyrrolizidine alkaloids (PAs), such as lycopsamine and others. In the present study, PAs such as lycopsamine, echimidine and lasiocarpine were determined using electrospray liquid chromatography–mass spectrometry (LC–MS) with the method precision (relative standard deviation, RSD) <10%. Detection of lycopsamine, symviridine and their N-oxides could be confirmed with a newly developed method based on HPLC ion-trap and orbitrap MS with electrospray ionization interface. With LC–MS, quantitative analysis of lycopsamine in the botanical extract was carried out. The effect of extraction solvent was optimized by sonication and methanol: H_2O (50:50) was selected. Then a rapid method based on pressurized hot water extraction (PHWE) was employed for the extraction of lycopsamine from comfrey followed by the comparison with heating under reflux with the RSD ranging from 2.49% to 19.32%. Our results showed a higher extraction efficiency for heating under reflux compared with PHWE. It was proposed that the lower extraction efficiency for PHWE was attributable to dissolved nitrogen from air which caused the reduction in the solubility of lycopsamine in the compressed hot solvent. In this study, quantitative analysis of PAs in comfrey was demonstrated. In addition, it was found that the use of subcritical water for extractions depended on the physical properties of the dissolved solutes and their tendency to degrade under the chosen extraction conditions.

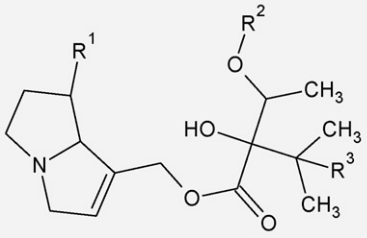
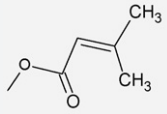
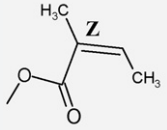
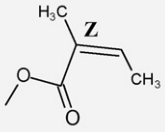
1. Introduction



Symphytum officinale L. (comfrey) is a well-known herb that has been used extensively to treat a wide variety of aliments such as arthritis, varicose ulcers and sprains. In addition, it is also consumed in tea form or as part of dietary supplements. Unfortunately, this herb is also potentially toxic and has been mentioned in monographs on poison plants. The toxins in comfrey include pyrrolizidine alkaloids (PAs), such as lycopsamine, echimidine and lasiocarpine (Table 1), and their N-oxides [1]. PAs are of special interest currently because several of them have been shown to cause toxic reactions in humans, primarily veno-occlusive liver disease, when ingested as food or herbal medicines. For this reason, it is necessary to monitor the concentration of toxic PAs and researchers have highlighted essential analytical requirements for confident assessment of pyrrolizidine alkaloid-related safety of food and herbal products [2]. As their occurrence is widely distributed, it is important to develop rapid methods for their qualitative and quantitative analyses in plant samples or food products.







For the chemical standardization of botanicals and herbal preparations, the extraction of bioactive components or marker compounds is an important step. The methods found in the monographs of Pharmacopeias and other reports [3,4] often use extraction methods that require significant volume of organic solvents and are rather tedious. In previous PAs extraction studies, the use of methanol at temperature 50–60 °C for 12 h was often recommended [5]. The best result of extraction of PAs from comfrey was obtained using 1% methanolic solution of tartaric acid and electric basket technique at the temperature 100 ± 5 °C for 2 h [6]. Recently, simpler and more environmental friendly extraction methods have been developed. These include supercritical fluid extraction (SFE), microwave-assisted extraction (MAE), pressurized fluid extraction (PFE) [7,8]. Pressurized hot water extraction (PHWE) is another

Lasiocarpine	$C_{21}H_{33}NO_7$				411.225702

new extraction technique which can be applied for the isolation of bioactive or marker compounds from botanicals and medicinal plants [9]. It is effective for a wide range of analytes and matrices because the physico-chemical properties of water are readily altered through changes in temperature and pressure. The applied temperature is generally the main parameter affecting extraction efficiency and selectivity in PHWE [9]. Pressure is usually applied to maintain water in the liquid phase, and its effect on the extraction efficiency is usually not significant. To our best knowledge, the application of PHWE on comfrey is limited.

Methods based on GC–MS and LC–MS have been reported for the detection of PAs due to their sensitivity and specificity [10–16]. However, GC–MS is not very suitable for the analysis of PA N-oxides due to their thermal instability. A pre-reduction of the N-oxides followed by derivatization is required if analysis is to be done by GC–MS. For these reasons, LC–MS is the preferred method in our study. LC–MS analysis of macrocyclic PAs in *Senecio* spp. using thermospray interface was previously reported [17,18]. Lin et al. [11], analysed various types of macrocyclic PAs with both in-source (collision induced dissociation in the collision cell) and out-source HPLC/MS or HPLC/MS/MS using electrospray interface. Mroczek et al., performed structure characterization of PAs in various plant species by RP-HPLC ion trap MS method with atmospheric pressure chemical ionization (APCI) interface [19] and gradient HPLC with diode array (DAD) and thermabeam electron impact (EI) MS [20]. Till now, HPLC ion-trap and orbitrap MS with electrospray ionization interface has not been used in the determination of PAs in comfrey.

The recent success with the use of LC–ESI–MS for the analysis of constituents in complex botanical extracts suggests that this technique can be effective for both the qualitative and quantitative determination of pyrrolizidine alkaloids in botanical extracts. Hence, one of the aims of the current work is to develop a new method based on HPLC ion trap and orbitrap MS with electrospray ionization interface for the qualitative analysis of hepatotoxic PAs such as lycopsamine present in *S. officinale L.* Another aim of the present study is to perform quantitative determination of lycopsamine present in comfrey. For this purpose, proper sample preparation is of utmost importance. Therefore, comparative studies on different extraction methods, including sonication, pressurized hot water extraction (PHWE) and heating under reflux were performed prior to quantitative analysis by LC–MS.

2. Experimental

2.1. Chemicals and reagents

All reagents were of HPLC grade. Methanol was the product of Merck (Nordic European center, Singapore). Ethanol, chloroform, isopropyl alcohol were purchased from Fisher scientific (Loughborough, Leicestershire LE11 5RG UK). Acetonitrile was the product of Tedia (Fairfield, OH45014, USA). Formic acid was obtained from Fluka (Sigma–Aldrich Pte Ltd, Science Park II, Singapore). Lycopsamine was purchased from Planta Analytica (USA), echimidine and lasiocarpine were purchased from Phyto Lab (Germany). Sand (white quartz, 50–70 mesh) was purchased from Sigma (St. Louis, MO, USA). Ultra-pure water was obtained using an Omega NANOpure ultrapure water system (Barnsteas Int., Dubuque, IA, USA). The plant comfrey of *S. officinale* L. was kindly provided by University of Quindío, Colombia.

2.2. Preparation of reference standards

Stock solutions of lycopsamine, echimidine and lasiocarpine at 200 ppm were prepared in methanol. For all analysis, the working solutions of lycopsamine, echimidine and lasiocarpine were prepared in the range of 0.05–2 ppm in methanol and their linearity was determined. For the quantitation of marker compounds, a four-point calibration based on the linearity established were used.

2.3. Preparation of medicinal plants

To prepare a homogenous sample, the real sample comfrey was ground using an IKA MF10 microfine grinder (Staufen, Germany) with sieve insert of hole size 0.5 mm. For PHWE, 1 g of the comfrey sample was weighed directly into a glass tube and mixed thoroughly with a high proportion of sand. The sand and plant material mixture were transferred into the extraction cell for PHWE as mentioned below. The extraction cell was finally filled with sand to avoid any voids.

2.4. Extraction

2.4.1. Sonication extraction

Briefly, 1 g of ground comfrey sample was extracted with 50 mL of solvent (methanol/water (50:50), methanol/chloroform (15:85), methanol, and ethanol) at room temperature for 10 min and filtered. The extracts were obtained, then excess solvent was evaporated with the rotary evaporator and the residues were transferred into a 10 mL volumetric flask.

2.4.2. Extraction by heating under reflux

Weigh 1 g comfrey into a round bottom flask, then add in 60 mL methanol/water (50:50) and gently reflux the mixture at 65 °C for 1 h in an electromantle before centrifuge at 2000 rpm for 10 min to isolate the extract. Excess solvent was evaporated on the hotplate and the residues were transferred into a 50 mL volumetric flask.

2.4.3. Pressurized hot water extraction (PHWE) system

For the instrumentation used for PHWE, the stainless steel tubings were 1/16 in. OD and 0.18 mm ID. The extraction cells from Phenomenex were of stainless steel with 10 mm ID × 1/2 in. OD × 250 mm (approx. 17 ml). The extraction cell was heated in a HP5890, gas chromatograph oven (Hewlett Packard, USA). The pump used was a Shimadzu LC-10AT HPLC pump (Kyoto, Japan). The pump flow was set at 1.5 mL/min and the oven temperature from 60 to 120 °C was studied. The pressure in the system indicated by the HPLC pump was between 20 and 30 bar. The extraction cell was pre-filled with methanol/water (50:50) to check for possible leakage before setting the temperature of the oven to the required value. Extraction with methanol/water (50:50) was carried out for a period of 40 min and 60–70 ml of liquid was collected. In between runs, the system was washed with methanol/water (50:50) for 5 min. The excess liquid was evaporated with the rotary evaporator under vacuum or by heating on a hotplate to 20–25 ml, and the residues were transferred into a 50 ml volumetric flask.

2.5. LC/MS analysis

Before HPLC analysis, all the real samples were filtered using the Acrodisc 32 mm Syringe filters with 0.2 μm Supor membrane (Pall Newquay, Cornwall, UK). For quantitative analysis, the LC/ESI–MS system comprised an Agilent 1100 series (Waldbronn, Germany) binary gradient pump, autosampler, column oven, diode-array detector and a LCQ-Duo ion trap mass spectrometer (Thermo Finnigan, San Jose, CA, USA). The column used for the separation was a Luna C18 (2), 100 × 2.0 mm, 3 μ (Phenomenex, USA). The gradient elution consisted of mobile phase of (A) water with 0.1% formic acid and (B) acetonitrile with 0.1% formic acid. The initial condition was set at 5% of (B), gradient up to 100% in 15 min and returning to the initial condition for 10 min. Oven temperature was set at 40 °C and flow rate was set at 0.2 mL/min. For all experiments, 5 μL of standards and sample extracts were injected. ESI–MS was performed in the positive mode. The LCQ mass spectrometer was operated with the capillary temperature at 270 °C, sheath gas at 80 (arbitrary units) and auxiliary gas at 20 (arbitrary units). The target was fixed at 2×10^7 ions and the automatic gain control was turned on. The electrospray voltage was set at 4.5 kV, the capillary voltage at 10 V and lens tube offset at 0 V. Mass spectra were recorded from m/z 100–600.

2.6. LC–MS^n analysis

For qualitative analysis of PAs and N-oxides, LC–MS^n experiments were performed using a Thermo Finnigan (San Jose, CA, USA) LTQ Orbitrap hybrid mass spectrometer coupled to a Thermo Finnigan Surveyor micro autosampler and liquid chromatography system. The extract was injected onto a Waters Symmetry 300 C18 column (3.5 μm, 2.1 × 50 mm ID). The mobile phase consisted of (A) 10 mM ammonium acetate and (B) acetonitrile. The gradient for elution was as follows: 0–5 min: 5% B; 5–15 min: 5–40% B; 15–30 min: 95% B; 30–45 min: 5% B. Flowrate was 0.2 mL/min.

The mass spectrometer was equipped with an electrospray interface as ionization source, an ion trap and an orbitrap for MS^n experiments and high mass accuracy determination. The mass spectrometer was operated in the positive mode with the following conditions: sheath gas N_2 with flow of 45 L/min; auxiliary gas at 5 L/min; sweep gas at 3 L/min; spray voltage, 4 kV; source current, 100 μA; capillary temperature, 400 °C; capillary voltage, 50 V; tube lens, 120 V. Full-scan mass spectra (50–500 amu) were recorded every 50 ms.

For MS/MS experiments, the conditions were: isolation width, 1 amu; normalized collision energy, 25%; activation time, 30 ms. The protonated parent ion $[M+H]^+$ of the PAs and N-oxides were chosen as precursor ions for isolation and fragmentation.

For MS^3 experiments, the conditions were: isolation width 1 amu; activation time, 30 ms; normalized collision energy, 25–35%. The most intense product ions with m/z greater than 150 (excluding parent ions) were chosen as precursor ion for isolation and fragmentation.

3. Results and discussions

3.1. Separation and determination of PAs in comfrey extracts

In other reports [12], one of the problems encountered in the development of a method to characterize the PAs in *S. officinale L.* was the lack of commercial standards. Using the HPLC conditions stated above, the three standards of lycopsamine, echimidine and lasiocarpine were separated well and their retention times were 2.82, 9.10 and 9.63 min, respectively. In positive ion ESI experiments, lycopsamine, echimidine and lasiocarpine form $[M+H]^+$ at 300.2, 398.2 and 412.0, respectively. Fig. 1 showed the selected ion chromatogram of lycopsamine, echimidine and lasiocarpine in their standard mixture solution (Fig. 1a) and comfrey extracts (Fig. 1b), respectively. As lycopsamine could be clearly identified from comfrey extracts, it will be quantitated in the following extraction study. Linearity was established from 0.05 to 2 ppm, and their

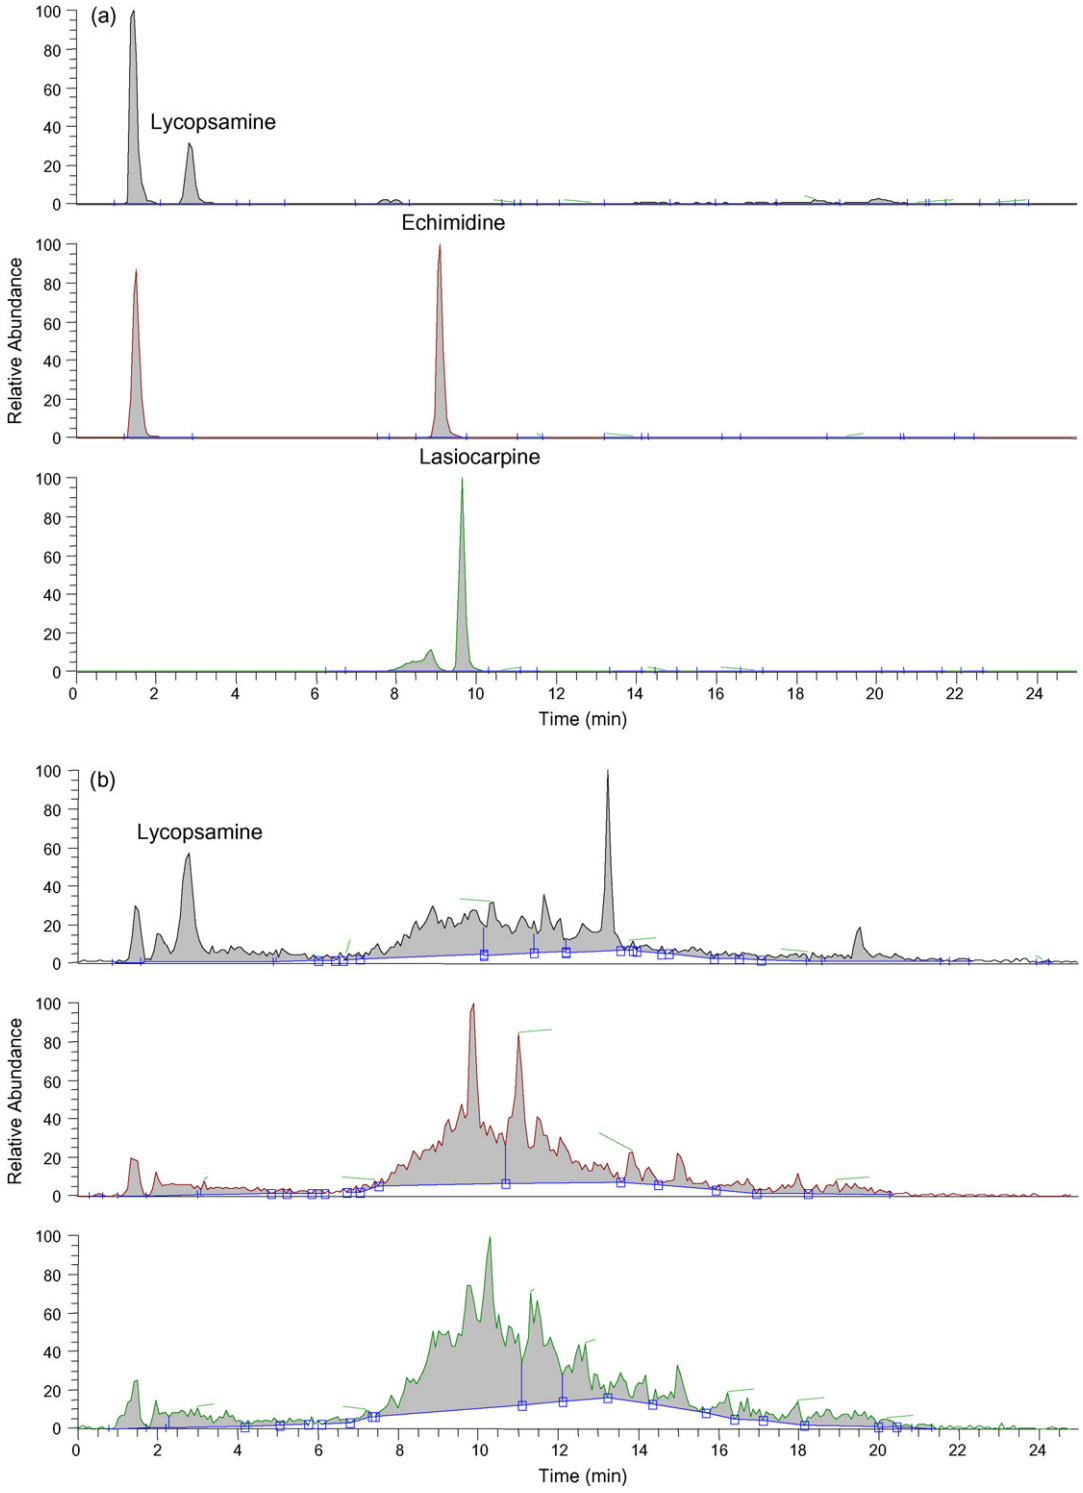

Fig. 1. Spectra under SRM of lycopsamine, echimidine and lasiocarpine in their standard mixture solution (a) and comfrey extracts (b); peak identification of (a): t_R = 2.82 min (lycopsamine); t_R = 9.10 min (echimidine); t_R = 9.63 min (lasiocarpine); peak identification of (b): t_R = 2.80 min (lycopsamine).

linear correlation coefficients r^2 all equaled to 0.999. The system precision (RSD) for the analysis of lycopsamine, echimidine and lasiocarpine by this method was determined at the concentration level 0.1, 1, 2 ppm and the results showed in Table 2 were found to vary between 2.06% and 9.21%.

3.2. LC–MS^n analysis of PAs

LC combined with MS^n detection can provide mass-based resolution of the PAs based on the specific product ions or fragments that arise from the MS^n. LC–MS^n with its low detection limit also allows the detection of trace amounts of PAs present. The results of the MS^n experiments for lycosamine, echimidine and lasiocarpine standards were summarized in Table 3 (mass spectrum not shown). All the three PAs contain the fragment, m/z 120, which is a characteristic of the retronecine moiety, the basic structure which they are derived from [21]. In comfrey extracts, lycopsamine was detected and its MS^2 spectrum was showed in Fig. 2a. As can be seen from the fragmentation pathway, lycopsamine showed characteristic frag-

Table 2
RSD ($n = 6$) values of LC–MS method for determination of lycopsamine, echimidine and lasiocarpine.

Compounds	Concentration (ppm)	RSD (%)
Lycopsamine	2.0	4.25
	1.0	2.06
	0.1	9.21
Echimidine	2.0	3.45
	1.0	5.29
	0.1	2.32
Lasiocarpine	2.0	5.24
	1.0	8.00
	0.1	5.29

ment ions at m/z 120.0806 and 138.0912, which were characteristic fragmentation ions of retronecine-type alkaloids [21]. In addition, mass spectral analysis has revealed some common fragmentation pathways that are shared by the PAs based on some of the product ions that they gave rise to. One of the fragmentation pathways that occur commonly among PAs is the McLafferty rearrangement [12,15], and the fragment ion at m/z 256.1546 was presumed as the product of this rearrangement.

In the analysis of $[M+H]^+$ at 398.22, two compounds share the same protonated molecular weight, the N-oxides of symviridine and the PAs of echimidine. Both share similar structure except that the R^3 of echimidine is a hydroxyl group instead of a hydrogen atom (Table 1). MS^2 of the echimidine standard produced fragments of m/z 120, 220, 336, and 380 with m/z 220 being the most intense. The fragment m/z 336 was derived from McLafferty rearrangement with the loss of an acetylaldehyde molecule and a water molecule ($[M+H]^+ - 44 - 18$). However, by comparing the MS^2 and MS^3 spectra that arise from m/z 398.22 (Fig. 2b and c) with that of the echimidine standard, it was found that the MS^n data did not match with that of the standard. By prediction, MS^2 of the N-oxides of symviridine via McLafferty rearrangement would give rise to the product ion m/z 354 (no water molecule is lost due to R^3 being hydrogen instead of hydroxyl) which was what was detected in the spectrum. A further confirmation was determined by performing a selected reaction monitoring (SRM) experiment on the parent/daughter ion pair of m/z 398.22/336 to determine the presence of echimidine. The result obtained suggested that echimidine was absent in *S. officinale L.* extract and the mass spectra in Fig. 2b and c were attributed entirely to the N-oxides of symviridine. Additionally, the PAs of symviridine were also detected in comfrey extracts and the MS^2 spectrum was shown in Fig. 2d. In the analysis of $[M+H]^+$ at 412.23, the absence of lasiocarpine was also confirmed. Thus, only lycopsamine of the PAs standards was detected in comfrey extracts, so in the following quantitative work, lycopsamine analysis would be focused on.

3.3. Extraction of comfrey

3.3.1. Sonication extraction of comfrey

Solvent has a significant effect on the extraction efficiency of PAs in comfrey [22,23] and the main aim of sonication extraction in this work is to choose the most appropriate solvent for lycopsamine extraction from comfrey. Hence, the effect of solvent was evaluated by using methanol/water (50:50), methanol/chloroform (15:85), methanol and ethanol and the results were showed in Fig. 3a. It is obvious that higher amount of lycopsamine could be obtained while using methanol/water (50:50) compared to the other solvent. Hence, methanol/water (50:50) was selected as the optimum solvent for subsequent studies. The effect of solvent pH was next investigated. Hydrochloric acid was added for the preparation of acidified solvent methanol/water (50:50) (HCl, pH 2.51). Fig. 3b showed that comparable amounts of lycopsamine were extracted using both the acidified and non-acidified solvent. Hence, there was no need to use the acidified solvent in the extraction of PAs from comfrey.

3.3.2. Pressurized hot water extraction (PHWE) of comfrey

To further improve the extraction efficiency and to reduce the extraction time, a new and rapid technique for the extraction of target compounds from comfrey based on PHWE was investigated. The key parameter that would have a significant effect on the extraction efficiency of PHWE was the applied temperature [24–26]. Hence, the effects of temperature from 60 to 120 °C on the extraction efficiency of lycopsamine in comfrey were studied and the results (Fig. 4a) showed that the amount of lycopsamine extracted decreased with increasing temperature. It was proposed that the presence of dissolved gases in the subcritical solvent could have caused the oxidation of lycopsamine in comfey at a higher applied temperature. Therefore, 60 °C was selected as the optimum temperature since the highest amount of lycopsamine was extracted out. The time for extraction was set at 40 min as it was observed that a significant amount of target analytes would be extracted in the first 30 min [27,28].

Table 3
MS^2 & MS^3 results of the pyrrolizidine alkaloids standards.

Compounds	Theoretical $[M+H]^+$	Retention time (min)	Experimental $[M+H]^+$	RSD (ppm)	Fragments derived from MS^2 (m/z)	Fragments derived from MS^3 (m/z)

3.3.3. *Extraction of comfrey by heating under reflux*

Due to the intrinsic property of plant extraction by PHWE, its extraction efficiency could be evaluated by comparing with other methods such as Soxhlet extraction, heating under reflux and others [27,29,30]. In this study, a comparison of PHWE with heating under reflux was carried out and the results obtained are showed in Fig. 4b–d and Table 4. For PHWE at 60 °C and 80 °C, the amount of lycopsamine was comparably lower than that obtained for heating

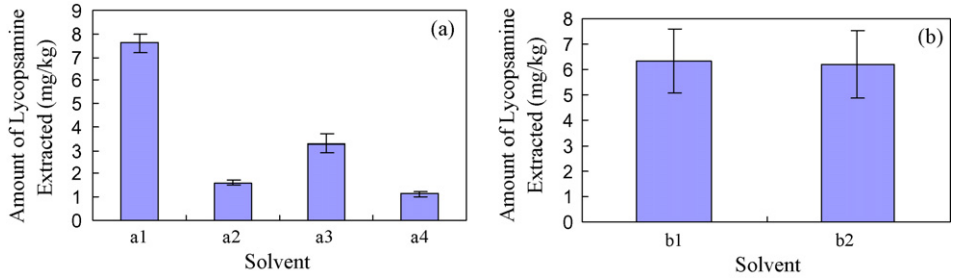

Fig. 3. (a) Effects of solvent on the amount of lycopsamine extracted from comfrey by sonication. Extraction solvent: a1-methanol/water (50:50), a2-methanol/chloroform (15:85), a3-methanol, a4-ethanol ($n = 3$); (b) pH Effects of solvent on the amount of pyrrolizidine alkaloids extracted from comfrey by sonication. Extraction solvent: b1-methanol/water (50:50), b2-methanol/water (50:50) (HCl, pH 2.51) ($n = 3$). Other sonication extraction conditions: time, 10 min; temperature, 25 °C.

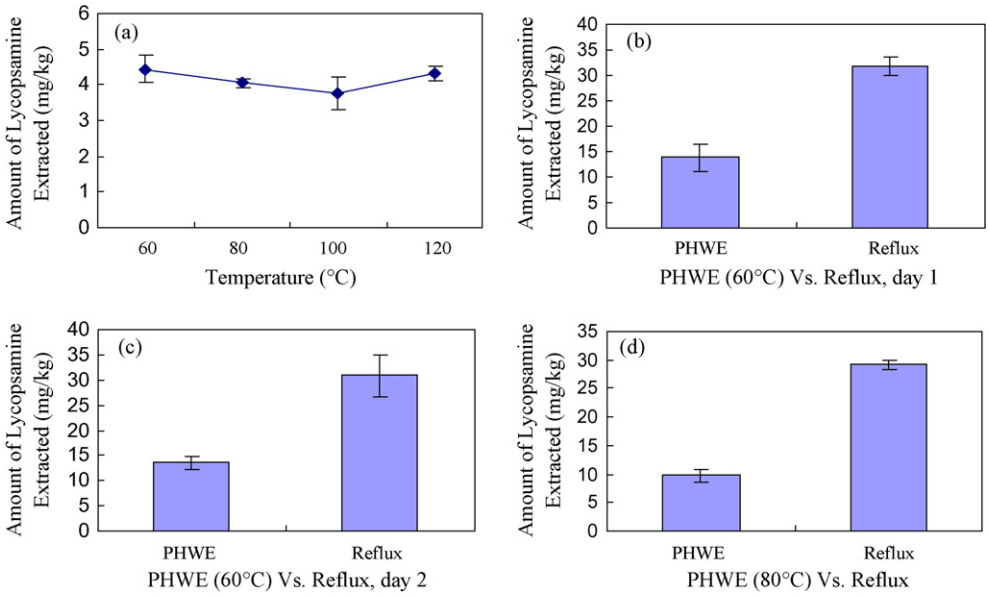

Fig. 4. (a) Effects of temperature on the amount of lycopsamine extracted from comfrey by PHWE ($n = 3$); and comparison of amount of lycopsamine extracted from comfrey by PHWE and heating under reflux ($n = 6$): (b) PHWE (60 °C) vs. Reflux, day 1. PHWE conditions, (c) PHWE (60 °C) vs. Reflux, day 2 and (d) PHWE (80 °C) vs. Reflux. PHWE conditions. under reflux. The reason for the lower extraction efficiency of PHWE was presumably due to the reduction in solubility of lycopsamine in the pressurized hot solvent caused by the dissolved nitrogen of air [31,32]. The results observed in the current work was consistent with our earlier work [29] where certain naturally occurring compounds in medicinal plants was observed to be degraded in hot pressurized water rather than hot water due to the high reactivity of hot pressurized water [33].

However, in one of our other studies on the extraction of senkirkine and senecionine from *Tussilago farfara* by PHWE, a comparable extraction efficiency was obtained [34]. Although senkirkine, senecionine and lycopsamine all belong to hepatotoxic pyrrolizidine alkaloids, their extraction efficiencies by PHWE vary significantly. It proves that PHWE is not a universalizable technique and the use of subcritical water for extractions depends on the physical properties of the dissolved solutes and their tendency to degrade under the chosen extraction conditions [31]. Concurrently, the method precision (RSD) of both the two methods was found to be varied from 2.49% to 19.32% (Table 4), respectively. The proposed reason of the relatively high RSD may be that lycopsamine is not stable enough under pressurized hot water conditions, its solubility may be affected by dissolved gases, and its content in comfrey is quite low. As a result, though PHWE is a more rapid method, heating under reflux was found to be more appropriate for the extraction of lycopsamine from comfrey in quantitative analysis considering its higher extraction efficiency.

4. Conclusions

The combination of HPLC with orbitrap mass spectrometry allows for the rapid and accurate determination of pyrrolizidine alkaloids such as lycopsamine in botanical extracts. At the same time, the MS^n spectra gave characteristic ions that are useful for the identification of PAs in unknown samples. Subsequently, quantitative analysis of lycopsamine in comfrey was carried out, which has seldom been reported previously. The extraction of lycopsamine from comfrey was studied by evaluating different methods, including sonication extraction, pressurized hot water extraction and heating under reflux. The results obtained showed that LC–ESI–obitrap MS provide a powerful method for the identification and determination of hepatotoxic pyrrolizidine alkaloids in botanicals and dietary supplements. In addition our results provide new insights into the understanding and practical application of PHWE.

ABSTRACT

A simple and sensitive method for the analysis of sterols, tocopherols and triterpenic dialcohols from the unsaponifiable fraction from oil samples in a single analytical run using liquid chromatography coupled to mass spectrometry was developed. With this method, the compounds could be detected directly after dissolving the unsaponifiable fraction in acetonitrile without necessity of time-consuming sample pretreatment or derivatization. Separation of the analytes was carried out at room temperature, by using a C18 column (5 μm i.d. 3.0 mm × 250 mm) with a linear gradient of acetonitrile/water (0.01% acetic acid) at a flow rate of 1.5 mL/min. The full scan mass spectra of the investigated compounds were measured by an ion trap mass spectrometer equipped with an APCI ion source. The optimized methodology was suitable for the identification of 23 compounds belonging to different families present in olive oil and other kinds of oils, as well as for the quantification of 15 analytes (vs. their commercial standards).

1. Introduction

Vegetable oils are mainly composed of triacylglycerols (95–98%) and complex mixtures of minor compounds (2–5%) of a wide-ranging chemical nature [1]. Among these minor compounds, tocopherols and phytosterols can be found; their beneficial health effects have sparked great interest in the past few years. Phytosterols have been receiving particular attention because of their capability to lower serum cholesterol levels in human resulting in significant reduction in the risk of cardiovascular disease [2]. They have also been described as a kind of natural product with anti-inflammatory [3], anti-bacterial [4], anti-oxidation [5] and anti-cancer properties [6,7]. On the other hand, tocopherols have also antioxidant properties, since they can act as scavengers of free radicals and prevent the propagation of lipid peroxidation in food and biological systems [3,8]. Thus, they protect body tissues against oxidative damage and play important roles in the prevention of cancer, cardiovascular and neurological diseases.

Phytosterols and tocopherols are bioactive components occurring in all vegetable foods, and make up the greatest proportion of the non-saponificable fraction of lipids [9], so it is mandatory to develop tools able to generate accurate quantitative data of these nutritionally important compounds. Tocopherols and sterols are mostly determined separately in oils and fats by using different techniques or different methods when the same technique is used. Capillary gas chromatography with flame ionization detection (GC–FID) is most frequently applied in plant sterol analysis [10,11]. The method mainly used for the analysis of sterolic fraction of edible oils involve several steps, namely, the saponification of the oil to remove triglycerides, the fractionation of the unsaponifiable matter into several classes of compounds by thin layer chromatography (TLC), and their subsequent analysis by gas chromatography as trimethylsilyl (TMS) derivatives in non-polar capillary gas chromatography columns [12]. This method is described in different regulations [13,14], and although is an useful tool, it is widely recognized that this conventional method is tedious, time-consuming, may involve the loss of analytes and is suitable only for a limited number of compounds. In the past few years, normal-phase (NP) and reversed-phase (RP) liquid chromatography (HPLC) have been widely used for the analysis of some classes of lipid and sterols from various sample matrices. In general, RP-HPLC has been more

doi:10.1016/j.talanta.2009.08.022

widely used than NP-HPLC for the separation of individual sterols [15]. Sterol detection has been carried out by UV (200–210 nm), photodiode array detection (DAD), refractive index (RI) detection, evaporative light scattering detection (ELSD), nuclear magnetic resonance (NMR) detection and mass spectrometry (MS) [9]. Because sterols are highly lipophilic with few polar functional groups, they are difficult to ionize through conventional electrospray (ESI) methods [16]. Recently, atmospheric pressure chemical ionization (APCI) with liquid chromatography mass spectrometry (LC–MS) was found to be suitable for sterol analyses in different samples matrices. LC–APCI–MS has been used to identify sterols in soybean oil [17], to characterize phytosterols in spelt [15], to determine ergosterol levels in bulrush [18] and to measure cholesterol oxides in different food supplies [19]. The direct infusion approach in MS has recently been used to classify vegetable oils according to their botanical origin, based on direct injection of sterol extracts into a mass spectrometer with either an ESI ionization or an atmospheric pressure photoionization source (APPI) [20].

For tocopherols determination two possible ways of elution using liquid chromatography have been used, normal and reversed phase. For routine analyses most of researchers still use high HPLC with UV–vis or fluorescent detection [21]. When a separation of carotenes or sterols from tocopherols is needed, the reversed-phased elution is advisable [22,23]. This type of elution is claimed to be more reproducible and sensitive than normal-phased elution for tocopherol analysis [24,25].

Our objective in this study was to develop a simple method for simultaneous analysis of different families from vegetable oils (tocopherols, triterpenic dialcohols and phytosterols) by RP-HPLC–APCI–Ion Trap MS. To the best of our knowledge, this is the first time that components of three different families from the unsaponifiable fraction of oils have been analysed by HPLC–APCI–MS in a single run. Analysing two different categories of phytosterols (4-desmethyl sterols and 4,4-dimethyl sterols), tocopherols and triterpenic dialcohols simultaneously reduce significantly the time, cost and effort needed. The method we describe here is robust and reliable and permits to identify 23 compounds (fifteen 4-desmethyl sterols, two 4,4-dimethyl sterols, two triterpenic dialcohols and four tocopherols). The analytical characteristics of the method were checked (linearity, detection limit, calibration range, absence of ion suppression phenomena) and all the MS and MS^n patterns observed were explained. When the standards were commercially available, we quantified them as well. The use of ion trap (IT) as MS analyzer provides an accurate identification of the compounds under study, since this analyzer is able to carry out MS/MS analyses.

2. Experimental

2.1. Samples, reagents and chemicals

Commercially available edible oils were acquired in a local supermarket: sunflower blended with soybean oil, corn oil, refined sunflower oil, olive oil, olive pomace oil, soy "plus omega 3" oil and walnut oil. Cholesterol was acquired from Riedel-de Haën (Germany), β-sitosterol and erythrodiol were from Fluka (Buchs, Switzerland). Sitostanol, uvaol, Δ5-avenasterol, stigmasterol, campesterol, brassicasterol were from Sigma–Aldrich (St. Louis, MO). The two 4,4-desmetyhl sterols under study were from Sigma–Aldrich as well. α-, β-, γ-, and δ-tocopherols were purchased as an isomer kit from Merck (Darmstadt, Germany).

Stock solution (0.1 mg/mL) was prepared by dissolving all standards in acetonitrile (ACN) and stored in dark at −20 °C over a maximum period of one month. Working standard solutions were prepared daily by dilution of this concentrated solution in acetonitrile. All reagents used were of analytical grade. HPLC grade acetonitrile, methanol, diethyl ether and ethyl acetate were purchased from Panreac (Barcelona, Spain). Potassium hydroxide and sodium sulphate anhydrous were from Sigma. Milli-Q water of 18.2 MΩ cm^{-1} resistivity was used throughout (Millipore, Billerica, MA, USA).

2.2. Instrumentation

Analyses were carried out at room temperature on a System Gold HPLC (Beckman Couter, Fullerton, CA, USA), including a 126 solvent module, a 168 diode array detector module and a manual sample valve injector with a 20 μl loop (Rheodyne, Cotati, CA, USA). The HPLC column used was a Phenomenex C18 (5 μm, 3.0 mm × 250 mm) fitted with a Phenomenex C-18 guard column (Phenomenex, Torrance, CA). The mass spectrometer used was a Bruker Esquire 3000 ion trap purchased from Bruker Daltonics (Bremen, Germany) equipped with an APCI interface.

Solvents were filtered using a Solvent Filtration Apparatus 58061 (Supelco, Bellefonte, PA, USA) prior to degassification by ultrasonication.

A model MicropH 2002 meter from Crison (Barcelona, Spain) was used to adjust the pH of the mobile phase with a precision of 0.01 pH unit. A Heidolph VV rotary evaporator (Schwabach, Germany) coupled to a Büchi B-169 Vacuum System (Flawill, Switzerland) was used to concentrate the sample extracts.

2.3. Sample preparation

The sample (5 g oil) was saponified by refluxing with 50 mL of ethanolic solution of KOH 2 M for 30 min. After cooling at room temperature, 100 mL of distilled water were added. After phase separation in a separation funnel, the aqueous phase was washed three times with diethyl ether. The diethyl ether fractions were collected and washed three times with distilled water and with ethanolic solution of KOH 0.5N successively. Finally, the ether extracts were washed with distilled water until the wash water gave a neutral reaction and dried with anhydrous sodium sulphate. They were then filtered and evaporated to dryness using a rotary evaporator at reduced pressure and the residue was dissolved in acetonitrile. Samples extracts were filtred through a membrane filter (0.45 μm) before being analysed by HPLC–APCI–IT MS.

2.4. LC–APCI–IT MS method

Compounds in the non-saponificable fractions of the oil samples were analysed by LC–APCI–IT MS. The compounds were separated with a gradient of acetonitrile/water (0.01% acetic acid) at a flow rate of 1.5 mL/min. The mobile phase were acetonitrile (Phase A) and water (acetic acid 0.01%) (Phase B) and the solvent gradient changed according to the following conditions: from 0 to 60 min, 90% A:10% B to 92% A:8% B. From 60 to 63 min, 92% A:8% B to 100% A:0% B; from 63 to 65 min, 100% A:0% B to 90% A:10% B. The column temperature was set to 30 °C during the whole run and the injection volume was 20 μl. The monitoring of the examined compounds was performed at 280/240 nm.

The HPLC system was coupled to an IT mass spectrometer equipped with an APCI interface operating in positive ion mode using the following parameters: optimized temperature and flow rate of the dry gas (nitrogen) were 350 °C and 5 L/min, respectively, and the APCI interface temperature was 450 °C. The pressure of the nebulizer gas (nitrogen) was set to 50 psi, and the voltage of the corona discharge needle was +3500 V. Capillary voltage was set at −3000 V and the end-plate offset, at -500 V. The IT MS scanned in the m/z range from 50 to 800. Source and transfer parameters were optimized by direct infusion experiments with solutions contain-

ing all the compounds under study which we had as commercially available standards looking for the best conditions regarding peak intensity and resolution. We confirmed that the MS compromise solutions found were the most appropriate for every compounds making direct infusion experiments with individual solutions as well.

Identification of analytes was based on the comparison of their retention times and mass spectra with those of authentic reference compounds. Peak identification was also done with spiked samples at different concentration levels.

2.5. Analytical parameters of the method

2.5.1. Method validation

Linearity of the MS detector response was verified with standard solutions at different concentration levels over the calibration range. To calculate the regression model, standard solutions at six different concentrations (10, 20, 33, 50, 100 and 200 mg/L) were used to define the calibration curves for all the reference compounds under study. In addition to that, some more points between 200 and 2000 mg/L were analyzed in the case of the β-sitosterol. Three independent injections were performed for each concentration of standard compound. Calibration curves were obtained for each standard with good linearity ($r^2 > 0.97$) by plotting the standard concentration as a function of the peak area obtained from HPLC–APCI–IT MS analyses. For this purpose, the stock solution (1000 mg/L) of the standards was diluted with ACN to have different concentrations. The analysis of variance (ANOVA) with a lack-of-fit test (LOF) at a confidence interval of 95% was performed to validate the regression data using the SPSS 13.0 for windows (SPSS Inc., 2004).

The limits of detection and quantification of the individual analytes in standard solutions were calculated according to the IUPAC method [26] when MS detection was carried out. The sensitivity of the method in that case was studied by defining the limit of detection (LOD) and limit of quantification (LOQ) for individual compounds in standard solutions. The limit of detection was considered S/N = 3, whilst the limit of quantification was S/N = 10).

The precision of the method described was measured as repeatability, it was assessed for each standard compound at two concentration levels (20 and 100 ppm).

2.5.2. Ion suppression

The ion suppression effect may be caused by a number of factors such as the matrix or interference co-eluting compounds. We used a strategy described by Nelson and Dolan [27] for systematic investigation of ion suppression in HPLC–MS analysis. So, we produced a continuous flow of analyte solution resulting in a constant but elevated baseline in MS detection. This flow was then continuously mixed with eluate from an LC-separated blank sample. Consequently, ion-suppressing components will be detectable as a drop in the baseline over the complete LC run. Such investigations enable optimization of HPLC conditions to prevent coelution of analyte and interfering substances.

3. Results and discussion

3.1. Extraction and isolation of sterols, tocopherols and triterpenic dialcohols from oil samples

We analyzed sterols, tocopherols and triterpenic dialcohols compounds from different kind of oils by HPLC–APCI–IT MS after saponification of the lipid matrix. The direct saponification method is employed frequently for the sample preparation of phytosterols in order to remove triacyglycerols from oils. It is usually performed at 60–85 °C [10,28] and sometimes at room temperature [16,29]. Both procedures were tested with comparable results. As cold saponification is time consuming (all overnight at room temperature and in the dark), we avoid this procedure of sample preparation although it seems more convenient in term of stability of the extracted compounds. So, we studied the saponification time effect at 80 °C on the profile of the extract analysed by LC–MS, since tocopherols and phytosterols are exposed to thermal degradation in the process of saponification at hot temperature. After the preliminary studies, we decided that the optimum time of saponification was 30 min at 80 °C. Also, in order to minimize risk of thermal degradation, we reduced the time in which the extract was exposed to vaccum. Several extraction solvents were used for extracting unsaponifiables, including petroleum ether, hexane, ether acetate and diethyl ether [30,31]. Diethyl ether is the most commonly used extraction solvent for unsaponifiable fraction of oils and, thus, diethyl ether was chosen as an extraction solvent in this study. Furthermore, we increased the amount of diethyl ether until 100 mL and also the extraction time of unsaponifiables as it increases the recovery rates of tocopherols [32].

So, taking into consideration the previous experience of other researches [31,33], we succeeded finally to reduce the time needed to isolate sterols in comparison to the official method. We simplified the official method, since we avoid the separation by TLC, and we offer the opportunity to enlarge the number of families from the unsaponifiable fraction of oils suitable to be analyzed by the described method. As a final step, the solvent was evaporated and the extract was redissolved in acetonitrile.

3.2. Chromatography separation

The experimental conditions that were established enabled the simultaneous analysis of three classes of compounds (sterols, tocopherols and the triterpene dialcohols, erythrodiol and uvaol). The high lipophilicity of tocopherols and sterols can make sample processing and chromatography difficult. In this respect, reversed phase C18 column was chosen for the elution of analytes. After realizing that water (with 0.01% acetic acid) (as phase A) and acetonitrile (as phase B) were the most appropriate mobile phases for achieving our aim, we found that with a C18 stationary phase and the following gradient between 90% acetonitrile: 10% water + 0.01% acetic acid and 92% acetonitrile: 8% water + 0.01% acetic acid from 0 to 60 min on column temperature of 30 °C gave the best separation. Several different flow rates were assessed to optimize the resolution among all the analytes and also the peak intensity. A flow rate of 1 mL/min offered the highest peak intensity but the separation of all the compounds was achieved over 60 min; we decided to choose 1.5 mL/min as the optimum flow rate for the analysis, as the resolution was still good enough and the analysis time was shorter. For the choice of an appropriate reversed-phase C18, we tested two different columns: Atlantis d C18 150 mm × 2.1 mm i.d., 5 μm (Waters) and Phenomenex C18 3.0 mm × 250 mm i.d., 5 μm. To compare column performances, we used a mixture of standards of all the compounds concerned in our aim. We found that longer reversed-phase column with MS detection was more appropriate for the separation of the standard mix we were working with. As seen in Fig. 1, brassicasterol was separated from β- and γ-tocopherols, cholesterol and Δ-5-avenasterol peaks in the longer reversed-phase column, whereas all of them were overlapped in the same peak when the separation was made with the shorter column. Also, a higher resolution between peaks of campesterol and β-amyrin, and between stigmasterol and α-tocopherol was obtained using longer reversed-phase column. Separation of analytes was achieved in 34.4 min using short column, whilst 39.0 min were necessary to do the same where the longer column was used. Although the baseline resolution of all the compounds was not achieved, the study of the analytical parameters (in particular linearity and ion

Fig. 1. Gradient from 90% acetonitrile: 10% water + 0.01% acetic acid to 92% acetonitrile: 8% water + 0.01% acetic acid from 0 to 60 min. (1) erythrodiol, (2) Uvaol, (3) γ-tocopherol, (4) lupeol, (5) brassicasterol, (6) β-tocopherol, (7) γ-tocopherol, (8) cholesterol, (9) Δ-5-avenasterol, (10) campesterol, (11) β-amyrin, (12) stigmasterol, (13) α-tocopherol, (14) β-sitosterol and (15) sitostanol.

suppression studies) assured the reliability of our method, which could be able to determine some interesting compounds in a very reasonable time. Indeed, in HPLC–MS baseline separation of peaks is not always mandatory due to high specificity and selectivity of the detection method. The optimum chromatogram (Base peak chromatogram (BPC)) and extracted ion chomatograms (EIC) of all the compounds under study sorted by families can be observed in Fig. 2. As lupeol and β-amyrin have the same molecular weight and both of them are ionized giving $[M+H-H_2O]^+$, we injected separately these compounds to make sure about the identify of each one. In the same way, we proceed to confirm the order of stigmasterol and (-5-avenasterol, which showed the same main fragment ion at 395 *m*/*z*. In both cases to bear in mind the chemical structure of the compounds and the previous reports already published was helpful.

3.3. APCI–IT MS fragmentation of sterols, tocopherols and triterpenic dialcohols

Atmospheric pressure chemical ionization is considered to be a soft ionization technique and should be therefore a suitable procedure for labile compounds. The effect of the following parameters was investigated: corona current, capillary voltage, end plate offset voltage, nebulizer, dry gas, dry temperature and vaporizer temperature. Optimized values are referred in Section 2. The IT MS scanned in the *m*/*z* range from 50 to 800. Source and transfer parameters were optimized by direct infusion experiments with solutions containing all the compounds under study which we had as commercially available standards looking for the best conditions regarding peak intensity and resolution.

On the current study, vaporizer temperature was one of the parameter which had more influence in the intensity and quality of the spectra. In general, most of the researches working with APCI claim that the increase of the vaporizing temperature leads to an improvement in desolvation and evaporation of the compounds and provides better ionization efficiency. However, the fact that the high temperatures can decompose the labile analytes has to be considered as well. The vaporizer temperature was varied between 250 and 450 °C in positive APCI. We found a compromise value for as high as possible signal for all the compounds in the mixture at 450 °C. Signal intensity for tocopherols was quite sensitive to changes in APCI interface temperature.

In APCI, the capillary voltage was varied between 2.0 and 4.5 kV (negative values). The response of sterols, tocopherols and triterpenic dialcohols was higher in the range between 2.8 and 3.2 kV. As the differences in this range varied depending on the family of analytes observed, we took as optimum value 3.0 kV.

In the current study, the drying gas flow rate was varied from 2 to 9 L/min. For APCI in positive polarity-that we chose after comparing the analytical performance with APCI in negative polarity-the optimum flow rate was found at 5 L/min. By using higher values than 5 L/min, the signal intensity for some compounds was even higher but the stability of the signal and also the currents was much lower.

Finally, the temperature of dry gas and the nebulizing pressure were checked; concluding that 350 °C was the optimum dry temperature and 50 psi was the most appropriate value for nebulizing pressure.

The positive mass spectra of analytes are shown in Fig. 3. Intense fragment ions at *m*/*z* 409.2 (for lupeol and β-amyrin), 381.2 (for brassicasterol), 369.2 (for cholesterol), 395.2 (for (-5-avenasterol and stigmasterol), 383.2 (for campesterol), 397.2 (for β-sitosterol) and 399.2 (for sitostanol) were observed, indicating the loss of water $[M+H-H_2O]^+$ (see Table 1). This seems to be characteristic for sterols as dehydration was observed in earlier reports with cholesterol oxides [34], phytosterols [16,17], and ergosterol [18]. For the tocopherols, we consistently observed that APCI generated major fragments ions at *m*/*z* 402.2 (for δ-tocopherol), 416.2 (for β and γ-tocopherols) and 430.2 (for α-tocopherol). However APCI

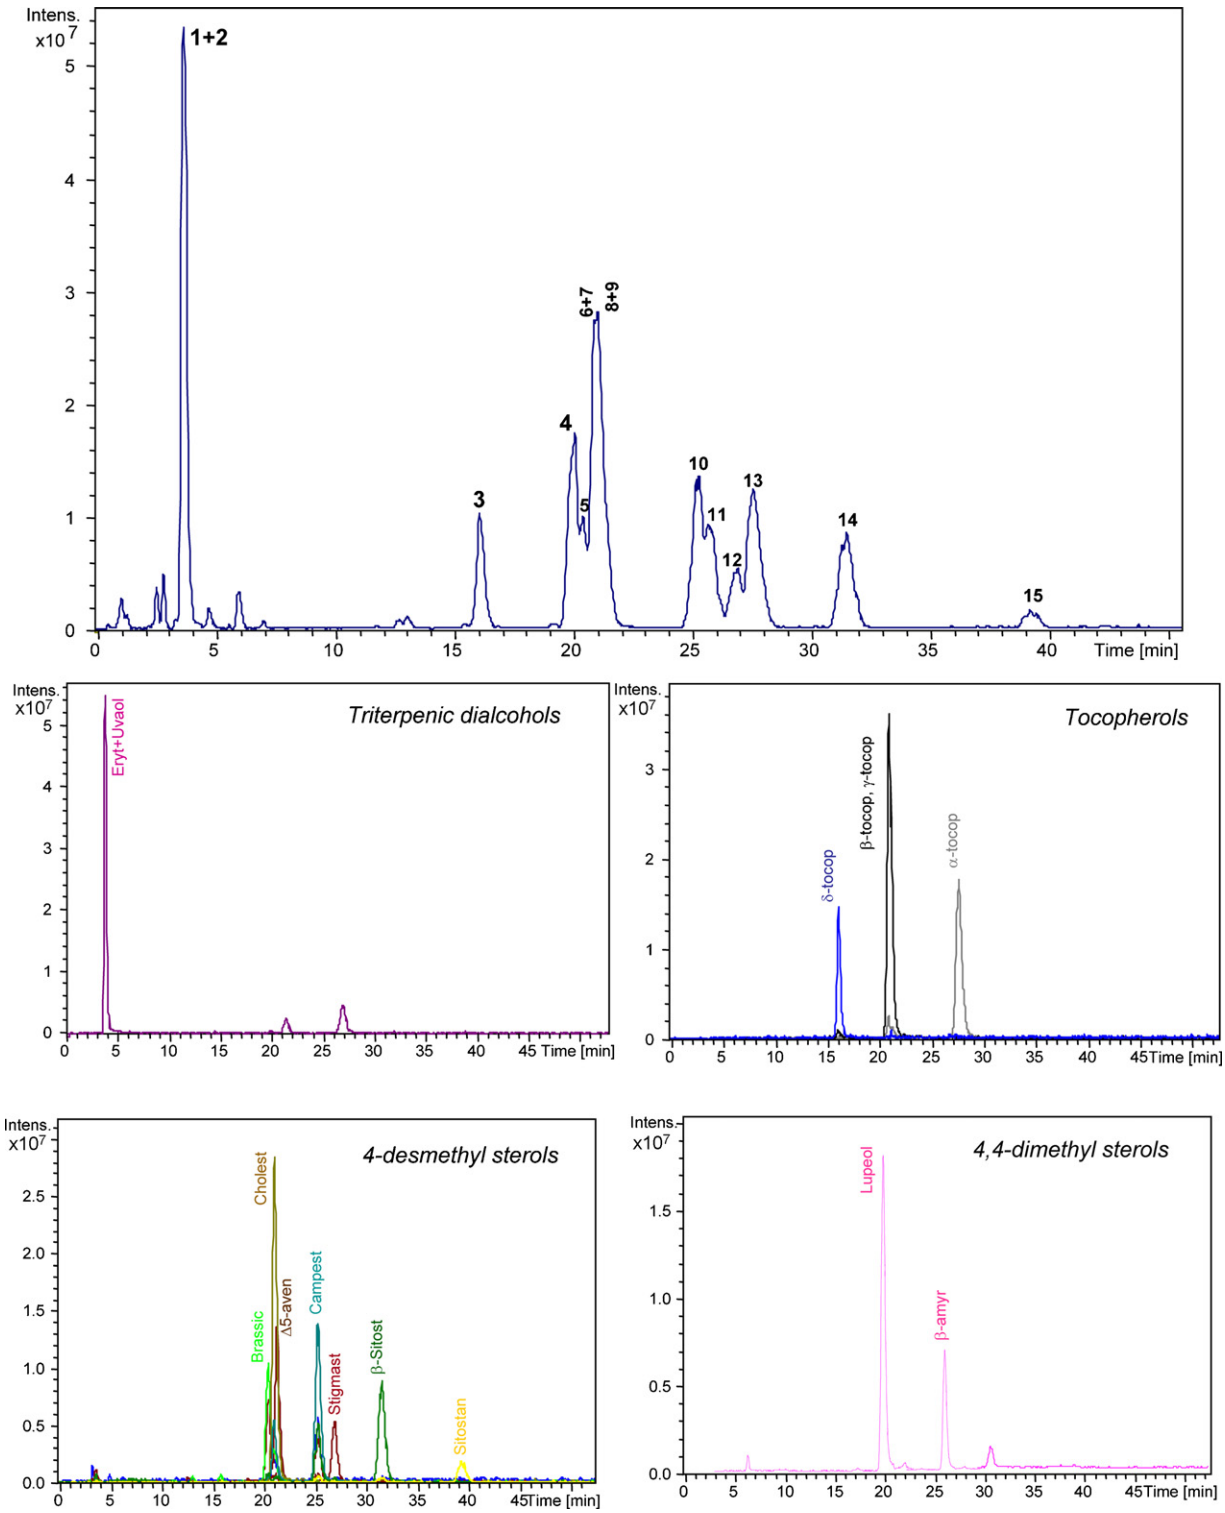

Fig. 2. Base peak chromatogram (BPC) of the standard mix containing sterols, tocopherols and triterpenic dialcohols analyzed at optima conditions and extract ion chromatograms of the compounds sortened by families. Peaks number as in Fig. 1.

typically produces protonated molecular ions $[M+H]^+$, which for tocopherols compounds would be expected at *m*/*z* 403, 417 and 431. The formation of the observed ions from tocopherols could be explained by the facile one-electron oxidation of tocopherol by the corona discharge in the APCI source [35,36]. Both the molecular ion $[M]^{\bullet+}$ and the protonated molecule $[M+H]^+$ in a constant ratio were observed for the tocopherols under study, although as said before the major ion in the mass spectra was $M^{\bullet+}$ for the four tocopherols. We can say that tocopherols (like most of non-polar compounds with systems conjugated π-bonds and donor substitutents) in positive ion mode, ionization proceeds via two competitive mechanisms: target pseudo-molecular ion $[M+H]^+$ formation via protonation of analyte and molecular ion $[M]^{\bullet+}$ formation via one-electron oxidation inside the MS interface.

The main ions in the mass spectra of erythrodiol and uvaol were *m*/*z* 407.2 $[M+H-2H_2O]^+$ and 427.2 $[M+H-H_2O]^+$.

Table 1
Ions observed in the APCI mass spectra of sterols, tocopherols and triterpenic dialcohols in positive mode and their retention time.

Analytes	Molecular mass	$[M+H-H_2O]^+$	$[M+H-2H_2O]^+$	$[M]^{\bullet+}$	Retention time
Erythrodiol	442	425.2	407.2		3.7
Uvaol	442	425.2	407.2		3.7
δ-Tocopherol	402			402.2	15.9
Lupeol	426	409.2			19.8
Brassicasterol	398	381.2			20.2
β- and γ-Tocopherols	416			416.2	20.6
Cholesterol	386	369.2			20.8
(-5-Avenasterol	412	395.2			21.0
Campesterol	400	383.2			25.0
β-Amyrin	426	409.2			25.5
Stigmasterol	412	395.2			26.6
α-Tocopherol	430			430.2	27.2
β-Sitosterol	414	397.2			31.1
Sitostanol	416	399.2			38.9

We carried out MS/MS analyses. IT provides a better understanding of the fragmentation pathways, as is able to make MS^n experiments. The use of tandem mass spectrometry can assure the identity of the compounds under study improves the selectivity and therefore diminishes matrix interference which is always critical in food analysis. The MS^n product-ion spectra were produced by collision-induced dissociation (CID) of the main detected ion for all the analytes at their respective HPLC retention times.

4-desmethyl sterols share a common fragmentation pattern during tandem mass spectrometry. The statistically dominant breaking sites of the molecule are situated in the sterol ring system between the carbon atoms with numbers 11–12, 12–13, and 8–14 according to IUPAC nomenclature. For the asymmetric structure of the sterol carbon skeleton it is possible to identify the fragmentation points of the molecule as shown in Fig. 4, taking as example cholesterol (MS/MS spectra for all the 4-desmethyl sterols are not shown to contain the size of the paper). Two main fragments of the sterol molecule are formed: one with *m*/*z* 178 (or 178-H_2O) and one with *m*/*z* 95 or 81.

It is possible to assume the first step during the fragmentation process is disconnection of the aliphatic side chain and the sterol ring system which would result in two primary fragments with *m*/*z* 113 and 273. Because the conditions in the collision cell are rather rough further fragmentations occur. The incidence of these processes is so high that the side chain fragment and the main sterol fragment are hardly detectable. The side chain fragment appears to further break into very small parts that are below the detected mass range. It is the sterol ring fragment that causes the typical MS/MS spectra found.

MS/MS spectra of lupeol and β-amyrin obtained after ion trap collision induced dissociation of the precursor ion at *m*/*z* 409 showed at our scanning conditions similar and characteristic fragmentation patterns. Fragment ion peaks appeared at *m*/*z* 259.0, 270.9, 285.1, 313.1, 340.2, etc. (Fig. 4); although significant differences in relative intensities of fragment ions allow to distinguish between the two compounds easily.

The full-scan spectrum of tocopherols displays a predominant cluster of ions at *m*/*z* $[M]^{\bullet+}$, as commented before. When we carried out MS/MS experiments, we found as shown in Fig. 4 (considering α-tocopherol as example) one main fragment with *m*/*z* 164.8, which is attributed to the loss of the phytyl chain. The same fragmentation pattern was observed for the other tocopherols; for example the main fragment for γ- and β-tocopherol was *m*/*z* 150.8 (observing 190.8 as well); for δ-tocopherol was *m*/*z* 136.8 (observing 176.8 too). To distinguish between γ- and β-tocopherol we changed the fragmentation conditions and by using other weaker conditions (width 4; CutOff 115 and Ampl 0.65), we observed a peak in the mass spectra of γ-tocopherol which was not present in β-tocopherol (*m*/*z* 276.0).

MS/MS spectra of erythrodiol and uvaol obtained after ion trap collision induced dissociation of the precursor ions at *m*/*z* 425.2 and 407.2 showed, at our scanning conditions, the characteristic fragmentation patterns included in Fig. 4.

3.4. Analytical parameters

Calibrations curves were constructed with standard solutions containing all the commercially available analytes. There were obtained by plotting the standard concentration as a function of the peak area obtained from HPLC–APCI–IT MS analyses. In order to calculate the regression equations and LODs we considered the extracted ion chromatogram (EIC) of the most intense or base peak in the mass spectrum for each compound, although it is important to bear in mind that for carrying out the identification of these compounds in real samples, we should consider all the detected ion fragments in the MS spectra, as well as their relative abundance.

Each point of the calibration plot was repeated three times in an independent solution prepared in the same way. The obtained calibration curves showed acceptable linear response between peak areas and analytes concentrations, since the regression coefficients (r^2) were higher than 0.97 for all the compounds quantified. The results of lack-of-fit test (LOF) obtained in the calibration range were estimated. For all the reference compounds, the probability of the *F* test statistic (*p*) was greater than the alpha level of significance of 0.05 and linear regression models were thus adequate for the obtained data at a confidence level of 95%, as we have seen from Table 2. The parameters of the regression equations, LOD, LOQ and calibration range are summarized in the mentioned table.

The limits of detections (LOD, based on signal-to-noise ratio of 3) achieved using these experimental conditions were within the range from 0.12 and 1.05 mg/kg for sitostanol and δ-tocopherol, respectively.

Repeatability was assessed for each standard compound at two concentration levels (20 and 100 ppm). The two solutions containing all the analytes were prepared and analyzed on the same day (intraday precision, $n=6$) and on 3 consecutive days (interday precision, $n=18$). The relative standard deviations of peak areas and the relative standard deviations of migration times were determined for each analyte at the two mentioned concentrations. The intraday repeatability of the migration time (expressed as relative standard deviation) was 1.32% and 1.93% for 20 and 100 ppm, respectively, whereas the interday repeatability of the migration time was within 1.89% and 2.24% for 20 and 100 ppm, respectively. The intraday repeatability of the total peak area (expressed as relative standard deviation) was 4.75% and 5.23% for the 20 and 100 ppm, respectively, while the interday repeatability of the total peak area was 7.34% and 7.89% for 20 and

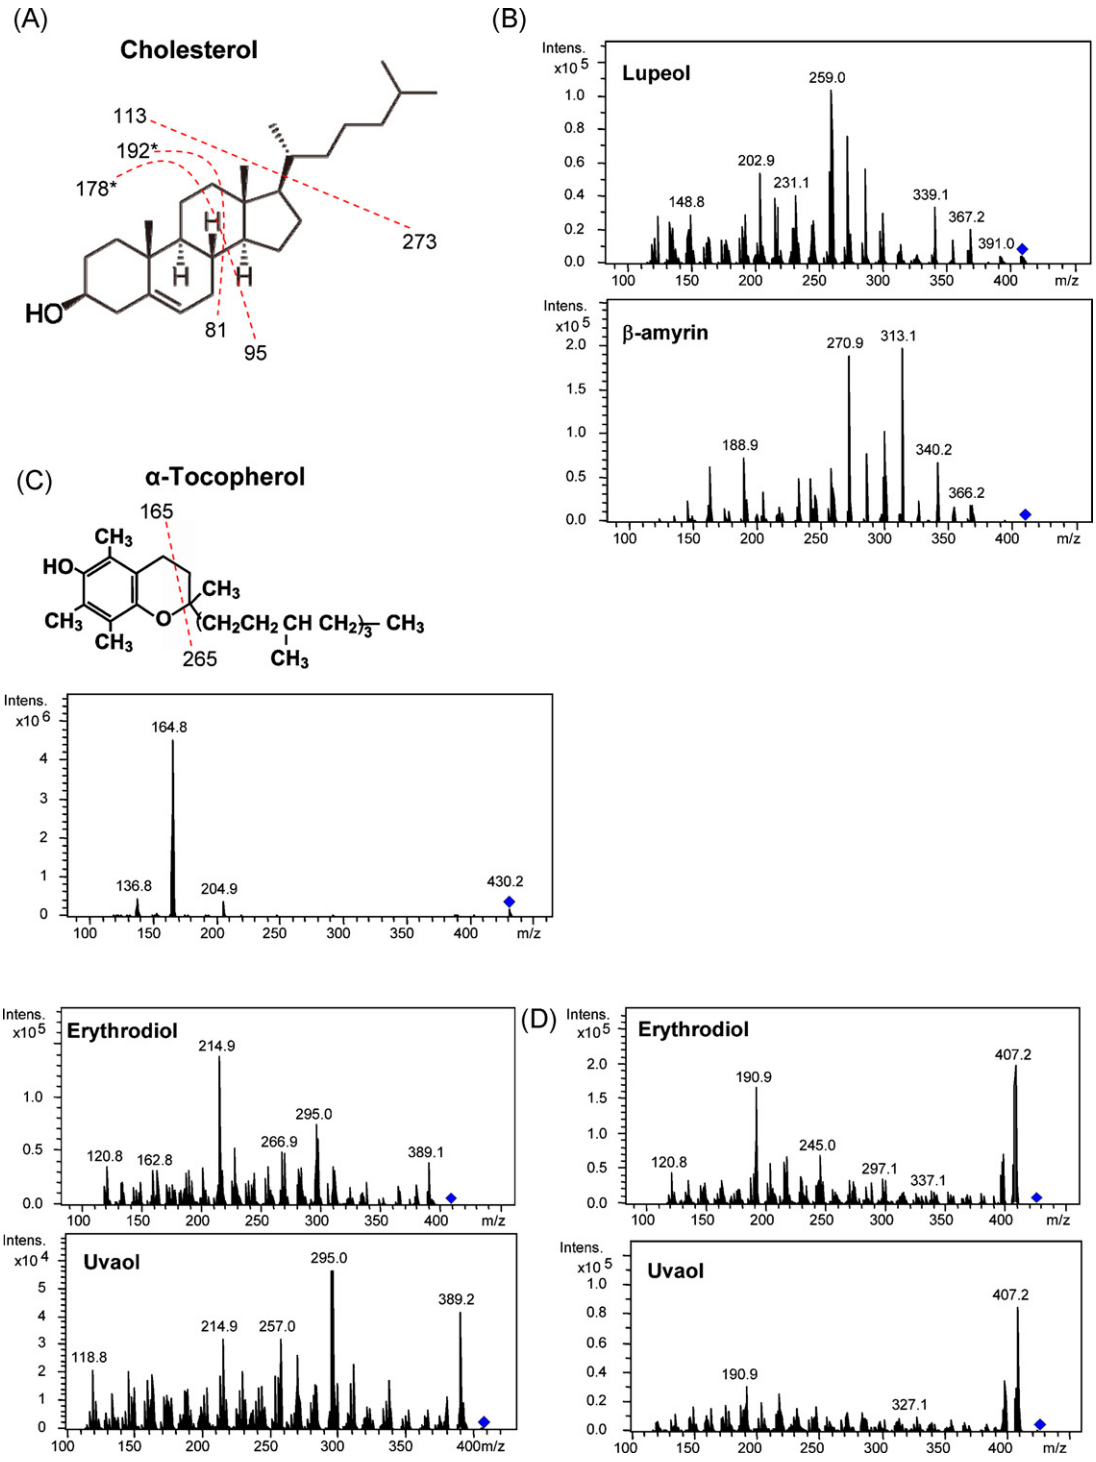

Fig. 4. MS/MS fragmentation patterns of the different families of compounds included in the current study ((A) 4-desmethyl sterols, (B) 4,4-dimethyl sterols, (C) tocopherols and (D) triterpenic dialcohols).

100 ppm, respectively. Although the interday precision was worse than the intraday precision, good overall repeatability was still obtained.

Concerning ionization suppression phenomena, the results obtained while a continuous flow of analyte solution (resulting in a constant but elevated baseline in MS detection) was continuously mixed with the eluate from an HPLC-separated blank sample did not show any drop in the baseline over the complete chromatographic run; that means the ion suppressions from co-eluting compounds were negligible.

3.5. Application and quantification to real samples

Using the described extraction protocol and the HPLC–APCI–MS method, we analyzed seven different oil samples (sunflower blended with soybean oil, corn oil, refined sunflower oil, olive oil, olive pomace oil, soy "plus omega 3" oil and walnut oil). Sample preparations of all oils were made as described in Section 3.1. The analyses were carried out under the optimum conditions described in Section 3.2 and compounds were identified by comparison of their retention times and mass spectra (MS

and MS/MS) with those of standards. Peak identification was also done with spiked real samples at different concentration levels. For the identification of the other sterols that can be analyzed by the official GC-FID method but are not available as commercial standard, we took into account the analyses carried out by GC-FID on each of the oil samples in question. These results helped us to identify them in the samples analyzed by HPLC. In other words, when we use the official method (GC-FID), we know the sterols are eluted in the following order: cholesterol, brassicasterol, 24-methylene cholesterol, campesterol, campestanol, stigmasterol, Δ-7-campesterol, Δ-5,23-stigmastadienol, chlerosterol, β-sistosterol, sitostanol, Δ-5-avenasterol, Δ-5,24-stigmastadienol, Δ-7-stigmasterol, Δ-7-avenasterol. That means we can identify and quantify all the mentioned compounds by GC-FID. After doing that, we could use these results and the relative concentrations of the different compounds to iden-

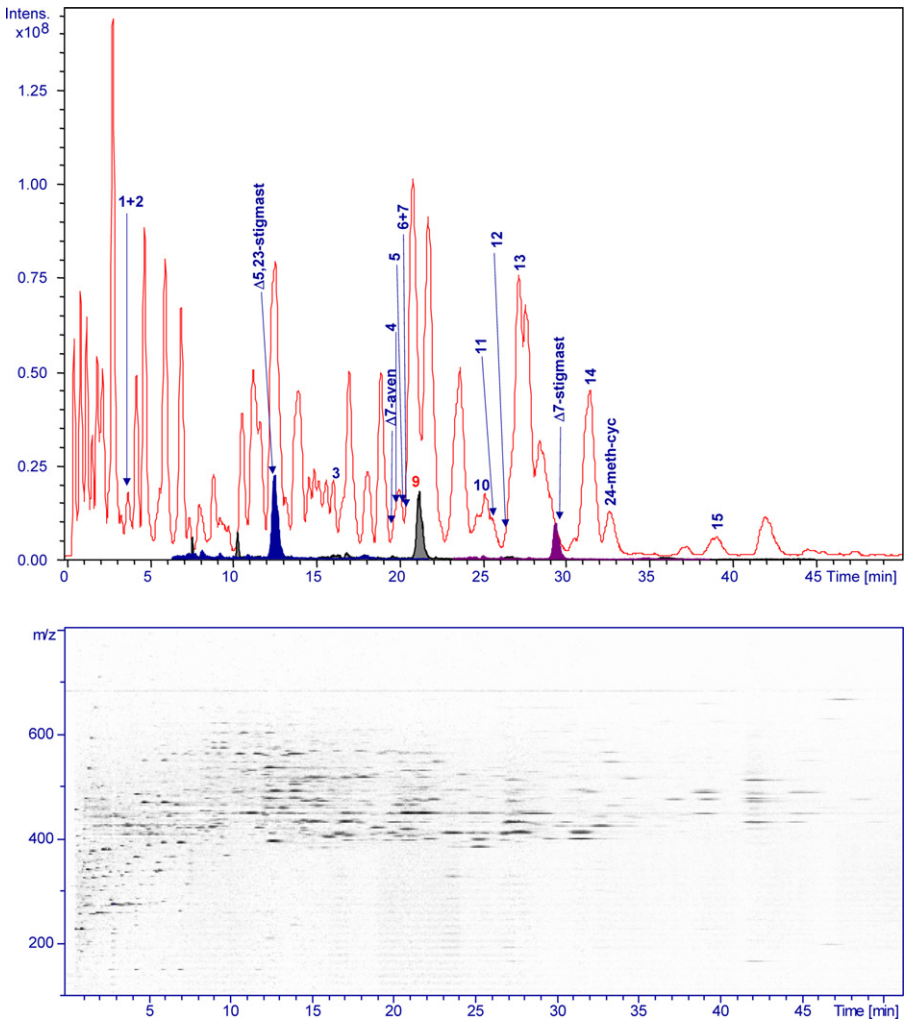

Fig. 5. BPC of sunflower blended with soybean oil identifying with numbers (as in Fig. 1) the compounds we had as standards. Some other compounds could be identified taking into consideration the GC data (using the official method) and their relative intensity. On the bottom of the figure, the 2D plot is shown to give to the reader an idea about the complexity of the sample analyzed and the potential of the method.

nd: non detectable. nq: non quantifiable.

tify those analytes in the HPLC profiles when they will be present.

In Fig. 5, we can observe the BPC of the extract of sunflower blended with soybean oil analyzed at optima conditions. We were able to identify all the compounds we had as standards and also some more sterols based on the GC-FID data previously achieved. In the bottom of the figure, we include a bidimensional plot of the same analysis to try to show the great potential of the developed method, since can generate information about a high number of molecules.

Quantification of the analytes was carried out using the extracted ion chromatogram at 369, 381, 383, 395, 397, 399, 402, 407, 409, 416 and 430 *m*/*z*. δ-tocopherol, brassicasterol, cholesterol, (-5-avenasterol, campesterol, stigmasterol, α-tocopherol, β-sitosterol and sitostanol were quantified individually in mg/kg (Table 3), whilst erythrodiol and uvaol, β- and γ-tocopherols were quantified together because they appeared at the same time (with the same retention time) and provided the same *m*/*z* in MS. The chromatograms of seven samples of different oils are shown in Fig. 6. All the compounds were eluted within the retention time range between 3.7 and 39 min and with an ascending order of: erythrodiol and uvaol, δ-tocopherol, brassicasterol, β- and γ-tocopherols, cholesterol, Δ-5-avenasterol, campesterol, stigmasterol, α-tocopherol, β-sitosterol and sitostanol. The peak

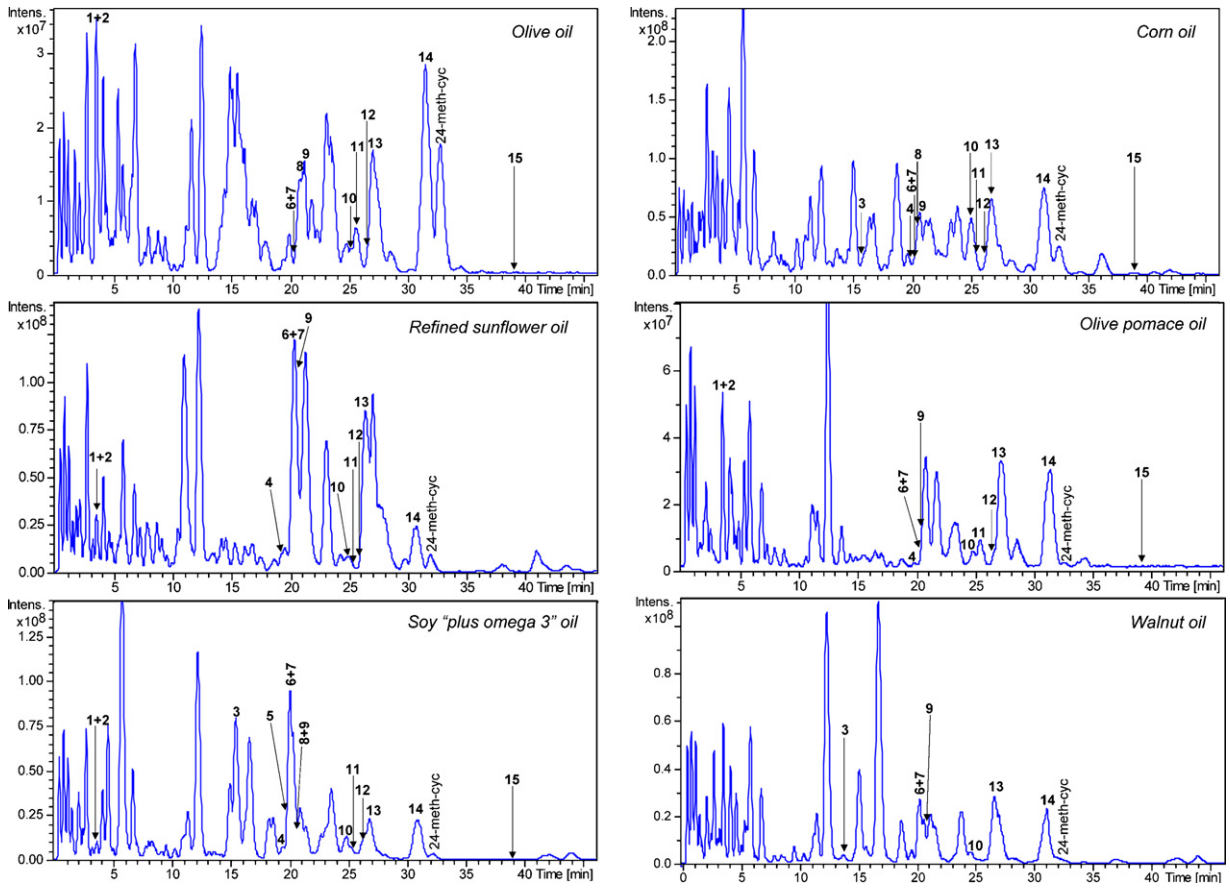

Fig. 6. BPCs of seven different kinds of oil samples (olive oil, corn oil, refined sunflower oil, olive pomace oil, soy "plus omega 3" oil and walnut oil). Peaks number as in Fig. 1. Note that we include in this figure only the most intense peaks detected; when the intensity of a peak was not remarkable, we did not add its identity in the profile.

which eluted directly after β-sitosterol is tentatively identified as 24-methylene cycloartanol based on MS data of the literature, the higher apolarity due to the additional methyl group in the molecular structure of this compound, and also with taking into account the huge quantity of this compound found in olive oils as reported by Azadmard and Dutta [37]. APCI fragmentation of this compound showed an intense fragment ion at m/z 423 $[M+H-H_2O]^+$. As seen in Table 3, β-sitosterol, (-5-avenasterol and campesterol are the predominant sterols in all the oils. Corn oil was distinguishable for its higher level of sitostanol in comparison the other oils. Concerning tocopherols compounds, a huge quantity of δ-tocopherol was recorded in soy "plus omega 3" oil. Erythrodiol and uvaol, as belong to triterpenic dialcohols family, were not detected only in corn and walnut oils.

4. Conclusions

In the present paper we report a rapid and effective HPLC–APCI–IT MS procedure to carry out a quantitative muticomponent analysis (sterols, tocopherols and triterpenic dialcohols) in vegetable oils. One of the main advantages of this new HPLC–MS method is its ability to simultaneously detect and quantify a great number compounds belong to three families of the unsaponifiable fraction of oils, taking into account the simplicity and the cheaper process of sample preparation. This new analytical method proved to be suitable for the sensitive quantitation of 15 compounds present in oil samples extracts and has the potential to identify 23 analytes. Furthermore, this study confirms that the liquid chromatography method coupled to APCI–IT MS can be applied in the direct analysis of lipophilic compounds such as sterols, which are typically processed and derivatized prior to gas chromatographic analysis.

The information that the analyst gets after applying this method is quite abundant and we will consider as future direction the identification of as many compounds as possible in the profiles by using MS^n data.

Tucker3 model

ABSTRACT

The present paper deals with the application of Tucker3 modelling to a sediment monitoring data set from the area of Mar Menor coastal lagoon (Spain). The aim of the study is to model and interpret the fractionation of heavy metals in the suspended particulate matter and sediment fractions resulting by sedimentation processes. Since the lagoon is seriously influenced by anthropogenic activities the modelling aims an assessment of the environmental hazard, too. After application of various scaling and centering procedures and estimation of the model dimensionality, an optimal (3, 3, 3) Tucker3 model was chosen for data interpretation. Using the model output (factor loadings connected to the four main core elements) it could be concluded that the heavy metal concentrations in the suspended particulate matter and sediment fractions increase in order Cu > Mn > Zn ≈ Pb > Cd and could be examined as estimation of basic levels for all heavy metals caused by different sedimentation processes. The second important core element summarizes the anthropogenic influence of the mining activity in the region. The third important core element shows the different mobility of the heavy metals. The fourth important core element should be related to the specific sediment formation at one of the sampling location.

1. Introduction

The Sierra of Cartagena-La Unión (Murcia, South-East Spain) has been subjected to mining for more than 2500 years. Regarding this, although all mining activities ceased in 1991, the opencast mining practised in this area in the second half of the 20th century has resulted in a highly altered and degraded landscape. As a result of it, huge amounts of wastes are present in the mining district Cartagena-La Unión (Murcia, South-East Spain). These mining wastes from the Sierra de Cartagena have been acting for centuries as a source of heavy metal pollution for all the surrounding areas. Therefore, these activities that have been developed historically in the mountains in the south basin of the Mar Menor coastal lagoon have caused the metal pollution of the marine sediments of this small sea.

Mar Menor is the largest lagoon of the Spanish Mediterranean coast with a high ecological, fishing and tourism value. Furthermore, it has been included in several international conservation agreements, like the Ramsar List of Wetlands of International Importance, Specially Protected Area under the EU Wild Birds Directive (SPA), Site of Community Importance (SCI) to be integrated in the Nature 2000 Network (EU Habitats Directive), and besides is a Special Protected Area of Mediterranean Interest (SPAMI). Although during the last three decades has been an increase in the inputs into the lagoon as a consequence of changes in agricultural practices [20], there is a remarkable lack of knowledge concerning the influence of metal inputs coming from the close mining areas [21]. Any case, the lagoon ecosystem is being affected to a degree that depends on the phase in which the metals are carried, since the bioavailability and toxicity of the metals are influenced by the distribution of trace metals in particulate, sediments or dissolved phases [21].

Learning about the phenomena occurring in the environment (especially in sea ecosystems which are multiphase ones) requires applying numerous tools including intelligent data mining at the last stages of data interpretation.

Scientists and policy makers are interested in pollutants environmental fate, transport, accumulation in different fractions and

doi:10.1016/j.talanta.2009.08.015

compartments in order to learn about routes and remediation strategies for specific distribution of pollutants of interest. Recently, some efforts have been made to interpret sequential extraction procedures for sediment monitoring data by the use of chemometrics [1,2]. Additional studies have been performed to examine the relationship between the distributions of elements in different compartments of a river catchment [3] and to predict the concentration of elements in river sediments from monitoring data [4]. Both studies use the PLS multiway models. No studies have been detected for advanced data treatment aiming to understand the fractionation due to sedimentation processes.

The aim of the present study is to model and interpret the fractionation of heavy metals in suspended particulate matter and sediment fractions resulting by sedimentation processes in Mar Menor coastal lagoon, South-East Spain. Since the lagoon is seriously influenced by anthropogenic activities, the modelling also aims an assessment of the environmental hazard.

2. Materials and methods

2.1. Study area

Mar Menor coastal lagoon is placed in the SE of the Iberian Peninsula, Spain. This ecosystem is one of the largest coastal lagoons of the Mediterranean (135 km^2 area, average depth 4 m, maximum 6.5 m), that is isolated from the Mediterranean Sea by a 24 km long sandy bar called "La Manga", that is crossed by five channels. La Manga is limited by "Cabo de Palos" to the South and "Punta del Mojón", to the North, with a width that oscillates between 900 and 100 m. It was formed over volcanic blooming and miocenic chalconsandstone. Through these channels there is an active water exchange that makes that the average water residence time being 0.79 years [22]. The lagoon is hyperhaline, with salinity levels (42–47 g/l) greater than the adjacent Mediterranean Sea because of low precipitation (around 300 mm per year) and high evaporation rates (mean annual temperature 18 °C).

From the geological origin of the Menor Sea, sediments from the watercourses flowing into the lagoon have filled it. However, in the last centuries deforestation, mining activities, agricultural practices and other human activities have accelerated the fill up [5].

Although there are no permanent superficial watercourses in the area, several ephemeral watercourses called "*ramblas*" of wide beds and planes form a surface hydrologic system that flow into the Mar Menor. These *ramblas* carry water from the rain during the episodes of torrential storms and some of their beds disappear before arriving to the lagoon. In the last decades, the flows of some *ramblas* have been increased due to the contributions of waters coming from the surpluses of the irrigated zones [6], in some cases loaded with fertilizers and pesticides, what could generate some environmental problems.

Since the lagoon is hyper saline during the whole year, it is unlikely to observe seasonal fluctuations of metal fractionation in sediments, at least concerning a time period of 1 year, as the sampling took place.

The expansion of intensive agriculture is linked to an increase in the use of water and fertilizers. The modern irrigation systems are designed to optimise water and nutrients inputs into the soils. However, the necessity to increase production according to social–economical causes, sometimes lead to large water and fertilizer applications. The latter can create a surplus of water enriched in nutrients that could generate some environmental problems. For these reasons, several technical solutions are being considered. One of this is the desalinisation plants.

In the mining areas, the soils of these places are strongly altered by human activity for over a thousand of years. Both the mining industry already initiated in times of the Phoenicians and continued until our days, and the intensive agriculture and, more recently, the industrial activities have exercised a strong disturbance of the natural soils of this zone that have been replaced in important proportions by soils derived from the human action.

Along mining area it can be found the remains of the mining exploitations: wells, dumps, sterile pools, opencast extractions, etc. The strong slopes and the scanty but intense rains typical of the Mediterranean climate have provoked an intense erosion of the soils which thinner materials have been dragged up to places very remote from its origin across the temporary riverbeds (*rambla*): Ramblas of Beal, Albujón, etc. Thus, sediments with heavy metals (Pb and Zn especially, but also Cu, Cd, Mn, etc.) high content are distributed by wide zones and even coming to the sea, both the Mediterranean Sea and the Mar Menor. Occasionally, as result of the uncontrolled exploitation of the mining resources and the spillage of enormous quantities of sterile to the sea, the depth of some marine zones has decreased. This process has driven to the filling and landfill of natural marine spaces as Portman Bay, whose recovery waiting a suitable plan. There are numerous mining wastes placed in southern part of the lagoon that have been dragged into the Mar Menor by temporary streams (*wadis*) through more than 2000 years.

2.2. Experimental

2.2.1. Sampling stations

The sampling work took place during May 2007 and included tracing points of interest concerning or affecting pollution conditions in the area (from farmlands or from a mining area). For this reason, in order to create a complete picture about the pollution in Mar Menor up to 10 different sampling points have been distributed among the three main seawater flows that seems to be in this coastal lagoon (Fig. 1). In this way, there are 10 sampling points, 9 inside the lagoon and 1 outside (Fig. 2). From each sampling 1l water samples and 1 surface sediment sample were collected (with a grab). *In situ* measurements of abiotic parameters in surface and

Water inputs from the Mediterranean sea and from inland by Rambla de Miranda, Rambla del Albujón and Rambla de los Alcázares (west part of the coastal lagoon), Rambla del Beal, Rambla de Ponce and Rambla de la Carrasquilla (south part of the coastal lagoon). Seawater flows inside the Mar Menor.

Fig. 2. Sampling stations in Mar Manor coastal lagoon.

subsurface waters and sampling of water and sediment cores also took place.

2.3. Chemical analysis

The chemical analysis aimed at estimating concentration levels of metals in the water column (total, dissolved and suspended) and in the sediments.

The water samples were filtered by Millipore nitrocellulose filters. Dissolved metals were preconcentrated with the resin Chelex 100 and measured with FAAS and GFAAS (flame and graphite furnace atomic absorption spectrometry). Suspended metals were determined by GFAAS and FAAS after digestion of the filters with concentrated nitric acid [7].

The sediment samples were wet sieved and dried. Not lattice held metals were extracted with dilute hydrochloric acid and total metals with condensed nitric and hydrofluoric acid. The acid extracts were analyzed for trace metals with FAAS [8].

2.4. Statistical analysis

A three-way modelling was chosen as a modelling technique since it directly takes into account the three-way structure of the data, allowing correct and easier interpretation of the results. In this study, a three-way factor analysis using Tucker3 model was applied to a three-dimensional data set, which represents concentrations of 5 heavy metals (Zn, Cu, Mn, Pb, Cd), measured at 10 sampling locations, for 5 different heavy metal distributions in water, 2 suspended particulate fractions and 2 sediment fractions (DISS, PM 0.45, PM 8, SED < 63, SED > 63). The dimensions of the three ways (i.e., the heavy metals, the sampling locations, the heavy metal distributions) are 5, 10 and 5, respectively, for a total of 250 results. The measurements below the respective heavy metal limit of detection (LOD) were replaced by the half of detection limit value – LOD/2. This simple substitution method is used as the detection frequency is higher than 90% [9]. In this way the major statistical parameters of the data set (means, standard deviations) are practically unaffected.

Two pre-processing procedures were tested to the three-way data structure. The first procedure includes scaling within and centering across the first mode (heavy metals) while the second one includes only scaling within the first mode. The first procedure was recommended as an appropriate way for removing the difference among variables arising from their different variations and magnitude, while retaining the differences within the other two modes (sampling locations and heavy metal distribution in the different phases) [10]. Preserving of the data structure is the reason for excluding of centering from the second procedure [11]. Here, only the results for scaling within the first mode are presented. The Tucker3 models obtained after implementation of both preprocessing procedures are discussed farther in Section 3.

Table 1
Convex hull method results for Tucker3 models obtained from scaling within first mode data array.

Model	Sum of components	Explained variance (%)	st-value
(2, 1, 2)	5	79.70	1.40
(3, 3, 3)	9	94.13	2.04
(4, 3, 3)	10	95.90	1.30
(4, 4, 3)	11	97.26	2.94

The Tucker3 model decomposes the three-way data array X (I, J, K) into three loading matrices, **A** ($I \times P$), **B** ($J \times Q$), **C** ($K \times R$) and a core matrix as indicated bellow:

$$X_{ijk} = \sum_{p=1}^{P}\sum_{q=1}^{Q}\sum_{r=1}^{R} a_{ip} b_{jq} c_{kr} g_{pqr} + e_{ijk}$$

where a_{ip}, b_{jq}, and c_{kr} are the elements of the loadings matrices **A**, **B** and **C**; g_{pqr} denotes the element (p, q, r) of the core array **G** ($P \times Q \times R$), and e_{ijk} denotes the error term for element x_{ijk} and is an element of the error matrix **E** ($I \times J \times K$). The number of factors extracted from modes A, B and C are P, Q and R, respectively. The squared element of (g^2_{pqr}) of the core array reflects the variance explained by the interaction between the three modes (A, B, C). More detailed descriptions of Tucker3 model could be found elsewhere [12–15].

Selection of the optimal model was done by numerical convex-hull method proposed by Ceulemans and Kiers [16]. Instead of free parameters estimation used in the original work [16], the sum of the components in each mode was accepted since only Tucker3 models were investigated in the present study. In addition, instead of term "goodness-of-fit", in the present study the expression "explained variation" was adopted since it is more widespread in multi way applications in chemistry.

3. Results and discussion

The first step in Tucker3 analysis is the estimation of the model dimensionality. All possible Tucker3 models with different number of components in each mode ($P = 1, \ldots, 4$; $Q = 1, \ldots, 4$; $R = 1, \ldots, 4$) were evaluated. All the solutions for each complexity ($P + Q + R$) were sorted according to the explained data variance. The six models lying on the upper convex hull boundary are shown in Fig. 4. Following strictly the convex-hull method the model (4, 4, 3) with the highest st-value should be selected (Table 1). However, the more relaxed way of modelling [16] suggests that not only the model with the highest st-value but also the models with high enough (not maximal) st-values could be considered as important alternative models. Some substantive considerations concerning interpretability of the model should also be taken into account. From the st-values presented in Table 1 one could see that the models (3, 3, 3) and (4, 4, 3) have high st-values. The explained variance difference between two models is only 3.13%. The increasing of components in the first mode seems to be not so important since the model (4, 3, 3) has the lowest st-value. On the other side, the increasing of the components in the second mode (sampling locations) does not correspond to the sampling plan (Fig. 1) where the sampling stations are arranged in three groups along north–south

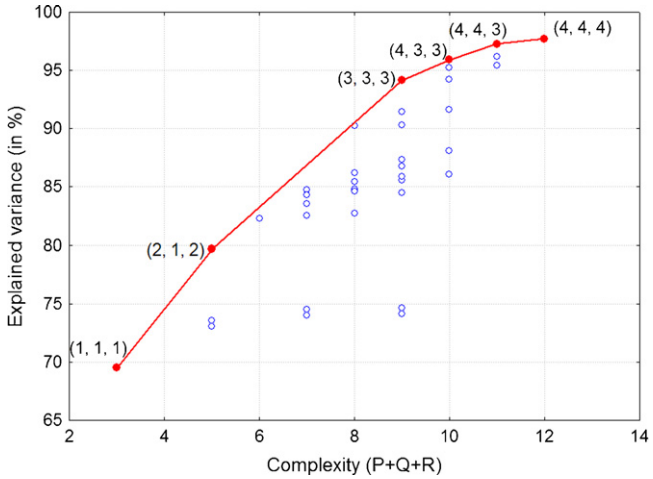

Fig. 3. Higher boundary of the convex hull graph.

direction. Thus, the model (3, 3, 3) was chosen as more interpretative for the investigated data array (Fig. 3).

The same convex hull method selection was performed for Tucker3 models obtained from scaling within and centering across first mode data array. The similar results were obtained and again the model (3, 3, 3) was chosen as more appropriate for further consideration. Comparison between the two (3, 3, 3) models obtained by different pre-processing procedures is shown in Table 2.

The explained variance for both models is quite good for an environmental data set possessing inherent variation caused by different natural and anthropogenic factors [10,17]. However, the core structure of the model obtained from scaling within first mode data array is simpler with smaller number of core elements representing significant interactions. Thus, the Tucker3 model obtained from scaling only pre-processed data was taken for further interpretation.

Two rotation procedures to selected core array (3, 3, 3), related to optimal diagonality and maximizing variance of squares, were performed. In both cases the reduction of the number of significant core elements was not achieved. That is why the unrotated core array will be discussed farther. The goodness of fit and stability of the selected Tucker3 model (3, 3, 3) was assessed employing the split-half method [2]. A mean difference of *1.37* among the elements of two cores suggested that the selected Tucker3 model is sufficiently stable.

The possible explanation for such a relatively "complex" core array could be found in the nature of sediment formation, which is affected by many natural and anthropogenic processes. The four of the most important core elements explaining 86.96% of the core variance and 81.86% of the data variance will be taken into consideration (Table 3).

In Fig. 4, the loading plots connected with the four main core elements are presented. These plots reveal similarities and dissimilarities between the elements in each mode. The similar loadings values of Zn and Pb separate them from the other heavy metals (Fig. 4a and b). This fact could be easily explained with the mining activity in the region, being the main emitter of these heavy metals [18] well documented since Phoenicians and Cartagenian times. The first mode loadings of Cd reflect the different behaviour of this element, which is indicated by the high positive A2 and A3 loadings. Probably, the reason for this particular situation could be found in the specific processes controlling the sedimentation of Cd. All sampling stations have negative loadings for the first factor in the second mode (Fig. 4c). The positive high loading of locations 4 for B2 is an indication for particular sediment formation at this site. All factor loading plots of the third mode (Fig. 4d and e) show that the dissolved and suspended particulate matter fraction below 0.45 μm distributions of the heavy metals posses loadings close to 0 and prove the uniform distribution of the heavy metals fractionalization for all sampling locations. These plots also reveal that the formation of both sediment fractions (higher and lower than 63 μm) is controlled by different processes.

Table 2
Explained variance and explained core variance by four main core elements.

Preprocessing	Explained variance (in %)	Explained core variance by first four core elements (in %)
Scaling and centering	89.57	75.97
Scaling	94.13	86.96

Table 3
Four most important core elements of a Tucker3 model of complexity (3, 3, 3).

Core element	Explained core variance (in %)	Core element value
(1, 1, 1)	73.58%	15.55
(2, 1, 2)	7.85%	−5.08
(3, 1, 3)	3.02%	−3.15
(1, 2, 2)	2.51%	−2.88

The detailed explanation of the loading plots and the relationships between the modes could be performed if they are interpreted parallel to the most important elements of core array [12,19].

The most prominent core element (1, 1, 1) explains 73.58% of the core variation and reflects the interaction between the first factors in each node (A1, B1, C1). Taking into account the positive loadings of all heavy metals along A1 (+), negative loadings of all sampling stations along B1 (−), negative loadings of all heavy metals distributions along C1 (−) and the sign of g_{111} (−), one can find that the sign of the product is "+". Thus, the heavy metal concentrations in the suspended particulate matter and sediment fractions increase in order Cu > Mn > Zn ≈ Pb > Cd. This sequence is observed for all sampling locations, most seriously pronounced for sampling locations 4 and 5, and for sediment fraction below 63 μm. This interaction represents the main order of concentrations of heavy metals in all fractions and could be examined as estimation of basic levels for all heavy metals caused by different sedimentation processes.

The second important core element (2, 1, 2) explains 7.85% of the core variation. It summarizes the interaction between the second factor in first mode (A2), the first factor in the second mode (B1) and the second factor in the third mode (C2). The negative loadings of Zn and Pb along A2 (−), the negative loadings of all sampling stations along B1 (−), the negative loading of SED < 63 along C2 (−), and the sign of respective core element (−) give a positive product. This interaction accounts for the anthropogenic influence of the mining activity in the region as was discussed above and is related to the accumulation of Zn and Pb in the sediment fraction below 63 μm. Another evidence supporting this hypothesis is the southern disposition of the most affected sampling sites 4 and 5 where the mining wastes are reaching the lagoon Mar Menor by Rambla del Beal, Rambla de Ponce and Rambla de la Carrasquilla. It is important to perform one more calculation for this core element related to Cd and Cu. The positive loadings of Cd and Cu along A2 (+), the negative loadings of all sampling stations along B1 (−), the positive loadings of SED > 63 and PM 8 along C2 (+), and the sign of g_{212} (−) give also a positive product, which is an evidence for the accumulation of Cd and Cu in the suspended particulate matter below 8 μm and coarse sediment fraction. The reason for this accumulation could be found in the agricultural activity in the region since the presence of Cu and Cd in some fertilizers is a well

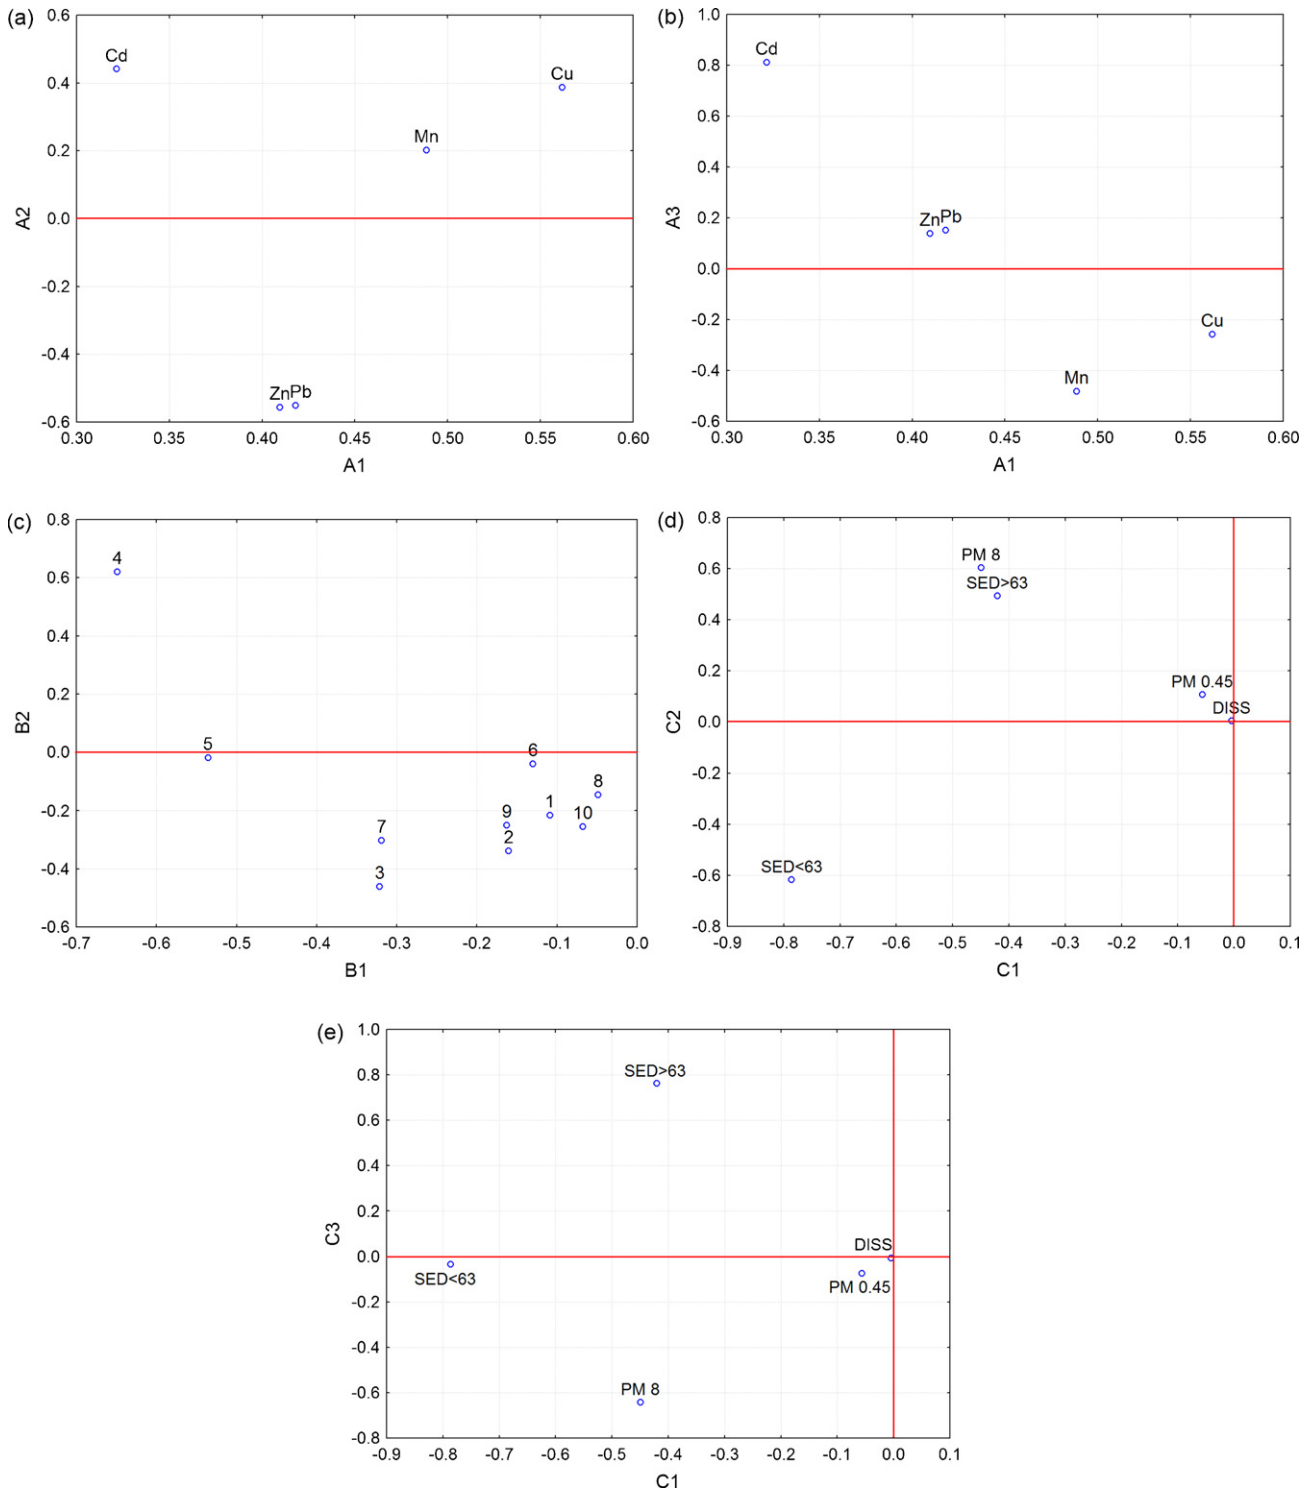

Fig. 4. Loading plots of the Tucker3 (3, 3, 3) model: (a) projection of heavy metals according to A1 and A2; (b) projection of heavy metals according to A1 and A3; (c) projection of sampling locations according to B1 and B2; (d) projection of heavy metal distributions according to C1 and C2; (e) projection of heavy metal distributions according to C1 and C3.

known fact and supports the farming impact, while Cd seems to be more related to mining activities due to the presence of this metal associated to sphalerite ores. It means that the second important core element has anthropogenic origin and represents mining and agricultural pollution influences on the heavy metal distributions.

The third important core element (3, 1, 3) explains 3.02% of the core variation. It shows the interaction between the third factor in the first mode (A3), the first factor in the second mode (B1) and the third factor in the third mode (C3). The interpretation of this core element should be related to the different mobility of heavy metals. The positive loadings of Cd, Pb and Zn along A3 (+), the negative loadings of all sampling locations along B1 (−), the negative loading of PM 8 along C3 (−) and the sign of the respective core element (−) give a positive product, which gives an explanation for the higher concentration of Cd, Pb and Zn in the suspended particulate matter fraction below 8 μm. This accumulation is more pronounced for Cd than for Pb and Zn. If one substitutes in the previous calculation the loadings of Cd, Pb and Zn with the loadings of Mn and Cu and the

loading of PM 8 with the loading of SED > 63, again positive product will be derived. The second calculation represents the accumulation of Mn and Cu in the coarse sediment fraction. It seems that this interaction represents redistribution processes in water column and sediment fractions. The more mobile heavy metals like Cd, Pb and Zn are accumulated in suspended particulate matter fraction below 8 μm while less mobile like Mn and Cu are accumulated in coarse sediment fraction.

The fourth important core element (1, 2, 2) explains 2.52% of the core variation. It reflects the interaction between the first factor in the first mode (A1), the second factor in the second mode (B2) and the second factor in the third mode (C2). The interpretation of this core element despite the low level of explanation of the core variance is important since it is related to the specific position of sampling location 4. The positive loadings of all heavy metals along A1 (+), the positive loading of the sampling location 4 along B2 (+), the negative loading of SED < 63 along C2 (−) and the sign of g_{122} (−) produce a positive product, which corresponds to increased concentrations of all heavy metals in the sediment fraction below 63 μm. This accumulation in the fine sediment fraction at sampling location 4 could be explained by its location in the southern mining affecting part of the lagoon. It seems that when mining wastes carried by the southern inlets and water flows in the lagoon reach sampling location 4 the initial accumulation in sediment fraction below 63 μm is observed.

Obviously, the first factor in sampling locations mode (B1) is involved in interactions related to the three most important core elements: g_{111}, g_{212} and g_{313}. These three core elements explain 84.45% of the core variation and 79.49% of the whole data set variation. The interactions represent the general heavy metal distributions for all sampling sites and reasons for its formation – anthropogenic influences and redistribution processes. In this sense B1 loadings could be taken as an indicator of the environmental risk for heavy metal distributions in the suspended particulate matter and the sediment fractions of lagoon Mar Menor. The potential environmental impact of the different sampling locations decreases with increasing of their negative B1 loadings in the order 4 > 5 > 3 ≈ 7 > 9 ≈ 2 > 6 > 1 > 10 > 8. The environmental hazard ranking of the sampling locations and the contour plot of B1 loadings as a function of the UTM coordinates (Fig. 5) shows that one region with the highest potential environmental hazard can be observed in south-eastern part of the lagoon. This fact is mainly connected with mining wastes reaching this part of Mar Menor coastal lagoon.

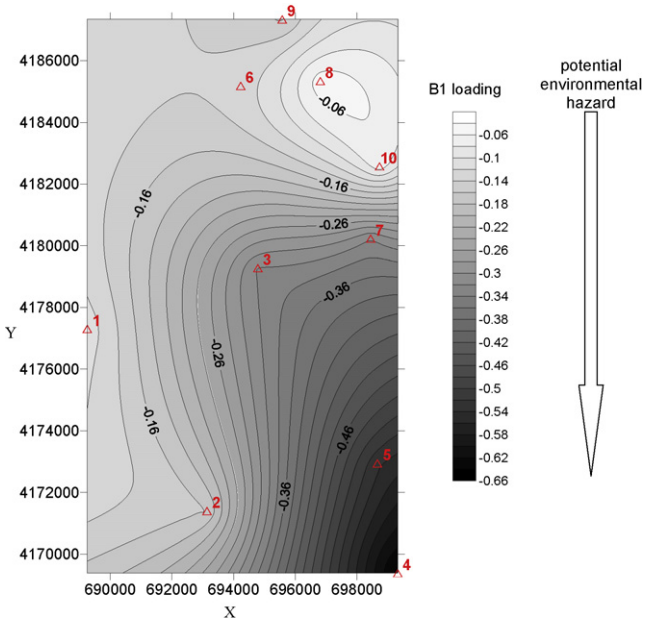

Fig. 5. Environmental hazard ranking of the sampling locations and the contour plot of B1 loadings as a function of the UTM coordinates.

4. Conclusions

The sediment monitoring data interpretation using multivariate statistics (Tucker3 modelling) has revealed some specific patterns of the fractionation of heavy metals in the suspended particulate matter and sediment fractions resulting by sedimentation processes as follows:

- Specific distribution of Cd as compared to the distribution of all other heavy metals in the sediment fractions.
- Increase of the heavy metal concentrations in the suspended particulate matter and sediment fractions in the following order: Cu > Mn > Zn ≈ Pb > Cd for all sampling locations, most seriously pronounced for sampling locations 4 and 5, and for sediment fraction below 63 μm; this could be accepted as an estimation of the basic levels for all heavy metals caused by different sedimentation processes.
- Assessing the anthropogenic influence of the mining activity in the region and relating it to the accumulation of Zn and Pb in the sediment fraction below 63 μm.
- The more mobile heavy metals like Cd, Pb and Zn are accumulated in the suspended particulate matter fraction below 8 μm while less mobile like Mn and Cu are accumulated in the coarse sediment fraction.
- Specific pattern of behaviour of sampling site 4 explained by the specific metallic mining source in the vicinity of the site.

ABSTRACT

This paper describes the characterization of the gold-catalyzed deposition of silver on graphite screen-printed electrodes (SPEs) using electrochemical impedance spectroscopy (EIS) and the application of this approach to the development of impedimetric immunosensors. After applying −0.1 V for 45 s, the amount of electrodeposited silver quantitatively changes the magnitude of two elements of the electrical equivalent circuit: the interface capacitance, *Ci*, and the charge-transfer resistance, R_{CT}. Better correlations have been found when considering the R_{CT} since this parameter is almost exclusively dependent on the amount of deposited silver under these experimental conditions. This approach has been successfully applied to the development of an impedimetric immunosensor for aflatoxin M_1. The R_{CT} magnitude shows good correlation with the amount of gold immobilized on the electrode surface after a competitive assay and thus, with the toxin concentration. This approach has been found sensitive in a wide range of concentrations, from 15 to 1000 free-AFM_1 ppt with a limit of detection of 12 ppt.

1. Introduction

Aflatoxins are toxic fungal metabolites produced by *Aspergillus flavis* and *Aspergillus parasiticus* with an important carcinogenic effect that can contaminate certain agricultural commodities and animal foodstuff [1,2]. For instance, aflatoxin M_1 (AFM_1, (6aR-cis)-2,3,6a,9a-tetrahydro-9a-hydroxy-4-methoxycyclopenta[c] furo[3′,2′:4,5]furo[2,3-h] [1]benzopyran-1,11-dione, CAS Number: 6795-23-9), the hydroxylated form of the aflatoxin B1 (AFB_1), can be found in milk or milk-derived products (cheese, yogurt, cream, etc.) from mammals that ingest AFB_1 infected feed [3]. The presence of these toxins cannot always be correlated to visible fungal infection and many efforts have been focused on the development of analytical methods for their quantitative determination [4–6]. Thin layer chromatography (TLC) [7], enzyme-linked immunosorbent assay (ELISA) [8] and especially the high performance liquid chromatography analysis with fluorimetric detection (HPLC-FD) coupled with a clean-up treatment by immunoaffinity columns (IC) [9], the method of reference for detection of aflatoxins in milk, have been developed and widely used last years. These methods show good sensitivity and high efficiency, although they are very tedious and time-consuming, especially the chromatographic methods that require an initial extraction step with organic solvents [10]. Electrochemical immunosensors, principally those based on the use of enzymatic labels, have been extensively applied to the detection of toxins for being rapid, simple and low cost methods [11–13]. Special attention has been given to the development of impedimetric immunosensors. In terms of aflatoxins, several strategies have been used, mainly based on changes in the charge-transfer resistance when redox couples are present in the medium [14]. Recently, the application of nanostructures in biosensing has also shown a remarkable interest. One of the most popular strategies is focused on the use of gold nanoparticles labels and silver enhancement [15]. This approach, initially used in chemical and biological analyses to improve microscopic visualization or to increase the sensitivity [16,17], has been successfully applied to the development of electrochemical immunosensors and genosensors by directly measuring the oxidation current response of the deposited silver [18,19].

This paper describes the characterization of the gold-catalyzed deposition of silver on graphite screen-printed electrodes (SPEs) using electrochemical impedance spectroscopy (EIS) and the application of this approach to the development of impedimetric immunosensors for toxins. The changes produced in the electrode-solution interface by the catalytic deposition of silver were monitored using impedance spectroscopy by following the mag-

nitude of the charge-transfer resistance, R_{CT}, and the interface constant phase element, CPE_i. These elements of the equivalent circuit showed good correlation with the amount of silver deposited on the electrode and thus, with the concentration of toxin in a wide range of concentrations. Better correlations were found when considering the R_{CT} since this parameter is almost exclusively dependent on the amount of deposited silver under these experimental conditions.

2. Materials and methods

2.1. Reagents and chemicals

Bovine serum albumin (BSA), bovine serum albumin-aflatoxin M_1 conjugate (BSA-AFM_1) and 20 nm colloidal gold suspensions were purchased from Sigma. The polyclonal anti-aflatoxin M_1 antibody (anti-AFM_1) from mouse was kindly supplied by C.E.A. (Paris, France). Silver nitrate (Fluka), ammonium nitrate (Prolabo), sodium chloride (Sigma), potassium chloride (Sigma–Aldrich), Tween 20 (Aldrich), dibasic sodium phosphate (Sigma), monobasic potassium phosphate (Sigma) and 3-[(1,1-dimethyl-2-hydroxiethyl) amino] 2-hydroxypropanesulfonic acid (AMPSO) (Sigma) were used as received without further purification. All solutions were prepared with distilled water.

2.2. Preparation of colloidal gold antibody conjugate

The antibody-colloidal gold conjugate was prepared following the protocol previously detailed in the literature [20]. Briefly, 25 μL of 0.9 mg mL^{-1} anti-AFM_1 prepared in 15 mM phosphate buffered saline (PBS, pH 7.4) and 100 μL of 20 mM AMPSO (pH 9.01) were added to 1 mL of a 20 nm colloidal gold suspension. After fixing the pH at 8, the solution was agitated for 30 min at room temperature. Next, 100 μL of 1% (w/v) BSA prepared in AMPSO buffer were added and the solution was centrifuged at 6000 rpm (Eppendorf Minispin centrifuge) for 30 min at 4 °C. The supernatant was removed and the pellet was re-suspended in 1 mL of 0.1% (w/v) BSA in AMPSO buffer. The centrifugation step was then repeated. The final pellet was re-suspended in 100 μL of 15 mM PBS, pH 7.4 and stored at 4 °C until needed.

2.3. Electrodes fabrication and preconditioning

The electrodes production was carried out in-house at the University of Perpignan (France) using a DEK 248 screen-printing system (Weymouth, UK). The fabrication process followed the protocol detailed in previous papers of the group [21,22]. Geometrically, these screen-printed electrodes (SPEs) contained a graphite working electrode disc of 0.12 cm^2 surrounded by a graphite counter electrode of bigger size area integrated on clear plastic sheets with a Ag|AgCl electrode, used as pseudo-reference.

Before measurement, SPEs were treated by successive cycling in 0.5 M H_2SO_4 between −0.5 V to 1.1 V versus Ag|AgCl to remove impurities (10 cycles; scan rate 100 mV s^{-1}, step potential 10 mV).

2.4. Immunosensor preparation protocol

In the impedimetric detection of AFM_1, an indirect competitive protocol was followed. A volume of 20 μL (15 μg mL^{-1} BSA-AFM_1 conjugate in 15 mM PBS, pH 7.4) was inoculated on the working electrode area and incubated overnight at 4 °C in a humid chamber to avoid drying. The un-adsorbed conjugate was removed by washing with 15 mM PBS + 0.5% (v/v) Tween 20 (pH 7.4). The non-reacted surface was blocked with 1% (w/v) BSA in 15 mM PBS (pH 7.4) for 1 h at room temperature. After washing with the PBS-Tween 20 solution, the competition assay was performed. During com-

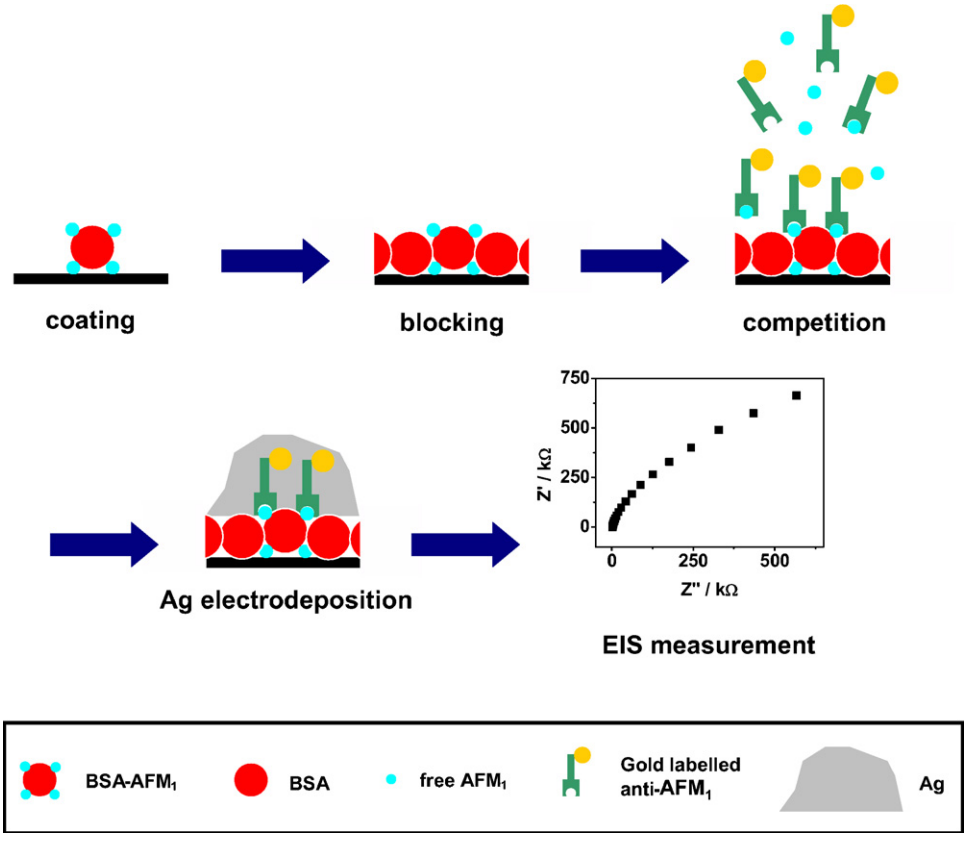

Fig. 1. Schematic illustration of gold-labelled antibody recognition and signal amplification with silver enhancement.

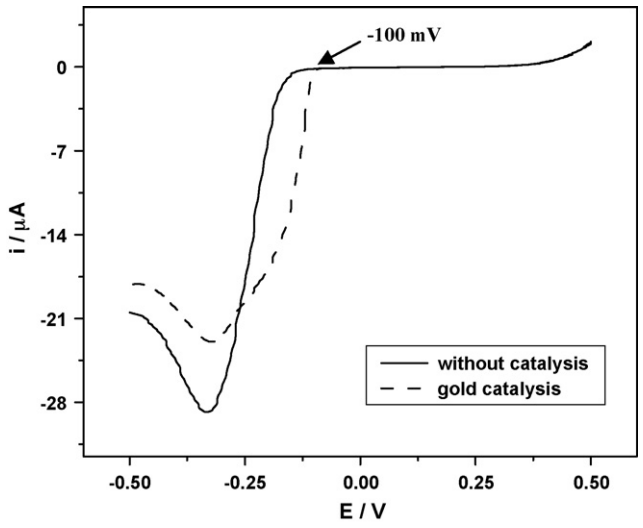

Fig. 2. Representation of the reduction peak of silver with and without the catalytic effect of 20 nm colloidal gold nanoparticles (scan rate: 100 mV s^{-1}).

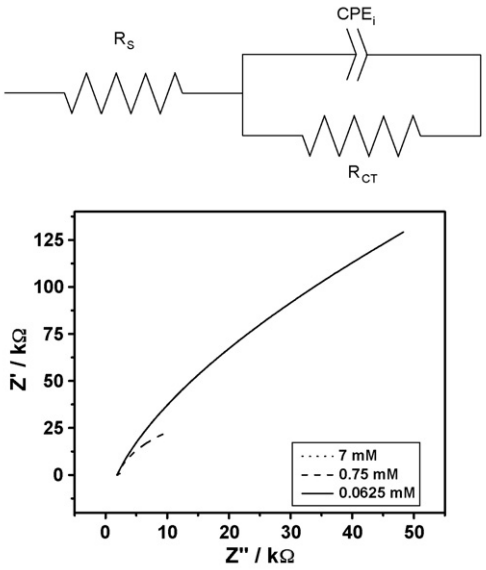
petition, equal volumes (50 μL) of free-AFM_1 (from 15.625 ng L^{-1} to 2500 ng L^{-1} prepared in 15 mM PBS + 0.5% (v/v) Tween 20, pH 7.4) and 1/250 gold-labelled antibodies were allowed to compete for 1 h, at room temperature. The optimal concentration of gold-labelled antibodies was obtained from previous works [23]. Finally, SPEs were washed as before and stored in 0.1 M NH_4NO_3 at room temperature until measurement. The immunosensor preparation is illustrated in Fig. 1.

2.5. Silver enhanced impedimetric measurements



All measurements were carried out in 0.1 M NH_4NO_3 to avoid silver precipitation as silver chloride. Before impedance measurements, SPEs were additionally washed with distilled water to remove chloride traces. Silver was electrodeposited using the catalytic effect of the gold nanoparticles immobilized on the electrode surface. A 1 mM $AgNO_3$ in 0.1 M NH_4NO_3 solution was electrodeposited on the working electrode surface by applying −0.1 V for 45 s. At this potential, the catalytic effect of gold was the responsible of the metallic silver deposition (see Fig. 2). Finally, electrodes were washed with distilled water and measured in 0.1 M NH_4NO_3 at room temperature following the protocol detailed above. It is important to note that the silver deposition and the measurement should be done in a free-Cl^- media to avoid undesirable AgCl precipitation.

Impedance measurements were performed with an AUTOLAB PGSTAT 12 (EcoChemie, BV, The Netherlands) containing a FRA-2 module controlled by the AUTOLAB FRA-2 software (EcoChemie, BV, The Netherlands). Spectra were recorded at −20 mV over a frequency range from 1 kHz to 0.1 Hz, using a sinusoidal AC potential perturbation of 10 mV. The measurement time was around 120 s after registering 10 points per frequency decade. Impedance measurements were made in the dark to avoid the oxidation of the electrodeposited silver. All measurements given in this work are in relation to the Ag|AgCl reference electrode.

3. Results and discussion

3.1. Fitting and interpretation of impedance data

Z-View software was used to fit impedance data to the equivalent circuit shown in Fig. 3, which included the solution resistance, R_S, the double layer capacitance, which appears as the interface

[$AgNO_3$] mM	R_S Ω	R_S (% error)	CPE_i Ω $s^{-\beta}$	CPE_i (% error)	R_{CT} Ω	R_{CT} (% error)
7	1969	0.04	3.07E-4	1.56	4706	7.58
0.75	1837	0.33	7.54E-6	1.14	194340	8.77
0.0625	1879	0.36	1.28E-6	0.70	744630	4.18

Fig. 3. Impedance complex plane plot for 7, 0.75 and 0.0625 mM $AgNO_3$ solutions. The impedance spectra were fitted to the equivalent circuit shown inset, which contains the solution resistance (R_S), the interface constant phase element (CPE_i) and the charge-tranfer resistance (R_{CT}). The magnitude and error percentage from the fitting for each silver concentration are also included.

constant phase element, CPE_i, and the charge-transfer resistance, R_{CT}.

The use of the CPE_i instead of a conventional double layer capacitance was discussed in previous works [24,25]. Briefly, the double layer impedance of most solid electrodes behaves as a non-pure capacitance with a phase angle always smaller than 90°. Although being still controversial, a roughness factor appears to be one important cause of this [26]. Consequently, the double layer capacitance is frequently fitted using a constant phase element. Following the protocol exposed in Sections 2.4 and 2.5, toxins, antibodies, gold and silver become part of the interfacial region, thus, modifying the dielectric properties of the electrode. Hence, the CPE contains more parameters than simply the surface roughness or the charge separation, such as gold concentration or the deposited silver. For this reason, Fig. 3 shows a CPE labelled CPE_i as a generic element that accounts for many complex processes which cannot, themselves, be deconvoluted.

Fig. 3 shows impedance measurements for 7, 0.75 and 0.0625 mM $AgNO_3$ solutions after 45 s of deposition at −0.1 V. The change in the magnitude of the impedance (Z) with the concentration of silver nitrate can be clearly seen.

3.2. Impedimetric characterization of the immunosensor

Impedance spectroscopy is a powerful electrochemical technique for the investigation of the electrode-solution interface. In this work, impedance spectroscopy was used for the characterization of the process of fabrication of the immunosensors. Electrodes were prepared following the protocol detailed in Section 2.4 and impedance spectra were recorded under the conditions specified in Section 2.5. The Nyquist plot illustrating the real and the imaginary components of the impedance in the range of frequencies under study after each modification step of the fabrication protocol are presented in Fig. 4.

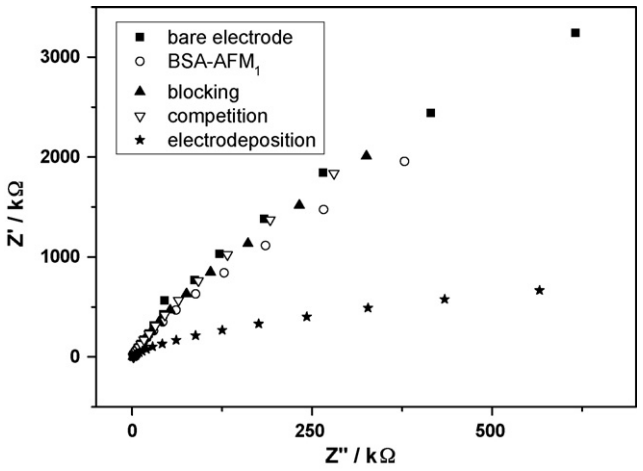


Fig. 4. Representation of the impedance complex plane plot for each stage of the immunosensor fabrication protocol.

Results show that the magnitude of the imaginary component of the impedance at low frequencies decreased with the modification of the electrode surface, which may be due to the isolating properties of the molecules covering the surface of the electrode [27]. For the suitable fitting of impedance data after the gold-mediated catalytic electrodeposition of silver, an extra element should be included in the equivalent circuit: the charge-transfer resistance, R_{CT}. Thus, the metallic silver layer was the responsible of the electron exchange with the electrode under the experimental conditions here described and the R_{CT} magnitude could be directly related to it.

3.3. Impedimetric characterization of the catalytic deposition of silver

For the characterization of the catalytic deposition of silver, SPEs were prepared as described in Section 2.4 and were measured following the protocol detailed in Section 2.5 using different concentrations of $AgNO_3$ (ranging from 7 mM to 0.0625 mM $AgNO_3$). In Fig. 5, the magnitude of both CPE_i and R_{CT} is represented versus the concentration of $AgNO_3$.

Fig. 5 shows that the CPE_i value increased with the amount of deposited silver whereas the magnitude of the R_{CT} decreased. As previously detailed, the CPE_i is an electrical element consisting in a group of parallel or branched resistive-capacitive transmission lines commonly used for adjusting deviations from the pure-capacitive behaviour of the interface capacitance, C_i, originating in surface heterogeneities [27]. The increase in the capacitance magnitude may be understood by considering how the deposition of silver modified the electrode-solution interface. Several factors (the increase of the bare electrode area, probably due to the roughness of the silver layer, or the compacting of the electrode double layer) might be thought to cause the increase of the C_i, since:

$$C_i = \frac{\varepsilon_0 \varepsilon_i A}{d} \quad (1)$$

where ε_0 is the permittivity of the vacuum, ε_i is the permittivity of the interface, A is the area of the bare electrode and d is the distance between layers in the electrolytic double layer. However, the change in the C_i could not be directly related to a single factor. Besides, the complex structure of the electrode-solution interface, a biometallic matrix containing immobilized biomolecules, gold and electrodeposited silver, suggested that the experimental results may be caused by a combination of factors that could not be deconvoluted. Hence, the huge number of parameters involved in the change of the CPE_i magnitude, some of them probably not directly related to the amount of silver electrodeposited on the electrode surface, did not recommend the use of this electrical element in the development of quantitative immunosensors.

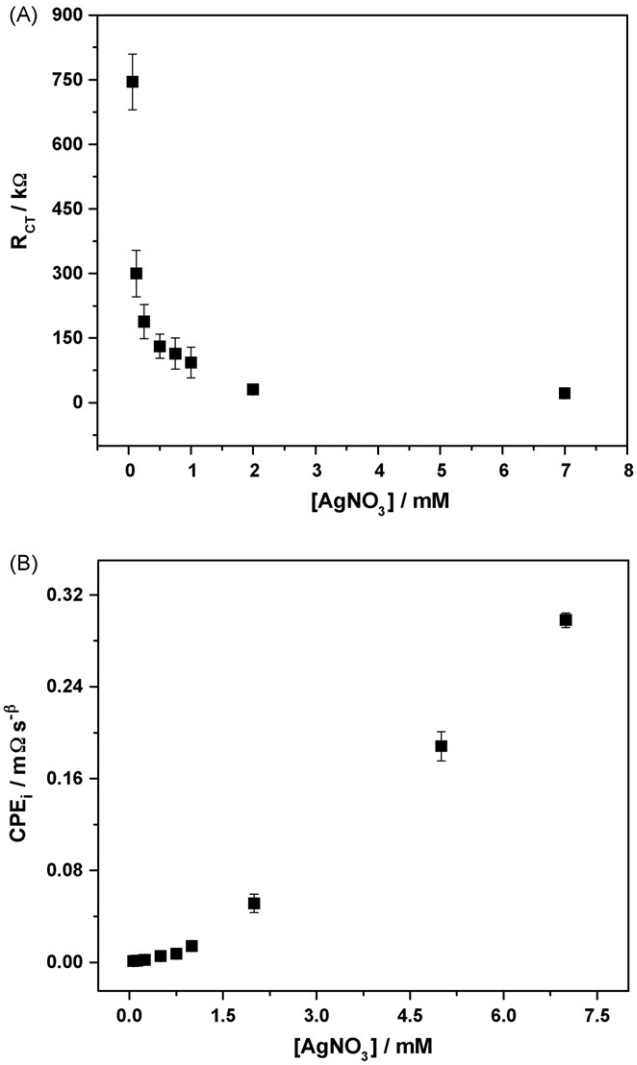

Fig. 5. Representation of the variation of the magnitude of the R_{CT} (A) and the CPE_i (B) with the concentration of $AgNO_3$. Individual points represent means from the measurement of two different electrodes and error bars are estimates of the relative standard deviation (R.S.D.).

On the other hand, the theoretical expression describing the behaviour of the R_{CT} magnitude is illustrated in Eq. (2).

$$R_{CT} = \frac{RT}{nFi_0} \quad (2)$$

where R is the constant of the ideal gases, F is the Faraday constant, T is the temperature, n is the number of electrons exchanged in the reaction and i_0 is the exchanged current density. Thus, the R_{CT} may be considered to be mainly dependent on a single parameter, the exchanged current density and consequently on the amount of redox species in the bulk or on the electrode surface. In this case, as the R_{CT} was only present in the equivalent electrical circuit when a silver layer was electrodeposited on the electrode surface, the R_{CT} magnitude could be directly correlated to the amount of silver deposited: the increasing amount of deposited silver increased the current density, decreasing the R_{CT} value. Hence, the R_{CT} is highly recommended in the development of silver enhanced impedimetric immunosensons.

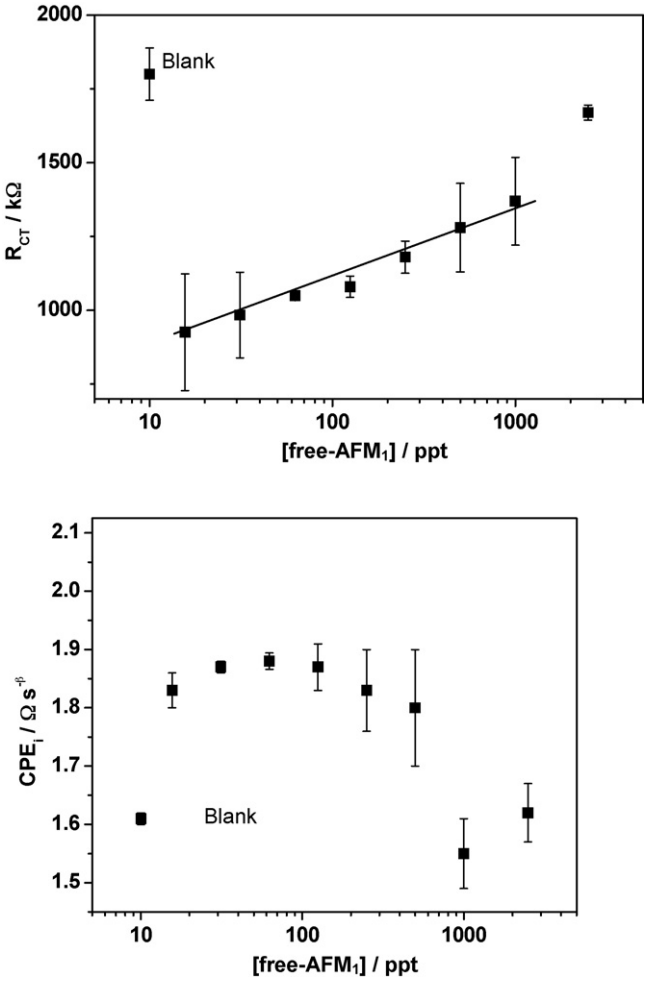

Fig. 6. Representation of the variation of the magnitude of the R_{CT} (A) and the CPE_i (B) with the concentration of free-AFM_1. The blank (samples containing AFM_1 antibody without colloidal gold nanoparticles) has been also included as control. Individual points represent means from the measurement of two different electrodes and error bars are estimates of the relative standard deviation (R.S.D.).

3.4. Immunoimpedimetric competitive assay

Finally, the sensors previously described were used in an immunoimpedimetric competitive assay. SPEs were prepared following the protocol described in Section 2.4 and measured as detailed in Section 2.5. The results are shown in Fig. 6, which illustrates the variation of the CPE_i and the R_{CT} with the concentration of free-AFM_1.

As expected, the R_{CT} magnitude tended to increase and the CPE_i to decrease when increasing the free-AFM_1 concentration. This should be caused by the decreasing amount of colloidal gold immobilized on the electrode surface after the competitive assay (when increasing the free-toxin concentration), which reduced the catalytic deposition of silver. It has to be pointed out that the charge-transfer resistance showed a better correlation with the toxin concentration than the interface capacitance. As previously discussed, this might suggest that, apart from the silver deposition, several factors not linked with that process could change the electrode-solution interface magnitude introducing a huge error in the measurement. In the case of the R_{CT}, an evident correlation was found between 15 and 1000 free-AFM_1 ppt with a limit of detection of 12 ppt. The limit of detection was calculated according to the $3 \times Sb/m$ criteria, where m is the slope of the linear calibration plot and Sb was estimated as the standard deviation ($n = 3$) of the impedimetric signals obtained in absence of colloidal gold.

4. Conclusions

We have impedimetrically charactarized the catalyzed electrodeposition of silver using graphite SPEs. We have demostrated that impedance spectroscopy, and particularly the charge-transfer resistance, can be used to quantitatively determine the amount of electrodeposited silver. This approach has been successfully applied to the development of an impedimetric immunosensor for toxins. Good correlations have been found between the logarithm of the toxin concentration and the magnitude of the charge tranfer resistance between 15 and 1000 free-AFM_1 ppt, with a limit of detection of 12 ppt.

ABSTRACT

One of the oldest groups of veterinary chemotherapeutic agents, sulfonamides have been widely used for more than 50 years, thanks to their low cost and their broad spectrum of activity in preventing or treating bacterial infections. Nowadays, those compounds are regularly detected in a wide variety of environmental samples, including natural waters, sediments and soils. Since the environmental concentrations of sulfonamides are usually very low and their occurrence multicomponental, their determination in these matrices still pose significant analytical problems. The present paper describes the optimization of ESI-MS/MS parameters and the chromatographic separation of 12 sulfonamides commonly used in veterinary medicine. The methodology developed in this study, unlike many others, satisfied the requirements of EU Commission Decision 2002/657/EC, which defines the criteria for both screening and confirmatory methods with respect to drug residues on the basis of identification points. Each MRM transition was tested not only for the qualitative but also for the quantitative analysis of sulfonamides. The method was validated for its analytical performance parameters and applied to the determination of those compounds in soil samples.

1. Introduction

Scientists have devoted much attention to the occurrence of pharmaceuticals in the environment. Consequently, large numbers of reports have been published on traces of drugs detected in many different environmental samples, e.g., fresh-, sea-, and wastewaters, soils, sediments and biota [1]. Because of their polar nature, however, a number of drugs are not significantly adsorbed onto soils and therefore easily reach groundwater, the usual source of drinking water [2]. At present, some 3000 different active substances are used in human and veterinary medicine [3]. Drugs commonly detected in the environment include antibiotics, non-steroidal anti-inflammatory drugs, beta-blockers, anti-epileptics, blood-lipid lowering agents, antidepressants, hormones and anti-histamines [1–5]. Antibiotics are of particular concern: continuous exposure to them, even to low concentrations, can induce bacterial resistance. This constitutes pose a serious threat to public health, as fewer and fewer infections can be treated with the existing suite of antibiotics [5]. The term "antibiotic" is normally reserved for a diverse range of compounds, both natural and semi-synthetic, that possess antibacterial activity [6]. In addition to the treatment of human diseases, those drugs are used extensively in veterinary medicine as growth promoters and to improve feed efficiency [7]. Playing a crucial role in modern agriculture and the livestock industry, their use has been on the rise in many developing countries [4].

As antibiotics do not undergo complete metabolism in animal organisms [4–5], a large proportion of them is excreted in unchanged form in feces and urine. Both antibiotics and their metabolites are released either directly into the environment by grazing animals or indirectly during the application of manure/slurry as fertilizer. Contaminated manure is considered to be the main source from which antibiotics and their corresponding resistant genes enter different environmental compartments, food and plants [8]. Moreover, once in the aquatic environment, antibiotics have been found to break through classical wastewater treatment facilities, thereby presenting a threat to surface and groundwater [9–10]. It has also been found that the conventional drinking water treatment processes of coagulation, flocculation and sedimentation do not completely remove these compounds, so they are detected in finished drinking waters in various concentrations [11–15].

Pharmaceuticals enter the environment in low or very low concentrations; this, together with their diverse physico-chemical properties and the complexity of environmental matrices, makes their determination difficult. It is therefore necessary to develop sensitive, selective and easily reproducible methods for tracing these chemicals in different environmental materials. Since in most

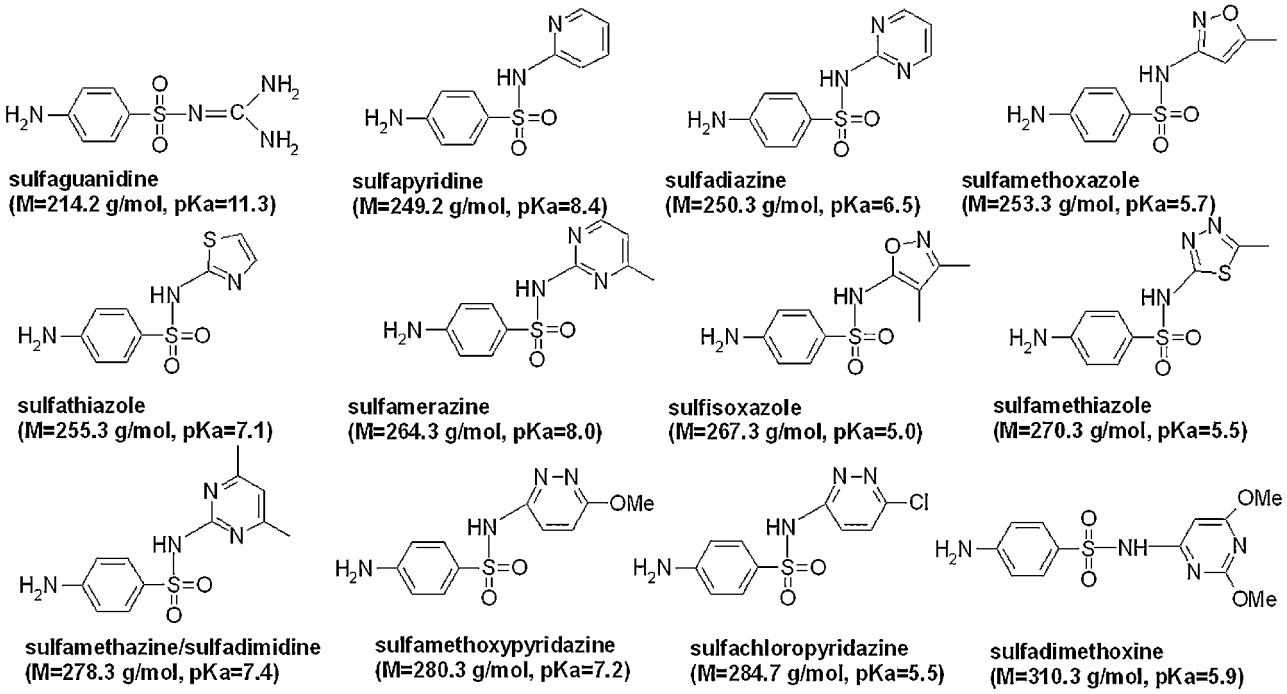

Fig. 1. The chemical structures of the sulfonamides under investigation [32,44].

cases we are dealing with complex mixtures of several chemicals from one or several groups of pharmaceuticals, chromatographic techniques need to be applied prior to their final determination. Their relatively high polarity and low thermal stability precludes gas chromatography (GC), so liquid chromatography (LC) coupled to mass spectrometry (MS), fluorescence, ultraviolet or radioimmunoassay [16] detection is used; among these latter techniques, LC coupled to MS, especially in tandem with MS, has made impressive progress in the analysis of residual pharmaceuticals [17–18]. The vast majority of studies have focused on the optimization of mobile phase composition, instrumental conditions and validation parameters (including limit of detection (LOD) and limit of quantification (LOQ)) in order to obtain favorable analytical protocols for the pharmaceuticals of interest. However, rather more methods have been described for the determination of antibiotics in different water compartments than in soil; the latter is more challenging owing to the complexity of soil matrices, interferences, and the longer sample preparation requirements (clean-up procedure). For these reasons, only a few papers have been published on the quantification of antibiotics in solid matrices (e.g. [19]). Likewise, sulfonamides as veterinary chemotherapeutics have usually been analyzed in water samples like wastewater [20–26], drinking water [13], surface/groundwater [27–28] or liquid manure [29–31] rather than in solid samples [32–37].

However, since there are no official guidelines for the trace analysis of pharmaceuticals in environmental samples, most of the reported methodologies suffer from a lack of confirmatory methods with respect to MS.

Reports on the qualitative and quantitative analysis of many different pharmaceuticals (including sulfonamides) in environmental samples using HPLC systems with UV-detection are still being published [23,25,30,36,38] this method cannot be used as a confirmatory technique, because identification of a compound in complex materials based solely on retention time is not sufficient. According to the EU Commission Decision of August 12, 2002 (2002/657/EC), also referred to as SANCO 1085/2002, determination of an analyte using LC with UV/VIS detection (single wavelength) is not suitable on its own for use as a confirmatory method.

The aim of this study was therefore to optimize MS/MS parameters using ion-trap mass spectrometry with electrospray ionization for the analysis of sulfonamides – the most common veterinary chemotherapeutics – and to select characteristic fragmentation ions of these compounds in order to work in multiple reaction monitoring (MRM) mode. The experiments were performed in accordance with the above-mentioned Commission Decision, which defines the criteria for both screening and confirmatory methods with respect to drug residues on the basis of identification points. A precursor ion and a minimum of two product ions were selected for every compound, which yields four identification points and enables confirmation of the compounds analyzed. The chromatographic separation of these compounds was optimized, and also validated using parameters such as selectivity, linearity, sensitivity, limits of detection and quantification, precision (intra-day and inter-day precision) and accuracy (recovery). Finally, the method was applied to the analysis of selected sulfonamides in soil samples.

2. Materials and methods

2.1. Chemicals

Standards of sulfaguanidine, sulfathiazole, sulfadiazine, sulfamethiazole, sulfamerazine, sulfamethoxypyridazine, sulfachloropyridazine, sulfisoxazole, sulfamethoxazole, sulfadimethoxine were purchased from Sigma–Aldrich (Steinheim, Germany), those of sulfadimidine and sulfapyridine from Serva (Heidelberg, Germany) (Fig. 1). Methanol (MeOH) and acetonitrile (ACN) (HPLC grade), used for the mobile phases and for the dissolution of standards, were obtained from POCH S.A. (Gliwice, Poland); the acetonitrile (LC–MS Chromasolv®) used for the LC–MS/MS analysis was purchased from Sigma–Aldrich (Steinheim, Germany). Deionized water was produced by the HYDROLAB System (Gdańsk, Poland). Ammonium acetate (NH_4Ac) and acetic acid (both of ana-

lytical reagent grade) were purchased from Chempur (Piekary Śląskie, Poland).

Standard stock solutions were prepared by dissolving each compound in methanol at a concentration of 500 μg ml^{-1} and stored at −18 °C in the dark. Working solutions (1 μg ml^{-1}) of sulfonamides were prepared by diluting the stock solutions in a mixture of ACN:H_2O (50:50, v/v) or in acetic buffer at pH 3.5 (acetic acid was added to the mixture of ACN:H_2O, 10:90, v/v, containing 1 mM NH_4Ac until pH 3.5 was reached), depending on the purpose, and stored at 4 °C. During the experiments pH was measured using a CP-411 laboratory pH-meter (Elmetron-Zabrze, Poland). The pH of the solution for the analysis of selected antibiotics ensured their stability and the appropriate conditions for the electrospray ionization and chromatographic separation. Strata-X Polymeric Reversed Phase (SPE-Phenomenex Inc., Torrance, CA) cartridges with 200 mg of packing material and a 3 ml reservoir were used for sample preparation.

2.2. Soil samples

Soils (fluvial meadow soil) were sampled from the region of Pomerania in northern Poland. The soil was air-dried, ground in a mortar and passed through a 2 mm sieve, then re-ground in a mortar with a small rubber pestle. Their organic carbon content was determined by loss-on-ignition. The pH of the soil (measured in 1 M KCl) was 5.3, the clay content (>0.01 mm fraction) was 94% and the organic content was 21.5%.

2.3. Optimization

2.3.1. Liquid chromatography conditions

Agilent 1200 Series LC system (Agilent Technologies, Inc., Santa Clara, USA) and ChemStation for LC systems software were used for the chromatographic separation of the sulfonamides. For the LC–MS/MS analysis Brucker Daltonics Data Analysis software was utilized. The separation was performed on Gemini C_{18} and Gemini C_6 columns (both 150 mm × 4.6 mm, 5 μm pore size) (Phenomenex Inc., Torrance, CA) with the direct infusion of the eluent from the LC to the mass spectrometer. To optimize the chromatographic separation, a serial of preliminary experiments were performed to test different mobile phases. Both acetonitrile and methanol mixed with water were tested as mobile phases. Additionally the flow rate of the eluent, injection volume and the column temperature as well as the pH of a mobile phase consisting of ammonium acetate and acetic acid was also optimized.

2.3.2. ESI-MS/MS parameters

All mass spectrometric measurements were performed on an HCT Ultra ion trap mass spectrometer (Brucker Daltonics, Bremen, Germany) equipped with an electrospray ionization (ESI) source. All the compounds were tested in both positive and negative ion modes. MS–MS parameters were optimized in continuous flow mode using an integrated syringe pump at a flow rate of 5 μl min^{-1} of standard solutions. EsquireControl software was employed to optimize spectrometric conditions such as the nebulizer gas and dry gas flow rates and the dry gas temperature. The nebulizer gas and dry gas was nitrogen, and helium (99.999%) was used as the collision gas in the ion trap. The parameters were optimized manually, separately for each compound. After the best conditions for isolating the precursor ion (proton adduct of the analyte) had been determined, full scan MS/MS mode was used to record product ions from the standard solution of chemotherapeutics. For each compound, the fragmentation amplitude and isolation width were also optimized manually to increase the sensitivity and selectivity of the method and to select three of the most intensive and characteristic fragmentation ions for qualitative analysis and one of the highest intensity for quantitative analysis.

2.4. Extraction method

Soil samples (1 g) were spiked with the solution (2.5 ml) of 12 sulfonamides of known concentrations (250 μg sulfonamide kg^{-1} soil) and then left to dry in the dark at room temperature for three days. Next, the analytes were extracted from the dry soil with 5 ml MeOH, placed in an ultrasonic bath (Polsonic, Warsaw, Poland) for 1 h, and finally shaken for another 1 h (RS 10 Control, IKA, Germany). The samples were then centrifuged (10 min, 4000 rpm; MPW-250 Centrifuge, Warsaw, Poland) and the supernatant transferred to a 10 ml flask, after which the procedure was repeated. The resulting extract was concentrated to a volume of about 1 ml. Two alternative procedures were applied in the next step. In the first one, the residual extract was transferred to a plastic tube, evaporated to dryness under a stream of nitrogen, after which 1 ml of mobile phase A was added. The sample was centrifuged (15 min, 5500 rpm; MPW-250 Centrifuge, Warsaw, Poland), transferred to an amber vial and analyzed by LC–MS/MS. In the second procedure, 250 ml water was added to the residual extract and the whole cleaned up on a Strata-X Polymeric Reversed Phase SPE-column (3 ml, 200 mg, Phenomenex Inc.). The cartridges were rinsed with 3 ml MeOH and conditioned with 6 ml H_2O:MeOH (95:5, v/v); after sample loading the cartridge was dried and then rinsed with 3 ml H_2O:ACN (95:5, v/v) to remove interferences. Sulfonamides were eluted with 6 ml of a mixture of MeOH:ACN (50:50, v/v) and allowed to dry under a stream of nitrogen. The dried extract was reconstituted in 1 ml mobile phase A and analyzed by LC–MS/MS.

3. Results and discussion

3.1. Optimization of the LC–MS/MS method

According to EU Commission Decision 2002/657/EC, the presence of the residues of veterinary drugs is confirmed so long as the drug is identified both chromatographically and spectrally. If these criteria are not satisfied, a new method or a better procedure should be developed for extracting and/or separating the analytes from interferences. Nowadays, LC–MS/MS in multiple reaction monitoring (MRM) mode is the 'state-of-art'. It is the technique of the highest sensitivity and selectivity, which for these reasons has been used in these experiments.

Comparison of positive and negative ion modes shows that working in the former mode causes more high-intensity product ions to be formed. During the optimization of sulfonamides in full scan MS, the most intensive ions were $[M+H]^+$; ions like $[M+Na]^+$ or $[M+NH_4]^+$ were also detected but were of lower intensity. All the MS/MS parameters were selected to obtain the most intensive precursor ions for every compound $[M+H]^+$. The most relevant parameters were: nebulizer gas (30 psi), dry gas (10 L min^{-1}), dry temperature (300 °C), maximum accumulation time (200 ms), average (3 scans), smart target (50,000), target mass (m/z = 250), capillary exit (109.8 V) and skimmer (40.0 V); ultra scan was used as the mass range mode. Moreover, for every compound a precursor ion and a minimum of two product ions were selected, earning, according to Commission Decision 2002/657/EC, four identification points for the confirmation of the compound. According to Council Directive 96/23/EC, veterinary drugs such as antibacterial agents, including sulfonamides and quinolones belong to Group B in Annex I of this Directive, and for those compounds a minimum of three identification points are required [39]. The value of a low-resolution MS precursor ion is 1.0 identification points and that of each low-

resolution MS product ion is 1.5 IPs. For these reasons, a minimum of two product ions in low-resolution MS must be monitored for the minimum number of identification points to be acquired. Note, that working in SIM or MRM mode with only one product ion in low-resolution MS does not fulfill the minimum IP requirement. Table 1 presents the results together with selected values of the optimized fragmentation amplitude for each of the transitions and the isolation width for every product ion. The fragmentation of sulfonamides has already been described [40]. For sulfonamides, the most characteristic ions described in the literature, such as m/z 156, 108 and 92, corresponding to $[M-RNH_2]^+$, $[M-RNH_2-SO_2]^+$, and $[M-RNH_2-SO]^+$, respectively, were also observed in this experiment. Additionally, fragmentation of some of those compounds produced such ions as 124, 186 and 204, which correspond to $[RNH_2+2H]^+$, $[RNH_2+SO_2]^+$ and $[RNH_2+SO_2+H_2O]^+$.

Although complete separation is not necessary for selective MS–MS detection, it much improves detectability and reduces the ion suppression effect; this was one of the main reasons for performing the experiments [18]. Therefore, the influence of different parameters on retention time was optimized. The separation was done by reversed-phase chromatography on two types of column—C_6 and C_{18}. The C-phenyl column was excluded from the later experiments because of the very strong hydrophobic and $\pi\cdots\pi$ interactions between the phenyl groups on the stationary phases and the specific groups in the sulfonamide structures. Retention times were therefore longer and peaks were broader. Both acetonitrile and methanol were tested as mobile phases, as were the pH and different salt contents. It was demonstrated that acetonitrile and water were preferable for sulfonamide separation. Moreover, it was necessary to work under acidic conditions for two reasons: first, to achieve better separation, and second, to improve ionization in the mass spectrometer. In the HPLC system, trifluoroacetic acid is usually used for this purpose; but it causes ion suppression so is not recommended for LC–MS/MS analysis. This was why an acetic buffer of different pH was tested. Generally, it was found that the lower the pH, the higher the retention time and the better the separation. This is because most veterinary sulfonamides have at least two nitrogen-containing functional groups (Fig. 1). The amine attached to the aromatic ring-referred to as N^4 – is protonated at pH < 2.5, whereas the one attached to the sulfur-referred as N^1 – is deprotonated at pH > 5.5–7.0. Hence, most of these compounds are positively charged under acidic conditions, negatively charged under alkaline conditions, and neutral between pH 2.5–6.0 [32]. Additionally, very weakly basic or acidic sites may also be present in the side R-group, which can also play a crucial role in retention on the stationary phase. As observed by Botsoglou et al. [41], the retention time of the investigated sulfonamides increased slightly in the pH range 2.5–3.5, the greatest retention being obtained for sulfonamides bearing an additional methyl group on the R-side-chain. This suggests that the R-side-chain plays a crucial role in the hydrophobic interactions of the compounds with the stationary phase [41], which was also observed in the

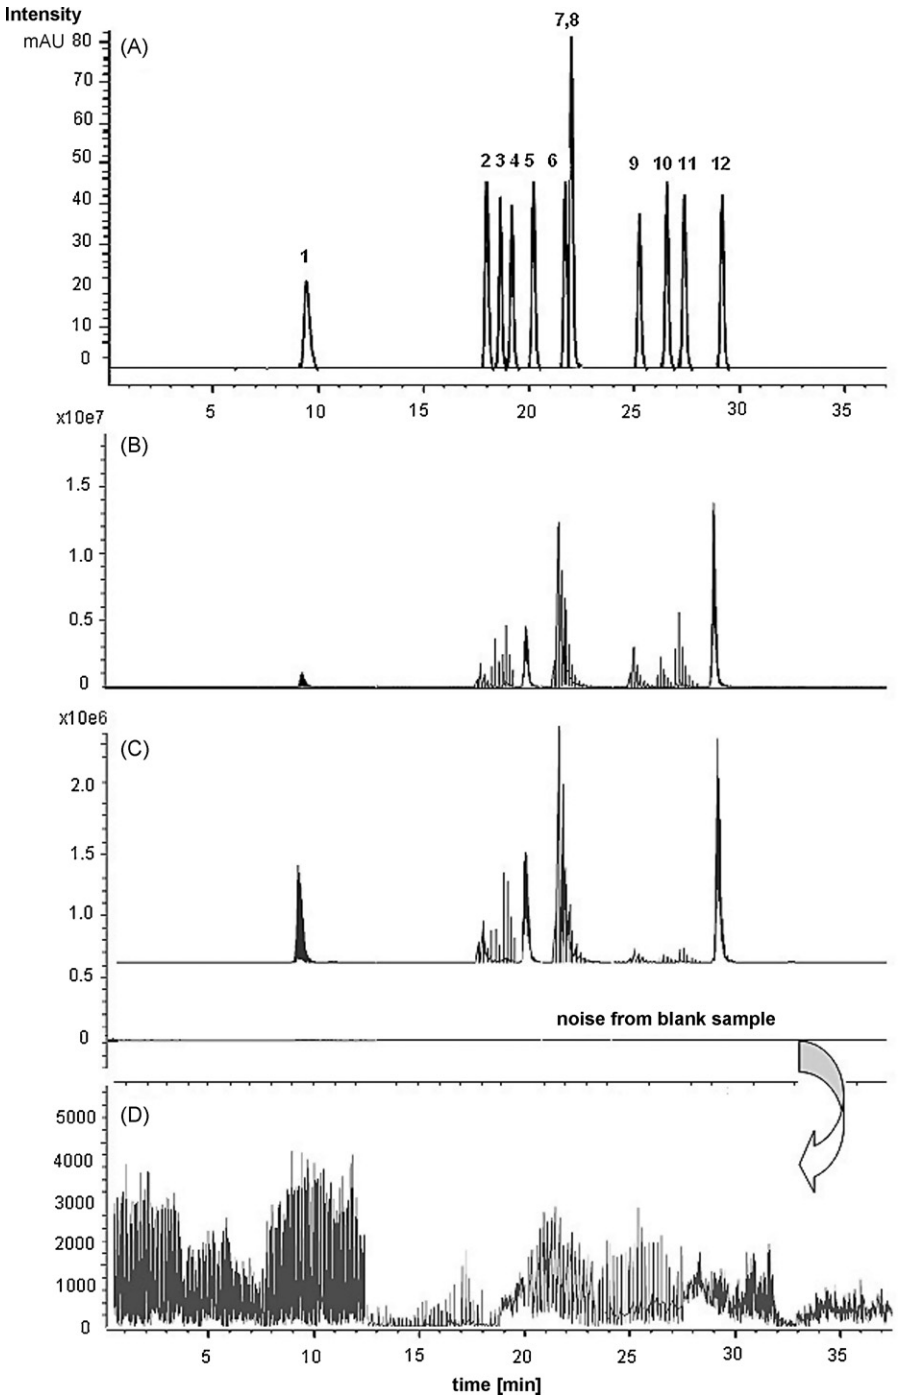

Fig. 2. Chromatograms of the optimized method: (A) (HPLC–UV) and (B) (MRM-LC–MS/MS) chromatograms of the standard mixture (1 μg ml^{-1}) of 12 sulfonamides: 1, sulfaguanidine; 2, sulfadiazine; 3, sulfathiazole; 4, sulfapyridine; 5, sulfamerazine; 6, sulfadimidine; 7, sulfamethiazole; 8, sulfamethoxypyridazine; 9, sulfachloropyridazine; 10, sulfamethoxazole; 11, sulfisoxazole; 12, sulfadimethoxine; C_{18}-column, detection wavelength 270 nm, 300 μl min^{-1}, injection volume 50 μl, mobile phase A – H_2O:ACN (90:10, v/v, 1 mM NH_4Ac, HAc at pH 3.5), mobile phase B – 100% ACN; gradient program: 0–64% B for 32 min, temperature 25 °C); (C) (MRM-LC–MS/MS) chromatogram of sulfonamides extracted from soil (procedure 1 – without any clean-up) spiked with the standard solution (250 μg kg^{-1}); (D) blank sample of soil.

present experiments. The selection of pH 3.5 for the mobile phase and the solution of the standard compounds was based on the pK_a of the sulfonamides (Fig. 1). Since it was below the lowest value of pK_a, a pH of 3.5 ensured that the sulfonamides were in their neutral form, their retention time increased and the baseline separation was better; all these observations were confirmed by Haller et al. [32]. Moreover, mobile phase A consisted of 1 mM ammonium acetate, which is the right concentration for ionization, because the higher the salt content, the greater the loss of MS sensitivity during measurements. Additionally, the flow rate in the 150–300 μl min^{-1} range as well as the injection volume in the range 10–50 μl and the temperature in the 25–45 °C range were also optimized. Increasing the temperature did not significantly improve sulfonamide separation but did diminish the intensity of chromatographic peaks. A temperature of 25 °C was therefore the best option. In summary, the antibiotics were separated on a C_{18}-column at a temperature of 25 °C, a wavelength of 270 nm, an injection volume of 50 μl, and a flow rate of 300 μl min^{-1}. Mobile phase A was a mixture of

H_2O:ACN (90:10, v/v, 1 mM NH_4Ac/AcH, pH 3.5) and mobile phase B was 100% ACN; both were selected in the gradient program. Elution began with 100% of mobile phase A, which was reduced to 36% within 32 min. Complete separation of 10 of the 12 sulfonamides was possible within less than 30 min (Fig. 2A and B), which is a satisfactory result compared to the methods described in the literature [23,25,27,30], where, for example, five sulfonamides were separated in 16 min or eight in 35 min.

3.2. Validation of the analytical method

3.2.1. Linearity

Linearity is a measure of the method's sensitivity: the greater the slope of the calibration curve, the more sensitive the method [42]. To determine the linearity of the method a minimum of five different concentrations were analyzed with six replicates each. The calibration curves obtained for both the quantification and the confirmation MRMs were linear for all compounds over a wide range of concentrations from 2.5 to 1000 $\mu g\,L^{-1}$ with a correlation coefficient (R^2) > 0.99. However, after taking into consideration the expected concentration of sulfonamides in environmental samples, and to improve the accuracy of the method, it was decided to work with the lowest concentrations. Only one MRM transition for the fragmentation ion of the highest intensity was selected for the quantification (Table 2), which resulted in lower LODs and LOQs. All calibration curves displayed good linearity with R^2 from 0.9984 to 1.000.

3.2.2. Limits of detection and quantification

The limits of detection (LODs) of the analytical methods developed in this study for all sulfonamides were evaluated by the measurement of 10 independent blank water samples fortified at the lowest acceptable concentration: LODs were equal to three times standard deviation of the measured signals [43]. The limits of quantification (LOQ) were calculated as twice the LOD values. The limits of detection (LODs) ranged from 0.31 to 2.74 $\mu g\,L^{-1}$ (Table 2). The method thus enables sulfonamides to be determined at very low levels.

3.2.3. Precision and accuracy

The precision of the method (expressed as RSD values) was determined in the intra-day and inter-day tests. The intra-day precision of the method was determined by calculating the relative standard deviation (RSD) for the repeated measurements ($n=6$). The accuracy of the method was determined by assessing the agreement between the measured and known concentration of analysed samples. All the results are presented in the Table 2. To determine the inter-day precision of the method, three selected concentrations (5, 10 and 50 $\mu g\,L^{-1}$), with the exception of sulfadiazine, sulfathiazole and sulfisoxazole (10, 50 and 500 $\mu g\,L^{-1}$) were analyzed by the same person under the same conditions on six consecutive days with three replicates on each day. Instrumental repeatability, expressed as RSD, was in general <20%. According to the U.S. EPA recommendations, the method is considered precise when RSD is less than or equal to 20% (Table 2).

3.2.4. Selectivity

Selectivity is the degree to which a method can quantify the analyte accurately in the presence of interferents. It is particularly important to check interferents that are likely, on chemical principles, to respond to the test [42]. To determine the selectivity of the method the blank sample of the soil extract was analyzed (Fig. 2C and D). None of the analyzed compounds was detected. Therefore, presented method is characterized by good selectivity.

3.3. Applicability of the method

The method's applicability was assessed by an analysis of 12 sulfonamides in soil samples. A very quick, simple and cost-effective method without any sample clean-up was implemented for this analysis using LC–MS/MS in MRM mode. The great advantage of this mode is its high selectivity and sensitivity when working with very complex matrices, which was also demonstrated in this experiment. Two different procedures in three replicates were performed to compare the results: one without any sample preparation and the other with sample clean-up using Solid Phase Extraction (see Section 2.4). The recoveries of the 12 sulfonamides from the spiked soil samples were calculated for both methods: they ranged from $8.78 \pm 0.79\%$ (sulfisoxazole) to $96.66 \pm 3.55\%$ (sulfadiazine) for the first procedure (six compounds had the recovery level over 50%, three between 20–50% and three lower than 20%), and from $5.59 \pm 0.47\%$ (sulfisoxazole) to $61.39 \pm 5.59\%$ (sulfadiazine) for the second procedure (three compounds had the recovery level over 50%, three between 20–50% and six lower than 20%) (the uncertainty is expressed as the standard deviation). The only matrix effect to be observed in the samples prepared without any clean-up was with sulfaguanidine, the recovery values of which were extremely high ($293.65 \pm 27.72\%$); however, after the extract had been cleaned up on an SPE-column, the recovery was $7.43 \pm 0.75\%$. Generally, the recovery results show that there is no significant difference between the two different sample preparation steps, from which it may be inferred that this methodology can be used to determine sulfonamides in soil samples without prior clean-up. These experiments are still at a preliminary stage, however, so further investigations into the extraction procedure are necessary to improve recoveries from soil samples and to validate this analytical procedure.

In summary, the optimized method for determining veterinary sulfonamides with LC–MS/MS in MRM mode, unlike many other methods, satisfied both the criteria laid down in the Commission Decision of August 12, 2002 (2002/657/EC) and the validation requirements. In the literature, many different meth-

ods are described for determining these compounds, which usually use LC–MS/MS full scan mode, SIM mode or only one MRM transition [26,27,31–33,35]. According to the Commission Decision, this is not sufficient to confirm the presence of these compounds. The methodology developed in the present work is characterized by good validation parameters, low LODs and LOQs, as well as good precision, repeatability and applicability to real samples. The fact that no preconcentration step was necessary is also worthy of note.

4. Conclusion

The optimized chromatographic separation and MS/MS parameters for the analysis of common veterinary sulfonamide antibiotics by LC–MS/MS was done in order to deliver a systematic analytical methodology for their determination in both environmental and biological samples. The experiments were performed using ion trap mass spectrometry with electrospray ionization in order to work in multiple reaction monitoring (MRM) mode. Four identification points for every compound (a precursor ion and a minimum of two daughter ions) were selected according to the existing criteria for both screening and confirmatory methods for drug residues based on the identification points proposed by EU Commission Decision 2002/657/EC. Each MRM transition was tested not only for the qualitative but also for quantitative analysis of sulfonamides, which is a huge advantage due to the fact, that the quantification of the sulfonamides in a very complex matrices can be done not only based on one-selected transition. If there are some interferences, it is always possible to use another transition for the quantification purposes. Unlike other methodologies, this one satisfied these criteria and is applicable to the qualitative and quantitative analysis of sulfonamide residues in environmental and biological matrices.

ABSTRACT

Highly luminescent Eu^{3+} and Tb^{3+} complexes of 10-[4-(3-isothiocyanatopropoxy)benzoylmethyl]-1,4,7,10-tetraazacyclododecane-1,4,7 triacetic acid $Eu^{3+} \subset \mathbf{1}$ and $Tb^{3+} \subset \mathbf{1}$ were conjugated with a goat anti-rabbit IgG and a rabbit anti-mouse IgG, respectively, and applied as markers in a time resolved immunoassay for simultaneous quantitative determination of anabolic compounds clenbuterol (CL) and hydrocortisone (HC). The assay was performed in horse urine, using a monoclonal antibody specific to CL and a rabbit polyclonal antibody specific to the free HC. These lanthanide chelates are very stable and highly luminescent in aqueous solution and allowed to reach 10 $\mu g\,L^{-1}$ and 40 $\mu g\,L^{-1}$ sensitivities for CL and for HC, respectively. Application to the horse urine, that is a very complex matrix, has a considerable interest in the control of illegal use of these compounds.

1. Introduction

Clenbuterol (4-amino-α-(t-butlaminomethyl)-3,5-dichloro-benzyl alcohol)(CL) and hydrocortisone (11β,17α,21-trihydroxy-pregn-4-ene-3,20-dione) (HC) are anabolic compounds used in veterinary field.

CL is a bronchodilatator used in non-infectious respiratory diseases or a supportive medication in infectious diseases [1,2]. Sometime CL is used for illegal purposes: it may be used as anabolic drug because it accelerates animals' growth developing of muscle mass and decreasing fat deposition. In this case CL presents a potential health problem in the consumption of food products from treated animals [3]. CL operates in any tissue with β_2-receptors; for protection of consumers, illegal treatment with CL is usually controlled by analysis in different tissues. In addition it may have a positive effect on the performance of racing horses. Furthermore its presence in urine in post race animals may lead to sanctions fixed by international racing authorities. In fact regulations regarding CL in race horses give zero tolerance. Therefore, several analytical approaches such as liquid-chromatography or gas-chromatography and mass-spectrometry [4–6], and immunoassay [7,8] have been described for detection of this compound.

Many natural or synthetic corticosteroids possess anti-inflammatory characteristics and also HC is used in veterinary medicine as anti-inflammatory drug [9]. Because its anabolic properties HC can be used for illegal purposes, as above reported for the CL. High urinary concentrations of HC in post race horses can be index of administration of this compound as doping substance for performance amelioration of the animals [10]. Considering the presence of endogenous hormone, the International Federation of Horseracing Authorities has fixed a threshold value of free HC in equine urine at 1 $\mu g\,mL^{-1}$. Many analytical methods, as above mentioned for CL, are used to control the presence of this compound [11–16].

Analysis of urine with conventional methods consist in separative techniques to isolate the target compound from other more concentrated compounds so that internal standard controls are necessary to monitor the recovery. For these techniques interferent peaks in the chromatograms and noisy base line must be removed to allow sensitivity. Therefore in conventional approach, the samples must be singly processed, that is laborious and time-consuming; furthermore the screening of many samples becomes very expensive. Moreover, each step of an analytical process introduces errors into the final result. Immunological methods appear to be a more convenient approach for these controls. These methods cover a wide concentration range and do not require pre-treatment

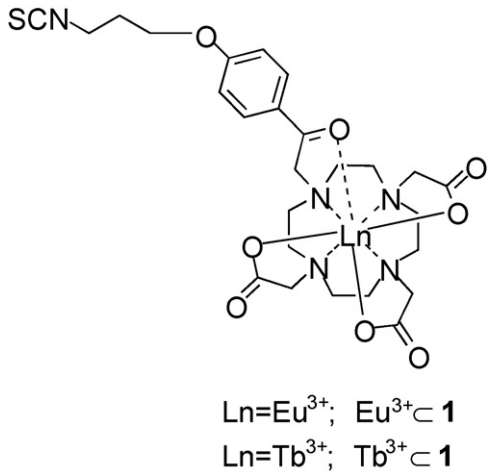

Fig. 1. Structural formula of $Eu^{3+} \subset \mathbf{1}$ and $Tb^{3+} \subset \mathbf{1}$ chelates.

of samples. They are simple, rapid, sensitive, and specific. Furthermore many samples can be analysed simultaneously in a short incubation time.

The use of lanthanide chelates as fluorescent labels in a time-resolved immunoassay results in the background elimination. In addition the high stability of complexes used in assay reported below allows the simultaneous determination of two different analytes, by reading the fluorescence at emission wavelengths specific for terbium or europium, respectively.

In this paper we report the preparation of goat anti-rabbit IgG and rabbit anti-mouse IgG conjugates with luminescent lanthanide chelates $Eu^{3+} \subset \mathbf{1}$ and $Tb^{3+} \subset \mathbf{1}$ (Fig. 1) and their use as markers in a time-resolved fluoroimmunoassay (TR-FIA) for simultaneous quantitative determination of anabolic compounds clenbuterol (CL) and hydrocortisone (HC). Application to the horse urine analysis, that is a very complex matrix (it contains a large excess of metabolites and conjugates that can interfere with assay), has a considerable interest to control the illegal use of these substances.

2. Materials and methods

2.1. Materials

Standard CL and the chemical related cross-reacting compounds (salbutamol, terbutaline, epinephrine, norepinephrine, fenoterol, ambroxol, phenylbutazone), standard HC and the chemical related compounds (prednisolone, cortisone, dexamethasone, betamethasone, flumethasone, beclomethasone,), hydrocortisone-3-(O-carboximethyl)oxime (HC-3CMO), hydrocortisone-21-hemisuccinate (HC-21HS) and all of the other chemicals, including bovine serum albumin (BSA), chicken egg albumin (OVA), rabbit anti-mouse IgG and goat anti-rabbit IgG, were obtained from Sigma–Aldrich (Milan, Italy). Complexes $Eu^{3+} \subset \mathbf{1}$ and $Tb^{3+} \subset \mathbf{1}$ were synthesized through a multi-step procedure [17].

2.2. Apparatus

A single-photon-counting time-resolved fluorometer (1232 DELFIA Fluorometer; Wallac, Turku, Finland) was used to measure fluorescence.

2.3. Specimen collection

Horse urine from five healthy animals were pooled, filtered in a glass vials, fractionated and stored at −20 °C until use.

2.4. Syntheses

2.4.1. CL-OVA and HC-BSA

The synthesis of CL-diazo-ovalbumin (CL-OVA) was performed according to [18].

HC-BSA was synthesized and used as immunogen and as solid phase on polystyrene microwells. Briefly 6.5 mg of HC-3CMO were dissolved in 0.2 mL of anhydrous dimethylformamide and cooled to 4 °C with 5 μL of tri-*n*-butylamine. After 5 min 5 μL of isobutylchloroformate were added and the solution was left for 30 min at 4 °C. This mixture was added to 19 mg of BSA dissolved in 0.5 mL 40% dimethylformamide in water and then 50 μL 1N NaOH was added. Reaction mixture was stirred at 4 °C for 1 h while the pH was kept at 8.5–9 by repeatedly adding 5 μL 1N NaOH, and then left at 4 °C overnight. The conjugate was purified by gel filtration on Sephadex G-50 column with 0.05 M NH_4HCO_3 and lyophilized.

2.4.2. IgG-($Tb^{3+} \subset \mathbf{1}$) and IgG-($Eu^{3+} \subset \mathbf{1}$)

$Tb^{3+} \subset \mathbf{1}$ was conjugated with a rabbit anti-mouse IgG and $Eu^{3+} \subset \mathbf{1}$ was conjugated with a goat anti-rabbit IgG, respectively. The conjugates were prepared using 2 mg of affinity purified IgG dissolved in 2 mL of 0.1 mol L^{-1} sodium carbonate buffer (pH 9). A solution of 500 μg of each chelates in 100 μL of ethanol was then added and the mixture was incubated for 30 min at room temperature. The labelled IgG was separated on Sephadex G-50 column, eluting with 0.05 mol L^{-1} Tris–HCl buffer (pH 7.5).

2.5. Antibody preparation

Monoclonal antibody specific for CL was obtained as described in [18].

Polyclonal antibody is specific for free HC and was obtained using as immunogen HC-3CMO-BSA. Antiserum was produced in New Zealand white rabbits with 100 μg of conjugate for each immunization. The rabbits were subcutaneously injected monthly with the conjugate suspended in 1 mL of saline solution and Freund's complete adjuvant. The antisera were characterized by immuno-enzymometric assay with anti rabbit IgG antibody conjugated with horseradish peroxidase. Antiserum with satisfactory characteristics was obtained 3–4 months after the first immunization. The anti-BSA present was eliminated by precipitation by adding 0.2% BSA to the rabbit serum. The affinity determined according to [19] was 1.6×10^9 L mol^{-1}. The antiserum was fractioned and stored at −20 °C in phosphate buffered saline 0.15 mol L^{-1} pH 7.4 containing 0.02% timerosal as preservative.

2.6. Antibody titre evaluation

The antibodies were assayed separately by incubation in wells coated with OVA-CL and BSA-HC respectively: 100 μL of serial dilutions of ascites or antiserum in 0.05 M Tris–HCl buffer pH 7.5 containing 0.9% NaCl (1:250, 1:2500 and 1:25 000) were applied to the coated wells, and the antibody bound to the solid phase was detected by means of rabbit anti-mouse IgG conjugated to $Tb^{3+} \subset \mathbf{1}$, or goat anti-rabbit IgG conjugated to $Eu^{3+} \subset \mathbf{1}$. After washing 100 μL of dissociation solution containing 4 mol L^{-1} urea and 1% sodium dodecylsulfate in water were added to each well. Fluorescence was measured after 10 min with the time-resolved fluorometer with Xenon lamp as source at 545 nm the delay time being 500 μs for Tb^{3+}chelate, and at 615 nm with delay time 400 μs for Eu^{3+} chelate. The dilution giving 70% of fluorescence intensity in comparison

with 100% of saturate solid phase fluorescence was chosen as working titre.

2.7. Solid phase

Polystyrene micro-titre wells were coated overnight at 27 °C with 200 μL of 0.1 M carbonate buffer, pH 9.0, containing 15 μg/mL of OVA-CL conjugate and 15 μg/mL of BSA-HC conjugate. The micro-titre wells were washed with carbonate buffer and a second coat was made with 250 μL of 2% BSA solution in the same buffer for 4 h at 27 °C. The wells were washed five times with 0.05 M Tris–HCl buffer pH 7.5 containing 0.9% NaCl and 0.05% NaN_3 and stored dry at 4 °C until use.

2.8. TR-FIA

TR-FIA was performed with the CL and HC standards dissolved in Tris–HCl buffer pH 7.5 containing 0.9% NaCl, and 0.25% BSA: the presence of BSA in solution avoids possible non specific adsorption. The use of chicken egg albumin, both in the second coating and in assay buffer does not change the results (not reported data).

Serial dilutions between 50 pg and 100 ng of the two standards were transferred in duplicate (20 μL + 20 μL) into polystyrene micro-wells coated with OVA-CL and BSA-HC conjugates. Specific antibodies were diluted at a working titre 1:1200 for anti-CL and 1:2500 for anti-HC; 50 μL of each dilution were added to all of the wells other than that used for the blank evaluation, to which the same volume of buffer was added. The volume in each well was adjusted to 200 μL with buffer. Assay was performed directly in urine by applying 20 μL of samples in duplicate instead of the standards. Validation of the method was performed by assaying recovery and matrix effect in urine samples spiked with 100, 1000 and 10 000 pg of standard CL and the same quantities of HC. The wells were washed and 100 μL of buffer containing an excess (0.3 nmol) of rabbit anti-mouse IgG-($Tb^{3+} \subset \mathbf{1}$) and 100 μL (0.3 nmol) of goat anti-rabbit IgG-($Eu^{3+} \subset \mathbf{1}$) complex were added and incubated for 30 min. After washing 200 μL of dissociation solution were added to each well and fluorescence was measured as described in antibody titre evaluation section.

3. Results and discussion

3.1. Antibody specificity

Specificity of the monoclonal antibody was evaluated by assaying the cross-reactions of CL related compounds, calculated at 50% of fluorescent signal reduction against the 100% of standard CL according to the formula:

$$\frac{IC_{50}(\mu g\,L^{-1})\ \text{of CL}}{IC_{50}(\mu g\,L^{-1})\ \text{of competitor}}\%$$

All assayed compounds did not significantly interfere in the assay, as shown in Table 1.

Specificity of polyclonal antibody was assayed in the same way, with HC related compounds.

Values are listed in Table 1.

3.2. Assay performances

In order to evaluate possible interferences between the reagents we previously set up the standard curves separately for each analyte. Each curve resulted superimposed to the corresponding curve obtained in the simultaneous determination: that may be ascribed to the lower affinity of anti-rabbit IgG-($Eu^{3+} \subset \mathbf{1}$) for anti-mouse conjugated with Tb^{3+} chelates in comparison with its affinity for non conjugated specific antibody.

Table 1
(A) Percentage of cross reactivity of CL-related compounds with CL specific antibody calculated at 50% of fluorescence signal reduction. (B) Percentage of cross reactivity of HC-related compounds with HC specific antibody calculated at 50% of fluorescence signal reduction.

A		B	
Compounds	%CR	Compounds	%CR
Clenbuterol	100	Hydrocortisone	100
Salbutamol	1.6	Prednisolone	5.5
Terbutaline	0.4	Cortisone	5.3
Epinephrine	<0.1	Dexamethazone	<0.1%
Norepinephrine	<0.1	Betamethasone	<0.1%
Fenoterol	<0.1	Flumethasone	<0.1%
Ambroxol	<0.1	Beclomethasone	<0.1%
Phenylbutazone	<0.1		

3.2.1. Sensitivity

The antibody dilution giving 70% of fluorescence intensity in comparison with 100% of saturate solid phase fluorescence was chosen as working titre. Dose–response curves for CL and HC were obtained by averaging eight individual curves normalized by reporting fluorescence values as $\%F/F_0$ where F was the mean of cps for each standard and F_0 was the mean of cps for zero CL or HC concentration; blank values (2100 ± 218 cps for IgG-Eu^{3+}chelate and 3650 ± 355 cps for IgG-Tb^{3+}chelate) were subtracted. The high slope of calibration graphs allows accurate and precise determinations. Sensitivity, defined by detection limit of the method, was determined by calculating the minimum amount of standards that could be significantly distinguished from zero (mean binding at zero dose at three times the SD). This value, calculated from three curves prepared in duplicate was 10 $\mu g\,L^{-1}$ for CL and 40 $\mu g\,L^{-1}$ for HC. These detection limits allow direct determination in horse urine using 20 μL of sample.

3.2.2. Recovery evaluation

Accuracy was assayed by evaluation of standard recovery: we compared the calibration graph with the graph obtained by spiking urine samples with 10, 100, 1000 and 10 000 pg of CL and HC. Results were shown in Fig. 2 for CL and in Fig. 3 for HC analysis. As shown in Fig. 2 the curve resulted superimposed to the standard curve obtained in buffer. In Fig. 3 HC determination was carried out as reported for CL: the curve resulted parallel to the standard curve obtained in buffer, with the difference due to the endogenous free HC, evaluated as 1.5 ng/well. Reproducibility and precision profile are reported in Figs. 1 and 2. The stability of two conjugated antibodies stored at −20 °C was evaluated by measuring the maximum binding capacity and was at least eight months. The coated plates are very stable if stored dry at +4 °C.

3.2.3. Matrix effect

TR-FIA was also validated by determining the matrix effect as recovery of CL and HC in different volumes of urine spiked with CL (500 ng/100 mL) and HC (500 ng/100 mL). Results are reported in Table 2.

The values obtained by TR-FIA show a good recovery for all sample dilutions.

HC recovery takes in account the presence of endogenous concentration of analyte.

This study combines advantages of immunological methods, sensitivity of time-resolved fluorescent revelation, and high stability constants of the new chelates. The detectability of labels is one of the most critical factors that limit sensitivity of immunoassay. The development of fluorescent labels provides an important

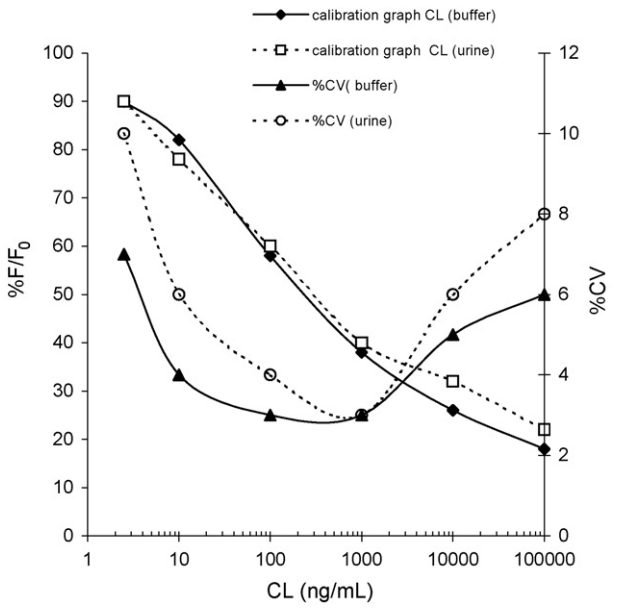

Fig. 2. Dose–response curve and precision profile (percent coefficient of variation) for TR-FIA of CL in buffer and in pooled horse urine. *F* and F_0 are expressed as cps. Each point represents the mean of eight determinations in duplicate.

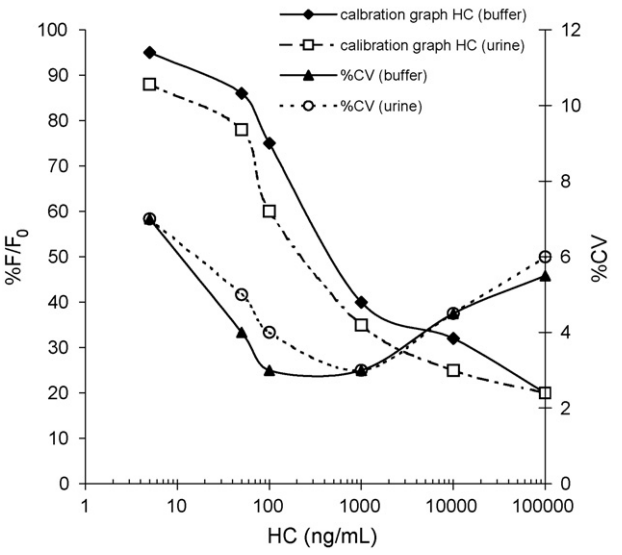

Fig. 3. Dose–response curve and precision profile (percent coefficient of variation) for TR-FIA of HC in buffer and in pooled horse urine. *F* and F_0 are expressed as cps. Each point represents the mean of eight determinations in duplicate.

simplification of immunological procedures. Their usefulness has, however, been limited by the high background fluorescence always present in the measurements, which seriously limits the sensitivity of the assay. Chemiluminescent signals also present similar problems.

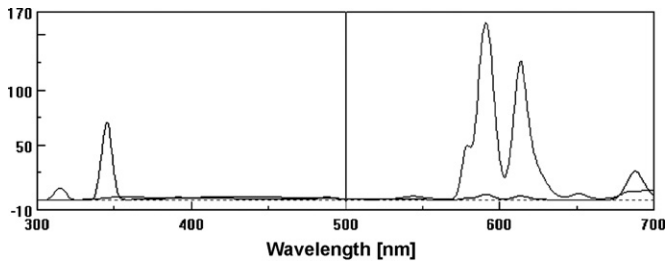

Fig. 4. Emission spectra of $Eu^{3+} \subset \mathbf{1}$ complex at 315 nm (grey) and 325 nm (black) excitation wavelength.

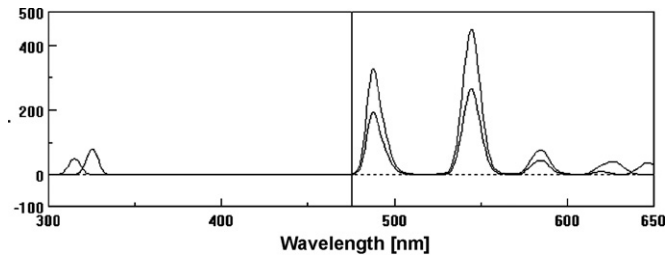

Fig. 5. Emission spectra of $Tb^{3+} \subset \mathbf{1}$ complex at 315 nm (grey) and 325 nm (black) excitation wavelength.

Lanthanide chelates show narrow and strong emission bands around 600 nm and an exceptionally long decay time (up to a millisecond instead nanoseconds of most molecules), which allow the elimination of the high background of the fluorescent labels.

Florescence spectra of $Eu^{3+} \subset \mathbf{1}$ and $Tb^{3+} \subset \mathbf{1}$ chelates are reported in Figs. 4 and 5.

Excitation by Xenon lamp without filter is useful for both derivatives.

Simultaneous dual label TR-FIA using Eu^{3+} and Tb^{3+} chelates are already reported [20,21]. In comparison with markers used in these assays, the Eu^{3+} and Tb^{3+} complexes described in this paper have an important advantage, because they are fluorescent in aqueous solution. Tanks to this characteristic, the addition of enhancement solution used to transfer lanthanide ions to β-diketone complexes can be avoided. This allows obtaining higher signal stability and cost reduction.

In addition the $Eu^{3+} \subset \mathbf{1}$ and $Tb^{3+} \subset \mathbf{1}$ complexes have high stability constants similar to those of the lanthanide complexes reported in [22], so we can directly determine the fluorescence, for two analytes simultaneously and with a good sensitivity. Fluorescent intensity of chelates decreases dramatically when they are bound to the antibodies, as already reported for same ter-pyridyne derivatives [23]. It decreases up to the 10% of value obtained with the same concentration of free chelates in Tris–HCl buffer. Nevertheless the fluorescent signals are still sufficient for application in time-resolved immunoassay with good sensitivity. The reagents can be easily obtained and moreover their use does not need expert technicians. This assay should thus provide a useful alternative to the conventional methods to control illegal use of CL and CH: in fact many samples can be analysed simultaneously in a short incubation time and with a low cost. In case a sample should result

Table 2

ABSTRACT

We have optimized the analytical parameters of a homemade instrument for the simultaneous measurement of the chlorofluorocarbons CCl_2F_2 (CFC-12), CCl_3F (CFC-11) and $C_2Cl_3F_3$ (CFC-113) in seawater. Seawater samples are flame sealed into 60 ml glass ampoules avoiding any contact with the atmosphere and stored in cold, dark condition until analysis. In the laboratory, after cracking the ampoule in an enclosed chamber filled with ultra-pure nitrogen, the seawater sample is transferred to a stripping chamber, where ultra-pure nitrogen is used to purge the dissolved CFCs from the seawater. The extracted gases are then cryogenically trapped, subsequently the trap is isolated and heated and the CFCs are transferred by a carrier gas stream into a precolumn and then are separated on a gaschromatographic packed column. To separate adequately CFC-12 from N_2O, during the early part of the chromatographic run, the gas stream passes through a molecular sieve, which is then isolated and backflushed. The CFCs are detected on an electron capture detector (^{63}Ni ECD). After a careful choice of the experimental conditions, the performances of the system were evaluated. The detection limits for seawater samples are: 0.0081 pmol kg^{-1} for CFC-12, 0.0073 pmol kg^{-1} for CFC-11 and 0.0043 pmol kg^{-1} for CFC-113. The reproducibility of replicate samples lies within 5% for the three CFCs. The system has been successfully employed for CFC measurements in seawater samples collected in the Ross Sea (Antarctica) in the framework of the Italian Antarctic research project.

1. Introduction

Several chemical compounds have been widely used as tracers of ocean circulation and mixing processes. They include nutrients and dissolved oxygen, which have a natural background level and a quasi-steady state distribution in the deep ocean, radiocarbon and tritium, which have background levels significantly altered by human activities and anthropic compounds such as chlorofluorocarbons (CFCs).

Production and release of CCl_2F_2 (CFC-12) and CCl_3F (CFC-11) in the atmosphere began in the 1930s and increased rapidly during the following five decades. Differently, the atmospheric concentration of $C_2Cl_3F_3$ (CFC-113) increased rapidly during the 1980s. CFCs are volatile, chemically stable and characterized by rapid mixing rates within the lower atmosphere, so their tropospheric concentrations are relatively uniform. The CFC concentrations in the atmosphere can be reconstructed as functions of location and time [1]. Atmospheric CFCs cross the air-sea interface and dissolve in surface seawater; their equilibrium concentrations can be calculated as a function of seawater temperature and salinity and atmospheric gas concentration [2]. Indeed, CFCs have a time-dependent oceanic input. Although the degradation of CFCs in marine environment under reducing conditions (such as fjords) was reported [3], in well-oxygenated waters (such as oceanic waters) they are chemically stable. Thus, they can serve as transient tracers of the ocean circulation.

Oceanic CFC measurements have been widely used to evaluate the variability of water mass formation and rates of ocean ventilation [4–7], to assess ocean circulation and climate models [8–13] and to quantify the ocean uptake of anthropogenic CO_2 [14–17]. CFCs are often used to calculate the "age" of a water sample, commonly defined as the time elapsed since the water parcels contained in the water sample lost direct contact with the atmosphere [18].

Volatile and semi-volatile organic compounds account for a large part of chemicals of environmental interest, which are analyzed by gas chromatographic (GC) methods. Several compounds, including CFCs, have low concentration levels in aqueous samples and the most used GC detectors are not able to detect them. For this reason, the sample preparation becomes essential. Further,

the number of operations and processes involved in the sample preparation stage should be kept to a minimum.

The CFC-11 and CFC-12 analysis in seawater was introduced by Bullister and Weiss [19] and it has been widely used in the succeeding years. The introduction of the CFC-113 measure, the necessity to improve the data quality and to reduce the sample contamination, the aim to shorten the analysis time and to eliminate most of the manual procedures encourage several laboratories to develop ocean tracer methods and measurements [8,20–22].

This paper describes the optimization of the main instrumental parameters of a purge and trap-gaschromatographic system for the simultaneous determination of CFC-11, CFC-12 and CFC-113 in seawater samples. Particularly, a thorough study of the CFC stripping from the seawater samples was carried out. The purge and trap system was built in our laboratories following the design provided by W. Smethie and E. Gorman (LDEO, Columbia University, New York, USA). Some design modifications have been made. They mainly concerned the ampoule housing, the nitrogen flow regulation and the trap heating system. These modifications are described in Sections 2.1 and 2.4. The optimized analytical system has been used to analyze seawater samples collected in the Ross Sea (Antarctica) during the austral summer 2002–03 Italian Antarctic Expedition.

2. Experimental

2.1. Apparatus

The apparatus consists of a purge-and-trap system interfaced to a gas chromatographer (GC) equipped with an electron capture detector (ECD). The purge and trap system and the interfacing devices were built in our laboratories following, and partially modifying, the instrumental schemes provided by W. Smethie and E. Gorman (LDEO, Columbia University, New York, USA). A part of the apparatus is devoted to gas analysis and it is used for calibration with standard gas mixture, while another part is devoted to CFC extraction from water samples.

The flow scheme is shown in Fig. 1, while Table 1 lists the main components of the analytical system.

Ultra-high purity nitrogen (N_2) is used as both stripping and carrier gas. Pressure from the gas cylinder is reduced to approximately 7 bar using a high purity pressure regulator. To remove CFC impurities present in the nitrogen supply, N_2 flows through a trap (molecular sieve MS 13X 60/80 mesh) held at room temperature. The trap is reconditioned by heating to 200 °C and by purging with a reverse N_2 flow of several hundred ml min^{-1} for about 4 h. The MS 13X reconditioning is required when the baseline increases during the analysis of system blanks due to a gradual CFC release from the trap. The nitrogen, downstream from MS 13X, is divided into three pathways: carrier gas, stripper gas and make up gas straight directed to the ECD. The upstream pressure of the stripper gas and of the carrier gas is adjusted to 2.0 bar and to 3.0 bar respectively, using two pressure regulators. We modified the Smethie's design by adding a needle valve for the fine adjustment of the carrier gas flow rate (approximately 30 ml min^{-1} as measured at the ECD inlet) (cf. F7 in Fig. 1). In addition, we split the carrier gas stream into three ways, each of them provided with an on/off valve (cf. FV5, FV6, FV7 in Fig. 1). This adjustment helped us in the leak procedure test and allowed a separate cleaning of the analytical column and the molecular sieve 5 Å, improving the control of the system contamination. The standard gas inlet is connected to a cylinder of a compressed calibration standard gas mixture, which is injected into the analytical system through an electro-valve (EV8). The sam-

Table 1
List of the components of the analytical system.

MS 13X	Molecular Sieve 13X columns are used for removing contaminants from the ultra high purity supply. Pressure from the nitrogen cylinder to the MS 13X is set at 7 bar using a SS pressure regulator (Air Liquide). MS 13X column consists of 1.5 m length of MS 13X 60/80 mesh, packed in 1/4 in. OD stainless steel (SS) tubing and is activated by heating at 300 °C for 12 h.
Pressure regulator	Air Liquide high precision SS pressure regulator is used to set upstream pressure of the nitrogen stream.
Flowmeter (F1- F5, F8)	Flowmeters used for checking the purged gas stream.
Metering valves (F6- F7, F9-F11)	Swagelok SS needle valves for regulating flow rate of the nitrogen stream.
Tubing	The SS tube diameters of the analytical system are 1/8 in. (Swagelok fittings).
Stripping chamber (SC)	Seawater sparging chamber with volume of about 75 cm^3, fitted with a fine pore glass frit at the lower end is used to extract the dissolved CFCs from the seawater sample. At the upper end glass flats orthogonally to the gas flow are attached to the chamber walls to reduce spray generated from bursting bubbles during the sparging process from being carried out the stripping chamber and through valve V2.
V1	An eight port Valco valve for directing flow from the MPV to valve V2.
V2	A six port Valco valve for connecting/isolating the stripping chamber from the rest of system.
V3	A six port Valco valve for directing water sample/stripper gas from calibrated volume to stripping chamber and for connecting ampoule in the cracking chamber with the analytical system.
V4	An eight port Valco valve for switching the trap in/off line with valve V6.
V5	A six port Valco valve for directing flow from MS 5A to ECD and from analytical column to ECD.
V6	A 10 port Valco valve for directing flow through pre-column and analytical column and for connecting V4 to V5.
EV	Electro-Valves automatically actuated via software input to enable/prevent gas stream.
MPV	A 10 port multi-position Valco valve with the calibrated gas loop.
FV(5-7)	On/off ball valve used to alternatively isolate a part of the gas analytical track.
Trap	A 1/16 in. OD SS tube 25 cm long packed in the central part with 10 cm of 80/100 mesh Unibeads 2S (Superchrom).
MS 5A	A 1/8 in. OD SS tube packed with 10 cm of Molecular Sieve 5Å (Superchrom) kept at 50 °C.
Precolumn (PreC)	A 1/8 in. OD SS tube packed with 1 m of 80/100 mesh Porasil B (Superchrom) kept at 140 °C in the GC oven.
Column (AC)	A 1/8 in. OD SS tube packed with 1.5 m of 60/80 mesh Carbopack B (Superchrom) held in the GC oven at 140 °C.
ECD	Electron Capture Detector with ^{63}Ni source held at 300 °C in a Varian 3400 gas chromatograph.
Calibrated Volume (CV)	A glass graduate burette with volume of about 34 cm^3 used to sub sample a known volume of seawater sample from the ampoule.
Drying Column (DC)	A 17 cm long 3/8 in. diameter glass tube packed with desiccant magnesium perchlorate ($Mg(ClO_4)_2$) held in place with glass wool.

ple gas passes through a short glass tube filled with magnesium perchlorate ($Mg(ClO_4)_2$), which acts as a drying agent preventing from the analytical column contamination. Then the sample flows through the trap to hold CFC-11, CFC-12 and CFC-113. The trap consists of 1/16 in. OD tubing packed with Unibeads 2S 80/100 mesh, cooled at -78 °C by directing a flow of compressed CO_2 in an enclosure around the trap. After 270 s, the trap is isolated by switching the valve V4, then it is rapidly heated to 100 °C by passing a high amperage current through the wall of the 1/8 in. SS tube that holds the trap. The trap temperature is controlled by a thermocouple welded to SS wall of the trap. The trap temperature maintenance was improved with respect to the Smethie's design by adding a further thermostatic cover outside the trap. After 120 s of heating, the valves V4, V5 and V6 are switched and the sample gases held in the trap are flushed onto the precolumn (80/100 mesh Porasil B packed in a 1/8 in. OD SS tube and held in the GC oven at 140 °C) for the elution of the higher molecular weight compounds and the initial separation of CFCs. During the trapping of the next sample, the precolumn and the main column are backflushed to purge the late-eluting compounds.

The separation of CFC-11, CFC-12 and CFC-113 occurs on the GC main column (80/100 mesh Carbopack B held in the GC oven at 140 °C). To adequately separate CFC-12 from N_2O, the gas stream passes through a Molecular Sieve 5 Å (MS 5A) kept at 50 °C, during the early part of the chromatographic run. After 130 s since the run beginning, the MS 5A is isolated by switching V5 and backflushed to allow any gases remaining in the MS 5A to be vented. The timing for the V5 valve switching was determined empirically to limit the baseline noise during the elution of the CFCs.

The GC is equipped with a ^{63}Ni ECD held at 300 °C. The frequency signal from the ECD is converted by a Varian Star 800 Module Interface to an output and sent to the Varian Star Workstation for data acquisition, plotting and integration of the peak areas.

All the procedures (loop selection, trap cooling/heating, etc.) and the valve switching are controlled by a personal computer equipped with multifunction cards (National Instruments PCI-6013 and PCI-6503) using a software exclusively written for this system by OMEGA s.r.l. (Genoa, Italy) utilizing a commercially available software library (National Instruments-LabVIEW 7 Express).

2.2. Standards and calibration

The CFC-11, CFC-12 and CFC-113 working standard mixture is obtained by diluting in ultra high–pure N_2 a concentrated standard mixture prepared and certified by SIAD S.p.A. (Bergamo, Italy).

As the three CFCs have different solubility in seawater [2,23], their amounts and ratios in seawater do not match the atmospheric ones. Thus, the working standard gas mixture matches the concentrations and the ratios of the CFCs extracted from samples of surface seawater. CFC concentrations in the working standard mixture were accurately measured and certified by the Lamont Doherty Earth Observatory tracer group (LDEO, Columbia University, New York, USA) against Scripps Institution of Oceanography (SIO, San Diego, USA) primary standard.

An example of the chromatogram obtained for a working standard CFC mixture injection is shown in Fig. 2.

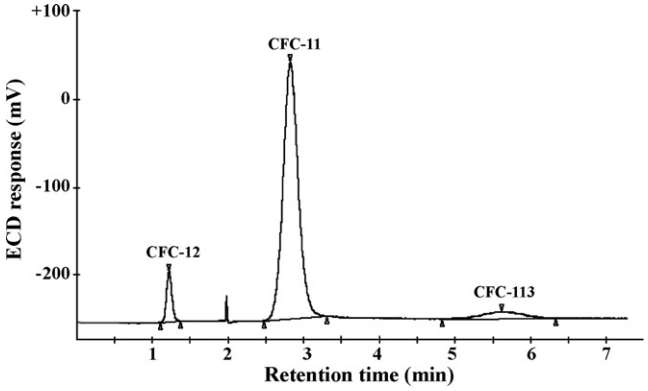

Fig. 2. Chromatogram of a working CFC standard gas mixture injection. The discontinuity of the baseline after the CFC-12 elution depends on a change of the carrier gas flow due to valve V5 switching.

The analytical system is calibrated by multiple injections of the working standard mixture in ten loops of different volumes (from few microlitres to few millilitres). The range of the volumes allows the system to be calibrated over a relatively wide range of seawater sample concentrations. The volume of the loops has been determined gravimetrically, by filling with distilled water, with a precision of approximately 0.5%.

Room temperature and pressure are recorded during each set of analyses to calculate the injected gas moles. A whole calibration curve is carried out before measuring each set of seawater samples; moreover measurements of a selected loop are daily carried out during and after the sample analyses to account for short-term system fluctuations depending on the variability of room temperature and pressure. Detector responses for the three CFCs are non-linear in the range of our measurements.

The CFC peak areas are converted into moles using polynomial expressions obtained by a non-linear least squares fit of the calibration data using a specially written software. System blank peak areas are subtracted from the peak areas of all the standard gas samples, while stripper blank areas are subtracted from seawater samples peak areas.

2.3. Water sampling

Seawater samples for CFC analysis are collected in 12 l Niskin oceanographic sampling bottles. To limit the possible sample contamination due to lubricants, greases and silicones employed on plastic devices, all the bottles and the stopcock O-rings were substituted with Buna-N O-rings previously treated in a vacuum oven set at 100 °C for 48 h. Following Bullister and Weiss [19], all rubber bottle closure systems were replaced with epoxy-coated stainless steel spring. To avoid the contact with air, the seawater samples for CFC analysis are drawn directly from the stopcocks of the Niskin bottles into 60 ml glass ampoules through dedicated 3-way sampling systems, following the optimized standard procedures [21,24,25]. The ampoules are flame-sealed meanwhile clean N_2 flows (at about 10 ml min^{-1}), avoiding any contact with atmosphere. This procedure leaves a gas space in the ampoules, which is necessary to allow thermal expansion of the seawater during the storage period. Corrections for CFC loss from the seawater into the ampoule headspace are therefore required. Seawater samples in flame sealed ampoules are stored under cold and dark condition until the analysis. CFCs in seawater samples in flame-sealed ampoules stored in these conditions remain stable for years [26].

2.4. Water sample analysis

The ampoule containing the seawater sample is positioned into the chamber containing the cracking device, which is connected through an electro-valve (EV17) to the ultra high pure N_2 cylinder. The N_2 flowing into the chamber is purified by passing through the MS 13X trap. The chamber has glass wall instead of tygon wall and a different cracking device system respect to the Smethie's design. After breaking the neck of the ampoule by a hand-moved rod with a chisel-shaped end, a 1/8 in. SS tube is inserted into the ampoule and the seawater transfer is started by purging the ampoule with the stripper gas. The seawater sample is transferred to a 34 ml calibrated volume (CV) until overflow through the V3 waste system. The exact volume of the CV was evaluated gravimetrically. The tubings connecting V3 to the cracking chamber are then purged by flushing of the carrier gas. Switching EV17, V2 and V3, the calibrated volume of the sample is then transferred to the stripping chamber by purging the calibrated volume with the stripper gas.

In the inert gas-stripping method an inert gas (N_2) is used to sparge an organic solute (CFCs) from an aqueous solution (seawater sample). Thus, in order to extract the CFCs from the seawater sample, the transfer gas stream is directed into the stripping chamber via V3 valve. The gas stream enters the bottom of the glass stripping chamber, where a fine frit element disperses the stripping N_2 into fine bubbles, thus enhancing the extraction efficiency for the dissolved CFCs. It is particularly relevant that the bubbles generated are small, because that leads to a high surface area to volume ratio. The extraction procedure is conducted at an upstream stripper gas pressure of 2.0 bar for 330 s. The extracted gases pass through V2, a dessicant column containing $Mg(ClO_4)_2$, V6 and V4, then they follow the same pathway as described for the gaseous samples (cf. Section 2.1 and Fig. 1).

The trap is cooled at −78 °C before transferring the seawater sample to the stripping chamber. At the end of the stripping process the trap is kept cool for an additional time (15 s) to allow all the extracted CFCs to be trapped. After the trapping, the trap is isolated by switching the valves V2 and V4 and it is rapidly heated to 100 °C. The injection and the gas chromatographic run take place as described for gaseous samples (Section 2.1).

In order to evaluate the stripping efficiency and the recovery of the procedure, the same seawater sample is subsequently extracted several times. If the stripper efficiency is not 100%, corrections are made accordingly to the number of moles.

The final CFC concentrations are calculated by dividing the moles of the gases by the net weight of the sample and they are expressed in pmol kg^{-1}. The analyzed water volume (ml) is converted to mass (kg), through the seawater sample density. An additional correction is made to take into account the CFC loss from the water sample to the overlying headspace during sample storage in ampoules.

3. Results

3.1. Performance optimization

An optimization of the operating conditions was required to improve the performances of the analytical method. In particular, the carrier gas flow rate, the filling and the rinsing loop time, the trap performances, the temperature of the analytical column and of the ECD detector, the efficiency of the CFC stripping from seawater samples were evaluated.

The carrier gas flow must satisfy some important requirements, such as an adequate current signal recorded by the detector, a good chromatographic peak resolution, an adequate analyte dilution and a satisfactory system sensitivity. Since literature studies reported that an optimal carrier gas flow at the detector entrance is 33 ml min^{-1} [18,22], we studied a range of carrier gas inflow pressures able to produce a comparable flow. We evaluated the system response setting the carrier gas pressure at 2.8 bar (equivalent to 29 ml min^{-1}), 3.0 bar (equivalent to 30 ml min^{-1}) and 3.4 bar (equivalent to 32 ml min^{-1}); higher carrier gas flows produce a drop in the detector signal to values lower than the minimum acquirable voltage. With this aim, repeated CFC measurements of a fixed standard gas aliquot were made at different carrier gas flows evaluating the column efficiency (i.e. the retention time versus the peak width ratio). In Fig. 3 the column efficiency values obtained for each carrier gas flow condition are reported.

The column efficiency for CFC-11 and CFC-12 does not differ varying the carrier gas pressure between 3.0 bar and 3.4 bar, whereas it significantly decreases when the carrier gas pressure is 2.8 bar. Differently, column efficiency does not vary for CFC-113 in the full range of the tested carrier gas pressures. Therefore, the carrier gas inflow pressure was set at 3.0 bar (corresponding to an ECD gas inflow of 30 ml min^{-1}), because increasing further the pressure the normalized peak areas decreased due to an enhanced dilution of the analytes.

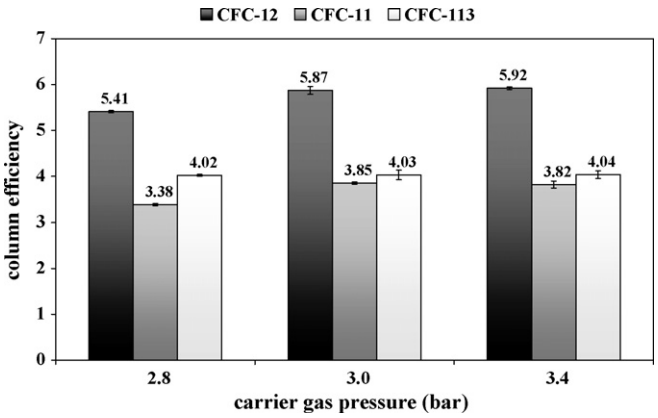

Fig. 3. Column efficiency (i.e. the analyte retention time versus the peak width ratio) calculated for CFC-12, CFC-11 and CFC-113 at different carrier gas upstream pressures. (mean value ± standard deviations; $n = 6$).

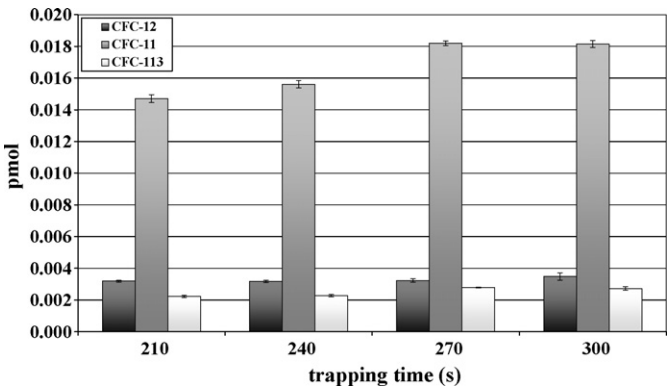

Fig. 5. CFC-12, CFC-11 and CFC-113 picomoles (mean value ± standard deviations; $n = 5$) pre-concentrated in the trap at −78 °C versus the trapping time. The gas flow rate was set at 30 ml min^{-1} throughout all the measurements.

Regarding the standard gas analysis, the time required for the loop filling and rinsing was evaluated. The optimal filling loop time corresponds to the time necessary to fill six times the loop volume. Different filling times between 60 s and 100 s (on the basis of the flow rate) were experienced employing the loop with the largest volume. Fig. 4 reports the detected picomoles against the loop filling time; the time at which the curve is plateau-shape (80 s) was chosen.

Secondly, the time necessary for rinsing the system with the carrier gas was analyzed in order to provide an efficient cleaning of the system between consecutive sample analyses. System blanks analyzed before and after a gas sample were compared for different rinsing times. The rinsing time at which the system blank analyzed before and after the standard gas sample did not significantly differ (equal or less than the system precision) was chosen (120 s).

Peak separation and resolution were optimized by testing different analytical column temperatures between 110° and 150 °C. A column temperature of 150 °C was at once discarded, because it causes a significant increase in the baseline noise. The 110 °C column temperature causes an increase in the retention times (and as a consequence in the analysis time), tailed peaks and a decrease in sensitivity. In addition, a column temperature at 110 °C could induce analyte condensation since the temperature of desorption from the trap is 100 °C. The best compromise between a low background, high sensitivity and peak resolution and short retention times is obtained for all the analytes when column is held at 140 °C.

Since electron capture detector response is temperature dependent, the temperature effect on the ECD sensitivity was considered. In particular, ECD responses at 250°, 300° and 350 °C were compared. CFCs display a wide range of thermal electron attachment coefficients and consequently large differences in relative ECD response. As already observed [27], highly responsive compounds such as CFC-11 have a decreasing signal to noise ratio (hence, sensitivity) when the ECD temperature increases, while more weakly electron capturing species, such as CFC-12, exhibit a small sensitivity increase. The 350 °C ECD temperature was at once rejected, because it caused an increased baseline, hence a decreased sensitivity. An ECD temperature of 300 °C was selected as the best compromise in overall sensitivity.

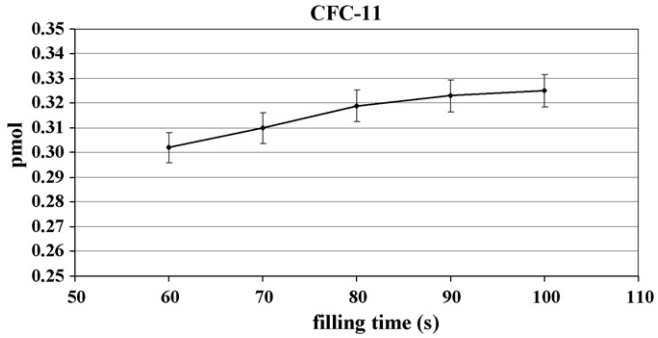

Fig. 4. CFC-11 picomoles (mean value ± standard deviations; $n = 5$) detected as a function of the filling loop time.

Since the concentration range of CFCs in aqueous samples is in ng l^{-1} range, generally too low for the direct GC analysis, a preconcentration step is required prior to the sample injection. The use of the trap allows larger volume to be analyzed for trace measurements. The trapping time was studied to obtain the best efficiency in the pre-concentration process. The Unibeads 2S consists of spherical porous silica beads as adsorbent and preconcentrator. The sorbent traps the CFCs as the carrier gas passes through it while the carrier gas and most of the other components pass through the cold trap. The retained analytes can be rapidly desorbed by resistive heating using a pulse of electric current. Fast desorption is essential for generating a narrow injection band so that a high resolution separation can be achieved.

The breakthrough volume (or sample capacity) and the desorption efficiency are important parameters of a trap. The traps, usually, are packed with small amount of sorbent and are designed to retain the analytes only for a few minutes. Since it is desirable to adsorb as much sample as possible to increase the sensitivity, the sample capacity of the employed trap has to be calculated. In fact, if a component breaks through, only a fraction of this analyte is desorbed during the injection in the GC column, generating a low signal. In other words, the trapping time and the trapped analyte amount are not necessarily in direct proportion.

At a given flow rate, the breakthrough volume can be evaluated considering the trapping time.

Following literature indications [18], the study was focused on a limited range of trapping time (210–300 s). At each trapping time five replicates of standard gas were injected in a calibrated loop and the procedure was repeated in three loops of different volume. Varying the loop volume no differences were noticed. The results (mean value ± standard deviation) obtained for a loop with an intermediate volume are reported in Fig. 5.

The trapped CFC picomoles rose significantly by increasing the trapping time from 240 s to 270 s, while a less significant increase was observed from 270 s to 300 s. Considering the standard deviation of the mean values, the best efficiency of the trapping process was achieved at 270 s, particularly for CFC-11.

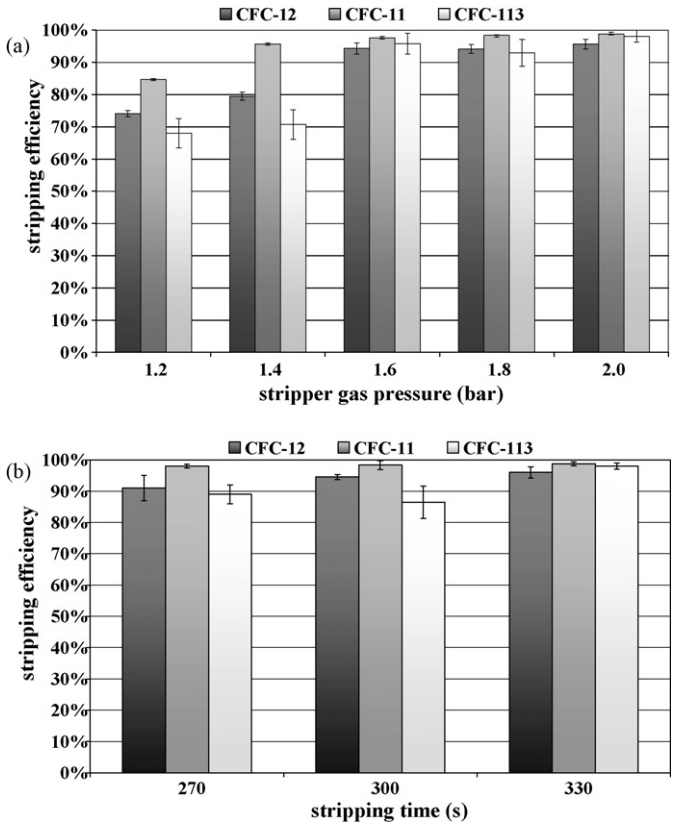

Fig. 6. CFC-12, CFC-11 and CFC-113 stripping efficiency (mean value ± standard deviations; $n = 5$) varying (a) the stripper gas pressure (stripping time set at 330 s) and (b) the stripping time (stripper gas set at 2.0 bar).

As already described in Section 2.4, during seawater analysis the CFC trapping phase is preceded by the analyte stripping from the seawater sample using a stripper gas stream.

The dispersion of the gas into the stripping chamber is a critical aspect determining the performance of the gas–liquid system.

In first instance the stripper gas flow was considered. Stripper gas flows corresponding to a stripper upstream pressure varying between 1.2 and 2.0 bar were tested. The stripping process efficiency was estimated by stripping, trapping and analyzing four times the same water sample. We calculated the stripping process efficiency dividing the area obtained from the first extraction by the sum of the areas obtained from the four carried out extractions. The stripping efficiency was assessed by analyzing several surface seawater samples characterized by relatively high CFC concentrations. In Fig. 6a the mean efficiencies obtained for the three CFCs with different stripper gas pressures using a 330 s stripping time are shown.

The efficiency significantly improves for CFC-12 and CFC-113, increasing the gas stripper upstream pressure from 1.4 bar to 1.6 bar, whereas for CFC-11 the best efficiency improvement is obtained varying stripper gas pressure from 1.2 bar to 1.4 bar. A further increase of the stripper gas pressure to 1.6 bar, 1.8 bar and 2.0 bar did not increase the efficiency of the CFC-11 and CFC-12 stripping. On the contrary, a significant improvement in the CFC-113 stripping efficiency was observed when the stripper gas pressure was set at 2.0 bar. Since the extraction is simultaneous for the three CFCs, the stripper gas upstream pressure was set at 2.0 bar.

Fixed the stripper gas pressure at 2.0 bar, the stripping time was considered. In particular, the stripping efficiency was studied for stripping times ranging between 270 s and 330 s. As shown in Fig. 6b, long lasting stripping times improve particularly CFC-12 and CFC-113 efficiency, while CFC-11 efficiency does not vary significantly in the studied time range. The increase of the stripping time improved the reproducibility of the stripping efficiency (evaluated as the standard deviation) for all the three CFCs. The best efficiency is obtained with a 330 s stripping time.

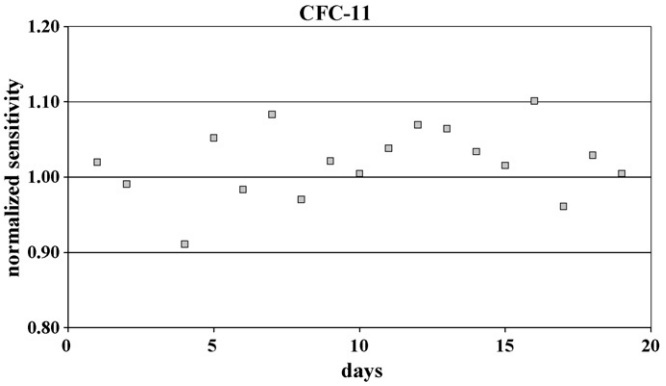

Fig. 7. CFC-11 normalized sensitivity control chart versus time throughout a 20 day analysis period.

Several surface seawater samples (70) were re-stripped. The results showed that on average 96% of CFC-12, 99% of CFC-11 and 98% of CFC-113 are stripped after 330 s of stripping at the lab temperature. In many cases the efficiency was about 100%, being the restripped sample peak areas of the same order of magnitude of stripper blanks. These efficiencies are comparable with the values obtained by Vollmer and Weiss [18] with a stripper gas-flow of 35 ml min^{-1} for 5 min (98% for CFC-12, 91% for CFC-11 and 95% for CFC-113).

Temporal changes in the CFC analysis sensitivity (peak area per amount of compound) are represented in Fig. 7, showing the repeated CFC-11 measurements of a fixed standard gas aliquot in the same loop for a period of daily sample analysis. The sensitivity was normalized respect to the mean value calculated for the whole period of analysis and respect to the measured laboratory pressure and temperature. The shape are quite stable in time; the sensitivity variations are mainly due to changes in the detector sensitivity. Comparable results were obtained for CFC-12 and CFC-113. The linear dependence of sensitivity on laboratory atmospheric pressure already observed [28] is confirmed.

3.2. Figures of merit

The analytical system blank was evaluated by trapping the carrier gas flushing the purge and trap system in the same way as during the standard gas analysis. System blank concentrations resulted 0.0003 ± 0.0001 pmol for CFC-12, 0.0005 ± 0.0001 pmol for CFC-11 and 0.0003 ± 0.0001 pmol for CFC-113.

The blank resulting from the seawater sample stripping and trapping procedure (stripper blank) was evaluated by passing the stripper gas through the empty stripping chamber for the same time adopted for the seawater. The stripper blank resulted 0.0004 ± 0.0001 pmol for CFC-12, 0.0005 ± 0.0001 pmol for CFC-11 and 0.0003 ± 0.0007 pmol for CFC-113.

The precision of an analytical procedure expresses the closeness of agreement between a series of measurements obtained from the same homogeneous sample under the prescribed conditions. It can be considered at different levels, in particular, the repeatability expresses the precision under the same operating conditions over a short interval of time.

Precision for the measurements (as repeatability) of each CFC in the standard gas was determined by the ratio of each standard to the mean of the considered measurements of standard gas in

Table 2
Mean retention time, limit of detection, precision and signal to noise for CFC-12, CFC-11 and CFC-113 in gas and seawater samples.

	CFC-12	CFC-11	CFC-113
Mean retention time (min)	1.26	2.84	5.49
D.L Gas Sample (pmol)	0.0002	0.0003	0.0002
D.L Water Sample (pmol kg^{-1})	0.0081	0.0073	0.0043
Precision (RSD%)	5.9	4.2	5.8
Signal to noise	481	1027	395

the same loop and expressed through relative standard deviation (RSD), as suggested by [29].

We calculated two different detection limits: one for the standard gas injection and one for the seawater samples. The detection limit of the analytical system is based on the analysis of 20 system blank replicates: we considered the detection limit as three times the standard deviation of this set of analyses. We define the minimal detectable CFC concentration in seawater as two standard deviations ($n = 18$) of the stripper blank concentrations divided by the stripper efficiencies, according to [18]. The limits of detection for the CFCs in seawater using this approach yield to a signal-to-noise higher than 400 (higher than 1000 in CFC-11 case), which allows the measurement of these compounds in the polar oceans (see Table 2). An increase in this ratio may be possible by changing GC conditions or by improving stripping and trapping techniques.

Precision and detection limits resulted comparable with the last applications [20,22] and are reported in Table 2 together with the mean retention time of the three CFCs obtained in the chosen analytical conditions.

Since a Certified Reference standard is not commercially available, checking the accuracy of the procedure was difficult. To the purpose an intercalibration exercise was carried out with LDEO (Lamont Doherty Earth Laboratory-Columbia University, NY, USA) on seawater samples collected during the XVIII Italian Antarctica Expedition. Considering LDEO data as the indicative reference values, our recovery was 89% for CFC-11, 93% for CFC-12 and 110% for CFC-113. Nevertheless, it has to be considered that these values refer to few samples only.

3.3. Applications

The purge and trap-GC-ECD system and the optimized method were used to determine CFC concentrations in seawater samples from the Ross Sea (Antarctica). Seawater samples were collected in the austral summer (January–February) 2003 aboard the RV *Italica*, in the framework of the CLIMA (Climatic Long-term Interactions for the Mass Balance) Project cruise as part of the PNRA (National Program for Research in Antarctica) activities. The samples were analyzed at Department of Chemistry and Industrial Chemistry, University of Genoa (Italy). The measurements carried out with our instrument allowed us to describe the distribution of CFCs in the main water masses of the Ross Sea and the storage of the anthropogenic CO_2 in the deep ocean [16,30,31].

Surface CFC concentrations cover a wide range of values in relation to the seawater temperature and salinity, which influence their solubility. The typical highest CFC-11, CFC-12 and CFC-113 concentrations calculated on the basis of the SIO scale 2004 [32], considering mean Antarctic seawater surface salinity and temperature, are roughly 7.8, 4.0 and 1.8 pmol kg^{-1}, respectively. These values are similar to those measured in surface samples. The surface CFC saturation percentage was calculated with respect to the southern hemisphere background [32] using the solubility functions [2,23]. The saturation values range between 80% and 90% in the Ross Sea areas free from pack-ice for a large part of the year.

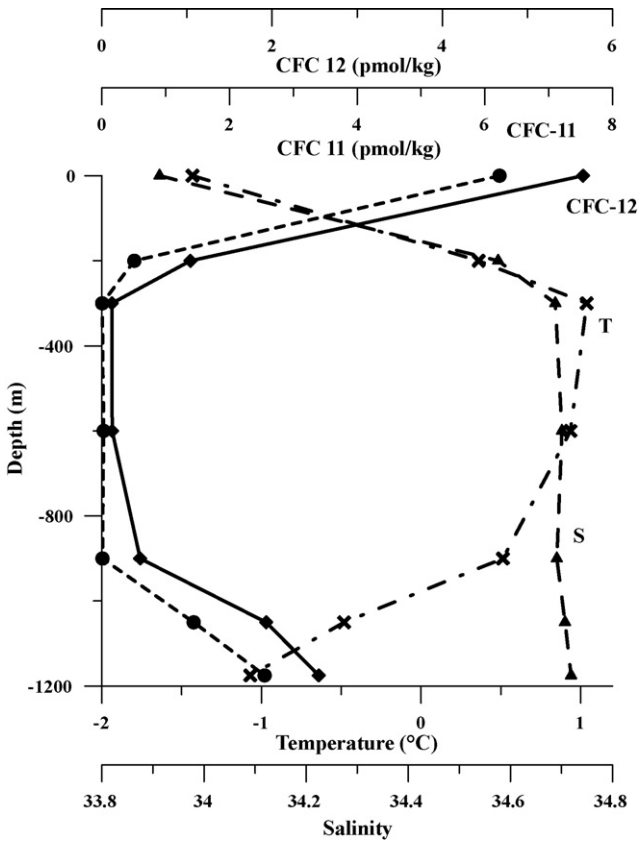

Fig. 8. Vertical profiles for CFC-11 (● dots), CFC-12 (♦ squares), Temperature (× crosses) and salinity (▲ triangles) at the CLIMA Project cast AN03091 in the northwestern Ross Sea (71°53.619' S; 172°13.150' E) on February 08, 2003.

On the other hand, the lowest CFC concentrations, close to the detection limit, are found in correspondence with the warmest temperature, identifying the Circumpolar Deep Water. Such low CFC levels proved the long time segregation at mid depths of this water mass. Beneath this layer CFC concentrations increase, indicating that the bottom layer is occupied by a recently ventilated water mass.

As an example, in Fig. 8 are shown temperature, salinity and CFC vertical profiles concerning a station located in the northwestern Ross Sea.

4. Conclusions

An automated purge and trap–GC-ECD system for the analysis of CFCs in seawater samples consisting of both hardware and software was manufactured with cheap cost in our laboratories.

This method resulted sensitive, reproducible and the sample contamination was negligible, as demonstrated by system and stripper blanks. The precision was always better than 6%. The stripping efficiencies and the limits of detection for CFCs in seawater were improved respect to previous methods and yield a signal to noise ratio higher than 1000 for CFC-11 and close to 400 for CFC-12 and CFC-113.

The method was successfully applied to the determination of chlorofluorocarbons in seawater samples collected in the Ross Sea (Antarctica).

We will study further improvements to increase the sensitivity of CFC-113 measurements and to extend the analytical method to the measurements of other compounds used as ocean tracer, such as SF_6.

Acknowledgements

This study was performed as part of the Italian "National Program for Research in Antarctica" (PNRA) and was financially supported by ENEA through a joint research programme.

Thanks are due to Dr. W. M. Smethie Jr and Mr. E. Gorman for their contributions during instrument start up and chemical analysis. We are grateful to Mr. S. Chiarugi and to OMEGA s.r.l. for their continuous and punctual technical support. We thank Mr. A. Scianca for his assistance with the CFC measurements. We are grateful to Prof. G. Gragnani (Department of Biophysical and Electronic Engineering-DiBE – University of Genoa) for writing the software used to obtain polynomial expressions from calibration empirical data. CTD data were kindly provided from Prof. G. Spezie and the CLIMA project physical oceanography group. We thank the two anonymous reviewers for providing helpful comments on the manuscript.

Visual detection

ABSTRACT

A detection system for a human papillomavirus (HPV) DNA chip based on the light scattering of aggregated silica nanoparticle probes is presented. In the assay, a target HPV DNA is sandwiched between the capture DNA immobilized on the chip and the probe DNA immobilized on the plain silica nanoparticle. The spot where the sandwich reaction occurs appears bright white and is readily distinguishable to the naked eye. Scanning electron microscopy images clearly show the aggregation of the silica nanoparticle probes. When three different sized (55 nm, 137 nm, 286 nm) plain silica nanoparticles were compared, probes of the larger silica nanoparticles showed a higher scattering intensity. Using 286-nm silica nanoparticles, the spots obtained with 200 pM of target DNA were visually detectable. The demonstrated capability to detect a disease related target DNA with direct visualization without using a complex detection instrument provides the prerequisite for the development of portable testing kits for genotyping.

1. Introduction

To perform highly sensitive but low-cost analysis of nucleic acids, a great deal of progress has been made to develop signal amplification and detection methodologies. Various types of fluorescent nanomaterials, such as quantum dots [1], fluorophore-doped silica nanoparticles [2–5], and metal nanoparticles [6–10], have been extensively explored for ultrasensitive DNA detection, both in homogeneous reactions and on microarrays. Other detection methods based on absorbance, scattering, or conductivity have also been employed. Recently, gold nanoparticles [11,12] and silver-amplified gold nanoparticles [13] have been used to perform highly selective and sensitive detection of DNA, utilizing the enhanced light scattering of nanoparticle probes. The advantages of light scattering [14] are that (a) high intensity signals can be obtained by using intense light sources without photodecomposing the light scattering probes, (b) there is negligible quenching by the substances normally used in biological studies, and (c) more importantly, the signal can be detected by relatively simple instruments, including the naked eye.

Silica nanoparticles and microspheres have been widely used in bioanalysis due to their easy synthesis and surface modification, biocompatibility, and high chemical and thermal stability. In addition, silica nanoparticles can load a large quantity of fluorescent dye molecules and serve as signaling probes of amplified sensitivity for cell imaging, DNA detection, and amino acid sensing [15]. However, plain silica particles, having neither dye molecules doped inside silica matrix nor a specific resonance light scattering band like gold or silver particles, have not been used as signaling tags for DNA detections.

Human papillomavirus (HPV) is the major etiological agent of cervical cancer which is the second most common form of cancer among women with a mortality rate of almost 300,000 per year worldwide [16]. Among more than 20 distinct HPV types which are associated with cervical carcinoma, the HPV-16 type is the most prevalent one in patients with cervical intraepithelial neoplasia and cervical carcinoma. Currently, a hybrid capture (HC) system [17,18], which has been approved by the U.S. Food and Drug Administration, and a PCR-based HPV test [19] are used for the detection of high-risk HPV subtypes in a cervical sample obtained with a Pap test. While the HC system is a ready-to-use test for routine diagnosis of the disease, low selectivity and sensitivity still limit its wide application in a clinical setting. Although the PCR-based HPV test has shown improved sensitivity, its low reproducibility, demanding work, and complex instrumentation hinder its use in point-of-care clinical diagnostics.

In this report, we outline our exploration of the potential of plain silica particles as signal tags for a HPV DNA chip. The detection is

Table 1
DNA sequences used for silica particle probes formation and hybridization experiments.

Name	Sequence	Description
Prm1	5′-TTTKTTACHGTKGTDGATACYAC-3′ K; G/T, H; T/A/C, D; A/T/G, Y; T/C	Primers used in PCR amplification of HPV DNA
Prm2	5′-GAAAHATAAAYTGYAADTCATAYTC-3′ K; G/T, H; T/A/C, D; A/T/G, Y; T/C	Reversed primers used in PCR amplification of HPV DNA
T1	5′-ACAGGTTCCTACCCTAAGGACCTTTATGTAGTTTCTGAAGTAGATATGGCAGCACATAT-3′	Target DNA (for HPV-16) complementary to the capture DNA on a DNA chip and P1
NT	5′-AAGAGAATTGACTTATATGTACCTTCCTTAGTTACTTCAGTG-3′	DNA non-complementary to the capture DNA on a DNA chip and P1
P1	5′-AAGGTCCTTAGGGTAGGAACCTGT-biotin-3′	Probe DNA immobilized on SP1
P2	5′-biotin-TAACTTAGTTCAACGAAGCTCGCC-3′	Probe DNA immobilized on SP2
L	5′-CCTAAGGACCTTGGCGAGCTTCGT-3′	Linker DNA complementary to P1 and P2

based on the light scattering of silica particle probes aggregated on a glass slide chip through DNA hybridization. The spots where DNA hybridization occurred appeared brightly white and were directly visible to the naked eye or by a simple flatbed scanner. To our knowledge, this is the first time that plain silica particles have been used as signal tags for a DNA chip. The detection system is quite simple and inexpensive and thus represents a promising step toward the development of portable testing kits for genotyping.

2. Experimental

2.1. Materials

All the oligonucleotides (see Table 1) used were purchased from Bioneer (Seoul, Korea). The HPV DNA chips with the capture DNA array spots of 120 μm diameter were obtained from Biomedlab (Seoul, Korea). The HPV DNA chip (25 mm × 75 mm) has four silicon-separated reaction chambers (20 mm × 5 mm × 1 mm) and each chamber has two 5 × 3 DNA array blocks composed of 10 probe spots to capture HPV-16, and -5 control spots to capture HPV-18. Tetraethyl orthosilicate (TEOS), 29 wt% aqueous ammonia solution, 3-(aminopropyl)trimethoxysilane (APTMS), 25 wt% aqueous solution of glutaraldehyde, sodium dodecyl sulfate (SDS), phosphate buffered saline (PBS, pH 7.4), anhydrous ethanol, and avidin were from Sigma–Aldrich (St. Louis, MO, USA). 3-(Trihydroxysilyl)-propylmethylphosphonate (THPMP) was from Gelest (Tullytown, PA, USA). Deionized water was prepared with a NANOpure II purification system (Barnstead, Dubuque, IA, USA).

2.2. Synthesis and surface modification of silica particles

2.2.1. Plain silica nanoparticles

Plain silica particles of 55 nm, 137 nm, and 286 nm in diameter were used. The plain silica particles of 137 nm and 286 nm were purchased from Bangs Laboratories (Fishers, IN, USA) and the 55-nm plain silica particles were synthesized using the Stöber method [20] with some modification. Briefly, to a mixture of 875 μL ammonia solution and 12.5 mL ethanol, 1 mL of TEOS was added and the resultant mixture was stirred at room temperature overnight. The reaction mixture was then centrifuged for 20 min at 4000 × *g* and washed with ethanol three times and PBS once, and then suspended in PBS for future use. All three kinds of plain silica particles were processed with the same surface modification procedures below.

2.2.2. Amine-modification

10 mg of plain silica nanoparticles were suspended in 4 mL of PBS with sonication. 50 μL of APTMS and 50 μL of THPMP were added to the suspension and the mixture was stirred for 4 h in a sealed glass vessel at room temperature [21]. The amine-modified particles were separated by centrifugation at 4000 × *g* for 15 min, washed three times with PBS, then dispersed in 2 mL of PBS, and stored at 4 °C until use.

2.2.3. Avidin-modification [22]

0.5 mL of the amine-modified silica particle suspension in PBS (5 mg/mL) was mixed with 0.9 mL of PBS for better dispersion of the silica particles. After adding 1.6 mL of glutaraldehyde solution, the mixture was sonicated for 10 min and then stirred for 1.5 h at room temperature. The silica particles were separated by centrifugation at 4000 × *g* for 15 min, washed with PBS and separated by centrifugation twice, and then dispersed in 3 mL of PBS, to which 1 mg of avidin in 1 mL of PBS was added. The mixture was stirred for 3.5 h at room temperature. To block any unreacted amine groups on the silica surface, 50 μL of 1 M glycine was added to the mixture which was then stirred for a further 30 min. The avidin-modified particles were separated by centrifugation at 4000 × *g* for 15 min, washed three times with PBS, dispersed in 2 mL of PBS, and stored at 4 °C until use.

2.2.4. Oligonucleotide-modification

Two kinds of silica particle probes were prepared from the avidin-modified silica particles through the avidin–biotin interaction with P1 DNA and P2 DNA, respectively. P1 DNA-modified plain silica nanoparticles (SP1) were used in both sandwich hybridization and three-step hybridization, while P2 DNA-modified plain silica nanoparticles (SP2) were only used in the three-step hybridization. To 0.5 mL of the avidin-modified plain silica particle suspension, 6 μL of 100 μM P1 DNA was added and the mixture was stirred at room temperature for 1 h. The resulting SP1 were separated by centrifugation at 4000 × *g* for 20 min and washed with PBS three times. The successful immobilization of probe DNA on the surface of the silica particles was confirmed by the absorbance at 260 nm. Then, the resulting SP1 were suspended in 0.5 mL of PBS and stored at 4 °C for future use. SP2 were prepared similarly using P2 DNA.

In order to estimate the number of DNA probe molecules immobilized on the surface of a silica particle, a double-labeled (5′-fluorescein and 3′-biotin) oligonucleotide with the same sequence as the P1 DNA was conjugated with the avidin-modified silica particle. By comparing the fluorescence intensities of the fluorescein-oligonucleotide-modified silica particles with free double-labeled oligonucleotides, the numbers of probe DNA molecules on a single silica particle were estimated to be about 42, 190, and 1100 for the silica particles of 55 nm, 137 nm, and 286 nm diameter, respectively.

2.3. Sandwich (two-step) and three-step DNA hybridization

2.3.1. Sandwich DNA hybridization

(1) Synthetic HPV-16 target (T1). Each 10 μL aliquot of HPV-16 DNA (T1) of various concentrations in water was mixed with 90 μL of PBS, containing 0.2 wt% SDS, and then injected into the reaction chambers of a HPV DNA chip. The hybridization was performed for 2 h at 40 °C with shaking. (2) PCR-amplified HPV-16 DNA target from the SiHa cell line (Korean Cell Line Bank, Seoul, Korea). The

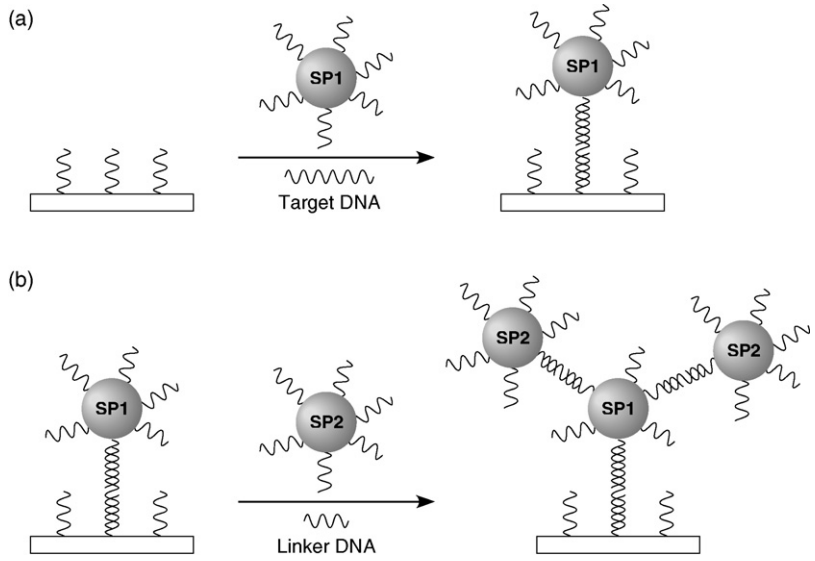

Fig. 1. Schematics of (a) sandwich or two-step DNA assay on a HPV DNA chip using SP1 and (b) the third step DNA hybridization reaction using SP2 to form dendrimer-like silica particle networks in a probe spot.

target DNA was extracted from the HPV-16 positive SiHa cell line using a DNA extraction kit (Intron Biotech, Seoul, Korea), and the L1 region of the HPV DNA was amplified with primers (Prm1/Prm2) using a thermocycler (Biometra, Goettingen, Germany) without dye labeling. The PCR-amplified HPV-16 DNA in PBS, containing 0.2 wt% SDS, was denatured at 95 °C for 5 min and chilled on ice for 3 min, then injected into the reaction chamber to perform the hybridization reaction as in (1). After hybridization, the silicon chamber with its cover was detached from the DNA chip. Then the opened DNA chip was washed with PBS in a dish at 40 °C for 2 min, to remove unbound DNA molecules, and dried in air. For the next step, a clean silicon chamber with a cover was attached to the DNA chip. Then, the second hybridization was performed by adding a mixture of 10 μL of 100 ppm SP1 suspension and 90 μL of PBS containing 0.2 wt% SDS to the reaction chamber and incubating for 2 h at 40 °C with shaking. Then, the hybridized DNA chip was washed with PBS in a dish at 40 °C and dried in air. Fig. 1 shows the schematics of this procedure.

2.3.2. Three-step DNA hybridization

The first two hybridization procedures were the same as those of the sandwich DNA hybridization. As shown in Fig. 1, after the second hybridization, a mixture of 10 μL of 100 nM linker DNA (L) in water, 10 μL of 100 ppm SP2 suspension, and 80 μL of PBS containing 0.2 wt% SDS was injected into the reaction chamber and incubated for 2 h at 40 °C with shaking. After hybridization, the silicon chamber was detached from the DNA chip first. Then the DNA chip was washed with PBS in a dish at 40 °C for 2 min and dried in air.

2.4. Instruments

A transmission electronic microscope (H-7600, Hitachi, Tokyo, Japan) was used to check the size and dispersion state of the silica particles. The hydrodynamic diameters of the silica particles were estimated using a light scattering system (BI-200SM, Brookhaven, New York, NY, USA) with a He–Ne laser (632.8 nm) light source. A silica particle sample for measurement was first diluted by water to 2.0 vol.%, filtered through a 0.45 μm filter (Whatman, Maidstone, England), and then transferred to a sample cell kept at 20 °C. The morphology of the silica particles in a probe spot was assessed with a field emission-scanning electron microscope (S-4000, Hitachi, Tokyo, Japan). Fluorescence measurements were conducted with a fluorescence spectrophotometer (Eclipse, Palo Alto, CA, USA). The UV–visible absorbance of silica particles was measured with a spectrophotometer (S-3100, Scinco, Seoul, Korea). The concentration of PCR-amplified DNA was determined by a NanoDrop Spectrophotometer (Thermo Fisher Scientific, Wilmington, DE, USA). A flatbed scanner (HP Scanjet 7400c, Palo Alto, CA, USA) was used to show the entire image of hybridized spots in each chamber. The scattered light from probe spots can also be observed with the naked eye by holding the chip toward a daylight lamp. A microscope illumination system was arranged for detecting the scattered light from the silica particles, as shown in Fig. 2, following the method in Ref. [24]. A light beam from a 20 mW argon-ion laser (Melles Griot, CA, USA) was focused onto a probe spot of an HPV DNA chip placed on the slide holder of a microscope (IX71, Olympus, Tokyo, Japan). The laser beam was incident from below the DNA chip at an angle of 35° for maximum contrast between the dark background and the bright scatter of the spots. Images collected by a 20× objective lens were recorded with an iXon CCD camera (Andor, Belfast, UK) and analyzed using a public domain software Image J (NIH, Bethesda, MD, USA). A photomultiplier tube (PMT) (Hamamatsu, Bridgewater, NJ, USA) was also used for monitoring light intensities.

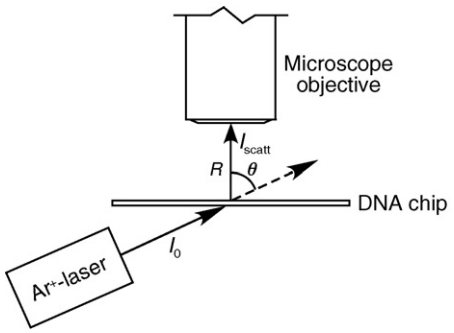

Fig. 2. Microscope illumination arrangements for detecting light scattering from silica particle probes hybridized on a DNA chip. θ is the angle between the incident light and the detector and R is the distance from the DNA chip to the detector.

3. Results and discussion

3.1. Characterization of the silica particle probes

Changes in the hydrodynamic diameters of the silica particles before and after the probe DNA immobilization were monitored by dynamic light scattering. The hydrodynamic diameters were estimated from the diffusion constants of silica particles obtained from the cumulant fit to the autocorrelation functions of scattering signals [23,24]. After the probe DNA immobilization, the hydrodynamic diameters of all three sizes of silica particles were increased from 67 ± 9 nm, 161 ± 1 nm, and 317 ± 2 nm to 93 ± 5 nm, 199 ± 1 nm, and 353 ± 2 nm, while the diameters from TEM remained at 55 ± 5 nm, 137 ± 10 nm, and 286 ± 11 nm, respectively. The discrepancies between the diameters were due to the water molecules and the probe DNA attached to silica particles in solution not being observable by TEM of a dried sample because of their low electron densities [25]. In the UV spectra of SP1 or SP2 around 260 nm, the characteristic peak of DNA was observed, which further confirmed the successful immobilization of the probe DNA on the silica particle surface. The increases of ~32 nm in the hydrodynamic diameters of the silica particles after series of modifications correspond reasonably well to the sizes of avidin and DNA moieties, as reported in the literature [26,27].

3.2. Light scattering from two-step hybridization

3.2.1. Detection with the naked eye

SP1 prepared from the plain silica particles of three sizes were two-step hybridized in different reaction chambers of a HPV DNA chip. The concentration of T1 in each reaction chamber was kept at 10 nM. The concentrations of SP1 for the silica particles of each size were also kept at 100 ppm, which corresponds to 640 fM, 47 fM, and 6.0 fM of 55-nm, 137-nm, and 286-nm silica particles, respectively and 26 pM, 12 pM, and 6 pM of probe DNA molecules, respectively. The fourth chamber was used as a control chamber to check non-specific interactions with similar hybridization reactions with a non-complementary DNA sequence (NT) instead of T1. The concentration of 100 ppm for SP1 was chosen as optimal for a sufficient hybridization reaction between SP1 and the target DNA but also low interferences from the nonspecific binding of SP1 to the chip surface (data not shown). When observed by the naked eye, the hybridized spots obtained with larger SP1 were brighter and larger than those with smaller SP1. The *S*/*N* ratios of the hybridized spots in the scanned image for SP1 of 55 nm, 137 nm and 286 nm diameter were 7.6, 8.3 and 10.6, respectively, which agreed with the trend observed by the naked eye (Fig. 3a–c). Using SP1 of 55 nm, 137 nm and 286 nm, probe spots of down to 1 nM, 500 pM, 200 pM of T1 were detectable by the naked eye, respectively. It is quite surprising that the DNA hybridization results can be observed with the naked eye, since, unlike gold or silver particles, both the plain silica particles and surface modified silica particles have negligible absorbance and no resonance light scattering bands in the visible range.

3.2.2. Aggregation of silica particles

SEM images of hybridized probe spots revealed the aggregation of SP1 immobilized onto the chip surface by hybridization (Fig. 3d–i). The whole region of a spot was neither regularly nor completely covered by SP1. In some regions of a probe spot, silica particles aggregated to form large particle complexes with sizes from several hundred nanometers to several micrometers. However, in some regions, only a few single silica particles were present. The 286-nm SP1 were likely to be bound in one layer, while the 137-nm and 55-nm SP1 often aggregated heterogeneously to show multilayer morphology in some regions. Inside the spots of the control chamber and the control spots of the T1 hybridized chambers, no silica particle probes were found. Decreasing the T1 concentration from 10 nM to 100 pM, the fraction of areas with 137-nm SP1 aggregation decreased roughly from 18% to 3%. When the T1 concentration was lower than 100 pM, it was difficult to find aggregated or single silica particles in a probe spot. We suppose the SP1 aggregation was through non-cross-linking mechanism [28], since no cross-linking DNA connecting two silica particles together was present. More investigation is needed to understand the aggregation mechanism of silica particle probes during the sandwich DNA hybridization on a DNA chip.

3.2.3. Laser light scattering

Using the microscope illumination system, the relationship between light scattering performance of silica particle probes and their sizes were investigated. In Rayleigh scattering by a small spherical particle of radius r much smaller than the wavelength of light λ in a particular medium ($r < \lambda/20$), the scattered light intensity is proportional to r^6. However, when the particle becomes larger, the intensity of scattered light is described by Mie theory [29]. Following the numerical method of Yguerabide and Yguerabide [14,30], the intensities of the scattered light, I_{scatt}, can be calculated as a function the particle radius. When linearly polarized light of intensity I_0 is scattered by a spherical particle of radius r and detected by a detector in the plane parallel to the polarization direction and at a distance R from the particle and an angle θ from the direction of incident light, the intensity is given as

$$I_{scatt} = I_0 \frac{\lambda^2 |S_2|^2}{4\pi^2 R^2} \tag{1}$$

where

$$S_2 = \sum_{n=1} \frac{(2n+1)(a_n \tau_n + b_n \pi_n)}{n(n+1)} \tag{2}$$

is a function that depends on the size parameter $x = 2\pi r/\lambda$ and the angle θ. The coefficients a_n and b_n are defined as

$$a_n = \frac{[(D_n(mx)/m) + (n/x)]\Psi_n(x) - \Psi_{n-1}(x)}{[(D_n(mx)/m) + (n/x)]\xi_n(x) - \xi_{n-1}(x)} \tag{3}$$

$$b_n = \frac{[mD_n(mx) + (n/x)]\Psi_n(x) - \Psi_{n-1}(x)}{[mD_n(mx) + (n/x)]\xi_n(x) - \xi_{n-1}(x)} \tag{4}$$

with

$$D_n(mx) = \frac{d \ln \Psi_n(mx)}{d(mx)} \tag{5}$$

where m is the relative index of the bulk particle material. The coefficients π_n and τ_n depend on θ and are evaluated by the recurrence relations

$$\pi_n = \frac{(2n-1)\cos\theta}{n-1}\pi_{n-1} - \frac{n}{n-1}\pi_{n-2} \tag{6}$$

$$\tau_n = (n \cos\theta)\pi_n - (n+1)\pi_{n-1} \tag{7}$$

starting with $\pi_0 = 0$ and $\pi_1 = 1$. Refer to Ref. [29] for the definitions of $\Psi_n(x)$ and $\xi_n(x)$ and detailed description of the numerical evaluations.

Fig. 4 shows the dependence of the scattering intensity on the silica particle radius. The solid line represents the theoretical ratio I_{scatt}/I_0 calculated from Eq. (1) using Mathematica (Wolfram, Champaign, IL, USA) with the values $m = 1.37$, $\lambda = 488.0$ nm, $\theta = 55^\circ$, and $R = 1$ cm. Instead of estimating the values of I_{scatt}/I_0 by measuring both I_{scatt} and I_0, we compared the relative changes in the light scattering intensity per particle with respect to the one by one SP1 of 55-nm diameter. The number of SP1 in a probe spot (N; 7×10^6, 5×10^5 and 7×10^4 for SP1 of 55 nm, 137 nm and 286 nm, respectively) was estimated by multiplying the fraction of SP1-covered

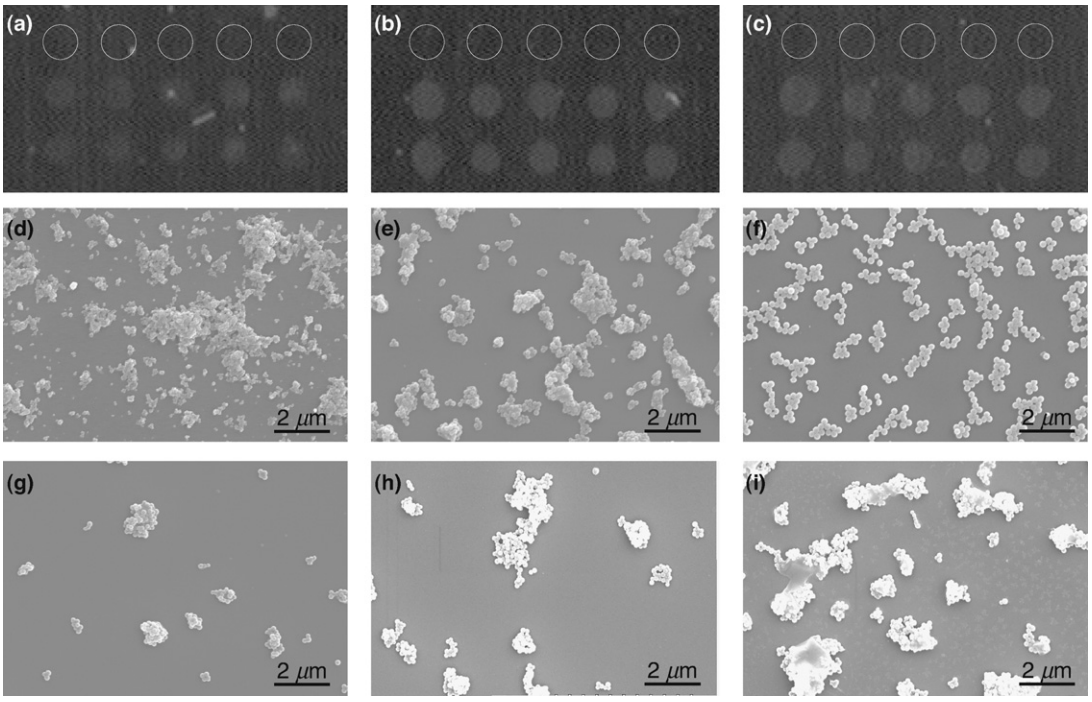

Fig. 3. (a–c) Images of DNA (both probe and control) arrays after sandwich hybridization using the SP1 of 55 nm, 137 nm and 286 nm, respectively, scanned by a flatbed scanner. The white circles highlight the region where control spots were present; (d–f) SEM images of one region of probe spots where three silica particle probes with diameters of 55 nm, 137 nm and 286 nm, respectively, hybridized with 10 nM target DNA in a two-step hybridization; (g–i) SEM images of one region of probe spots where silica particle probes with diameter of 137 nm hybridized with target DNA concentration of 100 pM, 1 nM, 10 nM, respectively, in a two-step hybridization. The spots are about 120 μm in diameter.

areas (21%, 18%, and 22% for SP1s of 55 nm, 137 nm and 286 nm, respectively obtained using Image J) and the average number of layers of the aggregated SP1s (4, 2, and 1 for SP1s of 55 nm, 137 nm and 286 nm, respectively, by visual inspection of SEM images) with the number of SP1s needed to cover the spot with a close-packed SP1 monolayer (8.6×10^6, 1.4×10^6 and 3.2×10^5 for SP1 of 55 nm, 137 nm, and 286 nm, respectively). Note that the obtained SP1 numbers were rough approximations only due to the randomly aggregated states of the SP1s and these numbers were used only for rough comparisons. The general trends of the light scattering intensity per particle with respect to the particle size — the larger the size of a particle, the stronger the light scattering intensity — showed a good agreement between theory and experimental data. However, the rate of increase in the observed scattering intensity (Fig. 4, solid circles) was

$$I_{\text{scatt}} \sim r^{3.4} \tag{8}$$

which is smaller than that expected by Mie theory (Fig. 4, solid line) for the SP1 used,

$$I_{\text{scatt}} \sim r^{5.8} \tag{9}$$

This is supposedly due to the different degrees of aggregation of the three kinds of SP1 particles as shown in Fig. 3d–i. If z particles aggregate together acting as one big particle, the number of aggregates and their radii are respectively given as $N_{\text{agg}} \sim N/z$ and $r_{\text{agg}} \sim z^{1/3} r$. If we assume the exponent f for the dependence of I_{scatt} on r does not change much in the range of particle sizes we are considering, the scattered intensity of the aggregates is given by

$$I_{\text{scatt}} \propto N_{\text{agg}} r_{\text{agg}}^f \sim \frac{N}{z}(z^{1/3} r)^f = N z^{(f/3-1)} r^f \tag{10}$$

Therefore, as long as $f > 3$, the aggregation of particles will give a scattering intensity higher than the scattering from unaggregated particles,

$$I_{\text{scatt}} \propto N r^f \tag{11}$$

In addition, from the visual inspection of the SEM images, it was clear that the smaller the particles, the larger the degrees of aggregation (z). Then the apparent increase in the scattering intensity with respect to the SP1 diameter should be slower than expected by Mie theory, as shown in Fig. 4.

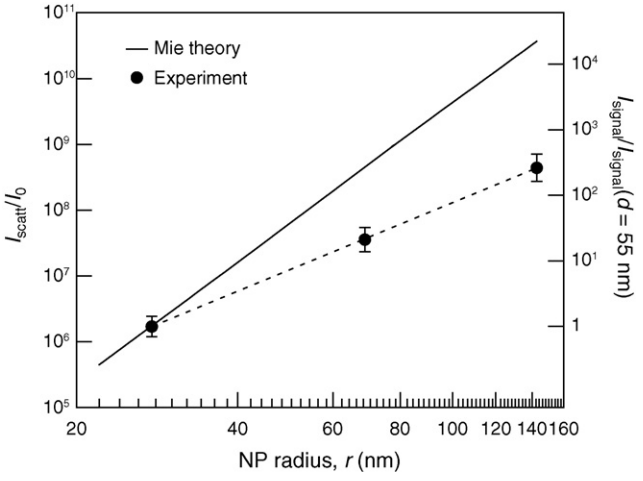

Fig. 4. Scattered light intensity *vs.* the radius of silica nanoparticles. The solid line represents I_{scatt}/I_0 calculated from Eq. (1) and circles are experimentally measured light intensity scattered by one silica nanoparticle normalized to the intensity scattered by one 55-nm SP1.

3.3. Enhanced light scattering from three-step hybridization

According to the above observation of aggregated silica particle probes, it was reasonable to expect that additional aggregation

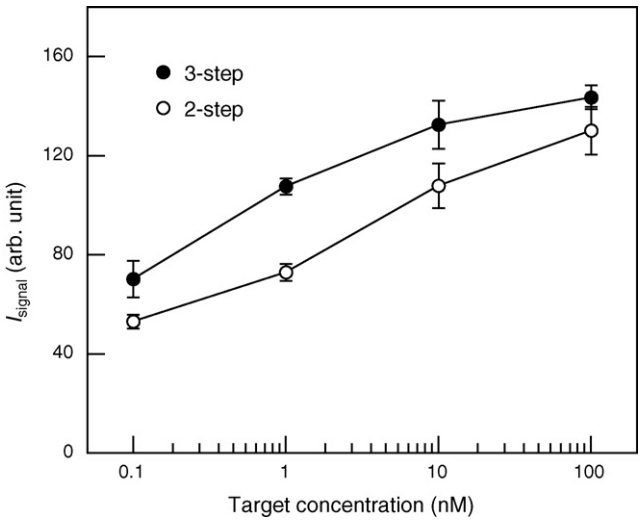

Fig. 5. Comparison of the scattering signals of probe spots between two-step and three-step DNA hybridization ($n \geq 10$). Target DNA concentration range: 100 pM, 1 nM, 10 nM, 100 nM. 286 nm diameter silica particle probes were used. The spots are about 120 μm in diameter. The solid lines are guides to the eye.

could improve DNA detection sensitivity. Formation of dendrimer-like silica particle networks may increase the aggregation degree of silica particle probes, as in Fig. 1b. As a proof-of-concept experiment, after the sandwich hybridization of SP1 of 286 nm, a second generation of silica particle probe (SP2) and a linker DNA was introduced into the reaction chamber. As expected, the light scattering signal from a probe spot, measured using the microscope set up, increased more by the three-step hybridization than by the two-step hybridization (Fig. 5). The improvement after the third step hybridization was also easily observed with the naked eye as much brighter spots. The SEM image in Fig. 6 shows a highly aggregated state of silica particle probes. After three-step hybridization, the probe spots for the target concentration down to 50 pM were discernable using the microscope system, while the probe spots for the target concentration down to 100 pM were discernable in the two-step hybridization.

3.4. Real HPV DNA assay using plain silica particle probes

The signal detection strategy based on the light scattering from silica particles can be applied to DNA genotyping to get yes-or-no answers, important in clinical HPV genotyping. The DNA sample extracted from the HPV-16 positive SiHa cell line was PCR amplified and then directly used to perform the two-step hybridization. The concentration of the amplified DNA was 350 μg/mL. When the

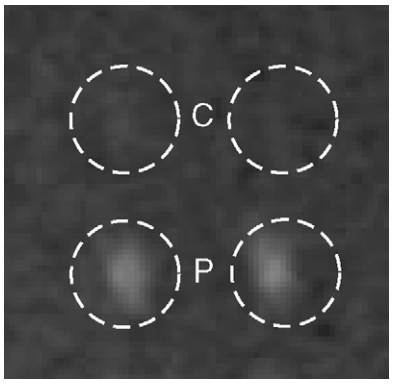

Fig. 7. Photograph of real HPV DNA detection with a sandwich hybridization reaction. The probe spots (P) show discernible patterns, while the control spots (C) remain unchanged as background. PCR-amplified HPV DNA concentration: 350 μg/mL. The dotted circles are guides to the eye.

hybridization reaction was finished, the probe spots were readily visible to the naked eye, while within the control spots no discernible patterns could be recognized (Fig. 7). The total time used for the two-step hybridization analysis, including the sample preparation and PCR, was 5–6 h, which is comparable to that required by the fluorescent dye-based test using a commercial HPV DNA chip (Biomedlab). Although the sensitivity of our system capable of detecting subnanomolar target DNA is relatively lower than those of both an HPV DNA chip test (LOD of low pM) and a fluorescent dye-doped silica nanoparticle based system (LOD of 1 pM) [3], our system offers the advantage of using a simple detection system such as a flatbed scanner or even the naked eye without requiring an expensive and complicated fluorescence detection system. Therefore, our detection system provides the possibility of developing portable clinical devices for diagnosing a disease related DNA of low to high nM concentrations after PCR.

4. Conclusions

We have described a novel and simple method for detection of specific DNA sequences based on light scattering from aggregated silica particles on a HPV DNA chip. The light scattering performance of the silica particles was analyzed by Mie theory, to account for the enhanced light scattering in terms of the increased effective sizes through aggregation. The scattering signal intensities were further enhanced after three-step hybridization compared with that after two-step hybridization due to the increased aggregation state of the silica particle probes. It was the first time that the scattering from plain silica particles was used for a DNA detection system. The detection method provides the possibility for the development of

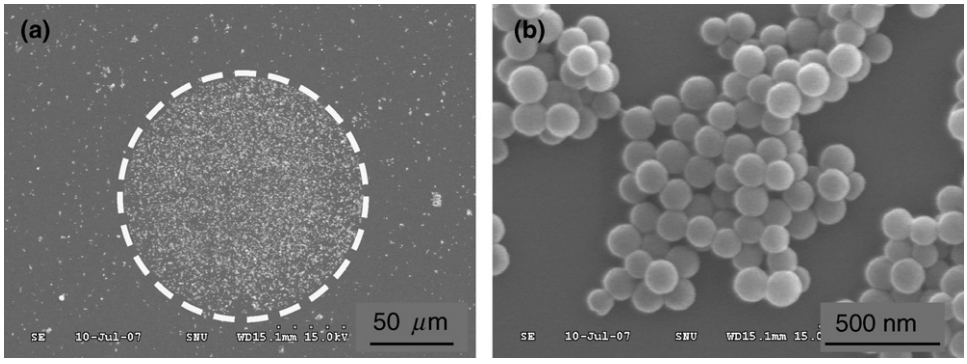

Fig. 6. SEM images of (a) a probe spot (guided by the dotted circle) and (b) one region of the spot after a three-step hybridization. 137 nm sized SP1 and SP2 were used and the target DNA concentration was 10 nM.

rapid, easy, and economic genetic diagnosis due to the advantages of using (1) a low cost light scattering detector systems such as a flatbed scanner or even the naked eye and (2) plain silica particles either commercially available or easily synthesized by the Stöber method. Even with only two-step hybridization, the limit of detections were about 100 pM with a simple microscope illumination system or 200 pM to 1 nM by the naked eye and a flatbed scanner, respectively, sufficient for most real DNA samples (usually in the nanomolar concentration range) obtained from a standard PCR protocol.

ABSTRACT

In the present paper, a procedure for the determination of total arsenic and arsenic (III) in phosphate fertilizers and phosphate rocks by slurry sampling (SS) with hydride generation atomic absorption spectrometry (HG-AAS) is proposed. Arsenic (III) is determinated directly and total arsenic is determinated after reduction reaction. The procedure was optimized for the flow rate of $NaBH_4$, $NaBH_4$ and hydrochloric acid concentrations using a full two-level factorial and also a Box-Behnken design. Slurry preparation with hydrochloric acid in an ultrasonic bath allowed the determination of arsenic (III) with limits of detection and quantification of 0.1 and 0.3 $\mu g\,L^{-1}$, respectively. The precision of results, expressed as relative standard deviation (RSD), was always lower than 3%. The accuracy of this method was confirmed by analysis of certified sediment reference materials, while the procedure also allows for calibration using aqueous external standards. This method (SS/HG-AAS) was used to determine total arsenic and arsenic (III) in two phosphate rock samples and two phosphate fertilizer samples. In these samples, total arsenic concentrations varied from 5.2 to 20.0 $mg\,kg^{-1}$, while As (III) concentrations varied from 2.1 to 5.5 $mg\,kg^{-1}$, in agreement with published values. All samples were also analyzed using acid digestion/HG-AAS. Both, a paired *t*-test and a linear regression model demonstrated no significant difference (95% CL) between the results obtained using these two sample preparation procedures.

1. Introduction

Arsenic is a highly toxic element, and arsenic exposure is a serious concern worldwide. Several studies have shown that the widespread use of phosphate rock in fertilizers is a significant source of arsenic contamination and exposure [1,2]. A study of 196 fertilizer samples from 12 European countries concluded that these fertilizers and the phosphate rock used to produce them were significant sources of arsenic, chromium, cadmium and lead [3]. Chen et al. [4], evaluated arsenic and cadmium exposure from the application of phosphate fertilizers to agricultural soils, while another study demonstrated adverse impacts from arsenic, antimony and lead in phosphorus-based fertilizers [5,6], and Mirlean and Roisenberg found significant arsenic and cadmium contamination of rainwater, groundwater, and soil in the area surrounding a phosphate fertilizer factory [7]. These studies underscore the importance of measuring and controlling arsenic inputs to soil from fertilizers prepared with phosphate rocks.

The toxicity of arsenic compounds is highly dependent on their speciation and valence state. Trivalent (As III) forms are more toxic than pentavalent (As V) forms, while inorganic arsenic species tend to be more toxic than organic forms [8,9]. Considering the high prevalence of As in phosphate rocks and fertilizers, as well as the role of chemical speciation in determining arsenic toxicity, optimizing rapid, low-cost analytical procedures for determining the concentration and speciation of arsenic in phosphate fertilizers and rocks is of great importance. In this work, a rapid method for the inorganic speciation of arsenic in phosphate fertilizers and phosphate rocks using slurry sampling is presented. Currently, several analytical techniques exist for determining arsenic concentration and speciation with adequate selectivity, accuracy, precision and sensitivity. These techniques include hydride generation atomic

absorption spectrometry (HG-AAS) [10–12], electrothermal atomization atomic absorption spectrometry (ET AAS) [13,14], hydride generation atomic fluorescence spectrometry (HG-AFS) [15,16], and inductively coupled plasma mass spectrometry (ICP-MS) [17–19]. However, sample preparation and decomposition can present significant problems, particularly for solid sample matrices [20]. This step is further complicated by the volatility of arsenic, which requires that all acid digestion procedures be performed in closed systems to reduce losses. Several efficient sample pre-treatment methods already exist for the determination of arsenic, including closed-vessel microwave-assisted digestion [21,22], in-line digestion systems [23,24] and others. Currently, solid sampling is the preferred technique for arsenic determination in solid matrices, due to the complete elimination of the sample pre-treatment step [25]. However, this technique requires specialized instrumentation that is not always available. Procedures involving this technique have been proposed for the determination of arsenic in barites [26] and sediments [27] employing electrothermal atomic absorption spectrometry (ET AAS) as a detection technique. When the required instrumentation for the above techniques is not available, slurry sampling [28,29] presents an excellent alternative, eliminating the need of sample pre-treatment and reducing the risk of analyte loss or contamination. Methods for As speciation analysis using slurry sampling have been reported [30]. Considering the advantages of the slurry sampling technique, several methods have been proposed for the determination of arsenic in solid matrices. Table 1 shows some of these methods published [30–42].

In this paper it has been proposed a procedure for quantification of total arsenic and arsenic (III) in phosphate fertilizers and phosphate rocks employing slurry sampling (SS) and hydride generation atomic absorption spectrometry (HG-AAS). Arsenic (III) is determinated directly and total arsenic is determinated after reduction reaction.

2. Experimental

2.1. Instrumentation

Arsenic concentrations were measured using a Varian model SpectrAA 220 (Mulgrave, Victoria, Australia) flame atomic absorption spectrometer with an arsenic hollow cathode lamp. The absorption wavelength was set at 193.7 nm, and measurements were made using a lamp current of 10 mA and slit width of 0.5 nm. A deuterium lamp was used for background correction. The flame composition was acetylene (2.0 L min^{-1}) and air (13.5 L min^{-1}). An Alitea C-6 XV peristaltic pump (Stockholm, Sweden) fitted with Tygon tubing was used to propel all solutions. High purity (99.99%) argon was used as a purge gas, with a flow rate of 100 mL min^{-1}. For arsenic determinations, a quartz T-tube cell with a path-length of 165 mm and a diameter of 12 mm was heated to approximately 900 °C. Sample slurries were sonicated at room temperature using a VWR model 75D ultrasonic bath.

2.2. Reagents

All reagents used were of analytical grade, and all solutions were prepared using Milli-Q water (18.2 MΩ cm^{-1}). A standard stock solution of 1000 mg L^{-1} As (III) was prepared by dissolving 0.1320 g of As_2O_3 in 25 mL of 1 mol L^{-1} KOH solution. This solution was neutralized with 2 mol L^{-1} H_2SO_4 and diluted to 100 mL with deionized water. The stock solution was stored at 4 °C. Working solutions of arsenic (0.3–5.0 μg L^{-1}) were prepared daily by diluting aliquots of the stock solution with deionized water. A solution of hydrochloric acid (6 mol L^{-1}) was prepared from concentrated HCl (37%, v/v, Merck). Aqueous solutions of 2% (w/v) sodium tetrahydroborate were prepared freshly daily by dissolving solid $NaBH_4$ in 0.5% (w/v) NaOH before 0.45 μm membrane filtration. Pre-reducing solutions containing 10% (w/v) potassium iodide and 2.0% (w/v) ascorbic acid

were prepared freshly daily in distilled water. A citric acid/sodium citrate buffer (0.5/0.5 mol L^{-1}, pH 7.1) was prepared freshly daily in water. Two marine sediment reference materials for trace metals, MESS-2 and MESS-3 (National Research Council of Canada, Ottawa, Canada) were used for method calibration and validation.

2.3. Samples

Two commercial phosphate fertilizer samples (Superphosphate Simple) and two phosphate rocks (from Algeria and Brazil) were analyzed as described below.

2.4. Slurry preparation

Slurries were prepared by combining 0.1 g of dry, granular sample material (particle size range: 20–100 μm) with 3.0 mL of 6.0 mol L^{-1} hydrochloric acid in a 25 mL flask and immersing this mixture in an ultrasonic bath for 30 min before diluting to 25 mL with Milli-Q water. All reagent blanks were prepared in exactly the same way as sample slurries. Aqueous standards were used to generate standard calibration curves.

2.5. Sample preparation using a digester block

In order to evaluate the accuracy of the slurry sampling method, triplicate samples were also prepared via temperature-controlled acid digestion. Briefly, 2 mL of concentrated nitric acid and 1 mL of 30% (v/v) hydrogen peroxide were sequentially added to 0.1 g of each sample in a digester tube. Each tube was then fitted with a cold finger and heated at 100–110 °C for 4 h in a digester block [43]. The resultant solution was diluted to 25 mL with Milli-Q water.

2.6. Analytical procedure

2.6.1. Total arsenic

For determination of total arsenic, 3.33 mL of a 6 mol L^{-1} hydrochloric acid solution, 1 mL of pre-reducing solution (KI 10% + ascorbic acid 2%) and aliquots of the sample slurries were added to reaction flasks. After 30 min, these resultant solutions were diluted to 10 mL with Milli-Q water. Sodium tetrahydroborate was introduced into the closed system at a rate of 2.70 mL min^{-1} using a peristaltic pump, and the arsine vapor generated was transported to the AAS spectrometer using argon as carrier, with a flow rate of 100 mL min^{-1}. Calibration curves were generated by processing aqueous As (III) standards (0.3–5.0 μg L^{-1}) using the same procedure.

For analysis of the digested samples aliquots of the sample solutions were substituted by sample slurries.

2.6.2. Arsenic (III)

For the determination of arsenic (III), aliquots of the samples slurries were transferred to reaction flasks containing 2 mL of citric acid/sodium citrate buffer solution and diluted to a final volume of 10 mL with Milli-Q water. Sodium tetrahydroborate was introduced into the closed system at a rate of 2.70 mL min^{-1} using a peristaltic pump, and the arsine vapor generated was transported to the AAS spectrometer using argon as carrier, with a flow rate of 100 mL min^{-1}.

For analysis of the digested samples aliquots of the sample solutions were substituted by sample slurries.

3. Results and discussion

3.1. Optimization of the procedure for hydride generation

Optimization was conducted using 10.0 mL of 3.0 μg L^{-1} As (III) solution and experiments were carried out in random order. Variables involved in the hydride generation step, including flow rate of $NaBH_4$ (FRB), $NaBH_4$ concentration [BH_4^-] and hydrochloric acid concentration [HCl], were optimized using a two-level factorial multivariate design. Experimental domains for each factor were defined based upon literature data. Coded and real values, as well as analytical signals (integrated absorbance), are shown in Table 2. The concentrations of sodium hydroxide (0.5% w/v), pre-reducing solution (potassium iodide and ascorbic acid) and the flow rate of argon (100 mL min^{-1}) were selected based on literature values.

Effect coefficients calculated for each factor [44] were: (+0.1109 ± 0.0237), (+0.0672 ± 0.0237) and (+0.0016 ± 0.0237) for [BH4], FRB and [HCl], respectively. The evaluation of these data demonstrated that [BH4] and FRB were significant factors, while [HCl] was not. The positive sign of the significant coefficients indicated that integrated absorbance increased with increasing borohydride concentration and flow rate as experimental domains established for each factor. However, an Analysis of Variance (ANOVA) indicated a poor fit of these data to a linear model ($p = 0.086$). A curvature test [45] was also applied, in which the curvature was calculated using the equation: curvature = c, where RFD is the average of the responses obtained from experiments specified by the factorial design, and RCP is the average of the responses obtained for the central point. An analysis of the results, RFD = (0.1812) and RCP = (0.2392), suggests negative curvature, and thus a maximum analytical signal in the region of the central point. On the basis of these results, a Box-Behnken design [46,47] was performed in order to fit a quadratic model to the data and identify the optimal conditions for the SS/HG-AAS procedure (Table 3).

This approach yielded the quadratic model:

$R = 0.2390 + 0.0469[BH_4^-] - 0.0571[BH_4^-]^2 + 0.0632FRB - 0.0413\ FRB^2 - 0.0301[HCl]$, which resulted in an improved fit ($p = 0.1346$). This model obtained has its maximum response for the following experimental conditions: ([BH_4^-] = 0.3178 and

Table 2

2.15%), (FRB = 0.7040 and 2.70 mL min^{-1}) and ([HCl] = −0.0241 and 1.97 mol L^{-1}) (coded and real values, respectively). Critical points were calculated as described previously [48]. The optimal delay time for analytical measurements was found to be 15 s.

3.2. Optimization of the procedure for speciation of arsenic

Effect of the addition of citric acid/sodium citrate buffer (0.5/0.5 mol L^{-1}) to standard solutions of As (III) and As (V) were studied with concentrations on the order of μg L^{-1}. In the absence of buffer, As (V) signal was observed (Fig. 1A), while the addition of from 2 mL of buffer masked the As (V) signal and hindered hydride formation.

Optimal [HCl] for arsenic extraction was found to be 6 mol L^{-1} for the extraction procedure described above, as illustrated by a plot of absorbance vs. [HCl] (Fig. 2). At this concentration, recovery was between 100 and 108%.

3.3. Method validation

The SS/HG-AAS method described above was validated according to IUPAC protocols [49]. HG-AAS signal was found

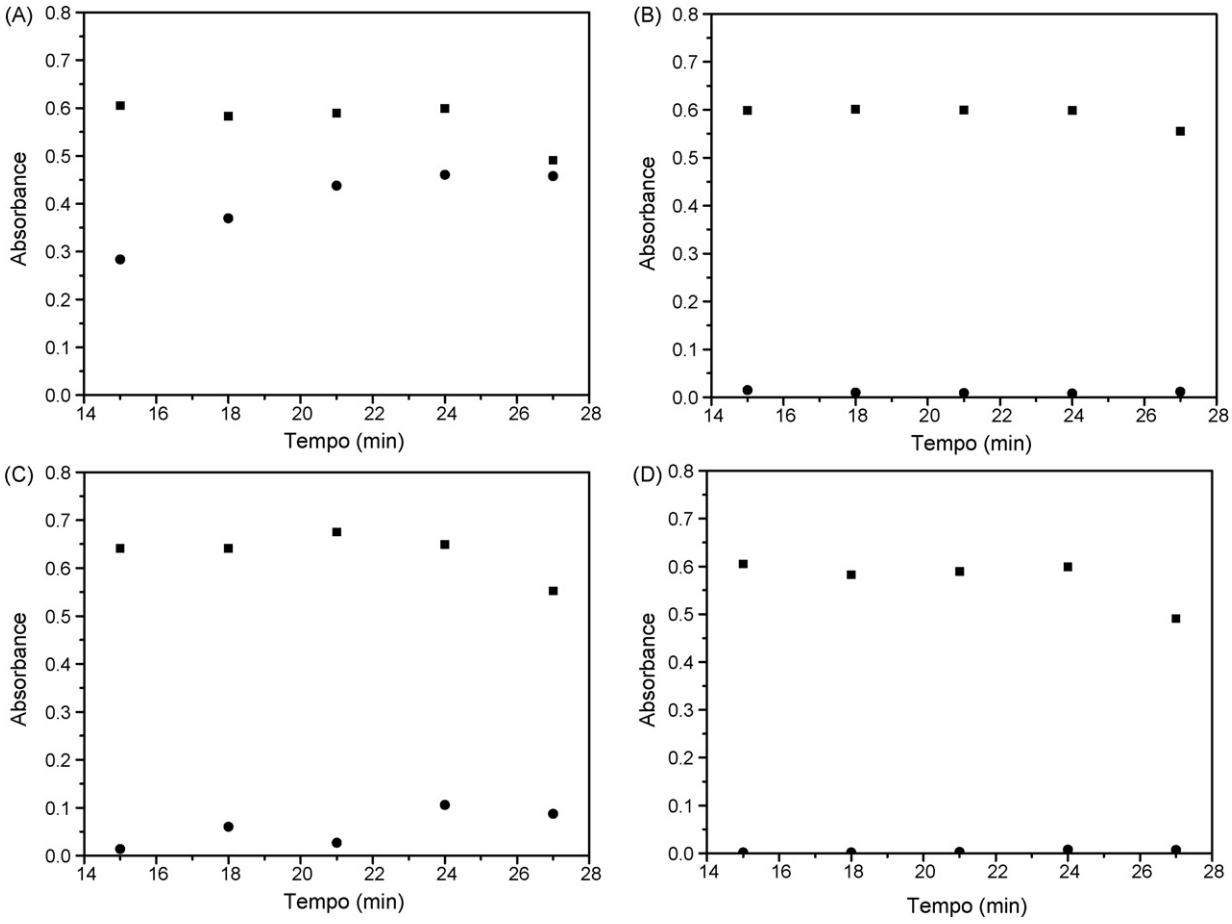

Fig. 1. Measure of the absorbance of ■ As (V) and ● As (III) in function of the time of analysis. 1A – without addition of buffer in the solution of As (V). 1B, 1C and 1D – with addition of 1, 2 and 3 mL of the buffer, respectively.

Table 4
Results of the determination of total arsenic after acid digestion and of total arsenic and As (III) in Marine Sediment Certificated Reference Material after slurry sampling and acid digestion ($n = 3$).

CRM	Certified values As total	Acid digestion As total		Slurry sampling As total		Slurry sampling As (III)	
	($mg\,kg^{-1}$)	($mg\,kg^{-1}$)	RSD%	($mg\,kg^{-1}$)	RSD%	($mg\,kg^{-1}$)	RSD%
MESS-2	20.7 ± 0.8	20.9 ± 0.9	1.7	20.5 ± 1.2	2.4	5.4 ± 0.4	3.0
MESS-3	21.2 ± 1.1	21.6 ± 0.9	0.1	20.2 ± 0.6	1.0	8.7 ± 0.1	0.3

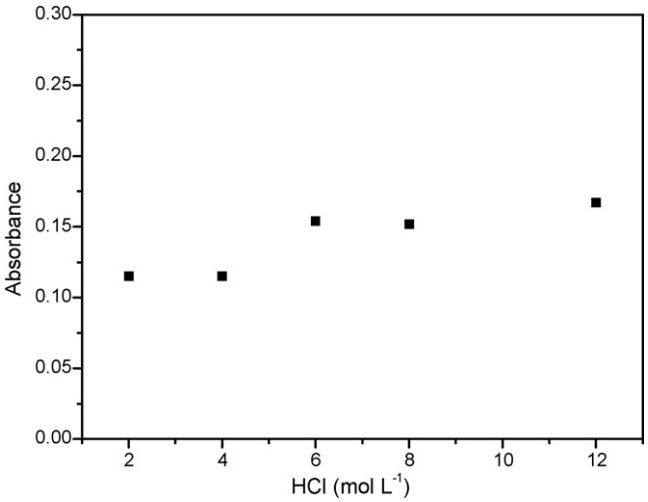

Fig. 2. Measure of the absorbance in function of the concentration of HCl.

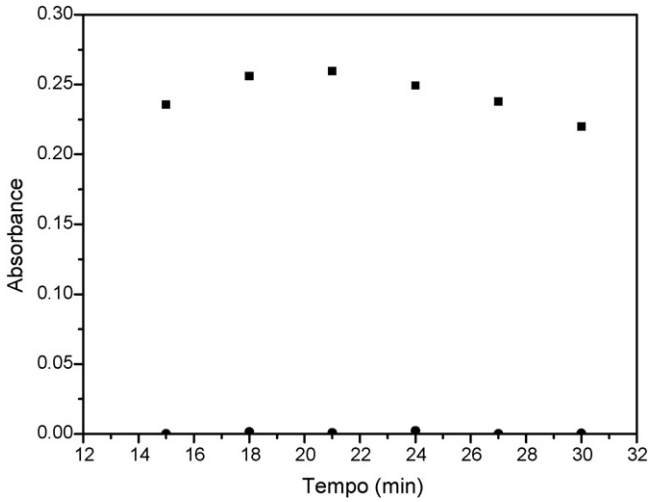

Fig. 3. Measure of analytical signal of ● As (III) and ■ As (V) in function of the time after taken to a bath of ultrasound for 30 min.

to vary with arsenic concentration according to the equation: $Abs = (0.0812 \pm 0.0024)CAs(mL\,\mu g^{-1}) + (0.0193 \pm 0.0042)$, $r2 = 0.9993$ within the linear range of 0.3–5.0 $\mu g\,L^{-1}$. The limits of detection ($3\sigma b/S$) and quantification ($10\sigma b/S$) were calculated as recommended by IUPAC [50], and were found to be 0.1 and 0.3 $\mu g\,L^{-1}$, respectively. These data are in good agreement with the literature values [37,31,51,52].

Standards of As (III) and As (V) were taken to a bath of ultasound for 30 min under the same conditions of samples. There was no significant change in the oxidation state of species after addition of 2 mL buffer (Fig. 3).

The precision (expressed as relative standard deviation) was evaluated during analysis of the four samples, and was found to be less than 8% in each case (Table 4).

The slope of the standard curve for arsenic concentration was found to be $(0.0816 \pm 0.0029)\ C_{As}$ and is quite comparable with the slope obtained by the external calibration technique, $(0.0812 \pm 0.0024)\ C_{As}$. These results demonstrate that the quantification of arsenic in phosphate matrices by slurry sampling can be performed using the external calibration technique with aqueous standard solutions.

The accuracy of the method was evaluated by analyzing marine sediment reference materials: MESS-2 and MESS-3. The certified total arsenic concentrations and the results obtained for As by SS/HG-AAS are presented in Table 4. Measured total arsenic concentrations were in good agreement with certified values.

3.4. Applications

The SS/HG-AAS method was applied for the determination of total arsenic and As (III) in two phosphate fertilizers and two phosphate rock samples. In these samples, total arsenic concentrations varied from 5.2 to 20.0 $mg\,kg^{-1}$ and As (III) concentrations varied from 2.1 to 5.5 $mg\,kg^{-1}$. Measured total arsenic concentrations were in good agreement with the literature values [53,54]. These results, expressed as 95% confidence intervals, are presented in Table 5. As a comparison to the SS-HG/AAS method, triplicate samples were digested with hydrochloric acid and hydrogen peroxide in a closed system prior to total arsenic determination by HG-AAS (Table 5). A statistical comparison using a paired *t*-test [55] (95% confidence level) showed no significant difference between the results obtained by both methods. A linear regression of the results obtained with the two methods followed the equation [slurry sampling] = 0.959 ± 0.046 [digestion method] + 0.259 ± 0.727, $r = 0.9982$.

These results demonstrate that the calculated slope and intercept do not differ significantly from the "ideal" values of 1 and 0, respectively, and that there is no evidence for a systematic difference between the results obtained employing either procedure for the determination of arsenic in the samples under study.

Table 5
Results of the determination of total arsenic and As (III) in phosphate fertilizers and phosphate rocks samples ($n = 3$).

Sample	Acid digestion As total		Slurry sampling As total		Slurry sampling As (III)	
	($mg\,kg^{-1}$)	RSD%	($mg\,kg^{-1}$)	RSD%	($mg\,kg^{-1}$)	RSD%
SSP1	20.4 ± 1.3	1.2	19.5 ± 0.6	2.6	5.5 ± 0.5	1.0
SSP2	13.0 ± 2.9	8.0	12.6 ± 2.5	9.0	7.5 ± 1.0	5.2
PR1	5.1 ± 0.2	1.8	5.2 ± 0.2	1.8	3.9 ± 0.2	2.5
PR2	20.2 ± 1.5	1.3	20.0 ± 0.6	3.0	2.1 ± 0.2	4.6

SSP = phosphate fertilizer (superphosphate simple) and PR = phosphate rocks.

4. Conclusions

The SS/HG-AAS method demonstrated appropriate precision, accuracy, and detection limits for the determination of arsenic in phosphate rocks and phosphate fertilizer. In this work, slurry sampling was found to be a useful extraction technique, particularly given the volatility of arsenic species and the low solubility of phosphate matrices in acid media. Arsenic concentrations found in the four samples analyzed agreed with the literature values for phosphate rocks and commercial phosphate fertilizers.

Cadmium

ABSTRACT

The process of ultrasound-assisted emulsification–microextraction (USAEME) was successfully applied for the first time for the extraction and pre-concentration of trace cadmium from water samples, followed by flame atomic absorption spectrometry (FAAS). In the proposed approach, sodium diethyldithiocarbamate trihydrate solution ($NaDDTC{\cdot}3H_2O$) was used as a chelating agent and carbon tetrachloride was selected as extraction solvent. Some effective parameters on the microextraction and the complex formation were selected and optimized. These parameters included extraction solvent type as well as extraction volume, time, temperature, and pH, the amount of the chelating agent, and salt effect. Under optimum conditions, an enrichment factor of 95 was obtained from only 5.0 mL of water sample. The calibration graph was linear in the range of 10–600 $\mu g\,L^{-1}$ with a detection limit of 0.91 $\mu g\,L^{-1}$. The relative standard deviation (R.S.D) for ten replicate measurements of 50 and 500 $\mu g\,L^{-1}$ of cadmium were 2.56 and 1.62%. This proposed method was successfully applied in the analysis of four real environmental water samples and good spiked recoveries over the range of 96.5–101.7% were obtained.

1. Introduction

Cadmium is known to be highly toxic for animals, plants and humans even at low concentrations and can be accumulated in several organs [1]. Long-term consumption of drinking water containing cadmium at levels higher than 0.005 $mg\,L^{-1}$ can cause nausea, salivation, diarrhea, muscular cramps, renal degradation, lung insufficiency, bone lesions and hypertension in humans [2]. Experimental and epidemiological studies have provided substantial evidence that low levels of long-term exposure to cadmium can attribute to an increased risk of cancer [3]. In light of this, trace determinations of Cd in environmental and in biological samples have become of increasing interest.

Flame atomic absorption spectrometry (FAAS) has been widely used for the determination of trace metal ions because of the relatively simple and inexpensive equipment required. However, direct determination of metal ions at trace levels by FAAS is limited not only due to insufficient sensitivity, but also to matrix interference. Under these circumstances, in order to determine trace levels of Cd, a separation and enrichment step prior to their determinations may be beneficial. Several methods have been proposed for separation and pre-concentration of trace Cd including: Liquid–liquid extraction (LLE) [4–7], coprecipitation [8,9], solid phase extraction (SPE) [10,11], and cloud point extraction (CPE) [12,13]. However, liquid–liquid extraction (LLE), as the oldest preconcentration and separation technique in analytical chemistry [14], is time-consuming and requires large amounts of organic solvents [15]. Compared with LLE, SPE offers simpler operation, a higher enrichment factor, and ease of automation, but the amounts of elution solvents are still relative large [16,17]. CPE is a comparatively simple, cheap and less toxic method [18,19], but it too has several limitations associated with it. For instance, because of the viscosity of the surfactant-rich phase, samples prepared this way cannot be injected directly into conventional analytical instruments. As well, the surfactants bear chromophores, which interfere with the UV detection by overlapping with the analyte signal [17].

Modern trends in analytical chemistry lean towards the simplification and miniaturization of sample preparation, as well as the minimization of the organic solvent used. Jeannot and Cantwell developed a liquid-phase microextraction (LPME) technique in 1996, which is based on analyte partition between a drop of organic solvent (extraction phase) and the aqueous sample bulk [20]. Several different types of LPME have been developed, including single drop microextraction (SDME) [21–23], hollow fiber LPME [24,25] and homogeneous liquid–liquid extraction (HLLE) [26,27]. Microextraction techniques are fast, simple, inexpensive,

doi:10.1016/j.talanta.2009.08.029

environmentally friendly and compatible with many analytical instruments. Nevertheless some drawbacks, such as instability of the droplet and relatively low precision are often reported [28].

Recently, Assadi and co-workers developed a novel microextraction technique, termed dispersive liquid–liquid microextraction (DLLME) [29]. This technique is based on the formation of tiny droplets of the extractant in the sample solution using a water-immiscible organic solvent (extractant) dissolved in a water-miscible organic dispersive solvent [30–32]. The advantages of the DLLME method are rapidity, low cost, and high enrichment factors. Its main drawback is the necessity of using a third component (disperser solvent), which usually decreases the partition coefficient of analytes into the extraction solvent [33].

Ultrasonic energy, when applied to solutions, causes acoustic cavitation: That is, bubble formation and implosion. The collapse of bubbles formed by ultrasonic energy results in the generation of extremely high temperatures and pressures at the interface of the collapsing bubble and another phase, leading to enhanced chemical reactivity [34]. The combination of microextracting systems and ultrasound radiation provides an efficient pre-concentration technique, named ultrasound-assisted emulsification–microextraction (USAEME). USAEME is based on the implosion bubbles generated by the cavitation phenomenon, which produces intensive shock waves in the surrounding liquid and high-velocity liquid jets. Such microjets can cause droplet disruption in the vicinity of collapsing bubbles and thus, improve emulsification by generating a smaller droplet size of the dispersed phase right after disruption. Submicron droplet size leads to significant enlargement of the contact surface between both immiscible liquids, improving the mass-transfer between the phases [35]. In USAEME, the appropriate extraction solvent is rapidly injected by syringe into aqueous samples containing analytes. After sonication, a cloudy solution forms. Then, this cloudy solution is centrifuged and the fine droplets sediment at the bottom of the conical test tube. The determination of analytes in the sedimented phase can be performed by instrumental analysis. In fact, this pre-concentration technique has been developed by Regueiro et al. [33] for the determination of synthetic musk fragrances, phthalate esters and lindane in aqueous samples. They demonstrated that USAEME is an efficient, simple, and nonexpensive extraction procedure for GC analysis. Up to now, it has been also used for the pre-concentration of polybrominated diphenyl ethers and polychlorinated biphenyls from water samples [32,35]. We extend its application to inorganic analysis, and have obtained the consistent conclusion.

This paper describes the first application of ultrasound-assisted emulsification–microextraction for the determination of trace cadmium in water samples without the addition of the dispersive solvent, thereby overcoming DLLME disadvantages. In order to obtain a high enrichment factor, the effect of different parameters affecting the complex formation and extraction conditions (such as type and volume of the extraction solvent, pH, the chelating agent amount, extraction time, extraction temperature and ionic strength) were tested. USAEME can be employed as a simple and efficient extraction and pre-concentration procedure for heavy metals in aqueous samples with satisfactory results.

2. Experimental

2.1. Apparatus

The experiments were performed with a Hitachi Z-5000 atomic absorption spectrometer (Japan) equipped with Zeeman background correction. A cadmium hollow cathode lamp operating at 228.8 nm was utilized as the radiation source. The instrumental parameters were adjusted according to the manufacturer's recommendations. All pH measurements were carried out using a pH_3-3C digital pH meter equipped with a combined glass-calomel electrode (Hangzhou Dongxing Instrument Factory, Hangzhou, P.R.China). A Model LD5-2A centrifuge (Beijing Jingli Instrument Factory, Beijing, P.R.China) was used to accelerate the phase separation. A 59 kHz, 200 W ultrasonic bath with temperature control (Shanghai Kudos Ultrasonic instrument Co, Ltd., Shanghai, P.R.China) was used to assist the emulsification process of the microextraction technique.

2.2. Reagents and solutions

A stock standard solution of cadmium at a concentration of 1000 $\mu g\,mL^{-1}$ was purchased from the National Institute of Standards (Beijing, China). Working standard solutions were prepared by serial dilutions of the stock solution with deionized water immediately prior to analysis. The chelating agent, 0.5 $g\,L^{-1}$ sodium diethyldithiocarbamate trihydrate solution ($NaDDTC{\cdot}3H_2O$), was prepared by dissolving the appropriate amount of $NaDDTC{\cdot}3H_2O$ (Beijing Chemistry Reagent Company, Beijing, China) in water. The NaCl solution was prepared by dissolving the appropriate amount of NaCl in deionized water. Carbon tetrachloride, chloroform and dichloromethane as extraction solvent were obtained from Tianjin Tianda Chemicals Reagent Company (Tianjin, China).

Nitric acid (0.1 $mol\,L^{-1}$) was used to adjust the pH 2–3, ammonium acetate buffers (0.2 $mol\,L^{-1}$) were prepared by adding an appropriate amount of acetic acid to ammonium acetate solutions resulting in solutions of pH 4–6. For pH 7–8, a phosphate (0.2 $mol\,L^{-1}$) buffer solution was prepared by adding an appropriate amount of disodium hydrogen phosphate to sodium dihydrogen phosphate. Ammonium chloride buffer solutions (0.2 $mol\,L^{-1}$) were prepared by adding an appropriate amount of ammonia to ammonium chloride solutions, resulting in solutions of pH 9–10.

All reagents used were of analytical reagent grade. Deionized water was used in the preparation of all solutions. The laboratory glassware was kept in 10% nitric acid for at least 24 h and subsequently washed four times with deionized water.

Tap, sea, river and waste water samples used for development of the method were collected in polytetrafluoroethylene (PTFE) containers from Hebei province, filtered using a 0.45 μm pore size membrane filter to remove suspended particulate matter, and stored in a refrigerator in the dark.

2.3. Ultrasound-assisted emulsification–microextraction procedure

A 5.0 mL sample of standard solution containing 500 $\mu g\,L^{-1}$ of cadmium was poured in a test tube with a conical bottom. 1.0 mL acetate buffer and 2.0 mL $NaDDTC{\cdot}3H_2O$ (0.5 $g\,L^{-1}$) solution were added. Then, 100 μL of carbon tetrachloride (extraction solvent) was injected rapidly into the sample solution using a syringe. The tube was immersed into an ultrasonic bath for 20 min at 50 °C. As a result, oil-in-water (O/W) emulsions of carbon tetrachloride (dispersed phase) in water (continuous phase) were formed. Emulsions were then disrupted by centrifugation at 4600 rpm for 5 min, which resulted in the organic phase sedimenting at the bottom of the conical tube. The sedimented phase was quantitatively transferred to another test tube and the solvent was allowed to evaporate at room temperature. Finally, the residue was dissolved in 0.5 mL 0.1 $mol\,L^{-1}$ nitric acid and the cadmium concentration was determined by flame atomic absorption spectrometry. Fig. 1 shows a scheme of the USAEME procedure.

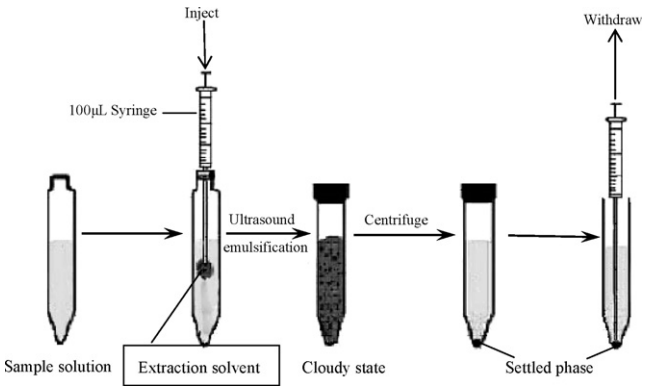

Fig. 1. Ultrasound-assisted emulsification–microextraction procedure.

3. Results and discussion

3.1. Effect of type and volume of the extraction solvent

Extraction solvent should have special characteristics: it should have a higher density than water, high extraction capability of the interested compounds and low solubility in water. Chloroform ($CHCl_3$), carbon tetrachloride (CCl_4) and dichloromethane (CH_2Cl_2) were examined in the extraction of cadmium.

The compatibility of these solvents with the USAEME technique was studied by adding 100 μL of each of the solvents mentioned above to a 5.0 mL aqueous solution containing 500 $\mu g\,L^{-1}$ of cadmium. Dichloromethane was completely dissolved in the ultrasonic process. Therefore, this solvent was ruled out for further optimization. Chloroform and carbon tetrachloride as extraction solvents resulted in enrichment factors of 50 and 95, respectively. Conversely, in comparison of these two extraction solvents, carbon tetrachloride forms a well stable cloudy solution; the sedimented phase can easily be removed by sampler and has less consumption volume to obtain the 80 μL sedimented phase. Therefore, Carbon tetrachloride was selected as the extraction solvent for further studies.

In order to obtain the highest extraction efficiency of the USAEME procedure, the extraction solvent volume was optimized. For this purpose, different volumes of carbon tetrachloride in the range of 50–130 μL were examined in the extraction procedure. It was found that by increasing the volume of CCl_4, the analytical signal increases, reaching the maximum value at 100 μL, after which, remained constant. Therefore, in the subsequent studies, 100 μL carbon tetrachloride was used as the optimum volume of the extraction solvent.

3.2. Influence of pH

The separation of metal ions by USAEME involves prior formation of a complex with sufficient hydrophobicity to be extracted into the small volume of the sedimented phase, whereby the desired pre-concentration is obtained. pH plays a unique role on metal-chelate formation and subsequent extraction. The effect of pH on the complex formation and extraction of cadmium from water samples was studied in the range of 2.0–10.0 by using nitric acid, ammonium acetate, phosphate and ammonium chloride. As can be seen in Fig. 2, the highest signal intensity of Cd was obtained at pH 6.0. Therefore, pH 6.0 was selected for further study.

3.3. Influence of the amount of NaDDTC·3H$_2$O

The effect of the amount of NaDDTC·3H_2O (0.5 $g\,L^{-1}$) on the absorption was studied using various volumes of the reagent ranging from 0.5 mL to 3.0 mL. The results showed that the signal of Cd was increased with the increase of NaDDTC·3H_2O volume up to 1.6 mL, and then remained constant. Hence, 2.0 mL of 0.5 $g\,L^{-1}$ NaDDTC·3H_2O solution was chosen to account for other extractable species that might potentially interfere with the assaying of cadmium.

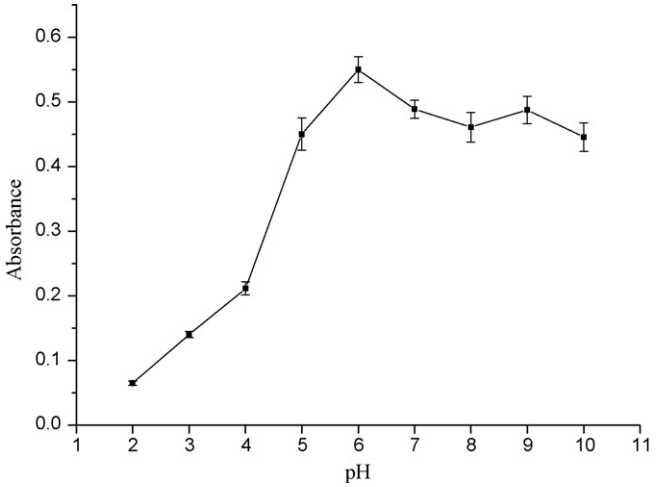

Fig. 2. Effect of pH on the absorbance of Cd obtained from USAEME. Extraction conditions: water sample volume, 5.0 mL; DDTC volume, 2.0 mL; extraction solvent (CCl_4) volume, 100 μL; concentration of Cd, 500 $\mu g\,L^{-1}$; extraction time, 20 min; extraction temperature, 50 °C.

3.4. Effect of the extraction time

Time plays an important role in the emulsification and mass-transfer phenomena. In USAEME, extraction time is defined as the time between injection of extraction solvent and the end of the sonication stage. The effect of extraction time was examined in the range of 5–35 min under constant experimental conditions. It was found that by increasing the extraction time, the absorbance increases reaching a plateau at 20 min, which is considered as 100% extraction. Therefore, 20 min extraction time was chosen as the working condition for further studies.

3.5. Effect of extraction temperature

Temperature affects organic solvent solubility in water as well as the emulsification phenomenon. Thus, this affects the mass-transfer process and the extraction efficiency. To determine the influence of the extraction temperature, 5.0 mL aqueous solution containing 500 $\mu g\,L^{-1}$ of cadmium was extracted at different temperatures ranging from 20 °C to 70 °C. At temperatures lower than 40 °C, it was difficult to get a homogeneous emulsion resulting in a prompt phase separation. Therefore, the mass-transfer process was limited to a short amount of time, leading to poor extraction efficiency, and consequently low absorbance. In the 40–60 °C temperature range, the emulsification was easily achieved and the highest absorbance obtained at 50 °C. At a temperature higher than 60 °C, carbon tetrachloride was partially dissolved into the aqueous bulk, leading to the reduction of the analytical signal. Hence, 50 °C is recommended for further studies.

3.6. Effect of salt

For investigating the influence of ionic strength on performance of USAEME, various experiments were performed by adding varying NaCl amounts from 0% to 5% (w/v). Other experimental conditions were kept constant. By increasing the NaCl from 0% to

Table 1
Effect of interferents on the recovery of 500 μg L^{-1} Cd^{2+} in water sample using USAEME–FAAS.

$Cr_2O_7^{2-}$	50,000	100	97.2
PO_4^{3-}	50,000	100	94.8

5%, the volume of the sedimented phase increases slightly from 80 μL to 83 μL. The results showed that salt addition has no significant effect on the enrichment factor, perhaps because of the two opposite effects of salt addition in USAEME of cadmium: one involves increasing the volume of the sedimented phase, which decreases the enrichment factor, and the other is the salting-out effect that increases the enrichment factor [36,37]. Therefore, the enrichment factor is nearly constant by increasing the amount of sodium chloride, and the extraction experiments were carried out without adding salt.

3.7. Effect of coexisting ions

The effects of common coexisting ions in natural water samples on the recovery of cadmium were studied. In these experiments, 5.0 mL solutions containing 500 μg L^{-1} of cadmium and various amounts of interfering ions were treated according to the recommended procedure. A given species was considered to interfere if it resulted in a ± 5% variation of the absorbance signal. The results obtained are given in Table 1.

3.8. Analytical figures of merit

In the optimum conditions, a calibration graph was obtained by preconcentrating a series of the solutions according to procedure under experiment. Table 2 shows the analytical characteristics of this method. The calibration graph was linear in the range of 10–600 μg L^{-1} of cadmium. The equation of the calibration curve after the pre-concentration procedure was given as $A = 1.75 \times 10^{-3}C + 0.0202$ with a correlation coefficient of 0.9954 ($n = 10$), where A is the atomic absorbance for cadmium in the rich phase at 228.8 nm and C is the concentration of cadmium in the sample solution in μg L^{-1}. The limit of detection, defined as $C_L = 3S_B/m$ (where C_L, S_B and m are the limit of detection, standard deviation of the blank and slope of the calibration graph, respectively), was 0.91 μg L^{-1}. The relative standard deviation (R.S.D) for ten replicate measurements of 50 and 500 μg L^{-1} of cadmium were 2.56 and 1.62%. Table 2 also shows the calibration obtained with standard solutions of Cd not subjected to the USAEME preconcentration step. Phase volume ratio, calculated as the ratio between the volume of the aqueous phase (8.0 mL) and the final injection volume (0.5 mL nitric acid containing the analyte), was 16 times.

Table 2
Analytical characteristics of the method.

Analytical parameters	Without USAEME preconcentration	With USAEME preconcentration
Linear range (μg L^{-1})	100–6000	10–600
Slope	1.31×10^{-4}	1.75×10^{-3}
Intercept	0.0155	0.0202
Correlation coefficient	0.9972	0.9954
Detection limit (μg L^{-1})	13.78	0.91
Relative standard deviation (R.S.D%) ($n = 10$)	3.62 (200 μg L^{-1})	2.56 (50 μg L^{-1})
	3.20 (500 μg L^{-1})	1.62 (500 μg L^{-1})
Phase volume ratio	–	16
The enrichment factor[a]	–	95
The enrichment factor[b]	–	15.3
The enhancement factor[c]	–	13.4

[a] The enrichment factor is the ratio of the cadmium concentration in the organic-rich phase(80 μL) to that in the bulk phase initially.
[b] The enrichment factor is the ratio of the cadmium concentration in 0.5 mL 0.1 mol L^{-1} nitric acid to that in the bulk phase initially.
[c] The enhancement factor is the slope ratio of calibration graph after and before extraction.

The enrichment factor (EF) [3,38] is defined as the ratios of the cadmium concentration in the organic-rich phase to that in the bulk phase, initially. Eq. (1) was used for calculation of the enrichment factor:

$$EF = \frac{C_{sed}}{C_0} \quad (1)$$

where C_{sed} is cadmium concentration (μg L^{-1}) in the organic-rich phase after phase separation (80 μL organic-rich phase) and C_0 is the initial concentration of cadmium (μg L^{-1}). The enrichment factor was obtained as 95 ($n = 3$).

As for the determination of the absorbance for cadmium in the organic-rich phase, the extraction solvent (80 μL) was evaporated at room temperature, Finally, the residue was dissolved into 0.5 mL 0.1 mol L^{-1} nitric acid; the enrichment factor for the proposed method is 15.3.

The enhancement factor [39,40], defined as the ratio of the slope of the calibration graph for the USAEME method, to that of the calibration graph in water phase without pre-concentration, was 13.4.

3.9. Analysis of natural waters

The proposed method was used for the determination of cadmium in several water samples and the results along with the recovery for the spiked samples were given in Table 3. The recoveries for the addition of different concentrations of cadmium to water samples were in the range 96.5–101.7%. To verify the accuracy of the proposed procedure, the method was then used for the determination of the content of Cd in National Standard Reference Material for Environment Water (GSBZ50009-88 and GSB07-1185-2000) after the appropriate dilution. These results are presented in Table 3. A good agreement between the determined values and the certified values was obtained.

Table 3
Analytical results of cadmium determination (dissolved fraction) in certified reference materials and spiked natural water samples with the USAEME–FAAS method ($n = 3$).

Sample	Certified	Added	Found[a]	Recovery (%)

4. Conclusions

USAEME combined with the flame atomic absorption spectrometry (FAAS) was evaluated for the pre-concentration and the determination of the trace amounts of cadmium (at $\mu g L^{-1}$ level) from water samples. USAEME is a sensitive, efficient, and simple method for pre-concentration and separation of trace metals with the use of low sample volumes. A high enrichment factor was easily obtained using this method. In addition, it is important to point out that USAEME is a low organic solvent consuming extraction technique, which turns it into a low cost and also an environmentally friendly technique [29]. In this method, the consumption of the toxic organic solvent (at μL level) was minimized without affecting the method sensitivity. Although the obtained results of this research were related to the cadmium determination, the system could be readily applied to the determination of other metals with the help of various chelating agents, extractable by other organic solvents.

ABSTRACT

The aim of this work is to describe the first example of aptameric molecular beacon (MB)-based probe for the detection of recombinant human erythropoietin (rHuEPO-α) in physiological buffer, using a novel 35 nt ssDNA aptamer (807–35 nt) originally isolated by Systematic Evolution of Ligands by Exponential enrichment (SELEX) technique in our laboratory. Both "Signal-on" and "Signal-off" MB modes were developed, respectively, in which the conformational alteration of aptamer before and after binding to rHuEPO-α can be demonstrated in terms of the correspondingly fluorescent changes. Comparing with "Signal-off" mode, "Signal-on" mode provided higher sensitivity, while with the addition of target rHuEPO-α, quenching between fluorescent 807–35 nt aptamer (F-Apt) and a short quencher-labeled complementary sequence (QDNA) was disturbed by the specific binding between rHuEPO-α and F-Apt. QDNA was thus loosened and released from F-Apt, leading to a consequently full fluorescent restoration. Systematic optimization of parameters in "Signal-on" mode were carried out, the choice of QDNA length, the hybridization site of a small supplementary DNA (SDNA) stabilizer, and the existence of Mg^{2+} cation played essential roles for the performance characterization. A convenient and sensitive determination of rHuEPO-α with a LOD of 0.4 nM was achieved.

1. Introduction

Erythropoietin is an endogenously hematopoietic growth factor, which can regulate erythropoiesis production by promoting the proliferation and differentiation of erythroid progenitor cells and maintains the red blood cell mass at an optimum level [1]. Recent development of biological recombinant techniques has allowed large scale production of biologically active erythropoietin called recombinant human EPO (rHuEPO) as pharmaceuticals for anaemia treatment in clinic. Meanwhile, rHuEPO was a kind of famous doping hormone which was strictly prohibited by International Olympics Committee [2,3], due that it can enhance the performance of athletes in endurance competition sports by stimulating more production of new red blood cells and boosting delivery of oxygen to the tissues. Immunological assays have the main applications in monitoring this widespread recombinant glycoprotein drug [4–6], but how to overcome the interference and narrow the specificity of anti-rHuEPO antibodies is still a challenge. For example, anti-rHuEPO monoantibody (mAb) AE7A5 was widely adopted in the assays as the capturing or probing molecules, but it has a broad cross-reactivity with eukaryotic or bacterial proteins, even human urothelium tissue [7]. In comparison with antibody, aptamers, known as "chemical antibodies", have a number of advantages such as higher specificity and affinity, non-immunogenic, stable, robust against denaturation, ease of chemical modification and ease of being synthesized, which would offer an alternative and novel way for the detection of rHuEPO-α in the analytical field.

Aptamers are the artificial single-stranded (ss) DNA or RNA sequences generated by an *in vitro* selection technique known as SELEX from an oligonucleotide pool with immense combinatorial random sequences [8–11]. They have attracted much attention as biosensors for many important biomedical targets, such as metal ions, peptides, proteins and even intact cell [12,13]. The oligonucleotide aptamers are one kind of excellent recognition module, they exert specific binding capability for the targets by the shape fit, *i.e.*, by forming special three-dimensional structures. These spatial structures are the natural result of their complicated secondary structures including partial Watson-Crick, Hoogsteen hydrogen bonds, hairpins, loops and bulges, *etc.* Particularly, aptameric MB sensors attract great concern in the diagnostics area in recent years, because the recognition events can be easily reflected by the Signal changes of an oligonucleotide ssDNA aptamer, and the fast, simple and cost-effective determination of targets can thus be achieved [14]. It is reported that MB are DNA sequences composed of one target recognition region of about 30 bases flanked by two short complementary stem sequences, which force the entire

sequence to form a stem-loop structure in the absence of a target [15].

In our recent work, we have firstly *in vitro* isolated a series of anti-rHuEPO-α ssDNA aptamers, in which aptamer 807 is a prevalent sequence (55% in 42 clones) [16]. The binding capacity of random sequence 807-39 nt was almost identical with the full sequence 807 (Fig. S1). The secondary hairpin structure of 807-39 nt meets the prerequisite of MB probe quite well, its loop would function as a recognition site, and its stem as a support. That makes aptamer 807-39 nt as an ideal framework to build signal transduction module. Therefore, a convenient aptameric MB approach was constructed in this paper, both "Signal-off" and "Signal-on" MB modes were investigated. Fluorescent conformational changes could be observed when the specific binding between aptamer and rHuEPO-α occurred. Systematic optimization on conditions in the case of "Signal-on" MB mode were undertaken by examining the quencher-labeled DNA (QDNA) length and concentration, the hybridization site of a short supplementary DNA (SDNA), the role of metal ions, and the concentration of glycerol as a fluorescence stabilizer. Finally a LOD of 0.4 nM for rHuEPO-α was achieved.

2. Experimental

2.1. Chemical and reagents

rHuEPO-α (3.89 mg/mL, purity higher than 98.5%) was donated by SCIPROGEN Bio-pharmaceutical Company (Shenzhen, China). Fluorophore and quencher dual end-labeled MB, fluorophore single end-labeled MB, QDNA and SDNA were synthesized in Shanghai Sangon Biological Engineering Technology & Services Company (Shanghai, China) (Table 1). In the dual end-labeled MB (FQ-Apt) and single end-labeled MB (F-Apt/QDNA) sequences, 6-carboxyfluorescein (6-FAM) and 4-(4′-dimethylaminophenylazo) benzoic acid (DABCYL) are used as the fluorophore and quencher groups, respectively. HSA, hemoglobin and cytochrome C were obtained from Sigma-Aldrich (St. Louis, Mo, USA). BSA and lysozyme were purchased from Shanghai Sangon Biological Engineering Technology & Services. Ig G was purchased from Tianlai Bioengineering Company (Beijing, China). Globin was purified by our laboratory. All other reagents were of analytical purity and obtained from Beijing Chemical Company (Beijing, China). The physiological buffer as well as the selection buffer consisted of 20 mM Tris, 140 mM NaCl, 5 mM $MgCl_2$ and 5 mM KCl (pH 7.4). Deionized, distilled water was purified from a Milli-Q water purification system (Millipore, France).

2.2. Measurements

All fluorescence experiments were performed on a HITACHI F4010 spectrofluorometer, using a 0.5 mL quartz cuvette as the sample cell. The fluorescence emission spectra of the aptameric MB were obtained from 510 nm to 600 nm with an excitation wavelength fixed at 494 nm ("Signal-on" mode) or 488 nm ("Signal-off" mode), respectively. The slit widths of excitation and emission were set at (5 nm and 10 nm) and (10 nm and 10 nm) for "Signal-on" and "Signal-off" modes, respectively. The concentrations of F-Apt and FQ-Apt in all samples were 10 nM. Prior to the fluorescent determination, the aptameric MB was denatured at 94 °C for 5 min and annealed at the optimum condition, then mixed with rHuEPO-α in selection buffer and incubated at room temperature for 1 h. The titration curves were ploted as quenching percentage ($y = (\bar{F}_0 - F)/\bar{F}_0$) or as $\Delta F(y = F - \bar{F}_0)$ versus increasing concentration of rHuEPO-α (x) for "Signal-off" and "Signal-on" mode, respectively. To examine the specificity of the aptameric molecular beacon for "Signal-on", other proteins were used, including HSA, BSA, IgG, hemoglobin, globin, lysozyme and cytochrome C.

2.3. Gel electrophoresis

Electrophoretic gel mobility shift assay was used to confirm the binding between rHuEPO-α and the MB. Aptamer 807–35 nt, FQ-Apt2 and F-Apt (1 μM) were incubated with rHuEPO-α (1 μM) in physiological buffer for 1 h at room temperature, respectively. Electrophoresis was performed on 12% non-denatured polyacrylamide gel electrophoresis at 22 V/cm for 1 h at 4 °C. The gel was stained in ethidium bromide and analyzed by UVP VisionWorks™LS Image System.

2.4. Determination of K_d and T_m

To calculate the K_d values, the changes of fluorescence intensity or the quenching percentage versus increasing rHuEPO-α concentrations (x) was plotted, and the data points were fitted by the non-linear regression analysis based on one-site direct binding model with the following equation using Originpro 7.5 software (OriginLab, USA):

$$y = \frac{B_{max} \cdot x}{K_d + x} \quad (1)$$

where B_{max} is the degree of saturation, and K_d is the dissociation constant.

T_m values for short probe (<15 nt) were determined by the Wallace rule [17]:

$$T_m = 2\,^\circ\mathrm{C}(A + T) + 4\,^\circ\mathrm{C}(C + G) \quad (2)$$

where T_m = temperature (°C) at which 50% of the oligonucleotides are annealed to its complementary sequence. The number of each particular nucleotide in the sequence is inserted into the equation in place of the letters. When the sequence is free in solution, add 7–8 °C to T_m.

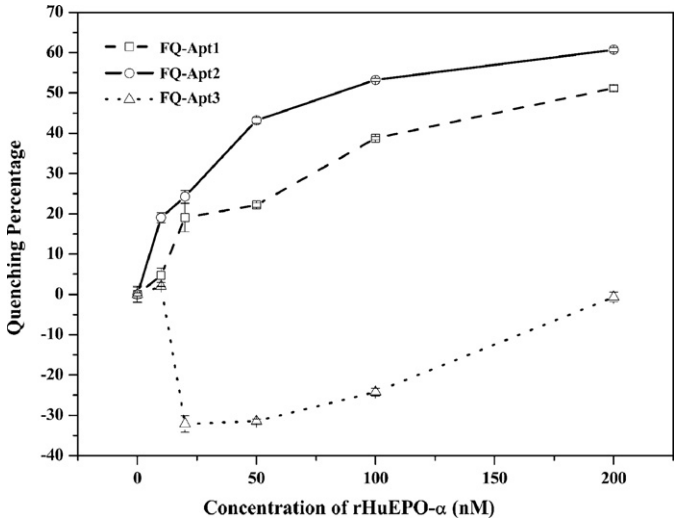

Fig. 1. The titration curves of the "Signal-off" aptameric MB mode. FQ-Apt (10 nM) of different stem length was titrated with increasing concentration of rHuEPO-α from 0 nM to 200 nM in the physiological buffer (20 mM Tris, 140 mM NaCl, 5 mM $MgCl_2$, 5 mM KCl; pH 7.4). Data are reported as mean ± SD values with RSD < 5.0% ($n = 3$).

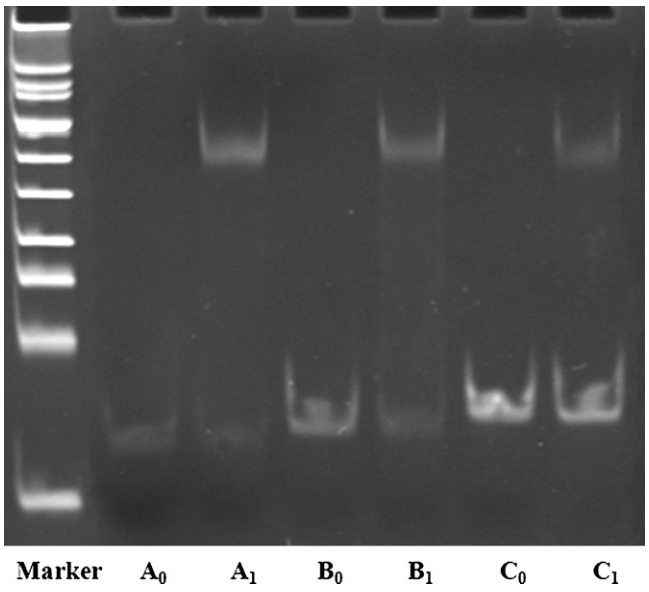

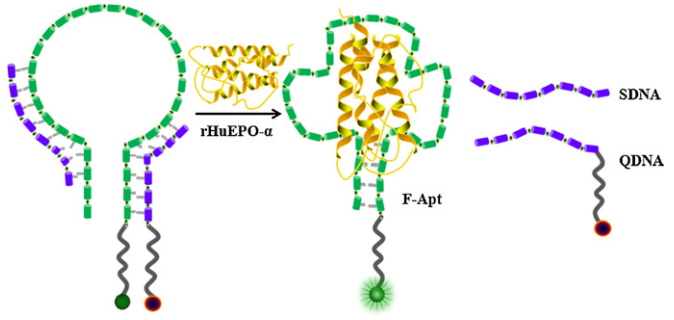

Fig. 2. Binding experiments of aptamer 807–35 nt with or without labeling group and rHuEPO-α in PAGE. Lanes X_0 and X_1 represent aptamer alone and aptamer with the addition of rHuEPO-α (1 μM). *X* represents A, B and C. A: 807–35 nt (1 μM); B: FQ-Apt2 (1 μM); C: F-Apt (1 μM), QDNA1 (10 μM).

3. Results and discussion

3.1. Design of "Signal-off" and "Signal-on" aptameric MB

Based on the simulated secondary stem-loop structure of our selected aptamer 807-39 nt by M-fold [18] (Fig. S2), a dual end-labeled design was chosen as a readily start to test the possibility in formation of MB alike structure [19]. Binding of dual end-labeled MB with rHuEPO-α target brought the fluorophore and quencher in close proximity, resulted in the decrease of fluorescence. The stems with 3 bp (FQ-Apt3)/4 bp (FQ-Apt2)/5 bp (FQ-Apt1) in the dual end-labeled MB form were investigated, respectively (sequences shown in Table 1), and 4 bp (FQ-Apt2) in the stem was found to be the minimum length to achieve the specific recognition. FQ-Apt2 (807–35 nt) was then considered as the shortest motif for binding with rHuEPO-α. The addition of rHuEPO-α mainly facilitates the forming and stabilizing of stem-loop structure of FQ-Apt2, drawing the distance closer between fluorophore and quencher. Because the fluorescent change is limited to the close proximate extent of fluorophore and quencher groups, a detection concentration of 10 nM rHuEPO-α was merely obtained by "Signal-off" mode (Fig. 1).

Another single-labeled "Signal-on" mode was followed on the fully utilization of the stem and loop binding ability of 807–35 nt aptamer for the target protein, it can further increase the detection sensitivity as expected (Scheme 1). In this "Signal-on" design, toward a single 3′ end-labeled F-Apt, a short 5′-end quencher-labeled complementary QDNA sequence was employed and the fluorescence background became "darken". When the "Signal-on" system was exposed to rHuEPO-α, QDNA was departed from F-Apt and the fluorescent signal was restored. This kind of structural-switching approach is obviously leading to an increase of a fluorescent signal.

Scheme 1. Illustration of "Signal-on" mode using 807–35 nt aptamer.

The fluorescent signal change either in "Signal-off" or "Signal-on" mode was indeed induced by the aptamer-target complexation by using binding experiments in gel electrophoresis. As shown in Fig. 2, aptameric MBs both adopted in "Signal-off" and "Signal-on" modes still maintain the binding ability with rHuEPO-α. The complex of MB with rHuEPO-α shifted slowly than free MB, and the binding capacity is not weaken by the labeling in comparison with the non-labeled aptamer 807–35 nt. Furthermore, since the degree of fluorescence recovery is depended on the binding ability of aptamer for rHuEPO-α, which is a reflection of the aptamer's spatial structure. Several factors that can affect the folding and binding efficiency of aptamer should be optimized firstly.

3.2. Systematic optimization on "Signal-on" mode

To achieve the most sensitivity of this aptameric MB-based fluorescent "Signal-on" mode, how to eliminate the background fluorescence and how to fully regenerate the inherent fluorescence of F-Apt in the presence of rHuEPO-α are both the key considerations. Such parameters as length and concentration of QDNA, the hybridization site of a short SDNA stabilizer, the role of metal ions, and the concentration of glycerol as a fluorescence stabilizer are systematically investigated.

3.2.1. The length and concentration of QDNA

QDNA adopted here should meet two points. One point is to hybridize with the 3′-end stem of F-Apt so as to compose a fluorescent quenching resonance energy transfer, and the other is to be a displaceable element when the rHuEPO-α as a competitor added. Only the suitable length of QDNA can offer both low background fluorescence in the absence of the target and a possibility for fast structural switching when the target is present [20]. In a series of

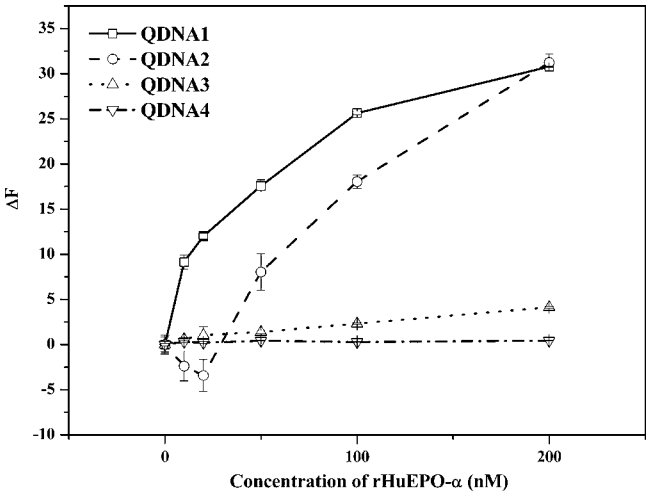

Fig. 3. Effects of QDNA length on the "Signal-on" aptameric MB mode. F-Apt (10 nM) and QDNA (100 nM) with different length were titrated with increasing concentration of rHuEPO-α from 0 to 200 nM in the physiological buffer. Data are reported as mean ± SD values with RSD < 7.0% (n = 3).

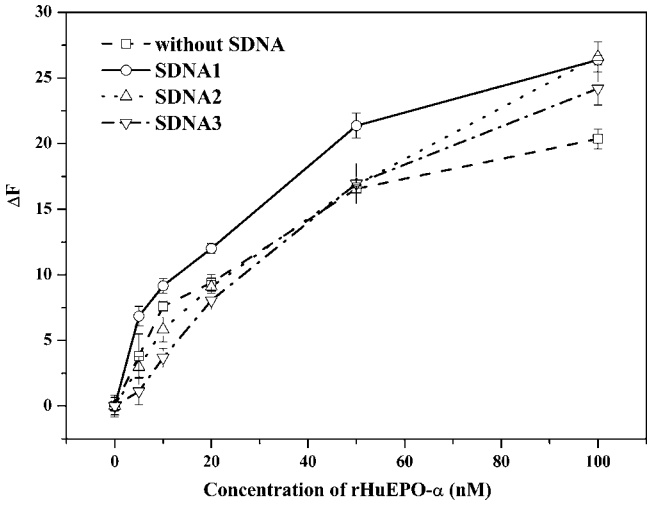

Fig. 5. Effects of the hybridization site of SDNA on the "Signal-on" aptameric MB mode. Concentrations of F-Apt, QDNA1 and SDNA were 10 nM, 100 nM and 100 nM, respectively. The MB solution was titrated against increasing concentration of rHuEPO-α (0–100 nM) in physiological buffer. Data are reported as mean ± SD values with RSD < 4.0% (n = 3).

QDNAs with different lengths, QDNA1 (7 nt), QDNA2 (8 nt), QDNA3 (10 nt) and QDNA4 (12 nt), QDNA1 shows the best signal response. The background of fluorescence was more decreased when QDNA with excess length (QDNA2-4) was added, but the specific competition ability of F-Apt was obviously weaken in some extent (Fig. 3). A possible explanation is QDNAs with excess complementary bases would produce a more tight duplex structure in MB, which induce the partially hybridized F-Apt is hardly to effectively bind with rHuEPO-α.

The fluorescent intensities of system background and the signal restoration with target addition were also influenced by the concentration of QDNA. The results showed that addition of 50 nM or 100 nM QDNA1 had the almost same contribution to the recovery of fluorescence, and lower background was obtained with 100 nM QDNA1. Although background of fluorescence is decreased by the higher concentration of QDNA1 (150 nM), the addition of excess QDNA1 would lead to fluorescence self-quenching, which affected the restoration of fluorescence (Fig. 4).

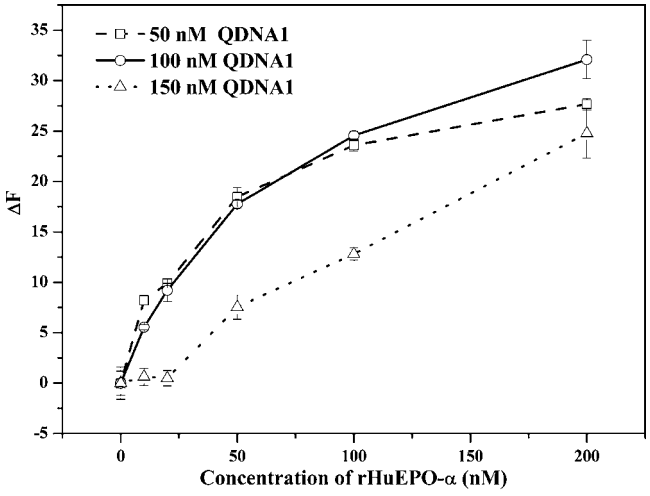

Fig. 4. Effects of QDNA1 concentration on the "Signal-on" aptameric MB mode. F-Apt (10 nM) and various concentration of QDNA1 (50 nM, 100 nM and 150 nM) were titrated with increasing concentration of rHuEPO-α from 0 to 200 nM in the physiological buffer. Data are reported as mean ± SD values with RSD < 5.0% (n = 3).

3.2.2. The hybridization site of SDNA

An aptamer with a hairpin motif, the loop part is generally considered as the key motif for recognizing rHuEPO-α [15]. In the "Signal-on" mode, F-Apt was partially hybridized with QDNA1 in a 7 bp from its 3′-end, other 28 nt sequence would remain a free coiling status. A short supplemental sequence which form a complementary duplex with the 5′-end stem of F-Apt is expected to aid the other 28 nt sequence in an order status and expose full recognition sites of loop for target rHuEPO-α. Different SDNA sequences with different binding sites of F-Apt were synthesized to confirm this presumption. SDNA2 and SDNA3, which were partly hybridized with the loop part in F-Apt, might interfere the binding between rHuEPO-α and F-Apt, so less QDNA1 was departed, and the fluorescent change was lower than the case of SDNA1. Only SDNA1 with 8 nt sequences participated in the 5′-end stem hybridization can achieve the most signal change by stabilizing the "Signal-on" mode and exposing the loop with possible recognition site (Fig. 5). Another possible reason is that the higher T_m value of SDNA1 (32 °C) than that of SDNA2 (18 °C) and SDNA3 (26 °C), which could make the aptameric MB system more stabilizer [21].

3.2.3. Concentration of metal ions

It is known that the presence of alkali and alkaline-earth metal ions has important effect on the aptamer–target interaction. For example, it is reported that the cations K^+ and Mg^{2+} can directly induce a dominant structural formation of nucleotides through a size-selective coordination mechanism in free solution [22]. In this work, the maximum fluorescence signal can be kept well in the range of 0–10 mM K^+, while the specific binding between aptamer and rHuEPO-α lowered when K^+ cation was higher than 10 mM (Fig. 6). It is assumed that under higher concentration of K^+, formation of complex was reduced by the possible distortion of aptamer spatial structures [23].

The concentration of divalent Mg^{2+} cation was also investigated. In the range of 0–50 mM Mg^{2+}, the fluorescent signal recovery was steadily increased at first and then significantly decreased at the concentration higher than 10 mM (Fig. 6), indicating that the formation ability of aptamer–target complex was greatly enhanced at lower Mg^{2+} concentration [24,25]. However, at the higher Mg^{2+} level, the fluorescence was quenched in some extent [26]. Since the existence of Mg^{2+} is reported to be helpful to form and stabilize the duplex of oligonucleotide [22], it is assumed that the spatial

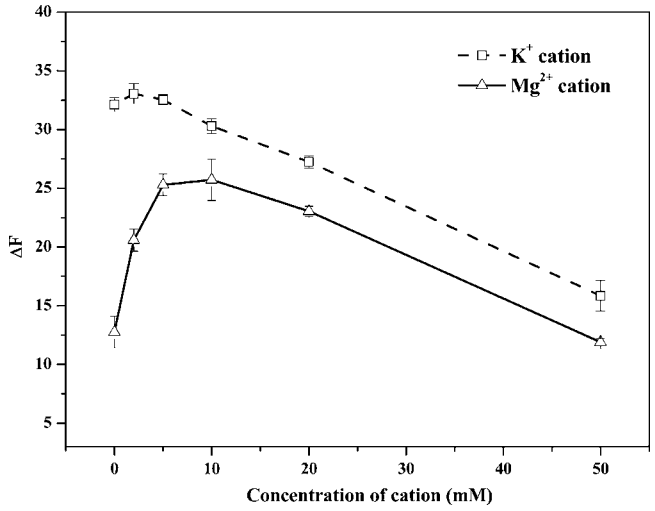

Fig. 6. Effects of cation concentration on the "Signal-on" aptameric MB. Concentrations of F-Apt, QDNA1 and SDNA1 were 10 nM, 100 nM and 100 nM, respectively. The MB solution was titrated with 100 nM rHuEPO-α in the physiological buffer contained various concentration of metal ion. Data are reported as mean ± SD values with RSD < 3.0% (n = 3).

recognition of F-Apt and rHuEPO-α was also benefited from the addition of Mg^{2+}. As shown in Fig. 7, specific recognition between F-Apt and target protein was deteriorated without Mg^{2+}. This behavior is in accord with other Mg^{2+}-dependent aptamer–ATP or OTA target binding [27,28]. Moreover, for such a negatively charged rHuEPO-α and the likelihood negatively charged aptamers, it is supposed that proper concentration of Mg^{2+} cation could shield the negative charges of DNA and act as the electrostatic attractive cation bridge, which probably facilitate the approaching of the negatively charged rHuEPO-α to the surface of the oligonucleotide [29]. Since higher Mg^{2+} concentration is disadvantageous for fluorescence intensity, the Mg^{2+} concentration kept at 5 mM was selected in the "Signal-on" mode.

3.2.4. Other parameters have effect on hybridization and complex formation

The hybridization of oligonucleotides complementary sequences is following a slow kinetics process, which requires a relative long annealing period [30]. Since the extent of quenching efficiency is directly depending on the Förster distance in such a fluorescent resonance energy transfer format, the tighter base-pairing of oligonucleotides, the more decreased background of fluorescence, and the best result was achieved in an annealing condition of 4 °C overnight. The background of fluorescence under other conditions such as room temperature 30 min, room temperature overnight and ice bath for 10 min are higher 27%, 15% and 30% than that under the condition of 4 °C overnight, respectively.

As a kind of additives with high viscosity and good biological compatibility, glycerol was tested to increase the viscosity of solution and stabilize the formation of F-Apt–QDNA hybridization or F-Apt–target protein complex. Although 0, 0.5%, 1.5% and 3% (v/v) glycerol have no significant effect on the change of fluorescence, addition of 0, 0.5% and 3% glycerol made the increasing extent of fluorescence lower 26%, 29% and 13% than addition of 1.5% glycerol, respectively, at a low concentration of rHuEPO-α (50 nM). So 1.5% glycerol was chosen to facilitate the improvement of sensitivity by stabilizing the MB system when low concentration of rHuEPO-α was added.

3.3. Determination of rHuEPO-α in "Signal-on" mode

Best performance of our "Signal-on" mode was found in the psychological buffer of 140 mM NaCl, 5 mM $MgCl_2$, 5 mM KCl, and with 1.5% glycerol added. Titration experiment was then performed with increasing concentration of rHuEPO-α from 0 to 600 nM under above optimized conditions. The fluorescence signal was first rapidly increased with an increased rHuEPO-α concentration from 0 to 50 nM, indicating that the added rHuEPO-α was largely bound to the F-Apt, and then steadily increased when the concentration of rHuEPO-α was beyond 50 nM. In the presence of 600 nM rHuEPO-α, full fluorescence was recovered. Using the "Signal-on" mode, 1 nM of rHuEPO-α could be detected without any pre-treated procedure in the physiological buffer. The linear range was 1–10 nM ($y = 1.976 + 1.229x$, $r = 0.9905$) (Fig. 7), and a LOD could be calculated according to the equation of $LOD = 3SD_{blank}/k$ (where k represents the slope of linear curve, the repeated number of blank is 11), so the LOD is 0.4 nM. The RSD values of high and middle concentration in the linear curve are determined as 3.3% and 4.2%, respectively. Also the dissociation constant ($K_d = 50 \pm 7$ nM) was

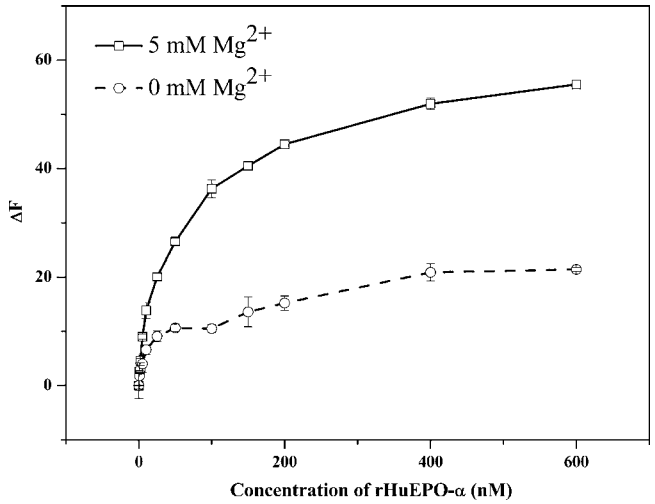

Fig. 7. The titration curves of the "Signal-on" aptameric MB against the increasing concentration of rHuEPO-α (0–600 nM) in physiological buffer contained 1.5% (v/v) glycerol with or without 5 mM Mg^{2+}. Data are reported as mean ± SD values with RSD < 5.0% (n = 3). Other conditions are same as in Fig. 6.

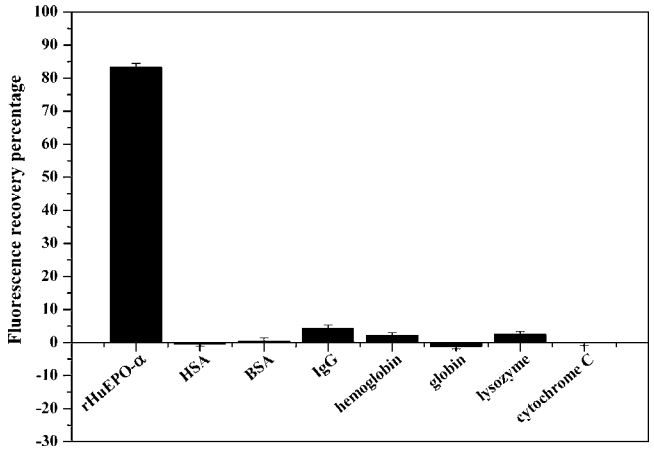

Fig. 8. Binding specificity of the "Signal-on" aptameric MB. Different proteins HSA, BSA, IgG, hemoglobin, globin, lysozyme and cytochrome C were compared with rHuEPO-α in their capability to bind with F-Apt in physiological buffer contained 5 mM Mg^{2+} and 0.5 μM BSA. Other conditions are same as in Fig. 7. The concentration of rHuEPO-α is 200 nM, other proteins is fivefold of rHuEPO-α. Data are reported as mean ± SD values with RSD < 2.0% (n = 3).

determined by the titration curve of "Signal-on" based on one-site direct binding model (Fig. S4), which is in agreement with the dissociation constant (K_d = 33 ± 4 nM) determined by "Signal-off" mode (Fig. S3).

3.4. Binding specificity of "Signal-on" MB

The specificity of the "Signal-on" MB mode was demonstrated in the physiological buffer containing 0.5 μM BSA as fluorescence sensitized stabilizer. Here the full recovery of 100% was defined as the fluorescence intensity reached the value of FDNA alone, when equivalent amount of F-Apt–QDNA (combined with SDNA) was considered as the background in the "Signal-on" mode. rHuEPO-α brought about 80% of fluorescence recovery, while fivefold of HSA, BSA, IgG, hemoglobin, globin, lysozyme and cytochrome C showed no cross binding toward the F-Apt. It is indicated that this "Signal-on" MB probe has good selectivity when compared with other interfering proteins (Fig. 8).

4. Conclusion

Here we reported an aptameric MB-based probe for direct determination of rHuEPO-α in homogeneous physiological buffer for the first time. The structural switchable "Signal-on" strategy demonstrated here using 807–35 nt aptamer as a proof of principle, the effective signal transduction module showed a potential practical utility of our new selected ssDNA aptamer for rHuEPO-α detection with a LOD of 0.4 nM. Improved sensitivity can be achieved when coupling preconcentration procedures and signal amplification strategies in the further work. Aptamer 807–35 nt was also expected to be a powerful biosensor probe or a potential clinic diagnosis element to facilitate new methodological developments for rHuEPO-α, including *in vitro* diagnostics, or high-throughput screening of abused samples in doping control area.

Nanoparticles

ABSTRACT

A two-probe tandem DNA hybridization assay including capture DNA$_1$, probe DNA$_2$, and target DNA$_3$ was prepared. The long-lived luminescent europium complex doped nanoparticles (NPs) were used as the biomarker. The complex included in the particle was Eu(TTA)$_3$(5-NH$_2$-phen)-IgG (ETN-IgG), the europium complex Eu(TTA)$_3$(5-NH$_2$-phen) linking an IgG molecule. Silica NPs containing ETN-IgG were prepared by the reverse microemulsion method, and were easy to label oligonucleotide for time-resolved fluorescence assays. The luminophores were well-protected from the environmental interference when they were doped inside the silica network. The sequences of *Staphylococcus aureus* and *Escherichia coli* genes were designed using software Primer Premier 5.0. Amino-modified capture DNA$_1$ was covalently immobilized on the common glass slides surface. The detection was done by monitoring the fluorescence intensity from the glass surface after the hybridization reaction with the NPs labeled probe DNA$_2$ and complementary target DNA$_3$. The sensing system presented short hybridization time, satisfactory stability, sensitivity, and selectivity. This approach was successfully employed for preliminary application in the detection of pure cultured *E. coli*, it might be an effective tool for pathogen DNA monitoring.

1. Introduction

Among many detection techniques of microbial pathogens, DNA hybridization method has been popularly developed for its accurate specificity and high selectivity [1–3]. Compared to the well developed electrochemical biosensors [4–6], there is increasing interest in the investigation of optical sensing systems. Fluorescence based detection, such as polymerase chain reaction (PCR) [7], fluorescence in situ hybridization (FISH) [8], and DNA chip technology [9] have become the standard techniques for quantifying extents of hybridization between surface-immobilized probes and fluorophore-labeled analytic targets in DNA microarrays.

A fluorescent dye is usually utilized to signal the hybridization. Many fluorescent dyes are well known as markers for nucleic acids, such as fluorescein [10], rhodamine [11] and cyanine [12] dyes. However, there is a main problem of how to eliminate background noises caused by autofluorescence from biological samples, the scattering light from solid substrates, and the luminescence from the optical components. For this purpose, more and more attention has been paid on the time-resolved fluorescent technique using lanthanide complexes as the fluorescence labels [13–15]. However, most reported time-resolved fluorescence DNA hybridization assay was based on fluorescence resonance energy transfer technology (FRET) [16–18]. It only occurs under very exacting conditions of overlapping of the emission peak of the donor and the excitation peak of the acceptor, the distance between the donor fluorophore and acceptor fluorophore, and the position of the fluorophores within the biomolecules, etc. It is difficult to find a suitable donor–acceptor system.

On the other hand, the demand of ultratrace gene analysis has driven nanomaterials toward biomedical fields and biotechnology. Recently, dye-doped silica NPs were extensively used in bioimaging and biochemical analysis due to its advantages like signal enhancement, photostability and surface modification for the immobilization of biomolecules [19–21]. To the best of the authors' knowledge, there are only a limited number of reports on the use of lanthanide complex doped NPs as biolabels [22–29]. Dye leakage can efficiently be reduced through covalent binding, and a special functional ligand is usually necessary. However, the synthesis of the chlorosulfonylated β-diketones such as 5-(4″-chlorosulfo-1′,1″-diphenyl-4′-yl)-1,1,1,2,2,3,3-heptafluoro-4,6-hexanedione

(CDHH), 4,4′-bis(1″,1″,1″,2″,2″,3″,3″-heptafluoro-4″,6″-hexanedion-6″-yl)chlorosulfo-*o*-terphenyl (BHHCT), and 4,4′-bis(1″,1″,1″-trifluoro-2″,4″-butanedion-4″-yl)chlorosulfo-*o*-terphenyl (BTBCT) was somewhat difficult. Furthermore, a number of reported biological detection systems were based on confocal fluorescence imaging technology to improve sensitivity [20,23,25,26,29–31]. The drawback is that confocal microscopes are expensive and require very precise mechanical alignment that can be difficult to maintain. DNA detection based on the measurement of time-resolved fluorescence intensity of a suitable labelling of lanthanide complex doped NPs is still an exciting area of research.

In this work, the authors synthesized a europium complex $Eu(TTA)_3(5\text{-}NH_2\text{-phen})$ with long fluorescence lifetime of 0.657 ms and intense time-resolved fluorescence intensity in simple steps. The amino substituent in the phenyl ring in phenanthroline allowed for facile conjugation to IgG. The ETN-IgG doped amino-modified silica NPs were prepared and allowed for facile conjugation to DNA. The DNA hybridization assay [20] was shown in Fig. 1. The combined sequences of capture DNA_1 and probe DNA_2 are complementary to that of the target DNA_3. The sequences of these DNA strands were designed using software Primer Premier 5.0, and commercially synthesized. The detection system showed satisfactory sensitivity, the detection limits could be as low as 4×10^{-10} mol l^{-1}. Additional applications will be used for detection in real samples of microbial pathogens.

2. Experimental

2.1. Instrumentation

All fluorescence measurements were conducted on a Perkin-Elmer LS-55 spectrofluorimeter with both excitation and emission slits set at 10 nm and controlled by a personal computer data processing unit. A modified home-made poly(tetrafluoroethylene) detection-cell and two arms of the bifurcated optical fiber were fixed in the detecting chamber of the spectrofluorimeter to carry the excitation and emission light. The excitation light was carried outside the spectrofluorimeter to the sensor fixed in the detection-cell through one arm of the fiber and the emission light was collected inside the spectrofluorimeter through the other. A foursquare glass plate (side length 12 mm, thickness 1.5 mm) covered with the hybrid of capture DNA_1, NPs labeled probe DNA_2, and target DNA_3 was fixed on the top of the flow chamber by the mounting screw nut. All measurements were performed at room temperature and atmospheric pressure.

2.2. Materials and reagents

Europium oxide was purchased from Sinopharm Chemical Reagent Co. (Shanghai, China). 2-Thenoyltrifluoroacetone (TTA), a ligand reagent, was obtained from J&K Chemical Ltd. Human IgG was purchased from Beijing Solarbio Science & Technology Co., Ltd (Beijing, China). Tetraethyl orthosilicate (TEOS), Triton X-100, 3-aminopropyltrimethoxysilane (APTES), 2-(*N*-morpholino)ethanesulfonic acid (MES), *N*-hydroxysuccinimide (NHS), and 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC) were purchased from Acros organics. The oligonucleotides were synthesized by Shanghai Sangon Biological Engineering Technology & Services Co. Ltd (Shanghai, China). All other chemicals of analytical reagent grade were commercially obtained. PBS buffer (pH 7.2) was used during the oligonucleotide label and immobilization. Double-distilled water was used for the preparation of all aqueous solutions.

2.3. Synthesis of europium ternary complexes

The europium ternary complex $Eu(TTA)_3(5\text{-}NH_2\text{-phen})$ (ETN) using thenoyltrifluoroacetone (TTA) and 5-amino-1,10-phenanthroline ($5\text{-}NH_2$-phen) as the ligands was synthesized, the formula of the complex was shown in Fig. 2. The synthesis of $5\text{-}NH_2$-phen was according to the literature [32].

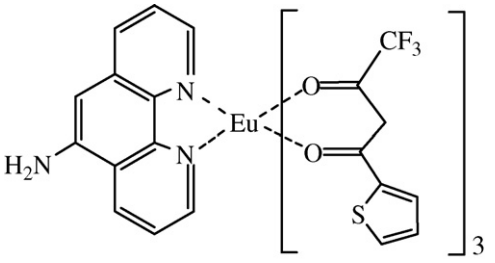

Fig. 2. Formula of complex $Eu(TTA)_3(5\text{-}NH_2\text{-phen})$.

The ternary europium complex was prepared by stirring an ethanol solution of the $EuCl_3$ (europium oxide was dissolved in hydrochloric acid to form europium chloride), TTA, and was adjusted to pH 6 by adding a sodium hydroxide solution, and the mixture was reacted for 40 min. Subsequently, another ethanol solution of 5-NH_2-phen was added, and the mixture was stirred for 5 h at 55–60 °C. A yellow precipitate formed upon cooling was filtered and recrystallized from a mixed solvent of methanol and chloroform (1:1, v/v), MS *m/z* 1032 (M^++H_2O). ^{1}H NMR (acetone) δ (ppm): 2.83 (6H, –CO–CH_2–), 6.02–7.28 (9H, -thiophene), 7.40 (2H, –NH_2), 8.01–11.11 (7H, -phenanthrene). The ternary complex was further characterized through IR and elemental analysis. The $\nu_{(C=O)}$ stretching vibration in the infrared spectrum at 1637 cm^{-1} of TTA shifts to 1626 cm^{-1} in the spectrum of ETN, and the $\nu_{(C=N)}$ stretching vibration at 1564 cm^{-1} of 5-NH_2-phen shifts to 1550 cm^{-1} of ETN. Elemental analysis: $EuC_{36}H_{24}N_3F_9S_3O_6$ (1013.66), Calcd. C, 42.62; H, 2.37; N, 4.14. Found C, 42.58; H, 2.31; N, 4.19.

2.4. Preparation of functional nanoparticles

It is reported that biomacromolecule conjugated organic dyes as the core material for the preparation of core–shell structure NPs can effectively improve the efficiency of dye-embedded and hydrophilicity [20]. The authors converted ETN to hydrophilic molecule by linking an IgG molecule to the ETN. The ETN-IgG doped NPs were successfully synthesized by the reverse microemulsion method [33]. A certain aqueous ETN-IgG solution was added in a microemulsion of 1.77 ml Triton X-100, 7.5 ml cyclohexane, 1.8 ml n-hexanol, and 340 μl water. The final luminophore concentration in the mixture was 1.2×10^{-3} mol l^{-1}. After stirring the microemulsion for 20 min, 0.1 ml of TEOS was added, the polymerization of TEOS was initiated by adding 0.06 ml of ammonium hydroxide. The reaction was allowed to continue for 24 h. Then 0.1 ml of silanization reagent APTES was introduced to the mixture, the reaction was allowed to continue for another 2 h. To release the NPs from the microemulsion and remove surfactant molecules, acetone and ethanol were used to break microemulsion and wash the NPs. After washing with ethanol and double-distilled water several times, the amino-modified ETN-IgG doped silica NPs were obtained and dried in a desiccator prior to modification.

2.5. Designing of oligonucleotide sequences

All the sequences were designed using Primer Premier 5.0 software, on the basis of the published specific nucleotide sequences of *Staphylococcus aureus* and *Escherichia coli* genes [34]. The sequences of these oligonucleotides and the hybridization conditions set for respective genes are shown in Table 1.

2.6. Glass slides surface modification with capture DNA_1

The glass slides surface was modified as described in the literature [35]. The glass slides were immersed in 25.0% ammonium hydroxide overnight then washed with double-distilled water. A solution of 2.0% APTES in 95% ethanol was prepared and adjusted to the desired pH of 4.5 with glacial acetic acid. The glass slides were soaked in this solution for 30 min then ultrasonically washed by ethanol and double-distilled water. Reactive amino groups were then introduced at the glass surface. The amine-modified glass slides were then immersed in the solution of 2.5% glutaraldehyde in PBS buffer stirring for 3 h, and washed with PBS buffer and double-distilled water (1 min/time), respectively, then dried at normal temperature.

The solution of capture DNA_1 was dropped onto the glutaraldehyde-treated glass slides, and was kept at room temperature overnight. The capture DNA_1 was then covalently immobilized on the glass surface. The DNA_1 modified glass slides were then soaked in a sodium cyanoborohydride solution for 30 min to block any remaining glutaraldehyde groups, and the carbon–nitrogen double bond was reduced. The final glass was dried at room temperature after washing with 0.2% SDS solution (sodium dodecyl sulfate) and double-distilled water.

2.7. Surface modification of NPs with probe DNA_2

Certain amine-modified silica NPs were suspended in PBS buffer by ultrasonication. Some 10% succinic anhydride DMF solution was added, the mixture was stirred for 3 h under the condition of nitrogen atmosphere. After centrifuging and washing with ethanol and double-distilled water, the NPs were dispersed in 0.1 mol l^{-1} MES buffer (pH 6.0). A certain probe DNA_2 dissolved in double-distilled water, EDC and NHS was added to the solution, and the reaction was continued for 3 h. The NPs were removed from the solution by centrifugal precipitation and then treated with 0.02 mol l^{-1} glycine solution for 1 h to remove the unreacted carboxyl groups. The final DNA_2 modified NPs were washed, and resuspended in PBS buffer for future usage.

2.8. Hybridization with target DNA_3

The target DNA_3 was first diluted in double-distilled water. The DNA_2 immobilized NPs and target DNA_3 were then added on the capture DNA_1 modified glass slides surface for hybridization under the condition of hybridization solution containing 5.0× SSC (NaCl, sodium citrate) and 0.1% SDS. Following hybridization, the glass slides were washed with 1× SSC + 0.03% SDS, 0.2× SSC, 0.05× SSC, and double-distilled water at room temperature in order to remove non-hybridized oligonucleotides. The detection of the DNA_3 was done by monitoring fluorescence signals of the DNA_2 labeled NP conjugates left on the glass slides surface with proper excitation.

3. Results and discussion

3.1. Nanoparticles characterization

ETN-IgG doped NPs were characterized by scanning electron microscopy (SEM), transmission electron microscopy (TEM), and fluorescence spectroscopy. As shown in Fig. 3, the average diameter of the NPs is about 55–65 nm. Europium ternary complex particles are visible as dark dots embedded inside the silica sphere as a result

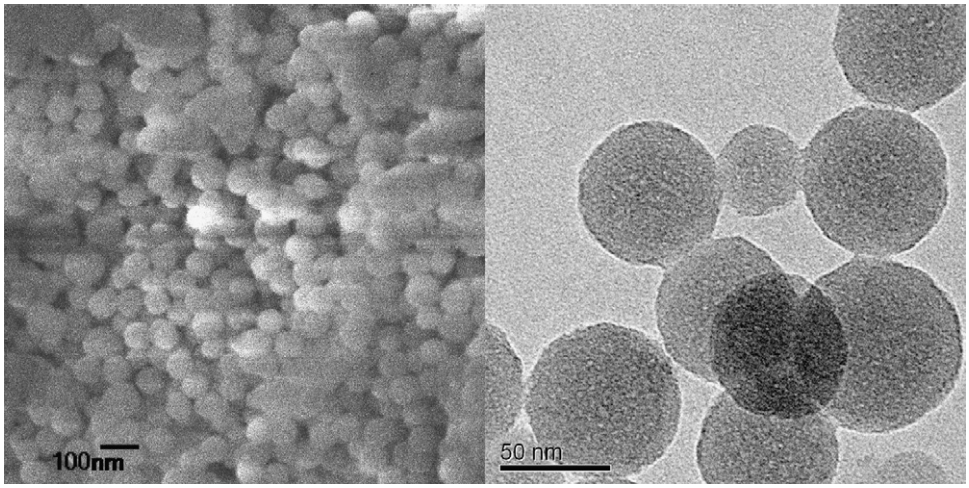

Fig. 3. SEM and TEM images of ETP-IgG NPs.

of the presence of the heavy metal europium atom from the TEM image. The time-resolved fluorescence spectra of the europium complex and its NPs were investigated (Fig. 4). Results showed that the bandwidth of excitation spectrum was compressed and the emission spectral maxima position shifts by 4 nm (from 615 to 611 nm) toward the shorter wavelength when compared to the complex ETN. This clearly confirmed that silica cell generally has no effect on the luminescence performance of europium complex.

The lifetime of ETN-IgG doped NPs was easily calculated with the spectrofluorimeter. As shown in Fig. 5, there is satisfactory linearity between the logarithm of the fluorescence intensity and delay time, and the lifetime is the negative reciprocal of the slope of 0.657 ms. The NPs gave an intense and long-lived signal which enables efficient elimination of background signal, and all measurements were carried out at a delay time of 0.1 ms.

3.2. DNA hybridization detection

It is desirable to use time-resolved fluorometry of lanthanide chelates-doped NPs in the area of nucleic acid hybridization assays as a means of improving the signal-to-noise ratio by increasing the signal intensity and decreasing the background associated with conventional fluorescence measurements. Time-resolved fluorescence intensity of different concentrations of target DNA_3 of *S. aureus* detected from glass surfaces was recorded at $\lambda_{ex} = 375$ nm, $\lambda_{em} = 611$ nm. As shown in Fig. 6, the time-resolved fluorescence intensity was increased with the increasing concentration of DNA_3 (from 11.55 of blank to 96.75 of 4×10^{-7} mol l^{-1}). The ETN-IgG doped NPs could be a super excellent labelling reagent for DNA detection with high sensitivity. The fitting spectra of *E. coli* detection were similar to that of *S. aureus*. The detection limit for *S. aureus* and *E. coli* was about 4×10^{-10} mol l^{-1}.

3.3. Dye leaching and stability experiment

In order to investigate the dye leakage from the NPs, appropriate NPs were ultrasonically exposed to an aqueous environment. The time-resolved fluorescence intensity at emission wavelength 611 nm was recorded after washing for 10 times. A mean value of 105.3 ($n = 10$) and a relative standard deviation of 3.18% were obtained. The ETP-IgG NPs displayed little dye leaching. Furthermore, the time-resolved fluorescence intensity has little decrease (from 125 to 121) under continuous lighting for 5 h.

3.4. Capability and selectivity of the prepared detection system

The experiments were carried out by recording the time-resolved fluorescence intensity of hybridization with different

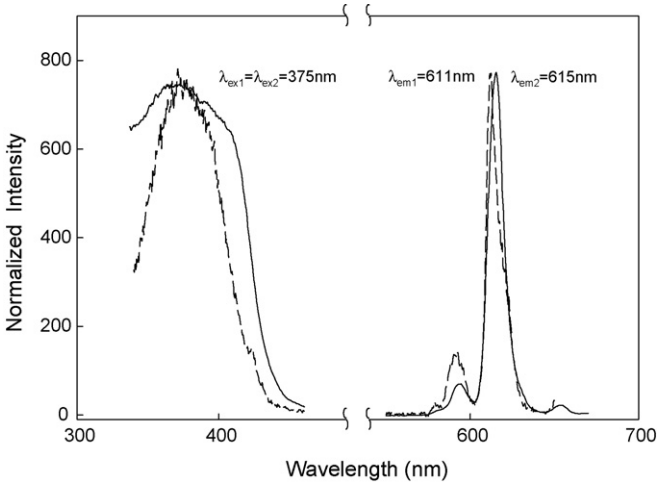

Fig. 4. Time-resolved fluorescence spectra for the ETN (—) and ETN-IgG doped NPs (- - -). For time-resolved spectra: delay time, 0.1 ms, gate time, 1.0 ms.

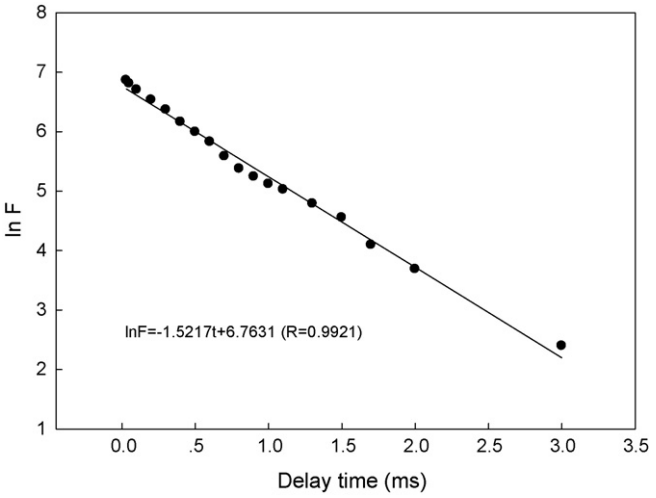

Fig. 5. The natural log of the intensity, ln *F*, as a function of the delay time.

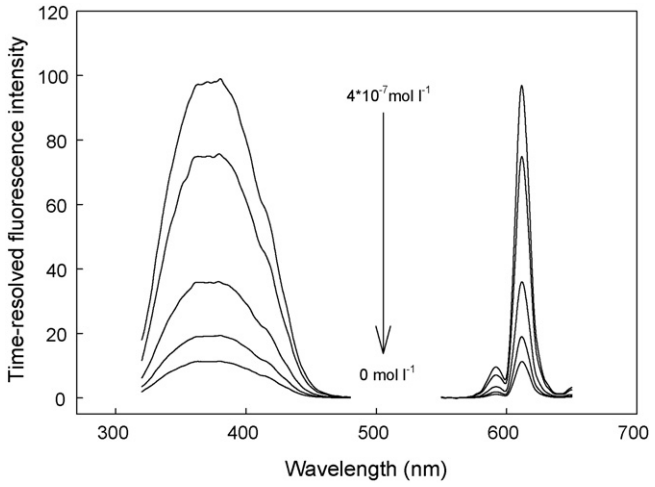

Fig. 6. Time-resolved fluorescence spectra for different concentrations of target DNA_3 of *Staphylococcus aureus* (from top to bottom: 4×10^{-7} mol l^{-1}, 4×10^{-8} mol l^{-1}, 4×10^{-9} mol l^{-1}, 4×10^{-10} mol l^{-1}, 0 mol l^{-1}), for time-resolved spectra: λ_{ex} = 375 nm, λ_{em} = 611 nm, delay time, 0.1 ms, gate time, 1.0 ms.

sequences of target DNA_3 and a mixture sample with other DNA species existed. Take *S. aureus* for example. In order to investigate the availability of this assay, the authors employed three random target sequences: s_1, 5′GAA GAA CAT TTA AGA AAA AGT GAA GCA CAA GCG AAA AAA GAG AAA AT3′; s_2, 5′AAG CCA TGA AGC GGC TTA TGA TTC TTA CCG CCC ACT TGA CGA AAG CG3′; s_3, 5′AAG GGA CGA TGA AAG CCG ATG AAG CCT CCT TTA CCT GGA CCG ATA AC3′. Five samples of different target DNA in same concentration including s_0 (the pure target DNA_3 of *S. aureus*), s_1, s_2, s_3, and a mixture sample of s_0, s_1, s_2, s_3 (same concentration of s_0 with first sample) were prepared. The results showed that fluorescence intensities of the five samples were 75.88, 15.22, 14.93, 19.92 and 80.67, showing little non-specific binding of random DNA sequences.

3.5. Optimal hybridization time

The optimal hybridization time for this assay was also investigated. The result showed that, in the initial stage of hybridization time less than 2.5 h, the hybridization signal increased, and then reached a steady state at a hybridization time longer than 2.5 h. On the basis of this, all the experiments were carried out for the hybridization time of 2.5 h.

3.6. Preliminary analytical application

Detections of DNA extracted from pure cultured *S. aureus* and *E. coli* were studied with the proposed hybridization assay. Strains of *S. aureus* and *E. coli* purchased from Guangdong Institute of Microbiology were cultured, and the double-stranded DNA was extracted using Genomic DNA extraction Kit (Generay Biotech Co., Ltd., Shanghai, China). The double-stranded DNA fragments were denatured to single-stranded DNA by heating at 90 °C for 15 min before use. Targets DNA of *S. aureus* and *E. coli* in a same concentration of about 2×10^{-7} mol l^{-1} were prepared. Satisfactory fluorescence intensities of 56.43 and 48.71 obtained showed that the method might have potential values for pathogen detection.

4. Conclusion

This work reported an approach of DNA detection using a lanthanide europium complex ETN-IgG doped NPs based two-probe tandem DNA hybridization assay. The oligonucleotide sequences of *S. aureus* and *E. coli* genes were designed. The NPs exhibited extremely long lifetime and excellent signaling ability of a trace amount of target DNA. The selectivity and capability of the prepared detection system were also investigated. The authors believe the method has enormous promise for applications to pathogen detection.

4-(*N*,*N*-Dimethylamino)benzoylhydrazine

ABSTRACT

A fluorescent and colorimetric probe bearing salicylaldehyde hydrazone functionality has been prepared for cyanide sensing. The detection of cyanide was performed via the nucleophilic attack of cyanide anion on the imine group of the probe with a 1:1 binding stoichiometry, which could be confirmed by ^{1}H NMR and MS studies. The specific reaction results in a prominent fluorescence enhancement and a color change from colorless to yellow.

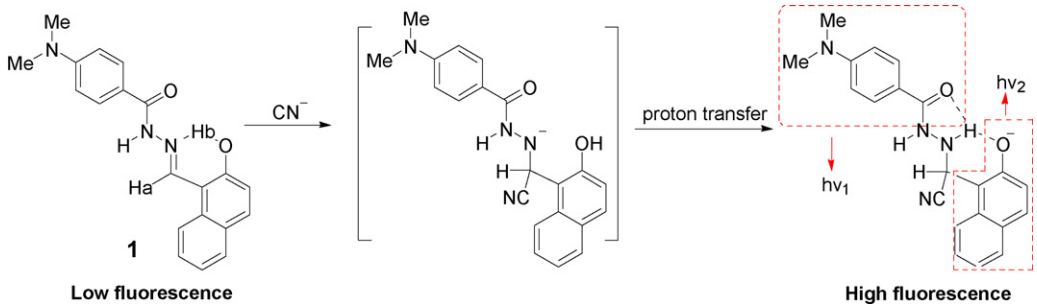
1. Introduction

Anion recognition is an area of growing interest in supramolecular chemistry due to its important role in a wide range of environmental, clinical, chemical, and biological applications, and considerable attention has been focused on the design of artificial receptors that are able to selectively recognize and sense anion species [1,2]. Among various anions, cyanide is one of the most concerned anions because it is being widely used in synthetic fibers, resins, herbicide, and the gold-extraction process [3]. Unfortunately, cyanide anion is extremely detrimental, and could be absorbed through lungs, gastrointestinal track and skin, leading to vomiting, convulsion, loss of consciousness, and eventual death [4–6]. Thus, there is a need for an efficient sensing system for cyanide to monitor cyanide concentration from contaminant sources.

Many of the cyanide anion receptors reported to date have relied on hydrogen-bonding motifs and, as a consequence, have generally displayed poor selectivity relative to other anions [7–9]. To overcome this limitation, reaction-based receptors, rationally designed cyanide anion indicators, have been developed recently [10–21]. This reaction-based recognition mode takes advantage of the particular feature of the cyanide ion: its nucleophilic character, and enables the recognition system with some characteristic features such as analyte-specific response and little competition from the aqueous media, which are highly desirable features for an efficient recognition and detection system. Based on this idea, nucleophilic addition of cyanide to oxazine [10,11], pyrylium [12], squarane [13], trifluoroacetophenone [14,15], acyltrazene [16], acridinium [17], salicylaldehyde [18,19] and carboxamide [20,21] has been reported in the past few years, in which the interference by other anions, such F^- and AcO^-, can be efficiently minimized.

Recently, we have developed a series of nitroaniline-based benzamide compounds for the 'naked-eye' detection of cyanide in aqueous environment with high selectivity [22]. These compounds react with CN^- in a 1:1 stoichiometric manner, a process which induces a large enhancement in absorption intensity and a marked color changes from colorless to yellow in DMSO–H_2O (1:1, v/v) at room temperature. In continuation of our work, in this paper, we wish to report a new type of probe molecule (**1**) bearing hydrazone functionality for highly selective cyanide detection in water (Scheme 1). **1** was designed on the basis of 4-(*N*,*N*-dimethylamino)benzamide fluorophore [22] and 2-naphthol fluorophore, which were connected by a rigid hydrazone functionality. Cyanide is expected to be detectable by nucleophilic attack toward an imine functional group of **1**, which is activated by an intramolecular hydrogen bond, and fast proton transfer of the phenol hydrogen to the developing nitrogen anion would then bring about a spectroscopic change (Scheme 1).



2. Experimental

2.1. Materials and apparatus

Commercially available compounds were used without further purification. Solvents were dried according to standard proce-

Scheme 1. Proposed cyanide-sensing mechanism of **1**.

dures. All reactions were magnetically stirred and monitored by thin-layer chromatography (TLC) using Huanghai GF_{254} silica gel coated plates. The fluorescence spectra were carried out on Varian Cary Edipse fluorescence spectrometer. The absorbance spectra were recorded with Agilent 8453 UV–vis spectrophotometer. NMR spectra were recorded on a Bruker Avance DRX300 MHz nuclear magnetic resonance spectrometer with tetramethylsilane (TMS) as internal standards. ESIMS were taken on Fourier transform ion cyclotron resonance mass spectrometry (Varian 7.0T).

2.2. Preparation of probe molecule *1*

A solution of 4-(*N*,*N*-dimethylamino)benzoylhydrazine (89 mg, 0.5 mmol) and 2-hydroxy-1-naphthaldehyde (86 mg, 0.5 mmol) in ethanol (20 mL) was heated under reflux for 1 h. After left to cool, the precipitated crystals were filtered and washed with ethanol to give pure **1** as yellow solid (160 mg, 95%). ^{1}H NMR (300 MHz, DMSO-d_6) δ 12.99 (s, 1H), 11.91 (s, 1H), 9.46 (s, 1H), 8.16 (d, 1H), 7.86 (m, 4H), 7.61 (s, 1H), 7.40 (s, 1H), 7.23 (d, 1H), 6.80 (d, 2H), 3.02 (s, 6H); ^{13}C NMR (75 MHz, DMSO-d_6) δ 168.1, 163.7, 158.3, 150.8, 137.8, 137.4, 134.8, 133.5, 133.1, 129.0, 125.8, 124.8, 124.4, 116.5, 114.3, 84.6, 84.2; HRMS (ESI): 356.1368 $(M+Na)^+$.

2.3. Titration experiment of *1*

Deionized water and a spectroscopic grade of DMSO were used as the solvent for titration experiment. The titrations were carried out in 10-mm quartz cuvettes at 25 °C. **1** was dissolved in DMSO to afford a concentration of 20 mM stock solution, which was diluted with DMSO–H_2O (1:1, v/v) up to 20 μM. The sodium cyanide stock solution of 1.0×10^{-1} M was diluted to 1.0×10^{-2} M with deionized water. The absorbance was measured from 250 to 550 nm, against a blank DMSO–H_2O (1:1, v/v) solution, and different cyanide solutions were added to the 20 μM host solution (2 mL) in portions (total volume: 4, 8, 12, 16, 20, 24, 32, 40, 48, 60 μL, of 1.0×10^{-2} M, and 62, 64, 66, 70, 74, 78, 82 μL, of 1.0×10^{-1} M). The emission was measured from 400 to 600 nm, and different cyanide solutions were added to the 20 μM host solution (2 mL) in portions (total volume: 4, 8, 12, 16, 20, 28, 36, 44, 52, 60 μL, of 1.0×10^{-2} M, and 62, 64, 66, 68, 70, 74, 78, 82, 86, 94, 102 μL, of 1.0×10^{-1} M). The resulting solution was shaken well and the absorption and emission spectra were recorded immediately. For detection limit measurements, 1.0×10^{-4} and 1.0×10^{-3} M solutions of sodium cyanide were used. Unless otherwise noted, for all measurements, the excitation wavelength was at 334 nm, and both the excitation and emission slit widths were 5 nm.

3. Results and discussion

3.1. Absorption and fluorescence spectral characteristics of *1*

The ability of **1** to complex with anions was explored with UV–vis absorption and fluorescence spectrometry. Among the eleven anions tested in solution (DMSO–H_2O, 1:1, v/v), namely, CN^-, F^-, Cl^-, Br^-, I^-, AcO^-, ClO_4^-, NO_3^-, $H_2PO_4^-$, N_3^-, and HSO_4^- as their sodium salts, **1** responded to only CN^- resulting in a color change from colorless to yellow and a bright green fluorescence (Fig. 1), indicating that probe **1** can serve as a "naked-eye" indicator

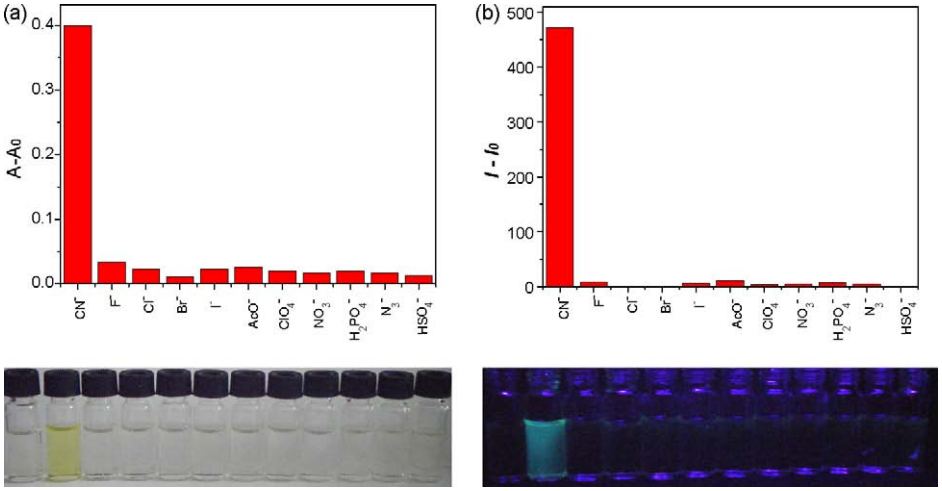

Fig. 1. (a) Absorbance changes, (b) fluorescence changes and the corresponding color changes of **1** (20 μM, 25 °C) in DMSO–H_2O (1:1, v/v) upon addition of 50 equiv. of various anions (vials from the left: only **1**, CN^-, F^-, Cl^-, Br^-, I^-, AcO^-, ClO_4^-, NO_3^-, $H_2PO_4^-$, N_3^- and HSO_4^-). The excitation wavelength for the complex was 334 nm, and the splits were 5.0 nm.

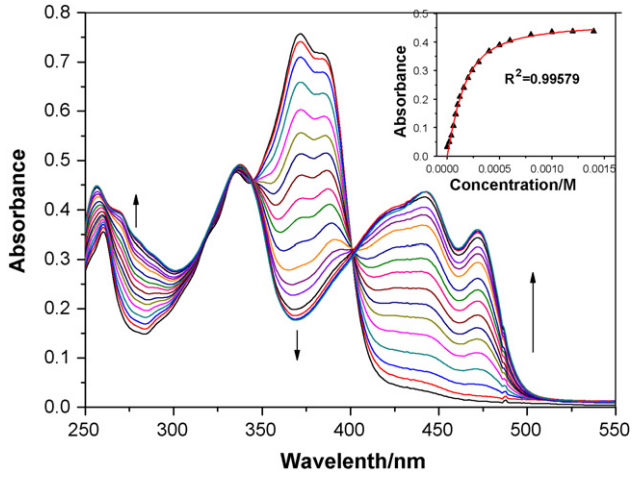

Fig. 2. Absorption spectra of **1** (20 μM) in DMSO–H_2O (1:1, v/v) upon addition of cyanide anion (0–70 equiv.). (Inset) Plots of absorption 443 nm vs. the cyanide concentration.

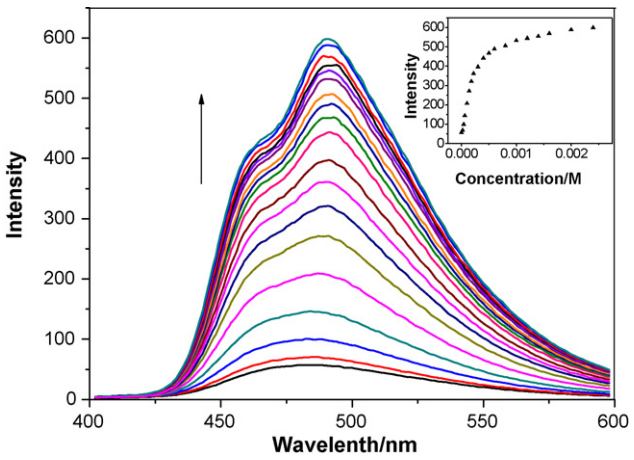

Fig. 3. Fluorescence spectra of **1** (20 μM) in DMSO–H_2O (1:1, v/v) upon addition of cyanide anions (0–120 equiv.). The excitation wavelength for the complex was 334 nm, and the splits were 5 nm. (Inset) Plots of emission at 495 nm vs. the cyanide concentration.

for CN^- in DMSO aqueous media. The absorption and fluorescence profiles of the sensor showed a remarkably higher selectivity for cyanide over the other anions in water.

The nucleophilicity of cyanide in water seems to be the major contributor to the high selectivity of **1** for cyanide. In 1:1 DMSO–H_2O (v/v), anion such as F^- and AcO^- should interact with the aqueous medium through H-bonding, and this solvation leads to a decrease in their basicity, thus, resulting in the poor deprotonation reaction. In contrast, cyanide has much weaker H-bonding ability in comparison with F^- and AcO^- but has stronger carbonyl carbon affinity, which results in the addition reaction of CN^- to imine group (Scheme 1). However, in DMSO, not only the nucleophilicity but also the basicity of anions (F^- and AcO^-) may cause large changes in the UV–vis spectra of **1** and therefore result in less selectivity for cyanide.

Fig. 2 illustrates the absorption spectral changes for **1** upon addition of CN^- in DMSO–H_2O (1:1, v/v). **1** shows an absorption band at 371 nm and two shoulders at 336 and 386 nm. The band at 336 nm can be assigned to 4-(*N*,*N*-dimethylamino)benzamide group of **1**, and the band at 371 nm and a shoulder at 386 nm can be assigned to 2-naphthol group. Upon addition of CN^-, the band at 336 nm kept almost unchanged; however, the bands at 371 and 386 nm were attenuated while two new bands appeared at 443 and 473 nm, which is similar to the observation on the deprotonation of 2-naphthol by anions where the new absorption was assigned to the naphtholate anion. Two isosbestic points at 344 and 403 nm were observed throughout the titration process. The variation of the absorbance at 443 nm was used to evaluate the binding constants of **1** with CN^- by assuming a 1:1 binding stoichiometry. Nonlinear least-squares regression analysis [23–26] of these changes gave a binding constant of $1.17 \times 10^5\ M^{-1}$. Nice fittings supported the 1:1 binding stoichiometry.

Fluorescence monitoring of the cyanide addition reaction was also performed by using a 20-μM solution of **1** in 1:1 of DMSO–H_2O at room temperature (Fig. 3). **1** shows a weak emission. Upon addition of CN^-, the fluorescence emission intensity of **1** was increased and was saturated at 2.4 mM cyanide (120 equiv.). It is noteworthy that the cyanide adducts display dual luminescence with two emission bands, 460 and 495 nm, in the visible region. Titration of **1** with CN^- ions gave a simultaneous increase in the intensity of two bands. The former can be assigned to the excited-state CT for the parent CT fluorophore 4-(*N*,*N*-dimethylamino)benzamide [27–29], and the latter can be assigned to the naphtholate anion [30–32]. The resultant Job plot indicated a 1:1 receptor–cyanide binding stoichiometry (Fig. 4).

Several factors can be proposed for rationalizing the observed emission enhancement of **1** upon the addition of the cyanide anion. Molecules with lowest excited singlet states of the $n\pi^*$ type are typically nonemissive in fluid solution [33]. In the presence of CN^-, as shown in Scheme 1, an intramolecular hydrogen-bond network will be created by nucleophilic attack of CN^- at the imine group, and followed by fast proton transfer of the phenol hydrogen to the developing nitrogen anion. With such an intramolecular hydrogen-bond network that interacts with the lone pair of the carbonyl oxygen of 4-(*N*,*N*-dimethylamino)benzamide group, the energy of the $n\pi^*$ state of this group would be raised so that the emission from the π–π^* transition of the fluorophore would be restored, leading to a substantial fluorescence enhancement [33]. There was no change in the UV absorption band at 336 nm on cyanide anion binding, which suggests that the fluorescence enhancement may also be a consequence of a restriction in the conformational flexibility of 4-(*N*,*N*-dimethylamino)benzamide fluorophore due to the intramolecular hydrogen-bond network that would otherwise lead to nonradiative decay through rotatory motion of the amide group [34–36]. In addition, the proton transfer of the phenol hydrogen to the developing nitrogen anion upon cyanide attack can also lead to the opening of another fluorescence emission channel relative to naphtholate anion, resulting in the emission enhancement [37].

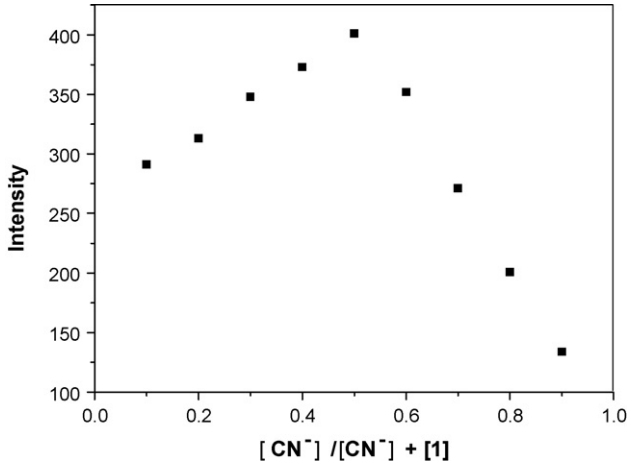

Fig. 4. Job's plot between **1** and cyanide anion in DMSO–H_2O (1:1, v/v) at 25 °C.

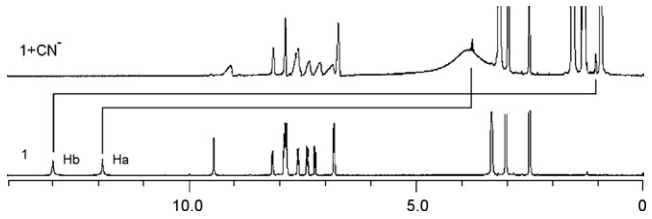

Fig. 5. ^{1}H NMR spectral change of **1** in DMSO-d_6 upon addition of cyanide anions: **1** only (bottom) and **1** and 20 equiv. of Bu_4NCN (top). *Note*: the broad peak at 3.8 is water.

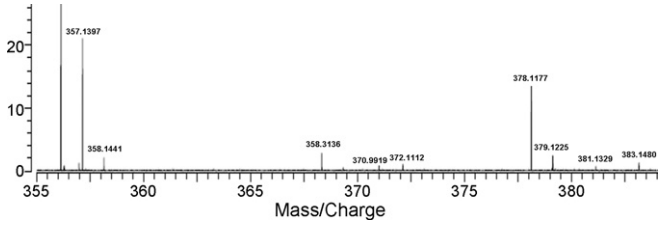

Fig. 6. The ESIMS for the cyanide adduct of **1** [(**1**+NaCN+H$^+$): 383.1478].

The detailed mechanism, however, remains to be further clarified. Detailed work is now underway in this laboratory.

3.2. ^{1}H NMR and ESIMS investigation

An analysis on the ^{1}H NMR spectra of **1** before and after the cyanide addition proved informative (Fig. 5). The imine proton of **1** (H_a) and the phenol proton (H_b) at around δ 11.9 and 13.0 ppm was dramatically shifted upfield to δ 3.7 and 1.1 ppm, respectively, upon cyanide addition at room temperature, indicating that the cyanide anion functions as a nucleophile in water. The formation of cyanide adduct was further confirmed by mass spectrometry. The electrospray ionization mass spectrum of the cyanide adducts for **1** showed a molecular mass of 383.1, which correspond to the formula of [**1**+NaCN+H$^+$] (Fig. 6).

3.3. Fast response

As known, chemosensors always have a problem of long response time. In our case, the binding process of CN^- to **1** was found to be very fast (Fig. 7). After adding the sodium cyanide, two new absorbance bands at 443 and 473 nm appeared and reached

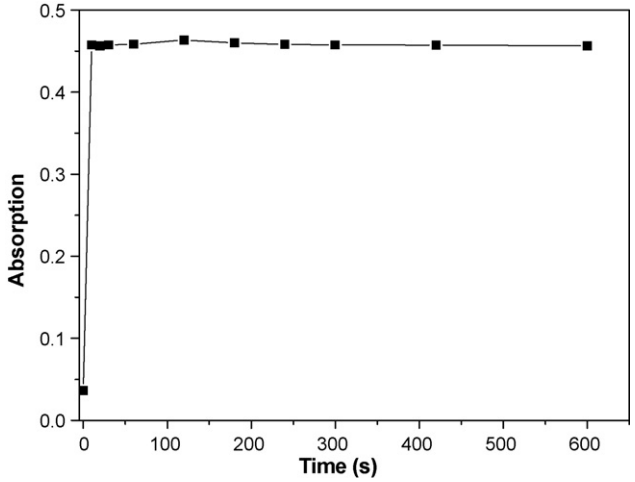

Fig. 7. Absorbance changes at 443 nm for **1** (20 μM, 25 °C) in a mixture of DMSO–H_2O (1:1, v/v) after addition of NaCN (1 mM).

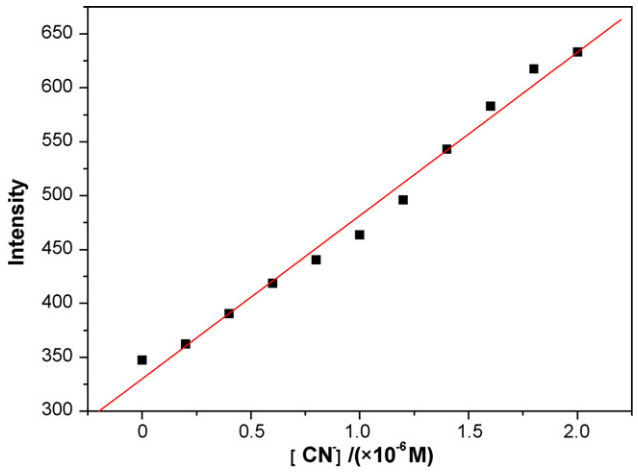

Fig. 8. Fluorescence intensity change at 495 nm for **1** (20 μM) in DMSO–H_2O (1:1, v/v) as a function of the concentration of cyanide anions. The excitation wavelength for the complex was 334 nm, and the splits were 10 nm.

the plateau region less than 2–3 s, and remains quite stable from 3 s to 10 min, suggesting that the addition reaction of CN^- to imine group of **1** might be completed instantly and the chemosensor has rapid detection ability for cyanide anion.

3.4. Detection limits

The detection limit was calculated based on the fluorescence titration. To determine the S/N ratio, the emission intensity of **1** without cyanide anion was measured by 10 times and the standard deviation of blank measurements was determined. Under the present conditions, a good linear relationship between the fluorescence intensity and the cyanide concentration could be obtained in the 2×10^{-7} to 2×10^{-6} M ($R^2 = 0.9935$), as shown in Fig. 8. The detection limit is then calculated with the equation: detection limit = $3\sigma_{bi}/m$, where σ_{bi} is the standard deviation of blank measurements, m is the slope between intensity versus sample concentration. The detection limit was measured to be 7.4×10^{-8} M. According to the World Health Organization (WHO), cyanide concentrations lower than 1.9 μM are acceptable in drinking water. This means that our proposed fluorescent method based on probe molecule **1** is sensitive enough to monitor cyanide concentrations in drinking water.

3.5. Applications

In order to assess the utility of the proposed method, it was applied to the quantitative determination of cyanide anion in drinking water sample (drinking water from commence). The water sample was found to be free from cyanide and so the sample was prepared by adding known amounts of cyanide to sample. The applications were performed using 2 mL of sample volume, and after addition of cyanide with the concentration of 1.9×10^{-6} M, which was within the linear calibration range, the sample was injected in triplicate. The average content of cyanide anion was found to be 1.88×10^{-6} M for drinking water. Then, the recovery percentage performed well with relative standard deviation lower than 2%.

4. Conclusion

In summary, an anion probe bearing 2-hydroxy-1-naphthaldehyde hydrazone moiety for cyanide anion recognition

was synthesized, and its absorption and fluorescence properties in the presence of anions were evaluated. The probe displayed an obvious color change from colorless to yellow and a dramatic change in fluorescence intensity selectively for cyanide anions over other anions in aqueous solution. Such selectivity results from the nucleophilicity of the cyanide anion and the imine activation by the neighboring phenol proton through an intramolecular hydrogen bond. The cyanide detection method described here should have potential application as a new family of probes for detecting cyanide in aqueous solution.

High-performance liquid chromatography-ultraviolet detection
Atorvastatin
Human plasma

ABSTRACT

A simple and sensitive methodology based on liquid–liquid–liquid microextraction (LLLME) followed by high-performance liquid chromatography-ultraviolet detection (HPLC-UV) has been successfully developed for the determination of atorvastatin (AT) in human plasma. AT was first extracted from 4.5 mL acidic aqueous sample (diluted plasma, donor phase, pH 1) at temperature 45 °C through 400 μL 1-octanol for 4.5 min, while being agitated by a stirring bar at 1250 rpm. Then, a 5.5 μL free suspended basic aqueous droplet (acceptor phase, pH 10) was delivered to the top-center position of the organic membrane. The mixture was stirred at 650 rpm for 7.5 min and the analyte was back-extracted into the droplet. Finally, the acceptor phase was taken into a microsyringe and injected directly into the HPLC. An enrichment factor of 187 along with substantial sample clean up was obtained under the optimized conditions. The calibration curve showed linearity in the range of 1–500 ng mL^{-1} with regression coefficient corresponding to 0.996. Limits of detection (S/N = 3) and quantification (S/N = 10) were 0.4 and 1 ng mL^{-1}, respectively. A reasonable relative recovery (91%) and satisfactory intra-assay (4.4–7.0%, $n = 6$) and inter-assay (4.9–7.7%, $n = 8$) precision illustrated good performance of the analytical procedure. This technique was eventually applied for the determination of AT in human plasma after oral administration of 40 mg single dose of drug. The protocol proved to be highly cost-effective and reliable for the screening purpose.

1. Introduction

Sample preparation is a tedious and yet unavoidable procedure in analytical chemistry [1]. The objective of this challenging and critical step is to transfer the analyte into a form that is pre-purified, concentrated and compatible with the analytical system [2,3]. The extracted and enriched analytes of interest from the sample matrix are often accomplished by procedures such as liquid–liquid extraction (LLE) [4,5] and solid-phase extraction (SPE) [6,7]. The invention of solid-phase microextraction (SPME) by Pawliszyn and co-worker [8] basically initiated the interest for microextraction techniques in analytical chemistry. SPME satisfies most of the requirements of a good sample preparation technique, including simplicity of use, automation, and low consumption of materials [9]. Thus, it has been applied to determine a broad range of organic compounds in numerous types of samples [10].

An alternative solvent-minimized sample preparation approach to complement SPME appeared in the middle-to-late 1990s [11–13]; liquid-phase microextraction (LPME) utilizes only a small amount of solvent (low microliter range) for concentrating analytes from aqueous samples. It is simply a miniaturized format of LLE and overcomes many of its disadvantages as well as some of those of SPME (e.g. non-dependence on a commercial supplier and sample carryover). LPME is simple to implement and use, generally fast, and is characterized by its affordability and reliance on widely available apparatus or materials [14]. The applications of LPME in environmental and biological analysis have been described in several papers [15–17].

LPME can be classified as two- and three-phase categories. In two-phase LPME, the target analytes are extracted from the aqueous sample matrix into the organic receiving phase [13,18,19]. Three-phase LPME (liquid–liquid–liquid microextraction, LLLME) is

doi:10.1016/j.talanta.2009.08.033

performed as hollow fiber or droplet based mode [20–24]. In hollow fiber LLLME, the analytes are first extracted from an aqueous sample matrix into the thin layer of the organic phase inside the wall pores of a hollow fiber, and then back-extracted into the acceptor phase located inside the hollow fiber [25]. In the other mode, the receiving phase is a microdrop of aqueous phase suspended from the tip of a microsyringe and located inside the organic phase [20,21,26]. Today, LLLME has been successfully utilized for the clean up and pre-concentration of ionizable analytes from a variety of matrixes [27–29], owing to its advantages.

Recently, Sarafraz-Yazdi et al. have developed a simple, efficient and novel LLLME that initially applied for the determination of diclofenac in environmental water samples [30]. The method was simplified droplet based LLLME using larger volumes of organic solvent to eliminate the use of microsyringe which is employed for suspending the acceptor drop at the tip of the needle. This quantitative LLLME is an efficient and satisfactory analytical procedure, because excellent accuracy and precision are demonstrated.

Atorvastatin ([R-(R*,R*)]-2-(4-fluorophenyl)-b, d-dihydroxy-5-(1-methylethyl)-3-phenyl-4 [(phenylamino) carbonyl] 1H-pyrrole-1-heptanoic acid, AT, $pK_a = 4.46$, $\log P_{ow} = 6.36$) is a potent inhibitor of HMG-CoA reductase, the rate limiting enzyme in cholesterol biosynthesis and has been demonstrated to be effective in reducing both cholesterol and triglyceride [31–33]. Also, AT is indicated to diminish the risk of myocardial infarction [34,35], stroke [36] which decreases the risk for revascularization procedures [37] and angina [38]. AT is rapidly absorbed after oral administration, however, due to pre-systematic clearance in the gastro-intestinal mucosa and metabolism in the liver, its absolute bioavailability is approximately 12%, and low plasma concentration is followed after taking the drug [39,40].

According to literature survey there have been several reports for the determination of AT in biological samples. Existing analytical methods for AT included an enzyme immunoassay [41], gas chromatography–mass spectrometry (GC/MS) [42] and also high-performance liquid chromatography equipped with mass spectrometry detection (HPLC-MS) [43,44]. GC–MS and HPLC–MS methods are sensitive and specific, but these devices may not be available in many pharmaceutical laboratories and need highly trained persons. In addition extraction and pre-concentration techniques, which are commonly applied to monitor the drug, are liquid–liquid extraction (LLE) [45,46] and solid-phase extraction (SPE) [47,48]. However, these sample pretreatment methods are considered expensive, time-consuming and labor-intensive, which often result in high blank values [49].

The aim of the present study is to assess the LLLME technique suitability for the determination of AT in human plasma. The factors affecting the microextraction efficiency were studied in detail and the optimal conditions were established. The resulting method was validated for quantitative purposes and applied to volunteer's plasma for sample analysis after oral administration of the drug in combination with high-performance liquid chromatography-ultraviolet detection (HPLC-UV).

2. Experimental

2.1. Materials and reagents

AT (purity 99%) and diclofenac sodium (DS, purity 99%), as internal standard (I.S.), were kindly supplied from Darou-Pakhsh Pharmaceutical Company (Tehran, Iran). All of organic solvents, sodium chloride, sodium hydrogen phosphate and hydrochloride acid were of analytical grade and purchased from Merck (Darmstadt, Germany). Trichloroacetic acid (TCAA) was obtained from Fluka (Buchs, Switzerland).

2.2. Instrument and apparatus

Separation, identification and quantification were performed with a Younglin HPLC system (ACME 9000, Korea), consisted of a Rheodyne 7725 injector (Cotati, CA, USA) equipped with a 5 μL sample loop. The separation was accomplished using a 150 mm × 4.6 mm i.d. × 5 μm particle size ODS-3 C_{18} analytical column (MZ, Germany) at room temperature (25 ± 0.5 °C). Isocratic mobile phase consisted of acetonitrile:0.1% acetic acid (70:30) was run through the column at flow rate of 1 mL min^{-1}. UV detection was performed at 246 nm and data were collected and processed with Autochrom 2000 software (Younglin, Korea). The temperature-controlling centrifuge (model: 2-16KC, Sigma, Germany) was used for centrifugation. The used water was purified with a Milli-Q water purification system (Millipore, Bedford, MA, USA). A 10 μL HPLC microsyringe (Bondaduz, Switzerland) was applied to introduce the acceptor phase and act as an injection syringe.

2.3. Preparation of standard solutions and plasma samples

Frozen, drug-free human plasma was obtained from the research center of Darou-Pakhsh pharmaceutical company (Tehran, Iran) and thawed at room temperature (25 ± 0.5 °C) before use. The plasma samples were obtained from healthy male volunteers. Stock solutions of AT (1 mg mL^{-1}) and I.S. (100 mg mL^{-1}) were prepared by dissolving proper amounts of pure substances in methanol, stored at 4 °C. Working solutions were prepared by diluting the stock solution with water. Spiked plasma samples were generated by adding 20 μL working solutions with different concentrations to 1 mL drug-free matrixes to yield final desired concentrations.

2.4. Directly suspended droplet LLLME procedure and deproteinization of plasma

The experimental microextraction setup is illustrated in Fig. 1. A water bath was placed on a magnetic stirring plate (IKA-Werke, Staufen, Germany) and the temperature (in the range of 25–55 °C) was controlled. 4.5 mL of the acidic aqueous sample (diluted plasma) was transferred in a 5 mL commercially available glass vial. A stirring bar (7 mm × 3 mm) was used to facilitate the mass transfer process. 400 μL of an organic phase was added to the sample solution by a 500 μL syringe (Hamilton, Reno, NV, USA) and stirred at 1250 rpm. After extraction for a prescribed time, the acceptor phase (5.5 μL, adjusted to pH 11 with 0.1 M Na_2HPO_4) was delivered to the top-center position of the organic membrane. The mixture was agitated at 600 rpm for a specified time and back-extraction was performed. Subsequently, the 5 μL of microdrop was taken into a microsyringe and injected into the HPLC system.

AT is extensively bounded to plasma proteins (98%) [50], and should be librated prior to extraction. Plasma sample (1 mL) was spiked with particular level of the drug and vortexed for 3 min. The mixture was acidified with 75 μL hydrochloric acid (37%) to disturb the drug protein binding. Then, 100 μL TCAA (100%, w/v) was added to denature the proteins. These processes eventually led to the precipitation of proteins. Subsequently, the sample was centrifuged at 10,000 rpm for 5 min. A volume of 0.75 mL of the supernatant was transferred to the sample vial, mixed with proper amounts of I.S (45 μL of the stock solution added to sample vial to achieve final concentration of 1 mg mL^{-1}) and then, diluted with water to 4.5 mL. The pH was adjusted to 1 with 0.1 mol L^{-1} HCl. To adjust the pH to desired value, a micropipette was used for the addition of appropriate amount of concentrated HCl.

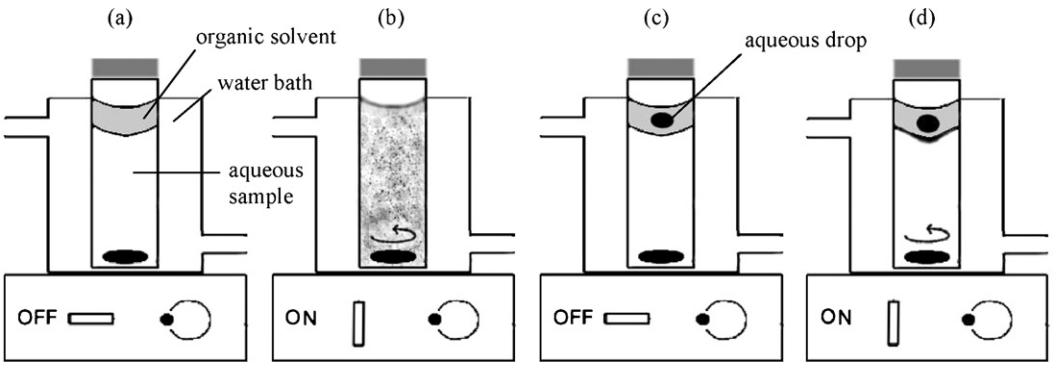

Fig. 1. Directly suspended droplet LLLME setup.

3. Results and discussion

The important aims of LLLME are to separate and clean up the analytes from the complex matrixes and to provide an efficient pre-concentration prior to HPLC or capillary electrophoresis (CE) determination. It involves the extraction of ionizable compounds from the aqueous sample (donor phase) at suitable pH into the organic layer (as membrane), followed by back-extraction into the receiving aqueous phase (acceptor phase) by adjusting the pH on the desired value. This back-extraction step introduces extra selectivity since neutral compounds will preferably stay in the organic phase. Extraction was induced by the pH difference inside and outside an organic membrane located at the interface [25,51,52].

3.1. Optimization of the LLLME process

A univariate approach was employed to optimize the influential factors in this method. The optimization was executed using 1 mL plasma containing 250 ng AT. In order to improve the precision and accuracy of the procedure in all of the experiments, DS with the concentration of 100 ng mL^{-1} was used as the I.S. and was added into the donor phase. Quantifications were performed by calculating peak areas relative to the I.S. from the average of 3 replicate measurements.

3.1.1. Selection of the organic solvent

The selection of appropriate organic solvent is of great importance in LLLME, in order to achieve satisfactory analyte pre-concentration [53,54]. Several organic solvents with different polarities were used to study their effects on extraction efficiency. The solvents including isooctane, 2-octanone, 1-octanol and hexyl acetate were examined. Fig. 2 depicts that 1-octanol presented the maximum extraction efficiency and thus was selected as the most suitable solvent.

3.1.2. Phase volume ratios

In three-phase LPME higher enrichment factors can be resulted by decreasing the volume ratio of acceptor to donor phase. However, in many cases optimization of the enrichment factor is not the primary goal, but rather optimization of recovery (R), defined by IUPAC as the ratio of the moles extracted (nA) and the number of moles initially present in the sample (nD):

$$R = \frac{nA}{nD}$$

At equilibrium the maximum recovery will be limited by the distribution coefficient and the volume ratio between the sample and acceptor phases [25,52]. To enhance recovery the acceptor volume must therefore be increased.

The phase ratio was varied by changing the volume of the microdrop in the range 3.0–6.0 μL, while the donor solution volume was kept constant (4.5 mL). It was found that the signal intensity of the analyte increased with the amplification of drop volumes. However, from a practical point of view, the drop greater than 5.5 μL was unstable especially with a high stirring speed. Accordingly, the following investigations were carried out with the drop volume of 5.5 μL to get higher extraction efficiency.

Due to the design of our extraction device, the volume of the organic phase was also important and needed to be optimized. The best volume of the organic solvent was found to be 400 μL. A smaller volume of organic solvent tended to cause instability of the aqueous drop during agitation, whereas the extraction efficiency is reduced if a larger volume of organic phase is used. Hence, a 400 μL volume of organic solvent was selected as the optimum on the basis of these observations.

3.1.3. The donor phase and acceptor drop pHs

The pH difference between donor and acceptor phases can promote the transfer analyte from the former to the latter [55]. To get a high distribution coefficient result leading to a high preconcentration, the donor solution should be sufficiently acidic to keep the drug in molecular form, and consequently reduce their solubility within this phase. The acceptor phase should be basic in order to promote dissolution of the acidic analyte.

The experiments were conducted to optimize the composition (leading to variation of pH) of both donor and acceptor solutions. First, the effect of the donor phase's pH on extraction efficiency was investigated. Solutions with different acidic pHs (0.5–3.5) were prepared by addition of appropriate amounts of HCl, while pH of the

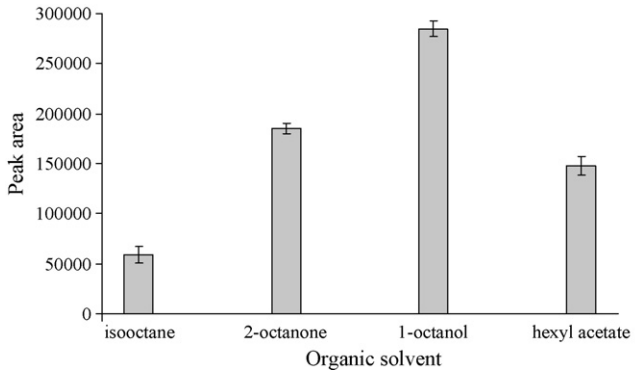

Fig. 2. Extraction efficiencies obtained for different organic solvents. Conditions: 4.5 mL aqueous sample (pH 1) at room temperature (25 ± 0.5 °C); organic phase volume: 400 μL; acceptor phase: 5.5 μL aqueous drop adjusted to pH 11 with 0.1 mol L^{-1} Na_2HPO_4; extraction and back-extraction time: 6.0 and 9.0 min, respectively; stirring rate for extraction and back-extraction: 1250 and 600 rpm, respectively.

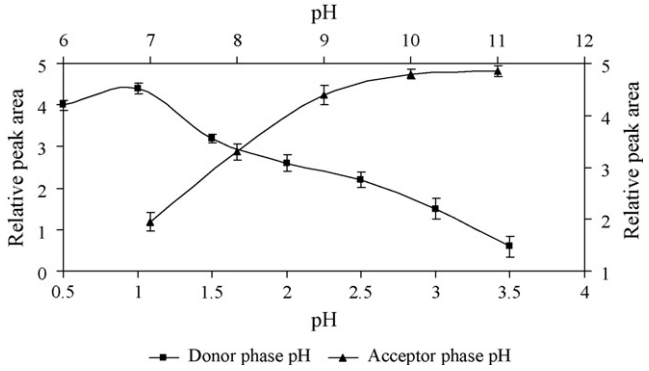

Fig. 3. Effect of the donor and acceptor phases' pH on the extraction of AT. Conditions: as with Fig. 2, organic solvent: 1-octanol.

acceptor phase was adjusted to 11.0 using 0.1 mol L^{-1} Na_2HPO_4. Since pH 1 provided the highest extraction efficiency (Fig. 3), it thus was selected for subsequent experiments. Secondly, the acceptor phase's pH, which was adjusted by 0.1 mol L^{-1} Na_2HPO_4 in the range of 7–11, was examined. The results, also shown in Fig. 3, indicate that the receiving phase with pH 10 could ionize the analyte more conveniently to prevent re-entering into the organic phase. Also, in order to investigate the effect of concentration of phosphate buffer on the extraction efficiency, aqueous solutions with various concentrations of Na_2HPO_4 (0.01, 0.05, 0.1 and 0.5 mol L^{-1}) were prepared and the extraction procedure was conducted. The results show that the best extraction efficiency was obtained at: 0.05 mol L^{-1} of Na_2HPO_4. Therefore, further experiments were done using the aqueous acceptor solutions containing 0.05 mol L^{-1} Na_2HPO_4 with pH 10.

3.1.4. Effect of the temperature

The temperature of extraction can influence the mass transfer rate and the partition coefficient of the analyte. So, it affects extraction kinetics and the time required to reach equilibrium diminishes [53,55]. The effect of sample solution temperature was studied in the range of 25–55 °C. An increase in analytical signal was observed up to 45 °C during this study (Fig. 4). After this point, some practical difficulties such as instability of the microdrop and reduction of its volume due to its higher solubility in the organic phase could occur. Thus, the sample temperature was held at 45 °C for the rest of the experiments as it gave a higher efficiency.

3.1.5. Effect of the ionic strength

The addition of salt to an analytical sample can potentially cause the formation of hydration spheres, which reduce the amount of water available to dissolve the analyte in water. This effect resulted in an increase in analyte recovery in microextraction procedures [56–58]. The NaCl concentration effect (0–20%, w/v) was investigated and the extraction efficiency was monitored. Based on the obtained results (Fig. 4), addition of salt did not improve the extraction efficiency. While the extraction efficiency was highest without the addition of sodium chloride, it subsequently decreased as more salt was added. This may be related to the formation of a physical barrier across donor phase and organic solvent interface, which could prevent the mass transfer of analyte into the organic phase. Hence, no salt was added in the subsequent experiments.

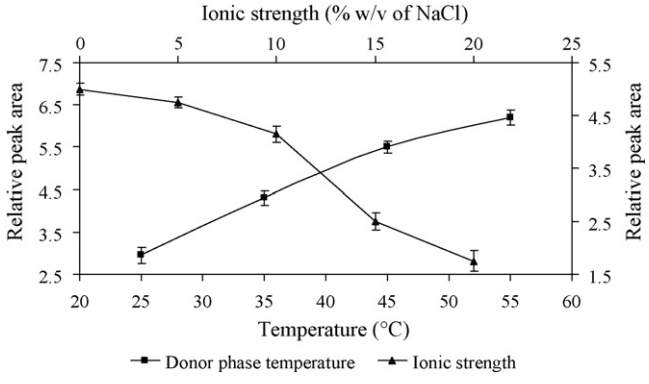

Fig. 4. Influence of the temperature and salt on the extraction efficiencies. Conditions: as with Fig. 3, donor and acceptor phases' pH 1 and 10, respectively.

3.1.6. Effect of the stirring rate

Magnetic stirring facilitates the mass transfer process and reduces the time required to reach thermodynamic equilibrium. So, it has been used universally to improve microextraction efficiency [59]. In this work, extraction was performed at the maximum magnetic stirrer performance, 1250 rpm. After utilizing the acceptor phase for back-extraction, this effect was studied at three different stirring rates: 0 (static case), 400 and 650 rpm. Faster stirring speeds were avoided due to the production of vortex flow in the membrane phase that could reduce stability of the microdrop. In this step, agitation of donor phase induces convection in the organic membrane. The obtained results show that the agitation improves the extraction efficiency of the target analyte significantly. Thus, a stirring rate of 650 rpm was used in the subsequent studies.

3.1.7. Extraction and back-extraction time profiles

LLLME system is an equilibrium based process that involves mass transfer from donor phase to organic layer and subsequently from organic layer to acceptor phase. The main objective in microextraction techniques is to achieve sufficiently high extraction efficiency within a relatively short period of time [60].

For the first equilibrium, extraction time was studied in the range of 0.5–6.5 min, while the time for back-extraction process was kept constant for 9.0 min. As shown in Fig. 5, the relative peak area was enhanced with the increase in exposure time up to 4.5 min and remained constant afterwards. An extraction time of 4.5 min therefore, was selected as the optimum.

The time of back-extraction was also investigated in the range of 3.0–12.0 min. As demonstrated in Fig. 5, the analytical signal increases quickly with sampling time of 7.5 min and after that the rate of increase slows down. It can be seen when the extraction time was set at 7.5 min, satisfactory extraction efficiency was achieved while equilibrium in the extraction of the analyte was not reached even at 12.0 min. Since it is not considered practicable for exposure time to be excessively long to allow equilibrium to occur, it

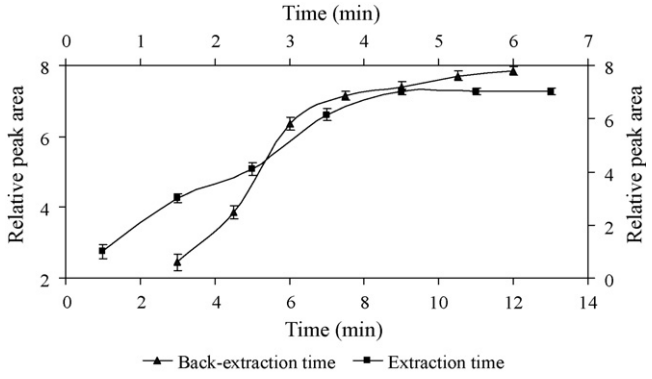

Fig. 5. Effect of the extraction and back-extraction time profiles on the LLLME efficiency. Conditions as with Fig. 4, stirring rate of back-extraction: 650 rpm and sample solution temperature: 45 °C.

Table 1
Quantitative data obtained after the LLLME–HPLC-UV determination of AT in human plasma.

Parameter	Analytical feature
Limit of detection (LOD based on S/N = 3, ng mL^{-1})	0.4
Limit of quantification (LOQ based on S/N = 10, ng mL^{-1})	1
Linear range (LR, ng mL^{-1})	1–500
Regression coefficient (r^2)	0.996
Enrichment factor (EF, at concentration level of 50 ng mL^{-1})	187
Extraction recovery (%) (ER)	22.9

should be just long enough for the extraction rate to have slowed to improve precision [12,61,62]. Furthermore, droplet lifetime cannot be too long due to drop dissolution or loss. Hence, a back-extraction time of 7.5 min appeared to be an appropriate value.

3.2. Evaluation of the method performance

To access the practical applicability of the LLLME method, the optimized conditions were adopted in the evaluation of linear range (LR), correlation coefficient (r^2), limit of detection (LOD, S/N = 3), limit of quantification (LOQ, S/N = 10), enrichment factor (EF) and also extraction recovery % (ER). An external calibration curve was plotted using plasma samples spiked with known concentrations of AT. For each level, three replicate extractions were performed. The results are summarized in Table 1. As shown, the LR is enough to cover the possible concentration of AT in various real samples. LOD and LOQ values imply a high sensitivity of the developed method.

For the EF calculation, three replicate extractions were performed from the aqueous solution containing 50 ng mL^{-1} of the analyte. EF was calculated as the ratio of the final analyte concentration in the acceptor phase and its concentration in the original solution. The AT standard solutions were prepared in acceptor phase and a calibration curve was drawn in the concentration ranges of 0.5–25 μg mL^{-1} with three replicate direct injections. The actual concentration of AT in acceptor phase was calculated from the non-extractive calibration curve and the EF value was determined.

ER% was calculated based on the following equation:

$$ER\% = (C_{acceptor} \times V_{acceptor}/C_{donor} \times V_{donor}) \times 100$$
$$= EF \times (V_{acceptor}/V_{donor}) \times 100$$

where $C_{acceptor}$ and C_{donor} are the analyte concentration in acceptor and donor phase, respectively. Moreover, $V_{acceptor}$ and V_{donor} are the volume of the acceptor and donor phase, respectively.

The results of the intra-day and inter-day precision at three different concentration levels are presented in Table 2. As it is illustrated, the intra-assay RSD measured at 6 runs a day of a sample was relatively low (4.4–7.0%). Also, the inter-assay precision evaluated on different days with a total of 8 runs provided RSD values in the range of 4.9–7.7%.

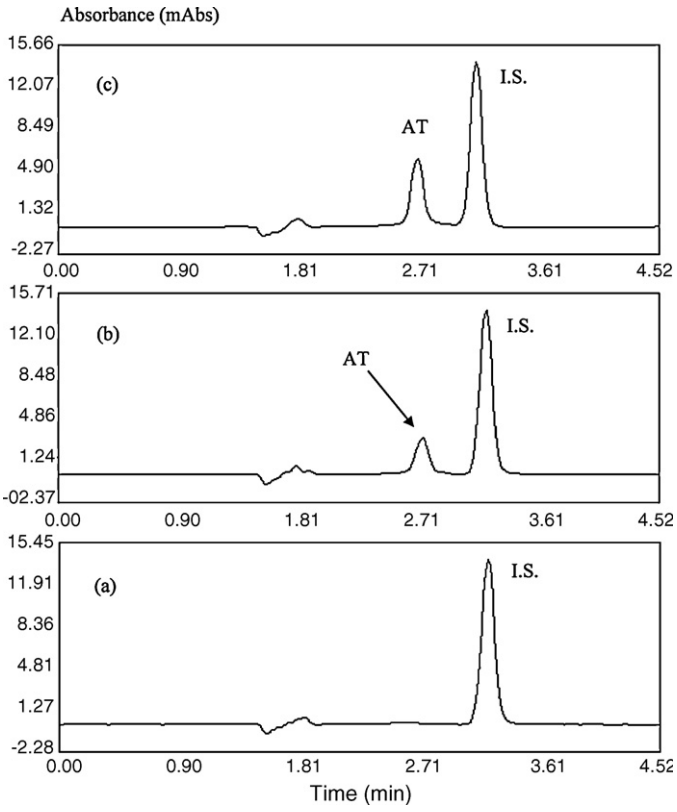

Fig. 6. HPLC-UV chromatograms obtained using developed method after oral administration of 40 mg single dose of AT at time (a) 0 h, (b) 2 h and (c) spiked sample.

Table 2
The intra-assay and inter-assay reproducibility of the method and instrument on plasma sample.

AT concentration (ng mL^{-1})	RSD (%)	
	Intra-day (n = 6)	Inter-day (n = 8)
5	7.0	7.7
50	5.8	6.4
250	4.4	4.9

As shown in Table 3, comparing LLLME–HPLC-UV with other analytical methods applied for the determination of AT in plasma samples, this technique along with its simplicity provided wider LR, lower LOD and an acceptable reproducibility.

3.3. Application

The developed protocol at optimal conditions was used to determine AT concentration in human plasma. Oral administration of a 40 mg single dose was performed to a healthy male volunteer. The concentration of AT 2 h after it was administrated was

Table 3

[e] ng zone^{-1}.

found to be 12.3 ng mL^{-1}. This sample was spiked with AT standard (C_{added} = 10.0 ng mL^{-1}) to assess the matrix effects. LLLME is a non-exhaustive extraction procedure and the relative recovery (determined as the ratio of concentrations found in real sample and reagent water sample, spiked with the same amount of analyte), instead of the absolute recovery (used in exhaustive extraction procedures), was employed. The relative recovery value of 91% (C_{found} = 21.4 ng mL^{-1} with RSD% = 7.2, n = 6) was achieved, which indicated that the real matrix in our present context had little effects on the LLLME. Fig. 6 shows the HPLC-UV chromatograms at 0 and 2 h after administration, and also the spiked sample. The obtained chromatograms reveal that in spite of the complex matrix of the sample, due to the high sample clean up performance, almost no other components than the target analyte were recovered in the acceptor solution.

4. Conclusion

The results from this work show that the LLLME technique in combination with HPLC-UV is a valid means of enrichment and quantification of AT at trace level in human plasma. The established protocol demonstrates good sample clean up with high sensitivity and reproducibility. Moreover, the entire analytical process presents an economical and rapid way for the screening purpose. Simplicity of operation and significant increase in acceptor phase volume (which causes major enhancement in the extraction recovery), are the important advantages of the method over conventional droplet based LLLME. Excellent extraction efficiency is achieved almost independent of the matrix in the actual application. Putting all the benefits together, it possesses great potential to be employed in bio-analytical and pharmacokinetic studies.

ABSTRACT

A novel 3-dimensional single wall carbon nanotubes (SWNTs)–polypyrrole (Ppy) composite was prepared as an electrode by chemically polymerizing polypyrrole onto SWNTs using a $LiClO_4$ oxidant. This composite electrode was characterized by scanning electron microscopy (SEM) and cyclic voltammetry with 1 mM $[Fe(CN)_6]^{-3}/[Fe(CN)_6]^{-4}$. The SWNTs were thickly coated with chemically polymerized polypyrrole and the composite had many surface pores and crevices which could enhance mass transfer. The SWNTs–Ppy composite electrode showed a large specific surface area (30 m^2/g) and a good reproducible current response, at about 100 times the peak current of a glassy carbon electrode (GCE). The diffusion coefficient was calculated to be 4.81×10^{-6} cm^2/s. As a biosensor application, tyrosinase was immobilized on the functionalized SWNTs and tyrosinase–SWNTs–Ppy composite was prepared in the same manner. This tyrosinase–SWNT–Ppy composite electrode was used for amperometric detection of dopamine in the presence of ascorbic acid and showed high sensitivity (467 mA/M cm^2) and lower detection limit (5 μM) compared to previous reports.

1. Introduction

Recently, the combination of nanoscale materials and biomolecules has been of great interest in the field of biotechnology, especially in bioelectronics [1–4]. Among several currently available nanoscale materials such as carbon nanotubes (CNTs), nanoporous silica, and gold nanodots, CNTs have drawn the highest interest since their discovery by Iijima in 1991 because of their extraordinary physical properties [5]. CNTs have been used as nanoscale conductors, catalyst carriers, and electrode materials [6–8]. In electrochemistry, CNTs have been widely used as a modified material in the preparation of electrodes because CNTs have advantages such as a large surface area, a good electrical conductivity, and easy surface functionalization that can enhance the performance of the electrodes. In previous studies, carbon nanotube modified electrodes (CNT-MEs) have been prepared by (1) filling a bare electrode with a mixture of the CNTs and mineral oil, (2) embedding or mixing carbon nanotubes into a graphite or a glassy carbon electrode and (3) coating directly onto the electrode surface [9–11]. However, the previous CNT-MEs have made a limited use of the advantages of CNTs, the large specific surface area and the good electrical conductivity. In the case of the CNT-MEs constructed by embedding or coating of the substrate electrode, which have a small, specific surface area, the large surface area of CNTs could not be used to the full effect. Also, chemical functionalization, such as an acidic treatment for the immobilization of proteins, can affect defeat sites, which are the broken parts of the bond network, and consequently affect the electrical properties of the CNT-MEs. In this paper, a single walled carbon nanotubes (SWNTs)–polypyrrole (Ppy) composite electrode was prepared to make the best use of the large surface area and the good electrical conductivity of CNTs. Although substrate such as glassy carbon electrodes or metal which can play a role as a current collector in the composite electrodes have been required in previous methods, a SWNTs–Ppy composite can be applied to the electrode itself without any substrate. For the electrode preparation, the conducting polymer polypyrrole was electrically polymerized as a thin film on the surface of the substrate electrode in general. However in this research, polypyrrole was chemically polymerized using $LiClO_4$ as an oxidant that played the role of a cross-linker for connecting the SWNTs and forming the thick 3-dimensional SWNT–Ppy composite, not an electrically deposited thin film.

Tyrosinase (E.C.1.14.18.1) is a multifunctional copper containing oxidoreductase widely distributed in nature. Tyrosinase has two catalytic activities in the presence of oxygen; hydroxylation of monophenols by a cresolase activity and oxidation of diphenols to quinine by a catecholase activity. Tyrosinase has a broad substrate specificity for various phenolic compounds such as phenol, catechol, cresol, dopamine and ephinephirine, which can be

doi:10.1016/j.talanta.2009.08.032

applied for the determination of phenolic compounds in food, environment and clinical diagnosis [12–14]. Dopamine, which can be a substrate of tyrosinase, is one of the most important neurotransmitter which affects the brain function. Deficiency of dopamine in the brain tissue causes Parkinson's disease, a neurological disorder which many elderly people have suffered from. Development of a tool for dopamine measurement in tissues can make a great contribution to diagnose Parkinson's disease. An electrochemical method has been widely used as a direct measurement for dopamine and has several advantages such as a small dimension, an easy operation, a fast response, and a high accuracy. However, the major problem of the electrochemical detection of dopamine in a real tissue is the co-existence of many interfering compounds. Among the interfering compounds, ascorbic acid is particularly important because both ascorbic acid and dopamine can be oxidized at similar potentials and these results in an overlap of the voltammetric response [15–17]. Therefore it is important to develop a method for the selective determination of dopamine with a high sensitivity and a low detection limit. For the biosensor application, tyrosinase was immobilized on the functionalized SWNTs and the prepared tyrosinase–SWNTs–Ppy composite was tested for determination of dopamine in the presence of ascorbic acid.

The goals of this study were (1) the characterization and the calibration of a 3-dimensional SWNTs–Ppy composite as an electrode and (2) the applications of the tyrosinase-immobilized SWNTs–Ppy composite to detect dopamine selectively in the presence of ascorbic acid.

2. Material and methods

2.1. Materials

SWNTs were purchased from IlJin NanoTech (Seoul, Korea). Tyrosinase (E.C. 1.14.18.1), monomer pyrrole, $LiClO_4$, $K_3Fe(CN)_6$, $K_4Fe(CN)_6$ and all other reagents were obtained from Sigma–Aldrich at the highest grade available and were used without a further purification.

2.2. Apparatus

Electrochemical measurements were performed with an AUTOLAB potentiostat at ambient temperature with a conventional 3-electrode system: working electrode, the SWNT–Ppy composite; counter electrode, coiled Pt wire; reference electrode, Ag/AgCl. Scanning electron microscope images were photographed out using a JEOL JSM-5210 to characterize the SWNT–Ppy composite electrode.

2.3. Tyrosinase immobilization

Before immobilization, 1 mg SWNTs were functionalized by 1.5 ml 1-pyrenebutyric acid (0.1 M in dimethylformaldehyde) for non-covalently introducing carboxyl groups on the surface, shaking at 200 rpm for 1 h. After washing the functionalized SWNTs with methanol and distilled water, respectively, tyrosinase was covalently attached onto the functionalized SWNTs by 100 mM EDC (1-ethyl-3-(3-dimethylaminopropyl)carbodiimide), in 50 mM phosphate buffer (pH 6.5),with an activation time of 30 min [18].

2.4. Preparation of 3D SWNTs–Ppy composite electrodes

The SWNTs–Ppy composite was prepared by chemical polymerization of monomer pyrrole by mixing the monomer pyrrole and 0.1 M $LiClO_4$ in a phosphate buffer (50 mM, pH 6.5) in a 2:1 volume ratio. SWNTs with/without tyrosinase were added rapidly to the mixture, which was then cast in an electrode holder and hardened overnight at the ambient temperature.

3. Results and discussion

3.1. Characterization of the composite electrode

3.1.1. SEM of the SWNTs–Ppy composite

Fig. 1 shows the SEM images of the SWNTs–Ppy composite electrode. As shown in Fig. 1(a), the SWNT was thickly coated by chemically polymerized polypyrrole. The SWNTs–Ppy composite had many pores on the surface which could prevent mass

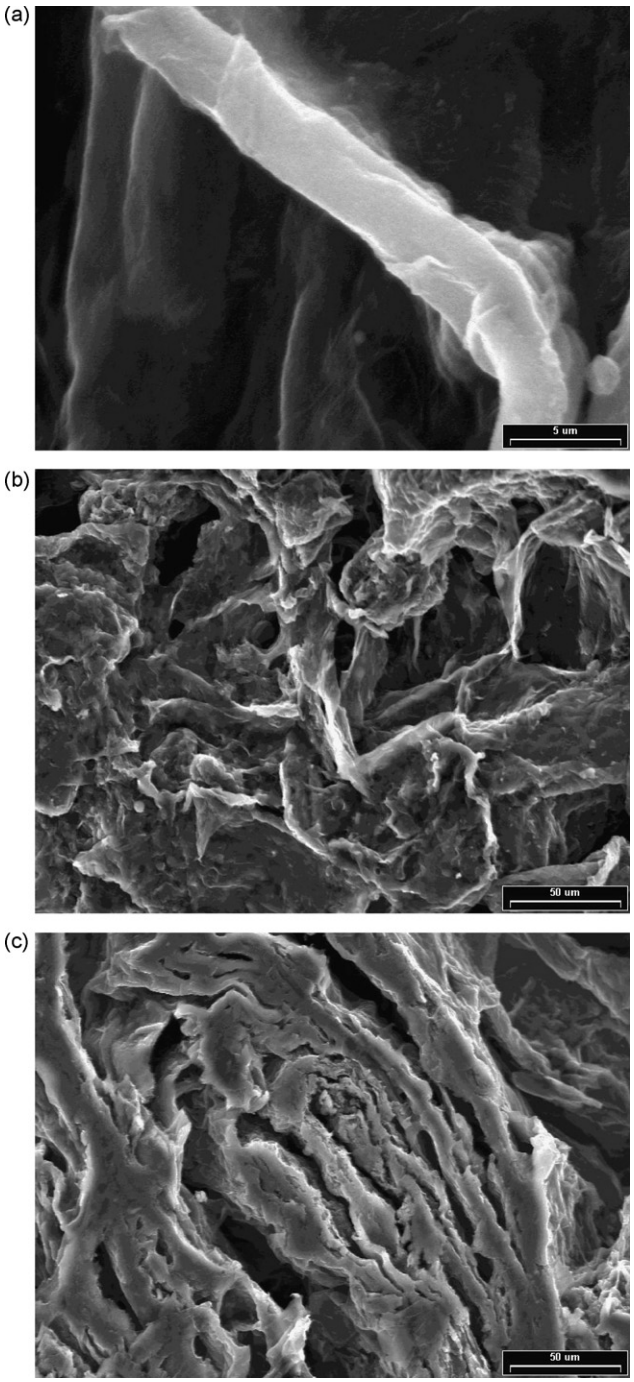

Fig. 1. SEM image of SWNT–Ppy composite (a) Ppy coated SWNT, (b) surface of SWNT–Ppy composite and (c) cross-section image of SWNT–Ppy composite.

transfer limitation as shown in Fig. 1(b). Fig. 1(c) reveals that the SWNTs–Ppy composite electrode had several layers and many crevices in the cross-section, which could also reduce mass transfer limitation. The composite surface was non-uniform and had some partially excessive polymerized surface. To prevent the excessive polymerization, the ratio of the oxidant $LiClO_4$ and monomer pyrrole was optimized. As a result, the excessive polymerization was minimized by using a 2:1 ratio mixture of the reactants (v/v, monomer pyrrole to 0.1 M $LiClO_4$) and 10 μl of the mixture was enough to produce 1 mg SWNT.

3.1.2. Cyclic voltammogram of the SWNTs–Ppy composite

Fig. 2 shows the cyclic voltammograms for a glassy carbon electrode(GCE) and the SWNTs–Ppy composite in 0.1 M $[Fe(CN)_6]^{-3}/[Fe(CN)_6]^{-4}$ solution in 10% H_2SO_4 (v/v%) with a scanning rate of 20 mV/s. From Fig. 2, the current response of the SWNTs–Ppy composite electrode was about 100 times larger than that of the GCE under the same testing conditions. As shown in Table 1, compared to other papers previously reported, the current response of the SWNTs–Ppy composite electrode was higher although the system was in low $K_3Fe(CN)_6$ concentration and with a slow scan rate. The difference between the GCE and SWNTs–Ppy composite also indicated that the SWNTs–Ppy composite had a larger capacitance than the GCE. This enhanced that the current response could be attributed to the much larger specific surface area of the composite (30 m^2/g, from BET result, data not shown) effectively increasing the electron transfer and consequently increasing the current response. The large specific surface area of the SWNTs–Ppy composite provides a high probability of contacts between electrons and the electrode surface and causes the increase in the current response, consequently. The larger current response of SWNTs–Ppy composite electrode was also the result of the increased numbers of defeat sites on the electrode surface.

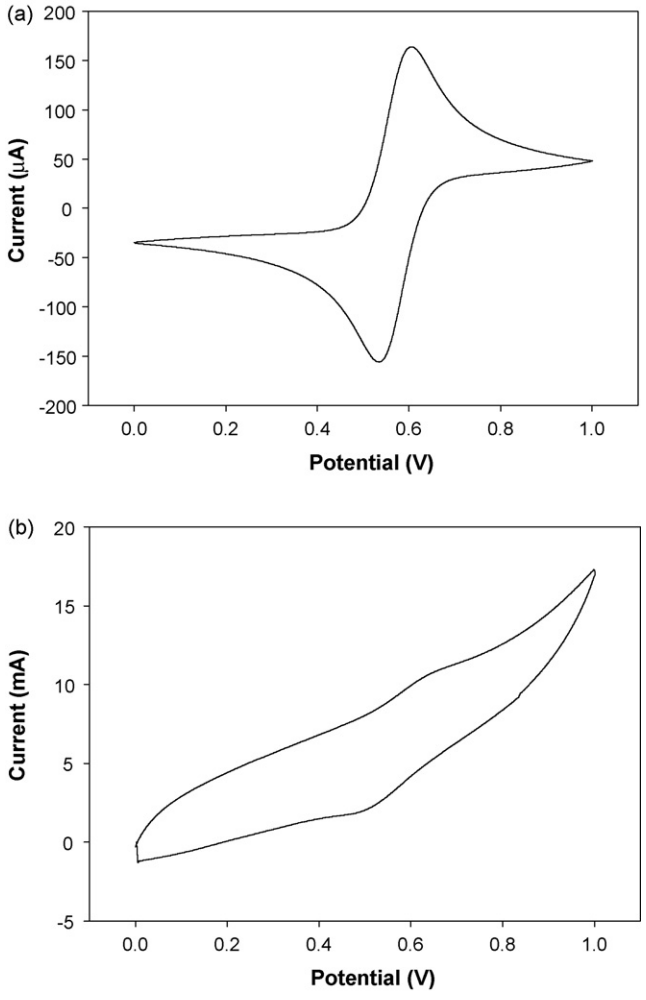

Fig. 2. Cyclic voltammogram of (a) glassy carbon electrode and (b) SWNT–Ppy composite with 0.1 M $[Fe(CN)_6]^{-3}/[Fe(CN)_6]^{-4}$ solution in 10% H_2SO_4 (v/v%) with a scanning rate 20 mV/s.

Table 1
Current responses for the different carbon based composite.

Graphite–poly(methylmethacrylate) composite	2.2×10^{-5} [d]	[26]
SWNT–Ppy composite	1.0×10^{-2} [e]	This study

[a] 5 mM $K_3Fe(CN)_6$, scan rate 100 mV/s.
[b] 10 mM $K_3Fe(CN)_6$, scan rate 100 mV/s.
[c] 5 mM $K_3Fe(CN)_6$, scan rate 50 mV/s.
[d] 5 mM $K_3Fe(CN)_6$, scan rate 200 mV/s.
[e] 1 mM $K_3Fe(CN)_6$, scan rate 20 mV/s.

The SWNTs–Ppy composite electrode, which showed the large current response and had the high effective surface area, may contribute to develop a biosensor system with a high sensitivity. Recently, amperometric enzyme-based biosensors have been developed for chemical and biomedical analysis [19–21]. However, the sensitivity of these biosensors is low without a mediator because the active sites of the enzymes are deeply buried and the electron transfer efficiency is not good in the absence of mediator. This SWNTs–Ppy composite with a high current response can be a potential candidate for the development of mediator-less enzyme-based biosensors. This SWNTs–Ppy composite can also provide a large surface, which is for a large amount of enzyme loading and for frequent contacts with electrons generated from the enzyme catalysis, and additionally enhance the current response.

In this study, a 3-dimensional SWNTs–Ppy composite electrode was prepared without a substrate electrode as a current collector. It was unknown whether the prepared 3-dimensional composite electrode could exhibit accuracy without a current collector, so the accuracy of the prepared composite as an electrode was also examined by the $[Fe(CN)_6]^{-3}/[Fe(CN)_6]^{-4}$ pair solution. As shown in Fig. 2, in the case of the GCE, the oxidation peak voltage and the reduction peak voltage were 603 and 535 mV, respectively. In the case of the SWNTs–Ppy composite, the oxidation peak voltage and the reduction peak voltage were 600 and 469 mV, respectively. The difference between the oxidation peak voltage and the reduction peak voltage was small, because the system was reversible. The high regression coefficient of the relationship between the oxidation peak current and the square root of the scanning rate also indicated the accuracy of the prepared SWNTs–Ppy composite electrode. Fig. 3 indicates that the $[Fe(CN)_6]^{-3}/[Fe(CN)_6]^{-4}$ system with the prepared SWNTs–Ppy composite electrode was a reversible system. In fact, the $[Fe(CN)_6]^{-3}/[Fe(CN)_6]^{-4}$ was a reversible oxidation–reduction pair. Consequently, the prepared SWNTs–Ppy composite electrode-incorporated system appeared reliable.

3.1.3. Diffusion coefficient

In the composite electrode, the accessibility of the reactant to the inner part of the electrode has been one of the most important factors. Although the SWNTs–Ppy composite electrode had enough pores and crevices detectable in SEM images to decrease mass transfer limitation, the question remains whether the reactant can actually access the SWNT through the thickly polymerized

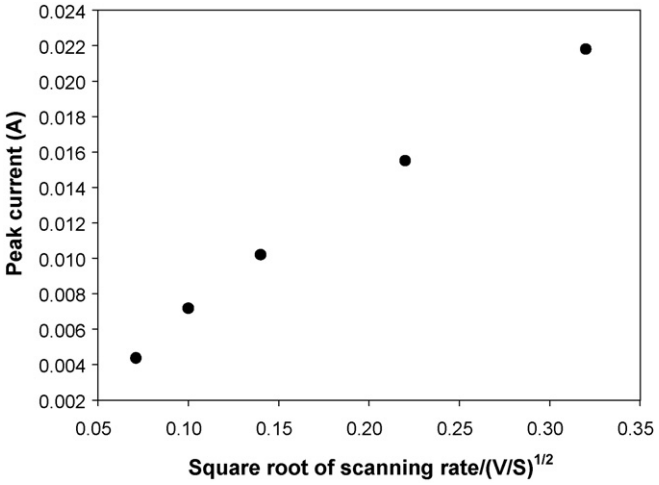

Fig. 3. Relationship between the square root of scanning rates and the peak currents of the SWNT–Ppy composite in the $[Fe(CN)_6]^{-3}/[Fe(CN)_6]^{-4}$ solution.

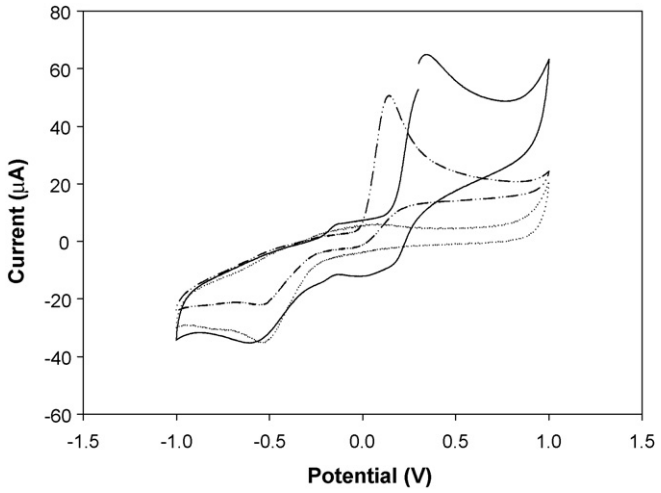

Fig. 4. Cyclic voltammogram of 1 mM dopamine (—), 1 mM ascorbic acid (— - - —), and phosphate buffer (- - - -) using 20 unit free tyrosinase and glassy carbon electrode, scanning rate 50 mV/s.

polypyrrole layer. To validate the accessibility of the reactants to the SWNTs–Ppy composite electrode, the diffusion coefficient was determined from cyclic voltammetry at different scanning rates operating with the $[Fe(CN)_6]^{-3}/[Fe(CN)_6]^{-4}$ solution. The relationship between the oxidation peak current and the square root of the scanning rate was studied as shown in Fig. 3, which yielded a linear relationship with a high regression coefficient ($R^2 = 0.996$). The slope is proportional to the diffusion coefficient of $Fe(CN)_6$ within the SWNT–Ppy composite and the diffusion coefficient was calculated from the following equation, shown in Table 2 [22].

$$I_p = 2.69 \times 10^5 \times n^{3/2} \times S \times C \times V^{1/2} \times D^{1/2} \quad (1)$$

where I_p, peak current (A); n, charge transfer number ($n = 1$); S, surface area of electrode (cm^2); D, diffusion coefficient (cm^2/s); V, scanning rate (V/s).

Based on the diffusion coefficient, we believe that this 3-dimensional composite electrode will solve the problem of mass transfer limitation in enzyme-based biosensors.

3.2. Application for dopamine sensor in the presence of ascorbic acid

3.2.1. Determination of working potential for dopamine detection

Fig. 4 shows the cyclic voltammograms of the 200 mM phosphate buffer (pH 6.5), 1 mM dopamine and 1 mM ascorbic acid with a glassy carbon electrode and 20 unit free tyrosinase at the scan rate 50 mV/s. In the absence of dopamine, there is no peak in the cyclic voltammogram. In the presence of 1 mM dopamine, the cyclic voltammogram had a definite oxidation peak at 346 mV, which was due to the oxidation of the dopamine by the enzyme catalysis on the electrode surface. As shown in Fig. 4, ascorbic acid is also oxidized at 143 mV. Therefore, the potential of 346 mV was determined as a working potential for the amperometric measurement of dopamine.

Table 2

[b] 1 mM $K_3Fe(CN)_6$.
[c] 1 mM $K_3Fe(CN)_6$.

3.2.2. Amperometric response of the tyrosinase–SWNTs–Ppy composite electrode for dopamine detection in the presence of ascorbic acid

Dopamine was detected by the tyrosinase–SWNTs–Ppy composite electrode in 50 mM phosphate buffer (pH 6.5) at a working potential of 346 mV (vs. Ag/AgCl) under constant stirring. The amperometric responses to the addition of various concentration of dopamine are indicated in Fig. 5. A well-defined oxidation current was observed in proportion to the concentration of dopamine. A major problem of the electrochemical detection of dopamine in real tissues is the co-existence of many interfering compounds. Among the interfering compounds, ascorbic acid is particularly important because both ascorbic acid and dopamine can be oxidized at similar potentials and this results in an overlap of the voltammetric responses. As shown in Fig. 5, only ascorbic acid solution with no dopamine did not show any amperometric response although the ascorbic acid concentration (40 μM) was 8 times higher than the initial concentration of dopamine (5 μM). The selective determination of dopamine in the presence of ascorbic acid is feasible

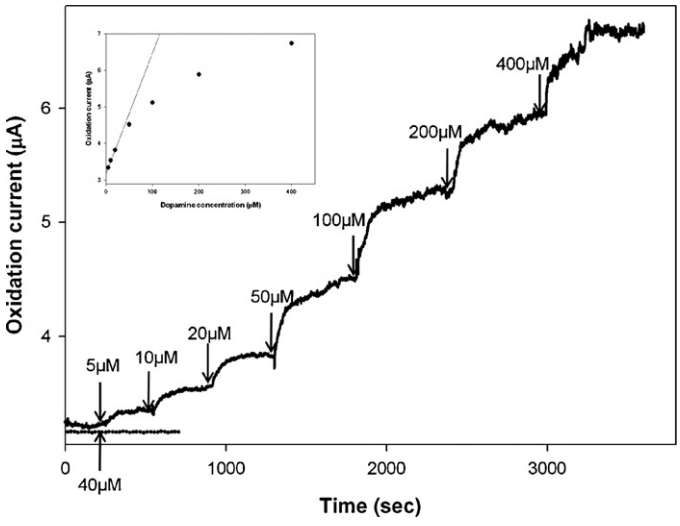

Fig. 5. Amperometric response of the tyrosinase-immobilized carbon nanoparticle polypyrrole composite electrode (- - - - -) ascorbic acid (—) dopamine in an air-saturated blank buffer (50 mM phosphate buffer, pH 6.5) under stirring. Inset: calibration plots of the electrode to dopamine.

Table 3
Performances of the tyrosinase-immobilized dopamine sensors.

Sensitivity (mA/M cm^2)	Linear range (μM)	R^2[a]	Detection limit (μM)	Response time (s)	Reference

using the tyrosinase–SWNT–Ppy composite electrode. This electrode also shows a rapid response within 5 s when dopamine was added to the system. Inset of Fig. 5 shows the dependence of the steady state current on the concentration of dopamine. Linearity was observed within the range 5–50 μM and the sensitivity corresponding to the linear range for dopamine was 467 mA/M cm^2. The characteristics of the tyrosinase-immobilized electrode for dopamine detection was summarized in Table 3, where the tyrosinase–SWNTs–Ppy composite electrode shows the highest sensitivity and a low detection limit compared with the previously reported tyrosinase-immobilized biosensor for dopamine detection. The tyrosinase–SWNTs–Ppy composite electrode showed a good reproducibility. The relative standard deviation estimated by 5 measurements of 20 μM dopamine at 346 mV (vs. Ag/AgCl) was about 2.5%.

4. Conclusions

The 3-dimensional SWNTs–Ppy composite was prepared with chemically polymerized polypyrrole using $LiClO_4$ as an oxidant without any substrate such as GCE or metal plate. The prepared SWNTs–Ppy composite electrode showed a much larger current response than the GCE, due to the large specific surface area that increased the frequency of contacts between the electrode surface and electrons and enhanced the electron transfer rate. This system has a great potential for applications in the amperometric enzyme-based biosensor for high sensitivity because the amount of enzyme loading could be increased considering the large specific surface area of the SWNTs–Ppy composite leading to a large current response. Considering the diffusion coefficient determined with the $[Fe(CN)_6]^{-3}/[Fe(CN)_6]^{-4}$ solution, mass transfer could not be a problem in the amperometric enzyme-based biosensors. The tyrosinase–SWNTs–Ppy composite was developed for the determination of dopamine. This composite electrode showed a high sensitivity and a low detection limit and could make a contribution to the diagnosis of neurological disorders.

ABSTRACT

We developed a simple and easy method for solution mixing based on the heat-induced regulation of capillary action in thermo-responsive polymer-coated microchannels. The channels having two T-junctions were fabricated on a glass plate by a sand-blast technique and then coated with a poly(*N*-isopropylacrylamide) film. The polymer-coating was performed by the modification with allyltrimethoxysilane and the subsequent radical polymerization of *N*-isopropylacrylamide and *N*,*N*′-methylenebisacrylamide. When the channel was warmed by a Peltier device, a capillarity-based solution flow completely stopped because of the water-repellency of channel surfaces. On the other hand, the cooling of the channels allowed the restart of the solution flow through hydrophilic channels. Solution mixing downstream a T-junction was readily conducted by a Peltier device that had placed at the junction. The technique was applied to the fluorometric analysis of polyamines in saliva. The saliva sample was mixed with nickel(II) chloride solution at the first junction to mask amino acids and then mixed with *o*-phthalaldehyde solution at the second junction to form the fluorometric derivatives of polyamines. Blue fluorescence was observed downstream the second junction. Linear correlation was obtained between the emission intensity and the spermine concentration in the range of 20–100 μM. No mechanical pump or valve was required for the fluid manipulation.

1. Introduction

Fluid manipulation has been an important research topic increasing interest in the microfluidic analytical systems. Highly precise micro-pumps or high-voltage power supplies have extensively been used for driving solution flows. Physically driven valves or electric fields have widely been utilized for regulating fluids. Various techniques have been examined and adopted to the fluid manipulation inside microchannels [1–8]. However, these techniques tend to require expensive instruments and delicate operations. Highly precise techniques are also necessary for fabricating channels including micro-valves, ators, or micro-patterns. The development of simple and easy methods for fluid manipulation helps the practical use of microfluidic systems in wide areas.

We have designed a novel fluid control technique based on the heat-induced wettability change on thermo-responsive polymer-coated microchannels [9–11]. The mechanism is explained by the significant decrease of the capillary action inside narrow glass channels coated with poly(*N*-isopropylacrylamide) [PNIPAAm] above the lower critical solution temperature (LCST, ca. 32 °C [12]). The surface of PNIPAAm-coated glass is hydrophilic below LCST, while it turned to be hydrophobic above LCST. Indeed, the water-contact angle was 32° at 30 °C, while it was 68° at 35 °C [9]. Discontinuous air/water flow generated by micro-syringe pumping was switched by warming the branch of PNIPAAm-coated capillary channel [9]. Another example is heat-induced actuation of a water plug inside a PNIPAAm-coated fused silica capillary. When a point of the capillary close to a water plug was warmed, the water plug was moved toward opposite direction of the warmed position [10].

More recently, heat-induced water-repellency was achieved when PNIPAAm-coated frost glass having sub-micrometer levels of surface roughness was used. The contrast of temperature dependent water-contact angles was remarkably extended (24° at 30 °C, while 104° at 35 °C) [11]. Switching of liquid flow downstream a junction of a PNIPAAm-coated microchannel was successfully demonstrated. In the present study, we examined the usefulness of the heat-induced fluid manipulation for a simple method for solution mixing. The applicability of the proposed technique to the fluorometric determination of polyamines in saliva was investigated.

2. Experimental

2.1. Materials and reagents

A microchannel (depth and width; 200 ± 5 μm, surface roughness; R_a = 0.3–0.7 μm) having three reservoirs and two T-

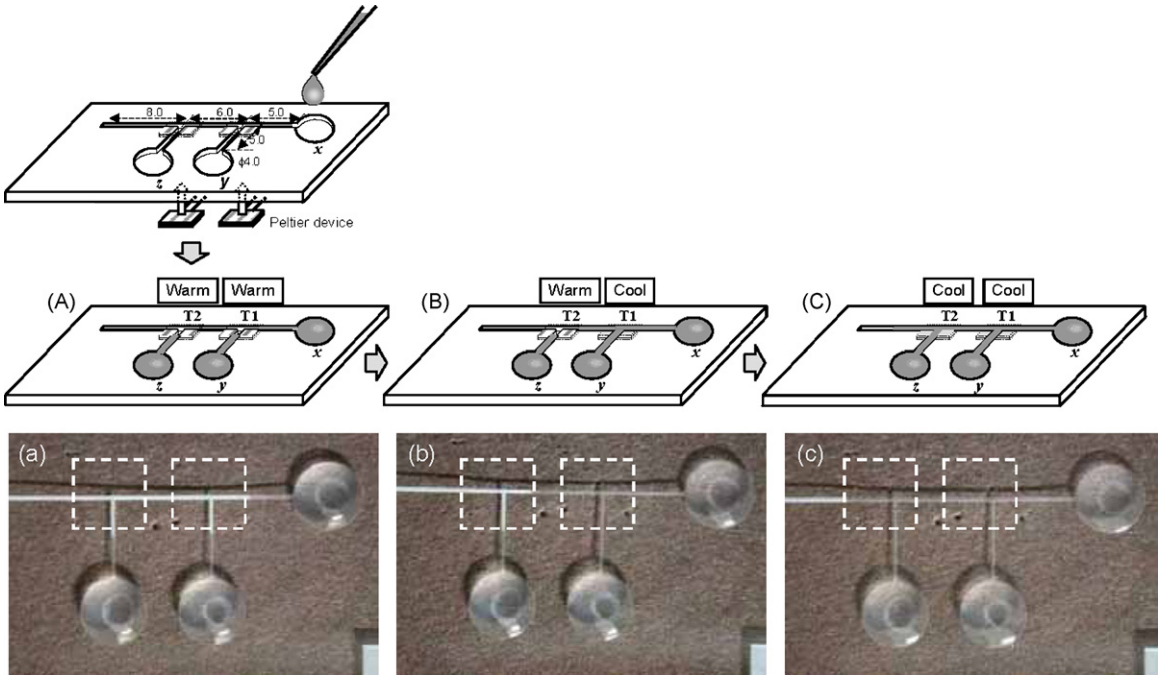

Fig. 1. Features of heat-induced solution mixing on a PNIPAAm-coated microchannel. The reservoirs *x*, *y*, and *z* are for sample solution, nickel (II) chloride solution, and OPA agent solution. Dashed lines in photographs indicate the position of Peltier device.

junctions (Fig. 1) was fabricated on a glass plate (borosilicate, 21 mm × 36 mm, 1.0–1.2 mm thickness, Matsunami Glass, Kishiwada, Japan) by a sand-blast technique (Fuji Manufactory, Tokyo, Japan). The polymer-coating on the surfaces of microchannels was performed by the similar manner to previously reported [11]. It included the modification with allyltriethoxysilane instead of Bind-Silane™ and the subsequent radical polymerization to form a PNIPAAm film. The modification was performed by immersing the microchannel plate in toluene solution of 10% allyltriethoxysilane (Tokyo Chemical Industries, Tokyo, Japan) for 48 h at 25 °C. After washing with ethanol and subsequently with water, the plate was placed into 25 ml of 10 mM phosphate (pH 7) containing 1.7 g *N*-isopropylacrylamide and 0.11 mg methylene bisacrylamide. The solution was precedently passed through a Sep-Pak C_{18} solid-phase extraction cartridge (for environmental analysis, Waters, Milford, MA, USA) for removing polymerization inhibitors. Under nitrogen atmosphere, 0.5 ml aqueous solution of 0.05 g ammonium persulfate and 25 μl of *N*,*N*,*N*′,*N*′-tetramethyethylenediamine were added to start radical polymerization. Four hours later, the plate taken out from the solution was washed with water and then dried by blowing air in a clean bench. The polymer-coating was evaluated from the ATR-IR spectrum (ν_{N-H} 3300 cm^{-1}, ν_{C-H} 2960 cm^{-1}, and $\nu_{C=O}$ 1640 cm^{-1}).

Spermine tetrahydrochloride (for molecular biology) was obtained from Sigma (St. Louis, MO, USA). A 0.5-ml aliquot of methanol [containing 20 mg of *o*-phthalaldehyde (OPA) and 20 μl of 2-mercaptoethanol] was mixed with 4.48 ml of 1 mM borate buffer (pH 9). The solution was 60-fold diluted with the borate buffer to prepare 0.5 mM OPA solution. A 0.5 mM nickel(II) chloride solution was used for masking amino acids.

2.2. Measurement of water-contact angle

The static water-contact angle was measured with a Kyowa Kaimen (Asaka, Japan) CA-D contact angle meter having a thermostatic module. After setting temperature, one drop (10 μl) of water was deposited on a surface of the PNIPAAm-coated glass plate. The water-contact angle was observed microscopically.

2.3. Observation of fluid in microchannels

One drop (ca. 10 μl) each of sample or reagent solution was placed into the respective reservoir of a PNIPAAm-coated microchannel. Two T-junctions were precedently warmed to 37 °C with attaching Peltier devices (Telecom grade thermo-module KSML007, 4.4 mm × 4.4 mm, Komatsu Electronics, Hiratsuka, Japan) below the glass plate of the channel. The electric current and voltage applied to the device were 0.45 A and 0.5 V, respectively. The fluid in the channel was photographed with a Nikon COOLPIX 4500 digital camera (4.0 mega pixels, Tokyo, Japan) to obtain JPEG images. In the fluorometric analysis, the channel plate was illuminated with a UV lamp SLUV-6 (365 nm, 9 W, AS ONE, Osaka, Japan). The experiment was performed in a dark room.

3. Results and discussion

3.1. Water-contact angle of PNIPAAm-coated glass surfaces

Hydrophilic or hydrophobic properties of PNIPAAm-coated glass surfaces were evaluated on the basis of static water-contact angle. As reported previously, the contact angle on the PNIPAAm-coated glass surfaces dramatically changed across the LCST of PNIPAAm [11]. However, the contrast of hydrophilic–hydrophobic property gradually decreased by soaking the PNIPAAm-coated glass plate in weakly alkaline media (pH 9) probably due to the hydrolysis of ester moiety of Bind-Silan™ or 3-(methacryloyloxy)propyltrimethoxysilane. Indeed, the water-contact angle (104°) above the LCST decreased to <90° after soaking the glass plate for 2 h. This problem was solved by using allyltrimethoxysilane having no ester moiety and by adjusting the solution pH to 7 (10 mM phosphate) during radical polymerization. Reversible and reproducible change of hydrophilic–hydrophobic properties on the surfaces was achieved. The water-contact angle was 106 ± 6° at 37 °C, while it was 24 ± 4° at 25 °C (n = 50). They were stable in the aqueous buffer solution of 10 mM of borate (pH 9) at least for 15 min.

3.2. Heat-induced solution mixing in a PNIPAAm-coated microchannel

Solution mixing on a PNIPAAm-coated microchannel was illustrated in Fig. 1. Firstly, both T-junctions (T1 and T2) of the channel were warmed to 37 °C with Peltier devices. Here, Milli-Q water was used instead of sample or reagent solution. Water placed in the respective reservoirs (*x*, *y*, and *z*) flowed through narrow channels and stopped at the edge of Peltier devices (Fig. 1A). The photograph for the situation of Fig. 1A is shown in Fig. 1a. The portion of channel filled with water is blackish, while the unfilled channel is bright due to the light scattering on the frost glass surfaces. A black paper was laid behind the glass plate in order to minimize reflection light. Capillarity-based flow was not further introduced into water-repellent portions of the channels.

When the electric current to the Peltier device at T1-junction was turned off, the solution flow soon restarted. This is ascribable to the rapid recovery of the wettability inside the channels. The solutions from reservoirs *x* and *y* joined at T1-junction and further flowed downstream the junction. Solution mixing was conducted only by the warming and the subsequent cooling of the junction. The position for brief solution stop was important to adjust the meeting of two fluids at the junction. The fluid stopped again at the edge of another Peltier device (Fig. 1B and b). Finally, the electric current to the Peltier devise at T2-junction was turned off. The solution from reservoir *z* joined to that from T1-junction and then further moved downstream T2-junction (Fig. 1C and c). The sequential mixing of fluids was conducted just by turning on and off the electric current to Peltier devices.

The width or depth of channels, orientation of junctions, and conditions of channel walls may affect the mixing ratio and accuracy of solution mixing. These factors would also be available to control flow rate or mixing ratio. For example, Y-junctions seem to be more suitable for the accurate and equi-volume solution mixing. In the present study, T-junctions were adopted because of the easiness in the disposition of Peltier devices and their manipulation.

3.3. Application to polyamine analysis

Aliphatic polyamines such as spermine, spermidine, putrescine, and cadaverine play important roles in DNA, RNA, and protein synthesis as well as in varieties of metabolic systems [13–15]. Therefore, the determination of polyamines is important for evaluating cell growth or cancer progress [16–18]. They can be fluorometrically determined by the *o*-phathaldehyde (OPA) method in the basis of the formation of fluorometric derivatives with OPA in the presence of 2-mercaptoethanol [19]. However, amino acids in saliva also react with OPA to form their fluorescent derivatives and, hence, give positive error to the determination of polyamines. Nickel(II) ions have been found to be a good masking agent for amino acids, because they form stable complexes with amino acids in weakly alkaline conditions [20]. Therefore, the sample solutions have to be mixed with nickel(II) solution before mixing with the OPA solution. The determination was started by depositing one drop (ca. 10 μl) each of sample solution, 0.5 mM nickel(II) chloride solution, and 0.5 mM OPA solution into reservoirs *x*, *y*, and *z*, respectively. The heat-induced solution mixing was conducted as described above. After two-step solution mixing, bright blue fluorescence was observed downstream T2-junction. The intensity became maximum and constant ca. 1 cm downstream the junction, indicating effective diffusion in the narrow channels.

The calibration curves of spermine are shown in Fig. 2, in which the fluorescence intensities are represented by 256-scale intensities of blue, green, and red color elements. The color images downstream T2-junction on the digital photographs were analyzed by the color evaluation method using Adobe Photoshop Elements® [21].

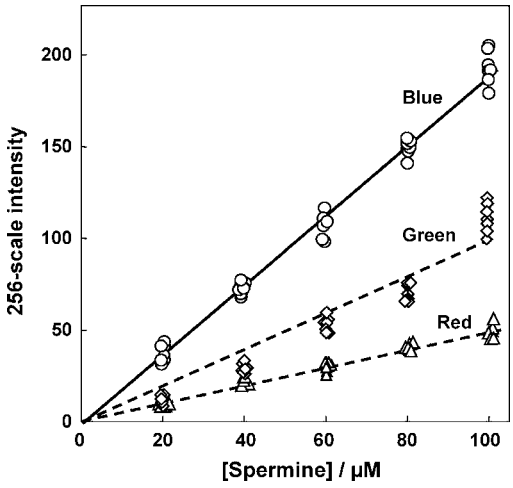

Fig. 2. Calibration curve of spermine based on 256-scale intensities of blue, green, and red color elements.

The angle between camera lens axis and light source axis was optimized to 60° for obtaining reproducible results with minimizing diffuse reflection. The net intensities were calculated by subtracting blank intensities. When blue color was used, linear calibration curves were obtained in the concentration range of 20–100 μM. Standard deviation in the determination of 40 μM spermine was ca. 10%. The determination using green or red color element was less sensitive.

The fluorescence intensities for four major polyamines (spermine, spermidine, putrescine, and cadaverine) reached constant after 1 min of the solution mixing. Venza et al. [19] reported that the fluorescence intensities were dependent on the kind of polyamine and rapidly decreased in the aqueous solution due to the low stability of the OPA derivatives. However, the fluorescence intensities of the derivatives of these polyamines were almost independent of the kind of polyamine and stable for 5 min in the present experimental conditions (ca. 0.25 mM OPA). Therefore, the calibration curve for spermine was used for estimating approximate concentration of total polyamines.

Next, the interference of amino acids was studied, because saliva contains sub-mM levels of total amino acids [22–24]. Table 1 shows the determination of 40 μM spermine in the presence of several amounts of glycine. Negligible interference was observed in the concentration of glycine up to 50 μM. However, the presence of more than 60 μM of glycine gave remarkable positive error. As described below, this problem was solved by diluting samples with a buffer solution.

Sample introduction was performed just by dripping one drop of saliva sample on a reservoir. However, saliva was so viscous for the smooth flow through narrow channels. Additionally, the con-

[a] Estimated by spermine.

centration of polyamines was remarkably greater than the upper limit of the calibration. Therefore, saliva was precedently 20-fold diluted with 10 mM borate (pH 9). The resulting solution smoothly flowed through microchannels. The dilution was also favorable for the determination of polyamines in the range of the calibration. Furthermore, amino acids were also diluted to lower concentration than the tolerance limit. Small amounts of proteins in saliva negligibly interfered with the determination of polyamines.

Table 2 shows the determination of total polyamines in saliva samples taken at different times. The values are in the range of 0.9–2.5 mM and dependent on time or daily activity. The concentrations of the respective polyamines reported in literatures are in the range from several to hundred μM levels [19,25–27]. The evaluation in the present study seems reasonable. Fairly good reproducibility (ca. 10%) is admirable for such simple method using no mechanical flow control system.

4. Conclusion

A simple method for fluid manipulation in microchannels was developed. Solution mixing was readily conducted just by warming and subsequently cooling at the junctions of the thermo-responsive polymer-coated microchannel with Peltier devices. The method was successfully applied for the quantitative analysis of polyamines with fluorometric detection. Because of the needless of mechanical pumps, high-voltage power supplies, or mechanical valves, the use of the heat-induced solution mixing can significantly simplify the fluid manipulation in microchannels. The application to varieties analytical reaction would be fruitful for designing simple and easy microchannel-based analytical methods.

ABSTRACT

The objective of this study was to establish a reasonably simple and reliable method to measure very low concentrations of polyhexamethylene biguanide (PHMB) in multipurpose contact lens solutions (MPSs). By using a weak cation exchange solid phase extraction cartridge to extract the PHMB from MPS, followed by HPLC analysis using an evaporative light scattering detector, low levels (0.1 ppm) of PHMB were detected. Application of this method to a series of off-the-shelf MPS with PHMB as the active ingredient demonstrated these solutions contain 1 ppm. The contact lens solution with hydrogen peroxide as the active ingredient gave no peak where the PHMB peak eluted. The Polyquad® contact lens solution generated a peak close to the retention time of PHMB. Recovery of PHMB from fortified hydrogen peroxide contact lens solution was good at 0.25 ppm and above; 105% with a RSD of 17% or less. The repeatability of the HPLC system ranged from 4 to 11% RSD; the reproducibility of the entire method was less than 17.5% RSD. Storage and stability studies indicated that storage of MPS with PHMB for chemical analysis are not temperature dependent, but are affected by the composition of the container in which the contact lens solution is stored.

Published by Elsevier B.V.

1. Introduction

PHMB[1] (polyhexamethylene biguanide) is a chemical germicide used in a variety of applications: as a preservative in wet wipe, to prevent microbial contamination in wound irrigation and sterile dressings, and to disinfect medical/dental utensils and trays. PHMB is also used as an active ingredient for recreational water treatment, in cosmetics, personal care products, fabric softeners, contact lens solutions, and hand washes [1]. This widely used biocide has been reviewed by EPA and noted, with the exception of occupational handlers, as having very low aggregate risk of adverse health effects to the public or environment [2].

This compound is a challenge to quantitate at low levels because it is a mixture of polymers with no distinctive chromophores [3] and is a polyelectrolyte with a mix of end groups [4]. Dye-binding assays [5–7] have limits of detection around 5 ppm and greater; the concentration of PHMB in some contact lens solutions is 1 ppm. High pressure liquid chromatographic (HPLC) using photodiode array detectors also are not sensitive enough because UV absorption of PHMB is too weak [7–9]. The mix of different end groups of the PHMB polymer prevents the possibility of quantitative derivitization. A capillary electrophoresis (CE) method [10] for determination of PHMB in eye drops was described with a limit of detection of 4 ppm. Other means of PHMB analysis include titrimetric methods [11] that do not have adequate levels of sensitivity or potentiometric titration methods that involve custom synthesis [12]. There appears to be no established method for measuring PHMB in contact lens solution or at sub-ppm levels.

In this paper, a method to reliably measure PHMB at sub-ppm levels in MPS[2] (multipurpose contact lens solution) is detailed. This was accomplished by developing a solid phase extraction method followed by HPLC analysis using an evaporative light scattering detector.

2. Materials and methods

2.1. Reagents and solutions

Several commercially available brands of MPS were purchased from local stores; six different brands contained PHMB as the active ingredient, two contained hydrogen peroxide, and the last one contained Polyquad® as the chemical disinfectant. Methanol and acetonitrile were obtained from Fisher Scientific (Waltham, MA, USA), and triethylamine (TEA), trifluoroacetic acid (TFA), and formic acid (FA) were from Sigma–Aldrich (St. Louis, MO, USA). Deionized water was produced with a Barnstead NANOpure Diamond water

purification unit. The PHMB, trade name Cosmocil CQ (a 20% solution in water), was graciously donated by Arch Chemical Company (Norwalk, CT, USA).

2.2. HPLC method

Samples were analyzed using a Waters HPLC system, equipped with 515 pumps, a 717 plus autoinjector, a 996 photodiode array detector and an evaporative light scattering detector (PL-ELS2100, Polymer Laboratories) with Waters Empower chromatographic software. Settings for the evaporative light scattering detector were: evaporator 111 °C, nebulizer 80 °C, zero-grade nitrogen at 1.6 SLM (standard liters per minute). The photodiode array detector was set at 254 nm, but was not used for quantitation. Separation was performed on a Supelco Supelcosil™ LC-8 column (5 cm × 4.6 mm, 5 μm). The mobile phase component was 100% deionized water held isocratically for 4 min, then an immediate change to 50:50 water: a solution composed of acetonitrile (76%), water (9.5%), triethylamine (5%), and formic acid (9.5%), pH adjusted to 3.1 with formic acid for the next 2 min, then a linear gradient back to 100% water at 10 min. The flow rate was 2 ml/min and the injection volume was 0.25 ml.

2.3. Extraction of contact lens solutions

Extraction and concentration of PHMB from MPS were performed with weak cation exchange solid phase extraction cartridge from Waters (WCX Oasis 1 cc, 30 mg). Cartridges were first pre-washed with two column volumes of 50:50 acetonitrile:distilled deionized water with 0.25% TFA, then two column volumes of acetonitrile, followed by two column volumes of distilled deionized water. Five ml of sample were then loaded onto the cartridge followed by washing with two column volumes of water, then with 0.5 ml of 50:50 acetonitrile:water with 0.02% TFA. PHMB was eluted with 0.5 ml of 50:50 water:acetonitrile with 0.25% TFA directly into 8 mm × 40 mm HPLC vials. Injection volume for the HPLC was usually 0.25 ml. HPLC vials were pre-washed with 50:50 water:acetonitrile with 0.25% TFA, then acetonitrile and left to air dry prior to use.

2.4. Storage stability studies

MPS brand A was used to examine the storage and stability of PHMB at three different temperatures (25 °C, 4 °C, and −20 °C). Using aseptic technique, approximately 20 ml of the MPS was placed in each of 12 separate 50 ml polypropylene test tubes. Four of these test tubes were left at room temperature (25 °C); four were placed in the refrigerator (4 °C), and four in a standard freezer (−20 °C). Over time, one test tube from each different temperature locale was removed and triplicate aliquots of 5 ml were extracted as previously described. In addition, the stability of PHMB in glass vials compared to polypropylene test tubes was examined by aseptically placing 20 ml of MPS brand A in glass or polypropylene containers and leaving them overnight at room temperature. The following day, triplicate extracts of the MPS brand A stored in glass vials was compared to triplicate extracts stored in polypropylene test tubes.

3. Results and discussion

3.1. Evaluation of dye binding methods

Initially, the colorimetric methods were explored because of the potential for high throughput and low cost. The method described by Rowhani and Lagalante [7] was tested first. However, the absorbance from a MPS with PHMB was roughly 100 times higher than the PHMB standard concentration. Other compounds in the MPS were probably exerting a large positive influence in this assay. The second colorimetric assay evaluated was detailed by Rosenthal et al. [5]. Again, the MPS overestimated the amount of PHMB, but only by a factor of four. The third colorimetric assay [6] overestimated the PHMB concentration in MPS by a factor of five. In addition, none of these assays were very sensitive; all the colorimetric methods had limits of detection around 5 ppm or greater. Because MPS labels state a concentration of 1 ppm of PHMB, a more sensitive and selective method was needed.

3.2. Solid phase extraction

A series of solid phase extraction cartridges were evaluated in sample extraction. Although PHMB is a cation, an anion exchange column and a lipophilic column were examined to see if they would trap interfering substances while permitting PHMB to pass through. However, significant interfering substances eluted with the PHMB from both the lipophilic and strong anion exchange columns. The weak and strong cation exchange columns were used to trap the PHMB while allowing most interfering substances to elute. Because it was possible to elute PHMB from the weak cation exchange column using less caustic conditions, this was the cartridge chosen. Coupling the solid phase extraction method to the colorimetric assays did not work as the strong acid needed to elute the PHMB occupied the binding sites for the dyes.

3.3. Detector performance

Although the reproducibility of the evaporative light scattering detector (ELSD) has been noted to be worse than UV [13] and the use of a gradient increases the variability of the analyte signal [14], this is a more sensitive detector for compounds without chromophores. The light scattering by the solute after removal of the eluent is measured [13]; detection is dependent on the amount of solute. Fig. 1 illustrates the difference between using an ELS detector (Fig. 1A) and a UV detector (Fig. 1B) in detecting PHMB extracted from contact lens solution brand A. The Refractive Index detector is useful for detecting compounds that do not absorb UV, it is not useful for gradient elution [15]. Attempts to generate a useful ion for mass spectroscopy with electrospray or atmospheric pressure ionization were not fruitful.

3.4. Recovery

MPS contain salts, surfactants, and other additives, as well as the active biocide; although not all brands are identical chemically or in quantity. Because the hydrogen peroxide contact lens solution gave no peak near the retention time of PHMB, it was used in the recovery studies as the best available approximation of a blank MPS. Recovery of hydrogen peroxide MPS fortified with 0, 0.125, 0.25, 0.5, and 1.0 ppm PHMB are depicted in Fig. 2. The recovery was determined from triplicate experiments each with triplicate samples. Recoveries were good, 107%, at the 0.25 ppm level and above (RSD 17% or less), but the error at the 0.125 ppm level was quite large (RSD 66%). The bias towards high recovery at low levels is likely due to intergration errors because of the steep gradient used and the increasing background and error of the detector over time (Section 3.6 Table 1).

3.5. Evaluation of commercially available contact lens solutions

Six different MPSs with PHMB as the active ingredient were purchased at local stores and analyzed. Fig. 3 details the PHMB levels found in these six different MPS with PHMB; the data represent triplicate experiments with each contact lens solution run in triplicate. The PHMB concentration in all the MPS was 1 ppm with RSD of 17.5% or less; this supported the utility of the method. The contact

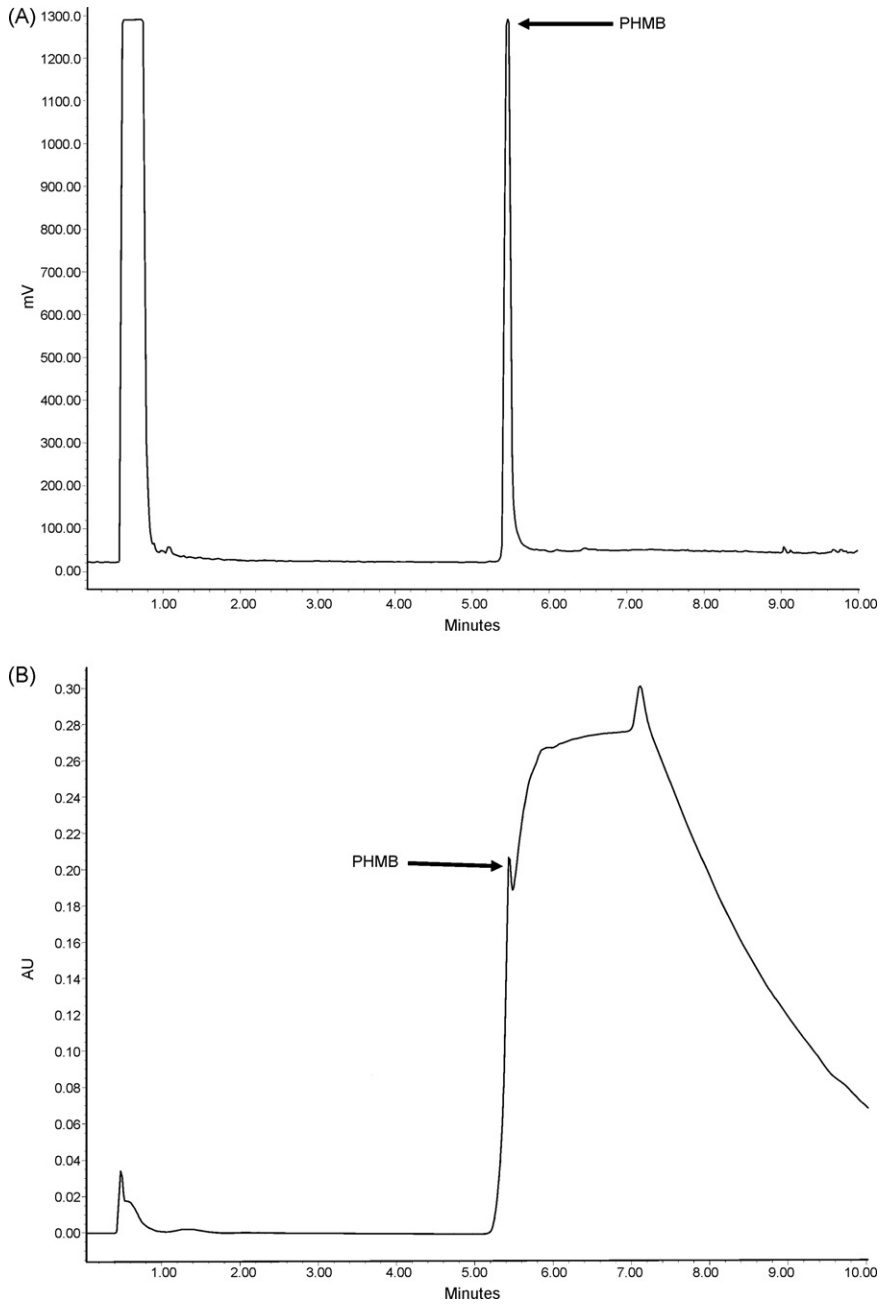

Fig. 1. The difference in the sensitivity of the ELSD detector (A) and the UV detector (B) for PHMB analysis of contact lens solution brand A.

lens solution with hydrogen peroxide as an active ingredient generated no peak in the PHMB area. The MPS containing Polyquad® generated a large peak that appeared 0.05 min ahead of the PHMB peak (data not shown). It can be possible to confuse this peak with PHMB based on the close retention times; however the Polyquad® peak area was three times larger than that of the PHMB. It might be possible to tease the Polyquad® peak away from the PHMB by using a gentler gradient. The purpose of using an immediate change in pH and mobile phase composition in this study was to generate one peak for PHMB [16]. Other investigators reported the need to integrate multiple peaks to quantitate PHMB [7]. The purpose of this study was to develop a sensitive reliable method for PHMB in contact lens solutions. The baseline separation of the Polyquad® from the PHMB peak was not considered to be necessary as, at present, both chemical disinfectants are not found together in commercially available MPS.

Table 1
The repeatability of the system as a function of peak area for a 10 ppm PHMB standard.

Peak area			
Number	Average	Std	cv%
6	1,311,365	135,376.7	10.3
5	1,423,358	159,430.7	11.2
10	3,171,998	145,270.5	4.6
8	4,170,078	318,143.5	7.6
8	4,412,432	172,020	3.9

3.6. HPLC system repeatability

The error of the system was evaluated by making a large volume of a 10 ppm PHMB in the elution solution (50:50 water:acetonitrile

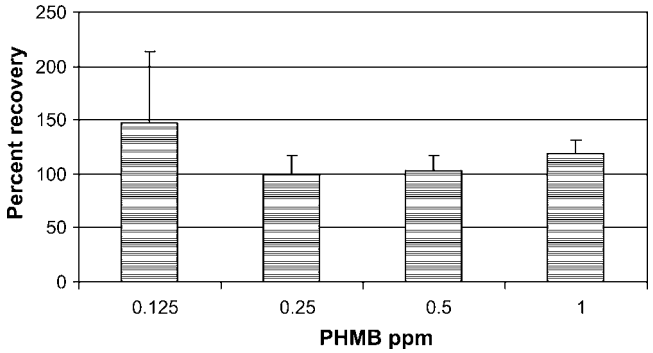

Fig. 2. Recovery of PHMB fortified with 0, 0.125, 0.25, 0.5, and 1.0 ppm into hydrogen peroxide contact lens solution. Recoveries were good, 107%, at the 0.25 ppm level and above (RSD 17% or less), but the error at the 0.125 ppm level was quite large (RSD 66%).

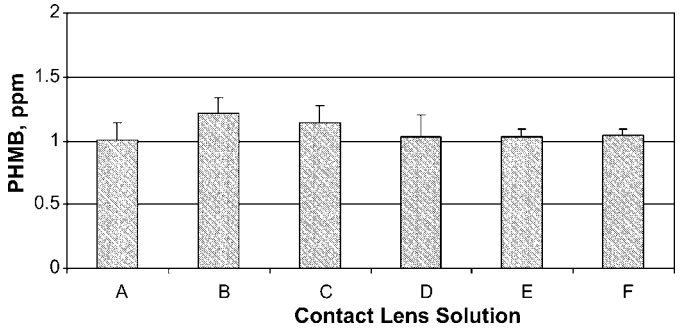

Fig. 3. The average concentration of PHMB in six different commercially available MPSs.

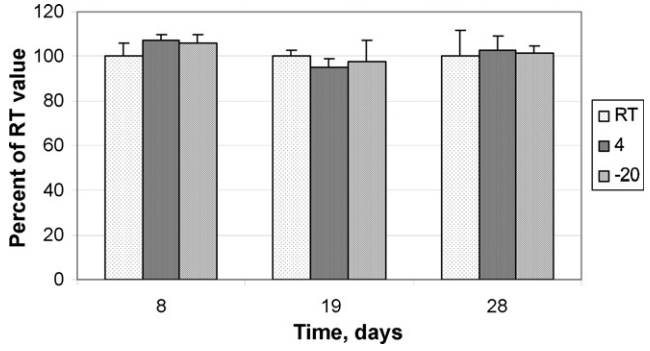

Fig. 4. The effect of temperature on the storage of PHMB, MPS brand A was used for this study.

with 0.25% TFA) and placing it into a series of HPLC vials. Single injections were made for each set of standards; the number of the 10 ppm standards prepared varied over time (Table 1). The variability of the peak area for the same concentration of PHMB was due to the need to 'steam clean' the ELSD every 40 h of use. Standards were run over a period of two months at various time points before and after the detector cleaning. Just after steam cleaning the detector, the peak area was largest and peak shape was sharpest. Table 1 summarizes the data; that increasing peak area shows decreasing error expressed as RSD%.

3.7. Storage and stability studies

Storage of MPS brand A was evaluated at room temperature, 4 °C, or −20 °C for up to a four week period. No significant difference in total PHMB concentration was seen. Fig. 4 illustrates the temperature stability of MPS brand A; the RSD for this data set was less than 10%. When MPS brand A was placed overnight at room temperature in a glass container and its peak area was compared to the same MPS stored in a polypropylene container at the same temperature, a 50% decrease in signal was observed (data not shown). This is likely due to the negative charge of the glass [17] binding the cation PHMB.

4. Conclusion

A reasonably simple method for the determination of PHMB in MPS was developed. Recovery from fortified solutions and commercially available MPS containing PHMB were around 100% at the relevant 1 ppm PHMB level, with a limit of detection at around 0.2 ppm. All commercially available MPS containing PHMB that were tested had concentrations around the labeled 1 ppm level. The storage stability studies conducted demonstrated that the temperature (25 °C to −20 °C) did not negatively impact the chemical analysis of PHMB from contact lens solutions over 28 days. In comparing glass and polypropylene containers for contact lens solution storage, polypropylene is superior to glass for maintaining the concentration of PHMB in MPSs. However, with out analyte-free MPS, the true accuracy cannot be unequivocally established. Still, the circumstantial evidence would support this method as a reasonable means for determining PHMB in MPS.

ABSTRACT

A novel sample preparation technique for the measurement of anions in particulate matter by ion chromatography is presented. The technique uses the eluant from the ion chromatography analysis stage to perform the extraction of the anions from the particulate matter. The demonstrated advantages of the new technique are manifold: faster sample throughput, minimised sample preparation, and a matrixed-matched sample for analysis. The repeatability of the technique has been tested using nominally identical ambient particulate matter samples (sub-sampled from one large filter) and the uncertainty of the technique has been estimated. The uncertainty estimate is transferable to other similar methods used to measure ions in particulate matter. Real data obtained using the new method are also presented.

1. Introduction

The chemical composition of ambient aerosols continues to be a subject of great interest to the environmental and atmospheric chemistry communities [1]. The determination of the anionic content of particulate matter (PM) is of increasing interest in this context because of the requirement to work toward mass closure in PM studies, and also because the presence of many anions in PM arise as a result of conversion from primary air pollutants such as CO, SO_2 and NO_x [2]. Moreover anions in PM can be precursors for acid rain formation [3]. Therefore there is a need to perform accurate and traceable measurements of the mass concentration of anions in ambient air, and the mass fraction of anions in PM, in order to provide reliable data sets to: measure the exposure of the general population to these compounds; assess compliance with legislative limits or similar target values; and inform policy development and assess the effectiveness of abatement strategies. To this end the anion mass concentration in ambient air is currently measured daily at three sites in the UK as part of the UK Airborne Particulate Concentrations and Numbers Network [4]. Moreover the requirement to perform these measurements (together with measurements of cations) will soon be mandated in the European Union [5] – and as a result of this requirement a standard method for the measurement of anions and cations in PM will be prepared by the European Committee for Standardisation Technical Committee 264 Working Group 34.

In this paper we present a novel method to extract the anions from PM more efficiently than current standard methods [6–9]. Repeatability data for this technique is presented, together with a proposed uncertainty budget for the measurement. The extraction technique described is not transferable to the measurement of cations because of the large sodium concentration following extraction, but the uncertainty budget presented is applicable to all similar measurements of the ionic content of PM. Whilst other techniques have been proposed for the measurement of anions in PM, ion chromatography remains by far the most popular [10,11]. Although some standard methods for anions in PM already exist, these use deionised water [6–8] or an ethanol–water mix [9,12] for extraction and none are accompanied by a rigorous uncertainty budget. Recent research work in this area has focussed on the development of techniques to examine an increased number of PM species in an individual scan [13], and also the use of surfactants to improve extraction efficiency [14]. However to the best of the authors' knowledge no study has examined the use of the ion chromatography eluant itself as the extraction medium, or has estimated the likely uncertainty due to the measurement.

2. Materials and methods

2.1. Chemicals and reagent preparation

All solutions were prepared in fully cleaned and dried (in a nitrogen flow (oxygen free nitrogen, BOC)) polypropylene labwear (Fisher) using deionised water (18.2 MΩ cm, Milli-Q system, Millipore). All chemicals were of high purity (99.9+%, Fisher) and were prepared according to the supplier's guidelines (drying at elevated temperatures for the inorganic salts). All solutions were prepared gravimetrically. Calibration solutions were prepared such that the solutions requiring measurement were approximately located towards the centroid of the calibration curve wherever possible, and usually constituted of at least four solutions of different concentration plus a blank solution. The eluent used for the IC analysis and for extraction of the anions from the filters was an aqueous solution of 11 mM Na_2CO_3 and 2 mM $NaHCO_3$.

2.2. Sample collection

In order to test the proposed method, samples of ambient particulate were taken onto quartz fibre filters (Whatman QM-A) using a Thermo GMW PM_{10} high volume air sampler at a flow rate of 68 $m^3\ h^{-1}$. To demonstrate measurements made using the final procedure, real samples were taken onto quartz fibre filters (Whatman QM-A) using Thermo Partisol 2000 PM_{10} low volume air samplers at a flow rate of 1 $m^3\ h^{-1}$. Samples were taken for one day periods. The use of the high volume air sampler is crucial to the development of the measurement method and to the assessment of the uncertainty of the method. Whilst having the same face velocity as the low volume sampler – therefore collecting approximately the same mass of particulate matter per unit area per unit time, the larger filter area means that several nominally identical sub-samples may be taken for the same large filter and used for studies to examine the repeatability of the extraction procedure. Up to twelve sub-samples may be taken from each high volume sample.

2.3. Sample preparation

Sampled filters were sub-sampled using a circular wad-punch with a 20 mm diameter (Fisher, UK). In order to ensure these sub-samples are as equal as possible, the centre of each was coincident with the centre of one of the nozzles within the sampler that delivers sampled material onto the filter. These sub-samples were then sonicated in an ultrasonic bath (37 kHz, 80 W RMS power, Ultrasonics Ltd.) in a weighed amount (approximately 10 g) of the IC eluent. Solutions were then filtered through 0.45 mm PPE filters (Whatman) as they were introduced into the ion chromatograph.

2.4. Analysis using ion chromatography

Analysis for chloride, sulphate and nitrate was performed with a Dionex DX-120 ion chromatograph (IC), with a G14 guard column, AS14 anion separation column, ASRS – Ultra II self-regenerating suppressor unit and a DS4 conductivity detector. A flow rate of 1.0 mL min^{-1} was used throughout. The volume of the sample injection loop was nominally 25 μL (although larger sample loops were used during method development to improve repeatability). Quantification was performed with NPL's XLGenline software [15], using the peak areas provided by the proprietary software (Peak Net Software, Dionex).

All experimentation, except for the sample collection, was conducted in a temperature-controlled laboratory at 20 ± 2 °C.

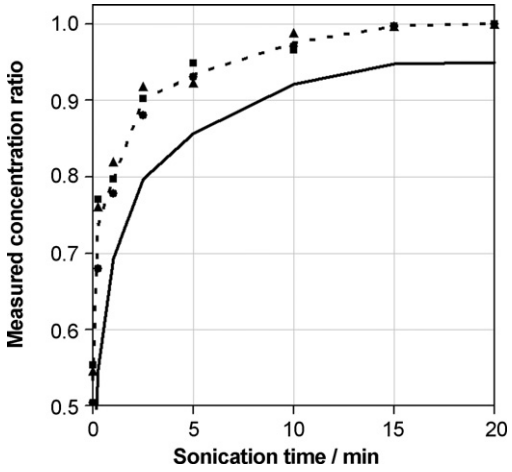

Fig. 1. Measured concentration of chloride (●), nitrate (▲) and sulphate (■) ratioed to the maximum measured concentrations over different sonication times and the average trend of these three species (dotted line). The average trend for the same investigation using just deionised water as the extraction eluant is shown as a solid line.

3. Results and discussion

3.1. Eluant extraction technique

The IC eluent has been used as a novel extraction media for the collected particulate matter in the results presented here. The advantages of this technique over the usual extraction media of deionised water or ethanol–deionised water mixtures are manifold, as will be demonstrated in the results below, but in summary: the use of this extraction medium wets the filter more quickly, speeds up the extraction process, results in a more complete extraction of anions within the particulate matter, and provides a sample which is already matrix matched to the IC eluent, thereby requiring no further sample preparation to eliminate the water dip which can obscure some anion species. A comparison of anion extraction using the IC eluant as compared to using deionised water is shown in Fig. 1, which shows that the IC eluant speeds up the extraction procedure, achieving full extraction after approximately 10–15 min compared to between 15 and 20 min for deionised water alone. Use of the eluant solution showed on average a 5% higher extraction than using only water as an extraction medium. One explanation for this higher extraction may be owing to the exchange of sodium ions from the extraction solution with the native cations in the particulates, leading to increased solubility. Moreover, for the use of both eluant and deionised water, extraction of anions from the particulate matter occurs more quickly than the time periods specified for the extraction procedure in most standard methods, which usually recommend an extraction time of 1 h [9]. However, it is best to err on the side of longer extraction times in all cases (assuming sample throughput is not adversely affected) since extraction conditions such as ultrasonic powers and frequencies are rarely standardised and may vary considerably, and in any event no sample is expected to be lost by using longer extraction times. The effect of elevated temperatures on extraction rate was also tested but did not give a significant enough improvement to warrant the extra complication of heating the samples in the sonic bath and the loss of extraction solution via evaporation that this might cause. However, as the elevated temperature did not extract significantly more anions we can conclude that the conditions routinely being used (room temperature sonication) are sufficient to extract fully the anions from the PM.

Fig. 2 shows the mass of chloride, nitrate and sulphate, measured on twelve filter cuts taken from a high volume filter sample

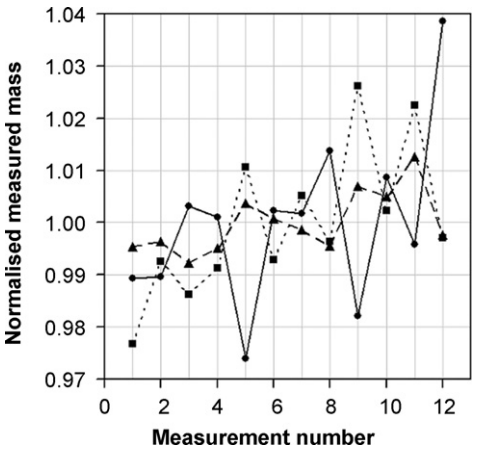

Fig. 2. The mass of chloride (●), nitrate (▲) and sulphate (■), measured on twelve filter cuts taken from a high volume filter sample. These results have been normalised to the average value for each anion and displayed in order of the average normalised mass of the three anions, from lowest to highest.

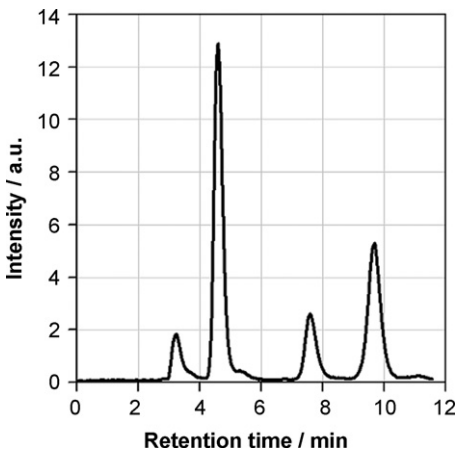

Fig. 3. Ion chromatogram from a sampled filter, extracted using the ion chromatography eluant itself, showing complete absence of a water dip (expected after approximately 2 min) with four anions clearly visible: fluoride at 3.25 min, chloride at 4.5 min (possibly with a nitrite shoulder), nitrate at 7.5 min and sulphate at 9.5 min.

– all nominally with identical mass loadings. These results have been normalised to the average value for each anion and displayed in order of the average normalised mass of the three anions on each filter, from lowest to highest. Each sub-sample extract was measured ten times and the use of a previously described [16] drift correction procedure was applied in order to minimise the contribution of instrument repeatability to the variability of the measurement. In addition a larger sample loop (100 μL) was used for these measurements to increase the amount of sample introduced, and therefore decrease further the relative repeatability of the instrument. The standard deviations of these measurements for chloride, nitrate and sulphate were, 2.0%, 0.8% and 1.8% respectively, showing that the extraction technique is highly repeatable. Following this extraction procedure an example of the ion chromatogram produced from a real sample, with no further sample preparation, is displayed in Fig. 3. In particular, it is important to note the flat baseline, showing the absence of any water dip, making elucidation of the peaks with low retention times simple, without any further sample preparation.

3.2. Uncertainty budget

The measurement of anions in particulate matter can be described by a simple set of equations given below:

$$\gamma_{amb} = \frac{m_{ion}}{V_{amb}\eta_{sam}} \quad (1)$$

$$m_{ion} = \frac{m_{ext}x_{ext}}{\eta_{ext}r} \quad (2)$$

$$x_{ext} = \frac{I_{ext}}{\dot{V}_{cal}} \quad (3)$$

where γ_{amb} is the mass concentration of anions in ambient air, in μg/m^3; V_{amb} is the volume of ambient air sampled, in m^3; η_{sam} is the sampling efficiency, in g/g; m_{ion} is the mass of anion on the filter, in μg; x_{ext} is the mass fraction of anion in the PM extract, in μg/g; m_{ext} is the mass of extraction solution, in g; η_{ext} is the extraction efficiency of anions from the PM, in g/g; r is the ratio of sub-sampled filter area to the total filter area, in m^2/m^2; I_{ext} is the blank corrected instrument response at the measured concentration; $\dot{V}_{cal}$ is the gradient of calibration curve, in g/μg.

Substituting Eq. (3) into Eq. (2), and Eq. (2) into Eq. (1) yields:

$$\gamma_{amb} = \frac{m_{ext}I_{ext}}{V_{amb}\eta_{sam}\eta_{ext}r\dot{V}_{cal}} \quad (4)$$

This allows a simple 'Guide to the expression of uncertainty in measurement' (GUM) [17] uncertainty treatment to be performed, which yields the exemplar uncertainty budget shown in Table 1. This estimates a relative standard uncertainty of approximately 6% at the anion mass concentrations expected in ambient air, yielding an expanded measurement uncertainty of approximately 12% at the 95% confidence level (assuming a coverage factor of $k = 2$). The contribution of individual parameters to this standard uncertainty,

Table 1
Exemplar uncertainty budget for the measurement of the mass concentration of anions in ambient air.

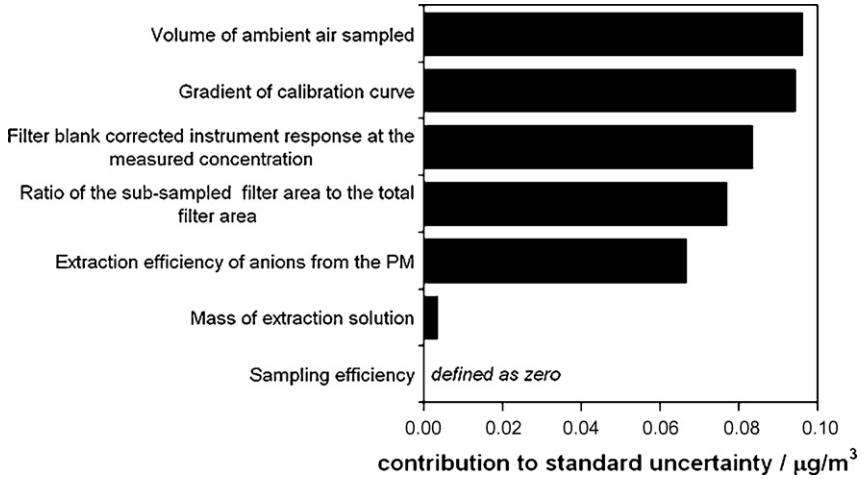

Fig. 4. Contribution of individual sources to the combined standard uncertainty of the measurement of anion mass concentration in ambient air as determined in Table 1.

as obtained during the work presented here, is given in Fig. 4. A brief discussion of the standard uncertainty $u(x)$ in the individual parameters x is given below.

- $u(m_{ext})$ can be estimated from the uncertainty of repeat weighing, and the calibration of the analytical balance.
- $u(\eta_{sam})$ is defined as zero, with η_{sam} defined as 1, because it is assumed that the sample is measured as received, following sampling according to EN12341 [18], and any losses of material during the sampling process are not considered (although it has been known for some time that some losses of volatile components may occur [19]).
- $u(V_{amb})$is defined in EN12341 [18] as a maximum of $5/\sqrt{3}$% (including flow rate calibration, drift in sampling flow rate during measurement, etc.).
- $u(\eta_{ext})$ may be estimated from the experimental data obtained from extraction of multiple nominally identical samples, as displayed in Fig. 2. A symmetrical distribution centred on 100% extraction has been considered for ease of calculation – although in reality this distribution is certainly asymmetrical and centred below 100% [20].
- $u(r)$ is a measure of the uncertainty in the ratio of the area of the sub-sample (if taken) to the area of the sampled filter. This may also include a component of uncertainty to recognise that a sub-sample may not be representative of the filter as a whole [21].
- $u(\dot{V}_{cal})$ may be estimated by regression software such as XLGenline [15], but will be approximately equal to the repeatability of the instrument response at the centre of the calibration range added in quadrature to the uncertainty in the composition of the calibration standards at this concentration (including consideration of the uncertainty of gravimetric preparation and the purity of the salts used).
- $u(I_{ext})$ can be estimated from the repeatability of measurements using the ion chromatograph. This has been gauged for representative concentrations of chloride, nitrate and sulphate solutions by performing repeat measurement of the same solution over the period of 1 h, and is shown in Fig. 5. The relative standard deviation of the repeat measurements for chloride, nitrate and sulphate were 1.8%, 0.6% and 1.4% respectively. Consideration of this parameter should also include drift of the measurement between calibrations. However, Fig. 5 shows that drift over the measurement period is negligible compared with the repeatability. As I_{ext} is the filter blank corrected intensity, $u(I_{ext})$ needs additionally to include a contribution to recognise the uncertainty in the anion content of the blank filter. Usually the anion content of the blank filter is very low (<2% of the anion content in a daily PM sample). However, it may be quite variable, and this needs to be gauged by repeat measurements of a series of filter blanks using Eqs. (2) and (3). As with all filter-based air quality measurements using destructive analysis it is unfortunately not possible to determine the blank levels of the filters being used for sampling – which would be the preferred measure of subtracting blank values.

The relative uncertainties of the individual components of the uncertainty budget would not be expected to change significantly with ambient mass concentration. The exception to this is I_{ext} which would be expected to show a dependence on anion mass fraction in solution, especially at very low mass fractions when the contribution of the blank becomes significant, and the uncertainty in I_{ext} would need to be reassessed.

Real data obtained using this proposed method on the NPL site, in Teddington, during a 19-day period in October 2006 is shown in Fig. 6, with the expanded measurement uncertainties estimated using the proposed budget also shown. The concentrations measured during this period were broadly consistent with those observed at the UK air quality monitoring network sites measuring chloride, sulphate and nitrate [4]. In general, the chloride concentrations recorded were lower than both the sulphate and nitrate concentrations, except in few cases. As expected, the chloride, usually from primary sources, showed little correlation

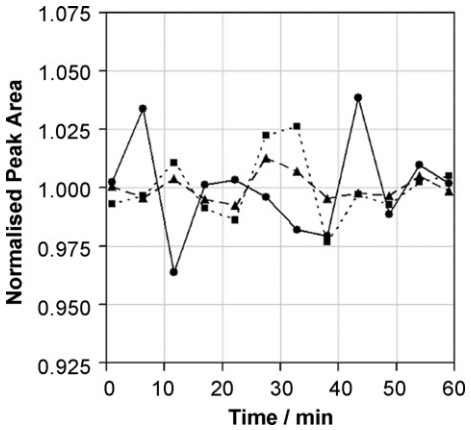

Fig. 5. Repeatability of chloride (●), nitrate (▲) and sulphate (■) measurements using the ion chromatograph, at concentrations relevant to those seen from real samples, over a 1 h period.

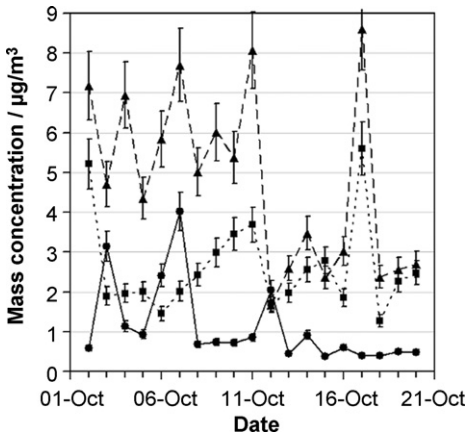

Fig. 6. The chloride (●), nitrate (▲) and sulphate (■) mass concentrations in the PM_{10} phase of ambient air, measured on the NPL site, in Teddington, during October 2006 using the method described in the text. The error bars represent the overall expanded measurement uncertainty at the 95% confidence level (assuming a coverage factor of $k = 2$).

with the sulphate and nitrate, usually from secondary sources. Conversely, the sulphate and nitrate values showed quite strong correlation, especially towards the end of the measurement period, as they originate from similar secondary sources. In general, the measured nitrate concentrations were higher than the sulphate concentrations.

In summary, a new method for the extraction of anions from particulate matter has been proposed, which uses the ion chromatography eluant as the extraction media. Data has been presented for the repeatability of this extraction technique and its comparability against the use of deionised water (as specified in other standard methods). It has been shown that the use of eluant as the extraction medium can speed up the extraction process as compared with deionised water also yielding a greater extraction efficiency. This method has the additional advantages of reducing the quantity of sample preparation required, and yielding a matrix-matched sample without further manipulation, thereby allowing a more accurate assessment of anionic species with low retention times. The drawback of this method is that it is not suitable for the measurement of cationic species by ion chromatography owing to the large sodium content in the extracted sample. However a similar technique could be applied for cationic species via the use of a suitable eluant (for instance sulphuric acid) as the extraction medium. In addition, the carbonate/hydrogen carbonate eluant used would interfere with the measurement of CO derived species, although these are not currently measured by the UK Airborne Particulate Concentrations and Numbers Network.

An uncertainty budget for the method has also been presented which has considered all factors contributing to the uncertainty of the measurements. This budget is generic and is extendable to the measurement of any ionic species in particulate matter by most measurement techniques that first rely on an extractive step. It has been assumed that the sampling of the PM is made according to EN 12341 and thus any volatile material lost during sampling, prior to analysis, is not considered in the uncertainty budget. That notwithstanding there are no particularly dominant contributions to the expanded measurement uncertainty, assuming a coverage factor of $k = 2$ at the 95% confidence interval, which was determined to be approximately 12% for these measurements.

4. Conclusions

This study has presented a new method to extract the anionic content of ambient particulate matter using the chromatography eluant as the extraction medium. This method has led to increases in extraction efficiencies of approximately 5% over the use of deionised water alone, and has shown reproducibilities of 2% or better, as gauged by extraction of nominally identical samples.

The relative expanded uncertainty of the overall method has been calculated to be approximately 12% assuming a coverage factor of $k = 2$ at the 95% confidence interval.

Real data obtained during a test sampling period has demonstrated the use of this method in practice. The method described in this work is now used on the UK Airborne Particulate Concentrations and Numbers Network to make daily measurements of anion mass concentration.

Acknowledgements

Aerosol

ABSTRACT

A rapid and environmental-friendly injection-port derivatization with gas chromatography–mass spectrometry (GC–MS) method was developed to determine selected low-molecular weight (LMW) dicarboxylic acids (from C2 to C10) in atmospheric aerosol samples. The parameters related to the derivatization process (i.e., type of ion-pair reagent, injection-port temperature and concentration of ion-pair reagent) were optimized. Tetrabutylammonium hydroxide (TBA-OH) 20 mM in methanol gave excellent yield for di-butyl ester dicarboxylate derivatives at injection-port temperature at 300 °C. Solid-phase extraction (SPE) method instead of rotary evaporation was used to concentrate analytes from filter extracts. The recovery from filter extracts ranged from 78 to 95% with relative standard deviation (RSD) less than 12%. Limits of quantitation (LOQs) ranged from 25 to 250 pg/m^3. The concentrations of di-carboxylated C2–C5 and total C6–C10 in particles of atmospheric aerosols ranged from 91.9 to 240, 11.3 to 56.7, 9.2 to 49.2, 8.7 to 35.3 and n.d. to 37.8 ng/m^3, respectively. Oxalic acid (C2) was the dominant LMW-dicarboxylic acids detected in aerosol samples. The quantitative results were comparable to the results obtained by the off-line derivatization.

1. Introduction

Currently, the investigations on aerosol water-soluble organic compounds (WSOCs) formed by vehicular exhaust emission and burning biomass have become increasingly concerned with the role of these compounds in atmospheric research owing to their effect on climate and human health. Low-molecular weight (LMW) dicarboxylic acids (from C2 to C10) have attracted the most interest because they are ubiquitous components in tropospheric aerosols, and have been detected in various ambient environments ranging from continental to remote Arctic atmospheres [1–6]. Reliable quantification of these LMW-dicarboxylic acids can help us to evaluate the importance of the secondary photochemical reactions.

Routinely, diazomethane or BF_3 with alcohol (i.e., propanol, n-butanol) method has been used to derivatize LMW-dicarboxylic acids for GC–MS analysis [1,3–6]. However, the procedure was time-consuming and the reagent was costly and toxic. Large-volume injection-port derivatization with various ion-pair reagent (i.e., tetrapropylammonium salts or tetrabutylammonium salts) has been successfully developed in our laboratory and widely used to determine various surfactants and their degradation products, acidic herbicides, naphthalenesulfonic acids and pharmaceutical residues in water samples [7–11]. Currently, this procedure has also been applied to determine long-chain fatty acids, perfluorooctane sulfonate isomers and phenolic herbicides because of its reducing solvent waste, simplifying sample preparation, and avoiding the use of hazardous reagents [12–16]. This convenient procedure has been successfully employed to the analytes with mono-carboxylate and sulfonate groups. However, the derivatization to the analytes with LMW-dicarboxylic acids has not been reported so far. For the molecules with dicarboxylated groups, the procedure may be initiated by reacting dicarboxylic acid with tetrabutylammonium hydroxide ($N(Bu)_4^+HO^-$), for example, to form dicarboxylate ion pairs [$^+N(Bu)_4{}^-OOCRCOO^-N(Bu)_4{}^+$] in methanol. Upon introduction to a high temperature (i.e., above 280 °C) in GC injection-port, the dicarboxylic acid groups were transformed to their corresponding volatile di-butyl esters [BuOOCRCOOBu] and then they were directly separated and determined by GC–MS.

This work presents the preliminary results of a modified method to rapidly and quantitatively determine the selected LMW-dicarboxylic acids in aerosol samples. The various tetraalkylammonium salts (TAA salts), its concentration and injection-port

temperatures were investigated and optimized. The off-line BF_3/n-butanol derivatization method was employed for comparison.

2. Experimental

2.1. Chemicals and reagents

Unless noted otherwise all high purity chemicals and solvents were purchased from Aldrich (Milwaukee, USA) and Merck (Darmstadt, Germany), and were used without further purification. Internal standards 1-phenyldodecane was purchased from Merck. Standards of LMW-dicarboxylic acids: oxalic acid (C2), malonic acid (C3), maleic acid (cis-C4), fumaric acid (trans-C4), succinic acid (C4), glutaric acid (C5), adipic acid (C6), pimelic acid (C7), suberic acid (C8), azelaic acid (C9), and sebacic acid (C10) were purchased from AccuStandard (New Haven, USA). Deionized water was further purified with a Mill-Q Plus water purification device (Millipore, Bedford, USA). Reagent-grade tetraalkylammonium salts (TAA salts): tetramethylammonium hydroxide (TMA-OH), tetraethylammonium hydroxide (TEA-OH), tetrabutylammonium hydroxide (TBA-OH) and tetrabutylammonium tetrafluoroborate (TBA-BF_4) were purchased from Acros Organics (Morris Plains, USA).

2.2. Sampling collection and preparation

Samples of atmospheric aerosols were collected by aerosol sampler (10 l/min) at the roof of the Graduate Institute of Environmental Engineering Center in National Central University (Chung-Li, Taiwan). Sampling time was 12 h. The aerosol sampler and sampling procedures acquired to determine selected LMW-dicarboxylic acids have been described elsewhere [17,18]. Particles and aerosol samples were collected on Pallflex quartz fiber filters (o.d. 102 mm).

The procedure used to extract selected LMW-dicarboxylic acids from the aerosol samples under ultrasonic agitation and solid-phase extraction (SPE) has been described by Limbeck et al. [5], and was used with minor modifications. The filter was extracted for 30 min using 50 ml of deionized water under ultrasonic agitation. The aqueous extract was then preconcentrated using Oasis HLB-SPE cartridges (3 ml, 60 mg; Waters, Milford, USA). After conditioning steps, the extract passed through the HLB-SPE cartridge at a flow rate of about 2–3 ml/min with the aid of a vacuum. The analytes were eluted from the cartridge with 3 ml of methanol/methyl-t-butyl ether (1:9, v/v) eluent. Then, the eluent was completely evaporated to dryness by a stream of nitrogen, and the residue was redissolved in 100 μl of methanol with 20 mM TBA-OH (optimized, see Section 3) containing 5 ng/μl of 1-phenyldodecane (as an internal standard), and made ready for GC–MS analysis.

2.3. GC–MS analysis

A Varian 3800CP gas chromatograph directly connected to a Saturn 2000 ion-trap mass spectrometry (Walnut Creek, USA) was used in the analysis of the sample extracts. A ChromatoProbe and a temperature-programmed injector (Varian) with a 3.4 mm i.d. liner, was used to introduce a large-volume sample (10 μl) for injection-port derivatization, as described elsewhere [10,11]. A DB-5 MS capillary column (30 m × 0.25 mm i.d., 0.25 μm film, J&W, USA) was used. After the injector temperature had reached 300 °C, the following GC temperature program was used: 80 °C for 5 min; following by a temperature ramp of 10 °C/min up to 300 °C; and then holding this temperature for 5 min. The transfer line was set at 280 °C. Full scan EI data was acquired under the following conditions: mass range 45–350 *m*/*z*, scan time 1 s, manifold temperature 160 °C, emission current 10 μA, automatic gain control (AGC) target 20,000 (represents as the target total ion current value).

3. Results and discussion

3.1. Optimization of injection-port derivatization

The precision of the injector-port derivatization with the GC–MS analysis, as determined from the relative standard deviation (RSD) of over 30 injections of LMW-dicarboxylic acids, ranged from 2.4 to 10%. No retention effect either for TBA-OH or analytes was observed since the disposable micro-vial was used for sample introduction.

The derivatization efficiencies were optimized with respect to three parameters: the type of TAA salt, the injection-port temperature and the concentration of TAA salt co-injected with the sample. Tetraalkylammonium hydroxides have been reported as the most common used ion-pair reagents for ion-pair formation in methanol [11,16,19]. Furthermore, according to our previous report [11] indicates that methanol was used as the final solvent increasing the solubilities of di-carboxylated analytes and ion-pair reagents, so enhanced their reaction efficiency. Therefore, three TAA-OH salts: TMA-OH, TEA-OH and TBA-OH, and TBA-BF_4 were evaluated according to the previous experimental conditions: injection-port temperature at 300 °C and 20 mM of TAA salt in methanol. The derivatization efficiency was obtained from the related abundance of the GC–MS peak area of the di-alkylated derivatives to the internal standard from four different TAA salts. Fig. 1 shows that related abundance increased with the long alkyl groups of TAA salts, both TBA salts gave highest yield of derivatives than those of TME-OH and TEA-OH. In here, TBA salt reagents produced the highest average peak areas and stable quantitative results in the extracted ion chromatograms of di-butylated derivatives. However, TAA salts with longer alkyl groups (i.e., tetraheptyl ammonium hydroxide (THA-OH)) cannot be employed as an ion-pair reagent because of their poor solubility in the methanol (data not shown). Due to the relatively higher peak abundances of di-butyl ester of C4 and C5 derivatives, higher related abundances were observed in this study. The effects of the injection temperature and the concentration of TBA-OH co-injected with the sample were also evaluated. The average peak areas ($16.3 \pm 5 \times 10^5$) for the di-butylated derivatives were not significantly different at the injection temperatures 280, 300 or 320 °C, and at the TBA-OH concentrations 10, 20 or 30 mM, respectively (data not shown). A detailed study was not made of the decrease in yield at a lower temperature since 280–320 °C represents a temperature range appropriate for most practical purposes. Since TBA-OH is the more commonly used ion-pair reagent, 20 mM of TBA-OH at the injection temperature at 300 °C were employed in this study.

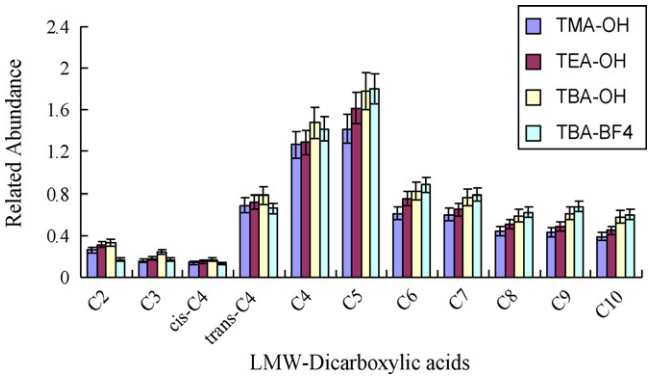

Fig. 1. Related abundance of injection-port derivatization with four ion-pair reagents. The derivatizations were performed on three replicates, standard deviation is reported as an error bar. "Related abundance" in *y*-axis was defined that the peak areas of analytes were normalized to the peak area of the internal standard obtained in each set of the experimental condition.

3.2. Mass spectra of derivatives

Table 1 presents an overview of the retention times and the major ions using as the quantitation ions for GC–MS analysis. These di-butylated derivatives showed some common fragmentation pathways. The molecular ions of di-butylated LMW-dicarboxylic acids were all detected with 10–40% intensities to their corresponding base peaks, furthermore, the base peaks of trans-C4 and C9 were their molecular ions. Two most intensive ions, [M−73]$^+$ and [M−129]$^+$, were observed and were tentatively attributed to the loss of OC_4H_9 and further loss of butene (m/z 56) from another side of the butyl ester end, respectively. This double-hydrogen rearrangement mechanism resulting in elimination of an alkene is common for propyl or higher esters [20]. For C2, the base peak m/z 101 may correspond to homolytic cleavage of carbobutoxy group ([$COOC_4H_9$]$^+$, m/z 101) at the α-position. The characteristic ion of [M−147]$^+$, m/z 111 for C6 and m/z 125 for C7 (as a base peak), was detected and was tentatively attributed to the loss of two OC_4H_9 from the molecular ion. These two or three characteristic ions as listed in Table 1 were used as the quantitation ions to obtain maximum detection sensitivity and specificity.

3.3. Method performance and applications

The analytical characteristics of the method, such as linear response range, reproducibility and quantitation limits, were investigated to evaluate the efficiency of the method and the possibility of the method application to atmospheric aerosol samples. Table 1 also presents the linear response range, linearity and limits of quantation (LOQ) for these derivatives. The quantitation of these derivatives was calculated from the five-level calibration curve (or average response factor) covering the range as shown in Table 1, each divided by the fixed concentration of internal standard (1-phenyldodecane). The calibration curves were linear with coefficients of determination $r^2 > 0.994$. The curve covered a range equivalent to the concentration of the analytes in aerosol samples after the extract was concentrated to 100 μl. The limits of quantitation (LOQs) ranged from 25 to 250 pg/m^3, at a nominal volume of 7.2 m^3 for a typical 12 h sample period (Table 1). Solid-phase extraction (SPE) method was used to concentrate analytes from filter extracts and the recoveries from filter extracts of the aerosol sample 1 ranged from 78 to 95% with relative standard deviation (RSD) less than 12%.

Table 2 lists the concentrations of selected LMW-dicarboxylic acids detected in atmospheric aerosols. The BF_3/n-butanol derivatization procedure [3,6] was also applied to the same aerosol samples (samples 1–3) to compare the results of on-line and off-line derivatization techniques. Student's t-test procedure was employed to compare individual differences [21], the two methods for analytes determination were evaluated. In this test, injection-port derivatization (on-line) and BF_3/n-butanol derivatization (off-line) methods were used to make single measurements on three samples, in this case, such that no measurement was duplicated. The t-test was to determine whether the two methods yielded the same results "within experimental error", or was one systematically different from the other in certain confidence level. The t-calculated

[a] Calculation from the equations in Ref [21], Eqs. (4-10) and (4-11).

values (in Table 2) were less than the *t*-table list values: 2.776 for samples 1 and 2; 2.447 for sample 3, in 95% confidence level with four and six degree of freedom, respectively. Therefore, these two methods are not significantly different at the 95% confidence level. Moreover, the percent differences of the total concentrations (from C2 to C10) obtained from these two methods were less than 2.8%. A comparison of the two methods reveals that, for off-line derivatization, the derivatization time and reagent consumption were 30 min (at 100 °C) and 250 μl per each sample, respectively [4], however, for on-line method, no derivatization time at high temperature was necessary and only 100 μl of methanol with 20 mM TBA-OH was used.

The concentrations of dicarboxylated C2–C5 and total C6–C10 in atmospheric aerosols ranged from 91.9 to 240, 11.3 to 56.7, 9.2 to 49.2, 8.7 to 35.3 and n.d. to 37.8 ng/m^3, respectively. The concentrations of maleic acid (cis-C4) and fumaric acid (trans-C4) ranged from 11.1 to 36.5 and n.d. to 23.5 ng/m^3, respectively. Oxalic acid (C2) was the dominant selected LMW-dicarboxylic acids detected in these aerosol samples, followed by malonic acid (C3) and succinic acid (C4). These values are similar to those measured in suburban southern Taiwan [22]. The profiles of these dicarboxylic acids in atmospheric aerosol samples are also similar to the profiles present in Hong Kong [6], urban Tokyo area [23], and urban and rural sites in Germany [24]. However, considerably lower concentrations have been detected in the atmospheres of the Arctic [2] and the savanna biome in South Africa [5]. Moreover, the different profiles in summer and winter times have been observed in urban and rural sites in Germany [25].

4. Conclusion

The improved large-volume injection-port derivatization with TBA-OH ion-pair reagent is a simple, rapid and accurate method for the determination of trace levels of selected LMW-dicarboxylic acids in atmospheric aerosol samples. Injection-port derivatization method completely avoided the open derivatization with hazardous reagents. This developed method could be adopted as an alternative rapid screen tool to obtain detailed information in understanding the transport and photochemical production of selected LMW-dicarboxylic acids in the atmosphere; it is a effective and environmental-friendly analytical method.

ABSTRACT

A novel strategy to fabricate hydrogen peroxide (H_2O_2) sensor was developed based on multi-wall carbon nanotube/silver nanoparticle nanohybrids (MWCNT/Ag nanohybrids) modified gold electrode. The process to synthesize MWCNT/Ag nanohybrids was facile and efficient. In the presence of carboxyl groups functionalized multi-wall carbon nanotubes (MWCNTs), silver nanoparticles (Ag NPs) were *in situ* generated from $AgNO_3$ aqueous solution and readily attached to the MWCNTs convex surfaces at room temperature, without any additional reducing reagent or irradiation treatment. The formation of MWCNT/Ag nanohybrids product was observed by transmission electron microscope (TEM), and the electrochemical properties of MWCNT/Ag nanohybrids modified gold electrode were characterized by electrochemical measurements. The results showed that this sensor had a favorable catalytic ability for the reduction of H_2O_2. The resulted sensor could detect H_2O_2 in a linear range of 0.05–17 mM with a detection limit of 5×10^{-7} M at a signal-to-noise ratio of 3. The sensitivity was calculated as 1.42 μA/mM at a potential of −0.2 V. Additionally, it exhibited good reproducibility, long-term stability and negligible interference of ascorbic acid (AA), uric acid (UA), and acetaminophen (AP).

1. Introduction

In recent years, there has been a considerable interest in the accurate determination of hydrogen peroxide (H_2O_2) because it is an essential mediator in food, pharmaceutical, clinical and environmental analyses [1,2]. Also many enzymatic reactions create H_2O_2 as an end product, so its concentration may be used as an indicator of the progress of a reaction [3–6]. Many techniques have been employed in the determination of H_2O_2, including spectrophotometry [7], chemiluminescence [8], and electrochemistry [9–11]. Among these methods, electrochemistry technique based on a simple and low cost electrode has been extensively applied for accurate determination of H_2O_2. For most electrochemistry sensors, the detection of H_2O_2 was achieved at a relatively high potential around 0.6 V. However, at this relatively high potential, there may be interferences from other oxidable species such as ascorbic acid (AA), uric acid (UA), and acetaminophen (AAP). Thus, it becomes significant to construct a sensor to detect H_2O_2 at a lower potential.

Recent studies indicated that Ag nanoparticles (Ag NPs) exhibited catalytic activity for the reduction of H_2O_2 [12,13]. Electrochemical results showed that the presence of Ag NPs was responsible for sensor response, in terms of cathodic current increment, regarding the reduction of H_2O_2 [14]. Welch et al. proved that the reduction of H_2O_2 could be facilitated by the modification of the glassy-carbon surface with nanosized silver assemblies [12]. In order to synthesize Ag NPs, many kinds of methods have been used. Several materials have been used to control the growth of Ag NPs, such as DNA [13], polyacrylonitrile [15], microemulsions [16], DNA–lipid thin films [17], polyelectrolytes [18] and mesoporous materials [19]. Additionally, type I collagen network was used as a template to fabricate Ag NPs because of its porous structure [20]. Reducing metallic ions were also taken in use to prepare Ag NPs [21].

Carbon nanotubes (CNTs) were discovered by Iijima [22] and have enormous potentials as components of nanoscale electronic devices and biosensors, as a result of their ability to promote electron transfer reactions and high thermal capacity [23–25]. Both single-wall carbon nanotubes (SWCNTs) and multi-wall carbon nanotubes (MWCNTs) have been utilized in the detection of various kinds of biological reagents [26]. CNTs [27,28] and Ag NPs [12–14] have been employed for detecting H_2O_2 respectively. In order to take full advantage of the two kinds of nanomaterials, it is desirable to create novel CNT/Ag nanohybrids, so that the unique properties of each material can be integrated, and the interactions between the two components may bring out novel properties.

To fabricate Ag NPs coated MWCNTs, electrochemical, chemical and physical methods have been employed [29]. Several kinds

doi:10.1016/j.talanta.2009.07.055

of chemical reagents, irradiations and temples were used in the synthesis of MWCNT/Ag nanohybrids. For instance, in the study of Wu et al., gamma-ray irradiation was taken in use to functionalize MWCNTs. MWCNT/polymer/Ag hybrids were synthesized relying on covalently bonded polymers [30]. The report of Bale et al. proved that proteins/polypeptides, including bovine serum albumin (BSA) and poly-L-lysine (PLL), mediated the formation of Ag NPs as bio-inspired template when adsorbed onto CNTs [31]. Lin et al. used trisodium citrate as reducing reagent and synthesized Ag NPs/CNTs/chitosan film by chemical plating method [32]. Electrodeposition of Ag NPs on MWCNTs was also carried out in some previous researches [33]. However, most of the methods in the synthesis of MWCNTs/Ag nanohybrids are verbose and complex, requiring different kinds of chemicals and templates.

In this article, by combining the advantages of carbon nanotubes and Ag NPs, MWCNT/Ag nanohybrids were designed and synthesized for the detection of H_2O_2. In our work, no additional chemical as reducing reagent or irradiation was employed, indicating the fundamental difference and extraordinary advantage of our approach over other reports. Utilizing the inherent properties of MWCNTs, the Ag NPs were reduced onto the MWCNTs surfaces. The resulted nanomaterials were characterized by transmission electron microscopy (TEM), and the properties of the modified electrode were investigated by amperometric measurements. The Ag NPs with good reduction catalysis for H_2O_2 would promote the ability of the electrode to eliminate the interferences from other electroactive biomolecules. The study can provide a promising platform for fabricating nonenzymatic electrodes, affinity matrix and detecting other biochemistry reagent.

2. Materials and methods

2.1. Materials

Multi-wall carbon nanotubes (30–50 nm diameter and 15 μm length), with >95% purity, and carboxylic acid groups 0.73 wt% were obtained from Institute of Organic Chemistry, Chinese Academy of Sciences (ChengDu, China). Hydrogen peroxide (30%, v/v aqueous solution), was obtained from Tianjin Eastern Chemical Reagent Company. Uric acid, ascorbic acid and acetaminophen were obtained from Tianjin Damao Chemical Reagent Co. (China). Sliver nitrate ($AgNO_3$) were purchased from Tianjin Yingda Rare Chemical Reagent Company. All other reagents were of analytical grade and used without further purification. All aqueous solutions were prepared with doubly distilled water. Phosphate-buffered saline (PBS) buffer: dissolve 6.8 g of KH_2PO_4 in 25 ml of doubly distilled water, adjust to pH 7.0 with 0.1 M NaOH and dilute to 100 ml with double distilled water. All experiments were performed in PBS at room temperature, approximately 25 °C.

2.2. Apparatus and electrochemical measurements

The MWCNT/Ag nanohybrids were characterized with transmission electron microscopy (TEM, Philips EM400ST microscopy). Electrochemical measurements were carried out in a conventional three-electrode electroanalysis system. The MWCNT/Ag nanohybrids modified gold electrodes (3 mm diameter) were used as a working electrode, and a platinum spiral wire (1 mm diameter) as a counter electrode, an Ag/AgCl electrode (saturated with KCl) as a reference electrode. Amperometric measurements were performed by using Potentiostat–Galvanostat (EG&G PARC Model 283 with a software M270) (USA).

2.3. Preparation of the biosensor

2.3.1. Modification of multi-wall carbon nanotubes

Pristine MWCNTs were dissolved in the mixture of concentrated H_2SO_4 and HNO_3 (3:1, v/v), and then dispersed in ultrasonic bath for about 4 h. The resulted MWCNTs were separated and washed with distilled water by centrifugation (10,000 rpm) until the pH of the resulted MWCNTs solution became neutral.

2.3.2. Synthesis of MWCNT/Ag nanohybrids

Synthesis of carbon nanotube/silver nanoparticle nanohybrids was carried out according to the previously reported method [34].

MWCNTs (1 mg/ml) were dispersed in an ultrasonic bath (40 kHz) for about 3 min, and then placed in a flask on magnetic stirrer. While stirring at room temperature, $AgNO_3$ (0.01 M) was added dropwise into the flask. After 20 h, the solid product (MWCNT/Ag nanohybrids) was collected by centrifuging.

In control experiment, the same protocol was employed to prepare the sample of MWCNT/Ag nanohybrids use the MWCNTs without carboxylic acid groups.

2.3.3. Electrode surface preparation and modification with MWCNT/Ag nanohybrids

Gold electrode was polished before each experiment with chamois leather containing 0.05 μm alumina powders, rinsed thoroughly with doubly distilled water, ultrasonically cleaned in ethanol and doubly distilled water, and dried at room temperature.

MWCNT/Ag nanohybrid solutions (5 μl, 1 mg/ml) were droped on the surface of polished gold electrode. In this way, the MWCNT/Ag nanohybrids were deposited on the electrode by absorption. After drying, the modified electrode was washed and used as an amperometric sensor in phosphate buffer (pH 7.0).

3. Results and discussion

3.1. Microscopic studies on the formation of MWCNT/Ag nanohybrids

The morphology of resulted nanohybrids was shown in Fig. 1. The observations of a transmission electron microscope (TEM) showed clearly that nanoparticles with a uniform size of about 8–12 nm were deposited onto the MWCNTs surfaces (Fig. 1(a)). By comparison, no such morphology of nanoparticles was observed on the surfaces of the neat MWCNTs (Fig. 1(b)). Fig. 1(c) shows the selected area electron diffraction (ED) image of the nanoparticles, indicating the phase structures of silver single nanoparticles [35–37]. After stored at 4 °C for a month, although the spherical structure of Ag NPs decomposed to some degree, the main structure could still be observed on MWCNTs (Fig. 1(d)), and the Ag NPs were binding well on the MWCNTs, proving the adsorption stability of the Ag NPs on the MWCNTs.

The inherent properties of MWCNTs such as rich-electron and strong absorption in a wide range of wavelength might be responsible for the synthesis of Ag NPs. The numerous carboxylic acid groups the MWCNTs possessed could play the roles of catalyst, silver 'catcher' and supporter. In this case, Ag NPs were *in situ* generated from the $AgNO_3$ aqueous solution at room temperature and attached to the convex surfaces of MWCNTs, forming the MWCNT/Ag nanohybrids [34]. MWCNTs without carboxylic acid groups were also used to compose MWCNT/Ag nanohybrids, but the result showed no Ag NPs appeared on the surface of the MWCNTs, which indicated that the reduction of Ag on the surface of MWCNTs depended on the assistance of carboxylic acid groups. In the report of Gao, either MWCNTs or SWCNTs could be utilized as the material for the synthesis of Ag NPs. The Ag NPs produced by the SWCNTs were much bigger than those produced by the MWCNTs, indicating that SWCNTs have a higher Ag productivity than MWCNTs, which was likely due to the higher special surface area or greater absorbance in water [34]. However, the nanoparticles which are smaller in size were considered to have better nano-effects. Thus, we chose the MWCNTs as the material in our research.

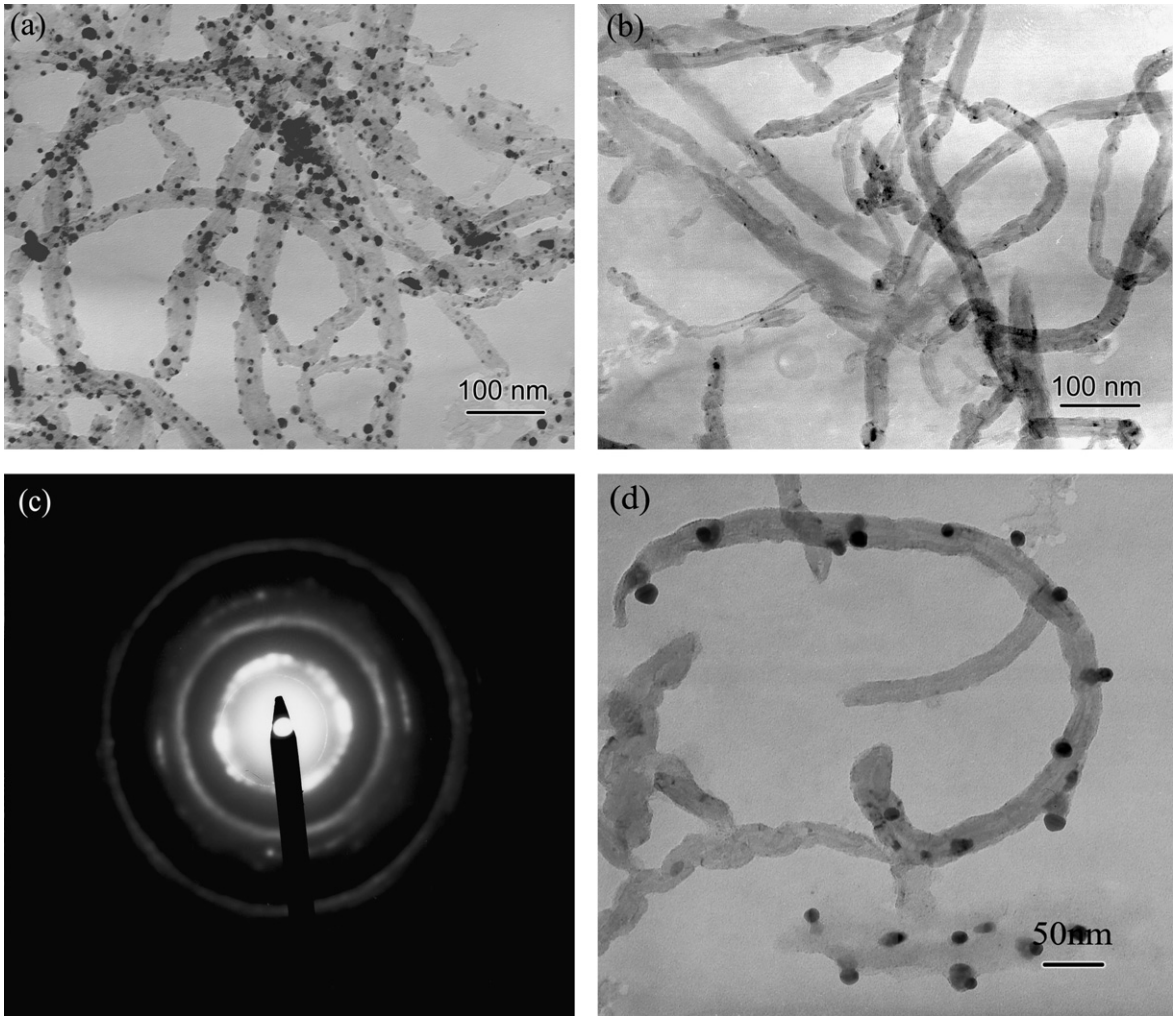

Fig. 1. TEM images of the MWCNT/Ag nanohybrids (a), MWCNTs (b), electron diffraction of Ag NPs (c), MWCNT/Ag nanohybrids stored at 4 °C for a month (d).

3.2. *Electrochemical response to hydrogen peroxide on MWCNT/Ag nanohybrids*

Cyclic voltammograms of the sensors were illustrated in Fig. 2. As shown in Fig. 2(a), in cyclic voltammograms of bare gold electrode there was no apparently redox process. After modified with MWCNTs (Fig. 2(b)), the diffused current increased clearly, because MWCNTs had a catalytically active surface, and they can increase the active surface area of the modified electrode. Two peaks at the potential of 0.2 V and 0.45 V were observed in MWCNT/Ag nanohybrids modified electrode (Fig. 2(d) and (e)). They were attributed to the reduction and oxidation of Ag, and could prove the existence of Ag NPs. The diffused current of MWCNT/Ag nanohybrids modified electrode (Fig. 2(d)) increased much more than that of MWCNTs modified electrode, due to the synergistic effect of MWCNTs and Ag NPs.

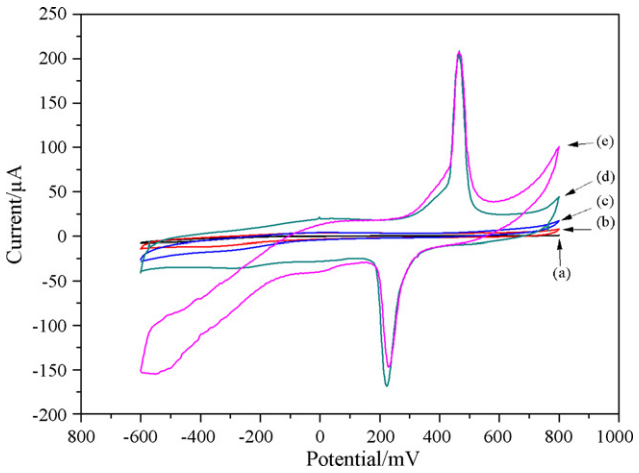

Fig. 2. Cyclic voltammograms of bare gold electrode (a), MWCNTs modified gold electrode (b and c), and MWCNT/Ag nanohybrids modified gold electrode (d and e) in PBS with (c and e) and without H_2O_2 (a, b and d).

When H_2O_2 was added into the PBS solution, it can be observed (Fig. 2(c) and (e)) that response current at the potential range of −0.15 V to −0.6 V indicated the reduction of H_2O_2, and the peak current appeared at the potential of −0.45 V. As it was shown, the reduction current in MWCNT/Ag nanohybrids modified electrode was markedly larger than that of MWCNTs modified electrode with the presence of H_2O_2. The difference was probably engendered by the synergistic amplification effect of MWCNTs and Ag NPs as well as the electrocatalysis reduction effect of Ag toward H_2O_2.

In the solution of PBS, the H_2O_2 was reduced via the mechanism shown below:

$$H_2O_2 + e^- \rightleftharpoons OH_{(ads)} + OH^-$$

$$OH_{(ads)} + e^- \rightleftharpoons OH^-$$

$$2OH^- + 2H^+ \rightleftharpoons 2H_2O$$

When the Ag NPs were deposited on the electrode, the reduction of H_2O_2 becomes more irreversible, as shown below [38]:

$$H_2O_2 \xrightarrow{Ag} \frac{1}{2}O_2 + H_2O$$

$$O_2 + 2e^- + 2H^+ \xrightarrow{electrode} H_2O_2$$

Then the O_2 generated in the action above would turn into the detection signal on electrode. It has been proposed [39] that the electro-reduction of oxygen on electrode occurs via the mechanism shown below [40]:

$$O_2 + e^- \rightleftharpoons [O_2^{\bullet -}]_{(ads)}$$

$$[O_2^{\bullet -}]_{(ads)} + H_2O \rightleftharpoons HO_2^{\bullet}{}_{(ads)} + OH^-$$

Then

$$HO_2^{\bullet}{}_{(ads)} + O_2^{\bullet -} \rightleftharpoons HO_2^{-}{}_{(aq)} + O_2$$

Or

$$HO_2^{\bullet}{}_{(ads)} + e^- \rightleftharpoons HO_2^{-}{}_{(aq)}$$

For most electrochemistry sensors, the detection of H_2O_2 was achieved at a relatively high potential around 0.6 V, which made it liable to interferences from electroactive compounds. In our work, we employed Ag NPs which had proved to exhibit catalytic activity for the reduction of H_2O_2 at lower potential to solve this problem. In contrast with Ag NPs modified GC electrode which showed a reduction peak current at −0.85 V [12], the wave that appeared at −0.45 V (Fig. 2(e)) on the MWCNT/Ag nanohybrids modified electrode due to the reduction of H_2O_2 means the smaller overpotentials of reduction of H_2O_2. At the same time, the cathodic current of the reduction of H_2O_2 on the MWCNT/Ag nanohybrids modified electrode is larger than that on the MWCNTs modified electrode. This may be due to that the Ag NPs on the MWCNTs could facilitate the reduction of H_2O_2 [12]. Although it exhibited the biggest response current at the electric potential of −0.45 V, we chose the potential of −0.2 V as work potential in consideration of anti-interference. At such a low applied potential, the background current decreased, the response of common interference species can be minimized, and the oxygen reduction current can be limited.

The amperometric responses of the electrodes modified with different nanomaterials were studied in Fig. 3, at the applied potential of −0.2 V. In order to check the catalytic performance of the two kinds of nanomaterials to H_2O_2, we compared the MWCNTs (a) and MWCNT/Ag nanohybrids (b) modified electrodes with the same amount of H_2O_2. For MWCNTs modified electrodes, small response currents can be observed. Whereas, the response current of MWCNT/Ag nanohybrids modified electrode was much larger, which could due to the excellent catalytic property of Ag NPs as well as synergistic amplification action of the MWCNT/Ag nanohybrids.

The insert (lower left) of Fig. 3 shows the steady-state calibration curve of the MWCNTs modified electrode (Fig. 3(a)) and MWCNT/Ag nanohybrids modified electrode (Fig. 3(b)). The experimental result showed that the two kinds of electrodes both gave a linear response to H_2O_2. In comparison with the sensitivity of 0.059 μA/mM in MWCNTs modified electrode, the MWCNT/Ag nanohybrids modified electrode had a sensitivity of 1.42 μA/mM, in the concentration range of 0.05–17 mM, and possessed a detection limit of 5×10^{-7} M at the signal-to-noise ratio of 3, and a fast current response time (within 5 s). The great sensitivity of MWCNT/Ag nanohybrids modified electrode could be attributed to the large catalytically electroactive surface area, the synergistic amplification effect of the two kinds of nanomaterials and the excellent catalysis reduction to H_2O_2 of Ag NPs.

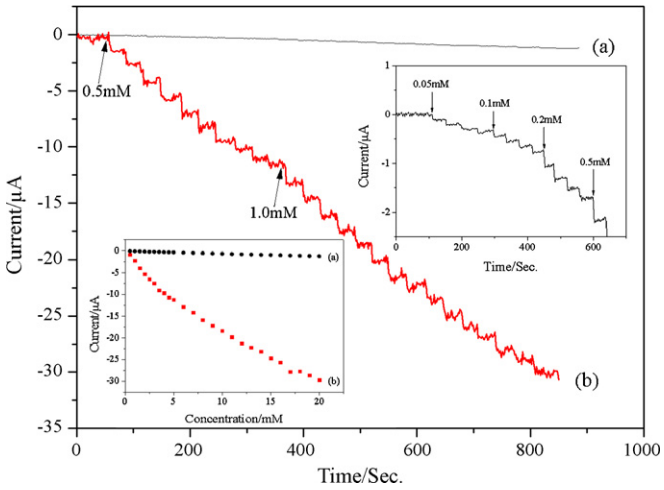

Fig. 3. Current–time recording obtained at the MWCNTs modified gold electrode (a) and MWCNT/Ag nanohybrids modified gold electrode (b) upon increasing the concentration of H_2O_2 in steps of 0.5 mM and 1.0 mM at −0.2 V. The insert (lower left) was the calibration curve of MWCNTs modified gold electrode (a) and MWCNT/Ag nanohybrids modified gold electrode (b) at −0.2 V in the concentration range of 0.5–20 mM of H_2O_2. The insert (upper right) was the current–time recording obtained at MWCNT/Ag nanohybrids modified gold electrode upon increasing the concentration of H_2O_2 in steps of 0.05 mM, 0.1 mM, 0.2 mM and 0.5 mM at −0.2 V.

3.3. Anti-interference experiment of hydrogen peroxide sensor

In real samples, some co-existing electroactive species might affect the sensor response, for example, ascorbic acid (AA), uric acid (UA), acetaminophen (AP), etc. The selectivity and anti-interference advantages were shown in Fig. 4, demonstrated by comparing the amperometric responses of three relevant electroactive species (UA, AA, AP, 0.1 mM, respectively) and H_2O_2 (1.0 mM) on a modified gold electrode at a working potential of −0.2 V. The successive addition of each interfering species brought out hardly discernible current response, and a well-defined H_2O_2 response was obtained. The good ability of anti-interference was largely attributed to the low working potential of −0.2 V used in the determination of H_2O_2.

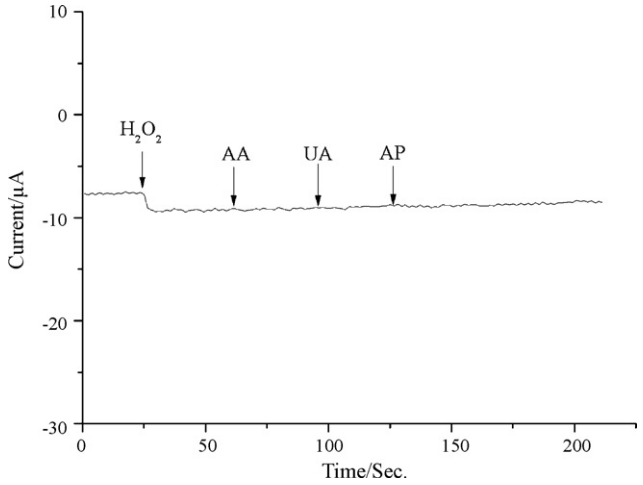

Fig. 4. Current–time curves for the MWCNT/Ag nanohybrids modified gold electrode exposed to AA, UA, AP, 0.1 mM each.

3.4. Reproducibility and long-term stability of the hydrogen peroxide sensor

To examine the reproducibility, repeatability and long-term stability of the sensor system, it was stored in phosphate buffer (pH 7) at 4 °C after several successive chronoamperometric experiments.

The reproducibility was estimated from the response to 5 mM H_2O_2 at five different H_2O_2 biosensors. A mean current response of −7.5 μA was acquired with a R.S.D. of 3.3%. It remained 90% of its initial current response for H_2O_2 after intermitting use over a month.

4. Conclusions

The main feature of this work was to propose a new nonenzymatic H_2O_2 sensor based on MWCNT/Ag nanohybrids, which was realized in a very fast and simple method.

In particular, experimental results indicated that Ag NPs were able to electrocatalyse the electro-reduction of H_2O_2. When they were used to modify MWCNTs, the two kinds of nanomaterials had a synergistic amplification effect, which could enhance the electrocatalytic properties of the sensor. There was an obvious difference in response current between the electrode modified with MWCNT/Ag nanohybrids and the one modified with MWCNTs at the potential of −0.2 V. When the two kinds of nanomaterials were used at one time the sensitivity enhanced 24 times than the MWCNTs modified electrode. Data collected from amperometric experiments showed that the performance of this kind of sensor made it suitable for the quantitative determination of H_2O_2. The resulted sensor exhibited good ability of anti-interference to electroactive biomolecules, which was attributed to the relatively lower potential at −0.2 V. The study may provide a feasible approach to develop new kinds of nonenzymatic amperometric sensors.

ABSTRACT

The reaction rate of the copper-catalyzed oxidation of iodide by oxygen in an aqueous acidic medium is first order in copper and oxygen concentrations, Michaelis–Menten in pH and a complex, asymmetrical bell shaped function in iodide concentrations. A theoretical, multivariate reaction rate equation was proposed which enabled to optimise the various kinetic coefficients. During the parameter optimisation, the experiments were weighted taking into account all measurement uncertainties, i.e. both on the reaction rate (output) and on the reactants' concentrations (inputs). This has two important advantages: (1) the model can be statistically checked to be acceptable for the description of the available measurements, and (2) the parameter uncertainties can be estimated accurately. In this case study, the model was indeed validated to be acceptable and the kinetic parameters could be estimated with a standard deviation between 5% (minimum) and 16% (maximum). As an application of this model, copper concentrations can be determined.

1. Introduction

This short note aims to model the copper-catalyzed oxidation of iodide by oxygen and to determine the various kinetic coefficients included in the rate equation. This study is based on the experimental work of Sigalla and Herbo [1] (hereafter abbreviated as SH58), more than half a century after their original study. They observed the remarkable kinetics of the oxidation of iodide by dissolved molecular oxygen, in an aqueous acid medium and in the presence of copper as a catalyst. They also proposed an incomplete reaction rate equation to account for these observations but did not take all factors into account. Hence they were not able to estimate all necessary kinetic constants and to further validate their suggestion.

The current study starts from their observations and their original model proposition to formulate a multivariate model describing the reaction rate as a function of the identified major reactant concentrations. Subsequently, this model is fitted on the observations and the optimal model is assessed statistically to verify its quality. This procedure results in a mathematical model for the reaction rate with all model parameters being quantified, such that the reaction rate can be predicted for any experimental conditions. Or, alternatively, one of the reactants' concentration can be predicted from the reaction rate, which is measured, and the remaining reactant concentrations, which are known. The presented parameter estimation and model validation procedure are very generic although not widely used, and may therefore be of interest to a wide audience.

The following reaction scheme of the copper-catalyzed oxidation of iodide by oxygen was proposed by SH58 (with their numbering):

$$2Cu^{2+} + 2I^- \leftrightarrows 2Cu^+ + I_2 \quad \text{(III0)}$$

$$O_2 + H^+ + Cu^+ \leftrightarrows O_2H + Cu^{2+} \quad \text{(III1)}$$

$$O_2H + H^+ + 2I^- \leftrightarrows H_2O_2 + I_2^- \quad \text{(III2)}$$

$$Cu^{2+} + I_2^- \leftrightarrows Cu^+ + I_2 \quad \text{(III3)}$$

$$H_2O_2 + H^+ + I^- \leftrightarrows H_2O + IOH \quad \text{(III4)}$$

$$IOH + H^+ + I^- \leftrightarrows H_2O + I_2 \quad \text{(III5)}$$

Table 1
Summary of optimisation results. Initial values are arbitrary, except for K_1 and K_2 for which the values proposed by SH58 were taken.

	Initial	Optimised	Standard deviation
k ($M^{-1}\,s^{-1}$)	100,000	40,211	2,000
K_S (M)	0.35	0.370	0.05
K_1 (M^{-6})	390	61,900	10,000
K_2 (M^{-3})	1,700	493	30
V_{WLS}	2,310	42.3	8.1 (assuming $\chi^2_{df=33}$)

The first step of this complex process, (III0), describes a rapidly established equilibrium which strongly favors the right hand side of the reaction. As such, the (very small) amount of copper introduced in solution, [Cu], will quasi-completely be under the form of Cu^+ species. The first step of the actual reaction, (III1), is the rate determining step. In addition, the following trends influencing the catalyzed reaction rate were observed:

(a) The presence of Cl^- ions and the ionic strength of the solution do not influence the reaction rate.
(b) The reaction is first order with respect to [Cu^+] (or [Cu] according to the above discussion of equilibrium (III0), and as it will be denoted from now on).
(c) When [I^-] increases, and all other concentrations are kept constant, the reaction rate first increases rapidly, then reaches a maximum and decreases almost as rapidly.
(d) The reaction order with respect to [H^+] changes from 1 to 0, as [H^+] increases.
(e) The reaction order is 1 with respect to [O_2].

Combining these observations, SH58 proposed the following overall kinetic equation:

$$v_c = k_c[O_2][Cu]f_1([I^-])f_2([H^+]) \quad (1)$$

In an appendix, they derive, from mechanistic assumptions, a possible expression for $f_1([I^-])$:

$$f_1([I^-]) = \frac{K_1^{1/2}[I^-]^{7/2}}{[I_3^-]^{1/2} + K_1^{1/2}[I^-]^{7/2} + K_1^{1/2}K_2[I^-]^{13/2}} \quad (2)$$

K_1 and K_2 are equilibrium constants associated with the following reactions, representing the actual nature of the copper complexes present in the equilibrium (III0):

$$2CuI^+ + 7I^- \leftrightarrows 2CuI_3^{2-} + I_3^- \qquad \text{(equilibrium constant } K_1\text{)}$$

$$CuI_3^{2-} + 3I^- \leftrightarrows 2CuI_6^{5-} \qquad \text{(equilibrium constant } K_2\text{)}$$

and SH58 even proposed values for K_1 and K_2 (see Section 3 and Table 1). Baeyens [2] studied the same reaction but with an auto-analyzer (AutoAnalyser Technicon) which allowed him to vary more easily and reproducibly one variable keeping the others constant. He observed similar trends in the reaction rate with changing reagent concentrations. However, his intention was not to decipher the mechanisms but to investigate the potential of this copper-catalyzed method as an analytical tool to quantify small concentrations of copper. Therefore, no further attempt was made to propose a model for the kinetics.

Kimura et al. [3], apparently unaware of the previous work of SH58 (which is not surprising as SH58 is written in French), performed a similar study on the kinetics and mechanisms copper-catalyzed oxidation of the iodide ion. Again, their observations concerning the influence of the different species on the reaction rate were essentially identical to those of SH58. In particular, they confirm the remarkable feature of this reaction, i.e. that v "*has a maximum around* 0.075–0.1 M *of* I^-" [for all other conditions kept constant]. Finally, they also propose an expression for the reaction rate:

$$v_c = \frac{k_5K_4[Cu^{2+}]_{added}[I^-]^2}{K_4[I^-] + 1} \quad (3)$$

However, they reported that the observed maximum rate relative to [I^-] might deviate from the one resulting from this equation. Consequently, this mathematical function expressing the rate dependence of [I^-], is probably not the most appropriate. It is also curious that the concentrations of [O_2] and [H^+] do not appear in Eq. (3). Therefore, we will not further consider this equation but continue on the proposition of SH58 (1)–(2).

2. Methods

2.1. Experimental data of SH58

In our search for a suitable model and its subsequent calibration and validation, we use the original data from SH58. The measurements of reaction rate and reactant concentrations are unavoidably associated with errors or uncertainties. These should all be taken into account in order to accurately estimate model parameters, and certainly their uncertainties. Most importantly, they must all be considered when assessing the goodness of fit of the final model. Indeed, a good model should fit the data "within their uncertainties". Quantitative statistical criteria exist to evaluate how acceptable the fit is, but these depend on a reliable incorporation of the measurement uncertainties. In particular, the uncertainties of the "input" or "independent" variables (in this case the concentrations of [O_2], [Cu], [H^+] and [I^-]) are often neglected, although they are more often than not highly significant. As we use the data from SH58 (number of experiments, $N = 37$) where any mention of the associated uncertainties lack, we estimated them as follows (s stands for the standard deviation estimate):

- $s(v_c)$ is estimated from the standard deviation of three replicate experiments (>2 replicates), resulting in a relative value of 3.58%, which seems reasonable;
- s(input concentrations) for concentrations > limit of detection: estimated to be equal to 2.5% of the measured concentration;
- s(input concentrations) for concentrations > limit of detection: an uncertainty was assumed equal to 2.5% of the limit of detection, i.e. a constant value [4].

2.2. Model

Combining the equations (1)–(2), the observations (a)–(e) and visual inspection of the data, we propose the following multivariate model to describe and predict the rate of the catalyzed reaction:

$$v_c([O_2], [Cu], [H^+], [I^-]) = k[O_2][Cu]\frac{[H^+]}{K_S + [H^+]} \times \frac{K_1^{1/2}[I^-]^{7/2}}{[I_3^-]^{1/2} + K_1^{1/2}[I^-]^{7/2} + K_1^{1/2}K_2[I^-]^{13/2}} \quad (4)$$

The overall reaction rate is represented as a product of the univariate reaction rate functions (i.e. the rate as a function of only one concentration). These univariate reaction rate functions are simply linear for [O_2] and [Cu], Michaelis–Menten-type with respect to [H^+] and a more complex kinetic function for [I^-]. Note that data for [I_3^-] were available only for a fraction of the dataset. Within these experiments it did not vary much [1], therefore we fixed its value to an average of 2.1×10^5 M. This model contains four parameters ($p = [k, K_S, K_1, K_2]$; $n_p = 4$), which are to be estimated by fitting the model on the available data. The advantage of this model equation

is that all unknown parameters can be interpreted kinetically. Note that as we are only concerned with the catalyzed reaction, we will from now on drop the subscript "*c*".

2.3. Parameter and uncertainty estimation

The unknown parameters were estimated by fitting model (4) on measurements of reaction rates y_i ($i = 1, \ldots, N$). The optimal fit was found by varying the values of the parameters p until the weighted least squares (WLS) cost function:

$$V_{\mathrm{WLS}} = \sum_{i=1}^{N} \frac{[y_i - v_i]^2}{s_i^2} \tag{5}$$

was minimal. v_i represents the reaction rate as computed using (4) and the input concentrations ($[O_2]_i$, $[Cu]_i$, $[H^+]_i$, $[I^-]_i$) associated with experiment *i*. The inverse weights s_i^2 are usually defined as the variance associated with experiment *i*. In a classical WLS approach s_i^2 is defined as the variance of measurement y_i, i.e. only the output uncertainty is used to weigh the pointwise misfit. Here, we use a refined approach where the input uncertainties are taken into account as well [5]:

$$s_i^2 = s_{y,i}^2 + \sum_{m=1}^{4} \left| \frac{\partial v_i}{\partial C_m} \right|^2 s_{C,m}^2 \tag{6}$$

In the above equation C_m ($m = 1, \ldots, n_C$) represents either of the n_C (4 in this case) input concentrations. All s_i^2 are inverted to form the weights and stored on the diagonal of a weighting matrix W.

As model (4) is nonlinear with respect to the parameters, there is no analytical expression for the optimal solution (i.e. the minimal V_{WLS}); instead a numerical optimisation procedure must be employed. Here, we used a Levenberg–Marquardt optimisation. This procedure requires knowledge of the Jacobian matrix J, containing the derivatives of the model output v_i ($i = 1, \ldots, N$) with respect to the parameters p_j ($j = 1, \ldots, n_p$):

$$J(i,j) = \frac{\partial v_i}{\partial p_j} \tag{7}$$

Once the optimal parameter values $\hat{p}$ are found, their associated covariance matrix is calculated by the following linear approximation:

$$Cov_{\hat{p}} = (J^T W J)^{-1} \tag{8}$$

where J and W are both dependent on the parameter values, and hence should be recomputed with the final, optimal parameter values before calculating $Cov_{\hat{p}}$. This linear approximation of the parameter covariance matrix is only exact in the case that the model is linear in the parameters. In the nonlinear case, (8) is only asymptotically valid, i.e. for the sample size tending to infinity [6]. Nevertheless, it has been demonstrated to be a satisfactory estimation in several cases [5,7]—although this is obviously only the case if all measurement uncertainties are taken into account (in W). Therefore, the inclusion of the input uncertainties (Eq. (6)) is essential.

Another advantage of such an overall weighting is that the final, minimal value of V_{WLS} can be interpreted statistically, or more precisely: its "acceptability" can be assessed. Indeed, assuming that

(i) the model (equation) is correct or appropriate for the observations under study, and
(ii) the measurement errors are independent, normally distributed with known variances:

$$(s_{y,i}^2 \text{ and } s_{C,m}^2 \text{ for all } i = 1, \ldots, N \text{ and } m = 1, \ldots, n_C)$$

the minimal V_{WLS} is a sample from a χ^2 distribution with $N–n_p$ degrees of freedom [8,9] (n_p = number of parameters, N = number of output measurements). Knowing this, the minimal V_{WLS} value can be compared to the percentiles of the relevant distribution, enabling an estimation of the probability to obtain this value. In practice, if the minimal V_{WLS} value is too high, this means that the remaining difference between model and measurements is too large to be attributable to only noise with the assumed properties. Consequently, either the noise variances are not estimated correctly (and are actually larger), or the model is not adequate. As a third possible cause the measurements could contain an error (e.g. an outlier), but these errors are usually removed in a preprocessing stage. The minimal V_{WLS} value can also be too low, which could indicate that the data are overmodelled (i.e. a too complex model is used) or that the measurement errors are overestimated.

To summarise, we are concerned here with a model, proposed to describe some (kinetic) measurements, but still containing some parameters that need to be estimated based on these measurements. In this case it is strongly advised to take into account all measurement uncertainties in the parameter estimation procedure (Eq. (6)). This has two main advantages: (1) the residual cost function can be interpreted statistically to assess whether the proposed model does an acceptable job in describing the measurements; (2) the parameter uncertainties can be estimated (more) accurately.

3. Results and discussion

The results obtained when fitting model (4) on the data from SH58 with the procedure outlined above are shown in Fig. 1 and Table 1. Both visually and statistically the fit is acceptable. The statistical evaluation was based on a comparison between the minimal V_{WLS} value (42.3) and the theoretical $\chi^2_{\mathrm{df}=33}$ distribution from which it should be a sample. The theoretical distribution has expected value $E\left\{\chi^2_{\mathrm{df}=33}\right\} = 33$ and standard deviation $\sqrt{\mathrm{Var}\left\{\chi^2_{\mathrm{df}=33}\right\}} = 8.1$. Hence, the minimal V_{WLS} value falls well within its expected value and ±2 standard deviations (95% probability interval) and cannot be rejected.

The results shown in Fig. 1 correspond to an optimisation starting from the values given in Table 1. These are not completely arbitrary as the initial values of K_1 and K_2 were the ones suggested by SH58, however, without giving details about the way they were estimated. A sensitivity study was performed to assess the robustness of the optimised results when starting from different initial parameter values. The optimal parameter values seem to be relatively well constrained: for initial parameter values ranging from 0 to 10 times the previously found optimal parameters (Table 1), the optimal parameter values (except diverged values) vary with a relative standard deviation of maximum 2.6% (for K_S).

In an attempt to further validate the model and the calculated parameter values, independent measurements of reaction rates at 25 °C were made using an automated Technicon system. Combining the experimental reaction rate, the concentrations of H^+, I^- and O_2 and the optimal parameter values from Table 1 into Eq. (4), we can predict the copper concentrations according to the proposed, calibrated model. These values compare well to the experimental copper concentrations (Table 2), especially considering the fact that the experiments are conducted with a completely different method, many years after the original measurements made by SH58.

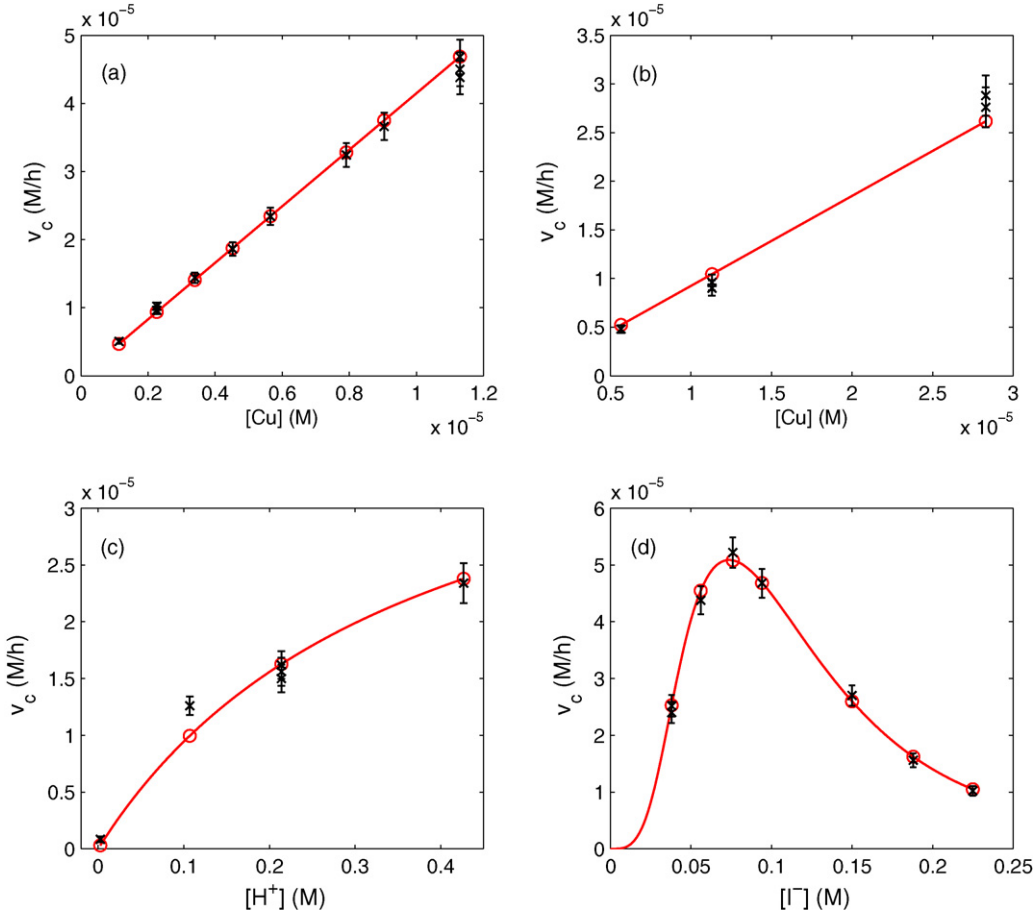

Fig. 1. Visual comparison between measurements (black crosses with error bars representing ±1 standard deviation s_i, as computed from Eq. (6)) and optimised model (red circles and line). Experimental conditions are: (a) $[H^+] = 0.488$ M, $[I^-] = 0.094$ M; (b) $[H^+] = 0.214$ M, $[I^-] = 0.188$ M; (c) $[Cu] = 1.13 \times 10^{-5}$ M, $[I^-] = 0.038$ M; (d) $[H^+] = 0.49$ M; $[Cu] = 1.13 \times 10^{-5}$ M. All experiments were conducted at 25 °C. All experiments were conducted at 25 °C and with saturated oxygen concentrations (2.69×10^{-4} M). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

Table 2
Comparison between measured and modelled copper concentrations for independent measurements. Concentrations are given in M, reaction rates in M/h.

	Measured v	$[H^+]$	$[I^-]$	$[O_2]$	Exper. [Cu]	Modelled [Cu]
Experiment 1	1.43×10^{-4}	1.25	0.050	2.69×10^{-4}	2.39×10^{-5}	1.92×10^{-5}
Experiment 2	2.66×10^{-4}	1.25	0.11	2.69×10^{-4}	2.39×10^{-5}	1.24×10^{-5}

4. Conclusions

This study continued the work of SH58 and added the following steps to the description of the copper-catalyzed oxidation of iodide by oxygen in an aqueous acidic medium:

(i) a multivariate model was proposed for the reaction rate as a function of the reactants' concentrations;
(ii) this model was fitted on the observations to estimate each of the kinetic coefficients;
(iii) the four coefficients were optimised simultaneously – not in a sequential procedure where one coefficient is optimised after the other – which gives more guarantee that the obtained values are truly optimal;
(iv) during the parameter optimisation, the experiments were weighted taking into account all measurement uncertainties, i.e. both on the reaction rate (output) and on the reactants' concentrations (inputs);
(v) this procedure allows a statistical analysis to assess the probability of the outcome; in this case accepting the optimisation results and hence the proposed model. This can be viewed as an internal validation of the model, which can be applied even if relatively few data are available (and thus cross-validation is not an option). On the other hand, information on the measurement uncertainties is essential.

Points (ii)–(v) are very generic and can be applied to any (chemical) dataset, as long as an appropriate model can be formulated for the reaction under study (i.e. point (i)). This step is indeed application-specific. Formulating an accurate model may not be so straightforward, especially if the underlying mechanism is only poorly understood. However, note that if the interest lies in prediction rather in the parameter interpretation, any functional expression can be used as a model, as long as it is able to satisfactorily describe the observations. For instance, we were able to find another effective expression for the rate dependence on $[I^-]$, giving the following multivariate model for the reaction rate:

$$v_c([O_2], [Cu], [H^+], [I^-]) = k[O_2][Cu]\frac{[H^+]}{K_S + [H^+]}\frac{[I^-]^3}{Ae^{B[I^-]} - 1}$$

This model was derived from the expression proposed by Max Planck to account for the black body radiation! Only based on the

statistics of the minimal cost function, this model was as acceptable as model (4). Furthermore, both models have the same number of parameters, so no considerations on parsimony can be used to discriminate between them. However, model (4) was preferred because it has the advantage of being derived from kinetic principles and the model parameters are chemically interpretable.

In short, this modelling work delivered a calibrated and internally validated model which enables the prediction of the catalyzed reaction rate under given experimental conditions (i.e. input concentrations), at 25 °C. In addition, the calibrated model parameters can be interpreted as kinetic/equilibrium constants and therefore also have some interest of their own.

Finally, the model has a potential added value for analytical applications. Indeed, on the basis of this model it is possible to estimate copper concentrations in a sample by measuring the formation of I_2 or I_3^- at optimal values of dissolved oxygen, pH and iodide concentration and after a fixed reaction time. A good agreement between our experimental and theoretical results was observed. Furthermore, the availability of a model permits advanced experimental design: future experiments can be designed to deliver maximal information. Although here the focus was on a specific kinetic reaction, the procedure could be used for other reactions, which may offer more application possibilities, e.g. the Fenton reaction.

ABSTRACT

Reasons for signal suppression during the analysis of light petroleum matrices by inductively coupled plasma mass spectrometry (ICP MS) were examined. A decrease of the ionization efficiency of the plasma was found to be the principal factor responsible for this loss of sensitivity. Consequently, an interface based on a total consumption micronebulizer and a heated spray chamber was constructed to alleviate this problem. A method based on flow-injection ICP MS using this interface was developed for the direct multielement analysis of undiluted fuels (gasoline, kerosene) and gas condensates offering an increase in sensitivity by at least a factor of 3–4 in comparison with the existing setups.

1. Introduction

Light petroleum matrices and refining products, such as gas condensates and fuels (gasoline or kerosene) contain several metals, including mercury [1–4], arsenic [5,6] or lead [7,8] present in the $\mu g\,kg^{-1}$ range. Their analysis is important in the different sectors of economy from refining to environmental risk assessment. Mercury or arsenic, identified as the major metals present in natural gas and gas condensates, are responsible for catalyst poisoning, fouling and corrosion of refining installations. Lead and manganese have been of interest because of their use in additives to improve the antiknock properties of gasoline [7–9].

A number of techniques have been developed for the metal determination in fuels and related petroleum samples [10,11]. They include graphite-furnace atomic absorption spectrometry (GF-AAS) [12–14], inductively coupled plasma atomic emission spectrometry (ICP-AES) [10,15], and, more recently, ICP-MS [10,16–18]. The latter is particularly attractive because of its capacity of the simultaneous multielemental analysis and the sub-$\mu g\,kg^{-1}$ limits of detection (LOD) theoretically allowing the direct analysis. However, the introduction of organic, especially oxygen-free, solvents in ICP-MS is known to be affected by plasma quenching and matrix effects [19]. Therefore, petroleum matrices were usually analysed after digestion [20] or considerable dilution [17,20].

Recent advances in ICP MS analysis of organic solvents were based on the reduction of the amount of solvent arriving at the plasma by lowering the uptake rate and desolvation as well as on operating the plasma at higher power levels. The use of conventional micronebulizers (100–300 $\mu l\,min^{-1}$) equipped with a low-volume spray chamber limits the risk of memory effects and allows an increase in sample throughput [21]. The use of conventional (double-pass Scott) spray chamber results in a low fraction of sample introduced into the plasma and can cause analyte fractionation. An interesting alternative is the use of direct injection nebulizers, such as the DIN (not commercially available anymore) and the DIHEN (direct injection high efficiency nebulizer) [18,22,23] because of a low internal dead volume, rapid response time, reduced memory effects, absence of analyte loss and the elimination of the problem of fractionation in the spray chamber. However, routine analyses of petroleum matrices with DIHEN have not been demonstrated, likely because of plasma perturbation, clogging and instability in time.

In our former works [4,21] an interface was developed, based on a total consumption micronebulizer for the introduction of xylene solutions into ICP MS. The increase in the nebulizer capillary diameter and the elimination of the internal connections has limited the problem of clogging, pressure instability and memory effects [24].

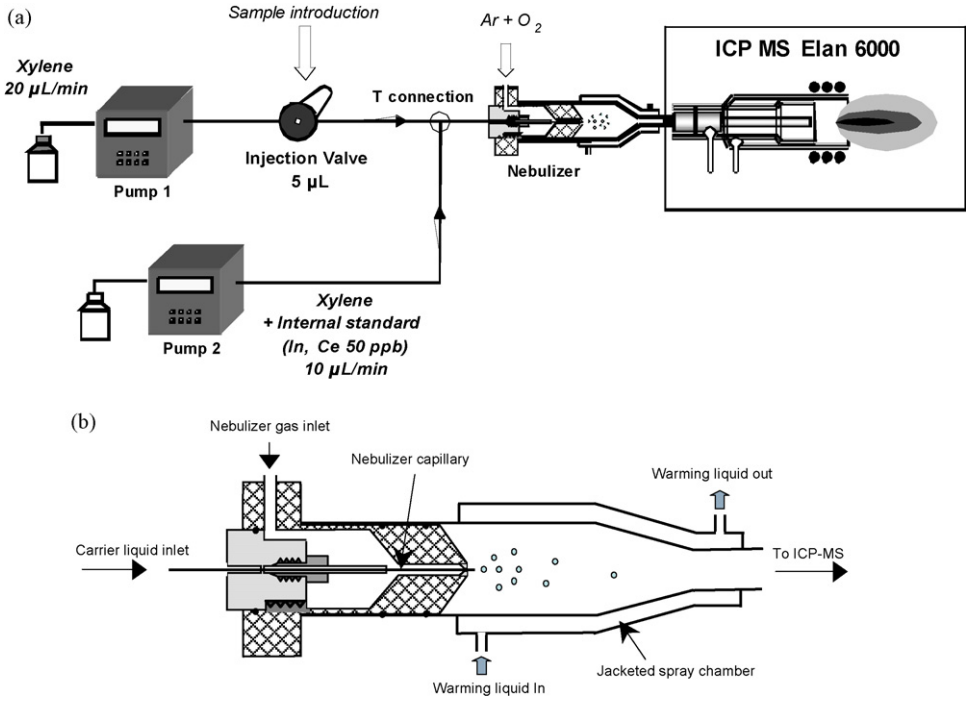

Fig. 1. (a) Scheme of the analytical setup used. (b) Blowup of the sample introduction system.

However, the introduction of light petroleum fractions (gasoline, naphta) using this interface resulted in a significant plasma perturbation and, consequently, required dilution of the sample. This negatively affected the detection limits and was unsuitable for the analysis of trace elements (<0.1 mg kg^{-1}).

The purpose of this study was to examine the reasons for this loss of sensitivity and to propose sample nebulization into a heated drain-free spray chamber to reduce the perturbation of plasma and to increase the sensitivity of the analysis. This setup is the origin of an analytical method allowing the multielement analysis of fuels without dilution resulting in the detection limits at the 1 µg kg^{-1} level (gain of a factor 3–4).

2. Experimental

2.1. Apparatus

The ICP MS instrument used was a PerkinElmer Elan 6000 (PE-SCIEX, ON, Canada). The ICP AES was a Spectro Arcos (Kleeve, Germany) with radial viewing. The analytical setup is shown in Fig. 1a. A dual syringe pump (Model 140C, Applied Biosystems, Foster City, CA, USA) was used to assure a stable delivery of xylene into the ICP at a flow rate of 20 µl min^{-1} without the use of a splitter to limit the solvent consumption. Another pump (Smartline Pump 1000, Knauer, Berlin, Germany) was used to deliver internal standard (In, Ce) in xylene to the nebulizer to control the stability of the instrument. Injections were made using a low port-to-port dead volume micro-injection valve (8125i, Rheodyne, Rohnert Park, CA, USA) fitted with a 5 µl sample loop. The fused silica capillary used was 180 µm i.d. (375 µm o.d.). The sample introduction system was based on a microflow total consumption nebulizer described elsewhere [21]. The spray chamber was jacketed to allow the thermostating at a desired temperature (Fig. 1b). The heating liquid (glycol/water) was circulated through a Neslab RTE–111 (Thermo Fisher Scientific, Waltham, MA) thermostat. For ICP MS analysis, oxygen gas flow, controlled by a mass flow controller, was mixed with the carrier argon nebulizer gas via a T-connection prior to nebulization, to prevent carbon deposition on the sampler and skimmer cones of the instrument. Oxygen was not needed for ICP AES analysis.

2.2. Samples and solutions

Alkanes (pentane, hexane, heptane, octane, decane, dodecane and hexadecane) were purchased from Acros (Acros Organics, NJ) and xylene (ACS grade) was purchased from Baker (Phillipsburg, NJ). Conostans monoelemental standards in oil (1000 mg kg^{-1}) and multielemental S-21 oil standard (100 mg kg^{-1}) were purchased from SCP Science (Baie D'Urfé, Canada). The standard reference material (CRM) crude oil 1634c was purchased from NIST (Gaithersburg, MD). Petroleum samples with different boiling range were provided by the French Institute of Petroleum (IFP-Lyon, France). They were kerosene (IBP = 162 °C and FBP = 252 °C), gasoline (IBP = 0 °C and FBP = 197 °C) and full range gas condensate (IBP = −25° and FBP = 470 °C) (IBP – initial boiling point; FBP – final boiling point).

2.3. Procedure

The ICP MS conditions were optimized daily using a solution of 50 µg kg^{-1} indium and cerium in xylene. The typical settings are RF power 1300 W, Ar nebulizer gas 0.8 l min^{-1}, and auxiliary O_2 flow 45 ml min^{-1}. The sample (5 µl) was injected into the carrier xylene at 20 µL min^{-1} and was mixed before the nebulizer with another xylene flow of 10 µl min^{-1} containing 50 µg kg^{-1} indium and cerium (internal standards) (Fig. 1a). Molybdenum was added at 50 µg kg^{-1} in each matrix analyzed to monitor the ionization efficiency. The isotopes measured in light petroleum matrices were ^{48}Ti, ^{51}V, ^{57}Fe, ^{107}Ag, ^{112}Cd, ^{114}Cd, ^{202}Hg, ^{208}Pb, and ^{53}Cr. ^{98}Mo was measured as a spiked analyte, ^{114}In as the internal standard and ^{58}Ni was measured in the CRM 1634c. The integration time per isotope was 20 ms, three readings were made per analysis, and each injection was made in triplicate. Quantification was made by the method of standard additions using the

multielement S21 standard at concentrations of 10, 25, 50, 100, 150 and 200 μg kg^{-1}.

3. Results and discussions

3.1. Signal intensity suppression by petroleum matrices

Direct injection of petroleum and automotive fuel matrices into an ICP leads to plasma quenching and loss of signal intensity. Fig. 2 shows the effect of μFIA-ICP MS injection of a kerosene sample on the sensitivity and on the internal standard intensity in operational conditions optimized in the previous work [21]. Molybdenum added to the samples was measured as an analyte. In addition, indium and cerium were continuously introduced into the plasma. The addition of these elements directly in the nebulizer allows the control of the plasma stability all along the analysis, before and during the injection of the petroleum sample. Therefore, the impact of the injection of the petroleum sample on the ionization efficiency of the plasma could be observed.

A significant effect can be seen on the intensity of both the analyte signal (^{98}Mo) added to the sample, and of the internal standard indium added to the carrier liquid at the moment of arrival of the injected sample to the plasma (Fig. 2a). The perturbation of the plasma results in a reduction of the flow-injection peak of the analyte. This effect can be avoided by a large dilution of the sample with xylene (Fig. 2b) which, however, results in an increase of the detection limits when referred to the metals concentration in the sample.

Two hypotheses can be put forward to explain this drop in sensitivity:

(i) The volatility of the injected sample creates an expansion of the plasma which disperses the ions formed in the central channel of the plasma; consequently, fewer ions arrive at the detector resulting in the decrease of the signal intensity.
(ii) The injected sample matrix is responsible for the decrease in ionization power of the plasma which results in fewer ions formed and, consequently, a decrease of sensitivity.

In order to validate one of these hypotheses, the signal intensity of the same elements molybdenum and indium was investigated during injection of series of alkanes with increasing boiling points *n*-pentane (36 °C), *n*-heptane (98 °C), *n*-octane (125 °C), *n*-decane (174 °C), *n*-dodecane (216 °C), and *n*-hexadecane (287 °C). These alkanes were chosen to simulate different petroleum matrices with different boiling points. Indeed, classical automotive fuels contain molecules with fewer than 14 carbons, and their boiling point is generally below 250 °C. The analyses were carried out using the same sample introduction system but with ICP AES as detector which allows an independent measurement of intensity at the atomic and ionic lines. During ICP AES analysis, the atomic and ionic lines of carbon were measured to monitor the stability of the plasma. Indeed, the carbon is the major element in petroleum matrix, with a high ionization potential. The impact on ionization and atomisation efficiency of the plasma during injection of organic matrices was reported to be reflected by this element [25].

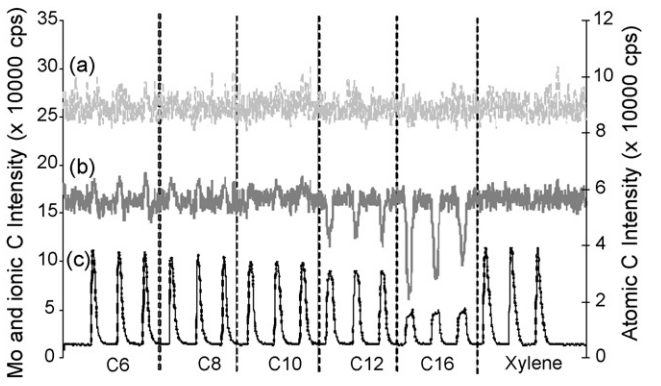

Fig. 3. Effect of boiling point of the matrix on the ionization efficiency. μFIA-ICP AES analysis of alkanes from C6 to C16. (a) Atomic carbon line intensity (λ = 146.334 nm); (b) ionic carbon line (λ = 133.571 nm); (c) molybdenum added at 50 μg kg^{-1} in each sample (λ = 281.615 nm).

The results (Fig. 3) show that the intensity of the carbon atomic line is stable along the analysis, which indicates that

the atomisation of the sample is effective, regardless the matrix injected (Fig. 3a). In contrast to that, the intensity of the carbon ionic line drops significantly when high-boiling point alkanes (C12 and C16) are injected (Fig. 3b). This perturbation of the signal measured using the ionic line indicates that the ionization step is not complete for the injection of heavy alkanes. Moreover, Fig. 3c shows a decreasing intensity of the analyte (molybdenum) signal with the increasing number of carbons of the alkane.

These conclusions correlate with the fact that the energy needed for vaporization, atomization and ionization steps increases with the number of carbons of the alkane. The vaporization and atomization of heavy alkanes in the plasma require more energy which is then not available for ionisation.

Hence, the loss of signal intensity is not due to an expansion of the plasma, as no expansion or perturbation of the plasma could be observed visually during the alkanes injections, but to a decrease of ionisation of the analyte elements in a plasma becoming not energetic enough. Following this conclusion we attempted to improve the ionization efficiency by pre-heating the aerosol in the spray chamber.

3.2. Effect of the spray chamber temperature on the signal intensity

A jacketed spray chamber was designed to heat the aerosol prior to introduction into ICP MS. Fig. 4a shows the effect of the spray chamber temperature on the molybdenum signal intensity for the different alkanes. The alkane solutions were injected at a spray chamber temperature of 20, 40 and 60 °C, respectively. No effect of the temperature observed for low boiling matrices (40–120 °C) confirms the observation made in Fig. 3 that the ionization is not perturbed at these conditions. However, for matrices with boiling points in the range between 150 and 250 °C (typical for fuels) a significant increase in sensitivity is observed with the spray chamber temperature of 60 °C. A possible explanation is that pre-vaporization of the organic solvent occurs in the heated spray chamber. Then, the introduction of the pre-heated solvent requires less energy from the plasma for vaporization and atomisation so more energy is left for efficient ionization.

Fig. 4b shows the effect of the spray chamber temperature on the analysis of undiluted kerosene. The heating of the spray

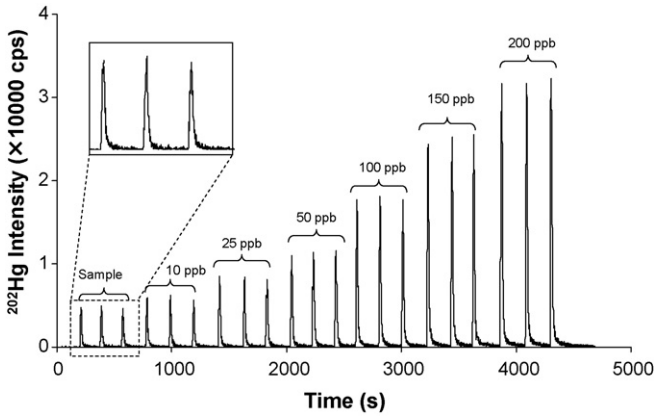

Fig. 5. μFIA-ICP-MS analysis of ^{202}Hg in a kerosene sample by the method of standard additions (each determination was carried out in triplicate). The added concentrations are 10, 25, 50, 100, 150 and 200 μg kg^{-1}, respectively.

chamber to 60 °C results in a decrease of the perturbation of the internal standard indium and in a 3–4-fold increase in signal intensity of the analyte measured. As the background does not change at different temperatures, the detection limits are reduced by a factor 3–4 when the spray chamber temperature increases. By heating the spray, the sample is probably partly vaporized in the chamber, which facilitates the atomization step in the plasma, and the sensitivity of the instrument increases.

3.3. Multielement μFIA-ICP MS analysis of metals in fuels and gas condensates

The interface developed was used for the multielement analysis of samples of kerosene, gasoline and gas condensate. Each petroleum sample was injected without dilution, and the spray chamber was heated to 60 °C. The analysis was done in triplicate followed by standard additions on 6 levels, each in triplicate in order to verify the repeatability of the method. A typical graphic recording of data acquisition for ^{202}Hg is shown in Fig. 5. Table 1 shows the figures of merit and demonstrates that the calibration curves were linear in the range 1–250 μg kg^{-1}. The limits of detection were from 0.04 μg kg^{-1} for Ag in gasoline, to 1 μg kg^{-1} for other elements in all the matrices, except iron and chromium where values up to 20 μg kg^{-1} were measured. The precision calculated according to the Student's *t*-test at 95% was in the 2–5% range. The table shows that heavy metals at concentrations at the μg kg^{-1} level can be successfully determined in light petroleum matrices and fuels by μFIA-ICP MS with spray chamber heated up to 60 °C. However, even if the measured concentrations were precise, the "*a*"-coefficient values show that a matrix effect still remains. The expectation would be the same "*a*" values for a given metal, regardless of the matrix.

The method was validated by the analysis of certified reference material (CRM) residual oil 1634c. This is a heavy oil so it was diluted 1000 times in xylene, in order to obtain metal concentrations in the appropriate range for analysis. Note that a light petroleum reference material was, to our knowledge, not available. The certified concentrations given are 28.2 ± 0.4 mg kg^{-1} vanadium and 17.5 ± 0.2 mg kg^{-1} nickel. The concentrations found on this work were 28.7 ± 0.9 mg kg^{-1} vanadium and 18.4 ± 0.7 mg kg^{-1} nickel respectively.

4. Conclusion

The direct flow-injection analysis of light petroleum matrices (kerosene, gasoline, gas condensate) results in a serious quenching of the plasma leading to the signal intensity suppression. An insight into the mechanism of this sensitivity decrease showed that it was not due to the expansion of the plasma following the introduction of a volatile solvent but to the insufficient energy of the plasma to assure effective ionization of the determined elements. Heating the spray chamber in the μflow-injection setup allows the alleviation of this effect, and a rapid simultaneous multielement analysis of petroleum-related samples with detection limits below 1 μg kg^{-1}.

Analysis

ABSTRACT

The purpose of this work was to present a chromatographic methods to analyse synthetic food dyes. The following techniques has been described: thin-layer liquid chromatography (TLC), high performance thin-layer chromatography (HPTLC), traditional column chromatography, high performance liquid chromatography (HPLC), include: ion-pair chromatography (HPLC IP), reversed phase chromatography (RP HPLC) and high performance ion chromatography.

1. Introduction

Food dyes are the most interesting group of food additives. Frequently color of a product determinates its attractiveness for consumer. Incentive hue associates with freshness and good taste value of nutrition. However natural dyes are unstable and easily undergo degradation during the food processing. That is why synthetic food dyes are so widely use according to Directive no 94/36/WE including its later changes. In European Union it is aloud to use following synthetic food dyes (SFD): tartrazine (E102); Quinoline Yellow (E104); Sunset Yellow (E110); Carmoisine (E122); Amaranth (E123); Ponceau 4R (E124); Erythrozine (E127); Allura Red (E129); Patent Blue (E131); Indigo Carmine (E132); Brilliant Blue FCF (E133); Brown HT (E155) [1].

SFD guarantees intensive and permanent color of food products. The costs of production process are much lower in comparison with production of natural dyes [2]. These advantages encourage producers to use them, in spite of many resources which confirm their negative influence on human organism. For instance azodyes are decomposing by natural intestinal flora to aromatic amines [3], which are the cause of frequent headaches in adults while children often become distractible and hyperactive [4]. That is why there is a necessity to control the content of the synthetic dyes in food. For that purpose many analytical methods has been used, such as: thin-layer chromatography; spectrometry [5], derivative spectrometry and other spectrophotometric methods correlated with chemometrics [6,7], for instance hybrid linear analysis a calibration method proposed by Goicoechea and Olivieri (HLA\GO) [8]; adsorptive voltammetry; differential pulse polarography [9,10]; capillary electrophoresis [11,12]; high performance liquid chromatography (HPLC) and ion chromatography.

Table 1
Examples of chromatographic conditions for TLC technique.

Matrix	Sample preparation	Stationary phase	Mobile phase	References position
0.1% aqueous solution of dyes standards	–	Kieselgel G (250 um) previously activated at 105 °C (2 h), cellulose CC4l previously dried overnight	Isopropyl alcohol/concentrated aqueous NH3 (4:1) isobutyl alcohol/water/ethanol/concentrated aqueous NH_3 (25:25:50:2)	[13]
Ethanolic solution of dyes standards	–	Kieselgel G (250 um) heated at 100 °C for 30 min, purified with ethanol and heated again before use	Ethanol/butanol/water (9:2:1)	[14]
Dyes standards	–	Glass plates coated with magnesia (250 um) activated for 1 h at 130 °C	15% sodium citrate/methanol (4:1)	[15]
Indian country liquors	Sample evaporated to dryness, residue dissolved in 40% ethanol.	KieselgelG (250 um)	Butanol/anhydrous acetic acid/ethanol/water (20:4:1:10)	[16]
Soft drinks, juices, Jello®	Acetic acid solutions of the samples boiled with white wool (first purified by boiling in dilute NaOH, then in water), washed the wool with cold water, then stripped the dye from it by boiling the wool with dilute ammonia. Extract evaporated to near dryness, then chromatographed.	Kieselgel G (250 um)	Butanol/ethanol/water/NH_4OH (50:25:25:10)	[17]
Gelatin- containing sweets	Sweets dissolved in warm pH 4,0 phosphate buffer, shook solution with polyamide powder, centrifuged the mixture, then removed the supernatant liquid. Polyamide powder washed by shaking with hot water, then centrifuged the mixture and removed the water layer. Extracted dyes adsorbed on the polyamide by shaking with methanol–aqueous NH_3 (19:1). Evaporated the extract to dryness, dissolved the residue in phosphate buffer pH 5,5. Then extracted colorants into Tri-n-octylamine in $CHCl_3$.	Cellulose plate	Ethyl acetate/propanol/ammonia/water (35:35:20:20)	[18]
Mustard and related products	Samples were treated with NH_3, then dyes were extracted with light petroleum and cleaned up by passing the extracts through a column of polyamide.	Cellulose plate	Ethanol/butanol/pyridine/water (1:7:6:6)	[19]
Drinks, solid foods	Acidify drinks applied to a C_{18} Sep-Pak cartridge then eluted color with ethanol, made alkaline with aqueous NH3. Foods macerated with ethanol or 50% acetone made alkaline with $Na_2B_4O_7$ solution and Celite 545, filtered, evaporated solvent, acidified residue with HCl and added it to a Sep-Pak as above.	Kieselgel 60 F_{254}	Ammonia/isopropanol (1:3), propanol/water/acetic acid (3:1:1), (propan-2-ol/ethanol/water/ammonium acetate (12:6:2:1), 2-methylopropanol/water/ethanol (3:2:2)	[20]
Aqueous solution of dyes standards	–	DC Plastikfolien Kieselgel 60[1]	Propanol/butyl acetate/water/pyridine (25:15:10:5)	[39]
Flavoured sugar, jelly, sugar candy	Sample solutions were prepared in 70% ethanol.	Silicagel 60	Isopropanol/amonnia/water (10:1:1)	[44]

Sample preparing is also very important problem in analysis of food dyes. Extracting them from different kinds of matrices is not an easy task. Substances contained in food samples can make colors determination impossible. That is why pretreatment stage is necessary for receiving satisfactory results. In this article chromatographic techniques and methods of sample preparing has been described.

2. Sample preparation

First stage of SFD analysis is extracting them from food sample, which sometimes can be difficult. Everything depends on the kind of matrices and substances which it contains. Pretreatment method is also strictly connected with analytical technique that will be using to determinate the food dyes. In many cases this stage is more complicated then instrumental analysis itself.

For TLC analysis, extracts must be purified from sugars, fats and other substances that can make dyes separation impossible. The most effective method is boiling acetic acid solutions of the samples with white wool. Then the wool is washed with water to remove impurities. The dyes are stripping from fabric by boiling with dilute ammonia. Next evaporated to near dryness extract is chromatographed [17]. In publications many modification of this method can be found, for instance replacing the wool with polyamide fiber or powder [18]. The last one may be use as a column filling [19]. That kind of pretreatment is using for candies, jams and greasy foods. Juices or alcoholic beverages in most cases do not need that complicated methods for extracting SFD, especially when determinate on HPLC. Dyes can be extracted from food with water, ethanol or methanol. Extracts usually are filtering through 0.45 μm filter [32,33] or centrifuging [38]. If analyzed beverage is carbonated it need to be degassed by ultrasonication [35] or heated to boiling.

Sample preparation is fundamental stage of analysis. It has large influence on interpretation of results. For instance in TLC technique partial removal of sugars or fats causes the blurring of spots. That is why careful realization of this stage of analysis allows to save time, it prevents of doing again the same analysis.

3. Thin layer chromatography (TLC)

The easiest chromatographic technique is thin layer chromatography (TLC), because it not needs expensive, complicated apparatus. The only one difficulty is choosing appropriate mobile phase and stationary phase, on which dyes are applied. In appropriate conditions it is possible to separate mixture few dyes and identify them as a result of comparison: migration coefficient R_f, spots shape and its color with standards spots.

Examples of chromatographic conditions (eluent and stationary phase) which have been used to qualitative analysis of dyes are listed in Table 1.

Organic solvents are the most popular in chromatographic techniques. Unfortunately usually they have intensive disagreeable smell and cancerogenic activity. To replace them water-methanol solution of β-cyclodextrine was proposed as mobile phase and polyamide sorbent as stationary phase. This chromatographic system assured satisfactory separation of following dyes: Eosin, Erythrosine and Rhodamine 6G [21].

Derivative of thin layer chromatography is high performance thin-layer chromatography (HPTLC). This method based on utilization of appropriate plates, which ensures better separation of analyze compounds and gives satisfactory result on shorter developing distance. The TLC and HPTLC differ with a kind of adsorbent. In first technique the size of stationary phase particles is 4–25 μm, while in second about 4–9 μm. This way of analysis had been used to assay synthetic dyes in alcoholic beverages. Separation was done on Whatman LHP-K, Analtech HETLC and Analtech HERPS using following mobile phases: butanol/2-butanol/actonitrile/tatrahydrofuran/ethylo-methylo ketone/NaCl 0.5% water solution/ammonia in ratio of 10:10:25:15:20:18:2 or propanol/actonitrile/tatrahydrofuran/ethylo-methylo ketone/ethyl acetate/NaCl 0.5% water solution/ammonia in ratio of (20:15:25:10:10:18:2) [22]. As a stationary phase porous silica gel with 3-aminepropyl functional groups connected with the matrix was used. As an eluent mixture of isopropanol/diethyl ether/ammonia in ratio of 2:2:1 was used [23].

HPTLC technique ensures better separation of chromatographed substances, the spots are less blurry and more clear.

TLC method has many advantages. First of all it does not require laborious preparation of the sample. Slight amount of impurities does not have greater impact on analysis process. Then, this is a rapid and cheap method which enables simultaneous assay of several dozen samples and breaking examination when results are satisfactory [24].

This is the best way for qualitative determination of analyzed mixture, because in relatively short time good separation results can be obtain.

However quantitative determination brings more difficulty, which connects with getting out separated components from the stationary phase. For example it can be done by scratching spots and extracting dye with appropriate solvent and then measure the absorbance of the solution on the spectrophotometer. Nevertheless this is very laborious, the color intensity of extracted dye might be weak and does not guarantee high precision.

Much better results can be received by utilizing digital processing of images. Chromatograms are scanned on flatbed scanner and processed using appropriate software [23], for instance the Adobe Photoshop [42] or ColorDens [43]. The intensity of the spots is measured in the RGB color mode (red, green and blue color channels), length and width are determined using ruler in the instrument bar and finally calculated in arbitrary units by appropriate equation.

This is a simple, rapid and precise method for quantitative determination of SFD. The difference between determined and initial concentration are shown on an example of tartrazine, it amounts 0.7% [44]. Which is better then results obtained by using extraction method.

Quantitative determination of food dyes by TLC technique is much easier when use of digital processing of images. It allows to assay concentration of SFD rapidly and precisely without using complicated apparatus.

4. Traditional column chromatography

Next separation technique is traditional column chromatography. Glassy columns filled with various sorts of adsorbents (e.g. aluminium oxide, polyamide) are using in this method. Subsequently with the help of appropriate eluent particular ingredients of analyze mixture are leaching. In case of food dyes stationary phase can be polyamide powder, while mobile phase is mixture of: 70% aqueous solution of methanol/25% aqueous solution of ammonia (49:1) heated to 55 °C [25]. As an eluent mixture acetone/ammonia/water (40:1:9) [26] or ammonia/methanol/water (5:15:80) can be used [27]. In order to remove of natural alkaline dyes, which are also adsorbing on polyamide carboxymethylcellulose can be used [28].

Currently this method is used very rarely with regard for long analysis time, which can last even a few hours. Additionally it does not ensure high separation of assaying components and it is eluent consuming.

Table 2
Examples of chromatographic systems for HPLC technique.

Column	Mobile phase	Flow rate (ml/min)/time of analysis (min)	Detector	Ref.
C_{18} (25 cm–4.6 mm, 5 μm)	(A) Tetrabutylammonium dihydrogen phosphate in Na_2HPO_3 (B) A/methanol (1:4) (gradient elution 45–100%A)	1/35	UV-DAD	[29]
Kromasil C_{18} (25 cm–4.6 mm, 5 μm) (Fig. 1)	(A) 10 mM tetrabutylammonium dihydrogen phosphate buffer (pH 4.2) (B) Acetonitrile (isocratic elution 45:55%)	1/25	Spectroflow	[30]
Kromasil C_{18} (25 cm–4.6 mm, 5 μm)	(A) Acetonitrile (B) 10 mM phosphate buffer (pH 4.2) (isocratic elution 20:80%)		575	
Tracer Analitica ODS (15 cm–4 mm, 5 μm)	(A) Methanol (B) Ammonium acetate 40 mM (pH 5), (gradient elution 10–75% A)	1/20	UV–vis (Uvicon 923)	[31]
C_{18} (25 cm–4.6 mm, 5 μm) (Fig. 2)	(A) Acetonitrile:methanol (20:80) (B) 1% Ammonium acetate buffer (pH 7.5), (gradient elution 100–47.5% A)	1.5/31	UV-DAD	[32]
ODS Zorbax (25 cm–4.6 mm, 5 μm)	I. (A) Methanol/(B) ammonium acetate (0.08 mol/L) II. (A) Methanol/(B) EDTA* (5×10^{-3} mol/L) + sodium acetate (3×10^{-2} mol/L), (pH 3.5) (I and II 45:55% isocratic elution)	1/5	UV-DAD	[33]
C_{18} (25 cm–4.6 mm, 5 μm)	0.25% Tryton X-100 water solution + phosphate buffer (pH 7) (50 mM/L)	1/8	UV-DAD	[34]
Zorbax Eclipse XDB-C_{18} Rapid resolution (50–4.6 mm, 1.8 μm)	(A) 0.1 mol/l water solution ammonium acetate (pH 6.7) (B) Acetonitrile/methanol (50:50 v/v)	1.5/19	UV-DAD	[35]
Cosmosil C_{18} (125–2 mm, 5 μm)	(A) Triethylamine + acetic acid (pH 6.2) (B) Methanol (gradient elution 95–30% A – 35 min, 30–95% – 5 min)	0.2/40	UV-DAD, ES-MS	[38]
C_{18} (25 cm–4.6 mm, 5 μm)	(A) 0.02 M ammonium acetate (B) Methanol (gradient elution – 20–100–20% B)	1/35	UV-DAD	[40]
Lichrospher 100 RP-18 (250–4 mm, 5 μm)	(A) Methanol (B) Triethylamine 5.00 mM and acetic acid 5.00 mM aqueous solution (pH 6.5), (45/55 (v/v)	0.3/19	UV-DAD	[41]
BDSHypersilC_{18} (250–4.6 mm, 5 μm)	(A) Methanol (B) Tetrabutyl ammonium hydrogenosulfate (0.005 M, pH 3.5) (gradient 25%, – 100% methanol)	0.8/16	UV-DAD	[45]
ODS-2 spherisorb phase Separations (250–4.6 mm, 5 μm)	(A) Water (B) Acetonitryl 5 mM octylamine (pH 4.6) (gradient elution – 70:30 v/v A:B)	1/30	UV–vis	[46]

*Sodium salt of ethylenediaminetetraacetic acid.

5. High performance liquid chromatography (HPLC)

Other method used for separation, qualitative and quantitative determination of synthetic food dyes is high performance liquid chromatography. This technique ensures separation of any mixtures to component substances whereas appropriate detector allow to identification and quantitative determination of them. Examining substances also can be identified by any other detector by comparison with their standard. The basis of separation is differences of affinity components to two phases, stationary phase and mobile phase. Dyes have different adsorption affinity to stationary phase. That appears from differences of their mass, structural space and presence of functional groups in each dye's molecule.

The most popular kind of HPLC technique is reversed phase high performance liquid chromatography (RP HPLC) and ion-pair high performance liquid chromatography (HPLC IP).

In reversed phase system, stationary phase is slightly polar or non-polar, while mobile phase has stronger polarity (e.g. tetrahydrofuran, acetonitrile, methanol, water) [24]. Application of the appropriate conditions allows analyzing most of the food dyes. Ionized samples must have possibility to form neutral molecules. The most important characteristics that must be taken into consideration during selection of analysis conditions are hydrophobic properties of assaying dyes and presence in theirs molecules acidic groups. Hydrophobicity of azodyes is larger then others. It is similar in case of dyes with naphthalene ring in comparison to dyes with benzene ring. In purpose to improvement of separation and shorten time of analysis inorganic electrolyte is added to mobile phase. That kind of modificator often is ammonium acetate buffer in optimal concentration above 0.1 mol/l. Larger concentration causes increasing of retention times. Probably the reason of this is "salting-out" effect. Testing substance precipitated on the surface of stationary phase. The limit of detectability amounts from about 2 μg/l for Tartrazine to 22 μg/l for Ponceau 4*R* [32].

HPLC IP consists in adding hydrophobic ionic substance to mobile phase. It could be quaternary ammonium cation (e.g. ammonium acetate buffer), alkilo- or arylsulfonium anion (e.g. $C_7H_{15}SO_3$). As a result of the reaction between sample and eluent neutral ionic pairs are formed and separated chromatographically in reversed phase system. Another way is preparing of sample which enables the conducting of analysis on ionic exchanger or modification of mobile phase which provides to obtainment of ion-exchanger [24].

In case of absence of ionic compound elution of many dyes (e.g. E102, E124, E132) from column occurs really fast, near dead volume. Addition of ionic substance significantly increases retention time of compounds containing acidic groups in their molecules. It ensures simultaneous separation of many dyes [30]. In this aim tetrabutylammonium phosphate (TBA) is used [28–30]. It promises the best separation of synthetic dyes in presence of natural dyes. It also extends usefulness time of chromatographic column. Ionic pairs create in mobile phase and retention is controlled by interaction with sorbent surface. When the concentration of TBA increases a part of dyes molecules, which occur in the form of ionic pairs also increases which provides to better separation. Significant role in determination of dyes by this method has pH. For column filled with silica gel optimal pH should be in the range of 4–6, what results from low hydrolytic stability of gel. Next important parameter is proportion of organic phase to buffer. In order to prevent overlapping of peaks it is necessary to increase concentration of organic solvent [30].

In most of liquid chromatography methods organic solvents are used. This substances negatively influences on environment and human health. That is why it is justifiable to use green methods. One of them is using a surfactant solution 4-(1,1,3,3-tetramethylbutyl)-phenyl-polyethylene glycol (Tryton X-100) as a mobile phase. This compound is changing the polarity of water and characteristic of a C_{18} column. In its presence column becomes more polar while charges of a dyes molecules are stabilized. Using these method three dyes had been analyzed: Brilliant Blue FCF, Sunset Yellow and Tartrazine. Optimal concentration of surfactant should be in the range of 0.25–1%. Too low concentration of Tryton X-100 makes correct preparation of a column impossible, while too high concentration causes inaccurate separation and quantitative determination of each mixture compounds. Essential role plays here pH as well. It should be equal to 7. Below of this value disappearance of peaks has been observed. The addition of the phosphate buffer was necessary. The charges of buffer components balance the charges of dyes molecules. This method allows getting satisfactory result in 8 min using 15 mg surfactant and 38.8 mg buffer. This is cheap and fast way of analysis of dyes. However if the differences in concentration of separating substances are considerable it could be difficulties in its application [34].

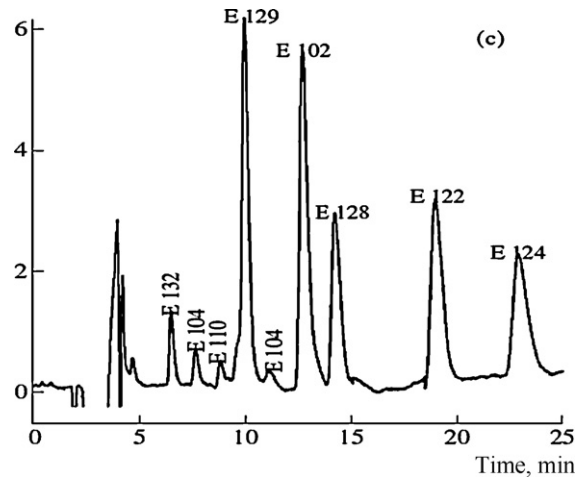

Fig. 1. Chromatogram of nine synthetic food dyes – the conditions of separation are listed in Table 2 [30].

Examples of chromatographic conditions for HPLC technique (eluent, stationary phase, flow rate and time of analysis) which have been used to determination of dyes are listed in Table 2. Figs. 1 and 2 are examples of chromatograms, which presents food dyes separation.

For analysis of the food dyes high performance ion chromatography (HPIC) is used. It consists in using of special column filed in resins with functional groups with constant charge bounded ions. In a direct surrounding of the core there are specified counterions, which ensure inertness of the system. Ions of the sample

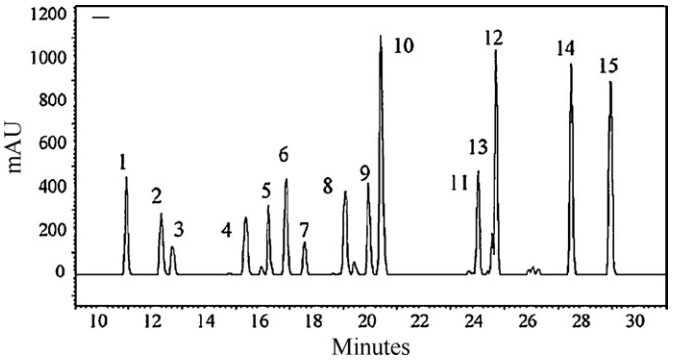

Fig. 2. Chromatogram of 13 food dyes, conditions of separation are listed in Table 2. (1) Tartrazine, (2) Amaranth, (3) Indigo Carmine, (4) Quinoline Yellow I, (5) Ponceau 4R, (6) Sunset Yellow, (7) Quinoline Yellow II, (8) Allura Red, (9) Red 2 G, (10) Green S, (11) Carmoisine, (12) Brilliant Blue, (13) Quinoline Yellow III, (14) Patent Blue, (15) Erythrozine [32].

Table 3
Chromatographic system for determination of dyes mixture by HPIC technique [37].

Time (min)	0.0	6.0	9.5	9.6	12.0	20.0	20.1	23.0	35.0	35.1
HCl (%)	10	10	10	2.5	2.5	2.5	10	10	10	10
Acetonitrile (%)	50	50	50	95	95	95	90	90	90	50
Water (%)	40	40	40	2.5	2.5	2.5	0	0	0	40
λ (nm)	625	430	430	480	480	480	480	525	525	625

are exchanging counter-ions and bonds with stationary phase for specific time. This time is dependent on ions affinity for core. On this ground the separation of the mixture can be done [36]. Theoretically HPIC should not be used for organic, multivalent, hydrophobic ions, because they are bound with stationary phase very strong result in a very long elution times. However using an anion exchange column with slight hydrophobic properties and strongly acidic eluent endures ionization, satisfactory separation can be obtained. It has been proved with eight dyes, among them: E102, E110, E123, E129, E132, and E133. Dione IonPac AS11 was used. It is stable in the range of pH value from 0 to 14. Mobile phase was mixture of 2 mol/l HCl/acetonitrile/water, gradient elution was applied, the chromatographic system is shown in Table 3. Hydrochloric acid was chosen for the sake of its better solubility in acetonitrile, but this last one guarantees better separation then methanol.

In the first succession dyes without azo-baond that is Brilliant blue and Indigo Carmine, then Tartrazine and monoazodyes were eluted. This sequence is connected with hydrophobic properties of the compounds. All assaying dyes had linear dependence between the concentrations and peak area. The detection limits were from 0.03 μg/ml for Brilliant blue to 2 μg/ml for Allura Red and Tartrazine.

This method is reliable and guarantees repeatability of results and the process preparation of the sample is not complicated [37].

6. Conclusions

Each of the described methods can be used to analyze synthetic food dyes successfully. It is necessary to take into consideration that none of them is ideal. To qualitative determination of dyes mixture TLC method is the best solution. It enables obtaining satisfactory results in short time. Quantitative determination in this case might be labour-consuming. For this kind of assays one of HPLC techniques will be better. Deciding for chromatography in reversed phase or ion pair we must be conscious that buffer negatively affects on chromatographic system.

In the future there will be a tendency to use more sophisticated apparatus. Already it can be adduce a few examples of publication about using in HPLC technique various kinds of detectors, like DAD-ESI-MS [38,41].

However using of expensive equipment connects with bearing high costs of amortization. Also the identification of dyes is more complicated then in TLC technique. Natural and synthetic dyes could have the same absorption maximum and similar R_f coefficient which can present a difficulties. TLC technique guaranties the correct interpretation of results of analysis because we take into the consideration a few elements: shape and color of spots, the R_f coefficient and light resistance (natural dyes expose to the light fades in the course of time). Additionally digital processing of images allowed to quantitative determination with high precision. TLC technique seems to be a little forgotten and underestimated method but in authors opinion it is worth to discover it anew.

Choose of analytical technique is also dependent to the method of sample preparation. For TLC and HPTLC chromatographed sample must be carefully purified, that assures satisfactory separation. For that purpose the most appropriate method is boiling acetic acid solutions of the samples with white wool and then stripping dyes from it by boiling with dilute ammonia. It allows to remove substances which may be a reason of problems with separation chromatographed dyes. That kind of sample pretreatment is also useful for other chromatographic techniques.

Environment

ABSTRACT

Organic pollutants include a very wide variety of chemical compounds with different structures, properties, functions and origins, which may produce diverse damages to the ecosystem and the human beings. This review presents the recent progress on the use of chemometrics to evaluate the occurrence of these substances in the environment. The main topics addressed are: (a) the problems related to the interpretation of the analytical measurements used in the determination of organic pollutants (*quantitative analytical determinations section*), (b) the profiling of the related environmental pollution sources through their compositional, geographical and temporal distribution patterns (*environmental exploratory studies section*) and (c) the prediction of the toxicological activity of these substances through models based on the use of structural or physical/chemical descriptors (*toxicity studies section*). Each section includes selected works related to pesticides, polycyclic aromatic hydrocarbons and other organic pollutants.

1. Introduction

In recent years, there has been a growing concern about the increasing environmental occurrence of persistent organic pollutants (POPs) [including polycyclic aromatic hydrocarbons (PAHs) and organochlorine pesticides] and emerging organic pollutants [e.g., brominated flame retardants (BFRs)] and the proven toxic potential of these compounds on human health and wildlife [1]. The existence of these harmful substances has disrupted the natural cycles and processes and, therefore, there is a need to obtain better and deeper knowledge on the organic pollutant discharge and the related environmental impact.

The increasing use of Chemometrics in environmental studies over the last two decades responds to the intensive research devoted to test and prove the power of data processing techniques in this field and to the availability of appropriate software. Three main areas of interest can be distinguished in chemometric environmental studies: quantitative chemical analysis, monitoring for environmental quality assessment and modeling and prediction of toxicological effects.

Difficulties on the quantitative chemical analysis of organic pollutants in environmental samples are linked to both the inherent complexity of these natural matrices and the low analyte levels to be quantified. The determination of organic pollutants in environmental samples is largely carried out using chromatographic techniques combined with specific detection schemes [2,3]. However, these methodologies are relatively expensive, time consuming and often require laborious sample treatment before analysis. Other authors have also proposed alternative strategies based on phosphorimetric and fluorimetric detection [4], which are suitable for the analysis of very low concentrations. Nevertheless, the spectroscopic measurement lacks the required selectivity, particularly when similar chemical compounds must be analyzed in complex samples. The lack of selectivity or the presence of interfering species linked to natural samples calls for the application of chemometric methods based on multivariate calibration techniques, in order to overcome these limitations and to complement these analytical methodologies.

Multivariate calibration methods focus on the establishment and application of mathematical models that relate multivariate instrumental signals with analyte concentrations or sample properties [5]. While in univariate calibration a single numerical value (scalar, zero-order data) per sample is recorded and analyzed, multivariate calibration works with increasingly complex data arrays per sample and allows analytical quantitative estimations in multicomponent systems lacking selectivity [6]. In first-order calibration methods, the response analyzed is a vector of numerical values (first-order data, e.g., spectra, voltammograms, time profiles) per each sample. The use of this information provides the so-called first-order advantage, i.e., the possibility to quantify an analyte in the presence of interferences, as long as the interfering compounds are present in the calibration samples during the establishment of the calibration model [7]. In second-order calibration methods, the instrumental response analyzed is a data matrix per sample (second-order data, e.g., an HPLC-DAD chromatogram or an excitation–emission fluorescence measurement). The so-called second-order advantage is achieved, which implies that the analyte contribution can be appropriately modelled, quantitatively estimated and resolved in the presence of unknown interferences, absent in the calibration samples [7]. Higher-order data sets and their related calibration strategies (higher-order tensors and higher-order calibration methods) are possible and improve resolution power and quantitative estimations.

The possibility to use very diverse instrumental responses to predict analyte concentrations explains why multivariate calibration methods have become very powerful analytical tools. Although the first publications in this research area appeared about 30 years ago, a significant growth of applications of second- and third-order instrumental data to different areas of analytical chemistry has taken place in the last decade [8]. Second- and third-order multivariate calibration algorithms and applications have been reviewed and discussed [9]. Apart from second-order calibration algorithms, such as multivariate curve resolution-alternating least-squares (MCR-ALS) [10,11] and parallel factor analysis (PARAFAC) [12], other techniques have been proposed based on flexible data modelling, such as partial least-squares (PLS) with residual bilinearization (RBL), as recently discussed [8] and applied to environmental analysis [13–16].

Environmental monitoring studies result in huge amounts of physical parameters and chemical concentrations, collected in different geographical sites, time periods and/or different environmental compartments (i.e., air, water, sediments and biota). In order to reveal relevant patterns and sources of variation in these large environmental data sets, chemometric approaches based on statistical multivariate data analysis and factor analysis have been proposed in the last decades. The basic assumption of these methods is that the variation of each of the parameters or chemical concentrations measured in a particular sample can be mostly explained by a reduced number of different contributions coming from independent environmental sources [17]. In this way, point and diffuse pollution sources can be compositionally characterized and attributed to a particular origin (natural, anthropogenic, industrial, agricultural) and their relative apportionment can help to reveal geographical, temporal or compartmental patterns [18]. In this context, the application of chemometrics to environmental pollution research is often referred to as source apportionment, receptor modelling and/or mixture analysis discipline [19,20].

Principal component analysis (PCA) is a multivariate statistical method frequently used in exploratory data analysis [21]. This method extracts the main orthogonal contributions (principal components) which explain most of the variance of the data matrix. The abstract principal components may be rotated to increase interpretability. In some approaches, the rotated profiles can be quantitatively interpreted as possible sources, such as in absolute principal component analysis [22]. Sometimes, the interpretability of PCA is enhanced by the so-called varimax rotation [23], a change of coordinates that maximizes the sum of the variance of the loading vectors. However, these methods suffer from several drawbacks: individual factors (components) can be seldom attributed to a single specific source, fully satisfactory rotation techniques have not been found [24] and most of them cannot properly handle missing values or data below the detection limit, often encountered in environmental measurements. To solve the limitations of PCA-based methods, several factor analysis-based approaches have been developed over the past decade, such as UNMIX [25], positive matrix factorization (PMF) [26] and, more recently, MCR-ALS [10,11]. Both UNMIX and PMF have been adopted by the US Environmental Protection Agency (EPA) as robust methods (i.e., accurate for different operating conditions) for air quality management and can be freely downloaded from its web page (http://www.epa.gov). MCR-ALS was initially developed to investigate evolving processes of multicomponent systems by means of spectroscopic methods. However, its application was satisfactorily introduced in the study of environmental pollution data from sediment [27], water [28] and, more recently, for air quality management [29].

Assessment of environmental pollution in different geographical sampling sites requires consequent and constant monitoring of carefully selected parameters as a function of time, compartment or other environmental variables of interest. This usually results in data with multi-way structure, i.e., data cubes or hypercubes, which contain in each of the directions the conditions identify-

Table 1
Classification of the different chemometric methods employed in the works reviewed in this paper, according to the different data structures and goals of the study.[a].

First-order calibration
- Artificial neural networks (ANNs)
  - (i) Back-propagation neural network (BNN)
  - (ii) Radial basis function-artificial neural networks (RBF-ANNs)
  - (iii) Wavelet neural networks (WNNs)
- Multiple linear regression (MLR)
- Partial least-squares
  - (i) Partial least-squares (PLS)
  - (ii) Partial least-squares-1 (PLS-1)
- Principal component regression (PCR)
- Projection pursuit regression (PPR)

Second- and higher-order calibration and resolution methods
- Absolute principal component analysis (APCA)
- Bilinear least-squares (BLLS)
- Factor analysis (FA)
- Generalized rank annihilation method (GRAM)
- Multivariate curve resolution-alternating least-squares (MCR-ALS)
- Parallel factor analysis
  - (i) Parallel factor analysis (PARAFAC)
  - (ii) Weighted parallel factor analysis (WPARAFAC)
- Partial least-squares
  - (i) N-way partial least-squares (N-PLS)
  - (ii) N-way partial least-squares with residual bilinearization (N-PLS/RBL)
  - (iii) Unfolded partial least-squares (U-PLS)
  - (iv) Unfolded partial least-squares with residual bilinearization (U-PLS/RBL)
- Positive matrix factorization (PMF)
- Trilinear decomposition (TLD)
- Unfolded principal component analysis (U-PCA)
- UNMIX

Unsupervised pattern recognition methods
- Artificial neural networks (ANN)
- Chemical mass balance (CMB)
- Cluster analysis (CA)
  - (i) Fuzzy
  - (ii) Hierachical (HCA)
- Concentration weighted trajectory (CWT)
- Multi-dimensional scaling (MDS)
- Principal component analysis (PCA)
- Polytopic vector analysis (PVA)
- Potential source contribution function (PSCF)
- Residence time weighted concentration (RTWC)
  - (i) Radial basis function-artificial neural networks (RBF-ANNs)
  - (ii) Self-organizing maps (SOM)
- Support vector machines (SVM)

Supervised pattern recognition methods
- Artificial neural networks (ANN)
  - (i) Adaptive fuzzy partitions (AFP)
  - (ii) Adaptive neural network-based fuzzy inference system (ANFIS)
  - (iii) Back-propagation neural network (BNN)
  - (iv) Counterpropagation artificial neural network (CP-ANN)
  - (v) Multilayer perceptron (MLP)
- Classification and regression tree (CART)
- Discriminant analysis (DA)
  - (i) Linear discriminant analysis (LDA)
  - (ii) Non-linear discriminant analysis (NLDA)
  - (iii) Partial least-squares discriminant analysis (PLS-DA)
  - (iv) Quadratic discriminant analysis (QDA)
  - (v) Regularized discriminant analysis (RDA)
  - (vi) Sparse linear discriminant analysis (SLDA)
- K-nearest neighbours (KNN)
- Nearest mean classifier (NMC)
- Soft independent modelling of class analogy (SIMCA)

[a] The theory behind the chemometric methods mentioned in this table can be found in books [5,43], reviews [8,9], and in the references cited in the presently reviewed application works.

Table 2
Analytical determinations.

Analyte	Multivariate method[a]	Sample and technique	References
Pesticides			
Captan, captafol, folpet	PLS, PCR, ANNs	River water by DC and DPP	[44]
Carbaryl, phoxim	PLS, PCR, RBF-ANNs	Tap, lake and pond water samples by kinetic/UV–visible	[45]
Chlordecone	PLS	Soil by NIRS	[46]
Carbaryl	PLS, PCR, BNN	Vegetables and water samples	[47]
Oxamyl, methomyl, resorcinol phenol, 4-nitrophenol, 2,4-dinitrophenol	GRAM, PARAFAC, MCR-ALS	River and waste water by HPLC-DAD	[48]
Methomyl, deethylsimazine, deethylatrazine, carbendazim, carbofuran, simazine, atrazine, alachlor, chlorpyrifos-oxon, terbutryn, chlorfenvinphos, pirimiphos methyl, chlorpyrifos	MCR-ALS	Wastewater and sediment by HPLC-DAD	[49]
Methomyl, deethylsimazine, deethylatrazine, carbendazim, carbofuran, simazine, atrazine, alachlor, chlorpyrifos-oxon, terbutryn, chlorfenvinphos, pirimiphos methyl, chlorpyrifos	MCR-ALS	Wastewater and sediment by HPLC-MS	[50]
Alachlor, atrazine, carbendazim, carbofuran, chlorfenvinphos, chlorpyrifos, chlorpyrifos-oxon, deethylatrazine, deethylsimazine, methomyl, pirimiphos methyl, simazine, terbutryn	MCR-ALS	Wastewater and sediments by HPLC-DAD-MS	[51]
Alachlor, atrazine, chlorfenvinphos, pirimiphos methyl, terbutryn	MCR-ALS and calibration methods	Mussels by HPLC-MS in scan and SIM mode	[52]
Bifenthrin, tetramethrin	MCR-ALS, PARAFAC	Synthetic samples by GC-MS	[53]
Metsulfuron methyl and hydrolysis products	MCR-ALS	Synthetic samples by kinetic/NMR	[54]
Triphenyltin	MCR-ALS	Sea water by EEFMs	[55]
Carbendazim, fuberidazole, thiabendazole	PARAFAC	Synthetic samples by EEFMs	[56]
Carbendazim, fuberidazole, thiabendazole	GRAM, TLD	Water by EEFMs	[57]
Carbendazim, thiabendazole	PLS/RBL, PARAFAC	Water by EEFMs in solid-phase	[13]
Fenvalerate, lufenuron, deltamethrin diflubenzuron	Three- and four-way PARAFAC	Synthetic samples by PI-EEKF	[58]
Carbaryl	PARAFAC	Water effluents by EEFMs	[59]
Fenitrothion, fenitrooxon 3-methyl-4-nitrophenol	PARAFAC, U-PLS, N-PLS, U-PLS/RBL, N-PLS/RBL	River water by Ad-SSWV	[60]
Polycyclic aromatic hydrocarbons			
Benzo[*a*]pyrene, fluoranthene, benzo[*k*]fluoranthene, benzo[*ghi*]perylene, benzo[*b*]fluoranthene, indeno[1,2,3-*cd*]pyrene	PLS	Artificial drinking water by fluorescence	[61]
Sixteen EPA-regulated PAHs	PLS	Submerged freshwater sediments by LIF system and PFE-GC-MS	[62]
PAHs	PARAFAC	Synthetic samples by EEFMs	[63]
Benz[*a*]anthracene, benzo[*k*]fluoranthene, dibenz[*a,h*]anthracene,	Three- and four-way PARAFAC	Synthetic samples by photocatalytic degradation EEFMs	[64]
PAHs	GRAM	Marine sediments samples by HPLC-DAD	[65]
Anthracene, pyrene, fluoranthene, 1-methylpyrene, 2,3-benzofluorene	TLD	Light gas oil sample by GC-MS	[66]
Dibenz[*a,h*]anthracene, benz[*a*]anthracene, benz[*a*]pyrene, benz[*k*]fluorantene	PARAFAC, MCR-ALS	Aqueous medium by photodegradation EEFMs	[67]
Pyrene, benzo[*a*]pyrene	PARAFAC, PLS/RBL	Artificial and real water samples by RT-EEPMs	[15]
Benzo[*a*]pyrene, dibenz[*a,h*]anthracene	PARAFAC, PLS/RBL	Artificial and real water samples by EEFMs	[16]
Ten EPA-regulated PAHs	MCR-ALS, PARAFAC2	Artificial and real water samples by HPLC-FSFS	[68]
Other organic pollutants			
Different organic compounds	PLS	Ambient aerosols by ATR-FTIR	[69]
Phenol, catechol, 4-acetamidophenol	WNNs	Synthetic water samples by voltammetry	[70]
Methoxy-2-propyl acetate, chlorobenzene	TLD and PARAFAC	Environmental sample containing fuel components, pesticides and natural products by GC × GC/TOFMS	[71]
2,3,7,8-Tetrachloro dibenzo-*p*-dioxin	Four-way PARAFAC	Water samples by Shpol'skii spectroscopy	[72]
Tetracycline, chlortetracycline, oxytetracycline	N-PLS, PARAFAC, BLLS	Water samples using photochemical-induced EEFMs	[73]
Antibiotics	MCR-ALS, U-PLS/RBL	Effluent wastewater by HPLC-DAD	[74]
Pyridine	N-PLS, PARAFAC	River water and field wastewater samples by pH-modulated UV data	[75]
1- and 2-Naphthylamines	U-PLS, RBL, PLS-1, N-PLS	Drinking waters by MIP-fluorescence optosensing system	[76]
Decabromo diphenyl ether	HS-MCR	Elucidation of the mechanism, resolution of kinetic profiles and pure spectra and evaluation of the rate constants	[77]

[a] See acronyms in Table 1. Ad-SSWV, adsorptive stripping square-wave voltammetry; ATR-FTIR, attenuated total reflectance-Fourier transform infrared; DAD, diode-array detector; DC, direct current; DPP, differential pulse polarography, DPV, differential pulse voltammetry; EEFMs, excitation–emission fluorescence matrices; FSFS, fast scanning fluorescence spectroscopy; GC, gas chromatography; HPLC, high performance liquid chromatography; LIF, laser-induced fluorescence; MIP, molecularly imprinted polymer; MS, mass spectroscopy; NIRS, near infrared spectroscopy; NMR, nuclear magnetic resonance; PFE-GC-MS, pressurized fluid extraction-gas chromatography-mass spectroscopy; PI-EEKF, photochemically induced excitation–emission kinetic fluorescence; RT-EEPMs, room-temperature excitation–emission phosphorescence matrices; SIM, selected ion monitoring; TOFMS time-of-flight mass spectrometry; UV–visible, ultraviolet–visible spectrophotometry.

ing the measurement (time, site, compartment, etc.). In certain cases, these data have been analyzed by unfolding them in large data tables, 'matricizing' them and employing bilinear models [28]. Alternatively, methods based on trilinear and multilinear models have been proposed for three- and multi-way data arrangements in the investigation of environmental problems, such as PARAFAC [12], TUCKER-3 [30] and multilinear engine (ME) [31]. More details and comparison of these methods can be found in the literature [29,32,33]. The use of multivariate factor analysis methods like those mentioned above has also been discussed in different books [5,18,20].

Organic pollutants often produce toxic effects. There are several in vivo and in vitro methods to test the toxicity of chemicals, which can provide reliable quantitative and qualitative indicators about the interaction of a given compound with a biological system. However, the direct estimation of the toxicological activity for a certain compound is expensive and time consuming and this explains the lack of available indicators for many compounds. Thus, the development of quantitative structure–activity relationships (QSAR) data analysis tools that allow for an indirect toxicity evaluation is of great importance for the purpose of pollutant risk assessment. QSAR models describe a mathematical relationship between the structural properties of a set of chemicals and the particular activity (toxicological or other), associated with them.

Several chemometric methods have been applied to develop valid and reliable QSAR models [34]. In a first phase, efficient methods are employed to select the most relevant parameters (descriptors) associated with the ranges of toxicity levels. Several selection strategies, based on methods, such as stepwise regression [35], PCA and genetic algorithms (GA) [36] have been proposed in the literature. The latter are probably the most powerful tools, since they are able to thoroughly explore the molecular descriptor hyperspace. The next step consists of using a chemometric method to develop robust predictive models. QSAR modelling techniques are based on: (1) linear regression, such as multiple linear regression (MLR) and PLS, (2) non-linear techniques, such as artificial neural networks (ANN) [37] and support vector machines (SVM) [37] and (3) classification methods [38]. In the present review, emphasis is directed to recently published QSAR models developed using chemometric methods beyond classical MLR.

Table 1 summarizes the different chemometric methods employed in the reviewed works, according to the different data structures and goals of the study. Detailed explanations about these methods can be found in previous works [39,40]. Data preprocessing techniques are not reviewed for brevity, in spite of their importance in the quality and interpretability of the results obtained.

The present paper reviews chemometric applications for the study of organic pollutants in the environment since 2000. Following the above discussion, we have organized the material in three sections: (1) quantitative analytical determinations, (2) environmental exploratory studies and (3) toxicity studies. In each section, rather than performing an exhaustive review, we critically selected some representative works, with the main purpose of showing the evolution of chemometric strategies and being representative of the different kinds of studied data sets. Attention is focused on families of compounds, such as pesticides, PAHs and other organic pollutants. Pesticides heavily influence water and soil pollution and they are defined as chemicals used to repel or destroy pests of any sort [41]. They include fungicides, insecticides and herbicides. PAHs, on the other hand, arise from the incomplete combustion of hydrocarbons. They consist of fused aromatic rings with no heteroatoms or substituents and they are toxic to aquatic life and suspected to be human carcinogens [42]. Other organic compounds can disperse in various environmental media, due their water solubility, vapour pressure or partition coefficient between organic matter (in soil or sediment) and water, inducing potential hazardous problems in the ecosystem and in humans.

2. Quantitative analytical determinations

2.1. Pesticides

A summary of selected works devoted to analytical determination of pesticides is shown in Table 2 [44–77]. Most determinations were carried out in water samples because the main pathway of ecological impact is water contamination by pesticide runoff, which may easily reach both surface and ground waters. Despite the known analytical advantages of higher-order methods, many of the pesticide systems were analyzed using first-order algorithms [44–47] (Table 2). However, there are some examples of use of second-order calibration methods, such as MCR-ALS or PARAFAC to process high performance liquid chromatography (HPLC) or molecular fluorescence data.

In [48], three second-order calibration algorithms, GRAM, PARAFAC and MCR-ALS, were compared for the determination of mixtures of pesticides and phenolic compounds at trace levels in river and wastewater samples. The authors showed that techniques that do not require the fulfilment of trilinearity, such as MCR-ALS, provide better results than methods based on trilinear models, such as PARAFAC or GRAM, when drift and baseline problems occur. This is due to the fact that MCR-ALS only requires that one of the two measurement dimensions (usually the spectral one) matches between the different data matrices and, therefore, variations among drifts and baselines coming from different runs are allowed.

MCR-ALS was used to resolve and quantify 13 different biocides in sediment and wastewater samples by HPLC coupled to diode-array detection (HPLC-DAD) [49] and by HPLC coupled to mass spectrometry detection (HPLC-MS) [50]. Despite the very strong coelutions and matrix interferences, the analyzed biocides were properly resolved and their quantitation could be performed satisfactorily by external calibration. The difficulties encountered in practice for optimal reproducible quantitative determinations by HPLC-MS come from the combination of complex environmental matrices, embedded peaks, strong coelutions and ion suppression effects. Interestingly, the fusion of DAD and MS detector signals improved the results and provided more reliable estimations compared to those obtained using only one of the two detection systems, as was demonstrated in [51].

To cope with sensitivity changes and matrix effects encountered in the HPLC-MS analysis of complex natural environmental samples, as those mentioned in [52], different analytical calibration approaches, such as external calibration, standard addition and the use of an internal standard, were evaluated for the quantification of coeluting biocides in mussel samples. HPLC-MS data coming from the scan mode detection were processed using MCR-ALS [52]. The authors showed that the combination of the multivariate extension of standard addition and internal standard methods together with MCR-ALS was the best calibration strategy for the optimal analyte quantification. Similar quantitative results to those obtained by HPLC-MS in the selected ion monitoring (SIM) mode were achieved. Moreover, the scan mode MCR-ALS results provided analyte confirmation *via* its resolved pure mass spectrum, complete information about the whole chromatographic process and allowed for the simultaneous determination of multiple analytes in the same chromatographic run using the same experimental and instrumental conditions. An intermediate situation among the classical univariate SIM mode and the scan mode can be found in a work, where GC-MS data built with several SIM mode detection channels were

analyzed by PARAFAC and MCR-ALS to quantify two insecticides (bifenthrin and tetramethrin) in synthetic samples [53].

MCR-ALS was also applied in kinetic–spectroscopic studies of degradation or hydrolysis of pollutants to provide quantitative and qualitative information about these processes. The objective is then the identification of by-products and end products in the process and the postulation of the underlying reaction model with the related kinetic parameters. Along this line, Bezemer and Rutan have shown the applicability of MCR to resolve overlapped nuclear magnetic resonance signals using a kinetic reaction constraint in the determination of metsulfuron methyl and its hydrolysis products [54]. The use of the kinetic constraint applied during the iterations resulted in the direct estimation of the reaction rate constants. This avoids the need for subsequent fitting of the kinetic profiles, reducing the analysis time and complexity, with the possibility of modelling a particular process in the presence of interferences.

Excitation–emission fluorescence matrices (EEFMs) are the best examples of trilinear data sets and, therefore, all the available second-order methods are potentially applicable to them. However, phenomena such as Rayleigh and Raman scatterings and diffraction harmonics are not trilinear and should be avoided by selecting a suitable wavelength range or modelled with a specific algorithm, e.g., weighted PARAFAC (WPARAFAC) [9].

In [55], the application of MCR-ALS allowed the resolution and quantitative determination of triphenyltin in sea water samples using EEFM measurements and a single synthetic analyte standard. The method was successfully applied to the determination of the analyte at very low concentrations (part per trillion levels), with overall prediction errors around 12%. Ordinary PARAFAC, GRAM, MCR-ALS, trilinear decomposition (TLD) and the combination of PLS with RBL, all achieving the second-order advantage [9], were used to determine carbamate pesticides using fluorescence data [13,56,57]. In cases of trilinearity losses due to inner filter effects or sample-to-sample spectral variations (because analyte–background interactions may vary between samples), methods taking into account deviations from trilinearity (MCR-ALS or PLS/RBL) were preferable.

A problem which hinders a wider application of fluorescence spectroscopy in environmental monitoring is the intrinsic lack of selectivity in excitation and emission fluorescence measurements. Data sets obtained from kinetic experiments may help to increase the selectivity of spectroscopic determinations in the calibration models. Indeed, time-dependent measurements introduce an additional dimension to the classical EEFM three-way data sets (excitation × emission × sample), leading to four-way data sets (excitation × emission × sample × time), which allow for a potential increase in the predictive ability of the models. Booksh and co-workers [58] extended EEFM determinations to four non-fluorescent pesticides after their photochemical degradation to fluorescent species. Three-way PARAFAC was employed to resolve the pure fluorescent spectra of the overlapping photolysis products. The time profiles yielded a fourth dimension (four-way data) that led to an increase in sensitivity and selectivity. The four-way PARAFAC models were then used to predict original pesticide concentrations. An analogous four-way PARAFAC model with kinetic information was successfully applied for the determination of carbaryl in effluent samples in the presence of an uncalibrated fluorescent background [59].

The adaptation of three-way stripping square-wave voltammetry (Ad-SSWV) to a second-order calibration strategy is described in [60] for the simultaneous determination of fenitrothion and its metabolites in environmental samples. To obtain the three-way data set, the Ad-SSWV profiles recorded at different accumulation times on the hanging mercury electrode were used as the third mode of the calibration data. In this way, the sensitivity of the electroanalytical signals was enhanced and the selectivity was improved from the differences in shape in the kinetic species profiles originated by adsorption processes.

2.2. Polycyclic aromatic hydrocarbons

The main difficulties linked to the determination of PAHs in environmental samples (Table 2) arise from the complexity of the sample natural background and the low analyte concentrations to be detected. However, the combination of different analytical methods with multivariate calibration has allowed for the successful determination of these pollutants. The luminescent properties of PAHs are useful for their direct analysis at very low concentration levels and have been widely exploited for PAH determination. Usually, fluorimetric methods involve recording synchronous fluorescence scanning EEFMs data, which are afterwards treated with suitable chemometric tools.

As can be seen in Table 2, many PAHs have been determined by coupling EEFMs with PLS and PARAFAC. In [61], PAHs were analyzed in synthetic drinking water by synchronous fluorescence spectroscopy and PLS. The use of a Plackett–Burman (PB) experimental design for the creation of the sample calibration data set is described and compared with a collinear analogue. External validation shows that the sample collinear data set is inappropriate to quantify PAHs in real samples, whereas the PB sample calibration data set affords optimal results.

Grundl et al. described a method for real-time *in situ* characterization of PAHs in freshwater sediments [62]. A cone penetrometer-type apparatus was designed for probe penetration and a field-portable laser-induced fluorescence (LIF) system was used for *in situ* measurements, in which the output of a pulsed exciter laser was transmitted by an optical fiber to a sapphire window in the probe wall. Fluorescent emission was collected by a separate optical fiber for transmission to the spectrometer on deck. Four wavelengths were selected via optical delay lines and multiple-wavelength waveforms were created. These waveforms contain information on the fluorescence frequency, intensity and emission decay rate. Field testing was conducted at ten different sites in the Milwaukee Harbor. The core samples were analyzed by gas chromatography-mass spectrometry and a PLS model was created based on laboratory LIF measurements and pressurized fluid extraction gas chromatography-mass spectrometry (PFE-GC-MS) of the core samples. The N-PLS model was applied then to the *in situ* field test data and 13 of the 16 EPA-regulated PAHs were quantified with a relative overall error lower than 30% (the remaining three PAHs were present under the quantification level).

A field-portable single-exposure excitation–emission matrix fluorometer was used together with PARAFAC for sub-ppb PAH determinations in the presence of spectral interferences [63]. It was found that reducing eight-sample PAH calibration sets to two or three calibration standards significantly decreased the computation intensity, yet generating adequate predictions. It was also found that spectral resolution can be decreased to reach an optimal compromise between calibration accuracy and analysis speed, while minimizing instrumental requirements.

The application of photocatalytic degradation EEFMs in combination with PARAFAC has been proposed to determine benz[*a*]anthracene, benzo[*k*]fluoranthene and dibenz[*a,h*]anthracene. Three- and four-way PARAFAC analyses were employed to extract the fluorescent species spectra from overlapping EEFMs [64]. The additional time dimension increased the selectivity for each PAH determination.

In [65], PAHs in marine sediment samples were determined by a method based on solvent extraction followed by chromatographic separation with diode-array detection. Second-order calibration with GRAM was used for quantification because interfering substances coeluted with the compounds studied. For calibration, a

spiked sample was used instead of a standard solution to cope with the complexity of the samples and the presence of matrix effects. With this method, the compounds do not need to be chemically separated from the interferences and quantification can be carried out with only one spiked sample for calibration. The ability of the method to quantify the studied compounds was comparable to the results with those of a univariate standard addition calibration, with the additional advantage of avoiding the previous isolation of the analytes.

Three-component (anthracene, pyrene, 1-methylpyrene) and four-component (fluoranthene, anthracene, pyrene, 2,3-benzofluorene) synthetic mixtures were resolved by TLD of third-order tensors formed by EEFM data modulated by the concentration of the fluorescence quencher nitromethane [66]. The addition of a quencher to PAH mixtures selectively reduces the fluorescence intensity according to the Stern–Volmer equation. TLD allows the three-way array to be decomposed to provide unique solutions for the excitation spectrum, emission spectrum and quenching profile for each component. TLD was applied to a real sample from a chromatographic cut from the analysis of a light gas oil and the TLD extracted spectra and quenching constants suggested the presence of three classes of PAHs, consistent with data from an independent GC-MS analysis.

PARAFAC and MCR-ALS were used to process EEFMs in order to obtain semi-quantitative information related to the concentrations of dibenz[*a,h*]anthracene, benz[*a*]anthracene, benz[*a*]pyrene and benz[*k*]fluoranthene stemming from a photodegradation process in an aqueous medium [67]. The results obtained showed no statistical differences with data obtained using an HPLC reference methodology and suggested the EEFM approach as a time saving and more ecological alternative.

Room-temperature excitation–emission phosphorescence matrices combined with second-order chemometric calibration were applied to the determination of pyrene and benzo[*a*]pyrene in both synthetic and real water samples [15]. The study was used to test the applicability of PARAFAC and PLS/RBL. The superior capability of PLS/RBL to model the profiles of potential interferences from other PAHs was demonstrated.

The simultaneous ultra-trace determination of benzo[*a*]pyrene and dibenzo[*a,h*]anthracene in the presence of the remaining fourteen US-EPA PAHs at total concentrations ranging from 1400 and 14,000 ng L^{-1} was reported [16]. The approach consisted of measuring EEFMs on a nylon-membrane surface, combining the ability of this membrane to retain and concentrate PAHs on its surface, the sensitivity of molecular fluorescence and the selectivity of second-order chemometric algorithms [PARAFAC and unfolded PLS/RBL (U-PLS/RBL)]. The superiority of U-PLS/RBL to quantify benzo[*a*]pyrene and dibenzo[*a,h*]anthracene at concentrations below 10 ng L^{-1} in tap, underground, mineral and river water samples was demonstrated.

PARAFAC2 and MCR-ALS coupled to HPLC-fast scanning fluorescence spectroscopy were employed for the analysis of ten selected PAHs (six of them heavy PAHs) in the presence of real interferences [68]. Analytical recoveries from different types of water and olive oil samples were analysed and the superiority of MCR-ALS to successfully resolve these clear non-trilinear complex systems was demonstrated.

2.3. Other pollutants

Table 2 collects analytical works on other organic pollutants. Coury and Dillner developed an ATR-FTIR spectroscopic method to quantify functional groups of organic compounds and ammonium sulphate and ammonium nitrate in size-segregated ambient aerosol samples for particles smaller than 1 μm in diameter [69]. The ATR-FTIR instrumentation and multivariate calibration improved sensitivity and accuracy of quantification over more commonly used transmission FTIR and univariate calibration.

Multivariate calibration was used to quantify four carbonyl functional groups (aldehydes/ketones, carboxylic acids, esters/lactones and acid anhydrides), nine additional functional groups associated with organic molecules (methyl, methylene, aliphatic and aromatic CH, alkene, carbohydrate ether and hydroxyl, amino acids and amine groups) and two inorganic compounds, ammonium sulphate and ammonium nitrate. Comparison of the sum of the mass predicted by the ATR-FTIR technique and the gravimetric mass indicated that this method can quantify on average 91% of the aerosol mass. This method bridged the gap between individual compound identification with GC-MS and total organic carbon (TOC) obtained by thermal/optical methods and provided a nearly complete characterization of size-fractionated submicrometer aerosol mass. The method characterized the organic fraction in a potentially useful way for climate modelling, source region identification and physicochemical investigation of the properties of this large and complicated part of atmospheric aerosols.

Three phenolic compounds (phenol, catechol and 4-acetamidophenol) were simultaneously determined by voltammetric monitoring of their oxidation reaction at the surface of an epoxy-graphite transducer [70]. Because of strong signal overlapping, wavelet neural networks were used in the data treatment, in a nice combination of chemometrics and electrochemical sensors, already known as the electronic tongue concept.

The determination of methoxy-2-propyl acetate and chlorobenzene in an environmental sample containing fuel components, pesticides and natural products was carried out by GC × GC/TOFMS and TLD and PARAFAC [71]. It was found that PARAFAC initialized by TLD performed a better resolution than TLD. After resolution, mass spectral profiles were matched to library spectra for identification. Quantification by TLD-initialized PARAFAC using the standard addition method for one of the resolved analytes was proposed to avoid retention time alignment between sample and standard data sets.

The analysis of 2,3,7,8-tetrachloro dibenzo-*p*-dioxin in water samples was carried out using solid–liquid extraction laser-excited time-resolved Shpol'skii spectroscopy. The measurement obtained provided four-way data that were processed by PARAFAC [72]. The work reported the first application of PARAFAC to high-order instrumental data generated from Shpol'skii matrixes at liquid helium temperature. Moreover, the authors demonstrated the feasibility to directly determine parts per trillion of the target compound in heavily contaminated samples of unknown composition.

The antibiotics tetracycline, chlorotetracycline and oxytetracycline were determined in surface water samples using photochemical-induced EEFMs and three-way analysis [73]. Aqueous basic solutions of the antibiotics were irradiated with UV light and the generated photoproducts after solid-phase extraction were fluorometrically determined. According to the obtained results, while N-PLS and PARAFAC were not able to handle the extreme collinearities found, especially in the presence of uncalibrated interferences, bilinear least-squares (BLLS) rendered the best results. The authors presented BLLS as a promising technique for processing this kind of data, yielding analyte profiles and concentrations in samples where both a strong overlapping and background signal occur. In [74], U-PLS/RBL was applied for the first time to second-order LC-DAD data and compared with MCR-ALS for the simultaneous determination of eight tetracyclines in wastewaters. The results showed that the eight analytes could be successfully determined in wastewaters and the drawbacks due to matrix interferences could be adequately handled and overcome by using U-PSL/RBL. The use of a latent variable structure could cope with complex LC-DAD data, which do not follow a trilinear structure and provided comparable predictive results with MCR-ALS. One of

[a] See acronyms in Table 1. VOCs, volatile organic compounds.

the most important advantages of MCR-ALS is the physical meaning of the results obtained, absent in the U-PLS/RBL algorithm. However, U-PLS/RBL showed good analytical performance and ease and speed of program operation.

Pyridine, considered by US-EPA as a priority pollutant [1], was quantified in a concentration range of 0.67–51.7 $\mu g\,mL^{-1}$ in river water and field wastewater samples, coupling pH-modulated UV-spectrophotometry with PARAFAC and N-PLS [75]. Both methods yielded satisfactory results.

Very recently, a chemometric-assisted molecularly imprinted polymer (MIP)-fluorescence optosensing system was developed for determining the contaminants 1- and 2-naphthylamine in drinking waters [76]. In this work, fluorescence emission spectra coupled to PLS-1 and EEFMs combined with N- and U-PLS were applied. The combinations of both N- and U-PLS with RBL allowed the achievement of the second-order advantage and satisfactory results were obtained in the presence of a potential interference (1-naphthalenemethylamine).

Decabromodiphenyl ether is the only polybrominated diphenyl ether (PBDE) of worldwide accepted use. However, it can degrade by the action of light into lower banned congeners in the environment. The photochemical degradation process of decabromodiphenyl ether was investigated by UV-spectrophotometric monitoring [77]. A novel hybrid data analysis approach, based on the combination of hard- and soft-multivariate curve resolution (HS-MCR), was applied to elucidate the mechanism of the degradation process, to resolve kinetic profiles and pure spectra of the photodegradation products and to evaluate the rate constants [78]. This method combines the qualities of deterministic (rate law) hard-modelling and of soft-modelling methods (no physicochemical model is assumed), allowing the simultaneous treatment of several experiments performed in different conditions with different kinetic models and rate constants in the presence of interferences.

3. Environmental exploratory studies

3.1. Pesticides

As seen in Table 3, PCA [21], PARAFAC [12], TUCKER-3 [30] and MCR-ALS [10,11] are the most commonly applied chemometric methods in environmental monitoring studies of pesticides. All these methods decompose an environmental data array into separate linear contributions or components describing the main sources of data variance, which are related to the main contamination sources or patterns. The differences among these approaches lie in the specific assumptions and type of data structure and decomposition.

PCA has been extensively applied as an exploratory tool to characterize pesticide sources and/or to evaluate their geographical and/or temporal distributions in environmental monitoring programs. For example, in [79], PCA was applied to historical data from 1996 to 2003 concerning the concentration of different organochlorine pesticides and PAHs in sediment samples from different sampling sites of the Ebro River basin. Three major contamination sources were identified and their composition and distribution profiles were resolved. The first contamination source was mostly loaded by PAHs, the second contamination source was loaded by some organochlorine compounds and the third contamination source was more specifically loaded by naphthalene. Samples from the different geographical regions of the Ebro River basin were grouped according to the contamination described by these three major sources.

The use of unsupervised exploratory techniques, such as cluster analysis (CA) and PCA and a supervised classification technique, linear discriminant analysis (LDA) led to the successful elucidation of the impact of pesticides (Directive 91/676/EEC) on the intensive horticulture performed in a particular vulnerable geographical zone located in Portugal [80]. CA was used as an unsupervised exploratory technique to discover unanticipated natural affinities within the data, considering associations of both pesticides and samples. Clusters of samples were further examined with the assistance of LDA in order to check the discriminant capacity of the measured variables. Finally, PCA was applied to reveal the main sources of data variance, thus allowing the interpretation of eventual relationships between the pesticide abundance and typology and the environmental mechanisms or agrochemical procedures.

PCA results from analysis of environmental data can be further improved for interpretation after the so-called varimax rotation [23]. As an example, PCA and varimax orthogonal rotation were applied and compared to investigate the main pollution sources in the Catalonia rivers basin [23]. The goal of this study was the evaluation of the geographical distribution and accumulation effects of these pollution sources in sediment and fish samples. A clear correspondence was found between different pollution sources in fish and in sediments, dominated by pesticides and by PCBs, respec-

tively. The geographical distribution, including hot pollution spots and the temporal evolution of these sources was also described.

A multivariate study of environmental data requires the integrated application of different multivariate methods to reciprocally validate the models obtained. In [28], multivariate correlations among the concentrations of selected herbicides and their derivatives in outflows from selected reservoirs in US Midwest were investigated by PCA and MCR. Whereas PCA allowed the identification and qualitative interpretation of the main contamination sources, MCR-ALS resolved their composition, geographical and temporal distribution profiles. In this work, a preliminary method for averaging PCA and MCR-ALS geographical profiles over time was proposed as an efficient and useful way to enhance either hidden geographical or temporal information of contamination sources. Additionally, the averaged source profiles obtained by MCR-ALS could be easily compared with the source profiles obtained using three-way methods, such as PARAFAC or TUCKER-3. In [81], several chemometric methods, such as PCA, MCR-ALS, PARAFAC and TUCKER-3, were compared to resolve and model the main contamination sources of pesticides in surface waters of Portugal.

An interesting adaptation of the MCR bilinear algorithm to perform the data set decomposition following PARAFAC and TUCKER-3 models has shown the flexibility of the former method to handle different data structures and to set different constraint schemes [33]. When MCR-ALS is applied to three-way data *via* matricization or matrix augmentation, trilinearity constraints may be implemented in a very flexible way using an algorithm previously developed [114]. A variant was developed to implement TUCKER-3 models using new component interaction constraints. The results obtained in this way could be easily compared to those obtained by classical PARAFAC or TUCKER-3 decompositions. TUCKER-3 models offer the advantage of defining a different number of components for each mode in the three-way data decomposition. This is of environmental significance, since it describes the real scenario of sources with different contamination patterns that may display a similar geographical or temporal distribution. A reduction of the number of components in the similar mode allows for an improved and more compact environmental description of the different contamination patterns.

Results of chemometric modelling and multivariate data analysis of large monitoring multivariate data sets may be coupled with geographical information systems (GIS) and mapping tools to facilitate the description of environmental patterns and to improve environmental knowledge and risk assessment. In [82], the environmental quality of the Ebro River delta (Catalonia, NE Spain) was assessed and the spatial and temporal distribution of pesticide pollution in the irrigation and drainage channels coming from the river during the rice-growing season were investigated in detail.

Receptor-based source apportionment of various potential pollution sources is also important in regional environmental management. Receptor models identify and quantify the sources of ambient air pollution and their effects at a site (receptor), primarily on the basis of concentration measurements at the receptor site and generally without the need of emission inventories and meteorological data studies [18]. PCA followed by varimax rotation, absolute scores recalculation and multilinear regression analysis (PCA/APCA, a popular receptor model [22]) have been used to apportion the different sources of contaminants (mostly inorganic particulate matter), especially in air pollution. The number of studies is smaller, however, in the case of organic pollutants. In [83], PCA with MLR analysis was used to distinguish the relative contribution of historic residues from current illegal usage of technical DDT and dicofol-type DDT in the Pearl River area (China).

Other non-linear chemometric methods have been applied to investigate pesticide contamination sources. Among them, three ANN models [a feed-forward back-propagation (BNN), a radial basis function (RBF) and an adaptive neural network-based fuzzy inference system (ANFIS)] [38] were employed [84]. The BNN neural network was found to be superior to the RBF and to the ANFIS types of ANN in the detection of pesticide occurrences in wells.

In other similar studies, PCA and related techniques have also been used to determine correlations between pesticide contamination and particular environmental properties. For example, the relationship of the concentration of some pesticides and organochlorine compounds with geographical and physical parameters, such as altitude, longitude, latitude or temperature and with physiological or biological parameters, such as lipid content, age, weight and size in fish was investigated by PCA and PLS in [85]. The results confirmed that temperature and altitude were the main factors influencing the accumulation of most investigated compounds in the lipids of fish muscle and liver tissues.

PCA, PLS, soft independent modelling of class analogy (SIMCA) and PLS discriminant analysis (PLS-DA) were used [86] to investigate the correlation between biological characteristics and pollutant concentration in eggs and muscle of birds. In this work, PLS was applied to investigate the relationship between the biological variables of guillemot eggs and the residue levels of OCs and BFRs and to investigate whether concentrations of OCs and BFRs in guillemot egg covaried. SIMCA classification was used to investigate whether the contaminant pattern in the two matrices, egg and muscle, differed significantly from each other. SIMCA performs a classification model using PCA on selected observations (e.g., contaminant concentrations in the eggs) and then determines class membership by calculating the distance between a new observation (e.g., the contaminant concentrations in an individual muscle or in an egg) and the PCA model. PLS discriminant analysis (PLS-DA) was used to identify the discriminating variables that contributed the most to the class separation between egg and muscle contamination. A PLS-DA model showed that some of the contaminants had significantly higher concentrations in egg than in muscle, although 7 of the 14 contaminants showed no difference in concentrations between the two matrices. The concentrations of lower chlorinated biphenyls were higher in egg than in muscle. This might be due to absence/low activity of metabolizing enzymes in the egg and/or differences in lipid composition between the two matrices.

Multivariate techniques can also be used to relate measured contaminant levels and general physicochemical parameters to biological responses and to eventually find causality behind the emergence of the responses. In a recent work [87], environmental factors of industrialized and urbanized Llobregat river (NE Spain) affecting aquatic invertebrate communities were assessed using *Daphnia magna in situ* bioassays and biological indices based on community assemblages of benthic macroinvertebrates. To explore causal relationships between the studied environmental variables and parameters and the biological responses, PCA and PLS methods were used. The authors showed that environmental variables, such as habitat degradation, suspended solids, nitrogenous and conductivity related parameters affected macroinvertebrate assemblages. On the other hand, river levels of organophosphorus pesticides and PAHs were high enough to trigger the responses of *Daphnia magna in situ* bioassays.

3.2. Polycyclic aromatic hydrocarbons

The high variability of PAHs concentrations according to the sampling site and to the environment (urban, rural, coastal and remote) requires a very careful evaluation and interpretation. Multivariate statistical approaches deliver substantial information on links among sampling sites and pollutant concentrations through latent factors responsible for the data set structure and pollutant sources allocated. Among these approaches, PCA and PCA with varimax rotation were the most used techniques.

As an example, Golobocanin et al. proved PCA and cluster analysis to be a very effective tool in finding patterns to explain PAH occurrence in surface soil. They found PAHs distributed in three groups, mainly according to the number of rings in their structure, for grossly contaminated areas [88].

PCA with varimax rotation has been used to identify contributing sources of particle-phase PAHs in rural areas of Candiota region, Rio Grande do Sul, Brazil [89]. The data analysis separated the compounds studied in 3 factors, grouping emissions from the combustion of coal and wood, vehicle emissions from the combustion of diesel oil and gasoline and emissions from unburned diesel oil and gasoline. This study also demonstrated the influence of weather parameters, such as rainfall and concentration of particulate matter, on the different PAHs present in the area under study; hence, physicochemical characteristics, such as size of particles and water solubility, are determinant to the distribution of these compounds in the atmosphere.

Distribution characteristics, probabilistic risk assessment and identification of possible sources of PAHs were investigated in the Yellow River delta (China) [90]. For PAH source identification, both diagnostic tools based on ratios of selected PAHs and principal component analysis (PCA) with multiple linear regression (MLR) analysis were studied, suggesting mixed sources of pyrogenic and petrogenic derived PAHs in this river.

23 PAHs were analyzed in surface sediments and oyster samples from the intertidal areas of Dar es Salaam (Tanzania) by GC-MS. Diagnostic indices and PCA were used to identify possible contamination sources. Interestingly, no correlation between sediment and oyster PAHs concentrations measured in the same sites was found. This conclusion was supported by completely different contamination patterns, suggesting different sources or accumulation mechanisms for both environmental compartments [91].

Different receptor models, such as chemical mass balance (CMB) [92], factor analysis (FA) with non-negativity constraints, PCA/APCA, UNMIX and positive matrix factorization (PMF) were used to determine the profiles and relative contributions of PAH sources in different environmental media.

CMB and FA with non-negativity constraints were the most used receptor models to apportion sources of PAHs. CMB uses historical emission source profiles that are assumed to be known and weighted regression methods to apportion their related mass. In CMB, the output does not include the source profiles because they are required inputs and are used to build the receptor models. Li et al. used CMB to apportion the major sources of PAHs found in the sediments of Lake Calumet and surrounding wetlands in southeast Chicago [92]. The results indicated the feasibility of applying CMB to pollutants found in aquatic sediments. To establish the fingerprints of PAH sources, 28 source profiles were collected from the literature. The profiles under the same source category were averaged and the fingerprints of six sources were established, including coke oven, residential coal burning, coal combustion in power generation, gasoline engine exhaust, diesel engine exhaust and traffic tunnel air. The results indicated that coke ovens and traffic are the two major sources of PAHs in the area. The average contribution from coke oven emissions ranged from 21% to 53% and that from traffic ranged from 27% to 63%. The pattern of source contributions also showed spatial and temporal variations. Bzdusek and Christensen used an FA model with non-negative constraints, which supported the results of the work mentioned above [93]. In addition, FA provided new insights, since wood burning and secondary coke oven profiles were not recognized in the CMB model studied by Li et al. [92]. This was the first application of an FA model for source apportionment of PAHs in sediments. This methodology does not require input of source profiles and provides factor loading and factor score plots, which can be interpreted as PAH source profiles and PAH source contributions, respectively.

A PCA/APCA receptor modelling approach has been proposed for the estimation of source contributions of PAHs in particulate depositions on near highway vegetation foliage in the urban environment of Lucknow City (India) [94]. PCA identified three major sources of PAHs, *viz*. combustion, vehicle emissions and diesel-based activities. Whereas APCA was used to quantify the contributions of all sources to each measured PAH, a subsequent MLR step related the sample mass concentration to the APCA-estimated mass concentration of each source. Finally, the PCA/APCA receptor modelling approach revealed that the combustion sources (natural gas, wood, coal/coke, biomass) contributed 19–97% to the total measured PAHs, vehicular emissions 0–70%, diesel-based sources 0–81% and other miscellaneous sources 0–20%. The chemically meaningful PCA/APCA receptor model enables their validation by comparison of estimated source profiles with literature data.

A linear mixing model using FA was proposed to identify site parameters that may influence the PAH concentrations in Swiss background soil and to assess whether it was possible to identify sources of PAH in background soils [95]. The application of the receptor model was performed taking into account the pattern of all 16 EPA-regulated PAHs sources. The comparison of three soil profiles identified with a linear mixing model from the pattern of 16 PAH with more than 300 PAH emission profiles from the literature suggested urban dust, wood combustion and binders from asphalt as main PAH sources.

In [96], two receptor modelling methods (PCA with MLR and PMF) were compared to determine the profiles and relative contributions of the sources of PAHs and sulphur heterocycles in the sediments of Hamilton Harbour (Ontario, Canada) and surrounding harbour creeks. Both methods identified four factors and gave excellent correlation coefficients between predicted and measured levels of pollutant compounds and they assigned similar contributions from coal and tar/coal combustion sources to the harbour (19 and 26%, respectively). One PCA factor was identified as contributions from vehicular emissions (61%). PMF was able to differentiate vehicular emissions into two factors, one attributed to gasoline emissions sources (28%) and the other to diesel emissions sources (24%). Overall, PMF afforded better source identification than PCA with MLR. In PMF, an explicit least-squares approach is considered, which individually weights measured values by its estimated uncertainty [26]. This individual data point weighting in PMF has been stated to outperform eigenbased analysis methods, such as PCA, since it deals better with values below the detection limit (DL) and with missing data and takes into consideration the real uneven uncertainty associated with the analyzed values [115]. Other weighted least-squares-based approaches (MCR) have also been recently proposed for the same purposes [29].

In another study [97], two eigenbased source apportionment methods (PCA with MLR and UNMIX [25]) and one non-eigenbased source apportionment method were applied and compared to determine the sources of PAHs in ambient air in Baltimore, MD (USA). Overall source contributions compare well among methods. Vehicles, both diesel and gasoline, contribute 16–26%, coal 28–36%, oil 15–23% and wood/other having the greatest disparity, 23–35% of the total (gas plus particle-phase) PAHs. Seasonal trends were found for both coal and oil. Coal was the PAH dominating source during the summer, while oil dominated during the winter. The information obtained from the different techniques is complementary and allows for a deeper and more reliable interpretation of the resulting source profiles. PMF was the only method to separate diesel from gasoline sources.

An ANN approach to the analysis of seasonal air pollution (e.g., PAHs) within the area of the city of Gdansk was introduced by Wesolowski et al. [98]. They applied two different types of ANN: multilayer perceptron (MLP) and SOM. MLP was used as a tool to predict the season in which a certain sample was collected and

SOM was applied for sample mapping to recognize similarities. This study also presented the comparison between two projection methods, linear (PCA) and non-linear (SOM), to extract valuable information from multi-dimensional environmental data.

Burns et al. used PLS to reassess the percentage contribution of coal, seep oil, shales and rivers to the total hydrocarbon loading in Prince William Sound (PWS) and the Gulf of Alaska (GoA) [99]. Data provided from NOAA and Exxon were analyzed using selected sites as sources in order to develop signatures. These signatures were based on 40 and 136 compounds, respectively and included PAH and terpane/sterane biomarkers in the case of the Exxon data. The authors used PCA to identify how many different sources could exist and to expand the number of PLS signatures to encompass all possible sources. These were then combined to determine the relative contribution from each source and to quantify the overlap among similar signatures. Using the Exxon data, a mixed combination of coal, seep oil, eroding shales and two different river sources described 13%, 18%, 24%, 26% and 20%, respectively, of the variance in PWS and GoA data. The first river signature was very similar to that of coal, while the second one was more similar to the eroding shales. With the NOAA data, the authors observed a considerable overlap in the signatures.

In [100], the influence of soil characteristics and PAH physicochemical properties in the chemical degradability of PAHs contained in aged soil samples from several contaminated sites was investigated using PLS. The PAH-contaminated soil samples were characterised and subjected to relatively mild, slurry-phase Fenton's reaction conditions. In general, low molecular weight PAHs were more degraded than large, highly hydrophobic variants. The presence of organic matter and the specific surface area of the soil were negatively correlated with the degradation of bi- and tri-cyclic PAHs, whereas the amount of degraded organic matter correlated positively with the degradation of PAHs with five or six fused rings. This was explained because larger PAHs were released from the organic matter as it degraded.

3.3. Other pollutants

Phthalate esters were investigated in surface soils from 37 sampling sites including roadsides, parks and residential areas of Guangzhou (China) [101]. These compounds were detected in all surface soils analyzed as ubiquitous environmental contaminants. PCA was applied to reveal their distribution patterns.

Because volatile organic compounds (VOCs) play an important role in the formation of photochemical O_3 and other oxidants in the troposphere, it is crucial the characterization of their sources and distribution in the atmosphere. Different multivariate techniques such as PCA/APCA, CMB, PMF and UNMIX were applied in order to identify and to apportion the VOCs sources in rural and urban sites.

In [102], the CMB receptor model has apportioned VOCs in more than 20 urban areas, mostly in the USA. The models in these areas differ in terms of the total fraction apportioned, the calculation method, the chemical compounds used in the calculation, the apportionment units and the source profiles applied. Nevertheless, they show similar results for VOC fractions contributed by different sources. Gasoline vehicle exhaust, liquid gasoline and gasoline evaporation contribute up to 50% or more of the ambient VOCs in many of these studies. In another study, a CMB receptor model and a multivariate receptor model (UNMIX) were used for the determination of the contributions of different non-methane hydrocarbon sources in Helsinki [103]. Source contributions were estimated for different seasons of the year and weekly and diurnal variations were examined using the CMB mode. UNMIX was used to confirm that the major sources were included in the CMB calculations. According to the CMB analysis, major sources of C2–C10 hydrocarbons were traffic and emissions from distant sources. For C6–C10 hydrocarbons, the major sources in both CMB and UNMIX analyses were gasoline exhaust.

Relationships between VOCs and transient high ozone formation in the Houston area were evaluated by Gan and Hopke [104]. Based on CMB analysis, a linear model was established between the subset of the VOCs data and the positive ozone transition. Non-negative least-squares were used to calculate the regression coefficient of the VOCs that have the most significant direct relationship to the positive ozone transition. The results show that more attention should be paid to additional non-considered VOCs, which can have significant relationship to the transient high ozone formation.

UNMIX and PMF were used to analyze ambient VOCs measured in a spring campaign in 1996 at Santiago de Chile. Two sites were sampled: a downtown site, close to major traffic emissions and a residential site, downwind of major industrial sources and highways [105]. It was found that the number of factors given by the UNMIX model was a good starting point to refine the solution using PMF. Both models showed good performance at discriminating between source profiles that had similar compositions in subsets of common species, but PMF was able to find better and cleaner source profiles than UNMIX.

Four receptor models (CMB, PCA/APCA, PMF and UNMIX) were used to describe personal exposure measurements to toxic VOCs. The measurements were from the total exposure assessment studies conducted from 1980 to 1984 in New Jersey and California and from the 1987 to 1990 California Indoor Exposure study [106]. From the four receptor models compared, PMF and UNMIX showed the closest agreement, extracting six similar factors from the New Jersey personal exposure data and four similar factors from the California data. Between the two methods, PMF has the advantage of reporting more complete information on model performance than the current version of UNMIX. The lack of a non-negativity constraint is a significant limitation of both PCA/APCA and CMB. Nevertheless, results from CMB were useful to help in the interpretation of factors extracted by the other models.

In [107], the effectiveness of using trace organic speciation data to identify sources influencing fine particulate matter (PM2.5) exposure concentrations was investigated. PM2.5 samples, with organic carbon as dominant constituent, were obtained from seven different individuals in and around Boulder, CO (USA). The data set was analyzed by PCA to determine the factors that account for the largest variance. Eight significant factors were identified and each of them was matched to a potential source according to the marker species that mostly loaded the factor. Meat cooking was an important source of variability and its associated factor was highly correlated to organic carbon concentration. The exposure time while developing an activity was generally not well correlated to the PCA factor scores because exposure time is not directly related to emissions intensity. The PCA results demonstrated that organic tracers can aid in identifying factors that influence personal exposures to PM2.5.

In [108], PM2.5 and VOCs data collected at Beacon Hill in Seattle between 2000 and 2004 were analyzed with the Multilinear Engine method [31] in order to quantify source contributions to the mixture of hazardous air pollutants (HAPs). ME solves a positively constrained bilinear mass balance model using an explicit least-squares equation. The required input data include the mass concentrations and uncertainties of each measured species. ME is an evolution of the different PMF methods towards an improved generalized multilinear modelling tool. The authors tested the performance of the model with and without the addition of VOCs data. They also used the 'missing mass', defined as the concentration of the measured total particle mass minus the sum of all analyzed species, as an additional variable and implemented an auxiliary equation to constrain the sum of all species mass fractions to be

Table 4
QSAR studies.

Compounds	Multivariate method[a]	Aim of the multivariate method in the study	References
Pesticides			
Pesticides	BNN	Prediction of the toxicity to *Lepomis macrochirus* under varying experimental conditions	[116]
Thiazoline derivatives	PCA, GA-MLR, LS-SVM, PPR	Fungicidal activities of thiazoline derivatives against rice blast. PCA was used to built a validate training set	[117]
One hundred and sixteen pesticides	PCA, GA, SVM, LDA, KNN	Prediction of the avian oral toxicity. GA for variable selection in PCA	[118]
Pesticides	MLR, GA, SOM, AFP	Prediction of toxicity against fathead minnow. SOM (selection training)	[119]
Two hundred and thirty-five pesticides	NMC, LDA, QDA, RDA, SIMCA, KNN, CART	Critical analysis of the different models and descriptors in order to predict ecotoxicity	[120]
Phenylureas and triazines	MDS, GA (for variable selection)-MDS	Selection of congeneric compounds with a similar toxicological mode of action	[121]
Polycyclic aromatic hydrocarbons			
PHAs	PLS	QSAR model to predict the phototoxicity .	[122]
Sixty-seven PAHs	GA (variable selection) KNN, CART, SOM (external validation)	QSAR model to predict mutagenicity in human cells of the pollutants	[123]
Other organic pollutants			
One hundred and twenty-five organic compounds	GA (for variable selection), PCA (*a priori* classification), KNN, CART, LDA, SLDA, RDA	Qsar models to predict toxicity on algae, *Daphnia*, and fish	[124]
Two hundred and fifty organic compounds	HCA (*a priori* classification), KNN, CART, CP-ANN	QSAR model to screen and rank POPs with regard to their tendency towards atmospheric persistence and mobility	[125]
One hundred and ninety-one organic compounds	RBF-ANNs, LDA, NLDA and SVM	Comparison of the QSAR models to predict aquatic toxicity	[126]
15 PBDEs	PLS/LOO-CV (variable selection), SVM and RBF-ANNs	QSAR models to predict the Aryl hydrocarbon Receptor Relative Binding Affinities (RBA) of pollutants	[127]

[a] See acronyms in Table 1. PBDEs, polybrominated diphenyl ethers.

100%. Using only PM2.5 data, the model distinguished two diesel sources with the 100% constraint, but identified only one diesel source without the constraint. When both PM2.5 and VOCs data were used, an additional feature was identified as the major contributor to total VOC mass. Adding VOCs data to the speciated PM2.5 data in source apportionment modelling resulted in more accurate source contribution estimates for combustion related sources, as evidenced by the less 'missing mass' percentage in PM2.5. Using the source contribution estimates, the authors did also evaluate the validity of using black carbon as a surrogate for diesel exhaust during different seasons.

Non-parametric regression is also a powerful technique that has many potential uses in air quality studies and atmospheric sciences. In [109], the relationship between the concentration of cyclohexane and other VOCs with wind direction was determined at two sites near a heavy industrial region in Houston (USA), by non-parametric regression using a Gaussian kernel. The results were smooth curves with error bars that allowed for the accurate determination of the wind direction where the concentration peaks and thus, the location of nearby sources. Cyclohexane was chosen to test the method because 70% of the industrial emissions in the region are known to be from this single source. Thus, the intersection of two lines drawn from each site in the direction of the largest concentration peak should be the location of this source. The success of the method can be judged by how closely the predicted position of the source corresponds to the known location. The non-parametric regression correctly identified the direction of this source from each site and the predicted location of the source was less than 500 m away from that given in the inventory.

Among the persistent organic pollutants targeted for monitoring, control and virtual elimination by international research projects and agreements (UNEP, 2001), polychlorinated biphenyls (PCBs) are ubiquitous contaminants in the environment. Polytopic vector analysis (PVA) has been used for the characterization of sources and alteration patterns of PCBs in complex environmental settings. As an example, in [110] the authors discussed PCB dechlorination processes measured in Lake Hartwell sediments using a PVA receptor model. The GC-MS resolution of 107 PCB congeners provided insight into PCB sources and the degree of PCB weathering in the sediments. Modifications in congener concentrations and typology were characterized by comparing surface sediment congener distributions with the distributions in buried sediments and were matched with literature-reported dechlorination patterns from other sites. PVA results were used to determine PCB sources and dechlorination end member (EM) patterns and their distributions in each of the cores. The authors showed the advantage of such an approach to identify fingerprints (EMs) with minimal assumption of contributing source patterns and/or alteration mechanisms.

The usefulness of the combination of the probabilistic model called potential source contribution function (PSCF) with PMF was proposed as a tool to identify atmospheric PCB sources regions in Philadelphia [111]. PSCF can only reveal the potential source location, but cannot give a quantitative indication of the source strength. Thus, the combination with PMF can provide an effective tool for identification of atmosphere source and apportionment.

Results of three hybrid receptor models, PSCF, concentration weighted trajectory (CWT) and residence time weighted concentration (RTWC), were compared for locating PCB sources contributing to the atmospheric concentrations in Chicago [112]. All three trajectories ensemble models consistently indicated similar PCB source locations. Each approach was found to have some advantages com-

pared to the others. Thus, when used together, they provide better information on source areas than the obtained by using only one of them.

Chemometric assessment of multivariate data sets generated in monitoring studies of other pollutant compounds, such as PBDEs, non-ionic surfactants and linear alkylbenzene sulfonates have also been done. As an example, identification, resolution and distribution of main microcontaminant sources of endocrine disruptors in Spanish harbours, coastal waters and sediments were investigated using PCA and MCR-ALS [113]. In this study, the authors interpreted the main environmental contamination sources of these endocrine disruptor compounds according to their chemical composition and to their resolved geographical distribution profiles. Whereas PCA allowed the qualitative interpretation of the major contamination sources, MCR-ALS confirmed these results and allowed a semi-quantitative view of contamination sources allowing their apportionment. Although 'hot spots' with point sources of municipal and industrial discharges were identified, it could be concluded that the investigated compounds were widespread contaminants in the marine environment of the Mediterranean Spanish coasts and harbours. Large accumulation effects of most of these contaminants were observed for sediment samples collected near discharges of domestic or industrial wastewaters in the studied harbour areas, as compared with less contaminated sea water samples.

4. Toxicity studies

4.1. Pesticides

As can be seen in Table 4, many pesticide toxicity studies have been conducted using ANN, which is appropriate in cases of highly non-linear relationships between the input and output variables. Several QSAR models have been developed to predict the aquatic toxicity of pesticides using ANNs. An example of these QSAR studies can be found in [116], where the estimation of the acute toxicity of pesticides against *Lepomis macrochirus* (freshwater fish) under different experimental and biological conditions (e.g., fish weight, exposure time, temperature, pH and water hardness) was done using a three-layer feed-forward neural network trained by the back-propagation algorithm.

However, ANNs may tend to overfit the training data set unless very careful external validation strategies are applied that will ensure reliable prediction models. Alternatively, genetic algorithm-multilinear regression (GA-MLR), least-squares support vector machine (LS-SVM, which performs classification tasks by constructing hyperplanes in a multi-dimensional space to separate cases of different class labels) and projection pursuit regression (PPR, which involves finding the most 'interesting' projections in multi-dimensional data, i.e., those which deviate more from a normal distribution) have been proposed to model the fungicidal activity of thiazoline against rice blast [117]. The GA-MLR method was used to select the most appropriate molecular descriptors from the large original set to develop a linear quantitative structure–activity relationship (QSAR) model. On the basis of the selected descriptors, two more accurate models (LS-SVM and PPR) were built. Both the linear and non-linear models gave satisfactory prediction results, but the non-linear models provided better prediction ability, which means that LS-SVM and PPR methods could simulate more adequately the real relationship between the structural descriptors and the fungicidal activity.

Mazzatorta et al. also demonstrated the ability of SVM combined with GA for feature selection and prediction of the avian oral toxicity of 116 pesticides [118]. A comparison with several other classification methods was performed.

A QSAR model to predict the toxicity of pesticides against fathead minnow (freshwater fish) was built by Pintore et al. [119]. In their work, the authors combined genetic algorithms and stepwise regression methods in order to select the best descriptors for the model. GA is very effective for exploratory search, applicable to problems where little information is available, but it is less appropriate for a local search. Then, a stepwise approach was combined with GA (GA/SW) in order to reach local convergence. The selection of the training set was performed by SOM, which provided a 2D-space representation of molecular descriptors obtained from the original multi-dimensional space. Finally, a QSAR model was built by the adaptive fuzzy partition (AFP) method. This consists of modelling the relationship between molecular descriptors and biological activities of pesticides by dynamically dividing the molecular descriptor hyperspace into new fuzzy subspaces. Several models were attempted for the study, classification and prediction of toxicities of 253 pesticides. Seven classification algorithms were used and compared in detail and the performance of the different models was assessed [120]. The methods used were nearest mean classifier (NMC), LDA, quadratic discriminant analysis (QDA), regularized discriminant analysis (RDA), SIMCA, KNN and classification and regression tree (CART). The first four are parametric statistical systems based on Fisher's discriminant analysis, the fifth and sixth are non-parametric statistical methods and the last is a classification tree. CART and RDA appeared to be the classification algorithms which best described the biological activities of the pesticides considered. RDA had a further advantage: because of the definition of RDA, the classification is easier to understand. The regularization was used to overcome the problems of linear and quadratic discriminant analysis.

Gramatica et al. proposed a new approach for the selection of chemicals with similar mode of action, based on the analysis of structural similarities by means of QSAR and chemometric methods (PCA, multi-dimensional scaling (MDS) and GA) [121]. PCA and MDS were used for data exploration. MDS gave the best two-dimensional projection able to approximate the whole set of the Euclidean distances among the compounds. GA was used as variable selection method. The proposed approach seems to be a very promising tool, even if the available information is too scarce to fully understand the precise role of the different molecular descriptors in explaining the toxicological behaviour of the investigated pesticides.

4.2. Polycyclic aromatic hydrocarbons

The increasing concern about the input of PAHs in the environment has stimulated the investigation of their properties and biological activities, mainly because of their carcinogenic and toxic potential. PAHs containing four or more condensed rings are particularly hazardous because most of them are carcinogenic, mutagenic and extremely resistant to enzymatic degradation. Recent research has demonstrated that the toxic effect of chemicals can be induced or enhanced by visible or UV radiation. The photocytotoxicity and mutagenic and carcinogenic activity have been studied in a number of aquatic organisms. However, these QSAR models were usually developed using MLR, which will not be reviewed in this paper.

Alves de Lima Ribeiro et al. proposed a QSAR model to predict the phototoxicity of PAHs using electronic descriptors and PLS [122]. The relationship between these molecular descriptors and the photoinduced toxicity is non-linear and Gaussian type functions were used to linearize them. Once the model was validated, the phototoxicity was predicted for a set of molecules in which experimental measurements were unknown. Among them, pentaphene, benzo[*b*]chrysene and dibenz[*a*,*j*]anthracene are the compounds potentially phototoxic as predicted by the model.

In [123], experimental data of a mutagenicity test on human B-lymphoblastoid cells (alternative to the Ames bacterial test) for a

set of 70 oxo-, nitro- and unsubstituted PAHs detected in particulate matter (PM), were modelled by QSAR classification methods (KNN and CART) based on different theoretical molecular descriptors selected by genetic algorithms. The best models were internally and externally validated for prediction. For external validation, SOM was applied to split the original data set. The best models, developed on the training set alone, also showed good predictive performance on the prediction set of chemicals. The classification of PAHs according to their mutagenicity, based only on a few theoretical molecular descriptors, allowed a preliminary assessment of the human health risk and the prioritization of these compounds.

4.3. Other pollutants

As previously stated, there is a need for predictive tools capable to perform a preliminary hazard ranking for the very large number of existing chemicals discharged into the environment and for which experimental data are insufficient. In [124], QSAR models were developed in order to produce additional toxicological data for unmeasured compounds. The QSAR models to predict aquatic toxicity (algae, *Daphnia* and fish) of 125 organic compounds were performed based on: (1) the use of a large set of traditional and non-traditional molecular descriptors, (2) the selection of molecular descriptors by a genetic algorithm and (3) the production of models by ordinary least-squares regression. This approach was proven to be suitable to build models with satisfactory predictive capability, even on a largely heterogeneous data set. Afterwards, the data set was analyzed by PCA to rank chemicals as a function of their toxicity on different representative aquatic organisms and to help in the definition of *a priori* classes of toxicity. Finally, several classification methods (CART, KNN, RDA and LDA) were applied in order to classify the hazard of chemicals for the aquatic environment as a function of their molecular structure. The authors emphasized that different classification models may produce, in some cases, different evaluations. Thus, the best way to obtain reliable results is the combined use of several classification models, taking as starting point the *a priori* classes suggested by the PCA results of toxicity data.

In [125], a quantitative structure–property relationship (QSPR) study for the prediction of the environmental persistence of a set of 250 heterogeneous organic compounds was presented. Three *a priori* defined classes of environmental persistence were suggested by HCA, from the analysis of half-life data in air, water, soil and sediment and three interpretable theoretical molecular descriptors for all the studied compounds. QSPR classification models were successfully developed using different techniques, such as KNN, CART and counter propagation-ANN (CP-ANN), which is an adaptation of the Kohonen network to solve supervised problems. The models obtained for the prediction of potential persistence of heterogeneous organic compounds could be potentially useful as preliminary tools for the identification and prioritization of new potential POPs among already existing chemicals. A step forward would be their use as 'screening prior to synthesis' procedures to prevent the production and consequent release into the environment of potential POPs. Among the three presented strategies, the CP-ANN model gave the best results and was robust and accurate in the classification task for the three classes of persistence level. The CART model gave the most unbalanced results among the three classes, but they were still satisfactory. However, the simplicity of this approach is a good point when CART is compared with the other classification techniques presented in this study.

The performance and predictive capability of SVM and RBF-ANNs for classification problems in QSAR/QSPR were investigated and compared with several other classification methods, such as LDA and non-linear DA (NLDA). In [126], two different data sets are evaluated. The first one involves the classification of four action modes of 221 phenols and the second deals with the classification of three narcosis mechanisms of aquatic toxicity for 194 organic compounds. In both cases, the predictive ability of the SVM model is comparable or better than those obtained by LDA, NLDA and RBF-ANNs. The results obtained indicate that the SVM model with the RBF kernel function can be used as an alternative tool for classification problems in QSAR/QSPR. In another study [127], PLS was used to extract the seven best descriptors from more than 80 quantum descriptors in order to predict the aryl hydrocarbon receptor relative binding affinities of PBDEs. The extracted seven descriptors were correlated with the relative binding affinities of 15 PBDE congeners using SVM and RBF-ANNs. SVM models were proven to be of more general applicability than the RBF-ANNs models.

Pulsed amperometry

ABSTRACT

The electrochemical determinations of 4-chlorophenol (4-CP) and 4-nitrophenol (4-NP) by chronoamperometry (CA) and multiple pulsed amperometry (MPA) using expanded graphite-epoxy composite (EG-Epoxy) and rotating spectral graphite disc (SG) electrodes are reported. The electrochemical behaviours of both electrodes in the presence of organics informed about oxidation peak potential and the electrode fouling with organics concentration increasing. Setting up the oxidation peak potential as detection potential, only SG gave good electroanalytical performance using CA. However, by MPA applying both electrodes exhibited the capability to assess electrochemically and quantitatively the pollutants from aqueous solutions. UV spectrometric method detecting 4-CP and 4-NP at $\lambda = 280$ nm and $\lambda = 398$ nm wavelength, respectively was used for validation and parallel determinations.

1. Introduction

Priority phenols consist of a number of substituted phenolic compounds including halogenated and nitrated phenols, e.g., chlorophenols (CPs) and respective, nitrophenols (NPs). Priority phenols are used/produced in several industrial processes, being commonly used as preservatives, disinfectants, in pulp processing, in pesticides and their intermediars manufacturing. Many priority phenols are known for their toxicity, carcinogenetic and environmental persistence character [1–3]. They are common pollutants found in water, sediments and soil. Due to their toxicity, stability and bioaccumulation, the European Union has set the "black list" of the dangerous substances that should be monitored in waters [4]. The phenols were included in that list that was later accepted in Water Framework Directive [5]. The severe toxicity of 4-chlorophenol (4-CP) and 4-nitrophenol (4-NP) requires the development of simple, sensitive and reliable determination method. Various methods have been employed for the measurement of phenol derivates, e.g., method using HPLC [6,7], gas chromatography [8,9], biosensors [10,11]. However, these methods require expensive and most often laboratory locked complicated instruments. The specific cost of analysis can be high, and the methods are not suitable for in situ measurements.

Electrochemical methods present a growing interest because of high sensitivity, good selectivity, rapid response, and the instruments are relatively simple with the possibility of miniaturization for in situ measurement. Successful application of chemically modified electrodes [12–15] and boron-doped diamond electrodes in combination with different electrochemical methods [16–18] was reported for the determination of phenol derivates. Recently carbon-based materials such as graphite, carbon fibers, etc. have been used most often as the conductive phase in preparing composite working electrodes [19–22].

Although phenol derivates in general, can be oxidized at many electrode materials, the oxidation at carbon-based solid electrodes produces phenoxy radicals which couple to form an insulating polymeric film fouling the surfaces of the electrodes. A simple method of renewing the electrode surface is based on the anodic treatment. This relies on adjusting the working electrode potential high enough to oxidize the insulating film and making it water soluble without damaging the electrode.

In different working programs applied in practice of the well-known pulsed amperometric detection (PAD) the measurement potential is kept for a short time (measurement pulse) after the electrode cleaning pulse and conditioning potential pulse. Among presently used electroanalytical techniques, multiple pulsed amperometry (MPA) has proved to be extremely sensitive for the detection of organic molecules because of the advantage of

in situ cleaning and reactivating the electrode surface during the electroanalytical detection [23].

The purpose of this work is to evaluate comparatively the application of the multiple pulsed amperometry (MPA) technique for determination of 4-chlorophenol and 4-nitrophenol in water samples. The performances of the rotating spectral graphite disc (SG) and expanded graphite-epoxy composite (EG-Epoxy) electrodes were compared. The development and optimization of a MPA method for the determination of 4-CP and 4-NP in aqueous solution using both graphite based electrodes are described. Finally, the proposed method applied to determine either 4-CP or 4-NP in drinking water using EG-Epoxy electrode was found advantageous.

2. Materials and methods

All measurements were carried out using an Autolab potentiostat/galvanostat PGSTAT 12 (Eco Chemie, The Netherlands) controlled with GPES 4.9005 software and a three-electrode cell, with a Ag/AgCl reference electrode and a platinum counter electrode. In the study of the detection properties ED/101 disc electrode (Radiometer Analytical S.A., France) was applied. The spectral graphite and EG-Epoxy composite electrodes were used as working electrodes. The spectral graphite (SG) was an OD 3 mm disc electrode (ED), purchased from Electrocarbon Topol'cany (Bratislava, Slovakia).

The EG-Epoxy composite electrode was prepared from two-component epoxy resin (LY5052, Araldite) mixed with conductive expanded graphite (EG) fillers powder (Conductograph, SGL Carbon). To prepare EG-Epoxy composite electrode, the two parts of the epoxy were mixed together and the full amount of the EG was added in steps forming a thick paste. Then the epoxy was cured in a hot press at 80 °C for 40 min. Simultaneously the material was shaped in a plate of 1 mm thickness. The plate was slowly cooled down (for about 12 h) to the room temperature without removing the applied pressure. The prepared carbon-based composite showed good mechanical strength and low electrical resistance [22].

Prior to use, the working electrode with the surface area of 4 cm^2 was gradually cleaned, first polished with abrasive paper and then on a felt-polishing pad by using 0.6 and 0.3 μm alumina powder (Metrohm, Switzerland) in distilled water for 5 min and rinsing with distilled water. The electrode was sonicated to clean from the alumina powder.

0.1 mol L^{-1} stock solutions of 4-chlorophenol (4-CP) and 4-nitrophenol (4-NP) were prepared using distilled water. The supporting electrolyte was 0.1 M sodium sulphate freshly prepared with distilled water. All reagents were analytical grade. Analytical curves were obtained by the standard addition method.

3. Results and discussion

Examples of cyclic voltammetric curves of different concentrations of 4-CP at EG-Epoxy and SG electrodes recorded at scan rate of 0.1 V s^{-1} are shown in Figs. 1 and 2. From such curves it is determined the peak potential, e.g., *ca.* +0.8 V vs. Ag/AgCl for EG-Epoxy and *ca.* +0.9 V vs. Ag/AgCl for SG electrode. The different curves were obtained using standard addition method, without electrode cleaning between additions. For both electrodes 4-CP concentration increasing led to the electrode fouling, because of the complex oxidation process on graphite electrodes. The oxidation process of phenols involves both the adsorption of reactant/intermediate or phenols oxidation products and the formation of passive, nonconductive layer of oligomer products of oxidation process on their surface by electropolymerization [24]. The electropolymerization process is proven by changing the shape of the voltammogram

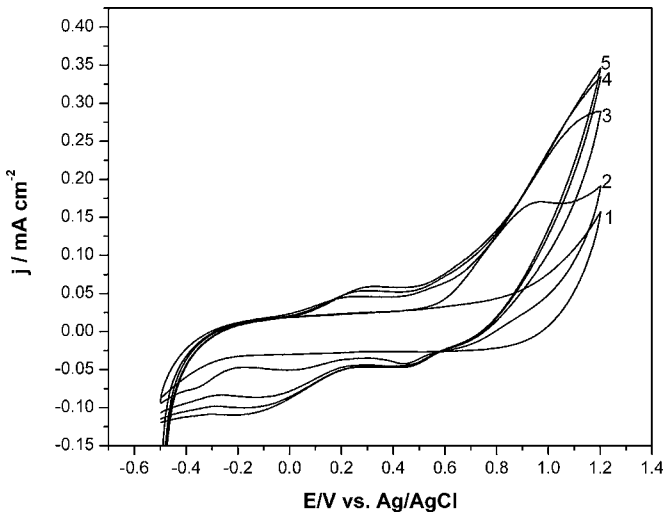

Fig. 1. Cyclic voltammograms recorded at EG-Epoxy electrode in 0.1 M Na_2SO_4 supporting electrolyte (curve 1) and in the presence of different concentrations of 4-CP: 2-0.2 mM; 3-0.4 mM; 4-0.6 mM; 5-0.8 mM; starting potential: 0 V vs. Ag/AgCl; potential range: −0.5 V → +1.25 V → −0.5 V vs. Ag/AgCl; scan rate: 0.1 V s^{-1}.

after the first scanning in the presence of 4-CP (curves 3–5 from Figs. 1 and 2). Compared with EG-Epoxy electrode behaviour, the rotating SG electrode exhibited the higher background current, and 4-CP concentration increasing did not lead to significant electrode fouling. This aspect could be attributed to the avoidance of the adsorption effect by rotating.

The similar results regarding the behaviours of the electrodes in the presence of 4-NP subjected to the electrode fouling were found (the results are not shown here). Based on these results, the chronoamperometry as the easiest electrochemical technique used for detection was applied for two detection potential values for each using the standard addition method. The two detection potential values were chosen based on the different considerations, the first was in line with the cyclic voltammetry, *i.e.*, +0.8 V vs. Ag/AgCl for EG-Epoxy electrode and +0.9 V vs. Ag/AgCl for SG electrode, and the second one had to be higher even under oxygen evolution process to assure a faster oxidation rate (+1.1 V vs. Ag/AgCl). As example,

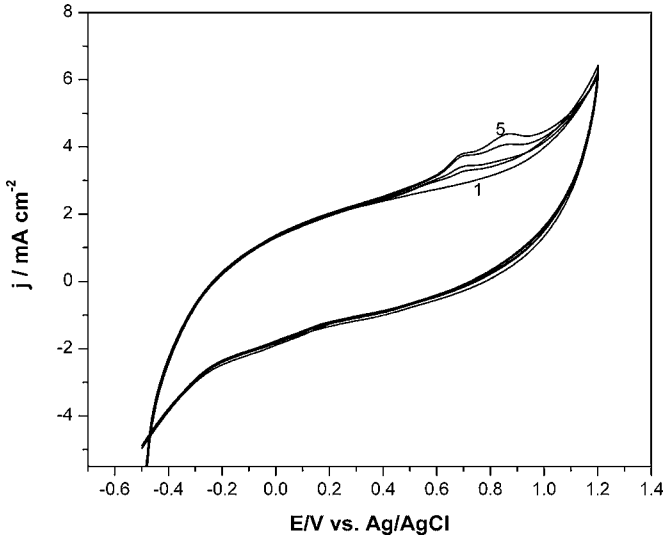

Fig. 2. Cyclic voltammograms recorded at SG electrode in 0.1 M Na_2SO_4 supporting electrolyte (curve 1) and in the presence of different concentrations of 4-CP: 2-0.2 mM; 3-0.4 mM; 4-0.6 mM; 5-0.8 mM; starting potential: 0 V vs. Ag/AgCl; potential range: −0.5 V → +1.25 V → −0.5 V vs. Ag/AgCl; scan rate: 0.1 V s^{-1}.

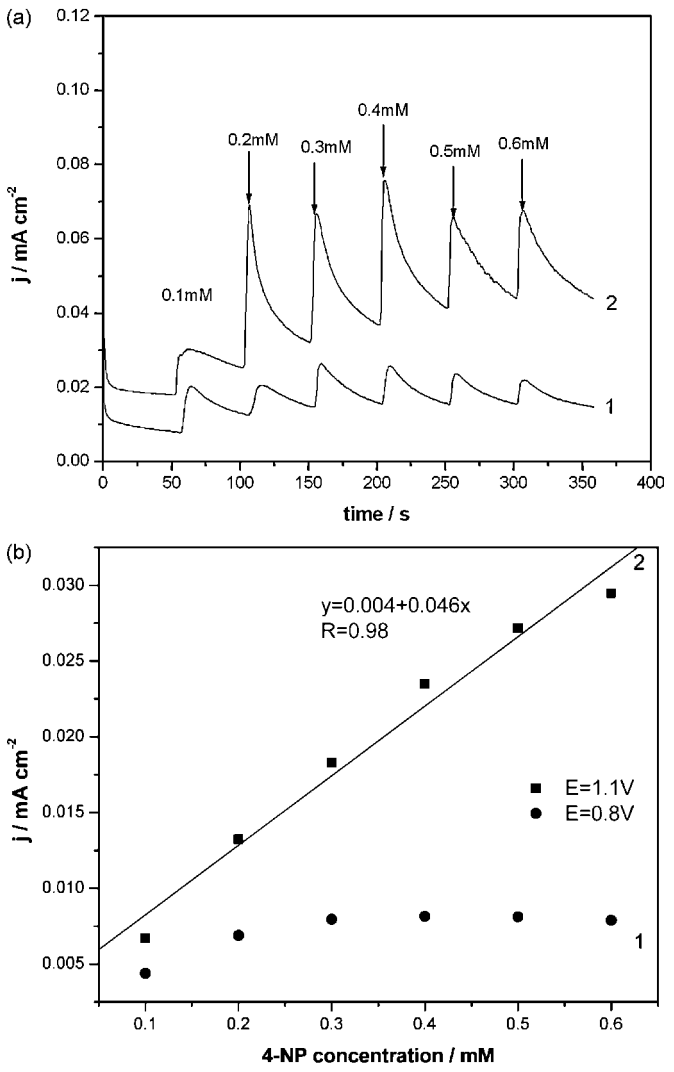

Fig. 3. (a) Chronoamperograms (CAs) recorded at EG-Epoxy electrode in 0.1 M Na_2SO_4 supporting electrolyte and in the presence of different 4-NP concentrations recorded at $E = 0.8$ V vs. Ag/AgCl (curve 1) and $E = 1.1$ V vs. Ag/AgCl (curve 2). (b) The calibration plots of the densities of the currents vs. 4-NP concentrations of the chronoamperograms recorded at $E = 0.8$ V vs. Ag/AgCl and $E = 1.1$ V vs. Ag/AgCl.

Fig. 3a shows the results obtained for EG-Epoxy electrode used for 4-NP detection using chronoamprometry technique.

Based on the two continuous chronoamperograms recorded at the two detection potential values, the calibration plots of current vs. 4-NP concentration was linear for the detection potential value of +1.1 V vs. Ag/AgCl, while for the detection potential value of +0.8 V vs. Ag/AgCl the amperometric current did not depend linear on the 4-NP concentrations, over the concentration range of 0.1–0.6 mM (Fig. 3b). Under the detection potential of +1.1 V vs. Ag/AgCl, the electrode sensitivity for 4-NP detection was 0.046 mA mM^{-1}, with the correlation coefficient of 0.98.

In Fig. 4a are presented the results of MPA applying to test the detection of 4-NP at the two detection potential at which CA was applied. For both situations, potential value for cleaning was +1.4 V vs. Ag/AgCl.

It can be concluded that MPA applying allowed the detection of 4-NP on EG-Epoxy electrode at the detection potential of +0.8 V vs. Ag/AgCl, which corresponds only to 4-NP oxidation, without oxygen evolution involving. For both detection potential, the linear relationships between amperometric current and 4-NP concentrations were obtained, with better electrode sensitivity at +1.1 V vs. Ag/AgCl (0.22 mA mM^{-1} vs. 0.14 mA mM^{-1} obtained at +0.8 V vs. Ag/AgCl), and the correlation coefficient higher than 0.99 (Fig. 4b).

In Fig. 5 is presented a typical batch chronoamperometry obtained by CA and adding 4-CP to 0.1 M Na_2SO_4 using rotating disc spectral graphite electrode. The applied potential was set at +1.1 V vs. Ag/AgCl and the response time was about 50 s. The calibration plots of current vs. 4-CP concentration was linear over the concentration range of 0.1–0.5 mM, with the electrode sensitivity of 0.12 mA mM^{-1}, and correlation coefficient higher than 0.99. The similar multiple pulsed amperograms in the presence of different concentrations of 4-CP on rotating disc spectral graphite for the same concentration range at the potential value and the cleaning potential value of 1.4 V vs. Ag/AgCl are presented in Fig. 6. The amperograms recorded at the cleaning potential value is also shown. Under these last conditions, a better electrode sensitivity was obtained as 0.25 mA mM^{-1}. Even the relationships between current recorded at +1.4 V vs. Ag/AgCl and 4-CP concentration is linear, the abundant oxygen evolution occurred and this aspect is undesired for electroanalysis.

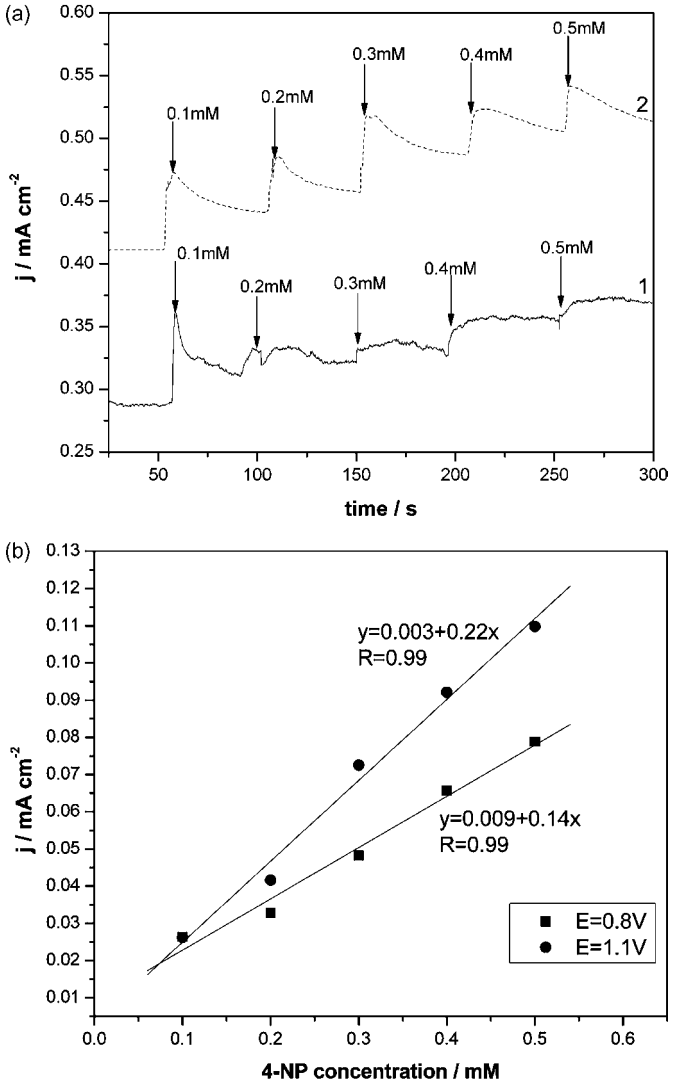

Fig. 4. (a) Multiple pulsed amperograms (MPAs) recorded at EG-Epoxy electrode in 0.1 M Na_2SO_4 supporting electrolyte and in the presence of different 4-NP concentrations; E_{det} was +0.8 V (curve 1), respective +1.1 V (curve 2) and E_{clean} was +1.4 V vs. Ag/AgCl; t_{det} was 0.05 s and t_{clean} was 0.15 s. (b) The calibration plots of the currents densities vs. 4-NP concentrations of the multiple pulsed amperograms recorded at the detection potential: $E_{det} = +0.8$ V, respective $E_{det} = +1.1$ V vs. Ag/AgCl; t_{det} was 0.05 s.

Table 1
Electroanalytical detection performance of EG-Epoxy and rotating SG disc electrode for the detection of 4-NP and 4-CP using CA and MPA.

Electrode	Pollutant	Technique		Sensitivity ($mA\,mM^{-1}$)	
		CA parameters	MPA parameters	CA	MPA
EG-Epoxy electrode	4-NP	E_{det} = +1.1 V	E_{det} = +1.1 V; t_{det} = 0.05 s E_{clean} = +1.4; t_{clean} = 0.15 s	0.046	0.22
		E_{det} = +0.8 V	E_{det} = +0.8 V; t_{det} = 0.05 s E_{clean} = +1.4; t_{clean} = 0.15 s	–	0.14
	4-CP	E_{det} = +1.1 V	E_{det} = +1.1 V; t_{det} = 0.05 s E_{clean} = +1.4; t_{clean} = 0.15 s	0.042	0.24
Rotating SG disc electrode	4-NP	E_{det} = +1.1 V	E_{det} = +1.1 V; t_{det} = 0.05 s E_{clean} = +1.4; t_{clean} = 0.15 s	0.17	0.28
	4-CP	E_{det} = +1.1 V	E_{det} = +1.1 V; t_{det} = 0.05 s E_{clean} = +1.4; t_{clean} = 0.15 s	0.12	0.25

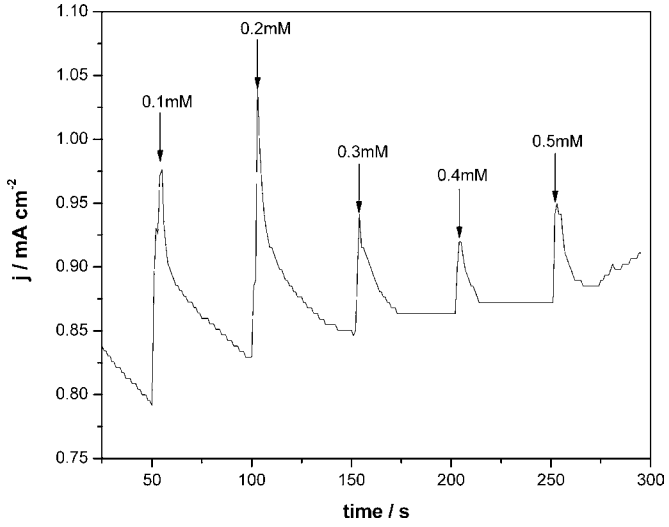

Fig. 5. Chronoamerogram (CA) recorded at the rotating disc SG electrode in 0.1 M Na_2SO_4 supporting electrolyte and in the presence of different 4-CP concentrations recorded at E = +1.1 V vs. Ag/AgCl.

The performance of both electrodes for the detection of 4-NP and 4-CP is summarized in Table 1. It can be concluded that rotating SG disc electrode showed a better sensitivity for the detection of both organic pollutants due to the adsorption effect was diminished by rotating. MPA applying improved significantly the detection performance of the electrode, owing the electrode cleaning during the detection experiments. Under the conditions of MPA applying (E_{det} = + 1.1 V, t_{det} = 0.05 s and E_{clean} = + 1.4 V, t_{clean} = 0.15 s), the detection limits of 0.01 mM for both organics were determined using a 3σ/slope ratio [14], where σ is the standard deviation of the mean value for three MPAs of the blank. The repeatability expressed as the relative standard deviation (R.S.D.) was 2.8% for 4-CP and 3.1% for 4-NP at three replicates.

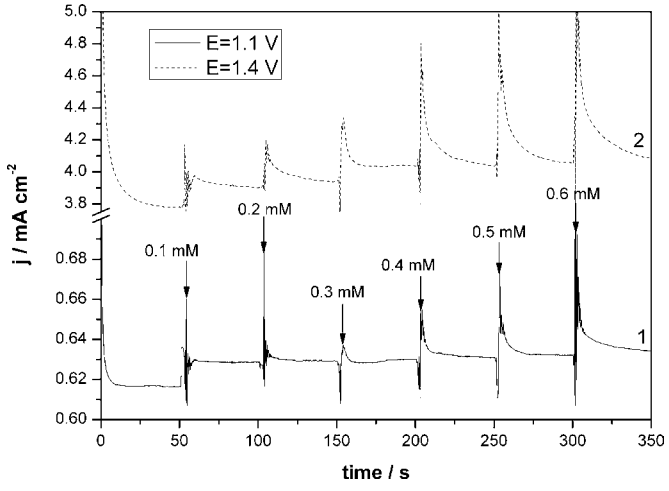

Fig. 6. Multiple pulsed amperogram (MPA) recorded at the rotating SG disc electrode in 0.1 M Na_2SO_4 supporting electrolyte and in the presence of different 4-CP concentrations; E_{det} was +1.1 V (curve 1) and E_{clean} was +1.4 V vs. Ag/AgCl (curve 2); t_{det} was 0.05 s and t_{clean} was 0.15 s.

Table 2
Recoveries of 4-CP and 4-NP in drinking water samples using continuous MPA method at EG-Epoxy electrode.

Spiked ($mg\,L^{-1}$)	Recovery, % (n = 3)	
	4-CP	4-NP
40	96.0	94.6
120	93.5	92.4

The electroanalytical performance for the detection of 4-CP and 4-NP using EG-Epoxy electrode and MPA technique exhibited the advantage of a simple and fast method with the results comparable to those published by us [25,26], which require the electrode renewing after each measurement and the use of specific voltammetric techniques.

A recovery test was also performed by analyzing three parallel tap water samples for two spiked levels of each pollutant. This test was run in 0.1 M Na_2SO_4 solution as supporting electrolyte and the results are summarized in Table 2. Finally, the results obtained by this method were compared with that obtained by means of a conventional UV spectrometric determination method at two certain wavelengths (λ = 280 nm for 4-CP and λ = 398 nm for 4-NP). By comparison the results in order to evaluate the precision of this electrochemical method using EG-Epoxy electrode by continuous application MPA, it can be concluded that the results obtained by the two methods are very closely and the accuracy of the proposed amperometric method is good.

4. Conclusions

In this paper the oxidation of 4-CP and 4-NP at the EG-Epoxy and the rotating SG electrodes studied by CV showed the loss of the electrode activity because of the electrode fouling effect. This phenomenon did not allow the application of CA, the easiest electrochemical technique for the detection of phenol derivates. The use of MPA technique improved the electroanalytical performance for the detection of 4-CP and 4-NP. The optimization of the experimental condition for MPA applying yielded to the detection results comparable to those obtained under the conditions of the electrode renewal and voltammetric techniques.

The good recovery degrees for both organic pollutants from drinking water suggested that this proposed method has good accuracy.

ABSTRACT

A new approach to modelling of some binary (hydro-organic, HL/H_2O + B) acid–base systems with organic co-solvent B fully miscible with water, is suggested and applied for the determination of acidity parameters pK for some weak acids HL. The models are designed to get the pK = p$K(x)$ relationships (x—mole fraction of B in H_2O + B) from results of pH titrations made in such systems and for the determination of pK_B = p$K(1)$ for HL in pure B. The Redlich–Kister equation, together with its asymmetric extensions, and the Legendre functions with orthogonal polynomials, appeared to be suitable for such purposes.

1. Introduction

Composition of mobile phase strongly affects chromatographic retention and electrophoretic migration of substances appearing acid–base behaviour [1]. The satisfactory knowledge of an effect of mobile phase composition on acid–base properties of solutes is therefore essential for analytical procedures applied in optimizing of the separation techniques. It enables to predict and optimize the influence of pH on selectivity and retention in reversed-phase liquid chromatography (RP-HPLC), especially in the gradient elution technique applied for the separation of ionizable compounds.

We focus our attention on binary-solvent hydro-organic systems, whose composition is expressed by the mole fraction $x = x_B$ of organic co-solvent B. Denoting the numbers of moles of A = H_2O and B in a solvent system by n_A and n_B, we have:

$$x = \frac{n_B}{n_A + n_B} \quad (1)$$

Acid–base properties of a weak monoprotic acid HL in aqueous solutions is expressed by its dissociation constant K, usually represented by pK = −log K value. In binary-solvent media, the pK value depends on x-value, pK = p$K(x)$, and changes when the solvent composition is varied, e.g. during the gradient elution. For this purpose, pK is termed as the acidity parameter [2] or as apparent acid dissociation constant [3] for HL. In further parts of the paper, pK will be referred to K expressed in terms of concentrations, i.e. $K = [H^+][L^-]/[HL] = [H^+]^2/(C - [H^+])$ for C mol L^{-1} HL.

pH measurements made for HL solutions in pure B and in close vicinity of $x = 1$ are not repeatable, and then the pK = pK_B value, calculated from the formula

$$pK = 2pH + \log(C - 10^{-pH}) \quad (2)$$

on the basis of a single pH measurement is doubtful. On the other hand, the results obtained for lower x assume firm values. Application of a regression equation that fits very well within the predominant part of experimental points obtained from pH titration, provides repeatable results for pK_B = p$K(1)$, also when the doubtful points (V_j, pH$_j$) from the immediate vicinity of $x = 1$ are included in the set of points taken for calculations, realised according to the least squares method. In other words, the approximating function firmly fastened in the predominant part of experimental points withstands the perturbations of the part of doubtful points; this approach has been assumed in this paper. The HL/A+B system, with HL introduced into binary-solvent system A+B, can be obtained by mixing two solutions of HL in pure solvents; the solutions will be denoted later as HL/A and HL/B, respectively. The mixing will be made according to potentiometric titration mode, with pH registration. In order to cover the whole x interval [0, 1], the initial solutions should be titrated mutually: HL/A → HL/B and HL/B → HL/A. The two titrations will be denoted briefly as HL/A ⇔ HL/B titration.

Except potentiometry and absorption spectrophotometry, as the well-established currently applied methods for pK determination

Nomenclature

Nomenclature

A = H_2O, B	organic co-solvent
C	concentration [mol L^{-1}] of HL in T and D
D	titrand (solution titrated)
HL	weak acid (solute)
HL/B	solution of HL in B
HL/A	aqueous solution of HL
LOP	Legendre function with orthogonal polynomials
M–S	Myers–Scott equation
pK	–log K acidity parameter
R–K	Redlich–Kister equation
T	titrant
V	volume [mL] of T
V_0	volume [mL] of D
x	mole fraction of B in the binary-solvent system A + B

[4–6], other techniques such as cyclic voltammetry [7], coulometry [8], NMR [9], HPLC [10] and capillary electrophoresis [11–13], appeared to be also applicable for such purposes.

For modelling purposes, designed to get the pK = p$K(x)$ relationships and pK_B values (pK_A = p$K(0)$ is determined incidentally), the principle of excess functions is applied.

2. Excess functions and their implications

Non-ideal behaviour of real solutions, formed of two miscible solvents: A = H_2O and organic co-solvent B, whose content is defined by x-value (Eq. (1)), can be expressed in terms of functions $y^E = y^E(x)$, referred to different excess variables [14], of physicochemical or physical nature: excess molar volume ($V^E = V^E(x)$) [15,16], excess molar enthalpy ($\Delta H^E = \Delta H^E(x)$) [17], excess molar free enthalpy ($\Delta G^E = \Delta G^E(x)$) [18] and many other excess properties, referred to surface tension, viscosity, speed of sound, refractive index, etc. The excess molar free enthalpy

$$\Delta G^E = \Delta G - \Delta G_{id} \tag{3}$$

expresses the deviation of the standard (s) free enthalpy (Gibbs function), $\Delta G = \Delta G^s$, from its ideal value:

$$\Delta G_{id} = \Delta G_{id}(x) = (1-x)\Delta G_A + x\Delta G_B \tag{4}$$

In other words, ΔG^E reflects the joint effect of solute–solute, solute–solvent, and solvent–solvent interactions [19–21]. The ΔG interrelates with pK in the relation:

$$\Delta G = b\,\mathrm{p}K, \text{ i.e. } \Delta G(x) = b\,\mathrm{p}K(x) \tag{5}$$

where

$$b = RT\ln 10 \tag{6}$$

Then we get:

$$\begin{aligned} \Delta G(0) &= \Delta G_A = b\,\mathrm{p}K(0) = b\,\mathrm{p}K_A \text{ and } \Delta G(1) = \Delta G_B \\ &= b\,\mathrm{p}K(1) = b\,\mathrm{p}K_B \\ \Delta G^E(0) &= \Delta G(0) - \Delta G_{id}(0) = b(\mathrm{p}K(0) - \mathrm{p}K_{id}(0)) = 0 \\ \Delta G^E(1) &= \Delta G(1) - \Delta G_{id}(1) = b(\mathrm{p}K(1) - \mathrm{p}K_{id}(1)) = 0 \end{aligned} \tag{7}$$

$$\mathrm{p}K(x) = (1-x)\mathrm{p}K_A + x\mathrm{p}K_B + \frac{1}{b}\Delta G^E(x) \tag{8}$$

In this paper, some approximating functions for $\Delta G^E(x)$ are applied for modelling the pK = p$K(x)$ relationships referred to different acid–base HL/A+B systems, tested experimentally according to pH titration, made in thermostated systems (isothermal titration). The functions applied here are as follows: (a) the function derived [22] from the empirical Redlich–Kister (R–K) [23,24] equation, together with its asymmetric versions, suggested by (b) Myers and Scott [25] (M–S) and (c) Michałowski and co-workers [22], where a hyperbolic transformation of x is applied. Moreover, (d) the Legendre function with orthogonal polynomials is applied; the latter function has been used hitherto only for modelling the V^E vs. x relationship, $V^E = V^E(x)$ [26,27]. In this paper, however, a growth in C value during the titration, $C = C(x)$, occurred as a result of contraction of mixed solutions, is neglected when compared with an error resulting from uncertainty ΔpH = 0.02 in common pH titrations [22]. In other words, $C(x) = C$ = const is assumed in HL/H_2O + B systems thus formed. At C = 0.01 mol L^{-1} HL, the inequality $x_{HL} \ll x_{H_2O} + x_B$, referred to mole fractions of HL, H_2O and B respectively, is valid. This way, one can assume that the densities of the solutions HL/A and HL/B are equal to densities ρ_A and ρ_B [g/mL] of the corresponding solvents A and B.

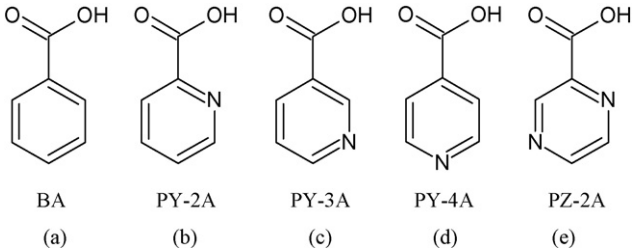

Fig. 1. The acids (HL) tested: (a) BA, (b), PY-2CA, (c) PY-3CA, (d) PY-4CA, and (e) PZ-2CA.

In this paper, the experimental data $\{(V_j, \mathrm{pH}_j)\,|j = 1, \ldots, N\}$, were obtained from pH titration HL/B ⇔ HL/H_2O, with C mol L^{-1} HL in both solutions: HL/H_2O and HL/B, i.e. $C(0) = C(1) = C$.

Benzoic acid (abbr. BA) and a series of heterocyclic compounds: pyridine-2-carboxylic acid (picolinic acid, PY-2A), pyridine-3-carboxylic acid (nicotinic acid, niacin, vitamin B_3, PY-3A), pyridine-4-carboxylic acid (isonicotinic acid, PY-4A), and pyrazine-2-carboxylic acid (PZ-2A) (Fig. 1) as weak acids (HL) in different hydro-organic media: H_2O + MeOH, H_2O + Me_2SO (Me≡CH_3) are applied in the titration, where V mL of titrant (T) was added dropwise into V_0 mL of titrand (D)

To recalculate V and V_0 on x-values, the formulae:

$$(1^\circ)\; x = \frac{V}{\chi V_0 + V} \text{ valid for titration HL/B} \rightarrow \text{HL/A, or}$$

$$(2^\circ)\; x = \frac{V_0}{\chi V + V_0} \text{ valid for titration HL/A} \rightarrow \text{HL/B}$$

are applied, where A = H_2O, $\chi = (\rho_A/\rho_B)\cdot(M_B/M_A)$; M_A, M_B—molar masses [g/mol] of A and B. Particularly, χ = 2.2431 for H_2O + CH_3OH system, and χ = 3.9293 for H_2O + $(CH_3)_2SO$ system of solvents [22].

3. Modelling the functions pK = p$K(x)$

3.1. Some earlier approaches

An effect of the solvent composition on pK value was considered in numerous papers issued recently, e.g. [28–31]. In all instances, acid–base titrations in mixed-solvent media were performed in the titrand (D) and titrant (T) systems (D + T systems), containing the same proportion of the solvent components (A and B), sometimes in the presence of a basal (background) salt securing approximately constant ionic strength value [30]. The linear relationship p$K = a_0 + a_1 x$ has been reported in a majority of earlier papers, e.g. [32–34], related to the determination of pK in binary-solvent systems. However, some reports [35,36] testify on account of non-linear relationships between the related variables.

Bosch et al. [36] determined p$K(x)$ values from results of pH titrations made in D + T systems, composed of two solutions, D and T, characterized by the same $x = x_i$-value of B (methanol, ethanol, 2-propanol); HL in D was titrated with tetrabutylammonium hydroxide in T. It was stated, however, that the hyperbolic approximating function $pK = pK_A + ax/(1 + bx)$ is satisfactory only for $x < 0.2$, $pK_A = pK(0)$. An inadequacy of the hyperbolic approximation for higher x was explained by stronger A ↔ B interactions, expressed through a kind of stability constant formulated for associates AB. The resulting expression for p$K(x)$ was acknowledged as a more adequate for modelling purposes.

Another approach was provided by the Jouyban–Acree (J–A) model [3,37], that is very similar to one derivable from R–K function [23] and Eq. (8) but involves the volume fraction (f) put for the mole fraction x of the co-solvent B [37,38]; however, contrary to x, f depends on the contraction/expansion and temperature effects. One should also notice that J–A model was derived in an unnecessarily complicated manner.

3.2. The approximating functions applied

The approach applied for derivation of the functions $pK = pK(x)$ is based on Eq. (8), where pK is expressed by Eq. (2), and pK_A and pK_B refer to the acidity parameter pK in pure solvents A and B, respectively, see Eq. (7). The expression for $\Delta G^E = \Delta G^E(x)$ in Eq. (8), when referred to x-interval [0, 1], can be written in terms of the R–K function:

$$\Delta G^E(x) = x(1-x)\sum_{i=0}^{n} a_i(1-2x)^i \tag{9}$$

or in terms of the shifted Legendre orthogonal polynomials, $s_i(x)$ [22]:

$$\Delta G^E(x) = x(1-x)\sum_{i=0}^{n} b_i s_i(x) \tag{10}$$

Putting (9) and (10) into (8) and denoting:

$$z = 1 - 2x \tag{11}$$

We get the functions:

$$pK = \varphi_0 + \varphi_1 z + (1-z^2)\sum_{i=0}^{n} \alpha_i z^i \tag{12}$$

$$pK = \varphi_0 + \varphi_1 z + (1-z^2)\sum_{i=0}^{n} \beta_i l_i(z) \tag{13}$$

Referred to the 'normal' Legendre orthogonal polynomials (LOP), $z \in [-1, 1]$, where

$$\varphi_0 = \frac{pK_A + pK_B}{2} \tag{14}$$

$$\varphi_1 = \frac{pK_A - pK_B}{2} \tag{15}$$

$$\alpha_i = \frac{0.25 a_i}{b} \tag{16}$$

$$\beta_i = \frac{0.25 b_i}{b} \tag{17}$$

Equations (12) and (13), expressed in terms of variable z (Eq. (11)), are related to LOP, where $z \in [-1, 1]$ in $l_i(z)$ [22]. The first five orthogonal polynomials, $l_i(z)$, in Eq. (13) are as follows:

$$l_0(z) = 1,\ l_1(z) = z,\ l_2(z) = 3z^2 - 1,\ l_3(z) = 5z^3 - 3z$$
$$l_4(z) = 35z^4 - 30z^2 + 3 \tag{18}$$

The numbers: 0.5 and 0.125 in expressions for $l_2(z)$, $l_3(z)$ and $l_4(z)$, cited in [39], enter the coefficients β_2, β_3 and β_4 in Eq. (13) as factors and then are omitted in (18). Note that the expressions for φ_0 and φ_1 are the same in (12) and (13). Then from (14) and (15) we have:

$$pK_A = \varphi_1 + \varphi_2 \text{ and } pK_B = \varphi_1 - \varphi_2 \tag{19}$$

In Eq. (2), the value $\gamma = 1$ [40] for activity coefficient γ of hydrogen ions in mixed-solvent system is assumed during the titration.

Other (asymmetric) modifications of R–K function were also considered for approximating purposes, namely the Myers and Scott (M–S) function:

$$pK = \varphi_0 + \varphi_1 z + \frac{1-z^2}{1-\varepsilon z}\sum_{i=0}^{n} \alpha_i z^i \tag{20}$$

and the function with hyperbolic transformation of variable z

$$pK = \varphi_0 + \varphi_1 z + (1-z^2)\sum_{i=0}^{n} \alpha_i \left(\frac{z}{1-\varepsilon z}\right)^i \tag{21}$$

proposed by Michałowski [22]; Eqs. (20) and (21) involve the assymetry parameter ε.

The parameters: $\varphi_0, \varphi_1, \alpha_0, \alpha_1, \ldots, \alpha_n$ in Eqs. (12), (20) and (21), or the parameters: $\varphi_0, \varphi_1, \beta_0, \beta_1, \ldots, \beta_n$ in Eq. (13) can be determined according to least squares (LS) method. Application of LS method in Eqs. (20) and (21) is possible after preliminary assignation for ε-value. The LS method is applied to results $\{(V_j, pH_j)\,|j = 1, \ldots, N\}$ obtained from pH metric titrations HL/B ⇔ HL/H_2O. Eq. (12) will be considered later as the modified R–K function, and Eq. (13) as the function with LOP, all used to formulate the $pK = pK(x)$ function. The number $n + 3$ of parameters on the right side of Eqs. (12) and (13) is equal to the number of parameters σ_i in the equation

$$pK = \sum_{i=0}^{n+2} \sigma_i z^i \tag{22}$$

to which (12) and (13) can be transformed. It means that the columns of a matrix obtained from (12) or (13) are linearly independent and the problem of singularity of the matrix does not occur. The latter case is closely related to the non-singular properties of the Vandermonde matrix [41].

The fit of the approximating function $pK = pK(x)$ to the data $\{(x_j, pK_j)\,|j = 1, \ldots, N\}$ obtained, by recalculations, from N experimental points $\{(V_j, pH_j)\,|j = 1, \ldots, N\}$ is expressed by the variance (s^2) value:

$$s^2 = s^2(n) = \frac{\sum_{j=1}^{N}(pK_j - pK(x_j, n))^2}{N - n - 3} \tag{23}$$

where n is the upper number in the sum on the right side of Eqs. (12) or (13); $pK(x_j, n)$ is the pK value calculated at $x = x_j$ from the model with $n + 1$ components in the sum involved in these equations; $N - n - 3$ is the number of degrees of freedom.

4. Experimental

4.1. Apparatus and reagents

The pH titrations: HL/H_2O ⇔ HL/B were performed in 30 mL thermostated (20.0 ± 0.2 °C) cell using Cerko Lab System microtitration unit fitted with pH electrode (Hydromet – ERH-13-6 type) and Ag/AgCl reference electrode and a self-made measuring cell equipped with magnetic stirrer and PT 1000 system. The temperature was controlled in the Huber thermostat system. The electrode was conditioned in the organic solvent B (MeOH and Me_2SO for 15–30 min and calibrated before each titration in HL/H_2O + B system, with the use of buffer solutions: potassium hydrogen phthalate (pH 4.00), citric acid/Na_2HPO_4 (pH 7.00) and boric acid/KCl/NaOH

(pH 10.00) from Eurochem BGD Company. The electrode was stored in water or KCl standard solution when not in use. The potentiometric microtitrator was automatically controlled by PC system.

Benzoic acid (extra pure, >99.5%), pyridine-2-carboxylic acid, pyridine-3-carboxylic acid, pyridine-4-carboxylic acid, were purchased from Sigma–Aldrich Laborchemikalian GmbH. The pyridine carboxylic acids were purified by recrystallization before preparing solutions for titration. Pyrazine-2-carboxylic acid was synthesized by hydrolysis of pyrazine amide and recrystallized from water (m.p. 225–226 °C).

Doubly distilled water with conductivity approx. 0.18 μS/cm was freshly produced in order to avoid carbon dioxide absorption; it was used throughout for preparation of aqueous solutions of organic acids under study. Other solvents: methanol (MeOH, analytical grade, 99.8%) and dimetylsulphoxide (Me_2SO, HPLC grade, 99.5%) were supplied by POCH S.A.

4.2. Procedures

The pH titrations $HL/H_2O \Leftrightarrow HL/B$, with HL = BA, PY-2CA, PY-3CA, PY-4CA, and PZ-2CA; B = $(CH_3)_2SO$ or CH_3OH), were performed with the use of a Cerko Lab System equipped with a syringe pump. In all titrations, $C = 0.01\ mol\ L^{-1}$ and titrand volume $V_0 = 3.000$ mL were applied. The titrations were performed at least two times for each $HL/H_2O + B$ system tested. The stability of indication of the measuring system was also tested. The titration parameters were: $\Delta V = 0.0100$ mL and pause 10–20 s. The pK values were obtained on the basis of Eq. (2) from the experimental points $\{(V_j, pH_j)\ |j = 1, \ldots, N\}$ and the resulting set of points $\{(x_j, pK_j)\ |j = 1, \ldots, N\}$ was modelled with use of the approximating functions specified in Section 3.2. Then $pK_A = pK(0)$ and $pK_B = pK(1)$ were calculated from Eq. (19), with use of self-prepared computer program, based on application of the least-squares (LS) method in its classical version.

5. Results and discussion

Examples of titration curves in binary-solvent systems $HL/H_2O + B$ are presented in Fig. 2 (HL = PY-3CA, B = MeOH) and Fig. 3 (HL = PY-4CA, B = Me_2SO). The related pairs of curves intersect at $V_{int} = 2.94$ mL (Fig. 2) and $V_{int} = 3.07$ mL (Fig. 3), near to the expected value $V = V_0 = 3.00$ mL. It should be noted that the point of intersection in Fig. 3 lies in the x-region of relatively flat course of the curves, see Fig. 3. The coincidence $V_{int} \approx 3$ mL testifies very well about reversibility of processes occurred during the titrations.

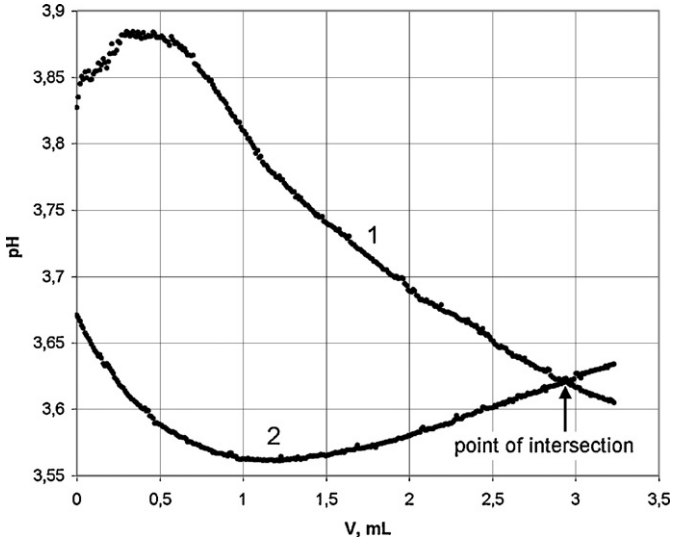

Fig. 2. The titration curves pH = pH(V) obtained for titrations: (1) $HL/H_2O \rightarrow HL/MeOH$ and (2) $HL/MeOH \rightarrow HL/H_2O$, where HL = PY-3CA.

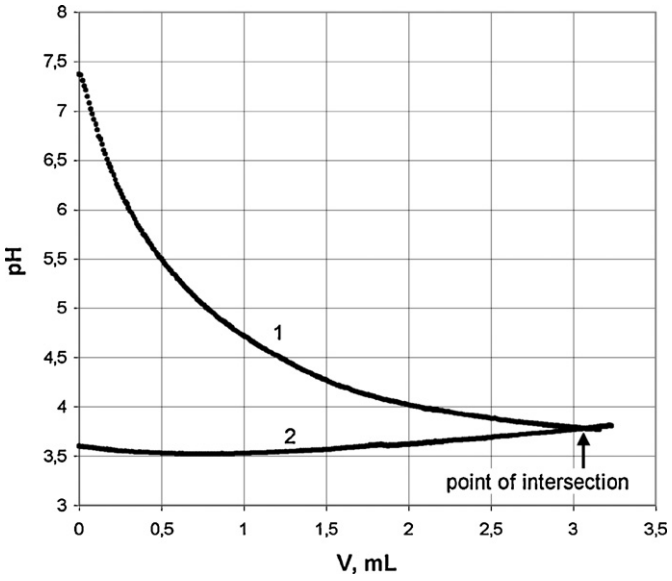

Fig. 3. The titration curves pH = pH(V) obtained for titrations: (1) $HL/H_2O \rightarrow HL/Me_2SO$ and (2) $HL/Me_2SO \rightarrow HL/H_2O$, where HL = PY-4CA.

Generally, the shape of the pH = pH(V) curve depends mainly on the co-solvent B used in the $HL/H_2O + B$ system. Particularly, the plot of pH-curves pH = pH(V) pass through extreme values for different acids HL applied in the titrations $HL/H_2O \Leftrightarrow HL/MeOH$ (Fig. 2) whereas the plots of the pH-curves in $HL/H_2O \Leftrightarrow HL/Me_2SO$ systems are monotonic [22] (Fig. 3), as a rule. The pH values, obtained at the start for titration $HL/H_2O \rightarrow HL/B$, i.e. at x-values close to 1 (see e.g. Fig. 2), are less repeatable than ones in the reverse titration $HL/B \rightarrow HL/H_2O$ and then the $pK_B = pK(1)$ values obtained from Eq. (2) for HL/B solution are doubtful.

The results $\{(V_j, pH_j)\ |j = 1, \ldots, N\}$ of titrations made in the system HL/H_2O + MeOH with HL = PY-2CA, PY-3CA, PY-4CA, were modelled with use of Eq. (12). The coefficients φ_0, φ_1, α_0, α_1, α_2, α_3, α_4 are specified in Tables 1–3, together with pK_A and pK_B values. As we see, the results obtained for $pK_B = pK(1)$ and $pK_A = pK(0)$ are repeatable within each series of titrations, at relatively low standard deviation (s) values stated at $n = 4, 3, 2$. The values obtained for pK_B and pK_A for defined system HL/H_2O + MeOH at $n = 4$ and 3 are similar, as a rule. It testifies in favour of the opinion that the R–E function with $n = 3$ appears to be sufficient for approximation purposes. The fit of the related curves $pK = pK(x) = pK(x, n)$ to the points $\{(V_j, pH_j)\ |j = 1, \ldots, N\}$, exemplified in Fig. 4 is excellent for $n = 4$ (and $n = 3$, as well). The values for $pK_A = pK(0)$ found for HL = PY-2-CA in titrations made in HL/H_2O + MeOH system (Table 1) are comparable with those found in $HL/H_2O + Me_2SO$ system (Table 2), when the results with the same n-values are compared. It testifies also about the repeatability of results obtained in different systems, where other values for the coefficients φ_i ($i = 0, 1$), α_j ($j = 0, \ldots, n$) are involved. At $n = 1$, the pK_B and pK_A assume lower values and s^2 values are relatively high. It is also confirmed by pK_B and pK_A values presented in Table 4, obtained with use of LOP function (Eq. (13)).

It can be stated (Figs. 5 and 6 a and b) that the asymmetry parameter ε in Eqs. (20) and (21) equalizes, to some degree, the effect resulting from lower n-value applied in approximating functions and the related curves cover nearly the same interval for pK_B and pK_A values.

Critical $F_c(f, f, \alpha)$ Snedecor's F-values at equal number of degrees of freedom, $f_1 = f_2 = f$, where $f = N - n - 3$ (see Eq. (23)) are equal to: 1.139 for $f = 640$ and 1.138 for $f = 650$, at confi-

dence level $\alpha = 95\%$. On this basis we have stated that application of Eq. (21) makes, as a rule, a significant improvement in variance (Eq. (23)) when compared with the M–S function (Eq. (20)). For example, the variances obtained at $N = 650$, $n = 4$, $\varepsilon = -0.4$ are: $1.0235/(650-7) = 15.92 \times 10^{-4}$ for Eq. (20) and $0.6116/(650-7) = 9.51 \times 10^{-4}$ for Eq. (21); then $F(643, 643, 0.95) = 1.674 > 1.139$.

The p*K* vs. *x* relationships for different acids are plotted for HL/H_2O + MeOH (Fig. 7a) and HL/H_2O + Me_2SO (Fig. 7b) systems; the enumeration of the curves is identical with those applied in Fig. 1. Nearly closely overlapped plots obtained on the basis of the related titration curves, exemplified in Figs. 2 and 3, are another proof of reversible behaviour of the indicator electrode applied in pH titrations.

Table 4
pK_A and pK_B values for HL = PY-4CA in HL/H_2O + Me_2SO system, found from Eq. (14) at different n-values.

n	pK_A	pK_B
4	5.228	12.766
3	5.225	12.844
2	5.220	12.848
1	5.007	12.494

The pK_A and pK_B values referred to different acids HL in (a) HL/H_2O + MeOH and (b) HL/H_2O + Me_2SO system are presented in Table 5.

The literature data for pK_A of the acids considered in this paper are scarce and incomplete. The pK_B values are unknown or not attainable in literature. The results obtained for pK_A are in satisfactory accordance with literature data. For example, the pK_A values for PZ-2CA in Table 1 are close to the value 2.79 [42]. The pK_A = 4.19 value [22] found for BA (Table 5) is close to 4.17 [43], 4.18 [44], 4.19 [45], 4.20 [46], 4.206 [47], 4.21 [48]. The pK_A values for PY-2CA (Table 1) are by ca. 0.1 higher than 5.47 [44] or 5.52 [49,50]. For PY-3CA, the values for pK_A (Table 1) differ significantly from 4.87 [44] and 4.90 [51]. The pK_A values for PY-4CA in Table 1 are somewhat higher than 4.96 [51].

Table 5
The pK_A and pK_B values obtained from Eq. (12) and referred to different acids HL (see Fig. 1) considered in HL/H_2O + MeOH and HL/H_2O + Me_2SO systems.

System		HL/H_2O + MeOH		HL/H_2O + Me_2SO	
No.	Acid, HL	pK_A	pK_B	pK_A	pK_B

6. Final remarks

The paper provides a new approach to modelling the systems with mixed solvents: H_2O + B, where B = MeOH or Me_2SO is the organic solvent, wholly mixed with water. The modelling aimed principally to get accurate $pK_B = pK(1)$ values for acids HL consid-

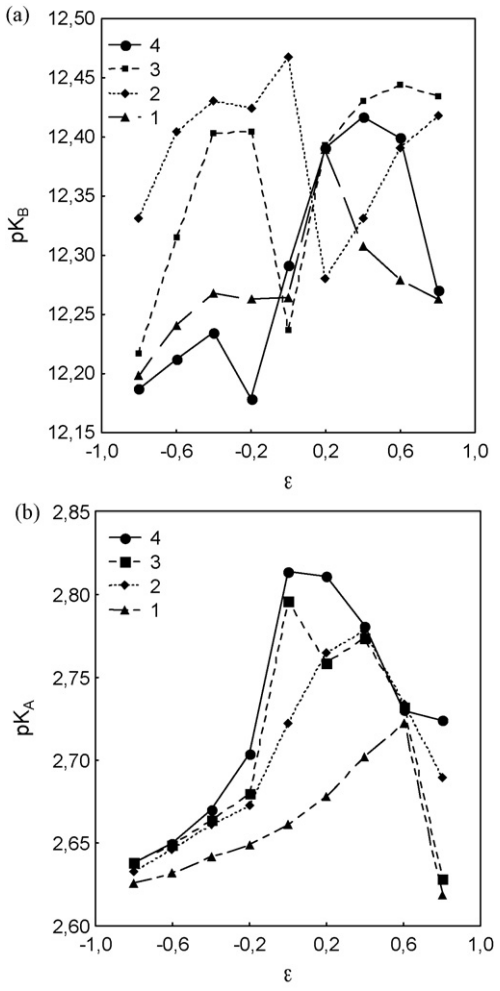

Fig. 6. The plots of (a) pK_A vs. ε and (b) pK_B vs. ε relationships for HL = PZ-2CA in HL/H_2O + Me_2SO system on the basis of Eq. (21) for n = 4, 3, 2, 1.

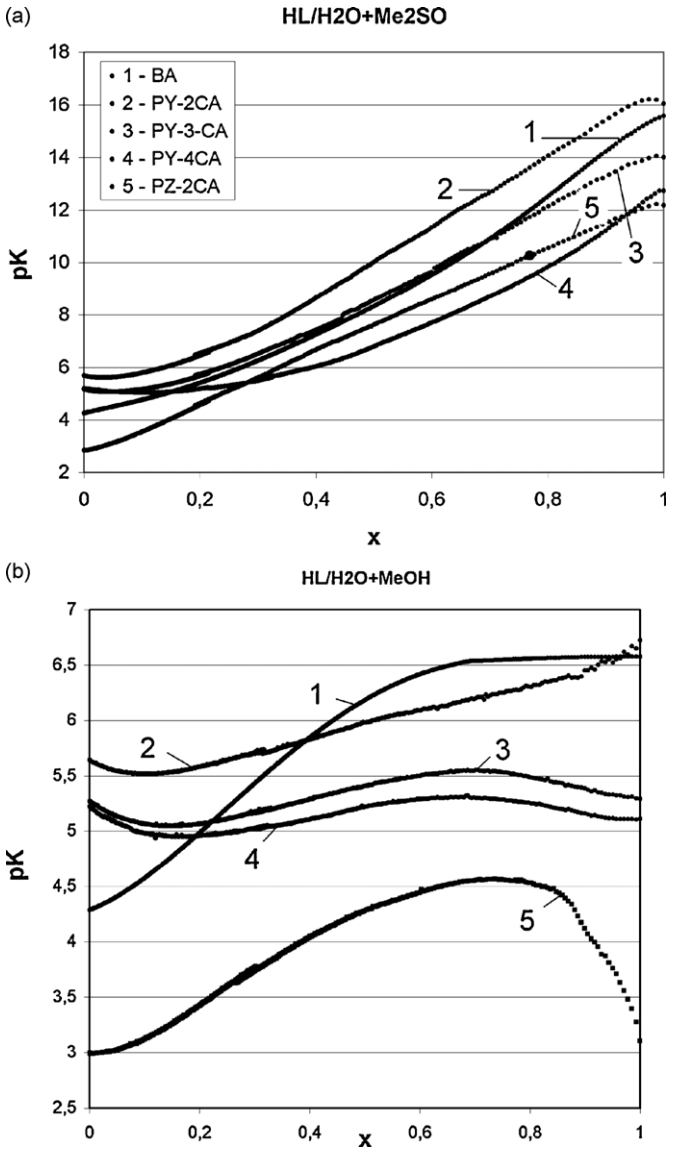

Fig. 7. The converted points referred to different acids HL in (a) HL/H_2O + MeOH and (b) HL/H_2O + Me_2SO system. Enumeration of the acids as in Fig. 1.

ered in pure organic solvent (B). An exact evaluation of pK_B is not an easy task from direct pH measurement in HL/B solution. The new approach is based on results obtained from mutual mixing two solutions, HL/H_2O and HL/B, of the same acids HL of the same molar concentration C, but dissolved in different solvents: H_2O and organic co-solvent B, respectively. The mixing is made according to titrimetric mode, with pH registration. This way, the entire x-range is covered by experimental points. The primary experimental points (V_j, pH$_j$) are recalculated in terms of the mole fraction (x) on the abscissa and pK on the ordinate and the (x_j, pK_j) points are obtained; some of the points can cover a common part of the x-range in both titrations: HL/H_2O → HL/B. The curves pK = pK(x) applied fit perfectly the experimental/transformed (Eq. (2)) results of titration, at n = 3 and 4 applied in the related functions: (12), (13), (20) or (21). The great advantage of this approach is the fact that the dispersed (in repeated titrations) points at x close to 1 do not affect substantially the pK_B = pK(1) value. Other advantage is the fact that pK_B and pK_A are calculated from the same formulae (Eq. (19)), irrespectively of the approximating function applied. The pK values for this system are obtained from Eq. (2), under assumption that pH = $-\log[H^+]$, i.e. at the activity coefficient of hydrogen ions equal to unity (γ = 1), see also [40].

All the remarks testify on account of the opinion that all approximating functions applied in this paper are applicable for modelling purposes. The results for pK_B are repeatable in the series of successive measurements. The pK_A values, referred to aqueous systems, are comparable with ones found in the literature.

Automated analytical methods
Enzyme inhibition

ABSTRACT

The development of new analytical techniques often requires the building of specially designed devices, each requiring its own dedicated control software. Especially in the research and development phase, LabVIEW has proven to be one highly useful tool for developing this software. Yet, it is still common practice to develop individual solutions for different instruments. In contrast to this, we present here a single LabVIEW-based program that can be directly applied to various analytical tasks without having to change the program code. Driven by a set of simple script commands, it can control a whole range of instruments, from valves and pumps to full-scale spectrometers. Fluid sample (pre-)treatment and separation procedures can thus be flexibly coupled to a wide range of analytical detection methods. Here, the capabilities of the program have been demonstrated by using it for the control of both a sequential injection analysis - capillary electrophoresis (SIA-CE) system with UV detection, and an analytical setup for studying the inhibition of enzymatic reactions using a SIA system with FTIR detection.

1. Introduction

Current trends in analytical chemistry clearly aim at developing fully automated, integrated analytical solutions, comprising necessary sample (pre-)treatment, the actual analyte detection, and data processing. Hence, nowadays, practically all newly developed analytical methods involve computers for system control and/or data recording. Yet, in research and development the configurations of the experimental set-ups change frequently, making it necessary to adapt not only the analytical system itself, but also very often the software. In this context, the possibility of flexible control software for the automation of an experimental set-up and the corresponding data analysis would be of great practical value. Such a software platform would allow quick adaptation of experimental set-ups to new findings and ideas, thus focusing on the evaluation of new approaches and characterisation of their analytical performance, rather than re-writing software.

LabVIEW, by National Instruments, is widely used as a control software development tool in both academic and industrial R&D. This software allows programming of virtual instruments (VIs), combining electronics with computer resources to control instruments and collect sets of data [1–3]. In contrast to C++ or Visual Basic for example, LabVIEW is a graphical programming language enabling the creation of high quality programs within short time periods. Typically, different (sub-)VIs, each fulfilling its own specific duties, are placed on a programming diagram and wired together. These virtual wires directly visualise the program and all data flows while writing the program, making it easier to interpret programs compiled by someone else and adjust them to specific needs. Furthermore, it also helps by keeping a sustainable knowledge base, allowing the handing over of software responsibility from one employee/student to another. Using controls and indicators from a large set of predefined elements, a user-friendly graphical user interface (GUI, called a panel) can easily be designed [4]. A final practical advantage of LabVIEW is that a parallelisation of code execution can easily be achieved, something that can be of great advantage, e.g. for decoupling data acquisition and data processing and evaluation.

A variety of previously published papers describe such LabVIEW-based programs aiming towards the automation of specific analytical systems fulfilling a particular task, including developing a new flow injection analysis (FIA) method by replacing the mixing coil with a continuously variable volume reactor [5], measuring picomolar concentrations of silver in seawater [6], monitoring particle/water interactions [7], determining morphine by a sequential injection analysis (SIA) system [8] or coupling such a system to a combined electro-generated chemiluminescence and amperometric detection [9]. Altogether, applications range from automating sample pre-treatment using a FIA system over autosampling devices to the possibility of combining versatile liquid handling with different kinds of detectors, like SIA with capillary

electrophoreses (CE) separation [10,11]. Irrespective of the actual analytical detection principle, a common denominator of these and many other analytical systems is the need to precisely handle fluids, very often different types of liquids. Still, each of these VIs is highly specialized and not very well suited to rapid adaptation for new systems and requirements.

This circumstance was the motivation behind the development described here. The goal was to develop a VI that allows the experimentalist to flexibly combine different laboratory equipment into new setups, without having to rewrite the control software. As outlined above, this requires combining fluid handling systems based, for example, on one of the various embodiments of flow injection, with different types of analytical detectors, and eventually some sort of analyte separation. A detailed analysis of these methods show that, while diverse and complex in overall operation, the active hardware core elements are essentially just a few pumps and valves. The resulting solution thus focused on designing a system that can flexibly control different such devices, irrespective of their specific combination or function in the analytical set-up. These functions are supplemented by a number of interfaces to optical detectors and auxiliary instruments, such as high-voltage supplies for CE separation.

The possibilities of the resulting control platform are demonstrated by successfully applying the identical control software to two widely different analytical devices, (i) a fully automated SIA-CE-UV system and (ii) label-free inhibition monitoring of an enzyme using a second SIA system coupled to an FTIR spectrometer. While the first analytical set-up includes capillary conditioning, sample preparation and analyte detection using a UV detector, the second example application requires rapid mixing of an enzyme solution with an inhibitor/substrate solution, transfer of the mixture into an IR measurement cell before the reaction of the enzyme with the substrate starts, and monitoring of minute spectral features changes over time.

2. Experimental

2.1. System components

In its present form, the program supports Vici's selection- and injection valves (Vici AG, Switzerland), Cavro's XP3000 and XL3000 syringe pumps and Smart Valves XL (Cavro Scientific Instruments, Sunnyvale, CA, USA), the kDS200 syringe pump (KD Scientific, Holliston, MA, USA) and Gilson's Miniplus peristaltic pump series (Gilson Inc., Middleton, WI, USA). For data acquisition, interfaces to both a UV detector (Dionex, Sunnyvale, CA, USA) and Bruker's FT-IR spectrometers (Bruker Optics GmbH, Ettlingen, Germany) have been implemented, together with a control device for a Spellman CZE 1000R high voltage power supply (Spellman, NY, USA).

The valves, the syringe pumps and the UV detector were interfaced to the PC running the LabVIEW VI using standard RS232 data connections, both for sending commands and receiving confirmation or error responses, which in turn allow the program to react to such events immediately. It is worth noting here that one RS232 interface can control up to nine different Vici valves.

The Gilson pump and the high voltage supply were connected via a cDAQ system from National Instruments using application specific protocols. For the Gilson pump this comprised two TTL signals, switching between the ON/OFF state and selecting the rotation direction, respectively, and a speed control in form of a continuously variable 0–5 V signal, corresponding to 0–100% of the maximum speed, as manually entered on the pump's control panel. The high voltage power supply was similarly controlled by a continuously variable 0–10 V input voltage signal, here corresponding to 0–30 kV output voltage.

Table 1
Typical example commands for sequence programming.

Command	Effect
PP*n*	Pick up *n* steps with the Cavro pump and do not wait to finish
PDW*n*	Dispense *n* steps with the Cavro pump and stay further program execution until it finishes
GO*n*|*k*	Switch the Vici valve with ID *n* to port *k*, choosing the fastest way (clockwise or counter-clockwise)
OS*n*|*k*	Start an IR measurement, where *n* is the number of spectra to be recorded and *k* the time between two spectra acquisitions in seconds
UV*n*|*k*	Start an UV measurement, where *n* is the sampling rate in microseconds and *k* the total measurement time in minutes
HV*n*|*k*	Apply *n* Volts in *k* seconds, using the Spellman high voltage power supply
SM	Stop running UV or IR measurements as soon as the Cavro syringe pump stops moving
WA*n*	Wait for *n* milliseconds
LOOP*n* END LOOP	Repeat the sequence between LOOP and END LOOP for *n* times

The Bruker spectrometers were controlled over a network connection through interaction with an OPC (OLE for Process Control) server, which is part of the "Process" package of the OPUS software. Due to the complexity of an IR measurement and to limitations in the OPC software itself, in its present development state the LabVIEW program is only capable of starting background and sample data acquisition; all setup parameters, such as optical resolution, number of scans as well as data post processing, have to be defined in a process control script in OPUS. Another restriction to the IR measurements is the fact that the "Process" package does not support rapid scanning or step-scan measurements yet.

Altogether, a large number of different system components can be integrated and controlled by the VI developed here, allowing the realisation of practically any relevant liquid sample pre-treatment. Furthermore, the modular approach of LabVIEW allows easy incorporation of sub-VIs for almost any other hardware component that can be controlled by LabVIEW.

2.2. The program

Since the program has been designed to control a variety of different hardware modules at once, and to keep the graphical user interface (GUI) as simple as possible (Fig. 1), all the commands controlling the hardware are entered in a text box (refer to Table 1 for command code examples out of more than 40 available commands). Every command is written on a separate line. This list of commands is then taken by the program code and executed from top to bottom. This approach keeps the graphical user interface simple and each of the sequences can be stored as plain text files for archiving. While running a sequence, all upcoming commands are displayed in a second text box in order to see the actual execution state of the sequence. The hardware setup parameters, including COM ports, channel numbers for the analogue outputs or the hostname of the computer running OPUS, can be entered in a separate setup area. The outputs of the UV detector and/or the IR spectrometer are displayed in two different tabs to save room on the GUI. A third tab holds all the error displays.

The internal design of the program code consists mainly of five parallel loops. The first loop, the master loop, executes the sequence entered by the user. When a command to move the plunger of the Cavro syringe pump is executed, a second loop is triggered by the master-loop, sending a notifier message to monitor the plunger movement. This can be done in parallel to the script execution, enabling data acquisition in the meantime, or the sequence can wait for the pump to finish its movement, which can be useful e.g.

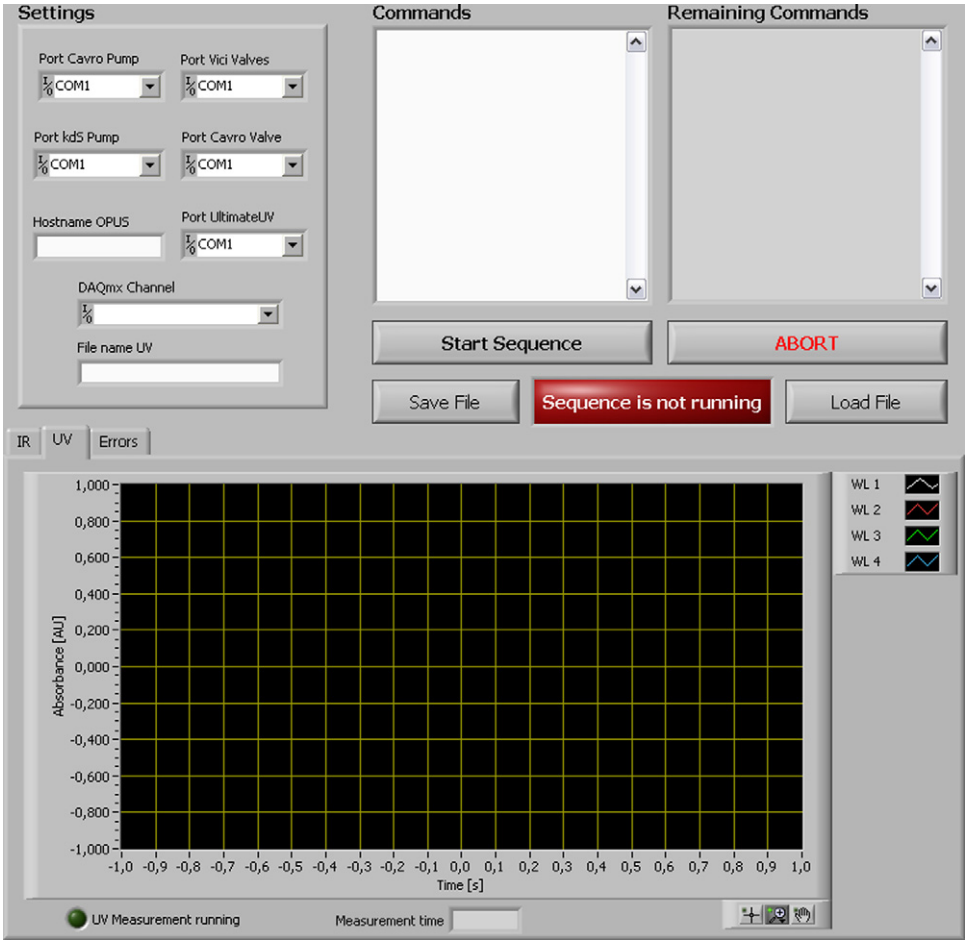

Fig. 1. Graphical user interface showing three different sections: in the upper row on the left is the communication port selector, on the right the interfaces for entering commands and surveying the sequence execution; in the lower row, a display with three tabs displays the data output of the UV and the IR detectors, and error messages, respectively.

during cleaning steps. The third loop polls an Abort button, so the user can terminate the script execution if an error occurs that is not recognized by the program itself. As soon as an error occurs or the Abort button is pressed, the program tries to shutdown any attached pump and the high voltage power supply. In addition, it switches to the error tab and displays a comprehensive error message. The two remaining loops handle IR and UV data acquisition. These two measurement loops are also triggered by the master-loop by a notifier message. The measurement loops will send back a notifier message to the main loop as soon as the measurement begins. This approach ensures that the entered sequence is kept in the event of any delay.

3. Results and discussion

3.1. Application I: sequential injection analysis – capillary electrophoresis with UV detection

Sequential injection analysis (SIA) is a viable tool to automate sample pre-treatment steps like pre-concentration and/or purification, applying chemical reactions and diluting samples. Capillary electrophoresis (CE) is a highly effective separation technique separating molecules by their charge to size ratio. Coupling SIA with CE has been successfully demonstrated in literature combining the advantages of both techniques making it even easier to apply conditioning or cleaning steps to the separation capillary. However, the main problem associated with this coupling arises from the discontinuous sample introduction mode of CE, where the system needs to be decoupled and coupled before and after the application of the separation voltage. This usually requires specially designed interfaces [11]. One of the first coupling systems by Arce et al. used a programmable arm to connect a FIA system to an at-line commercial CE analyzer [12]. Zacharis et al. used a special micro valve with a very low port-to-port volume and a CE capillary as a kind of injection loop [13] to couple the SIA system to the CE separation part. Wu et al. utilized a Lab-on-Valve approach for this purpose [14]. Both ways share the need for special equipment for the coupling process and the introduction of the electrodes needed to apply the separation voltage. Another approach by Kulka et al. used T-connection pieces connecting the capillary and the electrodes to the SIA system [10]. This manifold suffers from the fact that using capillaries with bigger inner diameters than 50 μm, as used by Kulka et al., can be problematic as the valve used to close the system for cleaning purposes creates some backpressure, even in the opened position. This results in the sample already being injected into the capillary while pumping it through the T-piece.

In the presented work the capillary is connected directly to an inexpensive valve, making special valves unnecessary, and overcoming pressure problems with capillaries.

3.1.1. Material and methods

3.1.1.1. Instrumentation. The manifold shown in Fig. 2 used a Cavro XP 3000 (Cavro Scientific Instruments, Sunnyvale, CA, USA) pump equipped with a 2500 μl syringe, a Valco (Valco Instruments Co.

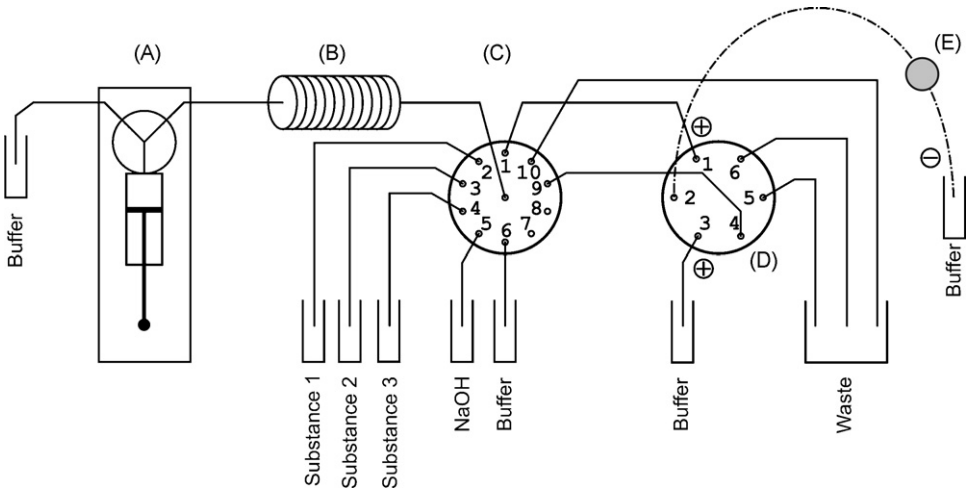

Fig. 2. Schematic view of the SIA-CE-UV manifold. (A) Cavro syringe pump; (B) 500 μl Teflon holding coil; (C) Vici selection valve; (D) Vici injection valve; (E) Capillary (100 μm ID) with UV detection window (not shown): Spellman high voltage power supply to apply 15 kV between the buffer reservoir and either Port 1 or Port 3.

Inc, Houston, TX, USA) six-port injection valve and a Valco ten-port selection valve. The HV system was a Spellman CZE 1000R (Spellman, New York, USA), capable of delivering up to 30 kV and 300 μA. Two metal tubings, each of the length of 2 cm, were connected to ports 1 and 3 of the injection valve and served as connections for the ground electrodes. The negative potential was applied by using a platinum wire (0.5 mm OD, ÖGUSSA, Austria) placed inside a glass vial. The capillary (Polymicro Technologies LLC, Phoenix, AZ, USA) had an ID of 100 μm, an OD of 350 μm, a total length of 60 cm and was covered by a Teflon tubing (1.588 mm OD) on the end connected to the injection valve. UV detection was achieved with a fiber optic Ultimate UV–Vis detector (Dionex, Sunnyvale, CA, USA) at 50 cm capillary length.

3.1.1.2. Procedure. A new capillary was first initialized by flushing it with 0.10 M sodium hydroxide and BGE buffer solutions using an automated sequence. By placing the injection valve in position B (ports 1–2, 3–4 and 5–6 connected), the syringe pump pressurized the whole SIA-CE system, forcing the solutions to flow through the capillary. Before each separation run the capillary was flushed, applying the same procedure with BGE buffer only. As the electrophoresis process alters the running buffer pH by electrolysis and subsequently changes the electro-osmotic flow (EOF), the separation buffer was renewed before every run by pumping buffer through port 9 of the selection valve.

The separation background electrolyte consisted of 100 mM phosphate buffer at pH 6.8. The UV detector was set to 241, 270 and 294 nm, corresponding to the absorption maxima of the three analytes, the applied voltage used for electrophoretic separation was 15 kV and samples were introduced into the capillary in the electrokinetic injection mode. The samples were prepared on the fly by aspiring small volumes of pyridine-2-aldoxime methochloride, thiamine and 1,10-phenantroline (3500 mg L^{-1} each) in a sequential order, repeating the sequence 10 times, into the holding coil. By varying the aspirated volume of each of the substances, different sample concentrations could be produced. In the electrokinetic injection mode, the sample flowed from the selection valve to port 1 of the injection valve, which was in position A (ports 1–6, 2–3 and 4–5 connected). Then, the injection valve changed to position B following counter clockwise rotation and the high voltage power supply applied a constant potential of 15 kV for 10 s. Finally, the 2-way valve switched back to position A by clockwise rotation connecting the capillary with the buffer reservoir at position 3 of the valve and the electrophoretic separation was initiated by applying 15 kV.

3.1.2. Results

The analytical performance of the SIA-CE-UV automated system was evaluated by considering the linearity, linear range, limit of detection (LOD), limit of quantification (LOQ) and precision expressed as relative standard deviation (RSD).

An electropherogram obtained is shown in Fig. 3. The linear relationships deduced between absorbance and drug concentration are summarized in Table 2. The LOD and LOQ were calculated as 3 and 10 times, respectively, the standard deviation of the intercept of the calibration line divided by the slope of the curve. The intra-day precision of the method was evaluated using the results obtained for five independent runs of 500 mg L^{-1} pyridine-2-aldoxime methochloride, 1000 mg L^{-1} thiamine and 500 mg L^{-1} 1,10-phenantroline standards mixture and the results were expressed as RSD. The linearity was tested using a pure error lack of fit test with simple regression, which was not significant at the 5% level.

3.2. Application II: SIA-FTIR coupling for enzymatic reaction monitoring

To demonstrate the suitability of the developed LabVIEW program for the automated control of analytical instrumentation in process monitoring and analysis of evolving systems, an enzy-

matic reaction, the dephosphorylation of fructose 1,6-bisphosphate (F16BP) to fructose 6-phosphate (F6P) and inorganic phosphate in the presence of divalent cations, such as Mg^{2+}, and its inhibition by adenosine 5′-monophosphate (AMP) was selected as a case study. In this way, the use of infrared spectroscopy allows the direct monitoring of enzymatic activity because of the specific absorption bands in the middle infrared spectral range providing molecular specific information on the substrate and reaction products.

The most critical step of reaction process monitoring, especially of enzymatic systems, is the accurate control of the process starting point. It is absolutely necessary to use of a fully automated system to define the starting point of the reaction, thus avoiding human error and thereby increasing the quality of the obtained analytical data. This problem has been overcome by using a SIA system coupled to a FTIR spectrometer both controlled by the developed LabVIEW program.

3.2.1. Material and methods

3.2.1.1. Instrumentation. Enzymatic experiments were carried out on an Equinox 55 FTIR spectrometer (Bruker Optics GmbH., Karlsruhe, Germany) equipped with a narrow band mercury cadmium telluride (MCT) detector. Spectra were recorded by co-adding 128 scans at a resolution of 4 cm^{-1} and a scanner velocity of 100 kHz HeNe frequency.

The IR cell consisted of a temperature-controlled aluminium flow cell [15] with CaF_2 windows (thickness 2 mm) separated by a polyethylene spacer of 25 μm, thus establishing a constant IR path length.

The SI manifold (Fig. 4) was set up with a Cavro XP 3000 syringe pump (Cavro Scientific Instruments, Sunnyvale, CA, USA; syringe size 5000 μL) and a Valco (Valco Instruments Co. Inc, Houston, TX, USA) 10 port selection valve. A 1.5 mL safe-lock Eppendorf tube placed in a TTS2 minishaker (IKA Works Inc., Wilmington, NC, USA) was used as a mixing chamber to ensure a complete and homogeneous mixing prior to measurement.

3.2.1.2. Procedure. Different and accurately measured volumes of F16BP, AMP and working buffer were aspirated sequentially into the holding coil, and delivered into the mixing chamber obtaining a final volume of 250 μL. After that, FBPase solution was added and homogenized by shaking. The mixture was injected into the carrier stream and the flow was stopped at a fixed time, with the bulk of sample in the flow cell. FTIR spectra were recorded for 15 min at equal time intervals of 30 s to monitor the course of the reaction taking place using the spectrum of the cell filled with working buffer as background.

Using FTIR difference spectroscopy enabled the monitoring of the progress of the enzyme catalyzed reaction even though enor-

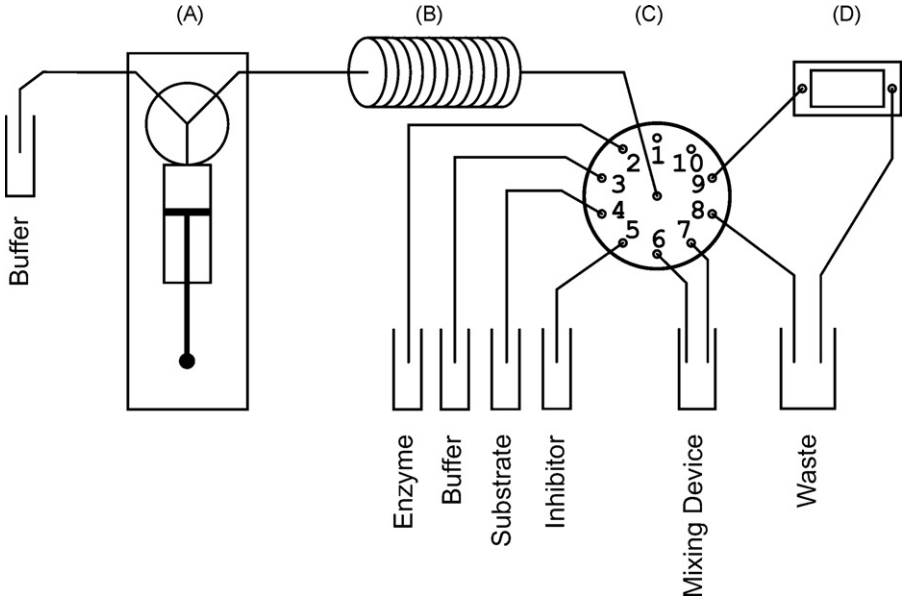

Fig. 4. Schematic view of the SIA-IR manifold for measuring enzymatic reactions. (A) Cavro syringe pump; (B) Teflon holding coil (500 μl); (C) Vici selection valve; (D) IR flow cell 25 μm path length.

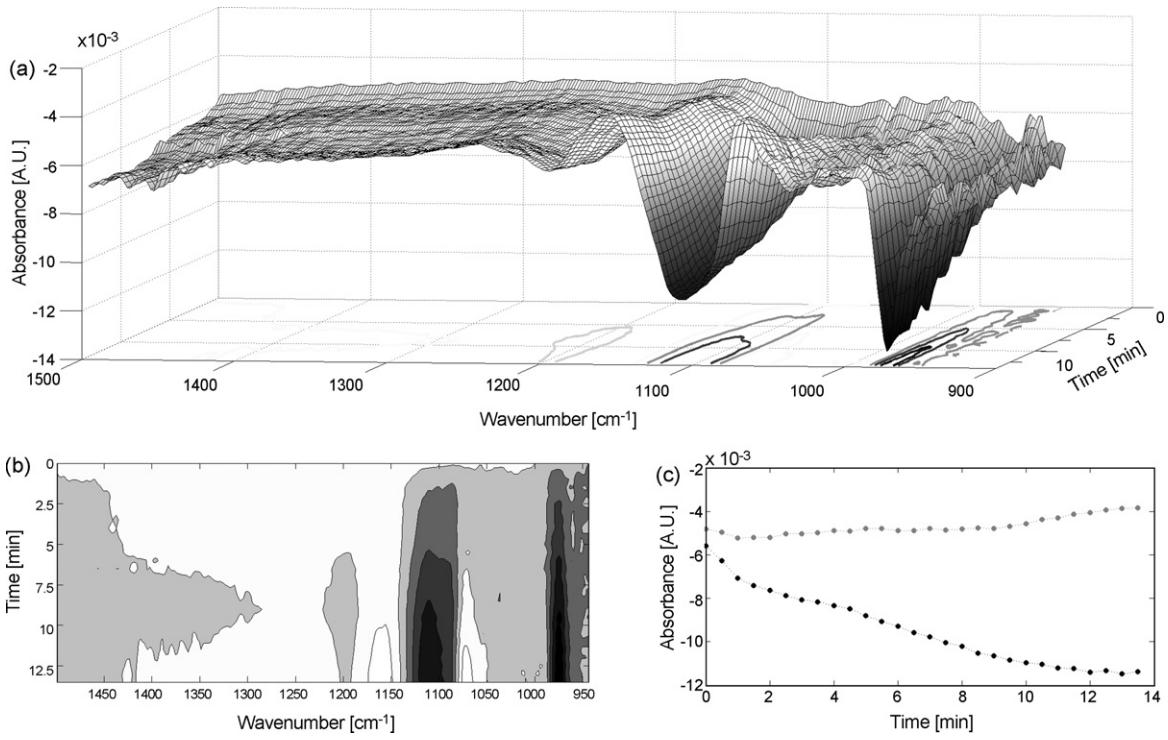

Fig. 5. FTIR difference spectra of the dephosphorylation of F16BP to F6P and phosphate in the presence of FBPase (a) three dimensional view, (b) projection on the space defined by the time and wavenumbers and (c) absorbance values of the selected wavenumbers (1109 and 1156 cm^{-1}) in the difference spectrum used for data evaluation.

mous similarities between the products and the substrate infrared spectra exist. Difference spectra, containing the spectral fingerprint of the reaction under investigation, were obtained by subtracting the first spectrum from the whole dataset, as it can be seen in Fig. 5. The absorbance difference between two selected wavenumbers (1109 and 1156 cm^{-1}), a maximum and a minimum, in the difference spectrum were used for data evaluation. The concentration of hydrolyzed F16BP was obtained by interpolation of those difference values in a calibration curve obtained from synthetic mixtures of substrate and products with the same data treatment.

3.2.2. Results

FTIR spectroscopy has been demonstrated to be an appropriate technique for the rapid investigation of enzymatic reactions [16,17] as the recording of a spectrum takes only a few seconds and is able to monitor the reaction of interest directly, in real-time. The starting point of the reaction can be accurately controlled and reproduced by using the automated SIA system for sample preparation and introduction into the FTIR cell. Thus, from the mixing of the enzyme with the substrate and buffer into the mixing chamber to the recording of the first spectrum only a few seconds (15 s approximately) passed, obtaining a highly reproducible starting point.

The Michaelis–Menten constant (K_M) can be determined in conditions of zero order kinetics with respect to the substrate. The K_M value was calculated from the Lineweaver-Burk graph, plotting the reciprocal of initial velocity against the reciprocal of substrate concentration. K_M was found to be 14.1 g L^{-1}.

Moreover, the inhibitor activity of AMP on the enzymatic dephosphorylation of F16BP at different inhibitor concentrations was evaluated. Kinetic studies demonstrate the capability of the methodology for label free monitoring of enzyme inhibition. The presence of increasing concentrations of the inhibitor AMP (0, 7.5 and 15 μM) reduces the maximum rate of the reaction without changing the apparent binding affinity of the catalyst for the substrate (Michaelis–Menten constant K_M^{App}). The obtained K_M^{App} values were determined to be 12.5 and 12.2 g L^{-1}, for 7.5 and 15 μM AMP, respectively. The results obtained were published in detail separately [18].

4. Conclusion and outlook

The developed LabVIEW program has been shown to be suitable for controlling various different liquid handling systems and coupling them to different analytical measurement techniques. The next steps will focus on expanding the program to work with other hardware, such as quantum cascade lasers or oscilloscopes. In essence, any hardware with LabVIEW drivers, or defined control interfaces reacting to specific input signals, could be incorporated into the program. Setting up an archive of relevant sub-VIs representing different hardware functionalities is another future step of this development. These VIs can be directly placed and wired in the program's case structure, executing corresponding hardware functionalities triggered by a command in a scripted sequence. This makes it easy even for inexperienced programmers to add new functionalities to the LabVIEW program.

If you are interested in using this program please do not hesitate to contact the authors by email.

Cell culture

ABSTRACT

A novel microfluidic chip integrating an osmosis-based micro-pump was developed and used for perfusion cell culture. The micro-pump includes two sealed chambers, i.e., the inner osmotic reagent chamber and the outer water chamber, sandwiching a semi-permeable membrane. The water in the outer chamber was forced to flow through the membrane into the inner chamber via osmosis, facilitating continuous flow of fluidic zone in the channel. An average flow rate of 0.33 μL min^{-1} was obtained within 50 h along with a precision of 4.3% RSD (n = 51) by using a 100 mg mL^{-1} polyvinylpyrrolidone (PVP) solution as the osmotic driving reagent and a flow passage area of 0.98 cm^2 of the semi-permeable membrane. The power-free micro-pump has been demonstrated to be pulse-free offering stable flow rates during long-term operation. The present microfluidic chip has been successfully applied for the perfusion culture of human colorectal carcinoma cell by continuously refreshing the culture medium with the osmotic micro-pump. In addition, in situ cell immunostaining was also performed on the microchip by driving all the reagent zones with the integrated micro-pump.

1. Introduction

Fluidic driving device is a key component for the transportation and distribution of liquid in a microfluidic system. An ideal driving device for this purpose should be featured by precision and stability in fluidic flow rate in addition to small scale. Since the application of electro-osmosis to microfluidic chip-based capillary electrophoresis [1], various micro-pumps have been exploited for microfluidic transportation [2], with diverse actuation mechanisms, e.g., piezoelectric [3], pneumatic [4], peristaltic [5], electrostatic [6], centrifugal [7], ultrasonic [8], electro-osmotic [9] or magneto-hydrodynamic effects [10]. For these approaches, however, external power supply is required. Power-free pumping methods have attracted considerable interests, including fluidic driving by gravitational approach [11]. Surface tension [12] or the combination of gravity and surface tension as the pumping force facilitates further miniaturization of the pumps, but it provides only short-term reliability [13]. Micro-pumps based on capillary and/or evaporation effects have also been used in microchip systems [14,15]. Recently, filter paper plug was reported as an on-chip integrated pump device [16], while the close dependence of flow rate on the ambient temperature and humidity limits its application.

The osmotic effect provides a potential power-free pumping approach. Osmosis plays an important role in fluidic transport in living organisms. The plant root hair cells entail the passage of water from a region of high water chemical potential to a region of low potential through a semi-permeable membrane (cell membrane), which allows small molecules to pass through but blocks larger molecules [17]. The driving force derives from osmotic pressure of the solute, and it has been used in microfluidics [18–20]. An osmotic microactuator was proposed and used for drug delivery in a microfluidic system [19,20]. Three different osmotic dispense pumps were reported to supply flow rate at 1 μL h^{-1} for a period of one year [21]. Another osmotic pump by simulating phloem loading in plant leaves with a hollow fiber as the permeable membrane and saturated salt solution as the driving reagent provided constant and pulse-free flow for 26 days [22]. Although these two types of pumps are durable, it is very difficult to integrate them into microchips owing to their complex structures.

Microfluidic chip provides ideal platforms for the study of cells. The scale of the microchannels is well suited to the size of cells, and the microfluidic flow feature mimics the in vivo cellular microenvironments. Continuously perfusion cell culture allows long-term cell cultivation owing to the constant supply of nutrients. Thus a variety of microfluidic perfusion culture strategies have been developed [23], and syringe/peristaltic pumps were usually used to deliver the culture media [24–26]. Gravity-driven pumping schemes were used for this purpose by providing steady pulse-free

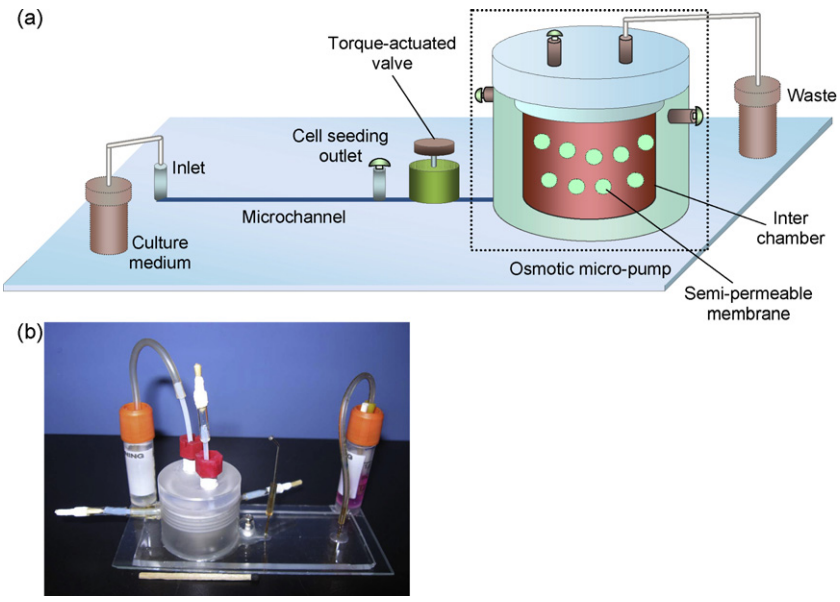

Fig. 1. Schematic diagram (a) and photograph (b) of the microfluidic chip integrating an osmotic micro-pump for perfusion cell culture.

flow [27]. Microfluidic perfusion culture lasting for two weeks was achieved [28]. However, the dead volume of the connecting tubes and off-chip valves brought long response time and large solution consumption. Therefore, some chip integrated micro-pumps were developed for cell culture. A computer controlled microfluidic perfusion cell culture platform was developed using integrated pumps and valves to precisely control fluidic flow [29], and a handheld recirculation perfusion platform was developed similarly [30]. An automated cell culture platform created arbitrary culture media formulations in 96 independent culture chambers and maintained cell viability for weeks using pneumatically actuated valves and pumps [31]. A similar cell culture platform with integrated pneumatic micro-pumps was used for high throughput drug testing [32]. Recently, electro-osmotic pumps were designed for cell culture in a microfluidic platform [33], but external energy sources and off-chip peripheral components were required, which is inconvenient when putting the devices into a CO_2 incubator or on the microscope platform. An osmosis-driven pump without bulky peripheral devices was developed for generating a concentration gradient of fetal bovine serum in the culture of human mesenchymal stem cells [34]. However, the osmotic pump, consisting of a PDMS chamber and a big vessel containing osmotic reagent solution, was connected to the chip by a tube instead of being integrated on the chip.

We have previously reported an off-chip osmosis-based pump for driving fluid [35]. In the present work, the osmotic pump was integrated on a microfluidic chip for perfusion cell culture and immunofluorescence staining. The micro-pump was positioned above the outlet of the microchannel, which provides pulse-free flow for the delivery of cell culture media.

2. Experimental

2.1. Fabrication of the device

The entire microfluidic chip integrating an osmotic pump is illustrated in Fig. 1. The chip (64 mm × 45 mm) is composed of two permanently plasma-bonded layers, i.e., the bottom glass substrate and the upper PDMS layer with microchannels of 500 μm (wide) × 80 μm (height) × 5 cm (length). There are two outlet holes located on the downstream channel, one serving as cell seeding outlet and the other connecting to the osmotic micro-pump (hidden under the osmotic micro-pump and not shown). A torque-actuated valve was integrated between the two holes for the control of opening/closing of the microchannel and the micro-pump. The valve was formed by fixing a small plastic block with a screw on the chip, and the opening/closing of the channel is facilitated by turning the screw to push down the PDMS layer [36].

The micro-pump was located at the end of the channel. It consists of a cup-shaped inner chamber and a cylindrical outer chamber. The inner chamber (1.5 cm in diameter and 1.6 cm in height) was used as the osmotic reagent reservoir (ca. 2.8 mL), and the outer chamber (2.4 cm in diameter and 1.4 cm in height) as the water reservoir (ca. 2.8 mL). An inlet and an outlet on the wall of the outer chamber were fabricated for the introduction of water. A semi-permeable membrane, i.e., a dialysis membrane (regenerated cellulose fiber, 16 mm i.d., Union Carbide, USA) with molecular weight cutoffs (MWCO) of 3500, was clamped tightly around the outside of the inner chamber wall using a flexible plastic pipe. Dozens of holes (2 mm in diameter) were drilled on the wall and plastic pipe, and total area of the holes serves as the effective osmotic area of the membrane. The inner chamber with membrane was assembled together with a plastic cap possessing an inlet and an outlet for the introduction of osmotic reagent. Then, the cap was screwed on the top of the outer chamber. A water-soluble polymer, polyvinylpyrrolidone (PVP, M = 30,000, Boai New Kaiyuan Pharmacy Co. Ltd, Henan, China), was used as the osmotic reagent.

2.2. Measurement of flow rate of the micro-pump

The flow rates of the micro-pump were measured with an electronic balance (Model BP211D, Beijing Sartorius Balance Co., China) by weighing the water driven out by the micro-pump within a defined period of time [15,16]. The waste outlet of the chip was blocked, and the inlet was connected with a plastic conduit addressing the water in a vessel which was positioned on the weighing pan of the balance. The water was covered by silicon oil to avoid evaporation during the operation. The micro-pump was placed in a sealed container of constant temperature. The temperature in the sealed container was controlled with a halogen lamp and a PID digital temperature controller (Model NE-6412–2, Shanghai Yatai Instruments, China).

2.3. Cell culture

The human colorectal carcinoma cell line CCL-187 was kindly donated by the Key Lab of Cell Biology of Ministry of Public Health, China Medical University. The CCL-187 cells were routinely maintained in Dulbecco's modified Eagle's medium (DMEM, Invitrogen, USA) supplemented with 10% fetal bovine serum (FBS), 100 U mL^{-1} penicillin (Amresco, USA) and 100 mg mL^{-1} streptomycin (Amresco, USA). The cells were cultured in a glass culture flask, which was placed in a CO_2 incubator at 37 °C with 5% CO_2. The CCL-187 cells were detached from the culture flask using 0.25% trypsin in a 1.0 mM EDTA solution when they have grown to approximately 80% confluence. The cells were centrifuged in a centrifugal tube at 1000 rpm for 5 min and then suspended in the culture medium at a cellular density of ca. 5×10^5 cells mL^{-1}.

2.4. Cell culture in the microfluidic chip

The microfluidic device was entirely sterilized by autoclaving at 120 °C for 20 min. Afterwards, the semi-membrane was immersed in deionized water to avoid degradation. Deionized water and the phosphate buffer solution (PBS) were autoclaved at 120 °C for 20 min, and the PVP solution at 115 °C for 15 min.

The torque-actuated valve kept closed in the following operations. The channel for cell culture was pre-coated at 37 °C first with poly-L-lysine (PLL, Sigma, USA) for 0.5 h, and then with 0.01% sterile rat-tail collagen for another 0.5 h. The coated channel was rinsed for 10 min with sterile water driven by a syringe pump (Model MD-1001, Bioanalytical Systems, Inc., USA) at a flow rate of 20 μL min^{-1}. It was thereafter washed with PBS for 10 min, and then filled with culture medium. After the cell suspension was introduced into the microfluidic channel using a syringe pump at a flow rate of 5 μL min^{-1}, the microfluidic device was put into the incubator for 6 h to ensure attachment of the cells onto the channel. Subsequently, water was introduced into the outer chamber, and osmotic driving reagent into the inner chamber. The channel inlet was connected to a vessel containing the culture medium, and the inner chamber outlet was connected to a waste bottle. Then the torque-actuated valve was opened, and the osmosis pump began working and continuously delivering the culture medium for the perfusion cell culture. Thereafter, the microfluidic device was placed again into the incubator. The osmotic driving reagent was refreshed every two days in order to keep long-term stability of the flow rate during the cell culture process. The osmotic driving reagent was completely refreshed to avoid any potential variation of its concentration. In addition, the connection between the microchannel and the osmotic pump was controlled by using torque-actuated valve in order to minimize the introduction of air bubbles into the system. All these procedures were carried out under sterile conditions.

2.5. Immunostaining on the microchip

The CCL-187 cells were cultured in the osmotic micro-pump integrated microchip for 24 h in the incubator, and identified by means of in situ indirect immunofluorescence staining. The osmotic micro-pump was employed for driving fluids in the following process. First, PBS was continuously driven into the microchannel for 5 min followed by introducing 1% bovine serum albumin (BSA, Sigma, USA) for 30 min to block the cells. Afterwards, the chip was placed in the incubator, and the first antibody, i.e., the murine monoclonal antibody ND-1 (diluted 1:100, provided by the China Medical University), was successively loaded for 1 h, and then the channel was washed with PBS for 10 min. The second antibody, i.e., the fluorescein-conjugated AffiniPure goat anti-mouse IgG (diluted 1:100, Zhongshan Goldenbridge Biotechnology Co. Ltd., Beijing, China), was used to incubate cells in the incubator for 1 h. The PBS solution was delivered once again for 10 min to wash away the free antibody, and the chip was right away placed on the platform of a fluorescence microscope (NMIL, Leica Co., USA) to obtain the fluorescent images of the cells excited by blue light.

3. Results and discussion

3.1. Considerations in the design of the osmotic micro-pump

Osmosis is a passive transport mechanism of fluids for achieving concentration balance in living organisms. Osmotic pressure π is expressed by van't Hoff's law [37]:

$$\pi = CRT \quad (1)$$

where C is the mole concentration of the solute, R the gas constant and T the absolute temperature. The volumetric flow rate of water across the membrane is thus given as [38]:

$$J = K \cdot A \cdot (\sigma \Delta\pi - \Delta P) \quad (2)$$

where J is the volumetric flow rate, K the water permeability of the membrane, A the effective area, $\Delta\pi$ the difference in osmotic pressure across the membrane, ΔP the difference in hydrostatic pressure, and σ the osmotic reflection coefficient of the membrane, which depends only on the characteristics of the membrane and the type of solute. When pure water is used as the driven fluid, $\Delta\pi$ is equal to the osmotic pressure of the solute. By neglecting the hydrostatic pressure difference between the two sides of the membrane, Eq. (2) can be simplified as

$$J = K \cdot A \cdot \sigma CRT \quad (3)$$

Eqs. (1) and (3) respectively indicated the dependence of the osmotic pressure on the concentration of the osmotic reagent and the dependence of flow rate on the concentration of the osmotic reagent. An ideal membrane, which is selectively permeable to water molecules but not to the osmotic driving reagent, should have an unity value of σ [38]. Thus the volumetric flow rate J will depend on the temperature, the concentration of the driving reagent and the characteristics of the semi-permeable membrane, e.g., area and permeability. In the present work, the water in the outer chamber moved across the semi-permeable membrane into the inner chamber containing osmotic reagent, resulting in a decrease of the pressure in the outer chamber, which actuated the flow of the fluid through the channel towards the micro-pump.

In a previous work, we reported a simple osmotic micro-pump consists of two reservoirs sandwiching a semi-permeable membrane [35], where an external tube was necessary to connect the micro-pump and the driven fluid. In the present work, the osmotic micro-pump was integrated on the chip without any additional tube, which reduced significantly the dead volume of the system and increased the reliability of the micro-pump.

According to the osmosis theory, the area of the semi-permeable membrane is one of the main factors affecting the flow rate. The chambers were designed into cylinder shape in order to obtain a larger membrane area for a micro-pump of limited dimension. The semi-permeable membrane is clamped around the outside of the inner chamber wall by plastic pipe. The effective area of the membrane can be adjusted by the number of holes drilled on the wall and the pipe, and the flow rate can be easily regulated by controlling the number of holes on the inner chambers.

The opening and closing of the micro-pump was facilitated by controlling a torque-actuated valve integrated on the chip. The valve was closed during the process of channel pretreatment and cell perfusion in order to avoid contamination of the water in the outer chamber.

3.2. Effects of various factors on the flow rate

The flow rates of the integrated osmotic micro-pump were investigated by varying the temperature, the osmotic reagent PVP concentration and the effective osmotic area. Table 1 illustrated a virtually constant flow rate within a temperature range of 22–42 °C, by fixing an osmotic area of 1.47 cm^2 and a PVP concentration of 50 mg mL^{-1}. It is obvious that only a slight variation of 0.03 μL min^{-1} was observed with a 20 °C increase of temperature, this well indicated the suitability of the integrated osmotic micro-pump for routine laboratories operated at ambient temperature.

Table 2 showed a linear dependence of the flow rate of water in the microchannel on the osmotic area, which is in accordance with that indicated in Eq. (3). This observation provides a convenient approach for the regulation of the flow rate by simply adjusting the effective area of the osmotic micro-pump.

PVP was chosen as the osmotic reagent because of its favorable biocompatibility and selective molecular weight. In the present work, PVP with molecular weight of 30,000 was used and the effect of its concentration within a range of 20–200 mg mL^{-1} on the flow rate of water was summarized in Table 3. A gradual increase of the flow rate was recorded with the increase of the PVP concentration. This phenomenon offers a further scheme for the control of the fluidic flow rate in the microchannel by varying the concentration of the PVP solution.

In practice, different fluids are drawn via the microchannel into the outer chamber. Consequently, various solutes dissolved in the fluid might cause fluctuation of the flow rate. The effect of the solutes on the flow rate was thus investigated by driving fluids containing solutes with different molecular weights,

Table 3
Effects of PVP concentration on the flow rate of water at 25 ± 1 °C and an osmotic area (evaporation area) of 1.47 cm^2.

PVP concentration (mg mL^{-1})	20	50	100	150	200
Average flow rate (μL min^{-1})	0.16 ± 0.01	0.36 ± 0.02	0.52 ± 0.02	0.66 ± 0.05	0.78 ± 0.03
RSD (n = 30)	2.9%	4.4%	3.1%	6.8%	4.0%

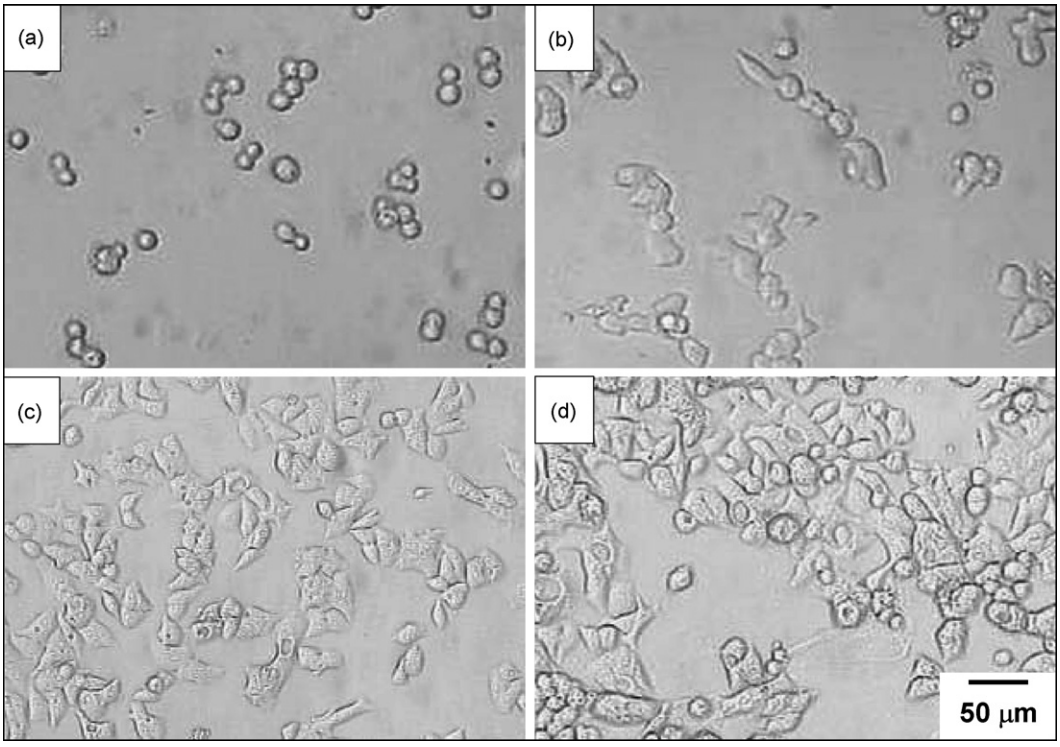

Fig. 3. Microscope images of CCL-187 cells cultured in the microfluidic chip. (a) 0 h; (b) 48 h; (c) 72 h; (d) 96 h.

e.g., sodium chloride, PBS and bovine serum albumin (BSA). The flow rates of 1.0 mol L^{-1} NaCl solution and 0.1 mol L^{-1} PBS were 0.44 μL min^{-1} and 0.46 μL min^{-1}, respectively by using an osmotic area of 1.96 cm^2, a PVP solution of 50 mg mL^{-1} and a temperature of 25 ± 1 °C. These flow rates are almost identical with that of water, i.e., 0.48 μL min^{-1} (Fig. 2a). This might be because that the diameters of inorganic ions are much smaller than the pore size of the membrane (MWCO 3500 of the dialysis membrane), and thus facilitates their free traveling through the membrane. Fig. 2b illustrated that the flow rate of BSA solution at 2 mg mL^{-1} was virtually constant in comparison with that of water. However, the increase of BSA concentration results in a gradual decline of the flow rate, and an obvious decrease was encountered after running the micro-pump for 10 h by continuously driving BSA solution of 50 mg mL^{-1} or 100 mg mL^{-1}. In fact, the molecular weight of BSA is larger than the MWCO of the membrane. As a result, the BSA molecules were blocked and accumulated outside the membrane, and thus a reverse osmotic pressure was generated, leading to a decline of the flow rate. The reverse osmotic pressure is negligible at a lower BSA concentration, while it becomes much stronger at higher BSA concentration and the drop of the flow rate has to be carefully considered in such a case. In the following cell culture experiment, the culture medium containing a total protein of 3.8 mg mL^{-1} was driven by the osmotic micro-pump. Similar trends of flow rate variation of the culture medium and water were observed within 20 h (Fig. 2c).

It is demonstrated that the osmotic micro-pump was capable of providing pulse-free flow in the absence of external power supply. When using a 100 mg mL^{-1} PVP solution as driving reagent, an osmotic area of ca. 0.98 cm^2 and a temperature of 25 ± 1 °C, an average flow rate of 0.33 μL min^{-1} was obtained within 50 h, with a precision of 4.3% RSD (n = 51). A maximum output pressure of 11.1 kPa for the micro-pump was achieved by using a measurement procedure reported previously [15]. The micro-pump can thus be operated for a long period by regularly replacing the osmotic reagent in the inner chamber.

3.3. Continuous perfusion cell culture

Microfluidic perfusion culture provides an opportunity to keep the culture environment more stable compared with traditional static culture mode. Continuous nutrition supply and waste removal were realized by means of the flow of fluids. In the present work, the microfluidic chip integrated with an osmotic micropump was used for cell perfusion culture. It is convenient to put the entire microfluidic system into the incubator. Considering that the PDMS cover layer has favorable gas permeability, it thus provides sufficient oxygen for keeping the cells in good condition during the culture process. The culture channel was pre-coated with poly-L-lysine and rat-tail collagen for enhancing the cell attachment on the channel surface.

The flow rate of the culture medium drawn into the culture channel by the osmotic micro-pump has obvious effect on the culture of cells, and its effect was investigated within a range of 0.2–0.9 μL min^{-1}. The results indicated that at a lower flow rate of 0.2 μL min^{-1}, very tiny bubbles were observed in the microchannel after 24 h. Owing to the gas-permeable property of PDMS and lower air pressure in the fluid, air bubbles might occur and grow until they occlude the microchannel and impede the flow as described in the literature [39]. In this respect, the bubbles would exert stress on the cells. Therefore, the elimination of bubbles is required. In our system, the bubbles can be readily carried away by the continuous flow of the culture medium at a flow rate of higher than 0.4 μL min^{-1}, while a large part of the cells cultured on the channel wall will be flushed away by increasing the flow rate up to 0.9 μL min^{-1}. Therefore, a flow rate of 0.4 μL min^{-1} for the culture medium was employed in the practice. This corresponds to a fluid shear stress of 0.37 dyn cm^{-2} on the cells attached on the channel [25,39]. This shear stress is significantly lower than those acceptable for common mammal cells [23].

The system was used successfully for continuous perfusion culture of CCL-187 cells. Fig. 3(a–d) showed the cell growth in the microchannel during a culture period of four days, indicating the

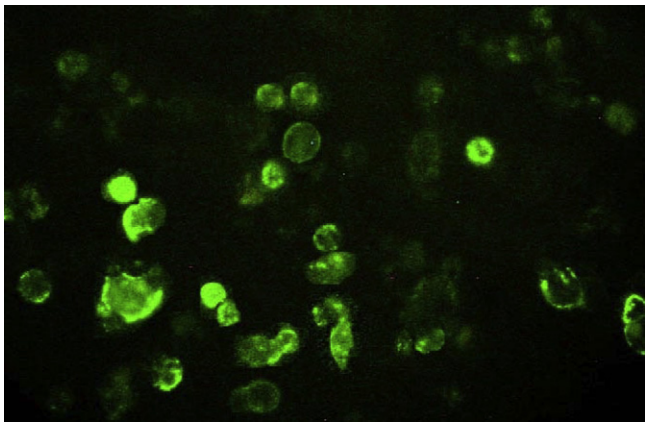

Fig. 4. Immunofluorescence micrograph of the CCL-187 cells labeled by ND-1.

attachment of the CCL-187 cells onto the channel wall followed by their elongation and gradual proliferation. The normal morphology and 95% viability of the cells cultured for four days were demonstrated by a Trypan Blue exclusion test. Further experiments illustrated that after seven days, the cells cultured began to aggregate with the increase of the number of cells in a limited channel space.

3.4. In situ cell immunostaining

An in situ indirect immunofluorescent staining was carried out to demonstrate the characteristics of CCL-187 cells cultured in the microfluidic device. The murine monoclonal antibody ND-1 has specific binding activity to the tumor-associated antigen LEA expressed in human colorectal carcinoma, which has high selectivity on well identifying colon carcinoma [40]. Fluorescein-conjugated affinipure goat anti-mouse IgG used as the second antibody has a maximal absorption at 492 nm. As shown in Fig. 4, the irradiated cells emitted green fluorescence via blue light excitation, showing a clear evidence for the remaining of the characteristics of the cultured CCL-187 cells. In the immunostaining experiment, the integrated osmotic micro-pump was desirable to deliver all the solutions by taking the advantages of less reagent consumption and minimized potential contamination.

4. Conclusions

A novel microfluidic chip integrating an osmosis-based micro-pump was developed.

The distinct features of the osmotic micro-pump include its simple structure by consisting of only two sealed chambers and a semi-permeable membrane, and the flow rate could be readily regulated by controlling the osmotic area of the membrane or the concentration of the osmotic reagent. In addition, the micro-pump is characterized by low fabrication cost, small dimensions and free operations without the need of external power supply. In comparison with the micro-pump based on evaporation effect, the osmotic micro-pump is independent on the humidity, and it is suitable for long-term operation at a steady flow rate by regularly refresh the osmotic reagent.

The feature of the osmotic micro-pump integrated microfluidic chip was illustrated by on-chip perfusion culture of the human colorectal carcinoma cell line CCL-187 with the osmotic micro-pump as fluidic driving device. The present osmotic micro-pump also has the potential in other applications, e.g., microfluidic flow injection system and fluid driving in parallel channels.

ABSTRACT

Conductive composite film which contains nafion (NF) doped multi-walled carbon nanotubes (MWCNTs) along with the incorporation of poly(malachite green) (PMG) has been synthesized on glassy carbon electrode (GCE), gold and indium tin oxide (ITO) electrodes by potentiostatic methods. The presence of MWCNTs in the composite film (MWCNTs–NF–PMG) enhances surface coverage concentration (Γ) of PMG to ≈396%, and increases the electron transfer rate constant (k_s) to ≈305%. Similarly, electrochemical quartz crystal microbalance study reveals the enhancement in the deposition of PMG at MWCNTs-NF film. The surface morphology of the composite film deposited on ITO electrode has been studied using scanning electron microscopy (SEM) and scanning tunneling microscopy (STM). These two techniques reveal that the PMG incorporated on MWCNTs–NF film. The MWCNTs–NF–PMG composite film also exhibits promising enhanced electrocatalytic activity towards the simple aliphatic alcohols such as methanol, ethanol and propanol. The electroanalytical responses of analytes at NF–PMG and MWCNTs–NF–PMG films were measured using both cyclic voltammetry (CV) and differential pulse voltammetry (DPV). From electroanalytical studies, well defined voltammetric peaks have been obtained at MWCNTs–NF–PMG composite film for methanol, ethanol and propanol at Epa = 609, 614 and 602 mV respectively. The sensitivity of MWCNTs–NF–PMG composite film towards methanol, ethanol and propanol in CV technique are 0.59, 0.36 and 0.92 $\mu A\,mM^{-1}\,cm^{-2}$ respectively, which are higher than NF–PMG film. Further, the sensitivity values obtained using DPV are higher than the values obtained using CV technique.

1. Introduction

Electropolymerization is a simple but powerful method in targeting selective modification of different type electrodes with desired matrices. However, the materials on the matrices do not possess peculiar properties when compared with those materials which are chemically synthesized by traditional methods. The electroactive polymers and carbon nanotubes (CNTs) matrices have received considerable attraction in recent years. Numerous conjugated polymers have been electrochemically synthesized for their application in the fabrication of chemical and biochemical sensor devices [1–3]. These conjugated polymers for sensor devices exhibit interesting enhancement in the electrocatalytic activity towards the oxidation or reduction of several biochemical and inorganic compounds [4] where, some of the functional groups in polymers will act as catalyst [5–7]. In this article, the word "enhanced electrocatalytic activity" could be explained as both; increase in peak current and lower overpotential [8]. The wide variety of applications of matrices made of CNTs for the detection of inorganic and bioorganic compounds such as IO_3^-, ascorbic acid, etc., have already been reported in the literature [9–12].

Even though the electrocatalytic activity of conjugated polymers and CNTs matrices individually shows good results; some properties like mechanical stability, sensitivity for different techniques, and electrocatalysis for multiple compound detections are found to be poor. To overcome this difficulty, new studies have been developed in the past decade for the preparation of composite films composed of both CNTs and conjugated polymers. The rolled-up graphene sheets of carbon exhibit π-conjugative structure with highly hydrophobic surface. This unique property of the CNTs allows them to interact with organic aromatic compounds through π–π electronic and hydrophobic interactions to form new structures [13,14]. There were past attempts in the preparation of composite and sandwiched films made of polymer adsorbed on CNTs, and used them for electrocatalytic studies such as, selective detection of dopamine in the presence of ascorbic acid [15]. The sandwiched films were also been used in the designing of nanodevices with the help of noncovalent adsorption, electrodeposition, etc. [16].

Among these conjugated polymers, a group of them representing azines such as phenazines, phenothiazines, phenoxazines, etc., have a wide use in bioelectrochemistry as redox indica-

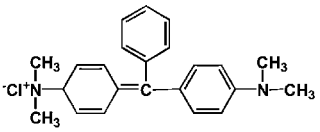
doi:10.1016/j.talanta.2009.08.034

tors and mediators [17]. The electropolymerization of azine group compounds are usually performed by anodic oxidation in acidic medium [18,19]. Similar to these azine dyes, malachite green (MG) is also a dye compound which has an open but ionized structure, and hence the resulting polymer is promising in exhibiting interesting features like fast rate of charge transfer and ion transport and nice catalytic ability towards small bio-molecules [20]. Previous studies reported poly(malachite green) (PMG) can be synthesized by electrochemical polymerization of malachite green. These studies also reported the growth mechanism of PMG along with the electrochemical, FT-IR and UV–vis studies [20,21]. The chemical structures of MG and PMG are given in Scheme 1.

The oxidation of simple aliphatic alcohols to the corresponding products is an important transformation in organic synthesis. Recently, from the environmental point of view, various catalytic methods using oxidants have been reported [22–25]. Among these, methanol has been widely used in the direct methanol fuel cells at lower temperatures, where the methanol oxidation was done with the help of metal oxide catalysts [26,27]. Similarly, ethanol is the most common substance consumed by humans and it is frequently a contributory factor in a variety of accidents. Further, the determination of ethanol is very important to control the fermentation processes in some industrial fields, which includes the pulp, food and beverage industries. The measurement of ethanol is particularly needed for quality control of beer, wines and spirits [28–30]. The oxidation of propanol is also an important transformation in laboratory and industrial synthetic chemistry, which could be used as important intermediate for the synthesis of chemicals [31]. Various methods have been reported for the determination of simple aliphatic alcohols with the help of different techniques [28,32]. Within these several methods of determination, the electrochemical methods have more advantages over the others in sensing the analytes [33–35].

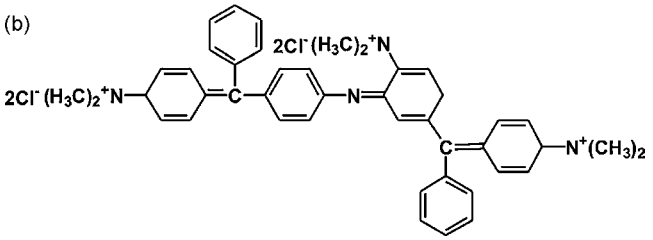
The literature survey reveals that there were no previous attempts made for the synthesis of composite film composed of CNTs, nafion (NF) and PMG for the use in sensor application. In this article, we report a novel composite film made of multi-walled carbon nanotubes (MWCNTs) which have been dispersed in NF, and incorporated with PMG. MWCNTs–NF–PMG composite film's characterization, enhancement in functional properties, peak current and electrocatalytic activity have also been reported along with its application in the determination of methanol, ethanol and propanol. The film formation processing involves the modification of electrodes with uniformly well dispersed MWCNTs–NF, and which is then modified with PMG.

2. Experimental



2.1. Materials

PMG, NF, MWCNTs (OD = 10–20 nm, ID = 2–10 nm and length = 0.5–200 μm), methanol, ethanol and propanol obtained from Aldrich and Sigma–Aldrich were used as received. All other chemicals used were of analytical grade. The preparation of aqueous solution was done with twice distilled deionized water. Solutions were deoxygenated by purging with pre-purified nitrogen gas. The pH 1.0 aqueous solution was prepared from H_2SO_4. The pH 4.0 aqueous solution was prepared from 0.01 M potassium hydrogen phthalate (KHP) solution, which was then added to 0.1 M Na_2SO_4 solution (1:1).



2.2. Apparatus

Cyclic voltammetry (CV), electrochemical quartz crystal microbalance (EQCM) and differential pulse voltammetry (DPV) were performed using analytical system models CHI-405, CHI-400 and CHI-750 potentiostats respectively. A conventional three-electrode cell assembly consisting of an Ag/AgCl reference electrode and a Pt wire counter electrode were used for the electrochemical measurements. The working electrode was glassy carbon electrode (GCE) modified with PMG, NF, NF–PMG or MWCNT–NF–PMG composite films. In these experiments, all the potentials are reported vs. Ag/AgCl reference electrode. The working electrode for EQCM measurements was an 8 MHz AT-cut quartz crystal coated with a gold electrode. The diameter of the quartz crystal is 13.7 mm; the gold electrode diameter is 5 mm. The morphological characterizations of the films were examined by means of scanning electron microscopy (SEM) (Hitachi S-3000H) and scanning tunneling microscopy (STM) (Being Nano-Instruments CSPM4000). All the measurements were carried out at 25 ± 2 °C.

(a)

(b)

Scheme 1. Chemical structure of MG and PMG.

2.3. Preparation of MWCNT–NF–PMG composite electrodes

The important challenge in the preparation of MWCNTs was the difficulty in dispersing them in to a homogeneous solution. Generally, the dispersion of CNTs has been carried out by physical (milling) and chemical methods (covalent and noncovalent functionalization). These methods cause damage to CNTs and add impurities to it [36,37]. To overcome these drawbacks, hydrophobic interaction between NF and MWCNTs has been used for our experiments [38,39]. Briefly, 5% NF prepared by adding 2 ml of NF in 10 ml water, which was used to disperse 10 mg of MWCNTs. The uniform dispersion of MWCNTs was obtained by 6 h ultrasonication of MWCNTs–NF mixture.

Before starting each experiment, GCEs were polished by BAS polishing kit with 0.05 μm alumina slurry, then rinsed and then ultrasonicated in double distilled deionized water. The GCEs studied were uniformly coated with 10 μl of MWCNTs–NF mixture (0.13 mg cm^{-2} of MWCNTs) and dried at room temperature. Then, MG (0.5 mM) was electropolymerized on the MWCNT–NF modified GCE, which was present in pH 4 KHP aqueous solution. The electropolymerization was performed by consecutive CVs over a suitable potential range of −0.3 to 1.4 V. Then, the modified MWCNT–NF–PMG electrode was carefully washed with double distilled deionized water. The concentrations of homogeneously dispersed MWCNTs–NF were exactly measured using micro-syringe.

3. Results and discussions

3.1. Electropolymerization of PMG at MWCNTs–NF composite film

The electropolymerization of MG (0.5 mM) using electrochemical oxidation on unmodified, MWCNT–NF modified, and only

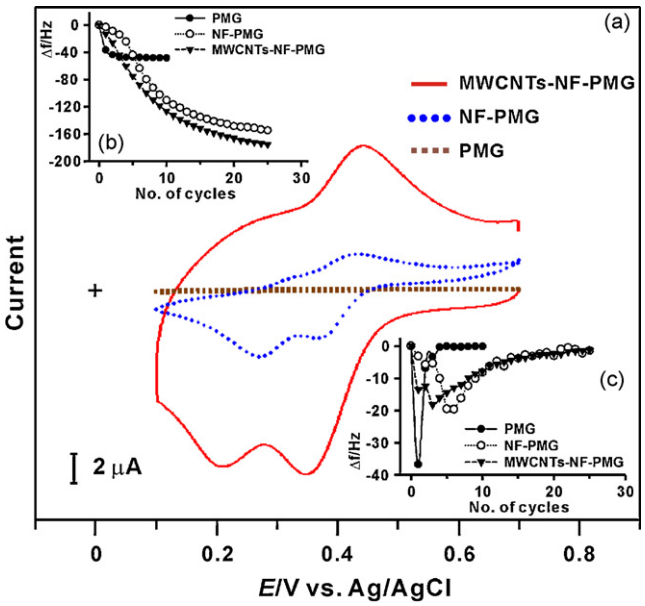


Fig. 1. (a) CVs of GCE modified from PMG, NF–PMG and MWCNTs–NF–PMG films in KHP solution, scan rate at 20 mV s^{-1}. EQCM frequency change responses recorded together with consecutive CVs (PMG formation on NF, MWCNTs–NF modified and unmodified gold electrodes, potential between −0.2 and 1.4 V; scan rate: 100 mV s^{-1}), where (b) shows the gross change in the frequency shift vs. scan cycles, whereas (c) shows the change between each consecutive scans.

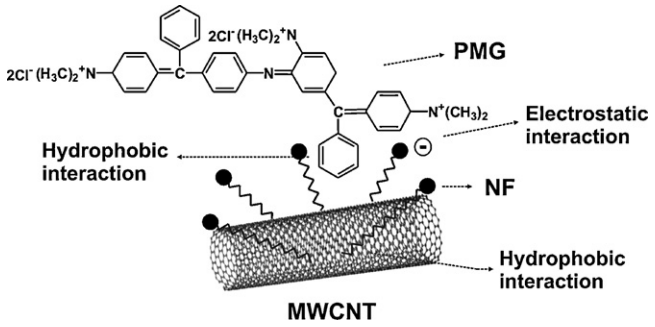
NF modified GCEs have been performed for the preparation and comparative studies of PMG, NF–PMG and MWCNT–NF–PMG composite films. On subsequent cycles, the redox peaks corresponding to PMG have found growing in all these films (figures not shown). This above result indicates that during the cycles, deposition of PMG takes place on the electrode surface. However, there are no peaks representing PMG appears at bare GCE. The optimized number of cycles for the deposition of PMG at MWCNTs–NF modified GCE using CV technique is 25. This optimization is done by observing the monomer oxidation current at Epa = 0.99 V, where the Ipa decreases during cycling and the oxidation peak disappears after 25 cycles. These above prepared three films (PMG, NF–PMG and MWCNT–NF–PMG) have been characterized using various electrochemical techniques in pH 4.0 KHP or pH 1.0 aqueous solution. Before transferring the films in to aqueous solution for other electrochemical characterizations, the prepared films have been washed carefully in deionized water to remove the loosely attached non-polymerized MG monomer on the modified GCE. Fig. 1(a) shows the reversible and irreversible redox couples of PMG, NF–PMG and MWCNT–NF–PMG modified GCEs. The corresponding CVs have been measured at 20 mV s^{-1} scan rate in the potential range of 0.7–0.1 V. Among these three films, the $E^{0\prime}$ values of both redox couples for MWCNT–NF–PMG composite film are at 395 mV (Redox-I) and 210 mV (Redox-II) vs. Ag/AgCl in KHP aqueous solution. Among these two redox couples, the $E^{0\prime}$ at 395 mV is the redox reaction of PMG and $E^{0\prime}$ at 395 mV could be the redox reaction of MG's dimer. The Epa, Epc and Ipc values of PMG at various film modified electrodes are given in Table 1. Interestingly the values in Table 1 reveal, MWCNT-NF modified GCE has higher polymerizing current for PMG than at other modified or unmodified GCEs. Further, the presence of MWCNTs in the MWCNT–NF–PMG composite film increases the overall back ground current. These above results represent more deposition of PMG on MWCNT-NF modified GCE than on other GCEs.

Table 2
Surface coverage concentration (Γ) of various species present in PMG at different modified electrodes obtained using CV studies.

Modified electrode	Type of film	Γ (pmol cm^{-2})	
		Redox-I	Redox-II
GCE	[a]-PMG	490	145
	[b]-PMG	2430	177
Gold	[a]-PMG	139	20.5
	[b]-PMG	229	115
ITO	[b]-PMG	675	–

[a] PMG electropolymerized on NF modified electrode.
[b] PMG electropolymerized on MWCNTs–NF modified electrode.



The increase in deposition of PMG in the presence of MWCNTs is evident with the active surface coverage concentration (Γ) given in Table 2 where, Γ of both species (Redox-I and -II) of PMG enhances at MWCNTs-NF film modified GCE when comparing at only NF and bare GCE. The calculated values from the same table shows that, MWCNTs enhances Γ of PMG by 15 pmol cm^{-2} μg^{-1}; and the overall increase in percentage of PMG Γ at MWCNTs film is 396%. In these Γ calculations, the number of electrons involved in PMG redox reactions is assumed as two. The comparison of PMG, NF–PMG and MWCNT–NF–PMG films on gold and indium tin oxide (ITO) electrodes are given in supplementary materials, which show that MWCNTs catalyze the PMG electropolymerization similar in that of GCE. However, the comparison of Epa and Epc values in Table 1 shows that the Redox-I of MWCNT–NF–PMG composite film at GCE and gold electrode is highly reversible than at ITO electrode, where ΔE at GCE and gold electrode is 93.2 mV and ITO electrode is 198 mV vs. Ag/AgCl. In these above experiments too, MWCNT-NF modified electrodes show higher polymerizing current for PMG than at other modified or unmodified electrodes, which are consistent with the Ipc and Γ values given in Tables 1 and 2, respectively. The possible interactions between MWCNTs, NF and PMG present in the composite film are given in Scheme 2, where the interaction between MWCNTs and NF is hydrophobic, and the interaction between NF and PMG is both hydrophobic and electrostatic interactions.

The MG electropolymerization is further confirmed using EQCM experiments, which have been carried out by modifying the gold in electrochemical quartz crystal with uniformly coated MWCNTs-NF or NF and then dried at 40 °C. The increase in voltammetric peak

Table 1
Epa, Epc and Ipc values of redox reactions of PMG at various modified electrodes present in pH 4.0 KHP aqueous solution.

Modified Electrodes		Epa (mV)	Epc (mV)		Ipc (μA)	
Electrodes	Films	Redox-I	Redox-I	Redox-II	Redox-I	Redox-II
GCE	[a]-PMG	434.5	366.9	270.8	−3.33	−1.41
	[b]-PMG	441.4	348.2	210.0	−10.42	−1.53

Scheme 2. Possible interactions between MWCNTs, NF and PMG present in MWCNTs–NF–PMG composite film.

current of PMG redox couple and the frequency decrease (or mass increase) are found to be consistent with the growth of PMG film on MWCNTs-NF or NF modified gold electrode (figures not shown). These results too show that the obvious deposition potential has started between −0.2 and 1.4 V. From the frequency change, the change in the mass of composite film at the quartz crystal can be calculated by the Sauerbrey equation (1), however 1 Hz frequency change is equivalent to 1.4 ng cm^{-2} of mass change [40,41]. The mass change during PMG incorporation on MWCNTs-NF modified, NF modified and unmodified gold electrodes for total cycles are 246, 217 and 68 ng cm^{-2} respectively.

$$\text{Mass change } (\Delta m) = -\tfrac{1}{2}(f_0^{-2})(\Delta f)A(K\rho)^{1/2} \quad (1)$$

where f_0 is the oscillation frequency of the crystal; Δf is the frequency change; A, the area of gold disk; K, the shear modulus of the crystal; ρ, the density of the crystal. Fig. 1(b) indicates the variation of frequency with increase of scan cycles for PMG at bare gold electrode, NF modified and MWCNTs–NF modified gold electrodes. Fig. 1(c) indicates every cycle of frequency with the increase of scan cycles for PMG at bare gold electrode, NF modified and MWCNTs–NF modified gold electrodes. These EQCM results prove that the deposition of PMG on the MWCNTs-NF film is more stabilized and more homogeneous than on the NF modified or bare gold electrodes.

3.2. Surface morphological studies of MWCNTs–NF, NF–PMG and MWCNTs–NF–PMG composite films

Three different films MWCNTs–NF, NF–PMG and MWCNTs–NF–PMG have been prepared on ITO electrodes with similar conditions and similar potential as that of GCE, and were characterized using SEM. Comparison of Fig. 2(a–c) reveals significant morphological difference between all the three films. The top views of nanostructures in Fig. 2(a) on the ITO electrode surface show uniformly deposited homogeneously dispersed MWCNTs in NF. The NF–PMG film in Fig. 2(b) shows elongated beads of NF and PMG deposited over ITO electrode surface. However, there are no bead formations if only NF coated over ITO, instead a porous NF film is formed (image not shown). Similarly, a uniform thin film with no morphology is formed for only PMG deposited over ITO electrode surface. The MWCNTs–NF–PMG composite film in Fig. 2(c) shows that plateaus of PMG formed over MWCNTs–NF film. Further, in Fig. 2(c) MWCNTs are not obviously visible as in Fig. 2(a), because PMG deposition covered over MWCNTs. These results in Fig. 2(c) could be explained as the increase in deposition of PMG over MWCNTs–NF, which creates plateaus instead of beads and covers over MWCNTs. The same three film modified ITO electrodes have been used to measure STM topography images shown in Fig. 3(a–c). The higher magnification (7 μm × 7 μm) of STM images than that of SEM images reveals that in Fig. 3(a)

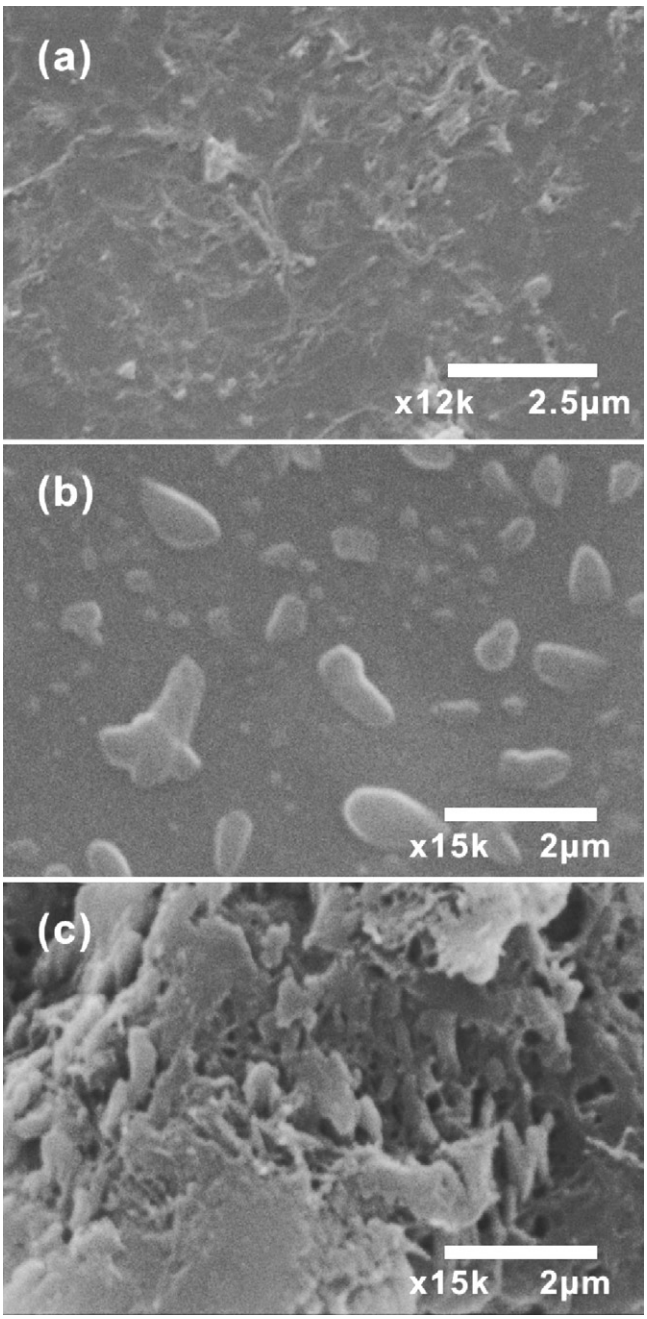

Fig. 2. SEM images of (a) MWCNTs–NF, (b) NF–PMG and (c) MWCNTs–NF–PMG films.

well dispersed MWCNTs in NF coated over ITO electrode. Similarly in Fig. 3(b), formation of nanometer sized grains in between PMG beads and in Fig. 3(c) more deposition of PMG over MWCNTs. These above details are not clearly visible in SEM images. Comparison of Fig. 3(a) with Fig. 3(c) also reveals that higher concentration of PMG deposited on MWCNTs modified ITO electrode, which is consistent with the Γ values shown in Table 2. Further, the thicknesses of MWCNTs–NF, NF–PMG and MWCNTs–NF–PMG obtained using STM results are 120, 70 and 180 nm respectively. These values too show MWCNTs–NF–PMG has higher thickness than the other two films, which is due to the presence of MWCNTs–NF covered under PMG film. These SEM and STM results reveal the coexistence of MWCNTs–NF and PMG in the composite film.

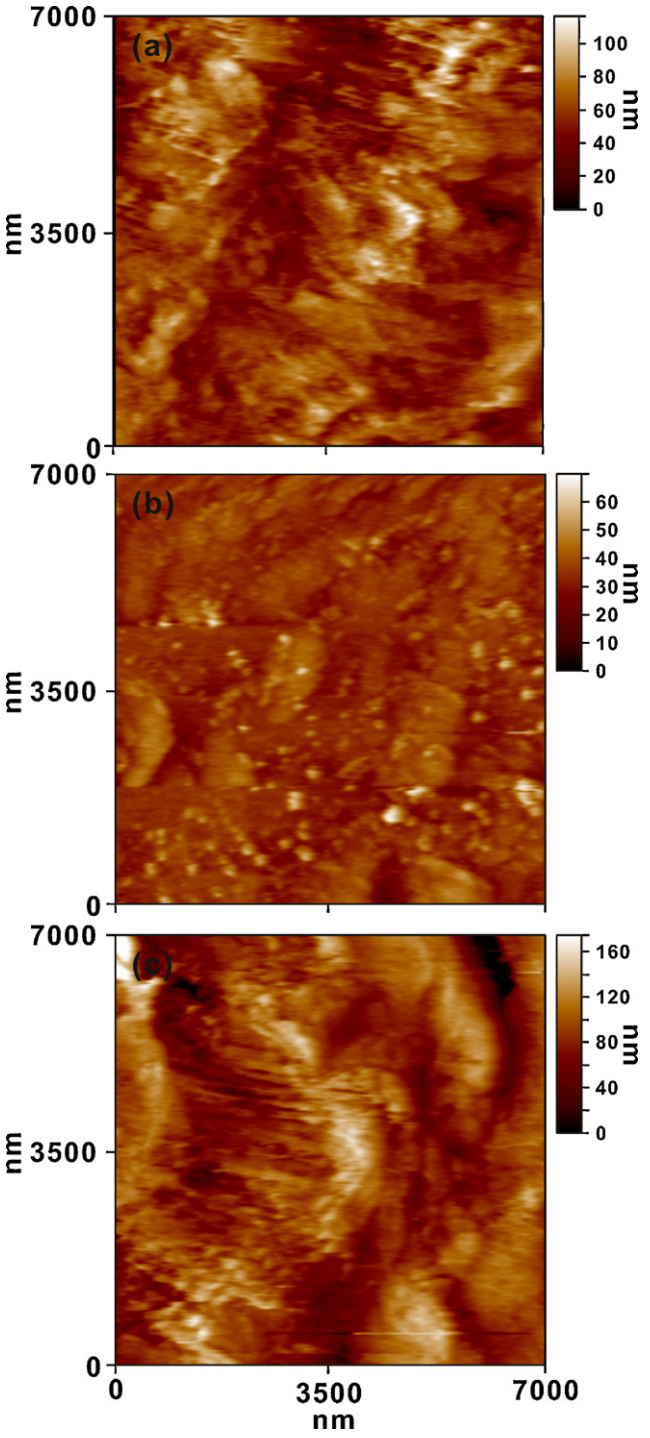

Fig. 3. STM images of (a) MWCNTs–NF, (b) NF–PMG and (c) MWCNTs–NF–PMG films.

3.3. Electrochemical and stability studies of MWCNTs–NF–PMG composite film

The CVs of NF–PMG and MWCNTs–NF–PMG composite films on GCE in pH 4.0 KHP aqueous solution at different scan rates show that the anodic and cathodic peak currents of the composite film's redox couple, which increases linearly with the increase of scan rates (figure not shown). The ratio of Ipa/Ipc for both the film demonstrates that the redox process is not controlled by diffusion. However, the ΔEp of each scan rate reveals that the peak separation of both film's redox couple increases as the scan rate increase. From the slope values of ΔE vs. log scan rate, by assuming the value of $\alpha \approx 0.5$, number of electrons involved as two, the electron transfer rate constant (k_s) has been calculated using Eq. (2) based on Laviron theory [42].

$$\log k_s = \alpha \log(1-\alpha) + (1-\alpha)\log \alpha - \log\left(\frac{RT}{nF\upsilon}\right) - \alpha(1-\alpha)nF\frac{\Delta E}{2.3RT} \quad (2)$$

In Eq. (2), the scan rate and ΔE values are in unit volts. The k_s values obtained are 0.12 and 0.49 s^{-1} for NF–PMG and MWCNTs–NF–PMG modified GCEs respectively. From these k_s values, the increase in ability of electron transfer between the electrode surface and PMG in presence of MWCNTs is ≈305%. The reproducibility of the obtained k_s values for both NF–PMG and MWCNTs–NF–PMG films have also been studied, where the relative standard deviation (RSD) values obtained are 5% ($n = 7$) for NF–PMG and 7% ($n = 7$) for MWCNTs–NF–PMG films. These results show the enhancement in functional property of MWCNTs–NF–PMG composite film in the presence of MWCNTs.

Fig. 4(a) shows the CVs of MWCNTs–NF–PMG on GCE obtained in pH 4.0 KHP aqueous solution, then washed with deionized water, and was transferred to various pH aqueous buffer solutions without the presence of MG. The results show that the film is highly stable in the pH range between 1 and 13. The values of Epa and Epc depend on the pH value of buffer solution. The inset in Fig. 4(a) shows the formal potential of MWCNTs–NF–PMG plotted over the pH range from 1 to 13. The response shows a slope of −65 mV pH^{-1}, which is close to that given by Nernstian equation for equal number of electrons and protons transfer. All these above results show the enhancement in functional properties of MWCNTs–NF–PMG composite film due to the presence of both PMG and MWCNTs.

The enhancement in stability of PMG in the presence of MWCNTs has been studied, and the percentage of degradation of MWCNTs–NF–PMG and NF–PMG calculated using an equation given in the previous literature [43]. The experimental results in Fig. 4(b) indicates the successive 280 min cycling (scan rate 20 mV s^{-1}) applied over a potential range of 0.1–0.7 V on MWCNTs–NF–PMG and NF–PMG in pH 4.0 KHP aqueous solution. The CVs have been recorded at the interval of 30 min each; from which the values of Ipc were noted and plotted against time. From these results it is clear that after 220 min the response of MWCNTs–NF–PMG becomes constant with time and cycling, indicating it is a stable film. However, the NF–PMG continues to degrade upon cycling. The amount of degradation after 280 min cycling for MWCNTs–NF–PMG and NF–PMG are 29% and 63% respectively. From this above result, the percentage of decrease in degradation of PMG in presence of MWCNTs is about 34% for 280 min cycling. Similar enhancements in CNTs with polymer composite properties when comparing CNT or polymer alone were already reported in the literature [44]. Repeatability of the stability studies have also been carried out at 280 min cycling for MWCNTs–NF–PMG film, where the RSD value obtained is 6% ($n = 3$).

3.4. Electroanalytical responses of methanol, ethanol and propanol at MWCNTs–NF–PMG composite film

The MWCNTs–NF–PMG composite film has been synthesized on GCE at similar conditions as given in Section 2. Then the composite film modified electrode has been washed carefully in deionized water and transferred to pH 1 aqueous solution for the electrocatalysis studies of methanol, ethanol and propanol. All the CVs have been recorded at the constant time interval of 1 min with nitrogen purging before the start of each experiments. Fig. 5(a–c) shows the electrocatalytic oxidation of methanol, ethanol and propanol

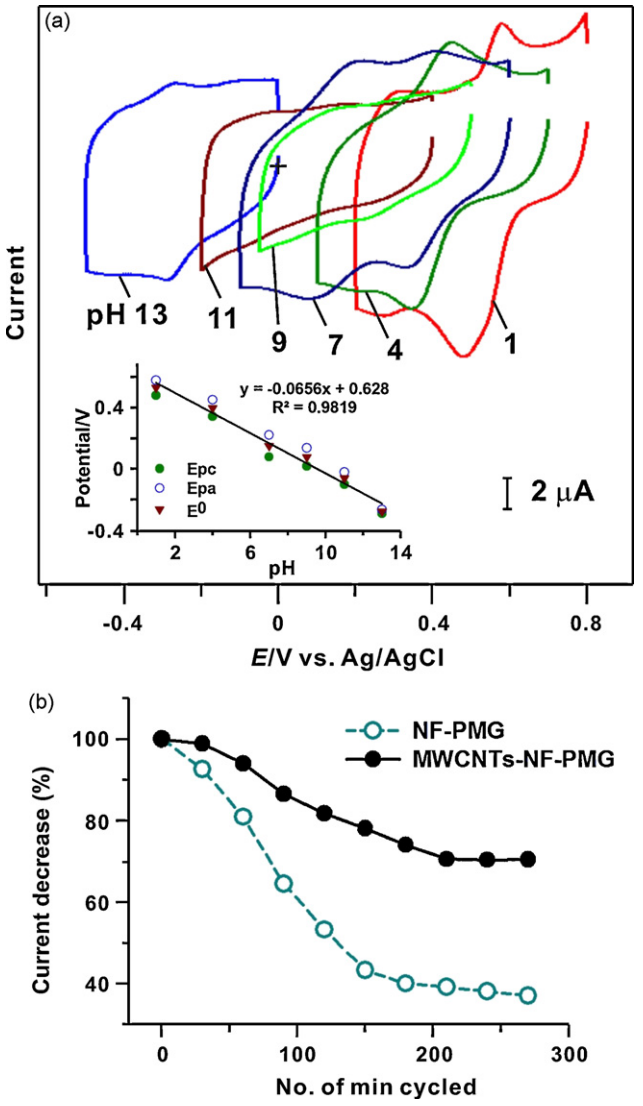

Fig. 4. (a) CVs of the MWCNTs–NF–PMG film synthesized using pH 4.0 KHP solution on GCE and transferred to various pH solutions. The insets shows Epa, Epc and the formal potential vs. pH from 1 to 13 (slope = −65 mV/pH), where the slope is almost nearer to Nernstian equation for equal number of electrons and protons transfer. (b) Number of minutes cycled vs. current decrease in (%) for NF–PMG and MWCNTs–NF–PMG films, which shows that MWCNTs–NF–PMG is highly stable when comparing with NF–PMG.

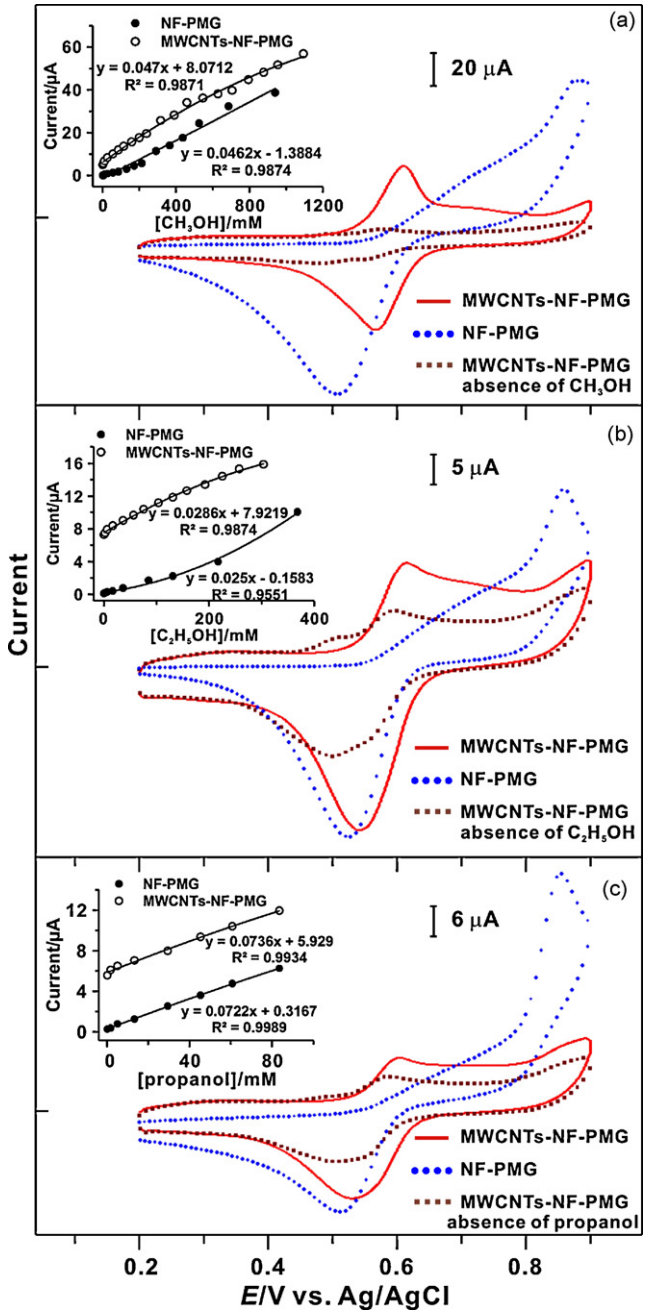

Fig. 5. The CVs in (a) is the comparison of 0 and 0.96 M of methanol at MWCNTs–NF–PMG with that of 0.96 M of methanol at NF–PMG in pH 1 aqueous solution; (b) is the comparison of 0 and 0.3 M of ethanol at MWCNTs–NF–PMG with that of 0.3 M of ethanol at NF–PMG at similar conditions and (c) is the comparison of 0 and 0.08 M of propanol at MWCNTs–NF–PMG with that of 0.08 M of propanol at NF–PMG at similar conditions. The insets in (a–c) show the plot of current vs. different concentration of methanol, ethanol and propanol respectively at MWCNTs–NF–PMG and NF–PMG. In these results, the analytes show higher electrocatalytic activity at MWCNTs–NF–PMG film.

at NF–PMG and MWCNTs–NF–PMG composite films respectively; scan rate 20 mV s^{-1}. In all the sections of Fig. 5, electrocatalytic activity at MWCNTs–NF–PMG composite films are shown with (higher concentration) and without the presence of analytes. However for NF–PMG film, only higher concentrations of analytes are shown, where the highest concentration of analytes are 0.96 M for methanol, 0.3 M for ethanol and 0.08 M for propanol. The CVs for MWCNTs–NF–PMG exhibits respective redox couples as discussed in Section 3.1 in the absence of analytes, and upon addition of analytes, new growth in the oxidation peak of respective analytes appears at Epa = 609, 614 and 602 mV for methanol, ethanol and propanol respectively. These peak currents show that electrocatalytic oxidation of all three analytes takes place at PMG redox couple. The methanol, ethanol and propanol oxidation at MWCNTs–NF–PMG composite film could be given by the following equations.

$$CH_3OH \rightarrow CO_{ads} + 4H^+ + e^- \quad (3)$$

$$C_2H_5OH \rightarrow CH_4 + CO_{ads} + 2H^+ + (1/2)e^- \quad (4)$$

$$(CH_3)_2CHOH \rightarrow C_2H_4 + CO_{ads} + 4H^+ + e^- \quad (5)$$

$$CO_{ads} + H_2O \rightarrow CO_2 + 2H^+ + 2e^- \quad (6)$$

In these above electrocatalysis experiments, an increase in concentration of methanol (3.12 mM) to (1.1 M), ethanol (2.06 mM) to (0.3 M) and propanol (1.65 mM) to (83.4 mM) simultaneously produces a linear increase in the oxidation peak currents of the respective analytes with good film stability at NF–PMG and

MWCNTs–NF–PMG films. The anodic peak currents are linear with the concentration of analytes. It is obvious that MWCNTs–NF–PMG shows higher electrocatalytic activity for the analytes. More specifically, the enhanced electrocatalytic activity of MWCNTs–NF–PMG can be defined in terms of both the lower in overpotential and higher peak current than that of NF–PMG film. These results can be observed from the Ipa and Epa values of various analytes, which are given in supplementary materials. Where, the increase in peak current and decrease in over potential; both are considered as the electrocatalytic activity [8]. The calculated limit of detections (LOD) at NF–PMG is 10.7 mM for methanol, 8 mM for ethanol and 1.8 mM for propanol. Similarly, the LOD at MWCNTs–NF–PMG is 8.3 mM for methanol, 5.1 mM for ethanol and 0.6 mM for propanol.

From the slopes of linear calibration curves, the sensitivities of NF–PMG and MWCNTs–NF–PMG composite film modified GCEs have been calculated. The sensitivity values of NF–PMG are 0.58 $\mu A\,mM^{-1}\,cm^{-2}$ for methanol, 0.31 $\mu A\,mM^{-1}\,cm^{-2}$ for ethanol and 0.90 $\mu A\,mM^{-1}\,cm^{-2}$ for propanol. Similarly, the sensitivity values of MWCNTs–NF–PMG are 0.59 $\mu A\,mM^{-1}\,cm^{-2}$ for methanol, 0.36 $\mu A\,mM^{-1}\,cm^{-2}$ for ethanol and 0.92 $\mu A\,mM^{-1}\,cm^{-2}$ for propanol. The correlation coefficients of linear calibration curves at NF–PMG are 0.9874, 0.9551 and 0.9989 for methanol, ethanol and propanol respectively. Similarly, correlation coefficients obtained at MWCNTs–NF–PMG are 0.9871, 0.9874 and 0.9934 for methanol, ethanol and propanol respectively. It is obvious that the sensitivity of MWCNTs–NF–PMG film is higher for all the three analytes when compared with NF–PMG film. The reproducibility of NF–PMG and MWCNTs–NF–PMG films on GCE has also been studied for all the three analytes using CV technique (36 h; $n = 4$). The results show that there is an enhancement in reproducibility for all the three analytes in presence of MWCNTs at the film. The values are 38% enhancement for methanol, 47% enhancement for ethanol and 62% enhancement for propanol in presence of MWCNTs. The overall view of these results, clearly reveal that MWCNTs–NF–PMG composite film is efficient than NF–PMG film for methanol, ethanol and propanol detection.

3.5. DPV studies of methanol, ethanol and propanol at MWCNTs–NF–PMG composite film

Fig. 6(a–c) shows the DPVs which have been obtained for methanol, ethanol and propanol at MWCNTs–NF–PMG composite film respectively. The DPVs have been recorded at a constant time interval of 1 min with nitrogen purging before the start of each experiment. They demonstrate that the calibration curves for the three analytes are linear for a wide range of concentrations; for methanol from 1.55 to 95.44 mM, ethanol from 3.09 to 72.48 mM and for propanol from 6.12 to 48.98 mM. The calculated LODs are 0.6 mM for methanol, 0.1 mM for ethanol and 6.9 mM for propanol. Similarly, the limit of quantifications (LOQ) is 2 mM for methanol, 0.4 mM for ethanol and 21.1 mM for propanol. From the slopes of linear calibration curves, the sensitivity of MWCNTs–NF–PMG composite film modified GCE towards all three analytes have been calculated. The sensitivity values are 19.62 $\mu A\,mM^{-1}\,cm^{-2}$ for methanol, 3.75 $\mu A\,mM^{-1}\,cm^{-2}$ for ethanol and 4.06 $\mu A\,mM^{-1}\,cm^{-2}$ for propanol. The correlation coefficients of linear calibration curves are 0.9786, 0.9933 and 0.9988 for methanol, ethanol and propanol respectively. When comparing these sensitivity values with the values obtained in CV studies reveals that DPV technique possess higher sensitivity than CV technique. These results show that DPV technique is more efficient than CV technique for methanol, ethanol and propanol detection at MWCNTs–NF–PMG composite film.

The interference of ascorbic acid (AA) and uric acid (UA) during methanol determination has been studied using DPV technique. In these experiments, methanol concentration has been kept constant

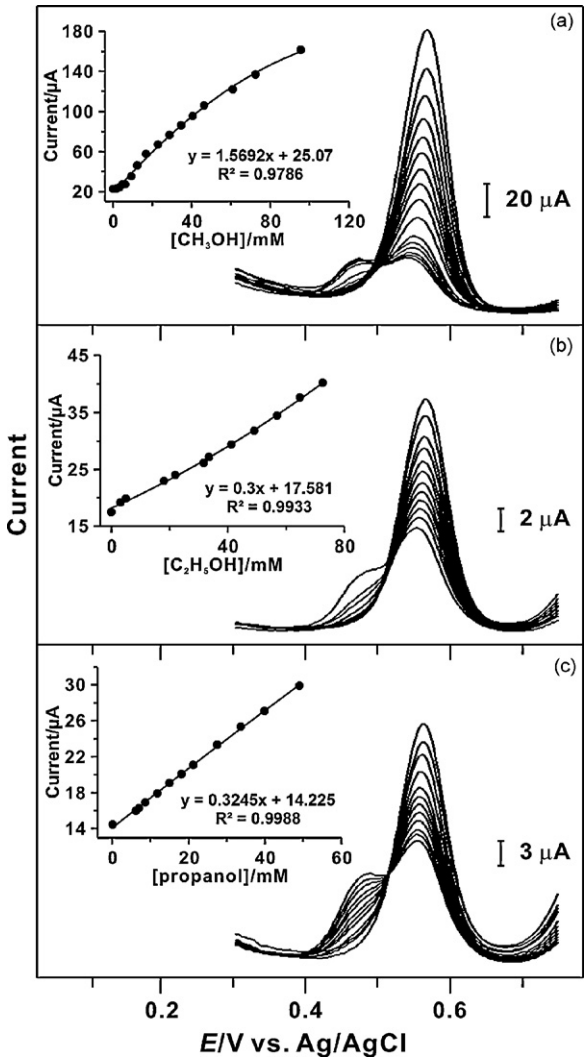

Fig. 6. DPVs of MWCNTs–NF–PMG film shown in (a) various concentrations of methanol (0.0; 1.55–95.44 mM); (b) various concentrations of ethanol (0.0; 3.09–72.48 mM) and (c) various concentrations of propanol (0.0; 6.12–48.98 mM) in pH 1 aqueous solution. The insets in (a–c) show the plot of current vs. different concentration of methanol, ethanol and propanol at MWCNTs–NF–PMG film respectively.

(2.3 mM) and the concentrations of AA and UA have been increased from 24.9 μM to 0.9 mM. The results reveal that there is no obvious change in the methanols' peak current during the addition of AA and UA. The change in peak current of methanol during the addition of AA is 2% with RSD = 1% ($n = 6$), whereas for UA it is 5% with RSD <1% ($n = 6$). Similarly, the interference of glycerin during ethanol determination has also been studied, where the ethanol concentration kept at 2.6 mM, and the concentration change of glycerin is from 1.3 to 87.2 mM. Results show that the change in ethanol peak current during the addition of glycerin is 9% with RSD = 2% ($n = 6$). The above data reveal that MWCNTs–NF–PMG composite film could be used for the efficient determination of simple aliphatic alcohols.

3.6. Analysis of methanol, ethanol and propanol containing real samples

The performance of MWCNTs–NF–PMG composite film modified GCE has been tested by applying it to the determination of the analytes present in real samples. The technique used for the determination was DPV. In these experiments, the real sample of methanol is green (scar removal and ache treatment agent),

Table 3
Electroanalytical results of simple aliphatic alcohol determination present in real samples using DPV in pH 1.0 aqueous solution at MWCNTs–NF–PMG composite film modified GCE.

Sample	Added (mM)	Found (mM)	Recovery (%)	RSD (%)	LOQ (mM)
Methanol (scar removal and ache treatment agent)	3.10	2.94	94.5	3	8.6
	4.64	4.74	102.1		
	9.23	9.00	97.4		
Ethanol (white wine)	0.56	0.58	97.0	2	8.3
	9.73	9.55	101.8		
	10.77	10.70	100.6		
Propanol (protan tablets)	16.02	15.98	100.2	2	3.5
	24.97	25.05	99.7		
	33.85	32.73	103.3		

ethanol is white wine, and propanol is protan tablets. The scar removal and ache treatment agent's labeled composition is triclosan, hyaluronic acid, collagen, glycerine, catechins, etc., along with methanol as solvent. Similarly, the white wine's labeled composition is 13% ethanol, and the protan tablet's labeled composition is 70% propanol. The scar removal and ache treatment agent was obtained from Stylecosmo International, France. The white wine is the product of Domaine de Pourthce, France, and the protan tablets were obtained from Protan, USA. In these experiments, the concentration added, concentration found, recovery, RSD and LOQ are given in Table 3. These above results show that MWCNTs–NF–PMG composite film is efficient for methanol, ethanol and propanol detection.

4. Conclusions

We developed a novel composite material using MWCNTs, NF and PMG at GCE, gold and ITO electrodes, which are more stable in pH 1–4 aqueous solutions. The developed MWCNTs–NF–PMG composite film for the electrocatalysis combines the advantages of ease of fabrication, high reproducibility and sufficient long-term stability. The EQCM results confirmed the incorporation of PMG on MWCNTs–NF modified gold electrode. The SEM and STM results have shown the difference between MWCNTs–NF, NF–PMG and MWCNTs–NF–PMG composite films morphology. Further, it has been found that MWCNTs–NF–PMG composite film has excellent functional properties along with good electrocatalytic activity towards methanol, ethanol and propanol. The experimental methods of CV and DPV with MWCNTs–NF–PMG composite film sensor integrated into the GCE which is presented in this article provide an opportunity for qualitative and quantitative characterization. Therefore, this work establishes and illustrates in principle and potential, a simple and novel approach for the development of a voltammetric sensor which is based on modified GCE.

Human milk

ABSTRACT

In this study we compared the use of ordinary least squares and weighted least squares in the calibration of the method for analyzing essential and toxic metals present in human milk by ICP-OES, in order to avoid systematic errors in the measurements used. Human milk samples were provided by maternity clinic Odete Valadares and digested by means of a high-performance microwave (MW) oven. Evaluation of plasma short and long-term stability was made using a solution of digested milk (1:50) with 2.0 mg L^{-1} Mg in HNO_3 2% (v/v). The detection power resulted to be at or below the μg L^{-1} level, whilst the precision expressed as relative standard deviation R.S.D. was almost always equal to or better than 3.3%. Certified reference material Infant Formula (NIST SRM 1846) was used to assess the accuracy of the proposed method, which proved to be accurate and precise. Recovery rates were in the range of 83–117%. Aqueous calibration was carried out for each element under study.

1. Introduction

When validating quantitative analysis methods, it is essential to know a function of the instrumental response, i.e., the relationship between response (the measured signal) and the concentration or quantity of analyte in the sample within an application range. This relationship is obtained by means of a simple linear regression, whose parameters (slope and intercept) are estimated through the least squares [1]. In instrumental chemical analysis, linear regression is used to perform the calibration of the measurement method, generally using the analyte concentration as the independent variable. The most commonly used linear regression method is the least squares (LS). There are two basic types of LS:

- OLS—ordinary least squares (data having constant uncertainty (σ^2)) and
- WLS—weighted least squares (data having varying uncertainty)

We obviously do not know the values of σ^2 or $\sigma^2(y_i)$ and, therefore, saying that they are known values means that we have a very safe estimate. According to ISO GUM [2], it is possible to use the square of the experimental uncertainties obtained from a systematic accounting of the contributions of all uncertainty sources as safe estimates of such variances. It is true that most of reports in the literature refer to OLS, however, this method can only be used if the following conditions are fulfilled: (1) linearity between y and x variables is available; (2) x is error-free or less than one-tenth of the error in y; (3) errors in y are normally distributed; (4) error in y is homoscedastic (constant variance across the entire response range); and (5) errors associated with different observations are independent [3,4]. Several in atomic spectroscopy researchers have been using OLS to calibrate the analytical method, without considering the behavior of the data obtained, such as instrumental responses to certain analyte concentration ranges. The inappropriate use of a method for performing linear regression and neglect of heteroscedasticity in calibration by using unweighted or "ordinary" least squares (OLS) instead of weighted least squares (WLS) can lead to significant loss of precision, especially in the low signal limit, which is often important for quantifying substances present at trace levels. It can also contribute to systematic measurement errors. Both OLS and WLS assume that all uncertainty resides in the dependent variable, y [5]. Several methods suggest the use of WLS in the case of heteroscedastic data, i.e., when there is varying uncertainty within the concentration range to be calibrated [6,7]. In this study, we compared the use of OLS and WLS to calibrate the analysis method for essential and toxic metals present in

milk by inductively coupled plasma optical emission spectrometry (ICP-OES).

2. The least squares method

In this section, we present the general least squares theory, mainly in matrix notation. Even though the mathematical explanation on the different linear regression construction methods (OLS and WLS) is a bit long, it is necessary to better understand how such methods are composed and the factors considered by them, such as heteroscedasticity instrumental responses. Another reason for keeping the explanations is that the data matrices shown have been constructed using Microsoft Excel® spreadsheets, and not programs integrated in Excel®. That is, the data matrices and respective multiplications have been "manually" constructed in the spreadsheets, and not performed by the software. Furthermore, most of the programs that construct linear regressions, including programs integrated in analysis tools, only consider OLS and do not take into account other linear regression methods, such as weighted least squares.

Consider that mensurand y depends on mensurand x and on parameters p_i, so that the observational equations may be expressed as:

$$y_1 = a_{11}p_1 + a_{12}p_2 + \cdots + a_{1m}p_m + e_1,$$
$$y_2 = a_{21}p_1 + a_{22}p_2 + \cdots + a_{2m}p_m + e_2,$$
$$\cdots$$
$$y_n = a_{n1}p_1 + a_{n2}p_2 + \cdots + a_{nm}p_m + e_n$$

These equations can be expressed in matrix notation [7]:

$$Y_{n,1} = J_{n,m}P_{m,1} + E_{n,1} \tag{1}$$

Matrix J is frequently called the design matrix and depends on the values of x_i:

$$J = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & a_{ii} & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{bmatrix} = \begin{bmatrix} \frac{\partial y_1}{\partial p_1} & \frac{\partial y_1}{\partial p_2} & \cdots & \frac{\partial y_1}{\partial p_n} \\ \frac{\partial y_2}{\partial p_1} & \frac{\partial y_2}{\partial p_2} & \cdots & \frac{\partial y_2}{\partial p_n} \\ \vdots & \vdots & \frac{\partial y_i}{\partial p_i} & \vdots \\ \frac{\partial y_n}{\partial p_1} & \frac{\partial y_n}{\partial p_2} & \cdots & \frac{\partial y_n}{\partial p_n} \end{bmatrix} \tag{2}$$

The e_i errors of matrix E have zero mean and finite variances. Our problem is to find the best estimator $\hat{P}$ for the P parameters. We will start assuming that the variances (uncertainty $u(y_i) = \sigma_i$) and covariances of all instrumental response values y_i are given by the variance–covariance matrix, V_y:

$$V_y = \begin{bmatrix} \mathrm{var}(y_i) & \mathrm{cov}(y_1, y_2) & \cdots & \mathrm{cov}(y_1, y_n) \\ \mathrm{cov}(y_2, y_1) & \mathrm{var}(y_2) & \cdots & \mathrm{cov}(y_2, y_n) \\ \vdots & \vdots & \mathrm{var}(y_i) & \vdots \\ \mathrm{cov}(y_n, y_1) & \mathrm{cov}(y_n, y_2) & \cdots & \mathrm{var}(y_n) \end{bmatrix} \tag{3}$$

The least squares method proposed by Gauss for the case of equal variances (OLS) consisted of minimizing the sum of the squares of deviations d_i (residuals), between the calculated experimental values, y_i, and the estimated values, $\hat{y}_i$:

$$SQ = \sum_{i=1}^{n} d_i^2 = \sum_{i=1}^{n} (y_i - \hat{y}_i)^2 \tag{4}$$

where

$$\hat{Y} = J\hat{P} \tag{5}$$

which is the same as minimizing:

$$SQ = \frac{1}{\sigma^2}\sum_{i=1}^{n} d_i^2 = \sum_{i=1}^{n} \frac{(y_i - \hat{y}_i)^2}{\sigma^2} \tag{6}$$

Defining the matrix of residuals:

$$D_{n,1} = Y - \hat{Y} = Y - J\hat{P} \tag{7}$$

Thus, minimizing SQ is the same as minimizing the quadratic form:

$$SQ = \sigma^{-2} D^t I D \tag{8}$$

When variances are not constant, i.e., in the case of the WLS, it is also necessary to minimize the quadratic form:

$$SQ = D^t V_y^{-1} D = (Y - J\hat{P})^t V_y^{-1} (Y - J\hat{P}) \tag{9}$$

Thus, we have:

$$\begin{aligned} D^t V_y^{-1} D = (Y - J\hat{P})^t V_y^{-1} (Y - J\hat{P}) &= Y^t V_y^{-1} Y + \hat{P}^t J^t V_y^{-1} J\hat{P} \\ &\quad - Y^t V_y^{-1} J\hat{P} - \hat{P}^t J^t V_y^{-1} Y \\ &= Y^t V_y^{-1} Y + (J\hat{P})^t V_y^{-1} J\hat{P} - 2\hat{P}^t J^t V_y^{-1} Y \end{aligned}$$

Deriving SQ in relation to the parameters to adjust, p_i, and equating to zero:

$$\frac{\partial SQ}{\partial \hat{P}^t} = \frac{\partial (D^t V_y^{-1} D)}{\partial \hat{P}^t} = 2(J^t V_y^{-1} J\hat{P} - J^t V_y^{-1} Y) = 0 \tag{10}$$

We obtain the so-called normal equations:

$$(J^t V_y^{-1} J)\hat{P} = J^t V_y^{-1} Y \tag{11}$$

The matrix of the normal equations, B, is defined by the equation:

$$B \equiv J^t V_y^{-1} J \tag{12}$$

Using Eq. (12), Eq. (11) can be rewritten:

$$\begin{aligned} B\hat{P} &= J^t V_y^{-1} Y \\ \hat{P} &= B^{-1} J^t V_y^{-1} Y \end{aligned} \tag{13}$$

The LS estimator of P, given by Eq. (13), is a minimum-variance and also minimizes the variance of the estimate of any linear function of the parameters. This is one of the reasons for the importance of the least squares estimates [7]. In particular, using the uncertainties of the adjusted parameters, it is possible to obtain the uncertainty of the interpolation of a given x_0 value from the experimentally measured instrumental response y_0.

The covariance matrix of the adjusted parameters is defined by:

$$V_p = B^{-1} = \sigma^2 (J^t W J)^{-1} \tag{14}$$

In order to obtain the uncertainties of the adjusted parameters, it is necessary to know the value of σ^2. Moreover, we can estimate the uncertainties in the adjusted parameters by replacing σ^2 in Eq. (14) by its unbiased estimator s^2:

$$\hat{V}_p = s^2 (J^t W J)^{-1} \tag{15}$$

So we must obtain s^2 from the experimental data. The moment method provides a unitary-weight unbiased estimator for variance σ^2 of the observation:

$$s^2 = \hat{\sigma}^2 = \frac{D^t W D}{n - m} \tag{16}$$

where n is the number of experimental points in the calibration and m is the number of adjusted parameters of B. s^2 is sort of a weighted variance of the adjustment. Finally, introducing Eq. (16)

into Eq. (14) or (15) gives an unbiased estimator for the covariance matrix for the parameters:

$$\hat{V}_p = s^2 B^{-1} = \frac{D^t W D}{n-m}\left(J^t W J\right)^{-1} \quad (17)$$

Or simply the inverse of the normal-equations matrix multiplied by the estimate of σ^2.

In the context of OLS, if the value of the common variance σ^2 is known, it is used in Eq. (14) to obtain the variances of the parameters on the diagonal of V_p and the covariances between them outside the diagonal. If σ^2 is unknown, we estimate σ^2 through Eq. (16) and obtain V_p through Eq. (15), where we calculate V_p using Eq. (17). In both cases we use $W = I$.

3. Experimental

3.1. Instrumentation

The experiments for this study were performed using the PerkinElmer® Model Optima™ 2000 DV inductively coupled plasma optical emission spectrometer (Dual View ICP-OES) with axial (AX-ICP-OES) and radial configurations (RD-ICP-OES) (PerkinElmer Life and Analytical Sciences, Shelton, CT, USA). The instrument was equipped with a radio frequency source of 40 MHz providing 0.75–1.5 kW power. It utilizes an Echelle grating (79 lines nm^{-1}), a solid-state detector, a plasma torch with a 2.0-mm internal diameter injection and a cross-flow nebulizer coupled with a double-pass Scott-type spray chamber. The equipment is also provided with an interface (shear gas) that introduces high air perpendicularly to the torch, in order to remove the low temperature extremity of the plasma. The sample introduction system was automated with a PerkinElmer Model 90 Plus autosampler. The operational parameters are listed in Table 1. The wavelengths used for the elements to be determined avoid any spectral interferences as described in the literature (Table 2). Human milk samples were mineralized by means of a closed-pressurized, high-performance microwave (MW) digestion oven (MLS 1200 MEGA, Milestone, Bergamo, Italy) equipped with 10 Teflon® vessels, capable of withstanding pressures of up to 30 bar.

3.2. Reagents and solutions

A standard multi-element 1000 mg L^{-1} solution (Std. 3 PerkinElmer Pure Plus) containing all the elements studied was used. Nitric acid (65%, v/v) and hydrogen peroxide (30%, v/v) were obtained from Merck. All working standard solutions were prepared daily from the stock solutions by simple dilution with Milli-Q ultrapure water. Ultrapure water was obtained with a Millipore (Millipore, Milford, MA, USA) Milli-Q water purification system. Certified reference material Infant Formula (NIST SRM 1846) was obtained from the National Institute of Standards and Technology (Gaithersburg, MD, EUA).

3.3. Samples

Human milk samples were provided by maternity clinic Odete Valadares, Belo Horizonte, Minas Gerais, Brazil. The method proposed was applied to 17 mature-milk and 12 colostrum-milk samples of approximately 10 mL each. Samples were kept frozen at −18 °C until the moment of analysis.

3.4. Sample preparation

In order to determine the concentration of the elements studied, human milk aliquots of 1.0 mL were transferred into Teflon® vessels, added with 2.0 mL HNO_3 and 0.5 mL H_2O_2 (Suprapur, Merck, Darmstadt, Germany) and digested by means of a high-performance microwave (MW) oven (MLS 1200 MEGA, Milestone, Bergamo, Italy) with power steps increasing from 250 to 600 W. After cooling the digest vials in water bath (30 min), the completely clear, colorless and homogeneous digests obtained were diluted 1:50 (v/v) with deionized water. The heating program for digesting human milk samples in microwave oven is summarized in Table 3.

The certified reference material Infant Formula (NIST SRM 1846) was digested in a microwave oven with 0.05 g SRM for 2 mL nitric acid, 0.5 mL H_2O_2 and 1 mL deionized water, into a final volume of 25 mL. A certified material solution was prepared in independent triplicates and read in random triplicates. The heating program for digesting samples of certified materials in microwave oven is summarized in Table 4.

3.5. Procedure

Evaluation of plasma short and long-term stability was made using a solution of digested milk (1:50, v/v) containing 2.0 mg L^{-1} Mg in HNO_3 2% (v/v). For short-term stability, 15 consecutive measurements of the intensity of the Mg II line of 280.265 nm were made with subsequent analysis of the relative standard devia-

tion. In order to test long-term stability, the emission line of Mg was monitored for 2 h and 8 measures were performed at 15-min intervals. Both tests were performed using the AX-ICP-OES with nebulization gas flow rate of 0.6 L min^{-1} and 1.3 kW power applied, as suggested by the literature [8].

The equipment was adjusted using a nebulization gas flow rate ranging from 0.3 to 1.1 L min^{-1} and power ranging from 1.1 to 1.5 kW. Plasma robustness as such parameters were changed was evaluated using the ratio Mg II/Mg I as diagnosis. Plasma is considered robust when the Mg II/Mg I ratio ≥ 8 [9].

The linearity range studied was between 2.0 and 70.0 μg L^{-1} for Al, Cr, Mn, Fe, Ni, Cu, Zn, Cd, Pb, Ba, V, Co and Li; 10.0 to 600.0 mg L^{-1} for Ca; 5.0 to 80.0 mg L^{-1} for Mg and 15.0 to 900.0 mg L^{-1} for K and Na. The linearity curve was plotted with standard aqueous solutions ($n = 3$) and digested milk ($n = 3$). The curve slopes for each analyte (angular coefficients) in water and digested milk were compared to assess the presence of significant matrix effect using Student's t test. The counts per second (CPS) for each concentration were measured three times and the average values were used to plot the linearity curves.

The choice of an internal standard was made by evaluating the profile of the analytical signals of Al, Pb and the elements tested as internal standards (Li, Co, Ni, and Y), using the same experimental conditions. To evaluate the internal standard performance, 2.0 mg L^{-1} of each analyte solution and 1.0 mg L^{-1} of the internal standard were added to the samples equivalent to each point of the calibration curve.

4. Results and discussion

4.1. Figures of merit

4.1.1. Evaluation of internal standard

The elements tested as internal standard and their analytical lines were Co 228.61 nm (13.7 eV), Li 670.78 nm (3.87 eV), Ni 231.60 nm (14.03 eV) and Y 371.03 nm (9.9 eV). It was not necessary to use an internal standard, since no significant differences were detected between the analytical signals of solutions with and without an internal standard.

4.1.2. Plasma stability

Plasma stability was assessed by short and long-term stability tests. Both tests were performed using the AX-ICP-OES, a nebulization gas flow of 0.6 L min^{-1} and an applied power of 1.3 kW. The precision obtained for the short-term and long-term measurements were 0.84% and 1.08%, respectively, which is consistent with the results obtained by Silva et al. [8]. The adequate R.S.D. values obtained allow continuous analysis with significant precision.

4.1.3. Calibration by OLS and WLS

In order to perform calibration by OLS and WLS, we started by multiplying various data matrices [7]. This procedure offers several advantages, including calibration line parameters and their uncertainties, residuals for evaluating the quality of the adjustment, uncertainties in x and y, confidence limit and prevision curves for the adjustment and others.

In order to construct the calibration by both linear regression methods we need:

- the Jacobian matrix or design matrix J (Eq. (2)), which depends on the values of x_i;
- the matrix Y (Eq. (1)), which corresponds to the average of the instrumental responses;
- the matrix $s_{\bar{y}}$, which corresponds to the mean standard deviation;
- the matrix V_y (Eq. (3)), which consists of the variance and covariance matrix for the instrumental responses; and
- matrices J and V_y, from which we obtain the transpose and inverse matrices.

The problem in this case is finding the best estimator $\hat{P}$ for parameters P of the calibration line. Therefore, to adjust the calibration for OLS, we must simply multiply matrix B^{-1} (the matrix of the inverse normal equations, obtained by multiplying matrix J by matrix J^t) by matrices J^t and Y:

$$P = B^{-1}J^tY \tag{18}$$

On the other hand, to adjust the calibration using WLS, we must only add the inverse variance and covariance matrix of the instrumental responses (V_y^{-1}) to the matrix multiplication used for the adjustment by OLS, which will weight the values according to the heteroscedastic behavior of the instrumental response variances:

$$\hat{P} = B^{-1}J^tYV_y^{-1} \tag{13}$$

With the covariance matrix for the adjusted parameters, V_p (Eq. (17)), we obtain the uncertainties s_a and s_b for the parameters adjusted. In this work, comparison was carried out only between the OLS and WLS methods, since we know the variances of the data and their behavior (whether they present equal or different variances).

4.1.4. Comparison between OLS and WLS regressions

Previous to performing calibration, an evaluation was carried out to choose the best linear regression method (OLS or WLS) to be used. The software used for the data matrices and respective calculations was Microsoft Office Excel 2003®, a simple and affordable tool.

It is known that the inappropriate use of a method for performing linear regression results in a systematic measurement error and precision loss. Thus, to avoid such errors, we verified whether the instrumental response variance of the analytes studied presented a homoscedastic (constant uncertainty) or heteroscedastic (varying uncertainty) behavior. Elements Ca, K, Mg, Na, Ba, Cd, Cr, Cu, Mn, Fe, Li, Ni, Co, Zn and Pb presented varying uncertainty and should therefore be calibrated by WLS. Elements V and Al showed constant variance and thus should be calibrated by OLS. Fig. 1 shows the heteroscedastic behavior of the data related to Ca and the homoscedastic behavior of the data related to V. Evaluation was performed whether these methods are statistically similar or different for calibrating the same analyte, bearing in mind that WLS is a more laborious method than OLS.

To assess the statistical similarity of the OLS and WLS methods, we applied the paired Student's t test to compare the angular coefficients of both aqueous curves (OLS and WLS) for all elements studied. Table 5 presents the equations corresponding to the linear regressions performed by OLS and WLS, along with the Student's t_c. The value of $t_{95\%,2}$ is 4.303, which indicates that the methods were statistically different for elements Cu, Cd, Zn, Al, Ca, Mg, Na, K and Fe. Therefore, calibration must be performed for these elements using

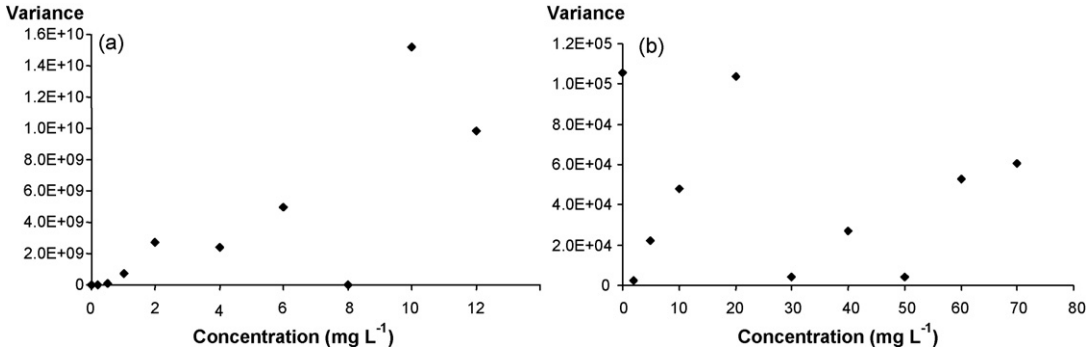

Fig. 1. (a) Heteroscedastic behavior of the Ca-related data. (b) Homoscedastic behavior the V-related data.

Table 5
Comparison between the OLS and WLS for ICP-OES analysis.

Analyte	Equation adjusted for OLS	Equation adjusted for WLS	Student's t_c[c]
Ba	$y = 23{,}527\ (\pm 33)^{a}\ x - 11{,}052\ (\pm 42)^{b}$	$y = 23{,}171.8\ (\pm 234.3)^{a}\ x + 9599.9\ (\pm 142.5)^{b}$	2.600
V	$y = 220.7\ (\pm 2.7)\ x + 405.0\ (\pm 3.0)$	$y = 230.4\ (\pm 2.8)\ x + 25{,}163.7\ (\pm 104.5)$	4.185
Cr	$y = 172.6\ (\pm 0.4)\ x - 12.8\ (\pm 0.1)$	$y = 173.4\ (\pm 2.5)\ x + 1157.8\ (\pm 9.4)$	0.562
Ni	$y = 26.4\ (\pm 0.1)\ x + 28.3\ (\pm 1.8)$	$y = 27.0\ (\pm 1.1)\ x + 68.6\ (\pm 2.4)$	0.893
Mn	$y = 1307.6\ (\pm 1.0)\ x - 70.3\ (\pm 0.9)$	$y = 1308.7\ (\pm 3.2)\ x + 2372.5\ (\pm 9.7)$	0.584
Pb	$y = 6.4\ (\pm 0.1)\ x + 7.2\ (\pm 0.1)$	$y = 6.3\ (\pm 0.2)\ x + 194.0\ (\pm 4.0)$	0.614
Cu	$y = 220.4\ (\pm 3.1)\ x + 1713.0\ (\pm 24.9)$	$y = 211.5\ (\pm 1.1)\ x + 150.3\ (\pm 1.4)$	4.627
Co	$y = 58.8\ (\pm 0.1)\ x - 68.8\ (\pm 0.5)$	$y = 59.0\ (\pm 0.1)\ x + 30.9\ (\pm 0.3)$	1.732
Cd	$y = 72.0\ (\pm 0.2)\ x - 192.4\ (\pm 1.2)$	$y = 74.7\ (\pm 0.2)\ x - 227.3\ (\pm 1.7)$	13.231
Zn	$y = 63.8\ (\pm 0.4)\ x - 86.4\ (\pm 2.0)$	$y = 66.7\ (\pm 0.1)\ x - 79.9\ (\pm 1.5)$	10.356
Al	$y = 183.6\ (\pm 3.6)\ x + 361.5\ (\pm 2.4)$	$y = 151.9\ (\pm 0.4)\ x + 5984.3\ (\pm 6.4)$	14.867
Li	$y = 29{,}541\ (\pm 1151)\ x - 27{,}109\ (\pm 114)$	$y = 26{,}743\ (\pm 1261)\ x + 41{,}528\ (\pm 118)$	2.837
Ca	$y = 1.14 \times 10^{6}\ (\pm 29{,}211)\ x + 2{,}430{,}964\ (\pm 9842)$	$y = 1.0 \times 10^{6}\ (\pm 28{,}143)\ x - 123{,}707\ (\pm 8211)$	5.971
Mg	$y = 4.5 \times 10^{6}\ (\pm 24{,}753)\ x + 2.1 \times 10^{6}\ (\pm 7147)$	$y = 5.0 \times 10^{6}\ (\pm 26{,}845)\ x - 2.0 \times 10^{6}\ (\pm 8286)$	23.717
Na	$y = 1.3 \times 10^{6}\ (\pm 31{,}128)\ x + 2.2 \times 10^{6}\ (\pm 2478)$	$y = 1.0 \times 10^{6}\ (\pm 31{,}657)\ x - 20{,}203\ (\pm 1101)$	11.703
K	$y = 5.06 \times 10^{5}\ (\pm 2642)\ x + 5.84 \times 10^{5}\ (\pm 121)$	$y = 480{,}815\ (\pm 2401)\ x - 85{,}804\ (\pm 140)$	12.217
Fe	$y = 163.4\ (\pm 1.3)\ x + 2388.9\ (\pm 6.3)$	$y = 172.1\ (\pm 0.2)\ x + 1447.7\ (\pm 5.4)$	11.193

[a] Standard deviation of the regression-line coefficient a: $y = a\ (s_a)\ x + b\ (s_b)$.
[b] Standard deviation of the regression-line coefficient b: $y = a\ (s_a)\ x + b\ (s_b)$.
[c] $t_{95\%,2} = 4.303$.

WLS (and not OLS, as in several atomic absorption studies). As for Al, calibration should necessarily be performed using OLS. The methods employed were not statistically different for the other elements (V, Ba, Cr, Mn, Li, Ni, Co and Pb) and so performing calibration using OLS or WLS does not significantly affect the final results in the case of such analytes for the sample of interest. Thus, we prefer using OLS, since it is a simpler method that can be performed by various programs, including the one used by the equipment.

Table 5 shows that all macrominerals present in human milk (Ca, Mg, Na and K), as well as microminerals Fe, Cu and Zn (with higher concentrations than those of other microminerals), presented significant differences in the comparison between the OLS and WLS methods at a 95% confidence level. This draws attention to the behavior of these elements.

Fig. 2(a) shows the comparison between OLS and WLS for K and Fig. 2(b) presents the comparison for Zn. The figures indicate that the inappropriate choice of the linear regression method directly affects the concentration of the analyte of interest, causing precision loss. In some cases (Fig. 2(b)), sensitivity loss of the analytical method can occur due to a simple systematic error when choosing the linear regression method. This work aims at awakening this concern, which is forgotten by several authors that study atomic absorption.

4.1.5. Matrix effect

The method presented linear response to the concentrations within the ranges tested for all analytes, both in aqueous and in digested milk curves. When verifying the presence of matrix effect,

[c] LOD and LOQ in mg L^{-1} to Ca, Na, Mg and K; and to the others analytes in μg L^{-1}.

the angular coefficients of the analytical curves presented no significant difference at a 95% confidence interval for the concentration ranges tested. This indicates the absence of matrix interference on the measurements. Thus, aqueous calibration was used to determine all the elements analyzed by ICP-OES.

4.1.6. Limits of detection and quantification

The limits of detection for each element under study, based on three times the standard deviation of the average of 10 individually prepared blank solutions, as well as the limits of quantification, based on 10 times the standard deviation of the average of 10 individually prepared blank solutions, are listed in Table 6.

4.1.7. Precision of the measurements

Method precision was evaluated by calculating the R.S.D. (%) of 10 independent samples, taken in random triplicates, for the following concentrations: 10.0 μg L^{-1} for Li, Ba, V, Cr, Ni, Mn, Pb, Cu, Co, Cd, and Al; 15.0 μg L^{-1} for Fe and Zn; 200.0 mg L^{-1} for Ca; 300.0 mg L^{-1} for K and 30.0 mg L^{-1} for Mg and Na. The detection power resulted to be at or below the μg L^{-1} level, whilst the precision expressed as relative standard deviation R.S.D. was almost always equal to or better than 3.3% (see Table 7), indicating repeatability.

4.1.8. Accuracy of the measurements

Method accuracy was evaluated by quantification of samples of certified reference material Infant Formula (NIST SRM 1846) and also by recovery tests using spiked samples. The reason why we make use of milk infant formula certified reference material to evaluate method accuracy is that there is no human milk certified reference material commercially available. Therefore, considering that the matrix of infant formula is very similar to that of human

Level 2: 200.0 mg L^{-1} to Ca; 300.0 mg L^{-1} to K; 40.0 mg L^{-1} to Mg and Na; and 20.0 μg L^{-1} to the other metals.
Level 3: 400.0 mg L^{-1} to Ca; 600.0 mg L^{-1} to K; 60.0 mg L^{-1} to Mg and Na; and 40.0 μg L^{-1} to the other metals.
Underlined values are values which showed recovery below or above of the recommended values.

milk (both contain the same concomitant elements and potential interference materials), it was used in order to get as close as possible to the real condition whilst studying method accuracy. The accuracy of the method, using reference material was evaluated by Student's *t* test. Milk reference materials were reconstituted as recommended by the supplier and the resulting solution was digested (as described, under microwave digestion procedures). In general terms, adequate equivalence levels were found between obtained and recommended values. Table 7 reports the analytical performance of ICP-OES in terms of LOQs, precision and accuracy.

Recovery assays were carried out to verify the presence of the interference effects on the developed method. Adequate amounts of the elements were added to milk before digesting of the sample. For the recovery tests, the digested milk solutions were spiked and prepared at three concentration levels: 5.0, 20.0 and 40.0 μg L^{-1} for analytes Al, Cr, Mn, Fe, Ni, Cu, Zn, Cd, Pb, Ba, V, Co, Li; 50.0, 200.0 and 400.0 mg L^{-1} for Ca; 20.0, 40.0 and 60.0 mg L^{-1} for Mg and Na; and 75.0, 300.0 and 600.0 mg L^{-1} for K, prepared in triplicate and measured under robust operation conditions. Recovery rates were in the range 83–117%, as listed in Table 8. It was not possible to recover elements Fe, Cu, Zn, Ca, Na and K at the first level, due to their low concentration levels at this level, considering the great amounts of these metals in human milk. It was also not possible to recover Al and V at the third level, possibly due to interferences occurred during the measurements.

Aqueous calibration was carried out for each element under study. Our method offers advantages such as simplicity and reduced time (<2 h), as well as reduced volume required (1 mL), when compared with other techniques [10–13]. The dilution level used in the assay, 1 mL of human milk to 50 mL of solution, is adequate for measuring the usual contents of the elements studied. However, microwave digestion has certain limitations. For instance, the number of samples that can be simultaneously digested is restricted to the number of slots (10) for digestion vessels in the microwave oven. Moreover, precautions must be adopted to prevent alterations on the inner surface of the digestion vessels, which may cause adsorption of the elements, leading to aggressive conditions, such as large concentrations of acid, high temperatures or prolonged times.

4.2. Quantification

Table 9 presents the results obtained for each element present in mature and colostrum milk, in terms of means and standard deviations (S.D.). In general, the data do not indicate the presence of potentially toxic metals beyond the national recommended values. Concentrations are also comparable to the values referred to in the literature, especially to those of an international collaborative WHO IAEA survey on the contents of trace elements in milk worldwide [14,15]. No values were found in the literature indicating the concentrations of analyte V in milk. The concentration ranges of the elements considered in this study in human milk were in satisfactory agreement with those reported in the literature. As indicated

Table 9
Concentrations of trace elements in 17 mature human milk samples and 12 colostrum human milk samples and reference ranges for human milk.

Analyte	Concentration[a]		
	Colostrum (mean ± S.D.)	Mature (mean ± S.D.)	Literature range
Ba	14.4 ± 14.1	7.9 ± 3.4	0.9–47

K	686.4 ± 90.3	571.7 ± 139.3	351–741
Fe	422.4 ± 319.7	433.4 ± 331.8	200–800

[a] Concentration in mg L^{-1} to Ca, Na, Mg and K, and μg L^{-1}, to the other analytes.
[b] Value with exception of 6 samples which has values less than LOQ.
[c] Value with exception of 7 samples which has values less than LOQ.
[d] Value with exception of 5 samples which has values less than LOQ.
[e] Value with exception of 12 samples which has values less than LOQ.

by the standard deviations of the samples analyzed, all metal concentrations vary widely from mother to mother. This suggests that diet, as well as the use of hair chemicals, cosmetics and others, may have a great influence on the concentrations of such metals in milk.

It was also observed that the concentration levels of most of the metals studied in colostrum milk were higher, on average, than those of metals present in mature human milk. This is because colostrum milk has a larger amount of nutrients (particularly metals) than mature milk.

5. Conclusions

Selecting the most adequate linear regression model (OLS or WLS) to be used for calibrating the analytical method in atomic spectroscopy, has proven extremely useful and necessary to reduce systematic errors embedded in the measurement results (in this case, the concentration of the analyte of interest in the sample). It also helps avoiding loss in the analytical method precision. Quantification of essential and toxic elements in human milk by ICP-OES offers several advantages, such as simple sample preparation, reduced time (<2 h) and a small volume of sample required (1 mL), comparing to other techniques.

Matrix-matched calibration

ABSTRACT

The detection and quantitation of four ethanolamines, tris(2-hydroxyethyl)amine (triethanolamine, TEA), *N*,*N*-bis(2-hydroxyethyl)methylamine (methyldiethanolamine, MDEA), *N*-(2-aminoethyl)ethanolamine (AEA), and *N*,*N*-diethylethanolamine (DEA), were achieved in wastewaters from two aerobic activated sludge bioreactors located in an industrial wastewater treatment plant. The streams had salt concentrations of approximately 3% and 7% by weight in Reactor 1 and Reactor 2, respectively. The use of liquid chromatography-electrospray ionization-tandem mass spectrometry avoided the need for some sample preparation steps such as extraction, concentration, and derivatization. Ion suppression in the electrospray, attributable to the presence of sodium clusters, was attenuated by a 10-fold dilution of the wastewaters with acetonitrile. A matrix-matched calibration model averted other potential interferences. For the compounds analyzed in selected reaction monitoring mode (TEA, MDEA, and DEA), the calibration curves presented linearity in a range of 10–1000 μg/L with corresponding detection limits ranging from 2 to 11 μg/L, depending upon the specific analyte and aqueous matrix. AEA was calibrated in selected ion monitoring mode (100–1000 μg/L), with corresponding detection limits in the two wastewaters of 74.6 and 85.3 μg/L, respectively. Overall good precision (<10%) and accuracy (97–110%) were achieved for both matrices, which fell within-laboratory reproducibility. Finally, the amines were introduced into six mixed liquor samples from both reactors and quantified following the reported protocol. Again, recoveries were close to 100% with a relative standard deviation of less than 10% in all cases.

1. Introduction

β-Hydroxylamines are generally synthesized through the reaction of epoxies and nitrogen reagents [1]. Common to all these synthesis reactions is the combination of ethylene oxide and aqueous ammonia, which represents the main pathway for the formation of ethanolamines [2]. These organic compounds are raw materials or synthetic precursors in the manufacture of herbicides, surfactants, textile fabrics, and metal cutting fluids. Furthermore, these amines are extensively used in gas plants and oil refineries as active components in aqueous scrubbing solutions during sweetening, that is, the removal of hydrogen sulfide and carbon dioxide from natural gas [3–5]. In the USA alone 1345 million pounds of ethanolamines were produced in 2004 [6].

This broad range of applications for these compounds is due to their chemical structure: an alkane backbone that combines the presence of both hydroxy- and aminofunctional groups. Hence, in aqueous solution, this combination gives a weakly-to-moderately basic behavior and complete solubility in polar solvents such as water, acetone, or methanol. Normally, these aliphatic amines have low vapor pressures (below 1 mm Hg at 20 °C), with boiling points ranging from 96 to 208 °C, and exhibit varying degrees of decomposition at temperatures above 200 °C [7]. Owing to the widespread use, the amines may be found in wastewaters, ground water, and soils located at industrial sites associated with the natural gas production [8,9].

Analytical methods for the identification and quantification of this group of amines have been developed in earnest since they are known degradation byproducts of nitrogen mustards [10]. The most commonly utilized technique involves the use of gas chromatography mass spectrometry because the protocols were developed for monitoring the parent compounds mainly [11]. Nevertheless, ethanolamines are problematic candidates for gas chromatography on account of their high polarity, basic nature, and low volatility. In fact, their identification in aqueous phases requires extensive sample preparation involving extraction, concentration, and derivatization. These preparatory steps can introduce analytical errors as manifested by poor extraction efficiency, low derivatization yields, and thermal destruction of the analytes [12].

doi:10.1016/j.talanta.2009.08.035

The development of electrospray tandem mass spectrometry (ESI-MS/MS) has led to marked improvements in the detection of polar compounds in water samples. In fact, this technique facilitates the measurement of trace concentrations without the need for the derivatization or intensive sample preparation [13,14]. It presents an alternative to the time-consuming classical approaches and research effort has been expended to adapt these methods to the detection of ethanolamines [15–17]. Nevertheless, to the best of our knowledge, no ESI-MS/MS analytical methods have been reported for these compounds in high saline wastewaters (over 3% (w/v) of total dissolved solids). These industrial streams are commonly generated during the manufacture of chemicals, textiles, and oil and gas recovery operations, which involve the use of ethanolamines. Hence, the objective of the present study was to develop and validate analytical protocols for measuring tris(2-hydroxyethyl)amine (triethanolamine, TEA) *N*,*N*-bis(2-hydroxyethyl)methylamine (methyldiethanolamine, MDEA), *N*-(2-aminoethyl)ethanolamine (AEA), and *N*,*N*-diethylethanolamine (DEA) in hypersaline effluents by ESI-MS/MS as a previous step for the study of the biodegradation of the compounds in highly saline industrial wastewaters. For this purpose, wastewater streams from two aerobic activated sludge bioreactors (denoted as Reactor 1 and Reactor 2) in an industrial wastewater treatment plant were used in this study. On a routine basis, these two reactors generate wastewaters whose saline content average 3% and 7% by weight in Reactor 1 and Reactor 2, respectively. These high salt concentrations represent a challenge to the application of ESI for detection of the analytes.

2. Experimental

2.1. Chemicals and reagents

Reagent grade triethanolamine was purchased from Sigma (St. Louis, MO, USA), while methyldiethanolamine, N-(2-aminoethyl)ethanolamine, and *N*,*N*-diethylethanolamine were obtained from Aldrich (Milwaukee, WI, USA). The organic solvents, acetonitrile (ACN) and methanol (MeOH), were HPLC quality and were purchased from Tedia (Fairfield, OH, USA). Deionized ultra-filtered water and ammonium formate were obtained from Fisher Scientific (Pittsburg, PA, USA). All chemicals and solvents were analytical reagent grade with a minimum purity of 98%.

2.2. Samples and standards

Stock solutions of the analytes (20 mg/L) were prepared in SuperQ water, using Class A volumetric glassware and then stored at 4 °C. Supernatants from Reactor 1 and Reactor 2 were used as aqueous matrices for the preparation of working standards. Matrix samples were prepared by combining biomass and supernatants from each reactor so that each sample contained 500 mL of mixed liquor with 1000 mg/L of total suspended solids with the final pH adjusted to 7.5 using concentrated HCl. Both bioreactors receive streams from various processes ranging from basic to performance chemicals. The typical salinities of the wastewaters were around 3% and 7% for Reactor 1 and Reactor 2, respectively. Prior to sample injection in the instrument, samples and standards were filtered through 0.2 μm membrane filters.

2.3. Instrumentation

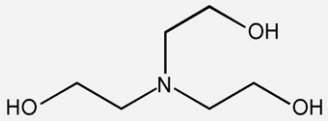
Chromatographic separation of the amines was performed on a 1200 Series rapid resolution liquid chromatograph (LC) from Agilent (Palo Alto, CA, USA) with an Inertsil ODS-3 (2.1 mm × 150 mm, 5 μm) column (Alltech, Deerfield, IL, USA). The target compounds were identified and quantified on a 6410A triple quadrupole mass spectrometer equipped with an electrospray ionization source (ESI) by (Agilent, Palo Alto, CA, USA). Nitrogen was the gas used in both the nebulizer and the collision cell.

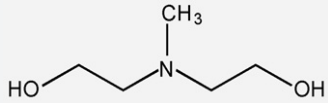
The equipment was tuned following the manufacturer's specifications, using an ESI calibrant mix from Agilent (Palo Alto, CA, USA). The software for the control of the LC–MS/MS, the data acquisition, and the qualitative and quantitative analysis was Agilent MassHunter Workstation.

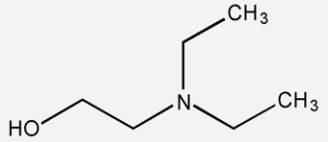
The conditions for the flow injection analysis (FIA) were gas temperature, 300 °C; gas flow, 10 L/min; nebulizer, 50 psi; and capillary voltage, 3000 V. The eluent composition was water and MeOH (1:1, v/v) with 5 mM of ammonium formate, and the flow was 0.4 mL/min. The MS was operated in full scan between 50 and 300 *m*/*z*.

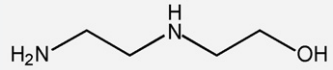
3. Results and discussion

3.1. Method development









3.1.1. Ionization and MS/MS conditions

In order to establish the precursor ions of the ethanolamines, FIA was individually performed on the analytes. Standards were prepared in water (20 mg/L) and 1 μL was injected. As expected, owing to the basic nature of the aminogroup, the target compounds presented strong protonated molecules $[M+H]^+$ in the positive ionization mode. Once the precursors were determined, product ion scans were conducted to identify the reaction products of each analyte. The ethanolamines presented typical cleavages of water with the subsequent loss of the vinyl groups. In selected reaction monitoring (SRM) the most abundant product ion was preferred for quantitative purposes and a second ion was also monitored for confirmation (see Table 1). Because of the poor fragmentation yield of AEA, detection was performed in selected ion monitoring (SIM) mode monitoring the precursor ion. After that, the electrospray parameters were optimized to achieve the maximum sensitivity when the instrument was operated in either SRM or SIM. For TEA and MDEA the conditions were as follows: gas temperature, 350 °C; gas flow, 12 L/min; nebulizer, 35 psi; and capillary voltage, 3500 V. The source parameters for DEA were gas temperature, 250 °C; gas flow, 10 L/min; nebulizer, 50 psi; and capillary voltage, 3000 V. Finally, for AEA, the ionization conditions were gas temperature, 350 °C; gas flow, 12 L/min; nebulizer, 35 psi; and capillary voltage, 4000 V. The dwell time for all the amines was 300 ms.

3.1.2. Background interferences

High salt concentrations imply an appreciable increase in background signal in the electrospray [18]. Actually, sodium may form clusters with analytes and solvents that, in the low mass region, entirely suppress the analyte response [19]. For this reason, working standards prepared with a sodium chloride solution (7% by weight) were analyzed. First, the standards were run in scan mode and adduct formation was ruled out; then the FIA conditions were re-tested. As Fig. 1(A) and (B) shows sodium chloride dramatically masked the TEA signal (20 μg/L). So 10-fold dilutions of the standards were carried out with different combinations of solvents (MeOH and ACN) as a way of reducing the impact of the clusters. When the 7% NaCl standard was diluted in water (Fig. 1C) or MeOH/water (Fig. 1D), TEA was detected, but the signal was, at best, 40% of the original standard in water alone. When water was substituted with a combination of ACN and MeOH or ACN alone (Fig. 1E and F), the dilution of the 7% NaCl standard further improved the sensitivity with the signal strength. In fact, the dilution in neat ACN reached approximately 60% of the original standard in water alone. It is speculated that such an increment in the signal was due to a combination of the dilution effect (i.e. less NaCl competing in the

ionization process) and the presence of ACN, an aprotic organic modifier. In fact, this solvent barely interacts with sodium chloride and, therefore, solvation is weak [20]. Hence, this lack of ion stabilization leads to a minimal presence of clusters. Similar results were observed with the remaining amines (data not shown).

3.1.3. Liquid chromatography

The final step dealt with the behavior of the amines in the LC. The objective was to achieve the best transfer of analytes in the electrospray as well as adequate resolution of the peaks. Hence, matrix-matched standards (i.e. supernatants fortified with the amines and diluted 1:10 in ACN) were separated by reversed-phase chromatography. After testing different combinations of eluents and flows, the optimal LC parameters were as follows: in the case of TEA and MDEA, the composition of the mobile phase was water (98%)/ACN (2%). The flow was 0.2 mL/min and the run time was 5 min at 50 °C. A mix of water and MeOH (1:1) was used as eluent for AEA, with ammonium formate (5 mM) added as a buffer. The flow was 0.4 mL/min and the run time was 5 min as well and the temperature 40 °C. The DEA composition of the mobile phase was water (30%) and MeOH (70%) with ammonium formate (5 mM) added as a buffer in both eluents. The flow was 0.4 mL/min and the run time was 2 min and the temperature 40 °C. One micro-liter of either calibration standards or samples was injected for TEA, MDEA, and AEA, whereas the injection volume for DAE was 10 μL. The retention times for the compounds were TEA, 2.53 min; MDEA, 1.94 min; AEA, 1.50 min; and DEA, 1.01 min. A chromatogram for a 10 μg/L standard of TEA, MDEA, and DEA as well as for 100 μg/L of AEA is shown in Fig. 2.

3.2. Calibration experiments and validation

Besides sodium chloride, other species could be present in the wastewaters and compete with the amines in the ionization process. For this reason, a matrix-matched calibration approach was used in order to neutralize disruptions of instrument signal. The advantage of this technique resides in the preparation of calibration standards with the sample matrix instead of a pure solvent. Hence, both translational and rotational effects are prevented during the analysis (i.e. signal modifications are just due to the detector's responses toward different concentrations of analyte) [21,22]. Under these circumstances, however, the cause of the background interferences remains unsolved; thus the impact on the signal may change depending upon the test material (e.g. the

[a] Precision calculated as the RSD of 5 replicates. Accuracy calculated as the percentage ratio between measured and theoretical concentrations. Concentration for TEA, MDEA, DEA 250 μg/L and for AEA 500 μg/L.
[b] Precision calculated as the RSD of one standard (500 μg/L) run on five days. Accuracy calculated as the percentage ratio between measured and theoretical concentrations.
[c] Recovery target concentration for all the compounds 500 μg/L. Precision calculated as the RSD of 6 replicates.

two saline wastewaters herein studied). Additionally, only blank matrices are suitable for this calibration method since the presence of endogenous analytes in the sample would require standard additions. Regardless of the ad hoc character defined by these two limitations, a matrix-matched calibration, when suitable, is a valid solution dealing with strong matrix problems as in the present case.

With this objective, the supernatants from Reactor 1 (3% NaCl) and Reactor 2 (7% NaCl), which were amine-free upon analysis, became the solvents used in the stock solutions of the analytes. Subsequently, the preparation of the calibration standards consisted in sequential 1:10 dilutions of the stocks with ACN. In this fashion, TEA, MDEA, and DEA presented linear calibration curves for both matrices in a concentration range of 10–1000 μg/L, with seven levels injected in duplicate; as to AEA, for the two salinities linearity was achieved between 100 and 1000 μg/L with five levels run in duplicate (see Table 2 and Fig. 3). For all the compounds, the two regression lines manifested the contrast between sensitivities as a consequence of the salt contents; this difference is significant after comparing the slopes by means of a *t*-test as described by Massart et al. [23]. The Student's test corroborated signal dependence on sample composition and the need for using the specific matrix in each calibration. The detection limits were calculated through the calibration curve method [24] and the obtained values were

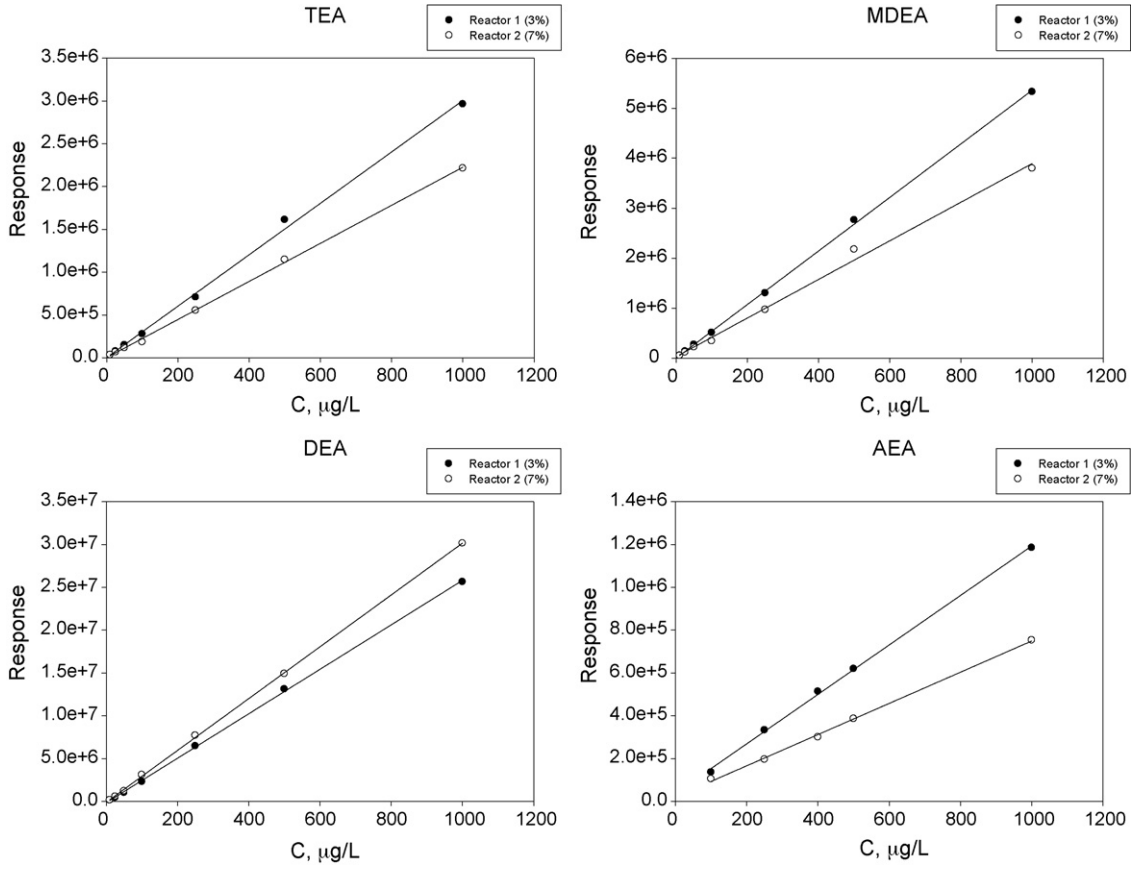

Fig. 3. Calibration curves for the target analytes in both Reactor 1 (3% NaCl) and Reactor 2 (7% NaCl) wastewaters.

comparable to other reported instrumental detection limits in less complex matrices [16,25].

For both salinities, an assay of the within-laboratory reproducibility was conducted and the results are listed in Table 3. In order to ascertain the precision, the relative standard deviation (RSD) of replicates was calculated, where the percentage of actual to expected concentration of the standards determined the accuracy. The study of the within-run repeatability consisted of the concurrent analysis of five standards (500 μg/L for AEA; 250 μg/L for TEA, MDEA, and DEA) and supernatant samples. With this objective, a standard was injected at the beginning of the run and after every ten samples. In all cases, the RSD values were under 10% and the accuracy values close to 100%. A second test was designed for determining the between-run variation. For five days, a standard (500 μg/L for all the amines) was injected and, each time, quantified with a fresh calibration curve. The precision values ranged between 3% and 9% and the accuracy varied from 97% to 108%. The validation of the protocol was completed with a recovery experiment. In this case, the ethanolamines (5 mg/L) were spiked in six mix liquor samples (500 mL) from each bioreactor and mixed for 30 min. Subsequently, aliquots (2 mL) were withdrawn and, after filtration and dilution in ACN, the measured concentration should be 500 μg/L. Again, good precision and accuracy were achieved: RSD values were smaller than 10% and the amines were recovered quantitatively.

4. Conclusions

An analytical protocol for the determination of ethanolamines is provided for its application to industrial saline wastewaters. Trace levels (10–1000 μg/L) were measured by LC–ESI-MS/MS without extraction, pre-concentration, or derivatization. Dissolution of hypersaline wastewaters in acetonitrile minimized the ion suppression attributable to sodium clusters. Other errors due to potential unknown interferences were compensated by the application of a matrix-match calibration model. The pertinent requirements for precision and accuracy were achieved in the analysis of working standards and fortified samples prepared with both mixed liquors from the industrial treatment plant.

Dust

ABSTRACT

The extraction of polybrominated diphenyl ethers (PBDEs) from SRM 2585 (Organic Contaminants in House Dust) was investigated using supercritical fluid R134a as an extraction solvent. Three methods of dust extraction were studied: (1) extraction of dry dust, (2) extraction of dry dust dispersed on Ottawa sand and (3) extraction of dust wet with dichloromethane. For each of the three sample preparation methods, extracts at three temperatures (110, 150, and 200 °C) above the critical temperature of R134a were performed. Eight PBDE congeners (BDE-28, -47, -99, 100, -153, -154, -183, and -209) in the SFE extracts were analyzed by liquid chromatography negative-ion atmospheric pressure photoionization tandem mass spectrometry (LC/NI-APPI/MS/MS). The optimum extraction of PBDEs from house dust using supercritical R134a is obtained when the dust is pre-wet with dichloromethane prior to extraction to swell the dust. For all sample preparation methods, higher temperatures afforded higher percent recoveries of the eight PBDE congeners. Only a combination of high-temperature (200 °C) and pre-wetting the dust with dichloromethane produced high recovery of the environmentally important, fully brominated PBDE congener, BDE-209.

1. Introduction

In comparison to liquid phase solvents, supercritical (sc) solvents possess the ability to manipulate the solvent strength based upon the fluid temperature and pressure. This can have a dramatic effect on the solvency properties of the fluid that can be advantageously selected to permit good-solvency at high fluid density and poor-solvency at low fluid density. This solvent strength manipulation is most readily accomplished by adjusting the fluid pressure of a gaseous solvent. At high-pressure, the dense, liquid-like solvent can selectively extract target analytes and then by rapidly reducing the pressure through expansion through a valve or restrictor the solvent is instantaneously transformed into a low-density gas with poor solvent strength. The dissolved analyte rapidly nucleates from the solvent and the target analyte can be collected and concentrated by directing the gas onto a solid support or by bubbling through a liquid solvent. The primary advantages of a supercritical fluid extraction (SFE) over liquid based extractions are the rapid extraction kinetics due to the high-diffusivity of the dense gas solvent, copious amounts of solvent are not utilized during the extraction, and that time and energy intensive solvent reduction steps are not necessary post collection. Despite these advantages, supercritical fluid extraction has not gained widespread use over conventional liquid based extractions or pressurized liquid extraction (PLE) due to the safety issues associated with high-temperature, high-pressure gases, the lack of commercial automated SFE instrumentation, and the lack of suitable solvents with reasonable critical points. The most widely used supercritical solvent is carbon dioxide which possesses a low critical temperature (T_c = 32 °C) yet has a relatively high critical pressure (P_c = 72 atm). The lack of a permanent dipole moment relegates $scCO_2$ extractions to applications where non-polar analytes need be extracted. While the use of small percentages of fluid modifiers in $scCO_2$ will increase the polarity range of the analytes that can potentially be extracted, other gaseous fluids are commercially available that do possess permanent dipole moments which may be better exploited for SFE.

One class of compounds that has a long history of use as vapor phase solvents are the chlorofluorocarbons (CFCs) and more recently the hydrochlorofluorocarbons (HCFCs). However, countries ratifying the 1987 *Montreal Protocol on Substances that Deplete the Ozone Layer* have agreed to phase-out CFCs and HCFCs. Consequently, industry has turned to hydrofluorocarbon (HFC) replacements for CFCs and HCFCs across a broad spectrum of applications. Studies concluded that best replacement for R12 (dichlorodifluoromethane) was R134a (1,1,1,2-tetrafluoroethane).

This increase in commercial availability and resultant lowered cost of R134a in combination with a permanent dipole moment (2.05 D) and reasonable critical properties (101.1 °C, 40.6 atm) led to evaluation of its use as an alternative to $scCO_2$ for the extraction of more polar analytes [1]. One group of semi-volatile analytes that has emerged as a ubiquitous contaminant in recent years are the brominated flame retardants (BFRs).

Flame retardant chemicals are required by law to be added to consumer products and have undeniably reduced the loss of property and human lives to fires [2]. The BFRs are currently the largest market group of flame retardants due to their low-cost and high-performance efficiency. The five major BFRs are tetrabromobisphenol A (TBBPA), hexabromocyclododecane (HBCD), and three commercial polybrominated diphenyl ether (PBDE) mixtures (pentaBDE, octaBDE, and decaBDE). Unlike the other two PBDE mixtures, decaBDE is almost exclusively BDE-209. Of the 209 unique PBDE congeners, BDE-28, BDE-47, BDE-99, BDE-100, BDE-153, BDE-154, BDE-183, and BDE-209 are the most prevalent in the environment due to their presence in these commercial mixtures. While the main producer of PBDEs in the U.S. voluntarily discontinued production of pentaBDE and octaBDE mixtures in 2004 [3] and Maine and Washington have recently banned the use of decaBDE; BDE-209 remains the most widely used PBDE globally (56,100 tons in 2001) with equal use in North America and Asia [4]. As of July 2008, the European Court of Justice has overturned a prior exemption for the use of DecaBDE in electronics and electrical applications [5]. Even with a cease on production and use of PBDEs, long-term monitoring of PBDEs will be necessary for an indefinite future time.

Since emergence the late 1970s, PBDE levels have increased in human blood and breast milk [6–11]. In addition to PBDE dietary intake [12–14], recent studies have found that the inhalation, ingestion, or dermal contact of house dust is the predominant route of human exposure [15–23]. The extraction, chromatographic separation, and detection of PBDEs have recently been reviewed [24,25]. While pure polyaromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs) exhibit high solubilities in supercritical fluids, when present in real-world matrices (e.g. dust), SFE is unpredictable due to the presence of organic co-contaminants, the matrix porosity, and analyte chemisorption [26–30]. Select applications for $scCO_2$, such as extraction of PBDEs from waste plastics [31] or for sample cleanup prior to analysis [32] have been reported. While di-brominated PBDEs show exhaustive extraction in $scCO_2$ from sediment samples [33], it is expected that the higher brominated congeners will not be highly soluble in $scCO_2$ similar to results found for higher molecular weight PAHs [26]. Though studies are limited, the use of scR134a in place of $scCO_2$ results in higher extraction efficiencies polar analytes from environmental matrices [34,35].

The scope of the current work is to evaluate R134a for the SFE of PBDEs from NIST SRM 2585 (Organic Contaminants in House Dust). Supercritical dust extracts will be quantified on a recently validated liquid chromatography with negative-ion atmospheric pressure photoionization tandem mass spectrometry (LC/NI-APPI/MS/MS) method [36] for the determination of the eight PBDE congeners of primary interest in dust.

2. Experimental

2.1. Chemicals

HPLC grade methanol (99.93%, Sigma–Aldrich, St. Louis, MO) and distilled–deionized water (>20 MΩ cm) from a Millipore Direct-Q water purification system (Billerica, MA) were used as LC mobile phase solvents. HRGC/HPLC-trace grade toluene (Pharmco, Brookfield, CT) was purified on an MBraun MB-SPS solvent purification system (Stratham, NH). HPLC grade dichloromethane (>99.9%) was purchased from Sigma–Aldrich (St. Louis, MO). SFE dispersants included diatomaceous earth (J.T. Baker, Phillipsburg, NJ), 40–63 μm silica (EM Science, Gibbstown, NJ), and Ottawa ignition sand (EMD Chemicals, Gibbstown, NJ). SRM 2585 (Organic Contaminants in House Dust) was obtained from NIST (Gaithersburg, MD). Individual PBDE standards prepared at 50 μg mL^{-1} in isooctane:toluene (9:1) of BDE-28 (99.3% purity), BDE-47 (100%), BDE-99 (100%), BDE-100 (100%), BDE-153 (99.3%), BDE-154 (100%), and BDE-183 (100%) were purchased from AccuStandard (New Haven, CT). Certified purity was determined by the vendor by GC/MS. Solid BDE-209 (98%) was purchased from Aldrich (St. Louis, MO).

2.2. Supercritical fluid extraction

A SFE instrument was constructed in-house. R134a is filled from the low-pressure side of an ISCO 260D syringe pump (Lincoln, NE). A Brinkmann circulating refrigeration bath (Westbury, NY) was used to cool the syringe pump to 5 °C and provided a liquid R134a fill. The high-pressure side of the syringe pump was connected to a temperature controlled (±0.1 °C) extraction cell. The extraction cell is comprised of a stainless-steel cell and a removable polyetheretherketone (PEEK) sample holder (Upchurch Scientific, part numbers C1000 and C-1035) with 0.5 μm stainless-steel frits at the entrance and exit of the sample holder. The extraction cell is capable of holding approximately 0.5 g of dust and has an internal volume of approximately 0.8 mL when empty. The extraction cell is placed in a heated aluminum block and controlled using the injection port heating control from a Hewlett-Packard 5890 gas chromatograph (Wilmington, DE). The aluminum block is large enough to accommodate a coiled section of tubing to preheat the R134a. Within the chromatographic oven, a 5 cm piece of 150 μm o.d., 75 μm i.d., fused silica capillary tubing (Polymicro Technologies, Phoenix, AZ) restricted the SFE cell exit flow out and maintained fluid backpressure when the ISCO 260D was operated in constant pressure mode.

Three methods of dust extraction were studied: (1) extraction of dry dust, (2) extraction of dry dust dispersed on Ottawa sand and (3) extraction of dust wet with dichloromethane. For the extraction of dry dust, approximately 0.25 g of NIST SRM 2585 was quantitatively transferred into an empty PEEK extraction cell. For the extraction of dry dust dispersed on Ottawa sand, approximately 0.25 g of NIST SRM 2585 and approximately 0.5 g of Ottawa sand were mixed and added to an empty PEEK extraction cell. For the extraction of dust wet with dichloromethane, approximately 0.25 g of NIST SRM 2585 was quantitatively transferred into an empty PEEK extraction cell and loaded into the stainless-steel extraction vessel. Dichloromethane was added to the dust in a 3:2 dichloromethane to dust ratio by mass. Once the PEEK cell was prepared it was placed into the stainless-steel extraction vessel. Immediately thereafter, 20 mL of liquid R134a (monitored at the syringe pump) was passed through the extraction vessel at a pressure of 204 atm, the valve at the syringe pump exit was closed and the cell was allowed to depressurize through the restrictor. Upon expansion out of the restrictor, gaseous R134a and the extracted solutes were bubbled through approximately 3 mL of dichloromethane in a 5 mL collection vial that resided on the inside of the GC oven. The GC oven was maintained at 40 °C to warm the expanding refrigerant and prevent restrictor freezing and plugging. Extraction efficiencies were evaluated at 110, 150 and 200 °C to investigate kinetics and solubility of the PBDEs.

REFPROP (Version 7.1, NIST 2006) was used to calculate the fluid densities from equations of state explicit in Helmholtz energy, the modified Benedict–Webb–Rubin equation of state, and an extended corresponding states model. At 204 atm, the R134a densities were calculated to be 1.04, 0.91, and 0.73 g mL^{-1} for 110, 150, and 200 °C, respectively.

2.3. Analysis of supercritical fluid extracts

BDE-28, BDE-47, BDE-99, BDE-100, BDE-153, BDE-154, BDE-183, and BDE-209 were quantified in the SFE extracts by LC/NI-APPI/MS/MS that is particularly well-suited for the analysis of the problematic BDE-209 [36]. Field blanks (n = 3) were obtained by SFE extraction of Ottawa ignition sand and analysis by LC/NI-APPI/MS/MS. Levels of tri- to hepta-BDE congeners in field blanks were below the detection limit and thus data were not blank corrected.

3. Results and discussion

3.1. SRM 2585 sample preparation

The levels of the eight PBDEs in SRM 2585 extracted with scR134a and quantified by LC/NI-APPI/MS/MS along with the certified NIST values for the PBDE congeners are presented in Table 1. The effects of wetting, not wetting, and dispersing SRM 2585 on an inert media on SFE recoveries and precision for the eight PBDE congeners were investigated. As a baseline to compare subsequent wetting and dispersant effects on SFE recoveries, a temperature study was performed on non-wet (dry) SRM 2585. At all temperatures studied, recoveries were approximately 50% for the tri- to hexa-PBDE congeners while recoveries were dramatically lower for the higher brominated congeners. Dispersing the dry dust onto an Ottawa ignition sand matrix was explored for its ability to evenly distribute the dust and permit a more uniform pathway for scR134a and increase the efficiency of R134a extraction by increasing the fluids access to dust particles. Dispersing SRM 2585 resulted in less restrictor plugging than without a matrix dispersant. Additionally, the micro-pores of the dust may become more accessible to the low viscosity, supercritical R134a which would increase the kinetics of extraction and recoveries over dry dust. For isothermal extractions, while neither SFE on dry dust nor SFE on the dry dust dispersed on Ottawa sand produced exhaustive extraction for the highly brominated congeners, an increased extraction of the higher molecular weight PBDE congeners was observed in the dust dispersed on Ottawa sand. The percent average relative standard deviation (%ARSD) for dry dust samples dispersed on Ottawa sand was 19.0%, while the %ARSD for the dry samples with no dispersant present was 29.1%, indicating that a higher precision was achieved by dispersing the dust on the Ottawa sand. Visually, it was observed that dry SFE changed the dust from a fluffy texture with a grey hue, to a compact, brick-like texture with a tan hue during extraction. When the R134a is flushed through a dry, compact dust sample, dust would entrain and block the stainless-steel frit on the SFE cell exit. The restricted R134a remains statically pressurized in the dust cell and the flow of R134a will either cease, or intermittently release from the restrictor giving irreproducible SFE flow and poor precision.

Benner studied the SFE of PAHs and PCBs from SRM 1649a Urban Dust standards and concluded that when the dust matrix is swollen with water or dichloromethane extraction efficiency is increased [26]. This increase in recovery over SFE on non-wet dust is hypothesized to be due to matrix sites interacting with high molecular weight PAHs which are not easily disrupted by fluid modified carbon dioxide [26]. Increased temperatures and water swelling have a greater effect than fluid modifiers such as dichloromethane for soil matrices, but dust matrices are an even more challenging matrix from which to extract large molecules. In our study, we also found severe restrictor plugging with SFE on dust wet with water. The use of an automated ISCO 3560 is recommended in such cases; however, as this instrument is no longer commercially produced and one was not available for our use, wetting of the dust matrix with dichloromethane was explored for its ability to swell the dust and increase the permeability of the matrix so that PBDE desorption is facilitated. Our dichloromethane wet dust samples were amenable to SFE using our in-house extraction unit. Additionally, less restrictor plugging was observed in the dichloromethane wet SFE experiments, allowing for greater extraction efficiencies at higher temperatures. When the SFE extraction cell was examined post-extraction it was noted that the dust retained its fluffy texture throughout the extraction and did not compact or change color.

Swelling of the dust matrix can potentially disrupt the strong matrix–analyte interactions and reduce the energy necessary to desorb and solvate the analyte from the matrix. Thus, lower extraction temperatures may be required for lower molecular weight analytes with wetting. As the micro-pores of the dust swell open, the low viscosity, supercritical R134a can more readily permeate the dust and increase the extraction kinetics. In comparing the isothermal extraction of dry and dichloromethane wet dust, an increased extraction of the higher molecular weight PBDE congeners was observed in the dichloromethane wet samples of Table 1. The ARSD for the dichloromethane wet samples was 23.6% while the ARSD for the dry samples was 29.1%, indicating that in addition to higher recoveries, a higher precision was achieved by wetting the dust. Although the recoveries are improved for the lower congeners with dichloromethane wetting, it is only by wetting the dust with dichloromethane at 200 °C that a high recovery (86.5 ± 6.1%) for BDE-209 was realized.

While it can be argued that in the dichloromethane wet R134a extracts the R134a fluid was modified with dichloromethane, this was not done in the traditional fashion of adding the fluid modifier to the high-pressure pump and delivering the fluid in a constant percentage of the modifier. In these experiments SRM 2585 was wet with dichloromethane primarily to swell the dust matrix and affect the extraction efficiency. Various models such as the Hildebrand solubility parameter, Hansen solubility parameters, and Kamlet–Taft solvatochromic parameters will afford the comparison of solvent properties between

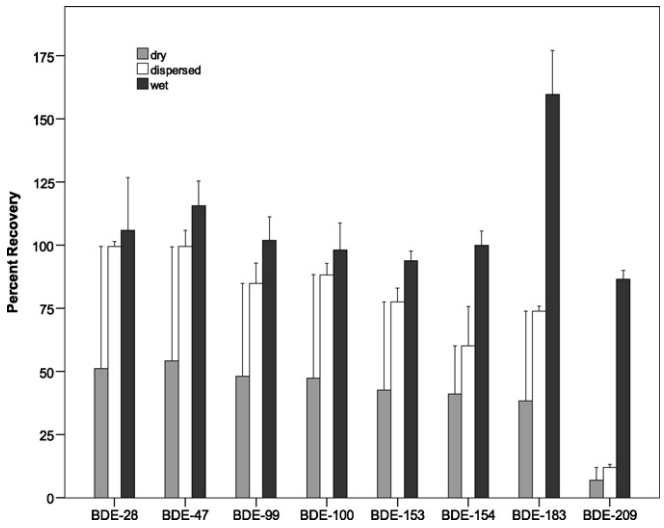

Fig. 1. Comparison of percent recoveries at 200 °C for SRM 2585 using the three SFE sample preparation techniques. Error bars represent ±1.0 standard error of the mean.

supercritical and liquid solvents [34,37–39]. Though the dipole moment of dichloromethane (1.55 D) and dielectric constant are slightly less than R134a, both the Hildebrand and Hansen parameters for dichloromethane suggest that the dispersion parameter can be enhanced by using dichloromethane modified mixtures. Kamlet–Taft solvatochromic parameters ascribe little to no acidity or basicity to both fluids but the dipolarity/polarizability parameter for dichloromethane ($\pi^* = 0.82$) is greater than that of scR134a (π^* is adjustable between 0 and 0.4 with fluid density above the critical point).

3.2. SFE temperature

For each SRM 2585 sample preparation method, SFE temperatures of 110, 150 and 200 °C were investigated. The thermodynamic relationship for the mole fraction solubility, y_2, of a solid in a supercritical fluid at equilibrium is given by

$$y_2 = \frac{P_2^{sat}[V_2^o(P - P_2^{sat})/RT]}{\phi_2} \approx \frac{P_2^{sat}[V_2^o P/RT]}{\phi_2} \quad (1)$$

where P_2^{sat} is the saturated vapor pressure of the solid, ϕ_2 is the fugacity coefficient, V_2^o is the solid molar volume, and P and T are the system pressure and temperature, respectively. Solid solubility in supercritical fluids can be envisioned as the enhancement over ideal solubility based upon vapor pressure alone. This enhancement scales with fluid pressure (density) and at pressures about the critical point the enhancement is more pronounced due to a microscopic phenomenon known as "clustering" where solvent molecules cluster about a solute and the local solvent density approaches 2.5 times the bulk fluid density. As solvent–solute clustering usually occurs at ~0.6 the critical density of the solvent (R134a $\rho_c = 0.51\ g\ mL^{-1}$), this effect will not be relevant to the liquid-like densities studied herein.

However, with elevated fluid temperatures, P_2^{sat} is increased and the solubility of higher brominated congeners with high enthalpies of vaporization and lower vapor pressures will benefit. The vapor pressures of the PBDEs range from 0.12 Pa for mono-brominated PBDEs to 58 μPa for the hepta-brominated congeners [40]. A drawback to an increased extraction temperature is decreased supercritical fluid density which will reduce fluid density, π^* values, and consequently solvent strength.

PBDEs can exist adsorbed to the surface of the dust particle and trapped in the bulk of the particle as the particle continues to grow. If PBDEs are simply adsorbed to the surface of the dust particle, the dry and dispersed SF experiments will produce similar recoveries. This should be dictated mainly by extraction kinetics exhibiting increased extractions at higher temperatures as is observed in Table 1. The effect of lowered fluid density at higher temperatures does not decrease recoveries indicating that the temperature effect on vapor pressure or overcoming the matrix interaction dominates the extraction efficiency. Fig. 1 compares SF extractions at high temperatures using the three sample preparation techniques investigated. When the dust is swollen with dichloromethane, (1) potentially the inner PBDEs trapped in the bulk dust particle become accessible to the fluid or (2) the fluid modifier effect is pronounced, or a combination of both. Regardless, enhanced recoveries are observed for the highly brominated PBDEs that cannot be achieved by the other two extraction techniques.

4. Conclusions

The optimum extraction of PBDEs from house dust using supercritical R134a is obtained when the dust is pre-wet with dichloromethane prior to extraction to swell the dust. An increase in fluid temperature is more important than maintaining high fluid densities at lower temperatures to increase extraction efficiencies and extraction at 200 °C. Only a combination of high temperatures and pre-wetting the dust with dichloromethane produced high recovery of the environmentally important, fully brominated PBDE congener, BDE-209.

ABSTRACT

Current work has evaluated uncertainty associated to quantification of several organic compounds present in particulate matter of atmospheric aerosols, setting out the stages of analytical procedure that contribute most to the global uncertainty. Several sources of uncertainty have been identified, which were clustered into five main contributions: sampling, extraction, clean-up, derivatization and analysis. A discussion of the main contributions to the overall uncertainty is reported, allowing authors to locate the largest ones and plan future improvements. Combined uncertainties ranged between 10–18% (alkanes), 12–16% (PAHs), 10–18% (alcohols) and 9–21% (acids). The analytical procedure was validated by analysing a standard reference material (SRM1649a, urban dust). Also, the proposed method was applied to the analysis of four samples of particulate matter.

1. Introduction

Nowadays, there is a growing concern about atmospheric aerosols due to two main causes: their hazardous effects on human health as far as its role in climate change [1]. Particulate matter can induce chronic respiratory illness, cancer and premature dead; so many studies related to aerosols have been published recently [2–4]. Also, aerosols influence the global climate, directly by scattering and absorbing solar radiation, and indirectly by modifying cloud optical properties due to their ability to act as cloud condensation nuclei [5]. Thanks to increased awareness of the scientific community and the suppression almost all analytical difficulties, number of published works related to atmospheric aerosols have increased considerably [6–13]. Particulate matter is comprised for thousand of organic components. Many studies have summarized into aliphatic hydrocarbons, PAHs and polar species (acids and alcohols). Despite so many published studies, nowadays it is not known the accurate composition of atmospheric aerosols; simply it is known only a part of the organic fraction of the atmospheric aerosol [14].

Sample preparation for quantifying organic compounds involves several steps: firstly extraction procedures, in second place a clean-up step, followed by a derivatization reaction when necessary, and eventually quantification by chromatographic techniques [6]. Almost all these stages can produce losses or contamination and therefore generate uncertainty. Published studies have focused on quantifying the maximum number of species associated with particles and are not published data on their associated uncertainty.

Studying organic composition of atmospheric aerosol will allow understand and reduce dangerous effects that aerosols could produce. In order to make decisions it is important to have data with high quality. In analytical chemistry, quality can be demonstrated by calculating the uncertainty associated with the outcomes [15]. Specifically, uncertainty is defined as "*A parameter associated with the result of a measurement that characterises the dispersion of the values that could reasonably be attributed to the measure*' [16]. For this purpose, the expanded uncertainty might be used because provides an interval within which the results measured are believed to lie with higher level of confidence. This uncertainty is obtained by multiplying the combined standard uncertainty by a coverage factor, which is function on the level of confidence desired [17].

This work presents an analytical method for the identification and quantification of some constituents linked to particulate matter of atmospheric aerosols, including *n*-alkanes, PAHs, alcohols and carboxylic acids. In light of the above, purposes of this work were to assess uncertainty associated to quantification of organic compounds presents in particulate matter of aerosol, and to study each uncertainty source to determine critical stages of the analytical method in order to reduce them. Validation of methodology has been performed by analysing a standard reference material. Also, this methodology has been implemented to samples of particulate matter collected in a rural area of Madrid (Spain).

2. Experimental

2.1. Chemicals

The analytical standards of *n*-alkanes and fatty acids were purchased to Sigma–Aldrich. Solution composed of alkanes from C_8 to C_{40}, was dissolved in hexane at 500 μg mL^{-1}. PAHs mixture (100 μg mL^{-1}) was obtained from Dr. Ehrenstorfer, GMBH. The analytical standard of alcohols (C_{12} to C_{24}) was acquired to Accustandart. Also, linoleic and oleic acids with purity higher than 99% were purchased from Fluka, meanwhile pinic, pinonic and norpinonic acids were obtained from Aldrich. Hexane, dichloromethane, acetonitrile, acetone, isooctane, ethyl acetate and methanol of GC grade were acquired to SDS. Other compounds, such as BSTFA, deuterated palmitic acid and 1–chlorododecane were supplied by Aldrich and Supelco.

All standards prepared from stock solutions were placed in sealed flasks and refrigerated at −4 °C until their analysis.

2.2. Materials and instruments

A high volume sampler with size cut <2.5 μm (CAV-A/HF, MCV España) was employed to collect aerosol particulate matter. Flow rate was 30.4 m^3 h^{-1}, sampling time was 24 h, collecting 730 m^3 of air. This volume of air generated 1.5 g of particulate matter.

Extraction was performed with an automatic Soxhlet device (Büchi B-811), being extracts concentrated using rotary evaporator (Büchi R-200). Clean-up step was carried out with silica gel column.

For gas chromatography, an Agilent 6890 chromatograph with automatic sampler and coupled to an Agilent 5975 mass spectrometer, was employed. For PAHs analysis, an Agilent series 1100 HPLC system with fluorescence detector was used.

2.3. Analytical procedure

Sample deposited on filters were Soxhlet extracted with 150 mL dichloromethane/acetone (4:1) for 8 h. The extracts were concentrated with a rotary evaporator to 1 mL and later with a slight stream of nitrogen to 100 μL. This extract was cleaned-up via sequential elution through a silica gel column using solvents of increasing polarity to provide four fractions to separate chromatographic analysis of: (1) alkanes; (2) PAHs; (3) alcohols; and (4) acids. Polar fractions were derivatized by reaction with N,O-bis-(trimethylsilyl)-trifluoroacetamide (BSTFA) to convert alcohols and acids to the trimethylsilyl ethers before GC/MS analyses.

Extracts with alkanes, alcohols and acids were analyzed using GC/MS. Operating conditions were as follows: initial oven temperature 50 °C, increased at a rate of 100 °C min^{-1} to 90 °C, held 5 min, then increased at rate of 5 °C min^{-1} to 200 °C and finally increased at rate of 10 °C min^{-1} to 300 °C and held for 23 min; PTV injector had a initial temperature of 60 °C, held for 0.5 min, then increased at a rate of 350 °C min^{-1} to 350 °C; operation mode: splitless with multiple injection; carrier gas: He; capillary column HP-5MS (30 m × 0.25 mm i.d. film thickness 0.25 μm) with flow-rate: 1 mL min^{-1}; detector operated in electronic impact mode (70 eV). For alcohols and acids temperature program changed slightly: initial temperature 50 °C, increased at a rate of 100 °C min^{-1} to 90 °C, held 1 min, then increased at rate of 10 °C min^{-1} to 150 °C and finally increased at rate of 5 °C min^{-1} to 290 °C and held for 5 min. PAHs were submitted to HPLC device according to an analytical procedure previously published [18].

Chromatographic peaks were identified by coinjection with authentic standard compounds, also compounds were identified by GC–MS analysis. Ions monitored were: alkanes (m/z = 51, 77, 85), alcohols (m/z = 75, 103) and acids (m/z = 75, 117).

3. Results and discussion

3.1. Validation of the analytical methodology

Validation can involve evaluating up to 14 parameters [19], without include uncertainty. In this paper, in addition to uncertainty, were determined the following parameters: precision, linearity and selectivity. For this purpose, calibration curves were obtained for all studied species.

Standard solution were analyzed in the range from 0.1 to 10 mg L^{-1} (alkanes), 5 to 500 μg L^{-1} (PAHs), 0.1–50 mg L^{-1} (alcohols) and 0.1–25 mg L^{-1} (acids) with good linearity (correlation coefficient > 0.996, >0.996, >0.990, >0.992 for alkanes, PAHs, alcohols and acids). Calculation of a seven-point linear plot with three replicates, based on linear regression and squared correlation coefficient were performed.

For an analytical system where the validation range does not include or approach it, the detection limit does not need to be part of a validation [19].

Sensitivity can be defined as the slope of calibration curve. For alkanes sensitivity ranged from 0.6 to 2.1 L mg^{-1}, for PAHs ranged from 0.2 to 5.7 L μg^{-1}, meanwhile ranged from 0.07 to 0.09 L mg^{-1} and from 0.04 to 0.08 L mg^{-1} for alcohols and acids, respectively.

Taking into account the lack of a certified reference material with all compounds involved in this work, traceability cannot be demonstrated for all ones. Just the reference material SRM1649a of urban dust certifies some PAHs. So, it has been employed to evaluate traceability of the analytical procedure described in this work for PAHs. Results are showed in Table 1.

3.2. Estimation of uncertainty

Uncertainty estimation associated with a result involves four main steps: (a) specify measure and; (b) identify uncertainty sources; (c) quantify uncertainty components; and (d) calculate combined uncertainty.

The expression to calculate the concentration of an analyte into atmospheric aerosol, expressed in ng m^{-3}, is shown in Eq. (1). This equation specifies measured in function of different variables:

$$\text{concentration} = \left(\frac{C_{\text{cal}} \times A \times V_{\text{s}}}{V_{\text{A}}}\right) \quad (1)$$

where C_{cal} is the analyte concentration obtained from calibration (in mg L^{-1}); A is the area of filter analyzed; V_{s} is the final diluted volume (0.5 mL for PAHs and 1 mL for the rest of compounds); V_{A} is the volume of air sampled (730 m^3). Area of filter affects final concentration because in this study we do not analyze the entire filter, half of the filter was used for inorganic analysis.

All parameters in Eq. (1) are main sources of uncertainty. However, they are not the only ones because each step of the analytical procedure can be an uncertainty source. The three schemes of the

analytical procedures to determinate the concentrations of alkanes, PAHs, alcohols and acids are presented in Fig. 1.

According to these schemes, the air concentrations of organic compounds were mainly affected by the following sources: sampling; extraction; clean-up; derivatization; chromatographic analysis.

The combined uncertainty (in terms of relative uncertainty) can be calculated using Eq. (2):

$$U_r(\text{Total}) = \sqrt{U_r^2(\text{Conc}) + U_r^2(\text{Samp}) + U_r^2(\text{Ext}) + U_r^2(\text{Clean}) + U_r^2(\text{Deriv})} \quad (2)$$

To calculate all variables present in Eq. (2), called sources of uncertainty, and resolve it, there are two alternatives: (a) evaluating uncertainty arising from each individual source and then combining them or (b) determining directly the combined contribution to the uncertainty on the result from some or all of the sources using method performance data [15]. In practice, a combination of both alternatives is usually necessary and convenient.

3.2.1. Estimation of the uncertainty derived from chromatographic analysis

This uncertainty is a combination of the uncertainties associated with chromatographic analysis. It includes uncertainty coming from sample volume, air volume, filter area and analyte concentration.

3.2.2. Sample volume

Uncertainty derived from volume of sample, $U(V_{\text{sample}})$, is calculated from three different sources: (a) the tolerance of volumetric material, through a triangular distribution within 0.01 mL as minimal division ($U_{\text{Vs1}} = 0.0041$ mL), (b) the volumetric repeatability is described by the standard uncertainty obtained from the weighing (four times) each volumetric material full of solvents ($U_{\text{Vs2}} = 0.0004$ mL) and (c) the temperature effect, that was negligible. The uncertainty from the volume of sample, $U(V_{\text{sample}})$, was 0.0041 mL for all compounds evaluated.

3.2.3. Air volume

This uncertainty is calculated in section 3.2.2.

3.2.4. Filter area

Uncertainty derived from filter area is calculated through a triangular distribution within 0.1 cm ($U_{\text{F}} = 0.041$ cm).

3.2.5. Analyte concentration

Uncertainty associated with analyte concentration (U_{AC}) is a combination of three sources which in turn are combination of several uncertainties. The three main sources are (a) analytical standards employed [U_{AS}], (b) chromatographic calibrate involve uncertainty from linear least squares calibration [U_{cal}] and (c) repeatability [U_{rep}].

In order to estimate uncertainty associated with analytical standards (U_{AS}) there were considered three main contributions: the first one was uncertainty of initial concentrations (U_{AS1}) according to certificates, the second one was uncertainty of dilution procedure along all analytical process (U_{AS2}) and the third one was uncertainty of weighty of each analytical standard ($U_w = 1.9\,\text{exp}^{-5}\,g$). Contribution to uncertainty of initial concentration was estimated from certificate values supplied by the manufacturer, 0.5% for alkanes and 1% for PAHs. Thus U_{AS1} was 0.1 mg L^{-1} for PAHs and ranged from 2.45 to 2.51 mg L^{-1} for alkanes. On the other hand, contribution to uncertainty of dilution procedure was 0.01 mL for alkanes and PAHs, and 0.02 mL for alcohols and acids. To calculate these uncertainties were considered contributions of temperature, repeatability and certified uncertainty in volumetric material. There is no information available about dilution procedure and 100% of the compound dissolves.

Uncertainty from linear least squares calibration [U_{cal}] is mainly due to variability in responses showed by the instrument. According with expression of linear regression, to calculate uncertainty of calibration, the subsequent expression is employed:

$$U^2_{C_{\text{calibration}}} = \frac{U^2_{\text{signal}}}{(\text{signal-intercept})^2} + \frac{U^2_{\text{intercept}}}{(\text{signal-intercept})^2} + \frac{U^2_{\text{slope}}}{(\text{slope})^2} \quad (3)$$

The first term have to be calculated by a repetition test. However, the second and third terms can be estimated from information given by software used to derive calibration. Table 2 includes the uncertainties associated with calibration of all compounds.

The last contribution to uncertainty of analyte concentration is repeatability [U_{rep}]. It was calculated by the standard uncertainty obtained from the repetition (four times) of the chromatographic measurement. Table 3 summarized these uncertainties.

As result, uncertainty associated with analyte concentration is shown in Table 4. In order to calculate this uncertainty, the subsequent expression is employed:

$$U^2_{\text{conc}} = U^2_{\text{AS}} + U^2_{\text{cal}} + U^2_{\text{rep}} \quad (4)$$

In order to estimate the uncertainty derived from chromatographic analyses, all contributions were expressed as standards uncertainties. For models involving only a product or quotient, for instance expression (1), the combined standard uncertainty is given by

$$U_{\text{chromatography analysis}} = \sqrt{\left(\frac{U_{V_{\text{sample}}}}{V_{\text{sample}}}\right)^2 + \left(\frac{U_F}{A_{\text{filter}}}\right)^2 + \left(\frac{U_{\text{concentration}}}{\text{concentration}}\right)^2} \quad (5)$$

In order to calculate combined standard uncertainty we chose the procedure that considers there is not covariance between each source of uncertainty. Thus, Table 5 shows the uncertainties derived from chromatographic analysis for each compounds.

3.2.6. Estimation of the uncertainty derived from sampling

High volume samplers do not maintain constant flow rate so can generate bias in caudal of sampling air. However, this bias is hardly ever published, only there is studies have compared different methods for sampling of atmospheric aerosol [20,21]. For this reason, uncertainty related to sampling is difficult to evaluate and thus to minimize.

This uncertainty is calculated considering two contributions: (a) temperature effect, produced by variation of temperature during sampling, through a rectangular distribution within ±15 °C (U_{S1} = 2.32 m^3) and (b) precision of samplers, in this case we assumed an error of 5% in the air volume collected by the samplers (U_{S2} = 36.50 m^3). The combination of these contributions, considering both independents, generate a final value for $U(V_{\text{sampling}})$ of 36.57 m^3. The high volume sampler used in this work, collected a total air volume of 730 m^3, so standard uncertainty $U^2_{(\text{sampling})}$ was 0.00251.

3.2.7. Estimation of the uncertainty derived from Soxhlet extraction

As part of the in-house evaluation of the method, an extraction experiment was planned to evaluate repeatability and recovery. It was performed four replicates. Filters, which are similar those employed to collect samples, were spiked with analytes at similar concentration to those of air samples (the standard solution range chosen (0.5 and 1 mg L^{-1}) was selected in order to averaging the entire compounds studied). The standard solution range chosen was selected in order to averaging the entire range of compounds studied. Uncertainties were calculated as uncertainties type A. However, uncertainties associated to this experiment actually included contributions from extraction process, chromatographic analysis and derivatization process when be necessary. Hence, to know the contributions from Soxhlet extraction, uncertainty value must be calculated as follows:

$$u^2_{\text{extraction}} = u^2_{\text{ext.exp}} - (u^2\text{chrom analysis} + u^2\text{derivatization}) \quad (6)$$

Table 6 summarizes the contribution of the extraction to uncertainty for each analyte.

3.2.8. Estimation of the uncertainty derived from clean-up step

It has been designed a method with performance data of the clean-up stage in order to evaluate its uncertainty. It was performed four replicates. As same as uncertainty derived from extraction, uncertainty calculated experimentally for clean-up included contributions from chromatographic analysis and derivatization procedure, so the uncertainty value is calculated as follows:

$$u^2_{\text{clean-up}} = u^2_{\text{clean-up exp.}} - (u^2\text{chrom analysis} + u^2\text{derivatization}) \quad (7)$$

Table 6 recapitulates results for this contribution.

3.2.9. Estimation of the uncertainty derived from derivatization

This source of uncertainty is only associated with polar compounds. To evaluate its contribution four derivatization experiments were performed. Uncertainty experimental includes the contribution from chromatographic analysis so it was necessary subtract it. Table 6 shows results obtained.

3.2.10. Calculating the combined uncertainty

Before combine the components of uncertainty, they must be expressed as standard uncertainties. The relationship between the combined standard uncertainty of a value y, $U_c(y)$, and the uncertainty of independent parameters $x_1, x_2, \ldots, x_n$ on which depends is shown in Eq. (3):

$$U_c(y(x_1, x_2, \ldots)) = \sqrt{\sum U(x, y_i)^2} \quad (8)$$

Standard uncertainties of each source are shown in Fig. 2. It has been shown that contributions derived of extraction are the most significant for several compounds. On the other hand, uncertainties derived of clean-up and derivatization are the lowest contribution for most compounds.

The final stage is to multiply the combined standard uncertainty by the chosen coverage factor k in order to obtain an expanded uncertainty (k = 2; coverage probability of 95%). Table 7 shows

uncertainties combined and uncertainties expanded for all compounds analyzed.

3.3. Application to real samples

The developed method was applied to the analysis of four particulate matter samples of atmospheric aerosol collected in a rural area of Madrid (Spain) during summer of 2004. The data results of these samples are summarized in Table 8.

4. Conclusions

Some figures of merit, such as accuracy, linearity and selectivity for the simultaneous determination of alkanes, PAHs, alcohols and acids linked to atmospheric aerosol particles have been determined. Validation of methodology has been accomplished by analysing standard reference material SRM1649a of urban dust.

This work aimed at identifying the main sources of uncertainty associated to determination of organic components of atmospheric aerosols, being the expanded uncertainty also calculated. From the analysis of each step of our analytical procedure, we could identify those steps of the method carrying the highest contributions to the overall uncertainty. It may be concluded from this study that the extraction stage generates more uncertainty, mainly for unsaturated acids and alcohols with high molecular weight. Thanks this assessment uncertainty we can try to plan specific improvements able to enhance accuracy of this procedure. Soxhlet is a conventional extraction procedure so it will be difficult to improve their results, however microwave extraction and accelerate solvent extraction (ASE), which are worldwide used and are accepted in EPA methods, can be an adequate alternative to reduce uncertainty associated to extraction.

Acknowledgements

The authors would like to thanks the old “Ministerio de Ciencia y Educación” for finance this work under the project REN2003-08603-C04-02. In addition, “Comunidad de Madrid” for their sampling support is acknowledged.

Fluoride in water

ABSTRACT

A new solid state fluoride ion selective electrode composed of 70% Ag_2S, 10% Cu_2S and 20% CaF_2 has been developed. An analytically useful potential change occurred, from 1×10^{-6} to 1×10^{-1} M fluoride ion. The slope of the linear portion (1×10^{-1}–1×10^{-5} M) was about 26 ± 2 mV/10-fold concentration changes in fluoride. It was found that pH change between 1 and 8 had no effect on the potential of the electrode. There was no interference of most common cations such as K^{+}, Na^{+}, Ca^{2+} and Mg^{2+} and anions such as Cl^{-}, NO_3^{-}, SO_4^{2-} and PO_4^{3-}. The lifetime of the electrode was more than 2 years, when used at least 4–5 times a day, and the response time was about 60 s.

The measurements were made at constant ionic strength (0.1 M $NaNO_3$) and at room temperature. This electrode has been used for the determination of fluoride ion in Ankara city tap water and in bottled spring water using standard addition method. The validation of the electrode has been made with a commercial fluoride ion selective electrode (Orion) and high consistency was obtained.

1. Introduction

The first investigations relating to the ion selective electrodes were done at the beginning of 1900. Increasing number of investigations about ion selective electrodes are being continuing as they have certain advantages such as they have good selectivity and give specific and sensitive results in short time. These electrodes are being used in clinical analysis and in routine control analysis of some ions and some biological species, because of their ease in use and selectivity characters [1,2]. They can be prepared rapidly, they can simply be produced with a very low cost and above all they allow us to analyze the solution without pre-treatments. Silver salts of spare solubility are used mostly for their preparation. It was found that solid state electrodes prepared from silver halogenides were sensitive to halogenides, however these electrodes could also be used for the determination of some cations such as mercury [3–5] indirectly. Pungor and Hollos [6] could determine iodide ion in the presence of chloride ion using an electrode prepared from silver iodide and paraffin. It was found that the electrodes made from two sulfide salts such as Ag_2S–PbS and Ag_2S–CdS were sensitive to lead and cadmium ions respectively [7]. A solid state ion selective electrode was prepared using Ag_2Se and Cu_2S which was selective to selenite [8].

Some of the ion selective electrodes are in solid state such as lead and cadmium [7], selenite [8], and hydroxide electrodes [9], some of them are prepared using PVC or silicon rubber membrane such as halide and sulfide [10], selenite [11], ferric ion [12], iodide [5] and glucose electrodes [1].

Small amounts of fluorine are vital for the human body, although larger quantities are toxic.

For two reasons the production of fluoride ion selective electrode is necessary.

(1) Fluoride is important in commerce and technology.
(2) Determining fluoride by previous techniques is difficult.

Some feeling for importance of a rapid and reliable method for monitoring fluoride can be gained by considering a list of materials in which fluoride occurs: (a) consumer products (toothpaste), (b) biological materials (present in tooth enamel, and bone), (c) pharmaceuticals (e.g. vitamins), (d) public water supplies (fluoridation), (e) water and air (pollution by discharge of industrial wastes), (f) electroplating and pickling baths (continuous monitoring for fluoride level regulation) and (g) manufactured materials (e.g. fertilizers, pesticides, glass, etc.).

For fluoride ion detection, LaF_3 membrane electrode [13] has been developed which is probably the most widely applied fluoride ion selective electrode for practical measurements. Thorium, calcium and the rare earth fluorides were also used for study as being suitably insoluble [14]. However, detailed investigation of precipitation procedures was necessary since normal precipitates of these fluorides tend to be gelatinous. In a recent study [15] a fluoride selective electrode with LaF_3 membrane and stainless steel internal contact has been prepared.

From the literature survey it maybe seen that there are very few electrodes for the determination of fluoride. The aim of this work

doi:10.1016/j.talanta.2009.08.037

was to fulfill this gap and to prepare an electrode selective for fluoride ion which is easy to prepare, easy to handle and has long lifetime. The present work describes the preparation and application of a new potentiometric fluoride selective electrode, which fulfills the above given futures.

2. Materials and methods

2.1. Apparatus and reagents

A JENWAY 3040 Ion Analyzer has been used for potential measurements and 924036 double junction Ag/AgCl reference electrode was used as the outer reference electrode. Chiltern H531 magnetic stirrer was used.

Reagent grade chemicals were used without further purification. Stock solutions were prepared with doubly distilled water and kept in dark. In order to keep the ionic strength constant, 0.1 M $NaNO_3$ was used. Measurements were made at room temperature 22 ± 2 °C and under nitrogen atmosphere.

2.2. Preparation of solid state crystal electrodes

For this purpose Ag_2S, Cu_2S and CaF_2 were mixed in various ratios so that the total weight was changing between 0.1 and 0.3 g.

Cu_2S was prepared by the addition of Na_2S to CuCl solution. To protect CuCl from air oxidation, this reaction was made under nitrogen atmosphere. About 2 g of CuCl were dissolved in 100 mL de-aerated water. By slowly addition of 0.1 M Na_2S and passing nitrogen, Cu_2S was precipitated. It was left waiting for about 30 min at 60 °C. Then it was filtered and washed until no precipitate formation was observed with silver nitrate. It was dried in an oven at about 110 °C and left waiting in a desiccator.

Ag_2S was prepared as given above for Cu_2S, except there was no need to protect from air oxidation but Ag_2S had to be kept in dark.

For the preparation of CaF_2, 4 g of $Ca(OH)_2$ was dissolved in 100 mL water with 1–2 drops of HCl and then 0.1 M NaF was added. CaF_2 precipitate was filtered and dried.

A certain amount of the salt or salt mixture of Ag_2S, Cu_2S and CaF_2 (10–15 mg) was taken and pellets were made by holding first under a pressure of 1940 atm for 1 min, then pressure was increased to 7760 atm by adding each time 1940 atm for 1 min. The pellets of 7 mm diameter were sealed with epoxy resin (0.7 g epoxy and 0.9 g hardener). To obtain a good sealing the epoxy resin on the edge of the tubing had to wait for about 10 min and then the pellet was sealed. One day after the pellet was sealed a silver wire is connected. For this purpose the inside of the glass tube was filled to about 1 cm with a mixture of 0.5 g graphite powder and epoxy resin. The electrode prepared had to wait for about 2 days so that the resin can get dry. The surface of the electrode is washed and then polished with a soft paper. These electrodes should be kept in air and in a dark place when they are not in use. The lifetime of these electrodes was more than 2 years, when used at least 4–5 times a day.

3. Results and discussion

3.1. Effect of electrode composition

Membrane composition has a great effect over the sensitivity, selectivity and stability of the ion selective membrane electrodes. In this study, electrodes in four different compositions were prepared to identify its effect. The measurements were made in 20 mL 0.1 M $NaNO_3$ solution, in order to keep the ionic strength of medium constant. The response of each electrode was measured after the additions of 0.2 mL NaF solutions so that fluoride ion concentrations changed from 0.1 to 1×10^{-6} M.

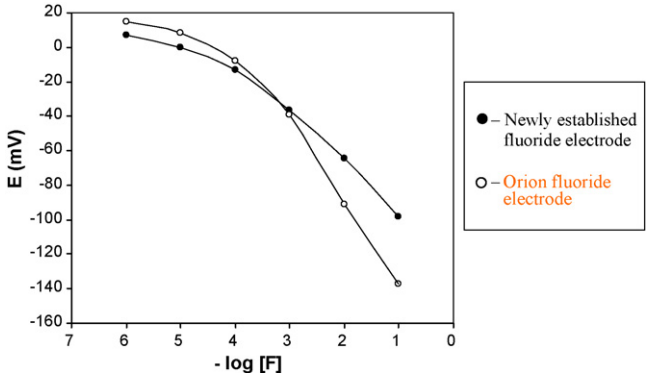

Fig. 1. Calibration curves for the new fluoride selective electrode (70% Ag_2S, 10% Cu_2S, 20% CaF_2) and for the commercial Orion electrode.

To obtain the calibration graph the potential readings were plotted against −log of fluoride ion concentration. For each composition four electrodes were prepared and their responses were measured. The Ag_2S percentage varied from 60% to 80% and CaF_2 from 5% to 30%.

The average slope of the curve in 1×10^{-4}–1×0.1 M concentration range was 5.6 mV ($R^2 = 0.9795$) for the electrode having 80% Ag_2S, 10% Cu_2S and 10% CaF_2 composition. The slope became very small at fluoride concentrations lower than 10^{-4} M. For the electrode having 75% Ag_2S, 25% Cu_2S and 5% CaF_2 composition the slope was about 12 mV for 1×10^{-4}–0.1 M concentration range. But no response was observed at concentrations lower than 10^{-4} M. The highest slope was obtained for the electrode having 70% Ag_2S, 10% Cu_2S and 20% CaF_2 composition. The slope was 26 ± 2 mV ($R^2 = 0.9923$) in 1×10^{-5}–1×0.1 M fluoride concentration range. The calibration curve for this electrode is shown in Fig. 1, together with the calibration curve obtained for the commercial Orion electrode. For the electrode having 60% Ag_2S, 20% Cu_2S and 20% CaF_2 composition, the slope was about 12 mV for 1×10^{-3}–0.1 M concentration range. The electrode with 30% CaF_2 could not be used since it was easily breakable.

The calibration curves for electrodes in different compositions are shown in Fig. 2. As can be seen the highest slope was obtained with the electrode in 70% Ag_2S, 10% Cu_2S and 20% CaF_2 composition.

3.2. The effect of pressure on the electrode sensitivity

The pressure applied on the electrode during preparation was changed from 4850, 7760, 9700 atm. The electrode with highest

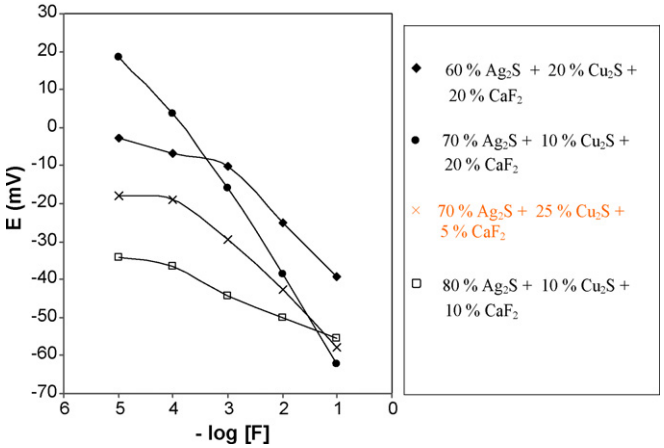

Fig. 2. Calibration curves for fluoride electrodes in different compositions.

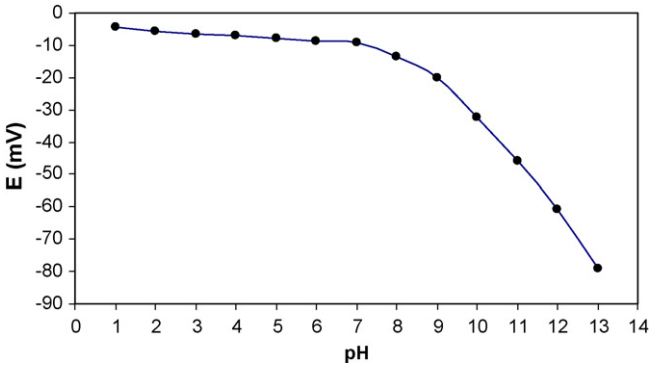

Fig. 3. pH dependence of (70% Ag_2S, 10% Cu_2S, 20% CaF_2) fluoride electrode.

slope was used for all pressures which had the composition of 70% Ag_2S, 10% Cu_2S and 20% CaF_2. It was found that the highest slope was obtained when 7760 atm was applied.

3.3. Effect of pH

Effect of pH on the potential readings at various fluoride concentrations, were investigated. For this purpose to 20 mL 0.1 M $NaNO_3$ solutions 0.02 mL aliquots of 1 M HCl was added and the potentials after each addition was measured. The same procedure was applied for the NaOH additions. The electrode with the highest slope (70% Ag_2S) was used during the measurements. The change in potential with pH was only 1–2 mV for each pH unit change from pH 1 to 8. At pH values larger than 8, the change in potential with pH was about 15 mV for each pH unit. As can be seen from Fig. 3, this electrode can be used between pH 1–8 safely.

3.4. The response time of the electrode

The response time of the electrode depends to the concentration change. The electrode with the highest slope was used throughout the measurements. The potential values were measured for each concentration change after 30, 60, 90, 120 and 150 s. When fluoride concentration was changed from 1×10^{-5} to 1×10^{-4}, 1×10^{-4} to 1×10^{-3}, 1×10^{-3} to 1×10^{-2}, and 1×10^{-2} to 1×10^{-1} M, the response of the electrode was about 60 s, which is a short period and it is an advantage. For this reason, this electrode can easily be used for routine analyses.

The responses of electrode obtained for various concentration changes are shown in Fig. 4. All these measurements were made at constant temperature.

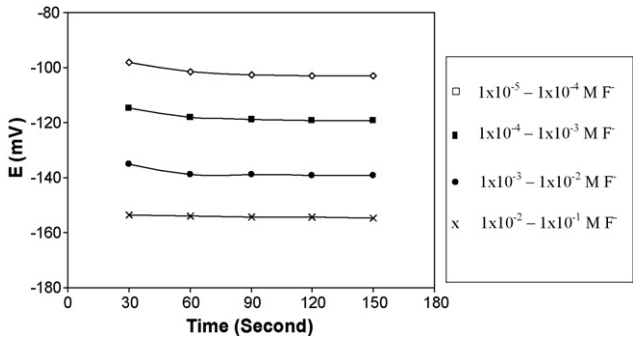

Fig. 4. The dependence of response time on the change of concentration.

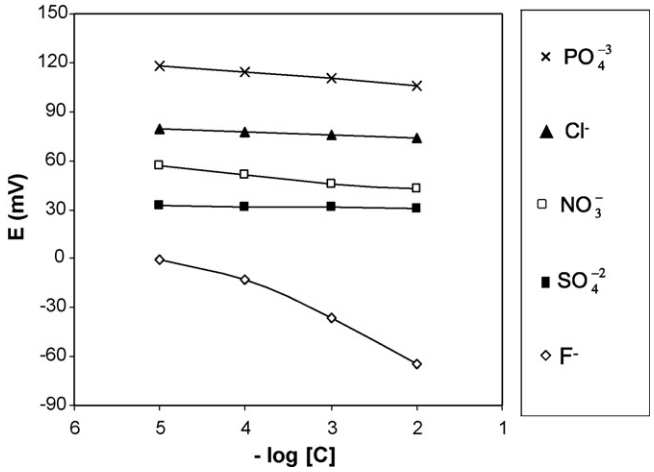

Fig. 5. The response of electrode against some anions in the presence of 10^{-3} M fluoride (70% Ag_2S, 10% Cu_2S, 20% CaF_2).

3.5. Conditioning of the electrode and lifetime

In order to identify the conditioning medium, electrodes having the same composition were kept in air (dark) and in distilled water and in 1×10^{-2} M $NaNO_3$ solution under same duration of time and their responses to fluoride ion were measured. Their performances were found out to be close to each other. In further studies the electrodes were kept in air (in dark) while not in use. The lifetime of this electrode was more than 2 years when it was used at least 4–5 times per day.

3.6. Interference effects of various cations and anions

It usually is not possible to obtain an ISE which is only specific for one ion. Thus, in order to achieve correct and sensitive results in analysis it is important to know the effects of all other ions in the medium. These effects are identified through selectivity coefficient. In this study mixed solutions method was used to determine selectivity coefficient, $k^{pot}_{A,B}$ [16], as it usually corresponds more closely to the situation in samples. Selectivity coefficient values were calculated via making use of the below given equation:

$$k^{pot}_{A,B} a_B{}^{n_A/n_B} = a_A\{\text{antilog}[(E_1 - E_2)/S]\} - a_A$$

Here, $S = 2.303RT/n_AF$ (the slope of fluoride electrode), a_A is the activity of the primary ion, a_B the activity of the interfering ion, E_1 the potential measured when only A is present, E_2 the potential responsive to the primary ion in the presence of interfering ion, $k_{A,B}$ the selectivity coefficient and n_A, n_B are the charges of A and B. In this method, solutions were prepared with a constant activity of the main ion (fluoride) and varying activity of interfering ion. For this purpose, interfering ion was added to 10^{-3} M fluoride solution (in 0.1 M $NaNO_3$) so that its concentration was 10^{-2}–10^{-5} M and after each addition, the change of potential was measured. The potentials obtained at different concentrations of interfering ions are plotted against concentrations as shown in Fig. 5 for anions and in Fig. 6 for cations. For comparison the curve obtained for fluoride electrode is also given in the same figure.

As can be seen nearly no interference was observed for chloride, nitrate, sulfate and phosphate ions. While no interference was observed for sodium, potassium, calcium and magnesium, slight interference was observed for silver ions.

For the determination of the selectivity coefficients, the $a_B{}^{n_A/n_B}$ values are plotted against the right hand side of the above given equation and the slope will be equal to the selectivity coefficient of

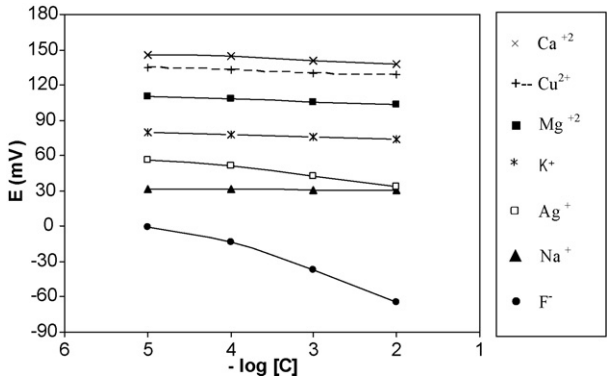

Fig. 6. The response of electrode against some cations, in the presence of 10^{-3} M fluoride (70% Ag_2S, 10% Cu_2S, 20% CaF_2).

Table 1
Selectivity coefficients ($k^{pot}_{A,B}$) for the fluoride electrode in mixed solutions (in the presence of 10^{-3} M fluoride) (B: interfering ion; A: fluoride ion).

Ions	$k^{pot}_{A,B}$
Cl^-	3×10^{-3}
NO_3^-	8×10^{-3}
SO_4^{2-}	6×10^{-4}
PO_4^{3-}	3×10^{-4}
K^+	3×10^{-3}
Na^+	8×10^{-3}
Ag^+	1×10^{-2}
Ca^{2+}	1×10^{-4}
Cu^{2+}	2×10^{-4}
Mg^{2+}	5×10^{-3}

the interfering ion. The selectivity coefficients obtained for mentioned anions and cations are given in Table 1. As can be seen the present fluoride ion selective electrode displayed very good selectivity for fluoride ion with respect to sodium, potassium, calcium and magnesium cations and to chloride, nitrate, sulfate and phosphate anions.

3.7. Determination of fluoride in spring and tap water

The aim of the sample study was to test the accuracy of the results achieved by the analyses done with the fluoride sensitive electrode prepared in our laboratory. A sample of spring water (bottled) was analyzed with the newly established electrode. For this purpose first the potential of 20 mL 0.1 M $NaNO_3$ is measured using fluoride ion selective electrode. Then 0.2 mL spring water sample was added and once more potential was measured. The fluoride content of this water was determined by standard addi-

Determination of fluoride in spring and tap water ($N = 4$).

	Newly established fluoride electrode (mg/L)	Orion fluoride electrode (mg/L)
Spring water	0.25 ± 0.01	0.29 ± 0.01
Tap water	2.87 ± 0.03	3.21 ± 0.02

tions. Same procedure was applied four times and the result found was 0.25 ± 0.01 mg/L. The same water sample was analyzed with the commercial Orion fluoride electrodes and the result found was 0.29 ± 0.01 mg/L. The fluoride content in bottled drinking water was given (on tag) as 0.20 mg/L. As can be seen there is about 12% difference in results between these two electrodes. The slope of Orion electrode is smaller at low concentrations, but then suddenly increases at higher concentrations Fig. 1. This large change in slope may be the cause of this difference.

The same procedure was applied to tap water of Ankara city. The fluoride content found with the new electrode was 2.87 ± 0.03 mg/L ($N = 4$), with Orion electrode it was 3.21 ± 0.02 mg/L. The results for two different kinds of water are given in Table 2.

4. Conclusions

This electrode enables the determination of fluoride ion in 1×10^{-6}–1×10^{-1} M concentration range in the presence of most common ions. The slope of the linear portion (1×10^{-1}–1×10^{-5} M) was 26 ± 2 mV per decade change in fluoride ion. The present fluoride ion selective electrode displayed very good selectivity for fluoride ion with respect to sodium, potassium, calcium, magnesium, copper, chloride, nitrate, sulfate and phosphate ions. It was possible to determine fluoride ion quantity in spring and tap water. The preparation of the electrode is simple, it displays very good performance in regard to reproducibility, sensitivity and long lifetime.

ABSTRACT

In this study a new method for determination of cadmium in alcohol fuel using *Moringa oleifera* seeds as a biosorbent in an on-line preconcentration system coupled to flame atomic absorption spectrometry (FAAS) was developed. Flow and chemical variables of the proposed system were optimized through multivariate designs. The limit of detection for cadmium was 5.50 $\mu g\,L^{-1}$ and the precision was below 2.3% (35.0 $\mu g\,L^{-1}$, $n = 9$). The analytical curve was linear from 5 to 150 $\mu g\,L^{-1}$, with a correlation coefficient of 0.9993. The developed method was successfully applied to spiked alcohol fuel, and accuracy was assessed through recovery tests, with recovery ranging from 97.50 to 100%.

1. Introduction

In Brazil, the oil crisis in the 1970s contributed to the implementation of a government program called Proálcool (National Alcohol Program) in 1975 to stimulate the production of ethanol from sugar cane [1,2]. Ethanol is a renewable fuel that contributes significantly to the energy independence of Brazil, attracting interest from several countries. However, for Brazilian ethanol to be introduced successfully in the international market it is extremely important to develop methods of analysis to ensure its quality. During the processes of production, transport and storage of alcohol fuel, several sources of contamination are present, including by metal ions. The presence of metal ions, even at low concentrations can adversely affect the performance of the engine [3,4], intensify the corrosive properties of ethanol and increase the emission levels of pollutants generated and the consequent environmental pollution [5–7].

Flame atomic absorption spectrometry (FAAS) has been extensively used for the determination of several metal species [8–11]. However, detection limits in the order of mg L^{-1} prevent the use of this technique in the analysis of samples containing low concentrations of analytes, requiring preconcentration steps to improve the sensitivity [12–16].

Among the existing preconcentration techniques, solid phase extraction has some advantages such as simplicity, high analytical frequency and enrichment factors, besides reducing the matrix effects [16–18].

Many studies involving metal preconcentration have been reported, mostly with the use of commercially available sorbents. However, other materials known as 'natural adsorbents' have recently been successfully employed in metal adsorption processes [19–21]. The term 'natural adsorbent' is assigned to any material that is not synthetically produced and has adsorptive properties in terms of chemical species of inorganic and organic origins.

The use of natural adsorbents in procedures for solid phase extraction becomes more attractive when coupled on-line with the detection system and when using an adsorbent with high adsorptive capacity, such as the seeds of *Moringa oleifera*. Table 1 lists various biosorbents and their applications in solid phase extraction procedures as well as their limits of detection.

M. oleifera is the best known species of the Moringaceae family. It is a plant native to northwest India but has spread all over the world, mainly in tropical countries. *M. oleifera* seeds have been used for the treatment of turbid water due to their flocculation properties. A flocculating protein from the seeds of *M. oleifera* Lam. was isolated by Gassenschmidt et al. [29] and its molecular mass was found to be around 6.5 kDa and the isoelectric point was above pH 10. Flocculation activity could be explained by the charge-patch mechanism due to low molecular weight and high charge den-

Bacillus subtilis immobilized in Amberlite XAD-4	Certified water samples and foods.	FAAS	0.0297 mmol L^{-1} Cu(II) 0.035 mmol L^{-1} Cd(II)	[28]

sity. The amino acids detected were mostly glutamic acid, proline, methionine and arginine. However, the mechanism of coagulation by polypeptides is still unknown. The shelled and non-shelled seeds contain approximately 37 and 27% of protein, respectively. Studies involving the use of natural adsorbents for the treatment of industrial effluents in terms of the removal of heavy metals have been published [30–32]. However, the use of this material in the preconcentration of metals in alcohol fuel has not been reported in the literature.

Thus, due to the possible sources of contamination by metal ions, such as cadmium, during the production of alcohol, the objective of this study was to develop a methodology for an on-line preconcentration system, using *M. oleifera* seeds as a biosorbent, coupled to flame atomic absorption spectrometry, for the determination of cadmium in alcohol fuel.

2. Experimental

2.1. Instrumentation

A Varian SpectrAA 50 (Victória, Australia) flame atomic absorption spectrometer (FAAS), equipped with a cadmium hollow cathode lamp and a deuterium lamp for background correction, was used for the detection of cadmium. The instrument was operated under the conditions recommended by the manufacturer, as shown in Table 2.

The pH value of the point of zero charge of the proposed biosorbent was measured over the pH range of 3–12 using a Microelectrophoresis Apparatus Mk II (Cambridge, UK).

Table 2
Operating parameters employed in Cd(II) determination by FAAS.

Parameters	
Wavelength (nm)	228.8
Lamp current (mA)	4
Burner height (mm)	17
Acetylene flow rate (L min^{-1})	1
Air flow rate (L min^{-1})	10
Aspiration flow rate (mL min^{-1})	5

A Fourier Transform Infrared (FT-IR) spectrometer (Shimadzu, IRPrestige-21, Tokyo, Japan) and a thermogravimetric analyzer (TA Instruments TGA 2950, New Castle, USA) were used to characterize the *M. oleifera* biosorbent.

A Mettler Toledo 320 pH meter was used to adjust the pH of the samples and working solutions. An Ismatec-IPC (Zurich, Switzerland) peristaltic pump equipped with eight channels and Tygon® and polyethylene tubes were used to pump the solutions through the mini-column (60 mm × 0.2 mm) in the elution and preconcentration steps. The mini-column was filled with 200 mg of seeds in the size range of 140–850 μm.

2.2. Reagents and solutions

All working solutions were prepared with ultrapure water obtained from a Milli-Q system (Millipore, Bedford, MA, USA). All reagents were analytical grade. All laboratory glassware was washed with a neutral detergent and then kept overnight in 10% nitric acid aqueous solution, followed by ultra-sonification for 1 h and finally rinsed with deionized water.

Working solutions were prepared daily through dilution of a 2000 mg L^{-1} stock solution of cadmium in a hydro-alcoholic solution containing 80% (v/v) of alcohol fuel and 20% (v/v) of water with a tris(hydroxymethyl)aminomethane buffer.

The nitric acid solution used as the eluent was prepared through dilution in water of concentrated nitric acid obtained from Merck (Darmstadt, Germany).

The 10^{-3} mol L^{-1} potassium chloride solution was adjusted within a pH range of 3–12 for the determination of the point of zero charge of the *M. oleifera* biosorbent.

2.3. Preparation of the biosorbent

The Moringa seeds used to construct the mini-column were obtained from trees cultivated in the city of Uberlândia (Minas Gerais, Brazil) and collected during September–November 2007. The seeds were separated from the pods, washed with deionized water and dried at 25 °C. After drying, the seeds were crushed in a blender (Black & Decker, São Paulo, Brazil) and passed through 850 μm sieves.

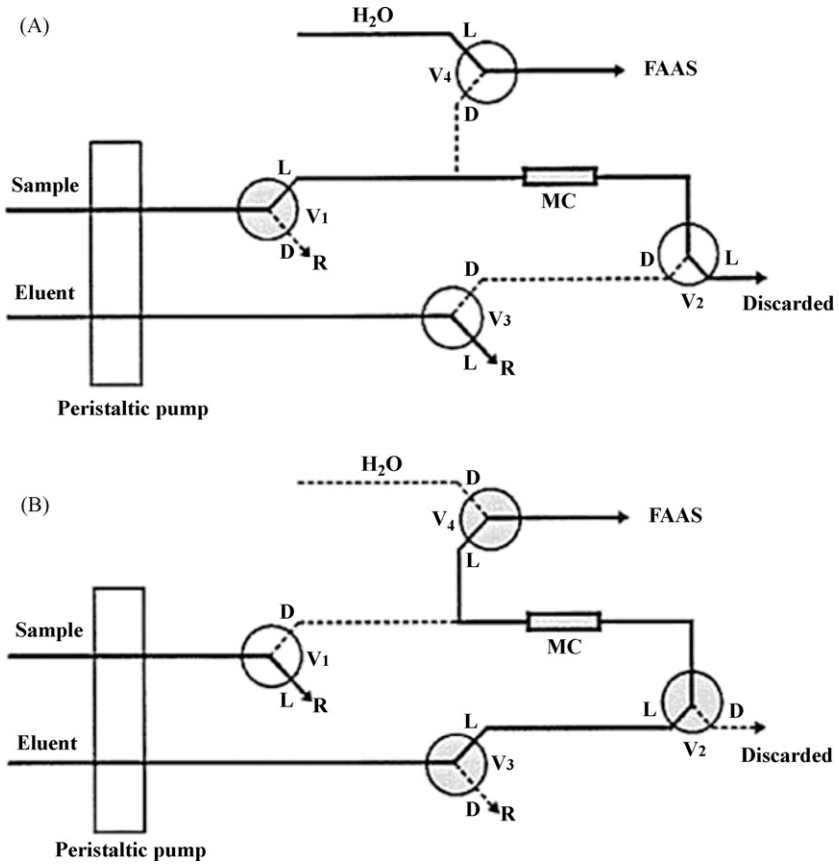

Fig. 1. Diagram of the on-line preconcentration system used in this study. (A) Adsorption process and (B) desorption process. V, valve; L, open; D, closed; MC, mini-column containing adsorbent; R, sample or eluent back stream; hatched circle, valve on; white circle, valve off.

The functional groups of the *M. oleifera* were characterized by FT-IR in the spectral range of 4000–500 cm^{-1}, with twenty-eight scans and a resolution of 4 cm^{-1}. TGA curves were obtained using 10 mg of seeds heated up to 950 °C in an oxidant atmosphere at rate of 20 °C min^{-1}.

2.4. On-line preconcentration system

The on-line flow system used for the development of the proposed method is shown in Fig. 1. The flow system consists of a peristaltic pump equipped with Tygon® tubes, four three-way solenoid valves and a mini-column filled with *M. oleifera* seeds. The system was coupled to the FAAS. During the preconcentration step (Fig. 1A), valve 1 is open and the other valves remain closed, the samples or working solutions are pumped through the mini-column and the effluent is discharged. In the elution step (Fig. 1B), valve 1 is closed and valves 2, 3 and 4 are open. Thus, the eluent percolates through the mini-column in the opposite direction to that of the preconcentration step. The eluate is carried directly to the nebulization system of the FAAS.

2.5. Optimization system

The optimization of the parameters affecting the sorption of Cd by the *M. oleifera* seeds was performed using a two-level full factorial experimental design involving four factors and a final optimization using a Doehlert matrix design. All experiments were carried out in duplicate, using 10.0 mL of 50 μg L^{-1} Cd solution. The variables studied were sample pH, buffer concentration, eluent concentration and sample flow rate.

3. Results

3.1. Characterization of biosorbent

The FT-IR technique was used to study the main functional groups of the Moringa seeds and Fig. 2 shows the FT-IR spectrum obtained.

The spectrum presents a broad band centered at 3420 cm^{-1} assigned to O–H stretching. This functional group appears predom-

inantly in protein and fatty acid structures of the Moringa seeds. Due to the high content of protein in the seeds there is also a contribution in this region from the N–H stretching of amide groups. The peaks at 2923 and 2852 cm^{-1} are assigned to symmetrical and asymmetrical C–H stretching of the CH_2 group present in fatty acids. In the region between 1800 and 1600 cm^{-1} there are three intense bands assigned to C=O bond stretching. The carbonyl group is present in the fatty acid and protein structures. In this case, the spectrum shows two bands at 1740 and 1715 cm^{-1} associated with fatty acids and a band at 1658 cm^{-1} associated with the amide group of the protein. The peak at 1587 cm^{-1} can be assigned to C–N stretching and/or N–H deformation. The presence of this band confirms the protein structure of the Moringa seeds.

The appearance of the curve obtained from the thermogravimetric analysis confirms the heterogeneity of the sample. Fig. 3 shows the mass loss curve for the Moringa samples. This curve can be divided into three phases. From 30 °C to 128 °C a mass loss of the order of 8% can be observed, associated with the dehydration of the seed. In the second phase, there was a 32% mass loss in the temperature range of 128–268 °C, due to the decomposition of organic matter. The third stage occurs from 268 °C to 541 °C, with decomposition of most components of the seed. At a temperature of 950 °C there was around 14.6% of residue, due to the presence of ash and probably inorganic oxides.

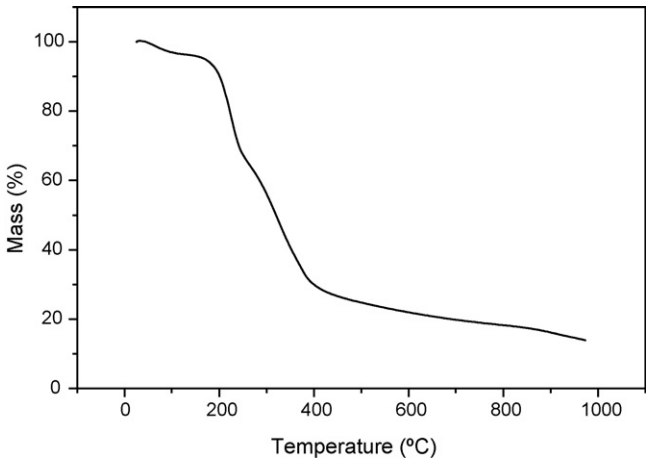

Fig. 3. Thermogravimetric curves of *Moringa oleifera* seeds.

The pH value of the point of zero charge for the proposed adsorbent was within the range of 6–7. Thus, above this pH range the surface of the sorbent will be negatively charged and will adsorb positively charged species.

3.2. Optimization

Preliminary tests were performed to investigate which factors exert significant influence on the adsorption of Cd (II) by the *M. oleifera* seeds. The factors selected were: eluent concentration, pH, buffer concentration and sample flow rate. The type of eluent and the mass of the mini-column were set as HNO_3 and 200 mg, respectively.

Table 3 shows the response for each factorial design experiment. The analytical response was taken as the integrated absorbance and the sample volume used for the preconcentration was 10 mL spiked at 50 μg Cd L^{-1}.

From the results reported in Table 3, a Pareto chart (Fig. 4) was plotted to check the influence of the factors and their interactions in the system. An effect was considered significant when it was above the standard error at the 95% confidence level ($p > 0.05$), which is denoted by the vertical line on the graph.

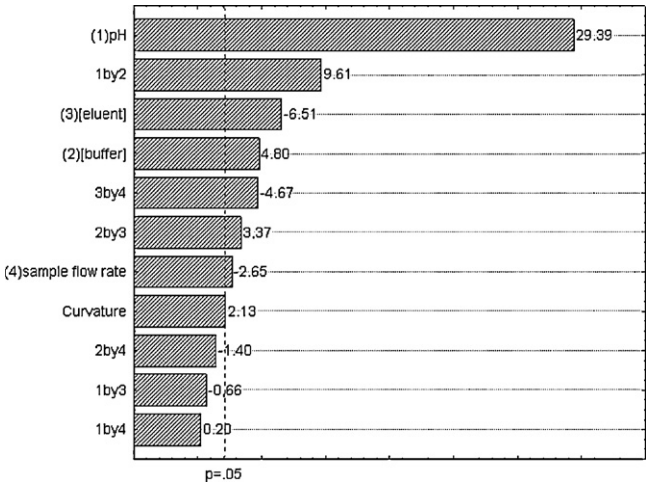

Fig. 4. Pareto chart obtained from the optimization study of the variables, with their significance, for the preconcentration of Cd(II) using *Moringa oleifera* seeds as the sorbent and FAAS.

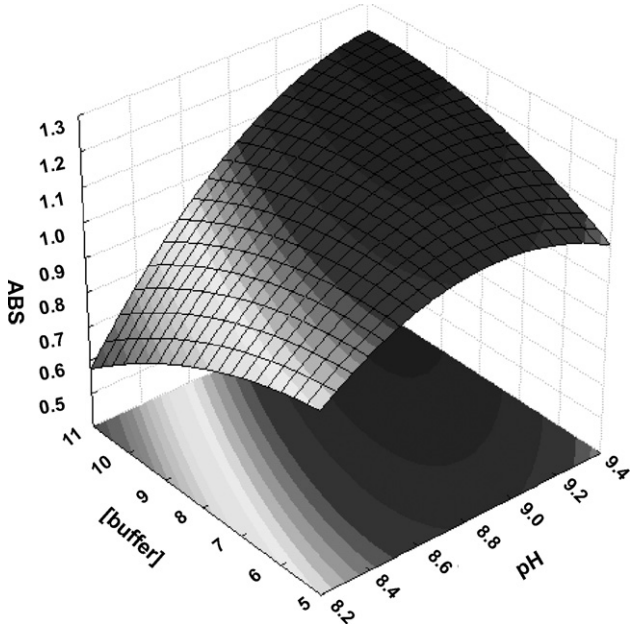

Fig. 5. Response surface for optimization of pH and buffer concentration: sample volume, 10.0 mL; sample concentration, 50 $\mu g\,L^{-1}$; sorbent mass, 200 mg; eluent concentration, 0.5 mol L^{-1}.

The sample pH, eluent concentration and buffer concentration, as well as the interaction between the sample pH and the buffer concentration, were the factors that had significant influence on the extraction efficiency.

The sample pH is one of the most important parameters for the adsorption process, since the capture of metal ions by functional groups of the biomass is highly dependent on pH. Thus, according to the Pareto chart, in the range studied, pH 9.3 leads to better results than pH 7.3. The eluent concentration showed low significance in relation to the interaction between sample pH and buffer concentration. Thus, an eluent concentration of 0.5 mol L^{-1} was chosen to increase the lifetime of the adsorbent material and reduce the consumption of reagents. The sample flow rate was fixed at 6.0 mL min^{-1} to ensure an adequate time for interaction between the sample and the mini-column, in spite of reducing the analytical frequency. The curvature parameter was not significant, indicating that the response is roughly linear between the minimum and maximum levels selected for each variable.

The most significant variables indicated by the factorial design (sample pH and buffer concentration) were then optimized using a Doehlert matrix. In this case, seven experiments were performed as shown in Table 4. The results were used to construct the surface response shown in Fig. 5.

As can be seen in Fig. 5, higher buffer concentrations combined with high pH will lead to stronger analytical signals. The literature shows that to ensure the interaction between the metal ion and the surface of the adsorbent, the pH must be such that Mn^{+} is the most abundant metal ion species [21] and the sorbent surface is negatively charged, that is, above its point of zero charge. The *M. oleifera* seeds have several functional groups, mainly amino groups. Most of these amino groups have isoelectric points between pH 4.0 and 8.0, which is in agreement with the pH range obtained for the isoelectric point in our study (6–7). Above this pH, the sorbent surface is negatively charged and the most abundant species of cadmium is Cd^{2+}. Thus, the interaction between the negative surface of the sorbent and the positive metal ion leads to the retention of the cadmium in the proposed preconcentration system [32].

Limit of detection ($\mu g\,L^{-1}$)	5.50

[a] Linear range studied.

Table 6
Relative recovery for the samples used to evaluate the proposed method.

Sample	Recovery (%)	R.S.D. (%)
Sample 1	99.10	3.2
Sample 2	97.50	4.5
Sample 3	100	5.4

On analyzing the results of the optimization procedures, the following working conditions were selected: tris(hydroxymethylaminomethane) buffer 0.05, 0.5 mol L^{-1} HNO_3 as the eluent, pH 9.1 and sample flow rate 6.0 mL min^{-1}.

3.3. Analytical features

With the optimized system, the method was evaluated through the main analytical features shown in Table 5. The results obtained were compared with those previously published by our research group [21], where preconcentration of Cd(II) in samples of alcohol fuel was carried out using vermicompost as the biosorbent. A good correlation coefficient was obtained (0.9993) between the analytical signal predicted by the linear function and the analytical signal observed experimentally in the linear range of 5–150 $\mu g\,L^{-1}$.

The repeatability of the proposed method was assessed by performing seven consecutive extractions at a concentration level of 35 $\mu g\,L^{-1}$, and expressing the result in terms of the relative standard deviation. A value of 2.3% was obtained demonstrating an excellent repeatability.

3.4. Application of the method and recovery tests

The proposed method was applied to three alcohol fuel samples. In all samples the analyte concentration was below the limit of detection of the method. Thus, in order to assess the analyte recovery, all the samples were spiked at concentration levels from 0 to 50 $\mu g\,L^{-1}$, and analytical curves were constructed in order to compare the slopes. The results obtained are shown in Table 6, where it can be seen that there is no difference between the recovery values for the three samples, indicating that the analyte is quantitatively retained in all of the samples evaluated.

4. Conclusions

The seeds of *M. oleifera* were shown to be an efficient adsorbent material of natural origin for the preconcentration of cadmium present in alcoholic matrices, thereby contributing to the development of low cost analytical methodologies which fall within the current concept of clean chemistry.

The method showed satisfactory limits of detection and good accuracy. The results are in agreement with a method previously developed by our research group, based on the adsorption of cadmium present in samples of alcohol fuel using vermicompost as the adsorbent material [21].

ABSTRACT

A greener and more sensitive spectrophotometric procedure has been developed for the determination of phenol and *o*-cresol that exploits an aqueous two-phase system (ATPS) using a liquid–liquid extraction technique. An ATPS is formed mostly by water and does not require organic solvent. Other ATPS components used in this study were the polymer, polyethylene oxide, and some salts (i.e., Li_2SO_4, Na_2SO_4 or K_2HPO_4 + KOH). The method is based on the reaction between phenol, sodium nitroprusside (NPS) and hydroxylamine hydrochloride (HL) in an alkaline medium (pH 12.0), producing the complex anion $[Fe_2(CN)_{10}]^{10-}$ that spontaneously concentrates in the top phase of the system. The linear range was 1.50–500 μg kg^{-1} ($R \geq 0.9997$; $n = 8$) with coefficients of variation equal to 0.38% for phenol and 0.30% for *o*-cresol ($n = 5$). The method yielded limits of detection (LODs) of 1.27 and 1.88 μg kg^{-1} and limits of quantification (LOQs) of 4.22 and 6.28 μg kg^{-1} for phenol and *o*-cresol, respectively. Recoveries between 95.7% and 107% were obtained for the determination of phenol in natural water and wastewater samples. In addition, excellent agreement was observed between this new ATPS method and the standard 4-aminoantipyrine (4-AAP) method.

1. Introduction

The restricted availability of unpolluted freshwater sources coupled with the high costs of obtaining potable water has caused increasing awareness about the use of water sources. Thus, there is a constant search for inexpensive and greener analytical methods that can provide reliable results for monitoring water pollutants such as phenolic compounds.

Phenol and its derivatives (e.g., cresol) are extremely harmful to the environment and human health [1,2] due to their high toxicity. As a result, they have been included on lists of high priority pollutants in several countries [2,3]. American and Brazilian environmental legislation established limits of 10.0 μg L^{-1} of total phenols permitted in bodies of water [4,5].

Several analytical procedures with different systems of detection were developed to determine phenolic compounds, including gas chromatography (GC) [6–9], liquid chromatography (LC) [10–13], capillary electrophoresis (CE) [14–16], voltammetry [17–19] and amperometric analysis [20–22]. However, these methods do not allow *in situ* continuous monitoring, are costly to implement, demand skilled operators and require derivatization of analytes. Spectrophotometric analysis is applied in the determination of phenols [23,24], exploiting mainly UV–vis detection [25–27].

The most commonly used analytical methods (e.g., those described in the Standard Methods for the Examination of Water and Wastewater [28]) are spectrophotometric methods based on the oxidative coupling of phenols with 4-aminoantipyrine (4-AAP). However, this procedure has many disadvantages, including (i) employment of large amounts of reagents, especially chloroform, which is toxic and carcinogenic [29]; (ii) difficulty in finding suitable buffers, due to the reactive sensitivity to pH variations; and (iii) tedious operations such as a distillation step required for some sample analysis.

An interesting spectrophotometric method for the determination of phenolic compounds has been reported by Nagaraj et al. [30] and improved by Kang et al. [31]. It is based on the reaction between phenol, sodium nitroprusside (NPS) and hydroxylamine hydrochloride (HL) in an alkaline medium, producing the blue-colored complex anion $[Fe_2(CN)_{10}]^{10-}$. However, this procedure is not yet suitable for the determination of phenols at concentrations lower than 50.0 μg L^{-1} and for analyses in the presence of elec-

trolytes such as phosphates and sulfates, which promote serious errors. Moreover, a previous distillation step for sample preparation is required.

A convenient approach to address these limitations is to promote the complex formation reaction at the interface between the bottom and top phase of an aqueous two-phase system (ATPS). This reaction avoids salt interference and the posterior transfer of the complex to a small volume of the ATPS top phase. Within this context, ATPS is a strategic liquid–liquid extraction technique for phenol determination. Under specific thermodynamic conditions, an ATPS can be formed by the mixtures of aqueous solutions of (i) certain inorganic salts and a polymer [32], (ii) two types of water-soluble polymers [33] or (iii) two types of salts [34]. The resulting systems are two immiscible liquid phases with a polymer-enriched top phase (or enriched with a salt) and a salt-enriched bottom phase (or enriched with the second polymer or salt). Moreover, water is the major component of both phases, thus providing an extraction technology that eliminates the use of hazardous solvents. Finally, ease of use, low costs, shorter times for phase splitting and recycling of the system components are advantages of the technique [35]. ATPS methodologies have already been applied successfully in the separation of different ions [35–38].

The aim of this work was to develop a novel, greener and more sensitive procedure for determining phenol and *o*-cresol compounds. The proposed method is based on the reaction between phenolic compounds, NPS and HL in ATPSs composed of polyethylene oxide 1500 (PEO1500) + salt (Li_2SO_4, Na_2SO_4 or K_2HPO_4 + KOH) + water, exploiting spectrophotometric detection of reaction products. Parameters, such as ATPS electrolyte nature, pH, reagent concentrations, sample stirring time and tie-line length (TLL) were also optimized for the method.

2. Experimental

2.1. Apparatus

Spectrophotometric measurements were performed with a UV-visible (UV/vis) spectrophotometer (Shimadzu UV-2550) with quartz microcells with a 1.00-cm optical path length and total capacity of 450 μL. The slit width was kept at 2.0 nm. The software used for system control and data acquisition was UVProbe. The pH measurements were collected with a combined glass electrode using a digital pH meter (Digimed model DM-20, Digicron Analítica Ltda, São Paulo, Brazil).

2.2. Chemicals

All reagents were of analytical grade quality and used as received without further purification. Distilled water was used throughout the experiments. The polymer was polyethylene oxide (Synth, Diadema, São Paulo, Brazil) with an average molar mass (M_m) of 1500 g mol^{-1} (denoted as PEO1500). The chemicals in the proposed method, Li_2SO_4, Na_2SO_4, K_2HPO_4, KOH, NaOH, NPS and HL, were obtained from Vetec (Duque de Caxias, Rio de Janeiro, Brazil). The reagents used in the 4-AAP procedure [28] were 4-aminoantipyrine, NH_4OH, $K_3[Fe(CN)_6]$ (Merck, Darmstadt, Germany), K_2HPO_4 and KH_2PO_4 (Vetec). Phenol and *o*-cresol were purchased from Sigma–Aldrich (Milwaukee, WI, USA).

2.3. ATPS composition, solutions and standards

The three types of ATPS applied in the development of the procedure were PEO1500 + Li_2SO_4 + water; PEO1500 + Na_2SO_4 + water [32] and PEO1500 + (K_2HPO_4 + KOH) + water. For each system at least three different compositions were studied to verify the effect of the TLL in the partitioning behavior of the $[Fe_2(CN)_{10}]^{10-}$ complex (Table 1). Moreover, global compositions shown in Table 1 are relative to an ATPS composed of 2.00 g of top phase and 10.0 g of bottom phase, which were used in most assays.

All solutions were prepared with distilled water. In the ATPS method, the pH of the water was adjusted to 12.0 with NaOH because this pH is more favorable to the complete reaction of NPS with phenol compounds. For systems composed of the salts K_2HPO_4 + KOH, correction was not necessary because the pH was 12. Stock solutions of top and bottom phases were prepared in distilled water (pH 12.0). PEO1500 and salt concentrations in the phase stock solutions are provided in Table 1. These solutions were used as solvent to prepare all solutions of phenols, NPS and HL. Working standard solutions of phenol within 5.00 and 2000 μg kg^{-1} were prepared daily by using the bottom phase as a solvent and the appropriate dilution of a 1.00 g kg^{-1} stock solution. HL working stock solutions (518 mg kg^{-1}) were prepared by weighing the appropriate quantity of hydroxylamine hydrochloride in the bottom phase using an analytical balance (Shimadzu, AY 220) with an uncertainty of ±0.0001 g. NPS working stock solutions (1992 mg kg^{-1}) were obtained by dissolving the appropriate amount of salt in the top phase. In the 4-AAP method, the solutions and standards were prepared as described in the literature [28].

2.4. Procedure

Liquid–liquid equilibrium cells were used to prepare the ATPSs. Working stock solutions of 5.000 g of phenol, 2.000 g of NPS and 5.000 g of HL were weighed. In spectroscopic measurement reference cell were carried out with the top or bottom phase stock solutions containing NPS and HL, respectively. Thus, a final composition of phenol within 2.50 and 1000 μg kg^{-1} in the bottom phase was obtained, and the global concentrations of NPS and HL were 332.0 and 216 mg kg^{-1}, respectively. The final concentrations of PEO1500 and salt in the ATPS were depended on the TLL studied (Table 1). Subsequently, the biphasic systems were manually stirred for 3 min and allowed to settle for 20 min at 25.0 ± 0.1 °C in a temperature-controlled bath (Microquímica, MQBTC 99-20). Finally, aliquots of the top phase were collected with a syringe and diluted by a factor of 1.50. UV/vis spectrophotometric measurements were carried out at 722.0 nm for phenol and 717.5 nm for *o*-cresol.

2.5. Partitioning experiments

To determine the $[Fe_2(CN)_{10}]^{10-}$ complex partition coefficient $\left(K_{[Fe_2(CN)_{10}]^{10-}}\right)$ between the two phases, the types of ATPS studied were kept for 24 h in a temperature-controlled bath to reach thermodynamic equilibrium. Subsequently, aliquots of top and bottom phases were collected. The parameter $K_{[Fe_2(CN)_{10}]^{10-}}$ can therefore be defined as

$$K_{[Fe_2(CN)_{10}]^{10-}} = \frac{A_T}{A_B} \quad (1)$$

where A_T and A_B are the absorbance (at 722.0 or 717.5 nm) of the $[Fe_2(CN)_{10}]^{10-}$ complex in the top and bottom phases, respectively.

The influence of TLLs in the partitioning behavior of the complex anion was studied by determining *K* as a function of the two different TLL values for each ATPS.

2.6. Environmental samples

A distilled sample of furnace coke effluent was used to determine the applicability of the method in environmental samples. To determine the concentration of phenol in these samples, without

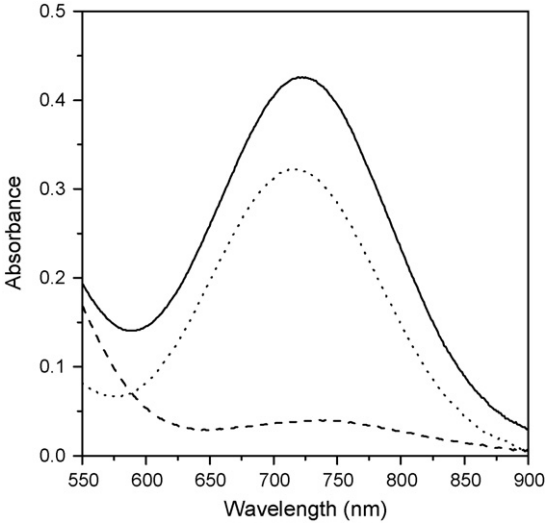
matrix effects, the Standard Addition Method was performed by adding 0.250 g of sample to each ATPS standard. The recovery rate provided by the proposed method was also determined in samples such as natural river water, industrial water, distilled water and samples from wastewater treatment plants (WWTPs). In these cases, samples without the distillation step were used as the bottom phase of the ATPS, to which appropriate amounts of phenol were added. The 4-AAP method [28] was also applied to the same samples for comparison and to check the accuracy of the proposed method.

3. Results and discussion

3.1. Chemical aspects

The procedure is based on an aromatic electrophilic reaction, which is represented by Eq. (2). In strongly alkaline mediums, phenol is converted to phenolate. Thus, the electrophilic reaction can take place more easily because the benzene ring becomes very active due to the presence of the negative oxygen (O^-). According to theoretical calculations, the sites that the nitroso group (^+NO) of the NPS attacks the phenolate molecule at *para*- or *ortho*-positions. The electrophilic or electrophobic properties of the substituents in the benzene ring affect the reaction extension, and consequently the sensitivity of the method [31]. Fig. 1 shows the absorption spectra of the reaction product ($[Fe_2(CN)_{10}]^{10-}$) obtained in the ATPS top phase. The complex chemical structure was determined by Kang et al. [31]. The maximum absorbance is at 722.0 nm for phenol and 717.5 nm for *o*-cresol. Blank signals are insignificant in the wavelength chosen for taking measurements. Moreover, the spectra show (Fig. 1) that the procedure is more sensitive for phenol than *o*-cresol, which confirms that substituents present on the benzene ring affect the properties of the compounds and the formation of the $[Fe_2(CN)_{10}]^{10-}$ complex.



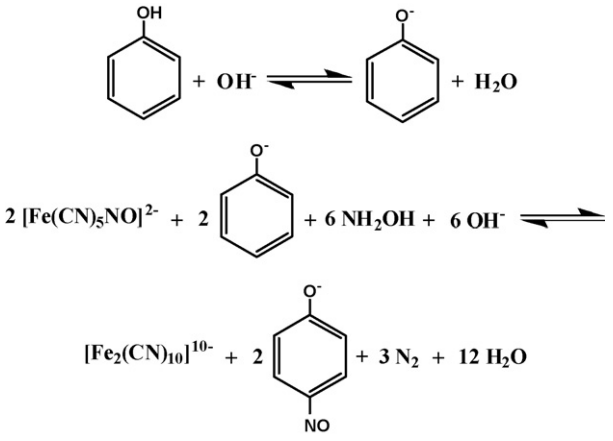


Fig. 1. Absorption spectra of the $[Fe_2(CN)_{10}]^{10-}$ anion formed by the reaction system between NPS, HL and (—) phenol or (···) *o*-cresol, and (---) blank assay spectrum in the PEO1500/Li_2SO_4 aqueous two-phase system (ATPS) with a tie-line length (TLL) = 41.71% (w/w).

(2)

3.2. Optimization of method

Method optimization was done to improve the sensitivity for low phenol concentrations. An experiment was carried out using Central Composite Rotatable Design (CCRD) in Response Surface Methodology (RSM) to evaluate the significance level of the factors. Five factors were investigated: system pH; NPS concentration; HL concentration; sample stirring time and phase splitting time. After exposure to conditions determined by the CCRD, analytical responses were evaluated by spectrophotometric measurements. Only significant coefficients at 5% probability were considered in the model using a Student's *t*-test. Table 2 shows the evaluated range and the optimum values for each variable.

Table 2
System optimization for the proposed aqueous two-phase system (ATPS) method using a standard of 600 μg kg^{-1} phenol in the bottom phase.

Parameter	Evaluated range	Selected value
pH	8.00–12.0	12.0
NPS concentration (mg kg^{-1})	140.0–670.0	332.0
HL concentration (mg kg^{-1})	110.0–385.0	216.0
Stirring time (min)	1–5	3
Phase splitting time (min)	20–60	20

NPS = sodium nitroprusside; HL = hydroxylamine hydrochloride.

3.3. Stability of the $[Fe_2(CN)_{10}]^{10-}$ anion in ATPS

In general, cyan complexes are photosensitive, so experiments were performed in the absence of light to avoid complex decomposition. Fig. 2 shows the stability of the $[Fe_2(CN)_{10}]^{10-}$ anion complex. Stability was studied through UV/vis absorption spectra of the top phase. After a period of 75 h, no change in the UV/vis spectra was observed, and the absorbance at 722.0 nm for phenol or 717.5 nm for *o*-cresol remained constant over 75 h.

3.4. Partition coefficients and effects of the tie-line length (TLL)

The TLL is a thermodynamic parameter that expresses the difference in intensive thermodynamic functions between the top and bottom phases at a constant pressure and temperature [39]. The TLL is expressed by the difference between polymer and salt concentrations present in the different phases. Generally, this parameter is a determinant in the partitioning process of some solutes and is calculated with the following equation:

$$\mathrm{TLL} = [(C_P^T - C_P^B)^2 + (C_S^T - C_S^B)^2]^{1/2} \quad (3)$$

where C_P^T and C_P^B are the polymer concentrations in the top and bottom phases, respectively, and C_S^T and C_S^B are applied in the same way to the salt.

Table 3 shows the values of $K_{[Fe_2(CN)_{10}]^{10-}}$ for two different TLL values for all ATPSs studied. Similar values of TLL were chosen to determine the influence of electrolytes in the partitioning behavior of the complex. The $[Fe_2(CN)_{10}]^{10-}$ anion shows a preferential concentration in the polymer-rich phase, reaching $K_{[Fe_2(CN)_{10}]^{10-}}$ values as high as 66.2 for a TLL of 41.71% (w/w) of the ATPS PEO1500 + Li_2SO_4 + water, which shows the best responses for both phenol and *o*-cresol. Moreover, the value of $K_{[Fe_2(CN)_{10}]^{10-}}$ increases as the TLL increases because more variable intensive thermodynamic difference between top and bottom phases properties (i.e., salt and polymer compositions) is associated with increasing TLL values [40]. As a consequence, higher concentrations of $[Fe_2(CN)_{10}]^{10-}$ anion are observed in the top phase [41].

Table 3
Partition coefficient values of the $[Fe_2(CN)_{10}]^{10-}$ anion complex for different aqueous two-phase system (ATPS) with different tie-line lengths (TLLs).

ATPS	TLL (% (w/w))	$K_{[Fe_2(CN)_{10}]^{10-}}$	
		Phenol	*o*-Cresol
PEO1500 + Li_2SO_4	29.43	17.8	56.6
	41.71	66.2	60.2
PEO1500 + (K_2HPO_4 + KOH)	30.09	13.7	27.3
	42.80	32.4	36.6
PEO1500 + Na_2SO_4	32.51	3.86	6.30
	40.10	7.52	8.88

Figs. 3 and 4 show the influence of the TLL on the sensitivity of the method for phenol and *o*-cresol determination for the three kinds of ATPS. These data were obtained by plotting analytical curves for all the TLLs of the ATPSs and then comparing the absorbance values of the same phenol standard (600 μg kg^{-1}). ATPS PEO1500/Na_2SO_4 studies in TLLs >40.10% (w/w) were not practical due to the precipitation of sulfate. Absorbance increases as the TLL increases, but for higher TLL values the signal becomes constant or even decreases. A possible reason for this behavior is that the increase in TLL also induces an ATPS salt concentration increase (Table 1), which interferes with the formation of $[Fe_2(CN)_{10}]^{10-}$ anion, as described by Kang et al. [31]. Thus, the sensitivity of the method depends on the competition between forming $[Fe_2(CN)_{10}]^{10-}$ anions and its concentration in the top phase, which in turn depends on the TLL. Since the reaction process occurs at interfaces using an ATPS method, it is interesting to note that the interference of ions, such as sulfate and phosphate, is insignificant compared to reports by Nagaraj et al. [30] and Kang et al. [31], indicating that the tolerance limit for sulfate and phosphate is lower than 25,000 and 5000 mg L^{-1}, respectively.

The effects of electrolytes on the determination of phenol are also shown in Figs. 3 and 4. A TLL value of 41.71% (w/w) using

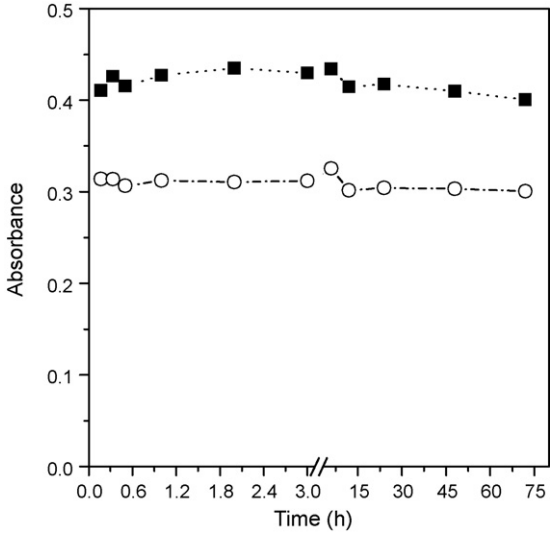

Fig. 2. Stability of the anion $[Fe_2(CN)_{10}]^{10-}$ formed by the reaction between NPS, HL and (■) phenol or (○) *o*-cresol in the PEO1500/Li_2SO_4 aqueous two-phase system (ATPS) with a tie-line length (TLL) = 41.71% (w/w).

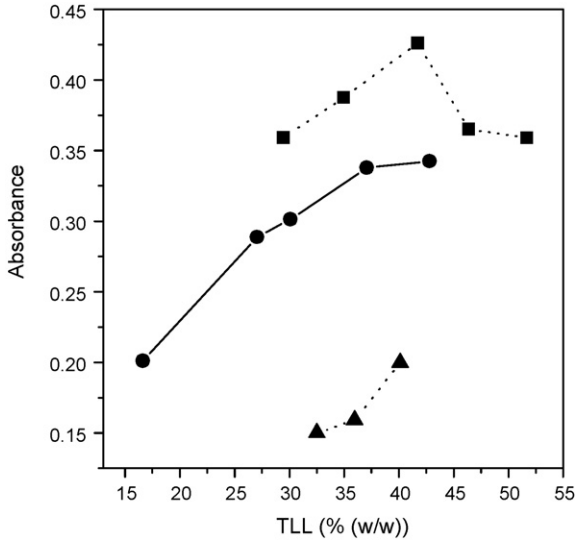

Fig. 3. Effect of tie-line length (TLL) and electrolytes on the phenol determination in an aqueous two-phase system (ATPS) composed of PEO1500, salt and water: (■) Li_2SO_4, (○) K_2HPO_4 + KOH and (▲) Na_2SO_4.

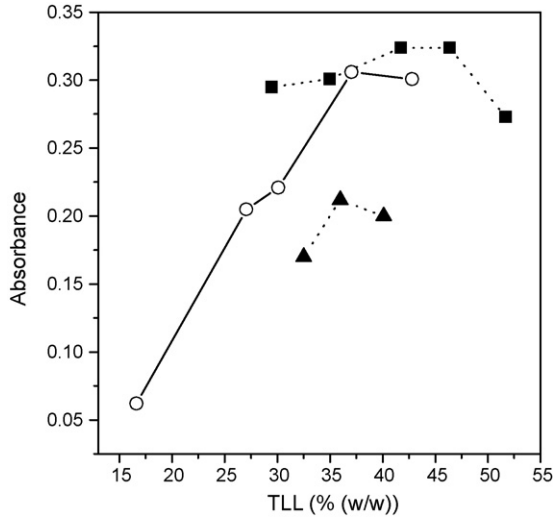

Fig. 4. Effect of tie-line length (TLL) and electrolyte on the *o*-cresol determination in an aqueous two-phase system (ATPS) composed of PEO1500, salt and water: (■) Li_2SO_4, (○) K_2HPO_4 + KOH and (▲) Na_2SO_4.

PEO1500/Li_2SO_4 ATPS presented the highest response among all the systems studied. This behavior may be explained by the model proposed by da Silva and Loh [42]. Through calorimetric measurements, it was suggested that the trend in the effectiveness of a salt to induce ATPS formation is associated with cation–polymer interactions. According to this model, when salts and polymers are mixed, cations of the salt interact with the ethylene oxide PEO groups, releasing water molecules that solvate the polymer in a process driven by an entropy increase. This cation binding continues as more electrolytes are added until saturation is reached and after which no further gain in entropy is possible, and phase splitting becomes more favorable. In da Silva and Loh's study [42], it was proposed that a higher amount of the Li^+ cation is necessary to energetically saturate the polymer chain compared to K^+ and Na^+ cations. Thus, in the ATPS composed of Li_2SO_4, the macromolecule of PEO is more positively charged than the systems composed of K_2HPO_4 + KOH or Na_2SO_4, which enables a stronger electrostatic interaction between the PEO segments and the $[Fe_2(CN)_{10}]^{10-}$ complex. Consequently, higher partitioning of the complex anion to the PEO-rich phase occurs. Therefore, the PEO1500/Li_2SO_4 ATPS system is more suitable for applying the proposed method in the determination of trace concentrations of phenols in environmental samples.

3.5. Analytical figures of merit

Under optimum experimental conditions (Table 2), additional experiments were performed to establish the analytical features of the procedure. The PEO1500/Li_2SO_4 ATPS system was used in these studies due to its higher sensitivity (Figs. 3 and 4).

Table 4 shows the main characteristics of the proposed method compared to the standard method [28] and described by Kang et al. [31]. To increase the limits of detection (LOD) and limits of quantification (LOQ), ATPS with 1.0000 g of top phase and 23.0000 g of bottom phase were used, offering a higher concentration factor of $[Fe_2(CN)_{10}]^{10-}$ anion and consequently a reduction in the range of the analytical curve. The linear responses ($R \geq 0.9997$) were within 1.00–500 μg kg^{-1} phenol, which is suitable for the determination of phenols in water samples according to the limits established by the American and Brazilian legislation [4,5]. The method achieves LODs of 1.27 and 1.88 μg kg^{-1}, and LOQs of 4.22 and 6.28 μg kg^{-1} for phenol and *o*-cresol, respectively. These values are lower than those obtained using the 4-AAP method [28] or the reaction between phenol, NPS and HL [31] without extraction. However, it is also notable that spectrometric UV/vis methods that provide the lowest LOD involve the use of an optical path length of 100 cm [27] or three consecutive extractions with chloroform [28]. Nevertheless, the employment of chloroform is harmful to the environment and human health.

The coefficients of variation (CV) were 0.38% for phenol and 0.30% for *o*-cresol. The proposed method offers a significant reduction in the volume of waste compared to the reference method. Hence, the new procedures are a suitable and environmentally friendly alternative to methods available in the literature that employ hazardous solvents, such as chloroform, or generate large amounts of waste. Furthermore, these results support the feasibility of applying the proposed method to the determination of phenol in environmental samples.

3.6. Analysis of environmental samples

Table 5 shows the results of recovery studies on water samples. The ATPS method was compared with the standard 4-AAP method [28] to check the accuracy and reliability of the proposed procedures. Studies were carried out using natural river water, industrial water, distilled water and samples from WWTPs. Recovery rates between 95.7% and 107% were obtained, and the results

Table 5
Recoveries of phenol and *o*-cresol in water samples ($n = 3$).

Sample	ATPS method recovery (%)		4-AAP method recovery (%)	
	Phenol	*o*-Cresol	Phenol	*o*-Cresol

had excellent agreement with the standard method [28] at the 95% confidence level according to a paired *t*-test [43]. Moreover, concentrations of total phenols in furnace coke effluent without spiked phenol were determined. This sample was previously distilled and diluted according to the linear range of the method. The concentration values of total phenols found in the sample with the ATPS and 4-AAP methods were 815.7 and 781.7 mg kg^{-1}, respectively, which correspond to a relative error of 4.35% between both methods.

4. Conclusions

The analytical utility of an ATPS method for determining trace phenols in water and wastewater was demonstrated for the first time by exploiting the reaction between phenol, NPS and HL. This reaction produced the $[Fe_2(CN)_{10}]^{10-}$ anion complex, which concentrated in the top phase of the ATPSs studied. The proposed method offers clearly advantageous analytical features in comparison to procedures involving the same reaction [31] or with a standard method [28], including an enhanced sensitivity and linear range as well as reduced waste volumes and no organic solvents. Pre-concentrations of analyte in the polymer-rich phase of the system allow the method to reach LOD and LOQ values that are suitable for determining total phenols in natural water and wastewater with high accuracy and in compliance with the regulatory requirements of environmental health agencies.

ABSTRACT

A novel amine–imide type conducting polymer, denoted as poly(PD–BCD), was molecularly imprinted on an indium–tin oxide (ITO) glass, with uric acid (UA) as the template and without any functional monomer. Intending to improve the imprinting efficiency, the polymer content was varied from 0.3 to 0.9 wt% during the preparation of the molecularly imprinted polymer (MIP), thereby varying the thickness of the polymer film; the content of UA as the template was maintained to be the same for all the films. The sensitivities of the thus prepared MIP electrodes were calculated to be more than 3-fold, compared to those of the corresponding non-MIP (NMIP) electrodes, which were obtained through the same method, however, without adding UA during their preparation. A polymer content of 0.6 wt% rendered the best performing MIP electrode, as judged by the imprinting efficiency and sensitivity of the electrode for UA. A linear relationship between steady-state currents and UA concentrations from 0 to 1.125 mM was obtained for both types of the sensors. The sensitivities of the MIP and the NMIP electrodes made with 0.6 wt% of polymer were calculated to be 24.72 and 6.63 $\mu A\,mM^{-1}\,cm^{-2}$, respectively. The limit of detection (LOD) for this MIP was found to be 0.3 μM at a signal to noise ratio (S/N) of 3. This MIP electrode was used as a biosensor for the detection of UA in the presence of ascorbic acid (AA) in a sample containing these species in the same concentrations as those in a human serum. The selectivity of MIP electrode is higher than that of NMIP electrode, and the values are 28.76 and 8.85, respectively. The results are substantiated by using cyclic voltammetry (CV), linear sweep voltammetry, amperometry, and scanning electron microscopy.

1. Introduction

There has been a very active research in this decade on molecular imprinting owing to its importance in a broad range of applications [1–3]. Molecularly imprinted polymer (MIP) is usually obtained by imprinting the polymer on a substrate through a template molecule. This template molecule is the analyte, which produces cavities specific to its detection in a bulk solution. After the extraction of the template molecule, the polymer matrix becomes complementary to the molecule and can rebind it with very high affinity and specificity.

During the last decade, molecularly imprinting technique has been developed as an analytical tool for the estimation of various electroactive species [4,5]. Efforts have been made to use MIPs for the detection of biomolecules [4–9]. MIP sensors can be substituted for enzyme-based sensors, because MIPs are enzyme mimics and can play the role of enzymes for catalyzing the reactions. In addition, they can be made at low cost and have higher thermal and chemical stability than that of enzymes [10,11]. There have been a number of reports on sensors based on molecularly imprinted conducting polymers, e.g., polyphenol [12], polypyrrole [13,14] and poly(phenylenediamines) [15]; in these reports, electrochemical methods, such as those with amperometry, impedance spectroscopy, and electrical capacitance were adopted. Malitesta et al. [16] reported the first successful application of electropolymerization for the preparation of MIPs. Ulyanova et al. [17] employed potentiodynamic electropolymerization technique to form a polyazine conducting polymer which was molecularly imprinted for the detection of theophyline. Benzimidazole compounds were determined in water samples by using MIPs [18] and performing the measurements in an HPLC system. Suedee et al. developed an MIP conductometric sensor for on-line sensing of haloacetic acids [19].

Uric acid (UA) is the principle final product of urine metabolism in human body [20] and is related to the occurrence of many disorders such as gout, hyperuricemia and Lesch–Nyhan syndrome [21]. Besides, UA is also one of the most important kidney calculus indices in human plasma. Thus, monitoring of the concentration of UA in human blood and urine is important for the prevention of the mentioned and other similar diseases. As mentioned above, electrochemical methods are very often used both at the stages of preparing and using the MIPs to detect the analytes. The common and well-developed electrochemical method for the detection of UA is based on the enzymatic approach. Uricase enzyme is

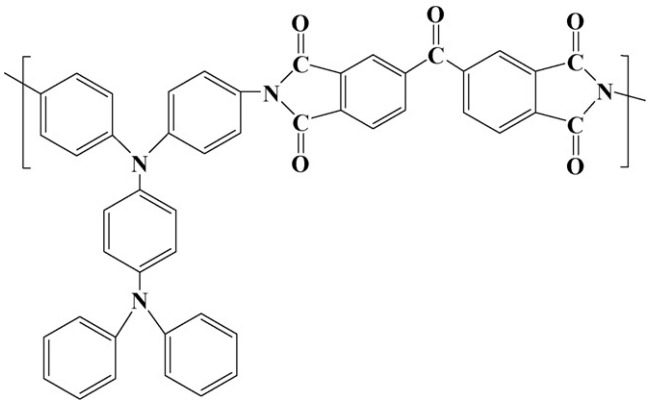

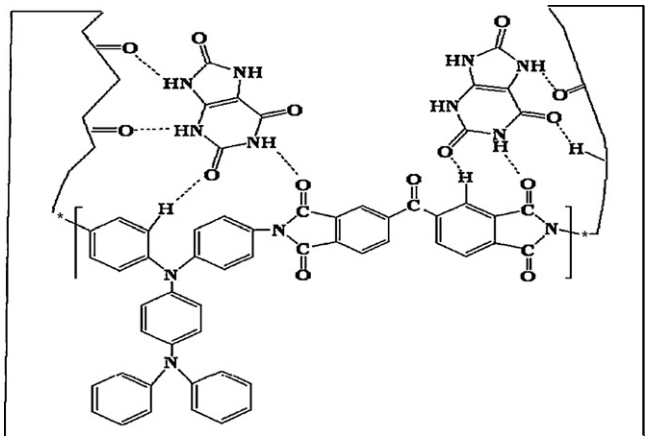

Fig. 1. Structure of poly(PD–BCD).

allowed to react with UA and the corresponding hydrogen peroxide is detected electrochemically. However, this method inherits some problems, such as high cost and low stability of enzymes; in addition the detection is indirect (detection of the reaction products). Several studies based on non-enzymatic methods have also been made to detect UA. These include the usage of carbon paste or activated glassy carbon electrodes [22,23], modified electrodes containing multi-wall carbon nanotubes (MWCNTs) [24] or a redox mediator [25].

The present study reports an electrochemical sensor for UA which is based on a novel molecularly imprinted amine–imide type conducting polymer. This is the first report using the polymer, denoted as poly(PD–BCD), as the MIP for sensing UA, in which the polymer was synthesized with N,N-bis(4-aminophenyl)-N′,N′-diphenyl-1,4-phenylenediamine (PD) and 3,3′,4,4′-benzophenonetetra carboxylic dianhydride (BCD). To the best of our knowledge, this is also the first quantitative study with regard to the content of any polymer to be used for optimizing the sensor for UA determination. Fig. 1 shows the structure of this polymer. Unlike the common approach of using a functional monomer and cross linker for the preparation of MIP, we directly applied for its preparation a sample of the polymer synthesized by us previously [26]. Incorporation of the analyte (UA) is purely a van der Waals interaction between the analyte and the sensor layer (polymer) (Scheme 1). The scheme shows formation of possible hydrogen bonds between the poly(PD–BCD) and the UA. Amine groups of UA can form hydrogen bonds with the ketone groups of poly(PD–BCD). In the same way, ketone groups of UA can also form hydrogen bonds with hydrogen atoms of benzene rings of the polymer. Such constitution can provide very strong adsorption force between UA and poly(PD–BCD). We studied the effects of varying the concentration of the novel polymer on its performance for the detection of UA. The optimum concentration of this polymer was evaluated in terms of the sensitivity of the MIP sensor for the detection of UA and in terms of the imprinting efficiency. This MIP electrode was also tested for the estimation of UA in the presence of ascorbic acid (AA) in a sample containing these species in the same concentrations as those of a human serum.

Scheme 1. Schematic representation of the formation of possible hydrogen bonds for the incorporation of UA in poly(PD–BCD).

2. Experimental

2.1. Chemicals and apparatus

The conducting polymer used for molecular imprinting was synthesized from N,N-bis(4-aminophenyl)-N′,N′-diphenyl-1,4-phenylenediamine and 3,3′,4,4′-benzo-phenone-tetracarboxylic dianhydride, and the synthesis steps were reported previously [26]. Uric acid (98%), ascorbic acid (99%), phosphate buffer saline tablet (PBS) and potassium chloride (KCl) were purchased from Aldrich (USA). 1-Methyl-2-pyrrolidinone (NMP, 99%) was purchased from Sigma (USA). Deionized water (>18 MΩ) was produced by Purelab Maximum (ELGA, UK). Indium–tin oxide (ITO, 10 Ω/□) glass was supplied by RiTdisplay Corporation (Hsinchu Industrial Park, Taiwan). All chemicals were used as received.

Amperometric measurements were carried out using potentiostat/galvanostat model CHI 440 (CH Instruments) and its compatible software. All electrochemical experiments were carried out at room temperature with a three-electrode system, containing a 50 mL glass cell with Ag/AgCl/saturated KCl reference electrode, platinum plate counter electrode and MIP or non-molecularly imprinted polymer (NMIP) working electrode.

2.2. Preparation of MIP and NMIP electrodes

The ITO glass was ultrasonically cleaned in a 0.1 M HCl for 5 min before using. The substrate was rinsed with deionized water and dried in air. After cleaning, epoxy tapes were fixed at the edges of the ITO-surface to restrict the active surface area to be 1.0 cm × 1.0 cm. For preparing the MIP electrodes, poly(PD–BCD) was mixed at various concentrations from 0.3 to 0.9 wt% with 1.5 mM UA dissolved in 1-methyl-2-pyrrolidinone, NMP, and the thus obtained solutions were drop-coated onto the ITO glass electrodes. The ITO electrodes were put into a vacuum oven and were subjected to a programmed temperature variation to remove the solvent from the electrodes. Then the temperature was kept at 60 °C for 4 h and raised to 80 °C for 2 h; finally the temperature was increased to 180 °C for 2 h. Such programmed temperature during the solvent removal is necessary to obtain uniform MIP films, and thereby higher detection currents in the amperometric analysis. After removing the solvent, Cu tape (3 M Company) was pasted at one edge of the conductive surface of the electrodes as a bus bar. Each electrode was then washed with deionized water to extract the UA template out of the polymer matrix, and then dried under nitrogen gas blow. The extracted MIP films were subjected to CV experiments within a potential window of 0.1–0.9 V (vs. Ag/AgCl/saturated KCl) for confirming the removal of the template. Disappearance of oxidation peak of the UA indicates its removal from the polymer. NMIP electrodes were also prepared in the same way, except that there was no addition of UA during their preparation.

2.3. Electrochemical measurements

Cyclic voltammetry (CV) was used to ascertain the complete removal of the template from the polymer film after the extrac-

tion with deionized water; the potential of the polymer electrode was swept from 0.1 to 0.9 V at a scan rate of 0.1 V s^{-1}. Furthermore, the charge capacities of MIP and NMIP electrodes were checked by comparing the areas under the pertinent CVs.

Linear sweep voltammetry (LSV) was performed to obtain the detecting potential of UA. The detection potential was determined by sweeping the potential of the MIP electrode (0.6 wt% of the polymer) in a window of potentials between 0.5 and 1.0 V. The corresponding background current was recorded in a 0.02 M phosphate buffer saline (PBS, pH 7.4), containing 0.1 M KCl as the supporting electrolyte, and the total current was recorded in a solution containing 1.5 mM UA. The net current was obtained by subtracting the background current from the total current. A proper operating potential was determined from the plateau part of the net current of the LSV curve. This way of estimating the operating potential was based on the fact that the plateau part corresponds to the diffusion control region of UA oxidation reaction and the sensing potential set at this region can obtain a current proportional to the concentration of UA.

UA was detected by the MIP and NMIP electrodes using an amperometric method. For this, steady-state current densities were obtained for MIP and NMIP electrodes at various concentrations of UA from 0 to 1.125 mM and the corresponding calibration curves were made with these values; the sensitivity and the detection limit were estimated from the calibration curve. Steady-state currents were also obtained by the amperometric method for the detection of 0.4 mM UA in the presence of 0.04 mM AA, which are their usual concentrations in a human serum; these experiments were simulated experiments intended to determine the selectivity of the MIP biosensor for UA in the presence of AA in a human serum. We mention here that the interference study of this work was restricted to AA and further study is envisaged with respect to other impurities such as dopamine and thiols.

We make here a simple comparison between amperometric and other electrochemical detection methods, to rationalize our preference of the former. Amperometric sensor has relatively short response time and can be designed easily as a portable sensor. Other special detection methods were used by several workers. Chou and Liu have used impedance detection method for sensing cholesterol with a thick film-MIP sensor. In this method a current decrease could be noticed when the analyte was attached to the MIP thick film [27]. A pulsed amperometric detection (PAD) method interprets the difference in currents obtained due to different bias potentials for dedoping and redoping as the analytical signal [28]; this method provides an accurate way for detecting the recombination of the target on the MIP electrode [29,30]. Potentiodynamic methods are usually suitable for sensing non-electroactive compounds, such as caffeine, protein and cholesterols. Both potentiodynamic and amperometric methods entail interferences, which disturb the current signal. This problem can be solved by modifying the electrodes with special materials such as Nafion® and mediators [31].

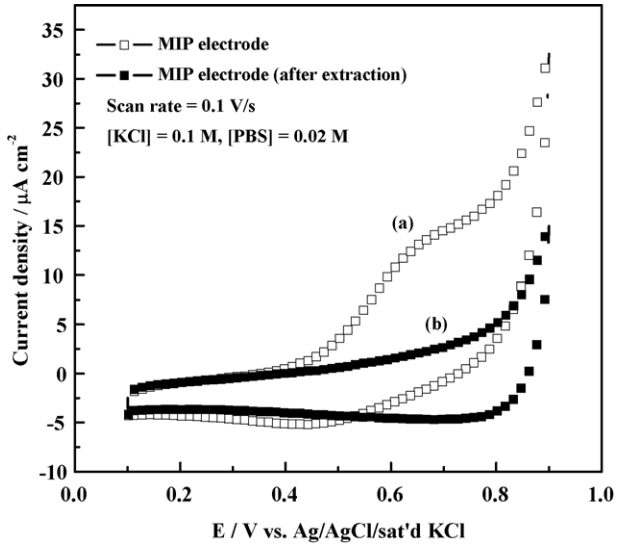

Fig. 2. CVs of the MIP electrode with 0.6 wt% of the polymer, in 0.1 M KCl + 0.02 M PBS (pH 7.4) at the scan rate of 0.1 V s^{-1}: (□) before extraction of UA and (■) after its extraction.

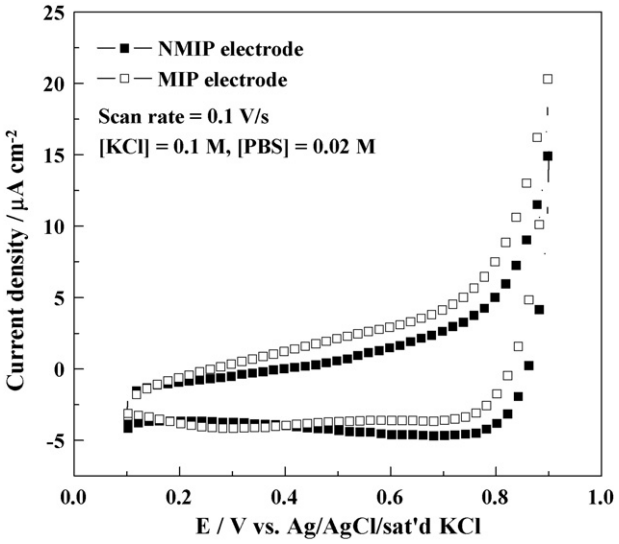

Fig. 3. Charge capacities of MIP electrode (□) and NMIP electrode (■) after the extraction of UA, both CVs being obtained in 0.1 M KCl + 0.02 M PBS (pH 7.4) at the scan rate of 0.1 V s^{-1}.

2.4. Morphological characterization

Scanning electron microscopy (SEM) images were obtained by Hitachi S-800 Field Emission SEM. For this purpose, the MIP and NMIP electrodes were sputtered with a layer of gold and the images were observed under a voltage of 20 kV.

3. Results and discussion

3.1. Performance evaluation of the MIP sensor

For evaluating the performance of a sensor, most important factors are sensitivity and selectivity. Fig. 2a shows the CV of the MIP electrode prepared with 0.6 wt% of the polymer in 0.1 M KCl and 0.02 M PBS. Fig. 2b shows the CV of the same electrode after the extraction of UA. The oxidation peak of UA can be clearly seen in Fig. 2a; after the extraction of UA its oxidation peak is absent in Fig. 2b, as desired and expected. This implies that UA molecules of the MIP electrode were removed after the extraction process. Further discussion will render evidence through SEM images that the extraction has removed only surface bound UA. In order to ensure that the same amount of poly(PD–BCD) remained after the extraction, the charge capacities of the MIP and NMIP electrodes were calculated using the CVs, as shown in Fig. 3. Calculation on the charge capacities was based on the integrated areas of the CVs. The charge capacities of the MIP and NMIP electrodes were found to be 4.812 and 4.475 μC, respectively, which clearly indicate that only UA was removed and not the polymer after the extraction process.

Before amperometric detection, the detection potential for UA was determined, using polarization curves of the MIP electrode in pure electrolyte and in electrolyte containing UA. Fig. 4 shows

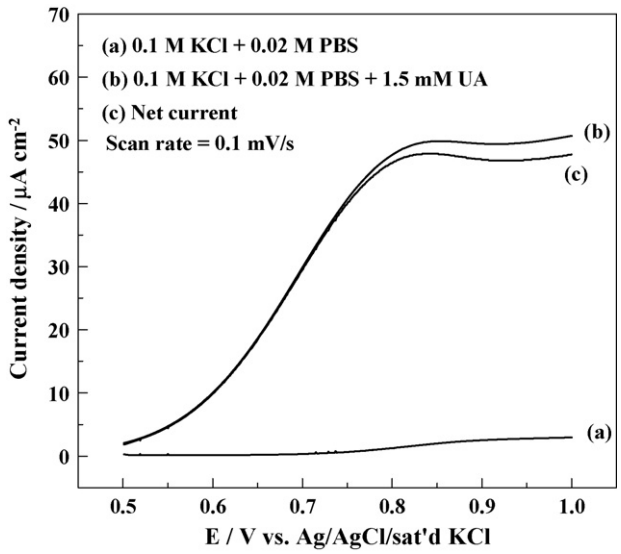

Fig. 4. Liner sweep voltammograms of MIP electrode in (a) 0.1 M KCl + 0.02 M PBS, and (b) 0.1 M KCl + 0.02 M PBS + 1.5 mM UA, at the scan rate of 0.1 V s^{-1}. This figure also shows the net current (c).

the LSVs of the electrode with 0.6 wt% of the polymer at a sweep rate of 0.1 mV s^{-1}. A plateau region between 0.8 and 1.0 V is the limiting current zone. Within this limiting current zone the current density is proportional to the concentration of an electroactive species. From these LSVs, the sensing potential was set at 0.85 V for obtaining amperometric steady-state current responses of UA. The mechanism is electro-oxidation of UA on the imprinted site of MIP modified electrode. At the limiting current region, diffusion of UA would control the whole system. The surface concentration of UA would be zero in this case and the current would depend on the bulk concentration of UA.

Amperometric experiments were carried out to examine the current responses of UA with the MIP and NMIP modified electrodes. The UA concentration was increased stepwise from 0 to 1.125 mM and the potential was fixed at 0.85 V. Fig. 5 shows the calibration curves of MIP and NMIP electrodes, both with a polymer content of 0.6 wt%. Both MIP and NMIP electrodes show good linear relationship between the current density and the concentration of UA for the entire concentration range of UA, with the correlation coefficients greater than 0.995 for both the electrodes. The calibration curves give the sensitivities of MIP and NMIP electrodes to be 24.72 and 6.63 μA mM^{-1} cm^{-2}, respectively. The current density responses of the MIP electrode are higher than those of the NMIP electrode at all the concentrations. The consistently enhanced current densities with MIP electrode reveal that imprinted sites were formed, most likely at the surface of the MIP electrode and they enabled the MIP electrode to recognize more UA molecules, than were recognized by the corresponding NMIP electrode. Indeed these sites or pores can be clearly seen in the corresponding SEM images in further discussions. When the template molecules were removed, a geometrically adopted polymer skeleton with fitting cavities and diffusion pathways for UA was left behind. The imprinting efficiency, defined as the ratio of the sensitivity of the MIP electrode to that of the NMIP electrode, is a property of an MIP electrode used for evaluating the recognition grade of the electrode. For the MIP electrode made by 0.6 wt% of the polymer, the imprinting efficiency is about 3.7, the highest in this study (Table 1). The limit of detection (LOD) for the MIP electrode was calculated to be 0.3 μM on the basis of signal to noise ratio (S/N) of 3. In real applications, the MIP electrode acts as the sensing electrode and the NMIP electrode as the reference one; this will be explained in further discussions.

3.2. Optimization of the polymer content for the MIP electrode

In our preliminary investigations we intended to study the effects of changing the polymer film thickness of the MIP electrode on the sensing performance of the electrode for UA. For this 0.3, 0.5, 0.6, 0.7, and 0.9 wt% of the polymer was mixed with 1.5 mM of UA for preparing the electrodes with different thicknesses of the polymer. Amperometric experiments were carried out with each of the thus fabricated electrodes, and the corresponding calibration curves were obtained. From these calibration curves sensitivities of the electrodes for UA detection were obtained. Sensitivities were also obtained for the corresponding NMIP electrodes. From the values of the sensitivities of the MIP electrodes and NMIP electrodes imprinting efficiencies of the MIP electrodes for various polymer concentrations were calculated. The performance parameters of the sensors with different polymer contents are listed in Table 1. Up to a polymer content of 0.6 wt%, the sensitivity of the MIP electrode shows an increase and reaches a maximum value of 24.72 μA mM^{-1} cm^{-2}. However, the sensitivity shows a decrease with higher polymer contents up to 0.9 wt%. This can be attributed to the inhibition to the electron conductivity in thick polymer films due to the presence of UA. It is known that electron conductivity cannot be sustained in a disproportionately thick conducting film

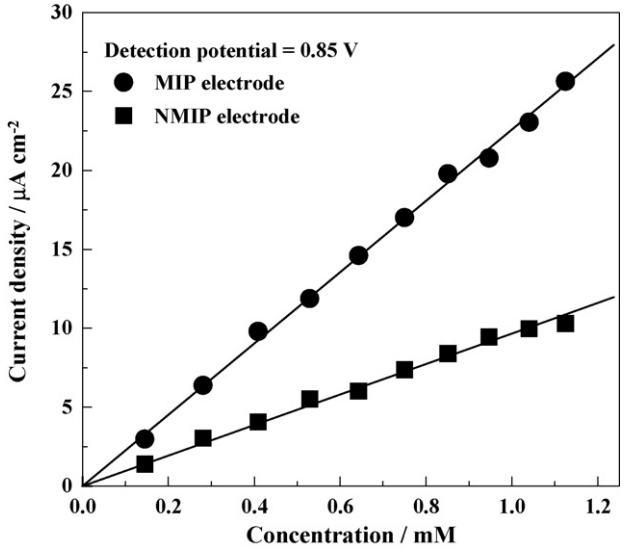

Fig. 5. Calibration curves of MIP (solid spheres) and NMIP (solid squares) electrodes with 0.6 wt% of the polymer in each case.

Table 1
Sensitivities of the MIP and NMIP electrodes and the corresponding imprinting efficiencies with different polymer contents of the electrodes.

Polymer content (wt%)	Sensitivity of MIP electrode (mA mM^{-1} cm^{-2})	Sensitivity of NMIP electrode (mA mM^{-1} cm^{-2})	Imprinting efficiency
0.3	22.59	9.67	2.34
0.5	22.94	6.53	3.51
0.6	24.72	6.63	3.73
0.7	17.43	7.16	2.43

on a substrate. In the case of high polymer contents, UA molecules are likely buried deep within the polymer film and the recognition sites are therefore much fewer on the surface of the polymer. As the imprint molecules are buried inside the polymer membrane, the effective electron diffusion coefficient within the membrane decreases, thereby decreasing the sensitivity of the pertinent electrode for UA detection. In order to verify the presence of these recognition sites, SEM was used to observe the surface morphol-

ogy of MIP and NMIP electrodes. Fig. 6a and b is the SEM photos of NMIP and MIP electrodes, respectively, with 0.6 wt% of the polymer. The NMIP surface displays a relatively smooth surface. The MIP electrode shows disordered but mostly circular cavities with scattered large irregular pores, all obviously due to the templating process of the polymer with UA. These are the recognition sites of the MIP film for UA. When the polymer content is increased to 0.9 wt%, the MIP electrode shows insignificant number of pores and buried pores (Fig. 6c) with reference to those with 0.6 wt% of the polymer (Fig. 6b). Since the quantity of the template, i.e., UA used for each film is the same, the recognition sites created by the template should depend on the polymer content. Again, as the content of UA is the same in both the cases of MIPs with 0.6 and 0.9 wt% of the polymer, same extent of pores should have appeared in Fig. 6c (with 0.9 wt% of polymer) as that in Fig. 6b (with 0.6 wt% of polymer), if all the UA was bound to the surface of the electrode. As the surface pores are obviously not the same in both the figures, it implies that most of the UA molecules were buried in the thicker polymer film with 0.9 wt% of polymer and the subsequent recognition sites for UA in this case were much fewer than those of the film with 0.6 wt% of polymer. We believe that the MIP electrode with 0.9 wt% of polymer with buried UA has lost its usual polymer conductivity due to the damage of conductive paths for electron transfer, caused by the irregular burial of UA in the matrix of the polymer film. We attribute this non-conductivity behavior for the insignificant sensitivity of this MIP electrode for UA. With slightly higher content of the polymer, i.e., with 0.7 wt%, the MIP electrode showed lesser sensitivity of 17.43 $\mu A\,mM^{-1}\,cm^{-2}$, compared to that of the MIP electrode with 0.6 wt% of the polymer, for which the sensitivity was 24.72 $\mu A\,mM^{-1}\,cm^{-2}$. The damage caused for this MIP electrode with 0.7 wt% of the polymer was obviously less, as this content of the polymer was only slightly higher than that of the MIP electrode (0.6 wt%). Thus now it is clear from the results, that the optimum content of this polymer is 0.6 wt% for achieving the highest imprinting efficiency, and thereby sensitivity.

Table 1 also shows that the highest sensitivity of an NMIP electrode is with 0.3 wt% of the polymer. With 0.3 wt% of the polymer the electrode is virtually an ITO film because the polymer coverage is negligible. This is evidenced from SEM image in Fig. 6d. The figure provides solid evidence that the coverage of the ITO substrate with the polymer is little and polymer islands are indeed formed. The templating possibilities of UA with the films with 0.3, 0.6, and 0.9 wt% of the polymer are schematically represented in Fig. 7. The NMIP electrode with 0.5 wt% of the polymer is a "polymer modified" electrode and is different from the one with 0.3 wt% of polymer which has only islands of polymer, and otherwise is virtually an ITO bare electrode. Thus the trend of the sensitivity of NMIP electrode should be considered beginning from the NMIP electrode with 0.5 wt% of polymer. Increase in the polymer content has rendered a consistent increase in the sensitivity of the NIMP sensor, which can be attributed to the intrinsic nature of the conducting polymer. The optimum thickness of the polymer film for the NMIP electrode has apparently not reached and we have not used higher contents of polymer to investigate this, as the focus of our study is with MIP, for which the optimum thickness of this particular film is with 0.6 wt% of the polymer, as judged from its imprinting efficiency and sensitivity for UA. In absence of UA, the NMIP electrode with 0.9 wt% of polymer was apparently not damaged and the thickness can be probably increased for this type of NMIP electrode.

3.3. Selectivity of the MIP electrode for UA in the presence of AA

Intending to verify the sensitivity of this MIP sensor for the bioanalysis of human serum, a preliminary amperometric analysis was made for its specificity for UA in the presence of AA, which is the most important interference in electrochemical routine analysis of UA in a human serum. The normal concentration of AA in a human serum is about $45.8 \pm 16.2\ \mu M$ and is less influenced by dietary or smoke behavior [32]. In this study, the interference test was carried out with AA concentration set at 0.04 mM. Fig. 8 shows the individual and the coexistence current density responses of the MIP and NMIP electrode (0.6 wt% of polymer) for 0.4 mM of UA and 0.04 mM of AA. The figure indicates that the MIP electrode detects negligible current densities for AA. The current response of 0.04 mM AA is less than 7% of the total current obtained with 0.4 mM of UA and 0.04 mM of AA. The selectivity is defined as the sensitivity of UA divided by the sensitivity of AA using the same electrode. Higher selectivity implies better performance in sensing UA against AA. The selectivity of MIP electrode is about 28.76, this result shows that AA has low interference on the sensing of UA by the MIP electrode. Fig. 8 also shows the current density responses of the corresponding NMIP electrode for UA, AA and UA + AA. From this result, the selectivity of NMIP electrode is about 8.85. Compared to the case of

the MIP electrode, the current density response of the NMIP electrode is far lesser for UA, though it is the same for AA. Measured with the NMIP electrode, the current response for 0.4 mM of UA and 0.04 mM of AA is about 48% higher than that for 0.4 mM of UA. These results clearly demonstrate that the interference due to AA is higher in the case of the NMIP electrode with reference to the MIP electrode and thus the selectivity for UA with MIP electrode is far better than that with NMIP electrode. As mentioned already, in real applications, the MIP electrode can act as the sensing electrode and the NMIP electrode as the reference electrode. This may be rationalized as follows. Since the MIP electrode offers specific recognition sites for UA detection, the difference in sensitivities for the optimized MIP electrode (with 0.6 wt% of polymer) and its corresponding NMIP electrode is essentially to be attributed to the UA. Contribution to the sensitivity from the polymer film is eliminated in this way. Therefore the difference in sensitivities between the MIP electrode and its corresponding NMIP electrode is a better measure for the estimation of UA. The 7% interference due to AA in the estimation of UA in human serum would thus be further reduced. The reusability of the MIP electrode is shown in Fig. 9. The figure shows the steady-state current densities of the MIP electrode obtained for 40 different operations. The values were extracted from the steady-state currents of the MIP electrode versus time (shown as inset). The reusability was tested in a solution containing 0.02 M PBS, 0.1 M KCl and 1 mM of UA. After forty operations, an average current density was calculated to be $20.6 \pm 0.6\ \mu A\ cm^{-2}$. The error range of these results indicates that the MIP electrode is reusable for at least 40 operations, without a significant reduction in its sensitivity.

4. Conclusions

The novel polymer, denoted as poly(PD–BCD) was used to prepare a molecularly imprinted polymer (MIP) electrode using the template UA for its sensing. This MIP electrode was directly made from the polymer without a functional monomer and cross linker. As expected the MIP electrode showed about 3-fold higher sensitivity for UA than its counterpart, i.e., a non-molecularly imprinted (NMIP) electrode. The limit of detection (LOD) for this MIP sensor was found to be 0.3 μM at a signal to noise ratio (S/N) of 3. It is well established that the sensitivity of the MIP sensor depends on the thickness of the polymer, and the optimum thickness of the polymer is with 0.6 wt% of it, for obtaining the best sensitivity, and thereby imprinting efficiency. SEM photographs show clearly that the polymer at a concentration of more than 7 wt% had buried the UA in it, causing an adverse effect with respect to imprinting efficiency and thereby sensitivity of the pertinent MIP sensor. The porous structure caused by the UA in the polymer determines the sensitivity of the sensor. The MIP electrode can be used for a human serum as the biosensor with high selectivity for the estimation of UA in the presence of AA as the major impurity. The MIP-sensor was observed to be highly stable for at least forty times of operation.

ABSTRACT

A series of supports functionalized with different alkyl chains and covered with magnetite were synthesized, characterized and applied in the sample pre-concentration of four non-steroidal anti-inflammatory drugs (acetaminophen, naproxen, diclofenac and ibuprofen) contained in wastewater samples. The general methodology involved magnetic solid phase dispersion followed by the analysis by high-performance liquid chromatography with ultraviolet detection. The magnetic supports were initially dispersed in the samples with the aid of Triton X-100, then supports were magnetically isolated and the analytes were eluted with methanol. Finally the extract was injected into the HPLC system. The highest recovery percentage (>90%) was obtained with the support containing octyl chains (C8) at pH 3. The lowest limits of detection achieved ranged within 1–2 $\mu g\,L^{-1}$ with repeatability (expressed as RSD) below 5% in all cases. The method was applied in the analysis of wastewater samples.

1. Introduction

The determination of non-steroidal anti-inflammatory drugs (NSAIDs) residues in the environment is a field of special interest due to the risks to human health and aquatic environment [1]. In these reports the critical point during the experimental part is the right selection of the quantification method. There has been a continuous increase on the improvement for the isolation of NSAIDs from environmental matrices in order to generate efficient and economical methodologies with a high sampling rate.

In most of the cases, the NSAIDs determination involves a pre-concentration step followed by the separation and quantification generally performed by liquid chromatographic methods [2–6]. The main disadvantages of the reported method are the time required for the pre-concentration of large sample volumes to minimize the interferences and the limits of detection [7]. The sample pre-treatment includes strategies such as liquid–liquid extraction [8], solid phase extraction (SPE) [9] and the use of molecularly imprinted polymers [10]. Recently the matrix solid phase dispersion (MSPD) [11] has been applied successfully in the isolation and analysis of estrogens, pesticides and natural components from complex samples matrices and animal tissues. In some cases the results obtained are equivalent or better than the classic methodologies like SPE. The MSPD is an extraction process based on the dispersion of solid adsorbent in the sample. The MSPD use solids with similar polarity than stationary phases used in liquid chromatography allowing the selective extraction of present compounds of interest in the sample in smaller time than the SPE.

Magnetic separation technology has received considerable attention in recent years due to their potential application in cell isolation, enzyme immobilization, protein separation and pre-concentration of organic compounds from large volume environmental water samples. A unique and attractive property of this technology is that magnetic supports can be isolated from sample solutions by the application of an external magnetic field. Therefore suspended magnetic particles tagged with the analytes can be removed from large volume samples by a magnet [12]. To achieve selective and easy isolation of NSAIDs, silica supports functionalized with organic chains of different polarities were synthesized and absorbed onto magnetite as solid phase.

In this paper, a method for routine determination of four anti-inflammatory drugs (acetaminophen, naproxen, diclofenac and ibuprofen) in wastewater effluents is proposed. Environmentally relevant pharmaceuticals were chosen according to human consumption in Mexico. The method involves sample pre-treatment by magnetic-MSPD and analytical determination by HPLC with ultraviolet (UV) detection.

2. Experimental

2.1. Starting materials and general information

Ferrous sulfate heptahydrate ($FeSO_4{\cdot}7H_2O$), ammonium solution (NH_3 25%, w/w), sodium hydroxide and hydrochloric acid were purchased from J.T. Baker (Phillipsburg, NJ, USA). Triton X-100, cetyltrimethylammonium bromide (CTAB), tetramethoxysilane (TMOS), phenyltrimethoxysilane (PTMS), octyltriethoxysilane (C_8-TEOS), octadecyltrimethoxysilane (C_{18}-TMOS), chlorotrimethylsilane (CTMS), 4-acetamidophenol (acetaminophen) 98%, (S)-(+)-6-metoxy-a-methyl-2-naphthaleneacetic acid (naproxen) 98%, 2-[(2,6-dichlorophenyl)amino]benzeneacetic acid sodium salt (diclofenac) 98%, α-methyl-4-(isobutyl)phenylacetic acid sodium salt (ibuprofen) 98% and methanol HPLC grade were obtained from Sigma (St. Louis, MO, USA).

Stock solutions of the NSAIDs were prepared at a concentration of 1 mg mL^{-1} by dissolving the pure substances in 0.001 M sodium hydroxide. These solutions were protected from light and stored under refrigeration (4 °C) until use to avoid possible decomposition. Calibration standards were prepared at concentrations of 20–1000 μg L^{-1} by mixing adequate volumes of each standard solution.

2.2. Synthesis of magnetic supports

The magnetic solids were synthesized by emulsion polymerization using a modification of the methodology of synthesis reported by Zhu et al. [13]. Magnetite particles Fe_3O_4 were synthesized by co-precipitation method reported by Barrado et al. [14,15]. The magnetite obtained was washed three times with 50.0 mL portions of deionized water and added to the flask containing the precursors indicated in Table 1. The silica precursors were previously solubilized in 24 mL of a solution that contained: Triton X-100 (2.0%, w/v), CTAB (0.20%, w/v), methanol (12.5%, v/v) and 200.0 μL of catalyst (NH_3 28%, v/v). The mixture was heated and refluxed at 120 °C for 12 h with stirring.

In order to block superficial silanol groups (–Si–OH), the solids obtained in the previous process were derivatized using a mixture of 0.9 g of clorotrimethylsilane (CTMS), and 1.0 mL of pyridine per each gram of support in 50.0 mL of toluene. The pyridine was added to neutralize the HCl produced during the derivatization. The supports were washed with 20.0 mL portions of each of the following solvents: toluene, ethanol and deionized water. The sequence was repeated until the washing liquid was colorless. The obtained magnetic particles were dried at 60 °C for 24 h.

2.3. Sampling and sample treatment

Two liter polypropylene bottles were conditioned by filling with 2% (v/v) H_2SO_4 for at least three days. Once at the sampling site, the bottles were rinsed several times with the water to be collected. Wastewaters were collected in October 2008 from three municipal waste effluents in Pachuca, Mexico. The samples were filtered through 0.45 μm cellulose acetate filters in a glass filtration device connected to a hand-operated vacuum pump into the prewashed sample bottles. Bottles were completely filled with the sample, wrapped in hermetic plastic bags and transported to the laboratory in iceboxes. Once in the laboratory, samples were stored not longer than five days at 4 °C prior analysis.

The magnetic-MSPD procedure using SiO_2–Fe_3O_4 of different polarities allowed rapid separation by a simple magnetic extraction. First 1.0 mL of Triton X-100 (2.0%, w/v) and 0.1 g of the magnetic support was added into an adequate volume of wastewater sample (0.2, 0.5 or 1.0 L), the pH was adjusted to 3 with HCl 1.0 M and the mixture was dispersed in an ultrasonic bath for 10 min. Subsequently, a magnet was placed on the bottom of the beaker and the magnetic support containing the analytes was isolated from the solution. After the retention process, the solid was flushed twice with 10 mL of deionized water. Finally, the analytes were eluted with 1.0 mL of methanol and the extract obtained was filtered through a 0.45 μm cellulose acetate filter and injected into HPLC system for their separation and analysis.

The SPE procedure was performed following the method reported by Santos et al. [9]. The SPE cartridges (60 mg, Oasis HLB from Waters, Milford, MA, USA) were conditioned using 3 mL of ethyl acetate, 3 mL of methanol and 3 mL of deionized water at a flow-rate of about 3 mL min^{-1}. Samples (1.0 L) were transferred to the SPE. The loaded cartridges were rinsed with 3 mL of methanol:water (5:95, v/v) and 3 mL of n-hexane at a flow-rate of about 1 mL min^{-1}. The elution was performed with three aliquots (1 mL) of ethyl acetate at a flow-rate of about 1 mL min^{-1}. The combined aliquots were evaporated to dryness by a gentle stream of nitrogen. The residues were dissolved in 1.0 mL of methanol and injected into the HPLC system.

Chromatographic separation was achieved with a Microsorb 100-C18 column (5 μm; 150 mm × 4.6 mm i.d.) (Varian, Palo Alto, CA, USA). The mobile phase was methanol–phosphate buffer (2:1, v/v), pH 2.5, 0.01 mol L^{-1}. A flow-rate of 1.0 mL min^{-1} was established at 25 °C.

2.4. Equipment

The structures of the products obtained were examined by X-ray diffraction (XRD) patterns using a PHILIPS PW1710 instrument equipped with a Cu anode, automatic divergence slit and a graphite monochrometer under the following experimental conditions: CuK_α radiation, 1.54 Å; generator tension, 40 kV; generator current, 30 mA; intensity ratio (α_2/α_1), 0.500; divergence slit, 1°; receiving slit, 0.1; start angle (°2θ), 5; end angle (°2θ), 70.

The solid products were characterized using a Fourier transform infrared (FTIR) spectrophotometer (PerkinElmer, model IRDM). Dry samples were prepared in the form of KBr tablets (1:100, w/w).

The morphological analysis of the products was performed using a JEOL JSM-820 scanning electron microscope (SEM).

Table 1
Synthesis conditions for magnetic supports, via emulsion polymerization using TMOS like co-monomer.

Support	Functionalized monomer (g)	Seed monomer TMOS (g)	Fe_3O_4 (g)	Calculated ratio SiO_2/Fe_3O_4 (w/w)

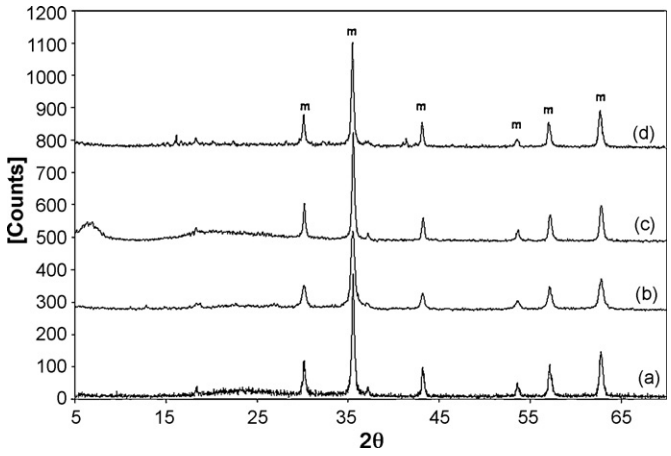

Fig. 1. Diffraction patterns for the magnetic supports (m: diffraction lines for magnetite). Solids synthesized from: (a) TMOS monomer, (b) C_8-TEOS, (c) PTMS and (d) C_{18}-TEOS.

All chromatography experiments were done using reverse phase HPLC (RP-HPLC), the standard technique used in pharmaceutical analysis [16]. The apparatus used was a PerkinElmer Series 200 liquid chromatograph (PerkinElmer, MA, USA) equipped with a UV–vis detector at 220 nm and a manual injector connected to a 20 μL external loop.

3. Results and discussion

3.1. Characterization of solids used as absorbent

The diffraction patterns for the magnetic supports show the reflections corresponding to magnetite ("m" in Fig. 1). Also, the presence of a wide band at 2θ angles from 10° to 40° is consistent with the amorphous phase of the silica gel [15].

Fig. 2 shows FTIR spectra for the magnetic supports. Magnetite has an inverse spinal type structure with a characteristic vibration M_T–O–M_O at ≈600–550 cm^{-1}, where M_T and M_O correspond to the metal occupying tetrahedral and octahedral positions, respectively [15]. On the other hand, the spectra showed a band of intense stretching at ≈3450 cm^{-1}, attributable to the vibration of the silanol group (SiOH). A group of signals above 3000 cm^{-1} are assigned to the vibration of–C=C–H and are observed only for the PH1 solid. The peaks below 3000 cm^{-1} corresponds to the vibration of $-CH_2-$ and they are observed in the solid obtained by polymerization of P1, C8-1 and C18-1. The bending band at ∼1630 cm^{-1} corresponds to H_2O occluded in the support. The flexion vibration band at ∼1400 cm^{-1} represents the C–H bond of the alkyl groups joined to the silicon. The stretching band at 1100–1000 cm^{-1} is assigned to the Si–O–Si bond and the deformation band at ∼888 cm^{-1} belongs to Si–OH bonds. The aromatic character of phenyl support (PH1) was corroborated by the vibrations at 1600, 1430, 740 and 690 cm^{-1}. The polarity of the solids decreases with the use of longer alkyl chains as confirmed with the decrease of the Si–OH and H_2O vibration signals.

SEM analysis of the morphology of the magnetic supports indicated differences between the compounds. Thus, according to the synthetic procedure, we expected solids with spherical morphology. However, as shown in Fig. 3a, irregular granules of mean size up to 5 μm were obtained with the TMOS monomer. This result indicates that the monomer TMOS presents an enhanced reactivity in comparison to that of the less polar monomers favouring polymerization at higher reaction rates and creating a hydrophilic tridimensional network. The supports obtained with less reactive monomers present a spherical morphology (Fig. 3b–d). In the case of the C8 solids two types of particles were observed. The first one was spherical with a particle size around 3 μm and the second one displayed a solid gelatinous appearance and they correspond to silica gel and magnetite, respectively. The phenyl solid is a homogenous solid with spherical morphology and with a particle size around 3 μm. The C18 solid is a homogenous porous solid with a particle size around 10 μm. The magnetite particles partly cover the surface of the silica gel particles, then the magnetic moments are randomly oriented such that when an external magnetic field is applied these moments become aligned parallel to the field providing to the magnetic support properties similar to those of pure magnetite. This feature makes the solids suitable for their use as supports in magnetic-MSPD pre-concentration.

3.2. Anti-inflammatory extractions by magnetic-MSPD

Fig. 4 shows the recovery percentages using spiked wastewater samples. The extraction of the NSAIDs depends on pH value and kind of support. It is possible to observe that as the value of pH increases the extraction percentage diminishes. Low recovery values were obtained (<2%) at pH values of 9 and 11, thus the results are omitted in Fig. 4. From the observed results it is possible to deduce that the species adsorbed on the solids are in their neutral form. If the pH value is higher than the anti-inflammatory pK_a value, ionization takes place, thus its adsorption in solids is affected in a negative way. Acetaminophen has a pK_a value of 9.38, remaining neutral in almost all the pH interval, then its extraction is higher with respect to the more acidic analytes with pK_a values around 4.0–5.0 [17,18].

The polarity of the support is also an important parameter in the recovery percentage. The polar solids P1 and P2, was not shown to be a good adsorbents in most of the anti-inflammatory results. Nevertheless, according to their polar characteristics, these solids could be used as stationary phases in normal phase for magneto-chromatography [19]. On the other hand, with the supports synthesized from the C18 monomer the recovery percentages were below 50%. It is possible that the highly hydrophobic character of these supports avoid the correct dispersion of the solid matrix in aqua samples even in presence of Triton X-100. The anti-inflammatory elution from the solid was carried out with methanol; this solvent is commonly reported in the pre-concentration sample of NSAIDs by solid phase extraction [9]. We found for the retention process using magnetic supports that NSAIDs were well-retained onto the solid and not eluted during the washing step. Thus, we studied the optimum dispersion time using 1, 5, 10, 15 and 20 min. Our results showed that recovery with 10 min was significantly higher than the experiments done with 1 and 5 min, while no improvement was observed at higher times. Therefore, we chose 10 min as the optimum value.

According to the results depicted in Fig. 4, the best conditions to make the extraction and quantification involve the use of the C8-2 support and a pH value of 3. Under the latter conditions, recovery percentages of 100% acetaminophen, 94% naproxen, and 96% for diclofenac and ibuprofen were obtained. The analytical parameters of the method and the quantification of the analytes in the wastewater samples were evaluated using the conditions mentioned above.

3.3. Analytical parameters of the method

In the selected conditions, the analytical parameters were evaluated using different volumes of spiked wastewater (0.2, 0.5 and 1.0 L) with an interval concentration of 50–700 $\mu g\,L^{-1}$. The results obtained are listed in Table 2. The limits of detection (LODs) was calculated for a signal/noise relation equal to (S/N = 3). The LOQ was determined using a signal/noise relation equal to 10 (S/N = 10). The calibration curves were constructed from the area versus concentration $\mu g\,L^{-1}$.

According to the results from Table 2, it is possible to observe that the LODs decrease when higher initial sample volumes are used. The lower limits of detection reached were between 1 and 2 $\mu g\,L^{-1}$ using 1 L of initial sample. LOD and LOQ obtained by the method are comparable to those reported by other methods. Despite that lower LOD can be achieved with SPE–HPLC–UV [9], the reduction in sample time treatment is the main advantage of the method proposed. This improvement makes the proposed method a viable alternative to be implemented as a routine in the analysis of NSAIDs, without the necessity of expensive or difficult access equipment.

3.4. Analysis of wastewater samples

Once the capacity of extraction of the absorbents was evaluated, C8-2 was used for the analysis of wastewater samples. The devel-

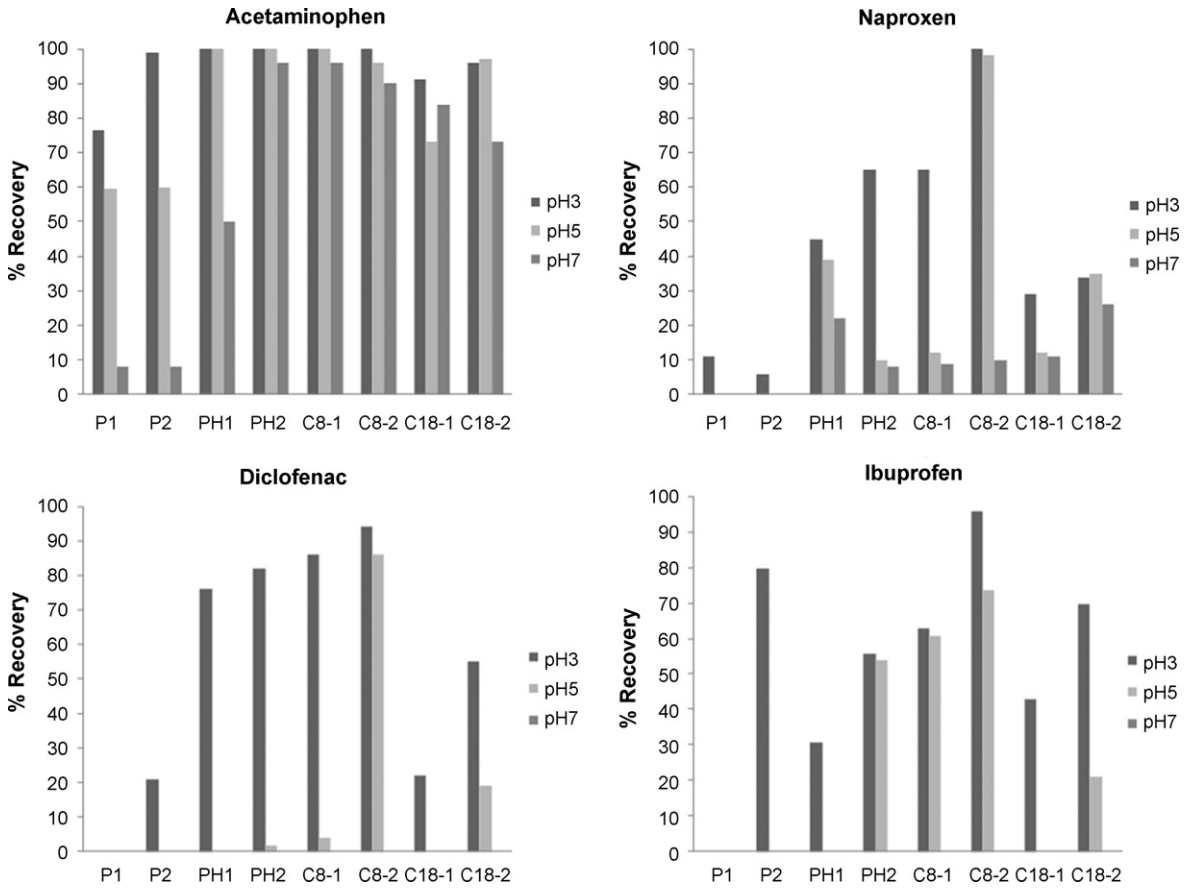

Fig. 4. Effect of polarity and pH value on the NSAIDs recoveries in spiked wastewater.

oped pre-concentration method was applied for the determination of the NSAIDs in wastewater samples. Five replicate determinations of the analytes were carried out on each sample. The samples were also analyzed by SPE–HPLC for comparison. Results are displayed in Table 3 and Fig. 5. For each sample, average of each analyte (determined by both methods) was compared by means of a *t*-test of comparison of means, assuming comparable variances (verified by a *F*-test). Calculated *t* values were compared with the tabulated *t* value for 8 degrees of freedom and a significance level of $p = 0.05$ ($t = 2.30$). In the case of diclofenac and naproxen, the tabulated *t*

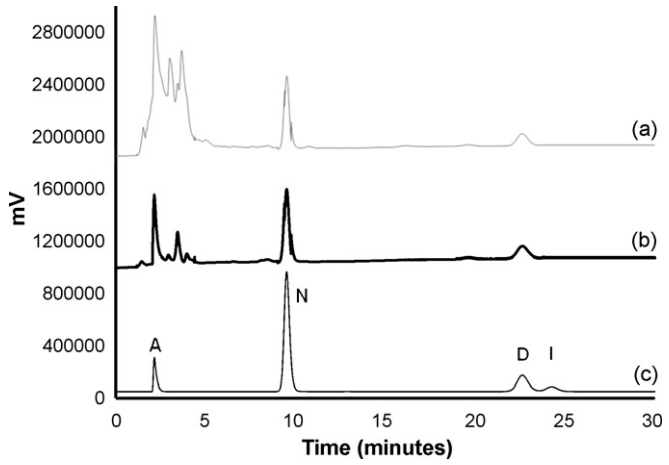

Fig. 5. Chromatograms obtained at the optimized conditions: (a) wastewater sample obtained by SPE pre-concentration method, (b) wastewater sample obtained by magnetic-MSPD pre-concentration method and (c) NSAIDs standard solution 100 $\mu g\,L^{-1}$. A: acetaminophen; N: naproxen; D: diclofenac; I: ibuprofen.

value exceeded the calculated one, thus allowing us to accept the null hypothesis that there are no significant differences between the results provided by both methods. In any sample ibuprofen was detected.

Acetaminophen cannot be quantified in samples, using the evaluated SPE method due to the clean-up process in this case did not eliminate the interferences present in the analytical matrix.

The obtained results are related to the medication prescribed in Mexico, where most of the population consumes the anti-inflammatory drugs found in greater amount.

4. Conclusions

A novel method for routine analysis of four non-steroidal anti-inflammatory drugs of frequent use in wastewater samples has been proposed. This method proposes the pre-concentration of the analytes by magnetic-MSPD, followed by its quantification by HPLC with UV detection. Different solids as adsorbent were tested, concluding that the solid C8-2 is adequate in the pre-concentration of NSAIDs. This solid is functionalized with organic chains C8, and covered with magnetite, characteristic that confers it paramagnetic properties. The sample pre-concentration time is around 30 min. This time is less than that required by other methodologies like SPE or even to that required by conventional MSPD. It has been demonstrated that pH is a determining condition in the adsorption process of the anti-inflammatory onto the solid, being pH 3 the best for the NSAIDs chosen for the analysis. In addition, the polarity of the supports also plays a determining role in the pre-concentration process. In the conditions proposed, the recovery percentages for all the NSAIDs are greater than 90% with adequate precision in terms of repeatability and reproducibility. The method proposed is faster and allows the NSAIDs determination, including acetaminophen. Then this technique is a novel alternative for the analysis of acetaminophen, naproxen, diclofenac and ibuprofen in wastewater samples.

ABSTRACT

Despite the necessity to differentiate chemical species of mercury in clinical specimens, there are a limited number of methods for this purpose. Then, this paper describes a simple method for the determination of methylmercury and inorganic mercury in blood by using liquid chromatography with inductively coupled mass spectrometry (LC–ICP-MS) and a fast sample preparation procedure. Prior to analysis, blood (250 μL) is accurately weighed into 15-mL conical tubes. Then, an extractant solution containing mercaptoethanol, L-cysteine and HCl was added to the samples following sonication for 15 min. Quantitative mercury extraction was achieved with the proposed procedure. Separation of mercury species was accomplished in less than 5 min on a C18 reverse-phase column with a mobile phase containing 0.05% (v/v) mercaptoethanol, 0.4% (m/v) L-cysteine, 0.06 mol L^{-1} ammonium acetate and 5% (v/v) methanol. The method detection limits were found to be 0.25 μg L^{-1} and 0.1 μg L^{-1} for inorganic mercury and methylmercury, respectively. Method accuracy is traceable to Standard Reference Material (SRM) 966 Toxic Metals in Bovine Blood from the National Institute of Standards and Technology (NIST). The proposed method was also applied to the speciation of mercury in blood samples collected from fish-eating communities and from rats exposed to thimerosal. With the proposed method there is a considerable reduction of the time of sample preparation prior to speciation of Hg by LC–ICP-MS. Finally, after the application of the proposed method, we demonstrated an interesting *in vivo* ethylmercury conversion to inorganic mercury.

1. Introduction

Speciation analysis of clinical samples is gradually becoming more widely accepted for nutritional and/or toxicological purposes. According to International Union of Pure and Applied Chemistry (IUPAC), speciation analysis is defined as the analytical process of identifying and/or measuring quantities of one or more individual chemical forms in a sample, and speciation of an element is defined as the distribution of an element among defined chemical species in a system [1,2].

Mercury (Hg) is one of the most hazardous pollutants in the environment. It exists in three basic forms: elemental mercury (Hg^0) known as metallic mercury, inorganic mercury compounds (Ino-Hg), primarily mercuric chloride, and organic mercury, primarily methylmercury (Met-Hg) [3,4]. Organic forms are more toxic than inorganic [4].

The main sources of human exposure to organic mercurials, mainly in the form of methylmercury (Met-Hg) or ethylmercury (Et-Hg), are the consumption of fish [4] and vaccines containing thimerosal, respectively [5]. On the other hand, the most common forms of exposure to inorganic forms are by inhalation of Hg vapor released from dental amalgams or from gold mining activities [4].

Measurements of Hg in both blood and hair are used to determine whether adverse health effects are likely to occur. The contents of mercury species in blood may represent a cumulative exposure from the daily diet and/or occupational environment exposure. However, despite the difference in toxicity related to the form of mercury, total mercury concentration (THg) in blood is usually used to estimate the clinical outcomes after mercury exposure. Moreover, the proportion between chemical forms of mercury in blood may vary among individuals. This makes it essential to have analytical methods, based on speciation analysis, which can differentiate between chemical forms in blood to diagnose risks of toxicity.

The most effective instrumental-based techniques for chemical speciation analysis rely on the use of chromatography (mainly gas chromatography (GC) [6–9] or liquid chromatography (LC)) [10–12] coupled to a specific and sensitive detector, such as inductively coupled plasma mass spectrometry (ICP-MS). Compared with GC, LC is

doi:10.1016/j.talanta.2009.09.001

the preferred separation technique used for mercury speciation, because the mercury species do not need to be derived to volatile compounds before HPLC separation.

Although several methods have been developed for measuring mercury in blood samples [13–17], there is merely a few proposing speciation analysis [18,19]. Moreover, all of them suggested very tedious and time-consuming sample preparation procedures. Moreover, artifact formation during the sample preparation step is a potential source of error [20,21]. On the other hand, clinical laboratories must cope with an increasing demand for trace element analysis in body fluids and tissues in response to increasing concern for occupational and environmental exposure to mercury. Thus, fast sample preparation procedures with minimal handling are extremely desirable in routine analysis.

The aim of this paper was therefore to evaluate a simple method for methylmercury and inorganic mercury determination in blood by high-performance liquid chromatography (HPLC) coupled to inductively coupled plasma mass spectrometry (ICP-MS) with a fast sample preparation procedure prior to analysis. The method was then applied for speciation of mercury in blood samples collected from a Brazilian riparians, living in the Amazon region, exposed to mercury from fish consumption. It was also demonstrated for the first time that ethylmercury is *in vivo* converted to inorganic mercury, making the determination of the inorganic form of mercury in blood relevant for thimerosal exposed populations.

2. Material and methods

2.1. Instruments and apparatus

All measurements were made with an ICP-MS (Elan DRC II PerkinElmer, Norwalk, CT) for total mercury determination and for speciation.

2.2. Measuring of mercury species

A PerkinElmer model L-200 LC pump, six-port injector (Rheodyne 9725) with a reverse-phase column (C18, 5 μm, 150 mm × 4 mm, Brownlee Columns PerkinElmer, USA) and a pre-column (guard column) RP18 (7 μm, 15 mm × 3.2 mm, Brownlee Columns PerkinElmer, USA) comprised the LC system. Samples were loaded with a syringe into a 100-μL sample loop. All separations were performed at room temperature under isocratic conditions. The isocratic mobile phase was 0.05% (v/v) mercaptoethanol, 0.4% (m/v) L-cysteine, 0.06 mol L^{-1} ammonium acetate and 5% (v/v) methanol. The flow rate was 1.0 mL min^{-1}. The effluent from the LC column was directly connected to the nebulizer with PEEK tubing (1.59 mm o.d.) and a low dead volume PEEK connector. Data evaluation was performed using Chromera® software supplied with the instrument, and quantification was based on peak high by external calibration.

The optimum experimental conditions for both ICP-MS and LC are given in Table 1.

2.3. Measurements of total mercury in blood

The method used for the determination of total mercury in blood samples was based on a previous publication described by Palmer et al. [13]. Briefly, blood specimens were diluted 1 + 49 into a 15-mL polypropylene Falcon® tube (Blue Max™ Jr., Becton Dickinson) with a diluent solution containing 0.5% (v/v) double-distilled HNO_3, 25 μg L^{-1} Rh as internal standard, 1 mg L^{-1} Au to control Hg memory effects in the spray-chamber, and 0.005% (v/v) Triton® X-100 and analyzed by ICP-MS.

Table 1
Liquid chromatography and ICP-MS operating conditions for Hg speciation in blood samples.

LC conditions	
Column	C18 (5 μm, 150 mm × 4 mm)
Pre-column (Guard column)	RP18 (7 μm, 15 mm × 3.2 mm)
Mobile phase	0.05% (v/v) mercaptoethanol 0.4% (m/v) L-cysteine 0.06 mol L^{-1} ammonium acetate 5% (v/v) methanol
Mobile phase flow rate	1 mL min^{-1}
Sample loop	100 μL
Measurement	Peak high
ICP-MS experimental conditions	
Radio frequency power (W)	1200
Scan mode	Peak hopping
Nebulizer gas flow (L min^{-1})	0.58
Resolution (amu)	0.7
Replicates	3
Isotopes	^{202}Hg

2.4. Reagents

All reagents used were of analytical grade and the solutions were prepared using high-purity water with a resistivity of 18.2 MΩ cm, obtained from a Milli-Q Plus water purification system (Millipore, Bedford, MA, USA). Nitric acid (Merck, Darmstadt, Germany), was doubly distilled in a quartz sub-boiling apparatus (Kürner Analysentechnik, Rosenheim, Germany).

A clean laboratory and laminar-flow hood capable of producing class 100 were used for preparing solutions and samples. All solutions were stored in high-density polyethylene bottles. Plastic bottles and glassware materials were cleaned by soaking in 10% (v/v) HNO_3 for 24 h, rinsed five times with Milli-Q water and dried in a class 100 laminar-flow hood before use. All operations were performed on a clean bench.

A 10-mg L^{-1} standard solution of inorganic mercury was obtained from PerkinElmer (PerkinElmer, Norwalk, CT). A 1000-mg L^{-1} standard solution of methylmercury chloride (CH_3HgCl) and 1000-mg L^{-1} standard solution of ethylmercury chloride (CH_3CH_2HgCl) in water were obtained from Alfa Aesar. Analytical calibration standards of mercury species were prepared daily over the range of 0.0–20.0 μgL^{-1} for the LC–ICP-MS method by suitable serial dilutions of the stock solution in the mobile phase.

Additional chemicals for the speciation studies were HPLC grade methanol (99.9%, v/v) and mercaptoethanol (Sigma–Aldrich, USA), L-cysteine (Fluka, Japan). Ammonium acetate (99.99%) was obtained from Aldrich Chemical Company (Milwaukee, USA).

For the ICP-MS method for total mercury determination, Rh and Au were each diluted from 1000 mg L^{-1} stock standards (Assurance grade; Spex Certiprep®). Triton® X-100 was obtained from the Sigma–Aldrich Co. (Sigma Ultra Grade, Sigma–Aldrich Co., St. Louis, MO, USA) and was diluted to 10% (v/v) with double-deionized water. A rinse solution consisting of 0.005% (v/v) Triton X-100® and 1 mg L^{-1} Au in 2% (v/v) nitric acid was prepared before each run.

2.5. Sample preparation for speciation analysis

Blood samples (250 μL) were placed in 15 mL polypropylene test tubes with 4.75 mL of a solution containing 0.10% (v/v) HCl + 0.05% (m/v) L-cysteine + 0.10% (v/v) 2-mercaptoethanol and then sonicated for 15 min in an ultrasonic bath 1400 A (UNIQUE, Brazil). The resulting solution was centrifuged and then filtered through 0.20 μm Nylon® filters (Millipore, USA). Sample extraction was performed in triplicate and extraction blanks were prepared in the same manner.

2.6. Standard reference materials and ordinary blood specimens

Standard Reference Material (SRM) 966 Toxic Metals in Bovine Blood was purchased from the National Institute of Standards and Technology (NIST, Gaithersburg, MD). For additional validation purposes, human blood specimens ($n = 10$) collected as part of another research study involving Hg exposure in the Brazilian Amazon region were available for method comparison purposes with identifiers removed [22,23]. These specimens had been obtained with informed consent from human subjects in accordance with procedures approved by our Institutional Review Board.

2.7. Blood specimen collection

Venous blood was collected into pre-screened, 3-mL draw lavender-capped BD Vacutainer® blood collection tubes containing K2EDTA anticoagulant (Becton Dickinson, Franklin Lakes, NJ, USA; part no. 367856). These tubes were used with BD Vacutainer® Eclipse™ 22 gauge, 1–1.25 in. blood collection needles (Becton Dickinson; part no. 368608). After blood was drawn into the Vacutainer®, the tube was inverted several times to mix blood with K2EDTA. Prior to freezing (−80 °C), an aliquot of blood was transferred under a Class II Biosafety cabinet into a 2-mL Nalgene® cryovial (sterile, bulk-packed part no. 5012-0020, or similar) for storage until analysis.

3. Results and discussion

3.1. Preliminary experiments

Different procedures have been proposed for the extraction of mercury species in biological samples for speciation purposes based on HPLC–ICP-MS [10,11] or GC–ICP-MS [18,19]. In general, protocols are based on acid [9,10] or basic extractions [18] mediums. However, most of these methodologies have several disadvantages when coupling with HPLC–ICP-MS. Moreover, as far as we know there are no papers dealing with mercury speciation in blood by using HPLC–ICP-MS.

Firstly, as far as a compatible pH value for the reverse-phase column is concerned, a laborious procedure usually has to be adopted to adjust appropriate pH of the extracted solution prior to injection into the HPLC. Secondly, Hg species transformation might occur during sample preparation [20,21].

In order to avoid the aforementioned limitations, alternative extraction procedures have been suggested with reagents containing thiol ligands, such as mercaptoethanol [10], L-cysteine [10] or thiorea [24]. These procedures are associated with the use of microwave energy [25]. Alternatively, quantitative mercury extractions from hair samples have been demonstrated even in low acid conditions when associated with ultrasound energy [26].

The method of extraction evaluated here is based in part on a previous method described by Chiou et al. [10] for Hg speciation in fish samples. In that method, the authors have suggested the use of an extraction solution containing L-cysteine and 2-mercaptoethanol in combination with microwave radiation. Thus, our preliminary experiments were carried out to explore the efficiency of using mercaptoethanol and L-cysteine for quantitative mercury extraction from hair samples with two basic differences from the method proposed by Chiou et al. [10] Firstly, we used ultrasound energy instead of microwave energy. Secondly, we also evaluated the use of a dilute solution of HCl (0.10%, v/v) in the extractant to accelerate the ultrasound extraction without a major change in the pH. The use of an ultrasound bath simplifies the method, since this system is much simpler and less expensive than commercial microwave systems.

3.2. Evaluation of the time of ultrasound extraction

For this experiment, it has been evaluated the extractor solution containing 0.10% (v/v) HCl + 0.05% (m/v) L-cysteine + 0.10% (v/v) 2-mercaptoethanol and different times of ultrasound energy (from 0 to 30 min). Different aliquots (250 μL) of the SRM NIST 966 were used for the experiment. Quantitative extraction of Hg (>95%) was observed for the NIST 966 blood by using the proposed extraction solution and 15 min of ultrasound energy. Then, for the subsequent experiments, mercury species were extracted from the blood samples by using the solution containing 0.10% (v/v) HCl + 0.05% (m/v) L-cysteine + 0.10% (v/v) 2-mercaptoethanol and 15 min of ultrasound energy.

3.3. Optimization of LC operating conditions

After the optimization of mercury extraction from blood samples, we optimized the mobile phase composition. Different combinations of reagents in the mobile phase are usually recommended for the speciation of Hg in biological samples by HPLC–ICP-MS. Some authors recommend the use of L-cysteine and mercaptoethanol [10] while others recommend methanol, mercaptoethanol and ammonium acetate [11] or a mixture of L-cysteine, pyridine and methanol [27]. Our preliminary experiments demonstrated more promising results (time of separation, resolution, selectivity and sensitivity) for the mixture of mercaptoethanol, L-cysteine, ammonium acetate and methanol. According to Chiou et al. [10] the retention time of mercury species increases with the increase in mercaptoethanol concentration in the mobile phase. We have observed the same results (data not shown). Thus, we fixed mercaptoethanol concentration at 0.05% (v/v) as a compromise between selectivity and time of analysis. Ammonium acetate was also fixed at 0.06 mol L^{-1}. This concentration is able to maintain a favorable pH at 6.7. On the other hand, different concentrations of methanol in the mobile phase were evaluated. For this study the concentrations of ammonium acetate, L-cysteine and mercaptoethanol were fixed at 0.06 mol L^{-1}, 0.05% (m/v) and 0.05% (v/v), respectively and the concentration of methanol was varied from 0.0% to 5% (v/v). A considerable increase in Hg sensitivity was observed with the increase in methanol concentration. Three mechanisms have been put forward to explain the above enhancement effect on signal intensities: (1) charge transfer reaction from C+ species to analyte atoms, (2) improvement in the nebulization transport of the sample, and (3) shift of the zone of maximum ion density [28]. Concentrations of methanol higher than 5% (v/v) were not evaluated, since they lead to plasma instability and an increase in carbon residues on cones. Thus the methanol concentration in the mobile phase was fixed at 5% (v/v) for further studies.

Subsequent experiments were carried out to optimize the concentration of L-cysteine in the mobile phase. Separation of mercury species can take place based on the cysteine–mercury complexes on the polymeric-based C18 reverse-phase column. Concentrations of L-cysteine between 0.05% and 0.4% (m/v) were evaluated with the concentration of mercaptoethanol, ammonium acetate and methanol fixed at 0.05% (v/v), 0.06 mol L^{-1} and 5% (v/v), respectively. It has been observed that the higher the concentration of L-cysteine, the lower the retention time of the three mercury species and the higher the sensitivity for all mercury species. The separation of the three mercury species is achieved in less than 8 min with L-cysteine concentration fixed in 0.4% (m/v) compared to 35 min when 0.05% (m/v) L-cysteine is used in the mobile phase. Concentrations of L-cysteine higher than 0.4% (m/v) do not provide a complete separation between Met-Hg and Ino-Hg peaks. As a result, a solution containing 0.4% (m/v) L-cysteine, 0.05% (v/v) mercaptoethanol, 0.06 mol L^{-1} ammonium acetate and 5% (v/v) methanol was used as the mobile phase.

3.4. Validation studies

Validation of the proposed method was accomplished using NIST SRM 966 Bovine Blood. For additional validation, it was also analyzed 10 human blood specimens. Data obtained with the proposed method were compared to the results obtained using direct sample introduction for total mercury determination by ICP-MS. Results for NIST SRM 966 are shown in Table 2. Values found using the proposed method are in good agreement with established target values for the SRM 966. Moreover, no statistical differences were observed between the sum of the Hg species concentration (proposed method) and the total Hg values found by an alternative method at 95% level on applying the *t*-test for the analysis of the 10 human blood samples (Table 3). Typical calibration graphics for methylmercury, ethylmercury and inorganic mercury are shown in Fig. 1 with a very good linearity.

3.5. Analytical parameters

The LC–ICP-MS proposed method detection limit (3 SD) was 0.1 $\mu g L^{-1}$ and 0.25 $\mu g L^{-1}$ for methylmercury and inorganic mercury, respectively. Typical within-day precision was always lower

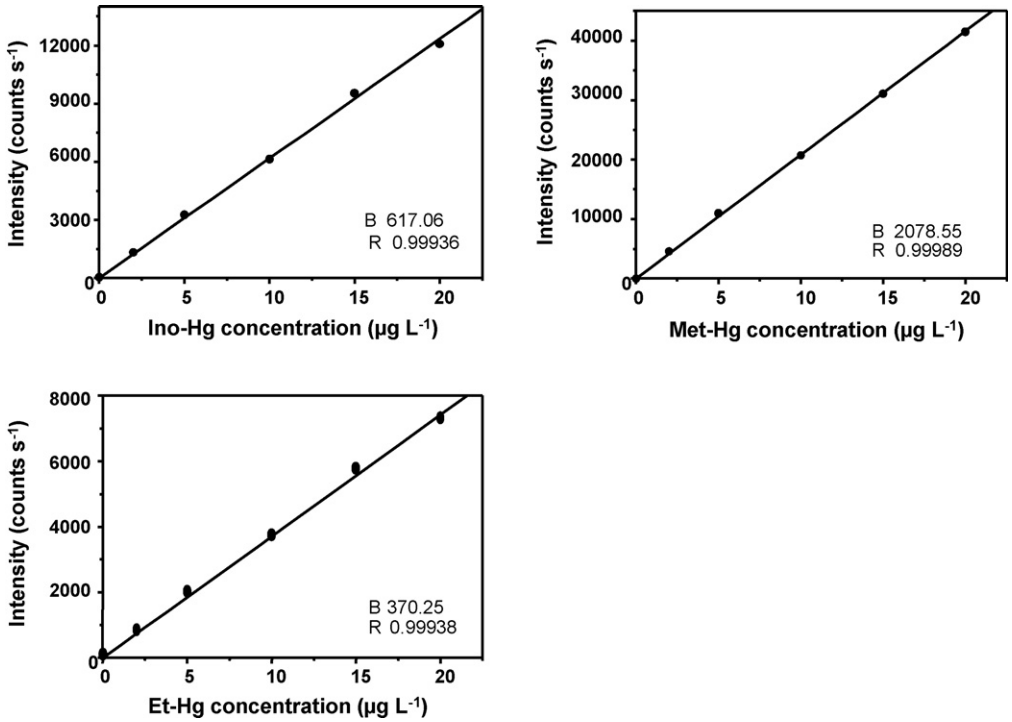

Fig. 1. Calibration curves for different mercury species by applying the proposed LC–ICP-MS method. Standards of each mercury form were prepared from 0.0 $\mu g L^{-1}$ to 20 $\mu g L^{-1}$. Mobile phase consisting of 0.4% (m/v) L-cysteine, 0.05% (v/v) mercaptoethanol, 0.06 mol L^{-1} ammonium acetate and 5% (v/v) methanol. For other conditions see Table 1.

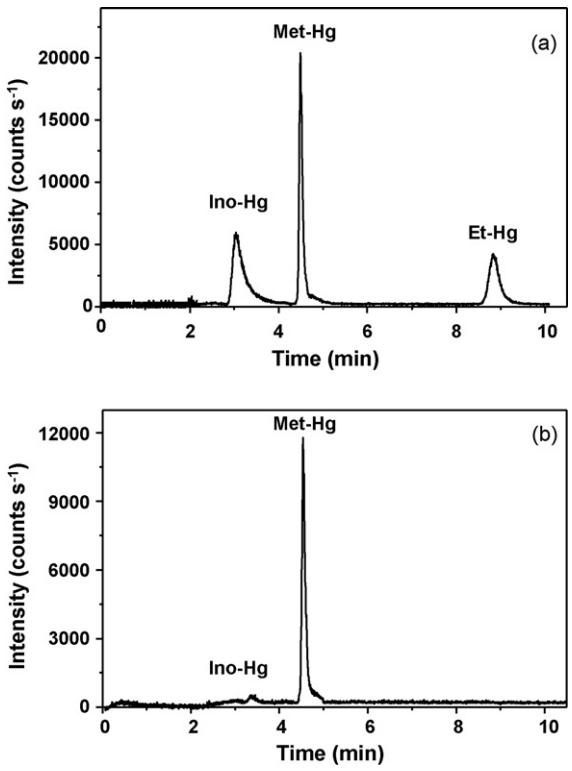

Fig. 2. Chromatograms showing the separation of mercury species in: (a) standards containing 10 μg L^{-1} of each mercury compound and (b) human blood (volunteer from fish-eating communities of the Amazon region). Mobile phase consisting of 0.4% (m/v) cysteine, 0.05% (v/v) mercaptoethanol, 0.06 mol L^{-1} ammonium acetate and 5% (v/v) methanol. For other conditions see Table 1.

than 7.0% (NIST SRM 966), while between-day precision was <12.0% RSD (NIST SRM 966) for both methylmercury and inorganic mercury determinations.

3.6. Method application for the speciation of mercury in blood samples collected from fish-eating communities

Human blood specimens were collected from 10 volunteers living in the Brazilian Amazon and exposed to high levels of methylmercury from fish consumption. Results are shown in Table 3. Only methylmercury and inorganic mercury were identified in these samples (Fig. 2). Moreover, total mercury levels found with the proposed method as a sum of inorganic and methylmercury are in good agreement with Hg values found by ICP-MS.

3.7. Stability of blood samples after collection for mercury speciation

After the speciation analysis of blood samples collected from fish-eating communities, they were left at −80 °C during 6 months to check the long-term stability of samples after collection. After this period, samples were re-analyzed by the proposed procedure. There were no statistical differences between the values in the two periods of analysis, demonstrating that samples are stable after collection at least 6 months at −80 °C.

3.8. Stability of mercury species after extraction

To verify the stability of the mercury species after extraction, a time study of sample storage at room temperature was carried out. For this experiment the SRM NIST 966 reference material was divided into four different fractions of 250 μL. From each fraction, mercury was extracted according to the proposed procedure and left at room temperature until analysis. Then, samples were analyzed after the first hour (T0), 3 h later (T1), 8 h later (T2), 24 h later (T3) and 4 days later (T4). Our results demonstrated that mercury species present in this certified material (methylmercury and inorganic mercury) can be extracted and left at room temperature up to 4 days before analysis. Since this blood reference material does not contain ethylmercury, additional experiment was carried out with an ordinary blood (human blood), divided in four fractions of 250 μL and each fraction spiked with ethylmercury to contain 10 μg L^{-1}. The proposed method of extraction was then applied and the resulted extracted solutions were left at room temperature at the same time of the previous experiment with the NIST 966. Contrary to methylmercury and inorganic mercury recovery of ethylmercury was lower than 30% even when the speciation analysis was performed just after the blood was spiked. Moreover, this loss was proportional to an increase on the amount of inorganic mercury. Since ethylmercury is stable in the standards (at room temperature and after 15 min of ultrasound energy application), it means that ethylmercury is converted to inorganic mercury in blood for some blood component with a mechanism not yet known.

3.9. In vivo conversion of ethylmercury to inorganic mercury

Based on the preliminary results with ethylmercury in blood, we did a further experiment with exposed rats. Two male Wistar rats weighting 200 g each were treated by gavage with ethylmercury solution during 3 days (100 μg kg^{-1} day^{-1}) and the blood was collected from the animals before the treatment (blank) and in the fourth day after the beginning of the treatment. Then, the determination of three mercury species (inorganic, methylmer-

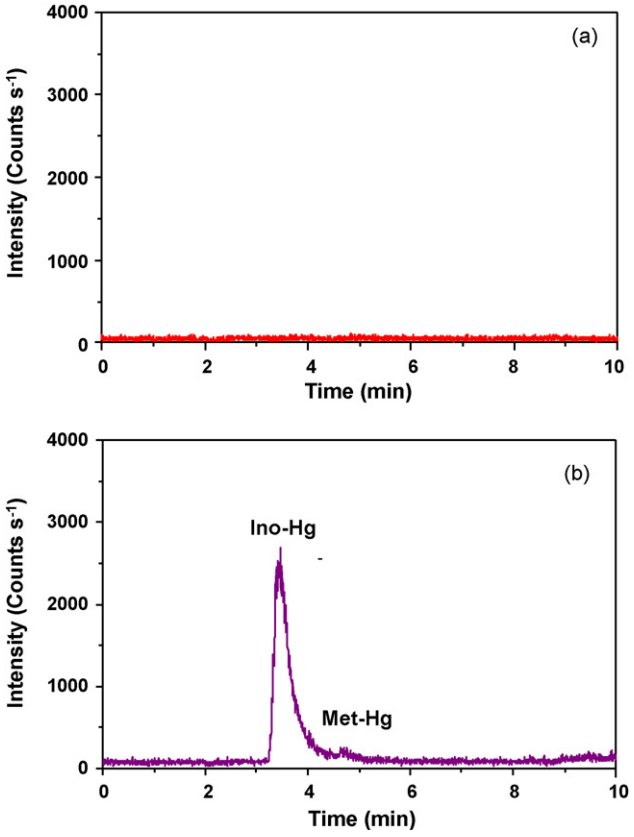

Fig. 3. Chromatograms showing the separation of mercury species in blood of: (a) rat before ethylmercury exposure (control) and (b) exposed to 100 μg kg^{-1} day^{-1} of ethylmercury during 3 days. For experimental conditions see Table 1.

cury and ethylmercury) was carried out by applying the proposed method. Fig. 3 shows the chromatogram of one of the rat's blood before (Fig. 3a) and after ethylmercury exposure (Fig. 3b). As can be observed two peaks were obtained in the blood of the exposed animal, one predominant of inorganic mercury and a very small peak of methylmercury. It demonstrates the *in vivo* conversion of ethylmercury largely to inorganic mercury and to much less extent to methylmercury. This finding is extremely relevant in the evaluation of thimerosal exposed populations, since, thimerosal, a preservative in many currently marketed vaccines throughout the world, releases ethyl mercury radical as the active species.

4. Conclusion

A simple method has been developed for mercury speciation in blood samples based on LC–ICP-MS. Sample preparation procedure is very fast and simple with a quantitative extraction of mercury in 15 min. In addition, the number of handling steps, sample preparation and analysis time, as well as potential sources of analytical errors, is reduced. The method was successfully applied for the speciation of mercury in blood samples collected from volunteers exposed to methylmercury by fish consumption. Finally, it was demonstrated the ethylmercury is practically fully converted *in vivo* to inorganic mercury and in much lees extend to methylmercury and then the inorganic form. It brings new insights to the toxicological aspects and mechanisms of thimerosal containing vaccines.

Electrochemical impedance spectroscopy

ABSTRACT

In this paper, we describe DNA electrochemical detection for genetically modified organism (GMO) based on multi-wall carbon nanotubes (MWCNTs)-doped polypyrrole (PPy). DNA hybridization is studied by quartz crystal microbalance (QCM) and electrochemical impedance spectroscopy (EIS). An increase in DNA complementary target concentration results in a decrease in the faradic charge transfer resistance (R_{ct}) and signifying "signal-on" behavior of MWCNTs-PPy-DNA system. QCM and EIS data indicated that the electroanalytical MWCNTs-PPy films were highly sensitive (as low as 4 pM of target can be detected with QCM technique). In principle, this system can be suitable not only for DNA but also for protein biosensor construction.

1. Introduction

In recent years, there has been considerable interest in the development of DNA sensors thanks to their numerous applications such as the analysis of unknown or mutant genes, diagnosis of infectious agents in various environments and detection of analytes (drugs, pollutants, etc.). Traditional methods for DNA detection, based on the radioisotopic and fluorescent detection, are labor and time consuming, and are, thus, not well suited for routine and rapid medical analyses, particularly for point-of-care tasks. Among some new approaches to DNA detection, electrochemical detection has many advantages such as the reduction of the assay time, simple protocol and therefore can be used for on-site monitoring. In this context, oligonucleotides (ODN, a short fragment of DNA) immobilization at an electrode surface has been used in the most studies [1–4].

Among known conducting polymers, polypyrrole (PPy) is most frequently used in the commercial applications due to the high conductivity, long-term stability of its conductivity and the possibility of forming homopolymers or composites with optimal mechanical properties. PPy offers potential applications in the domain of composite materials, tissue engineering, actuators, supercapacitors, electronic and electro optic devices [5–9]. Especially, functionalized PPy polymers have attracted great attention in label-free detection because of their surface functionality and electron transduction [10]. On the other hand, carbon nanotubes (CNTs) have attracted considerable studies since their discovery [11]. They display high electrical conductivity, good mechanical strength and excellent chemical stability. The ability of CNTs-modified electrodes to promote electron-transfer reactions has been reported in connection with many important biomolecules [12,13].

Therefore, the combination of conducting polymer with CNTs was a good idea and in reality it was proven to have enhanced charge density, electrical conductivity and electrocatalytic activity compared with each pure component [14–16].

Recently, agricultural enterprises in the world have developed new plant varieties by adopting modern biotechnology, including genetic transformation. In the US, more than 40% of the corn, 50% of the cotton and >45% of soybean acres planted in 1999 have been genetically modified; at least 60% of food production US supermarkets contain genetically modified organisms (GMOs) [17]. A GMO is referred to as a living organism whose genome has been modified by the introduction of an exogenous gene able to express an additional protein that confers new characteristics, i.e. herbicide tolerance [18–20].

doi:10.1016/j.talanta.2009.09.002

The exogenous DNA that has been integrated into a crop consists of a promoter (P), a structural gene ('encoding region') and a transcription terminator (T). Two particular sequences are inserted in most of the available transgenic products: the promoter of the subunit 35S of ribosomal RNA of *Cauliflower mosaic virus* (35S) and the Terminator of nopaline synthase (NOS) gene from *Agrobacterium tumefaciens*. In particular, they are widely used for the production of many transgenic vegetables commercially available, as Roundup Ready soy, MaisGard maize and the Flavr Savr tomato. Thus, the 35S and NOS sequences are the most frequently used targets for GMO screening in DNA detection approach (this approach is more often used than the second one of protein detection because DNA stability is much higher than that of proteins and therefore DNA detection can be used for both raw and processed materials while protein detection is suitable only for raw materials).

On the need of fast and sensitive analytical methods for GMO screening, in this study, we described the setup of a novel DNA label-free electrochemical biosensor for GMO (soybean) detection, based on MWCNT-doped PPy matrices for ODN immobilization and hybridization.

2. Experimental

2.1. Chemicals

Pyrrole (Py) 99% were purchased from Sigma–Aldrich. It was distilled under reduced pressure before use. Other reagents used were of analytical grade or the highest commercially available purity and used as supplied without further purification. The multi-wall carbon nanotubes (MWCNT, ~95% purity), prepared by the Chemical vapor deposition method, were obtained from Nanolab (China). The diameter of MWCNT is in the range of 40–60 nm and with a length of 1–2 μm. All aqueous solutions were prepared using Milli-Q water (18 MΩ cm).

2.2. Functionalization of MWCNT with carboxylic groups

The functionalization of CNTs has been achieved by an oxidation process, which involves extensive ultrasonic treatment in a mixture of concentrated H_2SO_4/HNO_3. The ends and sidewalls of the treated CNTs are mainly decorated with carboxyl groups. CNTs functionalized in this manner obtain good solubility in water and retain their primary electronic and mechanical properties [21].

A calculated amount of MWNTs was added into 3:1 H_2SO_4/HNO_3 mixture, then ultrasonicated in a water bath for several hours at 40 °C. The resulting suspension was diluted with deionized (DI) water and was centrifuged. The pretreated MWNTs (functionalized cMWCNT) were then washed with DI water for several times, treated with 0.1 M NaOH (to reach pH of 7), filtered, and dried at 60 °C overnight. The desired amount of the cMWCNTs (3 mg ml^{-1}) was added in DI water and ultrasonicated for about 15 min to form a uniform cMWCNTs black solution.

2.3. ODN sequences

In this study the herbicide-resistance RR soybean (product of Monsanto Inc.) has been chosen as a model. In this genome, promoter sequence is found as the CaMV 35S, which is extracted from *Cauliflower mosaic virus*. The synthesized ODN probe-pyrrole, non-complementary and complementary targets were purchased from Invitrogen. Their sequences were listed in Table 1. The PCR amplification of ODN 35S probe and its complementary target were presented in Fig. 1.

Table 1
Composition of PBS buffer and sequences of used ODN probe and targets (complementary and non-complementary strands).

Materials	Composition/sequence
PBS buffer	0.14 M NaCl; 2.7 mM KCl; 10 mM Na_3PO_4; 1.7 mM K_3PO_4; pH 7.4
ODN probe (P35S)	5′ GGCCATC **G**TTGAAG**A**TGCCTCTGCC 3′
ODN target CaMV 35S promoter (complementary target)	5′ GGCAGAGGCA**T**CTTCAA**C**GATGGCC 3′
2-Base non-complementary target (NC target)	5′ GGCAGAGGCA**A**CTTCAA**G**GATGGCC 3′

2.4. Electrosynthesis of films

Pure PPy film (denoted as PPy) was electrochemically deposited on the Au microelectrode either at a constant potential and time (+0.7 V vs. Ag/AgCl for 30 min or by voltammetric cycling from 0 to 0.9 V vs. Ag/AgCl for 30 scans, with the scan rate of 20 mV s^{-1}) from electrolytic solution containing PBS buffer, Py (0.3 M).

Probe immobilized PPy films (PPy-ODN) and probe immobilized CNT-doped PPy (C-PPy-ODN) films were obtained with the same procedure as described above with addition of ODN probe (1 μl ml^{-1}) and mixture of ODN probe (1 μl ml^{-1}) and cMWCNTs (3 mg ml^{-1}), respectively, followed by the action of ultrasonication.

2.5. ODN hybridization

For hybridization experiments, a set of ODN targets (1 μl ml^{-1}) was used: CaMV 35S as complementary target, and 2-base muted sequence, non-complementary (NC) target as a control. The hybridization experiments were performed in PBS buffer (pH 7.4) containing target strand for 30 min or 1 h at room temperature followed by an adequate rinse with the same buffer solution.

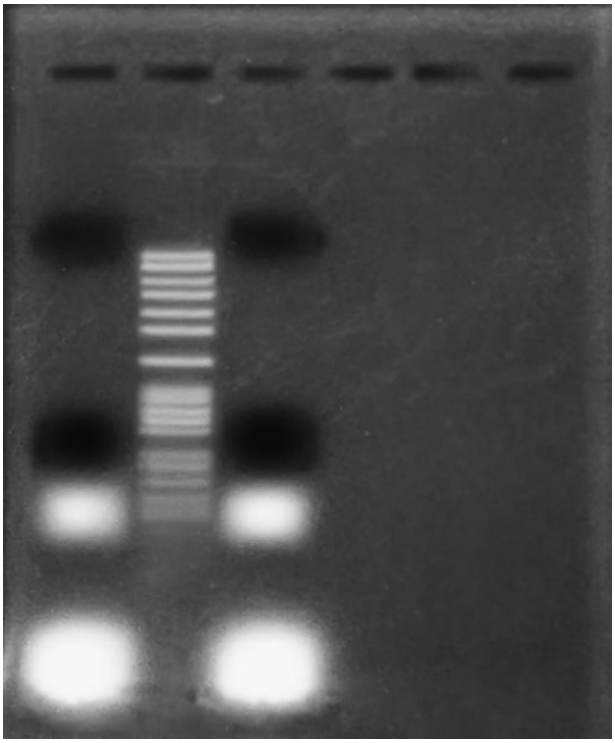

Fig. 1. The amplicon obtained by the PCR of ODN probe (P35S, left band) and its complementary target (right band).

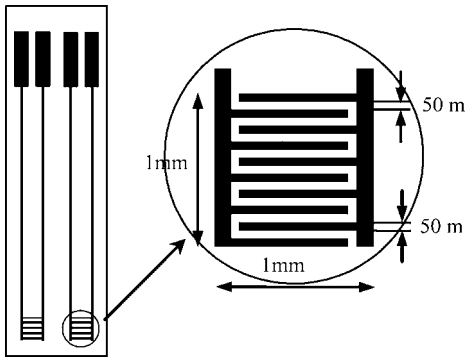

Fig. 2. Schematic representation of working interdigitated microelectrode.

2.6. Quartz crystal microbalance (QCM)

The quartz crystals employed in this study were sputtered AT-cut type (13.67 mm diameter) with Au electrodes (5.1 mm in diameter), nominal frequency (5 MHz) with Stanford QCM 200 frequency analyzer. Frequency variations are related to mass change following the Sauerbrey equation: $\Delta f = -(2/\rho\nu)f_0^2(\Delta m/S)$. The sensitivity is an experimental value determined by the constructor. ρ is the quartz density and ν its frequency coefficient. QCM measurements enable the detection of the variation of attached mass through the modification of the quartz crystal frequency to occur. Under the condition of linear behavior, occurred when the mass variation Δm is lower than some $\mu g\,cm^{-2}$, the mass uptake is directly proportional to minus the frequency variation Δf through an experimental factor determined by the following calibration equation: $\Delta m/\Delta f = -1.1 \times 10^{-9}\,g\,Hz^{-1}$. Regarding the aforementioned sensitivity, the QCM offers the ability to detect the hybridization of the immobilized ODN probes with the ODN targets (Table 2).

2.7. Electrochemical measurements

All electrochemical experiments in this work were performed using Autolab PGSTAT 12 system (EcoChemie B.V., Utrecht, The Netherlands). A conventional three-electrode cell was employed. Working electrode (WE) was either Au or Pt comb-type microelectrodes (Fig. 2) (in electrochemical experiments) or quartz (in QCM experiments). Pt foil was employed as the counter electrode (CE) and Ag/AgCl 3 M KCl was used as a reference electrode (RE). The electrolyte and the monomer (pyrrole) were mixed together to form a solution and then the solution was purged with nitrogen for 10 min to remove oxygen from the solution.

Electrochemical impedance spectroscopy (EIS) measurements were performed in the frequency range 200 kHz to 100 MHz using 5 mV alternating voltage superimposed on DC potential. Before each measurement, the same constant was imposed as a pretreatment for 120 s (Table 3).

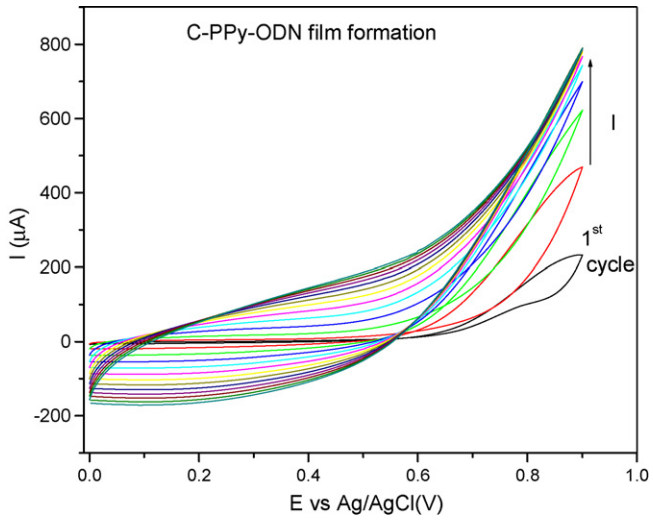

Fig. 3. Cyclic voltammograms during electropolymerization of C-PPy-ODN film.

3. Results and discussion

3.1. Film formation and morphology

Normally, sensitivity and reproductibility of DNA sensors are determined by the surface chemistry of the recognition interface, therefore immobilization of DNA probe on solid surfaces is the primary issue for DNA sensor construction. In our case, ODN probe immobilization was carried out via copolymerization of pure Py monomer with ODN modified Py moieties (Py-ODN) according to the following reaction:

$$\underbrace{\text{Py} + \text{Py-ODN}}_{\text{monomer}} \xrightarrow{\text{electro-copolymerization}} \underbrace{(\text{PPy-ODN})}_{\text{polymer}}$$

The cyclic voltammograms during film formation were presented in Fig. 3. The WE consists of two electrode pairs, called measuring and reference one, made of Pt thin film, sputtered on a silicon wafer of which the surface was oxidized. The thickness of the metal electrode is about 150 nm. The use of this couple of electrodes is aimed at eliminating the change of charges in solution allowing the improvement of the signal to noise (S/N) ratio of WE. Morphologies of pure PPy, PPy before and after hybridization with ODN were presented in Fig. 4: from left to right are SEM images of pure PPy, PPy-ODN and C-PPy-ODN, respectively.

3.2. Label-free detection of CaMV 35S complementary target by QCM measurements

The hybridization events with complementary and muted targets were detected by QCM and EIS. QCM is known to provide

extremely sensitive mass variation because of its resonance frequency decrease upon the increase of a given mass on the quartz crystal. Therefore, QCM is a direct and sensitive tool to assess the immobilization of biomolecules and to evaluate their affinity to react with complementary ones in certain specific biochemical reactions [22]. Fig. 5 shows the resonance frequency variation of a quartz electrode modified with C-PPy-ODN during the hybridization with CaMV 35S complementary strand. It can be seen from these graphs that ODN hybridization did occur at as low as 4 pM of target concentration, corresponding of mass variation of *ca.*

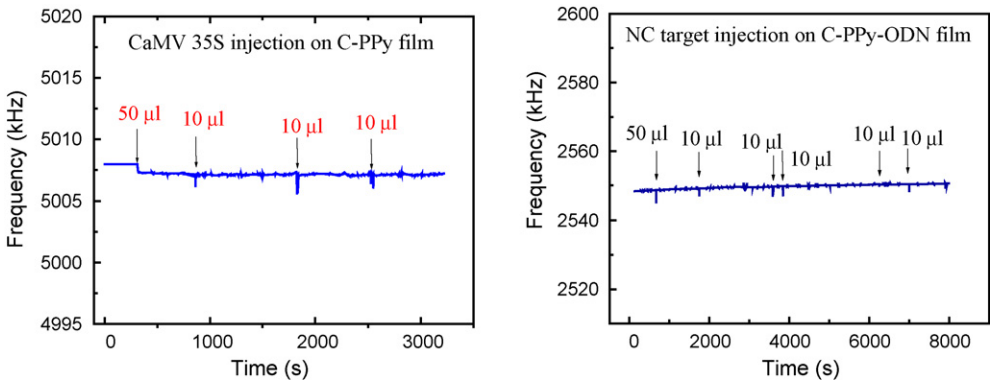

Fig. 6. QCM graph of frequency vs. time during CaMV 35S injection on ODN probe-free C-PPy film (left) and NC target (non-complementary) injection on C-PPy-ODN electrode surface (right) (blank experiments).

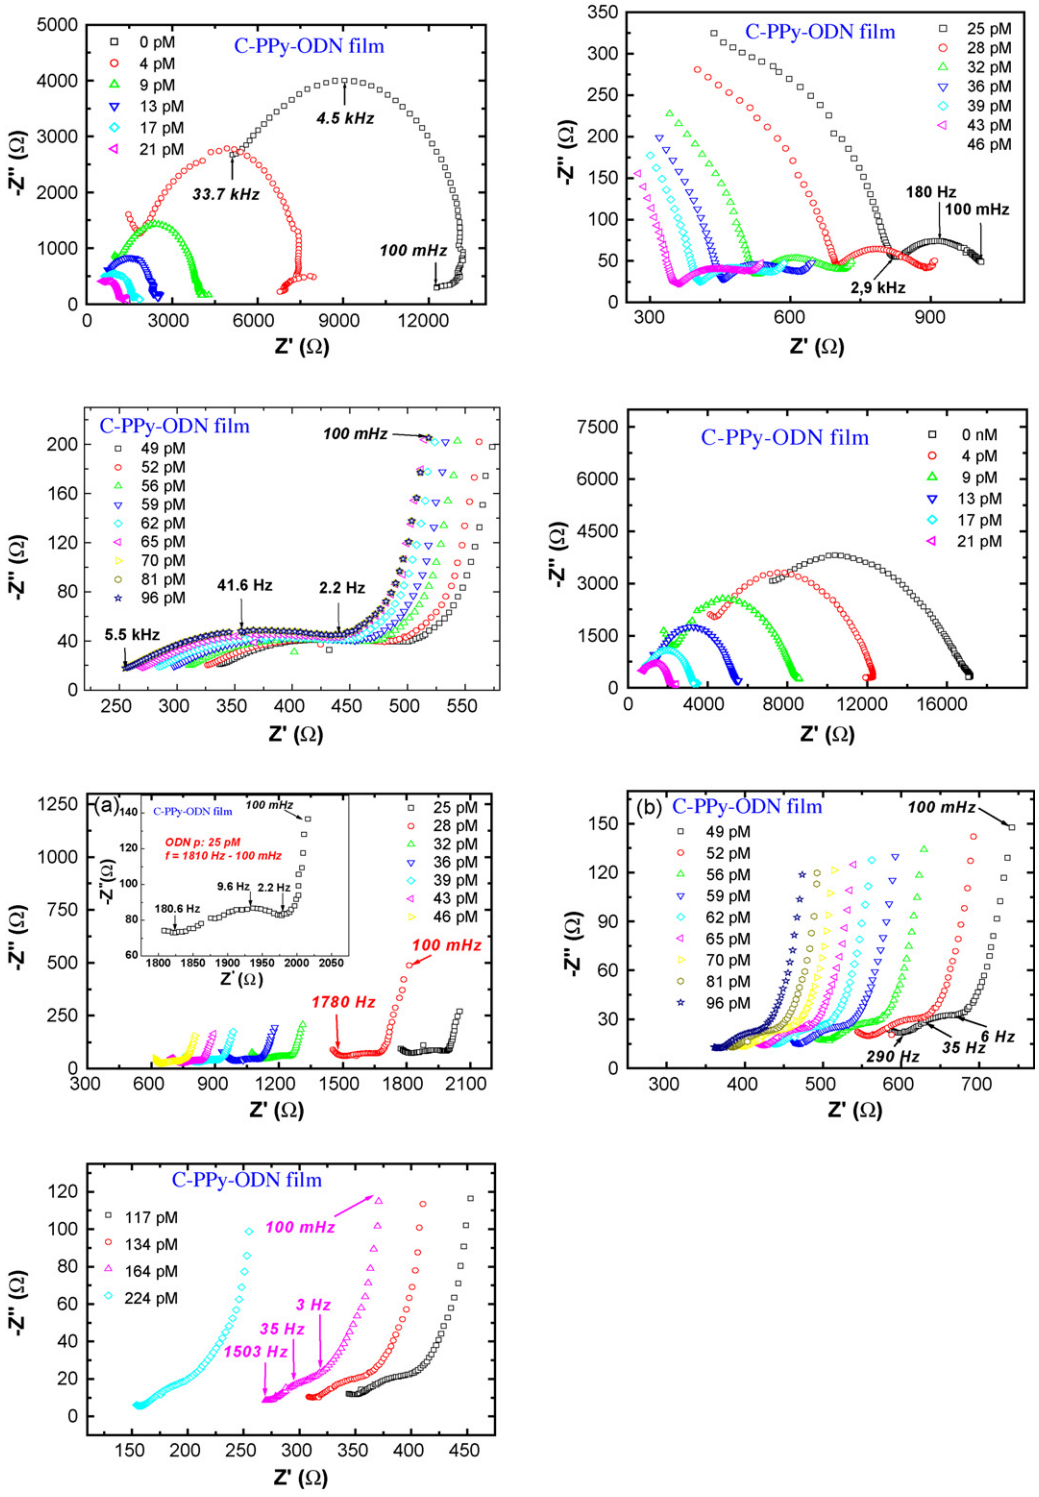

Fig. 7. EIS spectra of C-PPy-ODN films during hybridization with CaMV 35S sequence. Frequency range: 200 kHz to 100 mHz, E_{AC} = 5 mV, E_{DC} = 0.32 V vs. Ag/AgCl.

100 μg cm^{-2}. The frequency continued to fall with increasing injection volume of target. The saturation can be reached at concentration of 300 pM of target. In order to validate the transduction effect the first blank experiment with the injection of two-base mutative non-complementary (NC) target on C-PPy-ODN film and the other control of injection of complementary CaMV 35S on C-PPy film (without ODN probe!) have been carried out. In these two control experiments, the injection did not induce any frequency variation but only a slight destabilization of the quartz. It clearly demonstrated that the resonance frequency variation in case of CaMV 35S sequence injection on C-PPy-ODN film was uniquely due to hybridization (Fig. 6).

3.3. *Direct detection of CaMV 35S complementary target by EIS measurements*

EIS spectra were obtained at open circuit potential. For each set of experiment (each electrode) tree spectra were recorded

corresponding to pre-ODN probe immobilization, the post-ODN probe immobilization and post-hybridization with ODN targets events, respectively. EIS Nyquist plot spectra were shown in Fig. 7. Simulated values of kinetic parameters were derived from EIS experimental data by fitting an equivalent circuit model based on Randles model [23]. This equivalent circuit includes a solution resistance (R_s); a constant phase element (CPE); and the charge transfer resistance (R_{ct}). The CPE reflects inhomogeneities of the surface layer and the substitution of the double layer capacitance with a CPE improved the adequateness of fitting. The parameter n determines the extent of the deviation from the Randles model. When $n = 1$, 0 and 0.5 the CPE represents an ideal capacitor, pure resistor and Warburg element, respectively. The values of the fitted parameters were given in Table 3. Small values of χ^2 in the range of low CaMV 35S target concentration (from 25 to 80 pM) suggest that this Randles model fit the experimental data quite well in this low range of concentration. Furthermore, the value of $1/R_{ct}$ is linearly proportional to the target concentration according to the following equation: $1/R_{ct}\ (\Omega^{-1}) = 0.32 \times 10^{-4} \times C - 0.3 \times 10^{-3}$ (pM). In the higher (than 81 pM) concentration data the fitting with Randles model encountered big error, related to the diffusion element of Redox probe (n approaches 0.5). For this reason Vorotyntsev's model [24] was considered to be used for a high range of concentration (96–296 pM) (Fig. 8). Previously, this model was successfully applied for quinone-containing conducting polymers [25] Vorotyntsev's model choice for our C-PPy-ODN system was rationalized on the similar "signal-on" behavior (i.e. decrease of R_{ct} during hybridization, firstly reported by Pham's group [26,27]) of this C-PPy-ODN system to the quinone one. "Signal-on" effect means that DNA hybridization at the vicinity of the polymer/solution interface increases the switching rate of electronically conducting polymer. According to the studies of this group, two main explanations can be envisaged: the electrostatic effect and/or the steric effect due to the polyelectrolyte character of ODN strands. Both could modify the ionic transport to and across the polymer/solution interface [26–28]. However, the variation tendency of obtained kinetic parameters for C-PPy-ODN system was not fully interpreted and it will be subjected for the further study and discussion.

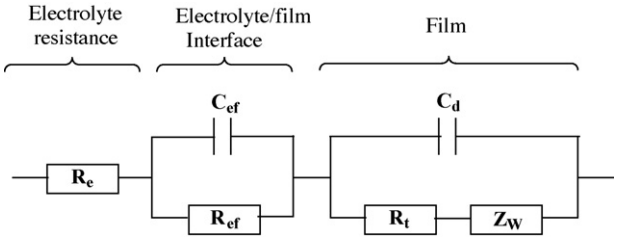

Fig. 8. Equivalent circuit of Vorotyntsev's model.

4. Conclusions

Electrochemical DNA detection is advantageous because of its fast performance and simple instrumentation. In this study, the free-label DNA detection (applied for GMO) is demonstrated based on C-PPy-ODN system. A quite low detection limit can be reached thanks to enhanced performance of C-PPy-ODN composite material. EIS data were well fitted with Randles model (in the low range of DNA concentration). In the higher range of DNA concentration, the other model, taking into account the diffusion of redox couple is needed to simulate the experimental data. Furthermore, complementary studies are necessary to interpreting all EIS values as well as understanding the signal-on mechanism of C-PPy-ODN system.

ABSTRACT

Atmospheric aerosol particles, collected with the particle-into-liquid sampler at SMEARII station in Finland in mid-August 2007, were analysed for biogenic acids. The sample pretreatment method, comprising solid-phase extraction with anion exchange and hydrophilic–lipophilic balance materials, was optimized. Extraction efficiencies of solid-phase extraction from 10 and 20 ml samples were about 100%, with average relative standard deviation of 8.9%, in concentration range from 12.5 to 50 ng/ml of the acid. Extraction of aldehydes was less successful, with efficiencies from 69 to 163% and average 10% deviation. Pretreated samples were analysed by reversed phase high performance liquid chromatography with ion trap mass spectrometric detection. Limits of detection achieved for organic acids with the analytical procedure developed ranged from 9 to 27 μg/l of extracted sample, while limits of quantitation were from 31 to 90 μg/l. Oxidation with ozone was used for the preparation of the acid of β-caryophyllene (β-caryophyllinic acid), which was also studied in aerosol samples. MS^2 experiments were used to confirm the identification of *trans*-pinic, *trans*-pinonic and β-caryophyllinic acids. Azelaic, hexadecanoic, *cis*-pinonic, and *cis*- and *trans*-pinic acids were quantitated in the samples with use of authentic standards, while the concentrations of *trans*-pinonic and β-caryophyllinic acids were determined with *cis*-pinonic acid as surrogate. Also, the contribution of β-caryophyllene oxidation products to aerosol organic carbon was evaluated. Aldehydes could not be analysed in real samples due to the insufficient extraction. The particle-into-liquid sampler proved to be suitable for the collection of aerosol particles for the elucidation of daily and diurnal variation of selected species. The optimized sample pretreatment, together with the analysis method, offer a promising approach for the study of aerosol chemical composition, where artifact formation is minimal and time resolution is good.

1. Introduction

The significance of atmospheric aerosol particles for climate and air quality is well recognized [1–3]. The effects of atmospheric aerosols are strongly dependent on their chemical composition, and numerous studies dealing with this topic have been published during recent years. Because the chemical composition of aerosols varies significantly with time and place, the research is challenging.

At present, the collection of aerosol particles is the most difficult step of the analytical cycle. Atmospheric aerosols are usually collected on a filter or an impactor plate and analysed either off-line with various techniques or directly with an aerosol mass-spectrometer [4,5]. The particle-into-liquid sampler (PILS), invented by Weber et al. [6] in 2001, has recently been recognized as a useful device for the collection of aerosols. It has also been modified for ground and airborne measurements of water-soluble aerosol composition [7]. The PILS combines two conventional techniques in aerosol measurements: particle growth in supersaturated water vapor and impaction of the particles on a quartz plate. Elsewhere, the device has been used for the determination of ion composition in atmospheric aerosols by on-line coupling it with an ion chromatograph [6,7] and for the determination of water-soluble organic carbon [8]. In our most recent work, we used PILS for the collection of aerosol samples for the determination of α-pinene and its oxidation products [9].

Typically, organic compounds in aerosols are investigated by gas chromatographic (GC) or liquid chromatographic methods with mass spectrometric detection (MS) [9–11]. Several methods have been developed for the sample preparation of aerosol particles. The sampling technique strongly determines the method selected. The

doi:10.1016/j.talanta.2009.09.004

most common method for extracting aerosol particles collected on filters is simple solid–liquid extraction (SLE), but other methods, such as sonication-assisted extraction (SAE), have also been utilized [10,11]. Liquid–liquid extraction (LLE) has been used for PILS samples [9]. Solid-phase extraction (SPE) has also been applied but, mainly for fractionation and concentration of samples extracted by SLE or SAE [12,13].

Our aim was to develop an easy and reliable analytical method for acids and aldehydes in aerosol samples collected by PILS. In our previous study, GC–MS was applied with LLE used for the sample preparation [9]. Although the results were promising, LLE proved to be laborious and time consuming. Furthermore, the analytical procedure was not sufficient in terms of selectivity, especially in the case of *cis*-pinonic acid. In this study, SPE was used in sample pretreatment, with hydrophilic–lipophilic balance (HLB) and anion exchange absorbents evaluated as the trapping material. After solid-phase extraction, the biogenic acids were separated by reversed phase liquid chromatography and detected by ion trap mass spectrometry (RPLC–ITP-MS). Use of RPLC–ITP-MS, instead of GC as earlier, makes MS^n experiments possible. In the determination of acidic compounds, special attention was paid to hexadecanoic and azelaic acids and β-caryophyllinic acid because of their presumed importance in aerosol chemistry [14–16]. Azelaic acid was recently identified as a marker compound in aerosol transport [17] and found to have cloud condensation nuclei properties [18]. Despite its importance, azelaic acid has rarely been analysed in aerosol particles [19,20]. The relevance of oxidation products of sesquiterpenes, especially β-caryophyllene, to aerosol growth has also been noted [21]. The presence of β-nocaryophyllone aldehyde in atmospheric aerosols has been demonstrated with the use of authentic standard, while β-caryophyllinic acid has been identified tentatively [22,23]. A part of our research was dedicated to the synthesis of β-caryophyllinic acid via ozonolysis of β-caryophyllene and to its determination in PILS samples.

2. Experimental

2.1. Chemicals

Azelaic acid (>99%) and stearic acid (≥99.5%) were purchased from Fluka Chemie GmbH (Buchs, Switzerland). Pinic acid (library of rare chemicals, no purity available), cis-pinonic acid (98%), palmitic acid (99%), 2,4-dichlorobenzoic acid (98%, used as internal standard), decafluorobenzophenon (98%, internal standard in GC) and bis(trimethylsilyl)trifluoroacetamide (BSTFA, 99%) used as a derivatization agent were obtained from Sigma–Aldrich Chemie GmbH (Steinheim, Germany). Methanol and pyridine were purchased from J.T. Baker (Deventer, The Netherlands), while ethyl acetate and dichloromethane were from LabScan (99.8%, Dublin, Ireland). Acetonitrile for the HPLC analysis (HPLC Far UV, Lab Scan, Analytical Sciences, Poland), and water (DirectQ-UV, Millipore Corp., Billerica, USA) with formic acid (98–100%, Merck, Darmstadt, Germany) were used. Pinonaldehyde was synthesised in the laboratory by oxidation of (1S,2S,3R,5S)-(+)-pinanediol (Aldrich, Steinheim, Germany) with periodic acid (Merck, Darmstadt, Germany) as described by Glasius et al. [24]. β-Nocaryophyllene aldehyde was synthesised as described by Parshintsev et al. [22]. Heptanal (98.5%), octanal (100%), nonanal (96%), undecanal (97%) and benzaldehyde (98.5%) were purchased from Accu Standard Inc. (New Haven, USA).

For the denuder coating, phosphoric acid (85%) and potassium iodide were purchased from Merck (Darmstadt, Germany); glycerol was obtained from Sigma–Aldrich (Steinheim, Germany), and XAD-2 resin (polystyrene-divinylbenzene) from EGA-Chemie (Steinheim, Germany).

2.2. Aerosol sampling

Samples were collected with the PILS during August 2007 at the Station for Measuring Forest Ecosystem Atmosphere Relations (SMEAR II) at Hyytiälä (61°51′N, 24°17′E, 180 m above sea level), which is 230 km north of Helsinki. The forest consists of Scots pines (*Pinus sylvestris* L.) 30–40 years old, homogeneously spread through 200 m in all directions from the measurement site. A more detailed description of SMEAR II is presented by Kulmala et al. [25].

A fuller description of the aerosol sampling with PILS can be found elsewhere [9]. Briefly, the sampling system consists of an ADI2081 particle-into-liquid sampler (Applikon Analytical, Schiedam, The Netherlands) coupled with an eight-channel peristaltic pump (Watson Marlow 205S, Wilmington, USA). DirectQ-UV water was used as a working liquid and for transport flow. To remove gas phase compounds, three channel annular denuders (242 mm length, Teflon coated, stainless steel sheath, URG, Chapel Hill, USA) with different coatings (XAD, phosphoric acid, potassium iodide) were added to the sampling line. Aerosols were size separated before the denuder line with a cyclone (PM2.5, URG, Chapel Hill, USA).

Two-hour samples were collected into screw-capped vials and stored in a refrigerator until sample pretreatment. The volume of samples varied from 20 to 40 ml. One half of each sample was used for the analysis, while the other half was stored for future need.

2.3. Solid-phase extraction

For the optimization of solid-phase extraction (SPE), standard mixtures of the studied acids and aldehydes were prepared in water, extracted and analysed. Acid standards with concentrations of 5, 10, 12.5, 25, 50 and 100 μg/l were prepared from methanol stock solutions (10 mg/l) in water, so amount of methanol could not affect the SPE. Both 10 and 20 ml of standard solutions were extracted with solid-phase materials to obtain the efficiency in the volume range of real PILS samples. Possible break through was also determined.

Two types of SPE materials were used in this research. At first, a hydrophilic–lipophilic balance sorbent (HLB, 3 ml, 30 mg of poly(N-vinylpyrrolidone)-divinylibenzene, StrataX, Phenomenex, USA) was tested with the following procedure: activation (5 ml of methanol), equilibrium (5 ml of water), addition of sample (10 or 20 ml), drying (20 min in reduced pressure) and elution with 1 ml of ethyl acetate. The second material was anion exchange OasisMAX (1 cm^3, 30 mg, Waters Corp., Milford, USA), which is basically HLB that has been chemically modified with quaternary amine group. The sample pretreatment procedure included the following steps: activation (2 ml of methanol), equilibrium (2 ml of water), sample addition (10 or 20 ml) and elution with 1 ml of 2% formic acid in methanol.

Water solutions of aldehyde mixture with concentrations of 125, 250, 500 and 1000 μg/l were prepared and extracted with HLB as explained above.

In all extractions, gravitational force was used without additional vacuum. Each concentration and volume were extracted three times. PILS samples from 12 to 20 ml (depending on original amount of sample) were extracted with OasisMAX material only.

2.4. Liquid chromatographic–mass spectrometric analysis

Analysis was performed with a Hewlett-Packard Series 1100 liquid chromatograph (Palo Alto, USA) coupled with an Esquire 3000 plus ion trap mass-spectrometer (Bruker Daltonics, USA). Electrospray ionization (ESI) in negative ion mode was used. The combination of eluents, gradient, injection volume, flow rate and ionization parameters was optimized. Final parameters for

the liquid chromatography were XBridge Shield column (RP-18, 2.1 mm × 150 mm, 5 μm, Waters Corp, USA), linear gradient from 10 to 100% of B (ACN; A: 0.1% formic acid in water) in 30 min with following 15 min of 100% B, flow 0.3 ml/min, and injection volume 3 μl for the standards and 15 μl for the samples. Parameters for the ESI-MS were capillary voltage +4000 V, end plate offset −500 V, nebulizer pressure 2.76 bar (nitrogen), 8 l/min of drying gas (nitrogen) and drying temperature of 300 °C. Mass range of 50–370 amu was recorded. For quantitation of the target compounds, extracted ion chromatograms were used with the masses 185 amu (*cis*-/*trans*-pinic acid), 183 amu (*cis*-/*trans*-pinonic acid), 187 amu (azelaic acid), 255 amu (hexadecanoic acid), 283 amu (octadecanoic acid), 189 amu (internal standard).

2.5. Gas chromatographic–mass spectrometric analysis

Standard solutions of aldehydes and HLB extracted samples were analysed by GC–MS. Before each analysis, 10 μl of quantitation standard, decafluorobenzophenone, was added to the vials. A gas chromatograph (Agilent 6890N, Santa Clara, USA) equipped with a mass selective detector (Agilent 5973N, USA) was used. The GC column was an HP-5 (28 m × 0.25 mm × 0.25 μm, Hewlett-Packard, USA) coupled with a 2-m deactivated retention gap (i.d. 0.53 mm, Agilent, USA) via a press-fit connector (0.30–0.75 mm OD, deactivated; BGB Analytik, Switzerland). The GC oven temperature was programmed as follows: initial temperature 60 °C (2 min), temperature gradient 8 °C/min with final temperature 300 °C (5 min). 1 μl of sample was injected by on-column injection. The injector temperature program was in oven tracking mode. Helium was used as carrier gas with a constant flow of 1 ml/min. The interface between the GC and the MS was maintained at 300 °C, while the ionization source was kept at 230 °C and the quadrupole temperature was 150 °C. Electron impact ionization (EI) was used at 70 eV. Selected ion monitoring (SIM) was employed. Two ions were monitored for each aldehyde: quantitative and qualitative ions. The GC–MS data was analysed with Enhanced ChemStation D.00.01.27 software (Agilent, USA), and the compounds of interest were identified by their retention times and selected ions.

2.6. Synthesis and purification of β-caryophyllinic acid

β-Caryophyllene (*trans*-(1R,9S)-8-methylene-4,11,11-trimethylbicyclo[7.2.0]undec-4-ene, 80+ %, GC, sum of enantiomers, Sigma–Aldrich Chemie, Steinheim, Germany) solution (10%, v/v) was prepared in dichloromethane (HPLC grade, Labscan Ltd., Dublin, Ireland). Aliquots of 10 ml were used for ozonolysis. A test-tube containing the sesquiterpene solution was placed in a beaker filled with cooled ethanol. Pieces of dry carbon dioxide (−78 °C) were added to the ethanol to reduce the temperature to at least −68 °C. Dried, purified and ozonolysed air was bubbled through the solution at a flow rate of 10 l/h (500 M corona discharge ozone generator, Fisher, UK). Temperature was controlled throughout the experiment. Reaction times were 15, 30 and 45 min.

The reaction mixture was extracted twice with 10 ml of 5% ammonia solution in water. Then aqueous fractions were combined and extracted by solid-phase extraction with MAX material as described in Section 2.3. The obtained sample was analysed by HPLC–MS as explained in Section 2.4. Ion 253 was used for the MS^2 experiments.

To obtain an EI spectrum for β-caryophyllinic acid, ten fractions of HPLC effluent containing target compound were collected to the vial and dried under nitrogen. Then 30 μl of derivatization reagent (BSTFA) was added together with 10 μl of pyridine and the mixture was held at 70 °C for three hours. For GC–MS analysis, the mixture was dried and redissolved in 100 μl of hexane. The parameters for the GC–MS analysis were the same as those given in Section 2.5 except that mass range from 50 to 550 amu was used in scan mode.

3. Results and discussion

The PILS sampling for the determination of oxidation products of α-pinene and acids was optimized in our previous study [9]. In this study, sample preparation based on SPE and analysis, mainly with RPLC–MS, were developed and applied to the study of selected compounds in aerosol samples.

3.1. PILS sampling

The volume of PILS samples varied significantly from sample to sample. The tubing used in the peristaltic pump did not provide a constant flow due to the deformation that takes place over time. Also, humidity and temperature of the sampled air may have affected the volume of samples. The inventors of PILS added lithium fluoride to the sample flow to correct for differences in sample volume during the on-line analysis [6,7]. In the present study, the addition of calibrant was unnecessary because the analysis was carried out off-line, and the final sample volume could be measured. Note that only half of the sample collected for two hours and representing 2 m^3 of sampled air was used, so that each analysed sample represented 1 m^3 of sampled air. This simplified the calculations.

3.2. Solid-phase extraction of acids

Two materials were tested for SPE of acids: HLB and anion exchange (MAX) materials. Two different sample volumes were employed. To guarantee sufficient retention of acids in the HLB material, the pH of the sample should have been optimized for all compounds. However, to avoid alteration of the sample this was not done. As a result, only azelaic acid was retained in the HLB material. Owing to the insufficient extraction, HLB was not used for the extraction of acids in PILS samples.

Fortunately, and as expected, anion exchange material worked well for acids because pH of the standards and samples was always about two units higher than pK_a values of the studied acids, so that the acids were deprotonated. Two sample volumes (10 and 20 ml) were tested because in PILS the volumes of the samples typically range from 10 to 20 ml per hour. Table 1 shows the extraction efficiencies for all studied acids, with different sample volumes, in all

Table 1
Extraction efficiencies obtained with OasisMAX SPE material (% ± RSD%, $n = 9$).

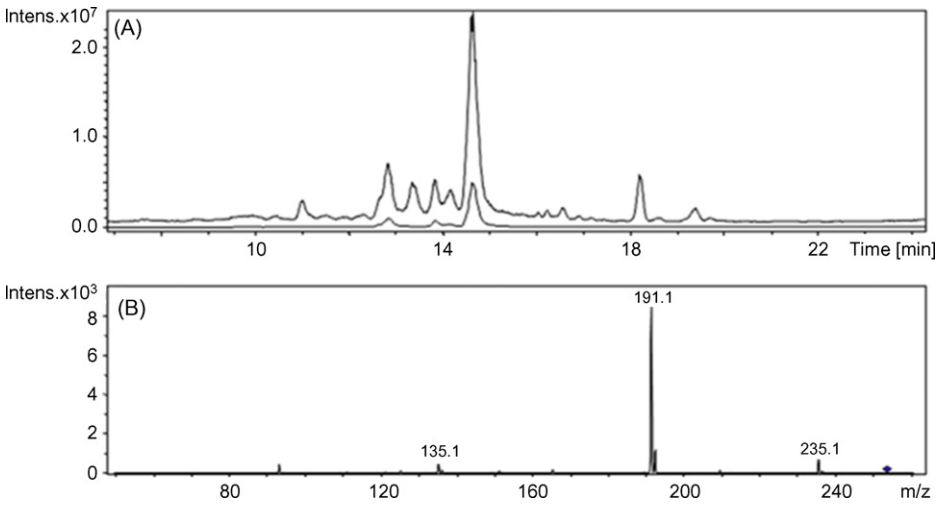

Fig. 1. HPLC–MS (TIC), MS^2 (from ion 253) chromatograms (A) and MS^2 spectrum (B) of MAX extracted β-caryophyllene oxidation products. Retention time of β-caryophyllinic acid is 14.8 min.

concentrations. As can be seen from Table 1, almost 100% recoveries (within the standard deviation) were obtained in concentration range from 12.5 to 100 ppb with both sample volumes. Evidently, compounds were retained and eluted well, and the retention was not affected by the volume of the sample.

The sample pretreatment procedure developed here was faster and easier than the liquid–liquid extraction employed in our previous research [9]. Reduced pressure, which is usually applied in SPE to make the flow faster and more stable, was not needed because the flow obtained simply by gravitation was sufficient (about 1 ml/min).

3.3. Solid-phase extraction of aldehydes

The results for the extraction of aldehydes with HLB material are summarized in Table 2. As can be seen, extraction efficiencies were not acceptable. Poor results were obtained even for high concentrations, such as 125 μg/l. Also, the limits of detection ranged from 50 ng/ml for pinonaldehyde and β-nocaryophyllene aldehyde to 250 ng/ml for undecanal. Since the concentrations of aldehydes in real atmospheric aerosol samples are much lower than the concentrations for which moderate extraction efficiencies could be achieved, our method is not suitable for the analysis of aldehydes in real samples. The sensitivity could be increased by concentrating the samples or by increasing the sample air flow during the sampling. However, because the repeatability of the extraction was not satisfactory, the HLB material was not used in the extraction of real PILS samples and aldehydes were not analysed.

3.4. Chromatographic analysis

HPLC–MS was used as the analytical technique for the analysis of acids because it is simple and fast, and has frequently been employed for the analysis of organic acids in atmospheric aerosols [11,26–28]. In our previous study [9], we analysed PILS samples for *cis*-pinonic and pinic acids by GC after sample derivatization. However, the amount of *cis*-pinonic acid was overestimated owing to its co-elution with other compounds, such as *trans*-pinonic acid [9,28].

Acetic acid and formic acid were tested as modifiers of the HPLC eluent. Formic acid gave better separation of the analytes than did acetic acid and it was chosen for further studies. The ionization of the studied acids in ESI suffers from low pH, but in this case a compromise was made between good separation and ionization. The limits of detection (LOD) and quantitation (LOQ) in μg/l obtained by HPLC–MS for the acids were as follows: *cis*-pinic 16/55; *trans*-pinic 12/40; *cis*-pinonic 27/90; azelaic 9/31; hexadecanoic 12/38. LOD and LOQ values were calculated from peak heights as three and ten times the background noise of the blank samples. The quantitation of target compounds was done from peak areas because of slightly better repeatability.

3.5. Ozonolysis of β-caryophyllene

In our previous study, β-caryophyllinic acid was only tentatively identified in aerosol samples. Since a commercial standard for β-caryophyllinic acid was not available, we synthesised this compounds by ozonolysis of β-caryophyllene and purified it by SPE, as described in Section 2.6. Fig. 1 presents the HPLC–MS and MS^2 (ion 253) chromatograms for the ozonolysed sample (30 min). From the anion exchange step it is clear that ozonolysis produces several acids of β-caryophyllene. Tandem mass spectrometric analysis showed the molecular mass of a few of them to be 254, with identical loss of water (M-18) and carbon dioxide (M-44), as is typical for the acids. For conformation of the identification of the synthesised β-caryophyllinic acid, GC–MS analyses were conducted after derivatization with BSTFA. Fig. 2 presents the EI spectrum obtained for the trimethylsilyl derivative of β-caryophyllinic acid. For more reliable identification, by nuclear magnetic resonance spectroscopy (NMR), a greater amount of β-caryophyllinic acid must be prepared and purified.

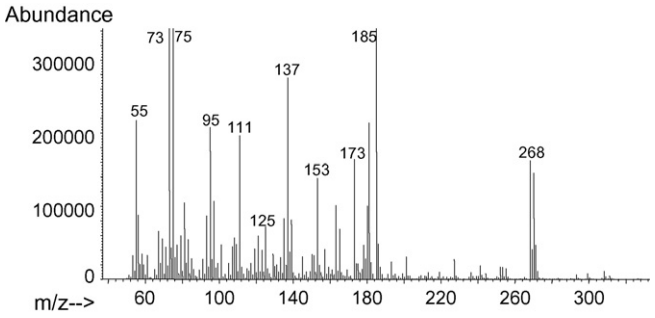

Fig. 2. MS (EI) spectrum of β-caryophyllinic acid trimethylsilyl derivative.

3.6. Analysis of aerosol samples

In the analysis of PILS samples by the LC method developed in this study, two peaks with mass of 183 amu, corresponding to [M−1] of *cis*-pinonic acid, eluted near each other. The reference *cis*-pinonic acid gave only one peak, with retention time matching that of the first of the two peaks. The results obtained from an MS/MS experiment (cleavage of water and carbon dioxide molecules in both peaks) showed the fragmentation patterns of the two peaks to be almost identical. Thus, the peak eluting slightly after that of *cis*-pinonic acid most probably is that of *trans*-pinonic acid (Fig. 3). The quantitation of *trans*-pinonic acid was done with use of *cis*-pinonic acid as a surrogate. The same situation was observed for pinic acid, which gave two peaks even from the reference material. The same logic was applied here since exact information about the standard was not available (library of rare chemicals). A tandem mass spectrometry experiment showed the two peaks to give the same MS/MS spectra. Most probably then, the first eluting peak was *cis*- and the second *trans*-pinic acid. Comparison of the peak areas obtained from the standard solution showed the ratio 75:25 for these acids, and this was taken into account in the quantitation.

The two-hour and overnight PILS samples collected between 13 August 2007 (10 am–12 am) and 16 August 2007 (4 pm–6 pm) were extracted with OasisMAX and analysed by HPLC–MS. Results of the quantitation are presented in Table 3 and plotted in Fig. 4. As can be seen, *trans*-pinic acid was not found in these samples, and octadecanoic acid was not quantitated due to problems with the zero samples. Long chain acids were well retained in the LC column causing a memory effect. Blank samples were run with pure methanol between the PILS samples, but they did not eliminate the problem. Subtracting the peak areas of zero samples lead to increasing in uncertainty and this is why it was decided to exclude the compound from the quantitation.

The concentrations of *cis*- and *trans*-pinonic acids were closely similar, probably because of the similar formation mechanism without a dominant formation route. This discovery is important because it means that, in our previous study, the amount of oxidation products of α-pinene in aerosols was underestimated. Unfortunately, the number of sampling days was too few to allow statistically reliable conclusions on the influence of *trans*-pinonic acid on the growth of aerosol particles.

The surprisingly high amount of azelaic acid in all studied samples can be considered as important and relevant for aerosol

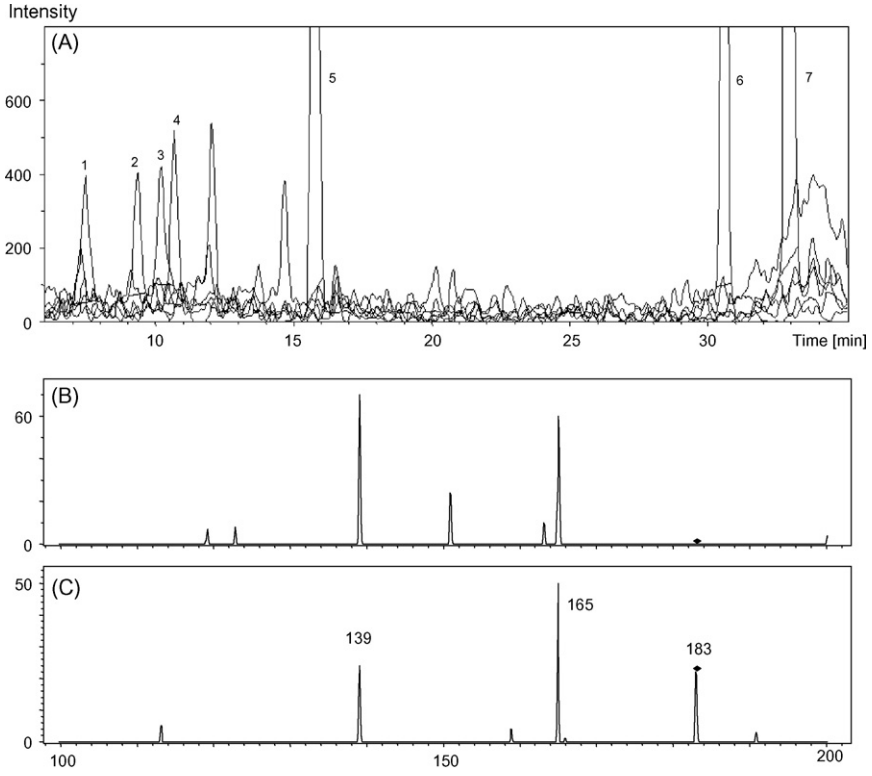

Fig. 3. (A) HPLC–MS extracted ion chromatogram of aerosol sample collected 13 August 2007 from 10 am to 12 am. Peaks: (1) *cis*-pinic acid (185 amu); (2) *cis*-pinonic acid (183 amu); (3) *trans*-pinonic acid (183 amu), (4) azelaic acid (187 amu), (5) ISTD (2,4-dichlorobenzoic acid, 189 amu), (6) palmitic acid (255 amu), (7) stearic acid (283 amu). (B) MS^2 spectrum of *cis*-pinonic acid and (C) MS^2 spectrum of *trans*-pinonic acid (cleavage of water at 165 amu and carbon dioxide at 139 amu).

chemistry. Aerosol samples have nevertheless rarely been analysed for azelaic acid. Reynolds et al. [29] have elucidated its formation from oleic acid, and also its potential to form large oligomeric structures (over 1000 Da), which are important in aerosol growth. Correlations between azelaic acid and oxidative species such as NOx, NO and ozone were not noticed here, and although a slight correlation was seen between global radiation and azelaic acid, it was not statistically significant. Clearly, more studies are needed before azelaic acid can be regarded as an important biogenic aerosol component. Although correlations between the studied compounds, aerosol growth properties and atmospheric conditions, including gas phase oxidants, were not clearly shown, the method we have developed for the collection and analysis of aerosol particles provides a valuable tool for the study of these relationships in the future.

The MS^2 analysis of PILS samples revealed the presence of one acid corresponding to the main peak in the chromatogram obtained from the ozonolysed sample of β-caryophyllene. The acid was identified as β-caryophyllinic acid. This identification is in agreement with previous work of Jaoui et al. [23]. The peaks found in two-hour PILS samples were too small to allow their integration, and thus six-hour samples were prepared by combining three samples (from 10 am to 4 pm) and evaporating them to a volume of 500 μl.

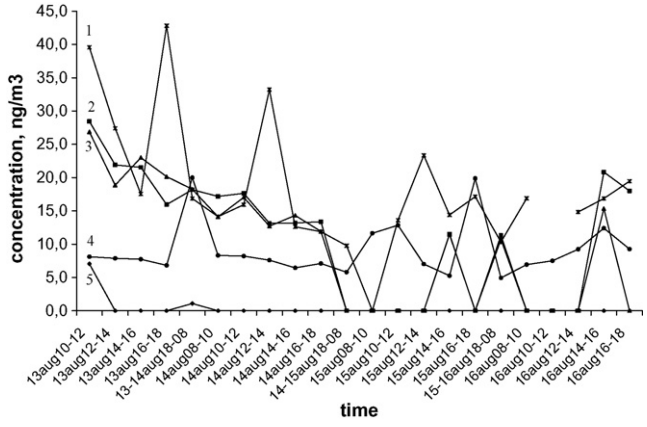

Fig. 4. Concentration trends of the studied acids in ng/m^3 of sampled air. (1) Stearic acid, (2) *cis*-pinonic acid, (3) *trans*-pinonic acid, (4) azelaic acid, and (5) *cis*-pinic acid.

Relative peak areas and the calibration curve of *cis*-pinonic acid were used for the quantitation (Table 3). Although the quantitation error, estimated with azelaic acid as reference, was about 50%, the concentration of β-caryophyllinic acid was still very high relative to the concentrations of α-pinene acids, and also the values of Jaoui et al. [23]. The reason for the disparity may be the stability of β-caryophyllinic acid, in contrast to α-pinene acids, which react to form more complex compounds after their formation. The stability of β-caryophyllinic acid was apparent in our study of various ozonolysis times in out synthesis of the acid. The ozonolysis time did not significantly affect the chromatographic profiles (HPLC–MS^2) of the samples, showing that the compound did not react further once the ozonolysis was complete. The relatively high concentrations of β-caryophyllinic acid in aerosol samples show that it is a relevant compound in atmospheric aerosol formation in boreal forest, and more detailed studies are desirable. The high concentration of the acid of sesquiterpene is not surprising in view of the results of Tarvainen et al. [30], who showed that the emission rate of β-caryophyllene may be as much as 40% of the emission rates of monoterpenes in northern Finland.

4. Conclusions

A particle-into-liquid sampler was used for the collection of atmospheric aerosols from Finnish coniferous forest. The sample pretreatment procedure with SPE for the extraction and concentration of selected organic acids was optimized, and extraction efficiencies were determined. Unfortunately, aldehydes were not successfully extracted and could not be quantified in the PILS samples. The analytical procedure, HPLC–MS, was optimized for the determination of acids. The amounts of the studied acids in atmospheric aerosol samples ranged from 1 to 40 ng/m^3 and are in the agreement with previous results. The oxidation product of β-caryophyllene, β-caryophyllinic acid was synthesised and determined in PILS samples by HPLC–MS^2. The amount of β-caryophyllinic acid ranged from 41.6 to 102.1 ng/m^3 with estimated error of 50%. Reliability of the method was moderate, and the limits of detection and quantitation were good. Our study confirmed that PILS is a highly promising collection device for aerosol samples and it, together with well-optimized sample pretreatment and analysis, can be successfully applied for the determination of acids in atmospheric aerosol particles.

Acknowledgements

This research was supported by the Academy of Finland Centre of Excellence program (project number 1118615). We are grateful to Hanna Brusin, Päivi Pöhö and Joonas Nurmi for helping in the laboratory and to Pasi Aalto from the Department of Physics for the instrument arrangements at the SMEARII station. Ilkka Kilpeläinen is thanked for his help with oxidation reaction mechanisms and Heikki Junninen for providing the meteorological data.

ABSTRACT

A quaternary ammonium-based room temperature ionic liquid trioctylmethylammonium salicylate (TOMAS) has been studied as an extractant of transition metal ions (Fe^{3+}, Cu^{2+}, Ni^{2+}, Mn^{2+}) in aqueous solutions. The effect of pH value on the recovery of metal ions has been investigated. The mechanism of extraction into the ionic liquid has been proposed. The possibility of stripping voltammetric determination of transition metals in aqueous solutions using TOMAS-modified electrodes has been demonstrated.

1. Introduction

Ionic liquids (ILs, low-melting organic salts) have been widely employed in liquid–liquid extraction for about a decade, since the first report by Rogers and co-workers [1]. Ionic liquids are growingly popular because of a combination of unique properties [2]. Though their widely declared environmentally friendliness may be over-estimated [3,4], a promising possibility of tuning of solvent properties by modification of IL cation or anion is beyond any doubt [5,6]. Such tuning may enable to find not only ILs with desirable physicochemical properties (density, viscosity, mutual miscibility with other solvents) but also ILs adjusted for particular applications (task-specific ionic liquids).

It has been reported that ionic liquids can be used in solvent extraction of metal ions. There exist two different approaches in the field. The first approach is using ILs as inert diluents for reagent-assisted extraction, while the second one implies that IL serves as a complexing reagent itself due to a presence of appropriate functionalities in either cationic or anionic component. Crown ether assisted extraction of alkali and alkaline earth metal ions [7–11] is a typical example of the former approach. The use of other IL/complexing reagents for heavy metals extraction has also been reported [12–20]. Several task-specific ILs (TSILs) incorporating complexing functionality have been reportedly used for extraction of metal ions representing the second approach [21–26].

Typically, TSILs bear complexing groups in cationic (imidazolium-based) part that makes them relatively expensive and difficult to synthesize. An attractive alternative may be ILs, which contain complexing anions, in particular, tetraalkylammonium carboxylates. Many carboxylates are known to strongly bind metal ions. Several tetraalkylammonium-based ILs (including carboxylates) obtained from commercially available Aliquat® 336 have been reported (see, e.g. [27]). Noteworthy is mentioning that an Aliquat-based thiosalicylate IL has been previously reported [28] as an extractant for metal ions. However, no detailed study of extraction has been published to the best of our knowledge.

Herein, we report on the study of extraction of transition metal ions into newly obtained task-specific IL trioctylmethylammonium salicylate (TOMAS). It is important that both starting substances used for TOMAS synthesis are readily available and inexpensive, and the procedure of synthesis is quite easy.

2. Experimental

2.1. Reagents and solutions

Aliquat® 336 (Aldrich; 2:1 mol/mol mixture of methyltrioctyl- and methyltridecylammonium chloride), sodium salicylate (Panreac, USP), chloroform (Ekros, Russia), ethanol, tetrahydrofurane (analytical reagent grade) were used as received. Transition metal salt solutions, $Fe_2(SO_4)_3$, $Cu(NO_3)_2$, $NiCl_2$, $Cr_2(SO_4)_3$, $CoSO_4$, $ZnSO_4$,

doi:10.1016/j.talanta.2009.09.003

and $MnCl_2$, were prepared by dissolving a weighted amount of a salt in distilled water. All transition metal salts were of analytical reagent grade. Aqueous ammonia, sulfosalicylic acid, 4-(2-pyridylazo)resorcinol, murexide, borate buffer (all of analytical reagent grade) were used for spectrophotometrical determination of metal ions. For adjusting pH values of aqueous phase, 0.05–3 M H_2SO_4 (analytical reagent grade) was used. Potassium hydroxide and chloride were of analytical reagent grade.

2.2. Synthesis of TOMAS

Aliquat® 336 (~0.2 mol) was mixed with 30% excess amount of sodium salicylate in 200 mL of chloroform. The mixture was shaken for 4 h and then rinsed with large amount of distilled water 20 times. After that solvent was evaporated in rotary evaporator and remained liquid was heated up to 100 °C under reduced pressure for 5 h. After cooling to room temperature white solid was obtained. ^{1}H NMR ($CDCl_3$, δ/ppm relative to TMS): 0.88 (t; 9 H), 1.24 (m; 30 H), 1.59 (m; 6 H), 3.19 (s; 3 H), 3.27 (m; 6 H), 6.70 (t; 1 H), 6.81 (d; 1 H), 7.20 (t; 1 H), 7.92 (d; 1 H). ^{13}C NMR (126 MHz, DMSO-d6, δ/ppm relative to TMS): 13.80 (C^*H_3C); 21.93 ($C^*H_2CH_3$); 21.25, 25.68, 28.27, 28.32, 31.04 (various CH_2CH_2); 47.41 (CH_3N); 60.50 (CH_2N); 115.35, 115.62, 120.73, 129.73, 130.88 (aromatic C); 163.17 (COH); 171.00 (COO). Density 0.943 g cm^{-3}. $T_m = (32.8 \pm 0.4)$ °C, $T_f = (14 \pm 2)$ °C. ^{1}H and ^{13}C NMR data were recorded with NMR spectrometer DRX500 (Bruker, Germany). After being equilibrated with water the compound becomes slightly yellowish viscous liquid with density 0.942 g mL^{-1} that does not freeze at least to −18 °C. Found water content is ca. 0.18 wt.% (0.09 M) and 4.83 wt.% (2.52 M) (Karl Fisher titration) for solid and equilibrated with water liquid compound, respectively.

2.3. Extraction procedure

Extraction experiments were performed by adding 0.5 mL of water-equilibrated TOMAS to 2.5 mL of aqueous solutions of transition metal salt (in the case of extraction of Mn^{2+}, 1.0 mL to 1.0 mL, respectively). The two-phase systems were shaken for the time necessary to reach the extraction equilibrium (15 min for Fe^{3+}, 25 min for Cu^{2+} and Mn^{2+}, 30 min for Ni^{2+}). After centrifugation for 30 min the necessary volume of aqueous phase was taken, and pH value was measured (pH-meter pH-410; combined glass microelectrode ESLK-13.7, Akvilon, Russia). Aqueous phase was diluted if necessary. The recovery (R, %) and the distribution ratio (D) of a metal ion were calculated using the Eqs. (1) and (2):

$$R(\%) = \left(1 - \frac{C_w}{C_w^0}\right) \times 100\%, \quad (1)$$

$$D = \frac{C_0}{C_w} = \frac{R}{100 - R} \times \frac{V_w}{V_0}, \quad (2)$$

where C_w^0 and C_w are the initial and equilibrium concentrations of the metal ion in aqueous phase, respectively, V_w and V_0 denote the volumes of aqueous and organic phases, respectively (mL). Metal ion concentrations were measured in aqueous phase using spectrophotometric techniques [29–31]. For determination of Fe^{3+}, aqueous solution of sulfosalicylic acid (0.6 mL, 5 wt.%) was added to 1.0 mL of aqueous phase; then aqueous ammonia (5 wt.%) and water were added to the total volume 3.0 mL (pH ~10). Absorbance was measured after 15 min at 423 nm. Determination of Mn^{2+} was performed by adding 2.4 mL of borate buffer (pH = 9.18), 0.3 mL of 4-(2-pyridylazo)resorcinol solution (0.05 wt.%) to 0.3 mL of aqueous phase; absorbance was measured at 500 nm after 10 min. Nickel (II) was determined by addition of 1.6 mL of murexide, 0.4 mL of aqueous ammonia (2%) to 0.3 mL of aqueous phase. Absorbance was measured after 24 h at 450 nm. Spectrophotometric measurements were performed with U-2900 UV–vis Recording Spectrophotometer (Hitachi, Japan), 1 cm quartz cells, after 30 min centrifugation of samples. The content of copper ions Cu^{2+} in aqueous phases was determined with atomic absorption spectrometer AAS Kvant-2A (Kortek, Russia).

2.4. The processing of Fe(III) loaded systems

These experiments were conducted by adding 4 mL of water-saturated TOMAS to 20 mL of aqueous solutions of $Fe_2(SO_4)_3$ (with $C_0(Fe) = 1 \times 10^{-1}$ and 2×10^{-1} M) and shaking of the systems for 15 min. After centrifugation (1 h) the phases were separated; two portions of aqueous phase (15 and 3 mL) were collected. The 3 mL portions were used for measuring pH, for determination of residual metal concentrations, and for spectral measurements. The 15 mL ones were placed into preliminary weighted round-bottom flasks and water was evaporated. After cooling down to room temperature in desiccators, the solid residues were weighed. The nitrogen content was determined by Kjeldahl's method.

A small sample was taken from each extract to determine nitrogen and sulphur by means of element organic analysis (Kjeldahl's method for nitrogen and gravimetric in the form of $BaSO_4$ for sulphur).

The acidity of extract was determined directly by potentiometric titration. The extracts were diluted by $CHCl_3$ to total volumes equal to 25 mL, rinsed 5 times by 50 mL of distilled water to remove possible admixtures of H_2SO_4, then aliquots (0.5 mL) of obtained solutions were dissolved in 30 mL of ethanol and titrated by 0.01 M aqueous KOH (pH-meter pH-410; combined glass microelectrode ESLK-13.7, Akvilon, Russia).

2.5. The study on separation of Fe(III) in synthetic samples

Two synthetic samples (10 mL) containing 1×10^{-3} M Fe^{3+} and equal molar concentrations of Ni^{2+}, Cr^{3+}, Co^{2+}, Zn^{2+}, Mn^{2+} (1×10^{-3} and 1×10^{-2} M) were shaken with 2 mL of water-saturated TOMAS for 2 h. After centrifugation (30 min), the residual concentrations of metals were determined with ICP-MS instrument Agilent 7500 (Agilent Technologies, USA).

2.6. Electrochemical apparatus and measurements

Screen-printed electrodes (SPE) were purchased form "RuSens" (Moscow, Russia). Three electrodes (work, counter and reference) were printed on the polyester substrate. Work and counter electrodes were fabricated using graphite paste (graphite powder dispersed in polymeric matrix); Ag/AgCl paste was used as reference electrode.

Electrochemical measurements were performed using "Intelligent Potentiostatic Control" IPC-Compact version 8.60× (Cronas Ltd., Russia).

For preparation of SPE-modifying compositions, weighed quantities of spectral pure (99.999%) high dispersion (<100 μm) graphite powder and TOMAS in a ratio 1:1 by weight were mixed intensively in tetrahydrofurane (THF); after full evaporation of THF the viscous composition was obtained. Actual amount of modifier was determined gravimetrically; average total mass of modifying composition was 0.5 mg.

For preparation of supporting electrolyte, potassium chloride was utilized as component for reference electrode potential stabilization while sulphuric acid was applied to regulate pH. Aqueous Fe(III) solutions were prepared by dissolving a weighed amounts of $Fe_2(SO_4)_3$ in supporting electrolyte.

Pre-concentration of Fe(III) in modifying layer of TOMAS-based graphite paste was performed under open circuit during 10 min of mechanical mixing of examined solutions. For performing the

stripping voltammetry, pre-reduction potential of −1.0 V during 1 min was applied. The potential scan was from −1.0 V to +1.0 V with scan rate of 100 mV/s.

3. Results and discussion

Iron(III) and copper(II) represent the most straightforward choice of metal ions for efficient recovery by TOMAS, because they are known to form stable salicylate complexes. In contrast, Ni^{2+} and Mn^{2+} form much less stable complexes, hence they were chosen to illustrate the effect of complex stability on the extraction.

The dependencies of distribution ratios for copper(II) and iron(III) on pH of aqueous solution are presented in Fig. 1.

As can be seen, in the absence of any additional reagents TOMAS effectively extracts Fe^{3+} and Cu^{2+} (99% and 89% for 1×10^{-3} M, respectively; note that the recovery values are given for phase volume ratio $V_{IL}:V_W = 1:5$). The pH-profiles of extraction have the characteristic shape with sharp decrease in log D at acidic media. The decrease may be explained by dissociation of salicylate complexes due to protonation of salicylate. In alkaline media the extraction has not been studied by reason of the precipitation of metal hydroxides.

The maximal distribution ratio of Fe^{3+} (log D = 2.70, pH 3.0, 1×10^{-3} M) into TOMAS is considerably higher than that of Cu^{2+} (1.49, pH 5.5, 1×10^{-3} M). Also, pH_{50} value of Fe^{3+} (1.45) is significantly lower than that of Cu^{2+} (4.36). This is in agreement with the fact that stability constants for mono- and disalicylate complexes of Fe^{3+} are higher than those of Cu^{2+} [32,33].

The pH-dependences of Ni^{2+} recovery have the shape similar to that found for Fe^{3+} and Cu^{2+} (Fig. 2). A rather different profile is observed for Mn^{2+} recovery, which may be explained by an instability of manganese salicylates.

As can be seen, the extraction efficiency ($\log D_{max}$, pH_{50}) is in good agreement with the stability constants of salicylate complexes with corresponding metal ions (Tables 1 and 2).

Table 1
Maximal distribution ratios, pH_{50} values, slopes of $\log D = f(pH)$ dependencies and stability constants [32] of salicylate complexes for the studied metal ions.

Metal ion	C_{Me} (M)	$\log D_{max}$	pH_{50}	Slope	$\log \beta_1$	$\log \beta_2$	$\log \beta_3$
Fe^{3+}	1×10^{-4} 1×10^{-3}	2.70	1.45	1.97	15.35	27.20	36.27
Cu^{2+}	1×10^{-4} 1×10^{-3}	1.03 1.49	4.36	0.83	12.02	20.70	–
Ni^{2+}	1×10^{-4} 1×10^{-3}	0.70	4.99	0.85	6.95	11.75	–
Mn^{2+}	1×10^{-4} 1×10^{-3}	−0.17 −0.49	–	–	5.90	9.80	–

We studied the mechanism of extraction of Fe^{3+} into TOMAS in details. The information about the composition of iron complex in the IL and aqueous phases was obtained from UV–vis spectra of corresponding phases. Organic samples were diluted with ethanol before measurements. As was reported by Babko [34], Fe^{3+} forms three types of complexes with salicylic acid in aqueous solutions (here and below the following notation is used: H_2Sal = *o*-$C_6H_4(OH)COOH$, $HSal^-$ = *o*-$C_6H_4(OH)COO^-$,

Table 2
The characteristics of salicylate complexes of iron(III) in aqueous solution [34].

Specie	Color	λ_{max} (nm)	ε_{max} (L/(mol cm))	Range of pH of complex formation
$[FeSal]^+$	Violet	510	900	<5
$[FeSal_2]^-$	Red	470	1800	2.5–8
$[FeSal_3]^{3-}$	Yellow	–	–	>8

$Sal^{2-} = o\text{-}C_6H_4(O^-)COO^-$):

$$Fe^{3+} + H_2Sal \Leftrightarrow [FeSal]^+ + 2H^+;$$

$$[FeSal]^+ + HSal^- \Leftrightarrow [FeSal_2]^- + H^+ \quad \text{or}$$
$$[FeSal]^+ + Sal^{2-} \Leftrightarrow [FeSal_2]^-;$$

$$[FeSal_2]^- + Sal^{2-} \Leftrightarrow [FeSal_3]^{3-}.$$

The other authors [33,35,36] reported on the formation of only monosalicylate complex $[FeSal]^+$. In all the cases, the value of $\lambda_{max} = 530$ nm is attributed to the monosalicylate complex.

In our extraction system, absorbance spectra of aqueous phases after extraction have maxima at 298 and 530 nm, which correspond to salicylate ion and monosalicylate complex of iron $[FeSal]^+$, respectively. Interestingly, the maximum absorbance decreases during 15 min of phase contact and then remains constant. Maximum of absorbance of IL phase spectrum is observed at 465 nm, suggesting a presence of iron bisalicylate complex in the extract.

Thus, the proposed mechanism of Fe^{3+} extraction into TOMAS includes the following steps:

a) Partial dissolution of TOMAS in aqueous phase:

$$TOMA^+HSal^-_{(O)} \Leftrightarrow TOMA^+_{(W)} + HSal^-_{(W)}$$

(as it was previously [37] established, the solubility of TOMAS in water is 2×10^{-4} mol L^{-1});

b) Formation of complex:

$$Fe^{3+}_{(W)} + HSal^-_{(W)} \Leftrightarrow FeSal^+_{(W)} + H^+_{(W)};$$

c) Extraction of ion pair:

$$FeSal^+_{(W)} + HSO^-_{4(W)} \Leftrightarrow [FeSal^+HSO^-_4]_{(O)}$$

(hydrosulfate comes from source Fe^{3+} salt);

d) Addition of the second salicylate in IL phase:

$$[FeSal^+HSO^-_4]_{(O)} + HSal^-_{(O)} \Leftrightarrow FeSal^-_{2(O)} + HSO^-_{4(O)} + H^+_{(W)}.$$

The total extraction equilibrium may be represented as follows:

$$Fe^{3+}_{(W)} + 2TOMA^+HSal^-_{(O)} + HSO^-_{4(W)}$$
$$\Leftrightarrow TOMA^+[FeSal_2]^-_{(O)} + TOMA^+HSO^-_{4(O)} + 2H^+_{(W)}. \quad (3)$$

This equation assumes the release of two protons that is in good agreement with the observed slope of pH-profile of Fe^{3+} extraction (≈2, Fig. 1).

As it is seen from Fig. 1, pH-profiles of Fe^{3+} extraction for $C_0(Fe) = 1 \times 10^{-4}$ and 1×10^{-3} M match each other, except strong-acidic medium (pH < 1.5). In wide range of initial concentrations of Fe^{3+} (1×10^{-4}–1×10^{-1} M) the metal ion (Fe^{3+}) is recovered almost quantitatively (at $V_{IL}:V_W = 1:5$, pH = 2.5–3.0) with average value of $\log D_{Fe}$ being equal to 2.7 (Fig. 3).

However, in the case of $C_0(Fe) = 2 \times 10^{-1}$ M, the recovery of iron drops to 81%. This fact may be attributed to the limited extraction capacity of TOMAS. Indeed, according to Eq. (3) 1 mL of TOMAS may extract 8.40×10^{-4} mol of Fe^{3+}, which corresponds to recovery of 84% (from 2×10^{-1} M Fe^{3+} solution), in a nice agreement with the experiment.

The Fe^{3+} extracts and aqueous phases (for $C_0(Fe) = 1 \times 10^{-1}$ and 2×10^{-1} M) were analyzed (elemental composition, titratable acidity, Fe and $TOMA^+$ content) to further verify the proposed mechanism of extraction (Table 3).

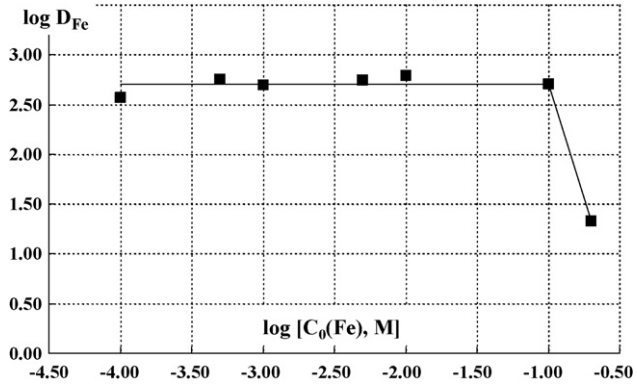

Fig. 3. The dependence of distribution ratio of Fe^{3+} on its initial concentration in aqueous phase.

One can see that the acidic protons found in extracts do belong to HSO_4^-, since they are in equimolar amount to sulphur determined *ibidem*. Calculated by Eq. (3) and actually found in extracts molar S/N-ratios are also in excellent agreement.

As to the extraction of divalent metal ions, the general two-phase equilibrium may be represented as follows:

$$Me^{2+}_{(W)} + TOMA^+HSal^-_{(O)} + HSO^-_{4(W)}$$
$$\Leftrightarrow MeSal_{(O)} + TOMA^+HSO^-_{4(O)} + H^+_{(W)}, \quad (4)$$

where Me^{2+} is Cu^{2+}, Ni^{2+}, and Mn^{2+}. The slopes of the dependencies $\log D_{Cu} - pH$ and $\log D_{Ni} - pH$, both close to 1, which is indicative of mode (4). As to the dependency $\log D_{Mn} - pH$ (0.25), it may be difficult to identify a characteristic slope because of low Mn^{2+} recovery.

We studied the selectivity of iron extraction in our TOMAS-based system. We have determined the separation factors of Fe^{3+} (1×10^{-3} M) with respect to the commonly coexisting metal ions (Cr^{3+}, Ni^{2+}, Mn^{2+}, Zn^{2+}, and Co^{2+}) at different ratios Fe: interfering ions. For equal concentrations of Fe^{3+} and other ions the separation factors are as follow: Fe/Mn 490, Fe/Co 387, Fe/Zn 382, Fe/Ni 370, Fe/Cr 62 (pH 2.60). For the ten fold excess of foreign metal ions, the factors are: Fe/Mn 142, Fe/Co 108, Fe/Zn 105, Fe/Ni 90, Fe/Cr 13 (pH 2.35). As is seen, the separation factors are rather high (with the exception of Fe/Cr pair; still, this separation factor is quite significant).

Noteworthy is mentioning that Papp and Inczédy [38] 35 years ago actually used TOMAS in a trichloromethane solution (that is, solely as a complexing reagent rather than solvent) for the recovery

Table 3
The composition of aqueous and organic phases after extraction as calculated according to Eq. (3) and found experimentally ($V_{IL} = 4$ mL; $V_W = 20$ mL).

[a] The limit of determination of nitrogen by means of element organic analysis (by Kjeldahl's method) was 0.2 wt.%, which corresponds in this case to 3×10^{-4} M of $TOMA^+$ in aqueous phase.

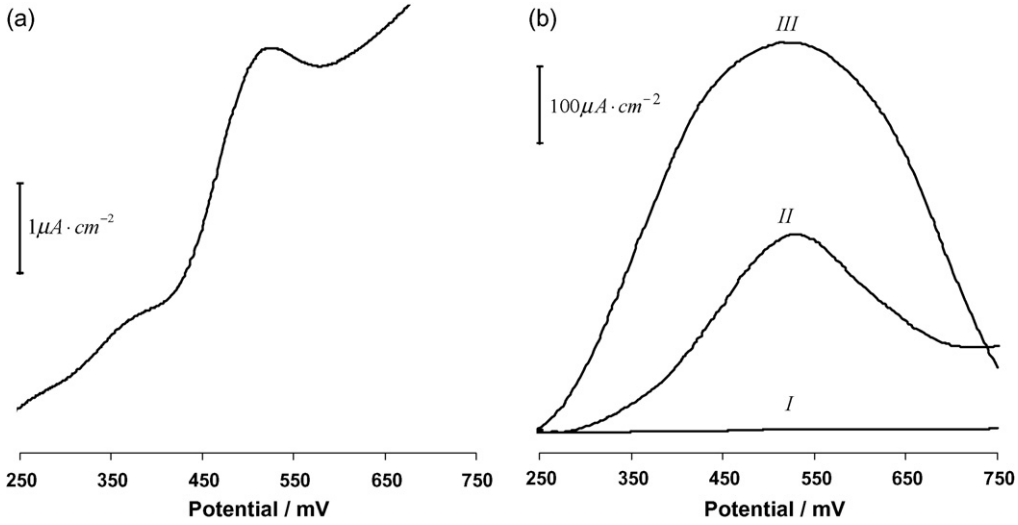

Fig. 4. Linear scan stripping voltammograms in aqueous solutions of 1×10^{-7} M Fe(III) at bare SPE (a and b, curve I); 1×10^{-7} M Fe(III) and 1×10^{-5} M Fe(III) (b, curves II and III, respectively) at TOMAS-modified SPE. Supporting electrolyte: 0.01 M H_2SO_4, 0.01 M KCl. Pre-concentration under an open circuit during 10 min under mixing. Pre-reduction potential is −1.0 V, the time is 1 min. The potential scanned from −1.0 V to +1.0 V, scan rate 100 mV/s.

of copper from aqueous solution in the presence of salicylate. The maximal $\log D_{Cu}$ they reported was 1.5 (at $C(NaHSal)_{W,0} = 0.10$ M and pH = 6), which is very close to our data (at the same values of pH and $C_0(Cu)$). However, our IL-based extraction system does not require any addition of salicylate to aqueous solution prior extraction and does not require the use of molecular solvent, $CHCl_3$.

Extraction of iron and copper with TOMAS may be favorably compared to other reported conventional solvent extraction systems, which use the reagents related to TOMAS constituents—amine/ammonium-based ion exchangers or salicylic acid.

For example, the authors of [39] described the extraction of copper(II) with Amberlite® LA-2 (a mixture of long-chain secondary amines) in thiocyanate form dissolved in isobutyl methyl ketone. However, there were serious problems associated with the necessity of ammonium thiocyanate addition to the aqueous solutions before extraction (to adjust its concentration equal to 0.06 M), emission of volatile and hazardous secondary amines (besides ketone), and, finally, low selectivity of extraction (especially, with respect to zinc). Methyldioctylamine, methyltrioctylammonium chloride, Amberlite® LA-1, Amberlite® LA-2, and trioctylamine were used for copper(II) recovery from hydrohalogenic media into benzene and xylene [40] and 1,2-dichloroethane [41]. Methyldioctylamine-based system demonstrated insufficient recovery of Cu^{2+}, while systems based on methyltrioctylammonium chloride, Amberlite® LA-1, and Amberlite® LA-2 showed a very low selectivity with respect to the common coexisting metal ions. The drawbacks also include a volatility of amine-based reagents themselves and the fact that a high recovery is achieved only in strongly acidic media. The last is also true for the iron(III) extraction into benzene with Aliquat® 336 (additionally, the problems with selectivity were also reported) [42].

Aggett et al. [43] investigated iron(III) recovery from aqueous solutions into tributylphosphate in the presence of salicylic acid. The maximum achieved $\log D_{Fe}$ was less than 1.0, which is almost two orders of magnitude lower than in the case of TOMAS. Moreover, the registered pH-profiles demonstrate very narrow range of optimal extraction (less than 0.5 pH units). The same disadvantage was also noted by Sonawale et al. [44] who studied the extraction of copper(II) from aqueous solutions into solutions of tributylphosphine oxide (TBPO) in toluene in the presence of sodium salicylate. The quantitative recovery of copper was reached only in the very narrow pH range, 2.9–3.1.

Finally, compared to all above described cases (and to other cases involving recovery of copper and iron with effective and/or selective complexing reagents, e.g. [45,46]), extraction with TOMAS looks advantageous as it totally eliminates the need in organic solvent.

As many other extraction reagents, TOMAS may be employed in various other analytical applications besides the separation and pre-concentration. One of the most obvious options is electrochemical determination of (efficiently extracted) metal ions with TOMAS-modified electrodes.

We found that combining TOMAS with conductive matrix (carbon-based materials; similar approach was described in [47]) in an appropriate proportion yields a viscous composition suitable for modification of the work-electrode surface and further electrochemical detection of appropriate metals.

In a model experiment, we compared the efficiency of analytical signal (current density) increase for bare and chemically modified screen-printed electrodes (SPE) in Fe(III) aqueous solutions in a chosen support electrolyte; linear scan stripping voltammetry was used (see Fig. 4). As is seen, in both cases the well-defined peaks of oxidative current have been obtained at approx 0.55 V (vs. Ag/AgCl reference electrode) which is well-known as characteristic redox-potential for Fe(II)/Fe(III) couple [32]. Nevertheless, in the case of TOMAS-modified SPE the absolute value of current density for the same 1×10^{-7} M concentration of Fe(III) (5.6 ppb) is much higher and, naturally, the signal increases with increase of analyte concentration (cf. Fig. 4a and b). Such an improvement of sensitivity cannot be associated solely with the enlargement of effective work-electrode surface because only a very negligible amount of graphite paste was used for modification. Evidently, the combination of highly efficient pre-concentration under an open circuit with further pre-reduction takes place. The principal possibility of the electrochemical determination of transition metals in aqueous solutions at TOMAS-modified electrodes has been clearly demonstrated.

4. Conclusion

In conclusion, a novel tetraalkylammonium-based ionic liquid TOMAS has been found to be a highly efficient extraction solvent for

recovery of some transition metal ions from aqueous solutions (99% for Fe^{3+} and 89% for Cu^{2+}, $V_{IL}:V_w = 1:5$, $C_w^0 = 1 \times 10^{-3}$ M). From the results obtained in the present work, it is seen that TOMAS extracts metal ions in the form of salicylate complexes. The extraction efficiency is directly related to the stability constants of corresponding salicylate complexes (this may be used for the separation of transition metal ions based on the different stability of salicylate complexes). The pre-concentration of Fe^{3+} or Cu^{2+} in voltammetric analysis may also be achieved with the use of TOMAS. The principal possibility of a sensitive electrochemical determination of Fe^{3+} in aqueous solutions at TOMAS-modified electrodes has been demonstrated.

ABSTRACT

Three sorbent materials (A18C6-MS, DA18C6-MS and AB18C6-MS) based on the crown ether ligands, 1-aza-18-crown-6, 1,4,10,13-tetraoxa-7,16-diazacyclo octadecane and 4′-aminobenzo-18-crown-6, respectively, were prepared by the chemical immobilization of the ligand onto mesoporous silica support. The sorbents were characterized by FT-IR, scanning electron microscopy-energy dispersive X-ray microanalysis, elemental analysis and nitrogen adsorption–desorption test. The applicability of the sorbents for the extraction of biogenic amines by the batch sorption method was extensively studied and evaluated as a function of pH, biogenic amines concentration, contact time and reusability. Under the optimized conditions, all the sorbents exhibited highest selectivity toward spermidine (SPD) compared to other biogenic amines (tryptamine, putrescine, histamine and tyramine). Among the sorbents, AB18C6-MS offer the highest capacity and best selectivity towards SPD in the presence of other biogenic amines. The AB18C6-MS sorbent can be repeatedly used three times as there was no significant degradation in the extraction of the biogenic amines (%E > 85). The optimized procedure was successfully applied for the separation of SPD in food samples prior to the reversed-phase high performance liquid chromatography separation.

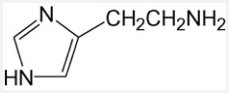
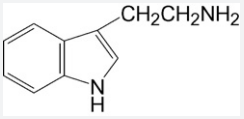
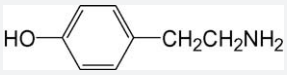
1. Introduction

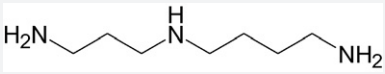
Biogenic amines (Table 1) are extensively studied because of their potential toxicity to humans and their usage as food quality markers [1,2]. They can be found in a wide range of food products of both animal and plant origin, as well as in beverages and fermented foods. They are mainly generated by microbial decarboxylation of amino acids [3,4]. The presence of high levels of biogenic amines in food constitutes a potential public concern due to their physiological and toxicological effects. Some of the effects of these amines are well known, e.g., headache, nausea, hypo- or hypertension, migraine, skin allergy and digestive problems. Moreover, they are precursors of carcinogenic nitrosamines and are not reduced by high-temperature treatment [3,5].

Many analytical methods for the separation and quantification of biogenic amines in various kinds of food have been developed, including thin layer chromatography [6], gas chromatography [3], liquid chromatography [4,7] and capillary electrophoresis [1,8]. As biogenic amines do not exhibit strong fluorescence characteristics, a suitable derivatization technique is frequently used to increase the method sensitivity.









The determination of biogenic amines in food is problematic not only due to their low concentration levels but also due to the complexity of the matrix. Thus, sample clean-up plays an important role for the isolation and enrichment of the biogenic amines prior to the analytical determination. Liquid–liquid extraction (LLE) [9–11], solid phase extraction (SPE) [12–15] and more recently, solid phase microextraction (SPME) [3] have been described.

LLE technique is not recommended because it involves long extraction procedures and often uses harmful organic solvents. Moreover, low recoveries for some amines is sometimes found [10,16]. SPE represents a good alternative to the LLE technique, especially by virtue of the wide commercial availability of sorbent materials and also due to the fact that the need to dispose organic solvents is to a large extent minimized [17]. Using sorbent materials based on anionic [13] and cationic [14] exchangers or non-polar functional groups (e.g., octadecylsilane groups (C18)) [12,15] often show better extraction efficiencies than the LLE counterpart. These kinds of sorbents, however, lack selectivity as constituents of similar polarities are also co-extracted [18]. On-line SPE has also been reported to increase the throughput [12].

Table 1
Structures and chemical properties of the biogenic amines studied [1,2].

Name	Abbreviation	Structure	Molecular weight	p*K*
Histamine	HIS		111.1	$pK_1 = 9.8$ $pK_2 = 6.0$
Putrescine	PUT		88.2	$pK_1 = 10.8$ $pK_2 = 9.4$
Tryptamine	TYP		160.2	$pK = 10.2$
Tyramine	TYR		137.2	$pK = 9.6$
Spermidine	SPD		145.3	$pK_1 = 9.5 pK_2 = 10.8 pK_3 = 11.6$

More recently, SPME and liquid-phase microextraction (LPME) represent interesting developments in extraction as solvent consumption is considerably minimized [19]. The drawbacks with SPME are the relatively high cost of the fiber, its fragility, limited lifetime and carryover effects between analysis [20].

Despite the various developments, the SPE technique still remains a practical approach in sample preparation. The lack of selectivity can be improved by incorporating molecular recognition compounds onto a suitable support [21]. A SPE method for the extraction of catecholamines (norepinephrine, epinephrine and dopamine) based on a chemically modified polymeric resin (Amberlite XAD-4) with 4′-carboxybenzo-18-crown-6 has been described [22]. Satisfactory recoveries (79.1–95.1%) were obtained. Thus, it was the aim of this work to develop selective extraction method for the determination of biogenic amines. This was realized by the immobilization of three crown ethers, namely 1-aza-18-crown-6 (A18C6), 1,4,10,13-tetraoxa-7,16-diazacyclo octadecane (DA18C6) and 4′-aminobenzo-18-crown-6 (AB18C6) within the mesoporous silica as support. The ability of crown ethers to form selective host–guest complexes with alkali, alkaline-earth, amines and amino acids have been documented [23]. The selectivity feature is due to the inclusion complex-formation ability of crown ether with the protonated cations that was made possible by the hydrogen bonding and electrostatic interactions between the cations and the unshared pair of electrons from oxygen, sulfur or nitrogen donor atoms [24]. These ligands have found wide applications such as ion carriers in LLE and ion transport, as well as in the preparation of sensors [25]. The preparation of a mesoporous π-complexing sorbent by covalently immobilizing ionic liquids onto SBA-15-supported ionic liquid compounds containing silver salts was described by Li et al. [26].

2. Experimental

2.1. Chemicals and reagents

All chemicals and solvents used were of analytical and chromatographic grades, respectively. They were used as received. 18 mΩ ultrapure water (Nanopure Diamond, Barnstead, USA) was used throughout. Standard amine hydrochlorides namely spermidine (SPD), putrescine (PUT), histamine (HIS) and tryptamine (TRP), maleic acid, ethanol, toluene and trichloroacetic acid were purchased from Sigma–Aldrich (Steinheim, Germany). Tyramine hydrochloride (TYR), dansyl chloride, A18C6, DA18C6, AB18C6, 3-chloropropyltrimethoxysilane and tetraethoxysilane (TEOS) were from Fluka (Buchs, Switzerland). HPLC grade acetonitrile was purchased from Fisher Scientific (Leicestershire, UK). Glutamic acid monosodium monohydrate, sodium hydroxide, diethyl ether and hydrochloric acid (Acros Organics, New Jersey, USA), sodium hydrogen carbonate (BDH Chemicals, Poole, England) and potassium dihydrogen orthophosphate (Merck, Darmstadt, Germany) were also used. Tomato ketchup, soy sauce, cheese, fish sauce and canned tuna were purchased from a local supermarket in Penang, Malaysia.

2.2. Apparatus

FT-IR spectrum (4000.0–400.0 cm^{-1}) were recorded using a PerkinElmer 2000 FT-IR system. LEO Supra 50vp field emission scanning electron microscope (SEM) equipped with Oxford INCA 400 energy dispersive X-ray microanalysis system (EDX) was used to study the surface morphology and semi-quantitative analysis of the sorbent surface. The samples were sputtered with a thin layer of gold using a Polaron (Fisons) SC515 sputter coater. Elemental analysis was carried out using a CHNS/O Analyzer (PerkinElmer, Series II 2400). The surface area, pore volume, pore diameter and pore size distribution were measured by nitrogen adsorption–desorption isotherms at 77 K on an Aurusorb Automated Gas Sorption analyzer (Quantachrome Corporation) using Brunauer–Emmett–Teller (BET) and Barrett–Joyner–Halenda (BJH) desorption methods. An Orion ion analyzer in conjunction with a glass pH electrode was used for pH measurements. An ultrasonic bath was used for the sonication during the preparation of mesoporous silica. A mechanical shaker (Stuart Scientific) was used for the extraction studies.

2.3. HPLC analysis

Quantitative analysis of biogenic amines was carried out using a Jasco HPLC system that consisted of a pump (Jasco PU-1580), a quarternary gradient unit (Jasco LG-1580-04), a UV–VIS detector (Jasco UV-1570 UV/VIS), an injector (Jasco model 7725) and a 20 μL sample loop. Separation was achieved using a 250 mm × 4.5 mm, Waters Spherisorb 5 μm ODS2 column. The HPLC was operated under isocratic elution (mobile phase of acetonitrile:water (67:33, v/v)) at a flow rate of 1.2 mL min^{-1}. 20 μL of sample was injected and was monitored at 254 nm. The mixture was filtered using 0.45 μm nylon membrane filter from Whatman and was degassed by an ultrasonic bath for 15 min prior to use.

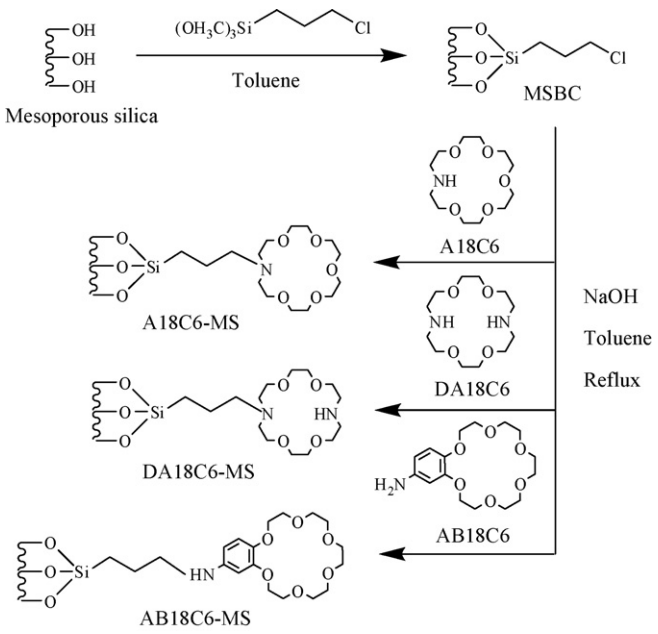

Fig. 1. Reaction for the immobilization of ligands on mesoporous silica.

2.4. Preparation of mesoporous silica

The preparation of mesoporous silica was adapted from procedure as described in the literature [27]. The silica was prepared using a sol–gel process where ethanol (24 mL) was first mixed with distilled water (3.2 mL) for 30 min to homogenize the reaction medium. This was followed by drop-wise addition of TEOS (9.6 mL) into the medium. The reaction was carried out for 1 h, followed by the addition of 0.1 M HCl (40 mL) as catalyst. The mixture was next sonicated for 5 h. Upon cooling to room temperature, the solution of 0.45 g mL^{-1} maleic acid solution (5 mL) was added drop-wise under stirring. The gel was aged at room temperature for 15 h, followed by drying in the oven (7 h) at 70 °C and finally the hard transparent solids were obtained. In order to remove the maleic acid template, the solid was ground into powder and was extracted with ethanol in a soxhlet apparatus (40 h), followed by drying in an oven until constant mass.

2.5. Preparation of sorbents

Mesoporous silica (10 g) was mixed with toluene (100 mL) and 3-chloropropyltrimethoxysilane (10 mL) in a round bottom flask and was refluxed with stirring for 24 h. The phase was left to cool, filtered, washed with toluene, ethanol and diethyl ether and the product (mesoporous silica immobilized with 3-chloropropyltrimethoxysilane (MSBC)) was dried in an oven (70 °C) for 7 h. Sorbents were prepared by mixing MSBC (0.25 g) with 0.5 g of A18C6, DA18C6 and AB18C6 ligand, respectively, in toluene (30 mL) in the presence of NaOH (0.16 g) as a catalyst. The mixture was refluxed for 24 h, left to cool, filtered, washed with toluene, ethanol and diethyl ether and dried (70 °C) for 7 h. The sorbents prepared (A18C6-MS, DA18C6-MS and AB18C6-MS) were stored in a vacuum desiccator. The preparation pathway is outlined in Fig. 1.

2.6. Preparation of standard solutions

Stock solution (1000 mg L^{-1}) of a mixture of TRP (61.4 mg), PUT (91.5 mg), HIS (82.8 mg), TYR (63.2 mg) and SPD (87.7 mg) was prepared in 0.1 M HCl in a volumetric flask (50 mL). The solution was stored at 4 °C and protected from light. Working solutions were prepared by appropriate dilution from this stock solution and was used to obtain the calibration curves.

2.7. Derivatization procedure of standards and sample extracts

The derivatization procedure was adapted from the studies of Mah et al. [28]. 1 mL of standard or sample extract was mixed with a saturated solution of $NaHCO_3$ (200 μL), 2 M NaOH (20 μL) and 2 mL of dansyl chloride (10 mg of dansyl chloride in 1 mL acetone). The mixture was heated in a water bath (70 °C) for 10 min. After the reaction, the unbound dansyl chloride was removed by adding 1 mL of glutamic acid (50 mg of glutamic acid in 1 mL water). After 1 h, the mixture was adjusted to 5 mL with acetonitrile. The solution

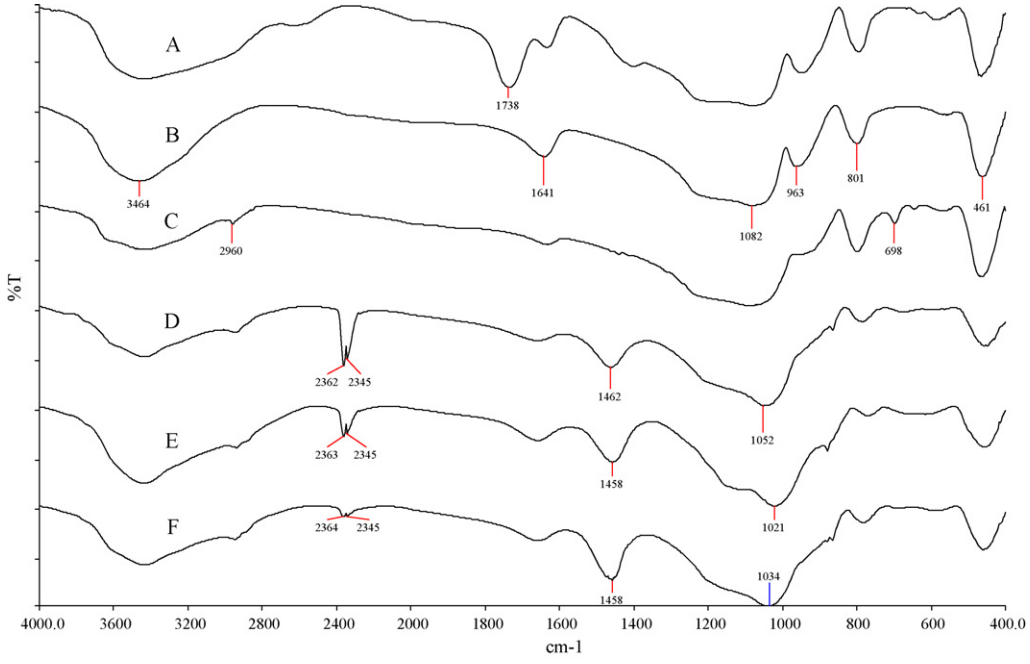

Fig. 2. FT-IR spectra of mesoporous silica (A) before, (B) after the removal of maleic acid, (C) MSBC, (D) A18C6-MS, (E) DA18C6-MS and (F) AB18C6-MS sorbents.

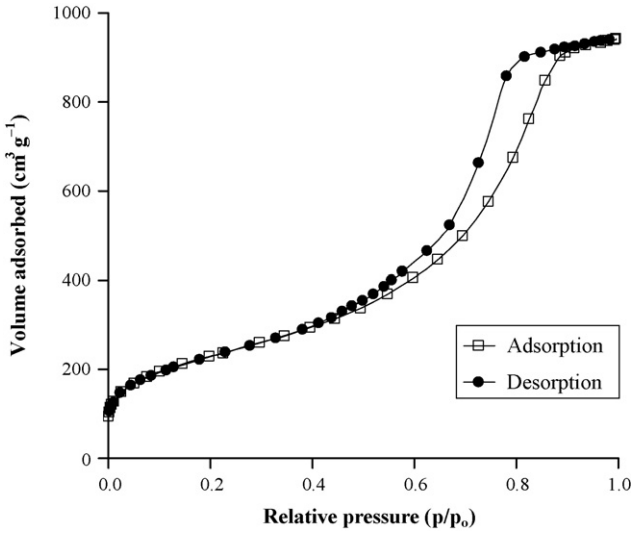

Fig. 3. N_2 adsorption–desorption isotherms of the mesoporous silica.

was filtered through a 0.45 μm nylon membrane filter and injected into the HPLC column.

2.8. Batch sorption method

Sorbent material (10 mg) was equilibrated with 5 mL of 1 mg L^{-1} mixture of standard biogenic amine solution (TRP, PUT, HIS, TYR and SPD) in a sample vial. The mixture was shaken mechanically at room temperature for 1 h. After equilibration, the mixture was briefly centrifuged and 1 mL of the mixture was derivatized. The amount of the biogenic amines left in the solution was analyzed by HPLC.

The sorbent was regenerated by shaking with of 0.1 M NaOH (5 mL) for 30 min, followed by rinsing several times with water. The sorbent was dried in an oven (60 °C) before the next extraction cycle was conducted.

2.9. Determination of SPD in food samples

Different preparation procedures were used according to the type of sample. TCA (5%) was used for the extraction of fish sauce and canned tuna while HCl (0.1 M) was used for the extraction of cheese, tomato ketchup and soy sauce samples. Each sample (5 g) was extracted twice with the respective acid (15 mL) and was homogenized using a vortex mixer (3 min). The homogenates were centrifuged (3000 rpm) for 15 min. For cheese and canned tuna samples, the homogenates were stored at 4 °C to allow the precipitation of fats [29]. The supernatant were combined, adjusted to pH 6 and made up to the 50 mL mark and filtered through a filter paper (Whatman no. 42). Some samples were spiked with SPD to give a final concentration of 1 and 5 mg L^{-1}. The sample (5 mL) was shaken in the presence of 10 and 30 mg of AB18C6-MS sorbent (15 min). The unextracted SPD was derivatized and determined by HPLC to determine the percentage removal of SPD.

3. Results and discussion

Mesoporous silica was prepared as they offer the possibility of producing sorbent materials of different physical properties (e.g., surface area, porosities, controllable and narrowly distributed pore sizes and ordered pore arrangements).

3.1. FT-IR analysis

FT-IR spectra of the prepared sorbents are shown in Fig. 2. For the mesoporous silica, the characteristic absorption band at 1738 cm^{-1} corresponding to the C=O stretching vibration of maleic acid molecule disappeared completely after the extraction with ethanol, indicating the complete removal of the template compound from the mesoporous silica (Fig. 2A and B) [27]. The peak at 1641 cm^{-1} and the broad absorption band at 3464 cm^{-1} are due to the absorbed water. The band at 1082, 801 and 461 cm^{-1} represent the fundamental vibration bands corresponding to Si–O–Si asymmetric stretching, symmetric stretching and bending vibrations for the mesoporous silica [30]. The absorption peaks at 963 cm^{-1} is due to the stretching vibrations of the silanol group (Si–OH) (Fig. 2B) [31,32]. The small absorption band at 2960 cm^{-1} is due to the stretching and bending of C–H bond of 3-chloropropyltrimethoxysilane (Fig. 2C) [31]. Moreover, the spectrum of MSBC shows evidence that the chloride group was attached to silica support because the characteristic C-Cl stretching band at 698 cm^{-1} was observed.

The spectra of the A18C6-MS and DA18C6-MS sorbents show characteristic absorption band at 1462 and 1458 cm^{-1}, respectively, due to CH_2–N–CH_2 stretching, while the NH–CH_2 stretching bands for AB18C6-MS appear at 1458 cm^{-1} (Fig. 2D–F). The CH_2–O–CH_2 linkage of six membered rings for crown ether that absorbs in ~1070 cm^{-1} due to the asymmetric stretching vibrations was not detected as it overlapped with the strong and broad Si–O–Si vibration. The Si–OH stretching frequency in mesoporous silica at 3464 cm^{-1} overlapped with the N–H stretching frequency in immobilized crown ether at ~3450 cm^{-1}. The N–H stretching bands at 1462, 1458 and 1458 cm^{-1} for A18C6-MS, DA18C6-MS and AB18C6-MS (Fig. 2D–F), respectively, indicate the presence of amine groups in the sorbents prepared. The characteristic stretching band at ~2340 and ~2360 cm^{-1} in the three sorbents is further evidence of the presence of a crown ether ligand in the structure. Hence, these spectra suggest that the A18C6, DA18C6 and AB18C6 ligands were incorporated into the mesoporous silica prepared.

3.2. SEM, EDX and elemental analysis

SEM reveals that the mesopores can be described as through pores, which preferentially determine the permeability properties. A high surface area is anticipated to provide a large stationary phase loading. The mesoporous structures are located on the silica skele-

Table 2
Analytical characteristics of the HPLC method.

R^2, square of regression coefficient; t_R, retention time; LOD, limit of detection; LOQ, limit of quantification; RSD, relative standard deviation.

ton and are the ones which provide the surface area needed for the extraction. Numerous interconnected wormhole-like framework pore structures can be observed, which are relatively regular in diameter but largely disordered in the channel arrangements [27].

The EDX results indicate the absence of nitrogen in the mesoporous silica. Analysis on A18C6-MS, DA18C6-MS and AB18C6-MS sorbents showed that nitrogen, ranging from 1.14–1.78% was detected, indicating the presence of crown ethers in the mesoporous silica matrix. This was further supported by the elemental analysis where nitrogen ranging from 0.42 to 1.00% was found for immobilized sorbents. Based on the elemental analysis results, the loading amount of A18C6, DA18C6 and AB18C6 are 0.71, 0.30 and 0.36 mmol g^{-1}, respectively.

3.3. Nitrogen adsorption–desorption test

BET surface area and pore volume were 796 $m^2 g^{-1}$ and 1.31 $cm^3 g^{-1}$, respectively, suggesting that the prepared materials have large surface areas and pore volumes. The isotherms of the mesoporous silica prepared can be classified as type IV with a type A hysterisis loop that is typical of mesoporous material according to the IUPAC nomenclature [33] (Fig. 3). The adsorption isotherm exhibited a large increase in p/p_0 range from 0.6 to 0.8, a characteristic of capillary condensation within the uniform mesoporous. The p/p_0 position of the inflection points is clearly related to the diameter in the mesoporous range and the step indicates the mesoporous size distribution [34]. A narrow pore size distribution with a mean pore size of 6.3 nm is obtained from the BJH desorption method.

3.4. Analytical characteristics of the HPLC method

The HPLC was evaluated for the linear range, limit of detection (LOD) and quantification (LOQ), precision and recovery. Results are summarized in Table 2. The linearity of the calibration curves was investigated by injecting five concentrations of standard mixtures (0.1–250 mg L^{-1}). All the analytes showed good linearity with squared regression coefficient (R^2) ranging from 0.9979 to 0.9999. LOD and LOQ based on signal-to-noise ratio (S/N) of 3 and 10, were in the range of 4.43–7.34 and 14.76–24.45 μg L^{-1}, respectively. These values were comparable to those reported in the literature [35,36]. To evaluate the precision of the method, the repeatability and reproducibility was investigated by injecting five times each of the five standard mixtures on the same day (intraday) and over 7 days (interday), respectively. Good reproducibility of both peak areas (RSD ≤ 3.09%) and retention times (RSD ≤ 0.71%) were found. Recovery studies were carried out by spiking three concentrations (1, 5 and 10 mg L^{-1}) of a mixture of amine standards to fish, cheese, soy bean and tomato ketchup samples studied. Satisfactory recoveries for all amines were obtained (90.7–106.3%) (Table 3).

3.5. Extraction of biogenic amines

The potential application of the sorbents prepared for the extraction of biogenic amines is studied by the batch sorption method. The extraction was optimized for key parameters such as pH, biogenic amines concentration, contact time and reusability. Extraction of a mixture of the five biogenic amines (TRP, PUT, HIS, TYR and SPD) using the sorbents were studied using reversed-phase HPLC. Biogenic amines ranging from 1 to 20% were extracted when blank mesoporous silica (without any crown ether ligand) were used.

3.5.1. Effect of pH

The extraction of the biogenic amines at various pH (2–9) were studied. It was found that SPD was the main analyte extracted for all sorbents (Fig. 4), the optimum extraction was at pH 6. SPD was 98%

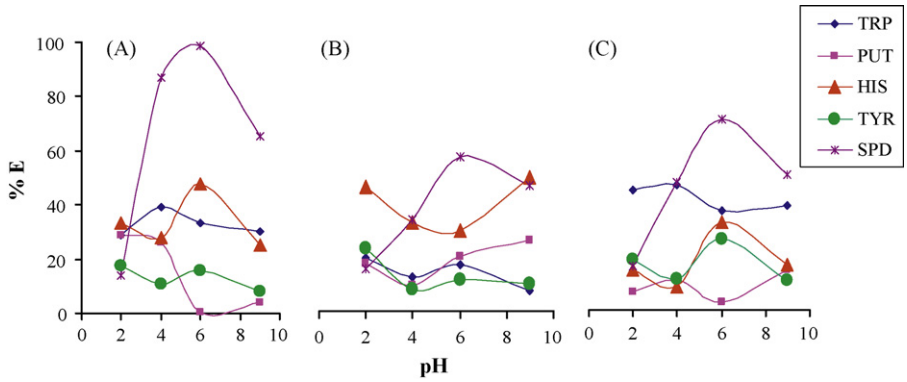

Fig. 4. Effect of pH on the extraction of biogenic amines with AB18C6-MS (A), DA18C6-MS (B) and A18C6-MS (C) sorbents. Mixture contained 1 mg L^{-1} of each biogenic amine. Contact time, 60 min.

extracted when AB18C6-MS sorbent was used compared to A18C6-MS and DA18C6-MS (70 and 60% extracted, respectively). The other amines were less than 50% extracted. Lower extraction at pH other than 6 is probably due to the fact that the amino group of the crown ether is protonated at low pH values while the amino group of the biogenic amine is unprotonated at higher pH values. These two conflicting factors lead to an optimum extraction at pH 6 as shown in Fig. 4. For the recognition of amines, crown ethers have been shown to coordinate with the primary ammonium ion by anchoring the R-NH_3^+ group into their cavity via three H-bonds (N–H···O) [37]. The good selectivity toward SPD is probably due to the ability of the aliphatic amine to fit into the host compared to the aromatic and heterocyclic amines (TRP, HIS and TYR). The good selectivity of SPD towards AB18C6-MS sorbent due to host–guest interaction is further supported by the lower loading of the ligand on the silica support (0.36 mmol g^{-1}) compared to A18C6 (0.71 mmol g^{-1}). The AB18C6-MS sorbent was further used due to its good extraction characteristics.

3.5.2. Effect of biogenic amines concentration

Four different concentrations (0.5–10 mg L^{-1}) of a mixture of biogenic amine were used to study the extraction efficiency (Fig. 5). It was observed that SPD was quantitively extracted up to 10 mg L^{-1} by the AB18C6-MS sorbent. The percentages of extraction for other biogenic amines were low (<50%) at any concentrations. Therefore, 1 mg L^{-1} of biogenic amines was chosen for subsequent experiments.

3.5.3. Effect of contact time

Fig. 6 shows the effect of contact time (5–120 min) on the biogenic amines extraction. It is evident that SPD is the efficiently extracted and within 15 min of contact time, the percentage of extraction was 98%. Therefore, 15 min of contact time was chosen for the subsequent studies.

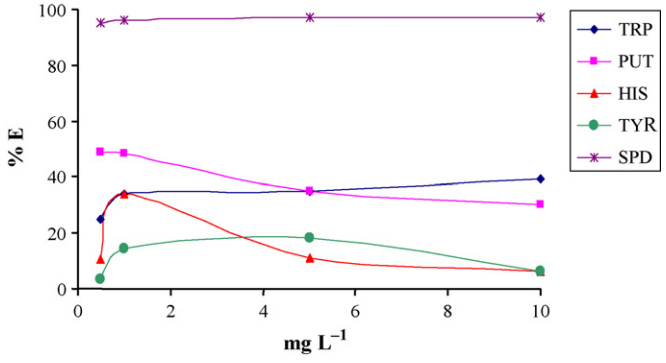

Fig. 5. Effect of biogenic amines concentrations on the extraction. Contact time, 60 min; pH 6; sorbent, AB18C6-MS.

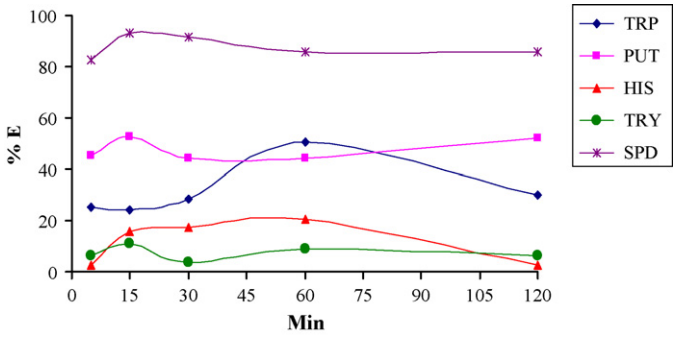

Fig. 6. Effect of contact time on the extraction of the biogenic amines. Mixture containing 1 mg L^{-1} of each biogenic amine; pH 6; sorbent; AB18C6-MS.

3.5.4. Reusability of sorbent materials

To test the reusability of the AB18C6-MS sorbent, it was used to extract biogenic amines through three extraction cycles. The stripping reagent used was 0.1 M NaOH (5 mL). The sorbent still maintained their extraction ability towards SPD through three extraction cycles. No major degradation of the performance was observed, and the sorption capacity was reduced by 9%. The loss of reactivity of the sorbent is probably due to the strong complexation of the crown ether with biogenic amines in the pores. It seems that the remaining biogenic amines in the pores do not affect the sorbent performance in the subsequent extraction cycle.

3.5.5. Adopted extraction conditions

The adopted conditions for the batch extraction were: AB18C6-MS mass, 10 mg; phosphate buffer (0.1 M), pH 6; contact time, 15 min; biogenic amines concentration, 1 mg L^{-1} (5 mL).

Table 4
Recoveries (%) of SPD from spiked food samples using AB18C6-MS sorbent ($n = 3$).

	AB18C6-MS mass		
	10 mg		30 mg
	Spiked concentration (mg L^{-1})		
	1	5	5
Fish sauce	99.8 ± 5.1	93.1 ± 0.3	97.6 ± 2.6
Soy sauce	98.4 ± 2.8	83.7 ± 1.5	96.6 ± 0.9
Tomato ketchup	98.8 ± 5.9	80.1 ± 0.8	93.4 ± 1.6
Canned tuna	99.6 ± 3.4	78.4 ± 1.0	98.9 ± 2.2
Cheese	88.9 ± 1.3	71.2 ± 0.5	92.9 ± 0.7

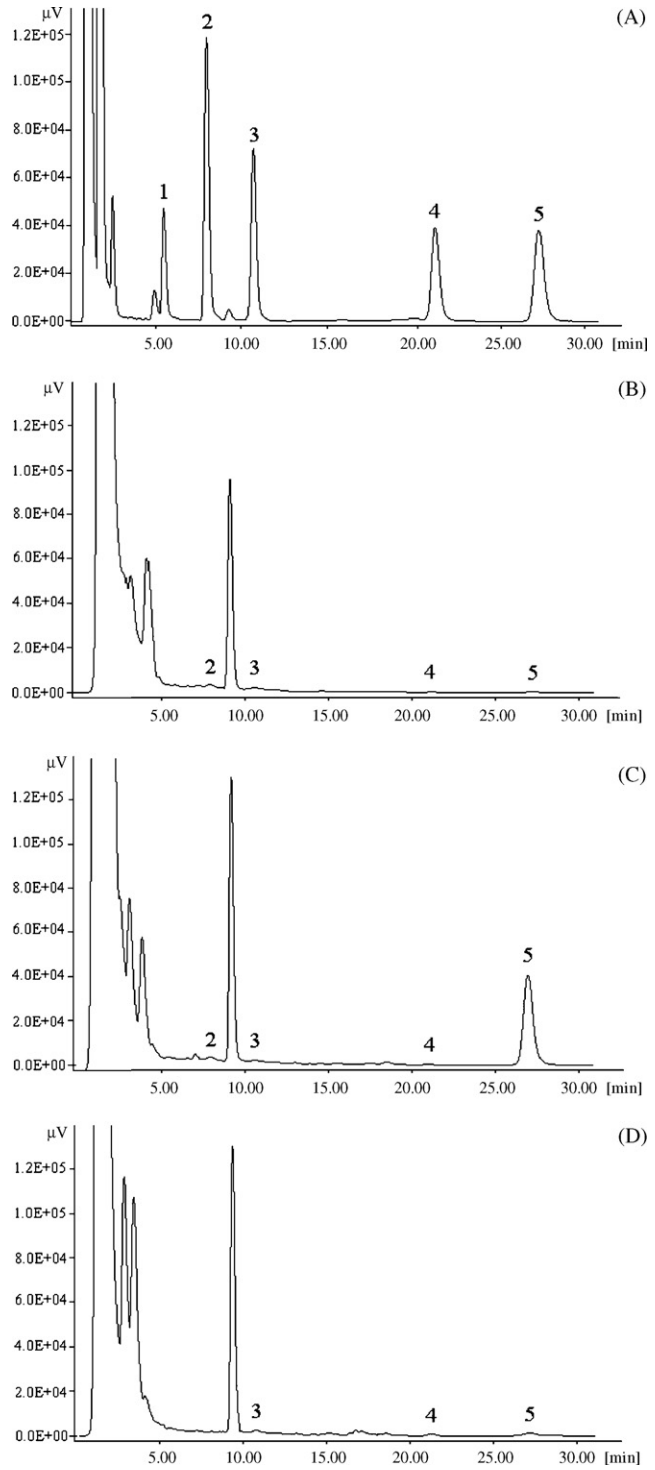

Fig. 7. HPLC chromatogram of (A) biogenic amines standard solution (5 mg L^{-1} each); (B) tomato ketchup; tomato ketchup spike with SPD at 5 mg L^{-1} level before (C) and after (D) extraction with AB18C6-MS sorbent. Peak identity: TRP (1), PUT (2), HIS (3), TYR (4), SPD (5).

3.5.6. Selectivity of the sorbent

Under the optimized conditions, the extraction of SPD is always higher than other biogenic amines. Therefore, based on the amount of biogenic amines remaining in the effluent solution, the distribution coefficient (K_d) and selectivity coefficient (k) was calculated [38]. From the K_d value, the selectivity coefficient of SPD over other biogenic amines can be calculated. The selectivity coefficients (k) of SPD over TRP, PUT, HIS and TYR when extracted using the AB18C6-MS sorbent were 48.6, 26.3, 48.6 and 150, respectively.

3.5.7. Capacity of sorbent

The capacity of the sorbents can be defined as the mmol of M^{n+} extracted/g of sorbent. As the concentration of SPD increases, the capacity also increases. The value of the capacity was found to depend on the initial concentration of SPD in solution, i.e., 1.6, 3.3, 16.7 and 33.4×10^{-3} mmol g^{-1} for 0.5, 1, 5 and 10 mg L^{-1}, respectively. The capacity of this sorbent is higher than those of the sorbents based on immobilized thia crown ethers ($3.8–26.8 \times 10^{-5}$ mmol g^{-1}) [39], but lower for some other researchers (e.g., 0.1–3.1 mmol g^{-1}) [31,40].

3.5.8. Extraction of SPD from food samples

In order to investigate the viability of the AB18C6-MS sorbent, five samples, namely tomato ketchup, soy sauce, cheese, fish sauce and canned tuna were used. To assess the matrix effect, two concentrations of SPD (1 and 5 mg L^{-1}) were spiked to the samples, and its concentration was later determined by the batch sorption method using AB18C6-MS sorbent. The results of the recoveries are shown in Table 4 while representative chromatograms of the standard solution and tomato ketchup samples are shown in Fig. 7. Over 88% of 1 mg L^{-1} spiked SPD was extracted using 10 mg of the sorbent (for cheese sample). However, as the amount of the spiked SPD increased to 5 mg L^{-1}, the percentage of extraction decreased to 71%. Thus, 30 mg of AB18C6-MS sorbent was further used to extract 5 mg L^{-1} of the spiked SPD. The high recoveries of SPD from the food matrices are good indicators that this method could be applied successfully for the determination of SPD in foods. Matrix components were effectively eliminated and only some of the interferences caused by by-products of derivatization reaction with dansyl chloride remained in the final extract. However, these peaks do not interfere with the analyte peaks.

The LOD and LOQ of the method were found to be 15.1 and 35.5 μg L^{-1}. This was carried out by subjecting standard SPD to the AB18C6-MS sorbent and the HPLC determination.

4. Conclusion

Three sorbent materials, namely A18C6-MS, DA18C6-MS and AB18C6-MS have been prepared by the chemical immobilization of the crown ether ligands onto mesoporous silica support. The sorbents have been evaluated for the extraction of five biogenic amines (TRP, PUT, HIS, TYR and SPD). Results obtained showed that all the sorbents exhibit highest selectively towards SPD. Among the sorbents, AB18C6-MS offers the higher extraction of SPD in the presence of other biogenic amines.

The applicability of the proposed method for the selective extraction of SPD was demonstrated by the reasonable recoveries attained (71.2–99.8%) when different food matrices were used. The sorbent also offer distinct advantages over the LLE technique as it does not require organic solvent during the extraction process. The studies further demonstrate that selective extractions can be realized by capitalizing on the host–guest interactions.

ABSTRACT

A new solid phase extraction method for separation and preconcentration of trace amounts of uranium, thorium, and zirconium in water samples is proposed. The procedure is based on the adsorption of U(VI), Th(IV) and Zr(IV) ions on a column of Amberlite XAD-2000 resin loaded with α-benzoin oxime prior to their simultaneous spectrophotometric determination with Arsenazo III using orthogonal signal correction partial least squares method. The enrichment factor for preconcentration of uranium, thorium, and zirconium was found to be 100. The detection limits for U(VI), Th(IV) and Zr(IV) were 0.50, 0.54, and 0.48 μg L^{-1}, respectively. The precision of the method, evaluated as the relative standard deviation obtained by analyzing a series of 10 replicates, was below 4% for all elements. The practical applicability of the developed sorbent was examined using synthetic seawater, natural waters and ceramic samples.

1. Introduction

Uranium and thorium find extensive application as nuclear fuel in power plants and their main sources are soil, rocks, plants, sand and water [1,2]. Uranium and thorium are known to cause acute toxicological effects for human and their compounds are potential occupational carcinogens [3]. These elements and compounds are highly toxic which cause progressive or irreversible renal injury. Zirconium is used in the nuclear industry as a fuel rod cladding, as a catalyst in organic reactions and, additionally, in the manufacture of water repellent textiles, in metal alloys and in dye pigments and ceramics [4,5]. Thus, there is a need for specific and precise determination of uranium, thorium, and zirconium traces in environmental and biological samples [6]. Flame atomic absorption spectrometry is an unfavorable method because of the difficult atomization of these elements [7]. The use of inductively coupled plasma atomic emission spectrometry and inductively coupled plasma mass spectrometry improve sensitivity but these methods are time-consuming and generally involve expensive instrumentation which is not available at all laboratories [8].

Spectrophotometric methods are most commonly used for the determination of uranium, thorium, and zirconium [9]. However, the simultaneous determination of uranium, thorium, and zirconium by traditional spectrophotometric techniques is difficult because, generally, the absorption spectra overlap in a bright region and the superimposed curves are not suitable for quantitative evaluation [10,11].

Under computer-controlled instrumentation, derivative techniques and multivariate calibration methods play a very important role in the multicomponent analysis of mixtures by ultraviolet (UV)/visible, molecular absorption spectrophotometry [12–14]. The application of quantitative chemometrics, particularly partial least squares (PLS), to multivariate chemical data is becoming more widespread owing to the availability of digitized spectroscopic data and commercial software for laboratory computers.

The theory and application of PLS in spectrometry have been discussed by several authors [15–21]. Several multicomponent determination of inorganic substances based on the application of these methods to spectrophotometric data has also been reported [22–30]. A particularly detailed study of multivariate calibration by PLS was carried out for the spectrophotometric determination of metals [31]. Orthogonal signal correction (OSC) was introduced by Wold et al. [32] to remove systematic variation from the response matrix (**X**) that is unrelated, or orthogonal, to the properly matrix (**Y**). Therefore, one can be certain that important information regarding the analyte is retained. Recently, multicomponent determinations based on the application of OSC-PLS method to spectrophotometric and voltammetric data have been published [29,33].
