In the United States in 1993, an approximate percent (75%) of the sold pesticides have been used in agriculture [30]. Government and industry have been used 18%, and home and garden consumption accounts for the remaining 7%. Industrial and commercial users consist of pest control operators, turf and sod producers, floral and scrub nurseries, railroads, highways, utility rights-of-way, and industrial plant site landscape management [31]. The U.S. estimated volume of the conventional pesticides in 1993 is shown in Fig. 6.

Many public health benefits have been gained from the use of synthetic pesticides, but in spite of the obvious advantages, the potential adverse impact on the environment and public health can be substantial. Once in the environment, contemporary pesticides are relatively labile and tend not to persist for long periods of time. However, with the widespread use of pesticides, it is virtually impossible to avoid exposure at some level. Due to the general population's exposure to pesticides, it is important to investigate the concentration levels of pesticides and their metabolites in samples from human origin [29,30].

Before the insidious effects of DDT on humans and wildlife were known, this potent nerve poison was widely used to control mosquitoes, black flies and other vectors that carry diseases such as malaria, typhus and yellow fever. Farmers also used it to control insect damage to their crops. In the 1950s and 1960s, DDT was embraced as a cheap, effective, broad spectrum chemical pesticide. It was used worldwide and applied generously and indiscriminately to communities and crops alike. It did the job, reducing the threat of malaria and the loss of income to the agriculture industry [24]. Residues of PCBs were found in all food samples analyzed. However, their concentrations were many times lower than the permissible limits in place in other countries [24].

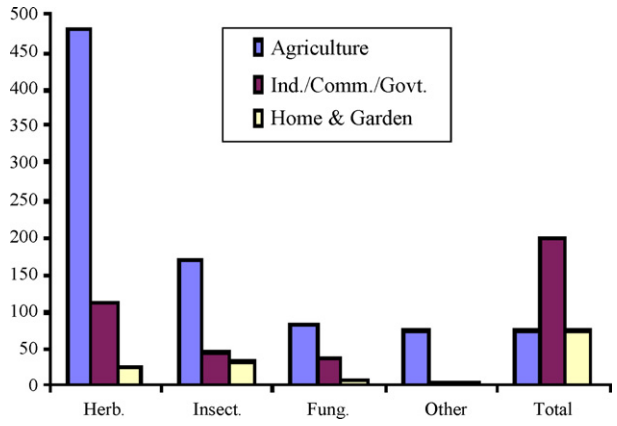

Fig. 6. The U.S. estimated volume for the conventional pesticides in 1993.

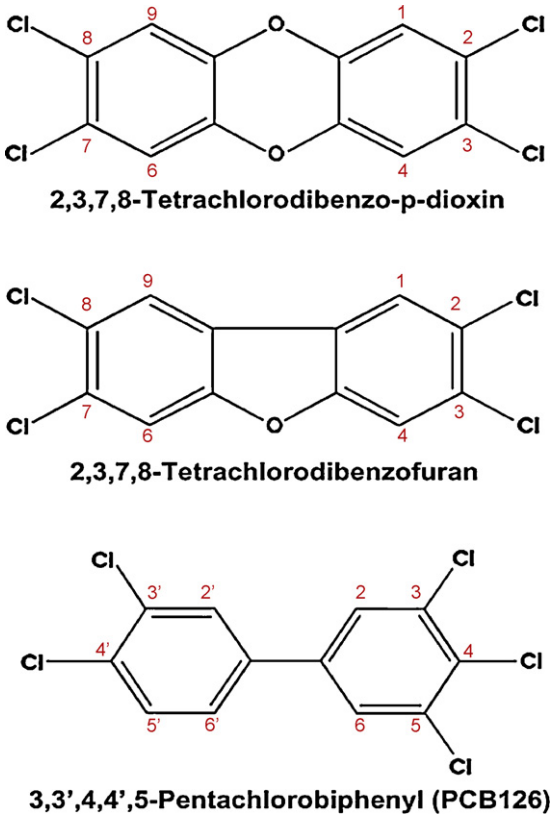

Fig. 7. Basic structures of the chlorinated dibenzo-p-dioxins (dioxins), chlorinated dibenzofurans (furans) and polychlorinated biphenyls (PCBs).

4.1.2. Industrial chemicals

First discovered as environmental pollutants in 1966, polychlorinated biphenyls (PCB compounds) have been found throughout the world in water, sediments, bird tissue, and fish tissue. These compounds constitute an important class of special wastes. PCBs are a class of chemical compounds in which 2–10 chlorine atoms are attached to the biphenyl molecule. Monochlorinated biphenyls (i.e., one chlorine atom attached to the biphenyl molecule) are often included when describing PCBs. The general chemical structure of chlorinated biphenyls is shown in Fig. 7. Theoretically, there are 209 different PCB congeners. Many of them are resistant to degradation, which allows them to persist in the environment for a long time and become widespread via atmospheric and water transport mechanisms [10,36,37].

PCBs are chemicals that were widely used in industrial processes from the 1930s until the late 1970s. Although their production ended in the late 1970s, the majority of the cumulative world production of PCBs are still in the environment. PCBs were used extensively in many industrial applications, including in fire-resistant transformers and insulating condensers. Prior to 1977, they were used as heat exchanger fluids, and in aluminium, copper, iron and steel manufacturing processing [37]. PCBs were also used as plasticizers, in natural and synthetic rubber products, as adhesives, insulating materials, flame retardant, lubricants in the treatment of wood, clothes, paper and asbestos, chemical stabilizers in paints, pigments and as dispersing agents in formulations of aluminium oxide. PCBs are often found both in the effluent and in the sludge of municipal wastewater. Since PCBs were widely used as dielectric fluids from the 1950s, they are present in transformers in several Brazilian cities, despite its prohibition in the 1980s [38,39].

Every year, over 6000 food samples from all over Poland are being analyzed to determine the contents of residues of pesticides,

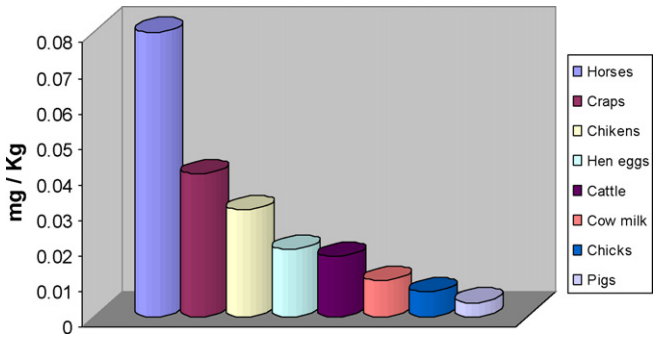

Fig. 8. Distribution of PCBs in food during the years 1995–1999.

polychlorinated biphenyls and other toxic substances in the fatty tissue of various animal species, cow milk and hen eggs. The results are summarized in the diagram given in Fig. 8. This diagram summarizes the results of research in the presence of PCBs in food during the years 1995–1999.

4.2. Unintentionally POPs

They were produced as unwanted by-products of combustion or chemical process that take places in the presence of chlorine compounds. They are divided into three types: polycyclic aromatic hydrocarbons (PAHs), dioxin and furan compounds.

4.2.1. Polycyclic aromatic hydrocarbons (PAHs)

The PAHs consist of two or more fused benzene rings in linear, angular or cluster arrangements, containing only carbon and hydrogen. The central molecular structure is held together by stable carbon–carbon bonds. The United States Environmental Protection Agency (EPA) listed 16 PAHs on a list of priority pollutants since they are considered either possible or probable human carcinogens. Hence, their distribution and the possibility of human exposure to them have been the focus of much attention. The PAHs have been detected in soil, air, and sediments as well as on various consumable products. They can occur naturally in the environment, mainly as a result of synthesis by plants or after forest and prairie fires. However, the greatest amounts of PAHs released into the environment are via anthropogenic processes like fossil fuel combustion and by-products of industrial processing. Agricultural fires as well as cooking may also release PAHs. The distribution of PAHs found in the sediments can give information on precursor sources, that is, if they are pyrogenic or petrogenic [40–42].

4.2.2. Dioxins and dibenzofurans

Chlorinated dibenzo-*p*-dioxins (dioxins) have been of concern for decades because of their toxic properties, as described below. A structurally similar series of compounds, the chlorinated dibenzofurans (furans), have similar chemical properties and toxic effects, and are generally determined as a group with the dioxins. In recent years there has been a growing trend to include a specific subgroup of the polychlorinated biphenyls (PCBs): the so-called dioxin-like PCBs (DLPCBs). This has been added to methods along with the dioxins and furans. Fig. 8 shows the structures of 2,3,7,8-TCDD, 2,3,7,8-TCDF and PCB-126. It is commonly recognized that man-made sources and activities are far greater contributors to the environmental burden of polychlorinated dioxins (PCDDs) and dibenzo furans (PCDFs) than natural processes, especially since the 1930s, from which time there had been a steady increase in environmental levels coinciding with the large-scale production and use of chlorinated chemicals [42,43]. Man-made sources of PCDDs and PCDFs can be divided into three main categories: chemical processes, combustion processes and secondary sources [44]. Municipal waste incinerator, coal combustion, chemical waste incineration plant, clinical waste incinerator, landfill gas combustion, crematoria, animal carcass incinerator and cement manufacture are the main sources of PCDDs and PCDFs in Hong Kong [45]. The dioxins and furans, congeners with chlorine substitution at the 2, 3, 7 and 8 positions are considered toxic. Of the 75 possible dioxin and 135 possible furan structures, only 17 have 2,3,7,8-substitution. The carbon numbering system is marked next to each carbon to indicate substitution positions. Dioxin and furan congeners substituted in the 2, 3, 7 or 8 position are toxic, while PCBs substituted in the 3,3′,4,4′,5 or 5′ position and no or only one 2- or 2′-substitution are considered to be dioxin-like (Table 4). This class of compounds was found able to exhibit dioxin toxicity (see Table 4).

5. Properties of POPs

The behavior and fate of chemicals in the environment are determined by their chemical and physical properties and by the nature of the environment. The chemical and physical properties are determined by the structure of the molecule and the nature of the atoms present in the molecule. The properties of their physico-chemical characteristics that permit these compounds to occur either in vapour phase or adsorbed on atmospheric particles, thereby facilitating their long-range transport through the atmosphere. Some of these properties are: very low solubility, high lipid solubility since, these two properties leading to their bioaccumulation in tissues, high toxic compound, and semi-volatile enabling them to move long distance in the atmosphere before deposition [47,48].

POPs can be present as vapours in the atmosphere or are bound to the surface of solid (dust) particles (particles of soil, of water sediments, of ashes). They are transferred to the ground surface from the atmosphere either by the deposition of the flying ashes (dry deposition) or by rain that absorbs substances present in the gas phase and pulls solid particles (wet deposition). The solubility of most POPs in water is minimal. They are, however, easily captured on solid particles (dust, ash, soil, and sediments). They are also fairly soluble in organic fluids (oils, fats, and liquid fuels). This implies that the more solid particles and polluting organic liquids present in the water, the higher the probability of their higher POPs content [49].

In the atmosphere, POPs undergo a slow decomposition due to of the solar radiation (photolysis) in the presence of water humidity and of other organic and inorganic substances. Their persistence in the atmosphere depends on thermal and reaction conditions of the given place. This durability in the tropical atmosphere is a maximum several days for a number of POPs; however, this can stretch up to several years for the occurrence of the same compound in the polar atmosphere [50].

Their stability in the atmosphere results into their long-distance transport of thousands of kilometers. This allows their transport from locations, where a number of them, namely pesticides, are still in use in significant amounts (Africa, South America) to the proximity of the North Pole. This was confirmed by a number of measurements of their presence in the snow and in the ice around the North Pole, as well as in the North Sea organisms. As these substances have never been used in these polar areas, their presence there is a clear proof of their long-distance transport [7,47].

POPs are anthropogenic compounds that are possessing characteristics toxic, persistent, bioaccumulate (build up in fatty tissues in individual organisms). Also, POPs are prone to long-range transboundary atmospheric transport and deposition, are likely to cause significant adverse human health or environmental effects near to and distant from their sources and concentrate further, or biomagnify up food chain. POPs can be divided into three categories: pesticides such as: aldrin, endrin, merix and chlordane, industrial

chemicals such as: PCB, PCP and HCB, and unintentionally produced by-product like polycyclic aromatic hydrocarbons (PAHs), dioxins and furans compounds. Long-range transport via the atmosphere is the most likely source of these persistent organic pollutants in the Arctic. However, efforts to quantify the amount of POPs transported in this way and to determine source regions are quite limited. POPs have been associated with a number of environmental risks. These risks include oestrogenic effects, disruption of endocrine function with observed impairments of immune system function, generation of functional and physiological effects on reproduction capabilities and reduced survival and growth of offspring [26,51].

6. Dosage and toxicity of POPs

POPs so including are significant concern due to their potential toxicity and prevalence in arrangement of environmental media, even at remote geographical location. The ecotoxicological effects of POPs in the environment have caused much concern in recent years, and this has led to the control or complete ban on the use of these chemicals in many countries. Among the wide range of organic substances contaminating the aquatic environment a major concern has so far focused on PCBs and (OCPs). High persistence and biological degradation resistance of these toxic organic pollutants make them continue to be yet largely present in the marine environment. POPs are found not only in living organism as animals and plants, but also in humans [26,52].

Public concern about contamination by POPs increased recently because several of these compounds are identified as hormone disrupters which can alter normal function of endocrine and reproductive systems in humans and wildlife. There are many risks and effects of having these chemicals in our environment and none of them are a benefit to the earth. After these pollutants are put into the environment, they are able to stay in the system for decades causing problems such as cancer, birth defects, learning disabilities, immunological, behavioral, neurological and reproductive discrepancies in human and other animal species [52].

POPs contaminate food, water and accumulate in the food chain such as eagles, polar bears, killer whales and human being. There is evidence that many people worldwide may now carry enough POPs in their body fat where POPs accumulate to cause serious health effects, including illness and death. Laboratory investigations and environmental impact studies in the wild have implicated POPs in endocrine disruption, reproductive and immune dysfunction, neurobehavioral and disorder and cancer [53,49].

More recently some POPs have also been implicated in reduced immunity in infants and children, and the concomitant increase in infection, also with developmental abnormalities, neurobehavioral impairment and cancer and tumor induction or promotion. Some POPs are also being considered as potentially important risk factor in the etiology of human breast cancer by some authors [54]. Human exposure to POPs is carried through the food chain. Because the animals are subsisting in water contaminated with these pollutants, they are affected as well when the humans consume these animals, they have also consumed the pollutant which then is accumulated in the body [49].

Because children are still developing, they are much more susceptible to the effects of pollutants. Their developing cells are sensitive to contaminants and are more likely to be affected by exposure of POPs. The brain is apparently in the greatest concern because some studies have shown that children exposed to POPs during infancy had remarkably lower scores on assessments determining intelligence and ability to shut out distractions [19,55].

At a young POPs can have serious consequences side effects such any of the following: birth defects, certain cancer and tumors at multiple sites, immune system disorders, reproductive problems, reduced ability toward off diseases, stunted growth and permanent impairment of brain function, POPs are a suspected carcinogen, diseases such as endometriosis (a painful, chronic gynecological disorder in which uterine tissues are affected), increased incidence of diabetes and others and Neurobehavioral impairment including learning disorders, reduced performance on standard tests and changes in temperament [55]. Commonly used analytical methods

Table 5
Analytical methods for determination POPs in different matrices.

Methods	Analyte	Environmental matrix	References

GC/FID	HCB	Soil	[87]

for POPs monitoring and surveillance are summarized in Table 5. Numerous methods have been published over the past 30 years related to specific analytical techniques for the determination of PCBs and OCPs in food and environmental matrices.

7. Extraction and analytical techniques

Classical extraction techniques like liquid/liquid extraction and Soxhlet extraction are described in detail in the methods listed in Table 6. A number of alternative extraction techniques are summarized in Table 3. Supercritical fluid extraction (SFE) uses a gas above the critical point (the combination of temperature and pressure where the gas has liquid-like properties enabling enhanced extraction capability) to extract analytes from the matrix. The main advantage with SFE is that the extracting gas can be evaporated and so solvent disposal is not required. SFE behaves significantly differently to classical solvent extraction and recoveries can be reduced or enhanced. Pressurized liquid extraction (PLE), also known as accelerated solvent extraction (ASE) evolved from SFE. Solvents were added to SFE extractions as modifiers in order to mimic classical liquid extractions. SFE without extraction gas and only solvent modifier best matched classical extraction recoveries. This led to the development of PLE. Microwave-assisted extraction (MAE or MASE) uses closed vessels to increase pressure and extraction efficiency. Polar solvents like acetone or water are required to supply heat for extraction. San et al. [95] reported the analysis of wet samples by MAE, indicating that significant time was saved by the reduced sample drying requirements. Solid-phase extraction can significantly reduce analysis times and solvent usage for the extraction of water and wastewater samples, even with significant particulate loadings [95]. Particles collected on C18 extraction disks can be extracted quantitatively without Soxhlet or PLE extraction. Water samples have also been analyzed using semi-permeable membrane devices (SPMDs). SPMD sampling is a form of passive sampling that can be used for water, air or sediments [86,96].

Recently, Namiesnik et al. [97] have reviewed passive sampling techniques in environmental samples. Passive sampling is based on the free flow of analytes from the sampling medium to the collecting medium. This technique eliminates the requirement for power, and is a composite sampling procedure that can reduce analysis cost because of reduced sampling events and analyte loss during shipping and storage as the analyte is on a trapping medium. Swipe tests of biofilms on surfaces can also be used to monitor ambient conditions, especially after fires or from fugitive emissions.

8. Removal and/or minimization of POPs

Environmentally relevant polar persistent organic pollutants (pharmaceuticals and diagnostic agents) have been chosen according to human consumption and occurrence in the aquatic environment (sewage plant effluents, rivers and groundwater) to investigate their behavior during photo catalytic oxidation. From

Table 6
Extraction techniques of POPs in various matrices at different regions.

Sample matrix	Extraction technique.	Region/country	Analyte	References
Sediment	SE, LSE, LLE, SFE, MASE	Argentine, Singapore, China, Germany, Italy, Canada	PCBs, OCPs, PAHs, HCB, HCH, DDT, PBDEs, PCDD/Fs	[56,60,63,77,82,90,93,97,98]
Soil	SE, SPE, PLE, LLE, sonication	Singapore, Australia, Europe, Brazil, China	PAHs, OCPs, HCB, PCBs	[60,78,21,87,89,99,100]

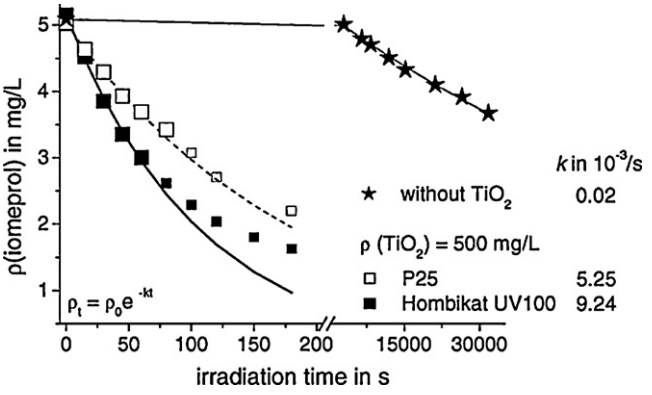

Fig. 9. Changes of iomeprol concentrations (2 mg L^{-1}, pH 6.5) during irradiation with and without suspended TiO_2 (Hombikat UV100 or P25 (TiO_2) = 0.5 mg L^{-1}).

the data compilation in the literature, the active metabolite clofibric acid of some lipid lowering agents, the antiepileptic drug carbamazepine and the X-ray contrast media imperils were selected. The degradation of the persistent pollutant was monitored by HPLC/DAD/FLD. The study has been focused also on the identification and quantification of possible degradation products by HPLC/DAD/FLD and HPLC/MS/MS. The degradation process has also been monitored the determination of sum parameters and inorganic ions. Various aromatic and aliphatic degradation products have been identified and quantified [104,105]. Since, the photochemical degradation (irradiation without TiO_2) of the persistent organic pollutants was studied [106]. It turned out to be negligible compared to their photocatalytic degradation. For example the photocatalytic degradation rate constant (k) of iomeprol with Hombikat UV100 was about 500 times higher than the photochemical degradation rate constant of iomeprol (Fig. 9). For the determination of the first order rate constant (k) only the concentration values with rt/r0—0.5 (large symbols) were used. The fitting was done by the least squares method [106]. Moreover, the stabilized nanoparticles of FeS have showed excellent degradation (over 94%) of lindane pesticide in its hexane extract to 1,2,4-trichlorobenzene or TCB, a key intermediate of lindane degradation pathway. The non-stabilized FeS could degrade merely 25% lindane in the same period clearly indicated that these nanoparticles catalyzed a rapid reductive dehalogenation reaction [107,108].

9. Conclusion

The determination of POPs in various matrices is characterized by instrumental complexity and highly cost. The electrochemical techniques in particular stripping analysis have no contribution on the analysis of such class of chemicals. Thus, the use of voltammetric techniques for the analysis of such class of compounds will provide an efficient and excellent alternative approach for the determination of POPs in different matrices because of its low cost, sensitively and selectivity for trace and ultra-trace concentration of the POPs in complicated matrices. However, further work is still continuing for the possible application of the on-line voltammetric stripping analysis of the pesticides in serum, routine and various environmental samples.

ABSTRACT

Porphyrins and metalloporphyrins fulfil a very important role in the metabolism of living organisms through biological pigments or biochromes and are therefore also employed in numerous applications in analytical chemistry. In flow-injection analysis the role of porphyrins and metalloporphyrins are centered as either that of analyte or that of a reagent or modifier in the determination of other species. This paper covers the attributes of porphyrin and metallophorphyrin complexes as enhancements in chemical analysis in flow-injection systems and points out the advantages and disadvantages in the implementation thereof.

1. Introduction

Porphyrins are a large class of natural occurring intensely colored, red or purple, macrocyclic pigmented compounds with the name originated from the ancient Greek word porphura that was used to describe the color purple (or royal purple) [1]. Porphyrins play a very important role in the metabolism of living organisms through biological pigments or biochromes that include plant and flower pigments. Through heme, an iron porphyrin, they are intimately associated with blood, and many of the redox enzymes involved in metabolic processes. Through chlorophyll, a reduced magnesium porphyrin, they orchestrate photosynthesis, without which life would be impossible [1]. The importance of porphyrins is not limited to their participation in oxygen transport as hemo proteins and essential biological photosynthetic activities alone. In fact they also do have valuable contributions and are applied in various fields, such as liquid crystalline materials [2] due to their remarkable electro-optical properties, measurements of oxygen *in vivo* using EPR techniques [3,4], photodynamic therapy [5,6], malaria treatment [7], molecular wires [8–11], light-energy conversion like solar cells [12–14] and fluorescence switches [15]. As a result porphyrins increasingly have found a place in numerous applications in chemical analysis [16] such as the design of electrochemical and optical sensors [17,18], modification of voltammetric electrodes [19,20], as spectrophotometric reagents [21–23], as

doi:10.1016/j.talanta.2009.10.016

stationary phases in HPLC [24,25] and as modifiers in open tubular electrochromatography [26].

The basic structure of the porphyrin molecule has in common a substituted aromatic macrocyclic ring consisting of four pyrrole-type rings linked together by four methine bridges [1,16,27] with an extensive system of delocalized π electrons that gave the highest degree of bond equalisation [4,28], and thus with an enhancement of the aromatic character and stability of the porphyrin ring system. Porphyrins can also be modified by adding different peripheral substitutes, incorporation of metal ions into the porphyrin ring, changing the central metal or expanding the size of the macromolecule [4]. Formation reactions of metalloporphyrins are very important processes from both analytical and bioinorganic points of view and therefore the large molar absorption coefficient (molar absorptivities of the order of 10^5 often found in the Soret band from 400 to 500 nm) and very high stability of metalloporphyrins (e.g. the stability constant for ZnTPP, TPP = tetraphenylporphyrin, is 10^{29} [27]) are very useful for the analysis of metal ions. A covalently linked porphyrin, 5,10,15,20-tetrakis(phenoxy acetic acid) porphyrin (PAAP), to Merrifield chloromethylated resin was used as sorbent for the separation and enrichment of the *d*-electron metals such as Mn(II), Co(II), Ni(II), Cu(II) and Zn(II) at pH 6–8 and of the *f*-electron metals such as U(VI) and Th(IV) at pH 4–5 with a concentration factor range of 115–215 [29]. However, a disadvantage is that the incorporation reaction of metal ions into the porphyrin ring is very slow with the rate of incorporation of metal ions typically around 10^9 times slower than that of the complex formation of metal ions with noncyclic ligands [30]. An account of this behavior has been given in a dynamic study of metal ion incorporation into porphyrins based on the dynamic characterization of metal ions and on sitting-atop complex formation [31]. To enhance the reaction rate, several procedures have been implemented. Acceleration of the rate of incorporation of the Fe(II) ion *in vivo* into the protoporphyrin IX is catalyzed by enzymes with the catalytic function of the enzyme proposed as the porphyrin distortion caused by steric and electronic interactions with amino acid residues at the enzyme active site. The incorporation of the fourth-row metal (II) ions, such as Mn(II), Cu(II), and Zn(II) ions are accelerated by the presence of a small amount of metal (II) ions having a larger ionic radius, such as Cd(II), Pb(II), and Hg(II) ions [31] and of metal ions incorporation into a cationic water-soluble porphyrin by 5-sulfo-8-quinolinol [32].

The systematic nomenclature of porphyrins, metalloporphyrins and related molecules is detailed by IUPAC [33] and a World Wide Web version [34], while Fisher numeration [33], trivial names [33] and abbreviations [16] are also found in literature.

Flow-injection analysis (FIA), introduced in 1975 [35], marked an important breakthrough in unsegmented automatic continuous flow analysis and has developed over three decades as a simple, convenient, feasible analytical technique with the capability of a high sample frequency and degree of automation [36–46]. FIA is an analytical technique that is based on injecting a known volume of sample, with a well-defined shape, into a moving, unidirectional unsegmented carrier or reagent stream (Fig. 1). In this moving stream, the sample is physically and chemically transformed into a detectable specie that causes a detector response downstream of the injection point. If all critical parameters (reproducible injection, controlled reaction time, and controlled dispersion) are held within certain tolerance levels, the result will be reproducible [36,40]. The basic instrumentation needed for an FIA system are a multichannel pump, an injection valve, a flow-through detector, and a signal output device (originally a recorder, lately a computer). With the establishment and advances inherent in FIA, the scope and potential of the technique caught the eyes of many analytical chemists and these features make the technique very suitable over the years for satisfying the increasing demand in various fields for control

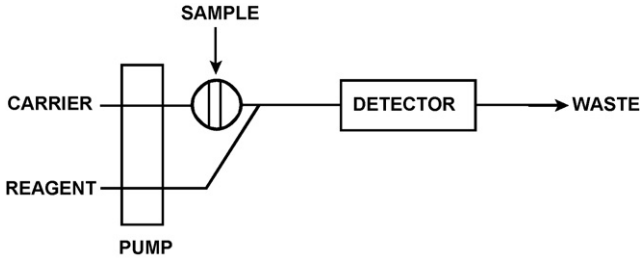

Fig. 1. Schematic diagram of a basic FIA system.

and routine analysis of analytical chemistry. With their pioneering innovation Ruzicka and Hansen [35] brought an entirely new concept to analytical chemistry by creating a concentration profile (gradient) of the sample, thus, allowing any point along the gradient to be used as a potential read-out, thus exploiting transient signals. As a result of this, the kinetic nature is one of the fundamental properties of FIA. Because of the inherent dynamic nature of FIA, measurements are always performed under non-equilibrium conditions, while the system is still in its kinetic phase; it is, therefore, properly classified as a kinetic system [36,41–50]. In addition to the reaction and/or dispersion rate, kinetic aspects of FIA can be further exploited by incorporation into the system strategies which rely on controlled kinetic processes such as catalysis, stopped-flow, rate of absorption and desorption, extraction, separation, diffusion of ions or gases through membranes or packed reactors, and enzymatic reactions [35,47–51].

There are basic two roles that porphyrins fulfilled in flow-injection analysis, that of an analyte or that of a reagent or modifier in the determination of other species.

2. Fast screening of porphyrins in biological samples

Although the fluorescence of metal-free porphyrins is most efficiently excited at the major absorption band, the Soret band, centered at about 400 nm with an UV light source, significant gain in selectivity can be achieved by performing fluorimetric excitation at one of the minor absorption bands located at the blue-green or yellow-red region of the visible spectrum since only a small number of organic substances present in biological materials actually absorb a photon efficiently and yield detectable fluorescence in these longer wavelength regions [52,53]. This information was used by Huie et al. [54] for the fast measurement of fluorescence from microtrace amounts of total porphyrins in biological fluids using FIA and visible laser fluorimetry. A high sample throughput was obtained by the fast sample introduction of diluted urine and serum samples without prior extraction directly into the FIA system. Urine and serum were diluted with 0.15 mol/l cetyltrimethylammonium bromide (CTAB) in a 0.01 mol/phosphate buffer at a pH 7.4 and the sample solutions were injected into a carrier stream of the same buffer. The fluorescence of the compounds was measured at an emission wavelength of ca. 620 nm with an excitation wavelength at 488 nm provided by an Argon-ion laser with a power of 1.0 W. The authors found that urine spiked with 0.02, 0.04 and 0.06 μmol/l of total porphyrin standard (corresponding to 0.15, 0.3 and 0.45 mg/l in undiluted urine) was clearly distinguishable from the urine blank; these concentrations representing the lower range for abnormal urine. With serum the limit of detection was around 0.015 μmol/l (ca. 0.05 mg/l in undiluted serum).

Lin and Huie [55] developed a flow-injection chemiluminescence (CL) method for the determination of porphyrins in biological fluids based on the reaction of bis-(2,4-dinitrophenyl) oxalate (DNPO) with H_2O_2 and porphyrin. The design of a proper detection flow-cell played a very important role in obtaining the highest

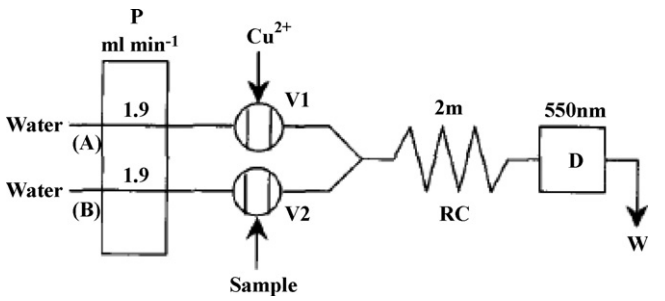

Fig. 2. Manifold used for determination of ascorbic acid with an FIA merging zone manifold. Reproduced from Ref. [56].

signal and this was achieved with a detection flow-cell that allowed the DNPO reagent to the carrier stream containing H_2O_2 and porphyrin at a position of approximately 1 cm from the detection window. The chemiluminescence emission was detected with a photomultiplier tube via a 570 nm cut-off filter. The effects of experimental parameters such as pH, solvents, flow-rate, and reagent concentrations on CL kinetics and intensity were investigated and optimized, resulting in optimum conditions with a flow-rate of 1.25 ml/min, concentrations of DNPO of 1.5 mmol/l and H_2O_2 of 3% and pH 6. Calibration graphs for porphyrins were linear up to 1000 μg/ml, recoveries for coproporphyrin from spiked urine were 97–98.2%, detection limit for urinary coproporphyrin was about 0.1 μg/l (S/N = 3) and the average precision was about 1.5%. The method was applied to determine coproporphyrin in urine samples from healthy adults.

3. Normal photometric detection

Tabata and Morita [56] used the accelerating catalytic effect of nanomolar levels of ascorbic acid on the formation rate of 5,10,15,20-tetrakis(1-methylpyridium-4-yl)porphyrincopper(II), $Cu^{II}(tmpyp)^{4+}$ with the subsequent increase in absorbance of the Cu(II) porphyrin to develop a simple, fast and sensitive flow-injection system for the determination of nanomolar amounts of ascorbic acid in tea, urine and blood. Ascorbic acid reduces Cu(II) to Cu(I) and the Cu(I) formed catalyzes the rate of incorporation of Cu(II) into the porphyrin core of H_2tmpyp^{4+} by deforming the porphyrin plane favorably for the attack of Cu(II) from underneath to form $Cu^{II}(tmpyp)^{4+}$. In this FIA procedure (Fig. 2) two solutions (each with a sample volume of 120 μl), one containing ascorbic acid and H_2tmpyp^{4+} and the other containing Cu(II) and acetate buffer (pH 5.0) were injected into two separate water carrier streams with equal flow rates of 1.9 ml/min. The two merging zones was allowed to react in a 2 m × 0.5 mm i.d. reaction coil and the colored solution of $Cu^{II}(tmpyp)^{4+}$ was monitored at 550 nm ($\varepsilon = 2.01 \times 10^4\,l\,mol^{-1}\,cm^{-1}$). The spectral changes during the course of the reaction were the disappearance of the characteristic absorption bands of H_2tmpyp^{4+} (Q bands at 520, 558 and 647 nm) and the growth of the characteristic band of $Cu^{II}(tmpyp)^{4+}$ (Q band at 550 nm). The isosbestic points were observed at 490, 534 and 577 nm. The change in absorbance was therefore monitored at 550 nm. The calibration graph was linear for 5.0×10^{-7} to 1.2×10^{-7} mol/l ascorbic acid and the RSD was 2.8% for the determination of 1.0×10^{-8} mol/l ascorbic acid. No detection limit or recoveries are given. Reducing agents such as sugars and vitamin B compounds did not interfere seriously.

The same concept was exploited by Lui and Itoh for the FIA kinetic determination of cysteine [57] in pharmaceutical injections and a permanent wave agent and ascorbic acid [58] in soft drinks by utilizing the catalytic complexation reaction of Cu(II) with 5,10,15,20-tetrakis(4-N-trimethyl-aminophenyl)porphyrin (TTMAPP). The absorbance increase belonging to the formed Cu(II)-TTMAPP was measured at the Soret band of 411 nm as the FIA signal for cysteine [57] as well as for the FIA system for ascorbic acid [58]. For cysteine [57] a RSD of 0.73% ($n = 10$) for 0.1 μg/ml cysteine at a throughput of $30\,h^{-1}$ was obtained, the detection limit (S/N = 3) was 15 ng/ml and the working dynamic range was 25 ng/ml to 1 μg/ml. Organic species like sugar, organic acids and amino acids could be tolerated at high concentration levels except for ascorbic acid that interfered seriously due to a similar catalytic effect. For ascorbic acid [58] a RSD of 0.11% ($n = 10$) for 0.1 μg/ml ascorbic acid at a throughput of $35\,h^{-1}$ was obtained, the detection limit (S/N = 3) was 5 ng/ml, broad dynamic range was 0.1–1000 μg/ml and at trace level between 20 and 100 ng/ml. Substances like amino acids, vitamins, sugars, organic acids and metal ions, showed no or little interference.

Merging zones FIA was also used for the spectrophotometric determination (absorbance of lead–porphyrin complex measured at 480 nm) of lead in tap water with 5,10,15,20-tetra (4-N-sulfoethylpyridinium)porphyrin [59], while a FIA system was also used for the differential-kinetic determination of lead in the soaking extract of pottery and porcelain, and human hair with *meso*-tetrakis (4-trimethylammoniumphenyl)porphyrin measuring the absorbance of the lead–porphyrin at 465 nm [60]. A kinetic method, based on the measurement of the absorbance due to the formation of Zn-*meso*-tetra(4-sulphophenyl)porphyrin(I) complex using imidazole(II) as catalyst, was also reported [61] for the determination of traces of Zn in hair, tap water and peach leaves.

The advances of water-soluble and difference in stability of metallo-water-soluble porphyrin complexes was used by Igarashi et al. [62] for the flow-injection spectrophotometric determination of ng/ml levels of cobalt(II). The cadmium(II) complex (CdL) of 5,10,15,20-tetrakis(4-sulfophenyl)porphine (TSPP) {Soret band: maximum wavelength (λ_{max}) = 432 nm, molar absorptivity ($\varepsilon = 4.8 \times 10^5\,l\,mol^{-1}\,cm^{-1}$} was found to be uniquely decomposed by irradiation with blue light around 432 nm. However, the cobalt complex of the same ligand ($\lambda_{max} = 432$ nm, $\varepsilon = 2.8 \times 10^5\,l\,mol^{-1}\,cm^{-1}$) was stable to visible light. The authors also confirmed that the composition of CdL and $Co^{III}L$ to be [M]:[L] = 1:1 by the mole ratio method. The authors used the photochemical properties mentioned above for the elimination of the absorbance blank of the chromogenic reagent CdL in the spectrophotometric detection of Co(II) following the exchange and oxidation reaction $CdL + Co^{2+} \rightarrow Co(III)L + Cd^{2+}$ for the FIA determination of cobalt(II) ions. A linear calibration graph was obtained in the range 1×10^{-7} to 1×10^{-6} mol/l, the detection limit (S/N = 3) was 3.45×10^{-8} mol/l (2 ng/ml) and the RSD ($n = 10$) for 6.8×10^{-7} mol/l cobalt was 0.6%. Mn(II), Cu(II), Zn(II) and Cr(II) interfered, masking agents for these metals were discussed.

The incorporation of the corresponding immobilized oxidase enzyme columns to yield hydrogen peroxide enhanced the selectivity of the respective FIA procedures for the corresponding compounds with spectrophotometric detection by a titanium(IV)–porphyrin reagent. Matsubara et al. [63,64] developed an acidic aqueous solution of oxo[5,10,15,20-tetra(4-pyridyl)porphyrinato]titanium(IV) complex, $[TiO(tpypH_4)^{4+}]$, (denoted as the Ti–TPyP reagent) as a highly sensitive spectrophotometric reagent for the determination of trace amounts of hydrogen peroxide. Following the addition of hydrogen peroxide to the Ti–TPyP reagent, the absorbance at 432 nm decreased and a new peak appeared at 450 nm (the Soret band) accompanied by the consumption of the $[TiO(tpypH_4)^{4+}]$ complex and the formation of the monoperoxo complex, $[TiO_2(tpypH_4)^{4+}]$ [65]. The degrees of the absorbance changes were found to be proportional to the hydrogen peroxide concentration with the apparent molar absorptivities of 1.9×10^5 (432 nm) and 1.1×10^5 (450 nm) $l\,mol^{-1}\,cm^1$. Both values are much larger than those obtained by conventional

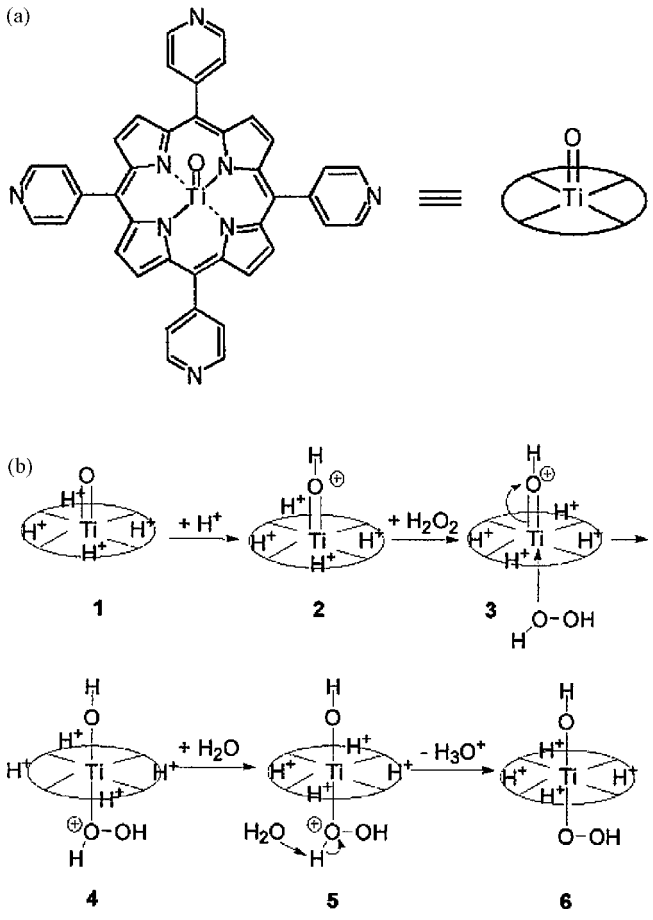

Fig. 3. (a) TiO(tpyp) complex and its simplified representation. (b) Proposed mechanism for the reaction of the $[TiO(tpypH_4)^{4+}]$ complex 1 with hydrogen peroxide under acidic conditions. Reproduced from Ref. [66].

analysis methods. However, a substantial account for the reaction specificity of the $[TiO(tpypH_4)^{4+}]$ complex to hydrogen peroxide should be quite important to secure the reliability of analysis using the Ti–TPyP reagent. Therefore, to ensure that the high specificity is free from the effects of interfering substances, Takamura et al. [66–68] studied the relationship between the $[TiO(tpypH_4)^{4+}]$ complex and hydrogen peroxide from the viewpoint of reaction mechanisms and theoretical calculations and reported a proposed mechanism (Fig. 3), in which assignment of the absorption peaks and the verification of the reaction mechanism (slightly revised) were made based on the spectral simulations [68]. Based on these facts, a FIA system was reported for the determination of hydrogen peroxide (Fig. 4) in rainwater [69], yielding a linear response from 10 nmol/l to 10 μmol/l for H_2O_2 (detection limit 5 nmol/l), with a coefficient of variation ($n = 10$) of 1% for 1 μmol/l of H_2O_2. The

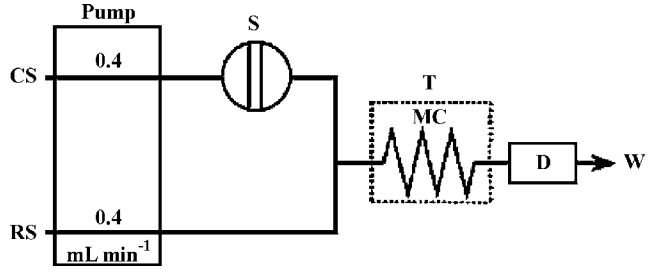

Fig. 4. Schematic diagram of the FIA system for the determination of hydrogen peroxide. Reproduced from Ref. [69].

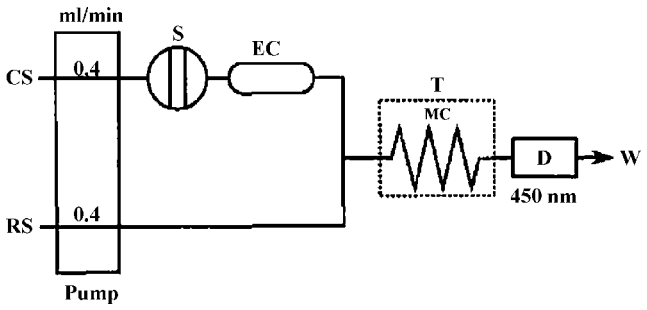

Fig. 5. Flow diagram for the determination of oxalate using an immobilized oxalate oxidase column reactor. Reproduced from Ref. [70].

same facts was used to develop also a rapid and sensitive FIA system for the spectrophotometric determination of oxalate in beverages, milled jelly, homogenized (details given in reference) fruit and vegetables using an immobilized oxidase reactor to yield hydrogen peroxide [70]. The flow-injection manifold comprised of a two-channel system with an immobilized oxalate oxidase column (Fig. 5). The calibration graph was linear between an oxalate concentration range of 5×10^{-7} and 2.5×10^{-4} mol/l ($r = 0.999$) with a sampling rate of 25 h^{-1}. The RSD was 0.48% ($n = 10$) at 2.5×10^{-5} mol/l (500 pmol/20 μl injection). The authors [71] used the same concept for the determination of trace components of physiological significance in human serum. The method was assessed for the determination of glucose, urate and galactose levels in human serum using the corresponding oxidase enzyme columns incorporated into the FIA system. Small sample volumes, 0.05 μl serum for glucose and 0.5 μl serum for urate, were used and the response was linear against concentrations ranging from 1 to about 1000 and 0.5 to about 600 μmol/l (5 to about 5000 and 2.5 to about 3000 pmol/test) for glucose respectively with a sample throughput of 40 samples per hour. No sample pretreatment such as deproteinization or preconcentration was necessary. For the determination of galactose in serum a 20 μl of deproteinized serum was, however, used. Response was linear for a galactose concentration range between 0.5 to about 500 μmol/l (10 to about 10 000 pmol/test).

Metalloporphyrins can also serve as modified artificial solid-catalysts in catalytic columns inside a FIA system for the determination of ascorbic acid [72]. In the FIA system (Fig. 6) a sample solution containing ascorbic acid is injected into an acetate buffer (pH 5.0) and oxidized in a pre-column, containing silica gels modified with Co-tetrakis(carboxyphenyl)porphine with the formation of hydrogen peroxide. The resulting hydrogen peroxide reacts with a chromogen solution containing phenol, 4-aminoantipyrine and borate buffer (pH 8.5) under catalyzed conditions in a main column, containing glass beads modified with Mn-tetrakis(carboxyphenyl)porphine to form a quinoid dye that was detected spectrophotometrically at 505 nm. The calibration graph was linear for ascorbic acid concentrations between 0.20 and 10.0 μmol/ml and the coefficient of variation ($n = 10$) was 4.1% for 8.0 μmol/ml. Ascorbic acid was determined in vitamin compounds and soft drinks and the results obtained compared favorably with an official phenol method.

Lead and cadmium from injected synthetic soil sample extracts and certified river water samples were separated by an in-line cation-exchange column with a carrier of malic acid, pH 5.5, as eluent solution in an FIA system before merging with TMPyP [5,10,15,20-tetrakis (N-methyl-pyridynium-4-yl)-21H,23H-porphine, tetrakis(*p*-toluenesulfonate)] in a basic medium (pH 10.1) to form water-soluble lead–TMPyP and cadmium–TMPyP complexes, respectively, before photometric detection at 476 nm [73]. The detection limits are 0.001 mg/l for

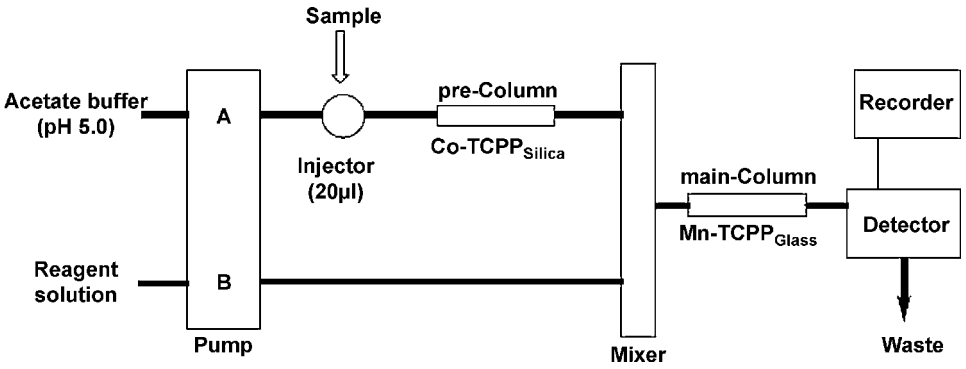

Fig. 6. FIA system for the determination of ascorbic acid. Reproduced from Ref. [72].

lead and 0.002 mg/l for cadmium. A novel indirect substitution spectrophotometric methodology using porphyrin was also developed [74] for the determination of some metals that do not react with porphyrin directly. This methodology was verified and further developed into an automatic procedure on a HPLC post-column FIA system that first separate the lanthanides before a multistep reaction system for the individual lanthanides is employed. The multistep reaction system consists of three complexation reactions that occur in sequence of EDTA with metal, EDTA with Cu(II) and porphyrin with Cu(II). The complexation reaction of Cu(II) with a cationic porphyrin, *meso*-tetrakis (4-N-trimethyl-aminophenyl)-porphine (ttmapp), which has a high molar absorptivity of about 5×10^5 l mol^{-1} cm^{-1}, serves for spectrophotometric detection as the signal from the absorbance decrease at 433 nm.

4. Multicomponent analysis with diode array detection

Metal ions of zinc, lead and cadmium frequently exist together in many real environmental and food samples and it is necessary to determine these metal ions simultaneously in most instances. Li et al. [75] developed a multicomponent analysis system with flow-injection diode array detection-absorption spectrophotometry using a partial least squares (PLS) calibration model for the simultaneous determination of zinc, cadmium and lead in a water standard reference material and samples of beverage, powdered corn and powder milk. The spectrophotometric determination is based on the reaction of the metallic ions and *meso*-tetra(4-trimethylammonium phenyl) porphyrin (TAPP) forming colored complexes. The overlapped spectra of these complexes are collected by charge coupled device (CCD)-diode array detector and the multi-wavelength absorbance data are processed using PLS algorithm. The results of environmental and food samples of the reported FIA method were in good agreement with a standard AAS procedure. Average spiked recoveries were 89.6–103.2% with an RSD of 2.8–7.1% at a sampling rate of 30 samples/h.

5. Waveguide optical metalloporphyrin-based sensors

Metalloporphyrin is not only useful as anion-selective ionophores, but can also be utilized as chromophores that exhibit optical changes upon binding with target anions. A very good example reported in literature is an optical chloride sensor based on a monomer–dimer equilibrium of indium(III) porphyrin where a hydroxo-bridged dimer of indium(III) octaethyl porphyrin, In(III)OEP, is broken into corresponding monomeric species as chloride replaces hydroxide as an axial ligand of the metalloporphyrin that results in a simultaneous optical shift of the Soret absorption band [76]. Scandium(III) porphyrins also form dimers that exhibit a hypsochromic shift of the Soret band from scandium(III) porphyrins [77]. These properties were used by the group of Meyerhof [78] to develop waveguide optical metalloporphyrin-based sensors with fast response times (1–2 s) towards solution phase chloride species in flow-through analytical systems like FIA. The sensors (Fig. 7) are based on the incorporation of In(III)OEP within ultrathin polymeric films (<0.5 µm) deposited via spin coating on a planar fused silica waveguide. In the FIA arrangement (Fig. 7 outlined in Ref. [78]) 50 µl sample solutions containing various levels of chloride prepared in 0.05 mol/l phosphate buffer (pH 3.0) were injected while the spectral change was recorded at 392 nm (dimer) and 408 nm (monomer) as well as 450 and 700 nm (background), simultaneously. The background shift originating from bubbles and osmolarity changes of sample solution [79,80] was corrected by using the absorbance changes at 450 and 700 nm. The response due to $[Cl^-] = 1.0 \times 10^{-3}$ mol/l for the FIA system was given. No calibration curve with chloride concentration range, no detection limit and no recoveries are given. A disadvantage is the leaching of membrane components that must be overcome to ensure more stable sensor response over longer time periods. The group of Meyerhof [81] reported also an optical fluoride sensor based on the monomer–dimer equilibrium of scandium(III)-octaethylporphyrin in a plasticized polymeric film for FIA measurements. Fast and reversible fluoride response over the range 10^{-4} to 10^{-2} mol/l was observed and the selectivity for fluoride over ClO_4^-, SCN^-, NO_3^-, Br^-, Cl^- is quite high. Only organic salicylate is a major interference.

6. On-line enrichment with FAAS/ICP-AES detection

Chelating of metal ions with porphyrin forms the bases for on-line enrichment FIA systems. The group of Pyrzynska investigated the suitability of 5,10,15,20-tetrakis(4-carboxyphenyl)porphine, TCPP, as a complexing agent for the on-line preconcentration of cadmium [82] and manganese [83] using an anion exchanger (Amberlite IRA-904) in a microcolumn. In the preconcentration

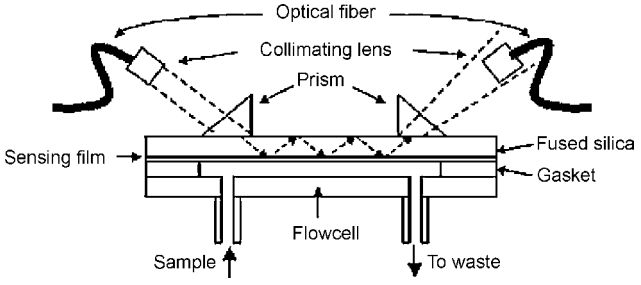

Fig. 7. Schematic diagram of the planar waveguide type optical sensor based on thin polymeric film containing In(III)[OEP] within the low volume flow-cell. Reproduced from Ref. [78].

step, a premixed cadmium [82] sample and TCPP solution, at 5×10^{-4} mol/l for TCPP in 0.05 mol/l borate buffer, pH 9, were pumped continuously through the manifold at a flow rate of 3.5 ml/min for 2 min. Cd–TCPP complex was retained on the microcolumn, and the sample matrix was sent to the waste system. A first injection valve was switched to its other position and a 2 mol/l nitric acid solution was injected by means of a second injection valve in order to release cadmium directly into the nebulizer of the spectrometer. Finally, a blank carrier (deionized water) was passed through the microcolumn for 30 s in order to condition it for the following sample introduction. A good precision (2.1% RSD for 40 μg/l cadmium) and a high enrichment factor (36) with detection limit (3σ) of 1.4 μg/l were obtained. The achieved analytical results for a standard reference material (SRM 1643d) were in good agreement with the certified values. In the preconcentration step for the determination of manganese [83], a 10^{-5} mol/l TCPP reagent was mixed on-line with an aqueous manganese sample solution and transported through the microcolumn packed with anion-exchange resin (Amberlite IRA-904) for 5 min. After the preconcentration step, the first injection valve was switched to its other position and a 0.5 ml of 2 mol/l nitric acid solution was injected by means of a second injected valve to release manganese directly into the nebulizer of the spectrometer. A good precision (2.2–3.1% RSD for 50 μg/l manganese) and good enrichment factor of 30 were obtained with a detection limit of 12 μg/l for a loading time of 5 min. Results obtained for the determination of manganese in natural water by the FI-FAAS system and ETAAS were in good agreement with differences between the results of the two methods not significant at the 5% level.

7. Luminescent detection with porphyrins

The use of metalloporphyrin complexes as a substitute for peroxidase has been applied in a number of analytical applications and various metalloporphyrins have been used as mimetic peroxidase in fluorescence and chemiluminescence analysis. Ci et al. [84] used the observation, that the catalytic activity of mimetic peroxidase (metalloporphyrin) in the chemiluminescence reaction between luminol and hydrogen peroxide is inhibited in the presence of an amino acid, to develop a FIA system for the detection of four amino acids. Only L-cysteine, L-tyrosine, L-tryptophan and L-cystine quenched the chemiluminescence intensity significantly giving detection limits (S/N = 3) of 6.8×10^{-8}, 1.3×10^{-7}, 8.5×10^{-6} and 2.2×10^{-5} mol/l, respectively. In a later publication Ci et al. [85] reported that the presence of DNA significantly enhanced the catalytic activity of the manganese *meso*-tetrakis(4-N-methylpyridinyl)porphyrin, Mn-TMPyP, on the luminol-H_2O_2 chemiluminescence reaction. They used a previously described [84] FIA chemiluminescence manifold for the determination of calf thymus DNA. A calibration graph was obtained between 20 and 200 ng/ml of DNA with a fixed concentration of Mn-TMPyP of 2×10^{-8} mol/l, the RSD ($n = 11$) was 2.6% at 10 ng/ml and the detection limit was 0.20 ng/ml. The on-line monitoring of NO complexed with porphyrin ring-bearing (PRB) materials using the chemiluminescence emission generated by the oxidation of luminol with H_2O_2 as detection system was employed [86] in a FIA manifold incorporating a UV-sensitive photomultiplier tube. The protein hemoglobin (Hb) and the enzymes horseradish peroxidase (HRP) and catalase (CAT) were used as PRB agents in complexes with NO. The method is quite sensitive, simple, rapid and precise with a sensitivity of 2.63×10^5 mV/mol NO, a range of 2.0×10^{-5} up to 1.0×10^{-2} mol NO (under the conditions used), a reproducibility of 1.0% over the range 1.0×10^{-3} up to 1.0×10^{-2} mol NO, a frequency of about five samples per minute and a detection limit of 1.0×10^{-5} mol NO.

Rana and Tamake [87–89] studied the formation of ferryl porphyrin, induced by the electrochemical reduction of iron(III)tetrakis-5,10,15,20-(N-methyl-4-pyridyl)porphyrin, Fe^{III}TMPyP, with FIA by measuring luminol chemiluminescence and recording the absorption spectrum. They found that both the anodic oxidation and cathodic reduction of iron(III) porphyrin induced the formation of a ferryl species, which is widely accepted to be responsible for stimulating luminol chemiluminescence. Emission was observed both below the reduction potential of Fe^{III}TMPyP (−0.08 V at pH 11, −0.02 V at pH 7 and 0.15 V at pH 3) and above the oxidation potential (0.6 V at pH 11, 0.75 V at pH 7 and 1.1 V at pH 3) [88,89]. The emission was relatively greater below the reduction potential than in the oxidative region. It was significantly higher especially at lower pH (<pH 4). The cathodic emission was largely dependent on the concentration of dissolved molecular oxygen while the anodic emission was not. Emission on both sides was inhibited significantly by the addition of alkene solutions downstream of the working electrode. The spectra on both the positive and negative potential sides were shifted to longer wavelengths (>424 nm) compared to the original spectrum of Fe^{III}TMPyP (422 nm). Computer analysis also showed that the spectra on both sides were perfectly reproduced by a combination of two spectra, those of Fe^{III}TMPyP and O = Fe^{IV}TMPyP (436 nm at pH 11). The authors [90] described a similar FIA chemiluminescence system for the detection of electrochemically generated H_2O_2 and ferryl porphyrin.

Vong et al. [91] developed a FIA system for the non-specific determination of iron–porphyrin-like complexes in natural waters that also allowed the direct injection of seawater with a detection limit of 0.11 nmol/l of equivalent hemin (Fe-protoporphyrin IX). Papkovsky et al. [92] reported a FIA system for the determination of sulfite based on the spectral-luminescent properties and quenching behavior of the covalent conjugate of the platinum(II) complex of coproporphyrin-I and bovine serum albumin (PtCP-BSA). The sensor membrane was excited with green light (535 nm) and the phosphorescence monitored at 650 nm.

8. Electrochemical detection involving porphyrins

Porphyrin-modified electrodes have received considerable attention in analytical and bioanalytical chemistry for the enhancement of selectivity in electrochemical detection of samples with complex matrices in biological fields. The group of Toma in Sao Paulo, Brazil [93–96] reported the properties and analytical application of a new polymetallic species containing four $[Ru(bipy)_2Cl]^+$ (bipy = 2,2′-bipyridine) groups coordinated to the pyridine residues of the *meso*-tetra(pyridyl)porphynate cobalt(III) complex in a series of publications. The electrochemistry of the polymetallated porphyrins is very rich owing to the presence of many electroactive groups in the supermolecules. It is well known that the complexes of ruthenium(II) 2,2′-bipyridine can be oxidized to the corresponding ruthenium(III) complexes, and each bipy ligand can be reduced by successive addition of electrons. Likewise, the porphyrin ring can either be oxidized or reduced generating the cation-radical and its corresponding dication, or the anion-radical and its corresponding dianion, respectively. The central metal ion is also electrochemically active. Araki et al. [93] reported, that in the range −1.8 to 1.6 V, it is possible to add up to twelve electrons and to remove up to four electrons from the tetraruthenated cobalt porphyrin complex, $[CoTPyP\{Ru^{II}(bipy)_2Cl\}_4]^{5+}$ complex (structure given in Ref. [93]). The cyclic voltammograms (given in Ref. [93]) of the tetraruthenated cobalt porphyrin, in DMF solution, exhibit an intense reversible wave at $E_{1/2} = 0.93$ V associated with the $Ru^{III/II}$ redox couple, and two irreversible cathodic waves at $E_{pc} = -1.37$

and −1.63 V, involving the stepwise reduction of the bipyridine ligands in each peripheral ruthenium complex. Three successive reductions of the cobalt porphyrin center were detected in the range between −0.5 and −0.7 V, using spectroelectrochemical techniques (given in Ref. [93]). The authors [93] also found that stable, homogeneous films of the polymetallic porphyrin was generated by dip-coating on to electrode surfaces, exhibiting pronounced electrochemical activity. They then successfully applied the modified electrodes as amperometric sensors in FIA systems for the determination of reducing analytes, such as nitrite and sulphite ions. A good linearity was obtained for nitrite in the range 2×10^{-7} to 8×10^{-7} mol/l with a slope of 0.48 A mol^{-1} cm^{-2} and for sulphite in the range 2×10^{-6} to 8×10^{-6} mol/l with a slope of 0.15 A mol^{-1} cm^{-2}.

Angnes et al. [94] employed modified electrodes with molecular films of the tetraruthenated cobalt–porphyrin complex in a FIA system for the determination of NADH and dopamine with amperometric detection. The electrochemical oxidation of these bioanalytes was monitored at the onset of the $Ru^{III/II}$ redox wave (E° = 0.70 V vs. Ag/AgCl), exhibiting a very sharp peak consistent with a rapid and efficient electron transfer process. Flow amperometric responses of glassy carbon electrodes modified with tetraruthenated cobalt porphyrin, at E = 0.85 V, to consecutive injections of NADH revealed a linearity between 2×10^{-6} and 8×10^{-6} mol/l with a slope of 0.114 and for amperometric responses of glassy carbon electrodes modified with tetraruthenated cobalt porphyrin, at E = 0.9 V, to consecutive injections of dopamine a linearity between 2×10^{-7} and 8×10^{-7} mol/l with a slope of 0.219. Azevedo et al. [95] reported a method for the determination of sulfur dioxide in wines by gas-diffusion flow-injection analysis utilizing modified electrodes with electrostatically assembled films of tetraruthenated porphyrin. The amperometric measurements were done using an applied potential of +0.90 V (vs. $Ag/AgCl_{KCl}$). The FIA system was implemented for the determination of free SO_2 (12.0–44.7 mol/l) and total SO_2 (62.6–83.7 mol/l) in wines with a typical frequency of injection of 30 injections/h. The RSD was 1.9% (i = 750.9 ± 14.3 nA) obtained for repetitive injections of a 1×10^{-3} mol/l sulfite solution (n = 10). The results demonstrate a good accuracy, comparable with those obtained using the conventional method. In addition, the method can be readily applied to red, white and rose wines, other compounds in wine do not interfere, it consumes small amounts of sample and is faster than the iodometric method. The continuous use of the same sensor indicates a small decrease (14%) on the signal after 5 days of use.

The modification of a glassy carbon surface by coating with an electrostatically assembled film of tetraruthenated cobalt porphyrin/*meso*-tetra(4-sulphonatephenyl) porphyrinate zinc(II) yields an indicator electrode that allows the determination of nitrite to be performed with a limit of detection of 0.1 μmol/l in a flow-injection configuration [96] with amperometric detection. The dynamic range extended up to 1000 μmol/l, the RSD (n = 20) was 1.5% for 5 μmol/l nitrite solutions and the analytical frequency was 50 samples/h. The efficiency of the bilayered film to mediate the electron transfer allows the determination to be performed at a less positive potential (+0.75 V) with enhanced sensitivity of about 15-fold current enhancement compared with results obtained with a bare electrode. The coating also prevents surface poisoning and its stability is maintained over several weeks. By incorporating a copper–cadmium reductor column into the FIA manifold, nitrate analysis was also achievable, both analytes being determined in several samples. Analytical characteristics for pure nitrate samples determinations were found to be a linear dynamic range of 5–100 μmol/l, an RSD (n = 20) of 1.5% and limit of detection of 1 μmol/l. The method was used for the determination of nitrate and nitrite in mineral water, saliva and cured meats and the results obtained were in good agreement with certified values and standard spectrophotometry.

Guerra et al. [97] described a FIA system for the determination of hydrazine using a carbon paste electrode modified with copper porphyrin occluded into a zeolite cavity. They used a sampling volume of 50 μl, applied potential of 270 mV vs. SCE and a flow rate of 1 ml/min. Operational range was between 5 and 60 μmol/l and the analytical frequency was 70 determinations/h. The recovery test carried out with the system presented good results; 97 ± 2% for a solution concentration of 5 μmol/l. The detection limit considering the signal to noise ratio as 3:1 was 1.0 μmol/l and the operational limit was 5.0 μmol/l. The authors reported that the system was stable for at least 3 months in continuous use and the response kept 76% of the initial response.

Li et al. [98] developed an amperometric biosensor based on the immobilization of acetylcholinesterase on a manganese(III) *meso*-tetraphenylporphyrin nanoparticles-modified glassy carbon electrode for the detection of trichlorfon, an organophosphate pesticide, with a FIA system. A wide linear inhibition response for trichlorfon was observed in the range of 1.0 nmol/l to 1.0 mmol/l corresponding to a 10–83% inhibition for acetylcholinesterase with a detection limit of 0.5 nmol/l.

Hassan et al. [99] described two novel potentiometric membrane sensors based on the use of manganese(III) porphyrin and cobalt(II) phthalocyanine ionophores dispersed in plasticized poly(vinyl chloride) PVC matrix membranes for the FIA determination of azide. The intrinsic characteristics of the manganese(III) porphyrin and cobalt(II) phthalocyanine-based detectors in a low dispersion manifold showed calibration slopes of −51.2 and −33.5 mV per decade for the concentration ranges of 1.0×10^{-5} to 1.0×10^{-2} and 1.0×10^{-4} to 1.0×10^{-2} mol/l azide and the detection limits are 1.0×10^{-5} and 3.1×10^{-5}, respectively. The detectors were used for the determination of azide in FIA at an input rate of 40–60 samples per hour. The responses of the sensors were stable within ±0.9 mV for at least 8 weeks and were pH independent in the range of 3.9–6.5.

9. Conclusions

The importance and successful implementation of rapid screening FIA systems for porphyrins in biological samples is marked by the efficiency with which metal-free porphyrins can be excited at the Soret band with measurement of fluorescence at an emission wavelength above 600 nm or the chemiluminescence reaction with detection of chemiluminescence emission with a photomultiplier tube via a 570 nm cut-off filter.

In normal photometric detection, the accelerating catalytic effect of ascorbic acid was applied to develop numerous simple, fast, sensitive and selective FIA systems with 5,10,15,20-tetrakis(macromolecular) methallated porphyrins as important part of the system. The solubility of porphyrins is a major drawback for employment in FIA systems, but the advances of water-soluble and difference in stability of metallo-water-soluble porphyrin complexes is clearly an asset.

The incorporation of the corresponding immobilized oxidase enzyme columns to yield hydrogen peroxide enhanced the selectivity of FIA procedures with the spectrophotometric detection with an oxo[5,10,15,20-tetra(4-pyridyl)porphinato] titanium(IV) complex and this FIA–Ti(IV)–porphyrin system was intensively studied in various papers and successfully implemented.

Porphyrins and metalloporphyrins also found a place in FIA systems for multicomponent analysis of metal ions with diode array detection-absorption spectrophotometry using PLS calibration for simultaneous determination in complex sample matrices,

as waveguide optical metalloporphyrin-based sensors, on-line enrichment with FAAS/ICP-AES detection and luminescent detection.

Porphyrin-modified electrodes have received considerable attention in analytical and bioanalytical chemistry for the enhancement of selectivity in electrochemical detection of samples with complex matrices in biological field. Although there were a number of successful applications of FIA-electrochemical detection systems, there is a large scope for improvement on validation with real samples.

Any new future exploitation of porphyrins lies in the way the characteristics of these macromolecules will be changed and adapted in multidisciplinary research and development to satisfy applications in process analytical technology (recently even more so for micro- and nanoprocess analytical technology) with roots in health sciences and energy sources. Of the current available variety of macromolecules, the colorful and other properties of porphyrins make it the most suitable for new developments of interdisciplinary significance. Looking at properties such as light-energy conversion in solar cells and fluorescence switches in the energy environment as well as photodynamic therapy and malaria treatment in health sciences a correct diversion of porphyrins structures for sure has a bright future. Among some of the disadvantages of porphyrins are the slow reaction rates for incorporation of species into the porphyrin ring and water solubility for process streams, but there are ways to change these properties to faster reaction rates by for example suitable catalysts and soluble substances by conversion to water-soluble salts. However, the low water solubility and stability are among some of the advances for use in electrochemical sensors.

Colloidal silver
Silver(I)

ABSTRACT

The increase in bacterial resistance to antibiotics has led to resurgence in the use of silver as a biocidal agent in applications ranging from washing machine additives to the drinking water treatment system on the International Space Station (ISS). However, growing concerns about the possible toxicity of colloidal silver to bacteria, aquatic organisms and humans have led to recently issued regulations by the US EPA and FDA regarding the usage of silver. As part of an ongoing project, we have developed a rapid, simple method for determining total silver, both ionic (silver(I)) and colloidal, in 0.1–1 mg/L aqueous samples, which spans the ISS potable water target of 0.3–0.5 mg/L (total silver) and meets the US EPA limit of 0.1 mg/L in drinking water. The method is based on colorimetric solid-phase extraction (C-SPE) and involves the extraction of silver(I) from water samples by passage through a solid-phase membrane impregnated with the colorimetric reagent DMABR (5-[4-(dimethylamino)benzylidene]rhodanine). Silver(I) exhaustively reacts with impregnated DMABR to form a colored compound, which is quantified using a handheld diffuse reflectance spectrophotometer. Total silver is determined by first passing the sample through a cartridge containing Oxone, which exhaustively oxidizes colloidal silver to dissolved silver(I). The method, which takes less than 2 min to complete and requires only ~1 mL of sample, has been validated through a series of tests, including a comparison with the ICP-MS analysis of a water sample from ISS that contained both silver(I) and colloidal silver. Potential earth-bound applications are also briefly discussed.

1. Introduction

The increased antibiotic resistance of many bacteria has led to a renewed interest in silver as a biocidal agent. Silver has been used for its antimicrobial properties at least since the ancient Romans used silver coins to treat drinking water [1]. Indeed, antimicrobial coatings of colloidal silver are present in a wide variety of applications, including deodorizing shoe inserts, washing machines, and wound dressings [1,2]. There are, however, risks associated with its use. High levels of silver are toxic to human cells, which can slow healing in the case of wound care. Other problems associated with silver include argyria, which is a condition characterized by a permanent blue-gray discoloration of the skin [3].

In light of these issues, the FDA ruled that over-the-counter products containing silver colloids or its salts are not generally recognized as safe for human use [2,4]. Moreover, the US EPA has been petitioned to regulate colloidal silver as a pesticide [5]. These dictates highlight the need for rapid, simple, field-deployable methods for determining colloidal silver concentrations in liquid samples. Test kits for the determination of silver(I) are available, most of which are based on colorimetric reagents that are "read-out" by a visual color matching of test strips or liquid samples. These methods, however, typically require large sample volumes (e.g., 10–100 mL), deliver only semi-quantitative results, and often use potentially hazardous, highly acidic reaction conditions [6–8]. Furthermore, none of these methods can be applied to the detection of colloidal silver.

This paper details the development and testing of a method capable of determining both colloidal and ionic silver (silver(I)) in water samples in under 2 min. Though clearly useful in many earth-bound applications, this method was created as part of an effort to monitor total silver concentrations in the potable water supply on the International Space Station (ISS), which employs electrolytically generated silver (i.e., colloidal silver and silver(I)) as a biocidal agent [9]. ISS documentation lists a target level for total silver of 0.3–0.5 mg/L to ensure effective biocidal activity while limiting exposure to ISS crewmembers [9]. At present, the approach to monitoring ISS water quality relies on samples returned to Earth for analysis by techniques like ICP-MS [10]. Unfortunately, the gap between sample collection and analysis can span several months, preventing the timely implementation of correction scenarios. The development of rapid, on-board methods for monitoring trace lev-

doi:10.1016/j.talanta.2009.09.056

els of critical components in spacecraft drinking water is therefore a priority for NASA. Importantly, these methods must have sufficient selectivity and sensitivity to detect analytes at low concentrations, be user-friendly, compact, lightweight, capable of operation in microgravity, and employ non-toxic materials. Recent reports from our laboratory have demonstrated that colorimetric solid-phase extraction (C-SPE) meets many of these requirements [11–26]. Indeed, a 6-month validation test of C-SPE on ISS (see below) is scheduled to begin before the end of 2009.

C-SPE typically involves the extraction of an analyte from a water sample by its passage through a solid-phase membrane impregnated with a colorimetric reagent. Using diffuse reflectance spectroscopy (DRS), quantification of the analyte after reaction with the colorimetric reagent is accomplished via a calibration plot of the Kubelka–Munk function [27,28]. The complete procedure usually requires less than 2 min per analysis. Note that impregnating the extraction membranes with colorimetric reagents eliminates the need to handle solvents and chemicals throughout sample workup, minimizing the exposure of crewmembers to hazardous materials. The use of a solid-phase extraction membrane also results in concentration factors on the order of 1000, leading to low limits of detection [29].

To date, our laboratory has developed C-SPE methods for the NASA-based biocides iodine (I_2) [11,20,30], silver(I) [12,20], the heavy metals nickel(II) [16,22], chromium(VI) [22], copper(II) [22], iron(III) [22], and formaldehyde [26]. We have also assessed the performance of C-SPE in microgravity flight simulations [15,20,23], which in tests to date have shown excellent agreement between flight and ground-based analyses of iodine and silver(I) [24,25].

The existing C-SPE method for silver(I) employs the colorimetric reagent DMABR (5-[4-(dimethylamino)benzylidene]rhodanine) [12,20], which is both sensitive and selective for silver(I), even in the presence of many common interferents [20]. However, as DMABR is unreactive to colloidal silver, we examined the use of an oxidizing agent as an additive to the collected water sample to exhaustively convert colloidal silver to silver(I). This paper presents the development and testing of a C-SPE method for determining the total silver content (i.e., colloidal silver and silver(I)) in drinking water using the well-known oxidizing agent Oxone.

Oxone, a potassium triple salt ($2KHSO_5 + KHSO_4 + K_2SO_4$), was selected for a number of reasons. It is: (1) readily dissolved in water, but very stable in powder form; (2) non-toxic, as evidenced by its popularity as an ingredient in denture cleansers and swimming pool disinfectant [31]; and (3) already approved for use on-board NASA spacecraft, being employed to pre-treat urine before its storage in the waste collection system [32]. The active ingredient in Oxone is potassium monopersulfate ($KHSO_5$), a neutralization salt of peroxymonosulfuric acid. Oxone solutions are slightly acidic, and are often buffered when used in cleansers to near-neutral pH by alkaline salts like sodium carbonate [31]. Our technique also uses sodium carbonate to raise the pH of the solution following oxidation of the silver. This step prevents Oxone from oxidizing, and hence decolorizing, the colorimetric reagent DMABR. The resulting C-SPE method determines the total concentration of colloidal and dissolved silver in the range of 0.1–1 mg/L in less than 2 min and, when combined with the existing C-SPE method for silver(I), provides the capability to determine colloidal silver in the presence of dissolved silver.

2. Experimental

2.1. Reagents

All solutions were made daily with deionized water prepared with Millipore Milli-Q water purification system.

2.1.1. Silver(I) sample solutions

Solutions with dissolved silver concentrations between 0.25 and 1.0 mg/L were prepared by diluting the appropriate mass of a 996 mg/L silver atomic absorption standard (Sigma–Aldrich) with deionized water.

2.1.2. Colloidal silver samples

Silver nanoparticle (20, 40, 60, and 80 nm in diameter) suspensions were purchased from Ted Pella at respective concentrations of 7.0×10^{11}, 9.0×10^{10}, 2.6×10^{10}, and 1.1×10^{10} particles/mL. These sizes were chosen to mimic the range found in ISS water, which is "silverized" by an electrolytic technique [10]. The actual concentration of silver, when converted to silver(I) in each suspension was determined by ICP-MS, and equaled (within 2.55% or less) 6.05, 5.91, 5.96, and 5.77 mg/L for the 20, 40, 60, and 80-nm particles, respectively. Colloidal silver samples were prepared by diluting either the 80 nm colloidal suspension or a mixture containing equal volumes of all four colloidal suspensions. The amount of silver, given as silver(I), in each sample solution was verified by ICP-MS.

2.1.3. Extraction cartridges

Two solutions were used for disk impregnation. The colorimetric reagent for silver(I) was prepared by dissolving 0.060 g DMABR (Aldrich) in 20 mL of dimethyl formamide in a 100 mL volumetric flask. After sonicating for ~5 min to dissolve DMABR, the solution was brought to volume using methanol. A second solution was prepared by pipetting 3.0 g of Brij 30 surfactant (Aldrich) into a Nalgene bottle and bringing the total mass to 100 g with deionized water.

These solutions were used to impregnate 3M Empore SDB-XC (polystyrene-divinylbenzene) 47 mm extraction membranes. Each membrane was placed into an all-glass filter holder assembly (Millipore), and 10.0 mL of the DMABR solution was pipetted into the funnel. Using a vacuum pump, a pressure differential of ~1 in. of Hg was applied to drive the solution through the membrane. After the DMABR solution had passed through the membrane, the pressure differential was maintained for another 10 s to remove residual liquid. The vacuum was then removed, the funnel on the glass filter holder was replaced with a second funnel, and 5.0 mL of the Brij 30 solution was added via a pipette. A vacuum-derived pressure difference of ~3.5 in. Hg was applied to pass the Brij 30 solution through the membrane. This pressure differential was subsequently increased to ~20 in. Hg for 30 s to dry the membrane. The addition of Brij 30 markedly enhances the uptake of water by the membrane, which we believe creates a microenvironment conducive to the rapid reaction of silver(I) with impregnated DMABR; there is no detectable complexation in the absence of this additive [12].

After impregnation, the membranes were fully dried by storage in the dark for ~16 h, cut into 13 mm disks, and placed on the support screen in the bottom portion of a Swinnex polypropylene filter holder (Millipore). The holder was assembled by sealing against a silicone gasket (11 mm inner diameter), which also defines the area of the disk exposed to the water sample.

2.1.4. Oxone cartridges

Oxidant-impregnated disks were prepared by pipetting a 1.0 mL aliquot of 300 mg/mL Oxone (Aldrich) in deionized water onto a 47 mm diameter glass fiber filter (Millipore). These filters were dried in an oven at 110 °C for ~1 h before being cut into 13 mm disks and loaded into Swinnex filter holders as described in Section 2.1.3. These holders contained ~25 mg Oxone.

2.1.5. Sodium carbonate cartridges

A 2.0 mL aliquot of 200 mg/mL sodium carbonate in deionized water was pipetted onto a 45 mm diameter media pad (Millipore) in a Petri dish. The pad was heated for ~20 min (110 °C) until excess

liquid had evaporated, leaving a saturated pad, and then cut into 9 mm disks. These disks, which contained ~16 mg sodium carbonate, were dried again at 110 °C for ~2 h, and then loaded into Swinnex filter holders.

2.2. Instrumentation

A BYK-Gardner color-guide sphere (d/8°) diffuse reflectance spectrophotometer (Model LCB-6830) was used to analyze the disks. This handheld spectrophotometer is small, lightweight, and battery-powered, and can collect reflectance data from 400 to 700 nm in 20 nm intervals in under 2 s [15]. The diffuse reflection spectra were used to calculate the Kubelka–Munk function ($F(R)$), which is given by Eq. (1) [27]:

$$F(R) = \frac{(1-R)^2}{2R} \quad (1)$$

where R is the diffuse reflectance measured relative to a reflectance standard. Note that the $F(R)$ at a given wavelength is directly related to the concentration of the complex in the membrane, C, by Eq. (2):

$$F(R) = \frac{2.303\varepsilon C}{s} \quad (2)$$

where ε is the molar absorptivity of the colorimetric product and s is the scattering coefficient of the sample surface, both of which are assumed constants [28].

3. Results and discussion

3.1. Overview of C-SPE method for silver(I)

Fig. 1a summarizes key components of the existing C-SPE method for silver(I). In Step 1, a 1.0 mL aqueous sample is collected in a 1 mL polypropylene syringe and passed through an extraction cartridge containing a DMABR reagent disk in Step 2. A second syringe is then used to pass ~60 mL of air through the cartridge to dry the disk. The cartridge is opened and the diffuse reflection spectrum of the reagent disk is acquired in Step 3.

Representative DRS data for the C-SPE analysis of silver(I) are presented in Fig. 1b. The reflectance at 580 nm is used to calculate $F(R)$ which, when used to prepare a calibration plot, yields a detection limit of 0.1 mg/L silver(I). Earlier tests of this method, which included interference studies, validated its effectiveness in measuring silver(I) levels in a wide range of ISS water samples [12,20].

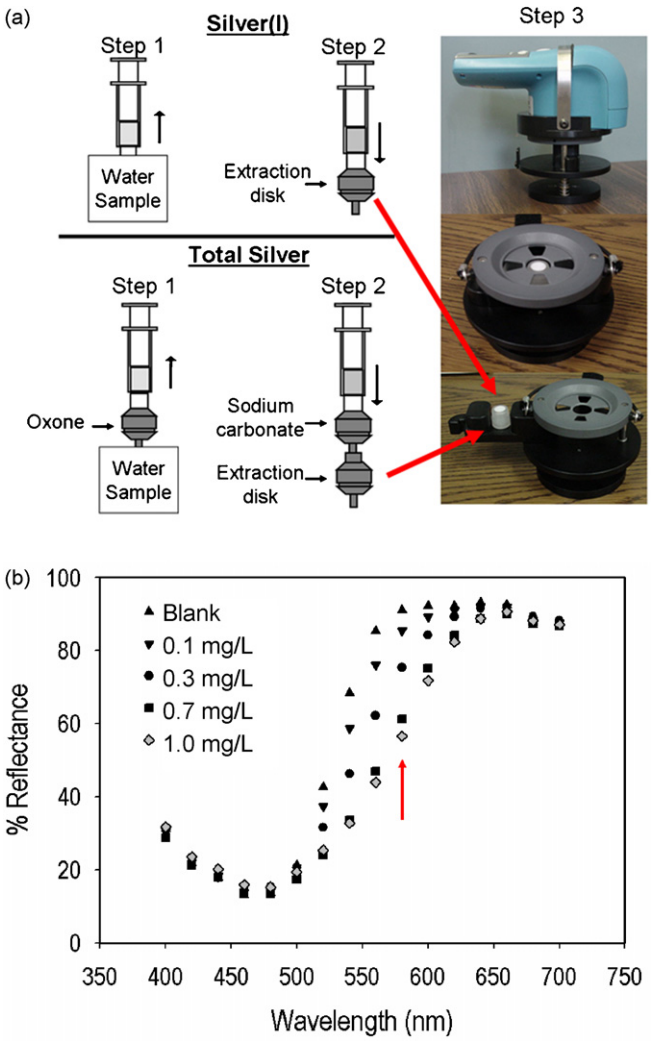

Fig. 1. (a) Schematic of the procedures for determining silver(I) and total silver by C-SPE. For both methods, Step 1 is sample collection, Step 2 is analyte extraction, and Step 3 is membrane interrogation using the handheld DRS instrument and sample holder. (b) Representative DRS data from an analysis of silver(I). The $F(R)$ value calculated from the reflectance at 580 nm is used for analyte quantification.

3.2. Assessment of Oxone as an oxidizing agent

To determine the efficiency of Oxone as an oxidizing agent for colloidal silver, various amounts of this reagent were added to separate suspensions (1.0 mL) of 0.57 mg/L colloidal silver (80 nm). After stirring, the reaction was allowed to proceed for 1 h, and the concentration of silver(I) was determined by C-SPE and ICP-MS. These results indicated that the optimum amount of Oxone needed to exhaustively convert colloidal silver to silver(I) is ~6 mg/mL. Moreover, higher levels of Oxone induced a rapid fading of impregnated DMABR from orange-yellow to white.

To determine the time required for Oxone to dissolve colloidal silver, a second set of the same test suspensions was prepared, vigorously mixed with Oxone (~6 mg) for 20 s, allowed to react for different lengths of time, and analyzed by C-SPE. The results, plotted in Fig. 2, indicate that the method requires ~1 h to fully dissolve the collected particles in the suspension, which is not only much too long in view of the time demands of crew members on ISS but also likely to be problematic for field-deployment on earth.

As mentioned, Oxone solutions are slightly acidic and often modified with alkaline salts to maintain a neutral pH. One example

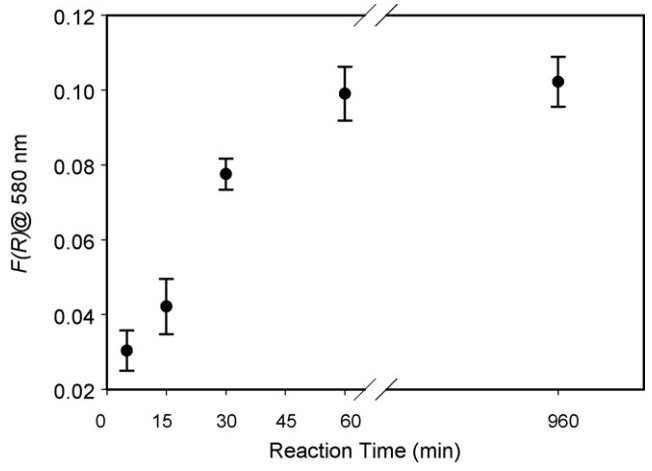

Fig. 2. Plot of KM function ($n = 3$) vs. reaction time for the C-SPE determination of total silver using ~6 mg/mL Oxone as an oxidizing agent and a sample containing 80 nm colloidal silver at a concentration of 0.57 mg/L.

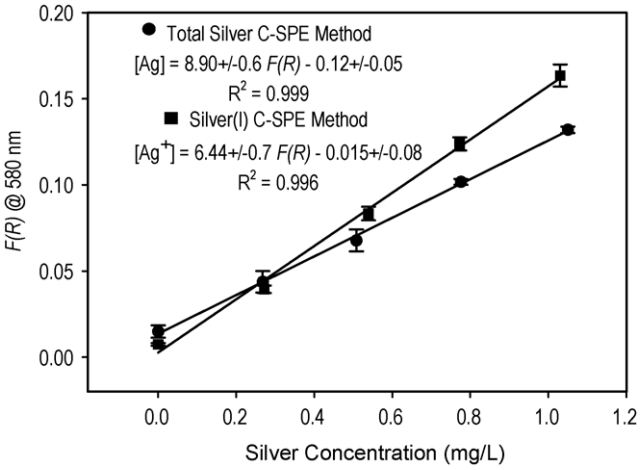

Fig. 3. Calibration plot of the C-SPE method for total silver, which uses ~25 mg/mL Oxone as an oxidizing agent and sodium carbonate to neutralize the excess Oxone before the extraction step. A calibration plot for the silver(I) C-SPE method is provided for comparison. Each plot was generated by carrying out the corresponding procedure in triplicate on samples prepared by diluting a silver atomic absorption standard. The uncertainties in the coefficients represent 95% confidence intervals.

mixes sodium carbonate and Oxone in a 1:4 mass ratio to create a pool disinfectant at neutral pH [31]. Initial tests of the effectiveness of combining sodium carbonate and Oxone (using another set of the same colloidal suspensions) showed that: (1) much higher concentrations of Oxone can be employed without any visible deterioration of the impregnated DMABR and (2) the conversion rate of colloidal silver to silver(I) increased with the Oxone concentration.

We also found that adding sodium carbonate before the Oxone notably reduced the amount of silver(I) produced at short reaction times. This situation can be explained by the fact that Oxone relies on peracid chemistry for colloidal silver oxidation, and therefore has a strong pH dependence, as shown by the reaction in Eq. (3) [31]. As such, sodium carbonate affects the sample in two ways. It neutralizes the hydrogen ions in the sample and decreases the oxidation strength of residual Oxone, both of which affect the color of impregnated DMABR.

$$HSO_5^- + 2H^+ + 2e^- \rightarrow HSO_4^- + H_2O, \quad E^\circ = +1.85\,V\,(NHE) \qquad (3)$$

3.3. C-SPE method for total silver using Oxone and sodium carbonate

Based on these initial assessments, a procedure for the C-SPE determination of total silver using the Oxone/sodium carbonate method, illustrated in Fig. 1a, was developed and tested. In Step 1, an Oxone cartridge is connected to a 3 mL Luer Lock polypropylene syringe and an aqueous sample containing colloidal silver is drawn into the syringe, passing through the cartridge and dissolving the ~25 mg of Oxone. Roughly 1.1 mL of sample is pulled into the syringe, along with air (~1 mL) from the dead volume of the cartridge. The Oxone cartridge is removed and the syringe capped and shaken by hand for ~20 s. The air and excess liquid are then expelled from the syringe to yield a 1.0 mL sample volume. In Step 2, the metered sample is passed through a sodium carbonate cartridge and then an extraction cartridge. These two cartridges are connected in series. Next, the sample syringe is separated from the cartridge assembly and replaced by a 60 mL syringe. About 60 mL of air are passed through the two-cartridge assembly to drive any sample remaining in the cartridge through the extraction disk and to dry the disk. Finally, the holder is disassembled and the diffuse reflectance spectrum of the reagent disk is acquired. The entire process requires less than 2 min to complete.

Table 1
Validation data of the C-SPE method for total silver using colloid silver suspensions. The three colloidal silver samples were prepared by mixing equal volumes of the 20, 40, 60, and 80 nm silver colloid solutions (such that each particle size accounts for ~25% of the total silver concentration) and diluting with deionized water.

Colloidal sample[a]	Total silver concentration (mg/L) by ICP-MS	Total silver concentration (mg/L) by C-SPE
1	0.95 ± 0.05	1.03 ± 0.09
2	0.42 ± 0.02	0.42 ± 0.01
3	0.12 ± 0.01	0.12 ± 0.01

[a] See Section 3.3 for additional information on sample preparation.

The calibration plot shown in Fig. 3 was obtained by performing this procedure in triplicate on solutions containing silver(I) at concentrations from 0 to 1.0 mg/L. For comparison, a plot of the response obtained from the C-SPE method for silver(I) (i.e., no Oxone or sodium carbonate) over this concentration range is also presented. The small differences between the two plots are an indication of the effects of Oxone and sodium carbonate on the membranes (see below). In spite of the slight deviation, the new method gives a linear response over the concentration range of importance to NASA, with a calculated limit of detection (using three times the standard deviation of the blank) of 0.1 mg/L silver. This value is comparable to the LOD of our silver(I) method (0.06 mg/L silver(I)), and is at the EPA limit set for silver(I) levels in drinking water.

To evaluate the developed method for use with samples containing colloidal silver, three samples were created by first mixing 2.0 mL aliquots of each silver colloid suspension (20, 40, 60, and 80 nm), and diluting the mixture with deionized water to give three sample solutions with approximate concentrations of 1, 0.5, and 0.15 mg/L silver. These samples were analyzed by ICP-MS and by the total silver C-SPE method. Using the calibration plot in Fig. 3, the concentration of total silver detected by C-SPE in each sample was calculated from the average $F(R)$ value at 580 nm ($n = 3$). As evident in Table 1, all the values given by the C-SPE method match those given by ICP-MS to within 10% (or better), demonstrating the validity of the new total silver method.

Interestingly, the data in Table 1 show that the error in the C-SPE measurement is the largest at the highest concentration of colloidal silver. Coupled with the deviation found in Fig. 3, we attribute this finding to the fact that samples with higher concentrations of colloidal silver reduce more of the Oxone present in the sample, leading to a relative excess of sodium carbonate. The result is a slight increase in the alkalinity of the sample, which causes a small change in the color of the membrane. This is a minor issue, however, since the accuracy of these determinations is on a level comparable to that for other C-SPE methods.

To assess the effect of colloidal silver on the analysis of silver(I) by C-SPE, suspensions containing 80-nm silver colloids at concentrations between 0 and 1.0 ppm Ag were analyzed by the C-SPE method for silver(I). The average $F(R)$ at 580-nm ($n = 3$) for all concentrations tested fell within two standard deviations of the $F(R)$ for the blank. Therefore, we can conclude that the presence of colloidal silver has a negligible effect on the silver(I)-sensitive membranes. These results indicate that C-SPE can be used to determine the concentration of colloidal silver in the presence of silver(I) by simply subtracting the concentration given by the silver(I) method from that given by the total silver method.

As a further validation of the C-SPE method for total silver, a sample of potable water from ISS, which was returned to Earth by the shuttle Endeavour (Mission STS-97) on December 11, 2000 and stored at ~5 °C, was analyzed by ICP-MS ($n = 10$) and by the silver(I) and total silver C-SPE methods ($n = 3$). The results of this analysis, presented in Table 2, demonstrate that (a) the total silver method can rapidly detect all of the silver present in the potable

Table 2

water supplies of ISS and (b) the combination of the silver(I) and total silver methods allows for the determination of colloidal silver in the presence of silver(I).

4. Conclusions

A rapid, simple method for reliably determining total silver has been developed. This method uses Oxone, a relatively safe and readily available oxidizing agent, to convert colloidal silver to silver(I), which is then detected using C-SPE. The entire procedure requires less than 2 min to complete, making this method an attractive option for a wide variety of applications. Moreover, by combining this new method with our C-SPE analysis of silver(I), colloidal silver concentrations can be determined in the presence of silver(I), thus enabling a rapid determination of silver speciation in aqueous samples.

This work has also presented preliminary data validating the potential utility of the total silver C-SPE method for determining the biocidal silver present in spacecraft water supplies. Present plans call for performance tests of this method in microgravity aboard NASA's C-9 aircraft, and we hope to report on results from an upcoming 6-month test on ISS of our C-SPE methods for biocidal silver and iodine in the near future. There is also considerable potential for earth-bound applications of this method, based on the widespread growth in the use of colloidal silver as a biocidal agent in recent years, particularly in view of the fact that this method is a viable alternative to the more expensive (ICP-MS) and less effective (test strip) methods currently available. Work to this end is also underway.

Seawater analysis

ABSTRACT

Two liquid-phase microextraction procedures: single-drop microextraction (SDME) and dispersive liquid–liquid microextraction (DLLME), have been developed for the determination of several endocrine-disrupting phenols (EDPs) in seawaters, in combination with high-performance liquid chromatography (HPLC) with UV detection. The EDPs studied were bisphenol-A, 4-cumylphenol, 4-tertbutylphenol, 4-octylphenol and 4-*n*-nonylphenol. The optimized SDME method used 2.5 μL of decanol suspended at the tip of a micro-syringe immersed in 5 mL of seawater sample, and 60 min for the extraction time. The performance of the SDME is characterized for average relative recoveries of 102 ± 11%, precision values (RSD) < 9.4% (spiked level of 50 ng mL^{-1}), and detection limits between 4 and 9 ng mL^{-1}. The optimized DLLME method used 150 μL of a mixture acetonitrile:decanol (ratio 15.7, v/v), which is quickly added to 5 mL of seawater sample, then subjected to vortex during 4 min and centrifuged at 2000 rpm for another 5 min. The performance of the DLLME is characterized for average relative recoveries of 98.7 ± 3.7%, precision values (RSD) < 7.2% (spiked level of 20 ng mL^{-1}), and detection limits between 0.2 and 1.6 ng mL^{-1}. The efficiencies of both methods have also been compared with spiked real seawater samples. The DLLME method has shown to be a more efficient approach for the determination of EDPs in seawater matrices, presenting enrichment factors ranging from 123 to 275, average relative recoveries of 110 ± 11%, and precision values (RSD) < 14%, when using a real seawaters (spiked level of 3.5 ng mL^{-1}).

1. Introduction

Several environmental contaminants, termed as endocrine disrupting chemicals (EDCs), can interfere with the function of the endocrine system in living organisms [1,2]. Chemical exposure to EDCs has been linked to neurological and reproductive effects on fish and wildlife [1,3], and may also affect human fertility [4]. These findings have raised public concern over their environmental and human health effects. Sewage treatment plants (STP) effluent outfalls constitute significant sources of EDCs to the receiving surface, coastal waters and regional environments [5,6], thus increasing the risk of exposure. Among the increasing list of substances classified as EDCs, an important attention has been paid to a selected group of endocrine-disrupting phenols (EDPs), alkylphenols (APs), including nonylphenol (NP) and bisphenol-A (BPA), due to their wide presence in household and industrial processes [5].

A number of analytical methods have been employed to determine EDPs in the aquatic environment, including drinking water, river water and wastewater [7–10]. Limited data are present in the literature about EDC determinations in marine water [11–13], due to the complexity of the salty matrix. Many conventional methods used to obtain quantitative extractions for APs are characterized as being labor-intensive and time-consuming, because in most cases derivatization and/or solvent-exchange steps are needed [6,13,14]. The conventional extraction methods are also hazardous to human health as they often use large amounts of organic solvents, which are known for being hazardous, flammable, and damaging to the environment. These disadvantages have been the basis of a trend to develop analytical methods aimed at eliminating, or at least minimizing, the organic solvent consumption in sample preparation [15]. Solid-phase microextraction (SPME) [16] and liquid-phase microextraction (LPME) [17,18] can be highlighted among them.

Single-drop microextraction (SDME) [18–20] is a liquid-phase microextraction technique which consists of the suspension of a drop of a solvent (typically few micro-liters of an organic solvent) at the tip of a micro-syringe. The drop, in which analytes suffer partitioning, is exposed to the sample, then retracted into the syringe and transferred to an appropriate analytical system. SDME can be conducted in headspace or in direct immersion mode, and it includes many advantages such as low cost and little sample and solvent consumption. It combines extraction, preconcentration and sample introduction in one step. In addition to this, the possibility of carry over between analyses is negligible.

doi:10.1016/j.talanta.2009.09.057

Dispersive liquid–liquid microextraction (DLLME) is another recent microextraction technique [21,22] which employs a mixture of a non-water-miscible extraction solvent and a water miscible polar disperser solvent. Analytes experience enrichment in the low volume of extraction solvent which is dispersed into the bulk aqueous solution, and separated by centrifugation. DLLME is a successful extraction technique due to the high contact surface of fine droplets of extraction solvent and analytes, which speeds up the mass transferring processes of analytes from aquatic phase to the extractant organic phase. DLLME presents characteristics of homogeneous liquid–liquid extraction and cloud-point extraction. Some advantages of DLLME are simplicity of operation, rapidity, low sample volume, low cost and high enrichment factor.

Main analytical applications of these two liquid-phase microextraction techniques, SDME and DLLME, have been conducted in combination with GC, HPLC and AAS [20–28].

The main purpose of this work was to carry out a comparison of the two liquid-phase microextraction techniques: single-drop microextraction and dispersive liquid–liquid microextraction, for the determination of a group of endocrine-disrupting phenols in seawaters close to a STP plant. To our knowledge, this is the first report in which both microextraction procedures are used in the analysis of this group of EDPs from seawaters.

2. Experimental

2.1. Reagents

The endocrine-disrupting phenols (EDPs) used in this study were bisphenol-A (BPA), 4-cumylphenol (4-CP), 4-tertbutylphenol (*t*-BP), 4-octylphenol (OP), and 4-*n*-nonylphenol (NP). They were all supplied by Sigma–Aldrich Chemie GmBH (Steinheim, Germany) except for NP, which was supplied by Alfa-Aesar (Karlsruhe, Germany). Individual standard solutions of these EDPs were prepared in acetonitrile of HPLC gradient quality (Merck, Darmstadt, Germany), with individual concentrations of 400 mg L^{-1}. Working standard solutions were prepared by adequate dilutions of these individual standards. 1-Decanol of 99% purity was obtained from Sigma–Aldrich.

Preparation of the artificial seawater was carried out by dissolving the following salts in 1 L of deionized water: NaF (3 mg), KBr (100 mg), $Na_2SiO_3{\cdot}9H_2O$ (20 mg), $SrCl_2{\cdot}H_2O$ (20 mg), KCl (3 mg), $MgCl_2{\cdot}6H_2O$ (10.780 g), $NaHCO_3$ (200 mg), H_3BO_3 (30 mg), $CaCl_2{\cdot}2H_2O$ (1.470 g) and NaCl (23.500 g) [29]. All of these pro-analysis salts were supplied by Merck. Deionized water was obtained from a Milli-Q gradient A10 system (Millipore, Watford, UK).

Real seawater samples came from two quite different sampling areas in Tenerife Island: the coasts of Candelaria and the surroundings of a petroleum refinery, where effluent waters are discharged from a STP. Amber glass bottles 100 mL in volume were used for sampling. Seawaters from Candelaria characteristically presented a content of 3.8 mg L^{-1} in suspended solids, a pH of 8.1, a content of dissolved oxygen of 8.0 mg L^{-1}, and a salinity value of 36.2 g L^{-1}. Seawaters close to the refinery had a variable content in terms of suspended solids, from 3.4 to 5.6 mg L^{-1}, salinity values, from 36.3 to 36.7 g L^{-1}, and dissolved oxygen, from 7.1 to 8.3 mg L^{-1} (depending on the sample location), and an average pH of 8.2.

Acetonitrile of gradient quality (Merck) and deionized water were used for HPLC analysis.

2.2. Instrumentation

The HPLC equipment consisted of a gradient system L-2130 Merck Hitachi Pump (supplied by Merck) and a Rheodyne valve (Supelco, Bellefonte, PA, USA) with a 20 μL loop. The detection of EDPs was carried out using a Waters Lambda Max 481 UV detector (Milford, MA, USA). The analytical column was a C18 Res Elut HPLC Column (5 μm, 150 mm × 4.6 mm) supplied by Varian (Harbor City, CA, USA), and protected by a Pelliguard LC-18 guard column (Supelco). Data were acquired with the Autoanalysis 2.4 software (Sciware, victor.cerda@uib.es). The HPLC method used for the separation and determination of the EDPs consists of a gradient elution procedure with a UV detector operating at 228 nm. For the mobile phase, a mixture of acetonitrile and water was used at a flow-rate of 1 mL min^{-1}. A linear gradient was employed from 50 to 80% of acetonitrile over 8 min, and then 80% of acetonitrile was maintained for 9 min.

A vortex model reax-control from Heidolph Instruments GmbH (Schwabach, Germany) and a centrifuge model EBA3 S from Hettich-Zentrifugen (Tuttlingen, Germany) were used in all DLLME experiments. A magnetic stirrer model Ikamag RCT basic (IKA Werke GmbH, Staufen, Germany) was used in all SDME experiments.

The Statgraphic (Statistical Graphics, Rockville) software package Version 5.1 was used for the statistical treatment.

2.3. Procedures

The syringe used for single-drop microextraction experiments, dispersive liquid–liquid microextraction experiments, and sample injection, was 25 μL in volume and from Hamilton (Bonaduz, Switzerland).

In SDME experiments, the vial was placed on the magnetic stirrer. The optimized technique is performed by suspending a 2.5 μL drop of decanol at the tip of the 25 μL micro-syringe immersed in the 5 mL of aqueous solution (7 mL vial) stirred at 100 rpm. The aqueous solution was a real seawater sample (spiked or not) or an artificial seawater sample (spiked). Following sample extraction, the magnetic stirrer was switched off and the drop was withdrawn into the syringe. Then, acetonitrile (Scharlau) was withdrawn into the syringe to complete around 20 μL. After the needle tip was carefully cleaned with a tissue, the content of the syringe was injected into the HPLC for analysis. The overall SDME method calibration was performed using artificial seawater calibration solutions submitted to the same SDME procedure described above. The agitation for the SDME extractions was performed by using PTFE stir bars. Sorption of EDPs can take place on PTFE stir bars, and so they were carefully rinsed after use with acetone, then methanol, then acetonitrile and finally with deionized water to avoid memory effects. The stir bars were also daily sonicated for 10 min with acetonitrile.

In DLLME experiments, 5 mL of real seawater samples (spiked or not) or artificial seawater samples (spiked) are placed in a glass tube of 8 mL. Then, 150 μL of an adequate mixture acetonitrile:decanol is rapidly injected to the sample. The optimum ratio acetonitrile:decanol was 15.7 (v/v). Under the optimized procedure, the mixture is vigorously shaken during 4 min using the vortex at 2000 rpm. Following extraction, the tube is subjected to centrifugation during 5 min at 3600 rpm. Afterwards, the upper phase of 1-decanol containing the extracted EDPs (~19 μL) is removed using the Hamilton syringe. The overall DLLME method calibration was performed using artificial seawater calibration solutions submitted to the same DLLME procedure described above.

3. Results and discussion

3.1. Optimization of the SDME method

Several considerations must be taken into account to select an adequate extractant solvent for a SDME application in direct

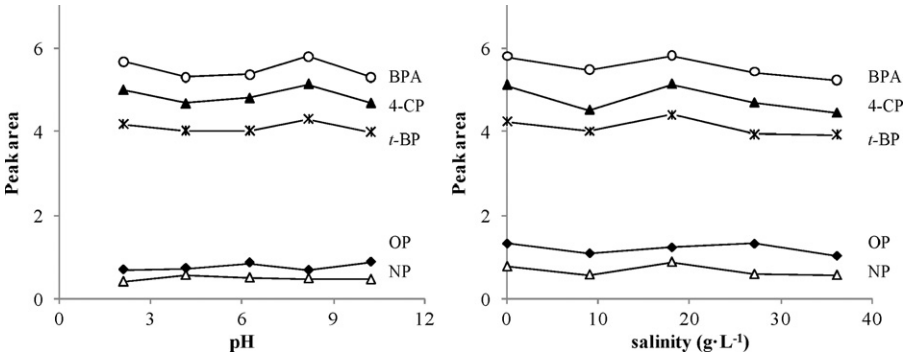

Fig. 1. Extraction efficiency of the SDME method when modifying the pH or the salinity of the water matrices (5 mL spiked with 50 ng mL^{-1} of each EDP).

immersion mode. The application is intended for a group of endocrine-disrupting phenols in seawater matrices. Therefore, the selected solvent must be immiscible with water. It must also be miscible with the mobile phase composition further used in HPLC and it should not absorb at the selected wavelength in the UV detector (228 nm), or at least should not co-elute with any of the EDPs studied. Furthermore, the solvent should ensure drop stability during long periods of time while stirring. Several solvents were initially selected to develop the SDME application: 1-octanol, dichloromethane, 1-decanol, and the ionic liquid 1-butyl-3-methylimidazolium hexafluorophosphate (BMIm-PF_6). The drop of dichloromethane, given its volatility, practically disappeared at extraction times of 15 min. The BMIm-PF_6 drop did not resist long extraction times either, and moreover its absorption signal in UV interfered with the identification of OP and NP. It has been described the difficulty to carry out SDME with ILs in direct immersion due to the fact that even hydrophobic ILs have some solubility in water resulting in a continual decrease in the drop volume with longer extraction times. This justifies the high number of applications of ILs in headspace compared to those in direct immersion mode [30,31]. The drop of octanol resisted long extraction times but its maximum size was smaller than the corresponding to 1-decanol. Given these results, 1-decanol was the solvent selected.

The drop size volume of 1-decanol was optimized by maximizing its size while ensuring its stability during stirring for long time (up to 2 h), being 2.5 μL the size of the drop finally selected. The stirring rate was fixed at 100 rpm to avoid drop instability.

The microextraction procedures for a number of phenols have been described to improve when utilizing low pH media and high ionic strengths, mainly in headspace applications [32]. The optimized SDME method is going to be applied in direct immersion mode for real seawater samples; therefore, high ionic strengths are going to be found in the matrices. Two different studies were conducted, one fixing the ionic strength to a salinity value of 36.1 g L^{-1} (artificial seawater matrices) and varying the pH of the aqueous solution from 2 to 10. The second one was performed without controlling the pH (pH 8.5 at room temperature) and varying the salinity of the aqueous solution from 0 to 36.1 g L^{-1}. The aqueous solution was spiked with a EDPs content of 50 ng mL^{-1} in these experiments. SDME was performed using 60 min of extraction time. In all cases, there were no significant variations in the obtained extraction efficiencies for the EDPs studied when the pH or the salinity were modified, as it can be observed in Fig. 1. Hence, no control of the pH or the ionic strength was carried out in further experiments, and the optimization was directly carried out in artificial seawater matrices.

SDME is an equilibrium extraction method rather than an exhaustive extraction method [19,20]. The amount of analyte extracted at a given time depends upon the mass transfer of analyte from the aqueous phase to the extractant drop. The equilibrium time determines the maximum amount of analyte that can be extracted by the drop, which controls the sensitivity of the method. The sorption time profiles were studied by monitoring the peak area as a function of extraction time, as can be seen in Fig. 2. Experiments were conducted in standard solutions of 100 ng mL^{-1} for the studied EDPs in artificial seawater samples, with stirring at room temperature for a time period that was increased from 15 to 80 min. It can be observed that the equilibration was not attained for any of the EDPs, and that efficiencies greatly increase when increasing the extraction time. For quantitative analysis, it is not necessary for the analytes to reach equilibrium, as long as the extraction time is carefully controlled.

3.2. Quality parameters of the SDME method

The overall SDME calibration method was carried out at two different extraction times, 20 and 60 min, with artificial seawater matrices. The purpose was to evaluate the sensitivity of the overall method as a function of the extraction time. Table 1 includes the quality parameters for these calibrations. Lower times are beneficial for achieving rapid analyses, but the sensitivity is compromised. Therefore, an extraction time of 60 min was considered adequate to reach acceptable sensitivity.

The limits of detection (LODs) were calculated as three times the signal to noise ratio, and were verified by injection of artificial seawater samples spiked at such levels and subjected to the overall optimized procedure. At the optimum extraction conditions (60 min for 5 mL aqueous samples) the detection limits oscillate from 4 ng mL^{-1} for BPA and 4-CP to 9 ng mL^{-1} for OP and NP. To our knowledge, only one SDME work has been reported for the determination of two endocrine-disrupting phenols, NP and 4-*t*-

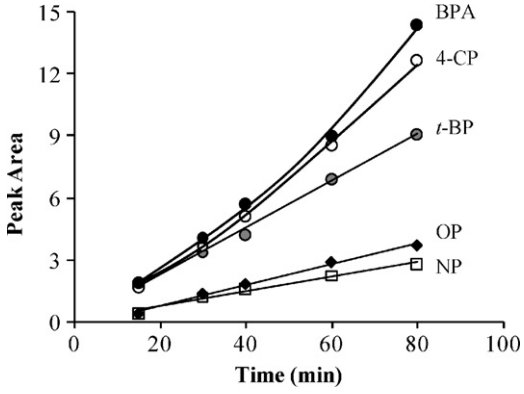

Fig. 2. Sorption time profiles for the SDME method obtained when utilizing artificial seawater samples (5 mL) spiked with 100 ng mL^{-1} of each EDP.

Table 1
Quality parameters of the overall SDME calibration method, using different extraction times.

Analyte	Extraction time (min)	Calibration range (ng mL^{-1})	Slope ± SD[a]	Error of the estimate	R	LOD (ng mL^{-1})
BPA	20	30–150	0.032 ± 0.002	0.253	0.989	15
t-BP	20	30–150	0.017 ± 0.001	0.077	0.995	19
4-CP	20	30–150	0.030 ± 0.002	0.236	0.989	18
OP	20	50–200	0.013 ± 0.002	0.089	0.988	39
NP	20	50–200	0.010 ± 0.001	0.056	0.993	32
BPA	60	15–125	0.110 ± 0.006	0.711	0.993	4
t-BP	60	15–125	0.071 ± 0.004	0.512	0.991	6
4-CP	60	15–125	0.090 ± 0.004	0.457	0.996	4
OP	60	20–125	0.037 ± 0.002	0.291	0.990	9
NP	60	20–125	0.025 ± 0.001	0.105	0.997	9

OP, in waters (tap, river and wastewaters) [25]. Such work was conducted with HPLC-fluorescence detection (FD) using the ionic liquid hexylmethylimidazolium hexafluorophosphate as extractant (10 μL microdrop in 15 mL aqueous samples) [25]. The work reports detection limits of 0.3 and 0.7 ng mL^{-1} for NP and *t*-OP, respectively, using a 40 min extraction time, with dynamic linear ranges of 10–100 ng mL^{-1}. These detection limits, obtained with HPLC-FD, are better than the ones reported with our SDME method, but it must be considered that our work uses HPLC-UV. The utilization of SDME in direct immersion mode in combination with HPLC-UV presents detection limits around 5 ng mL^{-1} for polar compounds such as formaldehyde using 30 min for the extraction time [33].

The precision of the SDME method was determined by performing five consecutive extractions from artificial seawater solutions with EDPs concentrations of 50 ng mL^{-1}. At the optimum extraction conditions, the relative standard deviation values oscillate from 4.1% for BPA to 9.4% for 4-CP, as can be observed in Table 2. The reported precision is comparable to common applications in SDME [30,34]. Precision values up to 7.8% (RSD) have been reported for NP (spiked level: 25 ng mL^{-1}) in waters using a SDME-HPLC-FD method [25].

Given the fact that SDME is not an exhaustive extraction method, there are several ways to evaluate its performance, by means of the enrichment factor or by means of the relative recovery. The enrichment factor (E_F) was calculated according to the following equation:

$$E_F = \frac{C_{drop}}{C_{initial}} \quad (1)$$

where C_{drop} is the concentration of the EDPs in the drop after extraction, and $C_{initial}$ is its initial concentration in the seawater solution. Table 2 shows the obtained E_F values for a spiked level of 50 ng mL^{-1}, which oscillate from 49 to 195. E_F values ranging from 130 to 163 have been described for a spiked level of 25 ng mL^{-1} for NP and *t*-OP using SDME-HPLC-FD [25]. Typical E_F values of 42–166 [30], 4–178 [35], and 83–157 [36], are described in regular direct mode-SDME applications.

The relative recovery (RR) was calculated according to the following equation:

$$RR\ (\%) = 100 \cdot \frac{C_{found}}{C_{initial}} \quad (2)$$

where C_{found} is obtained from the overall SDME calibration method. Table 2 shows the calculated relative recoveries for a spiked level of 50 ng mL^{-1}. Average relative recoveries of 102 ± 11% have been obtained with artificial seawater matrices. Relative recoveries around 100% are commonly described in SDME applications.

3.3. Optimization of the DLLME method

The primary requirements of an adequate extraction solvent in DLLME must be: low water solubility and high extraction capability for the analytes of interest. The choice of dispersive solvent in DLLME depends on the miscibility in the organic extraction solvent and in the aqueous sample, with the purpose to disperse the extraction solvent into very fine droplets in to the aqueous sample.

The DLLME method for determining EDPs in seawater matrices was carried out selecting 1-decanol as the extraction solvent in order to compare with SDME. The selected dispersive solvent was acetonitrile, avoiding in all cases water:acetonitrile ratios higher than 1:1 (v/v) to prevent the solubilization of 1-decanol. The aqueous sample volume was also fixed to 5 mL to make an appropriate comparison with SDME. Furthermore, 5 mL is the most common aqueous sample volume to perform a DLLME application [21,22,26–28].

Some authors have also pointed out the necessity of utilizing extraction solvents with higher density than water, to facilitate a fast mixing favored by gravity [27,37]. The selected extraction solvent for this application, 1-decanol, has a lower density than water. Therefore, the ability of the dispersive solvent to mix 1-decanol with water must be improved. It has been recently described that the utilization of ultrasounds improves the extraction efficiencies in DLLME [38]. Therefore, a comparison between ultrasound-assisted DLLME and vortex-assisted DLLME was conducted using 5 mL of artificial seawater samples containing 125 ng mL^{-1} of EDPs. 150 μL of the mixture acetonitrile:decanol were quickly added to the aqueous sample. Two different ratios of the mixture acetonitrile:decanol

Table 2
Extraction efficiency and precision of the optimized SDME and DLLME methods when utilized with artificial seawater matrices.

were tried: 15.7 and 61.5 (v/v). Then, vortex agitation or ultrasounds were applied during two different extraction times: 1 and 4 min. In DLLME, extraction time is defined as the time interval after injecting the extraction solution (mixture of dispersive solvent and extraction solvent) and before centrifugation. Following centrifugation, the final extractant phase containing EDPs was subjected to chromatographic analysis. The obtained extraction efficiencies, expressed as peak areas, can be observed in Fig. 3. In all cases, it can be observed that the vortex agitation is more efficient than ultrasounds for the extraction of EDPs from seawaters at any extraction time or any acetonitrile:decanol ratio used. Hence, it was decided to use vortex to assist the DLLME method rather than ultrasounds.

In DLLME, unlike other liquid-phase microextraction techniques, the extraction efficiency depends not only on the extractant, but also on the type and volume of the dispersive solvent. Given the fact that the variation of the dispersive solvent volume would result in the change of the volume of the final extractant phase, it is not possible to directly assess the effect of the volume of dispersive solvent on the extraction efficiency. It becomes much more convenient to evaluate the effect of the dispersive solvent:extractant solvent ratio (acetonitrile:decanol ratio), fixing the spiked volume of such mixture. In addition to this, it is also necessary to optimize the extraction time. An experimental design was then conducted in order to obtain the optimum conditions for the mixture ratio and extraction time. The variables investigated were evaluated at two levels using a response surface methodology, based on a factorial design with a two replicate center point. The peak area of each analyte was selected as the response variable. This design involved a total of 11 randomized runs. The levels selected for ratio of the mixture (acetonitrile:decanol) were 15.7 and 61.5, using 150 μL

Table 4
Quality parameters of the overall DLLME calibration method.

Analyte	Calibration range (ng mL^{-1})	Slope ± SD[a]	Error of the estimate	R	LOD (ng mL^{-1})
BPA	2–20	0.54 ± 0.03	0.371	0.996	0.7
t-BP	3–20	0.36 ± 0.01	0.188	0.997	0.8
4-CP	2–20	0.54 ± 0.02	0.267	0.998	0.2
OP	3–20	0.43 ± 0.02	0.256	0.997	0.8
NP	3–20	0.31 ± 0.01	0.137	0.998	1.6

[a] Error of the slope for $n = 6$ calibration levels.

as the fixed spiked volume of the mixture for 5 mL of aqueous sample. Higher ratios make difficult the obtaining of a final drop with enough size volume to be easily handled. Lower ratios generate a final drop of more than 20 μL, which is not convenient for HPLC requirements of sensitivity. With respect to the extraction time, the levels studied were 1 and 4 min, given the fact that higher times are rarely necessary in DLLME procedures, and in order to develop a fast procedure. The concentration of the analytes in the artificial seawater samples was kept constant at 7.5 ng mL^{-1} (5 ng mL^{-1} for BPA) during these experiments. Table 3 summarizes the experimental design matrix altogether with the obtained peak areas for each EDP. The chronological listing of the experimental design parameters represents the statistical randomized order in which the experimental runs were undertaken.

Fig. 4 shows representative response surfaces estimated from the design. For all EDPs studied, the maximum was observed in the region of low acetonitrile:decanol ratios (15.7). The maximum was attained at 4 min for all EDPs except for BPA, for which the extraction time was not a significant variable. Given these results, 4 min for the extraction time and 15.7 for the mixture ratio were the conditions selected to perform an adequate DLLME procedure.

3.4. Quality parameters of the DLLME method

The overall DLLME calibration method was carried out under the optimized conditions using artificial seawater matrices. Table 4 shows the quality parameters of the calibrations obtained. Detection limits were calculated as three times the signal to noise ratio, and were verified by injection of artificial seawater samples spiked at such levels and subjected to the overall optimized procedure. LODs oscillate from 0.2 ng mL^{-1} for 4-CP to 1.6 ng mL^{-1} for NP using this DLLME-HPLC-UV method. It must be highlighted that these LODs are comparable to others obtained with SDME-HPLC-FD [25], SPME-HPLC-FD [39] or GC-MS [40]. To the best of our knowledge, this group of EDPs has not been determined by DLLME in seawaters. DLLME applications conducted in combination with HPLC-UV (using aqueous samples of 5 mL) report LOD values of 1 ng mL^{-1} for the insecticide methomyl [41], of 3–7 ng mL^{-1} for several antioxidants [42], of 0.5–1.3 ng mL^{-1} for four insecticides [43], or of 0.4–1 ng mL^{-1} for several carbamate pesticides [44], among others.

The precision of the DLLME method was determined by performing five consecutive extractions from artificial seawater solutions spiked at two different levels (low and high) of EDPs contents, 3.5 and 20 ng mL^{-1}, respectively. Table 2 shows the obtained results, where it can be observed lower precision values for higher spiked levels, with RSD values ranging from 3.1 to 7.2% of RSD, than for lower spiked levels, with RSD values ranging from 5.9 to 16% of RSD, which is a logical trend. The reported precision is comparable to common applications in DLLME [28,37,43,45].

The performance of the method was also evaluated calculating the relative recovery (obtaining in this case C_{found} from the overall DLLME method) with these spiked artificial seawater samples. Average relative recoveries of 102 ± 12% for lower spiked levels and of 98.7 ± 3.7% for higher spiked levels were obtained, which also reflects the accuracy of the method. Relative recoveries around 100% are commonly described in DLLME applications.

The obtained enrichment factor values have also been included in Table 2, oscillating between 89 for BPA when spiked at 20 ng mL^{-1} and 257 for 4-CP when spiked at 3.5 ng mL^{-1}. For each spiked level, the higher E_F values are obtained for 4-CP and OP, and the lower E_F values for BPA and NP. Different DLLME-HPLC-UV applications (for 5 mL aqueous samples) report comparable E_F values: 71 for the insecticide methomyl [41], 168–220 for three antioxidants [42], 209–273 for four insecticides [43], 41–94 for several amines [46], or 101–145 for four carbamate pesticides [44], among many others.

3.5. Influence of real seawater matrices on SDME and DLLME

The applicability of both optimized extraction methods to real seawater samples was investigated to evaluate the matrix effects.

Table 5
Analytical performance of the optimized DLLME and SDME procedures when extracting real seawater samples spiked at different levels.

Analyte	SDME low spiked level: 15 ng mL^{-1}			DLLME low spiked level: 3.5 ng mL^{-1}		
	RSD (%)	RR[a] (%)	E_F	RSD (%)	RR[a] (%)	E_F
BPA	11	118	158	14	118	123

NP	6.7	96.0	44	9.9	85.5	100

[a] Average relative recovery for $n = 5$.

Seawaters from Candelaria (Tenerife Island) are known for presenting low contamination levels, and are usually employed as blanks in performing recovery studies. To avoid carry over problems, non-spiked seawater samples from Candelaria were subjected for the overall optimized procedures with both SDME and DLLME, and the presence of EDPs was not observed. The precision of both optimized procedures, SDME and DLLME, was then evaluated by performing five consecutive extractions from real seawaters from Candelaria spiked at two different levels (low and high EDPs contents, depending on the specific method). Table 5 shows the obtained analytical performance.

Average relative recoveries of $110 \pm 11\%$ at low spiked levels ($3.5\ ng\ mL^{-1}$) and $91.5 \pm 5.0\%$ at high spiked levels ($20\ ng\ mL^{-1}$) have been obtained when applying the DLLME method to real seawater samples. These efficiencies are totally comparable to the ones obtained with artificial seawater samples (Table 2) and so the matrix effect is not significantly affecting the extraction process in DLLME. With respect to the precision of the DLLME method, better precision is obtained at higher spiked levels, as it happened with artificial seawater samples. The overall precision of the DLLME method with real samples oscillates between 2.7 and 14% (RSD), being also comparable to the one obtained with artificial seawaters. It must be highlighted here the similarities in the E_F values obtained with artificial and real seawater samples when spiked at the same levels using the DLLME method (Tables 2 and 5), which reflects the robustness of the method.

The utilization of SDME with real seawater matrices presents average relative recoveries of $111 \pm 7\%$ at low spiked levels ($15\ ng\ mL^{-1}$) and $99.4 \pm 2.8\%$ at higher spiked levels ($125\ ng\ mL^{-1}$). These efficiencies are also comparable to the ones obtained with artificial seawater samples (Table 2). The overall precision of the SDME method oscillate between 3.8% and 11% (RSD), whereas the enrichment factor values range from 44 to 227.

The comparison between E_F values for SDME and DLLME must be conducted considering that a final drop of 2.5 μL is obtained in SDME, being of 19 μL in DLLME. In this sense, it results more convenient to carry out the comparison using the relative enrichment factor (RE_F). The relative enrichment factor, also known as real extraction recovery (E_R), can be calculated according to the following equation:

$$E_R\ (\%) = RE_F\ (\%) = 100 \cdot \frac{E_F}{E_{Fmax}} \quad (3)$$

where E_{Fmax} is the maximum preconcentration achieved if all analytes are effectively concentrated in the final drop (in both SDME and DLLME). E_{Fmax} can be calculated from the ratio $V_{initial}/V_{drop}$, being $V_{initial}$ the aqueous volume (5 mL). Therefore, E_R (%) is a measure of the real extraction efficiency of the method. At the lowest spiked level with real seawater matrices, E_R values oscillate from 3 to 11% in SDME, and from 49 to 108% in DLLME. In other words, the extraction is more efficient with DLLME. In fact, the extraction is quantitative, or practically quantitative, in DLLME for *t*-BP (72%), OP (88%) and 4-CP (108%). Few works report real extraction efficiencies, being more common to report relative recoveries. E_R values of 29–91% [22], 24–116% [45], 60–111% [21], or 55–74% [28], have been reported in DLLME applications for different analytes, being totally comparable to the values obtained in this work for the EDPs studied. Real extraction efficiencies are also rarely reported in SDME works. E_R calculated values of 1–3% [30], 11–21% [36], or 0.2–9% [35] can be observed in SDME applications for different types of analytes, with values of 9–11% for NP and *t*-OP in a SDME-HPLC-FD application [25]. These values are in agreement with the real extraction efficiencies obtained in this SDME application.

Finally, non-spiked seawaters coming from three different sampling points, all close to an oil-petroleum refinery and to a STP discharge outfall, were subjected to the overall optimized SDME and DLLME procedures. EDPs were not detected when applying SDME in any of the three samples studied. When using DLLME, *t*-BP was detected in two of these samples, but it could not be quantified ($\sim 0.8\ ng\ mL^{-1}$), and NP was also detected in one of the samples, but it could not be quantified either ($\sim 1.6\ ng\ mL^{-1}$).

4. Conclusions

Two liquid-phase microextraction procedures, single-drop microextraction and dispersive liquid–liquid microextraction, have successfully been developed for the determination of five endocrine-disrupting phenols in seawaters. Both optimized liquid-phase microextraction methods have shown comparable relative recoveries and precision in the developed application. Both methods are also environmental-friendly due to the low organic solvent consumption requirements (20 μL at most) and low sample volume (5 mL). The DLLME method has shown to be much more efficient than SDME to carry out the determination of EDPs, presenting better detection limits (down to $0.2\ ng\ mL^{-1}$) and better real extraction recoveries (from 49 to 108%). In addition, the DLLME method is rapid: around 10 min for the overall process compared to the necessity of 60 min in SDME.

ABSTRACT

In this paper, a rapid and sensitive method for the determination of ammonia and 22 aliphatic amines derivatized was established by cyclodextrin (CD) modified micellar electrokinetic chromatography with laser-induced fluorescence detection using 4-chloro-7-nitrobenzo-2-oxa-1,3-diazole as a derived reagent. By a series of unvaried studies, the best conditions were selected using 20 mM tetraborate (pH 9.70) containing 25 mM SDS, 7 mM β-CD, 10% acetonitrile, 0.5 M urea, and applied voltage 25 kV. Under the optimum conditions, ammonia and 22 aliphatic amines were separated successfully in 19 min. The signal response was linear over three-order of concentrations. The intra-day and inter-day relative standard deviations (RSD) were less than 0.81% and 1.00% for migration times, 1.76% and 2.01% for peak areas. Limits of detection (LOD) for the analytes was (S/N = 3) approximate 10^{-9}–10^{-12} M. The method was applied to the determination of ammonia and aliphatic amines in environmental water with recoveries in the range of 90.2–110.8%. In addition, a quantitative structure–property relationship (QSPR) model for the estimation of the electrophoretic migration time was established with the comprehensive descriptors for structural and statistical analysis (CODESSA) program for the first time. The multilinear regression (MLR) equation contained two theoretical descriptors and had the following statistical indices: $R^2 = 0.9668$, $F = 290.7839$, $R^2_{cv} = 0.9576$ and $S^2 = 0.8149$.

1. Introduction

Aliphatic amines are a group of low-molecular-mass active organic bases that usually act as an important class of environmental pollutants due to their odorous and toxic characteristic [1]. They are emitted into the environment from anthropogenic sources such as cattle feedlot operations, waste incineration, sewage treatment, automobile exhausts and various industries [2]. A natural background level of aliphatic amines can also be assumed to originate from animal waste and microbiological activities [3]. The many commercial uses and natural occurrences of aliphatic amines suggest that ultimately they will appear in the environment as pollutants which can be found in biological fluid, environmental samples and industrial process streams at trace levels. Furthermore, aliphatic amines, through nitrosation by nitrite as a reagent in conditions of defined pH and in other conditions similar to those in the mammalian stomach or small intestine [4,5], and some of nitrosamines products have strong mutagenic and oncogenic activities [6–8]. It is well known that nitrite is widely present in nature and is also produced in human saliva, and the possibility that nitrosation may occur in vivo, particularly in the gastrointestinal trace, upon ingestion of foods or water containing aliphatic amines has been reported [9]. The U.S. Environmental Protection Agency (U.S. EPA) maintains a continuing interest in analytical method for aliphatic amines because of their wide occurrences and toxicities.

In order to deeply understand the role of aliphatic amines in biological processes and their effects on human health, it is essential to develop simple and sensitive analytical techniques for quantifying these compounds in environmental samples. So far, some analytical methods have been exploited for the determination of some aliphatic amines in various matrices, including water, aerosol and beverages, such as GC [10,11], HPLC [12–16], RP-HPLC [17], CE [18–25] and ion chromatography [26]. By these methods only a few short chain aliphatic amines were examined. Furthermore, they cannot meet the requirement of the high sensitivity in analyzing real environmental sample matrix with low concentration. Thus, it is necessary to develop a rapid and sensitive method to determine ammonia and aliphatic amines derivatized.

Migration time is an apparent manifestation of material's separation in electrophoresis. Material can be separated in the electrophoresis was reflected in their different migration times.

doi:10.1016/j.talanta.2009.09.047

Therefore, migration time is a very important qualitative indicator in electrophoresis. We tried to establish the structure–activity relationship between the physical structure and electrophoretic migration time. QSPR provides a promising method for the estimation of compounds' electrophoretic behavior based on the descriptors derived solely from the molecular structure. CODESSA program is a comprehensive program for developing QSAR/QSPR models. It has been successfully employed in QSPR studies concerning the prediction of diverse physical properties and of chemical reactivity [27,28]. It also has shown promising results in medicinal chemistry applications [29]. To sum up, by dint of the chemical informatics to predict electrophoresis behaviors of compounds based on their chemical structures is important and necessary for developing new CE systems.

In this work, we report the first attempt to use MEKC-LIF for the rapid and selective determinations of ammonia and 22 aliphatic amines. The study included an extensive evaluation of different variables that affect derivatization, including the buffer concentration, pH, derived reagent concentration, reaction time and temperature. We also investigate the variables in separation, including pH, buffer concentration and various modifiers. Then the system was successfully applied in the analysis of ammonia and aliphatic amines in lake water, aquarium water, and the Yellow River water. Comparing with other chromatography methods reported previously, this developing method could provide bigger peak capacity with superior resolution in shorter analytical time. In addition, a multilinear regression (MLR) equation contained two theoretical descriptors were established for the estimation of the electrophoretic migration time.

2. Experimental

2.1. Instrumentation

CE was carried out on a Beckman P/ACE 5510 CE system (Beckman Coulter, Fullerton, CA, USA), equipped with a LIF detector. The excitation light from an argon ion laser (3 mW) was focused on the capillary window by means of a fiber-optic connection. The excitation was performed at 488 nm and a 520 nm bandpass filter was used for emission. The system was controlled by P/ACE Station software. The separation was carried out on a 57 cm (50 cm to the detector) × 75 mm ID fused-silica capillary (Yongnian Photoconductive Fiber Factory, Hebei, China). The samples were hydrodynamic injected by applying a pressure of 0.5 psi for 3 s. The separations were carried out at a constant voltage of 25 kV. The capillary was pre-treated with methanol, 0.1 M NaOH and water for 30 min sequentially. Each day before starting analysis and between two runs, the capillary was rinsed with 0.1 M NaOH for 5 min and water for 5 min and preconditioned with running buffer for 5 min. The capillary was maintained at 25 °C.

2.2. Materials and sample preparation

The aliphatic amine standards were all purchased from Sigma (Steinheim, Germany). The derived reagent, 4-chloro-7-nitrobenzo-2-oxa-1,3-diazole (NBD-Cl), was obtained from Acros Organics Company (Geel, Belgium). Analytical reagent grade chemicals were used along with distilled water to prepare solutions. Standard solutions of aliphatic amines were prepared individually in methanol (200 μg/mL each), stored at 4 °C and used after dilution to required concentration. A stock solution of derived reagent was prepared by mixing of 60 mg NBD-Cl with 10 mL acetonitrile and used as required. A PHS-10A acidity meter (Xiaoshan Science Instrumentation Factory, Zhejiang Province, China) was used for the pH measurement. The pH of buffer was adjusted using 1.0 M sodium hydroxide. Buffer solutions were freshly prepared for each experiment followed by filtration through a membrane filter of 0.45 μm pore size.

Water samples were collected in polypropylene bottles from aquarium, South-lake and the Yellow River, Lanzhou, China, respectively. The water samples were centrifuged to remove solid particles and then the supernatant was filtered through a 0.45 μm pore size membrane filter before analysis.

2.3. Derivatization procedure

20 μL of a mixture solution of ammonia and standard aliphatic amines, 200 μL of 30 mM tetraborate buffer (pH 9.0), and 80 μL of 1.5 mM NBD-Cl dissolved in acetonitrile were added into a 1.5 mL plastic tubes sequentially and thoroughly mixed. Then the mixture was heated at 70 °C for 20 min under dark. After cooling to room temperature, the mixture was diluted with 500 μL running electrolyte and then applied to injection for CE. The water samples and reagent blanks were treated in the same manner.

2.4. Computational methods

All molecules were drawn and pre-optimized using (MM+) encoded in the HyperChem 4.0 program (Hypercube, 1994). A more precise optimization was done with the semi-empirical PM3 method in HyperChem. The output files were transferred into the Microsoft Windows version of the CODESSA program version 2.6.3 (University of Florida, Gainesville, FL, 1994) developed by Katritzky et al. to calculate molecular descriptors. Then, a feature selection step was carried out to reduce the large set of descriptors to a suitable number without losing any important information. The HM in CODESSA was employed to select the suitable descriptors combinations to build the linear QSPR model. The lack of fit for the regression model was performed in the Minitab 15 program.

3. Results and discussion

3.1. Derivatization conditions studied

In order to achieve optimization derivatization efficiency, the effects of reaction variables were investigated: buffer pH (8.0–10.0), reaction temperature (25–70 °C), reaction time (3–60 min), NBD-Cl concentration (1–10 mM) and sodium tetraborate buffer concentration (10–50 mM). In our original experiment, we found that the buffer capacity of lower concentration buffer was not sufficient, whereas higher concentration buffer would result in the dismatch between higher concentration sample zone and lower concentration separation buffer. Therefore, a proper buffer concentration (30 mM sodium tetraborate) was applied as the derivatization buffer. The result implied that this value of 30 mM sodium tetraborate could enhance fluorescence intensity and meanwhile improve peak symmetry of the derivatives. In the experiment, in order to avoid the effect of delay time on fluorescence intensity, we injected immediately after derivative, and a fixed time interval from the end of derivative reaction to injection was strictly controlled.

3.1.1. Effect of buffer pH on derivatization

As the derivatization reaction of aliphatic amines with NBD-Cl is a typical nucleophilic reaction, basic reaction conditions were expected to be beneficial. The pH ranges of sodium tetraborate buffer from 8.0 to 10.0 were studied, respectively. Generally, NBD-Cl derivatization should be carried out at a higher pH (>8.4) to make the primary amine deprotonated [30,12], which is consistent with the results of aliphatic amine in our experiment. However, the fluorescence intensity of aliphatic amine derivatives decreased with

the increasing of buffer pH beyond pH 9.0. So the derivatization reaction at pH 9.0 was applied.

3.1.2. Effect of reaction temperature and time on derivatization

The effect of reaction temperature on the fluorescence intensity was investigated at 25, 50, 60, 70, 80 and 90 °C. The derivatization reaction was found to be rapid even at room temperature (25 °C), readily observed as a color change to yellow of the reaction mixture within a few seconds of the addition of NBD-Cl, while the reagent blank color changed to yellow only slowly (NBD-Cl hydrolysis reaction). However, there was a significant increase on the yield of fluorescent derivatives when the reaction temperature increased from 25 to 70 °C. But the fluorescence intensity at temperature above 70 °C was much smaller than that at 70 °C. It can be seen that the higher reaction temperature could provide higher derivatization efficiency, but the derivatives of aliphatic amines were not stable at temperature above 70 °C.

The influence of reaction time on the fluorescence intensity was investigated in the range of 3–60 min at 70 °C. The results showed that the fluorescence intensity increased with increasing reaction time, but the response of aliphatic amine derivatives exhibited a decreased tendency with prolonged reaction time exceeding 20 min. This maybe attributed to the fact that the derivatives of aliphatic amines were not very stable at 70 °C over a long time. So the derivatization reaction at 70 °C for 20 min was applied.

3.1.3. Effect of NBD-Cl concentration on derivatization

In addition, the fluorescence signal intensity depends also on NBD-Cl concentration investigated in the range of 1–10 mM. We observed that, for simple aqueous solutions of the aliphatic amines, concentrations of NBD-Cl as low as 1 mM could be used without sacrificing the yields. Considering that the method may be applied to a biological matrix which will contain other compounds capable of reacting with NBD-Cl, 1.5 mM was chosen as the optimal reagent concentration in the reaction mixture.

Based on the optimization studies, the derivatization conditions for further studies were chosen as a reaction medium consisting of NBD-Cl solution of 1.5 mM, 30 mM sodium tetraborate buffer with pH of 9.0, a reaction temperature of 70 °C for 20 min. In order to obtain high reproducibility, the derivatization mixture prepared freshly for each run was recommended.

3.2. Separation conditions studied

3.2.1. Effect of buffer concentration on the separation

In preliminary studies, CZE separation mode was chosen for the simultaneous separation of 24 compounds. A sodium tetraborate buffer was chosen as the background electrolyte. The effect of sodium tetraborate buffer concentration was investigated in the range of 5–30 mM. The result indicated that aliphatic amine derivatives could not achieve baseline separation at lower buffer concentration (5–10 mM). Higher concentration (30 mM) buffer would generally bring two results: (i) higher electric current resulting in generation of excessive Joule heat, thereby increasing the extent of diffusion for analytes and then causing poor peak shapes, and (ii) suppressing of EOF leading to longer analysis time, which can also cause poor peak shapes. In order to obtain high sensitivity and keep good peak shape, a buffer of 20 mM sodium tetraborate was selected for all further experiments.

3.2.2. Effect of buffer pH on the separation

The running buffer pH was noted to affect the separation efficiency and fluorescence quantum yields of the derivatives. The pH of running buffer was then examined from 9.5 to 10.1. It was observed that the resolutions increased dramatically with the increasing of buffer pH in the range of 9.5–9.7. But, some aliphatic amine derivatives still could not be separated absolutely. In addition, a significant influence of buffer pH on the fluorescence signal intensity was founded, which was accounted for the fact that derivatives were not stable at higher buffer pH. As a compromise of resolution and fluorescence signal intensity, pH 9.70 was chosen in subsequent experiments.

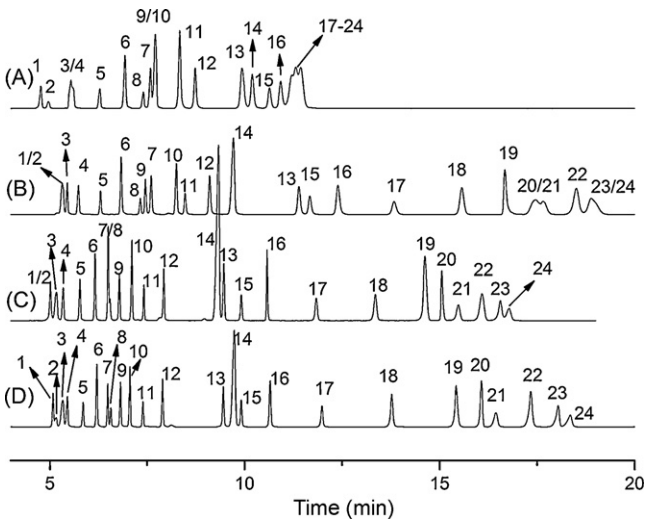

Fig. 1. Effect of the components of running buffer on the separation of ammonia and aliphatic amines. (A) Sodium tetraborate 20 mM, SDS 25 mM: peaks 3/4, 9/10, 17–24 overlapped; (B) sodium tetraborate 20 mM, SDS 25 mM, 10% acetonitrile: peaks 1/2, 20/21, 23/24 overlapped; (C) sodium tetraborate 20 mM, SDS 25 mM, 10% acetonitrile, 7 mM β-CD: peaks 1/2, 7/8 overlapped; (D) sodium tetraborate 20 mM, SDS 25 mM, 10% acetonitrile, β-CD 7 mM, urea 0.5 M: accepted resolution is obtained for all compounds. Analyte identities No. as in Table 1.

3.2.3. Effect of SDS concentration on the separation

Due to the pseudo-stationary phase effect of surfactant, SDS concentration showed a notable effect on the separation. In order to further improve the separation efficiency, the effect of SDS concentration (10–40 mM) was studied. It was found that the appropriate addition of SDS (25 mM) could improve separation efficiency and the peak shape. At the same time, the increasing of SDS concentration led to the delay of migration time with peak broadening. However, with sodium tetraborate and SDS as running buffer the 24 analytes involving ammonia, 22 aliphatic amines and NBD-Cl could not be completely separated (see Fig. 1A). It can be seen that only 15 peaks were obtained, due to that some of them have similar mobilities and comigrated.

3.2.4. Effect of modifier on the separation

Under normal MEKC conditions, these analytes cannot be separated completely, so efforts were shifted towards the use of modifiers. The addition of organic solvents to the buffer can improve the selectivity, efficiency and resolution of CE as they modify the partition coefficient, viscosity, and polarity of the mobile phase and electroosmotic flow. Here, acetonitrile was introduced into the running buffer and the effect in the concentration range of 0–20% (v/v) on the separation was tested based on the optimum conditions mentioned above. The result showed the resolution and analysis time increased with the increasing of acetonitrile concentration. Meanwhile, longer analysis time revealed severe tailed peaks. This could be explained by the change of the solubility of the derivatives in the water-acetonitrile mobile phase, which resulted in the change of the partition behavior of the derivatives between the mobile phase and the SDS pseudo-stationary phase. On the other hand, extension of time maybe due to the decreasing of the electroosmotic flow. Hence, the 10% (v/v) acetonitrile

was applied as a compromise consideration between resolution and migration time. However, the analytes could not be well separated in a shorter analysis time with higher separation efficiency when acetonitrile was applied (see Fig. 1B, nonyl-/decylamine and *t*-butyl-/cyclopropylamine both comigrated).

Then, β-CD as another modifier was introduced in the subsequent experiments and the effect in the concentration range of 5–12 mM on the separation was studied. The result showed that higher concentration (above 8 mM) was not beneficial to the separation of short chain aliphatic amines, but the lower concentration (below 6 mM) led to bad resolution of long chain aliphatic amines. Take care of two aspects, 7 mM was chosen in the subsequent experiments but separation was still incomplete with ammonia continuing to comigrate with methylamine, and same problem was also existed in the separation of heptyl-/dibutylamine (Fig. 1C). Urea was then added to the buffer to enhance the resolution and was tested in the concentration range of 0.2–1.4 M. As demonstrated in the literature [20], the addition of urea in MEKC allowed the reduction of the distribution of the solutes between the background electrolyte and the pseudo-stationary phase by increasing the solubility of the hydrophobic compounds in aqueous media. Finally, addition of 0.5 M urea led to the completely separation of all of the analytes. It is noted that the resolution was improved at the expense of analysis time as migration is finished within 19 min (Fig. 1D). This can be explained by the change of the solubility of the analytes in the water–acetonitrile mobile phase, which resulted in the change of the partition behavior of the analytes between the mobile phase and micellar pseudo-stationary phase, this is also the explanation to migration order change of the analytes with the addition of various modifiers.

According to the factors mentioned above, the best separation was obtained with running buffer containing 20 mM sodium tetraborate, 25 mM SDS buffer with 7 mM β-CD and 10% acetonitrile, 0.5 M urea at pH 9.70 and an applied voltage of 25 kV. Under the optimized condition, 24 compounds were well separated within 19 min. This results in the separation of the most aliphatic amines in the shortest analysis time ever reported in CE. The typical electropherogram for a standard mixture of MEKC system was shown in Fig. 2.

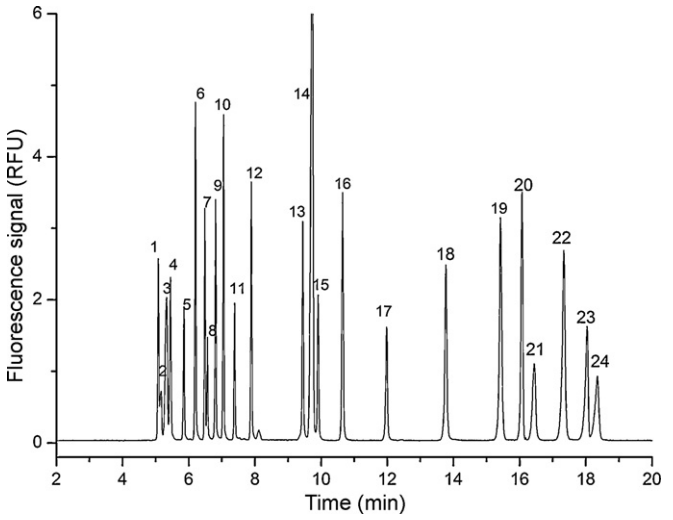

Fig. 2. Electropherogram of optimized MEKC separation of standard mixture of ammonia and aliphatic amines. MEKC system: 20 mM sodium tetraborate, 25 mM SDS buffer with 10% acetonitrile and 7 mM β-CD, 0.5 M urea at pH 9.7. Analyte identities No. as in Table 1.

3.3. Analytical calibration

The method validation including linearity, detection limits and precision was carried out using standard solutions under the optimized derivatization and separation conditions. Figures of merit are summarized in Table 1. The linear relationship between the peak area and the concentration of analytes was obtained by using the corresponding peak area (y) of the analytes versus their concen-

tration (c). The results indicated that excellent linear relationship is attainable over the concentration range studied with satisfactory correlation coefficients. The detection limits, calculated for an S/N of 3, and quantitation limits, calculated for an S/N of 10 were both listed in Table 1, indicating higher sensitivity than that of the previously reported method (see Table 2). The precision of the method, including intra-day and inter-day relative standard deviations (RSD) were also listed in Table 1, indicating good precision.

3.4. Application

The applicability of the proposed method was tested by determining ammonia and aliphatic amines in various environmental water samples (see Fig. 3). All peaks in water samples were identified by comparing the migration times and spiking the standards to the sample solutions. The results were given in Table 3. From the recovery results, there is no significant matrix effect. The RSD can be considered as generally acceptable, although – as might be expected – the errors (as a percentage) increased for lower concentrations of the analytes.

3.5. QSPR model

To predict the migration times of analytes, QSPR model was used and described by the following equation:

$$\mathrm{MT\ (min)} = 6.6573 + 2.4205 \times \mathrm{IC2} - 3.2347 \times \mathrm{AIC2} \quad (1)$$

MT: migration time; IC2: information content (order 2); AIC2: average information content (order 2)

According to the *t*-test, the most important descriptor for the model is the information content (order 2): IC2, which is equal to average information content (AIC2) multiplied by the total number of atoms, defined as [31,32]:

$$\mathrm{IC2} = \mathrm{AIC2} \times n \quad (2)$$

$$\mathrm{IC2} = -\sum_{i=1}^{k} \frac{n_i}{n} \log_2 \frac{n_i}{n} \quad (3)$$

n_i: number of atoms in the ith class; n: the total number of atoms in the molecule; k: number of atomic layers in the coordination sphere around a given atom that are accounted for.

By interpreting the descriptors in the regression model, it is possible to gain some insight into the factors that are likely to govern the electrophoretic migration of the compounds. The two information-theoretic descriptors take into account different aspects of the molecular structure. IC describes the information content or complexity of a hydrogen-filled graph, considered the ordering of the atoms relative to one another within a molecule and AIC encodes the connectivity and molecule branching, so it

is related to the molecular shape and symmetry. The molecule structures play an important role in the migration process, so the two topological descriptors have high correlation with the MTs. The model may be explained by the fact that the magnitude of intermolecular interaction between the compounds and the pseudo-stationary phase is directly related to the degree of branching and molecular size.

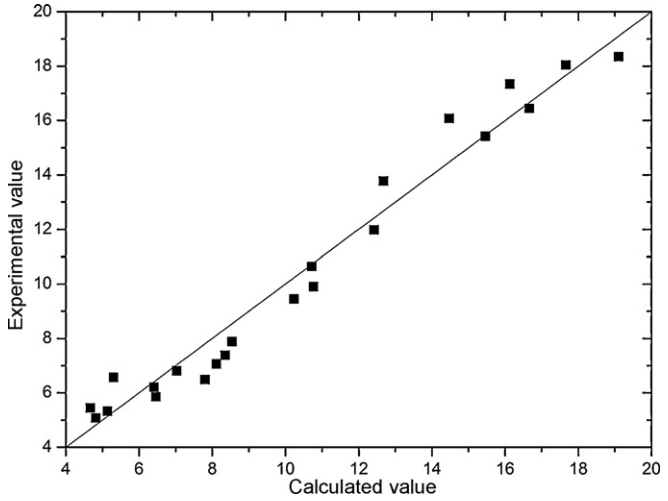

Fig. 4. Scatter plot of the calculated electrophoretic migration times vs. the experimental electrophoretic migration times.

Table 4
The linear model and the statistical characteristics of the regression model.

System		X^a	DX^b	*t*-Test	Descriptors
MEKC	0	6.6573e+00	1.0305e+00	6.4602	Intercept
	1	2.4205e−01	1.1072e−02	21.8611	IC (order 2)
	2	−3.2347e+00	5.1226e−01	−6.3145	AIC2 (order 2)

$R^2 = 0.9668$; $F = 290.7839$; $R^2_{cv} = 0.9576$; $S^2 = 0.8149$; lack of fit test, $P = 0.006$; X^a: regression coefficient; DX^b: regression coefficient mean square error; R^2: squared correlation coefficient; F: Fisher ratio; R^2_{cv}: cross-validated correlation coefficient; S^2: squared standard deviation;

In Fig. 4, the scatter graph represents the predicting migration times (MTs) versus experiment MTs for all of the analytes studied in MEKC system. The statistical characteristics of the regression model were presented in detail in Table 4. The cross-validated correlation coefficient R^2_{cv}, as compared with the correlation coefficient R^2, indicated the stability of the regression equation. And the P value of the lack of fit test indicated that the chance of lack of fit of the regression model is very little. All of the results suggested that the model possessed promising predictive ability for describing the migration times of analytes.

4. Conclusions

In conclusion, a rapid and sensitive MEKC-LIF method was developed for the separation and detection of ammonia and aliphatic amines after NBD-Cl derivatization. Compared with previous reported methods, this approach provided bigger peak capacity with superior resolution in shorter analytical time. So the proposed method displays great potential for the determination or confirmation of ammonia and aliphatic amines in various complex environmental samples. Furthermore, QSPR model was used to describe the relationship between migration time and molecule structure, which was an alternatively choice for the simplification of design and optimization CE system. The method can be extended to the analysis of carcinogenic N-nitrosamines upon their electrochemical reduction. It would be of great significance that allows the bulk of experimental work to be performed with innocuous aliphatic amines rather than the carcinogenic nitrosamines.

ABSTRACT

In this paper, a kind of β-amyloid peptide (Aβ1–16) conjugated gold nanoparticles (Aβ1–16@GNPs) are prepared and employed as colorimetric indicator for studying the interaction of β-amyloid peptide with metallic ions (e.g. Zn^{2+} and Ca^{2+}). In the presence of Zn^{2+}, mono-dispersing Aβ1–16@GNPs enable to form aggregates or attach on the SHG-44 (human glioma cell) cellular surface which results in significant color change of the solution. The experimental results indicate that Zn^{2+} can interact with Aβ1–16 and form Zn^{2+}–β-amyloid peptide complexes. In particular, in the presence of Zn^{2+}, a time-dependent interaction of cells with Aβ1–16@GNPs has been observed that may suggest different expression levels of β-amyloid peptide related proteins in various cell cycles. In addition, the aggregating/binding process can be easily reversed by adding EDTA, a good chelated ligand of Zn^{2+}, which gives further proof of the interaction mechanism.

1. Introduction

A variety of human diseases are suspected to be directly linked to protein misfolding and assembling because highly organized protein aggregates, called amyloid fibrils, and aggregation intermediates are observed in these processes [1]. In particular, neurodegenerative pathologies, such as Alzheimer's disease, are account for a major part of these protein misfolding diseases [2]. β-Amyloid (Aβ) 1–42 is an Alzheimer's disease related peptide consists of 42 amino acids, which is the predominant species found in plaque deposits. The Aβ1–42 peptide can change its conformation and lead to form amyloid-like aggregates or fibrils when it is exposed to some metallic ions, such as Zn^{2+} [3–7]. There is a general consensus that protein aggregate is the major element of cell toxicity [2], especially when the Aβ exposed to Zn^{2+}, the rate of aggregate process was increased dramatically [3]. The coordination and/or reactions of the amino acid residues (i.e. histidines at position 6, 13, 14 and tyrosine at position 10) in the chain of the peptide Aβ1–42 with Zn^{2+} is assumed as main reason for causing this consequence [6].

Although many biophysical and biochemical methods (e.g. circular dichroism (CD) spectroscopy, thioflavin T (ThT) fluorescence spectroscopy, electron paramagnetic resonance (EPR) spectroscopy and transmission electron microscopy (TEM)) have been employed to successfully study the details of Aβ conformation and aggregate morphology in the presence of metallic ions [5–9], there are problems associated with cost-consuming and complicated operation. There is a highly demand motive to develop a novel method requiring simple or no instrumentation yet still providing great sensitivity and accuracy of analysis in vivo. In this regard, colorimetric methods based on functionalized gold nanoparticles (GNPs) are convenient and attractive, and can satisfy to meet these requirements. As versatile optical probes, gold nanoparticles have been extensively applied in analytical and biomedical researches [10–20] since the surface plasmon resonance (SPR) absorption of GNPs are not only dependent on their shape and size, but also very sensitive to their local environments.

Here, a kind of Aβ1–16 (the core fragment of Aβ1–42 which consists of 16 amino acids (sequence: DAEFR HDSGY EVHHQ K)) conjugated gold nanoparticles (named as Aβ1–16@GNPs) are prepared and used to study the interaction of Aβ1–16 with metallic ions. The stability and functionality of the GNPs are achieved by surface modification with the biotinylated peptide, CALNN GK(biotin)G, and the Aβ1–16 is linked with the CALNN GK(biotin)G functionalized GNPs by standard biotin–streptavidin chemistry. The interactions of the Aβ1–16@GNPs with two metallic ions (Zn^{2+}, Ca^{2+}) with or without cells have been carefully studied by UV–visible spectroscopy and TEM. We demonstrate that the GNP-based approach is possible to (i) identify metallic ion inducing Aβ peptide misfolding/aggregation, and (ii) develop a simple assay for screening amyloid-like aggregate inhibitors.

2. Materials and methods

2.1. Materials and reagents

Peptides (CALNN), (CALNN GK(biotin)G), (GK(biotin)G DAEFR HDSGY EVHHQ K) were purchased from Scilight Biotechnology Ltd. (Beijing, China). Tetrachloroaurate ($HAuCl_4$) was purchased from Sigma–Aldrich Co. (USA). Streptavidin was purchased from Amresco Co. (USA). Other chemicals were analytical grade and used as received. Milli-Q water (18.2 MΩ cm) was used in all experimental processes.

2.2. Preparation of peptide-functionalized nanoparticles

The citrate stabilized 13 nm GNPs were synthesized by traditional Turkevich–Frens method [21,22]. Peptide-stabilized nanoparticles were prepared by previously reported peptide capping procedure [23,24]. Generally, an aqueous solution of peptide mixture (CALNN:CALNN GK(biotin)G) was added to the solution of 1 mL 13 nm GNPs (5 nM) to give a final concentration of total peptide of 1.5 mM. The ratio of CALNN and CALNN GK(biotin)G in the mixture is 9:1. After 1 h incubation, excess peptides were removed by repeated centrifugation at 8600 rpm (∼6900 × *g*, 3×) using an Eppendorf centrifuge (Eppendorf, Germany). The purified GNPs were resuspended in 1 mL water. Then a 30 μL streptavidin (2 mg/mL) aqueous solution was added to the peptide-capped GNPs solution. After 1 h incubation, excess streptavidin was removed by repeated centrifugation at 8600 rpm (∼6900 × *g*, 3×). The purified streptavidin-conjugated GNPs were resuspended in 1 mL HEPES buffer (pH 7.4, 10 mM HEPES, 0.8% NaCl), which were named as streptavidin@GNPs. Following a 50 μL GK(biotin)G Aβ1–16 (1 mg/mL) aqueous solution was added to the streptavidin@GNPs solution. After 1 h incubation, excess GK(biotin)G Aβ1–16 peptide was removed by repeated centrifugation at 8600 rpm (∼6900 × *g*, 3×). The purified Aβ1–16 decorated GNPs (named as Aβ1–16@GNPs) were then resuspended in HEPES buffer (pH 7.4, 10 mM HEPES, 0.8% NaCl) and stored at 4 °C. The CALNN GK(biotin)G conjugated GNPs (named as CALNN@GNPs) were also prepared under the similar procedure of Aβ1–16@GNPs synthesis except using CALNN GK(biotin)G replaces GK(biotin)G Aβ1–16. All experiments were carried out at room temperature and the HEPES buffer was used in the washing steps.

2.3. General chelation procedure

Aqueous solutions of Zn^{2+} and Ca^{2+} were prepared from their chloride salts. A series of aliquots with a desired amount of metallic ions were added to Aβ1–16@GNPs solution by a syringe and mixed thoroughly. After 30 min of incubation, the samples were ready for detection.

2.4. Reversibility study

For the reversibility experiment, equal molar of EDTA disodium solution was added to Aβ1–16@GNPs solution containing 50 μM Zn^{2+} by a syringe and mixed thoroughly. After 30 min of incubation, the samples were ready for detection.

2.5. Interaction of cells with functionalized GNPs

Before being treated with GNPs, SHG-44 cell line was grown with fresh medium (Dulbecco's Modified Eagle's medium, supplemented with 10% fetal bovine serum) in a humidified 5% CO_2 incubator at 37 °C. Then the cells were washed with HEPES buffer (three times) for the following studies. SHG-44 cell line was obtained from Chinese Academy of Sciences Cell Bank, which derived from a case of frontal lobe astrocytoma (grades II–III). This cell line contains S-100 protein specific for the nerve system and GFA protein specific for the astrocyte.

Firstly, the cells were incubated with CALNN@GNPs, streptavidin@GNPs or Aβ1–16@GNPs with the concentration of 2.4 nM in 150 μL of HEPES buffer with or without Zn^{2+} or Ca^{2+} for 2 h at 37 °C, respectively. Then, the cells were washed with HEPES buffer (three times) and imaged by an XSP-11CE optical microscope (Changfang Optical Instruments Ltd., China) equipped with a S5 IS digital camera (Canon, Japan).

2.6. Cell viability determination

The viability of cells was determined by a hemacytometer under a microscope. Generally, after being incubated with Aβ1–16@GNPs and/or Zn^{2+} as previously described, the cells were rinsed with HEPES buffer, detached by trypsin, and dispersed in the HEPES buffer; then the cell suspensions (50 μL) were incubated with 50 μL of trypan blue (0.4% w/v) for 5 min at room temperature. Experiments were repeated three times.

2.7. UV–visible absorption of stained cells measurements

After being incubated with functionalized GNPs in the absence or presence of metallic ions as mentioned above, GNPs stained cells were washed with HEPES buffer (three times), detached from the culture plates and dispersed in 150 μL HEPES buffer with a concentration of 2.3×10^4 cells/mL, then the spectrum of each cell sample was recorded, respectively. In the spectroscopic assay, corresponding streptavidin@GNPs stained cells (2.3×10^4 cells/mL in HEPES buffer) were employed as background.

2.8. Instruments

UV–visible spectra of all solutions were recorded on a UV–visible spectrophotometer (UV mini1240, Shimadzu Instruments, Japan).

TEM micrographs of all samples were obtained by a JEOL 2000FX (JEOL, Japan) operated at an accelerating voltage of 200 kV. Specimens for inspection by TEM were prepared by evaporating a droplet of sample solution onto a carbon-coated copper mesh grid.

3. Results and discussion

3.1. Metallic ions induced Aβ1–16@GNPs aggregation

UV–visible spectra of the Aβ1–16@GNPs with different amounts of ions (e.g. Zn^{2+} and Ca^{2+}) in solution are shown in Fig. 1. In the presence of Zn^{2+}, the SPR band of Aβ1–16@GNPs is gradually red-shifted from 527 nm to 537 nm with increasing the concentration of Zn^{2+} from 10 to 100 μM, corresponding to the color change of the solution from red to red-purple. The evolution of the UV–visible spectra reflects the decrease of free GNPs and the formation of nanoparticle aggregates in the solution. The interactions of Aβ1–16@GNPs with Ca^{2+} are relatively poor because the SPR band of Aβ1–16@GNPs does not change under same experimental conditions. As a control experiment, no significant change of the SPR band of CALNN@GNPs has been observed while Zn^{2+} is introduced into the solution below 100 μM. The experimental results indicate that Zn^{2+} is able to interact with Aβ1–16 which leads to form GNPs aggregates. This phenomenon agrees with previous reports on that Zn^{2+} can induce aggregation of Alzheimer's disease related β-amyloid peptides and forming fibrils [3,25].

The dependence of the maximum SPR band of Aβ1–16@GNPs solution on time is shown in Fig. 1. In the presence of 50 μM Zn^{2+}, the shift of the maximum wavelength of SPR band of Aβ1–16@GNPs takes place immediately and terminated in 30 min.

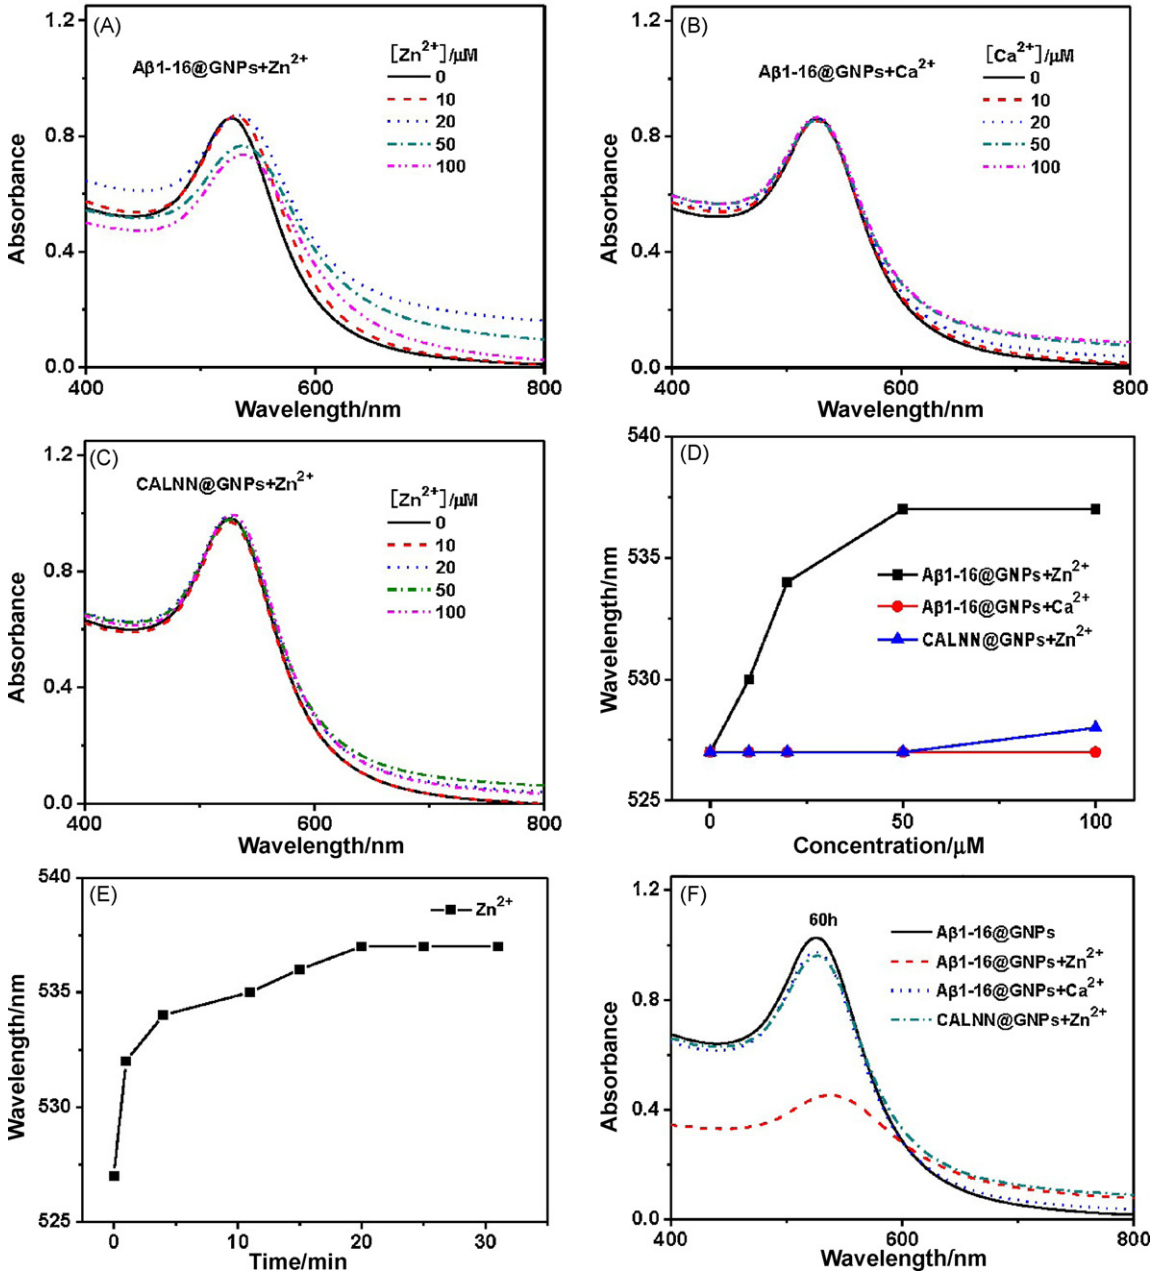

Fig. 1. The UV–visible spectra of Aβ1–16@GNPs and CALNN@GNPs versus different ion concentrations after 30 min incubation. The figures represent Aβ1–16@GNPs solutions with Zn^{2+} (A), Ca^{2+} (B), CALNN@GNPs solutions with Zn^{2+} (C) and the changes of maximum wavelength (λ_{max}) of GNPs solutions with metallic ions (D). Changes of λ_{max} as a function of time of Aβ1–16@GNPs with 50 μM Zn^{2+} (E), UV–visible spectra of Aβ1–16@GNPs or CALNN@GNPs after incubation with 50 μM metallic ions for 60 h (F).

However, the maximum absorption of Aβ1–16@GNPs is gradually decreased and the absorption peak becomes broaden with increasing the incubation time. This phenomenon indicates that large scale Aβ1–16@GNPs aggregation/polymerization is formed. On the contrary, no significant spectral change is observed in series of control experiments (i.e. Aβ1–16@GNPs without ions or with 50 μM Ca^{2+}, and CALNN@GNPs with Zn^{2+} under same condition). This result gives a further spectral evidence that the changes of Aβ1–16@GNPs were caused by the interaction of Aβ1–16 with Zn^{2+}.

To further confirm that the observed phenomenon is GNPs-based reaction, the system is examined by TEM. The TEM micrographs show that Aβ1–16@GNPs are stable and able to keep well mono-disperse in solution even after 60 h (as shown in Fig. 2A and D). In the presence of Zn^{2+}, large scale of Aβ1–16@GNPs aggregation has been observed (as shown in Fig. 2B and E). However, no significant aggregation of Aβ1–16@GNPs has been observed after being incubated with Ca^{2+} under same condition (as shown in Fig. 2C and F). This experimental result agrees with previous reports on that Aβ1–16 alone can hardly self-assemble into fibrils in water without metallic ions (e.g. Zn^{2+}) [3] and consistent with our UV–visible study.

3.2. Reversibility of aggregation of Aβ1–16@GNPs

In addition, the aggregation process can be reversed by the addition of EDTA, a good chelation agent of Zn^{2+}, resulting in a blue shift of the SPR peak of Aβ1–16@GNPs from 537 nm back to the initial position (527 nm), and the change can be cycled by the alternating addition of Zn^{2+} or EDTA (as shown in Fig. 3A and B), respectively. Furthermore, the process has also been examined by TEM (as shown in Fig. 3C and D). The TEM experimental result is consistent with UV–visible study.

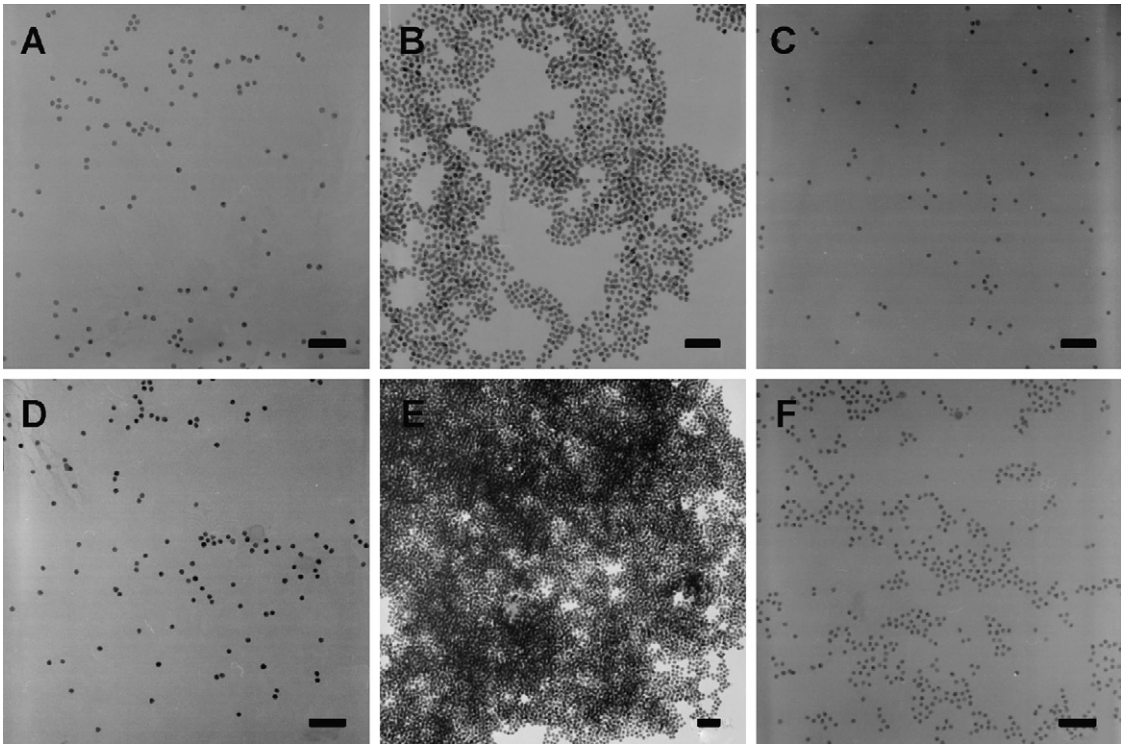

Fig. 2. TEM micrographs of Aβ1–16@GNPs without (A and D) and with 50 μM Zn^{2+} (B and E), 50 μM Ca^{2+} (C and F), respectively. The reaction times are 30 min (A–C) and 60 h (D–F). The scale bars indicate 100 nm.

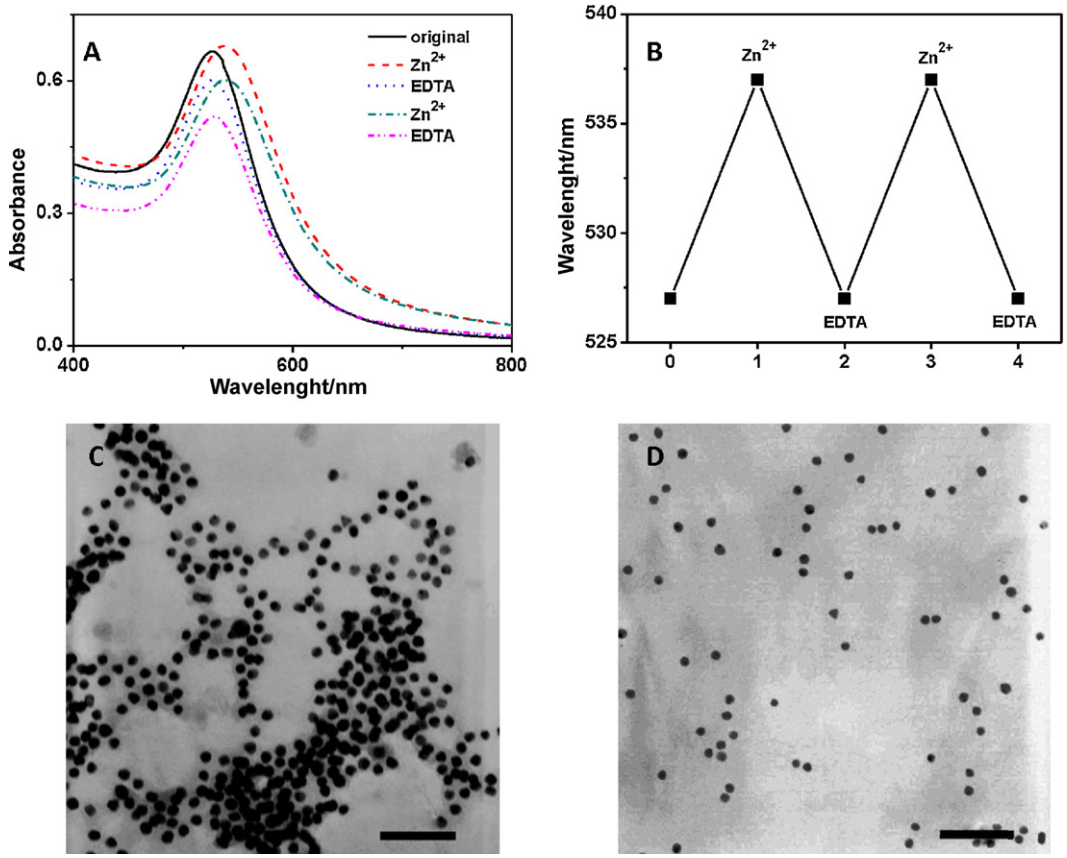

Fig. 3. The UV–visible spectra of Aβ1–16@GNPs after the addition of Zn^{2+} and EDTA (A), changes of λ_{max} in the presence of Zn^{2+} and EDTA (B), TEM micrographs of Aβ1–16@GNPs after the addition of 50 μM Zn^{2+} (C), 50 μM Zn^{2+} with 50 μM EDTA (D), respectively. The scale bars indicate 100 nm.

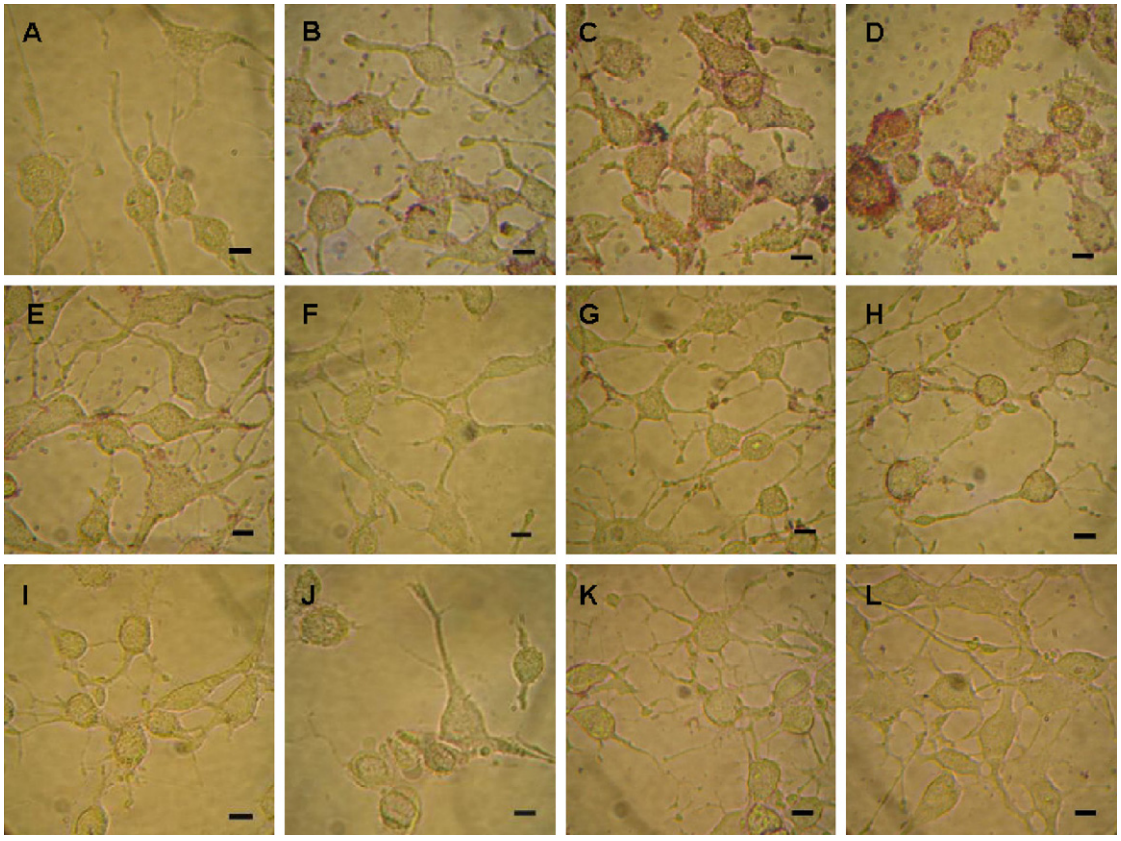

Fig. 4. Co-culturing of SHG-44 cells with GNPs. The figures represent cells alone (A). Cells co-cultured with Aβ1–16@GNPs and 20 (B), 50 (C), 100 μM (D) Zn^{2+} and 50 μM Zn^{2+} with 100 μM EDTA (E), respectively. Cells co-cultured with 50 μM Zn^{2+} (F) or Aβ1–16@GNPs (G). Cells co-cultured with Aβ1–16@GNPs and 50 μM Ca^{2+} (H). Cells incubated with streptavidin@GNPs without ions (I), with 50 μM Zn^{2+} (J) and cells incubated with CALNN@GNPs without ions (K), with 50 μM Zn^{2+} (L), respectively. The scale bars indicate 10 μm.

3.3. Interactions of Aβ1–16@GNPs with SHG-44 cells

SHG-44 cell line was chosen here to investigate the interaction of Aβ1–16@GNPs, living cells and Zn^{2+} since SHG-44 cell was derived from human frontal lobe astrocytoma which relates to some severe brain diseases. A clear Zn^{2+}-induced binding of Aβ1–16@GNPs with living SHG-44 cells has been observed. In the presence of Zn^{2+} in the culture medium, SHG-44 cell line exhibits a high level of Aβ1–16@GNPs binding. The phenomena were able to be observed by a conventional microscope and the amount of cellular binding particles was increased with increasing the concentration of Zn^{2+} (as shown in Fig. 4A–D). In addition, the Aβ1–16@GNPs staining cells can be reversed from bright red to colorless by the addition of EDTA (as shown in Fig. 4E). The experimental result is consistent with previous reports on that strongly metal chelating agents are able to reverse the aggregation of synthetic Aβ peptide and dissolve amyloid in postmortem human brain specimens [26–28]. In the control experiments, no significant cellular binding behavior of particles has been observed (as shown in Fig. 4F–L). The results indicate that it is possible to devolop a assay without complex instrumentation to identify metallic ion inducing Aβ peptide misfolding/aggregation and screening amyloid-like aggregate inhibitors in vivo.

3.4. Cytotoxicity of Aβ1–16@GNPs

Cellular cytotoxic effect is a critical issue of the protein aggregates/fibers. To determine cytotoxicity of Zn^{2+}, Aβ1–16@GNPs on SHG-44 cells, cell viability is investigated by classic trypan blue exclusion. As shown in Fig. 5, in the presence of Zn^{2+}, the Aβ1–16@GNPs reveal strongly cytotoxic effects on the cells, only half of the cells survived after co-culturing with Zn^{2+} and the Aβ1–16@GNPs for 2 h. The experimental results indicate that Zn^{2+} can induce Aβ1–16@GNPs binding on the cellular surface and inhibit cell viability. This phenomenon agrees with literature reports on the cytotoxicity of protein aggregates/fibers [29,30].

3.5. Time-dependent effect of Aβ1–16@GNPs on cells

When SHG-44 cells are co-cultured with Aβ1–16@GNPs and 50 μM Zn^{2+}, a time-dependent binding behavior is observed (as shown in Fig. 6A–E). The amount of cellular binding of

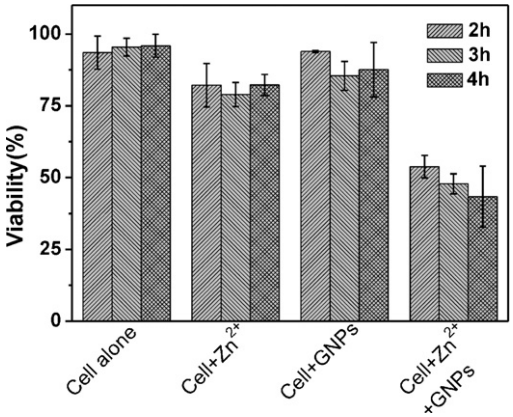

Fig. 5. Cell viability study after being co-cultured with 50 μM Zn^{2+} and/or 2.4 nM Aβ1–16@GNPs.

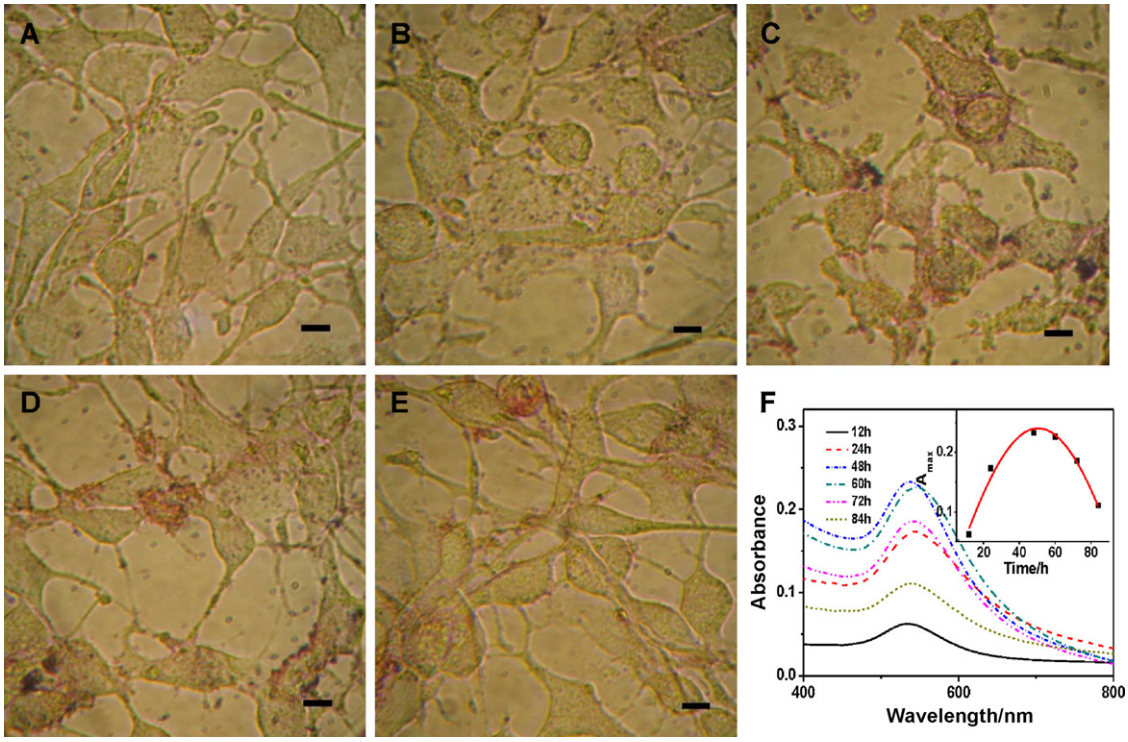

Fig. 6. Time-dependent study of SHG-44 cells co-cultured with Aβ1–16@GNPs and 50 μM Zn^{2+} after 12 h (A), 24 h (B), 48 h (C), 60 h (D), 84 h (E), respectively; the UV–visible spectra of cell solutions after co-cultured with Aβ1–16@GNPs and Zn^{2+} in the different time (F). Inset of (F) shows the maximum absorbance changes with time increasing. The scale bars indicate 10 μm.

Aβ1–16@GNPs is increased by increasing incubation time from 0 h to 48 h and reach saturation at 48 h. Then, binding amount of the particles on cellular surface was gradually decreased from 48 h to 84 h. This result may indicate changes in cellular membrane composition (i.e. amyloid precursor protein or tau protein expressing level) during progression of cells. Initial evidence has been obtained by the cellular DNA isolating experiment (data not shown) and further studies on the mechanism of this phenomenon are currently in progress.

4. Conclusions

In summary, benefit on the unique optical properties of GNPs, a simple colorimetric approach for studying the interaction of Aβ1–16 with metallic ions is developed. As proof-of-principle experiments, the interaction of two metallic ions (Zn^{2+} and Ca^{2+}) with Aβ1–16 functionalized GNPs in solution and co-culturing with SHG-44 cells have been carefully studied. The experiment results suggest that the Aβ1–16 conjugated GNPs could be used as an optical nanosensor to detect Aβ1–16 aggregation/polymerization induced by metallic ions both in solution and different cell circle phases. Therefore, this new type of GNP-based assay could open up a new possibility to develop simple biosensors for biological or biomedical applications, such as amyloid-like aggregate inhibitors screening and the aggregate process study of the peptide in vivo.

ABSTRACT

The paper describes a sensitive and highly stable label-free electrochemical impedance immunosensor for the determination of aflatoxin B_1 (AFB_1), which is based on the formation of silica gel–ionic liquid biocompatible film on the glassy carbon electrode. The electrochemical performances of the sensor were investigated by electrochemical impedance spectroscopy using a $Fe(CN)_6^{3-/4-}$ phosphate buffer solution as base solution for test. As new ionic liquid, 1-amyl-2,3-dimethylimidazolium hexafluorophosphate, offers a very biocompatible microenvironment for AFB_1 antibody, the sensor exhibits good repeatability (RSD = 1.2%), sensitive electrochemical impedance response to AFB_1 in the range of 0.1–10 ng ml^{-1} and lowers the detection limit of AFB_1 (0.01 ng ml^{-1}). The electron-transfer resistance change of the sensor after and before incubation with AFB_1 of 2.0 ng ml^{-1} can retain 95% over a 180-day storage period at 4 °C. The results present a remarkable improvement of sensitivity (2-fold) and long-term stability (190-fold) when compared to classical silica gel sensor. Moreover, proposed sensor has a high selectivity to AFB_1 alone with no significant response to AFB_2, AFG_1, AFG_2 and AFM_1 as single substrates, it has been successfully applied to the determination of trace AFB_1 in bee pollen samples with a spiked recovery in the range of 96.0–102.5%.

1. Introduction

Bee pollen has been widely used as food in human diets, providing a well-being sensation and contributing to functional and harmonious balance of the body [1]. However, during collecting, treating and storing bee pollen may be contaminated by aflatoxins (AFs) [1,2]. AFs are highly oxygenated polyketides produced as secondary metabolites by the fungi *Aspergillus flavus* and *Aspergillus parasiticus* [3]. Naturally, occurring AFs are composed of AFB_1, AFB_2, AFG_1, and AFG_2. AFB_1, which is the most abundant and carcinogenic, was classified as a carcinogenic substance of group 1 by the International Agency for Research on Cancer [4]. AFB_1 is of good thermal stability, it is hard to destroy them once they are formed [5]. Thus, the determination of AFB_1 in bee pollen is of very importance.

Some modern analytical methods have been developed for the determination of AFB_1 such as thin-layer chromatography (TLC) [6], high performance liquid chromatography (HPLC) [7–10], enzyme-linked immunosorbant assay (ELISA) [11] and spectrofluorimetry [12]. TLC, HPLC and spectrofluorimetry typically require skilled operators, extensive sample pretreatment and expensive equipment. ELISA is simple and rapid and was mainly used for screening purposes. To increase the selectivity, the antibody was widely used to clean up samples prior to measurement with a concomitant increase in assay sensitivity by LC, HPLC [13], electrochemical [14] and fluorescence spectroscopy [15]. Recently, various electrochemical sensors were given special attention due to their fast, simple, and low-cost. Some novel technologies were also employed for fabrication of the sensors to improve sensitivity, selectivity or stability, including biocatalytic amplification of enzyme labels [16], biocatalyzed precipitation [17], silver-enhanced gold nanoparticle label [18], biocatalytic deposition of silver nanoparticles [19,20], and biocatalytic metal deposition [19]. However, present electrochemical sensors are difficult to be widely applied to routine analysis due to the lack of enough stability.

Ionic liquids are compounds consisting entirely of ions that exist in liquid state around room temperature. The investigation of ionic liquids has gained increasing attention because of their unique chemical and physical properties, such as negligible vapor pressure, low toxicity, wide potential window, high ionic conductivity and good solubility. Although ionic liquids have been extensively used

doi:10.1016/j.talanta.2009.09.058

as biocompatible materials for the fabrication of biosensor [21–23] and non-aqueous biocatalysts [24,25], there is no report, in which ionic liquid was directly used for the fabrication of electrochemical immunosensor.

In this work, we present preliminary studies to establish a novel label-free electrochemical impedance immunosensor as a tool for AFB_1 detection. The sensor uniquely incorporates excellent biocompatibility of ionic liquid with highly efficient antibody immobility of silica gel. A new ionic liquid, 1-amyl-2,3-dimethylimidazolium hexafluorophosphate, was employed for improving electrochemical performance of the sensor. The main parameters governing the impedance responses were optimized, including operating pH and incubation time. Proposed immunoassay was overall proofed with simple, selective, sensitive and highly stable analysis feature by real bee pollen and spiked sample with known AFB_1 concentration.

2. Experimental

2.1. Materials and reagents

Tetraethoxysilane (TEOS), AFs and Triton X-100 were purchased from Sigma. Polyclonal antibody (Ab) was generated in rabbits in the laboratory by immunizing the animals with AFB_1-BSA [26,27]. 1-Bromopentane was purchased from Yixing Cheng Yuan Chemical Co., Ltd. (Yixing, China) and 1,2-dimethylimidazole was provided by Linhai Kaile Chemical Co., Ltd. (Linhai, China). Phosphate-buffered saline (PBS, pH 7.5, Na_2HPO_4–KH_2PO_4–NaCl–KCl, 0.01 mol l^{-1}) was prepared. All other reagents employed were of analytical reagent grade or with highest quality and were purchased from Shanghai Chemical Company (Shanghai, China), and ultra pure water (18.2 ΩM cm) purified from a Milli-Q purification system was used throughout the experiment.

2.2. Apparatus

Electrochemical experiments were performed with an IM6e electrochemical system (ZAHNER Elektrik, German). A conventional three electrode system was used with Ag/AgCl (saturated KCl) electrode as the reference electrode, platinum wire as the counter electrode, and a modified glassy carbon electrode (GCE, 2 mm in diameter) as working electrode. If not mentioned, all potentials given below were relative to Ag/AgCl (saturated KCl) electrode.

2.3. Preparation of the ionic liquid

Transfer equal amounts (0.5 mol) of 1-bromopentane and 1,2-dimethylimidazole (distilled freshly) to 500 ml of the round bottom flask, which is fitted with reflux condenser and nitrogen protecting facilities. Add 100 ml of toluene to the flask as solvent. After the mixture was stirred for 48 h at 40 °C, a transparent viscous product 1,2-dimethyl-3-amylimidazolium bromide was formed. The liquid was cooled and transferred to a 2000 ml of the beaker. And then 400 ml of potassium hexafluorophosphate (0.5 mol) was added to the well stirred mixture. After the addition of the reagent, the mixture was continuously stirred for 4 h. And then the water phase was discarded and the formed 1-amyl-2,3-dimethylimidazolium hexafluorophosphate was washed with distilled water until bromide ion was wiped off completely using a silver nitrate test. The collected ionic liquid was heated to 110 °C under vacuum to remove water for 30 min, the solvent and unreacted reactant, total yield was about to 95%. The ^1H NMR data of the product were listed in the following (400 MHz, CD_3OCD_3): 0.9 (t, 3H), 1.3(m, 4H), 1.8 (m, 2H), 2.6 (s, 3H), 3.8 (s, 3H), 4.0 (t, 2H), 7.15 (s, 1H), 7.2 (s, 1H).

2.4. Electrodes preparation

Procedure of the electrode preparation includes four assemble processes, i.e. pretreatment of GCE, preparation of silica gel/ionic liquid (SGIL), immobilization of Ab on the electrodes surface and immunity of the sensor (shown in Fig. 1). (1) GCE was polished successively with 1.0, 0.3, and 0.05 μm alumina powder, and sonicated in a 6.0 mol l^{-1} nitric acid/doubly distilled water and ethanol/doubly distilled water for 20 min, respectively. Then, the GCE electrode as working electrode was subjected to cyclic scanning in 0.5 mol l^{-1} H_2SO_4 solution in a potential range from −0.1 to 1.0 V. When the cyclic voltammogram was almost unchanged, the electrode was taken out, cleaned with water and dried under a stream of nitrogen. (2) The sol cocktail was prepared by mixing TEOS and acidified water (HCI, pH 2). In order to avoid occurring crack on the final composite film, a non-ionic surfactant Triton X-100 was added for the purpose. The volume ratio 10% (v/v) Triton X-100:TEOS:H_2O equal to 1:40:40 was held. The mixture initially comprising of two phases is made uniform by stirring vigorously under magnetic stirring at room temperature until SiO_2 was distributed evenly in the aqueous solution while the hydrolysis reaction occurs. After 10 h, the opaque silica sol was obtained. The silica sol/ionic liquid was prepared by mixing a 0.9 ml of the silica sol and 0.1 ml of the ionic liquid with a magnetic stirring for 1 h at room temperature. (3) After 1.0 ml of the silica sol gel/the ionic liquid mixed with 1.0 ml of the Ab solution containing 0.66 mg of the Ab under magnetic stirring for 0.5 h, immobilization of the Ab was completed by dropping a 0.7 μl of above mixture on the electrode surface, and it was then stored in a refrigerator at 4 °C overnight. (4) For immunity of the sensor, the modified electrode was incubated in the 20 ml of PBS (pH 7.5) containing different concentrations of AFB_1 at 37 °C under magnetic stirring for 25 min.

2.5. Electrochemical measurements

Prior to each experiment, the buffer solutions were purged with highly purified nitrogen for at least 30 min and a nitrogen atmosphere environment was kept in electrochemical measurements. Electrochemical experiments were performed with IM6e electrochemical system. Cyclic voltammetry (CV) and impedance measurements were performed in 10 ml of a pH 7.5 PBS containing 1.0 mmol l^{-1} $K_3[Fe(CN)_6]$/$K_4[Fe(CN)_6]$ (1:1 mixture as redox probe). The impedance spectra were measured in the frequency range from 10^5 to 1 Hz in a potential of 0.20 V versus Ag/AgCl (saturated KCl), with a voltage amplitude of 5 mV. The impedance Z was expressed in terms of a real (Z') and an imaginary (Z'') component. Impedance signals were recorded after reaction between the electrodes and the unstirred substrate solution for 5 min.

2.6. Sample preparation

Bee pollen samples were purchased from China market in Wuxi city. 5.0 g of the sample was extracted with 25 ml of extraction solvent (85% methanol in PBS) by shaking for 45 min. Then the extract was separated from the insoluble materials by centrifugation for 10 min at 6000 rpm. A 2 ml of the extract was diluted five times with PBS. The suspension was then hand shaken for 10 min. After the separation of the two layers, the aqueous layer was used for AFB_1 detection by the procedure described in Section 2.5.

3. Results and discussions

3.1. Cyclic voltammetry characterization

The cyclic voltammetric studies of pretreated bare GCE and modified GCE fabricated based on the silica gel–ionic liquid com-

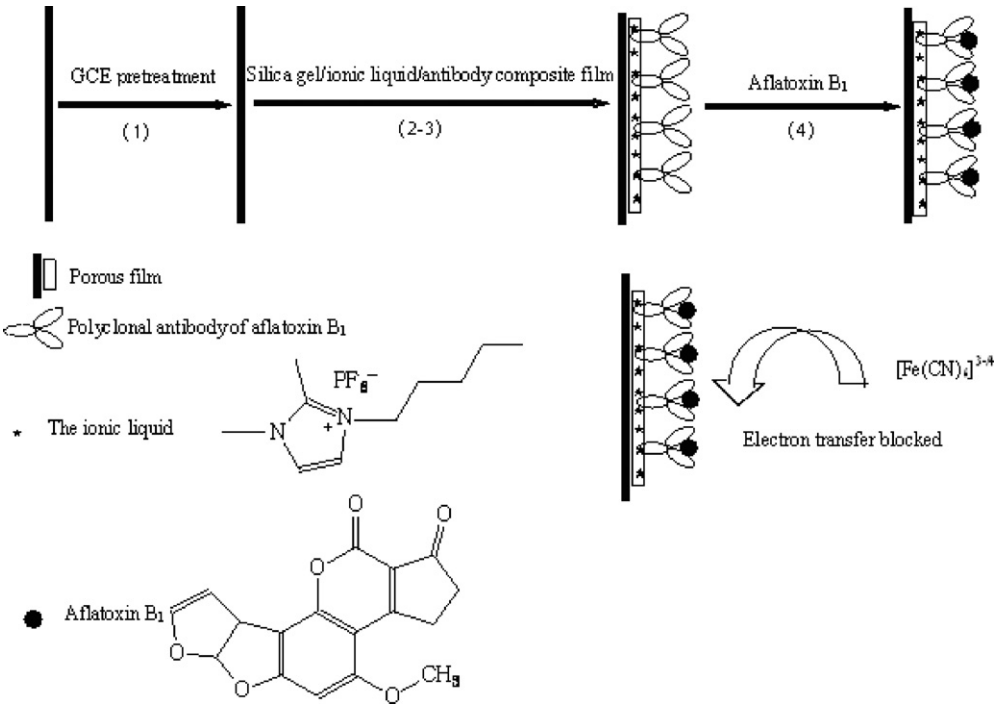

Fig. 1. Procedure of the immunosensor preparation.

posite film incubated in PBS (at pH 7.5) containing AFB_1 of 0.0, 1.0 and 7.0 ng ml^{-1} in 1.0 mmol l^{-1} $[Fe(CN)_6]^{3-/4-}$ at scan rate of 100 mV s^{-1} have been conducted to understand the nature of the bond between the ionic liquid and Ab as well and the effect of ionic liquid (Fig. 2). The cyclic voltammetric of pretreated bare GCE (curve a) shows well-defined reversible redox behavior attributed to highly electron-transfer between $[Fe(CN)_6]^{3-/4-}$ solution and the electrode. After attachment of Ab–SGIL film on the surface of the electrode, magnitude of current decreases (curve b) due to complex between –OH and –OH (or $-O^-$ and 1,2-dimethyl-3-amylimidazolium) partially block the electron-transfer between $[Fe(CN)_6]^{3-/4-}$ solution and the electrode, and the reduction potential is shifted towards the lower side at 0.24 V as compared to that of bare GCE (0.34 V). It appears the ionic liquid enhances electron conduction pathway due to its good

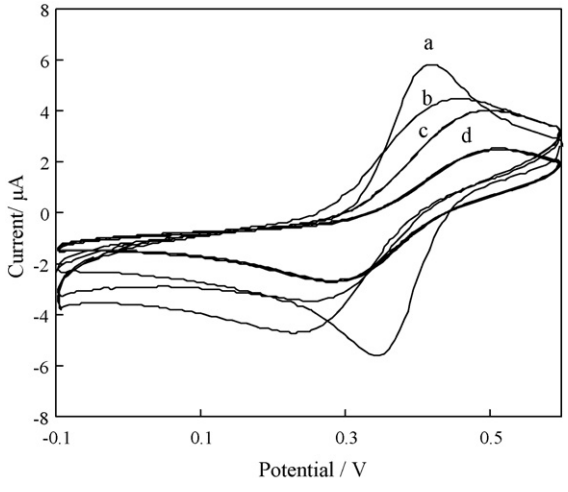

Fig. 2. Cyclic voltammograms for bare GCE (a) and modified GCE fabricated based on the silica gel/the ionic liquid composite films incubated in PBS (at pH 7.5) containing AFB_1 of 0.0 ng ml^{-1} (b), 1.0 ng ml^{-1} (c) and 7.0 ng ml^{-1} (d) for 25 min in 1.0 mmol l^{-1} $[Fe(CN)_6]^{3-/4-}$. The scan rate was 100 mV s^{-1}.

conductivity. After modified electrode was incubated in PBS containing AFB_1, the more decrease of magnitude of current was observed (curves c and d). The formation of Ab–AFB_1 complex on surface of Ab–SGIL–GCE results in an increasing block performance of electron-transfer between $[Fe(CN)_6]^{3-/4-}$ solution and the electrode, this lead to decrease of magnitude of current of Ab–AFB_1–SGIL–GCE.

3.2. Impedance spectroscopy characterization

The detailed electron-transfer behaviors of Ab–SG–GCE and Ab–SGIL–GCE electrode were also performed by electrochemical impedance spectroscopy. The clear semicircle portions were recorded in Nyquist plots of electrochemical impedance spectra for the bare GCE electrode (Fig. 3(a, EIS)), Ab–SG–GCE electrode (Fig. 3(b, EIS)) and Ab–SGIL–GCE electrode (Fig. 3(c and d, EIS)), indicating they are the electron-transfer limited process. From Fig. 3(EIS) it can be seen the electron-transfer resistances of the redox (R_{et}) for Ab–SG–GCE and Ab–SGIL–GCE electrodes increased obviously when incubated with AFB_1. The increase of R_{et} is caused by electrically insulating bioconjugates produced from specific interaction of AFB_1 and Ab, which will block the electron-transfer of $[Fe(CN)_6]^{3-/4-}$ solution to the electrode. Moreover, Fig. 3(EIS) indicated also Warburg impedance value (Z_w) of the Ab–SGIL–GCE electrode was obviously bigger than that of Ab–SG–GCE electrode, this was ascribed to diffusivity of the ionic liquid. Since taking into account the effect of the roughness of electrode surfaces, constant phase element (CPE), expressed as $Z_{cpz} = K\omega^{-\alpha}$, was chosen to replace the ideal element, i.e. capacitance or resistance. The deviation of frequency exponent α from ideal values was attributed to the homogeneities of the analyzed layer, like roughness or defects. Randles model was used as an equivalent circuit to fit all the data of electrochemical impedance measurement (Fig. 3(EC)) Here, R_s, R_{et}, Q and Z_w represented ohmic resistance of electrolyte solution, the electron-transfer resistance of the redox, constant phase element and Warburg impedance, respectively. It was found that all the square of standard derivations between original and simulated

Table 1
The electron-transfer resistance and other electrical parameters for different electrodes measured by electrochemical calculated by Randle electrical circuit.

Electrodes	R_s (Ω)	R_{et} (Ω)	Q (μF)	Z_w
Ab–SG–GCE	213.6	34930	2.782	2.54×10^{-5}
Ab–SGIL–GCE	202.3	18730	1.317	3.528×10^{-5}

data for the immunosensors which based on SGIL composite film were in the range from 0.0023 to 0.0034.

The detailed data of electrochemical impedance spectroscopy for two immunosensors were calculated. The results clearly indicated the electron-transfer resistance for Ab–SGIL–GCE electrode was obviously lower than that of Ab–SGIL–GCE electrode (see Table 1). Lower electron-transfer resistance for Ab–SGIL–GCE electrode is mainly ascribed to good conductibility of the ionic liquid.

To the compare effect of different ionic liquids on the electrochemical performance of the sensor, another similar ionic liquid, 1-butyl-2,3-dimethylimidazolium hexafluorophosphate was used to fabricate the immunosensor with a similar procedure in Section 2.4. The R_{et} of the sensor incubated in blank PBS solution (pH 7.5) and in PBS solution containing 3 ng ml^{-1} of AFB_1 were measured

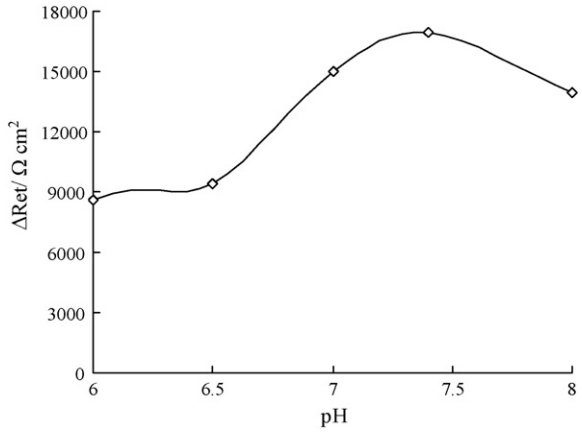

Fig. 4. Effect of pH of PHS on the specific binding of AFB_1 and the Ab immobilized on the surface of the immunosensor. The concentration of AFB_1 was 3.0 ng ml^{-1} and the interaction time 25 min.

and calculated, the results exhibited in Table 2. Table 2 clearly indicates the sensor with ionic liquid 1-amyl-2,3-dimethylimidazolium hexafluorophosphate provides a lower R_{et} in blank PBS solution and more sensitive the R_{et} response to AFB_1 than that with ionic liquid 1-butyl-2,3-dimethylimidazolium hexafluorophosphate, indicating 1-amyl-2,3-dimethylimidazolium hexafluorophosphate offers better conductivity and microenvironment to maintain activity of the Ab than 1-butyl-2,3-dimethylimidazolium hexafluorophosphate.

3.3. Optimization of the assay conditions

In order to optimize assay conditions, effects of the operating pH and incubation time were investigated well. The relationship of the relative changes of ΔR_{et} for Ab–AFB_1–SGIL–GCE electrode was evaluated over a pH range from 6.0 to 8.0 (shown in Fig. 4), in which the modified electrode was incubated in different PBS solutions containing 3.0 ng ml^{-1} of AFB_1 for 25 min. As shown in Fig. 4, the changes of ΔR_{et} for the sensor increased with the increase of pH value in value in range of pH 6–7.5, attained maximum value at about pH 7.5, and then reduced with increasing pH of buffer solution. This exhibited that specific interaction between AFB_1 and the antibody takes place more effectively at pH 7.5.

The incubation time also played an important role in the detection of AFB_1. Fig. 5 indicated with the increase of the incubation time electron-transfer resistance of the modified electrode rapidly increased until the incubation time reached 25 min. When the incubation time exceeds 25 min, the electron-transfer resistance reached maximum and remained almost unchanged. To obtain good sensitivity and rapidity, the operating pH 7.5 and the incubation time of 25 min were adopted in all the following experiments.

3.4. Analytical characteristics

A Nyquist diagram of the electrochemical impedance spectrum is an effective way to measure the electron-transfer resistance. Fig. 6 shows the representative Nyquist diagrams of proposed

Table 2
Comparison of the electron-transfer resistance (R_{et}) of the sensor with different ionic liquids.

The ionic liquid for fabrication of the sensor	R_{et} of the sensor before incubated AFB_1 (Ω)	R_{et} of the sensor after incubated AFB_1 (Ω)	ΔR_{et} of the sensor after and before incubated AFB_1 (time)
1-Butyl-2,3-dimethylimidazolium hexafluorophosphate	21,720	31,180	1.44
1-Amyl-2,3-dimethylimidazolium hexafluorophosphate	18,730	35,670	1.90

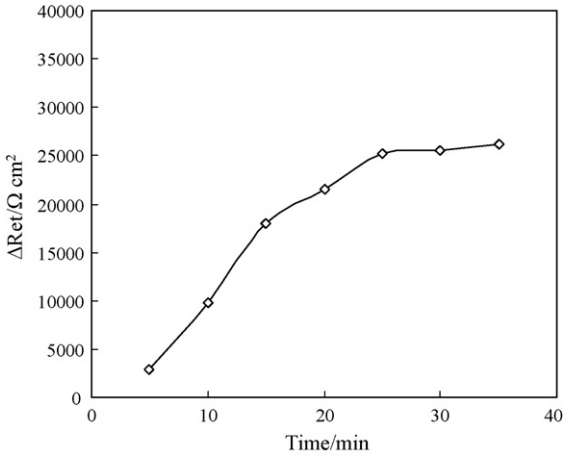

Fig. 5. Effect of the incubation time on the specific binding of AFB_1 and the antibody immobilized on the surface of the immunosensor. The concentration of AFB_1 was 7.0 ng ml^{-1} and the incubation process was performed in PBS solution (pH 7.5).

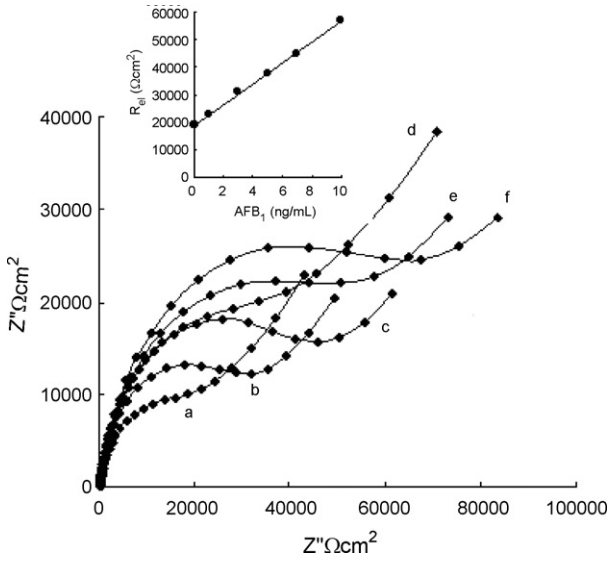

Fig. 6. Faradaic impendence spectra that corresponded to the immunosensor after incubating with different concentrations of AFB_1 in PBS (pH 7.5) containing 1.0 mmol l^{-1} $[Fe(CN)_6]^{3-/4-}$. (a), (b), (c), (d), (e) and (f) represented 0.1, 1.0, 3.0, 5.0, 7.0 and 10.0 ng ml^{-1} of AFB_1, respectively. Symbols represented the measured data, while solid lines were the theoretical spectra of equivalent circuit. The insertion: calibration curve for AFB_1.

sensor in 1.0 mmol l^{-1} $[Fe(CN)_6]^{3-/4-}$ after incubation for 25 min in PBS solution (pH 7.5) containing different concentrations of AFB_1. The electron-transfer resistance increased along with the increase of AFB_1 as shown in curves a–f. The insertion in Fig. 6 indicated the relationship of the electron-transfer resistance with AFB_1 concentrations. A linear relationship between the electron-transfer resistance and AFB_1 concentration value was found in an AFB_1 concentration range of 0.1–10 ng ml^{-1}. The linear equation was R_{et} = 3788.5C + 18,959, with a statistically significant correlation coefficient of 0.9996. The detection limit of label-free impedance detection assay was 0.01 ng ml^{-1} for Ab–SGIL–GCE electrode and 0.02 ng ml^{-1} for Ab–SG–GCE electrode that was obtained from the signal-to-noise characteristics of these data (S/N = 3). This indicated the sensitivity of Ab–SGIL–GCE electrode is 2-fold as same as that of Ab–SG–GCE electrode.

The long-term stability of both Ab–SGIL–GCE and Ab–SG–GCE sensors was examined. The electron-transfer resistance changes (ΔR_{et}) of the sensor after and before incubation with AFB_1 of 2.0 ng ml^{-1} retains 95% for Ab–SGIL–ECE electrode (from 77,577 to 7199 Ω) and 0.5% for Ab–SG–GCE electrode (from 6062 to 303 Ω) over a 180-day storage period at 4 °C. These present remarkable improvement of long-term stability (190-fold) when compared to classical silica gel sensor. We think good sensitivity and stability of Ab–SGIL–GCE electrode ascribe to relatively stable spatial configuration of the Ab, in which the ionic liquid provides favorable microenvironment for the Ab.

The precision was evaluated by successive determinations of 3.0 ng ml^{-1} AFB_1 for six times using the same Ab–SGIL–GCE electrode and experimental conditions. The relative standard deviation was calculated to be 1.2%. The fabrication reproducibility was estimated by the measurements of 3.0 ng ml^{-1} AFB_1, in duplicate, with six different electrodes made at the same GCE electrode independently. The relative standard deviation was 1.7%, showing a good reproducibility and acceptable precision.

3.5. Nonspecific interactions

Since selectivity is a very important characteristic, it was necessary to check it for Ab–SGIL–GCE electrode. Among 18 different types of AFs identified, the major ones are AFB_1, AFB_2, AFG_1, AFG_2 and AFM_1. The International Agency for Research on Cancer has classified all four AFs as Group 1 carcinogens. We, therefore, examined the proposed sensor response to AFB_1 and AFG_1, AFB_2, AFG_2, AFM_1. The results indicated proposed sensor has a high selectivity to AFB_1 alone with no significant response to AFB_2, AFG_1, AFG_2 and AFM_1 as single substrates.

3.6. Regeneration of the electrode

The regeneration of Ab–SGIL–GCE electrode was investigated by repeatedly monitoring the binding of 2.0 ng ml^{-1} AFB_1 under

Table 3
The results for the determination of real and spiked bee pollen samples (n = 5).

Samples	Added AFB_1 (ng g^{-1})	Found AFB_1 by proposed method (ng g^{-1})	Found AFB_1 by HPLC method (ng g^{-1}) [28]	Recovery (%)
Bee pollen 1	0.0	0.52 ± 0.011	0.50 ± 0.018	
	2.0	2.57 ± 0.030		102.5
Bee pollen 2	0.0	0.16 ± 0.046	0.13 ± 0.013	
	2.0	2.08 ± 0.055		96.0
Bee pollen 3	0.0	0.00 ± 0.002	0.00 ± 0.011	
	2.0	1.96 ± 0.019		98.0
Bee pollen 4	0.0	0.39 ± 0.11	0.32 ± 0.17	
	2.0	2.42 ± 0.23		101.5
Bee pollen 5	0.0	0.22 ± 0.006	0.23 ± 0.009	
	2.0	2.15 ± 0.030		96.5

same experimental conditions. Following each binding event, the electrode was regenerated for 30 min in 0.1 mol l^{-1} glycine buffer solution (pH 2) to desorb the combined Ab. The relative standard deviation of the changes of electron-transfer resistances for twenty binding and regeneration cycles was found to be 1.2%. The fact has demonstrated the method using the sensor for AFB_1 detection was of excellent reproducibility.

3.7. Analysis of real samples

The feasibility of the newly developed method for possible applications was investigated by analyzing real bee pollen samples. The preparation of sample was described in Section 2.6. The sample and the spiked sample with different amounts of AFB_1 were testified. The sample was used for the analysis to replace the PBS solution of AFB_1 as mentioned above. The concentration of AFB_1 in bee pollen sample was determined from the calibration curve and the value can be used to calculate the concentration in the original sample. The mean ± SD of each sample and recovery of each spiked sample were calculated, and the values are reported in Table 3. The analytical data for various samples given in Table 3 indicate a high degree of correlation between the results of HPLC and proposed sensor. The recovery of AFB_1 for spiked samples analysis is in the range from 96.0% to 102.5%. These indicated proposed method has a good accuracy and precision.

4. Conclusion

In this paper, a highly sensitive and stable impedance sensor based on silica gel/ionic liquid composite film was developed for AFB_1 detection in bee pollen. Because of good biocompatibility and conductibility of the ionic liquid, the resulting proposed sensor exhibited high sensitivity and stability, indicating the composite film can retain antibody activity. The sensor showed good precision, reproducibility, regeneration and storage stability, and acceptable accuracy for sample determination, which exhibited promising application prospect as novel sensor.

Flame atomic absorption spectrometry

ABSTRACT

Hydrophobic ionic liquid could be dispersed into infinite droplets under driving of high temperature, and then they can aggregate as big droplets at low temperature. Based on this phenomenon a new liquid-phase microextraction for the pre-concentration of lead was developed. In this experiment, lead was transferred into its complex using dithizone as chelating agent, and then entered into the infinite ionic liquid drops at high temperature. After cooled with ice-water bath and centrifuged, lead complex was enriched in the ionic liquid droplets. Important parameters affected the extraction efficiency had been investigated including the pH of working solution, amount of chelating agent, volume of ionic liquid, extraction time, centrifugation time, and temperature, etc. The results showed that the usually coexisting ions containing in water samples had no obvious negative effect on the recovery of lead. The experimental results indicated that the proposed method had a good linearity ($R = 0.9951$) from 10 ng mL^{-1} to 200 ng mL^{-1}. The precision was 4.4% (RSD, $n = 6$) and the detection limit was 9.5 ng mL^{-1}. This novel method was validated by determination of lead in four real environmental samples for the applicability and the results showed that the proposed method was excellent for the future use and the recoveries were in the range of 94.8–104.1%.

1. Introduction

Along with the development of industry, the environmental pollution induced by lead became more and more serious and threw a threat on the human health. Reports have indicated that lead had neurotoxicity [1], nephrotoxicity [2] and carcinogenicity [3,4]. Therefore, the environmental pollution of lead resulted in a public health problem and the monitoring of lead in environment was very important.

Nowadays, a variety of techniques are developed for the trace and ultra-trace determination of lead. Erta et al. [5] has established a hydride generation atom trapping flame atomic absorption spectrometry method for the determination of lead and the detection limits are in the range of 0.028–0.075 ng mL^{-1}. When an induction-heating electrothermal vaporizer (IH-ETV) ICP–MS was applied for use, the detection limit of lead reached to 0.04 μg g^{-1} [6]. A direct determination of lead in solid samples had been developed based on high-resolution continuum source graphite furnace atomic absorption spectrometry, and its detection limit was 0.01 μg g^{-1} [7].

In general, the low concentration of analyte and complex sample matrix would influence the sensitivity and accuracy of the developed method. Hence the enrichment or cleanup step is very necessary in the analytical procedure. Up to date, a variety of methods have been reported for the pre-concentration and separation of lead including solid phase extraction [8,9], cloud point extraction [10], capillary microextraction [11], solid phase microextraction [12], and single-drop microextraction [13], etc. Among them, solid phase extraction is the most widely used one due to the merits such as simplicity, low consumption of organic solvents, and stable extraction performance. Solid phase microextraction is a good sample pretreatment method, but it suffers from sample carryout and a decline in performance with the reuse of the fiber. As the determination of lead was concerned, a derivatization step is needed when solid phase microextraction is used [10]. Recently, dispersive liquid–liquid microextraction has been developed as a new mode of liquid-phase microextraction and attracted increasing attention for its simple operation, rapidness, and high extraction efficiency. In this extraction procedure, two organic solvents having different characteristics are involved in use, one is

doi:10.1016/j.talanta.2009.09.059

hydrophilic which performs as dispersive solvent such as methanol [14] and acetone [15] etc., and the other is hydrophobic which performs as extraction solvent such as chlorobenzene [16] and carbon tetrachloride [17]. The extraction solvent would form innumerable infinite small droplets, when it was rapidly injected into the sample solution. These droplets limitlessly enlarge the contact area between extraction solvent and analytes. So far, this method has been successfully applied to the enrichment of heavy metals [18,19], metallo-organic compound [17], polychorinated biphenyls [20], polycyclic aromatic hydrocarbons [21], polyphenol-like compounds [22–24], polybrominated diphenyl ethers [25], pesticides [26] and herbicides [27].

On the basis of traditional dispersive liquid–liquid microextraction, Zhou [28,29] established a better extraction mode termed temperature-controlled ionic liquid dispersive liquid-phase microextraction. This method used ionic liquid to substitute for the conventional organic solvents and utilized the change of temperature to realize the enrichment of the organophosphorus pesticides and pyrethroid pesticides. Ionic liquids (ILs), which have been considered as green solvent, and have been used as extraction solvent in solvent extraction [30] and single-drop microextraction [31] for the enrichment of nickel in water, rice flour, and black tea [32], mercury [33], and aromatic hydrocarbons [34]. However, ionic liquids have not been often used in dispersive liquid-phase microextraction. The goal of present work is to establish a new method for the trace determination of lead using temperature-controlled ionic liquid dispersive liquid-phase microextraction coupled with flame atomic absorption spectrometry. The effect of various experiment conditions on the extraction of lead is investigated and discussed in detail.

2. Experimental

2.1. Reagents and standard solution

1-Hexyl-3-methylimidazolium hexafluorophosphate [C_6MIM][PF_6] was purchased from Acros Organics and used as obtained. Stock standard solution of lead with a concentration of 1000 μg mL^{-1} was obtained by dissolving appropriate amount of lead acetate (Kermel Chemistry Reagent Company, Tianjin, China) in double-distilled water. Working standard solution was obtained by appropriate dilution of the stock standard solution. The solution of dithizone was prepared by dissolving an appropriate amount of dithizone (Shanghai Reagent Factory, Shanghai, China) in ethanol. The double-distilled water was prepared in the lab using quartz-glass vaporization purchased from Ya-rong (Shanghai, China) and all the other solvents were analytical reagent grade unless otherwise stated. 0.5 mol L^{-1} of sodium hydroxide and concentrated hydrochloric acid were used for adjusting the pH value of the water samples. All glassware used in the experiments were cleaned with pure water, then soaked in 6 mol L^{-1} nitric acid for 24 h and then washed with purified water.

2.2. Apparatus

A Z-5000 Polarized Zeeman Atomic Absorption Spectrophotometer (Hitachi, Ltd. Tokyo. Japan) fitted with lead hollow cathode lamp was used. This apparatus was equipped with Zeeman effect background correction. The main instrument parameters were listed as below, lamp current, wavelength, slit, burner height, flame, oxidant gas pressure and fuel gas flow rate are 9 mA, 283.3 nm, 1.3 nm, 7.5 mm, 160 kPa, and 2.2 L min^{-1}, respectively. Centrifuger (Shanghai Surgery Machinery Factory, Shanghai, China) was used to achieve the phase separation. 81-2 thermostatic magnetic stirring apparatus (Si-le Instrumental Company, Shanghai, China) was used for heating in water bath.

2.3. Temperature-controlled ionic liquid–liquid-phase microextraction

In the pre-concentration procedure of lead, 50 μL [C_6MIM][PF_6] was used as extraction solvent and added into a 10 mL glass marked conical tube. 50 μL dithizone was used as chelating agent and the working solution was spiked with a lead concentration of 200 ng mL^{-1}. Then the sample solutions were heated in a water bath with the temperature controlled at 80 °C. The IL was dissolved completely and would entirely mix with the working solutions in order to make the chelate complex migrate into the IL phase. The tube was thereafter cooled with ice water and the solution became turbid. Then the solution was centrifuged for 15 min. The upper aqueous phase was removed with a syringe, and the residue was dissolved in 150 μL methanol and 1.5 M nitric acid to 0.8 mL. The final solution was determined by flame atomic absorption spectrometry (FAAS).

2.4. Real water sample analysis

Four environmental samples were used to investigate the applicability of this proposed method. These samples included river water, groundwater, reservoir water and rainwater. River water was collected from Anyang River, Anyang City, Henan province, China. Groundwater was obtained from Henan Normal University, Xinxiang City, Henan province, China. Reservoir water was collected form Shi-men reservoir in Xinxiang City, Henan province, China. Rainwater was obtained from Henan Normal University. Before use all the environmental water samples were filtered through 0.45 μm micro-pore membranes and stored in brown glass containers under low temperature.

3. Results and discussion

Temperature-controlled ionic liquid–liquid-phase microextraction is a new process, but it has some similarities with the dispersive liquid-phase microextraction. Compared with a conventional liquid-phase microextraction carried out in a single solvent drop, these two extraction modes infinitely enlarge the surface area of the extraction solvent and the contact area between extraction solvent and analytes which significantly enhance recoveries of analytes. In addition, compared with dispersive liquid-phase microextraction, ionic liquid is used as a substitute for toxic organic reagents in temperature-controlled ionic liquid–liquid-phase microextraction. Some important parameters that would influence the enrichment performance had been investigated in detail, in order to obtain the maximal extraction efficiency.

3.1. Effect of sample pH

The acidity of sample solution plays an important role in an extraction procedure, because it determines the present state of analytes in most cases. In general, analytes would be preferably extracted in most of the extraction procedure as molecular state. Hence in this experiment lead ion should be converted into molecular form to make the extraction procedure available. For this propose, the effect of sample acidity was investigated systematically between pH 2 and pH 11 with dithizone as chelating reagent, which ensured that lead ion could be extracted as chelate complex. The results exhibited in Fig. 1 and it showed that the recovery of lead increased significantly as the sample acidity increased from 2 to 7 and decreased between 9 and 11. When pH was between 7 and 9, the recoveries of lead were up to 92.3–111.7% and the maximum recovery was achieved at 8. Thus, a sample pH of pH 8 was selected for use in the following experiments.

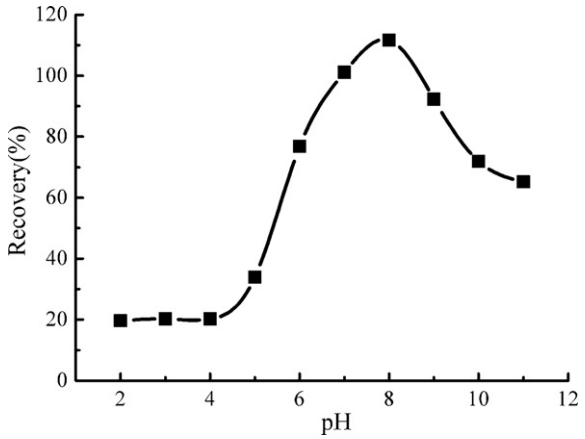

Fig. 1. Effect of samples pH. Concentration: 200 ng mL^{-1}; volume of ionic liquid: 50 μL; volume of dithizone: 40 μL; extraction time: 30 min; centrifugation time: 15 min; dissolve temperature: 50 °C; centrifugation rate: 4000 rpm.

3.2. Effect of the volume of dithizone

Dithizone was a better chelating agent for lead extraction and its chelating ratio was 2:1. Enough dithizone was needed to assure the lead would be extracted completely. Therefore, the volume of dithizone was investigated over the range of 15–50 μL with a concentration of 1×10^{-3} mol L^{-1} and using a standard solution of 200 ng mL^{-1}. Fig. 2 exhibited that when the volume of dithizone was up to 20 μL, the lead would be extracted completely. However, 50 μL of dithizone was used in the subsequent research to avoid the competitive chelation of coexisting ions in real samples.

3.3. Effect of volume of ionic liquid

In conventional liquid-phase extraction and microextraction, the volume of extractant was a crucial parameter, which significantly influences extraction efficiency of analytes. Theoretically, the larger the volume of extractant is, the higher recoveries of analytes would be. In practice, the volume of extractant of single-drop liquid-phase microextraction was limited to several microliters, as for the hollow fiber based liquid-phase microextraction, the extractant volume was not beyond to 20 μL, which seriously influences the absolute recoveries of analytes. In this experiment [C_6MIM][PF_6] was selected as extraction solvent because of its hydrophobicity. The volume of ionic liquid was optimized between 35 and 50 μL and the results were exhibited in Fig. 3. As can be seen,

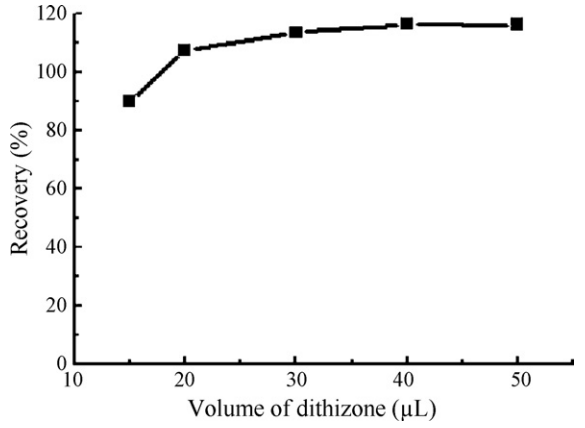

Fig. 2. Effect of volume of dithizone. Concentration: 200 ng mL^{-1}; volume of ionic liquid: 50 μL; pH: 8; extraction time: 30 min; centrifugation time: 15 min; dissolve temperature: 50 °C; centrifugation rate: 4000 rpm.

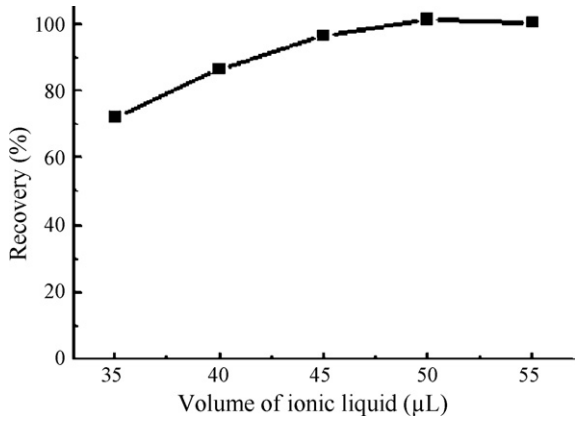

Fig. 3. Effect of volume of ionic liquid. Concentration: 200 ng mL^{-1}; pH 8; volume of dithizone: 50 μL; extraction time: 30 min; centrifugation time: 15 min; dissolve temperature: 50 °C; centrifugation rate: 4000 rpm.

the recovery of lead increased along with the increase of volume of ionic liquid from 35 μL to 45 μL, and kept stable between 45 μL and 50 μL. This was because of the fact that the fine IL droplets increased along with the increase of the [C_6MIM][PF_6] volume and more chelate complex were transferred into the IL droplets, which leaded to the higher enrichment performance. On the basis of these facts, 50 μL ionic liquid was selected in order to achieve the perfect analytical performance.

3.4. Effect of extraction time

In this experiment, extraction time was defined as the time from the moment that the solution started to be cooled to the moment that it was put in the centrifuger. This process was very important because it was the phase separation procedure. The effect of extraction time was examined over 5–45 min and the results indicated that the recovery of lead increased slowly when the extraction time was changed from 5 to 15 min and the recovery of lead had no obvious change when the extraction time was longer than 15 min. According to these, 15 min was chosen in the following study in order to reduce the analytical time of this experiment.

3.5. Effect of centrifugation time and centrifugation rate

Centrifugation time and centrifugation rate were important parameters that influenced the separation of ionic liquid from water phase. And the centrifugation time was optimized between 5 and 25 min. The results exhibited that when the centrifugation time was up to 15 min, the recovery of lead was over 95%. When the centrifugation time was shorter or longer, the recoveries were both lower than 95%. The short centrifugation time could not insure the preferable phase separation, and longer centrifugation time would induce the ionic liquid dissolved in water phase again. In addition, the centrifugation rate was optimized between 500 and 4000 rpm. When the centrifugation rate was at 500 rpm, the recovery was about 84.6%. When the centrifugation rate was over 500 rpm, the recovery was increased slowly and achieved the most value at 4000 rpm. So 15 min and 4000 rpm were selected for further use.

3.6. Effect of temperature

In the conventional dispersive liquid–liquid-phase microextraction, the dispersing of extractant was achieved with the help of hydrosoluble solvent such as acetone and methanol. In this experiment, temperature has been used as the driving power to make ionic liquid dissolved in aqueous solution. Therefore, temperature

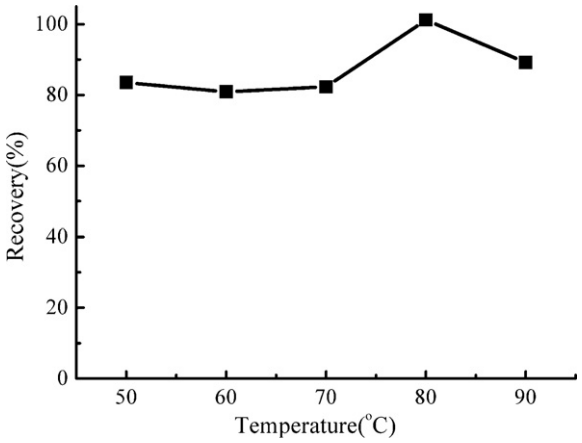

Fig. 4. Effect of dissolve temperature. Concentration: 200 ng mL^{-1}; volume of ionic liquid: 50 μL; pH 8; volume of dithizone: 50 μL; extraction time: 25 min; centrifugation time: 15 min; centrifugation rate: 4000 rpm.

became much more important because it significantly influenced the dispersive performance of ionic liquid in water solution. The effect of temperature was optimized in the range of 50–90 °C and the results were showed in Fig. 4. It was obviously that the recoveries were all lower than 85% when the temperature was between 50–70 °C due to that the lower temperature could not realize the complete dispersion. On the hand a higher temperature make the chelation of lead and dithizone difficult. So 80 °C was reasonable for the application in the following experiments.

3.7. Effect of coexisting ion

It has been documented that many metal ions existing in environmental waters would form stable chelating complexes with dithizone within a wide pH range and may be co-extracted along with the analytes. Moreover, this competitive chelating effect coupled with co-extracted effect would influence the chelating degree between lead and dithizone and make the extraction efficiency of lead decrease. Therefore, a series of experiments have been designed using a standard solution of 200 ng mL^{-1} of lead under the above-optimized conditions. The results were given in Table 1. The obtained results indicated that the presence of large amounts of cation and anion including Na^+, K^+, Mg^{2+}, and SO_4^{2-}, etc. had no obvious influence on the recovery of lead within a ±5% error range except for Fe^{3+}.

Table 1
Effect if coexisting ion (Pb^{2+}: 200 ng mL^{-1}).

Coexisting ion	Concentration of coexisting ion (μg mL^{-1})	Recoveries of Pb (%)
Na^+	400	97.4
Ca^{2+}	130	98.1
K^+	160	97.3
Mg^{2+}	100	103.0
Zn^{2+}	30	98.8
Cu^{2+}	30	96.8
Fe^{3+}	30	92.9
Cd^{2+}	25	99.4
Cr^{3+}	15	96.5
SO_4^{2-}	160	100.1
Cl^-	400	97.4

3.8. Analytical performance

The analytical performance of temperature-controlled ionic liquid–liquid-phase microextraction coupled with FAAS for the pre-concentration and determination of lead from environmental samples was systematically investigated under optimized experimental conditions. The results exhibited that there was an excellent linear correlation between ABS and the concentration of lead from 10 to 200 ng mL^{-1} and good correlation coefficient of 0.9995. The precision of this method was 4.4% (RSD, $n = 6$) at the spiked concentration of 50 ng mL^{-1}. And the detection limit (calculated as the concentration corresponding to three times the standard deviation of 11 runs of the blank samples) of proposed method for lead was 9.5 ng mL^{-1}. The proposed method was also validated with certified reference water sample (GSB 07-1183-2000). The standard value is 0.593 μg mL^{-1} and the mean determined value is 0.579 μg mL^{-1} ($n = 6$). The recovery and precision are 97.6% and 1.5%, respectively. This result indicated that the proposed method is very reliable. Compared to the developed method for the lead determination, present method was not the best sensitive method (see Table 2). The reason was that the small sample volume and the instrument with low sensitivity. If the proposed method could be in combination with ICP–MS or atomic fluoresce spectrometry, the detection limit of the method would be significantly improved.

Table 2
Comparison of proposed method with the reported methods.

Table 3
Spiked recoveries of four real water samples (Pb: 50 ng mL^{-1}).

Samples	Blank (ng mL^{-1})	Spiked recoveries(%)
Anyang river	–	94.9 ± 3.6
Shimen reservoir	–	101.8 ± 6.8
Rain water	–	94.8 ± 6.3
Ground water	–	104.1 ± 6.9

3.9. Analysis of real water samples

In order to demonstrate the applicability and reliability of the proposed method for realworld samples, four environmental samples, including river water, reservoir water, ground water and rainwater were collected. Three spiked and two blank experiments for each real water sample were carried out according to the above-mentioned procedure. There found no lead in blank solutions of four samples. Subsequently extraction of four samples spiked with lead at 50 ng mL^{-1} were processed as the described above. The concentration of lead was determination by FAAS and the results were given in Table 3. The recoveries of lead were in the range of 94.8–104.1%.

4. Conclusions

A novel and simple method temperature-controlled ionic liquid–liquid-phase microextraction was developed for the pre-concentration of lead in water samples. The experimental results demonstrated that this new extraction technique coupled with FAAS for the pre-concentration and determination of lead exhibited many merits such as excellent enrichment performance, sensitive, simple operation, cost-effective and no consumption of organic toxic solvents. However it could not reach the reported sensitivity level of SPE-FAAS, etc., it still offered a new procedure for the enrichment of lead in water samples and it would achieve much better detection sensitivity if ICP–MS, GFAAS and atomic fluoresce spectrometry could be used as the detector. Its high tolerance to coexisting ions and perfect analytical performance indicated that this proposed method was a well alternative for the determination of lead in environmental samples.

ABSTRACT

A solid-state electrochemiluminescence (ECL) biosensing switch based on special ferrocene-labeled molecular beacon (Fc-MB) has been successfully developed for T4 DNA ligase detection. Such special switch system consisted of two main parts, an ECL substrate and an ECL intensity switch. The ECL substrate was made by modifying the complex of Au nanoparticle and Ruthenium (II) tris-(bipyridine) ($Ru(bpy)_3^{2+}$-AuNPs) onto Au electrode. A molecular beacon labeled by ferrocene as the ECL intensity switch. The molecular beacon is designed with special base sequence, which could combine with its target biomolecule *via* the reaction of the repair and recombination of nucleic acids by DNA ligase. During the reaction, the molecular beacon opened its stem–loop, and the labeled Fc was consequently kept away from the ECL substrate. Such structural change resulted in an obvious increment in ECL intensity due to the decreased Fc quenching effect to the ECL substrate. The analysis results are sensitive and specific.

1. Introduction

Nucleic acid ligation is one vital process in the repair, replication and recombination of nucleic acids and also an important tool for editing DNA both *in vivo* and *in vitro* [1–3]. Therein, DNA ligase plays an indispensable role in catalyzing the formation of phosphodiester bonds at single strand nick between adjacent 3′-hydroxyl and 5′-phosphate ends in double strand DNA [4–7]. Therefore, specific recognition and quantitative detection of DNA ligase are crucial to fundamental research as well as clinical practice. Currently, the ligation process is usually assayed by radial P labeling, denaturing gel electrophoresis, autoradiography and fluorescence [4]. But these methods are time consuming and not sensitive [8–11].

Molecular beacon (MB), a stem–loop structure oligonucleotide, was initially described in 1996 as a switch able to undergo spontaneous conformational change following hybridization with the complementary nucleic acid target [12,13]. It possesses high selectivity, fast speed, convenience and excellent sensitivity. MB has been used in the investigation of genetic disease, the studies of DNA–protein interactions, the monitoring of the nucleic acids ligation process and the detection of DNA/RNA hybridization in living cells [14–19]. Tang et al. have used MB to monitor the nucleic acid ligation process in real-time, the sequence of which is designed to be complementary with the product of the ligation [9]. However, the MB, ligation substrate, nucleic acid hybridization complex and DNA ligase are all in solution. MB can only be used to detected DNA ligase in homogeneous solution.

In our recently studies, a solid-state electrochemiluminescence biosensing switch was developed successfully [20,21]. The biosensing system employed $Ru(bpy)_3^{2+}$-AuNPs modified Au electrode to emit ECL, and the ferrocene-labeled molecular beacon (Fc-MB) to control the ECL intensity with consideration of the high ECL quenching efficiency of Fc to $Ru(bpy)_3^{2+}$. It has been found that the ECL intensity of the $Ru(bpy)_3^{2+}$-AuNPs modified Au electrode was correlated to the conformation of the Fc-MB. The Fc-MB was designed with special base sequence, which could be combined with its target biomolecule *via* the reaction of DNA hybridization or aptamer–protein combination. Therefore, the system can be applied to recognize the relevant biomolecules selectively.

Based on these studies, we attempt to combine the solid-state electrochemiluminescence biosensing switch with the template of nucleic acids ligation as well as the repair and recombination of nucleic acids by DNA ligase to detect DNA ligase. The Fc-MB is not only a probe for the detection of the ligation process, but also a template for the two oligos in the ligation process. Using this method, an efficient bioassay for monitoring the activity of T4 DNA ligase has been developed. In this protocol, the MB, ligation substrate, nucleic acid hybridization complex and DNA ligase were all captured to the surface of the electrode to avoid the interference by the target

oligos and basal solution in detection. The method can be used to quantitate the T4 DNA ligase rapidly, sensitively and selectively.

2. Experimental

2.1. Reagents and apparatus

Oligonucleotides were purchased from Shenggong Bioengineering Ltd Company (Shanghai, China). The sequence of molecular beacon (MB): 5′-NH_2-$(CH_2)_6$-GGGCGTTGA*TGGTTCCACTTCTCGTGCGT* TCAACG-$(CH_2)_6$-SH-3′ (the underlined and italic sequences indicate the stem and loop of the MB), Fragment N1: 5′-CGCACGAGAAGTGGAACC-3′ (18-nt oligo matching the loop of the MB), N2: 5′-CGCACGAGA-3′ (9-nt oligo matching 3′ half part of the loop of the MB), N3: 5′-AGTGGAACC-3′ (9-nt oligo matching 5′ half part of the loop of the MB), N4: 5′-pAGTGGAACC-3′ (9-nt oligo matching 5′ half part of MB's loop and was phosphorylated at its 5′ end). T4 DNA ligase (5 U μL^{-1}) and diluted buffer (66 mM Tris–HCl containing 50% glycerol, 10 mM 2-mercaptoethanol, 0.1 mM EDTA and 50 mM KCl, pH 7.5) were purchased from Dingguo Biological Technology Corporation of Shanghai. $Ru(bpy)_3^{2+}$ (99.95%), $HAuCl_4$, 6-mercapto-1-hexanol (SH-$(CH_2)_6$-OH, >97.0%), cysteamine (SH-$(CH_2)_2$-NH_2) and 1-ethyl-3-[(3-dimethylamino)propyl]carbodiimide (EDC) were purchased from Sigma (USA). Ferrocenecarboxylic acid (FCA), dithiothreitol (DTT), horseradish peroxidase (HRP) and glucose oxidase (GOD) were purchased from Maoji Bioengineering Ltd Company of Shanghai. The following buffers were used: 66 mM Tris–HCl containing 0.8 M NaCl and 100 mM $LiClO_4$ (pH 7.5), 66 mM Tris–HCl containing 50 μM ATP, 20 mM $MgCl_2$, 10 mM DTT and 100 mM $LiClO_4$ (pH 7.5). 66 mM Tris–HCl containing 1.0 mM tri-*n*-propylamine (TPrA) and 5.0 mM $LiClO_4$ (pH 8.7) was used as the detecting solution. Other reagents were of analytical reagent grade. All of the solutions were prepared with ultrapure water from a Millipore Milli-Q system.

ECL was recorded with MPI-E electrogenerated chemiluminescence analyzer (Xi'an Remax Electronic Science Tech., Co. Ltd), a CHI 660A electrochemical analyzer (CHI instruments Inc., USA) was used to carry out impedance measurements.

2.2. Preparation of Fc-MB–$Ru(bpy)_3^{2+}$-AuNPs electrode

The Fc-MB–$Ru(bpy)_3^{2+}$-AuNPs electrode was prepared according to previously published protocols [20]. Briefly, a self-assembled monolayer of cysteamine is prepared onto Au electrode firstly (cysteamine-derivated Au electrode), then, the $Ru(bpy)_3^{2+}$-AuNPs composite is assembled onto the cysteamine-derivated Au electrode to form the luminescent substrate. The as-prepared electrode was $Ru(bpy)_3^{2+}$-AuNPs electrode. The Fc-MB is attached onto the above electrode *via* Au–S interaction, and the electrode was then treated with SH-$(CH_2)_6$-OH solution to occupy the unassembled surface of $Ru(bpy)_3^{2+}$-AuNPs as well as adjust the Fc-MB distribution on the electrode surface. Thus, the Fc-MB–$Ru(bpy)_3^{2+}$-AuNPs electrode was obtained which has a solid-state electrochemiluminescence biosensing switch of Fc-MB–$Ru(bpy)_3^{2+}$-AuNPs.

2.3. The specific recognition of T4 DNA ligase onto Fc-MB–$Ru(bpy)_3^{2+}$-AuNPs electrode

The Fc-MB–$Ru(bpy)_3^{2+}$-AuNPs electrode was incubated in 500 μL of 66 mM Tris–HCl (pH 7.5) containing 0.8 M NaCl, 100 mM $LiClO_4$ and the two short complementary DNA at room temperature for 2 h to form a DNA complex with a nick. By this way, the dsDNA with a nick electrode was formed.

The resultant electrode was incubated with T4 DNA ligase in 66 mM Tris–HCl (pH 7.5) containing 50 μM ATP, 20 mM T4 DNA ligase $MgCl_2$, 10 mM DTT and 100 mM $LiClO_4$ for 15 min. Then the electrode was washed with the same buffer to decrease the non-specific binding at most, and the dsDNA electrode was obtained.

2.4. Electrogenerated chemiluminescence detection

A three-electrode system was used with the modified Au electrode (2 mm in diameter) as the working electrode, an Ag/AgCl (sat.) as the reference electrode and a platinum wire as the counter electrode. Cyclic voltammetry mode with continuous potential scanning from 0.0 to 1.2 V and scanning rate of 0.1 V s^{-1} was applied to achieve ECL signal in 66 mM Tris–HCl containing 1.0 mM TPrA and 5.0 mM $LiClO_4$ (pH 8.7) at room temperature. A high voltage of −800 V was supplied to the photomultiplier for luminescence intensity determination.

3. Results and discussion

3.1. Recognition of T4 DNA ligase using the solid-state electrochemiluminescence biosensing switch

The ligation system is composed of a DNA ligase, two oligos to be ligated and a ferrocene-labeled molecular beacon (Fc-MB), in which the combined sequences of the two oligos are complementary to the loop sequence of the Fc-MB. Fig. 1 presents an illustration of the ligation process. In the beginning, each oligo is hybridized to one-half of the loop of the Fc-MB to form a DNA complex with a nick as shown in step a in Fig. 1. It cannot open the Fc-MB stem completely, but can slightly destabilize the stem. Once ligase is added, the ligation reaction closes the nick to form a longer DNA strand which is complementary to the Fc-MB, resulting in the Fc-MB opening completely and the Fc being pulled away from the electrode (step b).

The corresponding ECL intensity–potential curves of the electrodes are presented in Fig. 2. As shown in the figure, compared to the ECL signal of Fc-MB–$Ru(bpy)_3^{2+}$-AuNPs electrode without hybridization with any DNA (curve a), the ECL signal should be a slight increase for the slight torsion of the stem of Fc-MB and part of Fc being shifted from original position after the process of hybridization with the two short complementary DNA (curve b). The ligation reaction closes the nick to form a longer DNA strand which is complementary to the MB, resulting in the stem of Fc-MB being separated and Fc being pulled away from the electrode. So a remarkable increase of ECL signal was presented simultaneity (curve c). Thus, the difference of ECL intensity before and after the ligation (ΔI_{ECL}) can be used to quantify the T4 DNA ligase.

3.2. The characterization of solid-state electrochemiluminescence biosensing electrode

The fabrication processes of solid-state electrochemiluminescence biosensing electrode and the interaction between fabricated biosensing electrode and T4 DNA ligase were characterized by electrochemical impedance spectroscopy (EIS). For EIS measurements, $[Fe(CN)_6]^{3-/4-}$ was employed as the redox probe and Nyquist plots were used to calculate the R_{et} for modified electrodes. As shown in Fig. 3, the R_{et} for bare Au electrode was 246.4 Ω, and increased to 469.7 Ω for the cysteamine-derivated Au electrode, then declined to 327.9 Ω for the $Ru(bpy)_3^{2+}$-AuNPs electrode. It is attributed to the electronic conductive capacity of Au nanoparticles. The results showed that 10 μM Fc-MB was self-assembled onto the $Ru(bpy)_3^{2+}$-AuNPs electrode, the R_{et} increased to 737.6 Ω. This is attributed to fact that self-assembled biosensing switch of the Fc-MB having negative charges on its phosphate backbone makes an electrostatic repulsive force to $[Fe(CN)_6]^{3-/4-}$. The R_{et} of dsDNA with a nick electrode and dsDNA electrode was 1164.3 Ω and 2069.2 Ω, respectively. The successive increase in

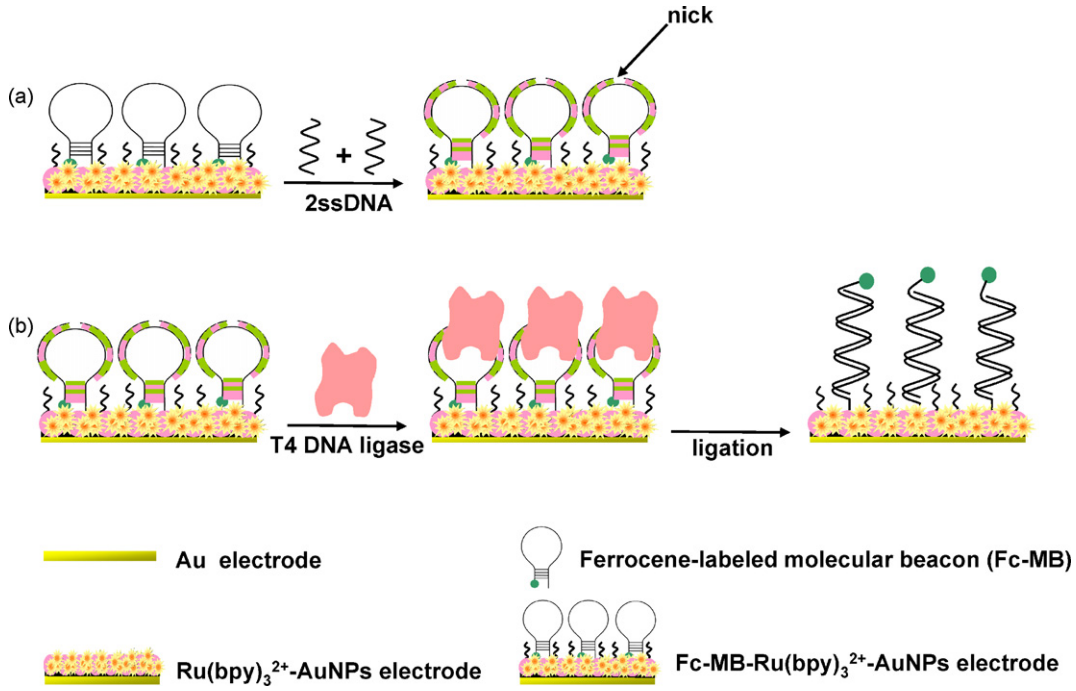

Fig. 1. The specific recognition of T4 DNA ligase by using the Fc-MB–$Ru(bpy)_3^{2+}$-AuNPs electrode. (a) The two half-matching oligos hybridize with the Fc-MB to form a nick. (b) The T4 DNA ligase binds to the nick and catalyzes the ligation of two short oligos to form a longer oligo.

the R_{et} illustrates the successful modification of the biomolecules onto Fc-MB–$Ru(bpy)_3^{2+}$-AuNPs electrode. It also indicates that the interactions between immobilized Fc-MB and the two short complementary DNA, dsDNA with a nick and T4 DNA ligase arise successively.

3.3. *The selectivity of solid-state electrochemiluminescence biosensing switch*

Two control experiments were performed for evaluating the selectivity of solid-state electrochemiluminescence biosensing switch. In order to confirm the repair and recombination specificity of T4 DNA ligase to target nucleic acids, ECL experiments were performed for different samples, such as Fc-MB with N1 (sample a), Fc-MB with N2 and N4 (sample b), Fc-MB with N2 and N3 (sample c) and Fc-MB only (sample d). The difference between N3 and N4 is that whether the 5′ end of DNA fragment was modified with a phosphate group or not, and it is a necessary condition for repair and recombination nucleic acids in DNA ligation reaction [5–7]. As presented in Fig. 4, there was no ECL change for samples a, c and d. It implied that there was no significant change in Fc-MB stem–loop structure after the addition of T4 DNA ligase into these sample solutions. However, the ECL of sample b increased rapidly and reached a plateau after 15 min, which is contributed to the ligation reaction of T4 DNA ligase to link N2 and N4 into one long DNA strand that is complementary to Fc-MB (displayed in Fig. 1). As a result, the Fc-MB opened completely, and ferrocene molecule was away from the $Ru(bpy)_3^{2+}$-AuNPs electrode, which finally led to the increase of the ECL intensity. An almost complete ligation reached after 15 min.

Another control experiment was carried out by using 5 U mL^{-1} T4 DNA ligase, horseradish peroxidase (HRP), glucose oxidase (GOD) or mixed sample to react with N2 and N4. It could be found

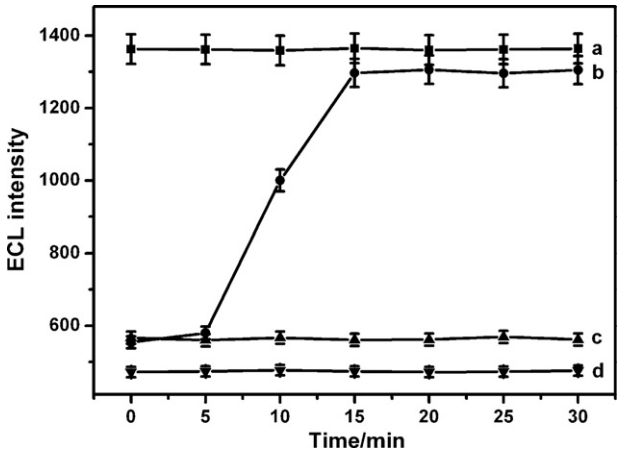

Fig. 4. ECL measurements for the repair and recombination specificity of T4 DNA ligase to target nucleic acids. The Fc-MB–$Ru(bpy)_3^{2+}$-AuNPs electrode incubated with N1 and T4 DNA ligase (a), N2, N4 and T4 DNA ligase (b), N2, N3 and T4 DNA ligase (c), and T4 DNA ligase (d).

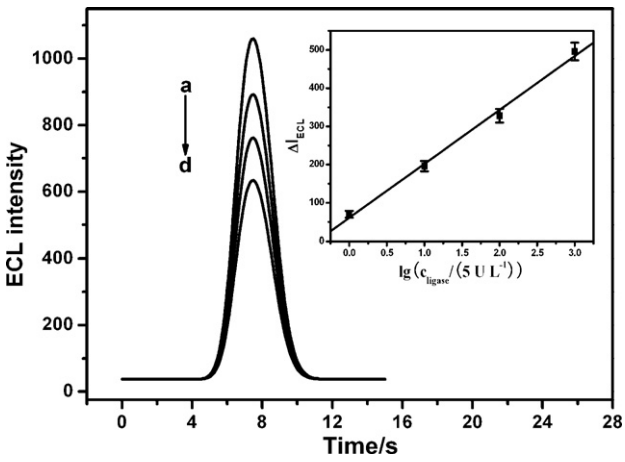

Fig. 6. ECL intensity–time curves for various dsDNA electrodes. The concentrations of T4 DNA ligase were 5×10^{-3} U μL^{-1} (a), 5×10^{-4} U μL^{-1} (b), 5×10^{-5} U μL^{-1} (c) and 5×10^{-6} U μL^{-1} (d), respectively. Inset: the calibration curve of T4 DNA ligase detection. ECL curves were measured in 66 mmol/L Tris–HCl containing 1.0 mM TPrA and 5.0 mM $LiClO_4$ (pH 8.7). Scan rate: 0.1 V s^{-1}, scan range: 0.0–1.2 V.

that only the samples containing T4 DNA ligase showed an obvious increase of ECL intensity as shown in Fig. 5. However, the change of the ECL intensity for the dsDNA with a nick electrode reacting with HRP or GOD can be neglected. It is therefore can be concluded that the ECL intensity increase is caused by the T4 DNA ligase combining with the nick as showed in Fig. 1, which suggested the unique repair and recombination specificity of the T4 DNA ligase to the nick between Fc-MB and the two short complementary DNA, N2 and N4. Above results also indicate that the solid-state electrochemiluminescence biosensing switch has a good selectivity for discriminating the two short DNA to other complementary DNA and T4 DNA ligase from other enzyme.

3.4. Optimization of experimental conditions

The ligation process can be affected by many molecular species including biomolecules and metal ions. The effect of four molecular species, including ATP, Mg^{2+}, K^+ and Na^+ was studied. The experimental results show that the ligation did not take place unless ATP or Mg^{2+} was added to the ligation mixtures. The ligation reached its maximum rate at 50 μM of ATP or at 20 mM of Mg^{2+}, respectively. The high concentration of K^+ and Na^+ obviously hindered the ligation process. The initial ligation velocity decreased proportionally to the concentrations of K^+ or Na^+, and the velocity was close to 0 when the concentrations were ~300 mM. In addition, the activity of T4 DNA ligase has been maintained by dithiothreitol (DTT). Therefore, the 66 mM Tris–HCl buffer solution (pH 7.5) containing 50 μM ATP, 20 mM $MgCl_2$ and 10 mM DTT was selected as the ligation buffer solution.

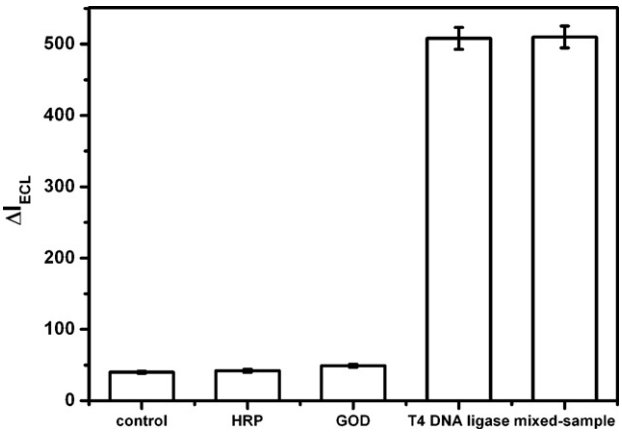

Fig. 5. Comparison of the ΔI_{ECL} of the dsDNA with a nick electrode when incubated with T4 DNA ligase, HRP, GOD and mixed sample (T4 DNA ligase/HRP/GOD).

The efficiency of the ligation, which effects on the ECL intensity of the second ECL determination, is in correlation with ligation time and ligation temperature. The ECL intensity increased with the increment the ligation time, and reached its plateau regions at the ligation time of 15 min. Thus, the optimal ligation time was chosen at 15 min. The influence of the hybridization temperature on the response is investigated, the ECL signal increased rapidly from 5 to 30 °C, then changed slowly from 35 to 40 °C, and reduced notably after 50 °C. So, 37 °C was chosen as the hybridization temperature at the following experiment.

3.5. The calibration curve of T4 DNA ligase detection

According to the Michaelis–Menten equation, the initial reaction rate catalyzed by enzymes is directly proportional to the concentration of the enzyme within a certain concentration range [22]. When the initial reaction rate of the T4 DNA ligation reaction was expressed as the increased rate of the ECL intensity, it was namely the increased value of the ECL intensity (ΔI_{ECL}) in a certain period of time. The sensitivity of the solid-state electrochemiluminescence biosensing switch was investigated. Fig. 6 shows the ECL profiles of the different concentration of T4 DNA ligase after binding with dsDNA electrode. The ECL intensity was enhanced when the T4 DNA ligase concentration increased, and the change of the ECL intensity, ΔI_{ECL}, was found to be linear with the logarithm of T4 DNA ligase concentration in the range from 5×10^{-6} U μL^{-1} to 5×10^{-3} U μL^{-1} (as shown in the inset). The equation for the resulting calibration plot was $y = 141 \lg x + 14$ (x: the concentration of T4 DNA ligase divide 5 U L^{-1}, y: ΔI_{ECL}) with correlation coefficient of 0.9975 and detection limit of 2.5×10^{-6} U μL^{-1}.

4. Conclusions

An efficient bioassay for monitoring the T4 DNA ligase has been developed using a solid-state electrochemiluminescence biosensing switch based on Fc-MB. The Fc-MB is not only a probe for the detection of the ligation process, but also a template for the two oligos in the ligation process. The conformation change information of the Fc-MB before or after the ligation was a reflection of the ECL

signal changes of the whole modified electrode. Thus, the ECL signal changes of the modified electrode can be detected once the nucleic acids were ligated. By this way, the ligation process can be monitored simultaneously and accurately. This method provides a new and effective platform for studying a wide variety of nucleic acids ligation processes and interactions between protein (enzyme) and nucleic acid. Furthermore, it is meaningful to the deeply study the dynamics of them.

Effective surface area

ABSTRACT

The electrocatalytic activity of a CuO flower-like nanostructured electrode was investigated in terms of its application to enzyme-less amperometric H_2O_2 sensors. The CuO nanoflowers film was directly formed by chemical oxidation of copper foil under hydrothermal condition and then used as active electrode material of non-enzymatic electrochemical sensors for H_2O_2 detection under alkaline conditions. The sensitivity of the sensor with CuO nanoflowers electrode was 88.4 μA/mM cm^2 with a linear response in the range from 4.25×10^{-5} to 4×10^{-2} M and a detection limit of 0.167 μM ($S/N = 3$). Excellent electrocatalytic activity, large surface-to-volume ratio and efficient electron transport property of CuO nanoflowers electrode have enabled stable and highly sensitive performance for the non-enzymatic H_2O_2 sensor.

1. Introduction

Rapid and accurate determination of hydrogen peroxide (H_2O_2) is of practical importance in various fields such as food, clinical and environmental analyses. To date, H_2O_2 detection has been mainly studied using spectrometry [1], fluorescence [2], chemiluminscence [3,4] and electrochemistry [5,6]. In particular, the electrochemical technique using an electrode modified with the redox active enzyme, horseradish peroxidase (HRP), has been extensively applied due to its simple, accurate, and fast analytical process [7,8]. The sensitivity of these sensors depends on the activity of the immobilized enzymes. However, one common drawback of enzyme-based sensors is insufficient stability originating from the nature of the enzymes, because enzymes are easy to deform thermally and chemically during fabrication, storage or use. In addition, the responses of most enzyme-based electrodes are not completely free from oxygen effects because the electron-mediating sites compete with oxygen dissolved in the solution [9].

Recently, it is of great interest to develop an enzyme-less electrochemical sensor with high sensitivity, fast response time, and long-term stability. In particular, electrochemically active nanomaterials consisting of metals [10–12], metallic carbon nanotubes [13–15], transition metal oxides [16,17], or conducting polymers [18,19] have been extensively studied for non-enzymatic electrochemical sensors, because they have large surface-to-volume ratio and increased catalytic activities.

Of these, CuO nanomaterials are one of the promising candidates for the active electrode material of non-enzymatic electrochemical sensors. Semiconducting CuO is a *p*-type semiconductor having a band gap of 1.2 eV and has shown its potential for applications in various fields, such as superconductors, magnetic storage media, solar energy transformation, electronics, batteries, sensors and catalysis [20,21]. Different synthetic methods have been developed for the fabrication of CuO nanostructures with various morphologies, including nanowire and nanosheet [22–24].

Although most of metallic Cu(0) nanomaterials are not stable enough to be used for electroanalysis because they are easily oxidized in air or aqueous solution, chemically more stable CuO nanomaterials have been studied for various applications including electrochemical H_2O_2 sensors [17,25].

For example, electrochemical H_2O_2 sensor based on Nafion and CuO nanoparticle modified Pt electrode was reported [17]. As another example, Jia et al. demonstrated the simple and convenient detection of H_2O_2 using vertically aligned CuO nanowires [25]. The nanowires-modified electrode has benefit for increase

doi:10.1016/j.talanta.2009.09.061

of sensor performance. However efficient use of the high surface area of the structure may be limited by undesirable effects including the internal electrical resistance due to high aspect ratio of the semiconductor nanowires. The electrochemical properties of CuO nanomaterials are strongly dependent on its structural features such as crystal sizes, orientations, stacking manners, aspect ratios, and crystalline densities, which promote the study in this paper.

Herein, we describe a facile approach for developing an enzymeless H_2O_2 sensor based on CuO nanoflowers. The electrochemically active CuO nanostructure was grown from the substrate in a single step, and they can be directly used as sensor electrodes without additional processes such as surface modification or immobilization of expensive enzymes. Moreover, we achieve extremely large surface-to-volume ratio and efficient electron transport property due to the high-density single crystalline nano-petals in the electrode.

2. Experimental

2.1. Chemicals

$(NH_4)_2S_2O_8$ and H_2O_2 were purchased from Sigma Chemical (St. Louis, USA). High-purity copper foils (Cu, 99.99%) were obtained from Nilaco Co. (Tokyo, Japan). Sodium hydroxide (NaOH) and potassium ferricyanide ($K_3Fe(CN)_6$) were obtained from Duksan Pure Chemicals (Gyeonggi-do, Korea). All reagents were of analytical grade, and doubly distilled water was used throughout the experiments.

2.2. Preparation and characterization of CuO nanoflower and CuO nanowire electrodes

CuO nanoflowers were grown on a copper foil by a simple solution-based method [21]. Briefly, a piece of copper foil (5 mm × 5 mm × 0.2 mm) was immersed in 5 ml of 10 M NaOH solution and 13 ml of H_2O in a Teflon-lined stainless steel autoclave and then 2 ml of 1 M $(NH_4)_2S_2O_8$ solution was added. The autoclave was sealed and maintained at 100 °C for 12 h and was then cooled in tap water. The product was obtained in the form of a black thin film covering the copper foil. The product was washed with distilled water and ethanol, and then dried in air. As a comparative electrode, nanostructured electrode decorated with highly dense CuO nanowires was also prepared by previously reported method [26]. In short, a piece of copper foil was cleaned in 1.0 M HCl solution and distilled water. After drying it under N_2 gas flow, it was treated in air for 4 h at 500 °C using a muffle furnace.

The morphologies and structures of the nanostructures were determined using transmission electron microscopy (TEM), high-resolution TEM (HR-TEM) equipped with selected area electron diffraction (SAED) and field emission scanning electron microscopy (FE-SEM). The images were taken with a JEM 2100F TEM (JEOL Ltd., Japan) operating at an accelerating voltage of 200 kV and a JSM 7000F SEM (JEOL Ltd., Japan). The samples for HR-TEM were prepared by placing a drop of precipitate on a carbon-coated copper grid and allowing it to dry in air. The phase purity of the CuO nanoflowers on the Cu substrates was characterized by powder X-ray diffraction (XRD) using a D8 DISCOVER powder X-ray diffractometer (Bruker AXS, USA) with Cu Kα radiation.

2.3. Electrochemical measurement

The electrochemical measurements were performed on a micro Autolab III potentiostat (Eco Chemie, Netherlands). A series of electrochemical experiments was conducted using a standard cell with three electrodes: a modified Cu electrode as the working electrode, a Pt counter electrode, and a saturated calomel electrode (SCE) used as a reference electrode. A 0.1 M NaOH solution was used as the supporting electrolyte because H_2O_2 is reduced in an alkaline medium. The active surface area was estimated by cyclic voltammetry in 3 M KCl solution harboring 10 mM $K_3Fe(CN)_6$ at a variety of scan rates. The applied potential ranged from −0.4 to 0.2 V versus SCE with a Pt counter electrode.

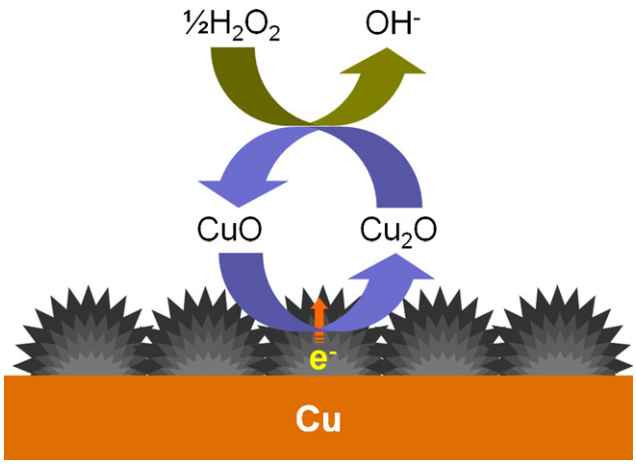

Fig. 1. A schematic view of the electrocatalytic mechanism of CuO nanoflowers for the reduction of H_2O_2.

2.4. Mechanisms for the formation of CuO nanoflowers and electron transfer in the modified electrode

The formation mechanism of the CuO nanoflowers film is as follows [23]:

$$Cu + 2NaOH + (NH_4)_2S_2O_8 \rightarrow Cu(OH)_2 + Na_2SO_4 + (NH_4)_2SO_4 \quad (1)$$

$$Cu(OH)_2 + 2OH^- \rightarrow [Cu(OH)_4]^{2-} \quad (2)$$

$$[Cu(OH)_4]^{2-} \rightarrow CuO + 2OH^- + H_2O \quad (3)$$

When metallic Cu foils were immersed in a basic solution with $(NH_4)_2S_2O_8$ oxidants, the foil surface quickly turned blue. Cu tends to dissolve in solutions that produce Cu complexes [27].

As shown in Eq. (3), $[Cu(OH)_4]^{2-}$ anions are produced as a precursor entity for the formation of CuO in a NaOH aqueous solution with a high concentration. Then, CuO is formed along with two hydroxyl ions and one water molecule. These CuO nuclei coalesce in order to decrease the total surface energy of the system and grow larger to form many CuO nanosheets with flower-like structures [24,27].

The electron-transfer mechanism in the modified electrode is shown in Fig. 1. In the catalytic mechanism for the reduction of H_2O_2, Cu(II) is reduced electrochemically to Cu(I), and H_2O_2 is simultaneously reverted to OH^- along with the regeneration of the catalyst [17].

3. Results and discussion

3.1. CuO nanoflowers film

CuO nanoflowers film was directly fabricated by the oxidation reaction of copper foil under hydrothermal conditions [21]. As shown in Fig. 2, a nanostructured film with high density, flower-shaped CuO nanocrystals were produced on the copper foil. The CuO flowers consist of many thin CuO single crystalline petals with

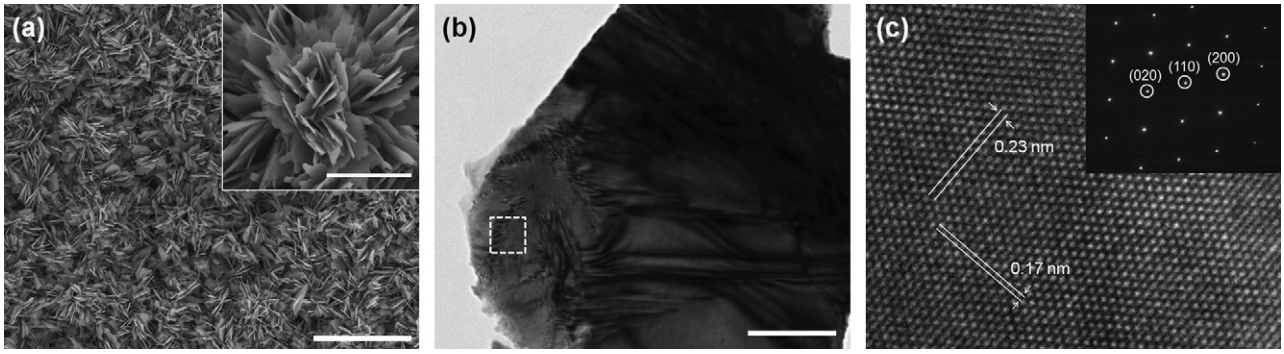

Fig. 2. (a) A SEM image showing high-density CuO nanoflowers grown out of a Cu foil. Scale bar, 5 μm. (Inset of a) A higher magnification SEM image of a CuO nanoflower, scale bar, 1 μm. (b) A TEM image of a single crystalline petal of the CuO nanoflowers. Scale bar, 200 nm. (c) A lattice-resolved TEM image taken at the marked region of (b). Scale bar, 5 nm. (Inset of c) A SAED pattern of the CuO single crystalline petal shown in (c).

an edge length of 100–500 nm and a thickness of ~50 nm. The CuO petals rooted in the center are connected to each other through their wider bases.

Typical TEM images and the corresponding selected area electron diffraction (SAED) patterns of the CuO petals clearly reveal that the petals are single crystals (Figs. 2(b) and (c)). The plane spacings of 0.17 and 0.23 nm correspond to the {0 2 0} and {2 0 0} planes of the CuO structure, respectively (Fig. 2(c)). The sharp diffraction spots in Fig. 2(c) can be indexed as the (0 2 0), (1 1 0), and (2 0 0) reflections of the CuO structure with the [0 0 1] zone axis, which further indicates that the [2 0 0] and [0 2 0] directions are perpendicular to the edges of a petal.

SEM images of in Fig. 3(a) shows highly dense CuO nanowires were also grown on a Cu substrate, which is quite similar to previously reported nanowires. Fig. 3(b) shows typical XRD spectra of the as-prepared CuO nanoflowers and CuO nanowires on the Cu surfaces. Two broad diffraction peaks of CuO nanoflowers located at $2\theta = 35.6$ and 38.8 are well indexed as $(\bar{1}11)$–(0 0 2) and (1 1 1)–(2 0 0) planes of monoclinic CuO structure (JCPDS Card No. 05-0661), respectively. There are no additional peaks except for the peaks (marked with an asterisk) from the Cu substrate. However, diffraction patterns of the as-synthesized CuO nanowire/Cu sample are more complex and have addition peaks which are corresponding to the Cu_2O structure. It has been known, when copper is oxidized in air, the initial product is Cu_2O, and CuO is formed slowly only through a second step of oxidation in which Cu_2O served as a precursor to CuO [26].

3.2. Determination of effective surface area of the CuO-nanoflower-modified electrode

The electroactive surface area of the nanostructured electrode was estimated by cyclic voltammetry using ferricyanide as a redox probe. Fig. 4 displays a series of cyclic voltammograms (CVs) on the CuO nanostructured electrodes as a function of different scan rates in 5 mM $K_3Fe(CN)_6$ solution with 3 M KCl as supporting electrolyte and the dependence of the peak current on the square root of the scan rate. At both of the nanostructured electrodes, the peak current (I_p) increases linearly with the increasing of the square root of the potential scan rate ($\nu^{1/2}$), which suggests that the reactions occurring on the modified electrode were nearly reversible, since the Randles' slope would be nonlinear if the redox reactions were either quasi-reversible or irreversible. This result also means that the mass transfer phenomenon in the double layer region of the electrodes is mainly diffusion controlled [27].

Under semi-infinite linear diffusion conditions and 25 °C, the dependence of peak current I_p on the scan rate ν is described by the Randles–Sevcik equation:

$$I_p = (2.69 \times 10^5) n^{3/2} A D_0^{1/2} C_0^* \nu^{1/2} \quad (4)$$

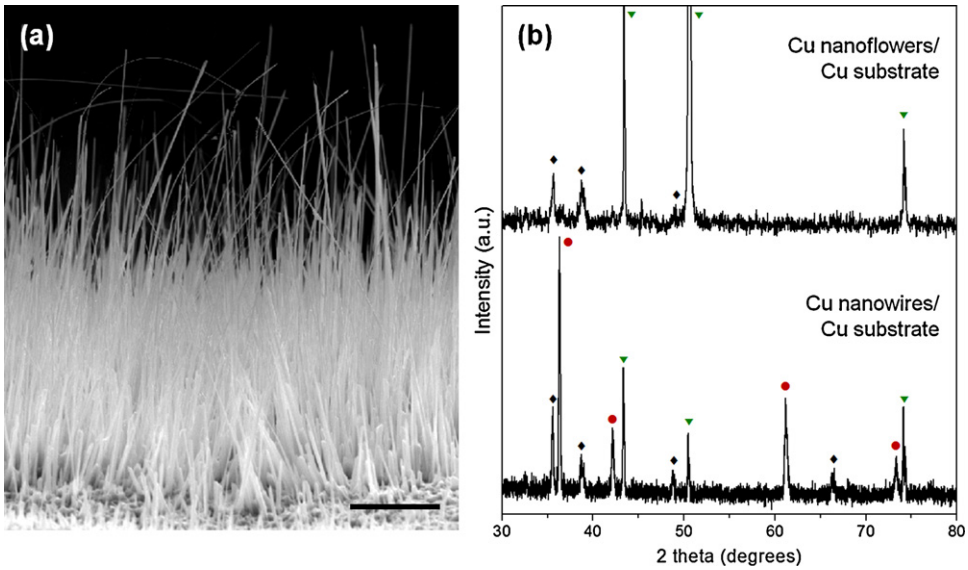

Fig. 3. (a) A typical SEM image of the CuO nanowires on the Cu substrate. (b) XRD patterns of the as-prepared CuO nanoflowers and CuO nanowires on Cu substrates. Diffraction peaks correspond to metallic Cu, cupric oxide (CuO) and Cuprous oxide (Cu_2O) are marked with ▼ (green), ♦ (black), and ● (red), respectively.

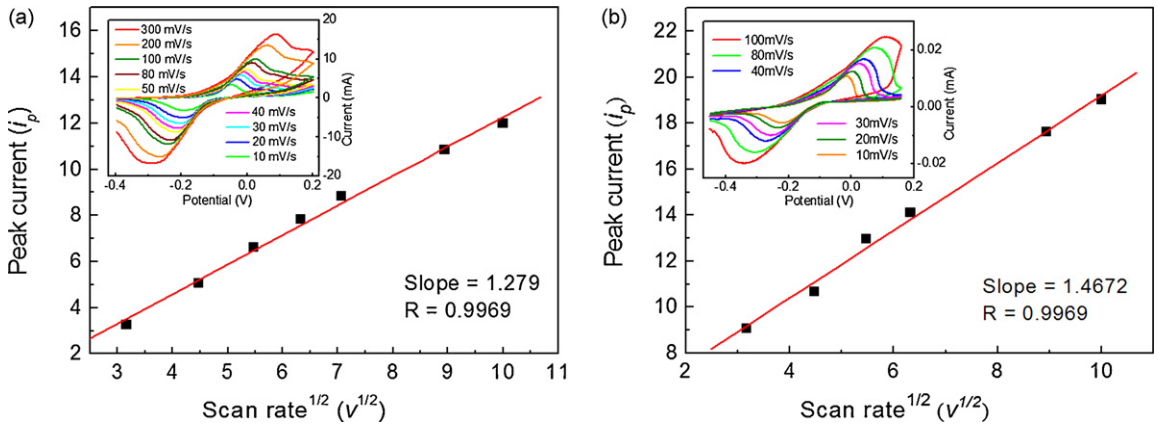

Fig. 4. Peak currents as a function of scan rate for the determination of the effective working surface area on (a) the CuO-nanoflower-modified electrode and (b) the CuO nanowire-decorated electrode. Insets: CV diagram of the modified electrodes in a 3 M KCl solution containing 10 mM ferricyanide at the different scan rates.

where n represents the number of electrons participating in the redox reaction, v is the scan rate of the potential perturbation (V/s), A is the area of the electrode (cm^2), D is the diffusion coefficient of the molecules in the solution (cm^2/s), C^* is the concentration of the probe molecule in the bulk solution (mol/cm^3), and I_p is the peak current of the redox couple illustrated in Fig. 1. In the equation, the effective surface area (A) can be calculated from the value of $I_p/v^{1/2}$ since D, n and C^* are constant values. As shown in Fig. 4(a), slope was 1.467 (R = 0.9969) as the value of $I_p/v^{1/2}$ and the calculated effective working area of the CuO nanoflowers electrode was 6.26 cm^2, which is ~25 times larger than the area of the equivalent bare Cu electrode (5 mm × 5 mm). The effective working area of CuO nanowires electrode was 5.46 cm^2, which are quite similar to that of CuO nanoflowers electrode.

3.3. Electrochemical characterization of the sensor

As previously mentioned, CuO displays excellent catalytic activity and can facilitate electron-transfer process. Here, the electrochemical process of the CuO nanostructured electrodes was examined for its amperometric response toward hydrogen peroxide. Fig. 5(a) shows that the CV of the CuO nanoflowers electrode has two pairs of oxidation and reduction peaks in the potential region from −0.9 to 0.8 V in an alkaline solution. The anodic peaks at −0.4 and −0.05 V represent the oxidation from Cu(0) to Cu(I) and from Cu(I) to Cu(II), respectively, while the cathodic peaks at −0.67 and −0.74 V correspond to the reductions from Cu(II) to Cu(I) and from Cu(I) to Cu(0), respectively.

As shown in Fig. 5(b), upon the addition of H_2O_2 to 5 mL of NaOH solution (0.1 M), the CV currents of the modified electrode changed dramatically with an increase of the reduction peak current and a decrease of the oxidation peak current, which is characteristic of electrochemical catalysis to H_2O_2.

Fig. 6 shows a typical amperometric response curve of H_2O_2 at the CuO nanostructured electrode. Well-defined, stable, and fast amperometric responses were observed at an applied potential of −0.3 V with successive step additions of H_2O_2 in the stirred 0.1 M NaOH solution. The addition of H_2O_2 is marked by arrows at the concentrations mentioned. It is clear that the response current of

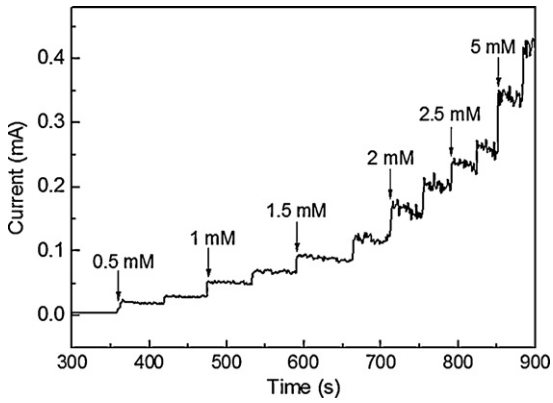

Fig. 6. Steady-state current time responses of H_2O_2 to various concentrations of H_2O_2 in a stirred 0.1 M NaOH solution at the CuO-nanoflower-modified electrode under an applied potential of -0.3 V.

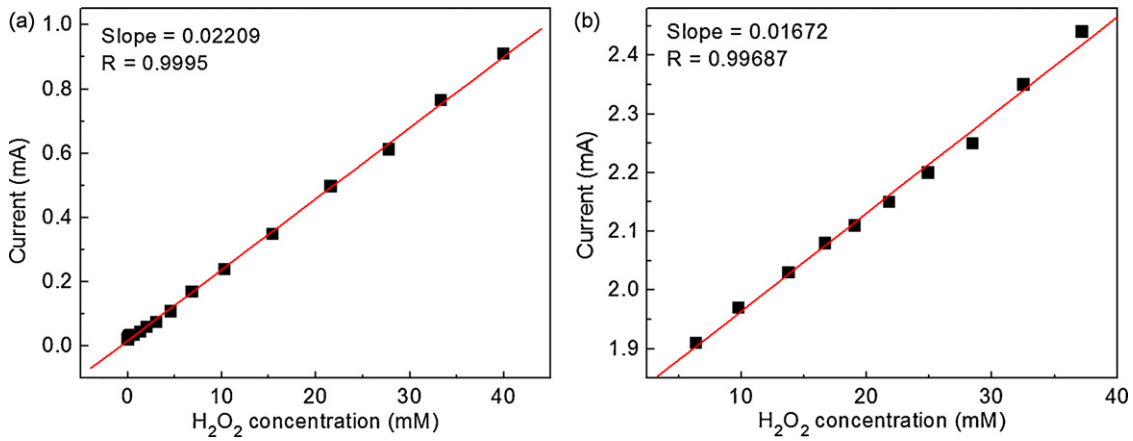

Fig. 7. Calibration curves of (a) the CuO-nanoflower modified and (b) the CuO nanowire-decorated electrodes in a NaOH solution (0.1 M) containing various H_2O_2 concentrations under an applied potential of −0.3 V.

the modified electrode abruptly increases to steady-state values upon the addition of H_2O_2. This sensor shows a very fast response, as the response reaches 95% of the steady-state value within 10 s.

Fig. 7 shows the calibration curves for nanoflowers and nanowires electrodes. The amperometric sensitivity of the nanoflowers sensor was 88.4 μA/mM cm^2 (R = 0.9995) with the linear range of 42.5 μM to 40 mM. And that of the nanowires sensor was 66.88 μA/mM cm^2 (R = 0.9969) with the linear range between 6.4 mM and 37.2 mM. The CuO nanoflowers sensor is 1.3-fold larger than that of the sensor based on the CuO nanowires electrode. And, it is ca. 3 times larger than that of the previously reported sensor based on a vertically aligned CuO nanowires-modified electrode, in which response of the sensor was linear up to 28.87 mM with a sensitivity of 30.11 μA/mM cm^2 [25].

The enhanced sensitivity of nanoflowers sensor compared to that of nanowires case may be explained by the difference in electron transport efficiency of the nanostructured electrodes, though CuO purity in the electrodes could be another source of the sensitivity difference. If the electrode is composed of semiconductor nanowires, the internal resistance contribution due to the electrodes with high aspect ratio can be significant, which may limit increase of sensitivity with increase of nanowire length. Therefore, the high sensitivity and fast response time of the sensor in the present study can be attributed to the fact that high-density nanoscale petals in the CuO nanostructured electrode can greatly increase the electrocatalytic active areas and also promote electron transfer in the reduction of H_2O_2, since plate-like structures have larger cross-section area than thin nanowires [14].

The good reproducibility and long-term stability of the electrodes are also critically important in the context of practical applications. In general, the insufficient stability of enzyme electrodes is the result of the loss and deactivation of enzymes [9,11]. Because the sensor fabricated in this study was enzyme-less, the long-term stability of the sensor was evaluated by measuring its sensitivity to H_2O_2 with the sensor stored in air at ambient conditions. The electrodes were not poisoned by the reduction product and can be used repeatedly for the detection of H_2O_2.

4. Conclusions

We demonstrated a sensitive non-enzymatic H_2O_2 sensor based on flower-shaped CuO nanocrystalline films. The CuO nanoflowers electrode was directly fabricated in a single step by the simple surface oxidation of Cu foil. The CuO nanomaterial as the cathode material exhibited remarkable electrocatalytic activity for the reduction of H_2O_2 under alkaline conditions. In addition, this non-enzymatic sensor has demonstrated both long-term stability and high sensitivity due to enzyme-less detection and the large surface area of the CuO nanostructure. The proposed electrochemical sensing technology is thus expected to generate new opportunities for the development of reliable and miniaturized sensor devices for monitoring H_2O_2 concentrations in food industry and clinical and environmental analyses fields.

Au nanoparticle ensemble
Sol–gel network
Amperometric sensor
Isoniazid

ABSTRACT

Au nanoparticle (nAu) based electrochemical platform for the amperometric sensing of isoniazid at sub-nanomolar level is developed. The sol–gel derived 3-dimensional silicate network pre-assembled on a conducting substrate is chemically decorated with nAu of 70–100 nm by seed-mediated growth approach. The Au nanoseeds are first chemisorbed onto the thiol functional groups of the silicate network and their size was enlarged by hydroxylamine seeding. The nanoparticles efficiently catalyze the oxidation of isoniazid at less positive potential. Large decrease in the overpotential and significant enhancement in the anodic peak current with respect to the polycrystalline Au electrode are observed. The nanoparticle based platform is highly sensitive (4.03 ± 0.01 nA/nM) and it linearly responds to isoniazid up to the concentration of 1 mM. It could detect as low as 0.1 nM (S/N = 5) of isoniazid at the potential of 10 mV in aqueous solution without any redox mediator. The catalytic response of the sensing platform depends on the amount of nanoparticles loaded onto the silicate network. Very interestingly, the sensing platform could simultaneously detect isoniazid and hydrazine in their coexistence without compromising the sensitivity. Well separated individual voltammetric response is obtained for both analytes. The sensing platform is highly stable and it can be repeatedly used for 7 days.

1. Introduction

Isoniazid is an important drug used in the clinical practice for the treatment of tuberculosis. It can cause hepatotoxicity in patient with an inflammatory response [1] and it is known to induce tumors in mice and cause chromosome aberrations [2]. It has been demonstrated further that long-term therapy of isoniazid can trigger systemic lupus erythematosus [3]. Various analytical methods based on spectral and electrochemical techniques have been developed for the quantitative determination of isoniazid [4–16]. The electrochemical methods are interesting as they require low cost equipment and isoniazid can be quantified without any special reagents [8–14]. However, the high overpotential required for the oxidation of isoniazid with unmodified electrode is a major concern with the electrochemical techniques. Traditionally, mediator and polymer based electrodes have been used to decrease the overpotential [8,10,12,14,15]. The lack of long-term stability due to the leaching of mediator is one of the disadvantages with the mediator modified electrodes. Liu et al. have utilized the palladium-modified microdisk array electrode for the electrocatalytic oxidation of isoniazid [4]. Although this microdisk array electrode has good sensitivity, it requires high overpotential as large as 1 V for the oxidation of isoniazid and the voltammetric response was not well-defined. Gao et al. used ferrocene derivative for the mediated oxidation of isoniazid [15]. Recently, carbon nanotube based electrode has been used for the detection of isoniazid in mild acid pH at the potential of 0.8 V [11]. Development of a highly sensitive and stable electrode for the sensing of isoniazid at less positive potential is desired for the accurate measurement of isonizid.

Tailoring of electrode surface with nanoscale metal particles is of significant interest in the recent years owing to the fact that the nanomaterials have excellent catalytic properties. The catalytic properties of nanomaterials depend on their shape, size and morphology; the catalytic activity is ascribed to the large surface-to-volume ratio and the existence of special binding site on their surface. Electrodes based on arrays or ensembles of micro/nanoparticles are of great interest in the development of electrochemical sensing platform. It has been shown theoretically and experimentally that the electrochemical platforms based on arrays or ensembles of nanoparticles have high sensitivity with respect to the macroelectrodes of same geometrical surface area [17]. In principle, very low detection limit can be achieved in array or ensemble based electrodes. The high sensitivity and low detection limit is ascribed to the enhancement in the signal-to-noise ratio (S/N) and high mass transport to the electrode surface [18]. Various methodologies have been used for the development of electrochemical interface based arrays/ensemble [17–22]. Bard and

co-workers have first explored the colloidal chemical approach for the development of ultramicroelectrode [22]. This approach has been extensively used in the recent past in the development of nanoparticle ensemble based electrodes for various electroanalytical studies [23,24]. We have recently developed nAu based ensemble electrode for the sensing of NADH, glucose, hydrazine, metal ions etc. and for the fabrication of biosensors [25–28]. In continuation of earlier efforts in the development of electrochemical sensors, herein for the first time we report the amperometric sensing of isoniazid and simultaneous electroanalysis of isoniazid and hydrazine using nAu based platform.

2. Experimental

2.1. Materials

(3-Mercaptopropyl)trimethoxysilane (MPTS), $HAuCl_4$, isoniazid and hydrazine were obtained from Sigma–Aldrich and used as received. All other chemicals used in this investigation were of analytical grade unless mentioned otherwise. All the solutions were prepared with Millipore water.

2.2. Instrumentation

Electrochemical measurements were performed with computer controlled CHI643B electrochemical analyzer according to procedures reported elsewhere [25,26]. X-ray diffraction analysis of nanoparticles was carried out with Phillips X'pert. PRO X-ray diffraction unit using Ni filtered CuKα ($\lambda = 1.54$ Å) radiation. Scanning electron microscopic measurements were performed with Jeol JEM 6700F field emission scanning electron microscope (FESEM).

2.3. Development of sensing platform

The electrode used for the detection of isoniazid was prepared according to our earlier procedures [26]. Briefly, a cleaned polycrystalline Au electrode was first modified with a 3D silicate network containing thiol functional groups. This silicate modified electrode was soaked in colloidal nanoseeds for 18 h. The colloidal Au nanoseeds chemisorb onto the thiol functional groups of the 3D sol–gel network. The Au nanoseeds on the silicate network have been enlarged by seed-mediated growth approach using hydroxylamine [29]. For FESEM measurements, the gold-coated cover slip was first modified with the MPTS sol to get the sol–gel network and the self-assembling of Au nanoseeds and hydroxylamine seeding were performed as described earlier. Hereafter, the nanoseed modified and hydroxylamine seeded electrodes will be referred as AuS and AuE, respectively.

3. Results and discussion

3.1. Characterization of nanoparticles on the sensing platform

The nanoparticles on the silicate network (Fig. 1) have been characterized according to our earlier procedures [26]. The nanoparticles have a size distribution between 70 nm and 100 nm. The nanoparticles are randomly distributed throughout the network and the interparticle distance is less than the particle diameter (Supporting information). XRD profile obtained for AuE show four peaks corresponding to (1 1 1), (2 0 0), (2 2 0) and (3 1 1) planes (Supporting information). The absorption spectral measurement shows characteristic spectral signature for nanosized Au particles [26]. The nanoparticle on the silicate network can be considered as ensembles of nanoelectrode. The electrochemically accessible area of the nanoparticles were obtained by chronoamperometric measurement using $Fe(CN)_6^{3-/4-}$ as a redox probe. The electrochemically active area of the AuS and AuE electrodes was calculated to be 0.03 cm^2 and 0.07 cm^2, respectively.

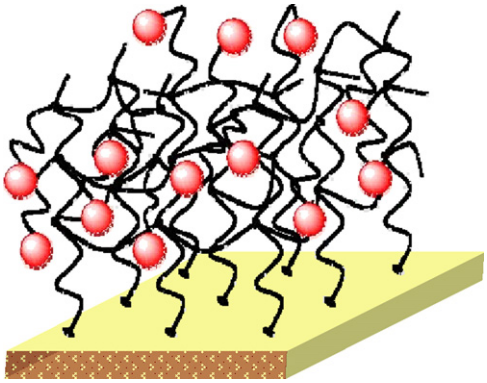

Fig. 1. Au nanoparticle decorated silicate network.

3.2. Electrocatalytic oxidation of isoniazid

Fig. 2 represents the voltammograms obtained for the oxidation of isoniazid at MPTS, AuS and AuE electrodes. The MPTS network modified electrode does not show any characteristic response for the oxidation of isoniazid in the potential window used. However, as can be readily seen from Fig. 2, well-defined voltammetric response at less positive potential was obtained for the oxidation of isoniazid on the nanoparticle modified electrodes. Interestingly, the isoniazid oxidation on AuE electrode occurs at 10 mV, which is 450 mV less positive than that on polycrystalline Au electrode. The onset potential for the oxidation of isoniazid on AuE electrode is much negative (~−100 mV) than the actual oxidation potential. The polycrystalline Au electrode shows a broad oxidation peak (Fig. 2 inset) at more positive potential (>450 mV), presumably due to sluggish electron transfer kinetics. The decrease in the overpotential associated with an enhancement in the peak current evidences the high catalytic activity of the nanoparticles. The peak current linearly increases with square root of sweep rate, supporting that the electron transfer involves a diffusion controlled process. The oxidation peak on the AuS electrode appears at the potential of 130 mV; the peak current on this electrode is significantly lower than the AuE electrode, suggesting that the surface area and particle coverage has great control over the oxidation process (vide

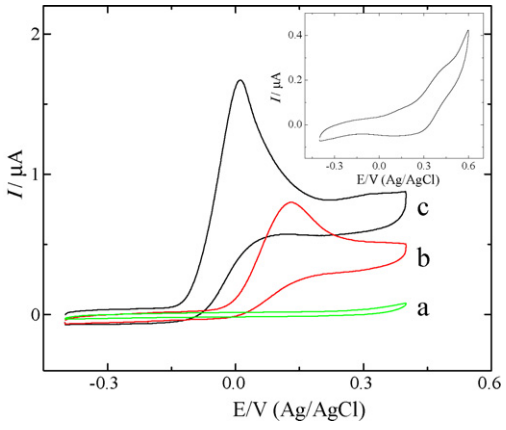

Fig. 2. Voltammetric profile obtained for the oxidation of isoniazid (0.1 mM) on (a) MPTS sol–gel network (b) AuS and (c) AuE electrodes in 0.1 M PBS (pH 9.2). Scan rate: 10 mV/s. Inset shows the voltammogram obtained for isoniazide on polycrystalline Au electrode.

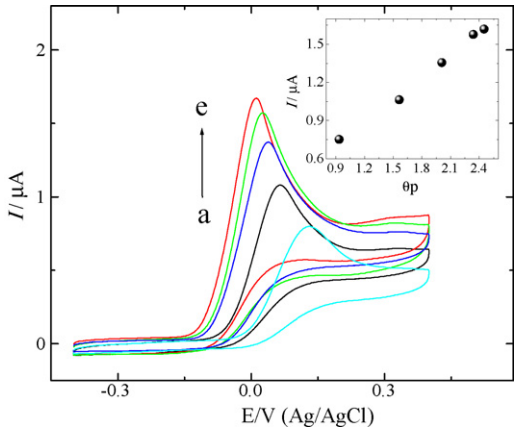

Fig. 3. Cyclic voltammograms obtained for the oxidation of isoniazid (0.1 mM) at different θ_p; other experimental conditions are same as in Fig. 2.

infra). The pH of the supporting electrolyte solution strongly influence the voltammetric peak potential and peak current (Supporting information). As expected, the peak potential shifts to more positive side as the solution pH was decreased. As the magnitude of peak current in alkaline pH is significantly high, amperometric sensing of isoniazid was performed at the pH of 9.2.

The particle coverage (θ_p) [30] on the electrode surface have great control over the catalytic activity of nanoparticles. In order to examine the influence of θ_p of the nanoparticle on the electrocatalytic oxidation of isoniazid, electrodes have been prepared by changing the hydroxylamine seeding time. Fig. 3 illustrates the effect of particle coverage on the electrocatalytic oxidation of isoniazid. Negative shift (120 mV) in the oxidation potential and enhancement in the peak current were noticed while increasing the particle coverage from 0.93 to 2.45. The negative shift in the peak potential evidence the facilitated electron transfer kinetics at the electrode surface. These results are in accordance with the theory of micro/nanoelectrode ensembles [17–21]. On such electrodes, sweep rate and interparticle distance dictate the voltammetric profile [17–21]. The negative shift in the oxidation potential while increasing the particle coverage can be ascribed to the change in the diffusion pattern [31]. The diffusion pattern would change from mixed non-linear and linear diffusion to a mostly linear diffusion while increasing the particle coverage.

3.3. Amperometric sensing of isoniazid

Fig. 4 is the amperometric *i–t* curve obtained for the sensing of isoniazid on AuE electrode at pH 9.2. The potential of the electrode was held at 10 mV and isoniazid was injected at regular time intervals. Steady and rapid increase in the amperometric current for the oxidation of isoniazid was noticed upon every injection. Steady state response was attained within 4 s. The sensitivity of the electrode was obtained from the calibration plot and was 4.03 ± 0.01 nA/nM. This electrode could detect as low as 0.1 nM (S/N = 5) of isoniazid. To the best of our knowledge this is the lowest detection limit achieved with electrochemical methods. The electrode offers linear response (0.1–1 mM) towards isoniazid. Table 1 compares the analytical performance of AuE electrode with the existing electrochemical sensors for isoniazid. Polycrystalline Au electrode has been used for the pulse voltammetric determination of isoniazid and the limit of detection (from the calibration plot) was 96 nM in strongly alkaline solution [9]. The stability of the electrode was not evaluated in this study. The polymer based electrodes could detect isoniazid in the range of 3–100 μM in neutral/alkaline pH [10,12]. Recently, carbon nanotube based electrode has been used for the voltammetric sensing of isoniazid at the potential of

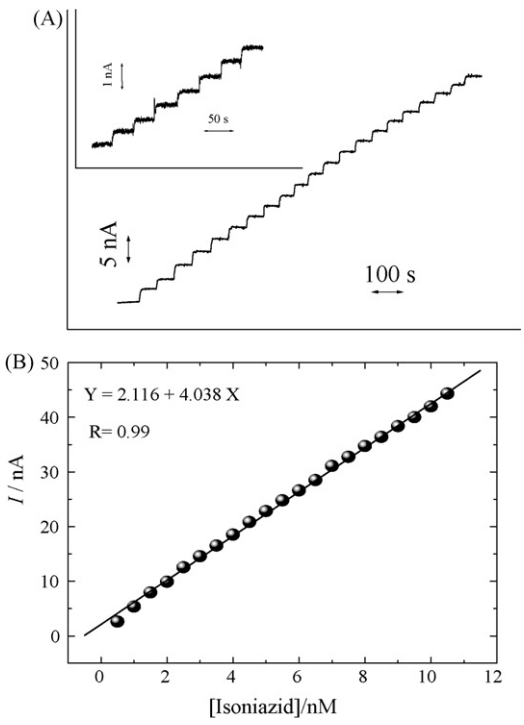

Fig. 4. (A) Amperometric *i–t* curve for the detection of isoniazid at AuE electrode. 0.5 nM of isoniazid was injected at regular time intervals. (B) Corresponding calibration plot. Inset shows the *i–t* curve for 0.1 nM.

0.85 V and it detects isoniazid at sub-micromolar level [11]. It is apparent from Table 1 that the present Au nanoparticle based electrode is superior to the existing sensors; it is highly sensitive, stable and it could detect isoniazid at sub-nanomolar level without any redox mediators.

3.4. Simultaneous electrochemical detection of isoniazid and hydrazine

Simultaneous voltammetric sensing of hydrazine and isoniazid is a challenging task, as both the analytes are expected to undergo oxidation almost at the same potential. We observed earlier that the oxidation of hydrazine on Au nanoparticle based electrode occurs at the potential of ∼−140 mV [27]. Fig. 5 displays the linear sweep voltammogram obtained for the oxidation of hydrazine and isoniazid in their coexistence. The voltammetric peak for the oxidation of hydrazine appears at the potential of ∼−140 mV whereas the oxidation peak for isoniazid appears at 10 mV. As the separation between the voltammetric peaks is >150 mV, the simultaneous detection of both analytes using the nanoparticle based platform is feasible. Linear increase in the peak current was obtained while increasing the concentration of isoniazid and hydrazine simulta-

Table 1
Electrochemical detection of isoniazid using different electrodes.

Electrode	Detection/peak potential	LOD (nM)	Reference

neously (Supporting information). However, slight positive shift (~20 mV) in the peak corresponding to isoniazid was observed while simultaneously increasing the concentration of the hydrazine and isoniazid.

3.5. Stability

The stability of the nanoparticle based platform was evaluated using the same electrode for 20 repeated measurements with 50 μM of isoniazid. The same electrode was again utilized for a set of another 20 measurements after one day. The peak potential and peak current remained almost same in both sets of experiments; the coefficient of variation in the peak current was 0.2%, indicating the high stability of the electrode. To examine the long-term storage stability, the same electrode was used for a period of 7 days (Supporting information). The electrode was stored in phosphate buffer solution after the everyday's measurement. No significant change in the peak current and peak potential was noticed for 4 days; 8% decrease in the peak current was noticed after 7 days, demonstrating the long-term stability of the electrode.

4. Conclusions

We have demonstrated the electrocatalytic sensing of isoniazid using the nanoparticle based sensing platform. Au nanoparticles efficiently catalyze the oxidation of isoniazid. The electrocatalytic property of the sensing platform strongly depends on the particle coverage on the electrode surface. Large decrease in the overpotential and enhancement in the peak current without any redox mediator was obtained. The sensing platform is highly sensitive and it could sense as low as 0.1 nM of isoniazid. Simultaneous sensing of hydrazine and isoniazid is achieved with the Au nanoparticle based platform for the first time. Well separated voltammetric peaks for the oxidation of both analytes were observed. This electrode is very stable and it offers linear response for a wide concentration range.

Simultaneous determination

ABSTRACT

A silver hexacyanoferrate nanoparticles/carbon nanotubes modified glassy carbon electrode was fabricated and then successfully used for the simultaneous determination of ascorbic acid, dopamine and uric acid by cyclic voltammetry. A detailed investigation by transmission electron microscopy (TEM) and electrochemistry was performed in order to elucidate the preparation process and properties of the nanocomposites. The size of silver hexacyanoferrate nanoparticles was examined by TEM around 27 nm. Linear calibration plots were obtained over the range of 4.0×10^{-6}–7.8×10^{-5}, 2.4×10^{-6}–1.3×10^{-4} and 2.0×10^{-6}–1.5×10^{-4} mol L^{-1} with detection limits of 4.2×10^{-7}, 1.4×10^{-7} and 6.0×10^{-8} mol L^{-1} for ascorbic acid, dopamine and uric acid, respectively. The practical analytical utilities of the modified electrode were demonstrated by the determination of ascorbic acid, dopamine and uric acid in urine and human blood serum samples.

1. Introduction

Dopamine (DA) is a chemical messenger produced within the nerve cells that is essential for the transmission of the nerve impulse and hence involved in a wide range of important functions, including movement, cognition and behavior. Dysfunctions in the central nervous dopamine system can lead to diseases such as Parkinson's and Schizophrenia [1]. Therefore, the determination of DA has attracted much attention of researchers. Similarly, ascorbic acid (AA) functions as a redox cofactor and catalyst in a broad array of biochemical reactions and processes. In humans, vitamin C cures and prevents scurvy, hence the designation ascorbic acid [2]. AA is present in mammalian brain in the presence of several neurotransmitter amines including DA. Uric acid (UA) is produced from the cellular breakdown products of the purine nucleosides, adenosine and guanosine [3]. As DA, UA and AA are copresent in biological fluids such as blood and urine, it is important to develop a technique to selectively detect DA and UA in the presence of AA conveniently in routine assay. Therefore, the selective detection of DA, UA and AA in the presence of other two species or their simultaneous determination has been a major goal of much research. For this purpose, various chemically modified electrodes have been constructed [4].

Metal hexacyanoferrate (MHCF) modified electrodes have been investigated intensively for a variety of application areas including electrocatalysis [5–11], ion selectivity [12], electrochromism [13,14], photoresponse [15] and solid state batteries [16,17]. Among these MHCF, Prussian blue is more used as sensors and biosensors, so far as Koncki [18] published a review about it. Some MHCF were used for determination of AA, DA or UA such as; lanthanum [19], palladium [20], tin [21], cobalt [22], nickel [23], copper [24] hexacyanoferrates and Prussian blue [7,11,25,26]. Recently, the use of nanoparticles has been reported [27] claiming that a better separation between individual signals, AA and DA, has been achieved. Based on our best knowledge, there is no report on the application of silver hexacyanoferrate nanoparticles (AgHCFNPs) for simultaneous determination of ascorbic acid, dopamine and uric acid.

Here we report for the first time a simultaneous voltammetric determination of AA, DA and UA using a glassy carbon electrode modified with a mixture of AgHCFNPs and multi-walled carbon nanotubes (CNT). Compared with the existing reports about simultaneous determination of AA, DA and UA, the proposed method is much more convenient to prepare the GC/CNT-AgHCFNPs modified electrode.

2. Experimental

2.1. Chemicals

Multi-walled carbon nanotubes (10–15 nm in diameter) were obtained from Aldrich and used without any pretreatment. All other chemicals used were of analytical reagent grade from

Merck. Aqueous solutions were prepared with doubly distilled water (DDW). The stock solutions of dopamine (0.01 mol L^{-1}) and ascorbic acid (0.01 mol L^{-1}) were freshly prepared by dissolving dopamine hydrochloride and ascorbic acid in DDW, purged with pure nitrogen gas (99.999%) before investigations. Uric acid solution (0.01 mol L^{-1}) was prepared by dissolving the solid in a small volume of 0.1 mol L^{-1} NaOH solution and diluted to reach desired concentration. Dichloroacetic acid (pK_a = 1.26) was used for preparation of buffer solutions between pH 1.0 and 1.8, it was prepared by adjusting it to desire pH with 0.1 mol L^{-1} NaOH solution. In a same way, chloroacetic acid (pK_a = 2.87) for pH between 1.8 and 3.8 and acetic acid (pK_a = 4.76) for pH between 3.8 and 5.6 were used.

Fresh urine and serum samples were obtained from the Omid Clinical Laboratory (Zahedan, Iran) and passed through a filter with suitable porosity.

2.2. Apparatus

Cyclic voltammetric experiments were performed using a SAMA500 Electroanalyser (SAMA Research Center, Iran). All experiments were carried out using a conventional three-electrode system with the glassy carbon (GC) electrode with 2.0 mm diameter as the working electrode, a platinum wire as the auxiliary electrode, and a saturated calomel electrode (SCE) as the reference electrode. Cyclic voltammetric experiments were performed in quiescent solution. Electrolyte solutions were purged with high-purity nitrogen prior to electrochemical experiments. All the measurements were performed at room temperature.

The nanoparticles size and distribution of AgHCFNPs assembled on CNT were investigated using a JEOL TEM-2010 transmission electron microscopy.

2.3. Preparation of AgHCFNPs

Silver hexacyanoferrate nanoparticles ($Ag_4[Fe(CN)_6]$) were synthesized according to following reaction [28]:

$$[Fe(CN)_6]^{4-} + 4Ag^+ \rightarrow Ag_4[Fe(CN)_6] \quad (1)$$

All glassware was thoroughly cleaned in aqua regain (3 HCl:1 HNO_3, v/v), rinsed in distilled water and air-dried prior use. In a typical synthesis, 25.0 mL 4.0×10^{-3} mol L^{-1} $AgNO_3$ was drop wised added (2 drops per second) to 25.0 mL 1.0×10^{-3} mol L^{-1} $K_4[Fe(CN)_6]$ solution (which was purged with pure nitrogen gas prior to use), in a ultrasonic bath and under dark condition. After the addition, the reaction mixture was turned milky immediately. The mixture was sonicated further for 30 min. The solid was isolated by centrifugation and washed five times by water to remove any unreacted impurities. At the end, the solid was dispersed in 10 ml water with the aid of sonication. The concentration of nanoparticles in resulted suspension was 2.5×10^{-3} mol L^{-1}. The suspension was stored at 4 °C and prevented from light. This suspension was stable at least for 3 weeks.

2.4. Electrode modification

The GC electrode was polished with 0.05-μm alumina slurry. After rinsing with double-distilled water, it was sonicated in water and absolute ethanol for about 1 min each. Next, the GC electrode was transferred to the electrochemical cell for further cleaning by using cyclic voltammetry between −0.5 and +1.5 V at a scan rate of 100 mV s^{-1} in freshly prepared deoxygenated 0.5 mol L^{-1} H_2SO_4 until a stable cyclic voltammetric profile was obtained. The treated electrode was dried under a nitrogen stream and used immediately

for modification. With the help of ultrasonic agitation, 2 mg CNT was dispersed into 5 mL *N*,*N*-dimethylformamide (DMF) containing 0.5 mL of AgHCFNPs for 1 h. This mixture was denoted as CNT-AgHCFNPs. The clean GC electrode was coated by casting 5.0 μL of the CNT-AgHCFNPs suspension and dried under infrared radiation to form the CNT-AgHCFNPs adsorbed GC electrode, denoted as GC/CNT-AgHCFNPs. When not in use, the modified electrode was stored in DDW.

3. Results and discussion

3.1. TEM characterization of AgHCFNPs

Silver hexacyanoferrate nanoparticles were successfully prepared by sonication method, which exhibits a milk-white turbidity due to the light scattering of the nanoparticles. Fig. 1A shows the TEM images of prepared AgHCFNPs, with an average diameter of around 27 nm based on the TEM measurement out of 200 nanoparticles. As shown in Fig. 1B and C, the attachment of nanoparticles onto multi-walled carbon nanotube were successful, and the carbon nanotube was surrounded with abundant nanoparticles.

3.2. Electrochemical characteristics of modified electrode

Fig. 2 showed the cyclic voltammograms (CVs) of the resulting electrode obtained in chloroacetate buffered solution (CABS) with pH 2.0 (0.1 mol L^{-1}) and in various potential sweep rates. The electrochemical response of AgHCFNPs exhibited a pair of well-defined redox peaks at 0.034 and −0.058 V, in CABS which can be attributed to the electron transformations between Fe(II) and Fe(III) in the nanoparticles. The electrochemical properties of modified GC electrode with CNT-AgHCFNPs (GC/CNT-AgHCFNPs) were studied by cyclic voltammetry in pure buffered aqueous solution (pH 2.0) at various scan rates.

Fig. 2A shows the cyclic voltammograms of GC/CNT-AgHCFNPs at various scan rates. The reaction of these voltammograms is as following:

$$Ag_4[Fe^{II}(CN)_6] \rightleftarrows Ag_3[Fe^{III}(CN)_6] + e^- + Ag^+ \quad (2)$$

The Eq. (2) includes the oxidation and reduction of $Ag_4[Fe(CN)_6]$ and production of $Ag_3[Fe(CN)_6]$ with loss of one electron in anodic sweep.

As can be seen, the peak separation potential, ΔEp ($\Delta Ep = E_{pa} - E_{pc}$), is greater than the $59/n$ mV expected for a reversible system; this result suggests that AgHCFNP does not act as a reversible system in the carbon nanotube paste matrix. These cyclic voltammograms were used to examine the variation of peak current versus sweep rate. Fig. 2A shows that the modified

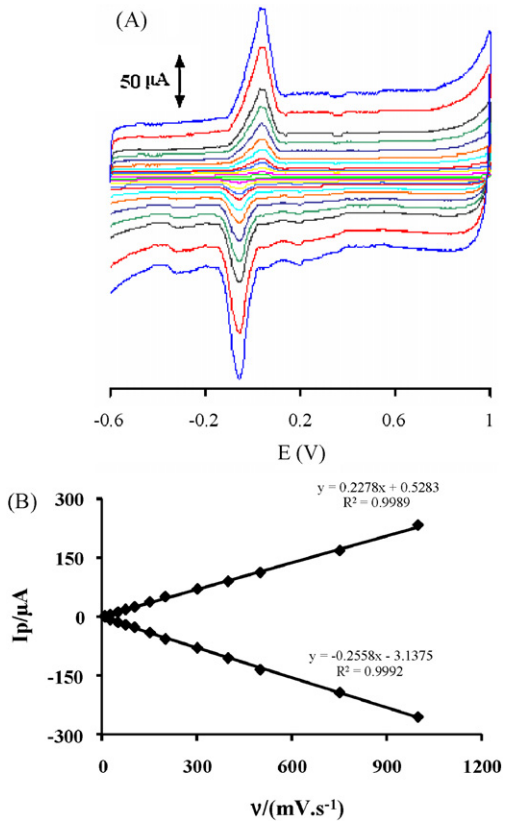

Fig. 2. (A) Cyclic voltammograms of the GC/CNT-AgHCFNPs electrode in CABS with pH 2.0 (0.1 mol L^{-1}) and at various scan rates (from inner to outer curve): 10, 25, 50, 75, 100, 150, 200, 300, 400, 500, 750, and 1000 mV s^{-1}. (B) Plots of peak currents versus scan rates.

electrode had a chemically reversible redox couple in pH 2.0) solution and the peak currents were increased due to the cyclic voltammetric scan rate. As shown in Fig. 2B, I_{pa} and I_{pc} were linearly dependent on scan rate, as expected for surface confined redox process. And the ratio of the anodic peak current to the cathodic peak current I_{pc}:I_{pa}, is almost equal to unity. These behaviors are consistent with a diffusionless system, reversible electron transfer process [29]. It suggested that the modified electrode reaction could be a one electron transfer process ($n = 1$).

An approximate amount of the electroactive species can be estimated by the method suggested by Sharp et al. [30]. According to this method, the peak current is related to the surface concentration

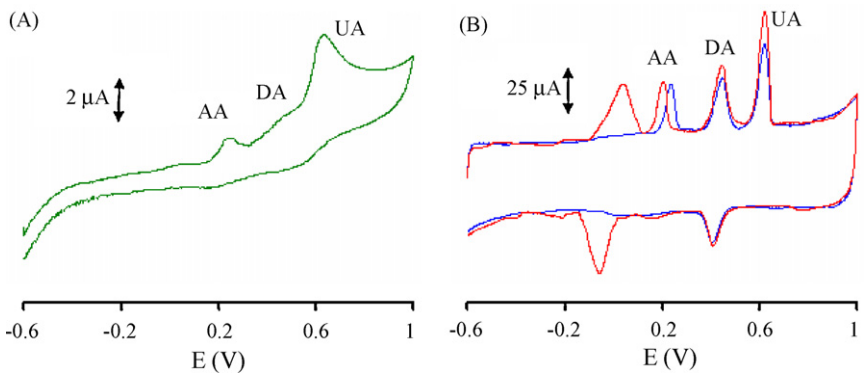

Fig. 3. CVs of 4.0×10^{-5} mol L^{-1} AA, DA and UA at the surface of (A) bare GC and (B) GC/CNT (blue line) and GC/CNT-AgHCFNPs (red line) electrode, in 0.1 mol L^{-1} CABS (pH 2.0). Scan rate: 100 mV s^{-1}. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

Table 1
Comparison of E_{pa} and I_{pa} at the surface of different electrodes in CABS (pH 2.0) containing 4.0×10^{-5} mol L^{-1} AA, DA and UA. Scan rate, 100 mV s^{-1}.

Electrode	E_{pa}/V			I_{pa}/μA		
	AA	DA	UA	AA	DA	UA
Bare GC	0.263	0.482	0.643	0.48	0.85	2.07
GC/CNT	0.246	0.448	0.624	37.09	42.77	58.22
GC/CNT-AgHCFNPs	0.19307	0.444	0.622	41.38	48.47	73.66

of electroactive species, Γ, by the following equation:

$$I_p = \frac{n^2F^2A\Gamma\nu}{4RT} \quad (3)$$

where n represents the number of electrons involved in the reaction, A is the geometric surface area of the electrode (0.0314 cm^2), Γ (mol cm^{-2}) is the surface coverage and other symbols have their usual meanings ν is the scan rate; R, F and T have their normal meanings. From the slope (0.2278 from Fig. 2b) of anodic peak currents versus scan rate (Fig. 1B) the calculated surface concentration of AgHCFNP is 7.72×10^{-9} mol cm^{-2} for $n = 1$.

3.3. Electrocatalytic oxidation of DA, UA and AA

The voltammetric behaviors of a mixture of AA, DA and UA on a bare GC electrode, GC/CNT and GC/CNT-AgHCFNPs, were studied, and a comparison of the CV results is shown in Fig. 3.

DA showed broad oxidation peak and could not be discriminated from AA and UA when a bare GC electrode was used (Fig. 3A). For DA, the anodic and cathodic peaks appear at 0.482 V and 0.552 V, respectively, and the separation of peak potential is about 0.070 V. Moreover, the cathodic peak current is much smaller than the anodic peak current. It is clear that the electrochemical reaction of DA at the bare GC is irreversible, indicating the sluggish electron transfer kinetic of DA at the bare GC, which may be related to the electrode fouling caused by the deposition of this compound and its oxidation product on the electrode surface [31]. When GC/CNT or GC/CNT-AgHCFNPs was used as the working electrode, the detection sensitivity was improved significantly and effective separation of the anodic peaks of AA, DA and UA was obtained (Fig. 3B). The large peak separation of the anodic peaks for these three compounds allows us to simultaneously determine them in the mixture solutions. Also, Fig. 3B compares the catalytic effect of CNT and CNT-AgHCFNPs for detection of these compounds. It can be seen from the Fig. 3, CNT-AgHCFNPs has more electrocatalytic effect toward the oxidation of AA, DA and UA. The results in Fig. 3B clearly show that the electrochemical responses of AA, DA and UA on the CNT-AgHCFNPs electrode occurred at different potential windows, which means that the electrochemistry of these three compounds can be well resolved from their mixed solutions. For better comparison, oxidation peak potentials and peak currents of AA, DA and UA on bare GC electrode, GC/CNT and GC/CNT-AgHCFNPs modified electrode are shown in Table 1.

The results in Table 1 indicate that in comparison with bare GC electrode, both GC/CNT and GC/CNT-AgHCFNPs electrodes reduce anodic overpotential of the analytes. Meanwhile, the enhancement of the anodic peak currents is most predominant at GC/CNT-AgHCFNPs than other electrodes. In addition, dopamine gives a more reversible redox behavior at the GC/CNT-AgHCFNPs and GC/CNT than at bare GC electrode. Having catalytically active surface and very high aspect ratio (length versus diameter), CNT can increase the surface area of the electrode, so the background voltammetric response for the CNT-coated surface is stronger than that for the bare surface [32].

Table 2
Cyclic voltammetric data of compositions with different ratios mg CNT mL^{-1} AgHCFNPs in CABS (pH 2.0) containing 4.0×10^{-5} mol L^{-1} AA, DA and UA. Scan rate, 100 mV s^{-1}.

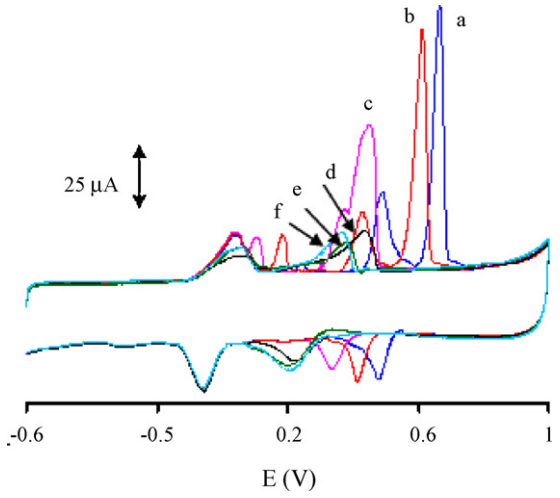

Fig. 4. Effect of pH on the peak separation and peak current for the oxidation of AA (2.0×10^{-5} mol L^{-1}), DA (4.0×10^{-5} mol L^{-1}) and UA (8.0×10^{-5} mol L^{-1}); pH= (a) 1.0, (b) 2.0, (c) 3.1, (d) 4.0, (e) 5.1 and (f) 5.6. Scan rate, 100 mV s^{-1}.

3.4. The effect of CNT-AgHCFNPs composition

The composition of the modified electrode was optimized by comparing the voltammetric response of different amounts of CNT to different volumes of AgHCFNPs suspension in CABS 0.1 mol L^{-1} (pH 2.0) containing 4.0×10^{-5} mol L^{-1} AA, DA and UA. The best composition is defined as the composition that by which maximum oxidation peaks separation and maximum anodic peak currents is achieved. For this purpose a series of experiments were carried out at above-mentioned conditions. The results are shown in Table 2.

According to table, when glassy carbon electrode was coated with 5 μL of a mixture containing 2 mg CNT and 0.5 ml AgHCFNPs suspension in 5 mL DMF, maximum peak separation and peak current was obtained. If the CNT content in the modificative mixture was too high (>3 mg) or too low (<1 mg), then the sensitivity was low due to the presence of a large background current or insufficient

amount of the CNT for adhesion nanoparticles to the glassy carbon electrode surface, respectively. In the later case, modificative film was easily removed from the electrode's surface.

3.5. Effect of pH on the oxidation of AA, DA and UA in a ternary mixture

The effect of solution pH on the electrochemical response of the GC/CNT-AgHCFNPs towards the simultaneous determination of AA, DA and UA was studied. A series of buffer solutions including phosphate buffer (0.1 mol L^{-1} H_3PO_4/KH_2PO_4 and KH_2PO_4/K_2HPO_4), universal buffer (0.1 mol L^{-1} CH_3COOH, 0.1 M H_3PO_4, and 0.1 mol L^{-1} H_3BO_3) and acetate-based buffer (0.1 mol L^{-1} CH_3COOH/CH_3COONa, $CClH_2COOH/CClH_2COONa$ and $CCl_2HCOOH/CCl_2HCOONa$, CCl_3COOH/CCl_3COONa) were prepared and tested as supporting electrolyte. In phosphate and universal buffers, modified electrode showed unstable responses for a certain concentration of AA, DA and UA. Therefore, future studies were carried out in the acetate based buffer solutions. The variations of peak separation and peak current with respect to the change in the pH of the electrolyte in the pH range from 1.0 to 5.8 are shown in Fig. 4.

It can be seen from Fig. 4 that except AA, the anodic peak current of DA and UA decreases slightly with an increase in the solution pH until it reaches 5.8; that of AA increases with increasing pH until pH reaches 2.0, and then it decreases when the pH exceeds 2.0. Hence, for AA, DA and UA, the highest anodic peak current was obtained at pH 2.0, 1.0 and 1.0, respectively. In addition, all the anodic peak potentials for the oxidation of AA, DA and UA shifted towards negative direction with increasing pH, showing that protons have taken part in their electrode processes. Its must be noted, that from pH 2.0 to higher pH the anodic peak potentials of DA and UA were broader and overlap together. Because of having most peaks separation and satisfactory peak currents and negatively shifts, a chloroacetate buffer solution with pH 2.0 was chosen as optimal pH.

3.6. Simultaneous determination of AA, DA and UA

The electro-oxidation processes of AA, DA and UA at the GC/CNT-AgHCFNPs in the mixture have also been investigated when the concentration of one species changed, whereas those of other two species are kept constant and the results are shown in Fig. 5.

Examination of Fig. 5A shows that the peak current of AA increased with an increase in AA concentration when the concentrations of DA and UA were kept constant. Although the charge current was enhanced after AA was oxidized, the peak currents of DA and UA did not change. Similarly and obviously, as shown in Fig. 5B and C, keeping the concentrations of other two compounds constant, the oxidation peak current of DA or UA was positively proportional to its concentration, while those of other two compounds did not change. Similar experiments were repeated at the GC/CNT and the results are shown in Fig. 6.

From our experimental results described above, it was known that in the ternary mixture containing AA, DA and UA when a GC/CNT-AgHCFNPs was used the oxidation peaks of these three compounds were clearly separated from each other, but when a GC/CNT was used as working electrode these species could not be determined simultaneously. If the concentrations of AA, DA and UA increased synchronously, on increasing the concentrations of the three compounds, the peak currents at the modified electrode increase accordingly as shown in Fig. 7. It can be seen that the peak currents for the three analytes increase linearly with their concentrations.

The voltammetric responses of the modified electrode (GC/CNT-AgHCFNPs) towards the simultaneous determination of AA, DA and UA are listed in Table 3. The relative standard deviations of the determination of 1.2×10^{-5} mol L^{-1} AA, 8.0×10^{-5} mol L^{-1} DA and 4.6×10^{-5} mol L^{-1} UA repeated seven times were 2.5%, 1.70% and 3.0%, respectively.

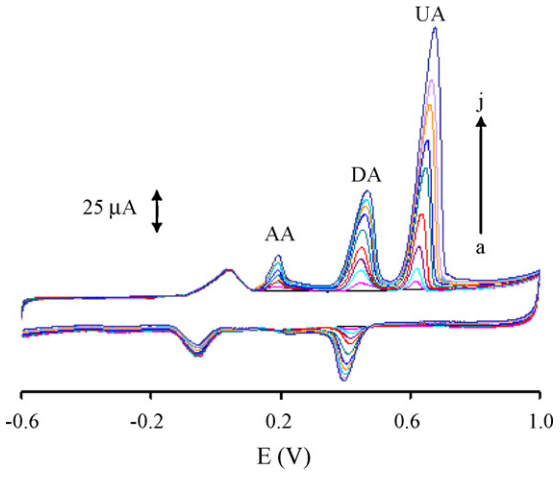

Fig. 7. CVs of the mixture containing AA, DA and UA at the GC/CNT-AgHCFNPs electrode in CABS (pH 2.0) at the scan rate of 100 mV s^{-1}. Concentrations of the three compounds (from a to j): 0.0, 4.0×10^{-6}, 8.0×10^{-6}, 12.0×10^{-5}, 2.0×10^{-5}, 3.0×10^{-5}, 4.9×10^{-5} and 7.8×10^{-5} mol L^{-1} for AA; 0.0, 2.4×10^{-6}, 8.0×10^{-6}, 1.2×10^{-5}, 2.0×10^{-5}, 3.0×10^{-5}, 4.9×10^{-5}, 7.8×10^{-5}, 9.7×10^{-5} and 1.3×10^{-4} mol L^{-1} for DA; 0.0, 2.0×10^{-6}, 8.0×10^{-6}, 2.0×10^{-5}, 4.0×10^{-5}, 6.9×10^{-5}, 9.7×10^{-5}, $1.1.\times10^{-4}$, 1.3×10^{-4} and 1.5×10^{-4} mol L^{-1} for UA.

3.7. Interference study

To evaluate the selectivity of the GC/CNT-AgHCFNPs modified electrode, the interference effects were investigated by detecting the response of the modified electrode to 2.0×10^{-5} mol L^{-1} AA, 8.0×10^{-5} mol L^{-1} DA and 4.0×10^{-5} mol L^{-1} UA in the presence of glucose and fructose, each in concentration 250 times of that of three analytes, 80 times of citric acid, 400 times of K^+ and Na^+, 150 times of Mg^{2+} and Zn^{2+}, 200 times of Ca^{2+} and chloride each. The results showed that the aforementioned species did not cause observable interference at the concentrations given.

3.8. Sample analysis

Human serum and urine samples were selected as real samples for analysis by the proposed method using the standard addition method. In order to avoid from the interferences of the real samples matrix and to fit into the linear range of AA, DA and UA, only 0.2 mL of urine samples and 0.5 mL serum samples were added to the electrochemical cell containing 25 mL of CABS. The results are presented in Table 4.

The recovery of the spiked samples ranged between 97.9% and 102.2%, indicating the detection procedures are free from interferences of the urine and serum samples matrix.

4. Conclusions

The modification of the GC electrode surface by CNT-AgHCFNPs not only improves the electrochemical catalytic activities towards the oxidation of AA, DA and UA, but also resolves the overlapped oxidation peaks of AA, DA and UA into three well-defined peaks at potentials 0.193 V, 0.444 V and 0.620 V in CV, respectively. Comparison between GC/CNT and GC/CNT-AgHCFNPs demonstrates that GC/CNT-AgHCFNPs more facilitates the simultaneous determination of AA, DA and UA with good stability, sensitivity and selectivity. In comparison with other electroanalytical methods that reported for the simultaneous determination of ascorbic acid, dopamine and uric acid, this method has better figures of merit (Table 5). The proposed method can be applied to the simultaneous determination of AA, DA and UA concentrations in real samples with satisfactory results.

Pure component spectral estimates

ABSTRACT

Raman spectra of human nail clippings from various sources were collected and then deconvoluted to obtain the pure component spectra of the underlying constituents present. This blind-deconvolution was performed using a self-modeling curve resolution technique, namely band-target entropy minimization (BTEM). The aim was to simplify the complexity of the Raman spectra and hence to identify the underlying biological molecules in more detail. BTEM analysis could recover 13 pure component Raman spectral estimates from the collected 438 spectra measured from 113 nail samples. Six recovered pure component spectral estimates correspond to proteins or polypeptides that contain various amino acids such as phenylalanine, tyrosine, tryptophan, and cysteine. Two are associated with the secondary structures of proteins, and five are associated with two carotenoid species, lipid, ferulic acid, and calcium phosphate. Subsequently, the relative concentrations of these bio-constituents were calculated from the measured mixture spectra and the pure component BTEM estimates. These profiles indicated that the concentrations of some bio-constituents are correlated while others are not. A further analysis using target transformation factor analysis (TTFA) revealed the possible presence of curcumin in the human nails. Since the present approach and analysis is rather general, it might be extended to many other biological tissues in a rather straightforward and similar manner, thus revealing more detailed underlying biochemical information such as biomarkers that may be useful for diagnostic purposes.

1. Introduction

Raman spectroscopy has been used repeatedly to characterize the molecular structures of keratotic tissues, such as skin, callus, hair, and nail [1]. Barry et al. [2] and Williams et al. [1] were the first to assign the Raman spectral bands of these keratotic materials to specific vibrational modes of the chemical bonds. They also found that the principal differences in the Raman spectra of these samples were mainly due to variations in the sulphur content, as shown by the relative intensities of the C–S and S–S stretching modes [1,2]. Raman characterization of human nail, in particular, has also received greater attention lately in forensic studies. In forensic science, Raman spectroscopy and multivariate classification have been used for the differentiation of finger nails and toe nails and for human gender classification [3,4]. Edwards et al. have also applied Raman confocal microscopy to detect explosives and drugs of abuse as well as other substances on human nails, which were present due to contact and handling [5,6].

Human nail is a complex biological tissue, whose main structural component consists of hard α-keratins [1]. Besides Raman spectroscopy, previous analyses of human nail have included the use of Fourier-transform infrared spectroscopy [7], gas–liquid chromatography (GLC) [8], gas chromatography–mass spectrometry [9], X-ray diffraction [10], etc. Typically, relatively simple analyses were performed with these measurements. For example, with FT-IR and Raman, the presence of different functional groups were determined by the observed spectral band positions and with GLC, comparisons of retention times with standards were used.

In the present contribution, the collected Raman data are analyzed together in order to determine the underlying spectral patterns. In this regard, a multivariate spectral processing approach based on self-modeling curve resolution (SMCR) method can be used [11]. More specifically, in the current analysis, band-target entropy minimization (BTEM) [12] is used to reconstruct the pure component spectra of the underlying biological constituents without recourse to any a priori information, particularly spectral libraries. BTEM method was developed for analyzing large sets of multicomponent spectroscopic measurements (FTIR [13–15], Raman [16,17], MS [18], UV–vis [19], NMR [20]). It has now been extended to various applications, including the analysis of spectral data collected from biomedical [21], pharmaceutical [17,22], commercial [23] and other samples [24]. Various biological molecules are identified in the present analysis and as such the complexity of human nail spectra can be considerably simplified. The identifica-

tion of these bio-constituents may facilitate better understanding of nail chemistry and its relationship to diet, disease, chemical exposure, etc. Furthermore, since the present approach is rather general, it can probably be extended to many other biological tissues, thus revealing more detailed underlying biochemical information such as certain biomarkers that may be useful for diagnostic purposes.

2. Materials and methods

2.1. Experimental

A total of 113 samples of both fingernail and toenail clippings were kindly donated, on a volunteer basis, by 55 adult people (27 males and 28 females) from the Institute of Chemical and Engineering Sciences. These volunteers were aware that no identification would be made between the donor and the samples (anonymity of donor). In addition, the volunteers were informed of the type of study undertaken, i.e. Raman measurements for the purpose of deconvoluting biomarkers. This multiracial group of individuals ranged in age from 20 to 50 years and consisted of both vegetarians and non-vegetarians. On average, nail clippings were stored for a few days before Raman measurements were performed. No rigorous sample pretreatment of any kind was performed, with the exception of simple cleaning using acetone to remove dirt or contaminants on the nail samples after clipping. Raman spectra of nail clippings were collected using a Renishaw InVia Reflex dispersive Raman microscope. The Raman scattering was excited with a 785 nm near-infrared diode laser. From each nail clipping, three or four Raman spectra were measured on three or four different spots, and thus altogether 438 measurements were taken. All measurements were carried out using a 20× objective lens. The acquisition time for each Raman spectrum was circa 25 seconds with laser power on the sample of circa 20 mW. The Raman shift range acquired was 400–1800 cm^{-1}. In general, these Raman measurements exhibited some intra-nail spectral variations, but considerably more inter-nail spectral variations.

2.2. Data analysis

The raw spectra acquired from the nail clippings were only despiked. No further preprocessing of any kind, such as noise filtering, baseline correction, or spectral normalization was used. The aim was to preserve all of the chemically relevant spectral information for subsequent BTEM analysis. BTEM is a self-modeling curve resolution technique, which was developed to recover the pure component spectra of underlying constituents from a set of mixture spectra without recourse to any a priori known spectral libraries. This type of analysis in the signal processing area is also known as blind-source separation.

Unlike most self-modeling curve resolution (SMCR) algorithms, BTEM was especially developed to reconstruct one pure component spectrum at a time from a set of mixture spectra. The first step in the analysis is the use of singular value decomposition (SVD) to extract the singular vectors that describe the variance of the original mixture data set. With the present data set, in order to extract an estimate of a pure Raman scattering coefficient, a selected band in the non-noise right singular vectors is targeted. The BTEM algorithm then retains this feature and, at the same time, returns an entire full-length spectrum containing this band and all correlated bands, which have minimum entropy. This routine is repeated for all important observable physical features in the selected right singular vectors.

The criterion for selecting the band-targets is quite simple. A user can first set a tolerance for accepting/rejecting a feature. Then, all the observed spectral features in the first few right singular vectors with intensity above this threshold are selected as band-targets for BTEM. After applying BTEM to all of these band-targets, a superset of reconstructed pure component Raman scattering coefficients is obtained, and this set can be reduced to eliminate redundancies. This results in an enumeration of all observable pure component spectra. As mentioned, the targeted bands are retained during the reconstruction. As part of the process, the resulting pure spectral patterns are returned in a normalized form. When all normalized observable pure component spectra have been reconstructed, relative contributions of these signals can be calculated by projecting them onto the original data set. For a detailed description of the BTEM algorithm, readers are referred to refs. [12–15].

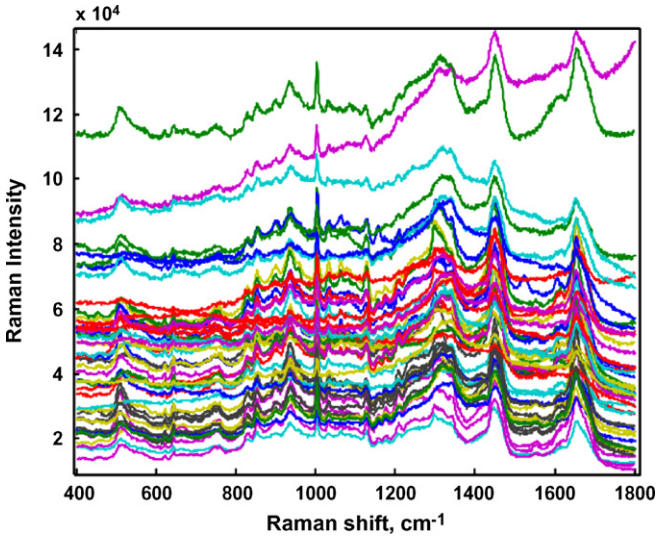

Fig. 1. The 48 despiked Raman spectra of human nail clippings.

All data analyses were performed in MATLAB 7.1 (The Mathworks Inc., Natick, MA). A personal computer with dual 3 GHz Pentium IV processors and 2 GB of RAM was used for all computations. In-house programs written in MATLAB were used for BTEM as well as other analyses.

3. Results and discussion

Fig. 1 shows the stacked-plot of 48 of the 438 acquired Raman spectra of human nails. Although broad autofluorescence signals are present, despite the use of a near-infrared 785 nm laser as the scattering source, clear Raman spectral features measured from all samples can still be observed. Relative peak intensities and small differences in Raman spectral features among different samples are also seen, which shows that biomolecular variations in human nails are quite high. These variations may be due to differences in race, gender, age, dietary habits, etc. of the individuals from whom nail samples were obtained.

Without any further spectral baseline correction or normalization, the collected 438 Raman spectra were subjected to SVD. The first 20 right singular vectors are shown in Fig. 2. There are many identifiable Raman bands (extrema) in the first twenty right singular vectors, and these peaks were subsequently used as the band-targets for the BTEM analysis. The entire set of data was analyzed together since larger variability in the original set of signals assists the analysis.

Exhaustive band-targeting was performed on all significant peaks and a superset of reconstructed pure component spectra was obtained. After eliminating the redundancies to reduce the number of BTEM estimates, 13 pure component Raman spectral estimates

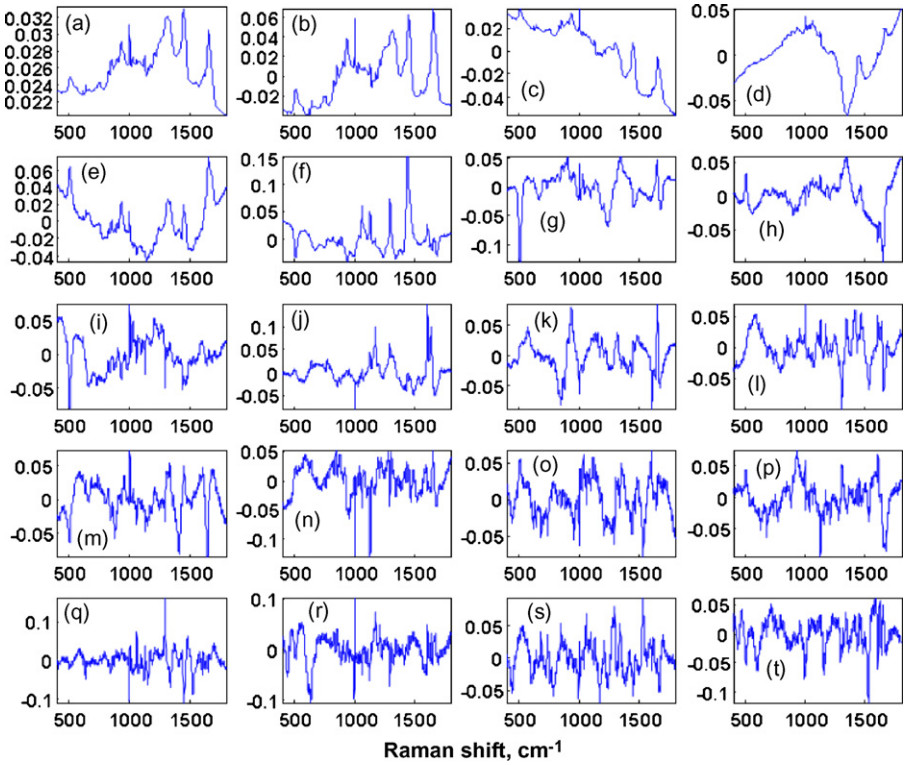

Fig. 2. The first 20 right singular vectors obtained from SVD decomposition, (a) 1st vector, (b) 2nd vector, (c) 3rd vector. . ., (t) 20th vector.

were obtained and these are shown in Figs. 3–5. Six of these estimates correspond to proteins and polypeptides that contain various amino acids such as phenylalanine, tyrosine, tryptophan, and cystine. Two estimates are associated with the secondary structures of proteins, and five estimates are associated with fatty acid, two carotenoid species, ferulic acid, and calcium phosphate (details are provided in the next section).

3.1. Pure component spectral estimates of proteins and polypeptides

The BTEM pure component spectra estimate in Fig. 3(a) shows a prominent Raman band centered at 508 cm^{-1}, which can be assigned to the S–S stretching mode of cystine and cysteine residues. This prominent band at 508 cm^{-1} also verifies that the conformation of the group C–C–S–S–C–C is gauche–gauche–gauche, which is the most stable form [25]. For other conformations, such as gauche–gauche–trans and trans–gauche–trans, S–S stretching modes commonly appear at 525 and 540–550 cm^{-1}, which are not observed in the present study. These other types of conformations are known to be more common in other types of tissue such as skin [25]. The relatively weak Raman bands at 638 and 663 cm^{-1} can be assigned to the C–S

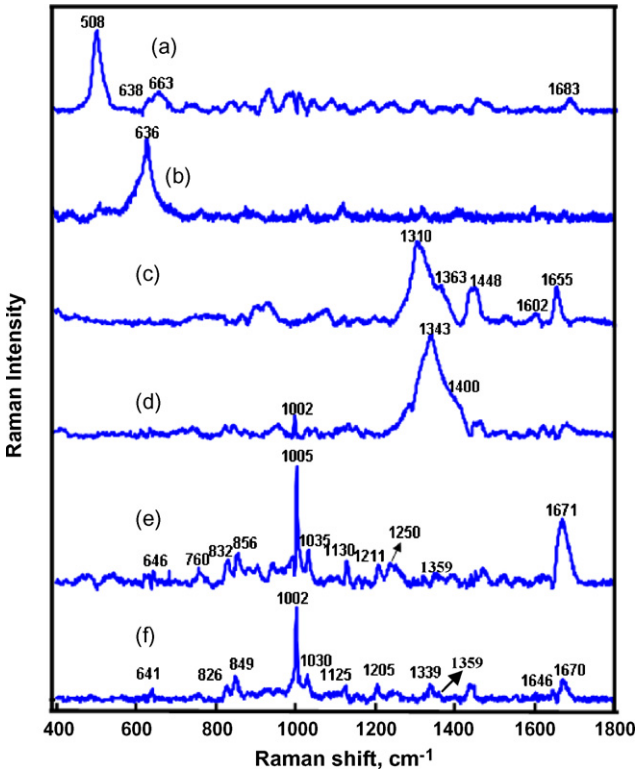

Fig. 3. Six BTEM pure component spectral estimates of various proteins and polypeptides.

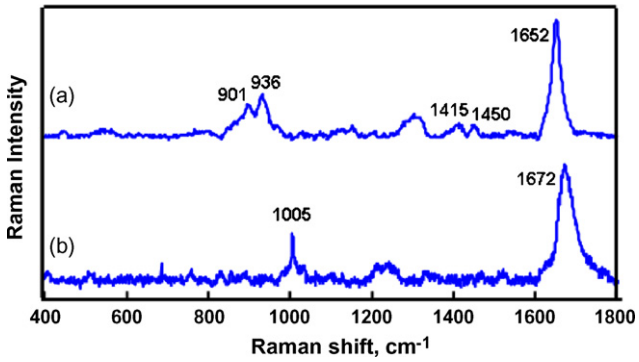

Fig. 4. BTEM pure component spectral estimates of secondary structures of proteins, (a) α-helix conformation, and (b) β-sheet conformation.

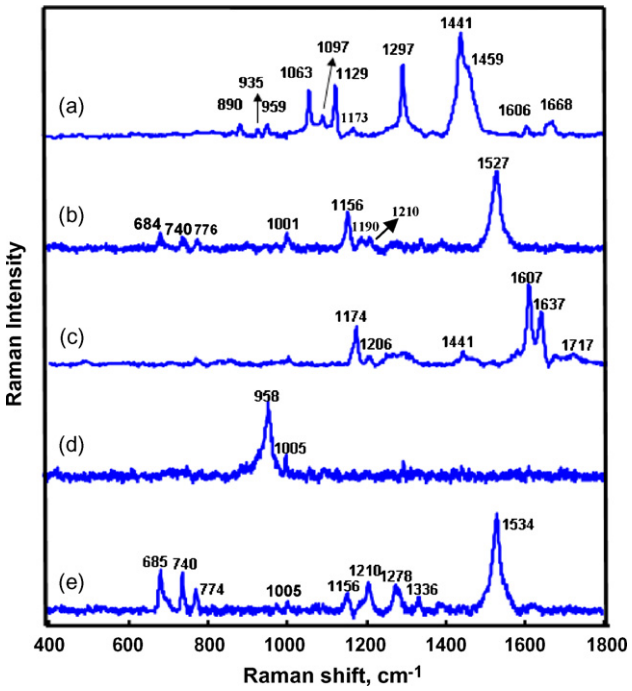

Fig. 5. BTEM pure component spectral estimates of other constituents found in human nails, (a) lipid, (b) 1st carotenoid species, (c) ferulic acid, (d) calcium phosphate like species, (e) 2nd carotenoid species.

stretching vibration of cystine and cysteine residues and the weak band at 1683 cm^{-1} corresponds to the amide I stretching vibration (although it is shifted to slightly higher wavenumber, see Section 3.2 for further details). From Fig. 3(b), another pure component spectrum associated with cystine and cysteine residues is resolved with a prominent Raman band at 636 cm^{-1}. This band can again be assigned to a C–S stretching mode [26].

The pure component spectral estimates in Fig. 3(c) and (d) show broad bands at 1250–1425 cm^{-1}, which may arise from the overlapping Raman signals of the C–H deformation and amide III [26]. The intensities of the methylene (CH_2) deformation, C_α–H stretching, and tryptophan appears at 1343, 1310, and 1304 cm^{-1}, and the intensity of the amide III band for α-helix structure appears around 1260–1300 cm^{-1}. Since all these bands are highly overlapping, broad bands arise as shown in Fig. 3(c) and (d). Additional bands at 1448, 1602, and 1655 cm^{-1} also appear in Fig. 3(c) and they can be assigned to CH_2 bending, C=C in-plane bending mode of phenylalanine and tyrosine, and amide I α-helix modes. The weak Raman band at 1002 cm^{-1} seen in Fig. 3(d) is associated with the symmetric breathing mode of the aromatic ring of phenylalanine.

Fig. 3(e) and (f) are two rather similar pure component spectral estimates which were recovered using BTEM analysis. However, these two estimates are certainly different species, as closer inspection shows that the peak maxima are significantly different. Fig. 3(e) exhibits Raman bands at 646, 832, 856, 1005, 1035, 1130, 1211 cm^{-1} whereas Fig. 3(f) shows bands at 641, 826, 849, 1002, 1030, 1125, 1205 cm^{-1}. With regard to their primary structures, these two spectral estimates certainly belong to proteins, as several amino acid residues can be clearly observed. The Raman bands of phenylalanine residues are clearly shown at 1005, 1035, 1211 cm^{-1} in Fig. 3(e) and at 1002, 1030, 1205 cm^{-1} in Fig. 3(f). Both sets of three Raman bands are associated with the breathing mode of the aromatic ring, δ(CH) in-plane and $\nu(C_6H_5–C)$, respectively [27]. Raman signals of tyrosine residues are also seen at the Raman vibration frequencies 646, 832, and 856 cm^{-1} in Fig. 3(e) and 641, 826, 849 cm^{-1} in Fig. 3(f). These sets of vibrations can be attributed to the aromatic ring and Fermi resonance doublet, respectively. The tyrosine doublets observed at 832/856 and 826/849 cm^{-1} in the current study have been well investigated and are due to the Fermi resonance between the ring-breathing vibration and the overtone of an out-of-plane ring-bending vibration of the para-substituted benzenes [28]. As the peak-height intensity of the band at 856 and 849 cm^{-1} is higher than the peak-height intensity of the band at 832 and 826 cm^{-1}, it is suggested that the tyrosine residues in human nails are mostly exposed and are likely to form intermolecular bonds with other amino acids [29,30]. Tryptophan residues are seen at the Raman vibrational frequencies 760 and 1359 cm^{-1} in Fig. 3(e) and at 1339 and 1359 cm^{-1} in Fig. 3(f). The band at 760 cm^{-1} can be attributed to indole ring-breathing and the bands at 1339 and 1359 cm^{-1} can be assigned to the Fermi resonance doublet of tryptophan, which has been used as an indicator of hydrophobicity. Higher intensity ratios of the doublet, I_{1339}/I_{1359} suggest that a hydrophobic environment is present, whereas lower intensity ratios suggest that the tryptophan is involved in the hydrogen bonding of a hydrophilic environment [31]. In Fig. 3(f), the peak-height Raman intensity of 1339 cm^{-1} is higher than 1359 cm^{-1}, which indicates that a hydrophobic environment may exist in some parts of human nails. On the other hand, in Fig. 3(e), it can be seen that the Raman band centered at 1359 cm^{-1} is weak and the corresponding Fermi resonance peak commonly observed at 1339 cm^{-1} is missing. The lack of this peak indicates that the tryptophan is exposed and linked to other amino acids [32]. In the two spectral estimates shown in Fig. 3(e) and (f), amide I bands are also recovered at 1671 cm^{-1} (Fig. 3(e)) and 1670 cm^{-1} (Fig. 3(f)). The position of these two amide I bands indicated that these two proteins have primarily β-sheet secondary structures [25,26].

3.2. Pure component spectral estimates of secondary structures of protein

Fig. 4 presents BTEM pure component spectral estimates of two different protein structures. The first estimate as shown in Fig. 4(a) has a strong and prominent band centered at 1652 cm^{-1} and some additional bands at 901, 936, 1415, and 1450 cm^{-1}. The band at 1652 cm^{-1} is unambiguously assigned to the amide I vibrational mode, which involves mainly C=O stretching vibrations, but also C–N stretching, C_α–C–N bending, and N–H in-plane bending of peptide groups [25,26]. This band at 1652 cm^{-1} also indicates that this estimate possesses a α-helix conformation, which is further confirmed by the presence of skeletal C–C stretching vibrations at 901 and 936 cm^{-1} [33]. The bands at 1415 and 1450 cm^{-1} correspond to methylene deformation and bending modes, respectively. The second estimate as shown in Fig. 4(b) has a strong band centered at 1672 cm^{-1} and relatively weaker bands at 1005 and 1180–1280 cm^{-1}, which correspond to the amide I stretching vibration of a β-sheet conformation, ring-breathing mode of phenylalanine, and amide III stretching vibration, respectively. The recovery of these two secondary structures of protein via BTEM analysis, α-helix and β-sheet, indicates that human nail specimens contain two protein conformations. As observed in Fig. 4, the recovered spectral estimate of β-sheet conformation has a lower signal-to-noise ratio compared to the recovered spectral estimate of α-helix conformation. This suggests that proteins in human nails contain predominantly α-helix structures and a lower content of β-sheet structures. The reliability of BTEM analysis in recovering pure component spectral estimate of minor constituents has been repeatedly shown in other studies [17,34].

3.3. Pure component spectral estimates of other constituents

As shown in Fig. 5, pure component spectral estimates of five other constituents are also recovered using BTEM analysis. The

first estimate as presented in Fig. 5(a) shows prominent and sharp Raman bands between 1050 and 1300 cm^{-1} that have typical characteristics consistent with palmitic saturated fatty acid [35]. Thus, this estimate can be assigned as a lipid constituent of human nail. Raman bands at 1063, 1097, 1129, and 1173 can be assigned to (C–C) skeletal stretching. The band at 1297 and a group of bands between 1400 and 1500 cm^{-1} can be assigned to $\delta(CH_2)$ twisting vibrations and $\delta(CH_3)$ or $\delta(CH_2)$ deformations, respectively. However, as shown in Fig. 5(a), there is an absence of the ester band commonly found near 1740 cm^{-1}, which is replaced by an amide-like band at 1668 cm^{-1}. Such an amide band can be assigned to the C=O stretching vibration coupled to a N–H bending vibration [36]. This amide band indicates that this lipid constituent belongs to the group called sphingolipids. Sphingolipids are a group of lipid constituents, which are composed of a sphingoid base backbone to which a fatty acid may be attached through an amide bond and/or a head group at the primary hydroxyl [37]. These may be associated, in part, with the hydrophobic regions mentioned earlier (Section 3.1).

The second estimate as shown in Fig. 5(b) has prominent Raman bands of carotenoid species at 1001, 1156, and 1527 cm^{-1}, which can be attributed to the δ(C=CH) methyl in-plane rocking vibrations, ν_2(C–C) in-plane single bond stretching, and ν_1(C=C) stretching mode respectively [38]. In addition, two smaller bands of carotenoid species appearing at 1190 and 1210 cm^{-1} are also recovered by BTEM analysis as seen in this estimate. These two bands can be assigned to $\nu(C–CH_3)$ stretching and combination of CH_3 deformation and in-plane CH methine vibrations, respectively [39]. The other three smaller bands found between 650 and 800 cm^{-1} are probably Raman bands associated with amino acid signals from cysteine and tryptophan. The presence of these three bands may indicate that this carotenoid species is bound with proteins.

The third spectral estimate shown in Fig. 5(c) has some prominent Raman bands centered at 1174, 1206, 1441, 1607, 1637, and 1717 cm^{-1}. This recovered spectral estimate may correspond to ferulic acid, a phenolic compound that is commonly found in leaves, seeds of many plants and especially grains such as brown rice, whole wheat and oats. Ferulic acid is normally bound to cell wall polymers. The pure ferulic acid Raman spectrum is characterized by a vibration at 1178 cm^{-1} and by the doublet stretching vibration C=C of the phenolic ring at 1603 and 1630 cm^{-1} [32,40]. However in the present estimate, the recovered pure component spectral estimate of ferulic acid has slightly shifted peak positions. The recovered spectral Raman bands at 1174 and 1206 cm^{-1} can be assigned to C–C stretching and C–O stretching vibrations. The recovered peak at 1441 cm^{-1} can be assigned to both symmetrically and asymmetrically CH_3 deformations and the recovered peaks at 1607 and 1637 cm^{-1} can be assigned to the C=C stretching vibration of the benzene or a phenolic ring [32]. The identification of ferulic acid in nail specimens via Raman microscopy and BTEM analysis is somewhat surprising. Since ferulic acid is known as a potent anti-oxidant, it has been added to skin and nail healthcare products, as it can neutralize free radicals that can cause oxidative damage of cell membranes and DNA. Ferulic acid is also added to some healthcare supplements to prevent damage to cells caused by ultraviolet light. In addition, adding ferulic acid to vitamins C and E also appears to increase protection from UV-induced skin damage. The long-term usage of skin and nail care products containing ferulic acid may have caused some incorporation of ferulic acid component into the nail plate. Simple nail cleaning using acetone prior to Raman measurements ultimately does not help to remove this anti-oxidant species and as such ferulic acid can still be identified in the present analysis.

The fourth spectral estimate shown in Fig. 5(d) shows one major band centered at around 958 cm^{-1} and one small band at around 1005 cm^{-1}. This spectral estimate may be associated with calcium phosphate found in human nails. As the amount of calcium phosphate in human nail is very small, the recovered pure spectral estimate via BTEM analysis has lower signal-to-noise ratio, and therefore, other peaks correlated with the main peak (958 cm^{-1}) are imbedded in the noise [41]. The two recovered peaks, 958 and 1005 cm^{-1}, can be attributed to the stretching vibration of PO_4 mineral and P–O stretching of monohydrogen phosphate and/or the phenyl breathing modes that might be present in human nails.

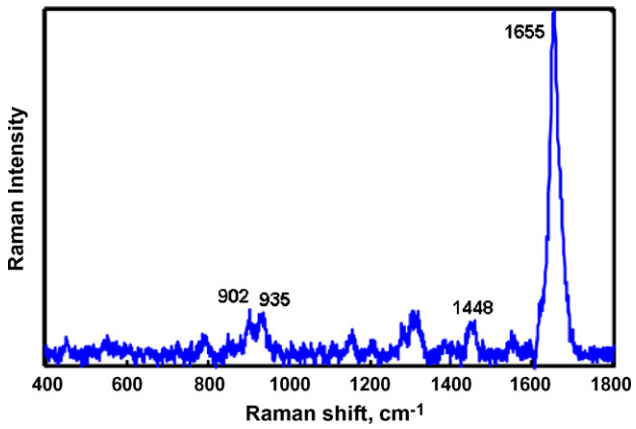

Fig. 6. Another spectral pattern estimate obtained from BTEM analysis—similar to an α-helix secondary structure.

As shown in Fig. 5(e), the recovered fifth spectral estimate looks quite similar to the second spectral estimate. This high degree of similarity indicates that this estimate is another carotenoid species found in human nail. The most prominent Raman band in this estimate, which can be assigned to a ν_1(C=C) stretching mode, is centered at 1534 cm^{-1}. This peak position is higher than the second estimate which is centered at 1527 cm^{-1}. A relationship between the peak position of the ν_1(C=C) stretching mode and the number of conjugated double bonds in the carotenoid chain has been previously studied [42]. It was found that the wavenumber of the ν_1(C=C) band decreases with the increasing number of conjugated double bonds in the carotenoid chain due to an electron–phonon coupling. Accordingly, the present estimates may suggest that the first species with ν_1(C=C) band at 1527 cm^{-1} is the nine-double bond conjugated carotenoid, whereas the second species with ν_1(C=C) band at 1534 cm^{-1} is the seven-double bond conjugated carotenoid. Additional Raman bands for the fifth spectral estimate were also recovered at 675, 740, 774, 1005, 1156, 1210, 1278, 1336, and 1534 cm^{-1}, in which the first three bands correspond to cysteine and tryptophan (675, 740, and 774 cm^{-1}). The Raman peaks at 1005, 1156, and 1210 cm^{-1} correspond to the other carotenoid signals, which can be attributed to δ(C=CH) methyl in-plane rocking vibrations, ν_2(C–C) in-plane stretching, and a combination of CH_3 deformation and in-plane CH methine vibrations. The Raman peaks at 1278 and 1336 cm^{-1} correspond to amide III and a methylene bending vibration. The presence of amino acids and an amide vibration again indicate that this estimate is a carotenoid species bound to protein, similar to the second estimate shown in Fig. 5(b).

3.4. Other spectral patterns

A few additional spectral patterns were obtained by BTEM analysis. However, these additional spectral patterns are all very similar to pure patterns already presented in Figs. 3–5. Fig. 6 shows one of these patterns. This spectrum surely represents an α-helix but the main peak maximum is shifted just slightly, and the relative intensities of the other bands are slightly lower. Mathematically, this high degree of similarity means that the inner product of Fig. 4(a) and the Fig. 6 will approach unity, and hence further analysis to determine

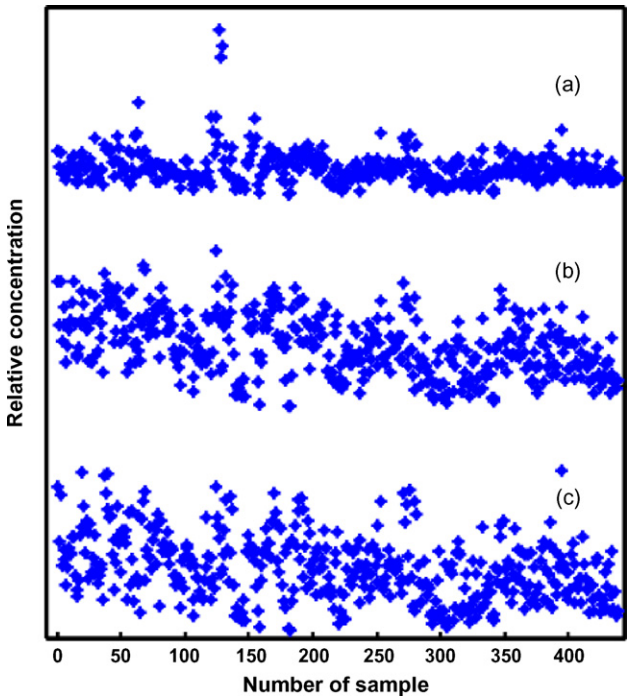

Fig. 7. The relative concentration profiles, (a) ferulic acid in Fig. 5(c), (b) polypeptide in Fig. 3(e), (c) an α-helix conformation structure in Fig. 4(a).

their individual signal contributions will be problematic. Accordingly, in the following section, only the 13 original BTEM estimates (Figs. 3–5) will be used, in order to facilitate further analyses.

3.5. Relative concentrations

A least squared fit of the 13 primary pure component spectra (Figs. 3–5) onto the baseline corrected nail spectra generally resulted in less than circa 2% mismatch. This indicates that most of the information content of the experimental measurements was captured by the above 13 pure component spectra. Accordingly, the relative concentrations of the previously identified components can be readily obtained. Fig. 7 shows the relative concentration profiles of 3 components, namely the ferulic acid in Fig. 5(c), polypeptide in Fig. 3(e), and an α-helix in Fig. 4(a). These were chosen to illustrate the wide range of concentration profile behaviors observed. For example, the concentration profile of ferulic acid Fig. 7(a) shows pronounced person-to-person variation. Indeed, the 3 concentrations associated with samples 127–129 (the 3 concentration outliers) all belong to one individual.

The issue of correlations between concentration profiles was also investigated. The inner product between the concentrations of ferulic acid in Fig. 7(a) and of polypeptide Fig. 7(b) was 0.60. A relatively low value is expected since there is no obvious correlation between ferulic acid and a polypeptide. In contrast, the inner product between the concentrations of polypeptide Fig. 7(b) and of an alpha-helix in Fig. 7(c) was 0.91. This relatively high value is not entirely unexpected since some polypeptides should exhibit an α-helical structure.

3.6. Potential of target transformation factor analysis (TTFA) in further analysis

Target transformation factor analysis is an established method for evaluating a set of 1D data for the presence of a test vector [43]. After consideration of the widely varying diets of the individuals from whom the nails were acquired, curcumin was chosen as the test constituent. It is well known that tuber turmeric/curcumin is a major constituent of some Southeast Asian foods [44]. It is also well known that the polyphenolic compound curcumin is rather hydrophobic [45]. A Raman spectrum was measured of an authentic sample of curcumin. Subsequently, the experimental data set was tested. Fig. 8 shows the experimentally measured Raman spectrum of curcumin as well as the predicted spectrum from the test. As can be seen, there is considerable similarity between the curcumin spectrum and the predicted spectrum (even though the latter has relatively low S/N). This suggests that curcumin (or closely related metabolites) are present in minute spectroscopic quantities in at least a few of the nail samples. Attempts at reconstructing a curcumin spectrum using BTEM were unsuccessful, probably due to the very low signal contribution.

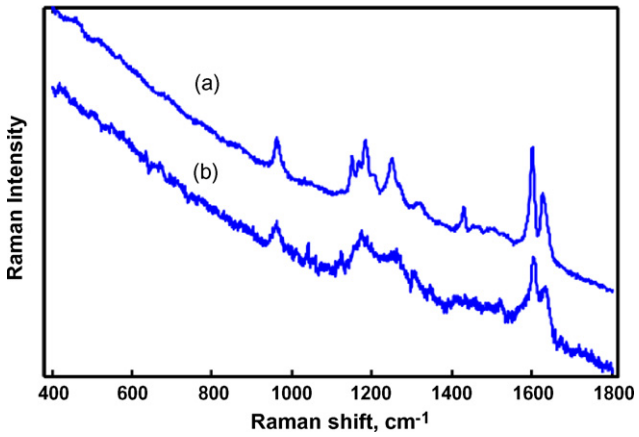

Fig. 8. Raman spectrum of curcumin, (a) experimental measured from authentic sample, (b) predicted spectrum via TTFA using 50 right singular vectors.

3.7. Limitations and extensions

Raman microscopy was used as the spectroscopic method throughout the present study. The primary limitation of the present approach is associated with the specificity of this spectroscopy. Reasonably good Raman scatter is an important pre-requisite to the subsequent signal processing, i.e. deconvolution and TTFA. Hence, molecules like water and functional groups such as OH may not be easily identifiable. A complementary vibrational measurement, such as FTIR microscopy might be able to fill this gap. As an extension of the present method, a laser change from near-infrared to UV, might dramatically increase the sensitivity for some molecules due to resonance enhancement. Indeed, the general increase in signal-to-noise afforded by the short wavelength excitation source could also possibly enhance the subsequent signal processing steps, and additional components may be detectable.

4. Conclusions

The present results have shown that combined Raman spectroscopy and BTEM analysis of human nail clippings can result in the reconstruction of the underlying pure component spectra of various constituents present in this complex biological tissue. This has subsequently allowed identification of some proteins and their secondary structures in greater detail. As shown in Fig. 3(e) and (f), the Fermi resonance doublet of tyrosine and tryptophan could be well resolved, and as such it was found that the tyrosine and tryptophan residues in human nails are mostly exposed and not buried and that they form intermolecular bonds with other amino acids. BTEM analysis has also helped to verify that the protein secondary structures in human nails are predomi-

nantly α-helix conformations but that β-sheet conformations are also present. Pure component spectra of minor constituents, i.e. lipid, carotenoid species, ferulic acid, and calcium phosphate like species, have also been recovered from some of the human nail clippings. The recovered pure spectrum of lipid without an ester band but with an amide-like band indicates that the lipid constituent in human nail plate mainly consists of sphingolipids. The two recovered carotenoid species with different ν_1(C=C) peak positions suggest that these two carotenoid species have a different number of conjugated double bonds in the carotenoid chain. The identification of carotenoid species and ferulic acid in the present study from some nail clippings is somewhat unexpected, since the presence of these components in human nails has not been reported before. Carotenoid species and ferulic acid are popular anti-oxidants, which are added into healthcare products particularly for skin and nails. Long-term usage of such healthcare products, and subsequent incorporation into nail, may be responsible for the observations made in this study.

The combination of Raman spectroscopy and BTEM analysis as shown in the present study can probably be extended to other complex biological tissues. This type of approach may help to identify certain bio-constituents in other biological tissues, or even identify biomarkers of disease or chemical exposure.

ABSTRACT

Aristolochic acids (AAs) are a mixture of structural-related compounds, in which aristolochic acid I (AA I) and aristolochic acid II (AA II) are reported to be correlated with Aristolochic acid nephropathy (AAN). In this work, a rapid and sensitive ultra-high-pressure liquid chromatography–tandem mass spectrometry (UHPLC–MS/MS) method was developed to determine AA I and AA II in herbal products and biological fluids. By using gradient elution with a mobile phase composed of a mixture of 10 mM ammonium formate buffer (pH 3.0) and acetonitrile, AAs could be determined within 10 min. Under optimum UHPLC–MS/MS conditions, the limit of detections was 0.14 and 0.26 ng mL^{-1} for AA I and AA II, respectively. Run-to-run repeatability and intermediate precision of peak area for AA I and AA II were less than 5.74% relative standard deviation (RSD). Accuracy was tested by spiking 10, 100 and 1000 ng mL^{-1} in rat serum and the recoveries were within 76.5–92.9%. Matrix effects were within 78.8–127.7%. The developed method was successfully applied to determine AA I and AA II in several herbal products and to investigate their pharmacokinetic behavior in female Wister rats. The result shows that the developed UHPLC–MS/MS method is efficient, sensitive, and accurate for the determination of AA I and AA II in herbal products and biological samples.

1. Introduction

Aristolochic acids (AAs) are found primarily in the plant genera *Aristolochia* and *Asarum* [1]. Pharmacological properties of AAs are anti-inflammatory, antitussive, antiplatelet aggregation. And they are also used as pain-relievers [2–4]. Inadvertent replacement of the plant *Stephania tetrandra* with *Aristolochia fangchi* in Chinese herbal medicines has caused many renal fibrosis problems, named Aristolochic acid nephropathy (AAN), in young women on a sliming regimen [5]. AAs were proved to be the major components that caused such toxicity [6]. Due to the serious side effect, USA, UK, Canada, Australia, and Germany government agencies have banned the use of a range of species of plants that contain AAs. For similar reasons, several Chinese herbal medicines, including *Aristolochia fangchi* (Guangfangji), *A. debilis* (Qingmuxiang), *A. manshuriensis* (Guanmuton), and *A. contorta* (Madouling), have been prohibited to be imported or manufactured in Taiwan since 2003.

Despite the warning and import alert issued by the US Food and Drug Administration that herbal products containing AAs are unsafe [7], 19 products containing AAs and 95 products suspected to contain AAs were found to be sold on the Web in 2003 [8,9]. A recent study used capillary electrophoresis with laser-induced fluorescence to analyze 61 herbal products, and found that 24 samples suspected to contain AAs [10]. One way to reduce the incidence is by controlling the quality of herbal preparation via regular checking. Therefore, it is essential to develop sensitive and efficient analytical methods for the determination of AAs.

AAs are a mixture of structural-related 10-nitrophenanthrene 1-carboxylic acids [11], where AA I, the 8-methoxy-3,4-

doi:10.1016/j.talanta.2009.10.003

methylenedioxy derivative, and AA II, the 3,4-methylenedioxy derivative, are the major components in the *Aristolochia* species [12]. Thin layer chromatography [13], high performance liquid chromatography (HPLC) with UV absorption detection [14–16] and capillary electrophoresis (CE) with UV detection [17,18] had been developed to analyze AA I and AA II in herbal products. Recently, HPLC coupled with fluorescence detection [19–21], CE coupled with laser-induced fluorescence detection [10], electrochemical detection [22], and on-line concentration technique [23] were developed to improve the sensitivity in detection.

HPLC and mass spectrometry hyphenated technique (HPLC–MS) has been proven to be a powerful tool in determining AAs in herbal products [24–29]. Due to the complexity in sample constituents, matrix effect is found to be remarkably significant in herbal extracts. The importance of eliminating matrix effect and ion suppressions during the development of quantitative methods based on HPLC–MS has been demonstrated in [30]. Various approaches have been used to eliminate matrix effect, including: (1) changing and improving sample extraction procedure by eliminating undetected matrix interferences, (2) performing the assay under more efficient chromatographic conditions to separate analytes of interest from other components, and (3) evaluating and changing the HPLC–MS interface [31]. The first two approaches, however, dramatically increase the analytical time, while the third approach may sacrifice sensitivity. In general, using the HPLC–MS/MS method to determine AAs in herbal products normally takes 20–60 min for an analysis [24–29].

Ultra-high-pressure liquid chromatography (UHPLC) is a recently developed technique which shows great advantages in providing better efficiency, sensitivity, and speed over ordinary HPLC. UHPLC columns packed with sub-2-μm particles can significantly increase the theoretical plate. Also, the increase in flow rate does not have negative impact on efficiency [32–34]. With sharper peaks and improved chromatographic resolution, matrix effect could be minimized without increasing the separation time [35]. There was one work which uses UHPLC–MS to analyze AAs, in which UHPLC–MS was applied to fingerprint analysis of AAs-containing preparations [36]. It used principal components analysis (PCA) and partial least square-discriminate analysis (PLS-DA) to identify the existence of AAs in pharmaceutical preparations. Due to the lack of selectivity and sensitivity consideration in that work, it is impractical to use the proposed method to quantitatively determine AAs in herbal preparations and biological samples. And the applicability to analyze biological samples is essential for the evaluation of nephrotoxicity. Up to now, there have been only two studies which investigated pharmacokinetic properties of AAI and AAII *in vivo*. Both of them used rabbits as their study animals because their analytical methods require a large sample volume [37,38]. The restriction of applying those methods to analyze rat serum limits the applicability of their approaches. Several studies revealed that AAs nephrotoxicity could be regulated by enzyme activity [39,40]. Since the pharmacokinetic properties of AAs are still unclear, it is necessary to develop a sensitive analytical method to facilitate these studies.

The primary goal of our research is to develop a sensitive and efficient UHPLC–MS/MS method to satisfy the demands on the aspects described earlier. To reach this goal, UHPLC–MS/MS conditions were systemically optimized for fast separation and sensitive detection. We used various herbal products, plasma samples, microsome incubation samples to demonstrate the practicability of the developed method. To the best of our knowledge, this is the first study using UHPLC–MS/MS to quantitatively analyze AA I and AA II in herbal products and biological samples.

2. Experimental

2.1. Chemicals

An AAs standard containing 90.9% of AA I and 5.7% of AA II was obtained from Acros (Geel, Belgium). Ammonium formate and ammonium acetate were obtained from Fluka Chemicals (Buchs, Switzerland). Methanol (MeOH) and acetonitrile (ACN) of chromatography grade were obtained from Mallinckrodt (Phillipsburg, NJ, USA). MeOH, ACN, and water of LC–MS grade were obtained from J.T. baker (Philipsburg, NJ). Dried fruits of *A. contorta* was collection from Liaoning, China in 2007. Dried roots of *A. debilis* was collected from Guangdong, China in 2007 and dried roots of *A. fangchi* were collected from Guangdong, China in 2007. The herbal samples were authenticated by Dr. Wei-Chu Li (Sheng Chang Pharmaceutical Corporation, Jhongli City, Taoyuan Country, Taiwan). The identification lab has laboratory accreditation issued by Taiwan accreditation foundation. Voucher specimens were stored at the Sheng Chang Pharmaceutical Corporation Herbarium. The concentrated powders of the decoction Bu-fei-a-jiau-tang was provided by Sheng Chang pharmaceutical co. (Chung-Li, Taiwan) under a research project contract (CCMP96-RD-044). Hsiao-Ching-Lung-Tang, Chuan-Chiong-Char-Tiao-San and Shin-Yi-San were obtained in the Taipei market (Taipei, Taiwan).

All solutions were filtered through 0.2-μm GH Polypro filters before use. All samples were filtered through 0.22-μm PVDF filters before use (Millipore, Bedford, MA, USA).

2.2. Isolation of AA I and AA II from AAs standard mixture

AA I and AA II standards were separated by semi-preparative RP-HPLC. The mobile phase was an ammonium acetate buffer–ACN mixture (72:28, v/v). The buffer was prepared by adjusting 10 mM ammonium acetate to pH 3.0 with acetic acid. The flow rate was 2 mL min^{-1}, and the detection wavelength was 254 nm. The AAs standard mixture was dissolved in tetrahydrofuran at a concentration of 10 mg mL^{-1}. The injection amount was 100 μL.

The equipments consisted of a Hitachi UV Pump L-7100 (Kyoto, Japan), a Rheodyne 7725i 5-mL manual injector (Cotati, CA, USA) and a Hitachi L-7400 UV detector. Separations were carried out on a Hibar Purospher RP-18 column (250 mm × 10 mm, 5 μm) (Merck, Darmstadt, Germany).

Stock solution (1000 μg mL^{-1}) was prepared by dissolving 1 mg AA I and 1 mg AA II in 1 mL MeOH separately. Adequate amounts of the stock solution were diluted with MeOH to prepare for the standard solutions for the respective experiment.

2.3. Apparatus

2.3.1. UHPLC–DAD

The equipments consisted of a Waters Acquity UPLC autosampler, column manager and thermostat, binary solvent manager, and an Acquity UPLC diode array detector (Waters, Milford, MA). The UV detection range was 200–400 nm. Separations were carried out on a Waters Acquity UPLC BEH C18 column (100 mm × 2.1 mm, 1.7 μm).

2.3.2. UHPLC–MS/MS

The Acquity UPLC system consisted of an autosampler, column manager with thermostat, a degasser, and a binary solvent manager (Waters, Milford, MA).

A Quatro Micro triple-quadrupole mass spectrometer (Micromass, Manchester, UK) equipped with an electrospray ionization (ESI) source was used. The mass spectrometer was operated in the positive ion electrospray mode with selective reaction monitoring (SRM). The analyses were performed in positive mode with a cone voltage of 20 V for AA I and 20 V for AA II, extractor voltage of 3.0 V,

RF lens voltage of 0.0 V, capillary voltage of 3.0 kV, ion source temperature of 80 °C, and desolvation temperature of 450 °C. A cone gas flow of 50 L h^{-1} and desolvation gas flow of 1100 L h^{-1} were used. Argon (99.999%) was used as a collision gas. Gas flow rate was kept at 0.13 nL min^{-1} in the collision cell. The collision energy was 12 eV for AA I and 10 eV for AA II. MassLynx 4.1 software was used for data analysis.

Chromatographic separation was performed by using an Acquity BEH C18 column (100 mm × 2.1 mm, 1.7 μm) (Waters, Milford, MA). The mobile phase was composed of 10 mM ammonium formate (pH 3.0) (solvent A) and ACN (solvent B). The gradient profile was: 0–2 min: 34% B; 2–10.5 min: linear from 34% to 36% B; 10.5–10.6 min: linear from 36% to 34% B and then re-equilibrium of the column. The flow rate was kept at 0.3 mL min^{-1} The column oven was set at 40 °C and the auto-injection system was set at 4 °C. Partial loop with needle overfill mode was used for sample injection, and the injection volume was 5 μL.

2.4. Pharmacokinetic study of AA I in rat

2.4.1. Drug administration and sample collection

AAs standard powder (90.9% of AA I and 5.7% of AA II) was dissolved in corn oil at a concentration of 0.5 mg mL^{-1}. The AA standard solution was administered to female Wistar rats at a dose of 10 mg kg^{-1} through an intragastric tube. Blood samples (0.2 mL) were taken from the femoral vein at 15, 30, 45, 60, 90, 120, 240, 360, 480, 600 min after oral treatment. The blood samples were centrifuged and the serum was taken and stored at −80 °C until analyzed by the UHPLC–MS/MS method.

2.4.2. Preparation of liver microsomes

Two adult male ICR mice were injected with β-naphthoflavone at a dose of 50 mg kg^{-1} for three consecutive days to induce liver CYP1A enzyme activities. Mice were sacrificed by cervical dislocation, and their livers were removed immediately on ice for further microsomes preparation.

Livers were homogenized in 1.15% KCl buffer, and the mixture was centrifuged at 8000 rpm for 20 min at 4 °C. The supernatant was further subjected to ultracentrifuge at 39,000 rpm (Beckman, Fullerton, CA) for 60 min. The pellet was rinsed with 1.15% KCl buffer and then ultracentrifuged again. The pellet was collected and dissolved in equal amount of 100 mM K_2HPO_4 (pH 7.4).

The microsomal protein concentration was determined by BCA protein assay (Thermo Fisher Scientific, Rockford, IL).

The animal study presented in this paper was approved by National Taiwan University, College of Medicine, and College of Public Health Institutional Animal Care and Use Committee (IACUC Approval No: 20070151).

2.5. Sample preparation

2.5.1. Extraction of plant material

Aristolochia plants and their pharmaceutical preparations were grounded to powder. Two grams of each powder were ultrasonically extracted with 10 mL of MeOH for 10 min and followed by centrifugation at 8000 rpm for 5 min. The extraction was repeated for three times and the supernantants were combined and concentrated under reduced pressure until dry. Suitable amount of the residue was re-dissolved with MeOH for the respective experiment.

2.5.2. Serum sample pretreatment

One hundred and sixty microliters of ACN was added to 80 μL serum for deproteination. After 15 min, the mixture was centrifuged at 12,000 rpm for another 15 min to remove proteins. Two hundred microliter of supernatant was evaporated to dryness under nitrogen flow, and then reconstituted in MeOH. The reconstituted solution was subjected to UHPLC–MS/MS analysis.

2.5.3. Microsome incubation sample

The incubation mixture (final volume 0.75 mL) contained 0.75 mg mice liver microsomes, 0.19 mM NADPH, 1.56 mM $MgCl_2$, 0.1 M sodium phosphate buffer (pH 7.4) and 0.3 mM AAI standard. The 0.3 mM of AAI standard was replaced with Bu-fei-a-jiau-tang in the study of herbals mixture study. The mixture was shaken (100 oscillations/min) for 5 min at 37 °C. Then the substrate was added to trigger the reaction. After 30 min of incubation with shaking at 37 °C, the reaction was stopped by adding 0.2 mL of methanol and the mixture was centrifuged at 39,000 rpm for 25 min at 4 °C. Part of the supernatant (100 μL) was mixed with 100 μL ACN. After 15 min, the mixture was centrifuged at 3000 rpm for 5 min to separate precipitated proteins. The supernatant was then transferred into a 1.5-mL tube containing 50–60 mg sodium chloride. The suspension was vortex-mixed briefly and incubated at room temperature for 20 min and vortex-mixing again. Finally, the mixture was centrifuged at 3000 rpm for 5 min, and then was subjected to UHPLC–MS/MS analysis.

3. Results and discussion

Parameters affecting UHPLC–MS/MS performance were systemically optimized in this study.

3.1. Optimization of UHPLC–MS/MS conditions

AA I and AA II tends to form ammonia adduct in the mobile phase [24]. The precursor ion were set at m/z 359 $[AA\ I + NH_4]^+$ and m/z 329 $[AA\ II + NH_4]^+$ to provide the best detection sensitivity. The most intense precursor–product transitions were selected as the quantification transitions in the multiple reaction monitoring (MRM) mode. The fragmentation mass spectra of the ion $[M + NH_4]^+$ derived from AA I and AA II are shown in Fig. 1. As depicted in the figures $[M + H\text{-}CO_2]^+$ was the base peak for both analytes. The fragment ions at m/z 298 $[AA\ I + H\text{-}CO_2]^+$ and m/z 268 $[AA\ II + H\text{-}CO_2]^+$ were therefore selected as the product ions. Both APCI (+) and ESI (+) (−) modes have been reported as the LC–MS ionization source in AAs analysis [21–26]. APCI with a mobile phase flow rate at 0.5 mL min^{-1} and ESI with a mobile phase flow rate at 0.3 mL min^{-1} were tested for their ionization efficiency. Signal intensity obtained under ESI (+) was found to be higher than that under APCI (+) over ten fold. Thus, ESI (+) was used as the ionization source in our study.

The UHPLC mobile phase was optimized to provide the best selectivity and the highest signal intensity in this study. The structures of both AA I and AA II contain one carboxylic acid group with a pK_a value being 3.2–3.4 and 3.3–3.5, respectively [41]. Due to the acidic properties of AA I and AA II, the acidic mobile phase gave better retention and chromatographic separation in the reversed phase column. The addition of buffer also assisted the ESI analysis. The influence of the buffer type and the pH value of the mobile phase on selectivity and sensitivity were further investigated.

3.1.1. Optimization of UHPLC mobile phase

Kite et al. had studied the effect of the LC buffer type on MS signal intensities of AAs [24]. In their study, 0.1% ammonium acetate gave the best results. The buffer type investigation presented by Chan showed that the addition of 1.0 mM ammonium acetate in 0.2% acetic acid dramatically increases the signal of the ammonium adduct [26]. In this study, mobile phase with the use of 10 mM ammonium acetate and 10 mM ammonium formate as buffer solution were compared to see their effect on MS peak intensity. The intensities of MS signals were shown in Fig. 2. It was found that peak intensity obtained under ammonium formate system was more

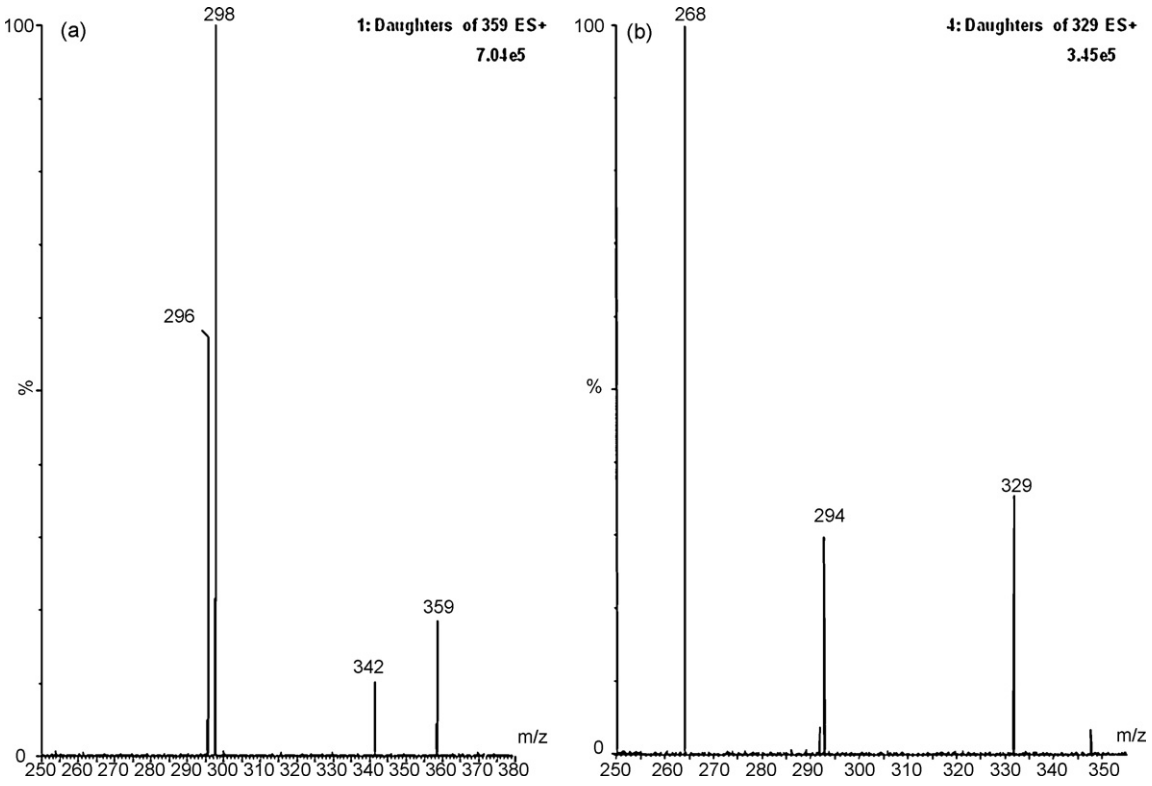

Fig. 1. MS/MS spectra of AA I (a) and AA II (b).

than two fold higher than that under ammonium acetate system. Therefore, 10 mM ammonium formate was selected to be the buffer system. The influence of organic solvent on the peak intensity was also investigated. Peak efficiencies were better when ACN instead of MeOH was used as the organic solvent in the mobile phase. Moreover, signal intensities obtained under the ACN system was higher than those under the MeOH system for more than five fold. ACN was therefore chosen as the organic solvent in the mobile phase.

Because radioactive isotope-labeled internal standards of AA I and AA II were not commercially available, the higher resolution provided by UHPLC played an important role in reducing the matrix effect. This is especially important for complicated samples such as herbal products. The pK_a value of AA I is between 3.2 and 3.4, and that of AA II is between 3.3 and 3.5. It was expected that in the mobile phase, various pH values from 3 to 5 would show significant effect on their retention. Several herbals containing AAs were tested in this experiment to evaluate the resolution of AA I and AA II from the complicated plant constituents. In order to test the selectivity of the developed conditions to herbals mixture, we used Bu-fei-a-jiau-tang as the tested formula. It was observed that the retention time of AA I and AA II increased while the pH value was decreased because AAs tend to be in their free form in more acidic conditions. The best resolution was obtained at pH 3.0. Gradient shape, gradient steepness and gradient range of the mobile phase were subsequently studied for the optimum separation conditions. The optimum gradient profile was: 0–2 min: 34% ACN; 2–10.5 min: linear from 34% to 36% ACN and then re-equilibrium of the column. UHPLC–UV and UHPLC–MS/MS chromatograms of the herbal extracts obtained under the optimum separation conditions are shown in Fig. 3. The results show that AA I and AA II could be baseline-separated from other herbal constituents within 10 min under optimum UHPLC conditions.

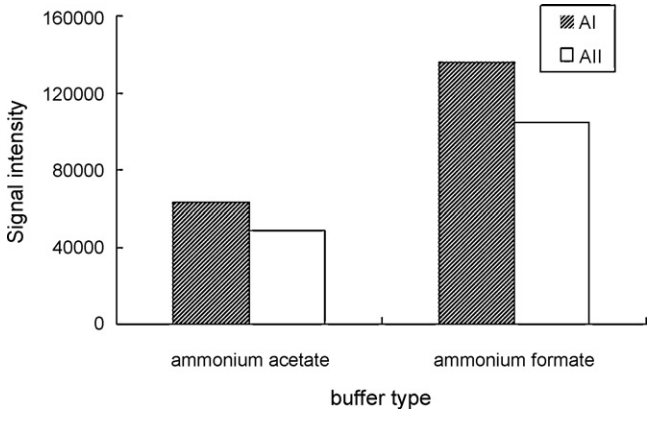

Fig. 2. Effect of buffer type on peak intensity of AAI and AAII in UHPLC–MS/MS system.

3.1.2. Optimization of ESI interface and mass spectrometry conditions

In the ESI mode, the distance from the emitter to the inlet has significant effect on mass sensitivity; at shorter distances, more of the ES plume will be sampled into the instrument. However, droplet evaporation time also reduces at smaller distances, resulting in lower ionization efficiency [42]. In this study, we found that the signals of AA I and AA II were intensified when the distance was increased from 3 to 4 mm, but dramatically weakened when the distance was further increased up to 5 mm, which was due to the low transmitted ES current. The value of 4 mm was consequently selected as the distance from the emitter to the inlet.

Cone voltage was shown to have the most profound effect on the signal intensity among all of the mass parameters. Signal intensity of AA I was increased more than four fold when the voltage was increased from 15 to 20 V, but decreased significantly if the voltage was further increased. This was attributed to the disappearance of ammonia in the mixture at the high voltage. The phenomenon is

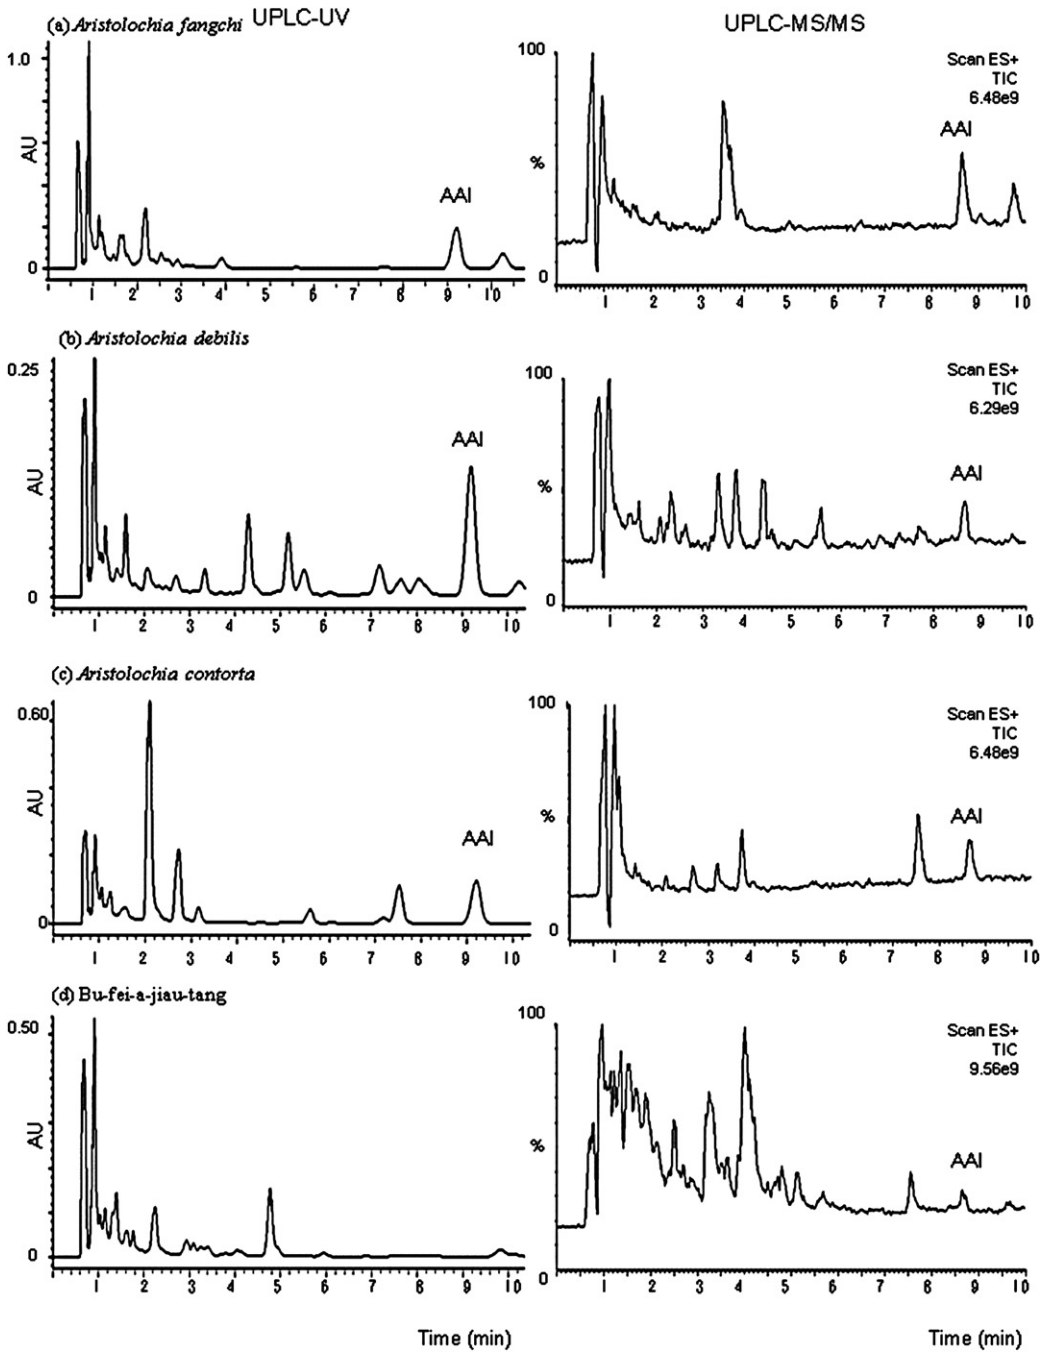

Fig. 3. UHPLC–UV and total ion scan (m/z = 200–1000) of UHPLC–MS/MS chromatograms of the crude extract of (a) *Aristolochia fangchi* 2000 μg mL^{-1}, (b) *A. debilis* 5000 μg mL^{-1}, (c) *A. contorta* 2000 μg mL^{-1} and (d) Bu-fei-a-jiau-tang 3000 μg mL^{-1} obtained under optimized conditions. UHPLC chromatographic conditions: solvent A: pH 3.0, 10 mM ammonium formate; solvent B: ACN. Gradient profile: 0–2 min: 34% B, 2–10.5 min: 34–36% B, 10.5–10.6 min: 36 –100% B, 10.6–16.9 min: 100% B, 16.9–17.0 min: 100–34% B, 17.0–20.0 min: 34% B. Flow rate: 0.3 mL min^{-1}. Injection volume: 5.0 μL. UV: 254 nm. MS conditions: cone voltage, 20 V; capillary voltage, 3.0 kV; collision energy for AA I, 12 eV; collision energy for AA II, 10 eV; ion source temperature, 80 °C; desolvation temperature, 450 °C; desolvation gas flow, 1100 L h^{-1}; cone gas flow, 50 L h^{-1}; probe distance, 4 mm.

consistent with what is reported by Kasai et al. [43]. Higher cone voltage should decrease the amount of ammonium-cation adduct. The value of 20 V was selected as the cone voltage for AA I and AA II analysis.

Since raising desolvation temperature would improve solvent evaporation and increase the amount of gas-phase ions and clusters, the desolvation temperature varied from 350 to 500 °C was investigated. Signal intensities of AA I and AA II were found to be increasing with the rise of desolvation temperature up to the highest applicable 500 °C, which was therefore selected as the desolvation temperature in this study. Collision energy larger than 20 eV resulted in higher degree of fragmentation which led to lower signal intensity. Values of 12 and 10 eV were selected for AA I and AA II, respectively. Other mass parameters (ion source voltage, temperature of the heated capillary, and flow rate of nitrogen gas) had minor influence on the mass sensitivity. Optimum values of these parameters are listed in the Section 2. Multiple reaction monitoring (MRM) chromatogram of AA I and AA II at 1 μg mL^{-1} obtained under the optimum conditions is shown in Fig. 4.

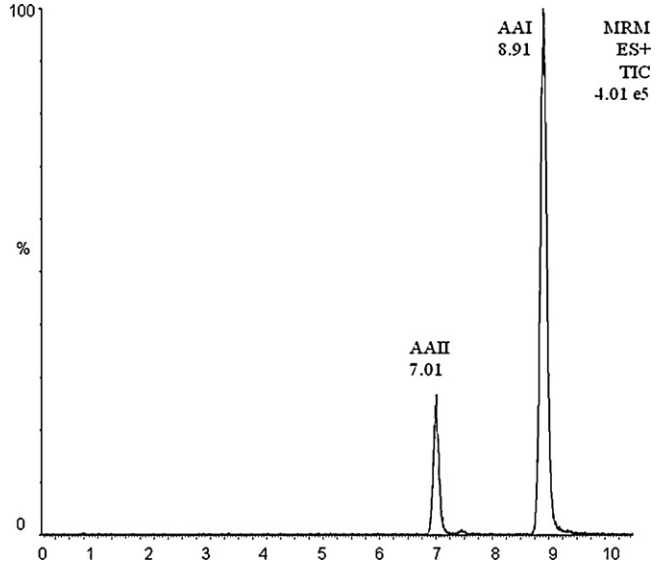

Fig. 4. UHPLC–MS/MS chromatogram (MRM) of AA I and AA II obtained under optimum conditions. UHPLC–MS/MS conditions are the same with those described in Fig. 3.

3.2. Method validation

3.2.1. Precision and accuracy

Run-to-run repeatability (intraday, $n = 3$) and intermediate precision (interday, $n = 3$) of migration time and peak area were tested. Both repeatability and intermediate precision of AA I and AA II in terms of migration time were within 1.25% relative standard deviation (RSD). The precision of peak areas of AA I and AA II were tested at 10, 100 and 3000 ng mL^{-1}. Repeatability ($n = 3$) and intermediate precision ($n = 3$) were within 3.99% and 5.74% RSD, respectively.

The accuracy of the method was studied by spiking AA I and AA II at 10, 100 and 3000 ng mL^{-1} in blank rat serum. The recoveries were within 76.5 ± 0.6% and 92.9 ± 1.1%, and the detailed data were shown in Table 1.

3.2.2. Linearity

Linearity of the method was tested with eight standard solutions of AA I and AA II at concentrations ranging from 10 to 3000 ng mL^{-1}. Each solution was tested for three times. The regression equation is $y = 84.501x - 99.882$ ($r^2 = 0.9999$) for AA I, and $y = 36.363x - 207.87$ ($r^2 = 0.9999$) for AA II.

3.2.3. Limit of detection (LOD) and limit of quantification (LOQ)

LOD of the method was defined as the concentration of AA I and AA II detected at S/N = 3. It was found to be 0.14 ng mL^{-1} for AA I and 0.26 ng mL^{-1} for AA II. LOQ of this method was determined with a concentration of AA I and AA II at S/N = 10. Its value was found to be 0.5 ng mL^{-1} for AA I and 0.7 ng mL^{-1} for AA II.

3.2.4. Matrix effect

Matrix effects may cause ion suppression or ion enhancement. Their magnitude may vary between sample components. Standard solutions of 10, 100 and 1000 ng mL^{-1} of AA I and AA II were added to the sample solutions of *A. debilis* and rat serum. Area of post-extraction spike was calculated against area of standard in order to study the matrix effect. The test results are shown in Table 2. Matrix effects of AA I and AA II in *A. debilis* and rat serum were within 127.7 ± 10.5% to 78.8 ± 3.9%.

Table 1
Recovery of AAI and AAII in rat serum.

Concentration (ng mL^{-1})	Recovery (%)	
	AAI	AAII
10	76.5 ± 0.6	80.4 ± 1.8
100	83.6 ± 3.5	80.4 ± 3.4
1000	92.9 ± 1.1	89.7 ± 1.1

Table 2
Matrix effects of AA I and AA II in *Aristolochia debilis* and rat serum.

Concentration (ng mL^{-1})	Matrix effect (%)			
	Aristolochia debilis		Rat serum	
	AA I	AA II	AA I	AA II
10	127.7 ± 10.5	120.0 ± 7.7	78.8 ± 3.9	83.5 ± 4.1
100	104.3 ± 5.9	95.6 ± 3.0	87.0 ± 2.2	88.0 ± 3.2
1000	93.8 ± 1.3	95.8 ± 1.9	115.6 ± 0.7	113.0 ± 2.6

3.3. Application

3.3.1. Herbal medicines

Herbal products were generally given as mixtures of herbs. Therefore, both plants of *Aristolochia*-genius and traditional Chinese medicines containing plants with AAs were included to investigate the applicability of our developed method to real samples. The UHPLC–MS/MS method validated above was applied to analyze the crude extract of *A. contorta* (dried fruits), *A. debilis* (dried roots), *A. fangchi* (dried roots), *A. heterotropoides* (dried roots), Bu-fei-a-jiau-tang, Hsiao-Ching-Lung-Tang, Chuan-Chiong-Char-Tiao-San and Shin-Yi-San. Bu-fei-a-jiau-tang is an antitussives preparation which has been banned in Taiwan since 2003, Hsiao-Ching-Lung-Tang and Shin-Yi-San are used to relieve cold symptoms, and Chuan-Chiong-Char-Tiao-San is used for migraine. And these preparations are still available in the market. Total ion scan and MRM chromatograms of the four of the herbal products were shown in Figs. 3 and 5, respectively, The constituents in Bu-fei-a-jiau-tang were the most complicated among them. The contents of AA I and AA II are shown in Table 3. AAI, the compound predominantly responsible for the nephropathy and urothelial cancer of AAN [39], is much higher than AAII in all tested herbal products. Among the tested herbal products, *A. debilis* contains the highest amount of AAs. With the high sensitivity of the developed method, several herbal products which are still available in the market were detected to contain small amount of AAI. It is worthwhile to investigate the safety of long-term exposure to these products.

3.3.2. Pharmacokinetics of AA

With the high sensitivity of the developed UHPLC–MS/MS method, the pharmacokinetic parameters of AA I and AA II in rats can be investigated. AAs standard containing 90.9% of AA I and 5.7% of AA II was dissolved in corn oil and intragastrically administered to a female Wister rat at a dose of 10 mg kg^{-1}. Blood samples were taken from femoral vein at the designed time intervals. Serum samples were subjected to protein denaturation and then analyzed by UHPLC–MS/MS. The serum concentration–time curves of AA I and AA II after oral administration of AAs are shown in Fig. 6. Table 4 presents the pharmacokinetics parameters of AA I and AA II calculated by WinNolin. The data revealed that AAs could be quickly absorbed in gastro-intestinal tract, and their T_{max} was within 1 h.

The role of biotransformation enzymes in the development of renal injury caused by AAs remains unclear. Xiao et al. had performed *in vivo* and *in vitro* studies to investigate the correlation between hepatic cytochrom P450 (P450) enzyme activity and AAI toxicity. The conclusion was that hepatic P450 1A1 and 1A2 could detoxify AAI through the metabolism of AAI into less toxic metabolites aristolactam I (AL I) [39]. In this study, we tested

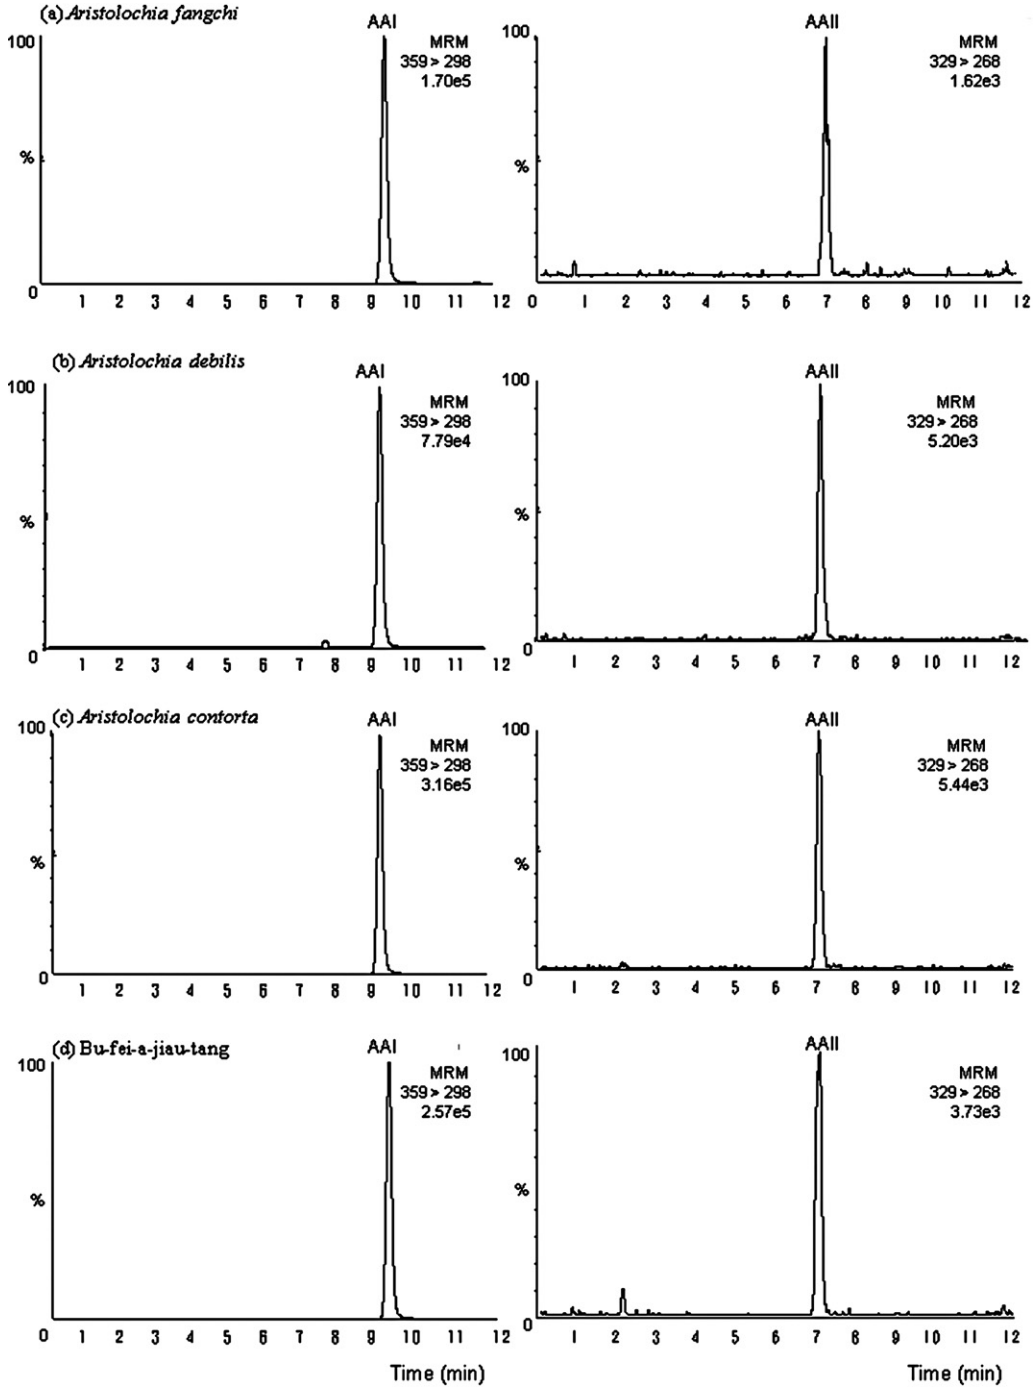

Fig. 5. MRM chromatograms of the crude extract of (a) *Aristolochia fangchi*, (b) *A. debilis*, (c) *A. contorta* and (d) Bu-fei-a-jiau-tang. UHPLC–MS/MS conditions are the same with those described in Fig. 3.

Table 3
Contents of AAI and AAII in herbal products.

Content	AA I ($\mu g\,g^{-1}$)	AA II ($\mu g\,g^{-1}$)
Aristolochia fangchi (fruits)	944.569 ± 36.206	50.078 ± 1.845
Aristolochia debilis (roots)	802.565 ± 38.238	148.687 ± 8.038
Aristolochia contorta (roots)	511.478 ± 19.275	29.386 ± 1.143
Asarum heterotropoides (roots)	7.572 ± 0.043	–[a]
Bu-fei-a-jiau-tang	119.674 ± 3.298	6.802 ± 0.289
Hsiao-Ching-Lung-Teng	0.194 ± 0.001	–
Chuan-Chiong-Char-Tiao-San	0.384 ± 0.012	–
Shin-Yi-San	0.525 ± 0.001	–

[a] Below detection limit.

the applicability of our developed method in the investigation of AAI metabolism. Both AA I standard and Bu-fei-a-jiau-tang were incubated with liver microsome. The microsome incubated samples were subjected to protein denaturation and then analyzed by UHPLC–MS/MS. The MRM chromatograms were shown in Fig. 7. AL I only appeared in sample treated with Bu-fei-a-jiau-tang. Since toxicity between AA I and AL I, are different, our finding showed that the toxicity of AA I standard and herbal mixtures containing AA I might be different. Although more experiments should be preformed to explain this phenomenon, our study showed that the developed UHPLC–MS/MS is a powerful tool to investigate the pharmacokinetic properties of AAs.

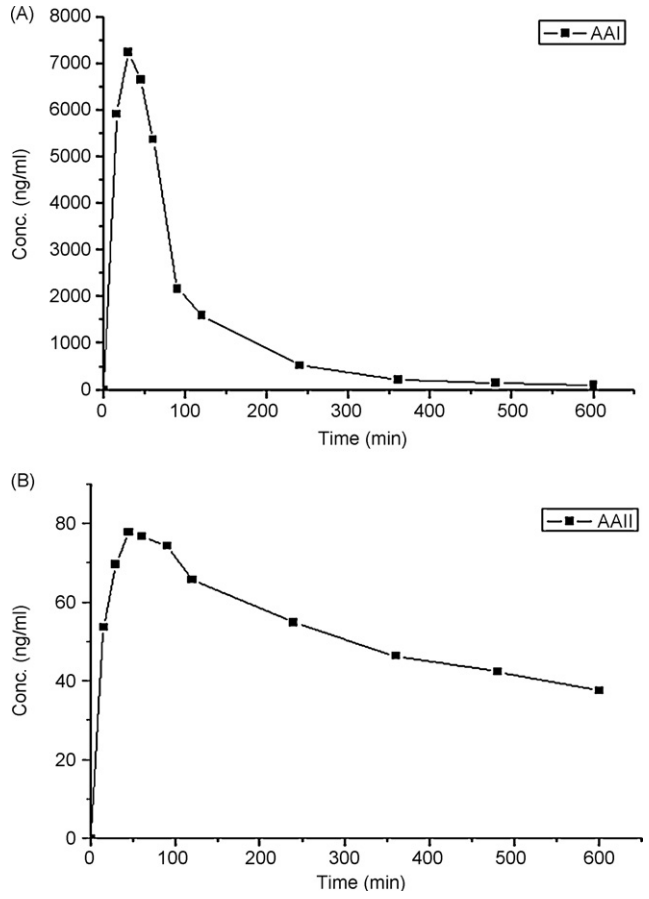

Fig. 6. Serum concentration–time plots of AA I (A) and AA II (B) after oral administration of AAs at a dose of 10 mg kg^{-1} in female Wister rats.

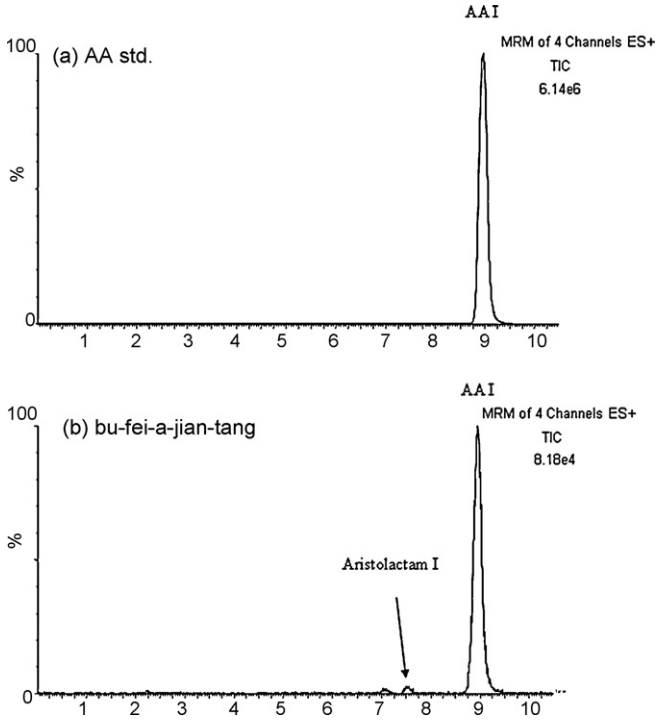

Fig. 7. UHPLC–MS/MS chromatogram (MRM) of liver microsome treated with (a) AA I standard; (b) Bu-fei-a-jiau-tang for 30 min. UHPLC–MS/MS conditions are the same with that described in Fig. 3.

3.4. Performance of UHPLC–MS/MS

Several HPLC–UV methods have been applied to analyze AAs in plants similar to this study [14–16,19,25]. The analytical time of those studies were all longer than 15 min. Other studies used the HPLC–MS methods and their analytical time were higher than 12 min. Also the LODs of these methods were higher than 3.99 ng mL^{-1} for AAI and 3.71 ng mL^{-1} for AAII [26,28,29]. By using the presented UHPLC–MS/MS method, AAI and AAII could be determined within 10 min, and the LODs were 0.14 ng mL^{-1} for AA I and 0.26 ng mL^{-1} for AA II. Our developed UHPLC–MS/MS shows advantages in both the analytical time and sensitivity. Jacob et al. used UHPLC–MS for the detection of AAs [34]. Their analytical time is close to our study. They used the chemometrics approach for AAs detection. Since quantitation work was not included in their study, they did not evaluate the accuracy and matrix effect of their system. They also did not optimize their conditions for the best sensitivity. The applicability of their method to quantitatively analyze AAs in herbal products and biological samples was unknown. Comparing to their method, the high selectivity of the presented UHPLC–MS/MS conditions significantly minimized the matrix effect, which allows this method to be applied to analyze complex samples. Recently, capillary electrophoresis and HPLC coupled with fluorescence detector have been used for sensitive detection of AAs in herbal products [10,19,22]. Although the LODs could reach the sub-ppb levels when coupling with fluorescence detection, chemical reaction should be preformed before analysis. The proposed UHPLC–MS/MS method is superior to those methods in its simplicity in sample preparation.

Table 4
Pharmacokinetic parameters after single oral administration of 10 mg/kg standard in female Wister rats.

	AAI	AAII
T_{max} (min)	30	45.0
C_{max} (ng mL^{-1})	7249.3	77.7
AUC (ng mL^{-1} min)	716,936.3	31,344.8
$T_{1/2}$ (min)	234.6	800.7
k (min^{-1})	0.003	0.0009
Oral clearance (mL min^{-1})	2.9	66.0

4. Conclusion

A fast, sensitive and reliable UHPLC–MS/MS method for the determination of AA I and AA II was established in this study. By using a mixture of 10 mM ammonium formate buffer (pH 3.0) and acetonitrile as mobile phase with gradient elution, AAs could be determined within 10 min. The LODs was 0.14 ng mL^{-1} for AA I and 0.26 ng mL^{-1} for AA II. Due to its high selectivity and sensitivity, the developed method could be directly used to analyze crude herbal extracts as well as biological samples without solid phase extraction or liquid/liquid extractions. The applicability of the method was demonstrated by applying the developed method to analyze various herbal products, rat serum and liver microsome incubation samples. The results revealed that the developed approach is powerful for quality control of herbal products and pharmacokinetic study of AAs.

ABSTRACT

The apparent density, an intrinsic physical property of polymer beads, plays an important role in the application of beads in micro-total analysis systems and separation. Here we have developed a new, facile and milligram-scale method to describe the motion of beads in aqueous solution and further detect the apparent density of beads. The motion of beads in solutions is determined by the viscosity of solutions and the density difference between beads and solutions. In this study, using various glycerol aqueous solutions with certain viscosities and densities, the motion time (i.e. floating or sedimentation time) of hybrid polymer beads was experimentally measured and theoretically deduced, and consequently, the apparent density of monodisperse beads can be quickly and easily calculated. The results indicated that the present method provided a more precise way to predict the movement of hybrid beads in aqueous solution compared with the approach for commercial use. This new method can be potentially employed in flow cytometry, suspension stability, and particle analysis systems.

1. Introduction

In micro-total analysis systems (μTAS), monodisperse hybrid polymer beads have been widely used in many fields of biological analysis, high-throughput screening, and immunoassay and among others [1–3]. However, due to the unmatched densities of hybrid polymer beads and aqueous solutions [4], a well suspension of polymer beads in aqueous solutions cannot be achieved, resulting in a higher measurement error and lower signal-to-noise ratio [5]. Obviously, a feasible solution is adjusting either the densities of polymer beads [4] or those of aqueous solutions (e.g. an addition of glycerol or sucrose [6]). Although, the densities of polymer beads can be measured by a density meter (ASTM D4052) [7], the measurement of apparent densities of hybrid beads is still a grand challenge due to hybridization of nanoparticles, surface hydrophilic liquid layer [8] and inner nano-scale pores [9]. Here a simple and robust method that can precisely describe the movement of hybrid polymer beads in glycerol aqueous solution, was demonstrated, and further applied to the measurement of apparent density. And it also has potential use in flow cytometry, microfluidics chips, bead suspensions, and particle analysis systems.

2. Materials and methods

2.1. Materials

Monodisperse polymer beads (PC06N/6182, with carboxyl group, size 9.77 μm) were purchased from Bangs Laboratories, Inc. Uniform magnetic beads were obtained from Micromod (micromod Partikeltechnologie GmbH, Micromer®-M, Prod.-No. 08-01-104, with amine group, size 10 μm). The densities of polymer beads and magnetic beads provided by vendor are 1.062 and 1.1 g/cm^3, respectively. Sodium dodecyl sulfate (SDS) and glycerol (≥99% (GC)) was procured from Sigma. The water used in all experiments was de-ionized water.

2.2. Motion of beads in glycerol–water mixtures

0.5 mg of polymer beads or commercial magnetic beads was dried under air at room temperature and re-dispersed in a 1.5 mL vial containing 0.5 mL of glycerol–water mixtures. Owing to the lower or higher densities of beads compared with those of glycerol solutions, the beads were buoyed up or sunk down in the

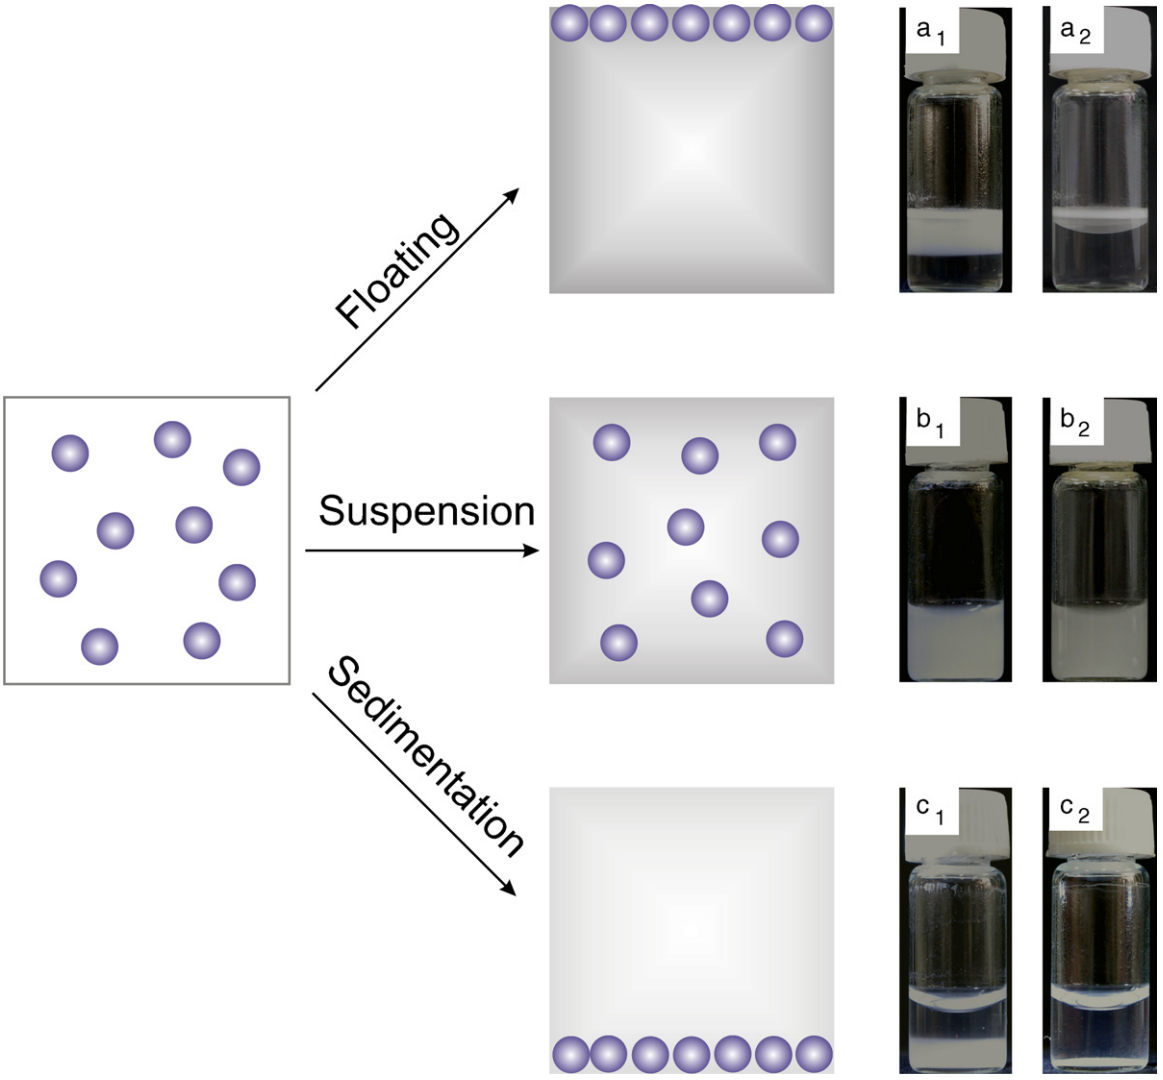

Fig. 1. Schematic description of bead motion in various glycerol–water mixtures (the darker color means higher mass fraction of glycerol in mixture); (a) 50 wt% glycerol solution, the digital pictures of a_1 and a_2 were taken at 1.2 and 2.7 h, respectively. (b) 23 wt% glycerol solution, b_1 and b_2 at 3.5 and 7.5 h, respectively. (c) 10 wt% glycerol solution, c_1 and c_2 at 0.7 and 1.4 h, respectively. The beads were obtained from Bangs Laboratories, Inc.

solution. The total time taken for entire-bead floating to the surface or sedimentation to the bottom of glycerol solutions was defined as floating or sedimentation time of beads. The accuracy of the measurements was evaluated from 5 repetitive determinations (repeatability) of the motion time of polymer beads in the same glycerol aqueous solution, and the relative standard deviations (*RSD*) were also calculated. The schematic process and digital photos are shown in Fig. 1. We have included more digital photos taken at different time in supporting information (see Fig. S1).

2.3. Characterization

The images of beads were taken using a microscope (Olympus, IX 51). Flow cytometry (Coulter, Epics XL) was utilized to measure the bead's relative size (forward light scatter, FS signal), relative granularity or internal complexity (side light scatter, SS signal). Flow cytometry was set up according to the standard operating procedure. During detection, a total of 20000 events were recorded for each time point, and the beads dispersed in water or glycerol solutions were detected at the low flow rate with a concentration of 1 mg/mL. The populations of single beads and doublet beads were selected based on forward and side scatter. The *mean* and *RSD* of these populations were also measured. All flow cytometric data were performed using FlowJo 5.7 software (Tree Star, San Carlos, CA, USA).

3. Results and discussions

3.1. Densities and viscosities of glycerol–water mixtures

The densities of glycerol–water mixtures were measured by comparing their mass to their volume. The viscosities were calculated using the following empirical equation [10].

$$\frac{\ln \nu_m - \ln \nu_w}{\ln \nu_g - \ln \nu_w} = C_m[1 + (1 - C_m)\{a + bC_m + cC_m^2 + \cdots\}] \quad (1)$$

where ν is kinematic viscosity ($\nu = \mu/\rho$), μ is dynamic viscosity, ρ is the density, C_m is the mass fraction of glycerol in the mixture, and subscripts m, g and w denote the glycerol–water mixtures, glycerol and water, respectively. The constants a, b and c at 20 °C are assigned to −0.76728, 0.12153 and −1.41519, respectively. As shown in Table 1, the detected densities are close to those provided by the vendor, and the interpolated viscosities are in accordance

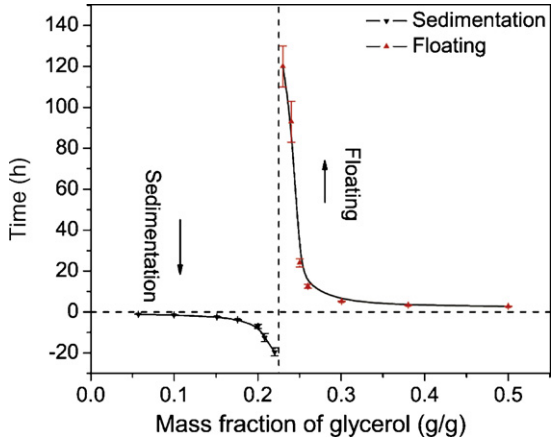

Fig. 2. The floating and sedimentation time of polymer beads in various glycerol–water mixtures, the positive and negative values indicate that the beads are floating and sedimentating, respectively.

with those published [10] (the comparison between the densities and viscosities in the present study and those published were shown in Tables S1 and S2 in supporting information, respectively).

3.2. Theory of bead movement in aqueous solution

The net force, ΔF_b, of a bead in aqueous solution is composed of following two contributions,

$$\Delta F_b = F_{b,1} - F_{b,2} \tag{2}$$

where $F_{b,1}$ and $F_{b,2}$ are the sum of the buoyant force and the bead's weight, and the force of movement resistance (Stokes' drag force), respectively.

According to Archimedes' principle, the $F_{b,1}$ is given by,

$$F_{b,1} = V_b \times (\rho_m - \rho_b) \times g \tag{3}$$

where V_b is the volume of a bead, ρ_m and ρ_b are the density of the aqueous solution and hybrid polymer beads (or magnetic beads), respectively, and g is the gravitational acceleration.

The force of the movement resistance (Stokes' drag force [11]) $F_{b,2}$ is obtained by the following equation.

$$F_{b,2} = 6\pi\mu R v \tag{4}$$

where μ is the viscosity of aqueous solution, R is the radius of a bead, and v is the velocity.

Hence, the ΔF_b is deduced by,

$$\Delta F_b = F_{b,1} - F_{b,2} = V_b \times (\rho_m - \rho_b) \times g - 6\pi\mu R v$$
$$= \frac{4}{3}\pi R^3 \times (\rho_m - \rho_b) \times g - 6\pi\mu R v \tag{5}$$

Based on Eq. (5), the suspended bead has a tendency to rise or sink in the glycerol–water mixture if ρ_b is not equal to ρ_m. The beads were buoyed up in aqueous solutions when their densities were less than those of the mixture (Fig. 1a). The beads were stably suspended in solutions as their densities were accurately equal to those of the

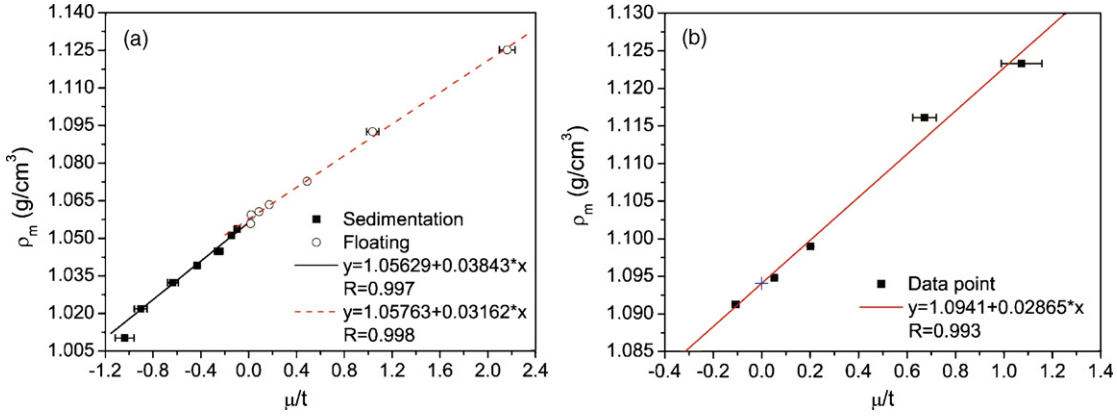

Fig. 3. Estimation of the density of (a) polymer beads and (b) commercial magnetic beads by Eq. (8), the apparent density of beads, ρ_b is equal to the ρ_m of the point where the fitted linear curve intercepts the line $x = 0$.

4e	30	746.31	20.9	445.70	25.42	–	–	–

mixture (Fig. 1b), and the beads were sunk to the bottom of the vial while their densities were larger than those of the mixture (Fig. 1c).

3.3. Estimation of bead density

The floating velocity is defined as positive, and sedimentation velocity as negative. As shown in Eq. (5), the velocity (floating or sedimentation) of beads reaches the maximum at equilibrium states ($\Delta F_b = 0$), and the equation of equilibrated floating or sedimentation velocity is given as follows (transformation of Eq. (5)),

$$v = \frac{2R^2 g(\rho_m - \rho_b)}{9\mu} \tag{6}$$

Since t is equal to d/v, the time (t) of floating or sedimentation is derived by,

$$t = \frac{9\mu d}{2R^2 g(\rho_m - \rho_b)} = k \cdot \frac{\mu}{\rho_m - \rho_b} \quad \left(k = \frac{9d}{2R^2 g}\right) \tag{7}$$

where the distance (d) of floating or sedimentation is a constant, and consequently, k is a constant.

According to Eq. (7), the floating or sedimentation time depends on the viscosities of aqueous glycerol solutions and the densities difference between the beads and the solutions [8]. Fig. 2 showed that the detected floating or sedimentation time of polymer beads is in accordance with Eq. (7).

Moreover, the density of polymer beads can be obtained by using the floating or sedimentation time. Changing the expression of Eqs. (7) and (8), the result is represented as follows,

$$\rho_m - \rho_b = k \times \frac{\mu}{t} \Rightarrow \rho_m = \rho_b + k \times \frac{\mu}{t} \tag{8}$$

where the ρ_m and μ are shown in Table 1, and the motion time (t) is illustrated in Fig. 2.

The density, ρ_m and the μ/t are illustrated in Fig. 3a. The ρ_b fitted by linear least square method is 1.0570 g/cm^3 ((1.0563 + 1.0576)/2). The calculated *RSD* was 0.07%. As shown in Table 1, the densities of 25 and 26 wt% glycerol solutions were 1.0606 and 1.0634 g/cm^3, respectively. The bead density provided by the vendor ($\rho_{b,\text{vendor}} = 1.062$ g/cm^3) stands between the densities of 25 wt% ($\rho_{b,\text{vendor}} > \rho_{m,25\%}$) and 26 wt% glycerol solutions ($\rho_{b,\text{vendor}} < \rho_{m,26\%}$). However, in experiments, the bead were buoyed up in both 25 wt% and 26 wt% glycerol solutions (see Fig. 2), which indicated that the density (apparent) of beads was lower than those ($\rho_{b,\text{apparent}} < \rho_{m,25\%} < \rho_{b,\text{vendor}} < \rho_{m,26\%}$, see Eq. (5)). In other words, by adopting the vendor-provided density, the movement of beads in aqueous solution cannot be precisely predicted. In contrast, the motion of hybrid beads in solution can be more accurately estimated by using the detected apparent density (see Eqs. (6) and (7) and Fig. 2).

Similarly, as shown in Fig. 3b, the detected density of magnetic beads, 1.0941 g/cm^3, is a little bit smaller than that provided by vendor. The *RSD* obtained was 0.11%. The smaller measured densities are probably due to surface hydrophilic liquid layer [8] and inner nano-scale porous [9].

3.4. Influence of the motion of beads on flow cytometric analysis

The motion of beads plays a crucial role in the flow cytometric analysis. As illustrated in Fig. 4 and Table 2, the *mean* of forward light scatter (FS) signals are increased with increasing of glycerol mass fraction. In the mean time, those of side light scatter (SS) signals are close to a constant. The light signals are generated as beads pass through the laser beam in a fluid stream. And the FS signal is proportional to the projected spot area or size which is related to the size of beads and the distance between the beads and the sensor [5b]. When the motion tendency of beads was changed from

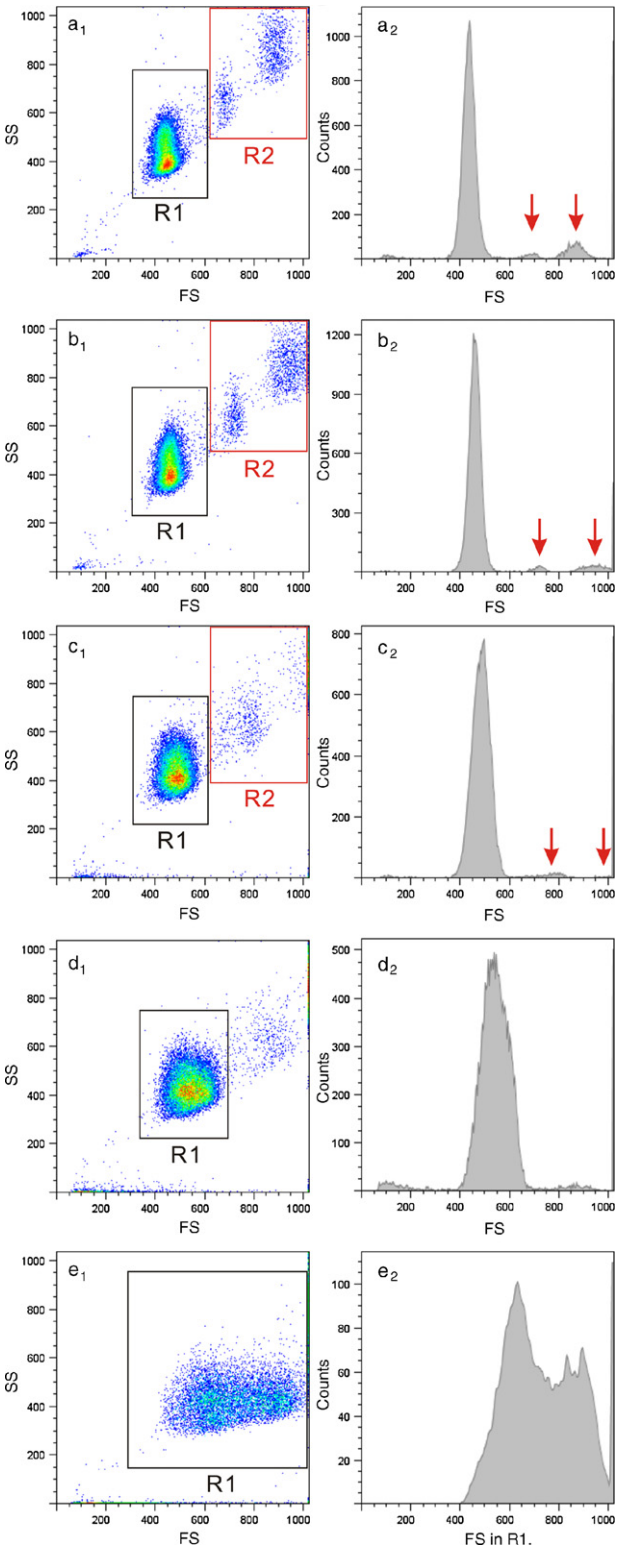

Fig. 4. Flow cytometry analysis of polymer beads. The dispersion solutions of a–e are pure water, 10, 20, 24 and 30 wt% glycerol solutions, respectively. (a_1–e_1) The bead subpopulations based on side light scatter (SS) vs. forward light scatter (FS); (a_2–e_2), the histogram of size distribution. The singlet beads were counted in the region 1 (R1, a_1–e_1), the doublet beads were recorded in the red region 2 (R2, a_1–c_1) and marked by red arrows in the diagrams a_2–c_2. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

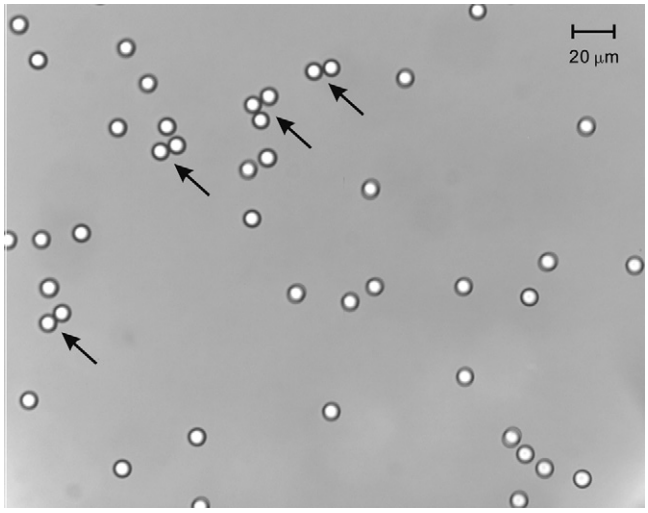

Fig. 5. The microphotograph of polymer beads dispersed in a solution containing 5 wt% glycerol and 0.05 wt% SDS, and the doublet beads were marked by arrows.

sedimentation to floating (Fig. 4a–e), the distance was increased, resulting in a larger FS signal. In addition, the increase of FS signals is not mainly due to the diffusion of glycerol from the core flow to the sheath flow [12], otherwise, the *mean* and *RSD* of SS signals should be also changed (see Table 2).

Moreover, the proportion of doublet beads is decreased with the prolongation of suspension time (Fig. 4a–c). The doublet beads suspended in a liquid are shown in Fig. 5. Their signals might affect the accuracy of flow cytometry detection [13]. The numbers of doublet beads depend on previous treatment of the suspension (e.g., sonication and vortex), age, and solvent [14]. Since all the samples were performed with the same operations, the proportion of doublet beads can be reduced by extension of their suspension time.

4. Conclusions

Theoretical description for the motion, including floating or sedimentation of polymer bead in aqueous solution was deduced by analysis of the net force of a liquid-suspended bead. Furthermore, the apparent density of beads can be easily calculated by using the measured floating or sedimentation time. For polymer beads and commercial magnetic beads, the detected apparent densities in the present study were 1.0570 and 1.0941 g/cm^3, respectively. The analysis showed that this milligram-scale method provided a more facile and precise approach to predict the movement of hybrid beads in aqueous solution than the general method. This work is beneficial to micro-total analysis systems, separation, suspension stability [15], particle analysis systems and so forth.

ABSTRACT

This paper describes the simultaneous determination of ascorbic acid (AA), dopamine (DA), uric acid (UA) and xanthine (XN) using an ultrathin electropolymerized film of 2-amino-1,3,4-thiadiazole (p-ATD) modified glassy carbon (GC) electrode in 0.20 M phosphate buffer solution (pH 5.0). Bare GC electrode failed to resolve the voltammetric signals of AA, DA, UA and XN in a mixture. On the other hand, the p-ATD modified electrode separated the voltammetric signals of AA, DA, UA and XN with potential differences of 110, 152 and 392 mV between AA–DA, DA–UA and UA–XN, respectively and also enhanced their oxidation peak currents. The modified electrode could sense 5 μM DA and 10 μM each UA and XN even in the presence of 200 μM AA. The oxidation currents were increased from 30 to 300 μM for AA, 5 to 50 μM for DA and 10 to 100 μM for each UA and XN, and the lowest detection limit was found to be 2.01, 0.33, 0.19 and 0.59 μM for AA, DA, UA and XN, respectively (S/N = 3). The practical application of the present modified electrode was demonstrated by the determination of AA, UA and XN in human urine samples.

1. Introduction

Dopamine (DA) is an important neurotransmitter molecule present in our body and it plays a significant role in the functioning of central nervous, renal, hormonal and cardiovascular systems [1]. Low level of DA is related to neurological disorders such as Parkinson's disease, schizophrenia and to HIV infection [2–4]. Uric acid (UA) is another important compound in our body and its abnormal concentration levels lead to several diseases such as hyperuricaemia, gout, leukemia and pneumonia [5,6]. Xanthine (XN) is an intermediate of the purine metabolism and is produced after adenosine triphosphate decomposition [7]. The concentration level of XN in blood plasma and urine may provide sensitive indicators of certain pathologic states, especially for xanthinuria. It is a rare genetic disorder where the lack of xanthine oxidase leads to high concentration of XN in body fluids and can cause health problems such as renal failure. The physiological conversion of XN by xanthine oxidase is of great interest in medical because this reaction is related to the formation of superoxide one of the reactive oxygen species involved in inflammation and cancer [7–9]. Ascorbic acid (AA) is used for the prevention of scurvy and treatment of common cold, mental illness, infertility, cancer and AIDS [10]. Usually AA, DA, UA and XN are coexisting in our body fluids. Therefore, it is very important to develop simple and rapid methods for their selective determination in routine analysis.

Various techniques have been utilized to determine these biomolecules including fluorimetry [11], chemiluminescence [12], ion-exchange column chromatography [13], ultraviolet–visible spectroscopy [14] and capillary electrophoresis [15]. However, such methods of detection are often complicated, very expensive, suffered from sensitivity, selectivity and reproducibility. To overcome these problems, several researchers have employed electrochemical method for the determination of biomolecules. In electrochemical method, electrodes modified with gold nanoparticles [16], self-assembled monolayers [17], carbon nanotube [18] and polymer film [19–26] were employed for the determination of AA, DA, UA and XN. Among them, polymer modified electrodes prepared by electropolymerization method have received extensive interest because chemically stable homogeneous film with controlled thickness can be prepared by this method. It has been demonstrated that electropolymerized films showed excellent selectivity and sensitivity with stable voltammetric response towards several biomolecules. For example, poly(*N*,*N*′-dimethylaniline) [19], poly(3,4-ethylenedioxy)thiophene [22], poly(methylene blue) [23], poly(eriochrome black T) [24], poly(3,4-ethylenedioxythiophene-co-(5-amino-2-napthalenesulfonic acid)) [25] and poly(5-amino-2-mercapto-1,3,4-thiadiazole) [26] modified electrodes have been used for the determination of DA and UA in the presence of main interferent AA. However, to the best of our knowledge, no report has been published for the simultaneous determination of AA, DA, UA and XN.

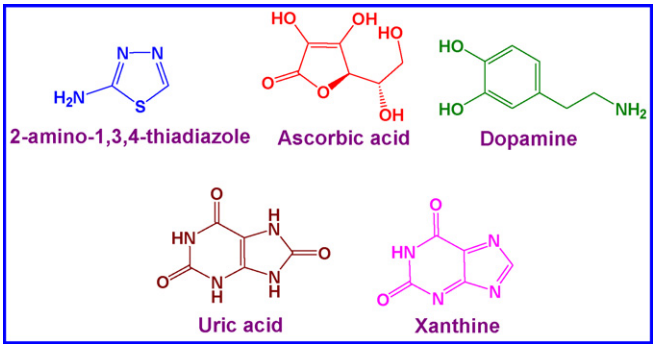

Chart 1. Structure of a monomer and biomolecules.

Very recently, we have prepared an ultrathin polymer film of 5-amino-2-mercapto-1,3,4-thiadiazole (p-AMT) on GC electrode by potentiodynamic polymerization and successfully used this film for the determination of dopamine [26], L-cysteine [27], folic acid [28], epinephrine [29] and nitrite ion [30]. In the present study, we have examined the utility of another ultrathin polymer film, 2-amino-1,3,4,thiadiazole (p-ATD) for the simultaneous determination of AA, DA, UA and XA in 0.20 M phosphate buffer (PB) solution (pH 5.0) for the first time (Chart 1). It was found that the p-ATD modified electrode not only separated the voltammetric signals of DA, AA, UA and XA but also enhanced their oxidation currents when compared to bare GC electrode. Further, the present modified electrode is successfully applied to determine AA, UA and XN in human urine samples.

2. Experimental

2.1. Chemicals

2-Amino-1,3,4-thiadiazole (ATD), ascorbic acid (AA), dopamine (DA), uric acid (UA) and xanthine (XN) were purchased from Aldrich and were used as received. Dopamine hydrochloride injections were purchased from Neon Laboratory Limited, India and were used as received. All other chemicals used in this investigation were of analytical grade. The PB solution was prepared using Na_2HPO_4 and NaH_2PO_4. Double distilled water was used to prepare the solutions used in the present study.

2.2. Instrumentation

Electrochemical measurements were performed in a conventional two compartment three electrode cell with a mirror polished 3 mm glassy carbon (GC) as the working electrode, Pt wire as counter electrode and a NaCl saturated Ag/AgCl as reference electrode. The electrochemical measurements were carried out with CHI Model 643B (Austin, TX, USA) Electrochemical Workstation. All the experiments were carried out under nitrogen atmosphere at room temperature. Tapping mode AFM image was recorded by using a Nanoscope (IV) instrument (Vecco).

2.3. Fabrication of p-ATD modified GC electrode

Prior to modification, the GC electrode was polished with 0.50 and 0.05 μm alumina slurries and then rinsed thoroughly with water. Then, the electrode was sonicated in water for 5 min to remove adsorbed alumina particles on the electrode surface. Electropolymerization of ATD on GC electrode was carried out by 15 successive potential sweeps between −0.20 and +1.70 V at a scan rate of 50 mV s^{-1} in 1 mM ATD containing 0.10 M H_2SO_4 [31].

3. Results and discussion

3.1. Atomic force microscopic studies of p-ATD film on ITO electrode

AFM was used to find the morphology and thickness of the p-ATD film. Fig. 1 displays the tapping mode AFM images of p-ATD film deposited on ITO electrode by 15 cycles. The p-ATD film deposited on ITO plate showed a spherical like structure with a thickness of ~25 nm. The diameter of each spherical was found to be 30–50 nm.

3.2. Electrochemical behavior of AA, DA, UA and XN at bare and p-ATD modified GC electrodes

The electrochemical impedance spectroscopy was used to investigate the conductivity of p-ATD film deposited by different cycles. The impedance measurements were performed in the presence of 1 mM $K_3[Fe(CN)_6]$ in 0.1 M KCl at scanning frequencies from 0.01 to 100,000 Hz. It was found that the radius of the semicircle in the Nyquist plot decreased when the deposition cycles increases. It indicated that the charge transfer resistance decreases when the

(c) p-ATD modified electrode in the absence of DA in 0.20 M PB solution (pH 5.0). (B) CVs for the oxidation of DA at p-ATD modified electrode in 0.20 M PB solution at different scan rates: (a) 100 mV s^{-1}, (b) 200 mV s^{-1}, (c) 300 mV s^{-1}, (d) 400 mV s^{-1}, (e) 500 mV s^{-1}, (f) 600 mV s^{-1}, (g) 700 mV s^{-1}, (h) 800 mV s^{-1}, (i) 900 mV s^{-1} and (j) 1000 mV s^{-1}. Inset: Plot of the anodic peak current vs square root of scan rate.

deposition cycles increases. We have calculated the charge transfer resistance (R_{ct}) for p-ATD film deposited by 15, 50 and 100 cycles using the equation $R_{ct} = RT/nFi_0$. Where R_{ct} is the charge transfer resistance due to electron transferring at the p-ATD film/solution interface, R is the gas constant, T is the experimental temperature, n is the electron transfer number of the redox process, as one for $[Fe(CN)_6]^{4-}/[Fe(CN)_6]^{3-}$, F is the Faraday constant, i_0 is the exchange current of the redox couple. The p-ATD film deposited by 15, 50 and 100 cycles showed the R_{ct} of 23.93, 14.39 and 11.63 Ω, respectively. The impedance measurements revealed that the resistance of the p-ATD film was decreased when the deposition cycles were increased. However, the double layer charging current increases while increasing the deposition cycles from 15 to 100 cycles. Thus, the sensitivity of p-ATD film was decreased towards AA, DA, UA and XN as the deposition cycles increased from 15 to 100 cycles. Thus, we have used p-ATD film deposited by 15 cycles for the determination of AA, DA, UA and XN in the present work. Further, we have performed the redox reaction of DA and oxidations of AA, UA and XN at different pH using p-ATD film. We obtained higher oxidation current, less positive oxidation potential for AA, DA, UA and XN at pH 5.0. Thus, p-ATD film deposited by 15 cycles and 0.20 M PB solution (pH 5.0) were chosen for all the electrochemical measurements.

Before carrying out the simultaneous determination of AA, DA, UA and XN, we have studied their electrochemical behavior individually at bare and p-ATD modified GC electrodes in 0.20 M PB solution (pH 5.0). Fig. 2A shows the cyclic voltammograms (CVs) of 0.50 mM DA in pH 5.0 PB solution at bare GC and p-ATD modified electrodes. At bare GC electrode, a broad redox wave was observed for DA with a peak separation of 140 mV (curve a). However, a well-defined redox peak as well as nearly two-fold higher oxidation current with 50 mV less positive potential and a peak separation of 56 mV were observed for DA at p-ATD modified electrode when compared to bare GC electrode (curve b). The observed redox peak corresponds to two-electron oxidation of DA to dopaminequinone and the subsequent reduction of dopaminequinone to DA [32,33]. The p-ATD film showed a redox wave at 0.11 V in 0.20 M PB solution (pH 5.0) (curve c) and it was attributed to a proton and electron addition/elimination reaction at the –NH– sites [31]. The effect of scan rate on the redox reaction of DA was studied at p-ATD modified electrode (Fig. 2B). Both anodic and cathodic peak currents were increased while increasing the scan rate. A good linearity between the anodic peak current and square root of scan rate with a correlation coefficient of 0.9994 was obtained within the range of 100–1000 mV s^{-1} (inset of Fig. 2B). This indicated that the electrode reaction process is controlled by the diffusion of DA. Further, at bare GC electrode, AA, UA and XN oxidations were occurred at 0.22, 0.52 and 0.89 V, respectively (figure not shown). On the other hand, p-ATD modified electrode oxidized them at 0.11, 0.46 and 0.83 V, respectively with 110, 60 and 60 mV less positive potential when compared to bare GC electrode. The oxidation currents obtained for AA and UA were nearly two-fold higher whereas three-fold higher for XN at p-ATD modified electrode in contrast to bare GC electrode.

3.3. Electrochemical behavior of ascorbic acid (AA), dopamine (DA), uric acid (UA) and xanthine (XN) in a mixture at p-ATD modified electrode

Fig. 3A displays the CVs of 0.50 mM of AA, DA, UA and XN in 0.20 M PB solution (pH 5.0) at bare GC and p-ATD modified electrodes. Bare GC electrode showed oxidation peaks for AA, UA and XN at 0.24, 0.47 and 0.88 V, respectively in a mixture (curve a). It is difficult to locate the oxidation potential of DA from Fig. 3a. It was almost merged with the oxidation potential of UA. Further, in the subsequent cycles, the oxidation peaks of AA, UA and XN were shifted to more positive potential and after eight cycles, oxidation peaks were observed for them at 0.31, 0.49 and 0.93 V, respectively with decreased peak currents (curve b). This revealed that bare GC electrode is not suitable for the stable determination of AA, DA, UA and XN. In contrast to bare GC electrode, p-ATD modified electrode oxidized AA, DA, UA and XN at 0.20, 0.33, 0.49 and 0.86 V, respectively with enhanced current response in a mixture (curve c). Oxidation of AA and XN was observed at p-ATD modified electrode with 110 and 70 mV less positive potentials, respectively than that at bare GC electrode. Further, the oxidation peaks of AA, DA, UA and XN were more stable at p-ATD modified electrode in the subsequent cycles (curve d). The separations of oxidation peak potentials of AA–DA, DA–UA and UA–XN were of 130,

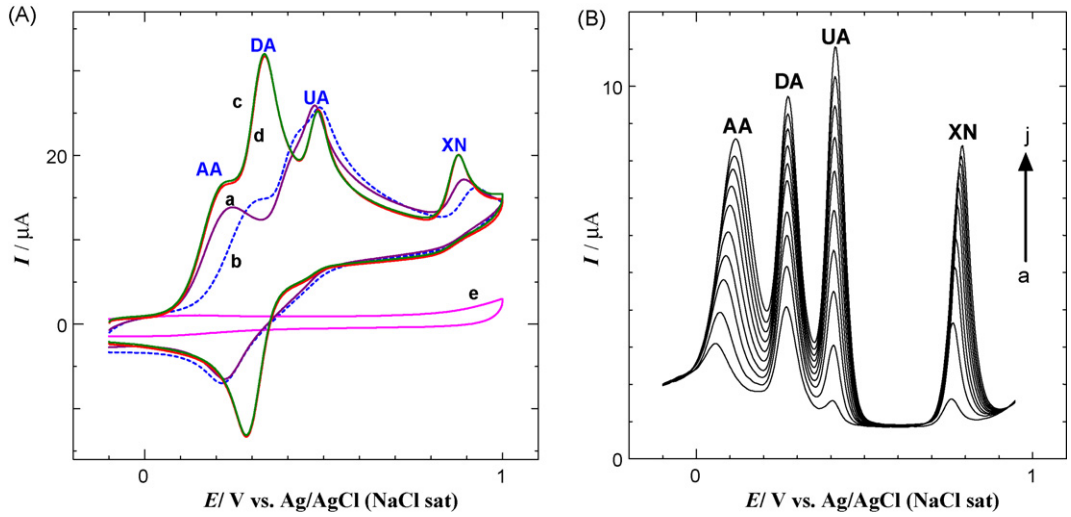

Fig. 3. (A) CVs for the oxidation of 0.50 mM AA, DA, UA and XN at bare GC electrode (a) 1st cycle and (b) 8th cycles and p-ATD modified electrode (c) 1st cycle and (d) 8th cycles at a scan rate of 50 mV s^{-1}. (e) p-ATD modified electrode in the absence of AA, DA, UA and XN in 0.20 M PB solution. (B) DPVs for the simultaneous oxidation of each addition of 30 μM AA, 5 μM DA, 10 μM each UA and XN at p-ATD modified electrode in 0.20 M PB solution. Pulse width = 0.06 s, amplitude = 0.05 V, sample period = 0.02 s and pulse period = 0.2 s.

160 and 370 mV, respectively which were enough for the simultaneous determination of them in a mixture. The observed clearly distinguished stable oxidation peaks for AA, DA, UA and XN at p-ATD modified electrode indicated that the oxidation processes of them at this electrode are independent. Thus, simultaneous or independent measurements of the four analytes are possible without any interference. The p-ATD film showed a redox wave at 0.11 V (curve e).

It is well known that AA (pK_a = 4.10), UA (pK_a = 5.7) and XN (pK_a = 7.4) exist as anionic forms whereas DA (pK_a = 8.87) exists as cationic form in pH 5.0 [25,34]. It is expected that anionic form of the AA, UA and XN were attracted by the positively charged backbone of p-ATD film [31] while positively charged DA was attracted by the hetero atoms (N and S) of the p-ATD film. Thus, enhanced oxidation peak currents were observed for anionic and cationic forms of the analytes at p-ATD modified electrode. This indicated that p-ATD film is very much suitable for the determination of both anionic and cationic forms of the analytes. Fig. 3B shows the differential pulse voltammograms (DPVs) for the simultaneous determination of AA, DA, UA and XN at p-ATD modified electrode. It showed the oxidation peaks at 0.06, 0.27, 0.41 and 0.76 V for 30 μM AA, 5 μM DA and 10 μM each UA and XN, respectively. The oxidation peaks remained same for DA, UA and XN whereas a slight shift in the oxidation potential of AA was observed for further addition of respective analytes. When the concentration was increased from 30 to 300 μM for AA, 5 to 50 μM for DA and 10 to 100 μM for each UA and XN, the peak currents of them were increased with correlation coefficient of 0.9992, 0.9994, 0.9998 and 0.9988, respectively. The lowest detection limit was found to be 2.01, 0.33, 0.19 and 0.59 μM for AA, DA, UA and XN, respectively (S/N = 3).

Further, we have compared sensitivity of p-ATD film towards the detection of DA with other polymer modified electrodes. The lowest detection limit of 1.5 and 0.38 μM (S/N = 3) was reported for DA at poly(cresol red) [35] and overoxidized polypyrrole/single-walled carbon nanotubes [36] modified GC electrodes. When compared to these electrodes p-ATD showed the lowest detection limit of 0.33 μM (S/N = 3) for DA. Furthermore, we have also compared the sensitivity of p-ATD film towards the detection of AA, DA, UA and XN individually with the p-AMT film electrode, recently reported from our laboratory [27]. Both p-AMT and p-ATD modified electrodes showed almost same sensitivity towards the detection of aforesaid analytes.

3.4. Simultaneous determination of DA, UA and XN in the presence of AA using p-ATD modified electrode

The main objective of the present study is to determine DA, UA and XN simultaneously in the presence of AA using p-ATD modified electrode. It is well known that AA coexists with DA, UA and XN in our body fluids and further its concentration is much higher than that of DA, UA and XN [37]. Therefore, determination of DA, UA and XN in the presence of higher concentration of AA is very important for the clinical point of view. Fig. 4 shows the DPVs obtained from the different concentration of DA (5 μM), UA (10 μM) and XN (10 μM) in the presence of very high concentration of AA (200 μM). The concentration of DA varied from 5 to 45 μM and UA and XN varied from 10 to 90 μM, respectively while the peak current of AA remains unchanged. The oxidation currents of DA, UA and XN were linearly increased with correlation coefficient of 0.9998, 09997 and 0.9993, respectively. These results showed that p-ATD modified

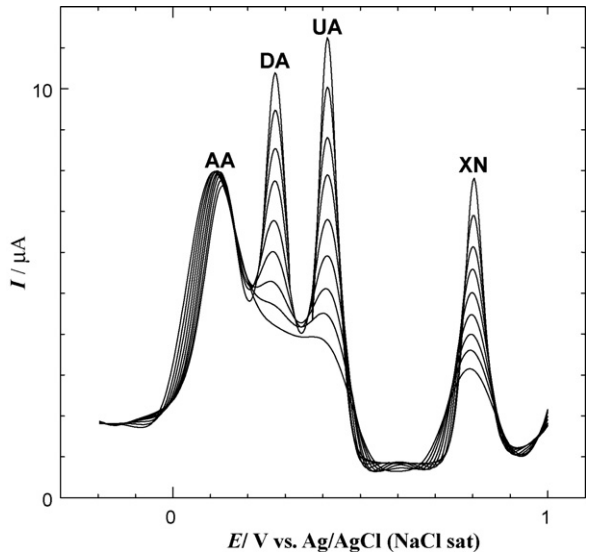

Fig. 4. DPVs obtained for the simultaneous increment of 5 μM DA and 10 μM each UA and XN to the 200 μM AA at p-ATD modified electrode in 0.20 M PB solution. Pulse width = 0.06 s, amplitude = 0.05 V, sample period = 0.02 s and pulse period = 0.2 s.

Table 1
Simultaneous determination of AA, UA and XN in human urine samples.

Samples	Original (μM/mL)			Added (μM/mL)			Found (μM/mL)			Recoveries (%)		
	AA	UA	XN	AA	UA	XN	AA	UA	XN	AA	UA	XN
Urine 1	2.12	15.20	5.60	5	5	5	7.12	20.18	10.60	100	99.9	100
Urine 2	1.43	14.50	6.20	10	10	10	11.42	24.40	16.14	99.9	99.6	99.6

Three replicate measurements were made on each sample.

electrode is more selective towards DA, UA and XN even in the presence of high concentration of AA.

3.5. Stability of the p-ATD film

In order to investigate the stability of the p-ATD modified electrode, the DPVs for 0.10 mM DA in 0.20 M PB (pH 5.0) solution were recorded for every 10 min interval. It was found that both anodic and cathodic peak currents remained same with a relative standard deviation of 2.4% for 20 times repetitive measurements indicating that this electrode has a good reproducibility and does not undergo surface fouling during the voltammetric measurements. After measurements the electrode was kept in pH 5.0 PB solution at room temperature. The current response decreased about 2% in 1 week and 5.1% in 2 weeks.

3.6. Anti-interference ability of the p-ATD film

The anti-interference ability of the p-ATD film was tested towards the detection of AA, DA, UA and XN from common physiological interferents such as glucose, urea, oxalate, Na^+, Ca^{2+} and Mg^{2+} by DPV. No change in the current response was observed for 10 μM each AA, DA, UA and XN in the presence of 10 mM of these interferents indicating that the present modified electrode is highly selective towards the determination of these analytes even in the presence of 1000-fold excess of common physiological interferents (figure not shown).

3.7. Determination of AA, UA and XN in human urine samples

The practical application of p-ATD modified electrode was tested by measuring the concentrations of AA, UA and XN in human urine samples. The standard addition technique was used for the determination of these biomolecules. The human urine samples were collected from laboratory co-workers and were diluted to 50 times with pH 5.0 PB solution without any treatment. The DPV of AA, UA and XN showed oxidation peaks at 0.15, 0.42 and 0.78 V, respectively (Fig. 5, curve a). The oxidation wave appeared at 0.05 V was due to the oxidation of p-ATD film. To confirm the observed oxidation peaks are due to AA, UA and XN, the urine sample is spiked with known concentrations of commercial AA, UA and XN (Fig. 5, curve b). The increasing peak currents at 0.15, 0.42 and 0.78 V after the addition of AA, UA and XN confirmed that the observed oxidation peaks are due to the oxidations of AA, UA and XN, respectively. The results obtained for the urine samples were summarized in Table 1. The present method showed better recoveries of spiked DA in injection and AA, UA and XN in urine samples indicating that this method could be efficiently used for the determination of these biomolecules in real samples.

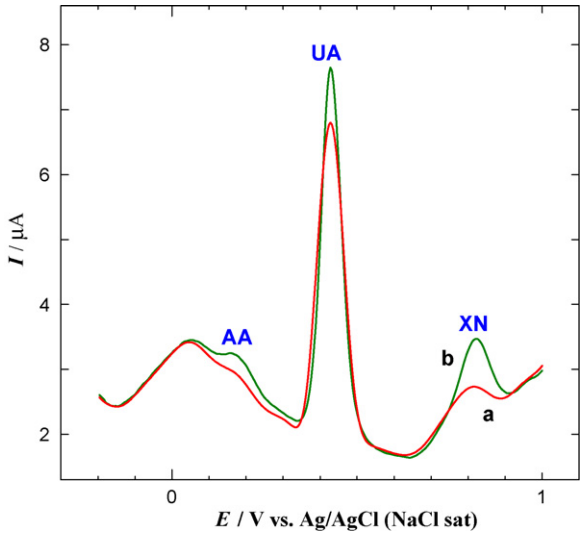

Fig. 5. DPVs obtained for (a) human urine (b) after the addition of 5 μM each AA, UA and XN to human urine at p-ATD modified electrode in 0.20 M PB solution. Pulse width = 0.06 s, amplitude = 0.05 V, sample period = 0.02 s and pulse period = 0.2 s.

4. Conclusions

In the present study, we have demonstrated the simultaneous determination of AA, DA, UA and XN using p-ATD modified GC electrode in 0.20 M PB solution (pH 5.0) for the first time. AFM image showed that the deposited p-ATD film having a homogeneous spherical structure with a thickness of ~25 nm. The bare GC electrode failed to distinguish the voltammetric signals of AA, DA, UA and XN whereas p-ATD modified electrode separated the voltammetric signals of them with potential differences of 110, 152 and 392 mV between AA–DA, DA–UA and UA-XN, respectively. It is expected that anionic forms of AA, UA and XN were attracted by positively charged backbone of the p-ATD film whereas positively charged DA was attracted by heteroatom of the p-ATD film. Thus, enhanced peak currents were observed for these analytes at p-ATD modified electrode. The oxidation currents were increased from 30 to 300 μM for AA, 5 to 50 μM for DA and 10 to 100 μM for each UA and XN, and the lowest detection limit was found to be 2.01, 0.33, 0.19 and 0.59 μM for AA, DA, UA and XN, respectively (S/N = 3). The present method was successfully applied for the determination of AA, UA and XN in human urine samples.

ABSTRACT

An effective method for immobilization of $Ru(bpy)_3^{2+}$ on glassy carbon electrode surface (GCE) is developed for the preparation of a novel electrochemiluminescence sensor. First of all, the positively charged $Ru(bpy)_3^{2+}$ is modified on the surface of negatively charged gold nanoparticles (nano-Au) via the electrostatic interactions to obtain the $Ru(bpy)_3^{2+}$/nano-Au nano-sphere (abbreviate as Ru-AuNPs). Subsequently, the large amount of Ru-AuNPs are immobilized on the multi-wall carbon nanotubes (MWCNTs)-Nafion homogeneous composite coated GCE by dual interaction: firstly, the Nafion, a kind of typical cation-exchange membrane, can absorb the Ru-AuNPs as the enrichment of cation $Ru(bpy)_3^{2+}$ on the Ru-AuNPs surface; secondly, the employment of carboxylic MWCNTs in the Nafion film can also chemosorb the $Ru(bpy)_3^{2+}$ cation on the Ru-AuNPs surface to increase the carrier content. At the same time, the experiment confirms that the enhancement of the ECL intensity on the sensor is attributed to following reasons. One hand, the employment of MWCNTs in the Nafion film enlarged the electro-active surface areas to benefit the contact between the signal probe on the composite film and coreactant used as reinforcing agent. On the other hand, the nano-materials of MWCNTs and nano-Au also improve the conductivity of the assembled film to increase the quantity of excited state of $Ru(bpy)_3^{2+}$ in the unit time under the electrochemical condition and finally cause better properties in luminescence. In the experiment, the influence of the coreactant tripropylamine (TPA) on proposed ECL sensor is investigated. The logarithm of ECL intensity is proportional to the logarithm of TPA concentration on the range of 4×10^{-10} M to 2.8×10^{-6} M and 2.8×10^{-6} M to 0.71×10^{-3} M. After optimizing these conditions, the ECL sensor with TPA as coreactant is employed to detect a kind of alkaloid medicine, Matrine, for evaluating the practical application in the medicine analysis. The present sensor with TPA as coreactant shows the good response to the medicine concentration of the Matrine from 2.0×10^{-6} M to 6.0×10^{-3} M, which is used to detect the Matrine concentration in the Matrine injection.

1. Introduction

Electrogenerated chemiluminescence (ECL) of tris(2,2′-bipyridyl) ruthenium has been a long history since Rubinstein and Bard demonstrated light emission triggered from $Ru(bpy)_3^{2+}$ and postulated the oxidation-reduction reaction mechanism for $Ru(bpy)_3^{2+}$ ECL [1]. Since many researches show that solid-state ECL system of $Ru(bpy)_3^{2+}$ is better than the solution-phase ECL system due to the advantages of low consumption, simple operation and reproducing property, extensive efforts have been made to create a solid-state sensor [2]. However, the leakage of $Ru(bpy)_3^{2+}$ as its inherent water-solubility is always a bottleneck to gain the stable ECL sensor. Therefore, the immobilization of $Ru(bpy)_3^{2+}$ on a solid electrode surface has been extensively focus over the past several decades.

Today many different methods for the immobilization of $Ru(bpy)_3^{2+}$ have been widely developed, such as Langmuir–Blodgett film [3], self-assembly monolayer [4] and sol–gel technology [5]. It is worth to be mentioned that the immobilizing $Ru(bpy)_3^{2+}$ technology with the help of the nanoparticles make the ECL sensor have a good perform on faster response and better stability. Among these methods, nanoparticles, such as Au [6], Ag [7], TiO_2 [8], ZrO_2 [9] and SiO_2 [10], exhibit unique physical and chemical properties because of their size, morphology and large surface area. Especially, citrate-capped gold nanoparticles have negative charges on the surface and some research indicates the treatment of citrate-capped AuNPs with cationic molecules in aqueous medium, such as $Ru(bpy)_3^{2+}$, can result in their aggregation and precipitate to form multiple nano-sphere with $Ru(bpy)_3^{2+}$ on the surface [11]. This method can be employed

to immobilize $Ru(bpy)_3^{2+}$ with the sharp increase of the carrier content of $Ru(bpy)_3^{2+}$ due to the nano size and morphology of nano-Au.

Nafion, a kind of ion-exchange polymer, contain a phase composed of fluorocarbon skeleton and an ionized sulfonate group [12]. Though the fluorocarbon skeleton is very resistant to chemical attack, the unique ion-exchange property can make the cation $Ru(bpy)_3^{2+}$ to be easily incorporated into the composite films via an ion-exchange process [13]. In pure Nafion film, the rate of charge transfer is relative slow due to the nearly insulated Nafion film which was a barrier of the electron propagation [14]. But after dispersing multi-walled carbon nanotubes (MWCNTs) into the Nafion film, the specific surface area of the composite film and the charge transport in the composite film should be enhanced, which is attributed to the characteristic of MWCNTs including good mechanical strength, high-aspect ratio, excellent electrical conductivity, favorable chemical stability and the ability to promote electron-transfer reaction [15]. And it is more important that the negatively charged carboxylic MWCNTs also can chemosorb the cation on their surface [16]. Thus the composite film also can increase the carrier content of $Ru(bpy)_3^{2+}$.

Tripropylamine (TPA) is an organic amine coreactant reported earliestly and used most widely, which can replace the organic acid, such as oxalate or pyruvate, to form the oxidative-reduction-type ECL reaction with $Ru(bpy)_3^{2+}$ [17]. One advantage of using the $Ru(bpy)_3^{2+}$/TPA reaction system is that a single $Ru(bpy)_3^{2+}$ molecule may participate in multiple ECL reaction cycles to produce multiple photons due to the formation of the luminescent excited state and its ground state near the electrode surface, thereby increasing sensitivity and lowering detection limits can be obtained [18]. And another advantage is that the $Ru(bpy)_3^{2+}$/TPA reaction sequence usually operate in the optimum pH value of 7–8 [19], which is applicable for the biological system. These advantages make TPA used as the preferred detected model to evaluate the capability of the sensor fabricated with $Ru(bpy)_3^{2+}$ [14,20], and make the coreactant system used widely in the biological diagnostic assays [18].

Considering above properties, we present a stable and efficient method for immobilizing $Ru(bpy)_3^{2+}$ by assembling the Ru-AuNPs nano-sphere on the MWCNTs-Nafion modified GC electrode surface, design an experiment to compare quantificationally the electro-active surface area of different nano-materials modified electrodes and evaluate the influence of MWCNTs and the nano-Au on the capability of the ECL sensor. The $Ru(bpy)_3^{2+}$–TPA reaction system is constructed by the $Ru(bpy)_3^{2+}$ immobilized on the sensor and the coreactant TPA in the base solution. Under the optimized condition of the $Ru(bpy)_3^{2+}$–TPA system, the present ECL sensor also has been employed in the determination of real world sample. Matrine, which is a kind of alkaloid found in the Chinese herb of *Sophora* and employed to treat with the cancer and hepatitis in the clinic [21], is the aliphatic amine. The structure of Matrine is shown in Fig. 1. In the experiment, we found the ECL intensity of the proposed sensor in the $Ru(bpy)_3^{2+}$–TPA system could increase with the adding of Matrine. Therefore, the ECL sensor could be employed in the medicine analysis of Matrine. As a result, the ECL sensor presents linear answers with the concentration of Matrine, exhibits low detection limit and good stability. Comparing with previous methods of immobilizing $Ru(bpy)_3^{2+}$ in Nafion film [13], these matrixes of MWCNTs-Nafion and the Ru-AuNPs could simplify the assembling operation, increase synchronously the immobilization quantity of gold nanoparticle and $Ru(bpy)_3^{2+}$ as the aggregation of $Ru(bpy)_3^{2+}$ and nano-Au, enlarge the electro-active surface areas and improve the conductivity, which finally benefit to enhance the intensity of ECL and increase the sensitivity of sensor.

2. Experimental

2.1. Materials

Nafion (5 wt%), $Ru(bpy)_3Cl_2{\cdot}6H_2O$, tripropylamine (TPA), gold chloride ($HAuCl_4$) and sodium citrate are purchased from Sigma–Aldrich Co. (St. Louis, MO, USA). Matrine (>98% purity) is purchased from Angsheng Biological Reagent Co. Ltd (Shaanxi, China). Matrine injection (50 mg:5 mL) is bought from the Ninth People's Hospital (Chongqing, China). MWCNTs (>95% purity) are purchased from Chengdu Organic Chemicals Co. Ltd., of the Chinese Academy of Science. And carboxylic MWCNTs are prepared as the literature method [22]. Nafion is diluted to 2 wt% with ethanol solution. All chemicals and solvents used are of analytical grade and are used as received. Double-distilled water is used throughout this study. Phosphate buffered solutions (PBS) (pH 7.4) are prepared using 0.1 M Na_2HPO_4, 0.1 M KH_2PO_4 and 0.1 M KCl. Gold nanoparticles with a diameter of 16 nm are produced by reducing gold chloride tetrahydrate with citric acid at 100 °C for half an hour [23]. Prepared solutions are kept at 4 °C before use.

2.2. Apparatus

Cyclic voltammetric (CV) measurements are carried out with a CHI 600B electrochemistry workstation (Shanghai CH Instruments, China). The ECL emission is monitored with a model MPI-A electrochemiluminescence analyzer (Xi'An Remax Electronic Science & Technology Co. Ltd., Xi'An, China) with the voltage of the photomultiplier tube (PMT) set at 800 V in the process of detection. All experiments are performed with a conventional three-electrode system. The three-compartment electrochemical cell contain a platinum wire auxiliary electrode, an Ag/AgCl (saturated KCl) reference electrode and Ru-AuNPs/MWCNTs-Nafion modified glassy carbon electrode ($\Phi = 4$ mm) as working electrode. The size of Au colloid is estimated from transmission electron microscopy (TEM) (H600, Hitachi Instrument, Japan) at an accelerating voltage of 200 kV. And the process of assembling working electrode is tracked by a scanning electron microscope (SEM, S-4800, Hitachi, Tokyo, Japan) at an acceleration voltage of 20 kV. The pH measurements are made with a pH meter (MP 230, Mettler-Toledo, Switzerland) and a digital ion analyzer (Model PHS-3C, Dazhong Instruments, Shanghai, China).

2.3. Fabrication of the electrochemiluminescence sensor

The nano-spheres of Ru-AuNPs are prepared according to the following method [11]. 300 μL of 50 mM $Ru(bpy)_3Cl_2$ aqueous solution is added into 20 mL of nano-Au (16 nm, citrate-capped) solution under vigorous stirring at room temperature. Several minutes later, a large amount of black precipitate (Ru-AuNPs) appear. Resulting precipitates are collected by centrifugation and suspension. Just as the TEM image of Ru-AuNPs shown in Fig. 2A, these nanoparticles are dispersed in the solution as the form

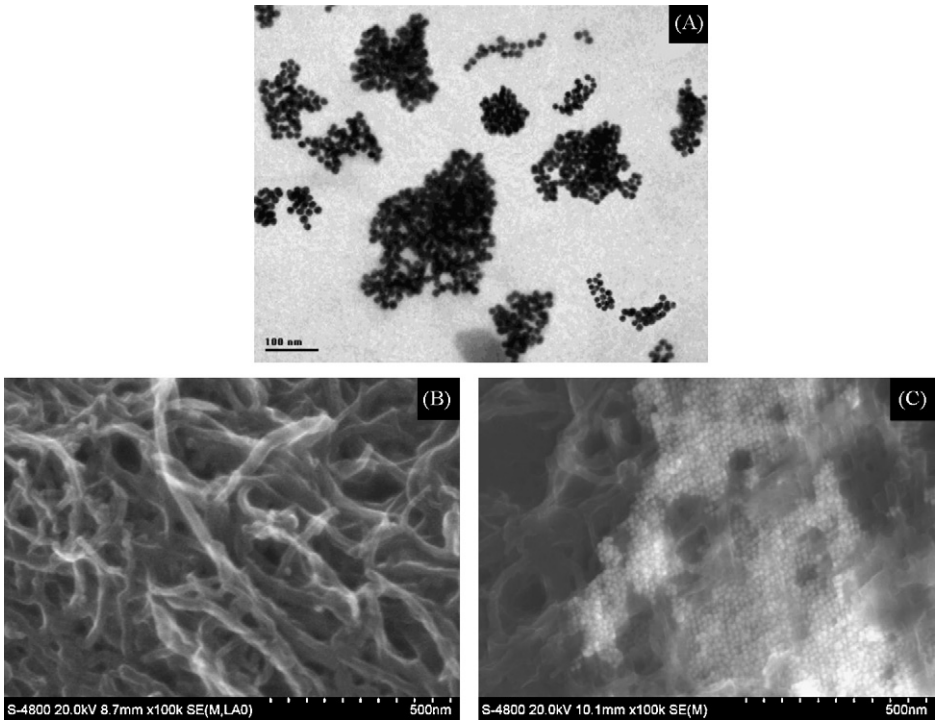

Fig. 2. TEM image of the resulting Ru-AuNPs precipitate (A); SEM images of assembling films on MWCNTs-Nafion modified electrode (B) and on Ru-AuNPs/MWCNTs-Nafion modified electrode (C).

of agglomeration because the charges lie on the particle surface. The phenomenon of aggregation can be attributed to the fact that the treatment of citrate-capped AuNPs with the cationic $Ru(bpy)_3^{2+}$ in aqueous medium results in their aggregation and precipitation, where the cationic molecules cause the cross-linking of the nanoparticles as a consequence of electrostatic interactions between the positive charges of cationic molecules and the negatively charged citrate coating on the nano-Au [24].

Before each modification, the GC electrode ($\Phi = 4$ mm) is polished with 0.3, 0.05 μm alumina slurry, successively sonicate in ethanol and double-distilled water for 5 min and dried in air. The resulting GC electrode is firstly coated with MWCNTs-Nafion suspension (3 μL, 1 mg/mL) and allowed to evaporate at room temperature. Then 5 μL suspensions of Ru-AuNPs is cast onto the modified electrode surface and dried in air. The finished sensor is stored at 4 °C when not in use. The schematic illustration of the stepwise self-assemble procedure of the sensor is shown in Fig. 3. The morphologies and microstructures of the prepared different modified films are studied by means of SEM. As shown in the SEM profiles (Fig. 2B), the homogeneous dispersion MWCNTs can be observed, which would benefit the sensor performance [25]. Fig. 2C show the treatment of above electrode with Ru-AuNPs. The nano-sphere of Ru-AuNPs are immobilized on the MWCNTs-Nafion modified electrode via the ion-exchange and electrostatic interaction between negatively charged MWCNTs-Nafion and positively charged Ru-AuNPs to assemble a novel ECL sensor.

In order to compare the ECL intensity without MWCNTs or AuNPs modified electrode, two kind of modified electrodes are fabricated. One is modified with the same volume and concentration of MWCNTs-Nafion suspensions and pure $Ru(bpy)_3^{2+}$ solution, another is assembled with pure Nafion and Ru-AuNPs suspensions.

3. Results and discussion

3.1. Electrochemistry and electrochemiluminescence of the sensor

Fig. 4 shows the cyclic voltammetry and ECL process of a bare GC electrode (a), a MWCNTs-Nafion composite film modified electrode (b) and Ru-AuNPs assembled successively on the electrode surface (c) in phosphate buffer solution (pH 7.4). All these results are recorded until the electrode has reached a steady-state response after scanning ~10 cycles. Comparing with the bare GC electrode, the background current at the MWCNTs-Nafion composite film modified electrode increase because of the strong background current of MWCNTs [16,26]. And at this step the ECL intensity weaken. Then, after modified with Ru-AuNPs, a distinguished response appears in the cyclic voltammogram and ECL in the absence of TPA. Because $Ru(bpy)_3^{2+}$ is the only electro-active and luminescent probe in the Ru-AuNPs, one broad anodic peak and one cathodic peak near 1.1 V in the cyclic voltammogram are characteristic redox waves of $Ru(bpy)_3^{2+}$. And in the ECL graph the strong luminescence at 1.15 V is the result of emission, which was caused by

the transition from the excited state to ground state of $Ru(bpy)_3^{2+}$ [27].

3.2. The influence of nanoparticles on the capability of the sensor

As many reports mentioned, $Ru(bpy)_3^{2+}$–TPA can give ~10-fold higher ECL compared to other commonly used reductant such as oxalate [28]. TPA acting as coreactant has the same aggrandizement operation to the sensor in our works. With addition of TPA into the PBS solution (pH 7.4), the ECL intensity enhance distinctly. The ECL at the higher potential is attributed to direct oxidization of $Ru(bpy)_3^{2+}$ on the electrode to form $Ru(bpy)_3^{3+}$, which further reacts with the $TPA^{\bullet}$ radical species to generate $Ru(bpy)_3^{2+*}$. And the transition from the excited state to ground state of $Ru(bpy)_3^{2+}$ causes the luminescence [27,17].

Since Bard's research group reported the electrogenerated chemiluminescence of nano-crystals in organic solvents, the study on the function of nanoparticles assembled electrode in ECL has received considerable attention [29]. The nanoparticle assembled electrode has different properties from conventional electrodes, which can lead to new ECL properties and new ECL reactions [30]. An enormous surface area-to-volume ratio, which is highly susceptible to heterogeneous redox chemistry with surrounding environment, is pivotal factor [31]. Bard and Faulkner mentioned in their book that the electro-active surface area of these electrodes can be estimated for a reversible process according to the Randles–Sevcik equation [32].

$$I_p = 2.69 \times 10^5\ A \times D^{1/2}\, n^{3/2}\, n^{1/2}\, C$$

I_p refers to the redox peak current; n and C represent the transferring electron number and the concentration (mol cm^{-3}) of the ferricyanide; A is the area of the electrode (cm^2), D is the diffusion coefficient of the molecule in solution ($cm^2\ s^{-1}$), and ν is the scan rate of the potential perturbation ($V\ s^{-1}$). D, C and n are constants. If the electrochemical behavior of the electrode surface is controlled by diffusion, the slope that is gained by plotting the picture of the peak current against the square root of scan rate and fitting linearly is the function of the electro-active surface area (A). According to the Randles–Sevcik equation, we can get the approximate value of A.

So we design this experiment to compare quantificationally the electro-active surface area of different electrodes and confirm the influence of nanoparticles on the sensor by mensurating steady-state CVs for proposed electrode (a), the electrode of absent AuNPs (b) and the electrode of absent MWCNTs (c) at a series of scan rates in 5.0 mM $Fe(CN)_6^{3-/4-}$ and 0.1 M KCl. The $Fe(CN)_6^{3-/4-}$ redox system used in this study is one of the most extensively studied redox couples in electrochemistry and exhibits a heterogeneous one-electron transfer ($n = 1$). The diffusion coefficient (D) at 25 °C is $6.70 \pm 0.02 \times 10^{-6}\ cm^2\ s^{-1}$.

In Fig. 5, the main graph is the CVs responses of three detected electrodes in the same 5.0 mM $Fe(CN)_6^{3-/4-}$ work solution containing 4.0 mM TPA (pH 7.4). And the inset graphs are respectively linear relations with the anodic peak current of electrode (a), (b) and (c) against the square root of scan rate. As Fig. 5 shown, the peak currents of three electrodes all present good linearity with the square root of scan rates, which indicate that their electrochemical behavior of the electrode surface are controlled by diffusion. According to above equation, the values of the electro-active surface area are respectively 9.6 mm^2, 3.7 mm^2 and 0.36 mm^2. And the CVs of three electrodes in the main graph show that the proposed electrode (a) has higher conductivity than other electrodes at scan rate of 100 mV/s. Comparing the luminescence of these electrodes, as Fig. 6 shown, the proposed electrode (a) has more strong ECL

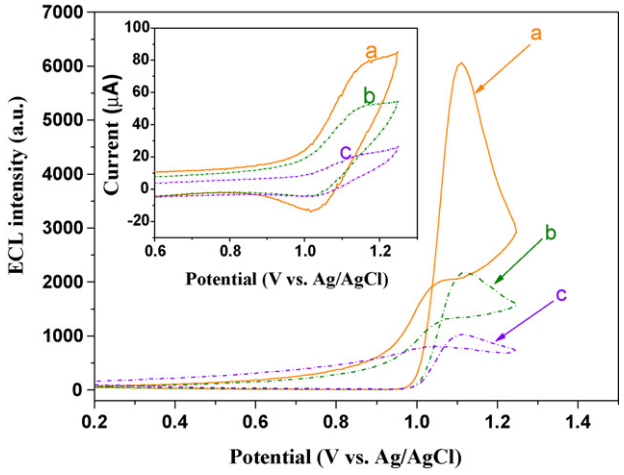

Fig. 6. The ECL intensity–potential curve of Ru-AuNPs/MWCNTs-Nafion modified electrode surface (a), MWCNTs-Nafion/$Ru(bpy)_3^{2+}$ modified electrode surface (b) and Nafion/Ru-AuNPs modified electrode surface (c) in PBS (pH 7.4) containing 4.0 mM TPA. *Inset*: the CVs of $Ru(bpy)_3^{2+}$ on three different electrodes.

intensity than other two electrodes. This trend is consistent with the electro-active surface area and the peak current. Thus it can be seen that firstly, MWCNTs and nano-Au with nanometer diameters can authentically increase the electro-active surface area, which benefit the contact between the signal probe $Ru(bpy)_3^{2+}$ on the composite film and coreactant of TPA. Secondly, the nano-materials of MWCNTs and nano-Au also can improve the conductivity of the assembled film to increase the quantity of excited state of $Ru(bpy)_3^{2+}$ in the unit time under the electrochemical condition and finally cause better properties in luminescence.

3.3. Capability of the presented sensor and ECL analytical performances of the proposed ECL sensor for Matrine

The $Ru(bpy)_3^{2+}$–TPA couple is a typical ECL system. The potential interferences on the system have been researched very extensively and deeply. The concomitant halide anion in solution, the pH value of solution and the scan rate during the detection process are main potential interferences on the ECL intensity of $Ru(bpy)_3^{2+}$–TPA system. Because the chemical adsorption of halide happened at platinum and gold electrodes can retard the formation of surface oxides and finally result a lower rate of the direct oxidation of TPA to weaken the ECL intensity [19,30], the glass carbon electrode (GCE) is chosen to fabricate the proposed sensor. The ECL system of $Ru(bpy)_3^{2+}$–TPA is sensitive to the solution pH value [33]. And the suitable pH value of the TPA buffer solution to the $Ru(bpy)_3^{2+}$ ECL analysis is usually about 7–8 [19]. Considering the application of the proposed sensor in the detection of medicine or biomolecule existed in the humoral environment, the pH value of 7.4 has been chosen [27]. The scan rate also has important influence on the ECL signal in the $Ru(bpy)_3^{2+}$–TPA system [13]. The effect of the scan rate on ECL signal of the Ru-AuNPs/MWCNTs-Nafion modified sensor is presented in Fig. 7. When the scan rate is below 100 mV/s, ECL intensity decreases faintly with the increasing of the scan rate. As the scan rate increased from 100 mV/s to 250 mV/s, ECL intensity decrease sharply. Therefore, the influence of the coreactant TPA on the ECL intensity of proposed sensor was investigated (Fig. 8A) at a scan rate of 100 mV/s. Each point on the calibration curve was the average of five ECL values obtained by consecutive cyclic potential scans at a rate of 100 mV/s in PBS solution (pH 7.4). The logarithm of ECL intensity is proportional to the logarithm of TPA concentration. The relation presented two linear sections. One linear range is from 4×10^{-10} M to 2.8×10^{-6} M, another is from 2.8×10^{-6} M to 0.71×10^{-3} M. Furthermore, with the increasing of TPA concentration, the change of ECL intensity is inconspicuous in the lower concentration range and obvious in higher concentration range. The lowest detection limit (S/N = 3) is 0.2 nM. Compared with previous results of $Ru(bpy)_3^{2+}$/MWCNT-Nafion composite films [13], the improvement of sensitivity could be attributed to the MWCNTs and Ru-AuNPs matrix, which aggrandize the contact surface of the sensor with co-reagent and make the transfer of electrons more easy on the solid modified electrode surface.

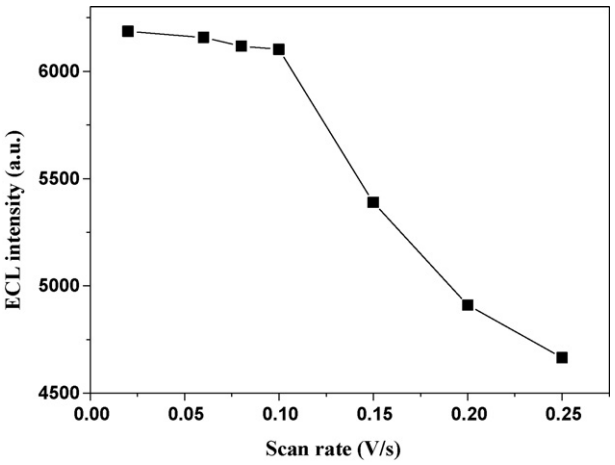

Fig. 7. Effect of scan rate on ECL intensity of Ru-AuNPs/MWCNTs-Nafion modified sensor in PBS (pH 7.4) containing 4.0 mM TPA.

In addition, with increasing the concentration of Matrine, the ECL intensity of proposed sensor enhances in $Ru(bpy)_3^{2+}$–TPA system. The ECL sensor presents linear response to the concentration of Matrine in the PBS (pH 7.4) buffer containing 0.01 mM TPA (shown in Fig. 8B), which can be employed to perform the determination of Matrine in pharmaceutical preparations. Because the enhancement ECL response of the sensor to the concentration of Matrine could not be found in same PBS buffer without TPA, the ECL response to the concentration of Matrine in the PBS buffer with TPA can attribute to the change of pH resulted by the Matrine. Each point on the calibration curve of Matrine was obtained by scanning consecutively at same scan rate of 100 mV/s and noting the ECL intensity after scanning for 14 cycles. The curve shows that the ECL intensity of present sensor is directly proportional to the concentration of Matrine from 2.0×10^{-6} M to 6.0×10^{-3} M (496.7 ng/mL to 1.5 mg/mL). And the lowest detection limit (S/N = 3) is 0.7 μM (165.6 ng/mL, Mr = 248.36). We employed the proposed ECL sensor to detect the concentration of Matrine in the Matrine injection bought from the Ninth People's Hospital in Chongqing. The Matrine injection (10 mg/mL) is diluted tenfold before the sample is detected. The obtained concentration of the diluted sample is 0.991 ± 0.052 mg/mL. Therefore, the detection concentration of Matrine in the Matrine injection is 9.91 ± 0.52 mg/mL, which is approximately equal to the label concentration of the Matrine injection (10 mg/mL).

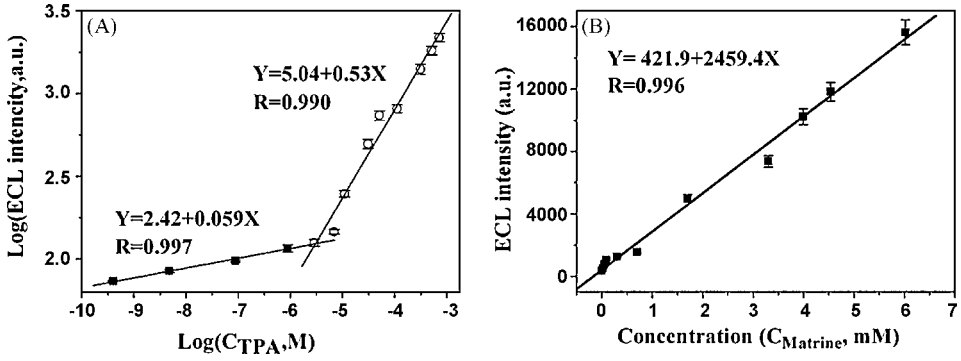

Fig. 8. (A) Calibration curve of TPA with the proposed sensor in PBS (pH 7.4); scan rate 100 mV/s. (B) Calibration curve of Matrine with the sensor in PBS (pH 7.4) buffer containing 0.01 mM TPA at same scan rate.

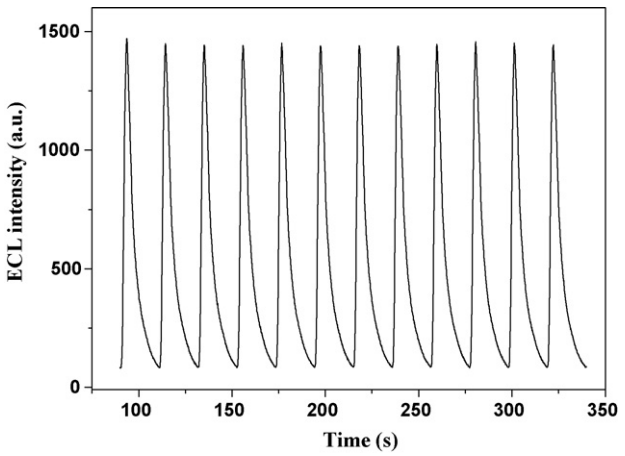

Fig. 9. ECL intensity–potential curve of Ru-AuNPs/MWCNTs-Nafion modified electrode in PBS (pH 7.4) containing 0.3 mM TPA under continuous cyclic potential scans for 12 cycles.

Fig. 9 shows the good stability of the working electrode under the present conditions. Under consecutive cyclic potential scans for 12 cycles at a scan rate of 100 mV/s, the relative standard deviation of the ECL is less than 0.8%. The mechanical stability of the sensor is due to enhanced ion-exchange and electrostatic interactions by MWCNTs and nano-Au particles.

4. Conclusions

A new method of ECL sensor assembling is constructed using the MWCNTs and nano-Au. After optimization of the influencing factors on the ECL signal, a well-performed ECL sensor with high sensitivity and good stability is obtained. Comparing with the previous assembled layer-by-layer method, the assembling method simplifies the operation, increases the immobilized quantity of nano-Au and $Ru(bpy)_3^{2+}$ as the aggregation of Ru-AuNPs nano-sphere, and makes the sensor have better performance on bio-compatibility and sensitivity due to the using of composite nano-sphere of Ru-AuNPs and composite MWCNTs-Nafion. It is more important that the experiment that can quantificationally evaluate the effect of nanoparticle on the capability of the proposed sensor has been designed. And the quantificational counting also successfully testifies that the nanostructure can increase the electro-active surface area, facilitate the electron-transfer processor, which benefit the contact between the $Ru(bpy)_3^{2+}$ and TPA, increase the quantity of excited state of $Ru(bpy)_3^{2+}$ in the unit time under the electrochemical condition and finally promote the ECL properties of the proposed sensor. Moreover, the present sensor is employed to detect the medicine of Matrine, show good stability and good response. Therefore, the ECL sensor also has great potentials in medicine analysis application combined with capillary electrophoresis and microfluidics.

ABSTRACT

Multivariate spectral analysis has been widely applied in chemistry and other fields. Spectral data consisting of measurements at hundreds and even thousands of analytical channels can now be obtained in a few seconds. It is widely accepted that before a multivariate regression model is built, a well-performed variable selection can be helpful to improve the predictive ability of the model. In this paper, the concept of traditional wavelength variable selection has been extended and the idea of variable weighting is incorporated into least-squares support vector machine (LS-SVM). A recently proposed global optimization method, particle swarm optimization (PSO) algorithm is used to search for the weights of variables and the hyper-parameters involved in LS-SVM optimizing the training of a calibration set and the prediction of an independent validation set. All the computation process of this method is automatic. Two real data sets are investigated and the results are compared those of PLS, uninformative variable elimination-PLS (UVE-PLS) and LS-SVM models to demonstrate the advantages of the proposed method.

1. Introduction

With the development of modern spectrometers, nowadays spectral data consisting of measurements at hundreds and even thousands of analytical channels can be obtained in a few seconds. The practical need for fast and reliable quantification of sought-for components in complex samples is increasing. Least-squares support vector machine (LS-SVM) [1,2], a relatively new algorithm from the machine learning community, has the capability of dealing with linear and nonlinear multivariate calibration. The superiority of LS-SVM to traditional support vector machine (SVM) [3,4] is that it requires solving a set of only linear equations (linear programming) instead of a set of nonlinear equations (quadratic programming) which is much easier and computationally very simple. It has been introduced into multivariate calibration by many investigators for its attractive features and promising empirical performance [5–9]. One problem in LS-SVM multivariate calibration is whether the whole wavelength range should be used or only a proper subset of the spectra would be enough. Theoretically, some variables of these full spectrum data may contain useless or irrelevant information for calibration model like noise and background, which can worsen the predictive ability of the calibration model. Recently, variable selection [10–20] or uninformative variable elimination [21–24] has attracted more and more attention for the development of multivariate calibrations. These variable selection methods could improve the predictive ability of the calibration models. But some wavelengths might represent similar data structure when kept together [25,26], selection of a few individual wavelengths from them would cause a loss of useful information. And for the spectra with heteroscedastic noises, wavelength ranges with comparatively high noise might carry useful relevant information for prediction and simply deleting such wavelengths would lead to a model with much less variables, which would spoil the multi-channel advantage of the model to some extent. So it is important for us to have a general view of variable selection. This paper addresses this significant issue of introducing the wavelength variable weighting to LS-SVM model. Unlike in ordinary variable selection methods, where the wavelengths selected are weighted 1.0 and the wavelengths deleted are weighted 0, we have introduced wavelength sampling with continuous nonnegative values.

Like SVM, the conventional LS-SVM is performed first by adjusting the parameters in regularization item and kernel function called hyper-parameters, which play an important role to the algorithm performance. The existing techniques for adjusting the hyper-parameters in LS-SVM can be summarized into two kinds: one is based on analytical techniques which are computationally intolerable to optimize these parameters [27,28]. The other is based on heuristic searches including genetic algorithms (GA), simulated annealing algorithms (EA) and other evolutionary strategies [29–32], which are the tricky tasks since a suitable sampling step varies from kernel to kernel and the grid interval may not be easy to locate without prior knowledge of the problem. Moreover, when

there are more than two hyper-parameters, the manual model selection may become intractable. The particle swarm optimization (PSO) method [33,34], a new optimization technique, developed by Eberhart and Kennedy in 1995, is a stochastic global optimization technique inspired by social behavior of bird flocking. Compared with GA and EA, PSO has no evolution operators and does not need any priori knowledge on the analytic property of the generalization performance measure and can be used to determine multiple hyper-parameters at the same time.

In this paper the idea of wavelength variable weighting is incorporated into LS-SVM for multivariate calibration. A global optimization algorithm, particle swarm optimization is used to automatically search for the variable weights and the hyper-parameters involved in LS-SVM simultaneously optimizing the training of calibration set and the prediction of an independent validation set. The details of this method will be described in the following part.

2. Theory

2.1.1. Optimized wavelength-weighted least-squares support vector machine (VWLS-SVM)

The least-squares support vector machine (LS-SVM), a relatively new algorithm from the machine learning community, has been described in detail by Suykens et al. [1,2]. It has attracted great attention and gained extensive application in pattern recognition and regression problems for its remarkable generalization performance. Typically, one solves a convex quadratic programming (QP) problem in dual space in order to determine the SVM model [3,4]. But in these LS-SVM formulations one works with equality instead of inequality constraints and a sum squared error (SSE) cost function as it is frequently used. This reformulation greatly makes the problem simpler in such a way that the solution is characterized by a linear system.

Consider an $n \times p$ matrix $\boldsymbol{X}$ including p predictor variables for n samples and an $n \times 1$ vector $\boldsymbol{y}$ including the corresponding dependent variable for the n samples. For simplicity and without loss of generality, both $\boldsymbol{X}$ and $\boldsymbol{y}$ is column centered. Not like in an ordinary LS-SVM model, where variables in $\boldsymbol{X}$ are considered as making the same contribution to the LS-SVM model, in VWLS-SVM, $\boldsymbol{X}$ is right multiplied by a diagonal matrix diag($\boldsymbol{w}$), which makes:

$$\boldsymbol{X_w} = \boldsymbol{X}\,\mathrm{diag}(\boldsymbol{w}) \tag{1}$$

where $\boldsymbol{w}$ is a $p \times 1$ variable weighting vector with all the elements being non-negative values and diag($\boldsymbol{w}$) is a $p \times p$ matrix whose diagonals are the elements of $\boldsymbol{w}$. A LS-SVM model is built between $\boldsymbol{X}_w$ and $\boldsymbol{y}$.

$$\boldsymbol{y} = \boldsymbol{X}_{\boldsymbol{w}}^{T}\boldsymbol{t_w} + \boldsymbol{b_w} \tag{2}$$

For prediction, the dependent variable $\mathbf{y}_\mathrm{u}$ of unknown samples with measurement matrix $\boldsymbol{X}_\mathrm{u}$ is predicted as:

$$y_\mathrm{u} = \boldsymbol{X}_\mathrm{u}^{T}\,\mathrm{diag}(\boldsymbol{w})\boldsymbol{t_w} + \boldsymbol{b_w} \tag{3}$$

It can be seen from Eq. (1) that when $\boldsymbol{w}$ is a vector with all the elements being 1, the above model is the same as a LS-SVM model built with the whole wavelength range. If the elements of $\boldsymbol{w}$ just consist of 0 and 1, a LS-SVM model with variable selection is obtained, where the variables in $\boldsymbol{X}$ corresponding to 1 s in $\boldsymbol{w}$ are selected variables and those corresponding to 0 s are deleted.

From the above analysis, a LS-SVM model with full wavelength range or variable selection are just special cases of variable weighting, so VWLS-SVM is expected to be more flexible and rational. The problem is how to determine the variable weighting vector $\boldsymbol{w}$. The PSO algorithm is simultaneously implemented for the sample weights and hyper-parameters training.

Since the present method is oriented to improve the predictive ability of LS-SVM, the weights and hyper-parameters are automatically configured that the training of calibration set and prediction of an independent validation set are optimized. The following objective function is minimized:

$$Re = \sqrt{\frac{(\mathrm{RSSC} + \mathrm{RSSV})}{(n + n_\mathrm{v})}} \tag{4}$$

where RSSC is the sum of squared residual of the original calibration set and RSSV the sum of squared residual of the independent validation set, n and n_v is the size of calibration set and validation set, respectively.

The steps of VWLS-SVM can be described as follows:

Step 1. With the 100 initial feasible solutions of variable weighting vector w and two hyper-parameters (kernel widths and the relative weight of the error term) in LS-SVM. A LS-SVM model between predictor matrix $\boldsymbol{X}_w = \boldsymbol{X}\,\mathrm{diag}(\boldsymbol{w})$ and dependent variable $\boldsymbol{y}$ is built.
Step 2. For different numbers of generations, PSO is used to search for w and two hyper-parameters that minimize Re defined in Eq. (4).
Step 3. With the best optimized variable weighting vector w and hyper-parameters determined in Step 2, an LS-SVM model is built and then applied to unknown samples

3. Data sets

The following two real data sets are investigated:

3.1. Meat data [35]

The experimental data set consists of NIR spectra of 240 samples of ground pork meat with corresponding wet-chemistry results on fat, water, and protein contents. These spectra are recorded on a Tecator Infratec spectrometer that measures the absorbance at 100 wavelengths with the region 850–1050 nm at intervals of 2 nm by the near-infrared transmission (NIT) principle. A Soxhlet method was used as the laboratory reference for the fat determination. Soxhlet values ranged from 2% to 59% fat content of pork meat.

3.2. Diesel fuels data [36]

The diesel database can be downloaded from http://software.eigenvector.com/Data/index.html. The research was conducted to develop instrumentation for fuel quality assessment on battle fields. The database contains only summer fuels, and outliers were removed. It consists of scans of approximately 250 diesel fuel samples. All spectra range from 750 to 1550 nm, has been discretized into 401 wavelength values. The total 256 samples include 20 high leverage samples. The spectra have been preprocessed by the original author and the wavelengths are not released.

4. Results and discussion

For the meat data, standard normal variate (SNV) is used to preprocess the spectra. The total 240 samples are split into a calibration set with 120 samples, a validation set with 60 samples and a prediction set with 60 samples by DUPLEX method [37]. The number of variable selected and root mean square error of prediction (RMSEP) of the prediction set by ordinary PLS with total wavelength, uninformative variable elimination-PLS (UVE-PLS), LS-SVM models with total wavelength, LS-SVM models with selected wavelength by UVE-PLS and VWLS-SVM models are listed in the Table 1. The PLS model is built on 180 samples containing the calibration

Table 1
A comparison of the results obtained by PLS, UVE-PLS, LS-SVM and VWLS-SVM.

Models	Number of variables	RMSEP
Meat data		
PLS	100 (total wavelength)	5.10
UVE-PLS	43	2.58
LS-SVM	100 (total wavelength)	2.78
LS-SVM[a]	43	2.58
VWLS-SVM	100 (total wavelength)	1.31
Diesel fuels data		
PLS	401(total wavelength)	0.86
UVE-PLS	227	0.79
LS-SVM	401(total wavelength)	0.83
LS-SVM[a]	227	0.81
VWLS-SVM	401(total wavelength)	0.78

[a] LS-SAM model is performed with the variables selected by UVE-PLS model.

set and the validation set. The number of latent variables is determined to be 10 by the Monte Carlo cross-validation (MCCV) [38]. As to LS-SVM, 60 samples picked are used as the monitoring set for training hyper-meters in LS-SVM model by PSO algorithms to mitigate the probability of overfitting the training data. It is obvious that LS-SVM obtains much better prediction ability than PLS model with total wavelength. It may result from the presence of the complex or unknown nonlinearity in the data set. The uninformative variable elimination-PLS (UVE-PLS) [21] as a popular wavelength selection method is carried out on the calibration set and it gets better results than PLS and LS-SVM models with total wavelength. When LS-SVM model is performed with the variables selected by UVE-PLS, it gets even better results than ordinary LS-SVM model with total wavelength and UVE-PLS models. For VWLS-SVM, an 800-cycle PSO is carried out to search for the variable weights and hyper-parameters minimizing the objective function defined in Eq. (4) and the corresponding wavelength weights are shown in Fig. 1. It can be seen that the VWLS-SVM model obtains the best precise prediction when wavelength weighting is introduced. It can be seen from Fig. 1 the wavelength ranges are differently weighted. A few of the wavelengths are highly weighted and much more wavelengths have smaller weights. Compared with traditional variable selection methods, much more wavelengths are included into the calibration model and thus useful information carried by the spectra would be retained for prediction.

For diesel fuels data, the total 256 samples are split into a calibration set with 128 samples, a validation set with 64 samples and a prediction set with 64 samples by DUPLEX method [37]. The number of PLS latent variables is determined to be 12 by MCCV. As to LS-SVM, 64 samples picked are used as the monitoring set for training the LS-SVM model. For VWLS-SVM, a 350-cycle PSO is carried out to search for the variable weights and hyper-parameters minimizing the objective function defined in Eq. (4). The corresponding variable weights are shown in Fig. 2. It can be seen that most of the variables are high weighted, and useful information carried by these variables would be retained for prediction. The results of all the models are also listed in Table 1. It can be seen VWLS-SVM can slightly improve the performance of other models in selecting wavelength weighting.

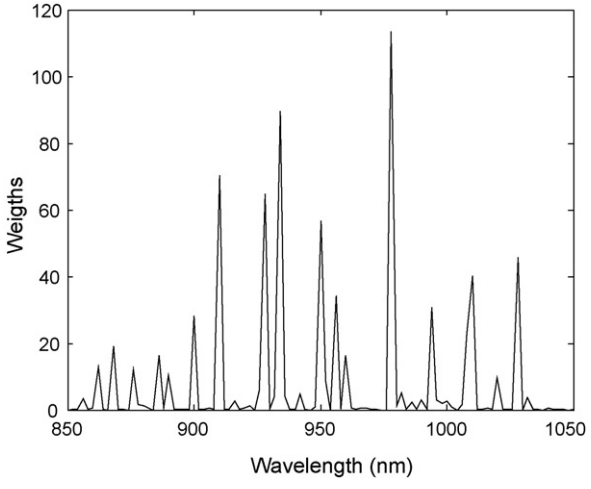

Fig. 1. Wavelength variable weights after an 800-cycle PSO search for the meat data by VWLS-SVM.

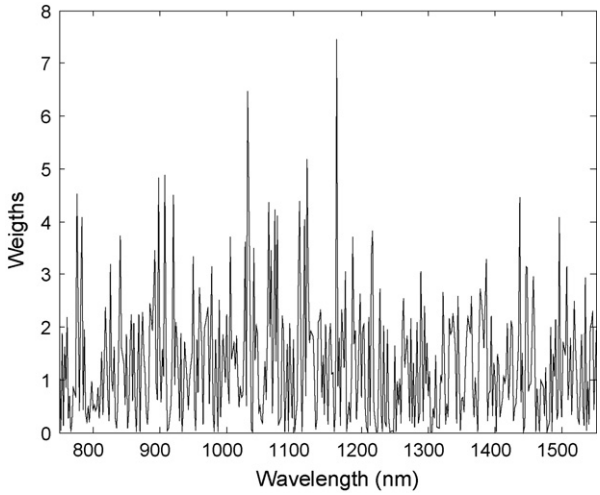

Fig. 2. Wavelength variable weights after a 350-cycle PSO search for the diesel fuels data by VWLS-SVM.

5. Conclusions

In this paper, we have extended the concept of wavelength variable selection and introduced the variable weighting to LS-SVM for multivariate calibration. A global optimization algorithm, particle swarm optimization is used to simultaneously search for the variable weights and the hyper-parameters involved optimizing the training of calibration set and the prediction of an independent validation set. From the results of real data sets, much more variables are included into VWLS-SVM than traditional variables selection methods and thus prevent the possible spoiling of multi-channel advantage. VWLS-SVM can provide better prediction ability comparing with PLS, LS-SVM with total wavelength and UVE-PLS models. The overall conclusion is that VWLS-SVM is a useful method for multivariate calibration, especially when the spectra data contains wavelengths with undesirable qualities like serous noise, nonlinearity and poor information.

Hypertension

ABSTRACT

We describe the procedure developed for the simultaneous detection and quantification of angiotensin II and angiotensin-(1-7), by capillary zone electrophoresis with UV detection by photodiode-array, at a wavelength of 200 nm, in the plasma and urine from hypertensive rats. Optimal separation was achieved with a 100 mM boric acid + 3 mM tartaric acid + 10 fM gold (III) chloride electrolyte solution at pH 9.80. The applied voltage was 30 kV and the capillary temperature was kept constant at 20 °C. The method was over the concentration range of 0.01–500 pmol/mL. All determination coefficients were higher or equal to 0.9985. Limits of detection and quantification for angiotensin II were 0.0110 pmol/mL (S/N = 3) and 0.0195 pmol/mL (S/N = 5), respectively. While for angiotensin-(1-7), the limits were 0.0112 pmol/mL (S/N = 3) and 0.0193 pmol/mL (S/N = 5), respectively. The present method offers a time-saving way to simultaneous determination of angiotensin II and angiotensin-(1-7), since it can be completed in 10 min, compared to other methodologies reported in the literature for capillary electrophoresis and liquid chromatography, which require more than 1 h for analysis of complex matrices, such as plasma and urine. The procedure is illustrated by experiments that quantify simultaneously angiotensin II and angiotensin-(1-7) in plasma and urine from hypertensive and normotensive rats, with and without antihypertensive treatment. The levels of angiotensin II and angiotensin-(1-7) detected in the experimental model, resulted in a recovery of 99.00–106.01% and a reproducibility of less than 10%. The proposed analytical method is a use full tool for the simultaneous detection of angiotensin II and angiotensin-(1-7) implicated in vascular remodeling in pathologies such as hypertension.

1. Introduction

Essential arterial hypertension is the most frequent chronic disease in the world and one of the main cardiovascular risk factors [1–4]. Over the past 60 years, studies have been carried out to elucidate its genesis and they show that this disease results from a syndrome of metabolic and structural abnormalities from genetic and acquired nature, in which the direct participation of the renin–angiotensin system has been evidenced. This system has been and still is one of the most studied mechanisms in relation to the physiopathology of arterial hypertension [1,3]. Angiotensin II, the main effector molecule of the renin–angiotensin system, is a potent vasoconstrictor that exerts diverse effects on multiple target organs that cause the increase in arterial blood pressure, this can be achieved by either an increase in vascular resistance or an increase in the extracellular fluid volume. Angiotensin II, exerts its actions by binding to AT1 and AT2 receptors G protein-coupled located in the heart, kidneys, arteries, etc. AT1 receptor mediates the vasoconstriction and cardiac and arterial hypertrophy, whereas AT2 receptor exerts an opposite effect [5–8]. For this reason, the inhibition of ACE with drugs such as captopril, enalapril, lisinopril and ramipril, among others, has been relevant for the antihypertensive treatment [1,3,6,8]. The angiotensin-(1-7) has different cellular functions from those established for angiotensin II. Angiotensin-(1-7) is neither dipsogenic nor aldosterone secretagogue, but it favors vasopressin, prostaglandins, and nitric oxide secretion [9–11].

The most commonly used methods to determine independent angiotensin II and angiotensin-(1-7) in biological fluids are radioimmunoassay (RIA), high performance liquid chromatography (HPLC), and capillary electrophoresis (CE) [12–14]. RIA requires the use and elimination of radioactive material and is relatively long and tedious, because peptides must be previously separated through liquid chromatography, then concentrated and analyzed

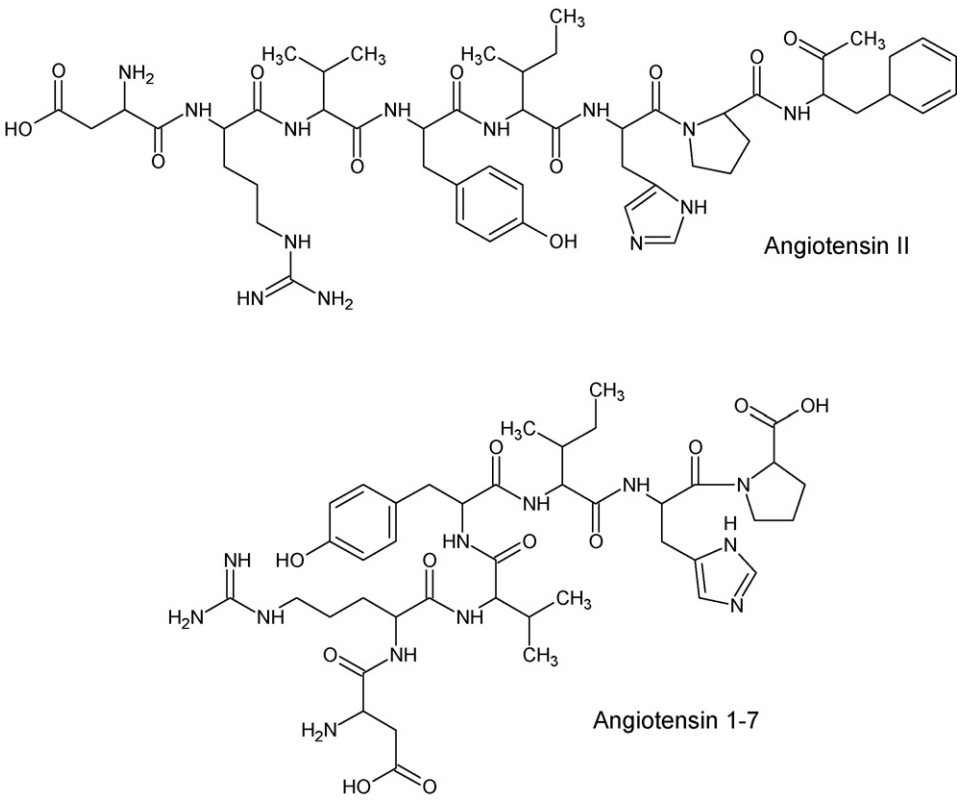

Fig. 1. Molecular structure of angiotensin II and angiotensin-(1-7).

by RIA. For this reason, alternative approaches have been oriented toward HPLC and CE studies for the detection of diverse peptides derived from angiotensinogen in blood [15–17].

Although angiotensin II and angiotensin-(1-7) (Fig. 1) according to the nature of the dispersion medium, are molecules that can be detected in the ultraviolet region (UV) at a 190–230 nm range, the detection is not very sensitive. Therefore, the techniques have included the use of fluorescence and electrochemical detectors coupled to HPLC and CE [11–13]. Later on, mass spectrometry detection systems were incorporated, which lowered the level of quantification in industrial and pharmaceutical samples, complicating and limiting severely the analysis of biological fluid studies, because of the complexity of a biological matrix. It has been seen that when highly pure reagents are used and extreme care is given to the management and treatment of the samples, detection through photodiode-array (PDA) in the UV region offers a versatile and low cost alternative for the quantification of a large range of analytes of biological interest, susceptible to be detected in that spectral region in matrices as complex as the blood [12].

There are additional complications in measure real angiotensin II and angiotensin-(1-7) concentrations in a biological sample. Angiotensin II and angiotensin-(1-7) are susceptible to degradation by proteases; therefore, the use of protease inhibitors becomes mandatory, but it sometimes is self-defeating in CE studies because they interfere with the resolution of peaks, complicating the separation and quantification of the peptides [18]. However, the use of protease inhibitors can be omitted if the physicochemical properties that inhibit the proteases are known. Likewise, a pH lower than 3.5 or higher than 9.0 inactivates them; the handling of biological samples at a temperature below 25 °C or above 45 °C, as well as the addition of methanol or acetonitrile, also inhibit their activity [19].

Regarding the quantitative analysis of angiotensinogen derivates with HPLC, a large variety of techniques have been published. The most employed includes the use of monolithic columns coupled to fast protein liquid chromatography (FPLC) [20], as well as the use of reverse phase C18 columns [21] and HPLC with hydroorganic phase systems (water/acetonitrile 1:2 with a 0.1% trifluoroacetic acid gradient) [22]. Another HPLC study, performed by Matsui et al. [23], used RP-C4 columns with fluorometric detection for quantitative analysis of angiotensin II and angiotensin-(1-7) contained in human plasma samples. Sakamoto et al. [24] used cationic exchange liquid chromatography for the analysis of angiotensinogen derivates, using a TSK-sulfopropyl column, which separates nitrated products through a linear ammonium acetate gradient (pH 9.0) at 210 nm in 50 min. Another analytical approach includes the use of western blot and ELISA methods, which are time-consuming and inconvenient procedures for the treatment of multiple samples, additionally the results are not accurate [25,26]. Nowadays, CE techniques are employed to separate molecules with a high resolution and the method has been extended to a large diversity of chemical compounds, as it contemplates the separation based on the number of theoretical plates, which improves considerably its efficiency with respect to HPLC. Other advantages of CE are its low consumption of samples and reagents, use of aqueous disolutions, compatibility with auto-samplers, easy cleaning and conditioning of capillaries, as well as the different modes of electrophoretic separation that can be coupled to diverse detection methods in the same equipment. These latter methods include UV detection, laser-induced fluorescence (LIF) excitation, electrochemical detection and mass spectrometry [18]. Several studies designed for the separation and quantification of angiotensinogen derivates through CE have been published, standing out the use of monolithic capillaries [27], molecular reconditioning through derivatization with macrocyclic polyamine [28], use of capillary isotachophoresis [29], monolithic microextraction using metacrylate-derived polymers [30], immunodetection [31], and by capillary zone electrophoresis

(CZE). This late study involves pre-treatment methodologies that increase the risk of losing the analyte of interest, as well as complex detection systems that focus on the independent quantitative determination of angiotensin II, or angiotensin-(1-7), or any other angiotensinogen derivate in biological samples, mainly urine. Some methodologies have been reported for blood samples in studies related to hypertension [32], endothelial function [33], hypothalamic effect on aortic coarctation [34], and preeclampsia [35], among others. Hence, it is convenient to establish a simple, fast, and robust procedure for simultaneous analysis of angiotensin II and angiotensin-(1-7) in both plasma and urine.

In this study, we developed a methodology through CZE–PDA, with UV detection, for the simultaneous quantification of angiotensin II and angiotensin-(1-7) in biological samples. The parameters assessed for optimization of the separation of the peptides under study were: pH, concentration of the background electrolyte (BGE), applied voltage, injection time and temperature, as well as conditions for PDA detection. For the applicability and optimization of the developed method, the levels of angiotensin II and angiotensin-(1-7) were assessed in the plasma and urine of normotensive and hypertensive rats.

2. Experimental

2.1. Chemicals

Acetic acid, boric acid, chlorhidric acid, ethylenediaminetetraacetic acid, tartaric acid, trichloroacetic acid, angiotensin II, angiotensin-(1-7), cyclosporine A, gold (III) chloride, enalapril, dibasic sodium phosphate, monobasic sodium phosphate, sodium hydroxide and polyvinylpirrolidone were obtained from Sigma Chemical Co. (St. Louis, MO, USA). Methanol was from Mallinckrodt Baker (Xalostoc, Estado de México, México). Angiotensin II (100 μM) and angiotensin-(1-7) (100 μM) stock solutions were prepared in 100 mM phosphate buffer at pH 10, and stored at −70 °C until use. The working standard solutions were prepared daily by dilution of the stock solution with 100 mM phosphate buffer at pH 10. Deionized water (≥18.2 MΩ cm) used throughout the study was obtained with a Simplicity System (Millipore SAS, Molsheim, Alsace, France).

2.2. Apparatus

All experiments were performed with a Beckman Coulter (Fullerton, CA, USA) P/ACE^{TM} MDQ Capillary Electrophoresis System equipped with PDA and controlled by means of the P/ACE MDQ Capillary Electrophoresis System software, version 7.0 (Beckman Coulter Inc., Fullerton, CA, USA). The fused-silica capillary of 57 cm (50 cm to the detector) × 75 μm i.d., manufactured by Polymicro Technologies (Phoenix, AZ, USA) was maintained at 20 °C in a cartridge with a 100 μm × 800 μm detection window. The use of a PDA allowed us to confirm the identity of the peaks, not only by their migration time, but also by the overlay of the UV–vis spectra of the samples with an angiotensin II and angiotensin-(1-7) standards solution. PDA was set at an acquisition range from 190 to 600 nm (bandwidth of 6 nm) at a spectral acquisition rate of 1.25 scans s^{-1} (peak width 0.2 min). A Corning pH/ion analyzer 350 (Corning Inc., Corning, NY, USA) with Hanna HI 1230B combined pH/ORP electrodes (Hanna Instruments, Woonsocket, RI, USA), calibrated with Sigma (St. Louis, MO, USA) reference standard buffers (pH 4.00 ± 0.01, 7.00 ± 0.01, and 10.00 ± 0.01, respectively), was employed for the pH measurement. Mean blood pressure was recorded using a pressure monitor for veterinary use (SurgiVet V60046 NIBP, Smiths Medical PM, Inc., Veterinary, Waukesha, WI, USA), equipped with a pneumatic bracelet (Vetronics VT-1201, VASi Vetronics, Bioanalytical Systems, Inc., West Lafayette, IN, USA).

2.3. Capillary conditioning and electrophoretic separation conditions

To activate a new capillary it was rinsed with 1 M NaOH for 60 min, deionized water for 60 min and finally with the BGE for 60 min, to ensure a clean capillary surface [13]. Daily, before the first sample injection, the capillary was flushed with 1 M NaOH for 2 min, followed by deionized water for 2 min and finally with the BGE for 4 min. Samples were introduced from the anodic end of the capillary by hydrodynamic injection for 10 s at 0.5 psi. PDA was set at an acquisition range from 190 to 600 nm (bandwidth of 6 nm) at a spectral acquisition rate of 1.25 scans s^{-1} (peak width 0.2 min). As BGEs, several solutions were prepared as follows: a 100 mM phosphates buffer at pH 2.05 was prepared by mixing equal volumes of a 55.73 mM H_3PO_4 solution and a 44.27 mM $NaH_2PO_4{\cdot}H_2O$ solution, and then the volume of the mixture was adjusted to 100 mL with deionized water; a 100 mM borates buffer at pH 9.00 was prepared by mixing equal volumes of a 68.57 mM H_3BO_3 solution and a 31.43 mM $Na_2B_4O_7{\cdot}10H_2O$ solution. Then, the volume of the mixture was adjusted to 100 mL with deionized water; a mixed buffer of boric acid, tartaric acid and gold chloride (III) at pH 9.80 was prepared by mixing equal volumes of a 100 mM H_3BO_3 solution, 3 mM $HO_2CCH(OH)CH(OH)CO_2H$ solution and 10 fM $AuCl_3$ solution. Then the volume of the mixture was adjusted to 100 mL with deionized water. Before use, BGEs based on borates were adjusted accurately to the desired pH value with either 0.1 M HCl or 0.1 M NaOH, whereas BGE based on phosphates was adjusted to the desired pH value with the addition of 0.1 M H_3PO_4. All BGEs were degassed by sonication (T490DH instrument, Elma, Singen, Germany), and filtered through 0.22 μm mixed cellulose ester filters (Millipore, Billerica, MA, USA). Unless otherwise stated, no more than 100 μL of 0.1 M HCl, 0.1 M NaOH or 0.1 M H_3PO_4 were required for pH adjustment. All operations were performed at 25 ± 0.5 °C. To avoid BGE and sample evaporation, BGE and sample reservoirs were capped. The migration times corresponding to the electroosmotic flow (EOF) were determined conventionally by injecting DMSO as the EOF marker. Between runs, a rinse cycle was performed by flushing the capillary with 1 M NaOH for 2 min followed by deionized water for 2 min, and then with BGE for 4 min. Data acquisition was achieved with a ThinkCentre (IBM Corporation, White Plains, NY, USA) workstation.

2.4. Animals

For this study, male Wistar rats (500–550 g) normotensive and hypertensive, maintained at the animal facility of the Instituto Nacional de Cardiología "Ignacio Chávez" were used. They were housed under standard conditions of temperature and light (12-h light:12-h dark cycle) and fed standard diet (Labdiet 5008, PMI International Nutrition, Richmond, IN, USA) and tap water *ad libitum*. All animal procedures were conducted in accordance with our Federal Regulations for Animal Experimentation and Care (Ministry of Agriculture, SAGARPA, NOM-062-ZOO-1999, Mexico), which follows the Guidelines for Care and Use of Laboratory Animals, and were approved by the Institutional Animal Care and Use Committee. During the experiments, all efforts were made to minimize animal suffering.

2.5. Induction of hypertension

Normotensive rats (200 ± 5 g), were made hypertensive through the chronic administration of cyclosporine A (10 mg/kg/day) dissolved in polyvinylpirrolidone (45% in H_2O, $M_r \approx 160{,}000$) and subcutaneously administered (400 μL/day) for 60 days (until animals reached 500–550 g body weight), according to Bartholomeusz et al. [36] and Phillips et al. [37]. Research started once animals were

confirmed to be hypertensive, by monitoring their mean arterial pressure.

2.6. Antihypertensive treatment

Enalapril, an angiotensin converting enzyme (ACE) inhibitor, was used for the antihypertensive treatment, at a 20 mg/kg/day dose, administered in the drinking water during 12 weeks. Animals were divided in four study groups: (1) normotensive control; (2) hypertensive control; (3) normotensive + enalapril; and (4) hypertensive + enalapril.

2.7. Measurement of mean arterial pressure

Mean arterial pressure of rats was monitored through a non-invasive technique by using a veterinary-use device, connected to a pneumatic bracelet at 0.5 cm from the base of the tail. Animals were placed in a smoked-acrylic box. Before starting arterial pressure measurements, animals were familiarized with the equipment and the personnel in charge of their handling to minimize stress. The adaptation period for each animal was of 5 min before starting the readings.

2.8. Preparation of biological samples

Blood samples, anticoagulated with ethylenediaminetetraacetic acid (1 mg/mL of blood), were centrifuged at 3500 rpm for 5 min at 10 °C (Sorvall RT 6000D, DuPont, Newtown, CT, USA). The obtained plasmas were preserved at −70 °C in cryogenic tubes (SARSTEDT AG & Co., Rommelsdorfer, Nümbrecht, Germany) until use. Samples were gradually thawed and maintained at a temperature of 10–15 °C. The plasma was deproteinized with methanol at a 10:1 proportion, homogenized and centrifuged at 16,000 × *g* for 15 min at 4 °C (Sorvall RC-28S, rotor SS34, DuPont, Newtown, CT, USA). Pellet was discarded and supernatant was deproteinized by the addition of 20% trichloroacetic acid, homogenized and centrifuged at 16,000 × *g* for 15 min at 4 °C. Supernatant was filtered through 0.22 μm nitrocellulose membrane filters (Millipore, Billerica, MA, USA), diluted 1:10 with 0.1 M NaOH, the sample (2 mL) was passed through a Sep-Pak Classic C-18 cartridge (Waters Corporation, Milford, MA, USA). A volume of 100 μL was employed for the CZE–PDA analysis. Urine preserved with 4% acetic acid (120 μL of the acid/2 mL of urine) was centrifuged at 6000 × *g* for 10 min at 4 °C. Supernatant was filtered through 0.22 μm nitrocellulose membrane filters, diluted 1:10 with 0.1 M NaOH and passed (2 mL) through a Sep-Pak Classic C-18 cartridge. 100 μL were employed for the CZE–PDA analysis.

2.9. Statistical analysis

Data analysis was carried out using SPSS 12.0.1 for Windows software (SPSS Inc., Chicago, IL, USA) with one-way analysis of variance (ANOVA) followed by a Student's *t*-test for independent samples. All results are expressed as the mean ± standard deviation of 10 independent determinations. A value of $p < 0.05$ was considered as statistically significant.

3. Results and discussion

3.1. Optimization of the test electrophoretic procedure

To optimize the CZE–PDA separation of angiotensins II and 1-7 from other compounds present in the analyzed matrix (plasma and urine), the effect of several variables was systematically explored: pH of the BGE (2.05, 9.00, and 9.80), BGE concentration (20–150 mM), applied voltage (5–30 kV), injection time (4–12 s), temperature (15–25 °C), as well as PDA conditions.

3.1.1. Effect of pH

It has been repeatedly demonstrated that the inner wall of the fused-silica capillary is a potential site for interactions among the separated analytes [18], because it controls the electroosmotic speed and provides active centers for adsorption of multiple charged molecules as are proteins [18]. This effect not only fosters loss but also decreases reproducibility and efficiency of the system. In CE, proteins can adsorb to the capillary wall causing alterations of the EOF and band broadening. The use of non-coated fused-silica capillaries the adsorption of proteins in the capillary wall can lead to a very poor migration time and low plate number. In order to minimize such effects, the separation of protein mixtures is run at extreme pH values, by which either the dissociation of the silanol groups of the capillary wall is minimized (at acid pH) or the dissociation of free amino groups of the proteinous solutes is decreased (at high pH values) [18]. On the other hand, pH regulation is an important purpose of the BGE in order to keep the migration velocity of the analytes and the velocity of EOF constant. In this way, a stable and reproducible migration behavior of the sample components can be obtained [18].

In CZE, the whole system is filled with a BGE, whose main purposes are to transport the electrical current if a voltage is applied over the system, to provide an electrical field strength and to facilitate the separation of the analytes. Optimization of the CE system started by selecting the BGE for the analysis of angiotensins II and 1-7 contents on biological samples (plasma and urine). For this purpose, the following buffer solutions were selected as BGEs: a 100 mM phosphate buffer at pH 2.05 (which may favor positive mobility since the net charge of the angiotensin II and angiotensin-(1-7) is positive at pH 2.05) [38], a 100 mM borate buffer at pH 9.00 (chosen because of its ability to generate an increase in the silanol groups charge, which intensifies the EOF, allowing thereby to mobilize rapidly molecules with high negative charge, as are proteins. It was also selected because borate can chelate the analytes to form more soluble complex anions) [38], and finally, a mixed buffer containing 100 mM boric acid + 3 mM tartaric acid + 10 fM gold (III) chloride at pH 9.80 (chosen due to the capacity of boric and tartaric acids to form stable chelates in a pH range from 9 to 10 with the analytes of interest) resulting in more soluble anionic complexes that can generate alterations in the charge arrangement of silanol groups that, in turn, alter EOFs intensity; the latter is minimized by the addition of small ionic molecules, such as Cu^{2+} and Au^{3+} to the BGE [39], or by inverting the EOF direction by the addition of cetyltrimethylammonium [40]. Under the experimental conditions, a 10 pmol/mL standard solution of angiotensin II and, separately, a 10 pmol/mL standard solution of angiotensin-(1-7), prepared in 100 mM phosphate buffer at a pH 10.0 showed an adequate behavior with all chosen BGEs. However, to explore whether each BGE showed an adequate performance when real samples were analyzed, it was decided to analyze plasma and urine samples of both normotensive and hypertensive animals, and were either unspiked or spiked with a angiotensin II (1, 150, and 400 pmol/mL) and angiotensin-(1-7) (1, 150, and 400 pmol/mL) standard solution prepared in 100 mM phosphate buffer at a pH 10.0. Then, performance parameters such as resolution, peak area and plate number were calculated for unspiked or spiked samples. Under this scheme, we found that at a low pH, resolution decreases (Fig. 2A). In order to achieve an adequate separation, the peak area and the plate number were calculated. It was observed that the best resolution (Fig. 2A), plate number (Fig. 2B) and peak area (Fig. 2C) were obtained when employing as BGE a 100 mM boric acid + 3 mM tartaric acid + 10 fM gold (III) chloride buffer at pH 9.8. Although a more convenient migration time (Fig. 2D) was

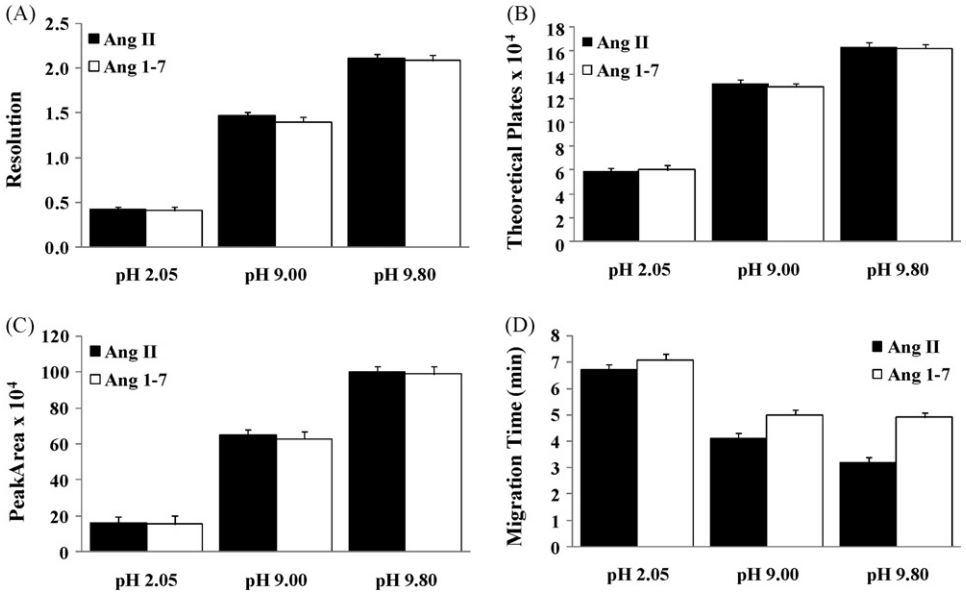

Fig. 2. Influence of the BGE pH on resolution (A), plate number (B), peak area (C) and migration time (D) of angiotensin II (Ang II) and angiotensin-(1-7) (Ang 1-7). Mean and standard deviation of 10 experiments are depicted.

obtained at pH 9.8, based on results obtained with respect to resolution, plate number and peak area, respectively, it was decided to employ a 100 mM boric acid + 3 mM tartaric acid + 10 fM gold (III) chloride buffer (pH 9.8) for further experiments. In addition, it was observed that with BGEs based on 100 mM phosphate buffer at pH 2.05 or on 100 mM borate buffer at pH 9.00, angiotensins (II and 1-7) and its coexisting interferences could not be separated well in these electrolyte solutions. Moreover, at high pH values, the analyte could be more susceptible to oxidation, this can be minimized by reducing the temperature of the disolution medium [39,41]. However, although it was initially hypothesized that angiotensins II and 1-7 may display a negative mobility because of their peptide nature, calculation of its effective electrophoretic mobility (μ, expressed in $m^2\,v^{-1}\,s^{-1}$), showed that angiotensin II μ was not opposite to the EOF ($\mu = 320.11\,m^2\,v^{-1}\,s^{-1}$). The same occurred for angiotensin-(1-7) ($\mu = 146.41\,m^2\,v^{-1}\,s^{-1}$). EOF effective electrophoretic mobility (μ_{EOF}) was calculated as $175.96\,m^2\,v^{-1}\,s^{-1}$ [42,43].

3.1.2. Effect of BGE concentration

The concentration of the BGE plays an important role in separation resolution in electrophoresis. If a constant voltage is applied over the capillary, the electric current will increase at higher BGE concentrations and this can cause extra peak broadening due to a strong increase in Joule heat. Provided that the generated Joule heat is not too high to affect peak efficiency, a higher buffer concentration can produce better peak shapes at high analytic concentrations and will lead to improved peak reproducibility [44]. Our previous experiments showed that the most adequate pH analyzed to study biological samples was 9.80 [44,45]. Therefore, the next step was to study the influence of BGE concentration, in the range 20–120 mM, on the separation of angiotensin II and angiotensin-(1-7). At BGE concentrations above 100 nM boric acid, keeping constant the tartaric acid concentration (3 mM) and that of gold (III) chloride (10 fM), unacceptably high currents were observed (data not shown). As the BGE concentration increased, both the resolution (Fig. 3A) and plate number (Fig. 3B) increased, achieving a resolution of 2.11 and a plate number of approximately 163,000 for angiotensin II. For angiotensin-(1-7) a resolution of 2.09 and a plate number of 162,100 was observed when 100 mM boric acid + 3 mM tartaric acid + 10 fM gold (III) chloride buffer at pH 9.8 was employed. The increase of the plate number observed for the positively charged angiotensin II and angiotensin-(1-7) is probably due to a reduced interaction with the capillary wall and not to a stacking, which is more apparent when the difference of conductivity between the BGE and the injection zone is very large.

3.1.3. Effect of the applied voltage

Ideal separation in CZE is usually obtained by using a voltage as high as possible in order to obtain the best separation in the shortest time with the best efficiency. However, high voltage lead to difficult heat dissipation during the electrophoretic separation due to Joule heat, which is known to affect the EOF, diffusion of analytes, and therefore, the efficiency and reproducibility of the separation.

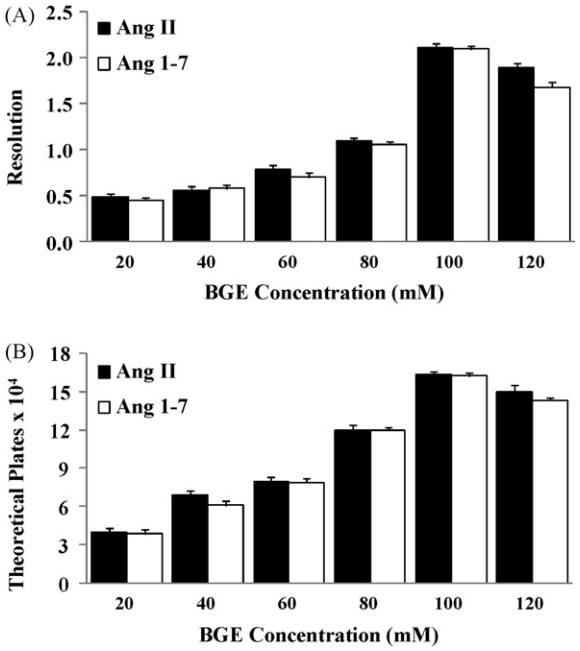

Fig. 3. Effect of BGE concentration on resolution (A) and plate number (B) of angiotensin II (Ang II) and angiotensin-(1-7) (Ang 1-7) of plasma and urine. Mean and standard deviation of 10 experiments are depicted.

For this reason, it is important to control this phenomenon [44]. To choose the most appropriate voltage in the electrophoretic separation, the effect of the voltage applied from 5 to 30 kV (steps of 5 kV) was investigated. A voltage of 30 kV of positive polarity, yielded the best compromise in terms of lower migration times and higher areas and resolutions.

3.1.4. Optimization of the injection time

In order to decrease the limit of detection, the injection time was varied between 4 and 12 s (steps of 2 s). As expected, when the injection time increased, the peak area of all compounds also increased, but for injection times lower than 10 s, a loss of resolution between peaks was observed. For this reason, a 10 s injection time was chosen as optimal value, while the separation efficiency remained largely unchanged. In all cases, the injection pressure was kept constant at 0.5 psi.

3.1.5. Effect of temperature

Changes in capillary temperature can cause variations in efficiency, viscosity, migration time, injection volumes and detector response. Temperature variations and corresponding changes in viscosity have been determined to be detrimental to obtain reproducible results [41,44]. The effect of temperature on the separation was investigated in the range 15–30 ± 0.5 °C (steps of 5 ± 0.5 °C). As temperature increases, the viscosity of the buffer decreases, so the resistance of the buffer decreases [41]. The decrease in the migration times of angiotensin II and angiotensin-(1-7) results in poor resolution, which might be caused by the direct effect of temperature on the rate of EOF, that might be increased, and buffer depletion occurs more rapidly. More directly, changes in viscosity alter the injected amount when using hydrodynamic injection. Therefore, the selected temperature was 20 ± 0.5 °C because it resulted in the best resolution.

3.1.6. Selection of optimal wavelength

Maximal absorption for angiotensin II and angiotensin-(1-7) lies in the range from 190 to 230 nm, at a pH of 2–12, this variation depends on the nature of the analytes dissociation medium [19]. We performed a spectral scan with a mixture of the standard solutions, in a 190–600 nm range, dissociated in 100 mM phosphate buffer at pH 10.0 [19]. The maximal absorption for the mixture of angiotensin II more angiotensin-(1-7) was 200 nm (Fig. 4A). A similar analysis of biological samples (plasma and urine) for the quantitative analysis of angiotensin II and angiotensin-(1-7), revealed that these molecules was best detected at 200 nm (Fig. 4B and C). Therefore, this wavelength was selected for the quantitative analysis of angiotensin II and angiotensin-(1-7) in plasma and urine.

The above results revealed that optimal separation conditions were: 100 mM boric acid + 3 mM tartaric acid + 10 fM of gold (III) chloride buffer, pH 9.80, applied voltage 30 kV, hydrodynamic injection mode at 0.5 psi for 10 s, capillary cartridge temperature maintained at 20 ± 0.5 °C and PDA operating at 200 nm (bandwidth 6 nm). Fig. 5 shows the electropherograms obtained for plasma and urine samples from normotensive and hypertensive animals, which were employed for the quantitative determination of angiotensin II and angiotensin-(1-7) release under the proposed experimental conditions.

3.2. Validation of the electrophoretic procedure

The protocol for the validation of the method encompassed stability, linearity, precision, specificity, limit of detection, limit of quantitation, recovery and robustness.

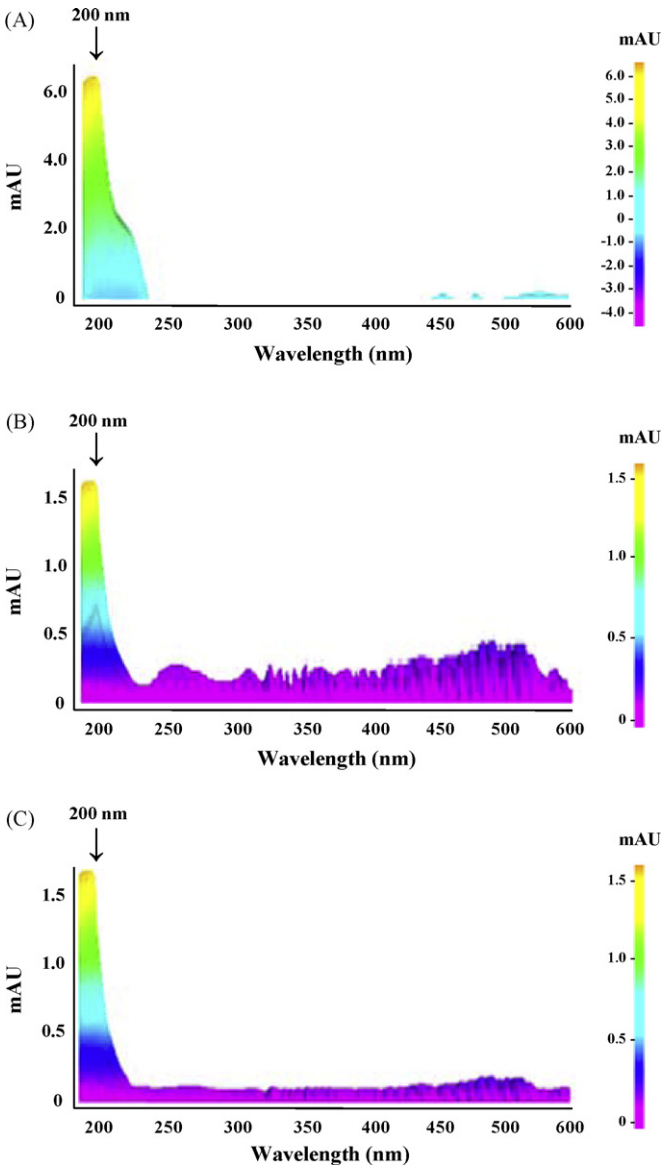

Fig. 4. UV–vis spectrum for a mixture of angiotensin II (10 pmol/mL) and angiotensin-(1-7) (10 pmol/mL) standards solution prepared in phosphate buffer (A). UV–vis spectrum for a plasma sample (B) and urine sample (C) from normotensive animals, were employed for the quantitative analysis of angiotensin II and angiotensin-(1-7).

3.2.1. Stability of the solutions

The stability of the standards and test solutions of angiotensin II and angiotensin-(1-7) was determined by comparing the response factors (concentration/average peak areas) of triplicate solutions stored at 4 °C, in darkness, with those of freshly prepared triplicate solutions. A concentration difference greater than 2% was found between the freshly prepared standard solutions and the solutions prepared 10 days before. For this reason, it is advisable to employ freshly prepared angiotensin II and angiotensin-(1-7) solutions (Table 1A).

The stability of unspiked and spiked biological samples (plasma and urine) was evaluated by comparing the relation peak areas obtained at different time intervals with those of freshly prepared biological samples. It was found that the biological samples were stable for at least 8 h (Table 1B). For this reason, we recommended that CZE–PDA analysis must be carried out within this period of time after the preparatory of such biological samples.

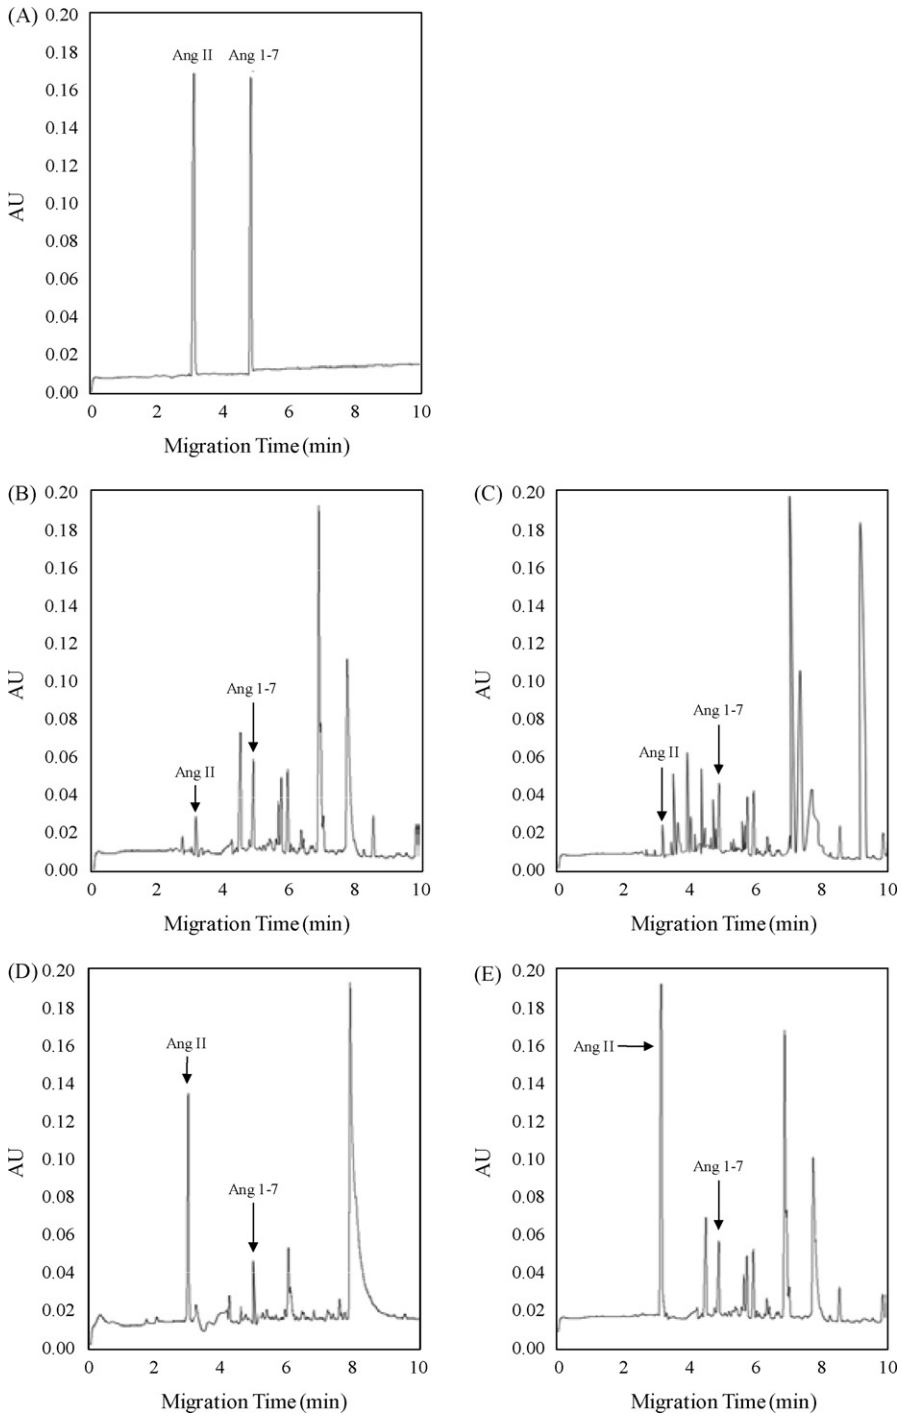

Fig. 5. Electropherogram obtained for a mixture of 10 pmol/mL angiotensin II (And II) and 10 pmol/mL angiotensin-(1-7) (Ang 1-7) standards solution prepared in phosphate buffer (A). Electropherograms obtained from a urine sample (B) and a plasma sample (C) of normotensive animals; of a urine sample (D) and a plasma sample (E) of hypertensive animals are also shown.

3.2.2. Linearity

Linearity is the ability to show that the results are directly proportional to the analytes concentrations in samples within a given range. The sample matrix can affect the area and migration rate of angiotensin II and angiotensin-(1-7) when real samples are analyzed in the CZE system, causing deviations from those of pure standards. Therefore, the quantitation of angiotensin II and angiotensin-(1-7) was performed by applying standards addition technique for plasma and urine. However, according to our experience, the conventional quantitation based on a calibration curve created by prepared standard solutions can be applied as well. To assess the linearity of the proposed CZE–PDA method, six independent calibration plots, analyzed per triplicate, were constructed over the calibration range of 0.1–800 pmol/mL. The curves were prepared on five different days, and linear regression was evaluated. Analytical figures of merit are shown in Table 2.

3.2.3. Precision

The precision of a method is determined by the extent to which the test results of multiple injections of standards agree. The precision of the proposed method is expressed in terms of relative standard deviation (RSD). In order to test the precision of the over-

Table 1A
Stability of the solutions.

Stored	Analyte solution	Time after preparation (days)	Analyte content (pmol/mL)
At 4 °C	Ang II	0	20.00 ± 0.02
		10	17.53 ± 2.52
	Ang 1-7	0	20.00 ± 0.03
		10	16.99 ± 3.69
In darkness	Ang II	0	20.00 ± 0.03
		10	17.87 ± 3.07
	Ang 1-7	0	20.00 ± 0.03
		10	16.49 ± 343
Freshly prepared	Ang II	0	20.00 ± 0.02
	Ang 1-7	0	20.00 ± 0.03

The optimal conditions were used. Results are expressed as mean ± standard deviation of three independent measurements. Ang II: angiotensin II; Ang 1-7: angiotensin-(1-7).

all process, five different samples of plasma and urine spiked with angiotensin II and angiotensin-(1-7) were carried out sequentially. The precision of the migration times and relative peak area were good with a RSD between 0.20% and 0.24% for migration times and between 1.18% and 2.05% for relative peak areas.

3.2.4. Specificity

Specificity can also be determined by measurement of peak homogeneity. Because there are different techniques available for PDA and they vary for the detection of possible impurities or interferences in an electrophoretic peak, the use of several techniques is recommended [45]. In this work, the techniques used to validate the peak purity of angiotensin II and angiotensin-(1-7) present in the plasma and urine were [46]: (a) normalization and comparison of spectra from different peak sections; and (b) absorbance at 200 nm. Both techniques revealed a high level of purity of the peaks corresponding to the studied compounds in the samples.

3.2.5. Limits of detection (LOD) and quantitation (LOQ)

The limit of detection (LOD), defined as the lowest concentration of an analyte that the analytical procedure can reliably differentiate from background noise; was evaluated based on a signal-to-noise ratio (S/N) of 5 (S/N = 5) [46]. The limit of quantification (LOQ), is defined as the level at, or above, in which the measurement precision is satisfactory for quantitative analysis. In our case, the LOQ was evaluated based on an S/N = 5 [46]. Results are shown in Table 2.

3.2.6. Recovery

Recovery is reported as the extraction efficiency of an analytical process, reported in percentage. It should be emphasized that the lack of suitable internal standards requires finding alternative ways to evaluate the recovery of angiotensin II and angiotensin-(1-7). In order to test the accuracy of the proposed method, several aliquots of angiotensin II and angiotensin-(1-7) standard solutions were added into the plasma and the urine. As can be observed in Table 3, good results were obtained. Recoveries of an added amount were calculated by using the calibration curves, taking into account the endogenous angiotensin II and angiotensin-(1-7) concentrations.

3.2.7. Robustness

Robustness is an important feature in the development of analytical methods since it evaluates the influence of small changes in the operating conditions of the analytical procedure on measured or calculated responses. Since variables such as BGE, pH, as well as its concentration, proved to be crucial in early stage of method development, it was decided to explore whether deliberate changes in these parameters could affect the CZE–PDA separation. Results showed that selectivity was good enough for all the responses in

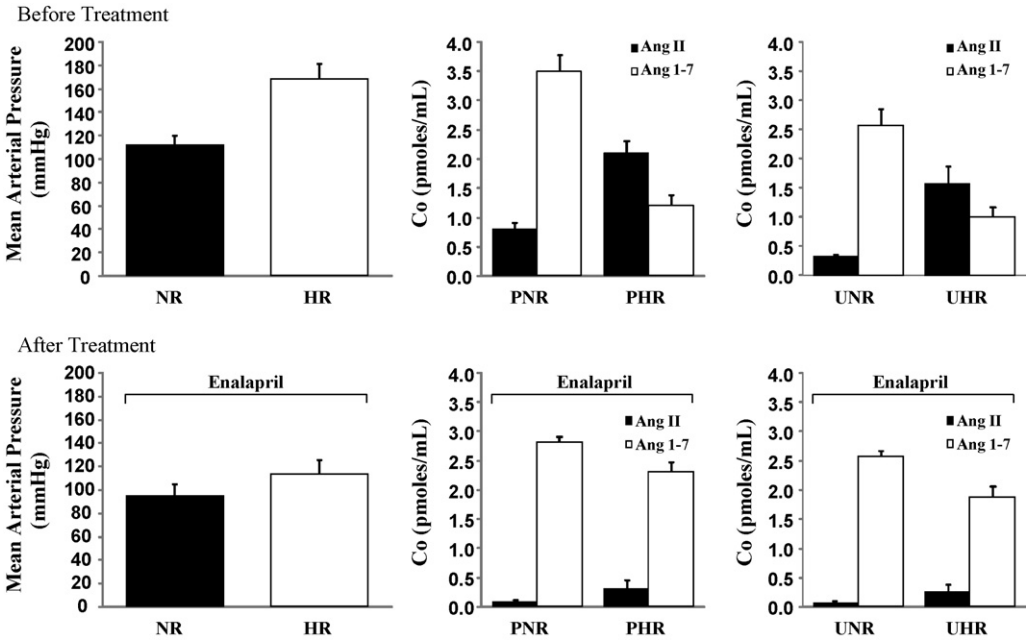

Fig. 6. Mean arterial pressure measurements of normotensive and hypertensive animals, before and after enalapril treatment. Results of angiotensin II (Ang II) and angiotensin-(1-7) (Ang 1-7) levels measured in plasma and urine of normotensive and hypertensive animals, before and after enalapril treatment. Results correspond to the mean ± SD of 10 experiments per study group. NR: Normotensive rats; HR: Hypertensive rats; UNR: Urine of normotensive rats; UHR: Urine of hypertensive rats; PNR: Plasma of normotensive rats; PHR: Plasma of hypertensive rats.

the buffer pH range from 9.00 to 10.00. Boric acid concentration is restricted from 95 to 105 mM in order to have a resolution greater or equal to 2.0. It means that the method is robust within this range.

3.3. Applications

3.3.1. Hypertension induction study

In order to test the applicability of the method, a hypertensive study was performed during 60 days and samples from plasma and urine from normotensive and hypertensive animals were analyzed with the developed CZE–PDA method. Under the optimized conditions, angiotensin II, angiotensin-(1-7) and unknown compounds, were all successfully separated. Angiotensin II and angiotensin-(1-7) produced, respectively, a single peak and was sufficiently resolved from other unknown endogenous compounds to permit accurate determination (Fig. 5). The concentration of angiotensin II and angiotensin-(1-7) (expressed as mean ± standard deviation) found in these samples, using the proposed method, as well as results from recovery experiments, are shown in Table 3. It has been repeatedly demonstrated that angiotensin II and angiotensin-(1-7) derive from the renin–angiotensin system. The renin secreted by the juxtaglomerular apparatus of the kidney acts upon a precursor, angiotensinogen, to generate angiotensin I, which has few pressor effects and is converted by ACE, during its lung passage, into angiotensin II that is a potent vasopressor that acts together with the G protein by coupling to receptors AT1 and AT2. Stimulation of AT1 receptors induces deleterious effects, such as vasoconstriction, myocardial hypertrophy, vascular cell proliferation, release of catecholamines, antidiuretic hormone, and stimulates thirst. To counteract these effects, the angiotensin converting enzyme inhibitor (ACEI) decrease arterial pressure rapidly by avoiding the transformation of angiotensin I in angiotensin II. In consequence, ACEI induce prolonged hypotensive responses. Although, at the beginning it was thought that ACEIs would only be efficacious in patients with high activity of the renin–angiotensin system, it has been observed that ACEIs are also efficacious in patients with a normal or even scarce activity of the renin–angiotensin system [10,11]. This fact suggested that, aside from the inhibition in angiotensin II production, there might be other mechanisms that would explain the hypotensive action of ACEIs. In this regard, inhibition of ACE increases angiotensin-(1-7) levels, because angiotensin I, by not being degraded to angiotensin II by ACE, which is inhibited, is degraded by neutral endopeptidases (NEP 24.11, NEP 24.15, and NEP 24.26) to angiotensin-(1-7) [7]. The prototype drug of the ACEIs group is captopril, a dipeptide that binds to the active site of ACE through a sulfhydril group (–SH) and acts as a competitive inhibitor of ACE. Another ACEI, the dipeptide enalapril, is administered orally as a pro-drug and it has to be transformed in the liver to its active metabolite, enalaprilate, hence, its antihypertensive effects start more slowly than those of captopril, although it is more potent and has a longer half life, it lacks the –SH group. In this *in vivo* study in which we used enalapril to control the induced hypertension, and measured angiotensin II and angiotensin-(1-7) in both plasma and urine of normotensive and hypertensive rats by means of the CZE–PDA, we observed that in hypertensive animals, as verified by monitoring the mean arterial pressure, the levels of angiotensin II were considerably elevated, whereas angiotensin-(1-7) was decreased compared with normotensive animals and before enalapril treatment (Fig. 6). After enalapril treatment at a dose of 20 mg/kg per day during 12 weeks, the mean arterial tension of the hypertensive rats decreased substantially as a consequence of a decrement in angiotensin II levels and an increment in angiotensin-(1-7) levels (Fig. 6). On other side, we were able to confirm that the primary pharmacological effect of ACEIs (reduction of arterial pressure) is also exerted on normotensive rats, as their mean arterial pressure was also decreased (Fig. 6), this is due to the reduction in angiotensin II levels by the blocking effect of enalapril by hindering the conversion of angiotensin I into angiotensin II, allowing for conversion of angiotensin I into angiotensin-(1-7), increasing levels of the latter in normotensive rats (Fig. 6).

4. Conclusion

The determination of angiotensin II and angiotensin-(1-7) in complex biological samples is an analytical challenge. Therefore,

a simple, rapid and sensitive capillary electrophoresis method has been developed for the simultaneous quantitative analysis of angiotensin II and angiotensin-(1-7) in both plasma and urine from rats. Although these analytes have been previously analyzed by HPLC with PDA using 190 and 230 nm detection, this is the first report, to our best knowledge, that deals with the simultaneous determination of angiotensin II and angiotensin-(1-7) in plasma and urine obtained from normotensive and hypertensive rats in an *in vivo* model. Compared to previous HPLC [23,24] and CE [30,41,47,48] methods, this method obtains comparable LOD (angiotensin II, 0.0110 pmol/mL; angiotensin-(1-7), 0.0112 pmol/mL) and LOQ (angiotensin II, 0.0195 pmol/mL; angiotensin-(1-7), 0.0193 pmol/mL) for these analytes. However, in previously reported methods, a non-linear response between peaks area and amount of angiotensin II and angiotensin-(1-7) below 0.011 pmol/mL has been observed (Table 2). The proposed CZE–PDA method has been validated and the reliability of the electrophoretic procedure for its desired application was demonstrated by means of the experimental results regarding linearity, accuracy, specificity, sensitivity and precision. Major advantages of the present CE method are the use of PDA detection and that no sample pretreatment other than filtration is needed, as well as no need to use coating and previous derivatization of the capillary, compared to previous CE methods with UV absorbance detection. The proposed CZE–PDA provides similar results regarding analysis time and recovery, with advantage of simultaneous detection of both analytes in complex matrices like plasma and urine. In addition, this method may be useful to elucidate the role of renin–angiotensin system, in particular in cases of hypertension, which is a fact that has attracted considerable attention as a potentially reversible cause of cardiac and systemic functional deterioration.

Core–shell polymer
Stereoisomer separation

ABSTRACT

Three monodispersed, molecularly imprinted polymers (MIPs) for cinchonidine (CD) have been synthesized by precipitation polymerization. MIP1 was prepared using methacrylic acid (MAA) as a functional monomer and divinylbenzene (DVB) as a cross-linker and MIP2 was prepared with further addition of 2-hydroxyethyl methacrylate (HEMA) as a co-monomer. For the preparation of MIP3, core–shell type MIP, monodispersed DVB homopolymers, which are prepared by precipitation polymerization, were used as a core and CD-imprinted MAA–DVB copolymer phases were coated onto the core. Three MIPs synthesized gave monodispersed, spherical beads in micrometer sizes. The binding characteristics and molecular recognition properties of MIP1–3 were examined by Scatchard analysis and chromatographic studies. The association constant of CD with MIP1 was the highest among MIPs prepared, while that with MIP3 was the lowest. The template molecule, CD, was more retained than its stereoisomer, cinchonine, on the three MIPs, and the stereoseparation factor of 38 was obtained with MIP3.

1. Introduction

Typically, molecularly imprinted polymers (MIPs) were prepared by a bulk polymerization method, where the resultant monoliths had to be crushed, ground and sieved to produce microparticles for their applications [1]. In recent years, monodispersed MIPs as selective stationary phases for a given target analyte in HPLC have gained significant interests due to their high column efficiencies [2]. Several synthetic strategies such as multi-step swelling and polymerization [3,4], precipitation polymerization [5,6] and grafting or coating thin films of MIP phases onto the surfaces of spherical materials [7–9] have been reported for the preparation of monodispersed MIP beads. Precipitation polymerization seems to be an attractive and straightforward method. This method involves dissolution of prepolymerization mixtures (functional monomer, template molecule, cross-linker and initiator) in a suitable solvent and their polymerization. Monodispersed MIP microspheres for theophyllin [6], thiabendazole [10], (*S*)-nicotine [11], 17β-estradiol [12] and propranolol [13] have been prepared by this method. Recently, Li and Stöver [14] reported to prepare monodispersed, core–shell microspheres by precipitation polymerization. We were hence interested in preparing monodispersed, core–shell type MIPs by precipitation polymerization.

Cinchonidine (CD) and its stereoisomer, cinchonine (CN), are cinchona alkaloids, which have antimalarial activities. The presence of rigid structures, bulky groups and hetero-atom functionalities in their molecules could give the possibility of forming a good molecularly imprinting site [15]. MIPs for CD and CN have been prepared using methacrylic acid (MAA) as a functional monomer and ethylene glycol dimethacrylate (EDMA) as a cross-linker by bulk polymerization [15], *in situ* polymerization [16], and multi-step swelling and polymerization [17] methods. The MIPs prepared by the three methods gave high stereoseparation factors for CD and CN [15–17]. In this study, three monodispersed MIPs for CD have been synthesized by precipitation polymerization. MIP1 was prepared using methacrylic acid (MAA) as a functional monomer and divinylbenzene (DVB) as a cross-linker and MIP2 was prepared with further addition of 2-hydroxyethyl methacrylate (HEMA) as a co-monomer. For the preparation of MIP3, core–shell type MIP, monodispersed DVB homopolymers, which are prepared by precipitation polymerization, were used as a core and CD-imprinted MAA–DVB copolymer phases were coated onto the core. The binding characteristics and molecular recognition properties of the three MIPs were examined by Scatchard analysis and chromatographic studies.

2. Experimental

2.1. Materials

MAA, DVB (a mixture of *m*- and *p*-DVB), HEMA and 2,2′-azobis(isobutyronitrile) (AIBN) were purchased from Wako (Osaka, Japan). CD and CN were purchased from Tokyo Kasei (Tokyo, Japan). Other reagents and solvents of an analytical-reagent grade were

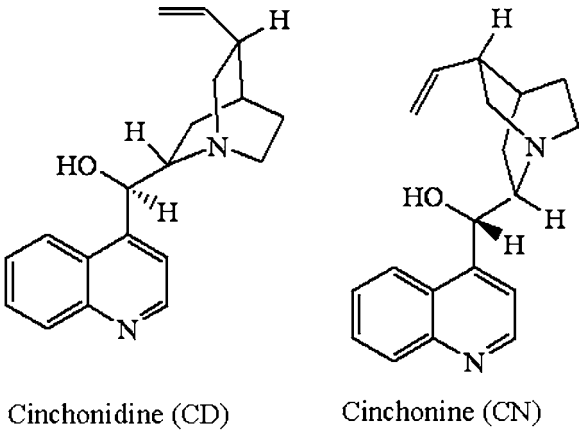

Fig. 1. Structures of compounds used in this study.

used without further purification. Water purified with a Purelab ultra (Organo, Tokyo, Japan) was used to prepare mobile phases and sample solutions. The structures of CD and CN are illustrated in Fig. 1.

2.2. Preparation of MIPs by a precipitation polymerization method

Table 1 shows the molar amounts of a template molecule, functional monomer and cross-linker used for the preparation of MIP1–3. Non-imprinted polymers (NIPs) were prepared similarly without a template molecule. MIP1 and MIP2 were prepared by one-step precipitation polymerization. For the preparation of MIP1, CD, MAA and DVB were dissolved with 0.475 mmol of AIBN in 32 mL of acetonitrile–toluene (3:1, v/v). In the case of MIP2, HEMA was further added as a co-monomer. The mixture was degassed with an argon gas for 15 min and then rotated slowly at 16 rpm using a Shellspin VS-60 rotor (Taitec, Tokyo, Japan). Reaction temperature was raised from 25 to 60 °C for 2 h and then kept at 60 °C for 15 h.

MIP3 was prepared in two successive precipitation polymerization processes. In the first reaction stage, 3.35 mmol of DVB were dissolved with 0.061 mmol of AIBN in 25 mL of acetonitrile and were polymerized at 70 °C for 6 h, resulting in the formation of monodispersed DVB homopolymers [poly(DVB)] used as a core. For the second reaction stage, CD, MAA, DVB and 0.061 mmol of AIBN dissolved in 25 mL of acetonitrile–toluene (1:1, v/v) were introduced into the same reaction vessel and the mixture was polymerized at 70 °C for 12 h, resulting in the formation of the imprinted shell. For each reaction period, the mixture was degassed with an argon gas for 15 min and then rotated slowly at 16 rpm using a Shellspin VS-60 rotor (Taitec). Reaction temperature was raised from 25 to 70 °C for 2 h and then kept at 70 °C for time intervals described above.

After polymerization, a dispersion of polymerized particles was poured into 200 mL of methanol and the supernatant was discarded after sedimentation of the particles. The obtained polymers were redispersed into methanol, and this procedure was repeated three times in methanol, once in water, and twice in tetrahydrofuran. The resulting μm-sized polymer particles were collected using a membrane filter, washed with tetrahydrofuran and dried at room temperature.

2.3. Porosity measurements

Surface areas and porosity of MIPs, NIPs and poly(DVB) were measured by nitrogen sorption porosimetry using a TriStar surface area and porosity analyzer (Micrometrics Instrument, Norcross, GA, USA). Prior to measurement, 200 mg of the particles were heated at 80 °C for 5 h in vacuo. The specific surface areas were calculated using the BET method, and the specific pore volumes and average pore diameters were calculated according to the BJH method.

2.4. Scanning electron micrographs

Scanning electron micrographs (SEMs) were performed on MIP1–3, NIPs and poly(DVB) using a Mighty-8 instrument (Technex, Machida, Tokyo, Japan).

2.5. Scatchard analysis

A 10 mg weight of MIP, NIP or poly(DVB) was added to 1 mL of acetonitrile including 0.09–1.2 mmol L^{-1} CD. After shaken at 25 °C for 24 h, an aliquot of each sample was taken and filtrated with a 0.45-μm membrane filter. The concentration of free CD, [CD], in the supernatant was determined by HPLC under the following conditions: column, Cosmosil $5C_{18}$-MS-II (150 mm × 4.6 mm ID, Nacalai Tesque, Kyoto, Japan); column temperature, 25 °C; mobile phase, 20 mmol L^{-1} sodium phosphate buffer (pH 3.2)–CH_3CN (85:15, v/v); flow rate, 0.5 mL min^{-1}; detection, 235 nm. The amount of CD bound to MIPs, n, was calculated by the subtraction of [CD] from the initial CD concentration. The association constant (K_a) and apparent maximum number of binding sites (N) are determined according to the Scatchard plot and Scatchard equation, $n/[CD] = (N - n)K_a$.

2.6. Chromatographic evaluation of MIPs

The obtained polymers were packed into a stainless-steel column by a slurry packing technique using methanol–2-propanol (2:1, v/v) as the slurry solvent and methanol as the packing solvent to evaluate their chromatographic characteristics.

The HPLC system used was composed of a PU-980 pump, a UV-970 spectrophotometer (both from Jasco, Tokyo, Japan), a C-R6A integrator (Shimadzu, Kyoto, Japan), a Rheodyne 7125 injector with a 20-μL loop (Rheodyne, Cotati, CA, USA) and a CO-1093C column oven (Uniflows, Tokyo, Japan). The HPLC conditions used are specified in the legends of a table and figures.

The retention factor (k) was calculated from the equation $k = (t_R - t_0)/t_0$, where t_R and t_0 are retention times of retained and unretained solutes, respectively. The retention time of unretained solute, t_0, was measured by injecting acetone. The stereoseparation

Table 1
The molar amount of template molecule, functional monomer and cross-linker used for the preparation of MIP1–3, NIP1–3 and poly(DVB), and their physical properties.

Entry	Template molecule (mmol)	Functional monomer (mmol)	Cross-linker (mmol)	Surface area (m^2 g^{-1})	Pore volume (cm^3 g^{-1})	Average pore diameter (nm)
MIP1	CD (0.375)	MAA (1.5)	DVB (7.2)	460	0.16	3.3
NIP1	–	MAA (1.5)	DVB (7.2)	600	0.26	3.2
MIP2	CD (0.375)	MAA (1.5) + HEMA (0.72)	DVB (6.48)	540	0.20	3.2
NIP2	–	MAA (1.5) + HEMA (0.72)	DVB (6.48)	610	0.34	3.5
MIP3	CD (0.375)	MAA (0.59)	DVB (3.01)	570	0.21	3.2
NIP3	–	MAA (0.59)	DVB (3.01)	650	0.26	3.0
Poly(DVB)	–	–	DVB (3.35)	8.36	0.03	7.8

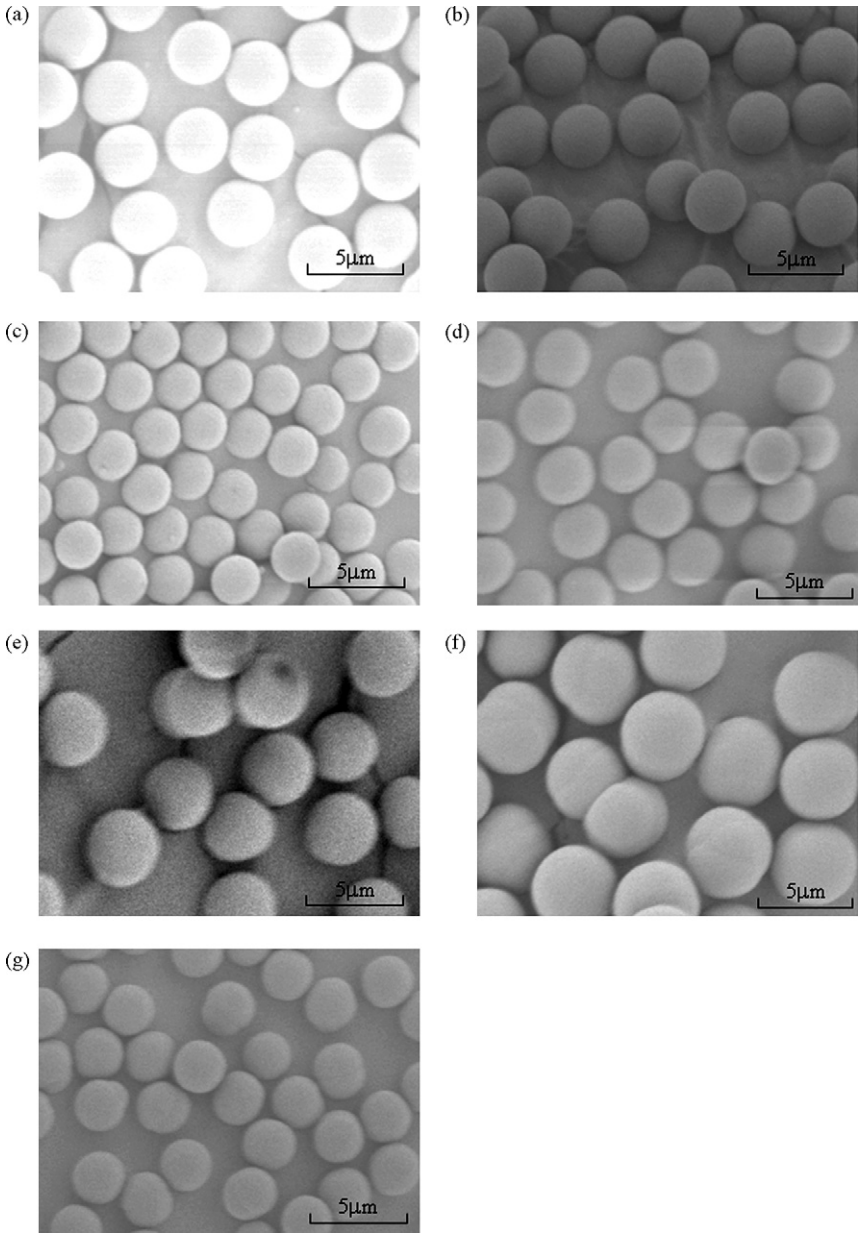

Fig. 2. SEMs of (a) MIP1, (b) NIP1, (c) MIP2, (d) NIP2, (e) MIP3, (f) NIP3 and (g) poly(DVB).

factor (α) was calculated from the equation $\alpha = k_{CD}/k_{CN}$, where k_{CD} and k_{CN}, respectively, are the retention factors of CD and CN on the MIP, NIP or poly(DVB) columns.

3. Results and discussion

3.1. Preparation of MIPs by a precipitation polymerization method

Previously, we prepared MIPs for (*S*)-nicotine using MAA as a functional monomer and DVB as a cross-linker by a precipitation polymerization method. The (*S*)-nicotine-imprinted MAA–DVB copolymers gave monodispersed microspheres of 3.5 μm in diameter and showed a high imprinting effect for (*S*)-nicotine [11]. Similarly, we tried to prepare MIPs for CD by a precipitation polymerization method using MAA as a functional monomer and DVB as a cross-linker. MIP1, CD-imprinted MAA–DVB copolymer, gave microspheres of 3.7 ± 0.07 (standard deviation) μm in diameter together with microspheres of a few hundred μm in diameter. The latter ones could be removed by repeated sedimentation and decantation. However, non-imprinted MAA–DVB copolymers gave only monodispersed microspheres of 3.5 ± 0.07 μm. This result suggests that the template molecule affected growth of microspheres during precipitation polymerization.

MIP2, CD-imprinted MAA–HEMA–DVB terpolymer, was also prepared by precipitation polymerization. MIP2 gave microspheres having two different particle sizes, 2.8 ± 0.11 μm and a few hundred μm in diameter, while non-imprinted MAA–HEMA–DVB terpolymers gave microspheres of 3.2 ± 0.09 μm and a few hundred μm in diameter. The particle sizes of these polymers prepared with addition of HEMA were smaller than those prepared without HEMA, suggesting that the co-monomer HEMA could have a profound influence on growth of microspheres during precipitation polymerization.

MIP3, core–shell type MIP, was prepared in two successive precipitation polymerization processes. In the first reaction stage,

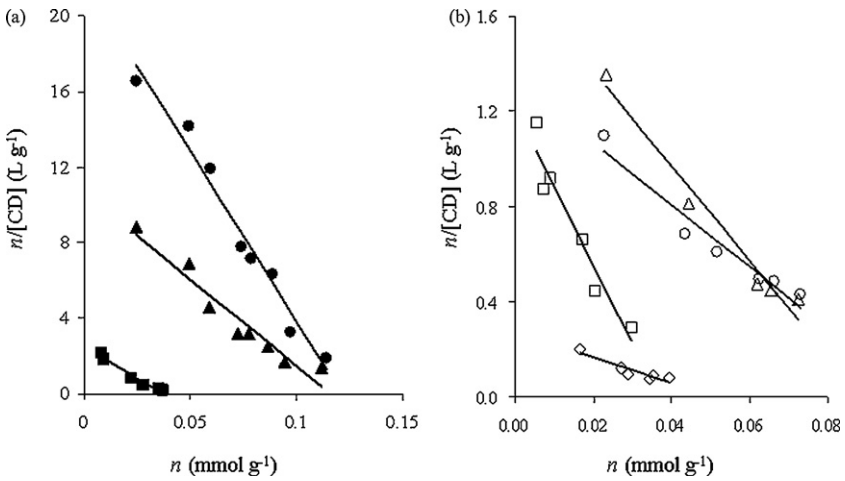

Fig. 3. Scatchard plots of (●) MIP1, (▲) MIP2 and (■) MIP3 (a), and (○) NIP1, (△) NIP2, (□) NIP3 and (◊) poly(DVB) (b). These plots were obtained based on the following equation: $n/[CD] = (N - n)K_a$, where K_a is the association constant and N is the apparent maximum number of binding sites.

Table 2
The association constant (K_a) of CD with MIP1–3, NIP1–3 and poly(DVB) and the apparent maximum number of binding sites (N).

	$K_a \times 10^5$ [L mol^{-1}]	N (mmol g^{-1})
MIP 1	1.8	0.12
NIP 1	0.13	0.10
MIP 2	0.92	0.12
NIP 2	0.19	0.087
MIP 3	0.67	0.037
NIP 3	0.27	0.040
Poly(DVB)	0.054	0.050

monodispersed poly(DVB) was obtained, and in the second reaction stage, *in situ* addition of CD, MAA, DVB and AIBN was followed by polymerization. Poly(DVB), MIP3 and NIP3, respectively, gave monodispersed microspheres of 2.8 ± 0.09, 4.1 ± 0.14 and 4.9 ± 0.08 μm in diameter, indicating that thickness of the imprinted and non-imprinted shells are about 0.65 and 1.1 μm, respectively. Fig. 2 shows SEMs of MIP1–3, NIP1–3 and poly(DVB). The good size uniformity was obtained with MIP1–3, NIP1–3 and poly(DVB).

Table 1 shows the physical properties (specific surface area, specific pore volume and average pore diameter) of MIP1–3, NIP1–3 and poly(DVB), measured using nitrogen sorption porosimetry. These data indicate that the obtained MIPs and NIPs have high specific surface areas associated with microporous structures and that MIP1–3 and NIP1–3 has similar morphology. On the other hand, poly(DVB) is non-porous polymer beads.

3.2. Scatchard analysis

To investigate their binding properties, Scatchard analysis of MIP1–3, NIP1–3 and poly(DVB) was carried out. The Scatchard plots shown in Fig. 3a and b gave straight lines, indicating that the affinities of the binding sites in MIP1–3, NIP1–3 and poly(DVB) are homogeneous among the concentrations tested. Similar Scatchard plots were obtained with the case of bisphenol A-imprinted polymers prepared by a precipitation polymerization method [18]. Table 2 shows the association constant (K_a) of CD with MIP1–3, NIP1–3 and poly(DVB) and the apparent maximum number of binding sites (N). The association constant of CD with MIP1 was larger

than that with MIP2 despite the similar apparent maximum number of binding sites in both MIPs, suggesting that hydrophilic HEMA had a negative influence on the CD binding. On the other hand, the association constant and apparent maximum number of binding sites for MIP3 was lower than those for MIP1 and MIP2. This could be due to that only the shell of MIP3 contributes to recognition of CD. Furthermore, the association constants of CD with MIP1–3 were larger than those with NIP1–3, respectively, and that with poly(DVB) is extremely small. These results indicate that MIP1–3 has complementary binding sites for CD.

3.3. HPLC separation of CN and CD on MIPs for CD

The retention and molecular recognition properties of MIP1–3, NIP1–3 and poly(DVB) were evaluated in HPLC using a mixture of phosphate buffer and acetonitrile as the mobile phase. Table 3 shows the effects of mobile phase pH on the retention factors of CN and CD and their stereoseparation factors on MIP1–3, NIP1–3 and poly(DVB). Extremely low retentions for CN and CD on NIP1-3 and poly(DVB) were observed, resulting in earlier elution of CD than CN, while the retention factor of CD was much larger than that of CN on MIP1–3, suggesting that stereoselective binding sites were formed in these imprinted polymers. With an increase in the mobile phase pH, the retention factors of CN and CD and their stereoseparation factors increased due to ionic interactions of their nitrogen atoms with negatively charged MAA in the imprinted polymers. On the other hand, the retention factors of CN and CD and their stereoseparation factors decreased with an increase in the acetonitrile content (data not shown). These results indicated that in aqueous media, the hydrophobic and ionic interactions between the analytes and polymers are dominant for the retention and molecular recognition process. Among the MIPs prepared, MIP1 gave the highest retention factor for CD, while MIP2 showed the lowest retention factor for CD. This might be due to a decrease in hydrophobicity of MIP2 by introduction of hydrophilic HEMA. It is interesting that MIP3 having imprinting sites only on its surface showed the highest stereoseparation factor among the MIPs prepared, whose value is estimated to be 38. The shorter diffusion paths of MIP3, compared to those of MIP1, could likely reduce the band broadening and give the higher column efficiency. It is apparent that resolution of CD and CN on MIP3 is superior to that on MIP1 (Fig. 4). MIP1 and MIP2 could be useful for preparative chromatography because of larger association constant and apparent maximum number of binding sites, while MIP3 could be useful for analytical applications.

In our previous study [17], we prepared the MIP for CD by multi-step swelling and polymerization. Under the same mobile phase condition with in Fig. 3a, the retention factors of CN and CD were 0.81 and 8.9, respectively, resulting in the stereoseparation factor of 11. This indicates that MIP1–3 prepared by precipitation polymerization gives higher recognition abilities for CD than the MIP prepared by multi-step swelling and polymerization. The MIP for CD prepared by bulk polymerization gave the stereoseparation factor of 31 in an organic mobile phase [15]. The advantage of precipitation polymerization is that higher stereoseparation factor of CD could be obtained without tedious preparation steps.

3.4. Effect of column temperature

Fig. 5 shows van't Hoff plots of CD and CN on MIP3, where the mobile phases used were 50 mmol L^{-1} potassium phosphate buffer containing 70 (v/v%) acetonitrile (final pH 4.2 and 11.7, respectively). It is interesting that the retention factors of CN and CD, and their stereoseparation factors increased with an increase in column temperature in a mobile phase of pH 4.2, while those decreased with an increase in column temperature in a mobile phase of pH 11.7. Thus, the stereoseparation process is entropy-driven in the former mobile phase, while the enthalpy-driven interactions seem to be dominant in the latter mobile phase. Similar results were observed with the MIP for CD prepared by a multi-step swelling and polymerization method [17].

4. Conclusions

Three monodispersed MIPs for CD have been synthesized by precipitation polymerization. MIP1 was prepared using MAA as a functional monomer and DVB as a cross-linker and MIP2 was prepared with further addition of HEMA as a co-monomer. For the preparation of MIP3, core–shell type MIP, monodispersed DVB homopolymers, which are prepared by precipitation polymerization, were used as a core and CD-imprinted MAA–DVB copolymer phases were coated onto the core. Three MIPs synthesized gave monodispersed, spherical beads in micrometer sizes. Scatchard analysis of MIPs revealed that the association constant of CD with MIP1 was the highest among MIPs prepared, while that with MIP3 was the lowest. The template molecule, CD, was more retained than its stereoisomer, CN, on the three MIPs, and the stereoseparation factor of 38 was obtained with MIP3. Thermodynamic studies suggested that the retention of CD and CN on MIP3 was entropy- and enthalpy-driven, respectively, in acidic and basic mobile phases.

Biosensing

ABSTRACT

Polymerized ionic liquid-wrapped carbon nanotubes (PIL-CNTs) were firstly designed for direct electrochemistry and biosensing of redox proteins. The CNTs were coated successfully with polymerized ionic liquid (PIL) layer, as verified by transmission electron microscopy (TEM), thermogravimetric analysis (TGA) and Fourier transform infrared (FT-IR) spectroscopy. The PIL-CNTs were dispersed better in water and showed superior electrocatalysis toward O_2 and H_2O_2 comparing to pristine CNTs and the mixture of IL monomer and CNTs. With glucose oxidase (GOD) as a protein model, the direct electrochemistry of the redox protein was investigated on the PIL-CNTs modified glassy carbon (GC) electrode and excellent direct electrochemical performance of GOD molecules was observed. The proposed biosensor (GOD/PIL-CNTs/GC electrode) displayed good analytical performance for glucose with linear response up to 6 mM, response sensitivity of 0.853 μA mM^{-1}, good stability and selectivity.

1. Introduction

The design of new biocompatible materials with good conductivity [1], large surface area [2], and good biocompatibility [3] for biosensors has been paid considerate attention over the last decade. Several classes of materials have been investigated including carbon [4–6], polymer [7,8], silicate [9], and metal nanoparticles [10]. Among these materials, carbon nanotubes (CNTs) are leading the development of the biosensor materials because of their outstanding physical and electronic properties (such as high conductivity, specific surface area and electrocatalytic activity) [11,12]. CNTs modified electrodes have been illustrated to improve electrochemical behavior of important biochemical matters such as hydrogen peroxide [13], NADH [14], catecholamine [15], dopamine, uric acid [16], 3,4-dihydroxyphenylacetic acid [17], hydrazine [18], and nucleic acid [19]. On the other hand, many redox proteins such as hemoglobin [20], myoglobin [21], horseradish peroxide [22], cytochrome c [23], and GOD [24,25] showed direct electron transfer in a series of CNTs modified electrodes.

On the other hand, room temperature ionic liquids (ILs), are composed of two asymmetrical ions with opposite charges that only loosely fit together with low melting point (<100 °C), high ionic conductivity and a wide electrochemical window. Due to the excellent physicochemical properties, ionic liquids have been extensively used as the modifiers for the CNT-based electrode to fabricate the biosensors with fast electron transfer rate and good enzyme stability [26–29]. Although the general method of physically mixing into composite matrix to immobilize ionic liquid units on the CNT-based electrode is facilitated, the quantity of IL unit binding on the surface of CNTs is limited and IL components leak easily from the electrode due to their wide solubility in the solutions, especially during the electrochemical measurements. Strategies in which ionic liquid monomer is directly polymerized on the surface of CNTs to form stable ionic liquid functionalized composites offer a solution to this problem. Recently, our group developed an approach to obtain high dispersion and narrow size distribution of metal nanoparticles on the surface of CNTs functionalized by polymerized ionic liquid (PIL) and the metallic nanoparticles/PIL-CNTs nanohybrids showed excellent electrocatalytic properties toward methanol oxidation [30]. However, according to our best knowledge, no works applied polymerized ionic liquid-wrapped carbon nanotubes (PIL-CNTs) to construct biosensors.

In this paper, with GOD as a protein model, we have developed a new biosensor based on the PIL-CNTs for the first time, which combined the excellent physicochemical properties of CNTs with the good biocompatibility and unique ionic properties of ILs. The immobilized GOD on the PIL-CNTs modified electrode shows excellent direct electrochemical response. This new bionanocomposite may offer an efficient strategy and a promising platform for the further study of direct electron transfer of the redox proteins and the development of biosensors.

2. Experimental

2.1. Reagents and apparatus

Multi-walled carbon nanotubes (CNTs, >95%, diameter 20–60 nm, length 5–15 μm) prepared by chemical vapor deposition (CVD) were purchased from Shenzhen Nanotech Port Ltd., and used without any purification. 1-Vinylimidazole was purchased from Alfa Aesar. Glucose oxidase (E.C. 1.1.3.4, Type X-S, 136100 U/G from *Aspergillus niger*), 5 wt.% Nafion 117 solution was purchased from Sigma–Aldrich (USA). Glucose stock solution was stored overnight at room temperature before use. All other chemicals were of analytical grade. Aqueous solutions used throughout were prepared with double-distilled water obtained from a Millipore system (>18 MΩ cm).

Micrographs of transmission electron microscopy (TEM) were obtained on a JEOL 3010 transmission electron microscope operating at 200 kV. The characterization of PIL-CNTs analyzed by the thermogravimetric analysis (TGA) was measured by Luxx STA 409 PC with 10 °C/min heating rate in the nitrogen flow and the FT-IR spectroscopy was carried on Nicolet 6700. All electrochemical measurements were performed on a IM6ex Electrochemical Workstation (Zahner-elektrik Gmbh & Co. KG, Germany) with a conventional three-electrode cell. A platinum wire was used as the counter electrode and a saturated calomel electrode (SCE) as the reference electrode. Except the specific statement, the electrochemical measurements were carried out in a phosphate buffer solution (PBS, 0.1 M, pH 7.0) at room temperature (25 ± 2 °C). All the potentials in this paper were referred to SCE.

2.2. Preparation of the PIL-CNTs

1-Vinyl-3-ethyl imidazolium bromide ([VEIM]Br) was synthesized according to the literature [31]. In brief, the mixture of 6.54 g bromoethane and 5.00 g 1-vinylimidazole was refluxed for 3 h at 70 °C under vigorous stirring. Then the excess bromoethane was removed on a Rotavapor for 2 h at 60 °C to obtain ILs. The PIL-CNTs were fabricated by the thermal initiation free radical polymerization of IL monomer ([VEIM]Br) to form ionic liquid polymer (PIL) on the CNT surface: a mixture of [VEIM]Br (1.56 g) and CNT powder (200 mg) was mixed and ground in an agate mortar for 30 min, subsequently mixed with 2,2′-azobisisobutyronitrile (AIBN 76 mg) as an initiator. The mixture was then placed in a flask and heated at 80 °C under nitrogen protection for 12 h. The formed black polymeric gel was then washed by ethanol to remove AIBN and unreacted monomer of [VEIM]Br. Finally the polymeric bucky gel was dried in vacuum at 60 °C for 12 h after centrifugation.

2.3. Preparation of PIL-CNTs modified electrode

Prior to use, glassy carbon electrodes (GC, 3 mm in diameter) were carefully polished to a mirror-like plane with 0.5- and 0.05-μm alumina slurries successively, followed by rinsing thoroughly with double-distilled water and dried in nitrogen atmosphere.

The PIL-CNTs modified electrode was prepared by casting 8 μL of uniform PIL-CNTs suspension (1.5 mg/mL) on the GC surface and dried under an infrared lamp. In control experiments, the CNTs (or ILs-CNTs) modified GC electrode was prepared by casting pristine CNTs (or ILs-CNTs) on the GC electrode according to the above procedure. Pristine CNTs was dispersed in DMF for better solubility and ILs-CNTs sample was prepared by dispersing ILs monomer and pristine CNTs (w/w = 35:65) in water.

For fabricating GOD biosensor, a 5 μL of GOD solution (10 mg mL^{-1} GOD in PBS, pH 7.0) was dropped on the PIL-CNTs modified GC electrode and dried at less than 4 °C, the obtained GOD/PIL-CNTs modified electrode was then washed carefully with double-distilled water and dried, followed by coating 1.5 μL of Nafion ethanol solution (1 wt.%) onto the electrode surface to avoid the leak of the GOD. The Nafion/GOD/PIL-CNTs electrode was washed thoroughly with double-distilled water. For comparison, CNTs modified electrode was also used to immobilize GOD via same procedure.

3. Results and discussion

3.1. Characterization of the PIL-CNTs nanocomposite

During the polymerization process, oligomeric 1-vinyl-3-ethyl imidazolium ion-base ionic liquid radicals, because of the strong π–π stacking interaction between the imidazolium ion moieties and CNTs, would attach to the surface of nanotubes, leading to the formation of PIL layer on the CNT surface [32,33]. Fig. 1A and B shows the TEM images of the PIL-CNTs. It can be observed that a PIL layer with the thickness of 7–8 nm presents on the outside wall of CNTs. Noteworthy is that the PIL layer is distributed uniformly along the whole tubes, which would create a uniform distribution of ionic species with positive charge that prevents aggregation of CNTs and induces stable nanotube suspensions in water.

The modification of CNTs by PIL has also been characterized by TGA and FT-IR. Fig. 1C shows the TGA spectra of the CNTs and PIL-CNTs. Comparing to the CNTs sample, the PIL-CNTs sample shows a significant weight loss in the range of 500–700 K, which confirms the PIL functionalization of CNTs. A ratio of PIL:CNTs in the as-prepared PIL-CNTs sample is also obtained to be about 35:65 (w/w). In addition, both of the PIL-CNTs and CNTs have been characterized by FT-IR spectroscopy (Fig. 1D), which shows a C=N stretch at 1500–1600 cm^{-1}. The peak of 1200 and 1258 cm^{-1} is strengthened by the modification of PIL, which may be due to increased C–N functional group from PIL.

3.2. Electrocatalysis of O_2 and H_2O_2 at the PIL-CNTs modified GC electrode

Fig. 2A shows the cyclic voltammograms (CVs) of bare GC, CNTs/GC, ILs-CNTs/GC and PIL-CNTs/GC electrodes in 0.1 M PBS (pH = 7.0) saturated with O_2 (or degassed with N_2). For the CNTs/GC, ILs-CNTs/GC and PIL-CNTs/GC electrodes, an obvious reduction wave of O_2 starts at about −0.16 V. However, for the bare GC electrode, the onset potential for O_2 reduction is about −0.32 V. It is further noted that the reduction current of O_2 on the PIL-CNTs/GC is obviously higher than that on the ILs-CNTs/GC, CNTs/GC, and bare GC electrodes and the following order can be obtained: PIL-CNTs/GC ≫ CNTs/GC ≅ ILs-CNTs/GC ≫ bare GC. This implies that the PIL-CNTs/GC electrode has the highest electrocatalytic activity for O_2 reduction, which should be beneficial to the third generation enzyme biosensors. In addition, H_2O_2 is an intermediate in most oxidase-based enzymatic reaction. Therefore, the electrocatalytic properties of the PIL-CNTs composite for the redox of H_2O_2 have also been investigated. Fig. 2B shows the background-subtracted CVs of the bare GC, CNTs/GC, ILs-CNTs/GC and PIL-CNTs/GC electrodes in 0.1 M PBS with 5 mM H_2O_2. The following order of the oxidation (or reduction) current of H_2O_2 at different electrodes can be observed: PIL-CNTs/GC ≫ ILs-CNTs/GC ≅ CNTs/GC ≫ bare GC. It is also noted that the PIL-CNTs/GC electrode has the highest electrocatalytic activity for H_2O_2 oxidation and reduction. The superior electrocatalytic activity toward O_2 reduction and H_2O_2 oxidation (reduction) of the PIL-CNTs/GC electrode might originate from the synergistic effect between the CNTs and PIL. Such excellent electrocatalytic activities for O_2 reduction and H_2O_2 oxidation (reduction) should lead to good properties of the PIL-CNT-based biosensors.

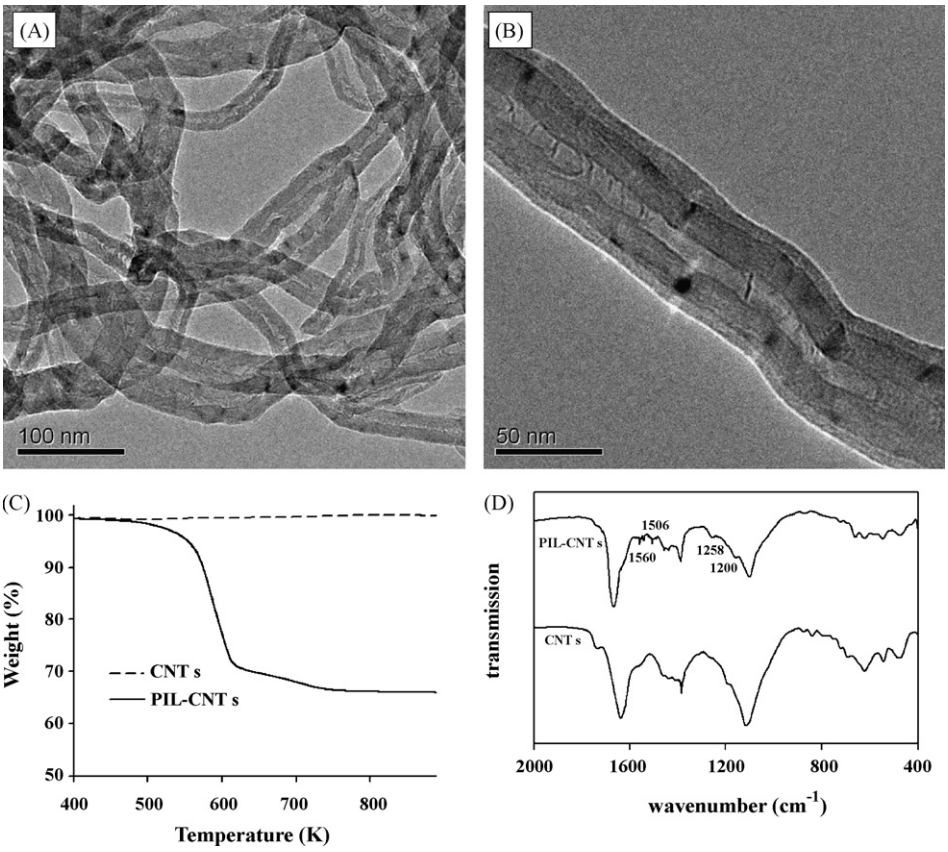

Fig. 1. TEM images of the PIL-CNTs at different magnifications (A and B) and TGA (C), FT-IR (D) spectra of PIL-CNTs and CNTs.

3.3. Direct electrochemistry of the Nafion/GOD/PIL-CNTs/GC electrode

In order to explore the application of PIL-CNTs composite in biosensors, GOD was selected as the model and the direct electrochemistry of the immobilized GOD on the PIL-CNTs/GC electrode has been investigated. Fig. 3 shows the cyclic voltammograms of the different electrodes in 0.1 M nitrogen-saturated PBS (pH 7.0) at 50 mV s^{-1}. A pair of well-defined and nearly symmetric redox peaks is observed on both of CNTs (solid) and PIL-CNTs modified electrodes (dashed) with immobilized GOD, while the related electrodes without GOD do not show such redox waves in the control experiments. This indicates that the redox waves are ascribed only to GOD redox. These features are the characteristics of the nearly reversible electron transfer process of the redox active centre (flavin adenine dinucleotide, FAD) in GOD biomolecules, suggesting that the direct electron transfer of GOD can be achieved on both CNTs and PIL-CNTs modified electrodes. From the integration of the reduction peak of GOD, the surface coverage of GOD on the Nafion/GOD/CNTs/GC and Nafion/GOD/PIL-CNTs/GC electrodes can be calculated to be 1.84 and 4.30×10^{-9} mol cm^{-2}, respectively. It is noted that GOD immobilized on the PIL-CNTs/GC electrode is much larger than that on the CNTs/GC electrode, demonstrating that the PIL-CNTs modified electrode is more beneficial to the immobilization of GOD than the CNTs modified electrode. All those may ascribe to the uniform distribution of ionic species with positive

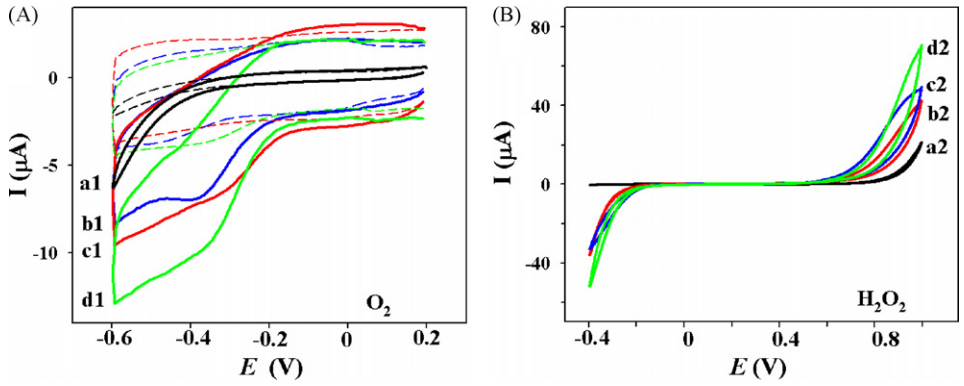

Fig. 2. (A) Cyclic voltammograms of the GC (black), CNTs/GC (red), ILs-CNTs/GC (blue) and PILs-CNTs/GC (green) electrodes in 0.1 M PBS solution saturated with O_2 (solid) or degassed with pure N_2 (dotted). Scan rate: 50 mV s^{-1}. (B) Background-subtracted CVs for 5 mM H_2O_2 at GC (black), CNTs/GC (red), ILs-CNTs/GC (blue) and PILs-CNTs/GC (green) electrodes in 0.1 M PBS solution. Scan rate: 50 mV s^{-1}. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

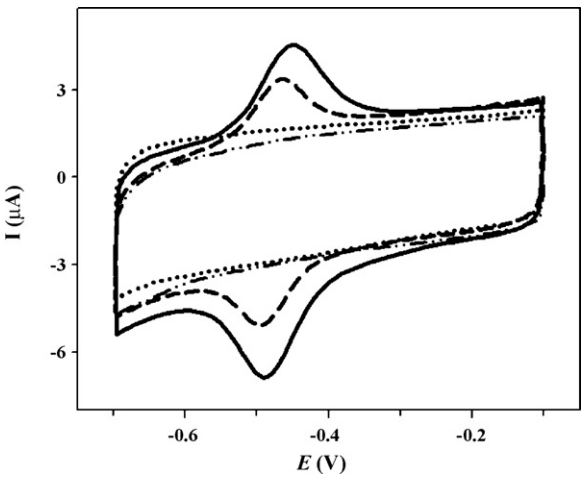

Fig. 3. Cyclic voltammograms of the Nafion/GOD/PIL-CNTs (solid), PIL-CNTs (dotted), Nafion/GOD/CNTs (dashed), CNTs (dashed-dotted) modified GCE in 0.1 M deoxygenated PBS (pH 7.0) at the scan rate of 50 mV s^{-1}.

charge present on the PIL-CNTs, resulting in more GOD molecules to be immobilized on the PIL-CNTs through electrostatic interaction between GOD (net negatively charged in the pH 7.0 PBS solution) and PIL-CNTs (positively charged). The more GOD molecules immobilized on the electrode imply that the Nafion/GOD/PIL-CNTs/GC electrode should have better analytical performance. On the other hand, for the Nafion/GOD/PIL-CNTs/GC electrode, the formal potential (E^0) was calculated by averaging the cathodic and anodic peak potentials and is ca. −0.471 V, which is close to the values reported previously [34,35]. The related anodic peak potential ($E_{p,a}$) and cathodic peak potential ($E_{p,c}$) are −0.455 and −0.487 V, respectively and the peak-to-peak potential separation is about 32 mV. The small peak-to-peak potential separation value indicates that GOD immobilized on the PIL-CNTs/GC electrode has a fast electron transfer rate, due to the strong interaction of GOD with the PIL-CNTs and the high conductivity of the PIL-CNTs [35].

The effect of the scan rate on the cyclic voltammetric response of the Nafion/GOD/PIL-CNTs/GC is shown in Fig. 4A and B. The anodic and cathodic peak currents increase linearly with the increase of the scan rate from 25 to 225 mV s^{-1}, indicating that the GOD immobilized on the PIL-CNTs/GC electrode demonstrates a surface-controlled process, not a diffusion-controlled process. It is well known that the direct electrochemistry of GOD is a two-electron coupled with two-proton reaction, which undergoes a redox reaction as follows [36]:

$$\text{GOD-FAD} + 2e^- + 2H^+ \leftrightarrow \text{GOD-FADH}_2 \quad (1)$$

Based on Eq. (1), the direct electron transfer process of GOD will be affected by the solution pH value. Fig. 4C shows the cyclic voltammograms of the Nafion/GOD/PIL-CNTs/GC electrode in the PBS with different pH values. From Fig. 4C, stable and well-defined cyclic voltammograms can be observed in the pH range of 5.0–8.0. The increase of the solution pH value causes a negative shift of both cathodic and anodic peak potentials. Fig. 4D shows the effect of the solution pH value on the formal potential (E^0) of the Nafion/GOD/PIL-CNTs/GC electrode. It can be seen that the formal potential depends linearly on the pH value in the range of 5.0–8.0 with a slop of −52.7 mV/pH (r = 0.9971), which is close to the theoretical value of −58.6 mV/pH according to the reaction shown in Eq. (1).

3.4. Biosensing application of the Nafion/GOD/PIL-CNTs modified GC electrode

On the basis of the high electrocatalytic activity of the PIL-CNTs nanocomposite toward O_2 reduction and good direct electrochemical behavior of GOD on the PIL-CNTs/GC electrode, a third

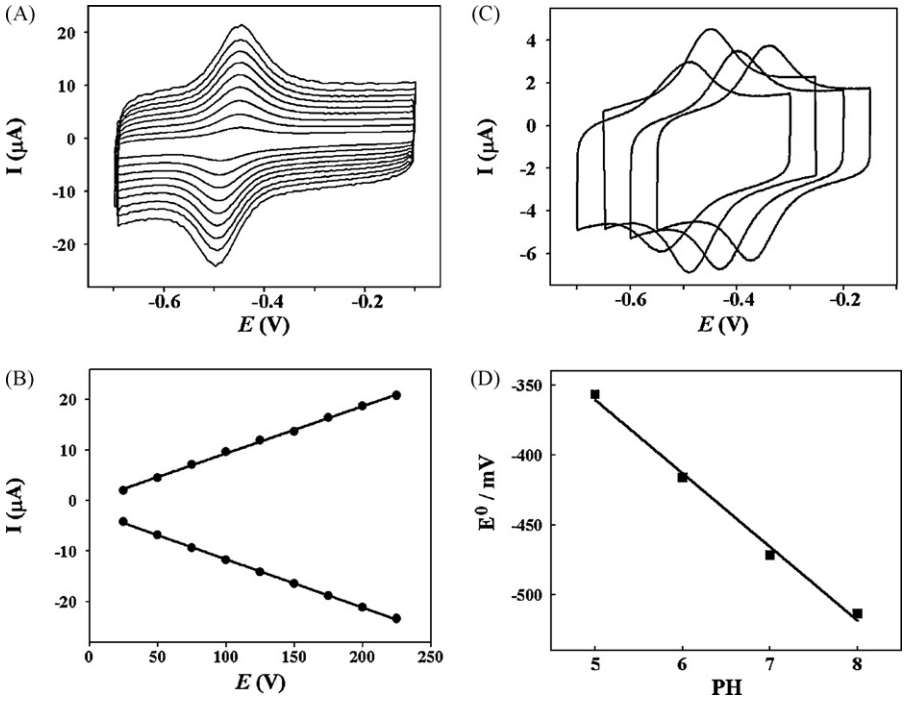

Fig. 4. (A) Cyclic voltammograms of the Nafion/GOD/PIL-CNTs modified GC electrode in 0.1 M deoxygenated PBS (pH 7.0) at scan rates of 25, 50, 75, 100, 125, 150, 175, 200, 225 mV s^{-1} (from inner to outer). (B) The dependence of the anodic and cathodic peak currents versus the scan rate. (C) Cyclic voltammograms of the Nafion/GOD/PIL-CNTs modified GC electrode in 0.1 M deoxygenated PBS with pH values of 5.0, 6.0, 7.0, and 8.0. Scan rate, 50 mV s^{-1}. (D) The dependence of the formal potential of the Nafion/GOD/PIL-CNTs modified GC electrode on the pH value.

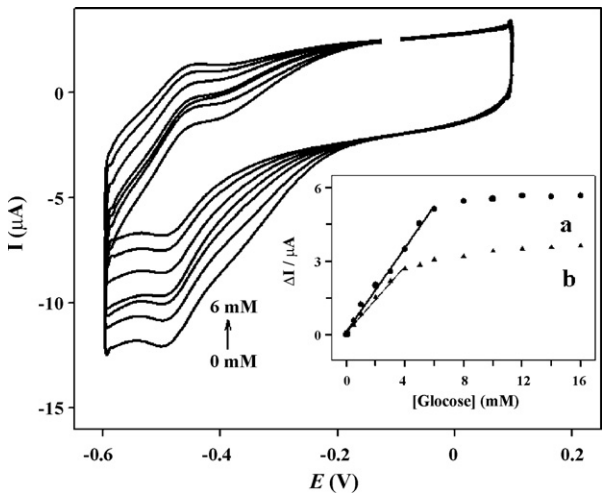

Fig. 5. Cyclic voltammograms of the Nafion/GOD/PIL-CNTs modified GC electrode in 0.1 M air-saturated PBS (pH 7.0) containing 0, 1, 2, 3, 4, 5 and 6 mM of glucose (from bottom to top) at the scan rate of 50 mV s^{-1}. The insert plot shows the dependence of the decreased reduction peak current of the Nafion/GOD/PIL-CNTs modified GC electrode (a) and Nafion/GOD/CNTs modified GC electrode (b) on the concentration of glucose in 0.1 M air-saturated PBS (pH 7.0).

generation glucose biosensor was developed further. Fig. 5 shows cyclic voltammograms of the Nafion/GOD/PIL-CNTs/GC electrode in 0.1 M air-saturated PBS (pH 7.0) with different concentrations of glucose (0.05–6 mM). The reduction current becomes smaller and smaller with the increase of the glucose concentration because of the consumption of dissolved oxygen. The insert plot in Fig. 5 shows the relationship between the decrease of the reduction peak current and the glucose concentration at the Nafion/GOD/PIL-CNTs/GC (a) and Nafion/GOD/CNTs/GC (b) electrodes. The linear response ranges for the Nafion/GOD/PIL-CNTs/GC and Nafion/GOD/CNTs/GC electrodes are 0.05–6 mM (R = 0.9946) and 0.05–4 mM (R = 0.9955), respectively. It is noted that the Nafion/GOD/PIL-CNTs/GC electrode has wider linear range than Nafion/GOD/CNTs/GC electrode. Furthermore, the sensitivity of the Nafion/GOD/PIL-CNTs/GC electrode is calculated to be 0.853 μA mM^{-1}, which is higher than that of Nafion/GOD/CNTs/GC electrode (0.676 μA mM^{-1}) and other third generation glucose biosensors reported in literatures [37–39].

To evaluate the stability of the electrode, the cyclic voltammetry measurements were carried out continuously in a 0.1 M PBS (pH 7.0). The decrease in the peak currents can be observed on both Nafion/GOD/PIL-CNTs and Nafion/GOD/CNTs electrodes. However, after 40 cycles, the decrease in the peak currents is less than 6% for the Nafion/GOD/PIL-CNTs/GC electrode and more than 20% for the Nafion/GOD/CNTs/GC electrode. It is noted further that more than 90% of peak current on Nafion/GOD/PIL-CNTs/GC electrode is retained even after 100 cycles successively scan in 0.1 PBS (pH 7.0). This implies that the Nafion/GOD/PIL-CNTs/GC electrode has better stability than the Nafion/GOD/CNTs/GC electrode, which may result from the additional electrostatic interaction between the positive sites on the PIL and negative charges in the GOD (FAD). Additionally, when the Nafion/GOD/PIL-CNTs/GC electrode was stored in 0.1 M PBS at 4 °C, it retains 94% of its initial current response toward glucose after intermittent use over a 2-week period, further corroborating the good stability of the biosensor and high efficiency of PIL-CNTs for retaining the activity of the enzyme.

Because of the low detection potential, the biosensor also shows good selectivity for glucose. In an air-saturated and stirred 0.1 M PBS solution (pH 7.0) containing 0.5 mM glucose, the response arising from 0.01 mM uric acid (UA) and 0.01 M ascorbic acid (AA) is negligible. The reproducibility of the glucose biosensor was also investigated by detecting the current response at −0.49 V to 2 mM glucose in the PBS for six successive times, the relative standard deviation (RSD) is 3.3%, demonstrating a good reproducibility of the biosensor.

4. Conclusion

In this work, we demonstrated the PIL-CNTs bionanocomposite for direct electrochemistry and biosensing application of redox protein. Due to the uniform distribution of ionic species layer and good stability of IL units, the PIL-CNTs show superior electrocatalytic activity for O_2 reduction and H_2O_2 oxidation (reduction) and provide a promising platform for direct electrochemistry of GOD. The immobilized GOD on the PIL-CNTs modified GC electrode shows good direct electrochemical response and biosensing performance for glucose. All these characteristics suggest that PIL-CNTs nanocomposite provides a potential material for direct electrochemistry and biosensing of redox proteins.

ABSTRACT

This report has described a convenient genotyping method capable of detecting point mutations directly in human genomic DNA based on the combination of ligase chain reaction (LCR) and microbead-enrichment technique. LCR primers, including a biotin-labeled common primer and two fluorescence-labeled allele-specific primers, are designed for two alleles of a mutated site. When genomic DNA carries the mutated site, the common primer and allele-specific primer are ligated to form exponential amplified biotin-labeled fluorescence ligation products. These ligated products are enriched by streptavidin-coated microbeads, and genotypes are identified conveniently according to the fluorescence color of microbeads using fluorescent microscopy. Due to amplification of LCR process and enrichment of microbeads, the detection limit of the proposed method is as low as 10^{-15} mol/L templates. The method provides a convenient and simple strategy to detect point mutation directly in human genome. We have confirmed the efficiency of this approach with the identification of β-globin gene point mutation, which results in the reduced production of globin in an inherited hemoglobin disorder *thalassemia* disease.

1. Introduction

Single nucleotide polymorphisms (SNPs) are the prevalent genetic variations and there are more than three million SNPs in the human genome [1,2]. Many pathogenic or genetic diseases are associated with single-base mutations of particular genes [3–5]. Identification of these single-base mutations offers the possibility of improved therapeutic and prophylactic measures of these diseases [6]. Many techniques have been developed for point mutation detection [7–14]. Overcoming the complexity of 10^9 bp in human genome remains one of the principal challenges for mutation detection [8]. Typical assays for reducing this complexity to detect point mutations usually come from preamplification of genomic DNA via PCR [9], such as ligase-mediated colorimetric method [10], specific primer extension [11], allele-specific PCR [12], molecular beacon assay [13]. Recently, we established a fidelity genotyping method for point mutation detection by enhancing the melting point difference among genotypes using PCR preamplification [14]. PCR-based methods provide high sensitivity in detection, but easy cross-contamination in PCR process results in rigorous and complicated operations [9]. Several strategies have been developed to detect point mutations directly in human genomic DNA without PCR [15–18]. For example, Wabuyele et al. [9] used ligase detection reaction (LDR) and fluorescence resonance energy transfer (FRET) to identify point mutations in Kras oncogenes. Yeh et al. [17] used ligation reaction and quantum dot-mediated two-color fluorescence coincidence analysis to detect point mutation in Kras gene. Bao et al. [7] employed gold nanoparticle probes to identify gene mutations in thrombotic disorders. These methods are highly specific and sensitive, however, expensive laser detection systems or rigorous design procedures cause great limitation to their applications.

In this paper, we report a convenient method to detect point mutation directly in genomic DNA. We combine ligase chain reaction (LCR) and microbead-enrichment technique to increase sensitivity, and employ fluorescence ligation products to allow identifying analysis. According to a point mutation site, a biotin-labeled common LCR primer and two fluorescence-labeled allele-specific LCR primers are designed. When genomic DNA carries the mutation site, ligation reaction occurs and forms exponential amplified biotin-labeled fluorescence ligation products. Then streptavidin-coated microbeads capture these fluorescence ligation products. Detection is performed according to fluorescence color of microbeads using fluorescent microscopy. The method has been demonstrated as convenient point mutation detection in human genome with the genotyping of the CD17 (A → T)

point mutation of β-globin gene associated with *thalassemia* disease.

2. Materials and methods

2.1. Materials

The point mutation CD17 (A → T) of β-globin gene associated with *thalassemia* disease [19] was investigated. A series of oligos were commercially synthesized by TaKaRa Bio Inc. (Dalian, China). Sequences of these oligos are listed in Table 1. N1 and N2 were 39-nt oligos, representing two alleles of the CD17 mutated site (N1 for mutated template and N2 for wildtype template); a 50/50 mixture of N1 and N2 symbolized the heterozygous [20]. pr1–6 (Primer1, 2, 3, 4, 5, 6) was LCR primers for two alleles of the CD17 mutated site (pr1, 2, 4, 6 for mutated template; pr1, 3, 5, 6 for wildtype template). Streptavidin-coated microbeads were purchased from Sigma–Aldrich (MO, USA) and TaqDNA ligase was obtained from New England Biolabs (MA, USA). Other reagents were of analytical reagent grade. Deionized water was obtained through a Nanopure Infinity™ ultrapure water system (Barnstead/Thermolyne Corp., IA, USA).

2.2. LCR amplification

LCR was performed on a GeneAmp™ PCR System 2700 (Applied Biosystems, CA, USA). Extracted genomic DNA or synthesized templates were used as LCR template. Each LCR reaction contained 50 μL reaction volumes: 5 μL of 10× Taq ligase buffer; 4 units TaqDNA ligase; 200 nmol/L pr1–6 probes; template (10^{-10} mol/L synthesized template or 20 ng genomic DNA). The conditions of LCR were the following: initial denaturation at 94 °C for 5 min, followed by 30 cycles of denaturation at 94 °C for 30 s, then 65 °C for 5 min. The reaction was terminated in addition of 0.5 nmol/L EDTA in reaction solution. In sensitivity experiments, the concentration of template N1 was adjusted.

2.3. Coupling LCR ligated products

The proposed method employed microbeads to capture fluorescence ligation products through biotin–streptavidin interaction. Firstly, microbeads were washed twice in PBS solution. Then the washed microbeads were resuspended in PBS solution and stored at 4 °C. The capturing process involved two major steps: (1) capturing fluorescence ligation products using streptavidin-coated microbeads; (2) removal of non-specific absorption components on the surface of microbeads using washing buffer as described before [21]. We optimized the capturing time and the concentration of formamide, an important component in washing buffer. All optimization assays were run in three sample replicates.

Experiments for the optimal capturing time were performed at room temperature. Microbeads were incubated with LCR reaction solution with end-to-end shaking. Then equal volume of incubated samples was drawn at different incubating times. Here, incubating times of 20, 45, 60, 75 and 90 min were chosen.

Microbeads captured fluorescence ligation products and all other components should be washed by washing buffer in order to eliminate background signal. The washing buffer was 10 mmol/L PBS (pH 7.6) containing 150 mmol/L NaCl, 0.1% Tween 20 and 80% formamide. After incubating process ended, the drawn samples were kept quietly for 3 min and then the supernatant was removed. The deposited microbeads were incubated with the washing buffer for 5 min with end-to-end shaking and then the supernatant was removed. Finally, some deposited microbeads were resuspended in 10 μL PBS (10 mmol/L, pH 7.6) to wait for detection. The concentration of formamide in the washing buffer was adjusted while its influence was investigated.

Table 1
Oligos*.

* Templates and probes used in this paper were designed according to Ref. [24] with some modifications. These designed sequences were used to detect CD17 (A → T) point mutation of β-globin in *thalassemia* disease. pr1 and pr2 were forward primers for mutated template, pr4 and pr6 for reverse primer. pr1 and pr3 were forward primers for wildtype template, pr5 and pr6 for reverse primer. ROX was 6-carboxy-X-rhodamine. FAM was 6-carboxy-fluorescein. p represented 5′-phosphorylation.

2.4. Fluorescent detection by fluorescent microscopy

Fluorescence ligation products on the surface of microbeads were detected by the cool CCD system in the Leica Inverted fluorescence microscopy and the corresponding quantitative values were obtained by calculating the gray scale of fluorescent particles with the software Image J as described before [22].

2.5. DNA extraction and determination genotypes by reverse dot-blot assay (RDB)

Patients, who originated from Guangzhou city, Guangdong province, South China, had classic β-*thalassemia* trait. Their genotypes were investigated using RDB method established in the laboratory of Department of Medical Genetics, Southern Medical University, China [19]. Genomic DNA was isolated from leucocytes in peripheral blood of normal subjects and patients using standard DNA extraction method [23].

3. Results and discussion

3.1. Assay principle

Schematic representation of the assay method is shown in Fig. 1. According to a mutated site, LCR primers are designed for two alleles of a mutated site (Table 1). Among these oligos, three label probes are needed for each biallelic marker. A 3′-biotin, 5′-phosphorylated common probe (pr1) is designed to terminate one base immediately upstream from the mutated site. Two fluorescence-labeled allele-specific probes are designed and have the allelic base at the 3′-end, respectively. In this study, pr2 (ROX-labeled) is the allele probe of mutated template N1 and pr3 (FAM-labeled) is the allele probe of wildtype template N2. Ligation reaction performs between two adjacent labeled probes when their hybridization is complementary to template. In contrast, in the presence of a mismatch between two adjacent probes and template, ligation will not occur. During LCR process, 3′-biotin, 5′ROX-labeled ligation product (ROX-LP) for mutated template is amplified and 3′-biotin, 5′-FAM-labeled ligation product (FAM-LP) for wildtype template is amplified. These fluorescence ligation products are captured by streptavidin-coated microbeads through biotin–streptavidin interaction, while other non-special absorption components on microbeads are washed away by washing buffer. Genotypes are determined by

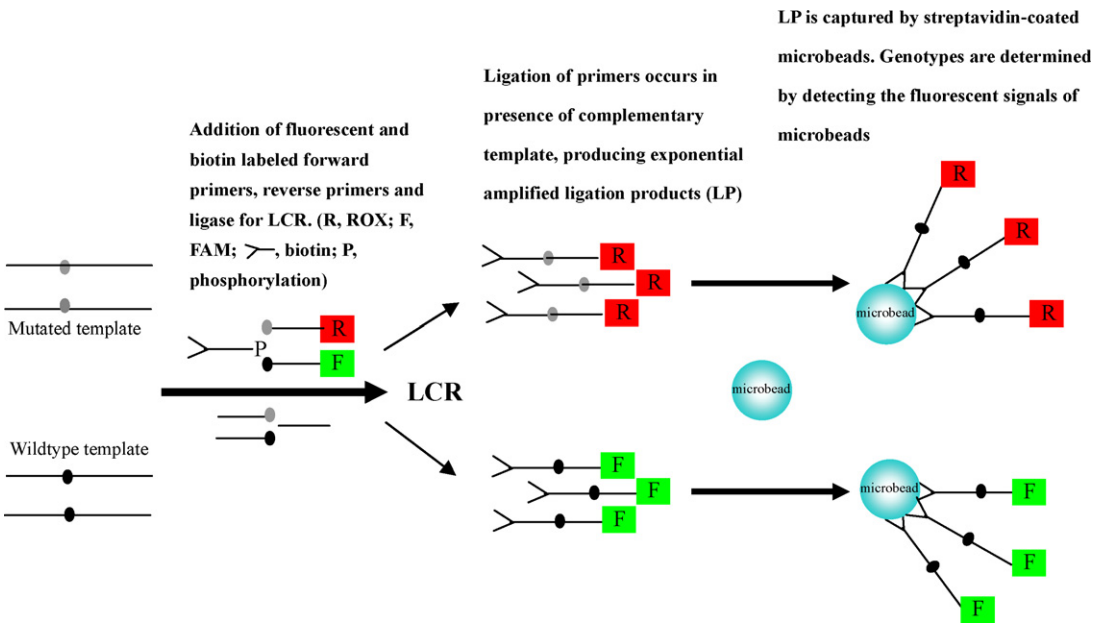

Fig. 1. Schematic diagram of the assay. Taq DNA ligase joins two adjacent primers when these primers perfectly match to the template. In this study, 3′-biotin, 5′-ROX-labeled ligation products (ROX-LP) for mutated templates are amplified and 3′-biotin, 5′-FAM-labeled ligation products (FAM-LP) for wildtype templates are amplified. These fluorescence ligation products are captured by streptavidin-coated microbeads. Genotypes are determined by detecting the fluorescence color of microbeads using fluorescent microscopy. Only three fluorescence ligation products are shown aligning in a microbead. In reality, large numbers are formed on it. R: ROX; F: FAM; P: phosphorylation; ⟩— : biotin; LP: ligation products.

detecting the fluorescence color of microbeads using fluorescent microscopy.

3.2. Detection of single-base mutations in oligos target

In evaluation of the assay, we began by analyzing single-base mutations in synthesized mock templates (Table 1). Mock template DNA (N1 for mutated template and N2 for wildtype template) and a 50/50 mixture of N1 and N2 (to mimic the heterozygous template) were detected [20]. The detection results are shown in Fig. 2. In the presence of template N1, there was only red fluorescent signal (Fig. 2A). This indicated the formation of ROX-LP, but not FAM-LP; in the presence of template N2, it occurred green fluorescent signal (Fig. 2B), which indicated the formation of FAM-LP and not

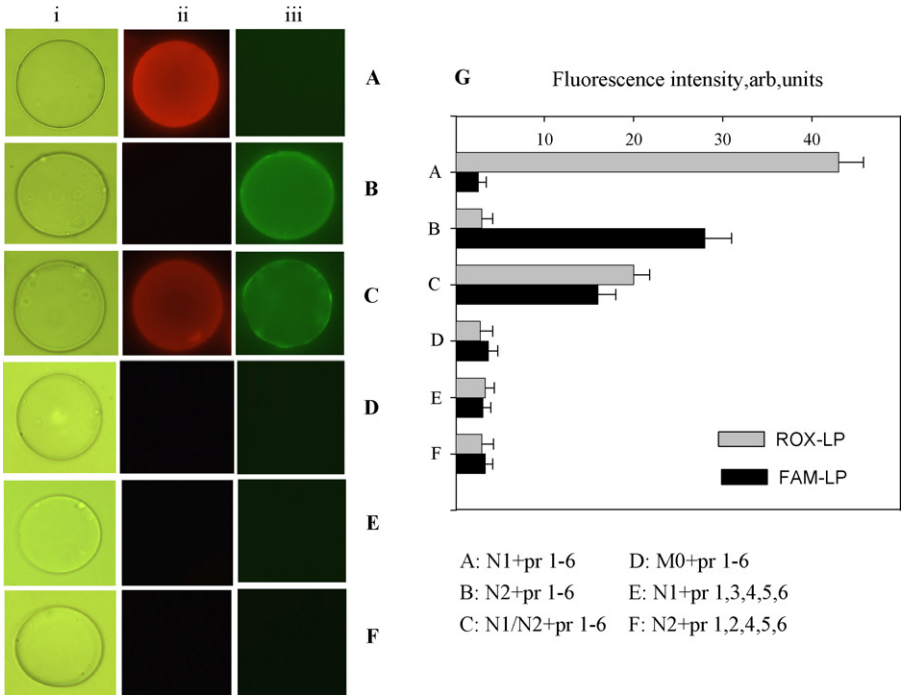

Fig. 2. Detection of point mutations in synthesized oligos target. A–F are images of samples on the fluorescent microscopy [(i) is optic images, (ii) is fluorescent images from ROX-LP (red) and (iii) is fluorescent images from FAM-LP (green)]. G was the corresponding fluorescence strength column blots of A–F. ROX-LP represented ROX-labeled ligation products; FAM-LP represented FAM-labeled ligation products. (For interpretation of the references to color in this figure caption, the reader is referred to the web version of the article.)

ROX-LP. While in the presence of a 50/50 mixture of N1/N2, it had red and green two fluorescent signals (Fig. 2C). This indicated the formation of FAM-LP and ROX-LP. By observing fluorescence color, three genotypes were identified conveniently and quickly.

In order to validate the fluorescent signal of microbeads resulting from ligation products, three control experiments were designed. One used random template M0; one used template N1 and pr3, but the corresponding ROX-labeled allele probe (pr2) was not added; another was template N2 and pr2, but the corresponding FAM-labeled allele probe (pr3) was not added. Detection results are shown in Fig. 2D–F. There was no obvious fluorescence as shown in Fig. 2D–F. This indicated that a mismatched duplex between template and allele-specific probes did not produced fluorescence ligation products. In order to quantify the fluorescence signal, the corresponding fluorescent volume blots of Fig. 2A–F are shown in Fig. 2G.

3.3. Assay refinement

It is shown clearly in Fig. 1 that this proposed method employed microbeads to enrich fluorescence ligation products through biotin–streptavidin interaction. Enhancement of the capturing number of fluorescence ligation products and reduction of the non-specific absorption on the surface of microbeads were very important to establish the method. Therefore, some experiments were performed to optimize the capturing time and the washing buffer components.

Fig. 3 displays the detection signal for template N1 at various capturing times. It showed that there was weak fluorescence strength at 20 min capturing time; however, there was strong and similar fluorescence strength at capturing times for 45, 60, 75, and 90 min, respectively. This indicated that capturing time in range from 45 to 90 min could capture effectively fluorescence ligation products. To ensure efficient capturing for fluorescence ligation products, 60 min was chosen as capturing time in experiments.

In this study, fluorescence ligation products were captured by microbeads through biotin–streptavidin interaction while all other components were washed using washing buffer. Therefore, appropriate washing buffer was important to the sensitivity and specificity of this method. We investigated the effect of formamide, an important component of the washing buffer in this method [21]. Fig. 4 shows the detection fluorescent signal for two alleles at various concentrations of formamide. It showed that there was strong fluorescent signal for mutated template N1 at various concentrations of formamide. For wildtype template N2, strong fluorescent signals was found at 30% formamide, but there was no obvious fluorescent background signal when the concentration of formamide in range from 60 to 85%. It was indicated that a wide concentration of formamide in range from 60 to 85% was very effective to remove non-specific absorption components. To eliminate efficiently non-specific absorption fluorescent signal, 80% formamide in washing buffer was chosen in experiments.

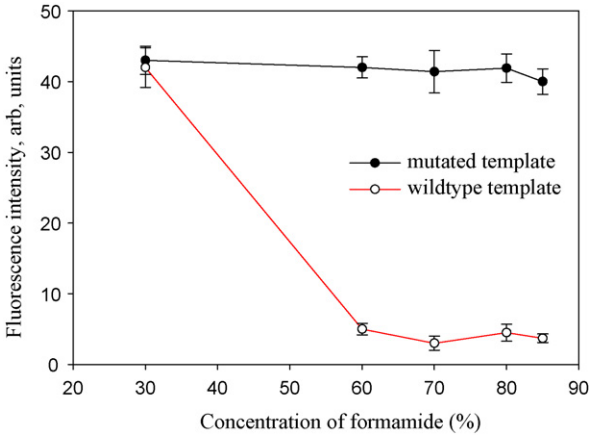

Fig. 4. The fluorescent signal of at various concentrations of formamide (30, 60, 70, 80, 85%) in washing buffer. pr1, 2, 4, 6, template N1 or N2 was used in LCR.

3.4. Detection sensitivity

The sensitivity of the system was investigated under the afore-mentioned optimized conditions. Various concentrations of template N1 were detected. It is shown in Fig. 5 that the fluorescent signal kept was rising with the enhancement of the concentration of N1. It was also found that there was obvious fluorescent signal when the concentration of N1 was low to 10^{-15} mol/L. The detection limit of the proposed method achieved to 10^{-15} mol/L templates, which made it possible to detect point mutations directly in human genomic DNA.

3.5. CD17 mutation detection in human genomic DNA

Here, genomic DNAs, isolated from leucocytes in peripheral blood of normal subjects and patients with CD17 (A → T) mutated site, were investigated. Their genotypes have been investigated using RDB method in clinic before [19]. We used the proposed method to detect these samples. Table 2 is the discrimination results of these samples. As expected, the mutated homozygosity

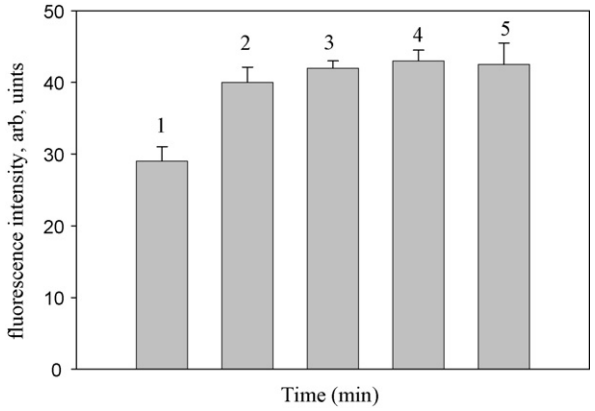

Fig. 3. The fluorescent signal at various capturing times. The capturing times of columns 1, 2, 3, 4 and 5 are 20, 45, 60, 75 and 90 min, respectively. Template N1, pr1, 2, 4, 6 were used in LCR.

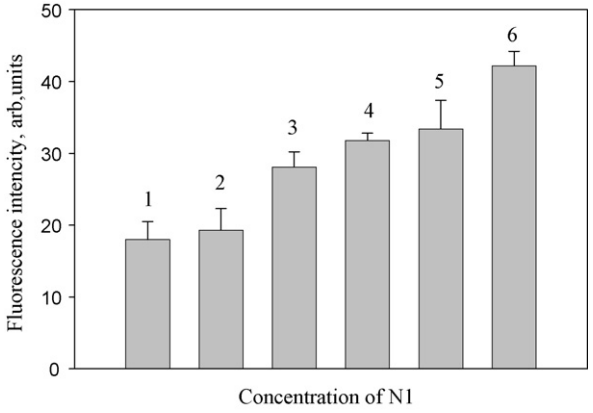

Fig. 5. The fluorescent signal at various concentrations of template N1. The concentrations of columns 1, 2, 3, 4, 5 and 6 are 1×10^{-15}, 1×10^{-14}, 1×10^{-13}, 1×10^{-12}, 1×10^{-11} and 1×10^{-10} mol/L. Template N1, pr1, 2, 4, 6 were used in LCR.

Table 2
Detection CD 17 point mutation of β-globin in *thalassemia* disease in human genomic DNA.

Sample	ROX-LP	FAM-LP	Detection resulting	RDB resulting
Sample 107			Mutant type	Mutant type
Sample 108			Mutant type	Mutant type
Sample 109			Wildtype	Wildtype
Sample 110			Mutant type	Mutant type
Sample 111			Heterozygote	Heterozygote
Sample 112			Mutant type	Mutant type
Sample 113			Wildtype	Wildtype
Sample 114			Wildtype	Wildtype
Sample 115			Heterozygote	Heterozygote
Sample 116			Mutant type	Mutant type

produced red fluorescent signal, but not green signal; the wildtype produced green fluorescent signal, but not red signal; the heterozygosity produced red and green two fluorescent signals. We found that the genotypes of these samples were all in agreement with the results of RDB. This method provides a convenient and efficient assay to detect point mutations directly in total genomic DNA. This could bring faster and cheaper genotyping possibilities in the nearest future.

4. Conclusions

In this paper, we describe a microbead-based LCR technique that could detect directly point mutations in human genomic DNA. The success of the system depends on three components: (1) accuracy of the allele discrimination reaction by thermal DNA ligase, which has been well-established, (2) specificity biotin–streptavidin interaction between microbeads and fluorescence ligation products, (3) the sensitive detection resulting from amplification of fluorescence ligation product during LCR and enrichment of streptavidin-coated microbeads.

ABSTRACT

The influence of the boron-doping levels in boron-doped diamond film electrodes on the electrochemical response of nitrofurantoin (NFT) and the development of an electroanalytical procedure for NFT determination were investigated. The investigations were carried out using the techniques of cyclic voltammetry and square wave voltammetry on diamond film electrodes with different boron-doping levels (i.e., 5000, 10,000 and 20,000 mg L^{-1}). The level of boron-doping in the diamond film electrodes influenced the electrochemical reduction of NFT. The appropriate cyclic voltammetric response of NFT was obtained with Britton–Robinson buffer at pH 4 and for diamond films doped with 10,000 and 20,000 mg L^{-1} of boron. These two films were selected for the development of the electroanalytical procedure. The use of square wave voltammetry with the optimized parameters demonstrated a good linear relationship between the peak current and the NFT concentration for a wide range of concentration. The lower limit of detection for the electrodes doped with 10,000 and 20,000 mg L^{-1} of boron were 2.69×10^{-8} mol L^{-1} (6.40 μg L^{-1}) and 8.15×10^{-9} mol L^{-1} (1.94 μg L^{-1}), respectively, while the lower limits of quantification were 8.96×10^{-8} mol L^{-1} (21.33 μg L^{-1}) and 2.72×10^{-8} mol L^{-1} (6.47 μg L^{-1}), respectively. The applicability of the proposed procedure was tested using a commercial pharmaceutical formulation of NFT, and the results were compared with the procedure recommended by the British Pharmacopeia. The proposed procedure was sensitive, accurate and precise for analysis of NFT and did not require complex preparations or renovations of the electrode surface. This presents the advantage of eliminating mercury waste and minimizing the adsorptive problems related to the use of other electrodic solid surfaces.

1. Introduction

The replacement of mercury electrodes with solid electrodes is difficult due to the poisoning of the electrode surface, which is caused by the adsorption of compounds, analytical solution constituents or redox reaction products. This results in a loss of sensitivity and reproducibility. The search for non-toxic solid materials to be used as electrodes for the electroanalytical determination of organic compounds has risen in the last two decades. This pursuit falls into the newly developed field of green electroanalytical chemistry.

Several materials have been tested toward this aim, including solid amalgam electrodes (SAE), carbon paste electrodes (CPE), nanotube carbon paste electrodes (NTCPE), glassy carbon electrodes (GCE), solid composite electrodes (SCE) and boron-doped diamond film electrodes (BDDFE). Several reviews illustrating the use of these materials in the electroanalytical field have been published in recent years [1–11].

Among these materials, BDDFE has attracted the attention of electroanalytical researchers as a candidate for the electrochemical determination of pharmaceutical compounds, since BDDFE presents a stable background current, wide potential window for aqueous and non-aqueous electrolytes, high thermal conductivity, high hardness, high electrochemical stability, low organic molecule adsorption and high sensitivity for analytical purposes [5,8,9,12–14]. However, little attention has been given in the literature concerning the influence of different boron-doping levels

on the electrochemical response of the pharmaceutical compounds.

In addition, some reports have been published showing that nitrofurazone, which is in the group of nitrofuran antibacterial agents, has a good electrochemical response on the BDDFE [15,16]. This enables the application of this electrode for the electrochemical detection and quantification of compounds belonging to the nitrofuran group. Among them, nitrofurantoin [NFT; 1-((5-nitro-2-furfurylidene)-1-amino)hydantoin] is a drug synthesized from nitrofuran that is very useful in the treatment of urinary tract diseases. Depending on its concentration at the inflammation site, this drug may act as a bacteriostatic or bactericidal agent [17]. As pointed out by Hamman [17], this drug can act against various gram-negative bacteria, as well as some gram-positive bacteria, including *Citrobacter*, *Corynebacterium*, *Enterobacter*, *Escherichia coli*, *Klebsiella*, *Neisseria*, *Salmonella*, *Staphylococcus aureus* and *Enterococcus faecalis*. It is efficient against these bacterias in the concentration range of 1–32 $\mu g\,mL^{-1}$. However, this drug is partially metabolized, and 24 h after the application of a single oral dose, 30–50% of this drug is excreted in its original form and 1% is excreted as aminofurantoin in the urine [17]. Thus, this drug can become a water contaminant, which can be dangerous for human health.

Several non-electrochemical techniques have been reported in the literature for the detection of NFT. Colorimetric and spectrophotometric methods have been used since the 1960s [18–20], and the use of high performance liquid chromatography (HPLC) began in the 1970s [21,22]. However, according to Jain et al. [23], the colorimetric and spectrophotometric techniques do not offer a satisfactory quantification limit for the determination of this drug. In addition, the chromatographic methods require pre-treatment and extraction stages for the sample, which demand a great amount of time and increase the cost of the analysis. These stages also increase the exposure time of the drug to light, which can promote the partial photochemical degradation of the compound.

On the other hand, electroanalytical techniques are increasingly used to detect organic compounds. These techniques have several advantages, including that they are quick and reproducible, present low limits of detection and quantification and have relatively low cost compared with the more traditional techniques [8]. The two initial reports about the use of electroanalytical techniques to determine NFT came from the sixties and seventies years, when Jones et al. [24] and Mason and Sandmann [25] reported the use of the polarographic method and the reductive voltammetric method using a rotating platinum electrode, respectively. Recently, three reports have been published that demonstrate the use of square wave cathodic adsorptive stripping voltammetry for the detection on mercury electrodes [17,23] and on activated carbon fiber microelectrodes [26]. In these works, this technique was shown to be a very sensitive and selective methodology for NFT analysis [17,23,26].

A literature survey revealed that no electrochemical studies have been published concerning the electrochemical behavior of NFT on BDDFE. Thus, the aim of this work was to investigate the electrochemical behavior of NFT and develop an electroanalytical procedure to quantify this compound in commercial formulations. This was performed using BDDFE with different boron-doping levels combined with the square wave voltammetry technique.

2. Experimental

2.1. Reagents and equipment

All voltammetric measurements were taken with a potentiostat (Autolab PGSTAT 30, Metrohm-Eco Chemie), which was controlled by a computer using the General Purpose Electrochemical System software, Version 4.9 (GPES; Metrohm—Eco Chemie). A Beckman Coulter model DU 640 spectrophotometer with 1.00 cm quartz cells was used for the ultraviolet–visible (UV–vis) measurements. A Micronal B474 pH meter equipped with a 3.0 $mol\,L^{-1}$ Ag/AgCl/KCl-glass combined electrode was used to adjust the pH values. All solutions were prepared with water purified by a Milli-Q system (Millipore Corporation). A conventional cell with a three-electrode system was used in all electrochemical experiments. The cell consisted of a saturated KCl Ag/AgCl/Cl^- electrode as the reference electrode, platinum wire as the auxiliary electrode and BDDFE with different boron-doping levels as the working electrode. Prior to the electrochemical measurements, N_2 gas was bubbled through the solution to eliminate any dissolved oxygen. The BDDFE employed as the working electrode was produced by LAS-INPE (São Paulo, SP, Brazil). The BDDFE were grown on planar silicon substrates by chemical vapor deposition, using previously described conditions [14]. Three boron-doping contents were used in this work: 1.9×10^{19}, 7.6×10^{20} and 1.5×10^{21} atoms cm^{-3}, corresponding to about 5000, 10,000 and 20,000 mg L^{-1}, respectively, for the ratio of boron to carbon dissolved in methanol. The working electrodes were built following the procedure described by Julião et al. [15,16]. In this procedure, the silicon substrate with the boron-doped diamond film was attached to a brass plate with silver paste for electrical contact, and it was further insulated with Teflon to protect areas other than the planar surface from contact with solutions. A stock solution of 1.0×10^{-3} mol L^{-1} USP-grade NFT dissolved in methanol (P.A.) was prepared daily. This was stored in a dark flask and kept in a refrigerator to prevent degradation. The stock solution was used as the supporting electrolyte in 0.1 mol L^{-1} Britton–Robinson (BR) buffer, which was prepared as described in the literature [27]. Solution pH was adjusted to the desired value by adding appropriate amounts of 2.0 mol L^{-1} NaOH stock solution. Prior to the voltammetric NFT experiments, the active electrode surfaces were determined by cyclic voltammetry of the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ in 0.1 mol L^{-1} KCl.

2.2. Working procedure

In this work, all electrochemical measurements were taken under ambient conditions. Prior to the experiments, the BDDFE was submitted to an anodic pre-treatment, which was carried out in 0.5 mol L^{-1} H_2SO_4 by applying a current of 500 mA cm^{-2} for 3 min, followed by a cathodic treatment, which was performed by applying −500 mA cm^{-2} for 10 min. Afterwards, the cyclic voltammetry (CV) experiments were conducted at 100 mV s^{-1} using the potential interval of +1.3 to −0.8 V in a cell containing 0.5 mol L^{-1} H_2SO_4 to provide the stabilized electrochemical profile of the working electrode. After each measurement with NFT, the solution was stirred thoroughly for 1 min to remove any possible residues adsorbed on the electrodic surface, thus ensuring experimental reproducibility. The cyclic voltammograms were recorded between −0.75 V and 0.0 V to evaluate the influence of different boron-doping levels on the electrochemical response of NFT on the BDDFE and also to determine the best electrolyte pH for electroanalytical purposes. Square wave voltammetry (SWV) was used for the electroanalytical determination of NFT. The following parameters were investigated to obtain the best analytical signal: peak current (I_p), peak potential (E_p), frequency of pulse potential (f), pulse amplitude (E_{sw}) and scan increment (ΔE_s). All parameters were duly optimized, as their values strongly affect the sensitivity of the voltammetry. After the optimization of the voltammetric parameters, analytical curves were obtained in pure electrolyte using the standard addition method. The standard deviation of the mean current, measured at the oxidation potential of NFT for 10 blank voltammograms in pure electrolyte (S_b), and the slope of the straight line from the analytical curves (s) were employed for the determinations of the detection

limit (DL) and of the quantification limit (QL), using $DL = 3S_b/s$ and $QL = 10S_b/s$ [28,29]. The proposed procedure was compared to the UV–vis spectrophotometric measurements, according to the procedure recommended by the British Pharmacopeia [30]. Thus, the spectrum and characteristic absorbance of NFT were evaluated at 368 nm. Analytical curves were also constructed, and the DL and QL values were calculated using the same relations employed for the voltammetric measurements. On the other hand, the S_b values were determined by the standard deviation of the y-intercept of the analytical curves. Recovery experiments were carried out using the voltammetry and spectrophotometry procedures. For this purpose, a known amount of a pharmaceutical formulation was added to the supporting electrolytes, followed by standard additions of the NFT stock solutions. The resulting analytical curves were plotted, and all measurements were taken in triplicate. The recovery efficiencies were calculated using the relationship between the determined NFT concentration, which was obtained by extrapolating the analytical curves of the corresponding spiked samples, and the NFT concentration added value, which corresponded to the nominal concentration of the samples, multiplied by 100. The precision of the proposed procedure was evaluated based on the reproducibility experiments, which were realized with different standard NFT solutions on different days (intra-day). The experimental accuracy was evaluated using the repeatability obtained in 10 replicated determinations with the same NFT solution (inter-day). The relative standard deviations (RSD) were calculated for the reproducibility and repeatability measurements, using the relationships between the standard deviation and the mean of the peak current values obtained.

2.3. Analysis of the commercial formulation

After calculating the DL and QL for the NFT determination in the supporting electrolyte, the accuracy, reproducibility, procedure precision and interference from excipients present in a commercial NFT formulation were studied. This was done by means of recovery experiments with a commercial product purchased locally. The commercial formulation chosen was Macrodantina (capsule form), which contained 100 mg of NFT. The content of 10 capsules was weighed, and the average mass of each capsule was calculated. The content was homogenized and the amount of NFT, required for the preparation of a solution with a final concentration of 1.0×10^{-3} mol L^{-1} NFT, was calculated based on the pharmaceutical product. This amount was then weighed and dissolved in methanol using an ultrasonic bath for 20 min. From this stock solution, a solution of 1.0×10^{-4} mol dm^{-3} was prepared in BR buffer. All solutions were used immediately after their preparation to prevent decomposition by light or heat.

3. Results and discussion

3.1. Cyclic voltammetry experiments

Fig. 1 shows the cyclic voltammograms of NFT in BR buffer at various pHs and the cyclic voltammograms obtained on the BDDFE containing different boron-doping levels. In these cyclic voltammograms, an irreversible reduction peak (C_1) can be observed in the cathodic scan. This cyclic voltammetric behavior was similar to that in previous reports in the literature that used other electrodic surfaces and other antibacterial nitro compounds [15–17,23,26]. The peak C_1 was shifted to more negative potential values with increasing pH, indicating the involvement of hydrogen ions in the electrode reaction. This dependence of the cathodic potential on pH is in agreement with other reports in the literature [15–17,23,26]. Experimental evidences indicate that the electrochemical reduction mechanism of the nitro group in the NFT molecule to the corresponding hydroxylamine involves four electrons and four protons [31].

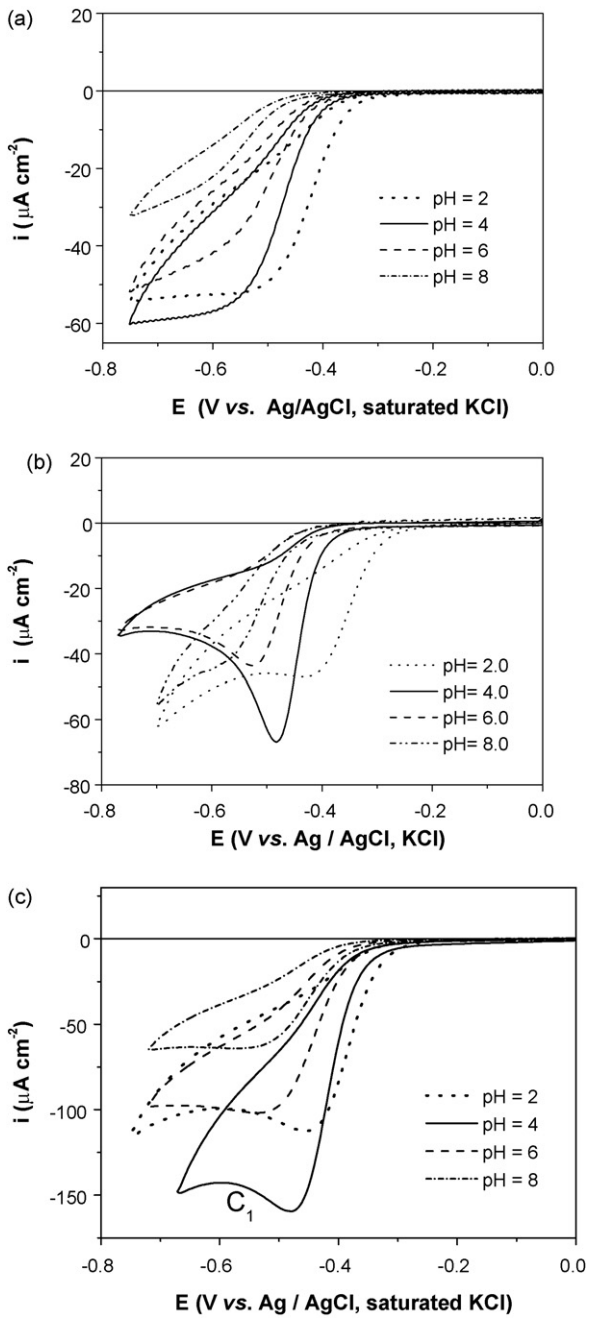

Fig. 1. Cyclic voltammograms for 1×10^{-4} mol L^{-1} NFT in BR buffer, at different pHs and at 100 mV s^{-1}, on the BDDFE with different levels of boron-doping: (a) 5000 mg L^{-1}; (b) 10,000 mg L^{-1}; (c) 20,000 mg L^{-1}.

Fig. 1 also shows that the boron-doping level affects the shape and the I_p of the peak C_1. For the electrode doped with 5000 mg L^{-1}, the peak was not well defined due to the competition between the NFT reduction and the hydrogen evolution reaction (HER). This suggests that this is not a suitable electrodic surface for the electroanalytical determination of NFT. For the electrodes with higher boron-doping contents, the peak C_1 was better defined in acidic pH because the hydrogen evolution reaction shifts to a more negative value, indicating that the increase in the boron-doping content in the diamond film decreased the electrocatalytic properties of this electrodic material for the HER. On the other hand, the peak C_1 was not well defined at pH 8.

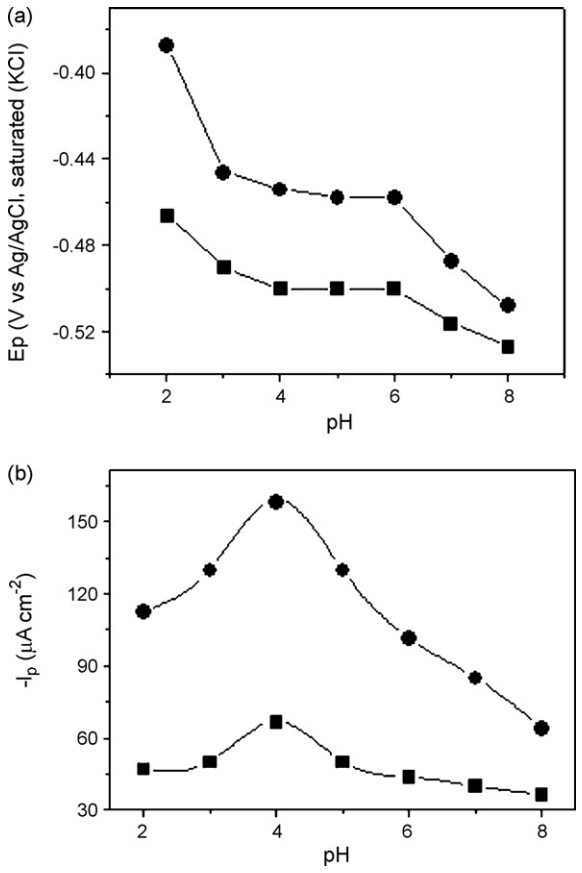

Fig. 2. Variation of E_p (a) and I_p (b) with pH for the electrochemical reduction of nitrofurantoin on the BDDFE doped with 10,000 mg L^{-1} (■) and 20,000 mg L^{-1} (●) of boron.

In order to better understand the influence of the pH in the electrochemical response of the nitrofurantoin, the variations of E_p and I_p with pH for the electrodes doped with 10,000 and 20,000 mg L^{-1} of boron are shown in Fig. 2. The E_p versus pH plot (Fig. 2a) shows three regions for both electrodes. Initially, a shift to more negative potentials was observed in the pH range from 2 to 4. For the pH range between 4 and 6, the E_p values remained approximately constant, followed by a shift to more negative potentials for higher pH values. Fig. 2a also shows that the E_p values obtained for the electrode doped with 10,000 mg L^{-1} of boron were slightly more negative than those obtained for the electrode doped with 20,000 mg L^{-1} of boron, suggesting that the increase in the amount of boron-doping favors the electrochemical reduction of the nitrofurantoin. Furthermore, the I_p versus pH plot (Fig. 2b) showed a maximum at pH 4, which indicates this pH as the optimum for electroanalytical purposes. In addition, comparing the electrodes doped with 10,000 and 20,000 mg L^{-1}, it can be observed that I_p increases about 2.4 times with twice the boron-doping level in the BDDFE. Zhang et al. [32] showed that the resistivity of the boron-doped diamond films decrease linearly with the increase in the amount of boron in the diamond film. Accordingly, the observed increase in I_p can be associated with the increase in the conductivity of the diamond film when the amount of boron is doubled. Unfortunately, a similar comparison cannot be done with the 5000 mg L^{-1} BDDFE because the current shown in the cathodic branch of Fig. 1a also has the contribution of the current related the hydrogen evolution reaction and well defined peaks were not observed. Morales et al. [33] used the polarographic technique to study the electrochemical reduction of nitrofurantoin on the Hg electrode; they observed three linear portions in the $E_{1/2}$ versus pH plot, and they found that the diffusion-limited current was also pH dependent. From the present authors [33], the decreases in the I_p for pH below 4 can be associated with an acid–base equilibrium. For pH higher than 4, the decrease in the I_p can be explained as due to the fact that the hydroxylamine intermediate in the reduction of the nitro group is no longer protonated and it is not easily reduced. Finally, the cyclic voltammetry studies at pH 4 showed a linear dependence between the peak current and the square root of the scan rate, indicating that the electrochemical reduction of NFT was controlled by diffusion. This is also in close agreement with the reports previously published in the literature for other nitro compounds [15–17,23,26].

Thus, to develop an electroanalytical procedure for the NFT determination on a BDDFE, a BR buffer solution with pH adjusted to 4.0 and electrodes doped with 10,000 and 20,000 mg L^{-1} boron were selected.

3.2. Square wave voltammetry experiments

Typical square wave voltammograms (SWV) for 1×10^{-4} mol L^{-1} NFT in BR buffer (pH 4) on the BDDFE are shown in Fig. 3. This figure shows a well-defined cathodic square wave voltammetric peak, which was observed for the two selected electrodes. The SWV parameters (f, E_{sw} and ΔE_s) were evaluated to determine the optimal values for obtaining the best analytical signal. The correlations between the peak current and the frequency of the pulse potential, the pulse amplitude and the scan increment are shown in Fig. 4.

The frequency was optimized in the range of 10–100 Hz, using an increment of 2 mV and a pulse amplitude of 50 mV. The variation of I_p with frequency for both selected electrodes is shown in Fig. 4a. A linear relationship was observed between the peak current and the frequency (f) for both selected electrodes, which yielded similar slopes. The increase in I_p with f suggests that the NFT was weakly absorbed on the electrode surfaces [34–36]. This was corroborated by the experimental evidence, as the voltammetric profile of NFT on the BDDFE surface was obtained again following agitation of the solution. For the BDDFE doped with 10,000 mg L^{-1} of boron, linearity was maintained up to 80 Hz. However, for the electrode doped with 20,000 mg L^{-1} boron, linearity was observed over the entire analyzed frequency range. In addition, the electrode doped with 20,000 mg L^{-1} boron presented higher I_p values, while the E_p values were approximately independent of frequency.

The influence of E_{sw} on the I_p intensities was evaluated for values of E_{sw} from 10 to 80 mV, and the results are shown in Fig. 4b.

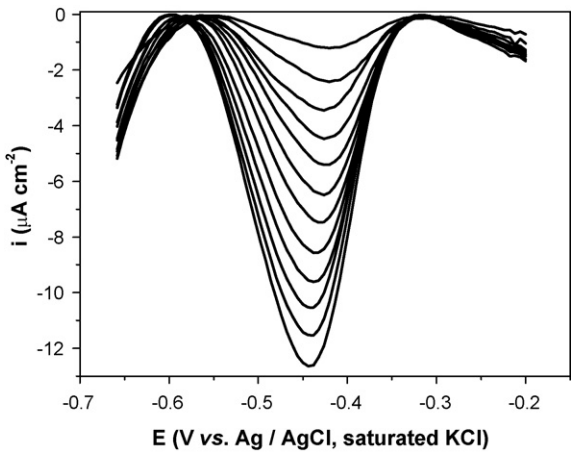

Fig. 3. Typical square wave voltammograms obtained for the NFT in BR buffer at pH 4 in the concentration range of 4.97–56.6 × 10^{-7} mol L^{-1} NFT on the BDDFE. In this case, the BDDFE electrode was doped with 10,000 mg L^{-1} boron.

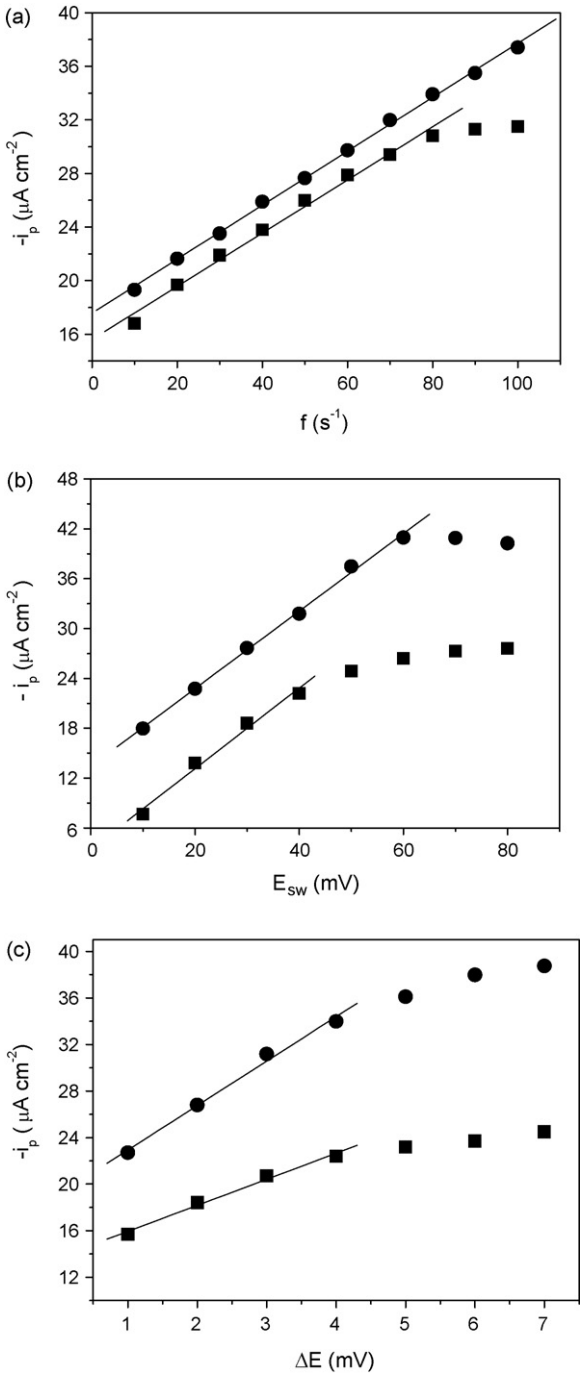

Fig. 4. Variation of the peak current with the frequency of the pulse potential (a), pulse amplitude (b) and scan increment (c) obtained from the square wave voltammograms of 1×10^{-4} mol L^{-1} NFT in BR buffer at pH 4 on the BDDFE doped with 10,000 mg L^{-1} (■) and 20,000 mg L^{-1} (●) of boron.

For both electrodes, the increase of E_{sw} led to an increase in I_p. For the 10,000 mg L^{-1} boron electrode, a linear relationship was observed up to 40 mV, while for higher E_{sw}, the I_p tended to reach a plateau. For the 20,000 mg L^{-1} boron electrode, a linear relationship between E_{sw} and I_p was observed up to 60 mV, and for E_{sw} higher than 60 mV, the I_p remained approximately constant. For the higher boron-doping contents, the I_p values were higher than those obtained for 10,000 mg L^{-1} of boron. Additionally, the E_p value showed no variation with E_{sw}.

The response of I_p with ΔE_s is shown in Fig. 4c. These results show that I_p increased with increasing ΔE_s. Additionally, a linear relationship between I_p and ΔE_s was observed from 1 mV to 4 mV, and the slopes were similar. For ΔE_s higher than 4 mV, the increase in the I_p values with ΔE_s was not linear.

Therefore, for investigations concerning the influence of the boron-doping content of the BDDFE on the electroanalytical NFT determination, the discussion presented in the previous paragraphs indicates that the optimized experimental conditions are as follows: f = 80 Hz, E_{sw} = 40 mV and ΔE_s = 4 mV for the electrode doped with 10,000 mg L^{-1} boron, and f = 100 Hz, E_{sw} = 60 mV and ΔE_s = 4 mV for the electrode doped with 20,000 mg L^{-1} boron.

3.3. Analytical curves

The optimized parameters were employed to draw the analytical curves for NFT reduction on the BDDFE in BR buffer solution. These parameters were also used to evaluate the influence of the boron-doping content on the sensitivity of the proposed procedure and for the applications of the commercial pharmaceutical formulation.

The NFT analytical curves were obtained, as described in Section 2, for the concentration range of 4.97–56.6 × 10^{-7} mol L^{-1}. Aliquots from the NFT stock solution were added consecutively to the electrochemical cell, and the voltammetric responses were recorded and are presented in Fig. 5. A linear relationship can be observed between the peak current and the added concentration of NFT for both BDDFE. The linear behavior was maintained for the electrode doped with 20,000 mg L^{-1} of boron for all studied NFT concentrations. However, for the electrode doped with 10,000 mg L^{-1}, the I_p values slightly deviated from colinearity for the higher concentrations of NFT.

Table 1 presents the analytical parameters obtained for the NFT determination using the SWV and UV–vis spectrophotometry procedures. These include the linearity range (LR), analytical curve equations, correlation coefficients (r; determined by the degree of linearity for the correlation between NFT concentration and peak currents), standard error of the intercept (SE_a), standard error of the slope (SE_b), standard deviation of the arithmetic mean of 10 blank solutions (S_b), detection limits (DL), quantification limits (QL), repeatability and reproducibility. All data shown in this table were obtained in triplicate, and the results reported here represent the average of the values obtained.

The results for the regression equation associated with the analytical curves exhibited good linearity, as shown in Table 1, indicating the validation of the proposed procedure. In addition, the electrode doped with 20,000 mg L^{-1} presented a higher slope

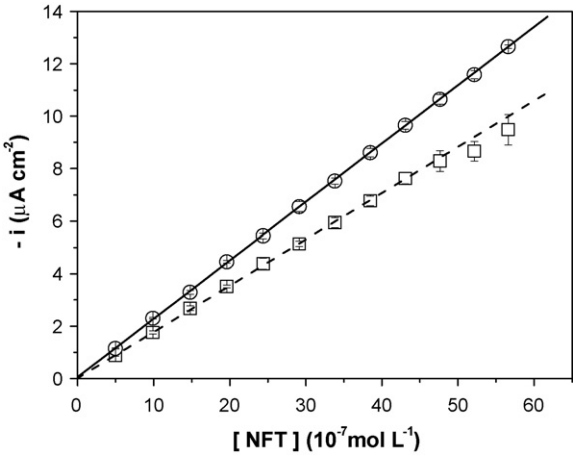

Fig. 5. Analytical curves obtained for the BDDFE with boron-doping levels of 10,000 mg L^{-1} (□) and 20,000 mg L^{-1} (○).

Table 1
Analytical parameters obtained for the NFT determination using SWV and UV–vis spectrophotometry procedures. LR: linearity range; r: correlation coefficient; SE_a: standard error of the intercept; SE_b: standard error of the slope; S_b: standard deviation of the arithmetic mean of 10 blank solutions; DL: detection limit; QL: quantification limit; RSD: relative standard deviation.

Parameters	BDDFE-SWV		UV–vis spectrophotometry

Reproducibility	3.40% (n = 5)	1.19% (n = 5)	7.22% (n = 9)

Table 2
Results obtained from the recovery curve of NFT for the commercial formulation and using the two analytical procedures employed here.

Parameters	BDDFE-SWV		UV–vis
	10,000 mg L^{-1}	20,000 mg L^{-1}	
$[NFT]_{added}$ (mol L^{-1})	9.9×10^{-7}	9.9×10^{-7}	10.15×10^{-7}
$[NFT]_{found}$ (mol L^{-1})	$(10.36 \pm 0.2) \times 10^{-7}$	$(10.23 \pm 0.2) \times 10^{-7}$	$(10.87 \pm 0.7) \times 10^{-7}$
Recovery (%)	105 ± 3	103 ± 2	107 ± 4

for the calibration curve, indicating that the increase in the boron-doping content led to an increase in the sensibility of the proposed procedure.

The validation of the procedure was also examined by evaluating the DL and QL, as described in Section 2 and as recommended by the IUPAC [28]. These values were compared to similar results obtained using UV–vis spectrophotometry, as recommended in the British Pharmacopeia [30]. As shown in Table 1, the more highly boron-doped electrodes presented lower DL and QL calculated values. The DL and QL values for both selected electrodes, as calculated by the proposed procedure, were very close to the values reported in the literature for NFT determination using SWV, with previous cathodic adsorptive stripping that utilized a mercury electrode [17,23] and a carbon fiber microelectrode [26]. The DL and QL of the proposed procedure were lower than those presented by the recommended procedure, indicating that the BDDFE combined with SWV is a suitable tool for the NFT determination. Furthermore, the BDDFE proved to be suitable electrodic surfaces for the NFT determination, as it was possible to perform the NFT determination without modification of the electrode surface or complex electrochemical pre-treatments. This enables the simplification of the analytical procedure, thus lowering the cost and providing reliable sensitivity for analytical purposes.

The precision and accuracy were also evaluated using the proposed SWV procedures, considering the two selected electrodes and using the recommended UV–vis spectrophotometry procedure. The precision was evaluated from reproducibility experiments in which five different measurements, performed on different days, were carried out employing a standard solution containing 9.9×10^{-7} mol L^{-1} NFT and using the procedure described earlier. The measurement accuracy was also evaluated from 10 repetitive determinations (repeatability) of the same standard solution.

From the obtained results (Table 1), it is apparent that the BDDFE with 20,000 mg L^{-1} boron as the doping level presented better reproducibility and repeatability compared to the BDDFE with 10,000 mg L^{-1} boron. However, the reproducibility and repeatability of the NFT electrochemical reduction process on both selected BDDFE were very good.

These results indicate that both electrodes are excellent electrodic materials for the NFT determination. They can replace other electrodic surfaces, such as mercury electrodes. Also, the proposed procedure using BDDFE with the SWV technique can be a substitute for the UV–vis spectrophotometry procedure.

3.4. Application of the proposed procedure to a commercial formulation

The determination of NFT in its pharmaceutical formulation was carried out to evaluate the applicability of the proposed procedure toward complex samples. There was no need for an extraction step prior to the drug assay. The experiments were carried out in triplicate with both the SWV and UV–vis procedures. The recovery curves were built by the standard addition method, and the recovery percentage was identified graphically, with the abscissa axis referring to the NFT concentration in the electrochemical cell. Extrapolating the curve along this axis yielded the sample concentration, allowing for the calculation of the recovery values. Table 2 shows the results obtained from the NFT recovery curve for the commercial formulation and using the two analytical procedures employed here. The calculated values are shown to be in a suitable range for analytical purposes (i.e., from 70% to 130%) [37,38], indicating that the proposed procedure is appropriate for NFT quantification in complex samples, such as pharmaceutical formulations. In addition, the recovery values for both selected electrodes were similar to those reported in the literature for the NFT determination on mercury electrodes using square wave cathodic adsorptive stripping voltammetry. These recovery values were 101.49 [18] and 99.87 [23]. Finally, the boron-doping content did not influence the recovery value.

4. Conclusions

The electrochemical reduction of NFT is influenced by the level of boron-doping in diamond film electrodes. The appropriate cyclic voltammetric response of NFT was obtained with a BR buffer at pH 4 on diamond films doped with 10,000 and 20,000 mg L^{-1} boron. The use of square wave voltammetry with the optimized parameters showed a good linear relationship between the peak current and the NFT concentration over a wide concentration range. The proposed procedure proved to be sensitive, accurate and precise for the

analysis of NFT and did not require complex preparations or renovation of the electrode surface. Finally, boron-doped diamond film electrodes can be considered as environmentally friendly alternatives for the electroanalytical determination of NFT. This presents the advantage of eliminating mercury waste and minimizing the adsorptive problems related to the use of other electrodic solid surfaces.

Nanoporous gold leaf electrode

ABSTRACT

A new electrochemiluminescence (ECL) DNA assay is developed using quantum dots (QDs) as DNA labels. When nanoporous gold leaf (NPGL) electrodes are used, sensitivity of the ECL assay is remarkably increased due to ultra-thin nanopores. In this assay, target DNA (t-DNA) is hybridized with capture DNA (c-DNA) bound on the NPGL electrode, which is fabricated by conjugating amino-modified c-DNA to thioglycolic acid (TGA) modified at the activated NPGL electrode. Following that, amino-modified probe DNA is hybridized with the t-DNA, yielding sandwich hybrids on the NPGL electrode. Then, mercaptopropionic acid-capped CdTe QDs are labeled to the amino group end of the sandwich hybrids. Finally, in the presence of $S_2O_8^{2-}$ as coreactant, ECL emission of the QD-labeled DNA hybrids on the NPGL electrode is measured by scanning the potential from 0 to −2 V to record the curve of ECL intensity versus potential. The maximum ECL intensity ($I_{m,ECL}$) on the curve is proportional to t-DNA concentration with a linear range of 5×10^{-15} to 1×10^{-11} mol/L. The ECL DNA assay can be used to determine DNA corresponding to mRNA in cell extracts in this study.

1. Introduction

As an analytical technique, electrochemiluminescence (ECL) assays possess several advantages such as low background noise, high sensitivity and selectivity, as well as high versatility [1]. A variety of ECL luminophores, including inorganic and organic luminophores, have been discovered and extensively applied in bioanalysis. Recently, quantum dots (QDs) as a new kind of ECL luminophores have been developed. However, analytical applications of QD ECL are still limited. It is noted that all reported analytical methods relying on ECL of QDs can be divided into two kinds based on relationship between signal and concentration. In the first kind, detected signal is proportional to concentration of target molecules. These methods are suitable only for coreactants such as H_2O_2 [2–5] and 2-(dibutylamino)ethanol [6]. In the second kind, ECL signal decreases with increasing concentration of target compounds. Some of the target compounds react with ECL coreactants (glucose [7]) or with their products in ECL pathways of QDs (thiol compounds [8–10]). Other target compounds are quenchers (proteins [11,12]) or products of their chemical (tyrosine [13]) or electrochemical reaction (catechol derivatives [14]) are quenchers. In conventional and commercial biological assays based on ECL of inorganic and organic luminophores, the luminophores are most commonly used as labels [1,15]. If QDs can serve as ECL labels of biomolecules, a variety of ECL bioassays will be developed.

Recently, Ding et al. reported a simple dealloying route to make ultra-thin nanoporous gold leaves (NPGLs) that are free-standing, highly conductive with tunable nanoporosity and very high surface area [16–18]. NPGLs can float on aqueous solution and be easily attached to a variety of substrates. Importantly, NPGLs are nearly transparent, an essential character for ECL applications. In this paper, we realize the new ECL assay mode at NPGL electrodes using CdTe QDs as the ECL label. DNA is chosen as the model biomolecule because of its importance in the study of genetic basis of diseases, clinical diagnosis and gene therapy. Indeed, our results show extraordinary and reproducible DNA detection at a concentration down to 5×10^{-15} mol/L. In order to verify the method, the DNA synthesized corresponding to cellular osteopontin (OPN) mRNA is quantified.

2. Materials and methods

2.1. Materials

Tellurium powder and sodium borohydride from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China), cadmium chloride from Alfa Aesar China Ltd. (Tianjin, China), Bovine serum albumin (BSA), thioglycolic acid (TGA) and mercaptopropionic acid (MPA, 99%) from Sigma (St. Louis, MO, USA), *N*-hydroxysuccinimide (NHS) from Huifeng Chemical Industry Ltd. (Weinan, China), L-cysteine

from KangDa Amino Acids Co. (Shanghai, China), 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC) from Shanghai Medpep Co., Ltd. (Shanghai, China), $K_2S_2O_8$ from Tianjin Dongfang Chemical Plant (Tianjin, China), RNase H (60 U/μL) and 5× hybrid RNA degeneration buffer from TaKaRa Biotechnology Co., Ltd. (Dalian, China) and diethypyrocarbonate (DEPC) from Bio Basic Inc. (Ontario, Canada) were used in this work. Other chemicals (analytical grade) were obtained from standard reagent suppliers. The phosphate buffer (PB) (pH 7.4) consisted of 7.6×10^{-3} mol/L NaH_2PO_4, and 2.4×10^{-3} mol/L Na_2HPO_4. The physiological buffer saline (PBS) consisted of 0.15 mol/L NaCl, 7.6×10^{-3} mol/L NaH_2PO_4 and 2.4×10^{-3} mol/L Na_2HPO_4 (pH 7.4). The borate buffer consisted of 0.2 mol/L H_3BO_3 and 0.05 mol/L $Na_2B_4O_7$ (pH 7.4). DEPC water was prepared by incubating 1 L of doubly distilled water with 1 mL of DEPC for 4 h.

Single-stranded DNAs (sequences shown in Table 1) were purchased from SBS Genetech Co., Ltd. (Beijing, China). 1.00×10^{-4} mol/L stock solutions for each DNA were prepared by centrifuging for 1 min at 1000 rpm and dissolving in an appropriate volume of borate buffer and stored at −20 °C. Dilute DNA solutions were obtained by a serial dilution with borate buffer. Preparation of the DNA solutions was performed in a clean bench. To prevent the contamination from the possible repeat sampling, aliquots of DNA stock solutions were stored in sterile plastic tubes. The DNA sample synthesized from intracellular OPN mRNA and its standard solutions were provided by School of Life Science, Shandong University. All aqueous solutions were prepared with doubly distilled water. Extra care was taken to minimize contamination accordingly to our previous description [19].

2.2. Apparatus

The voltammetric and ECL measurements were performed using a CHI832 electrochemical analyzer (CH Instruments, Austin, TX, USA). A PMT (model H9305-04, Hamamatsu Photonics K. K., Japan) with a spectral width of 185–830 nm was used to measure ECL emission. A TU-1901 UV–vis spectrophotometer (Beijing Purkinje General Instrument Co., Ltd., Peking, China) and an FL-4500 spectrofluorimeter (Hitachi, Japan) were used to acquire UV–vis absorption spectra and photoluminescence spectra, respectively.

2.3. Preparation of water-soluble CdTe QDs

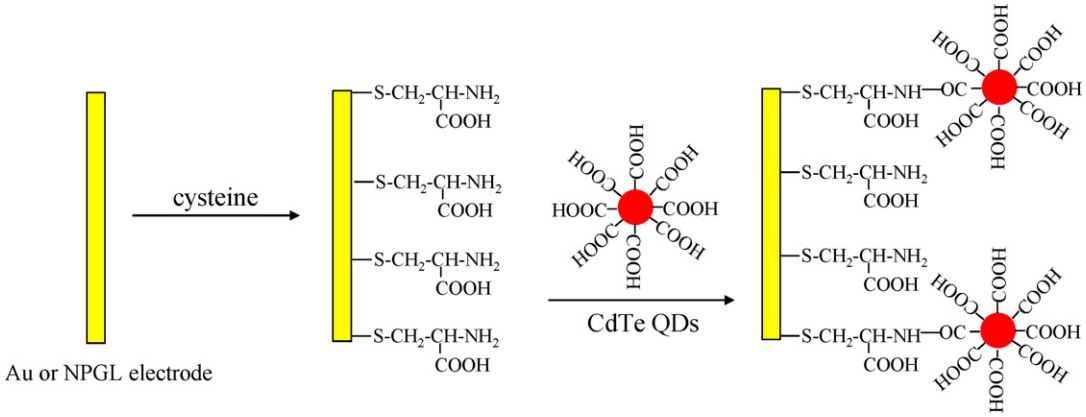
MPA-capped CdTe QDs were synthesized using a slightly modified procedure reported in Ref. [9]. First, NaHTe solution was synthesized. After 0.024 g of Te powder, 0.032 g of $NaBH_4$ and 5 mL of H_2O were mixed in a 50-mL three-necked pear-shaped flask, the mixture was bubbled with highly pure N_2 for 60 min at room temperature to obtain NaHTe solution (supernatant) for use. In a 100-mL three-necked flask with 50 mL oxygen-free water, 1 mL of 0.1 mol/L $CdCl_2$ and 30 μL of MPA were added and the pH value of the solution was adjusted to 9–10 using 1 mol/L NaOH. After bubbling with highly pure N_2 for 30 min, 800 μL of NaHTe solution was slowly added into the vigorously stirred oxygen-free solution. The solution was refluxed for 6 h under open-air conditions to obtain a yellow brown solution containing ~2.5-nm CdTe QDs. The mixture was dialyzed against doubly distilled water for 5 h to purify QDs. The CdTe QD solution is stable for more than 3 months at 4 °C.

2.4. Preparation of NPGLs

NPGLs were prepared by floating 12 carat white-gold leaves (Ag/Au, 1:1 by weight, Sepp Leaf Products, New York, USA) onto concentrated HNO_3 solution for 60 min [18], which were subsequently rinsed with doubly distilled water for a couple of times. During this process, nearly all Ag atoms were dissolved away, leaving behind a bicontinuous porous Au membrane structure with a thickness around 100 nm.

2.5. Voltammetric and ECL measurements

Voltammetric and ECL measurements were carried out using a three-electrode system consisted of an Au disk or a NPGL working electrode, a saturated calomel reference electrode and a Pt auxiliary electrode. The NPGL working electrode was fabricated by attaching an NPGL sample onto a 6-mm diameter Au disk electrode, which was then cured for 20 min at 120 °C in an oven. Before use, the Au disk electrode was polished with 0.05 μm γ-Al_2O_3 and cleaned with ethyl alcohol and doubly distilled water, respectively, in an ultrasonicator. Before measurements, the Au disk and NPGL electrodes were activated by performing repetitive cyclic scans between 0.0 and 1.5 V at 50 mV/s in 0.5 mol/L H_2SO_4 until stable voltammograms were obtained, followed by washing with doubly distilled water. In ECL measurements, the electrochemical cell with the three electrodes and the PMT were placed in a dark box in order to prevent any light from external sources. The Au disk or NPGL electrode faced the observation window of the PMT and was directly connected to the first working electrode port of the electrochemical analyzer. The output end of the PMT was connected to the second working electrode port of the electrochemical analyzer to record ECL intensity (I_{ECL}). ECL measurements were performed in PB-$K_2S_2O_8$ solution (0.1 mol/L PB (pH 7.4) containing 0.1 mol/L $K_2S_2O_8$ and 0.1 mol/L KNO_3). The curve of I_{ECL} versus applied potential (E) was recorded by scanning the potential from 0.0 to −2 V.



2.6. MPA-capped CdTe QDs immobilization on Au disk electrode and NPGL electrode

The procedure of immobilizing MPA-capped CdTe QDs onto the Au disk electrode or NPGL electrode was illustrated in Scheme 1. First, cysteine was self-assembled on the activated electrode described above by immersing the electrode in 0.02 mol/L cysteine

Scheme 1. Steps for immobilizing CdTe QDs onto Au disk electrode or NPGL electrode.

solution (5 mL) for 10 h. After washing twice with doubly distilled water, carboxyl group of the MPA-capped CdTe QDs was covalently conjugated to amino group of the cysteine on the electrode through EDC and NHS [20]. To do so, 25 μL of a solution containing 100 mg/mL EDC and 100 mg/mL NHS and 25 μL of 2×10^{-4} mol/L MPA-capped CdTe QD solution were dropped onto the Au disk or NPGL electrode and the assembly was incubated for 3 h for the Au disk electrode and 6 h for the NPGL electrode in a constant-humidity chamber as described in our previous work [21], followed by washing twice with doubly distilled water.

2.7. DNA determination using CdTe QDs as ECL labels

The activated NPGL electrode was immersed in 0.01 mol/L TGA solution (5 mL) for 10 h, followed by washing with doubly distilled water. Then, the NPGL electrode was incubated for 10 h with a solution consisted of 20 μL of EDC (100 mg/mL) and NHS (100 mg/mL), 10 μL of 1.0×10^{-5} mol/L amino-modified capture DNA (c-DNA) in borate buffer (pH 7.4) and 50 μL of 1 mol/L NaCl and for 3 h with 2% BSA solution (20 μL), respectively, in the constant-humidity chamber. After that, the NPGL electrode was incubated for 10 h with 2 mL of different concentrations target DNA (t-DNA) in 0.5 mol/L NaCl, for 10 h with 2 mL of 5×10^{-10} mol/L probe DNA (p-DNA) in 0.5 mol/L NaCl and for 10 h with 2 mL of 1×10^{-4} mol/L MPA-capped CdTe QD solution containing 50 mg/mL EDC and 50 mg/mL NHS, respectively. In the incubation steps, the solutions were shaken gently at 72 rpm. After each incubation, the electrode was washed five times with PBS (pH 7.4) and 1 mol/L NaCl, respectively. Finally, ECL emission of the CdTe QDs labeled on the sandwich DNA hybrids immobilized on the NPGL electrode was detected.

2.8. Quantification of DNA synthesized corresponding to intracellular OPN mRNA

The DNA sample contained the hybrid of OPN mRNA and its complementary DNA, which was synthesized from cellular OPN mRNA template in the cell extract using reverse transcription. In order to obtain single-stranded DNA, the mRNA in the RNA-DNA hybrid was digested by mixing 15 μL of the sample solution, 1 μL of RNase H, 15 μL of 5× hybrid RNA degeneration buffer and 44 μL of DEPC water, and incubating at 30 °C for 1 h. For purification of the single-stranded DNA, 7.5 μL of 3 mol/L NaOAC (pH 5.2) and 187.5 μL of 100% ethanol were added, followed by placing it at −20 °C for 1 h. Then, the DNA was collected by centrifuging for 10 min at 12,000 rpm. After washing with 70% ethanol, the DNA was dried in air. The resulting DNA was dissolved in 15 μL of DEPC water. After that, 1 μL of the DNA solution was diluted to 20 mL of 0.5 mol/L NaCl. Finally, the 2 mL of the diluted solution was used to determine DNA using the ECL method according to the procedure described above. In this case, the sequences of c-DNA and p-DNA are shown in Table 1. The maximum ECL intensity ($I_{m,ECL}$) on the I_{ECL}–E curves was used for quantification using the calibration curve method.

3. Results and discussion

3.1. Cathodic ECL behavior of CdTe QDs on NPGL electrodes

NPGLs are large scale, crack-free, large surface area, corrosion resistive and conductive electrode materials that can be easily transferred from various solutions to substrates. Because of the intrinsic hydrophilic nature of Au and the capillary force of nanopores, solutions and molecules can be readily pulled into the nanopores for electrode reactions. The scanning electron microscopy (SEM) image of NPGL in Fig. 1 displays a uniform pore size distribution centered around ~20 nm. The active surface area of the NPGL electrode can be estimated by cyclic voltammetry in 0.5 mol/L H_2SO_4 [22]. Based on the specific charge value of 386 μC/cm^2 for gold oxide reduction [23] and the area of the reduction peak on the voltammogram (Fig. 2, curve 1), we can calculate the active area to be 198 mm^2, whereas the active area of a flat Au disk electrode with the same geometric area, calculated from its voltammogram, is 26 mm^2 (Fig. 2, curve 2). This indicates a ~7.6-fold area enhancement for NPGL electrodes.

In this work, the as-prepared MPA-capped CdTe QDs in 0.1 mol/L PB (pH 7.4) can be characterized by its photoluminescence (PL) and UV–vis absorption spectra. The maximum absorption appears at 375 nm. When the QDs are exited at 385 nm, the PL maximum

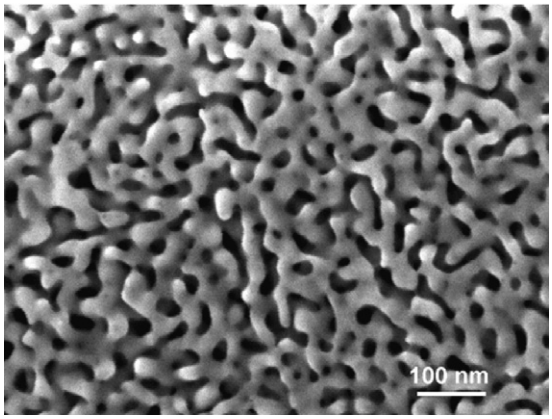

Fig. 1. Plan-view SEM image of NPGL.

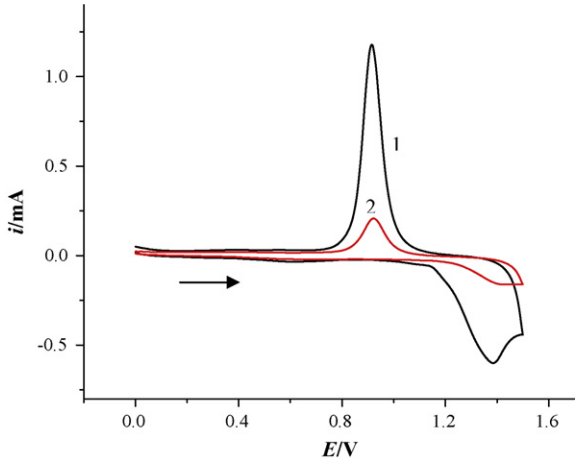

Fig. 2. Cyclic voltammograms of (1) NPGL electrode and (2) Au disk electrode with a geometric area of 28.3 mm^2 in 0.5 mol/L H_2SO_4. Scan rate: 50 mV/s.

wavelength (530 nm) is shifted to the red light direction, indicating quantum confinement [23]. The size of CdTe QDs is calculated to be ~2.5 nm based on the absorption peak on the UV–vis spectrum using the empirical equations [24].

Anodic ECL behavior and mechanism of MPA-capped CdTe QDs with O_2 [9] or sulfite/O_2 [7] as coreactant at an indium tin electrode [9] or at a paraffin-impregnated graphite electrode [7] and MPA-capped CdTe QDs with amines as coreactant at a glassy carbon electrode [14] have been investigated. Here we compare the cathodic ECL behavior of MPA-capped CdTe QDs with O_2, H_2O_2 and $S_2O_8^{2-}$ as coreactant at the Au disk electrode and NPGL electrode. The CdTe QDs were immobilized on the Au disk electrode and NPGL electrode according to the procedure described in Section 2. In this case, maximum coverage of CdTe QDs on both electrodes was obtained. Fig. 3 shows the I_{ECL}–E curves of MPA-capped CdTe QDs in air-saturated 0.1 mol/L PB (pH 7.4) containing 0.1 mol/L KNO_3 with and without H_2O_2 or $S_2O_8^{2-}$. MPA-capped CdTe QDs can emit light in all three solutions. The maximum ECL intensity ($I_{m,ECL}$) for $S_2O_8^{2-}$ is higher than that in the air-saturated solution with and without H_2O_2. Additionally, $I_{m,ECL}$ measured at the NPGL electrode is 5.7-fold higher than those at the Au disk electrode. A possible reason is that the amount of the CdTe QD immobilized on the NPGL electrode is more than that on the Au disk electrode due to its nanoporous structure with a large surface area, which results in the occurrence of ECL signal not only at the surface but also inside the nanopores of the NPGL electrode. The relationships between $I_{m,ECL}$ and the concentration of H_2O_2 or $S_2O_8^{2-}$ is shown in Fig. 4. When the concentration of H_2O_2 or $S_2O_8^{2-}$ is higher than 0.04 or 0.1 mol/L, $I_{m,ECL}$ hardly changes. The maximum value of $I_{m,ECL}$ using $S_2O_8^{2-}$ as coreactant is ~2.7-fold higher than that using H_2O_2. Therefore, ECL of CdTe QDs immobilized on the NPGL electrode coupled with $S_2O_8^{2-}$ as coreactant was used in our work.

3.2. Cathodic ECL mechanism of CdTe QDs with $S_2O_8^{2-}$ as coreactant at Au electrode

In order to investigate cathodic ECL mechanism of CdTe QDs/$S_2O_8^{2-}$ system in 0.1 mol/L PB (pH 7.4) containing 0.1 mol/L KNO_3, dissolved oxygen was removed from the solution by bubbling high-purity nitrogen, as oxygen can be reduced and catalyze ECL emission of QDs [5]. The cyclic voltammograms and I_{ECL}–E curves of PB (pH 7.4) containing 0.1 mol/L KNO_3 with and without $S_2O_8^{2-}$ at the Au disk electrode are shown in Fig. 5. In the solution without $S_2O_8^{2-}$, neither cathodic/anodic peak nor ECL was observed (curve 1 in Fig. 5A). In the presence of $S_2O_8^{2-}$, one cathodic

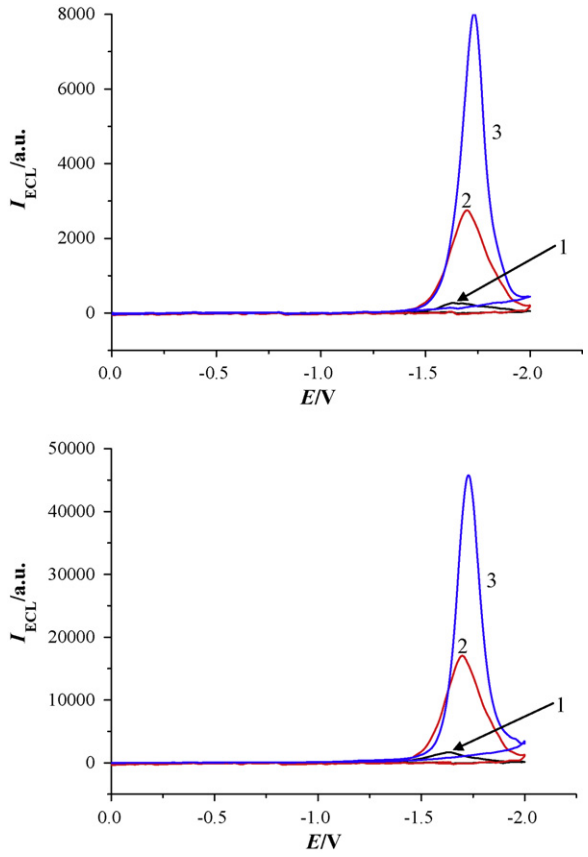

Fig. 3. I_{ECL}–E curves of MPA-CdTe QDs immobilized on (A) Au disk electrode and (B) NPGL electrode in air-saturated 0.1 mol/L PB (pH 7.4) containing 0.1 mol/L KNO_3 (1) without and with (2) 0.1 mol/L H_2O_2 or (3) 0.1 mol/L $S_2O_8^{2-}$ as the coreactant. Scan rate: 50 mV/s.

peak appears on the cyclic voltammogram (curve 2 in Fig. 5A), which corresponds to the reduction of $S_2O_8^{2-}$ to anion sulfate radical $SO_4^{\bullet-}$ according to reaction (1). In this case, no ECL emission was observed (curve 2 in Fig. 5D). The cyclic voltammograms and I_{ECL}–E curves of CdTe QDs at the Au disk electrode with and without $S_2O_8^{2-}$ in the same solution are also shown in Fig. 5. In the absence of $S_2O_8^{2-}$, a cathodic reduction peak is displayed on the voltammogram (curve 3 in Fig. 5B) and a very low ECL signal was observed (curve 3 in Fig. 5D). The cathodic peak attributes to electrochemical

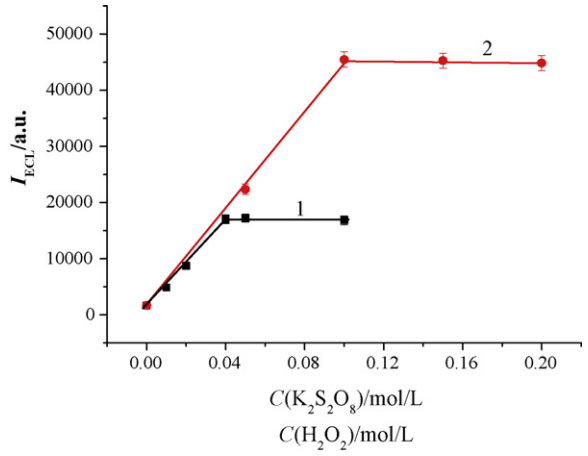

Fig. 4. Relationships between $I_{m,ECL}$ of MPA-CdTe QDs immobilized on Au disk electrode and coreactant concentration of (1) H_2O_2 and (2) $K_2S_2O_8$. 0.1 mol/L PB (pH 7.4).

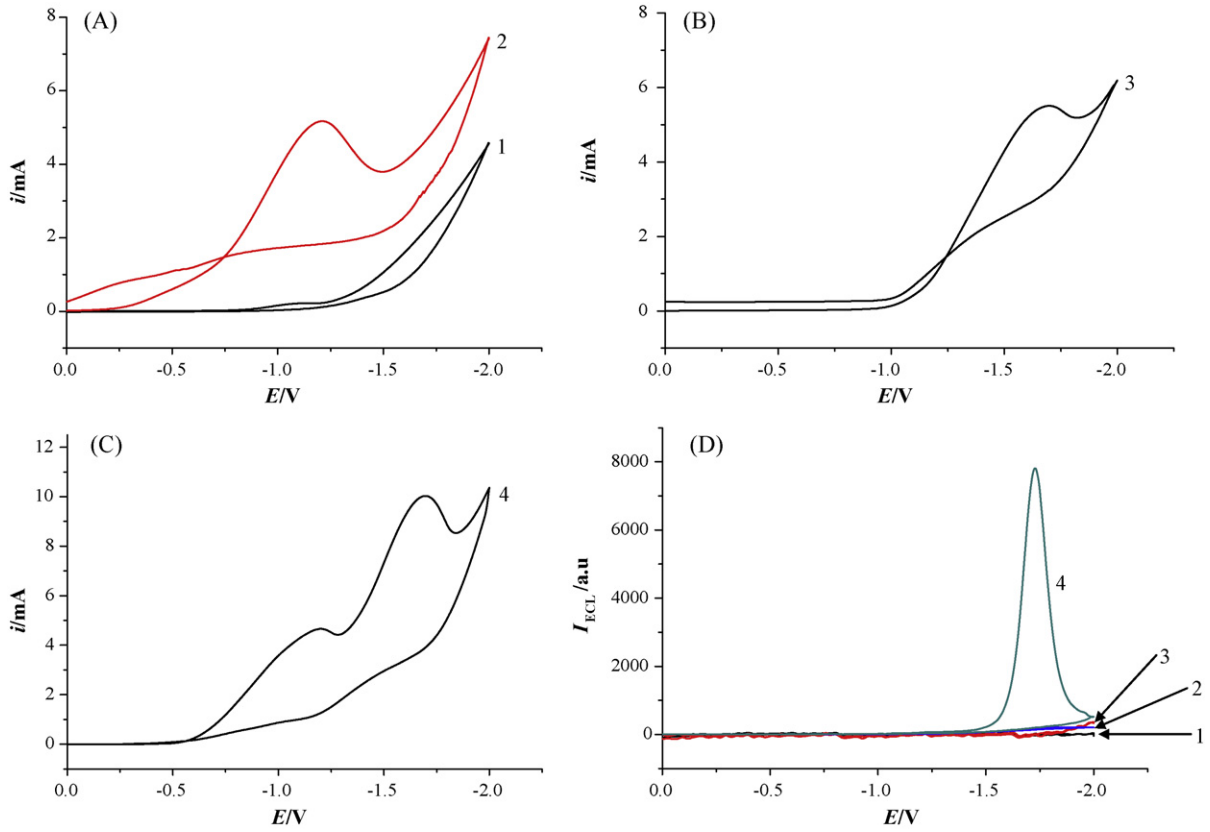

Fig. 5. (A–C) Cyclic voltammograms and (D) I_{ECL}–E curves at Au disk electrode. (1) PB (pH 7.4) containing 0.1 mol/L KNO_3 bubbled with nitrogen for 15 min, (2) (1) + 0.1 mol/L $K_2S_2O_8$, (3) (1) + MPA-CdTe QDs, and (4) (1) + MPA-CdTe QDs and 0.1 mol/L $K_2S_2O_8$. Scan rate: 50 mV/s.

reduction of the CdTe QDs, producing negatively charged radicals ($CdTe^{\bullet -}$). The electrochemical process can be expressed in reaction (2). In the presence of $S_2O_8^{2-}$, two cathodic peaks corresponding to the reduction of $S_2O_8^{2-}$ and CdTe QDs were still observed and no new peak was found (curve 4 in Fig. 5C), implying that no new electrochemical reaction occurs. In this system, a very strong ECL emission was observed with a peak potential of ~−1.75 V as indicated in curve 4 (Fig. 5D). According to the mechanism of other QDs such as Si [25], CdSe [11,26], CdS [12,27], Bi_2Te_3 [28], and ZnS QDs [29], the possible ECL mechanism of the CdTe QDs/$S_2O_8^{2-}$ system can be expressed as reactions (1)–(4): CdTe QDs and $S_2O_8^{2-}$ are electrochemically reduced to $CdTe^{\bullet -}$ and $SO_4^{\bullet -}$, respectively. The formed $SO_4^{\bullet -}$ reacts with $CdTe^{\bullet -}$ generated at the electrode by injecting a hole (h^+) into the highest occupied molecular orbital (HOMO) to produce the excited state CdTe*, which emits light.

$$S_2O_8^{2-} + e^- \rightarrow SO_4^{2-} + SO_4^{\bullet -} \quad (1)$$

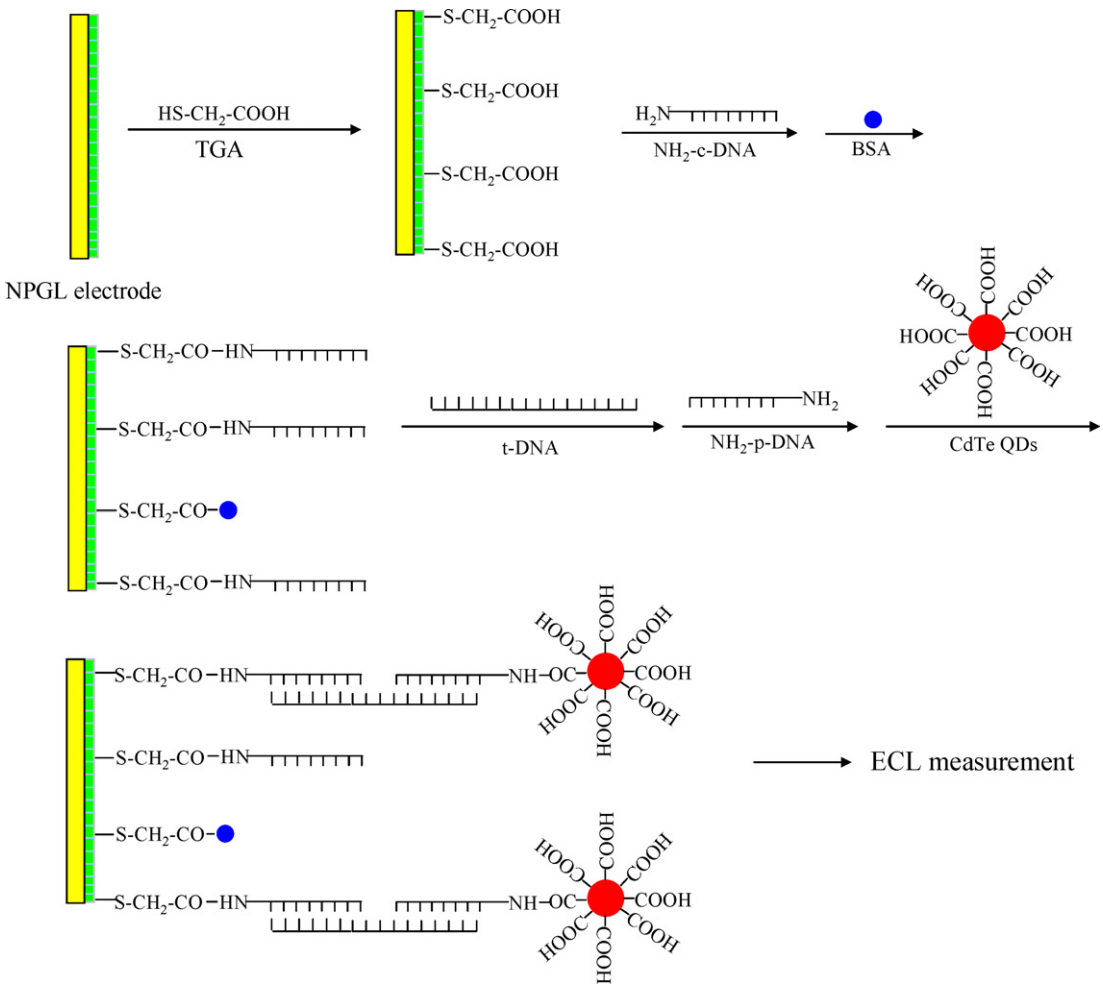
$$CdTe + e^- \rightarrow CdTe^{\bullet -} \quad (2)$$

$$SO_4^{\bullet -} + CdTe^{\bullet -} \rightarrow CdTe* + SO_4^{2-} \quad (3)$$

$$CdTe* \rightarrow CdTe + h\nu \quad (4)$$

In the air-saturated 0.1 mol/L PB (pH 7.4) containing 0.1 mol/L KNO_3, the cyclic voltammogram and I_{ECL}–E curve of CdTe QDs at the Au disk electrode are similar to those reported in Ref. [5]. Thus, in the air-saturated solution, the following reactions [5] should be involved in the ECL emission of CdTe QDs immobilized on the Au electrode.

$$CdTe + e^- \rightarrow CdTe^{\bullet -} \quad (5)$$



$$O_2 + H_2O + 2e^- \rightarrow OOH^- + OH^- \quad (6)$$

$$2CdTe^{\bullet -} + OOH^- + H_2O \rightarrow 3OH^- + 2CdTe* \quad (7)$$

$$CdTe* \rightarrow CdTe + h\nu \quad (8)$$

3.3. DNA determination using CdTe QDs as ECL labels

The basic protocol for DNA quantification is illustrated in Scheme 2. First, TGA was conjugated onto the surface of the activated NPGL electrode, followed by binding amino-modified c-DNA to it. The unbound TGA was blocked with BSA to prevent nonspecific binding. Then, t-DNA as the analyte, containing complementary sequence to both c-DNA and p-DNA, was hybridized with the c-DNA. Following that, the amino-modified p-DNA was hybridized with the t-DNA, forming the sandwich hybrid on the substrate. Subsequently, MPA-capped CdTe QDs were labeled to the amino group end of the sandwich hybrids. The DNA sequences used in our experiments are listed in Table 1. Finally, the ECL emission of the QDs labeled to the DNA hybrids on the NPGL electrode in the presence of $S_2O_8^{2-}$ was measured by scanning potential from 0 to −2 V with a scan rate of 50 mV/s. The I_{ECL}–E curves of the CdTe QD-labeled DNA hybrids fabricated using 1.0×10^{-11} mol/L t-DNA for seven consecutive cyclic potential scans shown in Fig. 6 indicates fine repeatability of the ECL signal. In order to evaluate the reproducibility of the method, the I_{ECL}–E curves of nine CdTe QD-labeled DNA hybrids fabricated using 1.0×10^{-11} mol/L t-DNA were measured. The relative standard deviation (RSD) of $I_{m,ECL}$ on the I_{ECL}–E curves is 4.3%. The reproducible $I_{m,ECL}$ suggests that this method is suitable for DNA determination. Fig. 7 shows the typical I_{ECL}–E curves of the CdTe QD-labeled DNA hybrids obtained from different concentrations of t-DNA in the range of 5.0×10^{-15} to 1.0×10^{-11} mol/L. The logarithmic relationship between $I_{m,ECL}$ and the concentration of t-DNA ($n = 3$) is displayed in Fig. 7 (Insert). A straight line with a slope of 1.03 and a correlation coefficient of 0.9996 in the concentration range was obtained. The limit of detection (LOD) was

Scheme 2. Schematic representation of the process of DNA determination.

4.7×10^{-15} mol/L according to LOD = $3\sigma/S$ where σ and S were the standard deviation for a series of nine measurements of the blank solution and the slop of the calibration curve.

To explore the selectivity of the method, in the interference test, the single base mismatched DNA sequence (1b-m-DNA) and a mixture consisting of five random noncomplementary DNA sequences as the interfere DNAs (their sequences are shown in Table 1) were detected using the ECL method described here. For 1.0×10^{-11} mol/L t-DNA and 1b-m-DNA, as well as the noncomplementary DNA mixture with a total concentration of 1.0×10^{-11} mol/L (2.0×10^{-12} mol/L for each DNA), $I_{m,ECL}$ detected from the 1b-m-DNA and the noncomplementary DNA mixture was 3.9% and 3.8% of that obtained from the t-DNA, demonstrating the high selectivity of the ECL DNA assay.

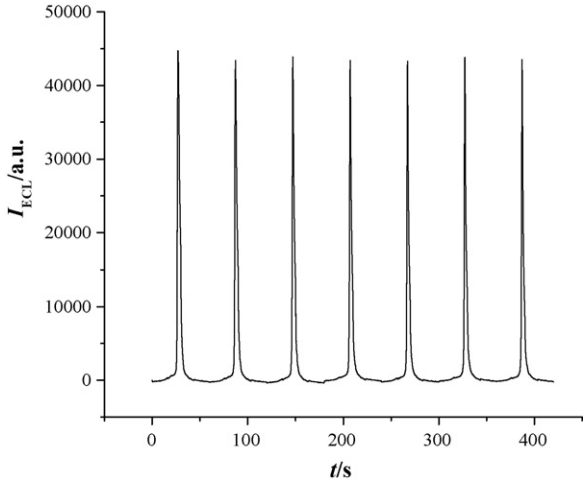


Fig. 6. ECL emission of the CdTe QD-labeled DNA hybrids fabricated using 1.0×10^{-11} mol/L t-DNA for seven consecutive cyclic potential scan with a scan rate of 50 mV/s. PB (pH 7.4) containing 0.1 mol/L $K_2S_2O_8$ and 0.1 mol/L KNO_3.

3.4. Quantification of DNA synthesized corresponding to intracellular OPN mRNA

In order to obtain information about specific gene expression levels in cells, the most widely used method is determination of DNA synthesized from a cellular mRNA template using RNA-dependent DNA polymerase reverse transcriptase (RT) coupled to the polymerase chain reaction (PCR). Here, we used the current ultrasensitive ECL assay to quantify the synthesized DNA without PCR amplification.

Osteopontin (OPN) is a glycophosphoprotein cytokine. Analysis of its contribution to immune responses suggests that OPN is essential for efficient development of Th1 immune responses. Therefore, determination of OPN mRNA in decidual stromal cells is selected as a model system. The synthesized DNA sample from cellular OPN mRNA contains the hybrid of OPN mRNA and its complementary DNA. Before detecting the DNA, the hybrid is dehybridized

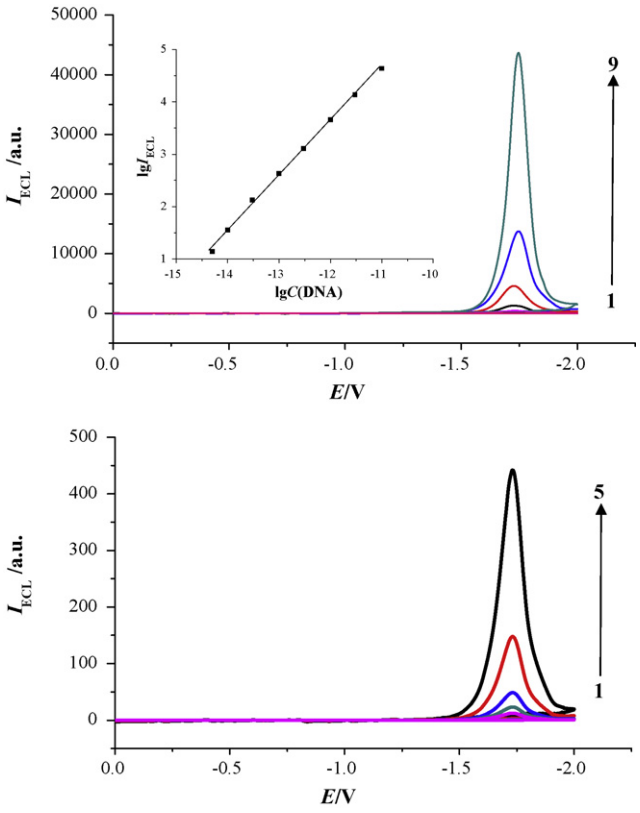

Fig. 7. (A) I_{ECL}–E curves of CdTe QD-labeled DNA hybrids immobilized on NPGL electrode in PB (pH 7.4) containing 0.1 mol/L $K_2S_2O_8$ and 0.1 mol/L KNO_3 for different t-DNA concentrations (10^{-15} mol/L): (1) 0, (2) 5.0, (3) 10, (4) 30, (5) 100, (6) 500, (7) 1000, (8) 2000, (9) 4000, (10) 6000, (11) 8000 and (12) 10,000. (B) Magnification of the I_{ECL}–E curves indicated in (1–5). Insert: Relationship between $I_{m,ECL}$ on I_{ECL}–E curves and t-DNA concentration.

in the presence of RNase H to remove the mRNA. After purification according to the procedure described in Section 2, the purified single-stranded DNA solution is analyzed using the present ECL method. In this assay, the sequences of the c-DNA and p-DNA are listed in Table 1. The profile of the recorded I_{ECL}–E curves is similar to that indicated in Fig. 7. Using the $I_{m,ECL}$ values on the I_{ECL}–E curves and the calibration curve, the DNA concentrations in the determined solutions are obtained. From the DNA concentrations, the average DNA concentration in the original DNA sample is calculated to be 5.6×10^{-10} mol/L with an RSD of 4.5% ($n = 10$). The value is in agreement with that (6.1×10^{-10} mol/L, provided by School of Life Science, Shandong Universite) determined using real-time quantitative PCR, suggesting that the ECL method proposed here is suitable to DNA assay.

4. Conclusion

The success of the application of QDs as ECL labels in bioanalysis may extend QD applications in chemical analysis, especially in bioassays. NPGL is a perfect electrode material and can be applied in ECL techniques to enhance the ECL intensity due to its unique features such as high conductivity, transparency and nanoporous structure. Although the strategy described here is used for DNA quantification, the same technique can be applied in many other assays, e.g., immunoassay.

Acknowledgments

This project was supported by the National Natural Science Foundation of China (Grant Nos. 20675047, 90713016 and 20705016), the National Basic Research Program of China (Grant No. 2007CB936602), the Natural Science Foundation of Shandong Province in China (Grant No. Y2008B20) and the SEM-NCET, SRF-ROCS Programs, the Shandong Natural Science Fund for Distinguished Young Scholars. We are grateful to Professor Jinxing Wang (School of Life Science, Shandong University) for providing the DNA sample synthesized from intracellular OPN mRNA and its standard solutions.

ABSTRACT

A novel and simple analytical procedure has been developed for the trace-level determination of lanthanides (rare-earth elements) in uranium-bearing materials by inductively coupled plasma sector-field mass spectrometry (ICP-SFMS). The method involves a selective extraction chromatographic separation of lanthanides using TRU™ resin followed by ICP-SFMS analysis. The limits of detection of the method proposed is in the low pg g^{-1} range, which are approximately two orders of magnitude better than that of without chemical separation. The method was validated by the measurement of reference material and applied for the analysis of uranium ore concentrates (yellow cakes) for nuclear forensic purposes, as a potential application of the methodology.

1. Introduction

Lanthanide or rare-earth elements (REE) are present in nuclear materials (uranium and plutonium) in widely variable concentrations. Certain lanthanides may be added intentionally to the nuclear materials. For instance, burnable poisons, such as erbium or gadolinium, are added to nuclear fuel in order to control the reactivity of the fuel in nuclear reactors. REE are also formed in the reactor as a result of nuclear fission. Lanthanides can also be present in nuclear materials in trace-level amounts either as residues from the raw material or as a contamination of the process.

There are several important applications of lanthanide determination in nuclear materials. Their measurements are used for the quality control and development of the nuclear fuel material [1], burn-up determination (e.g. via the isotopic analysis of neodymium) [2,3] or for the nuclear forensic investigation of found or confiscated illicit nuclear materials [4–6]. Therefore, accurate determination of these elements is of high importance.

Several analytical techniques can be applied for such purposes with or without prior chemical separation of the analytes [7]. Direct-current plasma emission spectrometry [8], atomic absorption spectrometry [1] or inductively coupled plasma atomic emission spectrometry (ICP-AES) [3,9,10] can be used for the lanthanide analysis if the analyte is present at a concentration close to or above μg g^{-1}. Because of the complex emission spectrum of uranium and the lanthanides, removal of uranium is usually necessary before the measurement. Recently mainly mass spectrometric techniques, such as inductively coupled plasma mass spectrometry (ICP-MS) or thermal ionisation mass spectrometry (TIMS) are used for the isotopic and elementary measurements of the lanthanides in nuclear matrices [2,11–13]. Very low detection limits and high precision can be achieved by mass spectrometry, however, the presence of molecular isobaric interferences and matrix suppression of signal intensity due to considerable amounts of matrix elements often hinder the low-level lanthanide determinations. The spectral interferences in the m/z = 146–170 mass region were generally caused by oxide and hydroxide molecular ions of barium [14,15]. As Ba is usually present in high amount compared to lanthanides in most investigated materials and the oxide production rate is relatively high in ICP-MS for most sample introduction systems (typically 1–2% of the parent ion), the isobaric interferences can cause erroneous results. Spectral interferences can be eliminated by the use of higher instrumental mass resolution or by the measurement of the doubly charged ions [14,16–18], however, these approaches also imply the strong decrease in the sensitivity (high increase in the detection limit). The mass resolution required for the separation of the interfering oxide ions from lanthanides are typically between 7000 and 10,000 [18].

Chemical separation of lanthanides from the matrix is another option to reduce spectral interferences and matrix-induced signal suppression. It also enables to pre-concentrate the analyte to a higher degree and to protect the instrument from a contamination of e.g. uranium or, if present, of different radioactive activation or fission products other than lanthanides. Most frequently precipitation (*i.e.* co-precipitation with carriers), solvent extraction, ion exchange or extraction chromatographic methods are used to separate and pre-concentrate the lanthanides. Co-precipitation is rarely used as the carrier has to be removed prior to the analysis, thus requiring an additional step [10,19]. Ion exchange offers a rapid possibility for the separation of the trivalent lanthanides, although it is less selective and robust to matrix effects compared to solvent extraction [3,8,19,20]. Various extractants, such as TBP (tri-n-butylphosphate), TBP–TOPO (tri-n-octylphosphine-oxide) or TOPO alone (in CCl_4, xylene or dodecane) are most often used for the solvent extraction of rare-earths [3,9,10,19]. Although high selectivity can be achieved and the methods do not require special instrumentation, the cumbersome separation, the high amount of generated organic and/or radioactive waste makes its routine use less attractive. Extraction chromatography, on the other hand, offers a possibility to combine the selectivity of solvent extraction method with the ease of use of column separation [3,21]. Extraction chromatography has already been used for the separation of trace-level activation products, such as Pu and Am from uranium materials [22–24].

The aim of this study is the development of a straightforward and simple extraction chromatographic method followed by inductively coupled plasma sector-field mass spectrometric analysis for the determination of lanthanide elements from uranium-bearing nuclear materials. Measurement of a certified reference material was used to validate the procedure. The method was applied for the measurement of lanthanide composition in uranium ore concentrates (yellow cakes) for nuclear forensic investigation. The sample preparation, elimination of possible interferences and figures of merit of the developed method are discussed.

2. Experimental

2.1. Instrumentation

The mass spectrometric analysis was carried out using a double-focusing magnetic sector inductively coupled plasma sector-field mass spectrometer (ICP-SFMS) equipped with a single electron multiplier (ELEMENT2, Thermo Electron Corp., Bremen, Germany). All measurements were carried out in low resolution mode ($R = 300$) to keep on sensitivity using a low-flow microconcentric nebulizer operated in a self-aspirating mode (flow rate was 60 μL min^{-1}). Optimized operating parameters are summarized in Table 1. Prior to the sample analysis the instrument was tuned using a 1 ng g^{-1} multielement solution (Merck, Darmstadt, Germany). The optimization was carried out with respect to maximum uranium sensitivity and low UO^+/U^+ ratio. The sensitivity was approximately 1.4×10^6 cps for 1 ng g^{-1} ^{238}U and the UO^+/U^+ ratio $\sim 3.5 \times 10^{-2}$.

2.2. Reagents and materials

For the lanthanide measurements external calibration standard solutions and spike solution used for the optimization of the separation were prepared from a 10 μg g^{-1} lanthanide standard solution (Spex, Metuchen, NJ, USA) by gravimetric dilution. Uranium and rhodium monoelemental standard solutions were purchased from Alfa Aesar (Karlsruhe, Germany). The TRU^{TM} extraction chromatographic column (100–150 μm particle size, active component: octylphenyl-N,N-di-isobutyl carbamoylphosphine oxide dissolved in tri-n-butyl phosphate) were supplied by Eichrom (Eichrom Europe Laboratories, Bruz, France). For the preparation of columns, 1.6 mL of the resin was placed in plastic Bio-Rad holders (diameter: 8 mm) and plugged with porous Teflon frit (Reichelt Chemietechnik Heidelberg, Germany) on the top of the resin to avoid mixing. The free-column volume (FCV) of the column is approximately 1.05 mL. For dilution high-purity water was used (UHQ System, USF Elga, Germany). Hydrochloric acid used for the sample preparation was of Suprapur grade (Merck, Darmstadt, Germany). Suprapur grade nitric acid was further purified by subboiling distillation in quartz equipment. Analytical grade phosphoric acid and sulphuric acid used for the robustness tests were purchased from Merck (Darmstadt, Germany). The U_3O_8 certified reference material, Morille, (Cetama, France) used for the validation of the method is certified for four lanthanide content (Dy, Gd, Eu and Sm). Uranium ore concentrates (yellow cakes) analysed in this study originate from three different milling facilities (Beverley in Australia; Cluff Lake and Stanrock in Canada).

2.3. Sample preparation for ICP-SFMS analysis

Approximately 300–500 mg of sample was weighed into a Teflon vial and dissolved in 9 ml 10 M ultra-pure nitric acid while heating to 90 °C on a hot-plate for 6 h. After cooling to room temperature, the weight of the solution was calculated as the difference of the weight of the vial containing the solution and the vial weight (M_{stock}). Approximately 300 μL of this stock solution was weighed gravimetrically into a polyethylene vial (M_{load}) and diluted four-fold using ultra-pure water in order to adjust the proper HNO_3 concentration. This aliquot was used for the lanthanide separation, corresponding to about 13 mg of sample (approximately 10 mg of uranium). The lanthanide content of the sample aliquots was separated using extraction chromatography by the selective retention of trivalent lanthanides and actinides on the TRU^{TM} resin in 3 M nitric acid medium. After conditioning of the resin with 10 mL 2 M HNO_3 the sample aliquot was loaded on the column. After washing the column and removal of the non-retaining matrix components with 2 mL of 2 M HNO_3, the lanthanides were stripped from the column into a Teflon beaker using 1 mL concentrated HCl followed by 4 mL of 4 M HCl. After the addition of 200 μL ultra-pure HNO_3 to the final fractions, the samples were evaporated to almost complete

dryness on a hot-plate in order to destroy the organic resin residuals. The residue was dissolved in 1 mL of 2% (m/m) ultra-pure nitric acid while heating slightly. After the gravimetric weighing of the final fraction and the gravimetric addition of Rh internal standard (m_{finfr}), the samples were analysed by ICP-SFMS using external calibration, *i.e.* the lanthanide concentrations were determined using a calibration curve established by analysis of separately measured (uranium free) standards.

For comparison purpose and to validate the separation procedure, the lanthanide content of the samples was also measured without chemical separation. In this case the dissolved sample solution was diluted to a uranium concentration of approximately 100 μg g^{-1}. After adding Rh internal standard, the lanthanide concentration was measured in the sample by ICP-SFMS using external calibration with matrix-matched standards. The matrix-matched standards were prepared by dilution of the monoelemental U standard to 100 μg g^{-1} U concentration and addition of diluted lanthanide standard mixture. All dilutions were performed gravimetrically.

2.4. Data evaluation

The concentration of the lanthanide elements in the starting sample material was calculated as follows:

$$c_{Ln} = \frac{m_{finfr} c_{finfr} M_{stock}}{M_{sample} M_{load} R} \quad (1)$$

where c_{Ln} is the concentration of the lanthanide element in the starting material, c_{finfr} is the concentration of the lanthanide element in the final fraction measured by ICP-SFMS, m_{finfr} is the weight of the final fraction, M_{stock} is the weight of the stock solution obtained after the dissolution of the material, M_{load} is the weight of the stock solution aliquot used for the separation, M_{sample} is the weight of the dissolved sample, R is the chemical recovery estimated by the measurement of certified reference material. The overall uncertainty of the result was calculated taking into account the uncertainties of the measured concentration values, weight measurements and chemical recovery.

3. Results and discussion

3.1. Optimization of the separation scheme

Relatively few commercially available extraction chromatographic resins retain lanthanides in nitric acid medium. For our work we chose TRU™ resin because of the following reasons: highly retains uranium (its distribution coefficient is typically higher than 900 at nitric acid concentrations in excess of 2 M [21]), relatively high retention of lanthanide in nitric acid medium, no retention of alkali metals, alkali earth elements and most transition metals. The lanthanides show relatively high retention in the range of 1–5 M nitric acid concentration and they can be stripped from the column using HCl [21]. In order to optimize the separation scheme, a laboratory-prepared standard solution containing 100 μg g^{-1} U and 1 ng g^{-1} of lanthanides was prepared and its elution behaviour on TRU™ column was investigated. The test solution was loaded on the columns in 2 M HNO_3 and eluted with HNO_3 followed by HCl. After loading, 8 mL of 2 M HNO_3 was added to the column in 1 mL portions, thereafter the resin was converted to chloride-form with 1 mL of concentrated HCl. Finally, the lanthanides were stripped with eight times of 1 mL of 4 M HCl. The aliquots were collected separately and their uranium and lanthanide contents were analysed by ICP-SFMS. The elution profile of the elements is shown in Fig. 1. We observed uranium visibly formed a yellow band on the upper part of the column, since under such circumstances uranium highly retains on the column (only a very small portion appears in the load fraction). As shown in Fig. 1, all lanthanides can be quantitatively recovered using the HNO_3 elution and the first two HCl strip steps (total chemical recovery was between 95 and 102%).

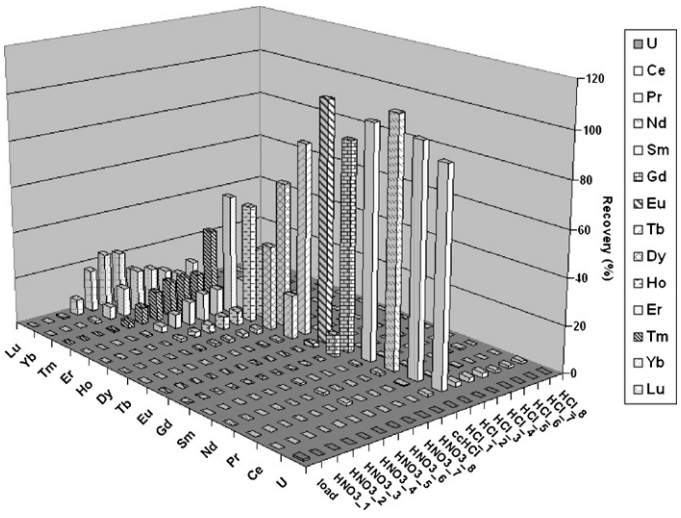

Fig. 1. Elution profile of lanthanides and uranium on TRU™ column. Column: 1.6 mL TRU™, diameter: 8 mm. Elution after load: 8 × 1 mL 2 M HNO_3, 1 mL *cc*HCl, 8 × 1 mL 4 M HCl.

Lanthanides sequentially elute from the column: the less-retaining heavy lanthanides start to elute from the column after about 2 mL 2 M HNO_3. As our aim was to measure all lanthanides simultaneously, in our final method described in Fig. 2 we used only 2 mL of 2 M HNO_3 in order to avoid any chemical fractionation of lanthanides (partial elution of heavy lanthanides), followed by the stripping using HCl. Using this scheme all the lanthanides can be collected in a single fraction, while uranium and most metal ions, which can cause interference or matrix effects, are separated from the analytes. Uranium content in the HCl fractions was very low (typically <50 pg g^{-1}), due to the high retention of U (VI) on the column in both HNO_3 and HCl media.

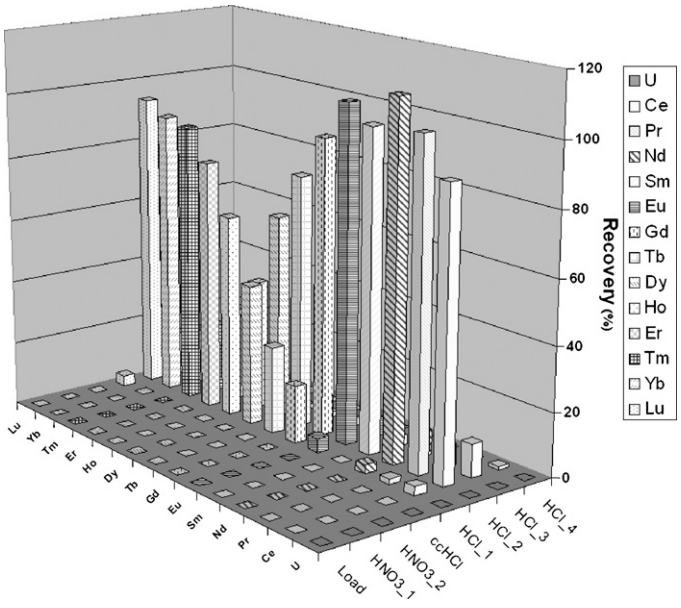

Fig. 2. Elution profile of the final method used for the separation of lanthanides. Column: 1.6 mL TRU™, diameter: 8 mm. Elution after load: 2 × 1 mL 2 M HNO_3, 1 mL *cc*HCl, 4 × 1 mL 4 M HCl.

Table 2
Limits of detection (LOD) of the method developed in comparison with the direct measurement using external matrix-matched calibration (in ng g^{-1} of the original material).

Element	LOD using external matrix-matched calibration (ng g^{-1})	LOD of the developed method with chemical separation (ng g^{-1})
La	37.6	0.080
Ce	12.7	0.082
Pr	2.3	0.014

Tm	0.51	0.0024
Yb	8.2	0.12
Lu	0.58	0.0039

3.2. Figures of merit

The calculation of the limit of detection (LOD) was based on three times the standard deviation of the method blank (3σ *criterium*). The detection limits of the method developed in comparison with the direct measurement of the sample after dilution using external matrix-matched calibration are shown in Table 2. The detection limit of the developed method is approximately two orders of magnitude better than that of without chemical separation. This is due to the higher pre-concentration (less dilution) and the lack of signal suppression due to the removal of the uranium matrix. Considering that approximately 13 mg of the sample was used for the analysis, the absolute detection limit corresponds to approximately 0.02–2 pg. Another advantage of the developed method is that the components of the possibly interfering molecular ions, such as barium, which would cause barium-oxide and hydroxide molecular ion interferences in the m/z = 146–170 region, are removed. This is often a serious problem with samples having complex matrixes, like uranium ores and spent nuclear fuels. The typical intensity of $^{137}Ba^{+}$ at m/z = 137 for these samples was less than 10^4 cps, thus the estimated level of oxides and other molecular ions are negligible taking into account the applied oxide formation rate. By the separation scheme the possible oxide interferences of the lighter rare-earth oxides on the heavier rare-earth intensities cannot be avoided, as they are co-separated. For samples with elevated light rare-earth content either mathematical correction of the oxide interference or proper modification of the sample preparation method by the separation of light and heavy rare-earth elements can be a possible option (Fig. 1).

3.3. Validation of the method

For the validation of the method, Morille certified reference material (CRM) was analysed by the method developed. In addition, the lanthanide concentrations were also determined in the dissolved CRM after only diluting the sample to approximately 100 μg g^{-1} U concentration without chemical separation. In this case, external calibration with matrix-matched standards was used for the quantification. The measured concentrations of the four certified lanthanides together with the certified contents are shown in Table 3. The concentrations presented are given relative to the uranium content, which was determined in an independent measurement. The measured values agree well with each other and also with the reference values. The chemical recovery of the chemical separation (calculated by the measurement of the reference material in the same batch) was 94 ± 6% for all the lanthanides. The overall uncertainty of the concentration measurement is slightly higher than that of the direct measurement (Table 3), which is due to the additional uncertainty of the chemical recovery (Eq. (1)). The overall uncertainties of the lanthanide determinations with and without chemical separation for the Morille reference material are ranged in 7.1–8.9% and 2.4–6.6% relative standard deviation, respectively. It is noteworthy that the precision of the chemical recovery can be further improved if any of the lanthanides can be measured just by the dilution of the sample. The replicate analysis of the Morille reference material yielded an analytical precision of 3.2–8.6% relative standard deviation for all the four certified lanthanide elements. The procedural blanks of the method proposed are 0.1–3 pg. The decontamination factor for uranium (defined as the ratio of uranium amount before and after the chemical separation) is approximately 2×10^6, thus the uranium concentration in the final fraction (typically 1–10 ng g^{-1}) is low enough to avoid any matrix effect and to protect the instrument from contamination. The concentration of uranium in the final fraction is also low enough to avoid the decrease in the sensitivity due to matrix effects.

3.4. Robustness test of the method

The robustness of the method was tested by the measurement of a dissolved uranium ore concentrate sample from Cluff Lake mine spiked with increasing amount of sulphate and phosphate, which are reported to be possible interferences during the extraction chromatographic separation [21]. The uranium content in the load was approximately 10 mg. Aliquots of the load solution were spiked with known amounts of sulphate and phos-

Analysis results of Morille reference material measured using the two methods and their comparison to the certified values.

Element	Developed method with chemical separation		Matrix-matched method	Certified concentration (ng g^{-1} U)
	Measured concentration (ng g^{-1} U)	Chemical recovery (%)	Measured concentration (ng g^{-1} U)	
Sm	482 ± 31	94 ± 3	492 ± 18	500 ± 120
Eu	499 ± 26	97 ± 4	507 ± 14	520 ± 30
Gd	503 ± 33	92 ± 4	487 ± 21	560 ± 60
Dy	525 ± 35	95 ± 3	514 ± 16	500 ± 120

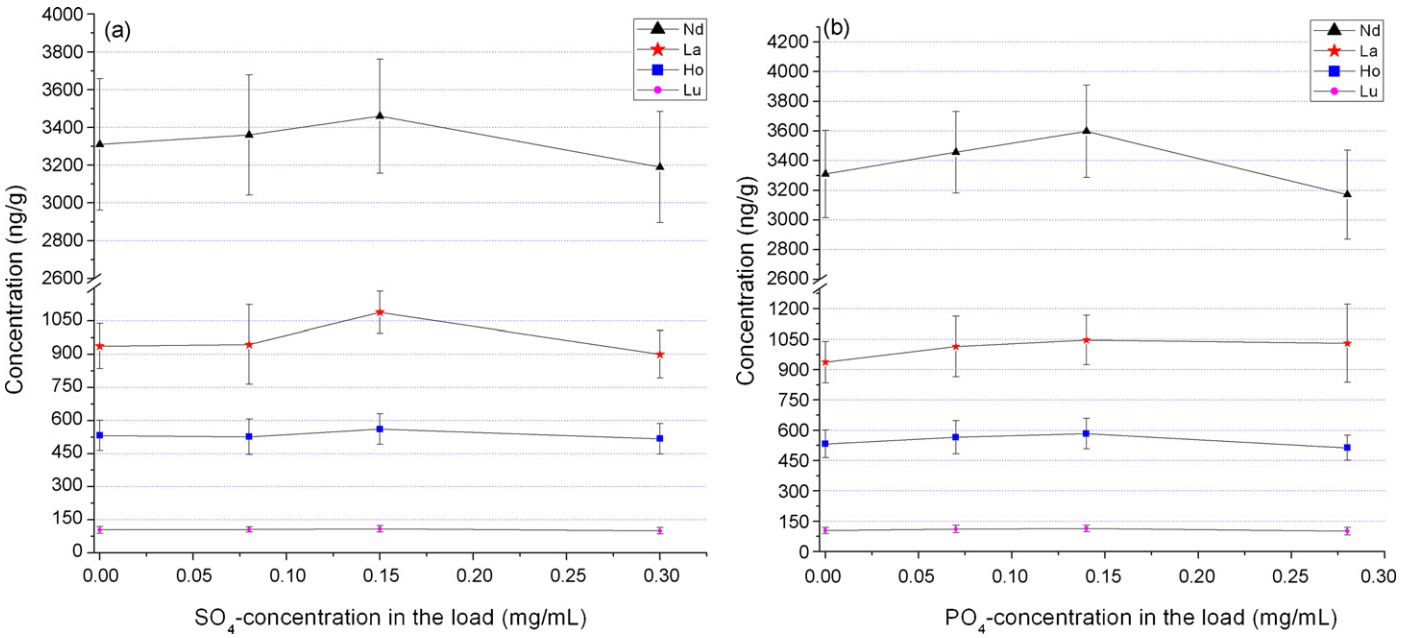

Fig. 3. Effect of sulphate (a) and phosphate (b) as possible interfering anions on the lanthanides separation method.

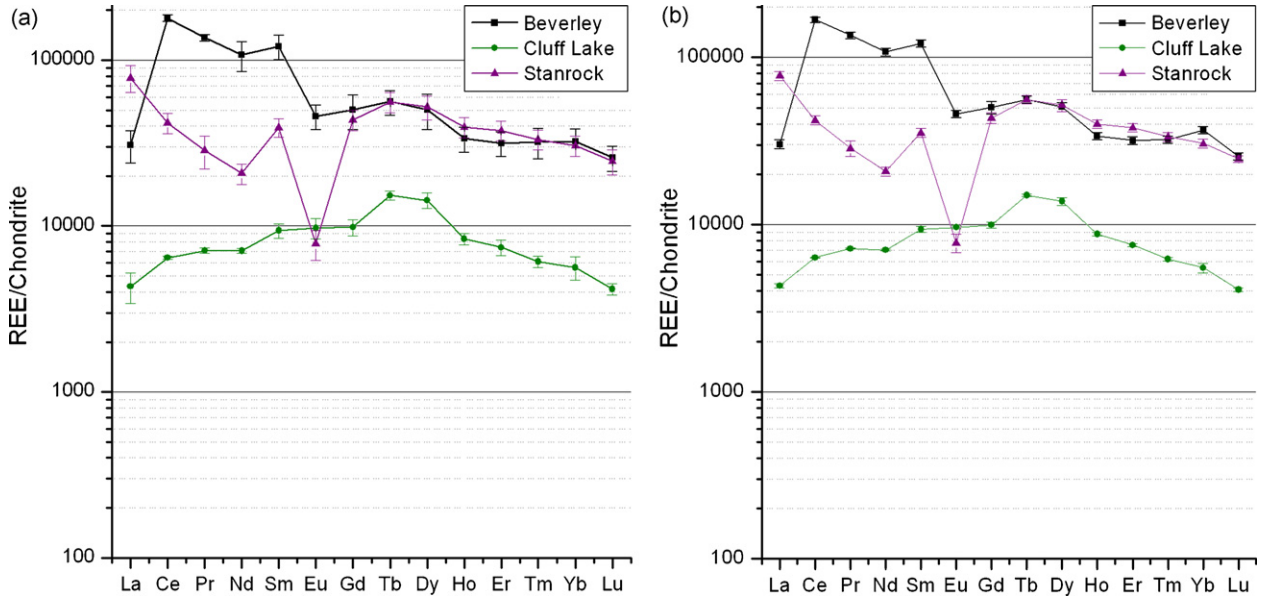

Fig. 4. Lanthanide pattern of three uranium ore concentrates of different origin. The lanthanide concentrations were measured with the method developed (a) and after only dilutions with matrix-matched calibration (b). The lanthanide concentrations are normalized to chondritic values [25].

phate prepared from diluted H_2SO_4 and H_3PO_4, respectively. The sample was then subjected to the chemical separation described above. The effect of sulphate and phosphate on the measured concentration of selected lanthanides is shown in Fig. 3a and b, respectively. As seen, the polyatomic anions have no adverse effect on the lanthanides retention even in case of Ho and Lu, which have the lowest retention coefficients to the resin and which are most prone to matrix constituents during the chemical separation. The lanthanide content of the sample was also determined without chemical separation performing only dilution of the sample and matrix-matched measurement by ICP-SFMS. The La, Nd, Ho and Lu concentrations were $963 \pm 48\ ng\ g^{-1}$, $3178 \pm 201\ ng\ g^{-1}$, $504 \pm 8\ ng\ g^{-1}$ and $102 \pm 4\ ng\ g^{-1}$, respectively. The values obtained are in good agreement with the results measured for the robustness test samples.

3.5. Application of the method

The method developed was applied for the analysis of three uranium ore concentrates (yellow cakes) originating from different mills in order to compare their lanthanide profiles (also called *rare-earth pattern*) for nuclear forensic studies. The measured lanthanide concentrations presented were normalized to chondrite values as a general practice in geochemistry in order to eliminate effects related to nuclear stability [25]. This normalization produces a smooth pattern. The lanthanide patterns of the samples after chemical separation are shown in Fig. 4a. For these samples the lanthanide content was high enough to determine it also after only diluting the sample (Fig. 4b). Moreover, as the samples are relatively pure intermediate products of uranium production, the level of possibly occurring interfer-

ents (especially barium) is relatively low. The Ba/La ratios in the samples investigated are between 0.2 and 16, thus the effect of isobaric interferences on the measured isotopes is negligible in this case even without chemical separation of the analytes. The measured values agree well using the two different methods. The lanthanide profile obtained for the yellow cake samples can be used to verify the origin of the material, as the rare-earth element pattern reflects the formation conditions of the uranium deposits [26].

4. Conclusions

A novel analytical method for the determination of lanthanides in uranium-bearing materials has been developed. The method, involving a rapid chemical separation of lanthanides by TRU™ extraction chromatography resin followed by ICP-MS analysis, has great advantage over direct measurement of the analyte especially when analysing lanthanides in difficult matrixes at trace-level (containing rare-earth at pg g^{-1} concentration level). For instance, if possible interferents are present at high level or in radioactive materials (e.g. U ores, spent fuels). The method also allows the reduction of the sample size due to the pre-concentration. The method described in the present paper separates lanthanides without any chemical fractionation and with good chemical recovery (above 94%) from uranium matrices and interfering elements. The amount of chemicals consumed for the separation and thus the waste generated is much less (only a few mL per sample) compared to other separation methods, e.g. ion exchange or solvent extraction, which is of vital importance for radioactive and nuclear materials. This also allows decreasing the background originating from the chemicals. As the TRU™ resin used in this study strongly retains Th and Pu, the method can be extended for the lanthanide determination from other types of nuclear materials and fuels. The method has potential application also in the field of nuclear forensics, where rare-earth element pattern can be used for the origin assessment of unknown samples.

ABSTRACT

A robust near infrared (NIR) method able to quantify the active content of pilot non-coated pharmaceutical pellets was developed. A protocol of calibration was followed, involving 2 operators, independent pilot batches of non-coated pharmaceutical pellets and two different NIR acquisition temperatures. Prediction models based on Partial Least Squares (PLS) regression were then carried out. Afterwards, the NIR method was fully validated for an active content ranging from 80 to 120% of the usual active content using new independent pilot batches to evaluate the adequacy of the method to its final purpose. Conventional criteria such as the R^2, the Root Mean Square Error of Calibration (RMSEC), the Root Mean Square Error of Prediction (RMSEP) and the number of PLS factors enabled the selection of models with good predictive potential. However, such criteria sometimes fail to choose the most fitted for purpose model. Therefore, a novel approach based on accuracy profiles of the validation results was used, providing a visual representation of the actual and future performances of the models. Following this approach, the prediction model using signal pre-treatment Multiplicative Scatter Correction (MSC) was chosen as it showed the best ability to quantify accurately the active content over the 80–120% active content range. The reliability of the NIR method was tested with new pilot batches of non-coated pharmaceutical pellets containing 90 and 110% of the usual active content, with blends of validation batches and industrial batches. All those batches were also analyzed by the HPLC reference method and relative errors were calculated: the results showed low relative errors in full accordance with the results obtained during the validation of the method, indicating the reliability of the NIR method and its interchangeability with the HPLC reference method.

1. Introduction

Near infrared (NIR) spectroscopy belongs to vibrational spectroscopy and covers a region between 14,000 and 4000 cm^{-1}. Vibrations like overtones and combination of fundamental vibration of hydrogen bonds such as C–H, N–H, O–H and S–H give birth to the NIR spectrum. Such vibrations lead to large overlapping bands which contain both physical and chemical information. Therefore, chemo-metrical tools such as mathematical pre-treatments and regression methods are required to extract the significant information [1–3].

FDA's Process Analytical Technology (PAT) is an analytical concept which focuses on the real time monitoring of each critical step of a manufacturing process leading to a better understanding of the process itself. Consequently, as the process understanding improves, PAT gives the opportunity to detect the endpoints inherent in a process and so to optimize it in order to lower the risk of losing batches. PAT may also reduce the batch release time as most of the conformity analyses are realized during the manufacturing process itself [4,5].

An analytical tool such as PAT requires analyzers able to perform fast data acquisition without any sample preparation and compatible with the use of optical fibers. Thanks to its own features, NIR spectroscopy matches the PAT requirements: it has already been used many times in this concept [6–10]. Indeed, once you overcome the calibration phase which takes into account a reference method as well as environmental constrains, near infrared spectroscopy offers many advantages such as suppression of sample

preparation and/or destruction and the use of optical fibers allows online analyses [1–3]. Moreover, the calibration set does not need to be updated or rebuilt as long as there is an agreement between the validation results and the Quality Controls (QCs) results.

The more complex is a manufacturing process, the more interesting becomes the PAT approach. An example of a complex manufacturing process associated with PAT can be found in the pellets manufacturing field [11,12]. Indeed, pellets fabrication can be split into plenty of crucial steps, including successively: weighting, blending, extrusion, spheronization, drying, coating, and a last drying step. For such a complex process, it would be interesting to evaluate the active content of the non-coated pellets before beginning the coating and final drying steps. The active determination is usually performed using time consuming and sample destructive HPLC methods. NIR spectroscopy can replace those tedious methods: it has already been used in different fields such as the pharmaceutical [9,13–15], the food [16,17] and the fuel industries [18].

To give laboratories guarantees about the accuracy of a new method, validation must be carried out, as defined by the ICH Q2 R1 regulatory documents [19]. Based on β-expectation tolerance intervals, the accuracy profile makes possible a visual and reliable representation of the actual and future performances of the analytical method [20–22]. This novel approach facilitates the analytical interpretation and enables a better risk management [23–29]. In addition, the accuracy profile integrates all the useful required validation criteria, such as accuracy, trueness, precision, quantitative limits and linearity [20–22].

The aim of the present study was first to develop a reliable near infrared method able to determine the active content of non-coated pilot pharmaceutical pellets. The second aim was to fully validate the method for an active content ranging from 80 to 120% of the usual active content. The final aim was to test the method reliability with new pilot batches containing 90 and 110% of the usual active content, blends of pilot batches used for the validation and industrial batches.

2. Materials and methods

2.1. Chemicals

2.1.1. Calibration samples

Pilot batches of non-coated pharmaceutical pellets were manufactured at Galephar Research Center M/F. The usual targeted formulation contains 57% w/w of Active Pharmaceutical Ingredient (API) T200999, this formulation will be further considered as the 100% active content formulation. For the calibration set, pilot batches containing 46 and 69% w/w of API were also manufactured (80 and 120% API formulations). Three independent batches were manufactured per formulation type.

2.1.2. External validation samples

New pilot batches of non-coated pharmaceutical pellets were manufactured at Galephar Research Center M/F. The same formulations as for the calibration samples were manufactured: 80, 100 and 120% API formulations, three batches per formulation type.

2.1.3. Reliability evaluation samples

To evaluate the reliability of the developed NIR method, new pilot batches containing 52 and 63% w/w of API were also manufactured at Galephar Research Center M/F (90 and 110% API formulations, 3 batches per formulation type). Industrials batches of non-coated pellets were also provided by Galephar. Besides, blends of batches belonging to the validation sets were made to obtain active content formulations between 80 and 120%.

2.2. FT-NIR equipment and software

Non-coated pharmaceutical pellets were analyzed with a multipurpose analyzer Fourier transform near infrared spectrometer (MPA, Bruker Optics, Ettlingen, Germany) equipped with a semiconductor room temperature sulfide lead (RT-PbS) detector. The NIR spectra of the samples put in vials were acquired using the integrating sphere module of the spectrometer which allows reflectance measurement of an 18 mm diameter sample area. An internal computer-controlled reference wheel enables an automatic background spectrum acquisition without the need to remove the sample from the integrating sphere window. The spectra were collected with the Opus software 6.5 (Bruker Optics). Each spectrum was the average of 32 scans and the resolution was 8 cm^{-1} over the range from 12,500 to 3600 cm^{-1}.

2.3. Reference method

A confidential HPLC method previously developed and validated by Galephar was used to determine the amount of API in batches of non-coated pharmaceutical pellets.

2.4. Near infrared method: calibration and validation protocol

An experimental protocol was followed for the calibration and validation steps to develop and to validate a robust near infrared model. This protocol included batches, operators, days and temperature conditions as sources of variability for the calibration as well as for the validation steps. Three concentration levels of active ingredients were evaluated.

NIR spectra of the pellets samples were first recorded before performing one active content measurement per vial using the reference method. Three different NIR measurements (*i.e.* replicates) of the same sample were performed. After each NIR acquisition, the vial was gently shaken to completely evaluate the sample.

2.5. Data treatment

The Opus software 6.5 (Bruker Optics) has been used to carry out the signal processing of the near infrared spectra.

Using the QUANT package of the Opus 6.5 software, prediction models based on PLS (Partial Least Squares) regression using stratified cross-validation were carried out with the calibration set and tested with the validation set. Each cross-validation fold contains the six spectra associated with a sample.

In PLS methods the regressions are computed with least squares algorithms. The goal of the PLS is to establish a linear link between two matrices, the spectral data X and the reference values Y (which can be of dimension above one). This technique works both on X and Y in order to find out the variables in the X matrix that will best describe the Y matrix through linear combinations of wavelengths, called factors, which describe best the studied properties [2].

Cross-validation is a classical way of building a model [30]. The first step consists in removing a group of samples from the calibration set. If the group of samples contains only one sample, the cross-validation is called leave-one-out cross-validation. Based on the remaining samples, a model is then built and tested with the removed samples. Afterwards, the removed samples are put back in the calibration set while a new group of samples is removed. A new model is then calculated and tested. The operations described above are repeated until all the samples from the calibration set have been removed once [3].

Two different types of data pre-treatment were used in our study: Standard Normal Variate (SNV) and Multiplicative Scatter Correction (MSC) pre-treatments. The first reduces mathematically the differences between the baselines of the spectra and then nor-

T_B: the sample is measured under high temperature conditions (35 °C). R_1, R_2 and R_3 represent different NIR measurements of the same sample.

malizes them while the second reduces the effect of scattered light on diffuse reflection NIR spectra [3].

The calculation of the accuracy profiles based on the validation set results were realized with e.noval V2.1 (Arlenda, Liège, Belgium).

3. Results and discussion

3.1. Calibration

In order to meet the requirements of routine analyses and to guarantee the robustness of the NIR method, the calibration was designed focusing on different parameters. First, prediction models were built using independent pilot batches of non-coated pharmaceutical pellets. Indeed, once a batch of pharmaceutical pellets was manufactured, the mixer-extruder and the spheronizer were successively dismantled, cleaned and put together again before the manufacturing of a new batch. As it is difficult to restore the exact manufacturing conditions of the previous batch, each batch is an independent batch. Secondly, as different operators are likely to use the NIR method, the calibration protocol was designed for two operators. In addition, as temperature changes can induce variations in the spectral response, samples were scanned under two different temperature conditions (25 and 35 °C).

As shown in Fig. 1, the calibration was designed using three different active content formulations: 80, 100 and 120% formulations. There are 3 independent pilot batches of non-coated pharmaceutical pellets per formulation type. All the calibration batches were analyzed by NIR spectroscopy and the reference method by the two operators two times: *operator 1* and *2* made their own series on *day 1*, *day 2* and *day 3*, *day 4*, respectively. The NIR measurements were realized under two different temperature conditions (25 and 35 °C) and in triplicate. For example, on *day 1*, operator 1 took a sample from the 9 batches of non-coated pharmaceutical belonging to the calibration set. Those samples were analyzed two times in triplicate by NIR spectroscopy: one first triple measurement when the sample was thermostated at 25 °C and one second triple measurement when the sample was the sample was thermostated at 35 °C. Afterwards, all the samples were analyzed once by the HPLC reference method. For one series, a total number of 54 NIR spectra were recorded and 9 reference measurements were carried out. As the calibration is built with 4 independent series of measurements, the entire calibration set contains a total of 216 NIR spectra and 36 reference measurements.

3.2. Validation

Fig. 2 illustrates the validation protocol that comprises the same type of formulations as in the calibration protocol: 80, 100 and 120% active content formulations. There are also 3 independent batches of non-coated pharmaceutical pellets per formulation type. All the validation batches were analyzed by NIR spectroscopy and the reference method by the two operators: one time by *operator 1* on *day 5* and 2 times by *operator 2* on *day 6* and *day 7*. The NIR measurements were realized under two different temperature conditions (25 and 35 °C) and in triplicate. For example, on *day 5*, operator 1 took a sample from the 9 batches of non-coated pharmaceutical belonging to the validation set. In the same way as for the calibration set, those samples were analyzed two times in triplicate by NIR spectroscopy: one first triple measurement when the sample was thermostated at 25 °C and one second triple measurement when the sample was the sample was thermostated at 35 °C.

Table 1
Type of spectral pre-treatment, R^2, spectral range selected, number of PLS factors, RMSEC and RMSEP of different models.

Model	(a)	(b)	(c)
Pre-treatment	None	SNV	MSC
R^2	0.991	0.994	0.994
Spectral range selected (cm^{-1})	7502.2–6098.2 5450.2–4597.7	12493.3–7498.3 6102–5774.2 4601.6–4246.7	12493.3–7494.5 6102–5774.2 4917.9–4543.7
Number of PLS factors	7	4	3
RMSEC (%)	1.18	0.95	1.02
RMSEP (%)	2.15	1.37	1.28

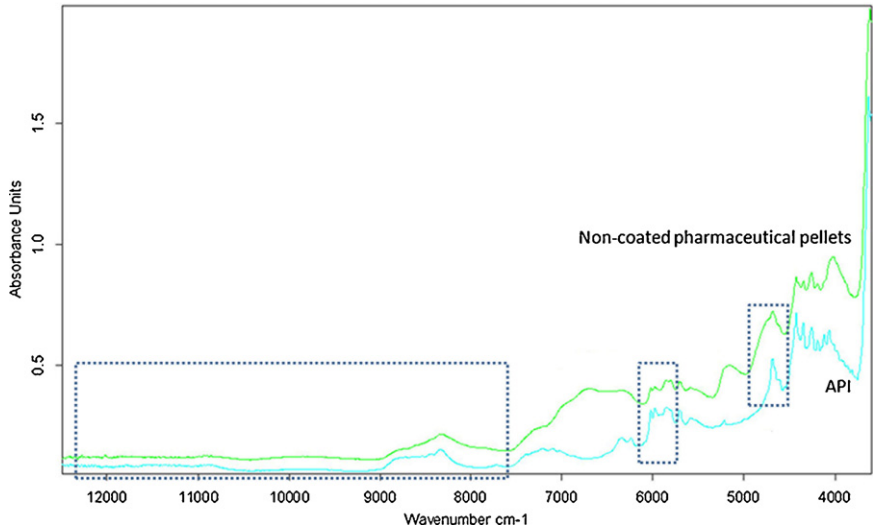

Fig. 3. NIR spectra of the non-coated pharmaceutical pellets and the API. The spectral areas selected for the (c) model are highlighted.

Afterwards, all the samples were analyzed one time by the HPLC reference method. For one series, a total of 54 NIR spectra were recorded and 9 reference measurements were taken. Consequently, as the validation is built with 3 series of measurements, the entire validation set contains a total of 162 NIR spectra and 27 reference measurements.

3.3. Validation results of the NIR method

Depending on the type of mathematical pre-treatment applied, the spectral range selected and the number of PLS factors chosen, a large amount of models can be generated. Classically, the models with the biggest predictive potential can be selected according to conventional criteria such as the R^2, the number of PLS factors, the Root Mean Square Error of Calibration (RMSEC) and the Root Mean Square Error of Prediction (RMSEP). Table 1 shows the conventional parameters of three potentially interesting models.

As the R^2 of the three models are very close, it does not allow any clear differentiation between the models.

Concerning the spectral regions selected, it can be seen from Fig. 3 that the spectral regions selected for the 3 models are related to the pellets active content.

Regarding the number of PLS factors, the bigger the number of PLS factors selected is, the more important is the risk to overfit the model. Hence, the (a) model seems to use too many factors to predict the active content with a good robustness.

Considering RMSEC and RMSEP, the (b) and (c) model seem to be slightly better than the (a) model: their RMSEC and RMSEP are

Table 2
ICH Q2R1 validation criteria of the (c) model.

	Concentration level (% active)	Mean introduced concentration (% active)	Relative bias (%)
Trueness	80	80.7	−0.25
	100	100.9	0.00
	120	122.0	0.05

	Concentration level (% active)	Mean introduced concentration (% active)	Repeatability (RSD %)	Intermediate precision (RSD %)
Precision	80	80.7	1.4	1.6
	100	100.9	1.0	1.2
	120	122.0	1.0	1.2

	Concentration level (% active)	Mean introduced concentration (% active)	Relative β-expectation tolerance limits (%)
Accuracy	80	80.7	[−3.65, 3.14]
	100	100.9	[−2.70, 2.71]
	120	122.0	[−2.59, 2.68]

Limits of quantification (LOQ)	
Lower LOQ (% active)	Upper LOQ (% active)
80.7	122.0

Table 3
Uncertainty of measurements of the (c) model.

Concentration level (% active)	Mean introduced concentration (% active)	Uncertainty of the bias (% active)	Uncertainty (% active)	Expanded uncertainty (% active)	Relative expanded uncertainty (%)
80	80.7	0.35	1.33	2.7	3.3
100	100.9	0.40	1.30	2.6	2.6
120	122.0	0.46	1.53	3.1	2.5

the smallest. However, it is impossible to select the model which is the most fitted for purpose. Moreover, those criteria do not allow the assessment of the model ability to quantify accurately over the investigated active content range.

Consequently, accuracy profiles based on tolerance intervals were used as a complementary decision tool to evaluate the models predictive performances. Tolerance intervals have the advantage to convey a predictive ability to the accuracy profile: for example, 95% of the future results will be included within a 95% tolerance interval. In opposition to a confidence interval which only takes into consideration the existing results but does not guarantee that the future results (routine results for example) will be situated within the interval.

Hubert et al. [20–22] showed that the accuracy profile which uses the total error concept meets the ICH Q2 (R1) guideline requirements. Facing the confusion found between accuracy and trueness in the ICH document, it seems important to remind that accuracy represents the total error concept which is the sum of the trueness (systematic error) and precision (random error).

Fig. 4 shows accuracy profiles based on the validation results obtained with the (a), (b) and (c) model, respectively. From this figure, it can be observed that the active content of validation samples belonging to the same concentration level is identical: it is caused by the alignment on the mean concentration, which is necessary to calculate a variance (for repeatability and intermediate precision estimates).

As this study focuses on the determination of the active content in a pharmaceutical formulation, the acceptance limits were set at ±5% for the validation of the NIR method while the maximum risk $(1-\beta)$ to obtain results outside the tolerance interval was set at 5%.

The lower and upper limits of quantification (LLOQ and ULOQ) define the range where an analytical method is able to quantify accurately. They are located where the β-expectation tolerance interval is included within the acceptance limits. If the β-expectation tolerance interval never crosses the acceptance limits, then the LLOQ and ULOQ are located at the beginning and at the end of the active content range investigated.

As can be seen in Fig. 4, the (b) and (c) models are able to quantify accurately over all the chosen active content range [80–122%]. However, the (a) model has a LLOQ of 95% making this model inaccurate for the 80% active content level. Moreover, of the 3 models, the (a) model has the most important bias.

Regarding the (b) and (c) models, although 95% of the future results will be included within the β-expectation tolerance interval which fall in the acceptance limits over the entire active content range, the (c) model is the best fitted for purpose. Indeed, the (b) model β-expectations tolerance limits are closer to the acceptance limits over the entire active content range than those of the (c) model. Consequently, the NIR method will use the (c) model to determine the active content of the non-coated pharmaceutical pellets.

Fig. 5 shows the evolution of the (c) model RMSECV according to the number of PLS factors chosen: as there is no significant change of the RMSECV value from 3 PLS factors, this number of PLS factors was selected for the (c) model.

The comparison of Fig. 3 and the first loadings of the (c) model displayed on Fig. 6 confirms that the spectral area selected are relevant for the determination of the active content.

Table 2 shows the ICH Q2R1 validation criteria of the (c) model. As seen in the accuracy profile, the bias is stable and points towards zero: the relative bias does not exceed [−0.25%, 0.05%].

The precision of the method was estimated by measuring repeatability and intermediate precision at the three active content levels shown in the validation protocol. The repeatability and intermediate precision are both good for the three levels of active content. As can be observed in the accuracy profile, the 80% active

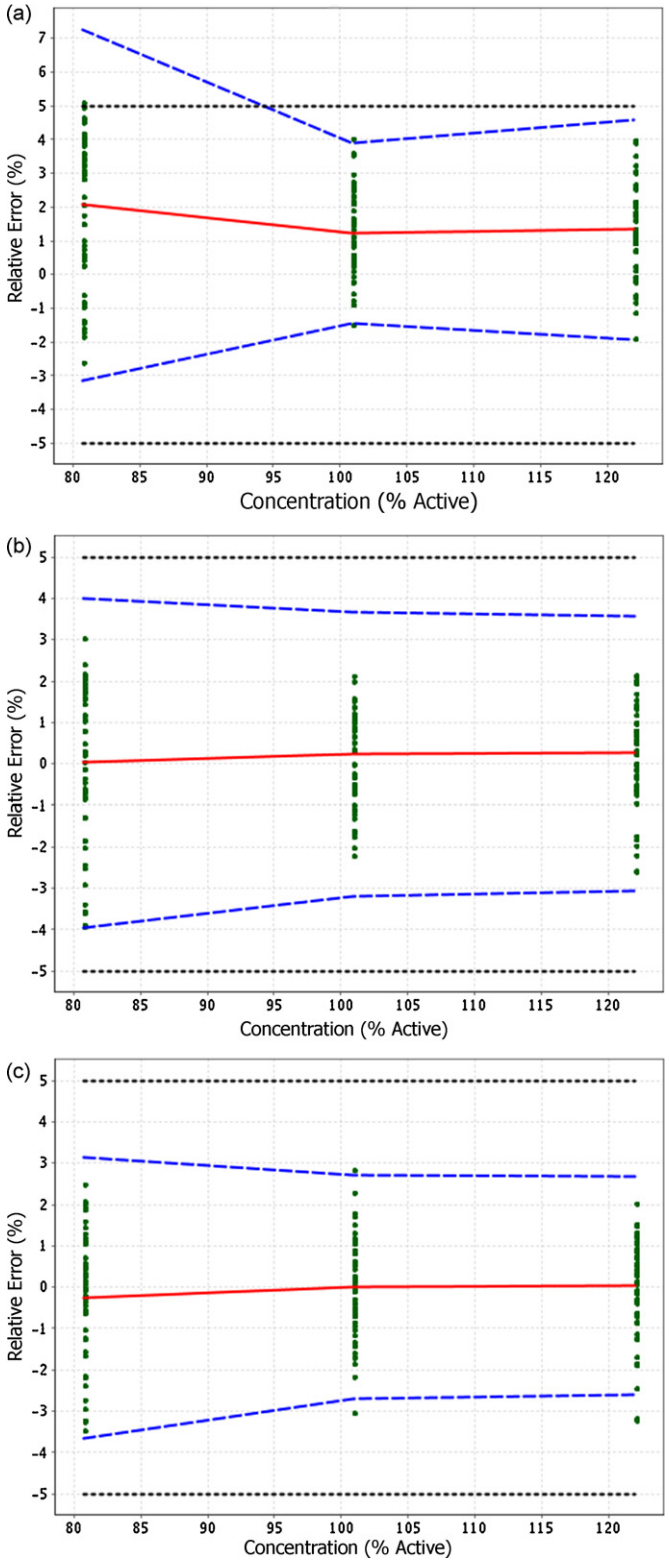

Fig. 4. (a), (b) and (c) Accuracy profiles based on the validation results of the (a), (b) and (c) models. The plain line is the relative bias, the dashed lines are the β-expectations tolerance limits (β = 95%) and the dotted lines represent the acceptance limits (±5%).

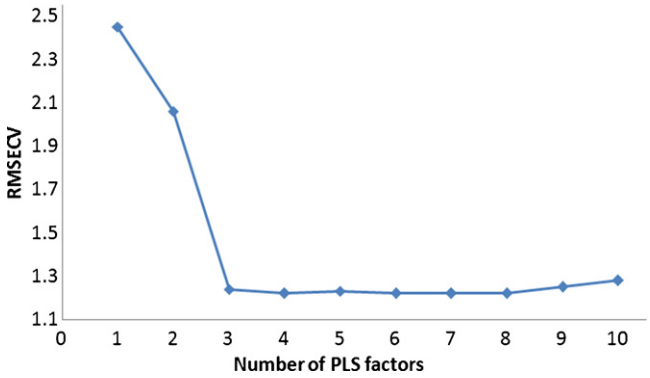

Fig. 5. (c) model: RMSECV versus the number of PLS factors.

content level is the worst level for the repeatability and the intermediate precision but this is still very satisfactory.

As shown with the accuracy profile, the accuracy is very good for the entire active content range as the values of the relative β-expectation tolerance limit never exceed [−3.65%, 3.14%].

Fig. 7 is showing the linear profile of the (c) model. A linear model was fitted on the calculated concentrations of the validation standards for all series as a function of the introduced concentrations. The intercept, the slope and the R^2 values are also presented in Fig. 7. The slope and intercept are close to 1and 0 respectively confirming the absence of proportional and constant systematic error of the (c) model. The linearity of the method for the 80–120% active content range is demonstrated since the β-expectation tolerance limits were included in the absolute acceptance limits. Further, the (c) model reliability was tested with 90 and 110% active content formulations, providing two additional active content levels to evaluate the NIR method linearity. As can be seen from Fig. 8, the linearity was confirmed as the slope and intercept are still close to 1 and 0, respectively.

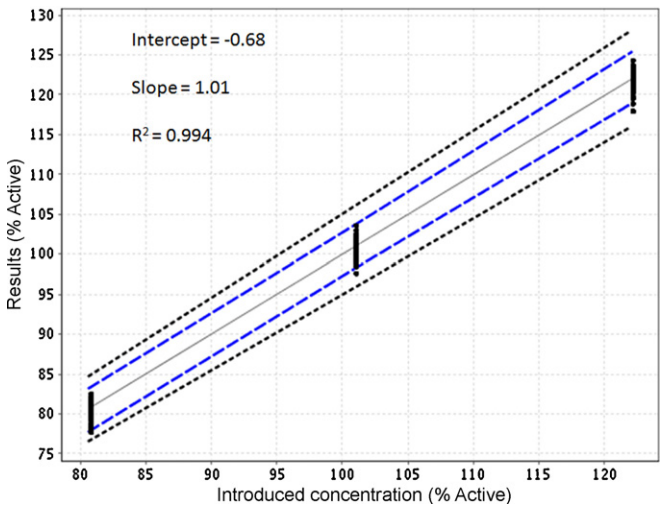

Fig. 7. Linear profile of the (c) model. The dashed limits on this graph correspond to the accuracy profile, *i.e.* the β-expectation tolerance limits expressed in absolute values. The dotted curves represent the acceptance limits at ±5% expressed in the concentration unit. The continuous line is the identity line $y = x$.

3.4. Uncertainty assessment of the NIR method (c model)

The uncertainty characterizes the dispersion of the values that could reasonably be attributed to the measurand [31,32]. Several uncertainty results were generated and are presented in Table 3: the uncertainty of bias of the method at each concentration level of the validation standard, the uncertainty which combines the uncertainty of the bias with the uncertainty of the method obtained during the validation step, *i.e.* the intermediate precision standard deviation, and the expanded uncertainty which equals to the uncertainty multiplied by a coverage factor $k = 2$ representing an interval around the results where the unknown true value can be observed with a confidence level of 95% [33,34]. In addition, the relative expanded uncertainties (%) for active content obtained by dividing the corresponding expanded uncertainties with the corresponding introduced concentrations (Table 3) are not higher than 3.3%, which means that with a confidence level of 95%, the unknown true value is located at a maximum of ±3.3% around the measured result.

3.5. Reliability evaluation of the NIR method

Method validation is the first step to evaluate the fitness of purpose and the reliability of a newly developed analytical method. In order to increase and further guarantee the reliability of the NIR method (c model), a three steps additional reliability evaluation

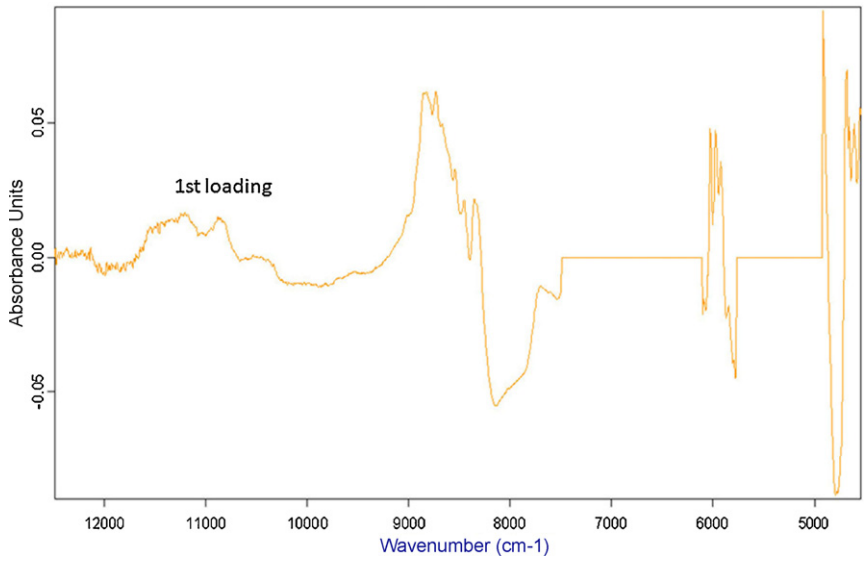

Fig. 6. (c) model: first loading factor.

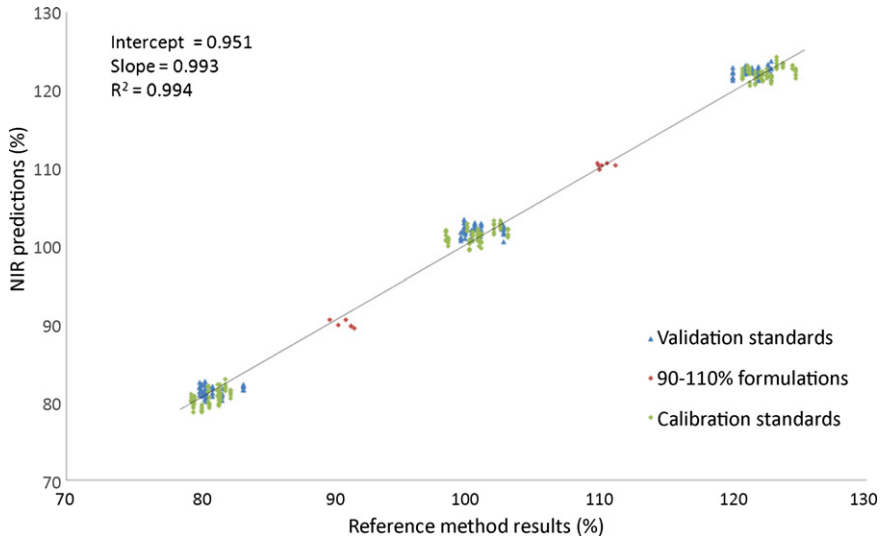

Fig. 8. (c) model: calibration set, validation set and 90/110% formulations NIR predictions versus the reference method predictions.

of the analytical method was performed. The aim of this evaluation is to check the robustness of the NIR method and to ensure its interchangeability with its HPLC reference method.

First, 90 and 110% active content formulations were manufactured. Those batches were analyzed by two operators using both the HPLC reference method and the NIR method (c model), relative errors were calculated. The aim was here to verify that the predictions of the accuracy profile at concentration levels not investigated during the validation step were reliable. Fig. 9 plots the relative error versus the active content level, 95% prediction intervals limits were defined for each level of active content. These prediction intervals define the area containing 95% of the relative errors. Regarding the 90% active content level, 95% of the future results are likely to show a relative error not exceeding [−2.44%, 0.44%]. Besides, 95% of the future results are expected to have a relative error within [−0.62%, 0.72%] for the 110% active content level. All those results indicate that the NIR method is able to quantify accurately 90 and 110% active content formulations. Fig. 8 summarizes the predictions of the (c) model versus the references measurements of the calibration and validation sets as well as for the 90 and 110% active content batches.

Secondly, using batches belonging to the validation set, blends containing different amounts of active content were realized by two operators to obtain between 80 and 120% active content formulations. The results of the reference HPLC method were used to calculate a theoretical active content for each blend. The average between the NIR results (c model) and the HPLC reference results and relative errors were calculated. A Bland and Altman plot is shown in Fig. 10. This plot represents the relative errors against mean (NIR + HPLC)/2 results. Regarding this plot, 95% of the relative errors between the two methods do not exceed [−2.25%, 1.74%].

Finally, the NIR method (c model) was also tested with 10 industrial batches of non-coated pharmaceutical pellets (100% active content formulations) belonging to 2 different production campaigns. Those batches were analyzed by the two operators. The average between the NIR results (c model) and the HPLC reference results and relative errors were calculated. Fig. 11 shows a Bland Altman plot of those results: 95% of the relative errors between the two methods are expected to have relative errors within [−2.32%, 3.40%].

As the results shown in this section are all in full accordance with the validation results, it can be concluded that the NIR method using (c) model was reliable and robust enough to quantify with good accuracy samples with an active content not included in the calibration set (90 and 110% active content formulations). Therefore, it was not necessary to include those levels of active content in the calibration set. Besides, the (c) model also gave accurate predictions for blends of validation batches, which were independent from the model calibration batches. Further, the predictive ability of the (c) model was also adequate to quantify the active content of 100% formulation industrial batches of non-coated pharmaceutical. Therefore, the NIR method can replace the HPLC reference method for the accurate quantification of the API in non-coated pharmaceutical pellets.

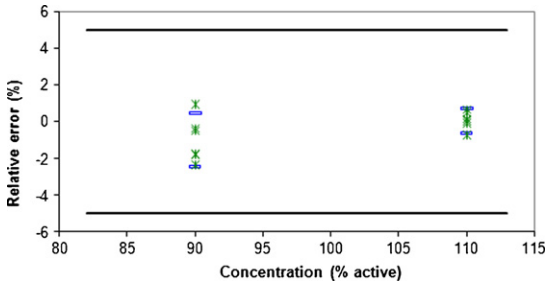

Fig. 9. Relative errors (100 × ((NIR − HPLC)/HPLC)) versus the active content level of batches containing 90 and 110% of the usual active content. The continuous lines are the ±5 acceptance limits. The boxes define the 95% prediction interval limits.

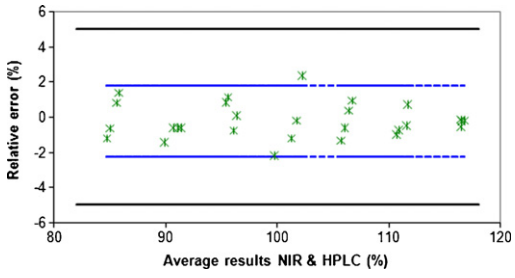

Fig. 10. Blends of batches of pharmaceutical pellets belonging to the validation set: Bland and Altman's plot: Relative errors (100 × ((NIR − HPLC)/HPLC)) against mean ((NIR + HPLC)/2) for different concentration levels. The continuous lines are the ±5 acceptance limits. The dashed lines define the 95% tolerance interval limits.

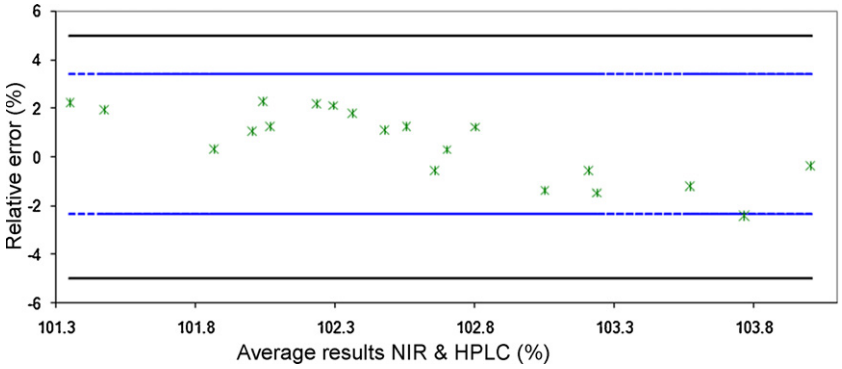

Fig. 11. Industrial batches of pharmaceutical pellets: Bland and Altman's plot: Relative errors ($100 \times ((NIR - HPLC)/HPLC)$) against mean ($(NIR + HPLC)/2$) for different concentration levels. The continuous lines are the ±5 acceptance limits. The dashed lines define the 95% tolerance interval limits.

4. Conclusion

A near infrared method was developed for the determination of the active content of non-coated pharmaceutical pellets. The method was fully validated and showed very good precision, trueness and accuracy for the determination of an active content ranging from 80 to 120% of the usual active content confirming the potential of near infrared spectroscopy in the PAT concept.

As the conventional criteria failed to select the most accurate model because of a lack of interpretation, a novel approach based on accuracy profiles was chosen, which translates the results of the validation set in an effective visual manner, showing the models ability to quantify the active content over the chosen active content range. As it is based on β-expectation tolerance interval, the accuracy profile also gives a representation of the future performances of the analytical method. Consequently, this approach has finally enabled to choose the best model in full accordance with the very final goal of the developed near infrared method: to quantify accurately an active content of non-coated pharmaceutical pellets ranging from 80 to 120%.

The validated near infrared method was successfully tested with pilot batches of non- coated pharmaceutical pellets containing 90 and 110% of the usual active content, with blends of validation batches and industrial batches of non-coated pharmaceutical pellets. The results were in full accordance with the validation results, demonstrating the reliability of the NIR method and its interchangeability with the HPLC reference method.

ABSTRACT

Recent developments in whole-cell spectroscopic methods allow rapid characterization of microorganisms of interest to human health, but have yet to be widely applied to marine microbiological studies. In this study of bacteria associated with the kelp *Laminaria digitata*, we have isolated 18 epiphytic bacterial strains from several thalli, sequenced their 16S rDNA, built corresponding phylogenetic trees, and characterized them using spectroscopic methods. Molecular taxonomy revealed Gram$^+$ *Actinobacteria* and Gram$^-$ *Alphaproteobacteria*, *Gammaproteobacteria* and *Bacteroidetes*. Twelve marine reference strains (Gram$^+$ *Firmicutes*, and Gram$^-$ *Alphaproteobacteria*, *Gammaproteobacteria* and *Bacteroidetes*) were treated accordingly. Whole-cell MALDI-TOF MS spectral profiles of 29 of the 30 strains were built into a database against which 16 replicate spectra of each strain were compared and categorized into groups. The proton HR-MAS NMR stack plots allowed visual delineation into taxonomic groups according to their most common peaks, in agreement with identifiable compounds from corresponding D_2O solution spectra. With both methods, these groups corresponded to taxa identified by 16S rDNA sequences, MALDI-TOF MS being more discriminative than HR-MAS NMR. Culture age did not influence the spectral signatures in both approaches. Most cells grown under minimal conditions (VNSS medium) afforded HR-MAS NMR profiles markedly different to those grown in enriched conditions (ZoBell medium), indicating different adaptive metabolic responses between the two media. Spectral signatures obtained under strictly controlled conditions can be used as rapid and reliable tools for taxonomic purposes and as markers of physiological status.

1. Introduction

The study of marine biofilms associated with living organisms or developing on inert surfaces under immersion requires the isolation of cultivatable bacterial strains in order to study surface interactions [1,2]. Similar to the studies of microorganisms of medical or food safety importance, the taxonomy of bacterial consortia associated with a specific aquatic niche is fundamental to any scientific investigation [3,4]. Characterizations through traditional bacteriological techniques such as culture on selective media and biochemical activity tests are prerequisite for identification of novel species [5], but are time-consuming and labour-intensive for routine checking. Molecular taxonomy using DNA–DNA re-association, PCR fingerprinting and DNA sequencing of reference organisms are generally more discriminatory than methods based on phenotypic characters. Currently employed for routine bacterial identification, molecular methods can be tedious and costly for applications such as contamination checks, strain selection, presence of new species, etc. Mass spectrometry (MS) and nuclear magnetic resonance spectroscopy (NMR) provide attractive alternative methods for routine bacterial differentiation. As a rapid and sensitive method, MS has been widely used for identification and typing of microorganisms during the last 30 years [6]. However, due to some limitations in ionization techniques, access to MS equipment or tedious sample preparation prior to analysis, these methods were not developed for chemotyping of bacteria. MALDI-TOF MS has been used since the 1980s for the determination of proteins within the 2000–20,000 Da range as molecular taxonomic biomarkers in microorganisms, and

doi:10.1016/j.talanta.2009.10.020

a useful user guide for optimizing the technique on whole cells was subsequently published by its pioneers [7]. Recent studies have demonstrated that bacteria from different species and strains could be rapidly identified and distinguished by matrix-assisted laser desorption/ionization—time-of-flight mass spectrometry (MALDI-TOF MS) in microbial mixtures with automated data analysis algorithms [6,8]. MALDI-TOF MS fingerprinting requires very small sample amounts and is relatively fast as product separation is not required. As illustrated by its routine use in proteomic studies, MALDI-TOF MS has proven very useful for the fingerprinting of peptidic masses [9]. Molecular signatures sorted out by mass to charge ratio (m/z) can be compared and matched with referenced proteins which are deposited online in protein databanks. However, not only whole cells or tissue proteome but also secreted biopolymers and membrane-associated components (proteins, carbohydrates, glycoconjugates and lipoconjugates) representing the secretome can be analyzed with the MALDI-TOF technique [10,11]. MALDI-TOF MS proteome analysis has a recognized taxonomic value [12], which has yet to be fully exploited in marine bacteria taxonomy [13]. Original metabolites produced by microorganisms, including bacteria and fungi, have proven useful to establish the chemo-type of microorganisms and are conveniently studied using NMR spectroscopy techniques. In addition, determination of bacterial types associated with pus [14] or from cell extracts [15], or metabolic studies [16], has validated the use of proton NMR for broad taxonomic use in medical microbiology. Delpassand et al. [17] have pioneered high resolution NMR (δ 0.5–4.5 ppm) for fingerprinting of bacterial extracts and found that identification of strains is straightforward and spectra are consistent within strains. NMR offers a high-throughput, rapid, polyphasic approach by providing information simultaneously on a large range of metabolites, and by unraveling bacterial amino acid biosynthesis from labeled precursors. ^{1}H NMR spectra of cell suspensions acquired in static mode provide an overview of mobile hydrogen-containing compounds which can be better identified by multidimensional NMR correlation spectroscopy on corresponding cell extracts. Water soluble metabolites typically include mono and oligomers of carbohydrates, amino acids and some of their derivatives, and organic ions involved in substrate-dependant metabolic pathways. Significant patterns emerge upon applying multivariate statistics on signals (peaks) most representative of a selected spectral window [18], often using the dedicated software developed by the instrument manufacturer. Bourne et al. [19] introduced PCA analysis to simplify classification of the spectra since significantly different metabolite pool sizes would be detected as differences between the ^{1}H NMR spectra of the different bacterial groups. In an effort to reduce handling and increase efficiency in preparation procedures, Motta et al. [20] successfully applied NMR directly to bacterial suspension media of marine strains in order to quantify the various released water solubles. A particularly interesting variant of whole-cell NMR is High Resolution Magic Angle Spin NMR (HR-MAS NMR) now extensively used in *in vivo* and *ex vivo* studies of biological tissues and of whole organisms by pathologists, environmental chemists [21,22], plant physiologists [23–25] and microbiologists [26]. HR-MAS NMR spectroscopy on live tissues, e.g. [27,28] and body fluids [18,29] was primarily used in clinical investigations of biomarkers of cancer and neurological dysfunctions and also proved useful in marine applications, e.g. for macroalgae [23] and for phytoplankton [24]. Bacteriological applications included some technical refinements, e.g. 2D ^{1}H–^{13}C HSQC on ^{13}C labeled cells to study membrane components [26]. The idea behind the MAS method is the tilting of the solid sample by an angle of 54.7° (the "magic angle") to the axis of the static magnetic field, and by rotating the sample at great speed (usually 5–15 kHz) about its own axis, the line broadening of signals is corrected due to a reduction of the anisotropic interactions in the tissue. Lengthy extraction procedures are thus avoided, and time series snapshot spectra can even be taken to monitor metabolic changes in live cells or whole organisms exposed to an experimental disturbance. As a rule, most small water soluble analytes can be observed with HR-MAS preparations, albeit with a lesser resolution than with preparations from extracts. As for MALDI-TOF MS, NMR spectroscopy has been applied to the study of only few marine prokaryotes, and to our knowledge, HR-MAS NMR has never been used as an analytical tool by marine microbiologists.

In this study, we have selected 30 cultivatable bacterial strains (18 regularly found on the thalli of the temperate brown kelp *Laminaria digitata*, 12 environmental isolates some of which are referenced) and we have matched their metabolic and their whole-cell proteomic fingerprints obtained by spectroscopic methods, to the 16S rDNA-based identifications. The aim is to evaluate each spectroscopic method as complementary or substitutive taxonomic tool to gene sequencing, and as a metabolomic (proton HR-MAS NMR) or proteomic (MALDI-TOF MS) tool, with databases constructed directly from whole cells grown under controlled conditions.

2. Materials and methods

2.1. Sample collection

Adult thalli of the brown kelp *L. digitata* Lamouroux were collected seasonally in 2006 on the upper subtidal portions of Bloscon harbour (48°43′19″N; 3°58′15″W) at Roscoff (France). Laboratory sampling of bacterial epiphytes at the holdfast, stipe, meristem and blade portions of the thalli was performed as follows: (i) 3 min sonication of (2–3 cm^2) of tissue coupons in filtered and sterile seawater in 50 ml Falcon tubes, followed by vacuum filtrations (60 μm, then 8 μm mesh, Millipore, France). The filtrates were then seeded in Petri dishes containing agar-enriched ZoBell culture medium [30]. Alternatively (ii) was used: fresh coupons of algae from various portions of algae (<1 cm^2) were placed directly on the surface of the medium. After suitable development, CFU (Colony Forming Units) were selected and each was spread on individual sterile plates to obtain monospecific clonal cultures. Only 18 maintainable strains within the Ld1 to Ld20 series were studied among the numerous strains originally obtained (Ld is used hereafter as shorthand notation for *L. digitata*—associated bacterial consortia). Reference bacterial strains previously isolated from inert or biological surfaces were obtained from various sources. Strains *Vibrio* sp. D01 [31] and *Pseudoalteromonas* sp. D41 were obtained from DERT at Ifremer (Plouzané, France); *Cytophaga* sp. 1M6 [32], *Paracoccus* sp. 4M6 [32], *Pseudoalteromonas* sp. 3J3 [32], *Pseudoalteromonas* sp. 3J6 [32] and *Pseudoalteromonas* sp. 3J6GFP (a plasmid transform of 3J6) and *Bacillus* sp. 4J6 [32] from LBCM at Université de Bretagne-Sud (Lorient, France); *Pseudoalteromonas carrageenovora* ATCC 43555^{T}, *Pseudoalteromonas haloplanktis* ATCC 14393, *Cobetia marina* ATCC 25374^{T} and *Zobellia galactanivorans* Dsij^{T} from Station Biologique de Roscoff (Roscoff, France). All strains are kept at −80 °C in 15% glycerol—ZoBell medium. All bacteria were cultivated on plates with ZoBell—agar medium or VNSS (Väätänen nine-salt solution)—agar medium [33] at 13 °C (±1 °C), during 6, 10 and 18 days (±1 day). Standard seawater (filtered and sterilized natural, 35‰ total salinity) was used for preparation to obtain equivalent final salt concentrations in both media.

2.2. Molecular taxonomy

2.2.1. Amplification of 16S rDNA genes

A small amount of CFU (1–2 μg) of all strains was directly diluted in 200 μl of sterile water MilliQ. Nearly full-length 16S rDNA genes were amplified by PCR with *Taq* polymerase (Promega), and two bacteria-specific primers: forward primer 8F (5′-AGAGTTTGATCCTGGCTCAG-3′) [34] and reverse primer 1492R

(5′-GGTTACCTTGTTACGACTT-3′) [35]. PCR amplifications were performed using reaction mixtures (final volume of 25 μl) containing 1.5 mM $MgCl_2$, 0.2 μM of each primer, 0.2 mM of each dNTP, 0.5 U of Taq polymerase, 1× GoTaq Buffer (Promega), and 1 μl of bacteria-water mixture. Reactions without DNA were used as negative controls. PCR reactions were performed using a thermal cycler (GeneAmp® PCR System 2700, Applied Biosystems) under the following conditions: initial denaturation at 95 °C for 10 min, 35 cycles consisting of 95 °C for 30 s, 53 °C for 30 s and 72 °C for 1 min 30 s, and a final extension at 72 °C for 4 min. Amplified PCR products were analyzed by electrophoresis on 0.8% (w/v) agarose (Eurogentec) in 0.5× TAE (40 mM Tris–acetate, 1 mM EDTA pH 8). Smart Ladder (Eurogentec) was used as the molecular weight standard.

2.2.2. 16S ribosomal DNA sequencing and phylogenetic analysis

PCR products were purified by using Montage™ μPCR96 Cleanup kit (Millipore, France). Full-length sequences were obtained using the primers 8F and 1492R and the ABI v. 3.1 BigDye kit (Applied Biosystems). After purification, sequencing reaction products were run using an ABI 3130xl capillary sequencer (Applied Biosystems) on the sequencing technological platform of the Marine Station Biologique de Roscoff, Genopôle Ouest. The sequencing strategy generated 16S rDNA gene fragments in-between positions 34 and 1404 corresponding to the numbering of nucleotides in the *E. coli* 16S rDNA molecule [36].

The 16S rDNA sequences were edited using the DNAMAN v. 4.15 software, and compared to public nucleotide databases using the advanced Basic Local Alignment Search (BLAST) program (www.ncbi.nlm.nih.gov/BLAST). The resulting sequences were aligned to currently available 16S rRNA gene sequences which showed significant identity to those in EMBL, GenBank and RDP databases, using the SINA Webaligner interface which considers to both their primary and secondary structures ([37], www.arb-silva.de/aligner/). The multiple sequence alignment, including both conserved and variable domains of the 16S rRNA primary structure, was used to generate pairwise similarities and genetic distances between Ld strains and related bacteria. The final alignment was edited using MEGA v. 4.0.2 software [38] and further curated using less stringent parameters of GBlocks freeware [39] available at: www.phylogeny.fr [40]. Phylogenetic analyses were carried out on 62 sequences and 948 nucleotide positions using two reconstructing methods: (i) the Maximum Likelihood (ML) using the PhyML software at www.atgc-montpellier.fr/phyml [41] and (ii) the neighbour joining (NJ) approach using the PHYLIP software package [42], both with F84 models. Other phylogenetic reconstructions with both methods were also conducted using HKY85, Jukes and Cantor and GTR, leading to highly similar topologies and bootstrap supports. For both methods, the input order of sequences into the various phylogenetic programs and the selection of outgroups were also varied in this study. Statistical evaluation of the genetic divergences was performed by bootstrap re-sampling of the sequence data (100 replicates) to provide confidence estimates for the phylogenetic tree topologies.

The partial 16S rRNA gene sequences fully sequenced in this study have been deposited in the GenBank database under the accession numbers FJ966928–FJ966945, for the sequences obtained from *L. digitata* of Roscoff and FJ966946–FJ966951 for the sequences of the other reference bacterial strains used.

2.3. MALDI-TOF mass spectrometry

For each sample with the exception of Ld1, approximately 1–2 μg of live bacteria was carefully collected from a single CFU, directly spotted onto a MALDI target plate (MSP 96 ground S/N, Bruker) as a thin bacterial film and allowed to air dry. Each spot was overlaid with 1 μl of a fresh solution of saturated α-cyano-4-hydroxycinnanic acid matrix solution in 50% acetonitrile/50% water acidified with 2.5% trifluoroacetic acid, and then air dried at room temperature. MALDI spectra were acquired on Microflex Bruker Daltonics «time-of-flight» instrument (Bruker Daltonics GmbH, Leipzig, Germany) in linear positive mode with an accelerating voltage of ±20 kV, a time allowed to 300 ns and an emission wavelength of 337 nm. A total of 200 consecutive laser shots were accumulated from each sample. The instrument was calibrated with the following 11 reference masses from *E. coli* CIP53.126 from CGI-IPL Bretagne (Lorient, France): RL36 4364,33; RS32 5095,82; RS34 5380,39; RS33 Meth 6254,39; RL32 6315,19; RL30 6410,60; RL35 7157,74; RL29 7273,45; RL31 7871,06; RS15 8476,74; RS19 10137,57. All spectra were smoothed with the *Savitzky-Golay* centroid algorithm and a TopHat baseline subtraction. Mass spectra were acquired with FlexControl v. 3.0 and worked with FlexAnalysis v. 3.0 (software provided with the instrument). Post acquisition Biotyper v.1.0 software was used to classify all 464 database matrix spectra using a PCA (principal component analysis) approach. First, 29 strains were analyzed with an acquisition of 16 individual spectra (replicate spectra) per strain, that had intensity signals between 2000 and 6000, in order to build a database of 29 "consensus" spectra, based on averaging of the 16 replicate spectra, i.e. 29 consensus spectra × 16 replicate spectra amounting to 464 individual spectra. Second, each of the 464 individual spectra was compared for consistency against the 29 consensus spectra, and an averaged identity score was assigned to the five most resembling strains. Once validated, the database was used to classify samples from two experiments: 29 strains were grown on both ZoBell and VNSS media, each with 4 different culture replicates, yielding (i) 116 new ZoBell individual spectra and (ii) 116 new VNSS individual spectra.

2.4. NMR spectroscopy

Whole-cell samples were obtained from individual monocultures by collecting isolated live CFU which were introduced in a 4 mm zircon oxide rotor. Samples were homogenized with D_2O (Euriso-top, Saclay, France) and after sealing, the rotor was spun at 5000 Hz at 298 K in a HR-MAS SB BL4 $^1H/^{31}P$ probe which equipped a 500 MHz DRX Bruker supraconductive magnet at Service Commun de RMN at Université de Bretagne Occidentale, Brest. Recordings were made using a standard protocol for presaturation of the residual water peak. For all ZoBell grown strains, three sets of HR-MAS spectra were recorded corresponding to day 6, day 11 and day 18 plates. D_2O extracts from 8 day cultures were made from whole plate surface scrapings of CFU which were homogenized in a French press (1.5 bar pressure). High resolution solution one and two dimensional ^1H and ^{13}C spectra were obtained using the 5 mm triple resonance TBI $^1H/\{BB\}/^{13}C$ probe head. Standard pulse sequences were used for COSY (^1H–^1H correlation spectroscopy), HMQC experiments (^1H detected ^1H–^{13}C heteronuclear multiple quantum coherence), and HMBC (heteronuclear multiple bond correlation). Using the same protocol, HR-MAS profiles of 16 strains cultured on VNSS medium were acquired for comparison to the HR-MAS profiles of same strains grown on ZoBell medium.

HR-MAS data preprocessing (normalization) included: (i) baseline corrections on all spectra using Bruker's XWIN standard baseline correction algorithms, (ii) referencing of all spectra according to most common identified peaks (glycine betaine methyl singlets at $\delta = 3.90$ and 3.26 ppm, or alanine at $\delta = 1.47$ ppm, respectively) and (iii) scaling. Spectra were first stacked using MestReNova v. 5.2.5 software (MestRec, Santiago, Spain), compared and grouped visually. Automated PCA analysis: spectra were processed with AMIX v. 3.8 software (Bruker Biospin, Rheinstetten, Germany) using the $\delta = 0.5$–4.5 ppm spectral region deemed the most representative, with a matrix comprising rectangular bucket sizes of 0.04 ppm.

Table 1
Bacteria used for comparative strain identification between molecular taxonomy (16S rDNA) using 1492R and 8F primers.

Series Ld was isolated from various parts (holdfast, stipe, proximal and distal areas of blade) of the brown kelp *Laminaria digitata*; strains *Pseudoalteromonas* sp. D41^T and *Vibrio* sp. D01 are from IFREMER culture collection; *Algibacter* sp. 1M6, *Paracoccus* sp. 4M6, *Bacillus* sp. 4J6, *Pseudoalteromonas* sp. 3J6 and a plastid transform *Pseudoalteromonas* sp. 3J6GFP, and *Pseudoalteromonas* sp. 3J3 are from LBCM culture collection; *P. carrageenovora*, *P. haloplanktis* and *C. marina* are from the DMSZ culture collection; *Z. galactanivorans* is from the Roscoff culture collection. Nomenclature follows NCBI recommendations: http://www.ncbi.nlm.nih.gov/Taxonomy/Browser/wwwtax.cgi?name=Eubacteria.
Note: Identification of strain 4M6 as *Paracoccus* sp. was made on the basis of (i) indications from supplier (LBCM) and (ii) spectroscopic profile resemblance, i.e. intact cell ^{1}H HR-MAS NMR metabolomes (Table 3) and whole-cell MALDI-TOF MS proteomic profiles (Table 2), but not on 16S rDNA sequencing.

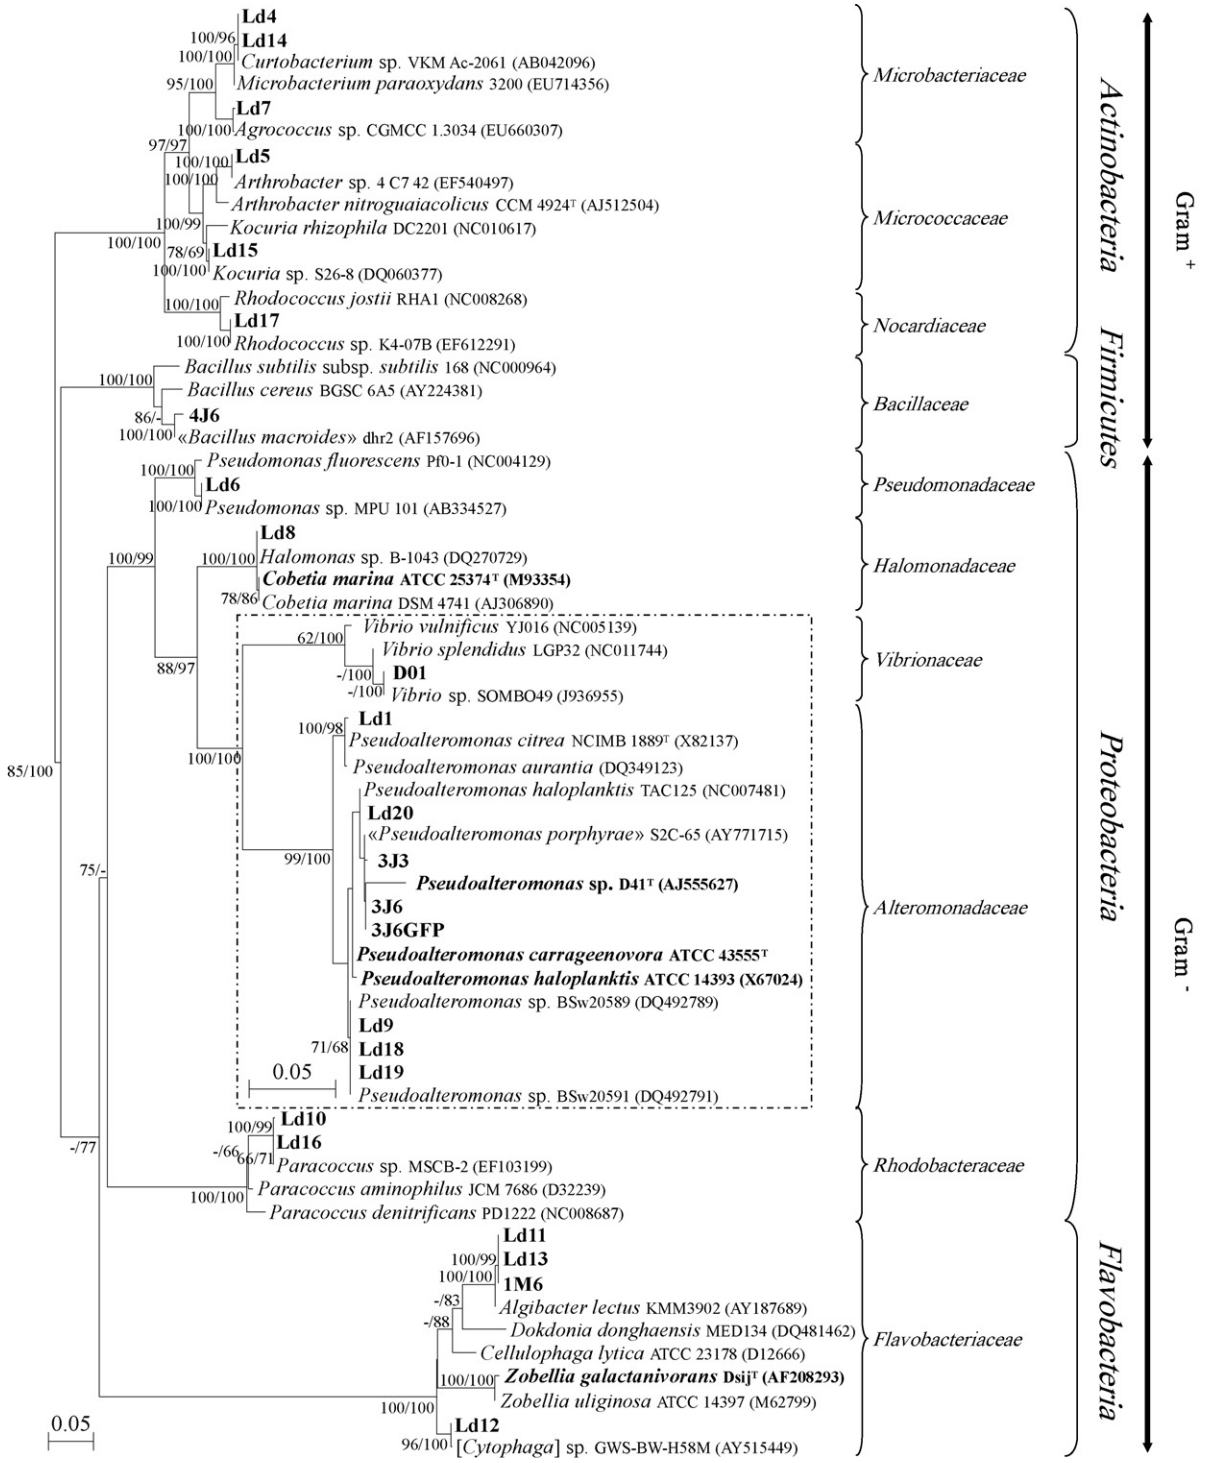

Fig. 1. Maximum likelihood tree of 68 *Laminaria digitata*—associated and reference bacteria sequences based on 16S ribosomal DNA genes. Neighbour joining and PHYML trees were constructed from 948 nucleotides sites. If above 65, bootstrap values (100 replicates) are provided for neighbour-joining (first value) and PHYML (second value) analyses. Dotted line box represents an enlargement of the subtree of *Vibrionaceae* and *Pseudoalteromonadaceae*. Bolding of strains indicates that the 16S rDNA was sequenced in this study whereas other sequences were retrieved from databases. The scale represents the expected number of changes per sequence position

3. Results

3.1. Molecular taxonomy of a selection of the cultivatable microbial epiflora of L. digitata

Eighteen strains isolated from *L. digitata* and cultivatable on ZoBell medium were each assigned a code number (Ld series, Table 1). Most 16S rDNA sequences of about 1370 bases were identified to genus level (up to 99% identity or better), using available Genbank databases. The tree topology shown in Fig. 1 is identical to other statistical representations of the sequence data, including parsimony, maximum likelihood and neighbour joining.

The twelve exogenous reference strains were identified to genus level exactly as expected, except for *Cytophaga* sp. 1M6. We confirmed that the Gram$^+$ *Bacillus* sp. 4J6 belongs to the *Bacillaceae* family (phylum *Firmicutes*). Accordingly, the Gram$^-$ include

Vibrio sp. D01 (phylum *Proteobacteria*; class *Gammaproteobacteria*; family *Vibrionaceae*), and *P. carrageenovora* ATCC 43555^T, *Pseudoalteromonas* sp. 3J3, 3J6 and 3J6GFP with 97% between *P. carrageenovora* and 3J6 and 100% between 3J6 and 3J6GFP. Finally, *Cytophaga* sp. 1M6 (phylum *Bacteroidetes*, family *Flavobacteriaceae*) presenting 100% identity with *Algibacter* sp. Ld11 and Ld13, which means that *Cytophaga* sp. 1M6 is in fact an *Algibacter* sp. 1M6. Additional data was merely retrieved from the NCBI site http://www.ncbi.nlm.nih.gov/sites/entrez. It included *C. marina* ATCC 25374^T, GenBank M93354 (class *Gammaproteobacteria*, family *Halomonadaceae*) presenting 99% identity with *Cobetia* sp. Ld8, *Pseudoalteromonas* sp. D41, GenBank AJ555627 (class *Gammaproteobacteria*, family *Pseudoalteromonadaceae*) presenting a 98% identity with *Pseudoalteromonas* sp. 3J6, *P. haloplanktis* ATCC 14393, GenBank X67024 (class *Gammaproteobacteria*, family *Pseudoalteromonadaceae*), presenting 97% identity with 3J6, and finally *Z. galactanivorans* Dsij^T, GenBank AF208293 (phylum *Bacteroidetes*, family *Flavobacteriaceae*).

3.2. Bacterial identification by MALDI-TOF MS

Table 2 summarizes all experiments undertaken on 29 strains (only 17 *L. digitata* isolates since Ld1 was not used in this experiment, and 12 environmental isolates from our marine culture collection), grown on ZoBell—agar (enriched medium) and on VNSS—agar (minimal medium) for approximately 7 days, and using a 2–18 kDa spectral window. The top block represents the comparison between the 464 individual spectra and the database of 29 consensus spectra (averaged by MALDI BioTyper software), in order to test the database for consistency. Scores over 50 are considered valid, i.e. there are enough similarities between each individual spectrum and the consensus spectrum to consider the corresponding strain as taxonomically related. In all cases, the consensus spectra (up to five) that are PCA selected as best matches include the same strain as the corresponding individual spectrum (highest self scores, up to 410), indicating a sound choice of spectral window and a good experimental reproducibility throughout. The other matching profiles may be taxonomically identical or related, as determined by 16S rDNA analyses (q.v. Table 1), and as suggested by neighbour scores above 50. With Gram$^+$ members, Ld4 and Ld14 which both belong to the genus *Curtobacterium* displayed scores of 264 and 122, respectively, strongly suggesting they are conspecific. On the other hand, the Gram$^+$ *Kocuria* sp. Ld15, *Arthrobacter* sp. Ld5, and *Agrococcus* sp. Ld7 are not related with any other strains because they are recognized only by their own consensus profile, confirming distinct genera within the family *Micrococcaceae*. Similarly, *Rhodococcus* sp. Ld17 from the family *Nocardiaceae* and *Bacillus* sp. 4J6 from class *Bacilli* do not match with any other strains. Within Gram$^-$ members, the *Alphaproteobacteria* 4M6, Ld10 and Ld16 are *Paracoccus*, the high neighbour scores between 4M6 and Ld10 (between 220 and 248) suggest conspecificity. However, Ld16 (low neighbour scores between 14 and 30) is very likely a distinct species. The *Gammaproteobacteria* includes the major genus *Pseudoalteromonas* which appears quite heterogenous. Ld9, Ld18 and Ld19 form a separate subgroup to other *Pseudoalteromonas*, Ld18 being quite distinct from Ld9 and Ld19 which are very similar. *P. haloplanktis* ATCC 14393 and *Pseudoalteromonas* sp. 3J6 and 3J6GFP appear to form another coherent subgroup. *P. carrageenovora* ATCC 43555^T is poorly related with only 3J6GFP with an insignificant score of 7, and finally *Pseudoalteromonas* strains Ld20, 3J3 and D41 which have very high self scores (296–410 level) do not match with any other strains. *Vibrio* sp. D01 (self score 236) and *Pseudomonas* sp. Ld6 (self score 214) do not match with any other strains, as expected. *Cobetia* sp. Ld8 and *C. marina* ATCC 25374^T both belong to the family *Halomonadaceae*, yet they are significantly different taxa with scores of 3. Within the *Flavobacteriaceae,* Ld11, Ld13 and 1M6 are *Algibacter* sp. display high neighbour scores suggesting conspecificity, whereas Ld12 (identified as *Cellulophaga* sp.) and *Z. galactanivorans* Dsij^T do not match with any other strains within the phylum *Bacteroidetes*.

The second block of Table 2 represents a classification of 116 individual spectra (4 individual spectra per strain, i.e. 4 × 29 strains) of ZoBell—newly grown bacteria, against the database of 29 consensus spectra (ZoBell profiles). In all cases (with the exception of Ld18 and Ld19) the new set of 116 spectra matches the consensus database, with scores above 50.

The third block represents a classification of individual spectra × 29 strains, i.e. 116 spectra of VNSS—grown bacteria, against the database. There is a total match of all 116 individual spectra with the corresponding consensus database, with scores comparable to those obtained with the top block, i.e. above 50.

3.3. Bacterial studies by NMR spectroscopy

3.3.1. Similarities in metabolic profiling

Stack plots of ^{1}H HR-MAS 6–11 day CFU's of ZoBell grown bacteria shown in Fig. 2 clearly delineate bacterial groups sharing similarities in their 0.5–4.5 ppm proton profiles. Some Gram$^-$ phyla, e.g. *Bacteroidetes* (Fig. 2D) and the Gram$^+$ phyla *Actinobacteria* and *Firmicutes* (class *Bacilli*) in Fig. 2A have visually characteristic spectral profiles while other groups, e.g. genus *Pseudoalteromonas* in Fig. 2B are somewhat less homogeneous in appearance, forming groups of more or less strongly resembling spectra. PCA analysis of NMR signals by the AMIX software on all normalized spectra (q.v. Supplementary Figure S2) could discriminate between different strains of a given age, but concluded that differences between cultures of different ages were not significant, despite visually important qualitative and quantitative changes in profiles in a number of strains. Out of the 16 strains analyzed by NMR on both ZoBell and VNSS media, (i) four pairs of spectra showed no significant qualitative difference, (ii) six pairs presented major differences to totally different spectra, and (iii) the remaining six pairs presented highly similar spectra, with few visible differences in the expression of one or more minor metabolites in one medium and not (or much less) in the other. Fig. 2E compares 6–10 day ^{1}H HR-MAS spectra of 3 selected strains grown on both media: *Pseudomonas* sp. Ld6 illustrating (i), *Pseudoalteromonas* sp. 3J3 illustrating (ii) and *Arthrobacter* sp. Ld5 illustrating (iii). The expression of several aliphatic amino acids and of glycine betaine in one medium and not in the other occurs in VNSS in some cases and in ZoBell in other cases. Other metabolites are medium-specific in our spectra: proline shows up in three VNSS spectra and not in corresponding ZoBell grown strains, whereas acetate and succinate ions appear in ZoBell grown strains and not in corresponding VNSS grown strains.

3.3.2. Compound identification by solution NMR

D_2O solution samples of all bacteria evidence the presence of medium to highly polar metabolites. All identifiable molecules are listed in Table 3 with their indicative chemical shifts. Their presence and abundance can be correlated to 16S rDNA determinations, as we order all strains according to the phylogenetic tree of Fig. 1., and clustering patterns of black (= dominant metabolite) and grey (= minor metabolite) boxes follow taxonomic distribution. Thus, some multi-species genera (*Curtobacterium*, *Paracoccus*, *Algibacter*) are homogenous, i.e. all compounds present in the poorest spectrum of a genus are found in all congeneric species. Other genera have a less coherent metabolite distribution, e.g. *Cobetia* and *Pseudoalteromonas*, with sometimes only half of the compounds shared between their members. Within the genus *Pseudoalteromonas*, the Ld9–Ld18–Ld19 cluster is fairly homogenous, forming a discrete subgroup (as in the MALDI-TOF MS analysis); the same is observed with the 3J6–3J6GFP–3J3–D41–*P. carrageenovora* and *P. haloplank-*

Table 2
MALDI-TOF profiling of macromolecules (essentially ribosomal proteins) from MW ca. 2,000–18,000 Da from cultured strains.

Top block: comparison of the 464 individual spectra against database of bacteria grown on ZoBell medium (see text). Top line: represents the 16 replicate spectra × 29 strains (with code names of the 29 strains), i.e. 464 individual spectra, which are individually compared to the 29 consensus spectra of the database (obtained by MALDI Biotyper averaging of the same 16 replicate spectra). Line 2: outcome of the comparison of the 464 individual spectra against the database, indicating up to three best matches. Line 3: entries represent the percentages of occurrence as top match. Line 4: average score based on spectral similarities of each of the 16 replicates of each strain against database. Self scores are highest (e.g. 4M6 vs 4M6 score 280), high neighbour scores suggest same or very closely related strain (e.g. 4M6 vs Ld10 score 248), and scores under 50 are not significant (e.g. 4M6 vs Ld16 score 21) whereas 16S rDNA taxonomy unambiguously assigns 4M6, Ld10 and Ld16 as *Paracoccus* sp. Intermediate block: new series of four individual spectra per strain grown on ZoBell medium compared with the database. Bottom block: series of four spectra per strain grown on VNSS medium compared with the database.

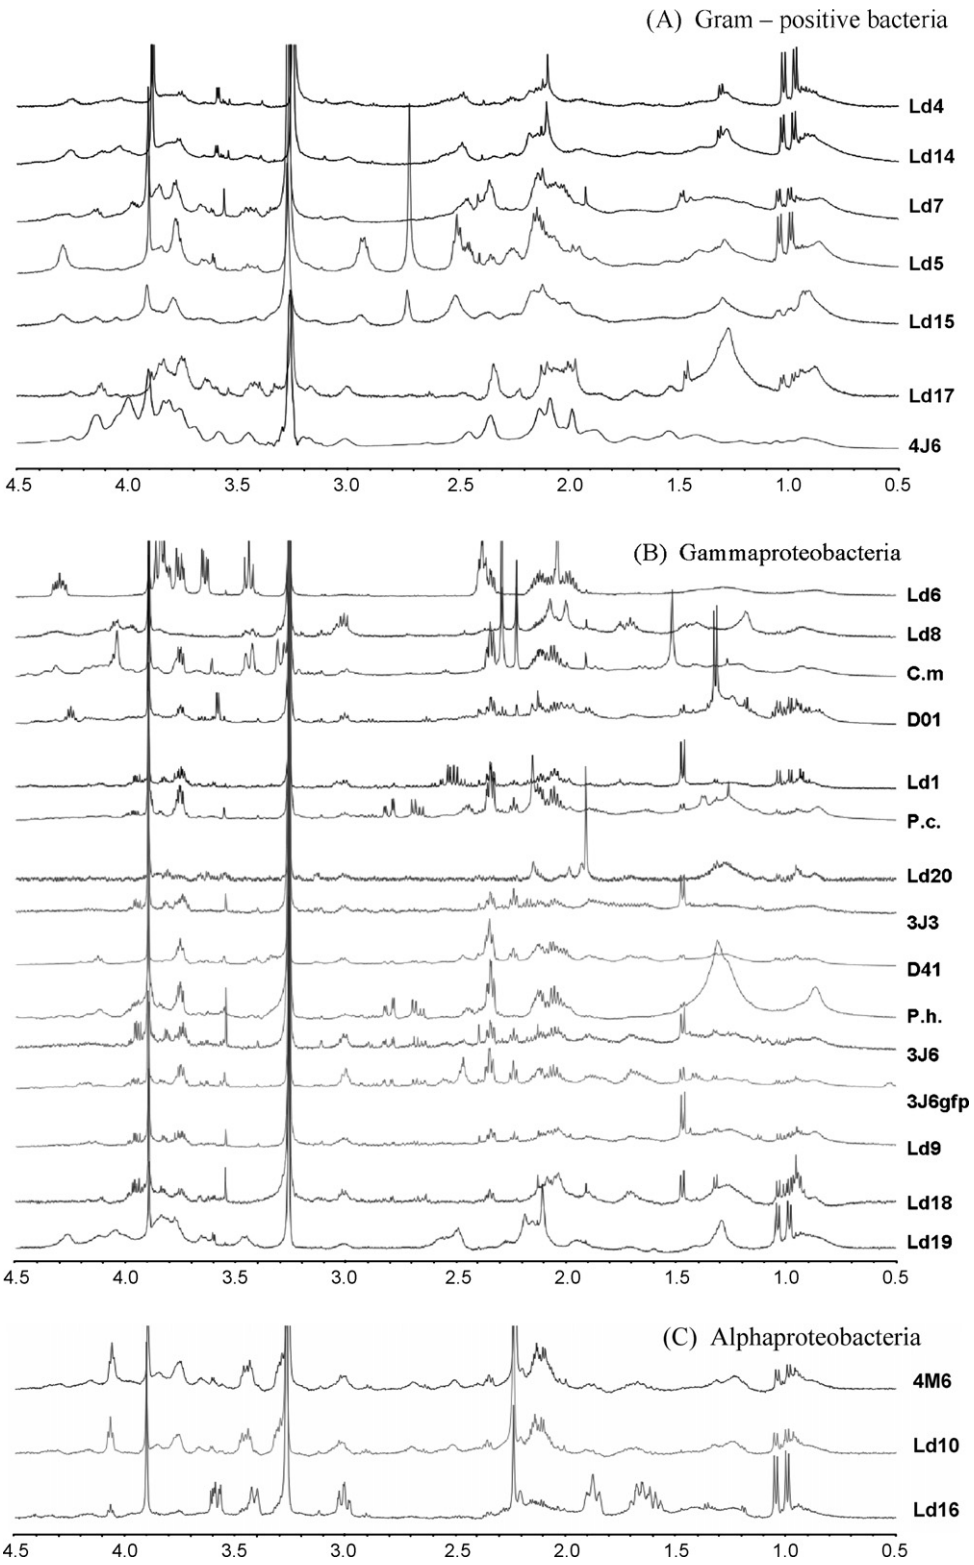

Fig. 2. Stackplots of HR-MAS NMR (δ = 0.5–4.5 ppm) profiles of bacteria isolated from *L. digitata* thalli or from environmental samples, arranged according to tree of Fig. 1. (A) Gram$^+$ (i) phylum and class *Actinobacteria*. Families are *Microbacteriaceae* (*Curtobacterium* sp. Ld4 and *Curtobacterium* sp. Ld14; *Agrococcus* sp. Ld7), *Micrococcaceae* (*Arthrobacter* sp. Ld5; *Kocuria* sp. Ld15 and *Nocardiaceae* (*Rhodococcus* sp. Ld17), and (ii) phylum *Firmicutes*. Only represented genus is *Bacillus* (*Bacillus* sp. 4J6). (B) Gram$^-$ class *Gammaproteobacteria*. Families are *Pseudomonadaceae* (*Pseudomonas* sp. Ld6), *Halomonadaceae* (*Cobetia* sp. Cm and Ld8), *Pseudoalteromonadaceae* (3J6, 3J6GFP, Pc, Ph, D41, 3J3, Ld20, Ld19, Ld18, Ld9, Ld1, all *Pseudoalteromonas* species) and *Vibrionaceae* (*Vibrio* sp. D01). (C) Gram$^-$ class *Alphaproteobacteria*. Family is *Rhodobacteraceae* (Ld16, Ld10, 4M6, all *Paracoccus* species). (D) Gram$^-$ phylum *Bacteroidetes*. Family is *Flavobacteriaceae* (*Algibacter* sp. Ld11, Ld13 and 1M6; *Cytophaga* sp. Ld12 and *Zobellia galactanivorans* Zg). (E) Examples of VNSS vs ZoBell fingerprints of metabolites (i) presenting no differences, e.g. in *Pseudomonas* sp. Ld6, (ii) with no signals in common, e.g. in *Pseudoalteromonas* sp. 3J3, and (iii) with few differences, e.g. in *Arthrobacter* sp. Ld5. Note: scaling represents chemical shifts in the F1 dimension ($4.5 < \delta < 0.5$ ppm) and was added to each original stackplot spectra.

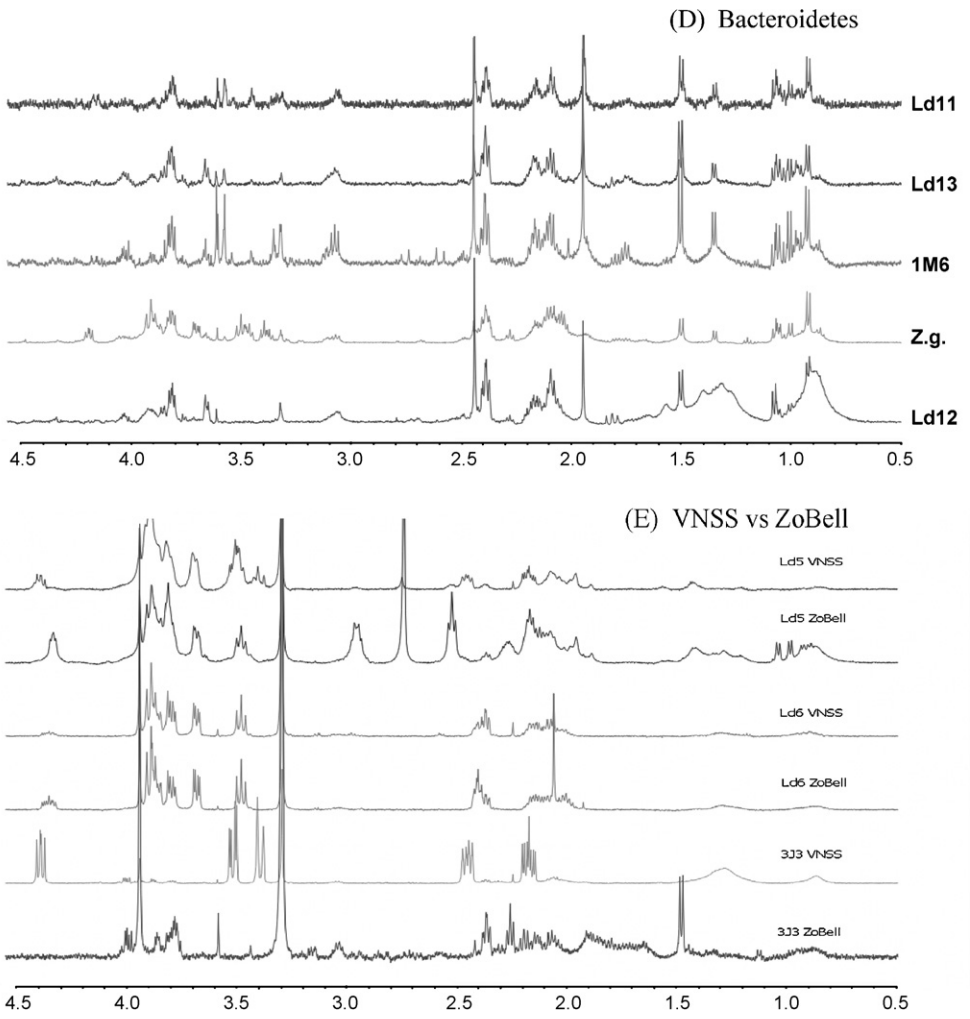

Fig. 2. (*Continued*).

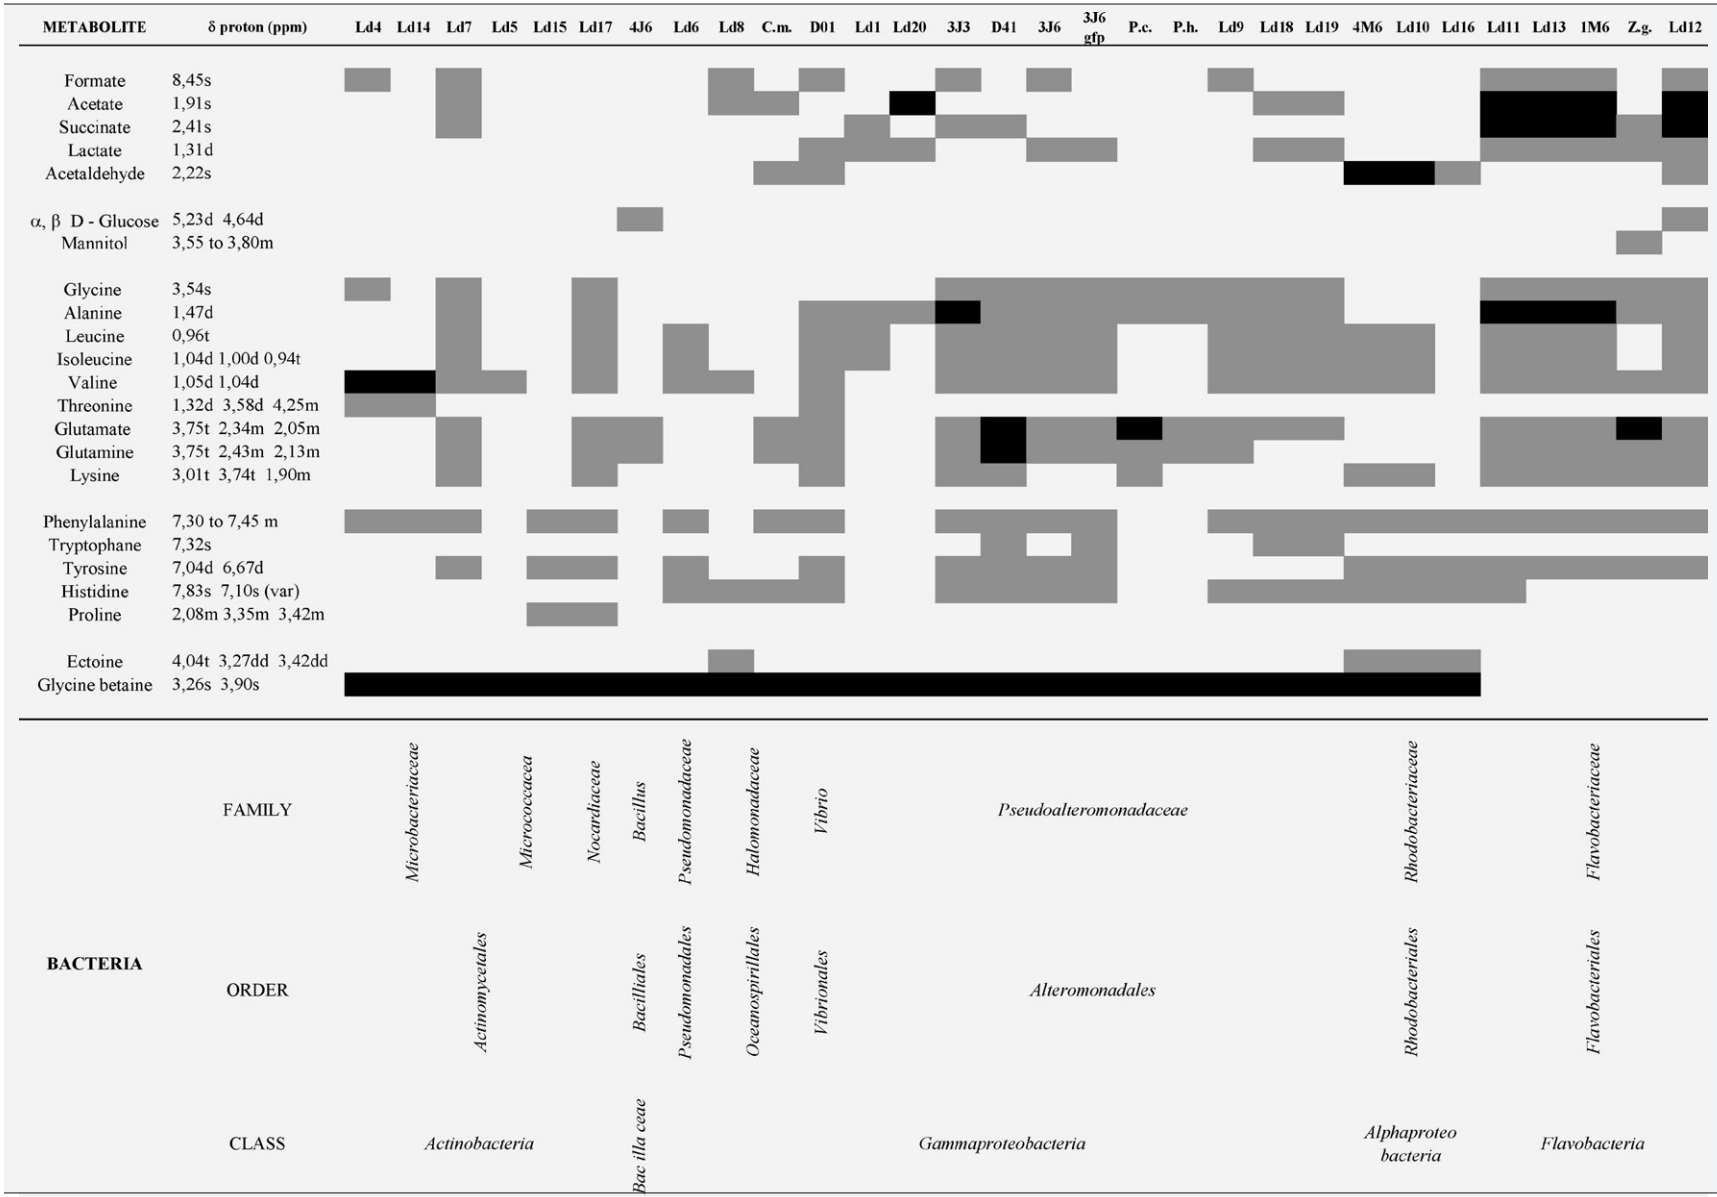

tis subgroup of the phylogenetic tree of Fig. 1. The molecules are conveniently organized in three categories in Table 3: easily ionizable molecules (salts) and aminated compounds, simple carbohydrates (carbon sources), non-cyclic and cyclized amino acids. Among the polyaminated compounds, glycine betaine is the most prevalent compound (present in all Gram$^+$ and in most Gram$^-$ strains except for the phylum *Bacteroidetes*), and ectoine was tentatively identified almost exclusively in class *Alphaproteobacteria*. Regular amino acids are better identified in solution spectra than in HR-MAS NMR spectra, especially for species that are less soluble or present in very small concentrations. Alanine was present in most Gram$^-$ samples (except class *Alphaproteobacteria*) but was less frequent in the Gram$^+$ strains and was the dominant compound in the two *Curtobacterium* sp. (Ld 4 and Ld14), in the phylum *Bacteroidetes* (Ld11, Ld12, Ld13, 1M6 and Zg) and in *Pseudoalteromonas* sp. 3J3. Likewise, the other aliphatic amino acids leucine, isoleucine and valine had similar distributions across both Gram$^+$ and Gram$^-$ taxa. Glycine was also represented in all groups, and was the dominant metabolite in *Pseudoalteromonas* sp. Ld19 and the long chained lysine was just detectable in 40% of all samples. Glutamate and glutamine were also widely found in both Gram$^-$ and Gram$^+$ samples, except again in class *Alphaproteobacteria*, and it was the dominant compound in two *Pseudoalteromonas* sp. (D41 and *P. carrageenovora*) and in *Z. galactanivorans* (phylum *Bacteroidetes*, class *Flavobacteria*). Proline was only found in two Gram$^+$ *Actinobacteria* (*Kocuria* sp. Ld15 and *Rhodococcus* sp. Ld17). Other compounds included mannitol only found in *Z. galactanivorans*, and all *Bacteroidetes* were conspicuously lacking glycine betaine, present in all other strains. Glucose (or related species, e.g. trehalose) was identified only on the basis of their alpha and beta anomeric protons, in low amounts and in very few strains: *Bacillus* sp. 4J6 (Gram$^+$) and *Cellulophaga* sp. Ld12 (Phylum *Bacteroidetes*). Lactate resulting from carbohydrate fermentation was found in all *Bacteroidetes* and in several *Gammaproteobacteria* (all *Pseudoalteromonas* sp.). Organic ions appearing as sharp singlets on proton spectra may be useful taxonomic markers, e.g. formate, acetate and succinate were well represented in all five *Bacteroidetes*. Acetate and succinate occasionally dominated the proton spectra as possible products of carbohydrate catabolism (*Flavobacteriaceae* Ld11, Ld12 and Ld13). Finally, aldehydes which are considered volatile were found in all studied *Alphaproteobacteria* (*Paracoccus* sp. Ld10, Ld16 and 4M6) where they occasionally dominated the spectrum (*Paracoccus* sp. Ld10 and 4M6), but also in the *Gammaproteobacteria Vibrio* sp. D01 and *C. marina* and in the *Bacteroidetes Cellulophaga* sp. Ld12.

4. Discussion

4.1. MALDI-TOF MS spectrometry provides a useful technique for rapid identification of marine bacteria

This study demonstrates that MALDI-TOF MS of CFU of marine bacteria provides reliable and strain-specific profiles in the 2–18 kDa range, which appeared here to consist mostly of peptides

Table 3
Compounds from HR-MAS NMR spectra, using corresponding solution spectra for tentative identification, and their distribution according to 16S phylogeny.

From right to left: metabolites are arranged by type: simple salts, sugars, non cyclic amino acids, cyclised amino acids, aminated osmolytes, chemical shifts (δ in ppm) of protons that characterize the above metabolites in HR-MAS spectra and in solution spectra, bacterial strains arranged in taxonomic categories as defined in tree of Fig. 1. All extracts are from 10 to 11-day-old CFUs grown on ZoBell enriched medium. Black blocks represent metabolites present in major concentrations from corresponding proton signals, grey blocks represent metabolites in minor concentrations, and white blocks correspond to traces or no metabolite. Block clusters follow a phyletic distribution thus confirming visual inspection of HR-MAS NMR spectra (Fig. 2), the presence in specific taxa of some of the listed metabolites being characteristic of their known osmoregulatory pathways.

and small proteins. MALDI-TOF MS is now considered as the main tool in the analysis of proteome signatures in response to changing environmental conditions [9]. For example, Arnold et al. [43] have shown that culture age makes the MALDI proteomic profile of *E. coli* strain K-12 present considerable quantitative variations between 2 and 84 h of incubation in liquid medium. Interestingly, we found that CFU grown on solid media did not vary significantly with age (according to Biotyper analysis), and we may attribute this fact to different gene expressions relating to different lifestyles, one planktonic and the other as microcolonies. The fact that MALDI-TOF MS profiles obtained from colonies grown on VNSS (minimal medium) were not found to vary significantly from same grown on ZoBell medium (enriched medium) in the present study is more puzzling, inasmuch as the profiles established by proton HR-MAS NMR can be visually very different. In this respect, MALDI-TOF MS spectra are not as responsive as physiological markers as HR-MAS NMR spectra on whole cells (see below). Our findings agree with [44] who have used MALDI-TOF MS to discriminate between Gram$^+$ *Arthrobacter* sp. isolates at strain level with 100% agreement with 16S rDNA gene sequences. They found that age differences between agar-plated *Arthrobacter* sp. strains appear less important than when the same are grown in liquid medium. This could be due to changes in protein profiles in the growth phase in liquid medium. In the same study, *Arthrobacter* sp. profiles from enriched vs minimal culture media did not present significant differences, in agreement with our own observations, indicating no major changes in biopolymer expression between the two media. Unwanted variability requires that a reference database be constructed from of spectral profiles using strains grown under strictly controlled conditions. The full taxonomic potential of a reliable reference database is indeed only revealed against samples series grown under identical conditions [8] and in our case it could discriminate *Pseudoalteromonas* sp. D41 (probably a new species, C. Compère, pers. com.) from *P. haloplanktis* as tentatively attributed by 16S rDNA sequence analysis with 98% sequence identity! The metabolomic potential of individual strains can thence be exploited by changing selected parameters one at a time, e.g. different culture medium, salinity, temperature, etc., and compare the profiles against the consensus database. Bacterial proteomics is an actively growing field with great medical and biotechnological importance, e.g. in adhesion studies in which both membrane proteins and EPS (extrapolymeric substances) are involved.

In this study, the cultivatable *Gammaproteobacteria* are dominated by the recently revised [45] genus *Pseudoalteromonas*, which is ecologically diverse [46] and often associated with algal surfaces. This genus has provided several useful models for adhesion and quorum-sensing studies [47]. Among the several *Pseudoalteromonas* "control" (environmental) strains used in our study, MALDI-TOF MS was expectedly capable of discriminating between strain 3J6 and its plasmid transform 3J6GFP, indicating major changes in the proteome expression of the transformants. Thomas et al. [48] compared several genomes and secretomes of *Pseudoalteromonas* sp. and related *Alteromonas* sp. genomes, and singled out the "antifouling subgroup" among which *P. tunicata* is a superior competitor [49]. Our MALDI-TOF MS data on Ld series rather agrees with this analysis (no 16S rDNA matching with *P. tunicata* and several subgroups among which *P. haloplanktis*, *P. carrageenovora* and *Pseudoalteromonas* sp. D41. Our study indicates only two *Alphaproteobacteria* (*Paracoccus* sp.) out of 18 ZoBell cultured strains, but this may not reflect the overall natural biodiversity of this class in association with *L. digitata*. In fact, in a culture-independent experiment, it was found that planktonic *Alphaproteobacteria* strains are not as efficiently eliminated by *Laminaria* allelopathic exudates as planktonic *Roseobacter*, i.e. they may be differentially selected for [50]. This culture-based bias may also explain the absence in our isolates of *Vibrio*, a prominent planktonic *Gammaproteobacteria* taxon. Specific primers and especially formulated growth media were not investigated, the purpose of this study being to validate the use of spectral fingerprints as taxonomic, proteomic and metabolomic aids rather than to optimize the corpus of cultivatable bacteria.

4.2. NMR spectroscopy, a powerful complementary tool for chemotaxonomy and physiological studies

The combination of HR-MAS and solution (D_2O) proton NMR on whole bacterial cells proved very useful both as a rapid chemotaxonomic indicator and as a metabolomic tool for compounds most of which are known to have an important role in bacterial environmental adaptation [20,51,52]. The spectral database we constructed from 30 strains of bacteria associated with *L. digitata* (Ld series) and isolated from inert surfaces and grown under strictly controlled conditions on ZoBell medium can be visually analyzed and strains segregated into taxonomic groups that agree with assignments from 16S rDNA sequence analyses and MALDI-TOF MS spectral groups, down to genus or family level. High resolution solution NMR (δ 0.5–4.5 ppm) has been successfully applied for fingerprinting of bacterial extracts, with good reproducibility [17]. During the course of our study, using the ^{1}H HR-MAS NMR method, we have indeed been able to evidence one hitherto unsuspected label error on two accidentally swapped strains in the reference collection. The present study indicates its potential use in investigations on marine strains. The distribution of the metabolites tentatively identified in our 30 strains and presented correlates with the HR-MAS (δ = 0–4.5 ppm) profiles grouped by visual resemblance. They are small molecules that are generally involved in medium adaptation and chemical communication, and their distribution into different taxonomic groups as presented in the results section above is consistent with information found in textbooks on microbial physiology and biochemistry, and in specialized reviews [e.g. [51]]. NMR has been usefully applied to the elucidation of bacterial amino acid biosynthesis from labeled precursors [e.g. [53]]. The fact that some taxa utilize different regulatory pathways may confer some value to individual molecules as biomarkers, e.g. the *Flavobacteriaceae* examined here do not use glycine betaine but present high levels of ions such as succinate or acetate, in contrast to other groups. Likewise, the *Rhodobacteriaceae* identified here (*Alphaproteobacteria*) do not contain alanine, glutamine and glutamate, all prevalent transient metabolites in many bacteria, and seem in turn to produce large amounts of aldehydes which are rarely encountered in other taxa. In practice, the NMR informations provided on individual strains grown on a given medium under controlled conditions can be useful to evaluate in each case the biochemical suitability and the limitations of this medium, or to follow enzyme kinetic studies on live bacteria and other applications beyond the aims of this study. Furthermore, Motta et al. [20] successfully applied NMR directly to bacterial suspension media of marine strains in order to quantify the various released water solubles, a feature which cannot be achieved with HR-MAS analysis.

HR-MAS NMR thus represents a useful chemotaxonomic tool for rapid characterization of unknown bacteria, as one proton acquisition takes less than 10 min per CFU. The requirement is that all bacteria be grown under conditions identical to database samples, a restriction already noted on ^{1}H NMR of bacterial extracts [15]. In some cases, physiological adaptation to a different culture medium must be achieved by activation of different regulatory pathways if the precursor is not present in the minimal medium, i.e. if the default carbon sources are different, overall salinity levels being equivalent. Our comparative analysis of spectra of bacteria grown on minimal (VNSS) and complete (ZoBell) media shows examples of major qualitative differences in NMR spectral profiles of CFU of same age, which can be attributed to differential adaptive capabilities between the different strains (e.g. strain *Pseudoalteromonas*

sp. 3J3 in Fig. 2). Other strains are capable of growing on both media with no visible change in adaptive responses (e.g. strain *Pseudomonas* sp. Ld6 in Fig. 2E). Finally, over one third of our strains presented profile modifications of varying extent, sometimes more complex on the VNSS medium, sometimes on the ZoBell medium (e.g. strain *Arthrobacter* sp. Ld5 in Fig. 2E). The ability to rapidly monitor such sensitive physiological responses on live cells by HR-MAS NMR spectroscopy may indeed help in improving specific growth media targeted to VBNC (viable but not cultivatable) bacterial species, which represent over an estimated 98% of the bacterial diversity found on natural algal samples. The fact that PCA-based AMIX analysis was not capable of globally discriminating between the ZoBell vs VNSS profiles may be attributed to an insufficient dataset, to inadequate spectra preparation or simply to the inability of establishing a trend of significance with such highly diverse responses (q.v. S2 as Supplementary data). Exometabolome responses as reflected by amino acid and by other regulatory metabolites is in fact quite very complex, both medium and age-dependant, and can escape PCA-based signal treatment discrimination. Again, using CFU grown under strictly identical conditions on medium-agar cultures, and profiled (either by HR-MAS NMR spectroscopy or in solution NMR) at the same incubation stage limits signal variability in the fingerprinting and appear as essential procedures for constructing a reliable comparative fingerprint database. For single-strain investigations, the use of HR-MAS NMR can be extended as a rapid method to monitor the metabolic responses at different growth stages, and hence to compare the kinetics of appearance and disappearance of metabolites between different media, as proposed by [54] who successfully monitored and compared in particular the exometabolome of *E. coli* on two liquid media at different growth stages, using NMR on cell extracts.

4.3. Combining molecular taxonomy, MALDI-TOF MS spectrometry and NMR spectroscopy

Earlier approaches to studies of eukaryote and associate microflora often involved tedious physico-chemical and visual characterizations, e.g. on brown algal kelp microepiphytes [55–57]. These are progressively replaced by global diversity studies on environmental samples using molecular taxonomy, e.g. on *Laminaria saccharina* [58] and by more specific studies using cultivatable strains to investigate allelopathy between competing epiphytes [48,50] and host-related defense responses [59–61] in *L. digitata*. Addressing community-level investigations, our study indicates that rapid, informative and reliable spectroscopic techniques can not only provide useful chemotaxonomic fingerprints, but also evidence adaptive responses at proteome and at metabolome level, thus offering a dynamic dimension to former physico-chemical characterization. To this end, spectral databases must be constructed from strains under strictly controlled culture parameters. Pursuing at single-strain level, we believe that MALDI-TOF MS and HR-MAS NMR can complement genomic and transcriptomic investigations, by varying selectively key parameters, e.g. time-resolved metabolic footprinting [54].

5. Conclusion

We show for the first time that two different spectroscopic techniques can usefully be associated with molecular taxonomy on cultivatable marine bacterial populations. Rapid identification can be achieved directly on entire cells by providing metabolic fingerprints that can be checked against a customized database of profiles of bacteria that are cultivated under strictly identical conditions, and previously characterized by their 16S rDNA sequences. MALDI-TOF MS profiles have a definite taxonomic interest with fingerprints that are highly reproducible irrespective of culture age and even culture conditions (within the limitations of the present study). In addition, MALDI-TOF fingerprints can be of assistance in proteomic studies and glycopolymer expression in adhesion studies. HR-MAS NMR spectra have an indicative taxonomic value if cultures are carried out under controlled conditions, but they are of great interest in monitoring specific adaptive responses of bacterial strains to different conditions. We suggest that the combination of molecular and spectroscopic methods has a great potential in studying the biology of cultivatable bacteria.

Acknowledgments

The authors would like to thank L. Delage for helping with PCR work, T. Barbeyron and C. Leblanc for helping construct the phylogenetic tree from 16S rDNA sequences, and X. Pennanec for introducing S. Salaün to MALDI-TOF whole-cell spectrometry. *Pseudoalteromonas* sp. strain D41 and *Vibrio* sp. strain D01 were kindly provided by C. Compère (IFREMER at Brest, France). S. Salaün benefits from a 3-yr student living allowance by Région de Bretagne (ARED 2842). This study was also partially funded by GIS EUROPOLE-Mer Project “Biofilms”.

On-line liquid chromatography–Fourier transform infrared spectrometry
Reference spectra matrix background correction
Point-to-point matching algorithm

ABSTRACT

A new background correction method for the on-line coupling of gradient liquid chromatography and Fourier transform infrared spectrometry has been developed. It is based on the use of a point-to-point matching algorithm that compares the absorption spectra of the sample data set with those of a previously recorded reference data set in order to select an appropriate reference spectrum. The spectral range used for the point-to-point comparison is selected with minimal user-interaction, thus facilitating considerably the application of the whole method. The background correction method has been successfully tested on a chromatographic separation of four nitrophenols running acetonitrile (0.08%, v/v TFA):water (0.08%, v/v TFA) gradients with compositions ranging from 35 to 85% (v/v) acetonitrile, giving accurate results for both, baseline resolved and overlapped peaks.

1. Introduction

Infrared (IR) spectrometry has been extensively used as a general research tool for the identification and quantification of analytes in a variety of fields of application. The potential of coupling liquid chromatography (LC) to IR spectrometry combines the high resolution provided by LC with the molecular specific information extracted from the IR spectra. LC–IR methods can be clustered in two groups: those that perform an off-line IR detection after eluent elimination using solvent removal interfaces, and those that use flow-through cells for the continuous on-line measurement of the LC eluate.

On-line detection presents a series of advantages over the off-line approach: (i) from a technical viewpoint the on-line coupling is less complicated, (ii) it can be implemented applying flow through cells, (iii) non-volatile buffer systems can be used, (iv) there exists the possibility of further hyphenation with additional detectors and (v) it also allows the measurement of IR spectra without any orientation, crystallization or degradation occurring during the solvent elimination in the off-line measurement [1].

Nevertheless, it is worth paying some attention to the main drawbacks of the on-line approach: (i) the limited concentration sensitivity of IR detection and (ii) existing difficulties in on-line measurements arising from the dominating absorption of most of the commonly used mobile phase components [2]. Concerning the lack of sensitivity, it is reasonable to expect that recent advances in instrumentation will help to overcome the low sensitivity of the IR detection. Laser sources emitting more intense IR radiation that can be tuned across 275 wavenumbers (24% of the laser's center wavelength at 8.8 μm) [3], room temperature mercury–cadmium–telluride (MCT) detectors with improved sensitivity [4] and miniaturized flow cells with nL volumes and capillary-LC systems [5], are among the most relevant developments of special significance that could be highlighted. However, to increase the use of on-line LC–IR the combination of the aforementioned instrumental advances, with chemometric techniques allowing for an efficient compensation of the eluent absorption, would permit a significant extension of the usefulness of on-line LC–IR in many areas including industrial and biochemical analysis. Therefore, there is an interest in the development of chemometric methods for background correction in on-line LC–FTIR.

Basics of the on-line detection approach are well known: if there are k absorbing species in the reaction system, according to the Lambert–Beer's law the recorded absorbance at each wavelength (A_r) is assumed to be the sum of contributions of all components. This can be extended to the whole spectrum and written in a matrix notation as:

$$D = CS^{T} + E \quad (1)$$

doi:10.1016/j.talanta.2009.10.021

where D ($z \times c$) is the original raw LC–FTIR data matrix with the overall spectral information of all absorbing species present in the system, C ($z \times k$) is the vector of the concentration profiles of the species, S ($k \times c$) is matrix containing the pure spectra of the k compounds, E ($z \times c$) is the error-related matrix and k, c and z are the number of absorbing species, variables (wavenumbers) and spectra, respectively. Under isocratic conditions, the eluent composition and hence its spectrum is known and theoretically constant. Therefore, direct subtraction of the solvent spectrum in the raw data matrix D allows a reduction of the systems complexity as the IR active eluting analytes are the only remaining components in the background corrected data matrix. Of course, this approach has its limitations. For example, minor changes in the mobile phase delivered by the LC pump can lead to strong changes in both, intensity and shape of the eluent absorbance spectrum. Thus, a direct subtraction of a reference spectrum might lead to inaccurate background compensation obtaining noisy chromatograms and distorted spectra of analytes. In spite of that, the overall simplicity of this approach has proven to be very useful in on-line isocratic LC–FTIR methods [1,6–10].

Under gradient conditions, the background correction process is not as straightforward as under isocratic conditions. A common mobile phase system in LC composed by acetonitrile and water can be used as an example: increasing the acetonitrile concentration of aqueous solutions, the composition of the mixture progressively shifts from pure H_2O to the $(CH_3CN)\cdot(H_2O)$ complexes and to pure (CH_3CN). Different species with characteristic infrared absorptions have been identified [11] including: $(CH_3CN)\cdot(H_2O)_5$, $(CH_3CN)_2\cdot(H_2O)_4$ and $(CH_3CN)_2\cdot(H_2O)$. Therefore, the IR absorption during the LC run raises due to the presence of the eluting sample components and to a variable number of IR absorbing solvent complexes difficult to estimate.

Recently a straightforward strategy was developed to overcome the problems of background absorbance elimination in on-line LC–FTIR systems. This chemometric approach is based on the use of the information content of a set of spectra of different eluent compositions named '*reference spectra matrix*' *(RSM)*. The *RSM* acquisition is carried out in practice measuring a blank LC gradient with eluent compositions falling within known limits. Besides, the *Sample Matrix (SM)* corresponding to the measurement of the injection of a sample into the LC–FTIR system is viewed as a series of independent spectra with different unknown solvent compositions. Then for each spectrum included in the *SM* an appropriate reference spectrum is selected or calculated from data included in the *RSM* matrix. Afterwards, background correction is accomplished subtracting the selected or calculated reference spectrum from the *SM* spectrum. Detailed descriptions of the procedure and examples of its application can be found in previous works [5,12–15].

In spite of the promising results obtained till now, the selection of the optimum parameters used to find an appropriate reference spectrum might become troublesome and time consuming when a gradient covering a wide range of eluent compositions is used for the LC analysis. In order to overcome this limitation, this paper reports a new approach for the selection of appropriate *RSM* spectra based on the direct comparison of characteristic absorption bands of the eluent during the chromatographic run with those of a reference data set in a point-to-point way. Following previous results, this paper focuses on the development of a new background correction approach paying attention to features that facilitate its use reducing the number of user-defined variables which increases the applicability of the background correction approach. Different alternatives are presented and discussed on real LC–FTIR data sets obtained from the analysis of a solution of four nitrophenols as a model system using an acetonitrile (0.08%, v/v TFA):water (0.08%, v/v TFA) gradient with compositions ranging from 35 to 85% (v/v) acetonitrile.

2. Proposed background correction procedure

As indicated above, a new criterion for the selection of appropriate reference spectra from the *RSM* is introduced. The proposed procedure compares characteristic absorption bands of the eluent during the chromatographic run of a sample injection with those of a reference data set using a point-to-point matching method (point-to-point – univariate background correction – reference spectra matrix, p2p-UBC-RSM). Similarity or distance methods based on point-to-point matching are methods in which equal-length vectors describing two spectra are compared point by point, and a single statistic is obtained [16,17]. Thereby, the usefulness of a matching method relies on the ability of the selected statistic to discriminate subtle differences in similar spectra. There are a number of different similarity indices that can be used [17]. As an example, in this work the performance of the correlation coefficient on the mean centered absorbances (COR) was evaluated.

The spectral similarity index COR between two spectra, S_A ($1 \times c$) and S_B ($1 \times c$), is calculated as described in Eq. (2) from the mean centered vectors (z_A and z_B), where $\bar{S}_n$ is the arithmetic mean absorbance in spectrum S_n (n = A, B):

$$COR = \frac{z_A^T z_B}{||z_A|| \cdot ||z_B||} \tag{2}$$

where $Z_n = S_n - \bar{S}_n$.

The background correction process of each spectrum S_i ($i = 1, \ldots, z$) included in the *SM* ($z \times c$) can be described in two steps:

1. Using the absorbance values in a defined spectral interval, r similarity indices for the set of spectra included in the *RSM* ($r \times c$) with the sample spectrum S_i are calculated. Then, the *RSM* spectrum showing the highest similarity value is selected as the corresponding reference of spectrum i (RS_i).
2. The background corrected spectrum (CS_i) is calculated by direct subtraction of the selected or calculated eluent spectra:

$$CS_i = S_i - RS_i \tag{3}$$

The process is repeated for each *SM* spectrum until the whole LC chromatogram has been corrected.

This simple background correction strategy presents a series of requirements and conditions of applicability, equal to those in previously published RSM-based approaches: (i) very good instrument stability and performance (e.g. apart from spectral noise, spectral drifts have a very strong negative effect on the accuracy of RSM-based background corrections); (ii) appropriate measurement of the *RSM* and *SM* data sets; (iii) the mobile phase spectra should present a spectral region characteristic of its composition and free from interferences from the eluting compounds.

It must be emphasized that slight drifts in the experimental conditions (T or pH, for example) might affect the spectrum of a defined mobile phase composition and thus, changes in these parameters must be minimized. From our experience with real (i.e. not simulated) data sets, we recommend to use RSM spectra measured during the re-equilibration of the LC–FTIR system after each gradient run. This straightforward approach can minimize some instrumental effects such as T changes, detector drifts or water vapor interferences, for example, which strongly affect the background correction.

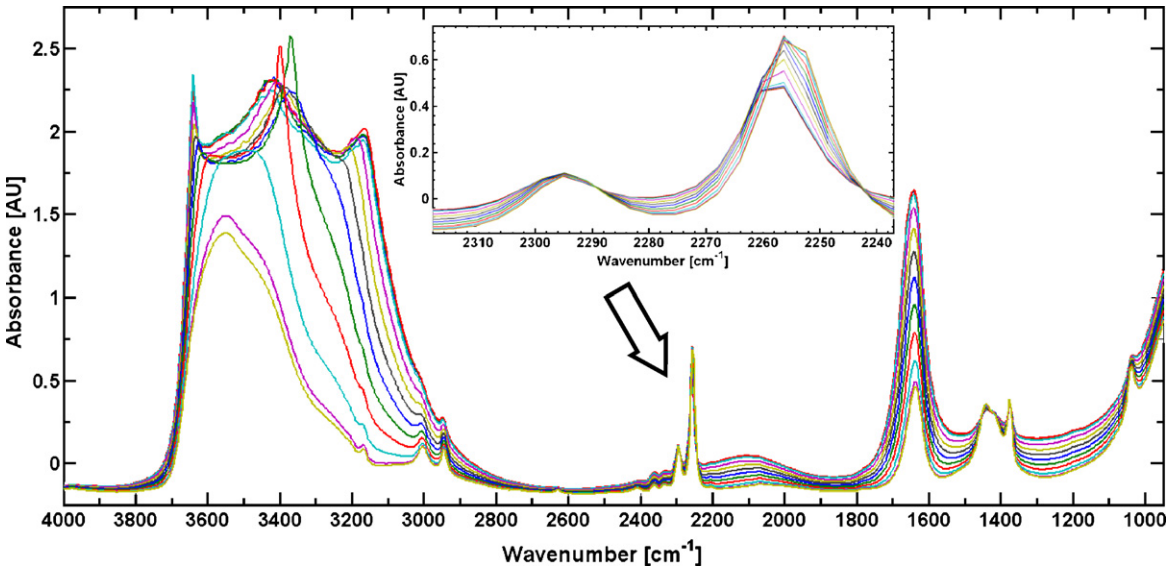

Fig. 1. On-line FTIR spectra measured during a LC gradient with mobile phase compositions ranging from 35:65 (v/v) to 85:15 (v/v) acetonitrile (0.08%, v/v TFA):water (0.08%, v/v TFA).

3. Experimental

3.1. Apparatus and reagents

4-Nitrophenol (4-NP), 2,4-dinitrophenol (2,4-dNP), 2-nitrophenol (2-NP) PESTANAL grade (Fluka, Buchs, Switzerland) and 3-methyl-4-nitrophenol (3m4-NP) (98%, Sigma–Aldrich, Switzerland) standard solutions were prepared by dissolving an appropriate amount of each compound in a 85:15 (v/v) water (0.08%, v/v TFA):acetonitrile (0.08%, v/v TFA) solution. Solutions were filtered (0.22 μm) prior to injection. HPLC grade acetonitrile and trifluoroacetic acid (TFA) were obtained from Scharlau (Barcelona, Spain) and Sigma–Aldrich, respectively. De-ionized water was purified with a Millipore system.

A Dionex (Sunnyvale, CA, USA) P680 high performance liquid chromatography system, equipped with a C_{18} column (150 mm × 2.0 mm, 5 μm) at 22 °C was employed using a sample injection loop of 20 μl. Mobile phase gradients were run from 65:35 (v/v) water (0.08%, v/v TFA):acetonitrile (0.08%, v/v TFA) to 15:85 (v/v) water (0.08%, v/v TFA):acetonitrile (0.08%, v/v TFA) in 20 min (recording of the *SM*), re-equilibrating the system in 7 min (recording of the *RSM*). Reference spectra were recorded in stopped-flow mode filling the flow cell with standard solutions of each analyte using a 85:15 (v/v) water (0.08%, v/v TFA):acetonitrile (0.08%, v/v TFA) solution as reference background.

An IR transparent flow cell was constructed using CaF_2 windows and an aluminium spacer with a channel of 2.5 mm width and a pathlength of 16.5 μm. For FTIR spectra acquisition a Bruker (Bremen, Germany) IFS 66/v FTIR spectrometer equipped with a liquid nitrogen refrigerated mercury–cadmium–telluride (MCT) detector, a vacuum system and a dry air purged sample compartment was used. The scanner for the interferometer was operated at a HeNe laser modulation frequency of 100 kHz. Spectra were recorded in the range between 4000 and 950 cm^{-1} using the spectrum of the empty sample compartment as background, with a resolution of 8 cm^{-1} and a zerofilling factor of 2. An aperture of 3 mm and a grating to attenuate the intensity of the irradiating light on the detector element were used to achieve optimum signal intensity. During gradient experiments, 25 scans per spectrum were averaged, providing a spectra acquisition frequency of 15 spectra min^{-1}. For instrumental and measurement control as well as for data acquisition, the OPUS program (version 6.5) from Bruker was employed. Background correction was run under Matlab 7.7.0 from Mathworks (Natick, USA) using an in-house written Matlab function available from the authors.

4. Results and discussion

4.1. Selection of the spectral interval used for the calculation of the similarity index

Fig. 1 shows FTIR spectra measured during an on-line LC–FTIR gradient as described in the experimental section. The spectra show clearly the strong change in both, intensity and shape of the background absorption spectrum due to the acetonitrile and water bands in the 4000–950 cm^{-1} region. It can also be seen in the detailed view of the spectral region between 2318 and 2237 cm^{-1}. Detailed description of these bands can be found elsewhere [18]. The need for an accurate background correction technique is evident if we consider on the one side, that the absorption of the

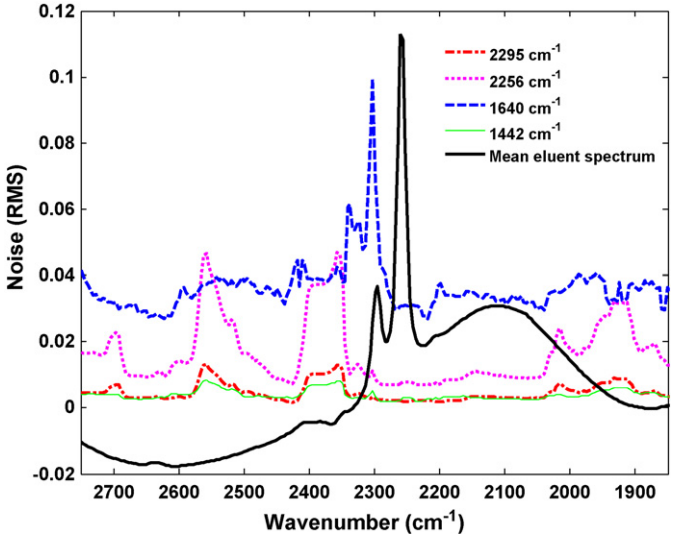

Fig. 2. Chromatographic noise values in a background corrected chromatogram calculated at four mobile phase characteristic wavenumbers, found during the selection process of the spectral interval. *Note*: see the text for details.

analytes rarely lies above 10×10^{-3} AU due to the reduced path-length of the flow cell and because of the inherent low absorptivity of mid-IR bands. On the other side, changes in the eluent absorbance in the studied mobile phase composition interval ranged between 0.32 AU at 2252 cm^{-1} and −1.82 AU at 1658 cm^{-1}.

The selection of an appropriate spectral interval is a critical step of any point-to-point comparison approach which can be time consuming. The number of selected variables should be kept as low as possible to reduce the effect of spectral interferences from the eluting compounds but it must include an adequate number of variables capable to discriminate minor differences between eluent spectra with very close compositions. Taking into account the chemical and spectroscopic information about the studied mobile phase system, some regions of the absorbance spectrum can be excluded of further considerations. The very intense water absorbance band at about 3500 cm^{-1} leads to spectral saturation affecting a large part of the spectrum and therefore the region above ~2750 cm^{-1} cannot be used. Furthermore, in the evaluation of nitrophenols the region below 1800 cm^{-1} was not considered because of spectral overlapping of the mobile phase spectrum with the spectra of the sample constituents.

In this work, an intuitive 'moving window' approach is proposed for the selection of an adequate spectral interval for background correction in the present mobile phase system and concentration interval. Briefly, in this approach, a spectral window starting at the variable t and ending at the spectral variable $(t + ws - 1)$, where ws is the window size, is selected. The spectral window is moved through a predetermined spectral range. At each position, the background eluent spectra are selected comparing the absorption spectra of the sample LC data set with those of the reference data set using the calculated spectral similarity index, as described in Section 2. Therefore, for each tested variable window, a background corrected chromatogram is obtained. Then, the noise level in the corrected chromatograms is calculated and plotted at wavenumbers where

the eluent present intense absorption bands, giving a quick and easy indication about the regions which provide accurate results. Visual inspection of this plot is used afterwards to select a combination of contiguous or non-contiguous variables to define the optimal spectral window used for the background correction.

In this work the chromatographic noise in the corrected chromatogram was measured as root mean square (RMS) at the wavenumbers 2295, 2256, 1640 and 1442 cm^{-1}, corresponding to characteristic acetonitrile and water vibrations. Results obtained for the considered similarity for an evaluated spectral interval between 2750 and 1800 cm^{-1}, using a window size of 21 variables and no correction factor, are shown in Fig. 2. From this figure it can be seen that the best results for the studied similarity index COR were obtained when the selection was made according to the changes in the CN stretching band. From the information obtained by the 'moving window' approach applied to the present mobile phase system, the use of the spectral interval between 2318 and 2237 cm^{-1} centered at 2280 cm^{-1} was selected for the background correction of further LC–FTIR runs.

4.2. On-line LC–FTIR injection of nitrophenols standard solutions

On-line LC–FTIR chromatograms obtained from injections of standard solutions of four nitrophenols were background corrected using the point to point matching algorithm COR and the region selected in the previous section. The experiments shown in Fig. 3 were carried out using a gradient of water (0.08%, v/v TFA):acetonitrile (0.08%, v/v TFA) from 65:35 (v/v) to 15:85 (v/v) in 20 min. It can be seen that peaks are not baseline resolved using a rapid gradient of 20 min. However, as illustrated in this figure, the overlapping of chromatographic peaks does not affect the accuracy of RSM-based background correction approaches. Even when peak overlapping occurs, the background correction algorithm works well resulting in a low noise in the background corrected spectra over the whole mid-IR region where the spectra are not saturated. Peaks of the four analytes could be identified from the depicted chromatograms measured in 20 min at 10.4, 12.1 and 13.0 and 14.1 min corresponding to 4-NP, 3m4-NP, 2,4-dNP and 2-NP, respectively (see Table 1). The negative peak which can be observed at 10.4 min in the 2-NP chromatogram in Fig. 3 is due to the baseline correction used for the extraction of the trace.

Table 1 summarizes the main analytical figures of merit considering the whole process and the background correction method. Appropriate values for linearity were achieved resulting in R^2 between 0.97 and 0.9993, injecting a series of five independent standards solutions with different concentrations of each analyte. The applied concentration ranges of the injected solutions as well as on column mass ranges are listed for all four analytes in Table 1.

In a previous work Quintás et al. [5] evaluated the on-line hyphenation of FTIR spectrometry and a capillary LC system with

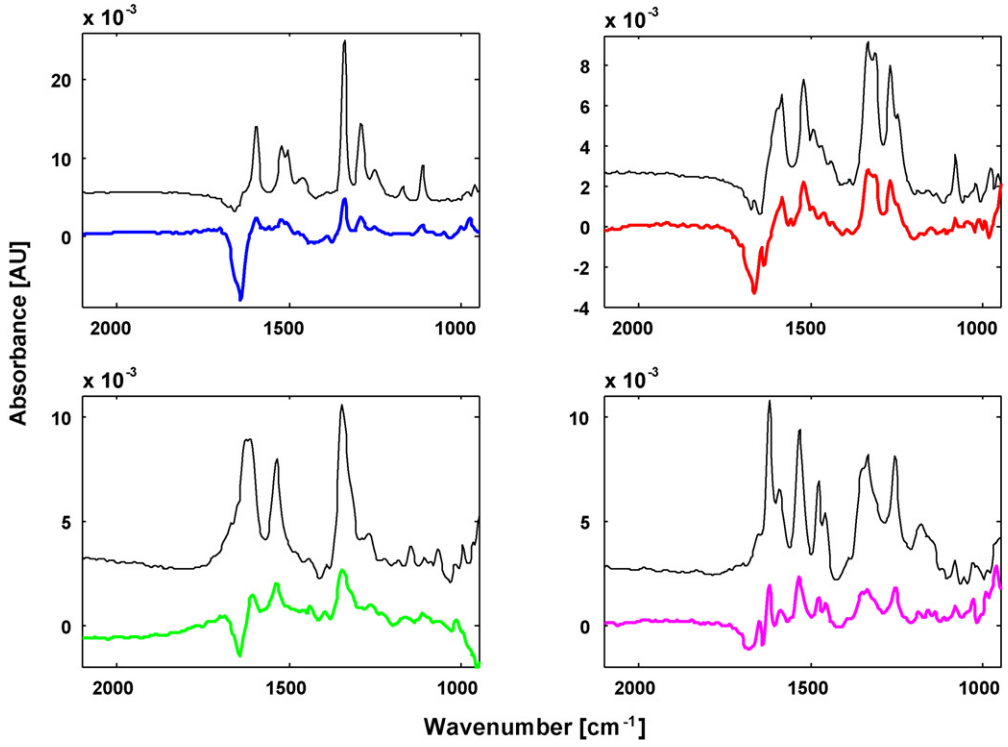

Fig. 4. Background corrected spectra of the four nitrophenols at the peak apex extracted from the injection of a solution containing 1.25 mg ml^{-1} 4-NP (A), 2 mg ml^{-1} 3m4-NP (B), 2.25 mg ml^{-1} 2,4-dNP (C) and 4.5 mg ml^{-1} of 2-NP (D). Reference spectra (black fine lines) measured in stopped-flow are included for comparison.

a mobile phase composed by acetonitrile (0.05%, v/v TFA) and water (0.05%, v/v TFA) within a composition range between 50 and 65% (v/v) acetonitrile, for the separation of the set of analytes used in this work. In the aforementioned study, accurate results were obtained using a RSM-based background correction approach which used the difference in absorbance (relative absorbance – univariate background correction – reference spectra matrix, RW-UBC-RSM) between 2256 and 2260 cm^{-1} and a correction factor established at 2260 cm^{-1} to improve the obtained results. To allow comparison of the aforementioned RW-UBC-RSM background correction method with the p2p-UBC-RSM approach, both procedures were applied to the same gradient measured between 35 and 85% (v/v) acetonitrile in 20 min injecting a standard solution. Whereas both approaches provided comparable results (data not shown), the selection of the conditions for the background correction in p2p-UBC-RSM was significantly simpler as compared to that required for the RW-UBC-RSM previous procedure.

One of the biggest advantages of FTIR detection in LC, compared to other detection methods like for example UV, is its potential for identification of the analytes, which obviously depends on an accurate background correction. Fig. 4 shows recovered spectra from the peak maxima for all analytes obtained from a standard injection after applying the p2p-UBC-RSM background correction method and the corresponding reference spectra previously obtained. For evaluation of the spectral accuracy, the correlation coefficient between each pair of spectra was calculated. The spectra extracted at the peak apex from the background corrected gradient chromatograms correlate well with the reference spectra using the region between 1200 and 1550 cm^{-1} where all analytes show typical absorption bands. The calculated spectral correlations were 91.7, 98.6, 97.8 and 98.4% for 4-NP, 3m4-NP, 2,4-dNP and 2-NP, respectively. These results evidenced that the selected conditions of measurement and background correction were appropriate for the identification and quantification of the considered analytes.

5. Conclusions

The proposed background correction process has been used in on-line LC–FTIR using acetonitrile (0.08%, v/v TFA):water (0.08%, v/v TFA) gradients between 35 and 85% acetonitrile for the determination of nitrophenols as model compounds, obtaining accurate results. Comparing the p2p-UBC-RSM method to a previously published approach (RW-UBC-RSM), similar results were obtained with both procedures. However, the selection of the parameters for background correction was facilitated considerably as the user-interaction was reduced to the selection of the spectral interval and the window size used for the point-to-point spectral comparison. On the other hand, it could be shown that the background correction process is not influenced by the chromatographic resolution as it works not only with baseline resolved peaks but also with overlapping peaks.

In short, the main features of the proposed point-to-point selection criterion for RSM-based background correction approaches in on-line LC–FTIR are: (i) simplified and fast initial selection of the RSM-BGC parameters (window size, variable interval and correlation coefficient), and (ii) the use of a single criterion for the selection of appropriate RSM reference spectra through a gradient elution with a wide range of the mobile phase compositions.

Whereas the present work only shows results obtained from an acetonitrile:water mobile phase system, further work is in due course to investigate the applicability of the proposed strategy to other common solvent systems in both normal and reversed phase LC including THF, methanol and hexane.

ABSTRACT

Vapor generation-inductively coupled plasma-optical emission spectrometry was used for the determination of sulfide in water samples preserved by the addition of a zinc acetate and sodium hydroxide solution. Hydrogen sulfide and acid-volatile sulfides were transformed, by acidification, to a gaseous phase in a vapor generator and subsequently detected by inductively coupled plasma optical emission spectrometry. Compounds interfering with iodometric titration and spectrophotometric determination were examined as potential chemical interferents. The proposed method provides results comparable to iodometric titration in the tested concentration range 0.06–22.0 mg L^{-1}. Limit of detection for the determination of hydrogen sulfide by this method is 0.03 mg L^{-1}.

1. Introduction

Sulfide concentration in a water sample is an important parameter for the assessment of spring, surface or waste water pollution [1]. There are several established methods for the determination of sulfide and/or hydrogen sulfide such as iodometric titration, spectrophotometric determination, potentiometry or ion chromatography [2–5]. Some drawbacks of these methods (insufficient limit of detection and their laboriousness) led to the development of their modification and to the establishment of completely new methods. The application of inductively coupled plasma (ICP) spectrometry hyphenated to a vapor generator (VG) for sulfide determination is one such innovative approach.

Inductively coupled plasma-mass spectrometry hyphenated to vapor generation (VG-ICP-QMS) was used for the determination of sulfide in water samples in ref. [6]. The quadrupole analyzer of the mass spectrometer suffers from insufficient spectral resolution hence the measurement of sulfur is strongly interfered by polyatomic ions mainly from molecular ion O_2^+. Oxygen forming these interfering ions arises particularly from water when nebulizing aqueous solutions. Generation of water-free gaseous hydrogen sulfide into the ICP results in the suppression of polyatomic interference. Further elimination of O_2^+ can be achieved by using a collision-reaction cell (CRC) in mixed H_2/He mode. In this work, optimization of the CRC parameters was primarily solved to obtain a satisfactory LOD. The LOD obtained for VG-ICP-MS determination of sulfide in water was 2 μg L^{-1}.

Inductively coupled plasma-optical emission spectrometry (ICP-OES) can also be used for sulfur detection. Measurement of the main sulfur analytical emission lines in vacuum UV range are not usually subject to spectral interference as the ICP emission spectrum in this region is relatively low in emission lines. In the case of ICP-OES, two techniques of sample introduction, both taking full advantage of vapor generation, can be used. A vapor generator with a gas/liquid phase separator enables introduction of the gaseous phase and thus only volatilized sulfide is detected [7]. The advantage of this technique is the elimination of spectral and non-spectral interferences in the ICP resulting from matrix separation. Nebulization of the reaction mixture (sample and acid) is another concept for the introduction of a volatile analyte allowing sensitive determination of sulfide as well as sulfate, latter being introduced into the ICP as an aerosol. Both these techniques were applied by [7,8]. Limits of detection for sulfide using VG and aerosol were 6 and 5 μg L^{-1}, respectively, with an axially-viewed ICP.

Hydrogen sulfide and sulfide concentration in water can be influenced by volatilization and/or oxidation; hence preservation of the samples is necessary in the sampling step. Preservation can be provided, for example, by adjustment of the pH to 8.5–9 with sodium hydroxide and ascorbic acid [9], or by zinc or cadmium acetate with subsequent alkalinization [10] and storage at a low

temperature (1–5 °C). Sodium hydroxide solution (2 mol L^{-1}) and ascorbic acid (0.2 mol L^{-1}) was used in ref. [6] for sample treatment by mixing the same volumes of both water sample and buffer. Separation of the gaseous analyte from liquid waste is achieved in a vapor-generator, thus high concentrations of sodium in a sample does not present a problem. In the case of nebulization of a reaction mixture [7,8] into the ICP, high Na concentrations in the solution lead to plasma instability. In this case an ammonium/ammonium chloride buffer was successfully used for alkalinization. Both ICP methods were successfully applied to spiked and natural water samples [6–8] and to the determination of acid volatile sulfide in marine sediment [6]. Results of these techniques were compared to those of a potentiometric method.

A vapor generator with a phase separation – ICP-OES method was also applied in our work for the determination of sulfide in water samples. The addition of zinc acetate/sodium hydroxide was used for the sample preservation with subsequent dissolution of the precipitate by adding EDTA prior to the measurement. Considering the lack of study of chemical interference in the above-mentioned works [6–8], we have dealt with the effect of some ions in the vapor generation of hydrogen sulfide. Our method was applied to real spring water samples with sulfide concentrations in the range 0.06–22 mg L^{-1} and the results were compared with the results from iodometric titration following distillation separation of hydrogen sulfide from the sample.

2. Experimental

2.1. Instrumentation

An optical emission spectrometer with inductively coupled plasma Jobin-Yvon 170 Ultrace (JY-Horiba, Longjumeau, France) and hydride generator HG-1 (Labtech Ltd., Brno, Czech Republic) were used in this work. The schematic of the vapor generation system can be found in [11]. Operating conditions are shown in Table 1. Standard alumina injector (i.d. 2.5 mm) in the JY demountable plasma torch was replaced by a quartz injector because of the significant memory effects with the alumina injector. Similar effects were observed with iodine vapor generation as presented by Niedobova et al. [11].

2.2. Chemicals

Chemicals of reagent grade quality (Lach-Ner, Neratovice, Czech Republic) and deionized water were used throughout the experiments. Zinc acetate, sodium hydroxide, di-sodium EDTA (dihydrate) and hydrochloric acid (6 mol L^{-1}) were used for the preservation of the samples and following the generation of hydrogen sulfide. Chemical interferences were examined using the following chemicals: sodium nitrite, nitrate, sulfate, sulfite, bicarbonate, copper (II) sulfate pentahydrate, iron (II) sulfate heptahydrate, and iron (III) chloride hexahydrate.

Standard sulfide solutions were prepared by dissolving an appropriate amount of sodium sulfide (nonahydrate) in sodium hydroxide solution (0.1 mol L^{-1}) and by subsequent dilution. These calibration solutions were standardized by iodometric titration because of the poorly defined content of sulfide in sodium sulfide and its instability. In the case of distillation separation of hydrogen sulfide from the real samples, glycerol was used in a trap solution of sodium hydroxide [2]. Iodine volumetric solution (0.01 mol L^{-1}) was prepared by precisely weighing potassium iodate and the excess of potassium iodide after acidification by sulfuric acid. Sodium thiosulfate solution (0.01 mol L^{-1}, prepared from sodium thiosulfate pentahydrate) was standardized by titration of an iodine solution using starch as an indicator.

Table 1
Operation conditions of ICP spectrometer and vapor generator.

ICP spectrometer	
Forward power ICP (W)	1200
Plasma gas flow (L min^{-1})	12.0
Carrier gas flow (L min^{-1})	0.5
Sheath gas flow (L min^{-1})	0.5
Monochromator purging (Ar) (L min^{-1})	3.0
Plasma viewing	Radial
Vapor generator	
Carrier gas flow (L min^{-1})	0.5
Sample flow rate (mL min^{-1})	1.0
Acid flow rate (mL min^{-1})	0.5

2.3. Samples

The proposed method was applied to spring water samples with different concentrations of sulfide which were preserved immediately after sampling. The preservation was performed by adding of 1 mL 10% (m/m) zinc acetate and 0.5 mL 4 mol L^{-1} sodium hydroxide to 100 mL of water sample. For VG-ICP-OES determination powdered $Na_2EDTA{\cdot}2H_2O$ (about 200 mg) was added to each sample and mixed thoroughly to dissolve the precipitate in the sample prior to the analysis. The amount of $Na_2EDTA{\cdot}2H_2O$ depends on the amount of the precipitate formed by the preservation.

The preservation was performed in the laboratory during the development of the method and during the investigation of chemical interferences. Real samples were preserved immediately after the sampling procedure. Real samples of spring waters (100 mL) were sampled from the inspection wells in the region around Hodonín city (Southern Moravia, Czech Republic). The inspection wells are located near petroleum and exploratory wells where a high concentration of sulfate and variable concentrations of hydrogen sulfide can be found, probably as a result of microbial reduction of sulfate. Reference values of sulfide concentration in the samples were obtained by iodometric titration with a separation step [2].

Concentration of potential interferents was determined by an outside analytical laboratory. Sulfate in samples A, B and G was found to be in range 450–500 mg L^{-1} and for other samples 60–100 mg L^{-1}. Concentrations of other ions in all samples was as follows: NO_3^- < 5 mg L^{-1}, NO_2^- < 0.1 mg L^{-1}, Fe (total) < 1 mg L^{-1}, Cu < 5 μg L^{-1}. The following pH values of original samples were measured: samples A, B and G (6.9), C (8.2), D, E, F (7.4), and H (7.1).

2.4. Determination of sulfide by VG-ICP-OES method

Determination of sulfide in water samples was realized by the continuous generation of gaseous hydrogen sulfide to the ICP source. Generation and separation of hydrogen sulfide from a sample has been performed in a hydride generator HG-1 with siphon gas/liquid separator. Hydrochloric acid (6 mol L^{-1}) was applied for acidification and releasing of hydrogen sulfide from the sample. An ICP spectrometer was used for measuring the emission intensity of S(*I*) 180.676 nm line in radial mode. Linearity of the calibration curve was checked in the concentration range of sulfide 4–40 000 μg L^{-1}.

Interference effects of some potential interferents were checked for the VG-ICP-OES method. The compounds (ions) which interfere with iodometric and spectrophotometric determination (based on methylene blue reaction) were selected as potential interferents. Ions were added to model samples with a constant concentration of sulfide (100 μg L^{-1}) at the following concentration levels: 10, 100 and 1000 mg L^{-1} (for sulfate and bicarbonate), 1, 10 and 100 mg L^{-1}

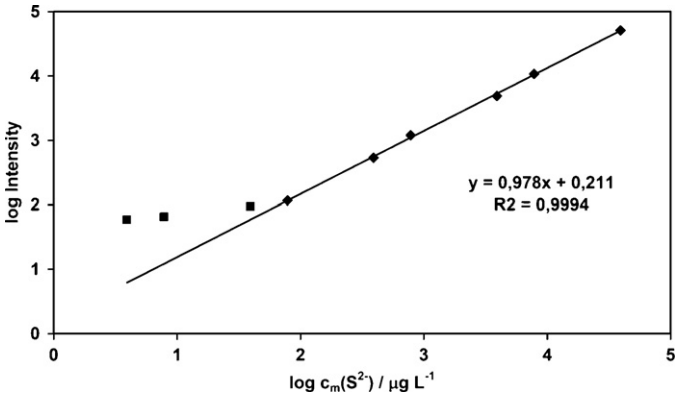

Fig. 1. Logarithmic form of calibration graph (sulfur emission line S(*I*) 180.676 nm) for the determination of S^{2-} in the concentration range 4–40 000 µg L^{-1}. Values below 80 µg L^{-1} (black squares) are not included in linear regression.

(for nitrite, nitrate, sulfite, Fe^{3+}, Fe^{2+}) and 0.1, 1 and 10 mg L^{-1} for Cu^{2+}. The concentration range for the interferents was selected with respect to their concentration in the real spring, surface or waste water samples.

3. Results and discussion

3.1. Method development

Determination of hydrogen sulfide and sulfide in water samples through vapor generation ICP optical emission spectrometry is based on the separation of hydrogen sulfide and the detection of sulfur. Hydrogen sulfide dissolved and/or fixed in sulfides is released from a sample by acidification. Separation of hydrogen sulfide from the liquid phase is provided by a gas/liquid phase separator and then the gaseous phase is introduced to plasma where the atomization and excitation of sulfur atoms is performed. Subsequently optical emission is registered by optical emission spectrometry. The intensity of emission is proportional to the concentration of sulfidic sulfur in the sample.

Linearity of the calibration curve with our VG system was tested in the concentration range 4–40 000 µg L^{-1} S^{2-} for two sulfur emission lines S(*I*) 180.676 nm and S(*I*) 181.978 nm. Sensitivities of both sulfur emission lines were comparable thus only emission line S(*I*) 180.676 nm was used for further measurements. The calibration curve was found to be linear in the range 80–40 000 µg L^{-1} (Fig. 1). Determination of concentration below about 80 µg L^{-1} was found to be influenced by a non-zero blank value which is caused by the presence of impurities, such as hydrogen sulfide or sulfur dioxide, in argon, the atmosphere and probably in the chemicals. Limit of detection for sulfide, calculated as 3σ of blank measurement ($n = 10$), was 30 µg L^{-1}. The blank samples were prepared with deionized water by the preservation method described below. LOD value of our configuration is about five-times higher when compared to other works [7,8] as axially-viewed ICP was also applied in these works.

3.2. Sample preservation and treatment

The real samples have to be preserved immediately after sampling otherwise changes in sulfide concentration caused by oxidation or vaporization can be observed. For the preservation, alkalinization with a reducing agent [9] or the addition of a heavy metal salt (Zn, Cd) with subsequent alkalinization [10] can be used. Hydrogen sulfide and sulfides are precipitated as ZnS or CdS and hence are protected from oxidation and/or vaporization. Excess of a heavy metal cation is precipitated as hydroxide. When pumping such a sample for analysis by continuous flow vapor generation, vigorous mixing of this mixture is necessary to ensure a constant input of sample and, as a result, constant analyte signal.

Dissolution of the formed precipitate by di-sodium EDTA salt was used as an alternative technique. The amount of EDTA must be sufficient for dissolution of all the sulfide and hydroxide precipitate and depends on its amount. In our case 200 mg of $Na_2EDTA{\cdot}2H_2O$ was sufficient for 100 mL of water sample preserved with 1 mL 10% (m/m) zinc acetate followed by mixing the contents for 5 min. Dissolution of the precipitate results in a homogenous solution or very fine dispersed colloid particles and, as a consequence, repeatability (RSD) of the measurement is significantly improved. Results of analysis of two different samples by both methods, with and without dissolution of the precipitate, are shown in Table 2. Results of both methods are comparable in terms of accuracy. However, repeatability of the measurement is improved in the case of precipitate dissolution and there is no need for sample mixing during analysis.

3.3. Interference study

Spectrophotometric determination of sulfide, iodometric titration and other methods can be interfered by a family of compounds. Therefore the effect of known interferents and some major anions in natural waters on the vapor generation technique was investigated. The influence of the following ions was tested: nitrite, nitrate, sulfate, bicarbonate, sulfite and the effect of Fe^{2+}, Fe^{3+} and Cu^{2+} cation. The effect of the interferents was tested with preserved samples of sulfide with subsequent dissolution of precipitate by Na_2EDTA.

Sulfate does not interfere with sulfide determination as it does not form volatile species after acidification and thus is separated in a gas/liquid separator as liquid waste (see Table 3). Nitrate in the sample does not interfere in the investigated range (up to 100 mg L^{-1}). A weak suppression of the sulfide signal could be observed with a higher bicarbonate concentration. Concentration of bicarbonate over 100 mg L^{-1} can frequently be found in natural water and, moreover, the concentration of dissolved free carbon dioxide must be taken into account since it forms (bi)carbonate with an alkaline reagent (hydroxide) used for the sample preservation. The mechanism of this effect was not investigated in this study. Significant positive interference was observed in the case of sulfite. Even the lowest concentration 1 mg L^{-1} caused a significant increase of the sulfur signal. The signal appearing at 1 and 100 mg L^{-1} of sulfite corresponds to 0.09 and 16.4 mg L^{-1} of sulfide, respectively. This positive interference is induced by volatilization of sulfur dioxide formed by acidification of the sulfite. Hydrogen sulfide and sulfur dioxide cannot be distinguished in the detector as ICP-OES is an element-specific detector. On the other hand, this fact can be employed in the determination of sulfur dioxide and/or sulfite, for example, in wine samples [12]. Conversely, the determination of sulfide at lower concentrations of sulfite can be influenced by a mutual reaction of both gases (ions in acidic solution) producing elemental sulfur as described in [13]. Due to this fact we can

Table 2
Influence of precipitate dissolution on repeatability of results.

Sample	Dissolution[a]	Sulfide concentration (mg L^{-1})	RSD (%)
B	+	1.14 ± 0.02	2
	–	1.2 ± 0.2	13

1000	102 ± 3	88 ± 3	–	–	–	–	–	–

The value ± denotes standard deviation of relative signal (n = 3).

speculate that, in such cases, the ICP signal of the volatile sulfur species would decrease as elemental sulfur is not vaporized under these conditions. The amount of volatile sulfur species entering the plasma will depend on the molar ratio of sulfide and sulfite and, in the case of an equimolar ratio (2 mol sulfide + 1 mol sulfite), the signal should reach the minimum. The excess of sulfite will result in production of sulfur dioxide and a subsequent increase in the emission signal. However, interferences of sulfite at the equimolar sulfide to sulfite ratio and below were not investigated. This interference can be significant in the case of waste water from the pulp and paper industry where both sulfite and sulfide can be found. Their mixture is however stable only in an alkaline environment for the reasons given above.

Negative interference was also observed for nitrite at concentrations over 1 mg L^{-1}. Oxidative properties of nitrite in acidic solution result in an oxidation of sulfide to elemental sulfur and signal suppression. However, nitrite concentration in spring water should be far below this limit which is not the case of waste water. For Fe^{2+} and Fe^{3+} ions, the signal suppression can be observed at Fe concentrations over 10 mg L^{-1}. For Fe^{3+} at 100 mg L^{-1} signal suppression is about 10% which is an acceptable measure of error. The same concentration of Fe^{2+} results in 40% decrease in signal. In the case of Cu^{2+} only 0.1 mg L^{-1} results in 10% decrease of signal, 1 mg L^{-1} Cu^{2+} results in even more than 50% decrease. Formation of insoluble sulfides causes signal suppression in the cases of Fe and Cu as these sulfides do not react with hydrochloric acid quantitatively in the hydrogen sulfide generation step. Other cations forming stable, acid resistant sulfides can be expected as interfering ions for this technique. On the other hand, the proportion of sulfur related to metallic insoluble sulfides is considered to be non-toxic in an aquatic environment. The distillation separation step for the determination of this type of sulfide requires a reaction performed at higher temperatures with over a prolonged time sufficient for almost the complete sulfide decomposition. The same technique can be used for determination of acid-volatile sulfide (AVS) in sediments [6].

3.4. Application to real samples

The VG-ICP-OES method was applied to a series of spring water samples from the inspection wells in the region Hodonín (South Moravia, Czech Republic). Results from the VG-ICP-OES method and iodometric titration with distillation separation step are presented in Table 4. Results of both methods were tested by the Student's t-test (α = 0.05, critical value t_α = 4.303). Because of the low power of this test (due to low n = 3), results were also tested using the pair t-test with t = 0.988 (α = 0.05, critical value t_α = 2.365). Both these tests revealed non-significant statistical differences between the values from LOD to 22 mg L^{-1}.

Routine elemental analysis of samples indicated that concentrations of Fe and Cu, as the main cationic interferents, were below maximal acceptable limits resulting from the study in Section 3.3. These limits can be determined as 10 and 0.1 mg L^{-1} for total Fe and Cu, respectively. Hence concentrations of both these elements in real samples did not affect the accuracy of sulfide determination.

Table 4
Results of the real samples of water with different concentration analyzed by VG-ICP-OES method and iodometric titration with distillation step.

Sample	Iodometric titration (mg L^{-1})	VG-ICP-OES (mg L^{-1})	t-test
A	0.06 ± 0.01	0.06 ± 0.01	0
B	1.05 ± 0.07	1.14 ± 0.02	1.748
C	3.10 ± 0.05	3.18 ± 0.05	1.600
D	3.7 ± 0.1	3.5 ± 0.1	1.500
E	6.2 ± 0.1	6.2 ± 0.1	0.571
F	6.5 ± 0.2	6.4 ± 0.3	0.513
G	7.2 ± 0.1	7.26 ± 0.08	0.588
H	20.3 ± 0.8	22 ± 2	1.070

The value ± denotes standard deviation of measured concentration (n = 3).

4. Conclusion

The applicability and reliability of the vapor generation technique with ICP detection for sulfide determination has been demonstrated in previous works and in our recent work. These methodologies have certain advantages compared to the methods usually applied for the determination of sulfide, including better LOD, lower time and chemical consumption and higher sample throughput, especially when compared to iodometric titration following distillation separation. The main disadvantage of these instrumental methods is the need for standardized calibration solutions resulting from the inaccessibility of defined chemicals and the instability of sulfide solution. In our work, applicability of sulfide preservation by co-precipitation with zinc hydroxide was demonstrated. Dissolution of precipitate by EDTA prior to VG-ICP-OES analysis results in a homogenous mixture and improves measurement repeatability.

As a chemical reaction is involved in the vapor generation step, chemical interferences can be expected with this method. Generally, three groups of chemical interferents can be mentioned:

1. Sulfur-containing species forming volatile compounds in acidic conditions (sulfite demonstrated here, predictably thiosulfate, dithionate and volatile organic sulfur-containing species).
2. Oxidants oxidizing sulfide to non-volatile sulfur.
3. Heavy metal ions forming insoluble sulfides.

These interferences will definitely be observed in the VG technique with experimental setups, gas-phase separation or reaction mixture nebulization, and ICP-OES or ICP-MS detection.

ABSTRACT

An analytical methodology incorporating a molecularly imprinted solid-phase extraction procedure (MISPE) has been developed for the determination of parabens in environmental solid samples. Four different polymers were prepared combining the use of acetonitrile or toluene as porogen, and 4-vinylpyridine (VP) or methacrylic acid (MAA) as monomer, using benzylparaben (BzP) as a template molecule. Although all the polymers were able to recognize the template in rebinding experiments, the MIP prepared in toluene using MAA showed better performance. This polymer was also capable of recognizing other parabens (methyl, ethyl, isopropyl, propyl, isobutyl, butyl and benzylparaben) allowing to develop an appropriated MISPE procedure for this family of compounds. The extraction of the parabens from environmental solid samples was performed by ultrasonic assisted extraction in small columns (SAESC), and this procedure next to MISPE as clean-up step followed by HPLC–UV determination was successfully used for the determination of parabens in soil and sediment samples of different locations. Recoveries ranging from 80% to 90% have been achieved depending on the compound and the samples, and limits of detection (LODs) were under 1 ng g^{-1} for all the compounds, making this method suitable for the determination of parabens in environmental solid matrices. The method was further applied to the determination of paraben contents in real samples, founding levels up to 11.5 ng g^{-1} in sea sediments.

1. Introduction

Parabens are a group of synthetic compounds used worldwide as preservative and antimicrobial agents in different products because of their broad antimicrobial spectra, good stability and non-volatility [1–4]. They are esters of 4-hydroxybenzoic acid (Fig. 1) and their antimicrobial activity increases when increasing ramification of the esteric chain. Although they were considered to have low toxicity, recent studies have demonstrated the endocrine disruption activity of parabens [5,6], have reported allergic contact dermatitis [7], and a relation with male infertility [8]. Moreover some studies suggest a connection between parabens and the risk of breast cancer [9], in fact, MeP in human breast tumours has been found with an overall mean value of 12.8 ng g^{-1}. Due to this fact, various companies are trying to produce products free of these classical preservatives and different patents have been registered in the last year for Givaudan S.A. and L'oréal S.A. [10,11]. Moreover, The European Community with The Council Directive 76/768/EC have restricted paraben contents up to concentration of 0.4% (w/w) for a single ester or 0.8% (w/w) for ester mixtures, expressed as p-hydroxybenzoic acid content [12].

Parabens, however, can still be found nowadays in a high number of pharmaceutical preparations, cosmetics, medications, personal care products, as well as in food and beverages. Among them, methylparaben (MeP) and propylparaben (EtP) are the parabens most commonly used in cosmetics, since they are added together and have synergistic effects. Due to that, concentrations as high as 5 mg g^{-1} have been found in these products [13,14]. On the other hand, and as a consequence of continuous dispatching of urban waste waters, the presence of parabens in the environment has been confirmed in different environmental compartments (water, air, dust, soil and sediments) using different techniques of extraction (accelerated solvent extraction (ASE), solid-phase extraction (SPE), matrix solid-phase dispersion MSPE, ultrasonic assisted extraction) and separation and determination (specially GC–MS with derivatization). Concentrations of 21 ng m^{-3} of MeP in indoor air [15], and 2.92 ng ml^{-1} in water from sewage treatment plants [16] have been reported, the highest concentration corresponding to methyl paraben. In a previous work of our group [17], an extraction procedure for the determination of parabens in solid

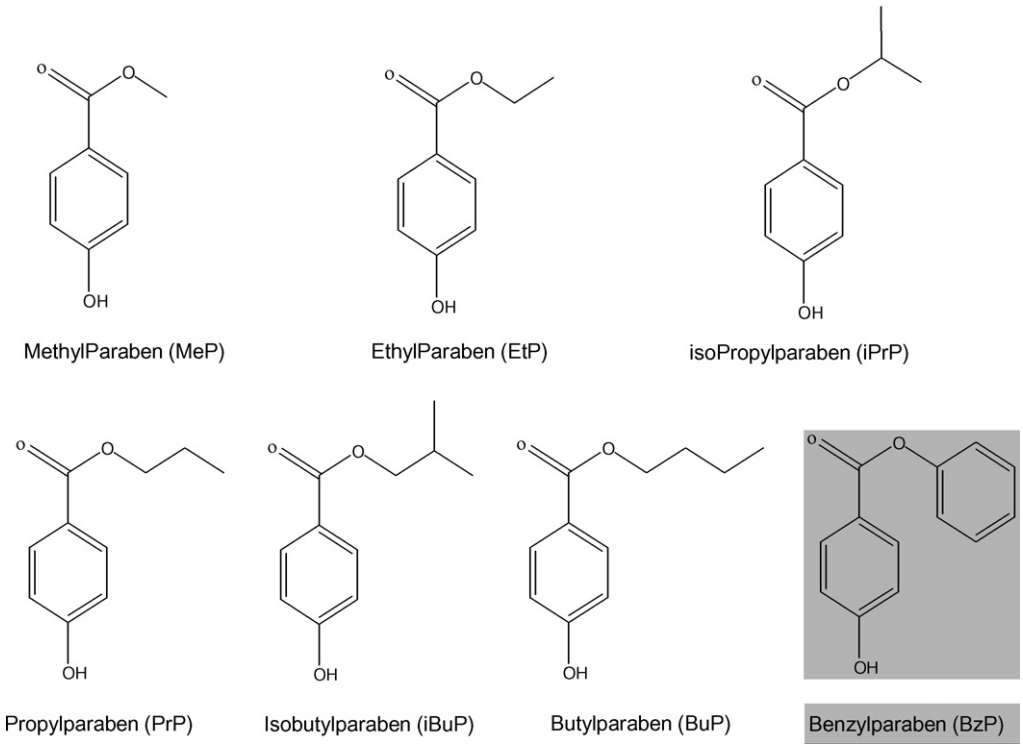

Fig. 1. Chemical structures of parabens. BzP, used as template, is highlighted.

environmental samples was for first time reported, and paraben contents up to 6 ng g^{-1} were found in soil and sediment samples. Due to the complexity of the samples and the lack of selectivity of the extraction, final analysis by HPLC–UV was not possible, and determinations required the use of MS–MS in tandem, which considerably increases the cost per sample preventing its use in routine analysis, this technique has been also used for the determination of parabens in sludge samples [18].

Molecular imprinting allows preparing polymeric sorbents with high selectivity for predetermined analytes, to be used in multiple areas of analytical chemistry. One of the most promising technical applications has been the use of molecularly imprinted polymers in SPE procedures (MISPE) for the selective extraction of organic compounds from complex sample extracts, such as biological and environmental samples, food, plants and tobacco [19]. Molecularly imprinted polymers (MIPs) preparation involves the interaction of a template molecule with an appropriate functional monomer to establish specific interactions. Later, removal of the template molecule from the resultant polymer leaves behind specific recognition sites for template and closely related compounds. Thus, the present work is focused on the synthesis of a MIP sorbent and further development of a selective MISPE procedure to permit HPLC–UV multiresidue analysis of parabens in solid environmental samples.

2. Experimental

2.1. Reagents

Methacrylic acid (MMA), 2,2′-azobis-2-metylbutyronitrile (AIMN) and divinylbenzene (80) (DVB) were obtained from Sigma–Aldrich Química (Madrid, Spain). Methylparaben (MeP) (CAS N° 99-76-3), ethylparaben (EtP) (CAS N° 120-47-8), isopropylparaben (iPrP) (CAS N° 4191-73-5), propylparaben (PrP) (CAS N° 94-13-3), benzylparaben (BzP) (CAS N° 94-18-8) and butylparaben (BuP) (CAS N° 94-26-8) were obtained from Sigma–Aldrich (St Louis, MO, USA) and HPLC grade organic solvents were supplied by Scharlab S.L. (Barcelona, Spain). Stock solutions of 1000, 100 and 10 μg ml^{-1} were prepared in acetonitrile and stored at −18 °C.

2.2. Instruments and materials

2.2.1. Extraction equipment

Glass columns (10 cm × 2 cm i.d.) were obtained from Scharlab S.L (Barcelona, Spain). Polyethylene frits (20 ml) were purchased from Supelco (Bellefonte, USA). The ultrasonic water bath (290 W, 50/60 Hz, S 40 H Elmasonic) was supplied by Elma (Singem, Germany). A vacuum manifold (Supelco Visiprep, Madrid, Spain) was employed to collect the extracts.

2.2.2. Polymer preparation and MISPE

The polymer preparation was carried out in a STR1 Roller Mixer located inside an incubator from Stuart (USA). Empty glass SPE cartridges with one teflon frit (6 ml) were obtained from Supelco (Bellefonte, PA, USA). Nylon filters (0.45 μm) were supplied by Jasco Analitica S.L (Madrid, Spain). A vacuum manifold (Supelco Visiprep, Madrid, Spain) was employed to collect the elution solvent.

2.2.3. HPLC–UV analysis

All measurements were performed using an Agilent 1100 LC instrument equipped with gradient pump, autosampler and programmable ultraviolet (UV) detector from Agilent Technologies (Wilmington, DE, USA). The chromatographic separation was carried out with Zorbax Eclipse XDB-C_8 HPLC column (4.6 mm × 150 mm, 5 μm) column from Agilent Technologies.

2.2.4. LC–MS/MS analysis

The confirmation measurements were carried out in a LC–MS/MS system from Agilent Technologies consisting of a 1200 LC instrument coupled to a triple quadrupole mass spectrometer (6410 TripleQuad). The chromatographic separation was carried

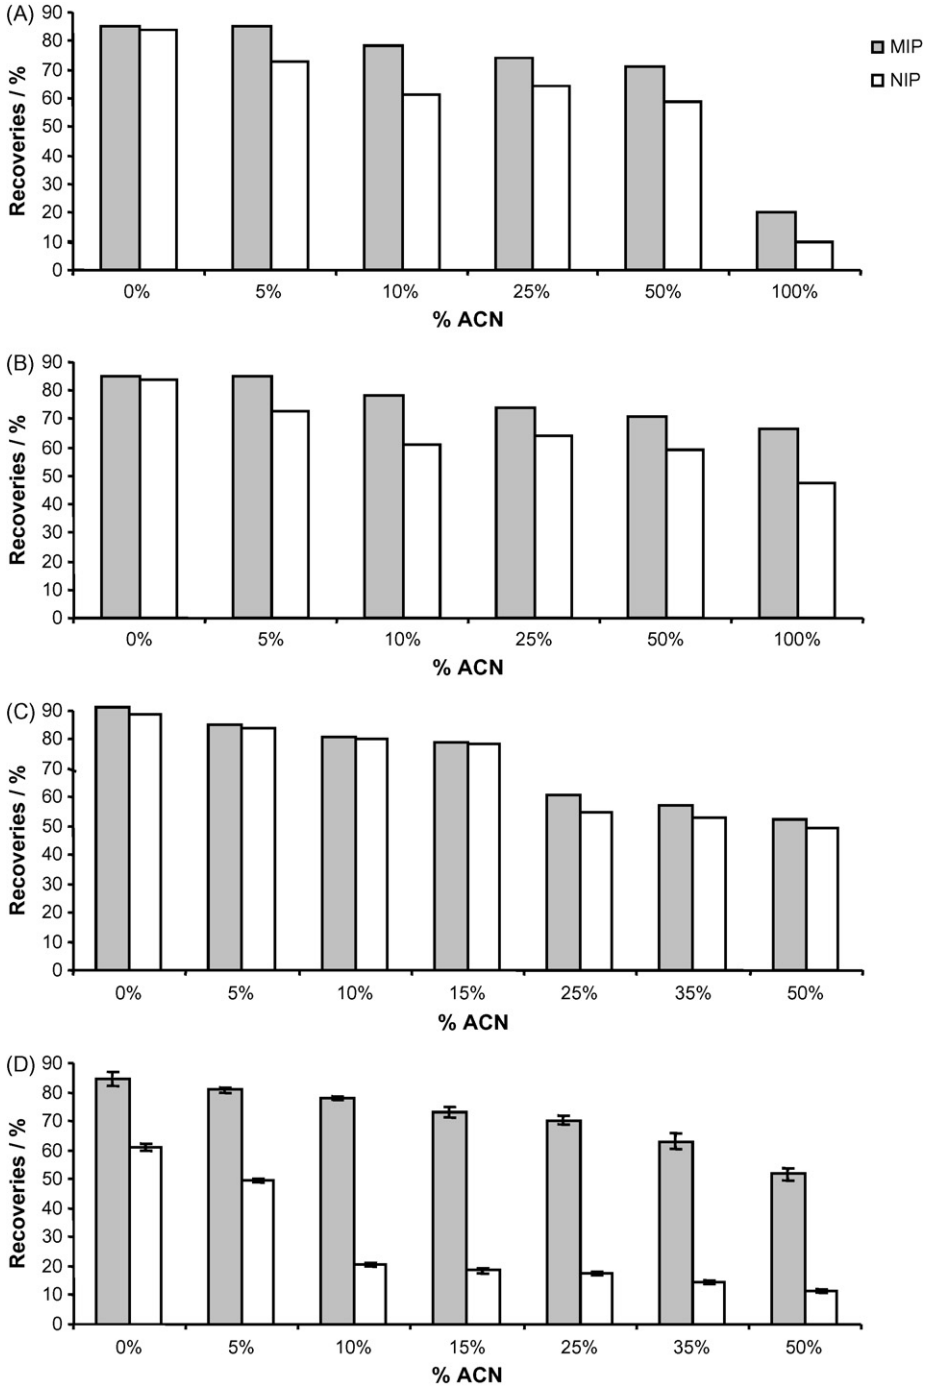

Fig. 2. MISPE optimization using A: P1 (VP and mixture 75:25 Tol:AcN), B: P2 (MAA and mixture 75:25 Tol:AcN), C: P3 (VP and Tol) and D: P4 (MAA and Tol).

out with a Zorbax Eclipse XDB-C_8 HPLC column (4.6 mm × 150 mm, 5 μm) column from Agilent Technologies.

2.3. Procedures

2.3.1. Polymer preparation

Different molecularly imprinted polymers were prepared by precipitation polymerization as follows: 0.14 mmol of template (BzP), 0.54 mmol of monomer (MAA or 4-VP), and 10 ml of different porogen (toluene and mixtures acetonitrile/toluene) were placed in a 15 ml glass tube (Table 1). The mixture was left in contact for 5 min and then 2.71 mmol of DVB and 0.2 mmol of AIMN were added. The tube was placed in a rotor oven at 60 °C to start the polymerization process. After 24 h the polymer particles obtained were air dried and the template was removed by Soxhlet extraction with a methanol: acetic acid mixture (1:1) for 12 h. After that procedure, no template leaking was detected in any of the polymers used in this work. Non-imprinted polymers (NIPs) were prepared following the same procedure but without the addition of the template molecule. All polymers have been prepared with the molar relation of 1:4:20 between template: monomer: cross-linker, which has been proved to be the best for the polymerization.

2.3.2. Sample preparation

Forest and agricultural soil samples were collected from different locations of Spain (Madrid and Badajoz). Sediments were

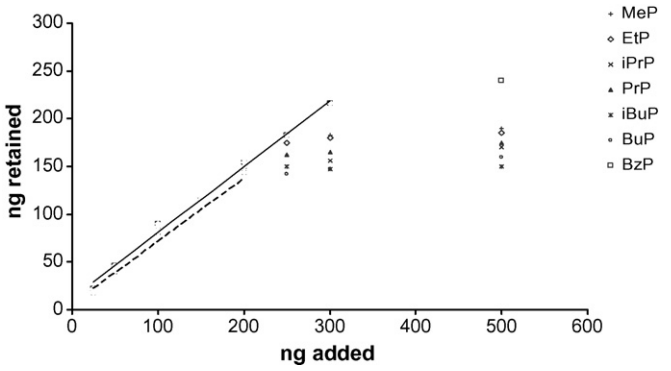

Fig. 3. Capacity study of P4 for selected parabens. Solid line: linear regression for template (BzP), dotted line: linear regression for BuP.

obtained from Ria Arousa and Ria Pontevedra (Galicia, Spain) and from Mediterranean Sea (Piles, Valencia, Spain).

Extraction of samples was carried out by ultrasonic assisted extraction in small columns following a procedure used in this laboratory for the analysis of parabens and other contaminants [17,20]. Polyethylene frits were placed at the end of each glass column and 15 g of sample was added. Subsequently, 8 ml of acetonitrile was added and the columns were immersed in the ultrasonic water bath to perform two consecutive extraction cycles of 15 min. After extraction, the columns were placed in a vacuum manifold and the extracts were collected.

2.3.3. MISPE

An amount (200 mg) of molecularly imprinted polymer was placed in a SPE cartridge and conditioned with 50 ml of methanol, 50 ml of acetonitrile and 50 ml of toluene. The conditioning step used between samples consisted of 2 × 6 ml of methanol (MeOH), 2 × 6 ml of acetonitrile (AcN), 2 × 6 ml of toluene (Tol) and 2 × 1 ml Tol. Next, sample was loaded in toluene (1 ml), and cartridges were washed with 1 × 1 ml of toluene and 1 × 1 ml of a mixture of Tol:AcN 90:10. The elution was achieved with 1 × 1 ml of AcN, 1 × 1 ml of MeOH and 5 × 1 ml of methanol containing 2.5% of acetic acid. The obtained extract was evaporated under nitrogen stream to dryness and redissolved in 0.5 ml of AcN:H_2O 50:50 for HPLC analysis.

2.3.4. High pressure liquid chromatography

HPLC separations were performed using a Zorbax Eclipse XDB-C_8 HPLC column (4.6 mm × 150 mm, 5 μm), injection volumes of 50 μl and an elution program as follows: (1) 60% A (water), 25% B (AcN) and 15% C (MeOH) during 10 min; (2) increase organic content up to 40% AcN and 30% MeOH in 10 min and (3) return to initial conditions in 3 min. For real samples it was necessary to add an extra step to clean the column with 80% B and 10% C. Flow rate was always 1.5 ml min^{-1} and the selected analytes were monitored at λ = 254 nm.

2.3.5. LC–MS

The confirmation with mass-spectroscopy was performed using a method with a Zorbax Eclipse XDB-C_8 HPLC column (4.6 mm × 150 mm, 5 μm) column, injection volumes of 10 μl and a gradient elution program with 5 mM ammonium formate in methanol (B) and 5 mM ammonium formate in water (A), 40–85% B in 10 min maintained 2 min, reduced to 80% in another 2 min, and to 78% in 1 min. LC–MS/MS was operated in the negative ionization mode and nitrogen was used as drying gas and was pumped into the interface at 9 l/min with a temperature of 350 °C. Nitrogen was also used as nebulizer gas at 50 p.s.i.

For each compound the optimized settings for fragmentor (cone voltage) and collision energy were adjusted by flow injection analysis. The deprotonated molecular ion (M-1) was chosen as parent ion and collision energy was optimized by selecting the more intensive ion as quantifier. A dwell time of 882 s $scan^{-1}$ was chosen for all compounds. The main MS/MS parameters for these compounds appear in a previous article [17].

Table 1
Conditions for the preparation of different BzP-molecularly imprinted polymers.

Polymer no.	Monomer	Porogen	Volume (ml)
Polymer 1	4-VP	ACN/Tol 75/25	10
Polymer 2	MAA	ACN/Tol 75/25	10
Polymer 3	4-VP	Tol	10
Polymer 4	MAA	Tol	10

3. Results and discussion

3.1. Polymer selection and MISPE

Precipitation polymerization is one of the most attractive and reliable methods available that allows the preparation of polymer particles [21–23]. Apart from the inherent advantage of avoiding crushing and sieving steps, this technique leads to a more homogeneous binding site distribution and higher performance in comparison to bulk polymerization. This method involves carrying out polymerization under high dilution conditions (<5%, w/v monomers/porogen) in a suitable solvent, therefore parameters such as monomers, solvents, cross-linking agent, temperature and stirring conditions have an important effect on particle morphology.

The mixture acetonitrile/toluene (75:25) has proven to be useful for the synthesis of DVB-80 based polymers with good performance [23]. On the other hand, both MAA and 4-VP monomers are expected to interact with the selected template (BzP) by hydrogen bonds. Thus, in a first approach, two different polymers were prepared using MAA (P1) or 4-VP (P2) and 75/25 acetonitrile/toluene porogenic mixture, as well as the corresponding non-imprinted polymers. Next, and in order to evaluate the presence of specific binding sites, rebinding experiments were carried out over 200 mg of each polymer in empty solid-phase extraction cartridges.

The mixture acetonitrile/toluene 75/25 was firstly tested as loading solvent, since specific interactions in MIPs use to be maximised in the solvent that has been used as porogen. However, in this case, the template molecule was poorly retained, and more than 60% of added BzP was recovered in the breakthrough fraction for both in P1 and P2. In contrast, quantitative retention (higher than 80%) could be achieved by performing loading in pure toluene, although in this case non-specific interactions were also very high in both cases. Subsequently, in order to disrupt non-specific interactions, various washing conditions with acetonitrile and mixtures of acetonitrile and methanol, with toluene were assayed, and relevant results are plotted in Fig. 2. The best results were obtained using AcN/Tol mixtures, where some differences between the MIPs and the corresponding NIPs could be observed, confirming the creation of selective binding sites for both MAA and VP based MIPs. However, such low differences were not useful for MISPE applications and thus P1 and P2 were finally discarded.

The use of toluene as porogen has proven to produce MIPs with improved selectivity for low polarity analytes [24]. Accordingly, polymers 3 (P3) and 4 (P4) were synthesized using 4-VP and MAA monomers, respectively, in pure toluene, and the success of the imprint effect was evaluated in the same way as P1 and P2. Fig. 2C and D shows the results obtained after loading 1 ml of 0.5 mg ml^{-1} of BzP in toluene and subsequent washing with toluene/acetonitrile mixtures in different percentages. As can be observed, the behaviour of P3 was quite similar to P1 and P2.

Although BzP was quantitative retained in the VP-MIP, it was not possible to ensure the presence of selective binding sites on it, since the washing conditions needed to remove non-specific interactions also disturbed selective recognition. In contrast, very satisfactory results were obtained in the evaluation of the MAA based polymer, in which a clear imprint effect could be observed. As can be seen in Fig. 2D, increasing the content of acetonitrile in the washing solution drastically reduced recoveries in the non-imprinted polymer, whereas BzP was selectively retained in the MIP, demonstrating the success of the imprinting process. Thus, Polymer 4 was selected for further development of a selective MISPE procedure for parabens.

According to data plotted in Fig. 2, the mixture Tol/AcN 90/10 was selected as optimum washing solution, and the volume was fixed in 1 ml. Washing steps consisting in 2×1 ml and 3×1 ml of this solution were also assayed, but a decrease in MIP recovery was observed. Concerning elution, quantitative elution was easily achieved with 1 ml methanol followed by 5×1 ml of 2.5% acetic acid in methanol.

The recognition of other parabens (MeP, EtP, iPrP, PrP, iBuP, BuP) in the optimized MISPE conditions was then evaluated. In a first study, aliquots of 1 ml of toluene containing 0.5 mg l^{-1} of each analyte were independently extracted both onto MIP and NIP cartridges. All the selected parabens were quantitatively recovered from the MIP while the non-specific interactions were lower than 30% in all cases. These results confirmed that the imprinted polymer was able to recognize the common structure of parabens (class selective), making in principle this material suitable for multiresidual analysis of parabens. In this sense, a second study focused on the determination of the capacity of the MIP was performed. Mixtures of all the studied parabens in concentrations ranging from 25 to 500 ng ml^{-1} were extracted onto the MIP and the corresponding binding curve for each analyte was obtained. Results are shown in Fig. 3. A linear relationship was obtained for all the analytes under study up to 200 ng ml^{-1}, with correlation coefficients higher than 0.994 in all cases. Regression curves of BuP and BzP are plotted as an example in that figure. In the case of the template, the linearity range is extended up to 300 ng ml^{-1}. Although the obtained capacity of the polymer was not very high, it is enough to be used in environmental solid sample analysis (soils and sediments) where, as it was previously reported, the concentration of parabens is in the low ng g^{-1} level [17].

3.2. Analytical performance in real samples

To determine the potential of this polymer for environmental applications, it was evaluated for the clean-up of soil and sediment extracts containing all the studied parabens at concentration levels in the range of those found in real samples. Extracts were obtained by ultrasonic assisted extraction as described in Section 2. Both non-spiked and spiked samples at 0.5 and 5 ng g^{-1} concentration levels were prepared and analysed by HPLC–UV with and without performing MISPE, and the results obtained for soils and sediments are illustrated in Figs. 4 and 5, respectively. As can be seen, analysis

of selected parabens without MISPE was almost impossible, especially in the case of soil samples. In fact, the different parabens that were found in these samples could only be detected after MISPE. The developed procedure allows to selectively retain parabens in

the MIP, whereas matrix compounds were washed out from the cartridge. In that way, the obtained chromatograms were almost free of interferences allowing to detect the studied analytes in these samples. The UV spectra of the obtained peaks were recorded and compared with the corresponding standards and match factors higher than 950 confirming the presence of parabens in the studied soil and sediment samples.

Tables 2 and 3 summarize the results obtained in the analysis of spiked samples together with data derived from the analytical performance study. As can be seen, mean quantitative recoveries were obtained for both levels of concentration studied with RSDs values lower than 8% in al cases. Internal calibrations curves with matrix matched standards were also obtained for the range 0.5–25 ng g^{-1} for each analyte using the selected soil and sediment samples. All calibrations were linear with regression coefficients higher than 0.993. Also, comparison of the obtained results with those of an external calibration in pure solvents proved the absence of matrix effect for all the analytes studied. The LODs and LOQs were calculated as 3 and 10 times respectively the standard deviation of the lowest point of the internal calibration curve and are also included in Tables 2 and 3. The obtained values were low enough to determine the selected compounds at concentration levels required for environmental studies, and they were one order of magnitude lower than those obtained without the MISPE procedure.

3.3. Analysis of soil and sediments samples

Finally, the developed procedure was applied to the determination of paraben contents in soil and sediment samples from different locations. Table 4 summarizes the analysed samples and the concentrations encountered for the different parabens. As can be seen, residues of parabens were found in all the analysed samples, and sediment samples had in general higher contents of parabens than soil samples. Among them, it is remarkable the highest content for MeP that was found in sediments collected in Piles (Valencia) beach of the Mediterranean coast of Spain. This result can be attributed to the intensive use of sun creams in this area, which, as mentioned in Section 1, usually contain parabens and MeP is the most frequently used additive.

It is important to stress that all samples were further analysed by a LC–MS–MS confirmatory method previously developed in our laboratory [17]. Confirmation of the results obtained by HPLC–UV could be done in all cases, proving the selectivity of the MIP for extraction of parabens in sediment and soil samples. Therefore, the developed MISPE–HPLC–UV method can be considered a clear low cost alternative to LC–MS–MS for multiresidue monitoring of parabens in the selected environmental solid samples.

4. Conclusions

In this work, a selective MISPE procedure for multiresidue analysis of parabens in solid environmental samples has been successfully developed. The optimized MISPE protocol allows the quantitative determination of parabens in soil and sediment samples at the concentration levels that have been found in the environment.

Several soil and sediments samples from different parts of Spain were analysed and parabens were detected in all of the samples but in general, at trace levels. The highest concentration found belongs to MeP in sediments from the Mediterranean coast, which is not really strange because this preservative appears in the composition of the majority of the sun lotions.

Distributed system

ABSTRACT

In this work we propose the implementation of a distributed system based on a Wireless Sensor Network for the control of a chemical analysis system for fresh water. This implementation is presented by describing the nodes that form the distributed system, the communication system by wireless networks, control strategies, and so on.

Nitrate, ammonium, and chloride are measured in-line using appropriate ion selective electrodes (ISEs), the results obtained being compared with those provided by the corresponding reference methods. Recovery analyses with ISEs and standard methods, study of interferences, and evaluation of major sensor features have also been carried out.

The communication among the nodes that form the distributed system is implemented by means of the utilization of proprietary wireless networks, and secondary data transmission services (GSM or GPRS) provided by a mobile telephone operator. The information is processed, integrated and stored in a control center. These data can be retrieved – through the Internet – so as to know the real-time system status and its evolution.

1. Introduction

Water quality monitoring is usually carried out off-line in the laboratory. This is a cumbersome process and often does not provide the required spatial discrimination and/or the large sets of data necessary to describe the temporal evolution of the parameters of interest. It is also known that during storage the integrity of the sample may not be preserved, due to a number of effects that include biological activity and matrix effects, even when correct sample handling protocols are strictly followed. An alternative approach consists in performing the measurements at the location of interest (in-line analysis), since this is probably the best way to overcome a major problem facing aquatic analytical chemists, i.e., how to maintain the sample in its original state during sampling and handling, without stimulating any of the very dynamic chemical, biological and physical processes which may continue after sample collection [1].

The major advantages of in-line analysis compared with the classical off-line procedures are the following: (a) elimination of contaminants due to sample handling, i.e., no or minimum sample transformation; (b) minimization of the overall cost of data acquisition (in particular, due to a reduction of time for sampling, handling and analysis of the sample); (c) possibility of real-time analysis, allowing the rapid detection of pollutants (e.g., monitoring of industrial wastewater or water quality in water treatment plants); (d) ability to obtain detailed spatial and temporal data sets of complete ecosystems (lakes, aquifers, etc.) and (e) possibility of performing measurements in locations which are difficult to access (deep lakes or oceans).

There has been an extensive effort to design chemical sensors and analyzers that are capable of operating *in situ*. Much of this work has been summarized in a monograph on chemical sensor systems for aquatic sciences, which describes a variety of continuous flow analyzers, electrochemical sensors and optical sensors for in-line measurements of dissolved chemical species [2]. In this sense, the constant development of new sensors with increasingly better features undoubtedly permits to minimize the sometimes unavoidable problem of interferences from other species occurring in the analyzed water.

Among the *in situ* chemical sensors, ion selective electrodes (ISEs) are able to continuously monitor a system [3]; this is invaluable when it is necessary to use large sets of data to calibrate mathematical models that describe the behavior of complex ecosystems and when the sample matrix can be altered by sampling and storage and/or by inflow of nutrients or elements from various sources (such as, for example, wastewater and agricul-

doi:10.1016/j.talanta.2009.10.025

ture). In this work, we analyze nitrate, ammonium, and chloride concentration using the corresponding ion selective electrodes (described in Section 3.1) placed *in situ* in a suitable analysis probe.

Nitrate and ammonium are important because they are the major forms of nitrogen which are directly assimilated by plants and organisms, the former being one of the most common contaminants of groundwater, originating mainly from agricultural fertilizer application and release of sewage. Chloride is one of the major inorganic anions in water and wastewater. A high value of chloride may indicate the inflow of wastewater or industrial effluents into the river. The chloride concentration is higher in wastewater than in raw water because sodium chloride is a common constituent of the diet and passes unchanged through the digestive system.

The monitoring of these three chemical species is therefore very important in rivers, lakes, etc. In this sense, nowadays there are commercial systems based on great-size buoys that are able to carry out in-line measurements in aquatic systems, although they are somewhat expensive and have a limited communication capability [4].

Nevertheless, the present work represents a step forward in in-line chemical monitoring of water and wastewater, since it proposes an automatic system, based on Wireless Sensor Networks, that allows a real-time, economic and efficient monitoring of the wastewater generated by any type of use [5,6].

In our case this system arises from the need at both institutional and private level of controlling the quality of the water spilt into Lake Albufera, which is located a few kilometers away from the city of Valencia (eastern Spain), due to the presence of many potential sources of pollution in the surroundings.

For this purpose, an automatic distributed system [7] of chemical analysis is proposed that replaces the current system [8] of analysis and control that usually operates in a manual and decentralized way, so that it could obtain a faster and more effective response against the different problems of pollution that may occur. However, the fact that the sampling points are physically distributed implies the need to place a set of devices, called 'sensor nodes' from now on, at each of these points. The set of these nodes, interconnected by means of a communication network and supervised from a 'control center', can be considered a distributed system of acquisition of information.

Among the most important requirements of this system it can be remarked the need that the functioning of the nodes [9] be as automatic and intelligent as possible, which will allow us to obtain two significant advantages. First of all, the possibility of self-diagnosis will permit to reduce the visits of maintenance of the nodes, then being reducing to a minimum. The information monitored by each node is sent to the control node for its storage and handling. In this sense, the utilization of a private communications network allows to establish an optimal system for the information exchange among all the system elements without any additional expense, a Wireless Sensor Network being used for this purpose [10]. Only in case of emergency or upon user's request, a public telephone network will be employed, thus drastically reducing the use, and therefore the investment, of the system operation.

The aforementioned self-diagnosis does not exclude the possibility of performing a centralized diagnosis, which can be carried out by means of analyses of the obtained data. This would further improve the reliability of the results.

We try to achieve this intelligent and robust functioning without excessively increasing the cost of the nodes; another purpose is also to keep the simplicity in their design, but with the possibility of automatically updating the program depending on the need of the moment. Additionally, the nodes should be as autonomous as possible [11].

2. Why a Wireless Sensor Network?

In the last few years, huge advances have taken place in the field of electronic circuits, as well as in that of wireless communications [5]. They have opened an interesting research line with the development of low-energy, cheap electronic devices that are able to carry out data acquisition tasks; these data are then processed and the results transmitted to a process center for their storage and further study. This research field is the so-called Wireless Sensor Networks (WSNs) [5,12], which makes low consumption prevail over bandwidth and coverage, hence achieving to cover long distances thanks to the application of multi-hop communications [13,14]. Moreover, these networks offer a greater fault tolerance and provide interesting features in terms of real-time, composability, and scalability [15].

On the other hand, important advances have also been obtained in the field of transducers [16], which allows for the development of new devices for the detection and measurement of chemical and physical properties in an easy and inexpensive way. Therefore, they replace the traditional techniques since they are usually slower, more expensive, and more difficult to be automated. These new transducers, mainly in solid state (ion selective electrodes, ISEs) have provided important advantages such as easiness, lower size, precision, easy automation, and low-cost. ISEs are membrane electrodes that respond selectively to ions in solution in the presence of others. The nature of the membrane determines the selectivity of the electrode.

In this paper, and taking into account the aforementioned advances, a new approach in the field of Chemical Wireless Sensor Networks (CWSNs) is proposed. Although this is an important topic that inherits the benefits from WSN technology (it being able to be used as in-line chemical tool for gathering sensor data in real-time with an spatio-temporal resolution), currently there is still limited amount of work describing fully operational CWSNs. Anyway, some interesting contributions have been described in the monograph edited by Ilyas and Mahgoub [17]. Special mention should also be made to the recent work of Okolisa [18], who has created an integrated wireless network of sensors for measuring the concentration of several chemical species in water and wastewater. However, our present work provides additional, interesting features such as the possibility of real-time analysis of different space points; for each one of them, the spatial distribution of the analyzed parameters, as well as its variation with the passing of time, is obtained. In many cases, this information is as important as the own value of the parameters.

Given the low price of the sensor nodes, it is possible – with no heavy expenses – to display a great amount of nodes to cover wide areas and/or decrease the distance among them, thus increasing the precision of the spatial distribution function of the analyzed parameters. Furthermore, unlike in the case of other solutions based on phone systems, the cost of the communications disappears-except in the case of long distances and warnings to cell phones-due to the use of private wireless networks.

Finally, we believe that the proposed model has a promising future thanks to the continuous improving of WSN technologies as well as those of transducers, which opens a wide way of new applications.

3. System description

The system architecture, as shown in Fig. 1, consists of three major subsystems:

(a) Data acquisition subsystem. It is formed by a set of transducers that are in charge of getting information on the different parameters to be analyzed.

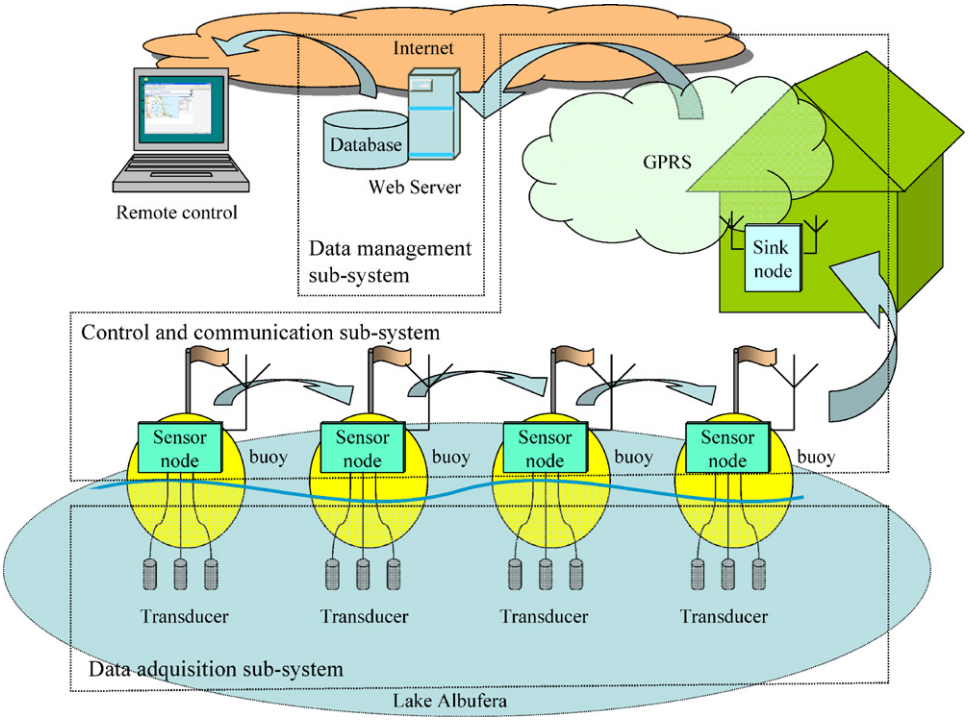

Fig. 1. System architecture.

(b) Control and communication subsystem. It is the sensor network itself, which controls the chemical analysis subsystem, collects the information that it provides, and carries it to the data management subsystem.
(c) Data management subsystem. It is in charge of receiving the information from the control and communication subsystem, which is then handled and stored. This information can be accessed through the Internet, and it can generate the appropriate warnings.

3.1. Data acquisition subsystem

Nitrate, ammonium, and chloride are monitored in-line. They are measured using three homemade ISEs incorporated in a probe (the sensor node). These ISEs were prepared and conditioned following some of the guidelines provided by the literature [16].

The probe nitrate ISE employs a silver/silver chloride wire electrode in a custom filling solution. The internal solution is separated from the sample medium by a polyvinylchloride (PVC) membrane, which selectively interacts with NO_3^- ions. The probe ammonium ISE makes use of a silver/silver chloride (Ag/AgCl) wire electrode in a custom filling solution. A nonactin membrane separates the internal solution from the sample medium and this membrane selectively interacts with ammonium ions. Finally, the probe chloride ISE utilizes a solid state poly-crystalline membrane attached to a conductive wire. Details of membrane preparation are given in Section 5.5.

For all three ions, when the probe is immersed in water, a potential is established across the membrane that depends on the relative amounts of analyte in the medium, this potential being read relative to the reference electrode of the probe. Double-junction reference electrodes have been used in all instances, each sensor having its own reference electrode.

It should be remarked that the control of all transducers is carried out through the microcontroller node itself, their tension values being measured through analog inputs; the acquired value is then interpreted and so are the suitable calibration mechanisms.

3.2. Control and communication subsystem

Fig. 1 shows that this subsystem is formed by a set of sensor nodes and a sink node, all of them interconnected by means of a private wireless network. On the other hand, the sink node is communicated with the data management system through a public network.

3.2.1. Sensor node

Each one of these nodes, as shown in Fig. 2, is based on a microcontroller that (a) controls the different aforementioned transducers, and (b) has a communication module and a power

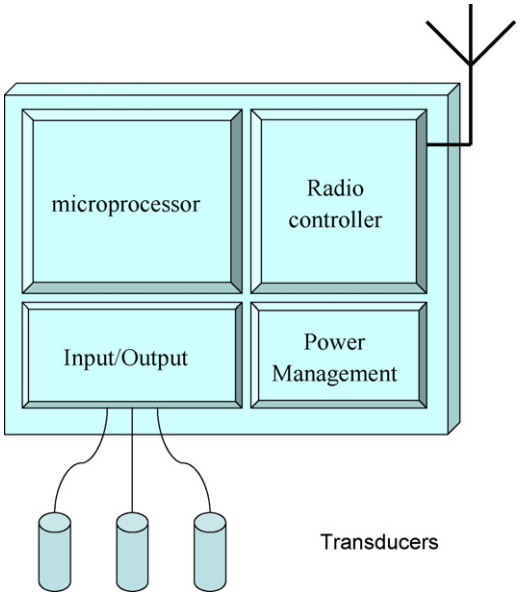

Fig. 2. Sensor node structure.

mode. Everything is located inside a small-size, inexpensive buoy.

We have chosen the CC1110 microcontroller system (Texas Instruments, Inc., TX, USA) – based on I'8051 (Intel Corporation, CA, USA) – due to their excellent features for WSN implementation, namely: low price and consumption, and the availability of a chip-integrated radio circuit for communications in the ISM 800/900 MHz band, as well as a suitable number of I/O lines for the interconnection of the utilized transducers. On the other hand, the potential is (after the appropriate amplification) being measured through analog inputs that the microcontroller has to connect with its own internal A/D converter. Finally, a typical differential amplifier has been used, whose input impedance is similar to that of the electrode in order to achieve a correct impedance adaptation.

It should be remarked that these nodes have an autonomous power supply. A set of rechargeable batteries along with a specific, intelligent system of charge control and management make them able to provide with enough power to ensure a nearly perpetual supply. Energy management is complemented with an RTC (real-time clock), which allows the sensor to work in a low-energy mode during a certain period of time, thus saving energy in a significant way [10].

The power supply of the node is then based on the use – among other components – of lithium-ion batteries, which are capable of storing 10 W. Since the processor consumption is negligible, that of each electrode is around 0.2 W per measurement. Thus, taking into account the number of electrodes utilized and the number of measurements taken every day, the whole network could be working for 16 days without power supply. If a longer working time is required, each buoy has been equipped with a 50 mm × 70 mm solar panel that can provide up to 0.75 W/h. It can be noticed that, in most cases, nodes work by directly using the energy captured by the solar panel; nevertheless, under no-sun conditions batteries are employed to ensure an uninterrupted service. On the other hand, if the level of these batteries falls below a certain threshold (in our case when the charge is less than 90%), batteries are recharged provided that the environmental conditions allow for it. It is important to remark that this recharging process should not begin if the intensity provided by the panel is not enough, since it could result in battery malfunction.

Thanks to this mechanism, and considering the possibility of 10,000 battery recharging processes and an average of 65% sunny days (usual in the region of Lake Albufera), the operational lifetime of the system could exceed 10 years. In the absence of solar panels we estimate that this figure could decrease 10,000 times, although we have not been able to check it for obvious reasons.

3.2.2. Sink node

This node is in charge of receiving data from all the sensor nodes of the network, performing an intelligent processing of them, and resending them to the data management subsystem. Furthermore, it carries out key tasks in the wireless network management, such as the creation of its topology, the diagnosis on the status of the sensor nodes, and the recovery mechanisms in case of malfunctions. Finally, from the point of view of the data, it is an interesting passing route between local and remote communications, since it can carry out different treatments (filtration, compression, summary, and aggregation) on the data received before resending them.

As shown in Fig. 3, an ARM9 microcontroller has been used for its implementation, to which the following devices have been connected:

- An RF module in the ISM 800/900 MHz band: it is based on a CC1101 chip, and connected by SPI.
- A GSM/GPRS [19] communication module based on an integrated TELIT GM 862 [20] connected to the microcontroller by means of an RS232 link. Nowadays, a new WiMax communication system is being set up to replace the GSM/GPRS, which will provide a communication system without any cost for amount of data nor for connection time [21].
- A supply module, capable of getting the energy from either the mains supply or solar panels (when the former is not available).

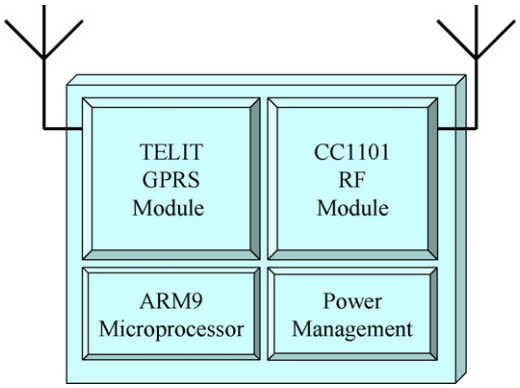

Fig. 3. Sink node structure.

Finally, this sink node is located in a small hut securely anchored on the floor.

3.3. Data management subsystem

The data management subsystem is based on a server with a PC-architecture equipped with an uninterruptible power supply (UPS), and is located at our university (Polytechnic University of Valencia, Valencia, Spain) and connected to the Internet. The following software is then run:

- A web server. It is based on a GNU software (Apache). This server has two major functions: on one hand, it permits the sink node to introduce the data on the database, but it also contains the reference pages that allows for getting (from this database) reports, statistics, and graphics. With the appropriate permissions, these pages can be accessed from any device (PC, Laptop, PDA, SmartPhone, and so on) connected to the Internet, by using a standard web browser. Furthermore, it is also possible – by means of these pages – to modify the working parameters of the system.
- Database manager system. It is also based on GNU (MySQL) software; it contains all acquired data recorded so far.
- Program of management and supervision of the information. This homemade software is in charge of analyzing the data received and checking their coherence, as well as of warning generation if necessary.

A detailed description of the functioning of the system is shown in the following section.

4. How the system works

In order to carry out the distributed analysis of the water, the system periodically takes measurements at the different points where the sensor nodes are located, this information being led to the sink node, which introduces it in the remote database. The different data can then be consulted in real-time as well as those coming from previous times. The process of all these information flow will now be described.

4.1. System initialization

In the establishment phase, when a node is connected for the first time, it looks for all other nodes within reach. If in this search the sink node is found, an association between each other is established; otherwise, the association occurs with that closest to the sink node. In this way, from the beginning this association gives rise to a tree structure (routing tree) [9] whose bottom part is the sink node, which provides the node sensors with the working parameters, thus making the nodes enter the normal operation mode (low consumption) until the timer begins to work. The sink node remains waiting for the data transmission from the sensor nodes.

4.2. Data gathering

Each sensor node – when its timer shows it – gets the data from the transducers, and builds a frame that contains the obtained measurements, a node identifier, and a time stamp. This frame is transmitted towards its parent node and then retransmitted again following the routing tree until the sink node is reached. This one, after handling the information, introduces it in the server database by means of the GPRS link. These mechanisms will be described now.

4.2.1. Functioning at node level

Timing is in charge of scheduling the chemical analyses, following the established guidelines, which can be configured by the user in advance as well as in running time in a remote way. This timing is achieved thanks to the real-time clock (RTC) included in the microcontroller, which also permits synchronization functions among nodes. It should be remarked that this scheduling can be modified by the same node according to the data interpretation.

As regards data acquisition, an ion selective electrode measures the potential against a stable reference electrode of constant potential. The potential difference between the two electrodes will depend upon the activity of the specific ion in solution. This potential difference is conveniently amplified and read by means of an internal A/D converter (12 bits, with an impedance of 192 kΩ, and a time conversion of 132 μs for 12 bits). This value provides the concentration of the ion in solution, i.e. the analyzed parameter.

Once the measurement is obtained, the sensor node will interpret it, considering – in a logical way – if the value is as expected. This interpretation is based on predetermined values, for instance, (a) the working range of the sensor in previous values of the parameter, (b) the evaluation of the variation from the last measurements, and (c) the values from other sensors with which a known relationship exists.

In case the obtained measurements do not comply with the aforementioned logical checking, the node may decide to repeat the measurement (if enough energy is available); if the result obtained is confirmed, it is sent to the sink node.

This process is carried out for each one of the parameters to be analyzed by the sensor node. After taking all the measurements, they are communicated.

4.2.2. Communications in the WSN

For the data transmission to the sink node, we have implemented a routing-tree-based protocol. In this algorithm, each node sends data (either of its own or from its sons) towards the sink node through its parent node, and the process goes on in this way until the data reach the sink node. The communications from the sink node to the sensor nodes follow the opposite direction. In this protocol, and for the tree maintenance, the necessary mechanisms have been implemented, nodes with malfunction problems being detected; in such cases, the corresponding data are re-sent through another alternative parent node.

Another feature of the developed protocol is that, most of the time, nodes remain in a stand-by mode, thus ensuring a longer system working although it is supplied by solar panels, even in cloudy days or at night. For this purpose, a reliable system based on RTC has been required so as to allow for the nodes to return to their normal activity in a controlled way.

4.2.3. Sink node working

Once the information from a sensor node has reached the sink node, this one manages a first data evaluation; in this way, and according to the parameters, threshold values, and methods provided by the user (all of them modifiable in a remote way at run time, a data management is carried out before the transmission). Although several treatments (filtration, compression, addition, and so on) can be performed on the received data before being re-sent, in this application we have chosen a single aggregation in order to minimize the number of GPRS messages.

Finally, the sink node utilizes TCP/IP to transfer – through the GPRS module – the data to the server, so that this one stores them in the database. The protocol used is HTTPS, specifically, the POST command, calling for a PHP page [22] available in the server.

4.2.4. Database update

The last step in the data gathering is their introduction into the database. For this purpose, the recalled PHP page opens a link with the SQL (structured query language) server and inserts the data contained in the POST method into the corresponding fields of the SQL database, which is managed by the MySQL software. This architecture, in spite of giving rise to a certain delay in the data flow, permits the possibility of locating the database in a server other than the web server. In the case of our implementation, both Apache [23] and MySQL are situated in the same computer.

4.3. Data management

The previous PHP program also performs a continuous monitoring on the received data by applying the user's guidelines. If necessary, an alarm must be generated. This may be reported (a) through the Internet (e-mail, Microsoft Network—MSN, etc.), (b) by using mobile phones (SMS's, phone calls), or (c) visually on the web pages, by means of color codes.

The information introduced in the database may also be used upon request to consult – through the suitable permissions – the system status and guidelines configuration from any Internet-connected device. This function is carried out by the so-called Management and Supervision Program.

For both the access to the data stored in the database and guideline changes, a graphic user's interface based on web technologies has been developed. It is intuitive, customizable, and powerful, and allows for the total monitoring of the system in an easy way, as shown in Fig. 4.

The advantages of utilizing a standard web browser are obvious. These applications are familiar to all types of users and, as it is standard, non-specific software, allows for accessing the information from a PC or laptop as well as from a cell phone or a PDA. In all cases, it is carried out after the correct identification of the user by means of digital certificates or a password.

The aforementioned interface helps to display the sensor network in the lake by showing us – at every moment – the connected, running nodes, as well those having malfunctions. Furthermore, it permits their geographical location by means of a GIS (geographical information system), informing us about the situation and status of the nodes on a map.

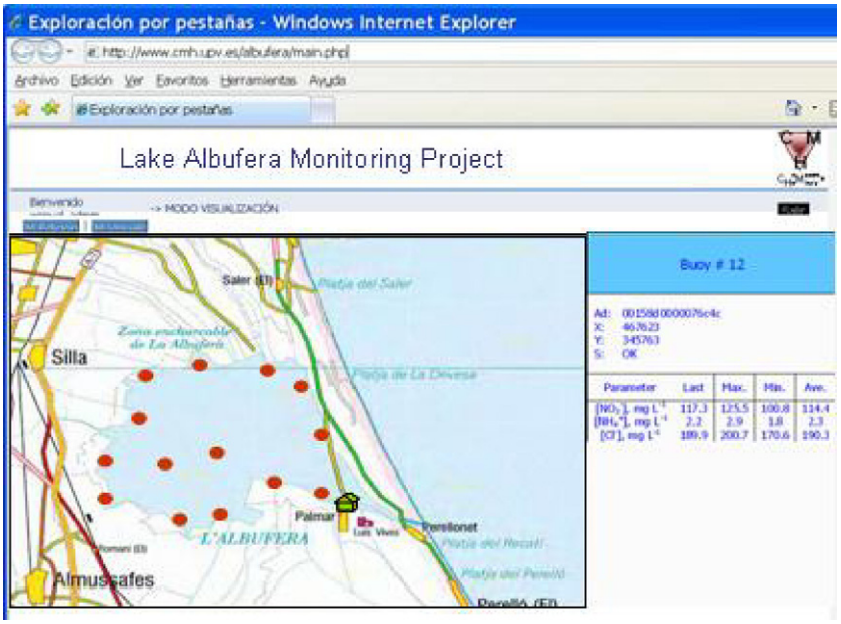

Fig. 4. Web interface.

On the other hand, by means of this interface we can know the concentration of the specified pollutants at any time, at any point, and from anywhere (only a connection to the Internet is required); this can be achieved by simply clicking on the desired node or looping at the data tables and graphics provided, which also permit to carry out searches according to different criteria. Moreover, the system can inform about risk situations or warnings, for instance, in the case that a determined pollutant exceeds the maximum value permitted. From this interface, it is possible to configure the warnings, as well as the way of sending them (e-mail, SMS, and so on).

The flexibility of the system is also an outstanding feature, since it is very easy to implement new treatments on the stored data through the edition of consulting PHP pages.

This web interface also offers the possibility of customizing the system on nearly every aspect of functioning, be it acquisition (interval between measurements, calibration parameters, etc.), warning generation (threshold values), working parameters of the wireless network (routing parameter selection, node reprogramming, etc.), or database management (maximum number of samples, safety permissions).

The access control mechanism of the Apache web server has been used for modifying the input parameters of the control system, three functioning profiles being established: (a) consult only; the reception of parameters from the browser is not implemented (b) modification of references; only the variables defined as web inputs can be modified, and (c) total control; the user can alter (under his/her own responsibility) any variable of the system. This access control is carried out through user and password validation. It is also possible to perform an IP address filtration to allow the connection only for certain machines, as well as to use digital certificates to authenticate the user's identity. Furthermore, the safe HTTPS protocol (based on public key cryptography) has been used, and it also implements the Apache server. On the other hand, the server keeps a log of all the events occurring in the system, such as user authentication, start/end of session, control instructions sent, and so on; each one of them is recorded along with the user identification, remote IP address, date, and time. This also ensures that the information cannot be altered (accidentally or intentionally) during its transmission.

All these security procedures are compliant with international regulations such as CFR 21 part 11 [24].

5. Experimental

5.1. Sampling and storage for reference measurements

Water samples were regularly collected at the study site between 9 and 10 a.m., maintained at 4 °C during transportation and filtered through 0.47 μm glass fibre filters (Schleicher & Schuell) immediately at the arrival in the laboratory. Sample conservation was suitably carried out.

5.2. Probe procedure

The probe containing the ISEs was cleaned with distilled water (and soft paper) and calibrated for all parameters (see Section 5.6) before being placed in the lake, inside a metal structure for security reasons.

5.3. Reference methods

The reference methods used in the laboratory for comparison with the in-line measurements were the cadmium reduction for nitrate, the phenate method for ammonium, and the argentometric method for chloride [25]. In the cadmium reduction method, nitrate is reduced almost quantitatively to nitrite in the presence of cadmium treated with copper sulfate and packed in a glass column. The nitrite thus produced is determined by diazotizing with sulfanilamide and coupling with *N*-(1-naphthyl)-ethylenediamine dihydrochloride to form a highly colored azo dye that is measured colorimetrically at 540 nm. A correction may be made for any nitrite present in the sample by analyzing without the reduction step. As for the phenate method, it is based on the formation of indophenol, an intensely blue compound (spectrophotometrically monitored at 640 nm), that results from the reaction of ammonia, hypochlorite and phenol, which is catalyzed by sodium nitroprusside. Finally, the argentometric method consists of the precipitation of silver chloride, which is indicated by the formation of red silver chromate

(potassium chromate is used as indicator). Three replicates were done for all the methods.

5.4. Chemicals and apparatus

All standard and reagent solutions were prepared from analytical reagent grade chemicals using distilled and deionized water from a Milli-Q water purification system. The deionized water had a specific conductivity less than 0.1 $\mu s\,cm^{-1}$.

A Shimadzu UV/Vis spectrophotometer was used for all reference measurements of nitrate and ammonium with the cadmium reduction method and the phenate method, respectively.

5.5. Membrane preparation

A mixture of 45 mg tridodecylammonium nitrate for nitrate electrodes, 45 mg nonactin for ammonium electrodes, and 45 mg poly(3,4-ethylenedioxythiophene) doped with chloride for chloride electrodes, 370 mg dibutylphthalate as plasticizer and 160 mg PVC is thoroughly dissolved in 7 mL tetrahydrofuran. The resulting solution is then poured into small glass rings and the organic solvent is evaporated, thus obtaining homogeneous membrane layers with a thickness ranging between 450 and 500 μm.

5.6. Probe calibration

Nitrate standard solutions of 100 and 200 $mg\,L^{-1}$, ammonium standard solutions of 1 and 5 $mg\,L^{-1}$, and chloride standard solutions of 100 and 300 $mg\,L^{-1}$ were used for probe calibration. For all three ions, a two-point calibration was performed everyday at noon.

6. Results

6.1. Analysis of real samples with the probe and the respective standard methods. Comparison with standard solutions

To establish the validity of our procedure, before using the multi-parametric probe in real samples we compare the ISE results with the standard methods, using standard solutions. In each case, three replicates were measured, Figs. 5–7 showing the corresponding average values obtained.

For nitrate, the probe ISE was compared with the cadmium reduction method. Fig. 5 depicts the results obtained with these methods in a standard solution and in real samples. It can be seen that in a solution with a known concentration of nitrate (126.2 $mg\,L^{-1}$ NO_3^-) the values obtained are in close agreement for both methods, considering the experimental errors associated with each method. For real samples, the values obtained with the cadmium reduction method showed to be lower than those yielded by the probe ISE.

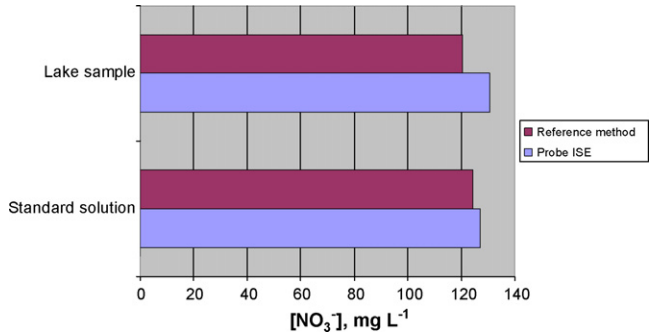

Fig. 5. An example of nitrate determinations in standard solutions and lake samples using the probe ISE and the reference method (cadmium reduction method).

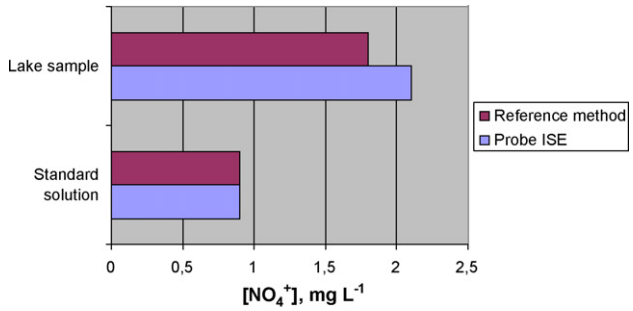

Fig. 6. An example of ammonium determinations in standard solutions and lake samples using the probe ISE and the reference method (phenate method).

The results obtained with the probe and the phenate method on a standard ammonium solution (0.9 $mg\,L^{-1}$ NH_4^+) agreed, within experimental error (Fig. 6). On the other hand, in real samples, the values obtained with the probe ISE were higher than the values obtained with the phenate method.

Finally, Fig. 7 shows that the values obtained for chloride using a standard solution of 167.4 $mg\,L^{-1}$ Cl^-, were almost the same for the probe ISE and for the argentometric method, within the experimental errors. Nevertheless when the chloride concentration was determined in real samples the probe ISE results were higher than those obtained with the argentometric method.

6.2. Recovery analysis with probe and standard methods

We have studied the response of the probe and of the adopted standard methods using field samples. For nitrate the recovery values obtained with the probe were 103% ($n = 3$; R.S.D. = 4.2%), whereas with the cadmium reduction method they were 97% ($n = 3$; R.S.D. = 3.1%). For ammonium the values obtained were 82% ($n = 3$; R.S.D. = 0.6%) with the probe and 98% ($n = 3$; R.S.D. = 2.1%) with the phenate method. For chloride the recovery obtained in real samples was 99% ($n = 3$; R.S.D. = 3.8%) using the probe and 97% ($n = 3$; R.S.D. = 0.3%) using the argentometric method. The recoveries obtained were therefore good, with the exception of the one obtained for ammonium using the probe, which can only be considered as acceptable.

6.3. Study of interferences

The effect of potential interfering ions normally found in association with NO_3^- (chloride and hydrogen carbonate), and Cl^- (hydrogen carbonate) was studied. It should be taken into account that a given ion was considered to significantly interfere with the

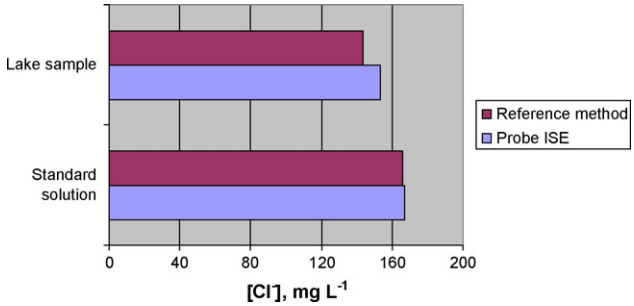

Fig. 7. An example of chloride determinations in standard solutions and lake samples using the probe ISE and the reference method (argentometric method).

determination when a mean change was observed in the results that reached at least 5%.

6.3.1. Chloride interference

In order to study the influence of Cl^- in the determination of nitrate, we measured nitrate using standard solutions of 100 mg L^{-1} (NO_3^-) in the absence and presence of several chloride concentrations (50, 100, 150, and 200 mg L^{-1} Cl^-). All these concentrations were chosen according to the range of concentrations likely to be expected from our previous knowledge of nitrate and chloride measurements in Lake Albufera samples. It was observed that the presence of chloride in such concentrations enhances the nitrate measured values by 8–12.5% for both methods used (cadmium reduction and ISE), 10% being an approximate average value. It can be concluded that chloride indeed interferes with the measurement of nitrate by such methods, but because such interference goes in the same sense and is of the same range for both methods, it may be not particularly relevant if our goal is the determination of trends in the concentration variation in the course of time.

6.3.2. Hydrogen carbonate interference

To test the possible interference of HCO_3^- on the determination of nitrate we measured nitrate, by both the reference and the ISE methods, using standard solutions of 1 mg L^{-1} (NO_3^-) in the absence and in the presence of hydrogen carbonate ion, with known concentrations (100 and 200 mg L^{-1}). These hydrogen carbonate ion concentrations were chosen according to the range found in previous field sample analysis.

For the cadmium reduction method the changes observed were lower than 5%. However, the hydrogen carbonate ion contributed to increase the values given for the concentration of nitrate when using the probe ISE, by a relative change of 17%. Furthermore, the probe ISE measurements were more affected by the increase in the hydrogen carbonate concentration.

In order to study the influence of hydrogen carbonate ion on the determination of chloride we determined chloride using standard solutions with 70 mg L^{-1} (Cl^-) in the absence and presence of hydrogen carbonate ions in two concentrations (100 and 200 mg L^{-1}). The HCO_3^- ion does not interfere with the determination of chloride, the relative error associated being lower than 2%, both for the probe and the reference (argentometric) methods.

6.4. Sensor features

The efficiency of the electrodes was evaluated on the basis of their limits of detection, slopes, dependence of interfering ions (see the preceding section), response times, and long-term stability behavior. Calibrations were carried out as stated in Section 5.6; based on the respective calibration graphs, the lowest limit of detection (LLD) were (a) 0.3 mg L^{-1} for the probe nitrate ISE, (b) 0.1 mg L^{-1} for the probe ammonium ISE, and (c) 0.5 mg L^{-1} for the probe chloride ISE. The slope in the linear range amounts to 60 mV/decade for all three electrodes. The potential response for all of them was linear in the range over which the concentrations of nitrate, ammonium, and chloride varied in Lake Albufera. All three ISEs were previously tested for long-term stability by continuous immersion in the lake over 3 days. The potential drift was less than 1 mV h^{-1}. It was not a monotonic drift, and after 24 h we observed a drift of about 1.5 mV. It was also found that the electrodes had response times of less than 20 s to changes in ion concentration (it far exceeds our needs, since no significant changes in analyte concentrations are expected to occur in the lake in seconds range). The responses were determined by rapidly changing the concentration of standard ion solutions with short rinsing time between the measurements. The time required to obtain a 90% response to a stepwise change from 10 to 100 mg L^{-1} of the ions in a stirred solution was 15 and 10 s in the opposite direction. And last but by no means least, the half lifetimes of the electrodes turned out to be >3 months, when stored in solutions of 0.8 g L^{-1} potassium nitrate or 0.8 g L^{-1} ammonium chloride.

6.5. In-line measurements

A series of 14 buoys, each one of them containing a sensor node as the one mentioned above, have suitably been placed at several points of the lake, according to a spatial distribution shown in Fig. 4. As mentioned in the preceding section, the ISEs were exposed to the lake water at all times along the whole monitoring process (i.e. there is no system that drives the sample to the electrodes at certain times). The results obtained in the in-line continuous monitoring of nitrate, ammonium, and chloride for 7 days are summarized in Table 1. It should be noted that – for each buoy – the average value was obtained from ten consecutive measurements (every hour, 9 a.m. to 6 p.m.). The temperature of the water at the different points of the lake where the probes were located was measured during the whole week, the obtained values varying between 21 and 23 °C. This is quite normal, since Lake Albufera is a shallow lake, with an average depth of 1 m. Furthermore, its geographical location (39° north) and the proximity (less than 500 m on average) to the Mediterranean Sea, allow for the lake to enjoy a mild weather throughout the year. Taking into account this small temperature variation, a very scarce influence of this parameter is to be expected on ISEs measurements, without a significant relationship between system drift and temperature changes.

On the other hand, a test of reliability was also carried out by comparing the results obtained by the probe with those provided by the corresponding reference methods. Buoy No. 9 was chosen as an example and, in this case, measurements were taken daily at noon for 7 consecutive days. Reference analysis was performed simultaneously following the previous steps shown in Section 5.1. The results are summarized in Table 2. In general, a satisfactory agreement between both procedures was achieved.

Moreover, the sensor nodes have shown a correct behavior regarding the supply system as well as the electrode control system and the wireless transmission of the results. The reliability observed in the system as a whole can then be considered satisfactory.

Finally, it should also be remarked that the data management system has allowed for studying the concentrations of all monitored parameters at any time, as well as their evolution. Another interesting achievement has been the possibility of knowing the node status, with a low rate of communication failures and no con-

[a] Measurements using both the probe and the reference methods were taken everyday at noon, right before the calibration procedure. See Section 5.1 for details concerning the reference measurements.

trol errors at all. Additionally, several parameter sets have been evaluated in terms of measurement schedule, working cycle (time on/off), and warning thresholds; in this way, a fine tunning of the system has been achieved, thus obtaining a highly efficient energy management. The main drawback to be taken into account is that we have 'suffered' some faults in the functioning of the GPRS public network, which reinforces our trend towards the use of the WiMax technology.

As regards the obtained values themselves, the following aspects are to be highlighted:

(a) The content in nitrates is relatively high, probably due to the fertilizers used in the surrounding cultivated areas. Since these cultivars are widespread all around the lake, no determined sequence may be inferred from the values obtained at the different sampling points (buoys), higher and lower values occurring somewhat at random. A serious problem may be deduced from the nitrate concentrations obtained, as all of them far exceed 50 mg L^{-1}, which make Lake Albufera waters unsafe for human consumption according to Spanish regulations.
(b) In the case of chloride ions, their high values can be attributed to the special characteristics of Lake Albufera, which is linked to the Mediterranean Sea through three natural channels (none of them exceeding 200 m). No relationship can be established between the concentrations found and the locations at which they were measured.
(c) The concentration of ammonium ions found is rather low. These are good news for fishes since high values of this parameter can be toxic for them. However, further complications may arise if the content of organic matter in the lake increases, since it can reduce nitrate ions to ammonium, thus increasing its concentration.

7. Conclusions and future works

A new model has been proposed based on WSN and IES transducers that allows for the implementation of flexible, low-cost, high-performance chemical analysis systems, which are suitable for a distributed monitoring of processes undergoing variations of chemical parameters in the course of time.

These systems are straightforward with (a) a low maintenance thanks to the use of suitable ISEs and low consumption nodes with endless supply, and (b) a high flexibility, which permits their application to different situations as well as the remote configuration of the working parameters.

Our proposal has been applied to carry out the implementation of a distributed system for in-line chemical analysis of wastewater based on WSN. In comparison with the results obtained in previous works, it can be observed that, owing to the introduction of WSN, a considerable decrease in the price of both the nodes and the communications has been achieved; this offers the possibility of increasing the number of nodes (higher spatial precision) and decreasing the time between measurements (higher time precision).

Nevertheless, a certain amount of work is still needed in the calibration step. The aforementioned accumulated drift of about 1.5 mV during a day could be acceptable for a small-scale CWSN and the manual calibration used in this work could also be suitable for a 1-week monitoring period, but larger networks and/or longer monitoring processes will undoubtedly require a somewhat automated calibration procedure, for example the one proposed by the authors of this work [8] which we are currently trying to couple to the CWSN before being tested. If this implementation succeeds, a more frequent re-calibration will be carried out, which will undoubtedly yield even more accurate and reliable results, with a better correlation between the measured values and those obtained by the reference methods.

All in all, we can finally conclude that the proposed approach has a promising future, since the constant development of the technologies on which it is based will result in lower expenses and, at the same time, higher performances.

ABSTRACT

Two of the most important categories of pesticides used in agricultural practice are organophosphates and dithiocarbamates. Their extensive and inappropriate use has rendered their reliable monitoring at trace levels more and more necessary. This study presents the construction of a rapid and sensitive cellular biosensor test based on the measurement of changes of the cell membrane potential of immobilized cells, according to the working principle of the Bioelectric Recognition Assay (BERA). The cells were immobilized by entrapment in a sodium alginate bead and directly applied in different pesticide dilutions and agricultural samples. The pesticides used were the organophosphate insecticide diazinon and the dithiocarbamate fungicide propineb. Two different cell types, N2a (neuroblastoma) and Vero (fibroblast) were used as the biosensory elements in order to investigate their differential response against the pesticides. In this way, we hoped to increase the selectivity of the assay. Based on the observed patterns of response, we demonstrate that the sensor can be used for the qualitative and, in some concentrations, quantitative detection of the pesticides with a high degree of reproducibility. The lowest detected concentration was 3 nM. Finally, for the investigation of the effects of different pesticides on the accumulation of cytosolic Ca^{2+}, we conducted a fluorescent assay on N2a cells treated with tomato sample extracts, which were replicates of the E.U. proficiency test sample. The tomato samples were either organically grown or contained 14 different pesticides. The experimental results showed a higher increase of the intracellular Ca^{2+} concentration in cells treated with non-organic samples compared to the cells treated with organic samples.

1. Introduction

During the last two decades there have been growing societal concerns over issues related to public health, environmental quality, and food safety. One of the major controversies inciting these concerns involves the production and consumption of fresh fruits and vegetables [1]. It is well known that the level of risk is closely related to the daily intake of chemically contaminated food and that for certain products which are frequently consumed the risk is higher than others [2]. Tomato (*Lycopersicon esculentum*) is one of the most widely grown vegetables in the world and a basic component of the Mediterranean diet and is used almost daily in several European countries, raw, home-cooked or processed as a canned product, juice or paste [3].

In environmental pollution monitoring, it is becoming a general opinion that chemical analysis by itself does not provide sufficient information to assess the ecological risk of polluted waters and wastewaters [4]. Although conventional techniques such as HPLC/MS and GC/MS give satisfactory analytical results for pesticide determination, new assays and sensors for cheaper and faster on-site analysis are being developed.

Biosensors are being developed for different applications, including environmental and bioprocess control, quality control of food, agriculture, military, and, particularly, medical applications. In fact, most of the commercially available biosensor systems are applied in the clinical and pharmaceutical markets. Accordingly, most research and development has been devoted to this area. In the food industry, the detection of contaminants, verification of product content, monitoring of raw materials conversion and product freshness [5] are areas of potential biosensor application.

Based on the inhibition of acetylcholinesterase (AChE) and choline oxidase, many biosensors have been developed for the detection of organophosphorous and carbamate pesticides such as those described by Andres and Narayanaswamy [6], Choi et

al. [7], Andreou and Clonis [8] and Mavrikou et al. [9]. The biological effects of organophosphorous (OPs) insecticides such as diazinon are exerted by reversible or irreversible inhibition of acetylcholinesterase (AChE), which results in decreased catalysed hydrolysis and excessive accumulation of extracellular acetylcholine (ACh). The ensuing hyperactivation of ACh receptors results in various toxic effects including hypersecretions, convulsions, respiratory distress, coma, and ultimately death [10,11].

Propineb is a fungicide with the propylene-bis-dithiocarbamate structure. It is widely used in fruit and vegetable horticulture. Dithiocarbamates (DTCs) form lipophilic complexes with di- and trivalent metallic cations, bonding through the sulfur atoms. In the case of propineb, a zinc ion is chelated. It was shown that Zn^{2+} concentration is dose-dependently accumulated in liver and kidney tissue [12]. In addition, DTCs-induced neurobehavioral and extrapyramidal symptoms have been related to the impairment of central neurotransmitter release mechanism; alteration of dopamine [13–15], noradrenaline, and acetylcholine (ACh) [16] levels were mainly observed in rat and mouse brain areas after DTCs administration.

Interactions of mammalian cells with pesticides are frequently associated with changes in cell membrane functions: in the case of neuronal cells these changes are associated with altered responses to neurotransmitters, such as ACh. The presence of pesticidal compounds is directly associated with changes of the immobilized cell membrane potential. Even changes associated with non-membrane effects, such as the cytoplasmic induction of apoptotic pathways will frequently involve changes in calcium ion (Ca^{2+}) concentrations that could be eventually translated in changes of the membrane potential [17]. In this way, a pesticide assay could be based on electrically active cells, interfaced with microelectrodes which allow the capture of extracellular spikes or impedance changes associated with cellular response against the pesticide under detection. An example is the Bioelectric Recognition Assay (BERA) which has been originally developed for the detection of viruses on the basis of their specific interaction with appropriately immobilized, mammalian cells and the measurement of the change of the electric potential that is caused by the aforementioned interaction [18,19]. It has been recently demonstrated that the assay could be used for the detection of the organophosphate pesticide chlorpyriphos and the carbamate carbaryl in a concentration-dependent pattern [9]. According to the working principle of the method, the presence of the pesticides is detected by the degree of inhibition of cellular AChE, which is inversely associated with ACh concentration. Inhibition of AChE lead in increased excitatory ACh transmission and depolarization of the cell membrane, which was measured as a change of the sensor's potential, due to changes in the concentration of electrolytes in the immediate vicinity of the working electrode. This methodological approach displays many advantages over other biosensor techniques, such as high speed (assay time = 3 min), sensitivity (1 ppt to 1 ppb, depending on the pesticide), reproducibility and low cost. However, the selectivity of the assay is questionable, because a given cell type can react in roughly the same manner against a large number of different pesticides (a common problem in cell-based toxicity assays).

One method to increase the selectivity of the assay could be the use of different cell types having a different response pattern to the assayed pesticides. Therefore, in the present study we report the development of a cellular biosensor utilizing the BERA working principle and based on neuroblastoma N2a or Vero cells, two cell types quite different in their physiology. The novel sensor was tested against standard solutions of the organophosphate insecticide diazinon and the dithiocarbamate fungicide propineb and validated against tomato samples containing a mixture of pesticides.

2. Experimental

2.1. Materials

Mouse neuroblastoma (N2a) and monkey African green kidney (Vero) cell cultures were originally provided from LGC promochem (UK). Diazinon (diethoxy-[(2-isopropyl-6-methyl-4-pyrimidinyl)oxy]-thioxophosphorane; CAS [333–41–5]; Mw = 304.35; Sigma–Aldrich, USA) was used as a standard organophosphate insecticide and propineb ([[2-[(dithiocarboxy) amino]-1-methylethyl]carbamodithioato]](2-)-k*S*,k*S*′] zinc; CAS [235–134–0]; Mw = 289.80; Bayer Cropscience, Germany) as a standard dithiocarbamate fungicide. Pesticide mixtures which contained 10 μM of each pesticide, were prepared daily in acetone solution. All other reagents were purchased from Fluka (Switzerland).

2.2. Cell culture and sensor fabrication from N2a and Vero cells

Cells were cultured in Dulbecco's medium with 10% heat-inactivated fetal calf serum (FCS), 10% antibiotics (streptomycin) and 10% L-glutamine. After cell detachment from the culture vessel by adding trypsine/EDTA for 10 min at 37 °C and cell concentration by centrifugation (6 min, 1200 rpm, 25 °C), 1 ml of cells (at a density of 2.5×10^6/ml) were mixed with 2 ml of 4% (w/v) sodium alginate solution and then the mixture was added drop wise, by means of a 22G syringe, in 0.8 M $CaCl_2$. Each of the resulting calcium alginate beads had an approximate diameter of 2 mm and contained approximately 5×10^4 cells.

The sensors were storable at room temperature in culture medium, under normal atmospheric conditions (i.e. non-CO_2 enriched) for at least three weeks without any loss of performance.

2.3. Sample preparation

Thirteen blended tomato samples were analysed. Five of them were replicates of a control sample derived from strictly organically grown tomatoes, free of pesticide residues while the rest of them were replicates of the E.U. proficiency test sample containing a mixture of fourteen pesticides at concentrations ranging from 0.05 to 3.955 mg/kg (Table 1).

Standard aqueous solutions of either diazinon or propineb were prepared in the range of concentrations 0.003, 0.016, 0.03, 0.16, 0.33, 1.65 and 3.30 μM in water. The concentrations 1.65 and 3.30 μM of the pesticides had to be dissolved in a small amount of ethanol and diluted with water (5%, v/v) because of their insolubility in water.

2.4. Assay principle

According to the working principle of the method, the presence of organophosphate compounds is detected by the degree of inhibition of cellular AChE, which is inversely associated with ACh concentration. ACh is an excitatory neurotransmitter [20], the activity of which is regulated by AChE. Therefore, inhibition of AChE can lead in increased excitatory ACh transmission, which can be measured by the depolarization of the cell membrane. In other words, inhibition of AChE by pesticide residues in the sample will result to excessive stimulation of N2a cells by ACh, which will further lead to membrane depolarization above a pre-determined threshold. The presence of DTCs is also detected by the increase of ACh concentration: it has been previously reported that propineb (0.001–100 nM) dose-dependently increases ACh release from PC12 differentiated by NGF [21]. In addition, previous data obtained from Marinovich et al. [22] indicated a possible involvement of nicotinic

Table 1
Fourteen pesticides contained in E.U. proficiency test tomato samples.

Acrinathrin0.284 mg/kg	Azoxystrobin 0.225 mg/kg	Bromopropylate 0.490 mg/kg	Chlorothalonil 1.626 mg/kg	Diazinon 3.955 mg/kg
Dimethoate0.132 mg/kg	Endosulfan 0.344 mg/kg	Imazalil 0.167 mg/kg	Imidacloprid 0.232 mg/kg	Dithiocarbamates 0.810 (as CS_2)

receptors present on nerve terminals in propineb-induced ACh release.

Correspondingly Vero cells were used as a non-responsive biosensory element for the case of organophosphates. On the other hand propineb may exert a high sensitivity response in kidney-derived Vero cells due to its Zn-containing molecule: zinc concentration varies widely in different tissues, but Zn is known to accumulate in two particular organs, namely the liver and kidney, where it may cause biochemical and histopathological changes [23,24]. According to Davies et al. [25] and Houtani et al. [26] zinc-activated ion channel (ZAC) is a mammalian protein, expressed in prostate, thyroid, trachea, lung, brain (adult and fetal), spinal cord, skeletal muscle, heart, placenta, pancreas, liver, kidney and stomach. The L2 sequence of ZAC gene is conserved among species including human, chimpanzee, dog, cow, and opossum [26]. Membrane depolarization events and associated electrolyte influx/efflux will reflect themselves on the sensor's response as a change of the sensor's potential, due to changes in the concentration of electrolytes in the immediate vicinity of the working electrode.

2.5. Assay procedure

Each cell-bearing bead (cell sensor) was manually connected to a working electrode (the electrode was inserted through the entire length of the sensor without extruding from the opposite end) made from pure silver, electrochemically coated with an Ag/AgCl layer and having a diameter of 0.75 mm. The distance between working and reference electrode was 3 cm. Electrodes were connected to the recording device, which comprised the PMD-1608FS A/D card (Measurement Computing, Middleboro, MA). The software responsible for recording the signal and data processing was InstaCal (Measurement Computing).

For each assay, the sensor system, comprising of the bead attached to the working electrode and a reference electrode, was immersed into each sample solution (200 μl). The response of each sensor was estimated by recording the average change of the sensor potential for a period of 180 s after sample application.

2.6. Fluorescence assays of pesticide–cell interaction

Changes in cytoplasmic Ca^{2+} concentration in N2a cells were measured microscopically, after the addition of pesticide-free tomato samples and tomato samples containing 14 different pesticides were monitored by the uptake of the acetomethyl ester of Fluo-3 [27]. After application of 5 μl of the dye, the fluorescence of the specimens was recorded for 5 min at 10 s intervals. Slides with stained cells were mounted on a Zeiss Axiolab fluorescent microscope equipped with a BP-546 excitation filter and an FT-580 chromatic beam splitter. A digital camera (SONY S75 digital still camera) was attached to the microscope with adjustable BP-546/FT-580 excitation filter/chromatic beam splitter combinations. In order to control photobleaching, we kept specimen exposure times at a minimum level.

In addition, a fluorescence assay was conducted spectrophotometrically. Cells were plated on special optics 96-well plates (black, clear-bottom; Greiner) coated with poly-L-lysine (100 μg/ml) at a density of 2×10^4 cells per well. After 3 days in culture, Fluo-3 AM (10 μM) was added to the cell suspension of each well, which was subsequently incubated for 60 min at 37 °C. The cells were then washed two times with sterile deionized water. The cells were incubated with either tomato samples or with K^+ (70 mM) in a standard medium (containing 140 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 5.6 mM glucose, 1.5 mM $CaCl_2$, and 20 mm HEPES-Na (final pH 7.4)), which was used for loading and for the subsequent fluorescence measurements. The fluorescence intensity of Fluo-3 was quantified by a fluorescence spectrophotometer (Molecular Devices Spectramax M2e microplate reader), with a single excitation wavelength set at 492 nm and an emission wavelength monitored at 520 nm. All data points were done in triplicates, and experiments were repeated at least three times with different batches of N2a cells.

2.7. Data analysis and experimental design

Both biosensor and conventional sample analysis were conducted according to a double-blind protocol. Experiments were set up in a completely randomized design and each experiment was repeated four times. Results were assessed by a standard analysis of variance. In each application, a set of five biosensors was tested against each individual sample. Data means among different days were compared using Duncan's multiple range test (with significance at $p < 0.05$).

3. Results

3.1. Response of the sensor to standard pesticide solutions

The results of the assay of standard propineb solutions at different concentrations with neuroblastoma and Vero biosensors are shown in Fig. 1A, while the results of assaying standard diazinon solutions with neuroblastoma and Vero biosensors are shown in Fig. 1B. In the case of Vero cells, when no pesticide was present in the sample (control sample), a constant sensor response of -70 ± 5 mV was observed. The sensors responded to propineb by considerable positive increase of the sensor's potential (Fig. 1A). This response was concentration-depended in the range of 0.03–0.33 μM ($r^2 = 0.9816$, $y = 7.788x - 37.758$), so that both the qualitative and the quantitative detection of the pesticide was possible, at least at concentrations lower or close to either 0.33 μM (Vero cells) or 1.65 μM (N2a cells). The biosensor based on N2a cells gave also a concentration-depended response in the range of 0–0.16 μM ($r^2 = 0.9527$, $y = 15.5x - 68.386$).

A similar, concentration-dependent pattern ($r^2 = 0.9046$, $y = 6.4788x - 59.268$) was observed in the N2a sensor's response against diazinon (Fig. 1B), in the range of 0–0.33 μM. In contrast, the Vero cell biosensor's response did not follow a concentration-depended pattern.

Depending on the concentration of each pesticide, representative recovery rates ranged from 51 to 93% for diazinon and from 52 to 122% for propineb (Table 2).

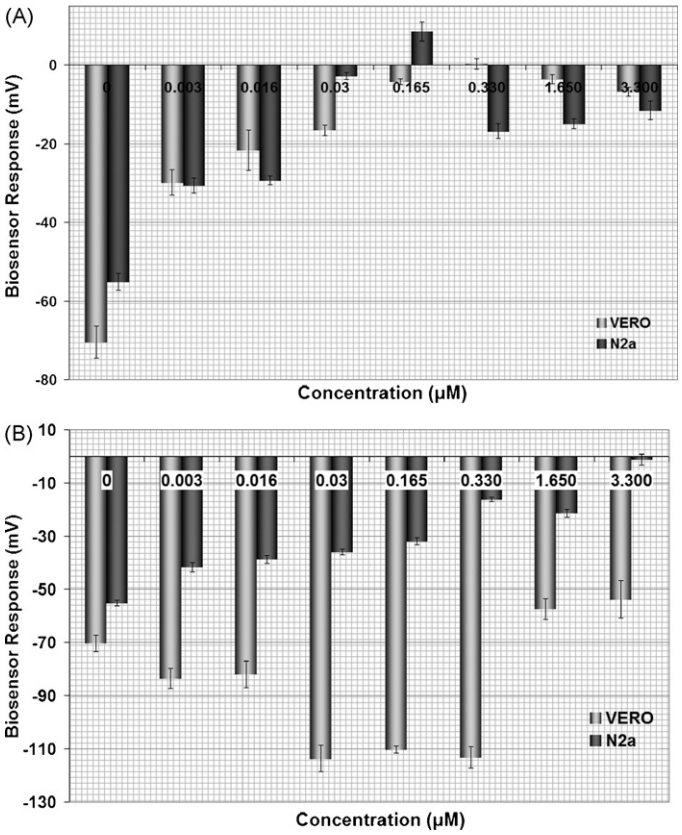

Fig. 1. Biosensor response against standard solutions containing propineb (A) or diazinon (B) at various concentrations. Sensor response is expressed as a change in the membrane potential of immobilized cells. ($n = 15$ replications (different sensors) for each sample and error bars represent standard errors of the average value of all replications with each sample.) The white columns represent Vero cells and the gray columns N2a cells. With each different colour, columns marked with different letters indicate statistically different values ($p < 0.01$).

3.2. Residue profile by conventional analysis of tomato samples

Eight of the thirteen tomato samples contained a mixture of fourteen pesticides which are presented in Table 1, while the biosensor responses for the thirteen tomato samples are presented in the *y* axis of Fig. 2. The white columns represent organic tomato samples and the gray columns represent tomato samples containing the fourteen pesticides in various concentrations. Pesticide residues in tomato samples caused a considerable cell membrane depolarization on neuroblastoma cells immobilized in the sensor, as indicated by the decrease of the negative sensor potential, which was clearly distinguishable from the sensor's response against pesticide-free control samples. There were no false-negative measurements.

Differences in responses between replicates of the control sample may be due to enhanced matrix effect of the tomato samples on the neuroblastoma cells immobilized in the sensor. Tomato is rich in carotenoids, such as lycopene. It has been previously shown that carotenoids and their oxidation products promote gap junctional communication [28]. It is, therefore, quite possible, that differences in the oxidation rate of lycopene and other carotenoids between individual samples resulted in the observed differences in responses between replicates of the control sample.

Table 2
Recovery rates for diazinon and propineb with the novel cell biosensor assay.

Pesticide	Concentration (μM)	Recovery rate (%)
Diazinon	0.01	51.01
	0.05	92.81
Propineb	0.01	121.93
	0.05	51.62

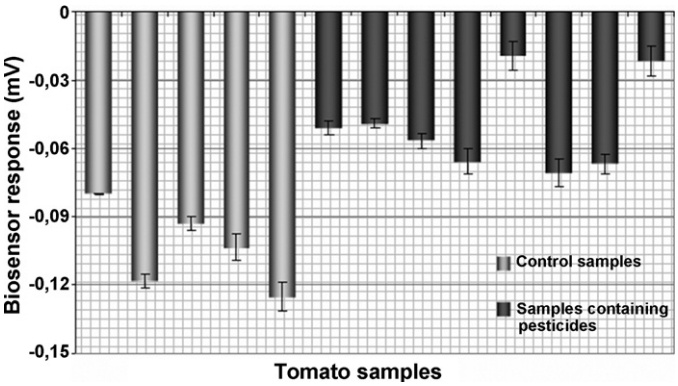

Fig. 2. Biosensor response against thirteen different tomato samples. The sensor was based on neuroblasoma N2a cells. The white columns represent pesticide free tomato samples and the gray columns represent tomato samples containing fourteen pesticides in various concentrations. Sensor response is expressed as a change in the membrane potential of immobilized cells. ($n = 15$ replications for each samples and error bars represent standard errors of the average value of all replications with each sample.)

3.3. Fluorescence assays on calcium uptake by N2a cells after treatment with various tomato samples

Neuroblastoma cells responded to the presence of tomato samples containing 14 different pesticides in various concentrations, by a rapid and very considerable increase of their intracellular Ca^{2+} concentration (Fig. 3), compared to cells treated with pesticide free tomato samples. The spectrophotometric assay gave similar results in the fluorescence intensity (Fig. 4). The pesticide free samples indicated a significant difference compared with the samples containing pesticides. Cells incubated with a Krebs HEPES buffer containing a high concentration of K^+ (70 mM) were used as a positive control, while cells incubated with Krebs HEPES buffer were used as a control. The purpose of the microscopy fluorescence assay was to investigate the participation of Ca^{2+} traffic through the cell membrane as a possible mechanism underlying the observed changes in cell membrane potential, as measured with the biosensor. This measurement was not meant to include a complete fluorescence-based assay for pesticide detection, therefore different pesticide concentrations were not tested.

4. Discussion

Cell-based biosensors constitute a promising field that has numerous applications ranging from pharmaceutical screening to environmental monitoring. Cells provide an array of naturally evolved receptors and pathways that can respond to an analyte in a physiologically relevant manner. Enzymes, receptors, channels, and other signalling proteins that may be targets of an analyte are maintained and, as necessary, regenerated by the molecular machinery present in cells [29].

The results of the present study clearly demonstrate that detection of different pesticide substances with BERA, was primarily based on the specificity of the cell line used in the biosensor. The biosensor presented in this study belongs to a new category of pesticide residue detectors based on mammalian cell lines. Previous studies report the use of genetically modified bacteria for the detection of toxic and especially mutagenic compounds [30]. Even though the biosensor development is at an early stage the biosen-

sor gave satisfactory results due to the high reproducibility and the differentiation between control and positive samples.

Vero cells are widely used in studies of in vitro cytotoxicity [31]. The results of the present study, as expected, indicate that Vero cells present higher specificity to the dithiocarbamate fungicide, propineb than to the organophosphate insecticide diazinon. These results provide an indication that the zinc organometallic fungicide propineb, reacts with the zinc receptors on the kidney cells [26]. Furthermore, N2a cells, as expected due to their membrane-bound AChE [32], demonstrate higher selectivity to the organophosphate diazinon in contrast to propineb (Fig. 1A). However, propineb resulted in a satisfactory response between the concentrations 173 nM and 3 nM (the latest being the lower detectable concentration). In previous studies using rat pheochromocytoma cells differentiated by NGF (PC12), propineb (0.001–100 nM) dose-dependently increased ACh release from PC12. At concentrations between 0.001 and 1 nM propineb-induced ACh release reached a maximal effect (~50%) while at higher concentrations (10–100 nM), propineb caused a progressive disappearance of the effect [21]. It seems that pesticide concentrations above a limit caused cellular toxicity or otherwise major, non-reproducible biochemical changes that could not fit in a linear response pattern. This effect was cell line- and pesticide-dependent, as observed by the results presented in Fig. 1, whereas cells responded to the applied pesticides in a linear pattern only within a certain range of concentrations.

The results of the present study showed a higher fluorescence intensity of the samples containing pesticides compared to pesticide-free samples. Calcium ions (Ca^{2+}) are universal secondary messengers that are key players in many cellular signal transduction pathways [17]. Cell damage induced by environmental insults or by overstimulation of physiological pathways results in pathological Ca^{2+} signals, which trigger necrotic or apoptotic cellular death [33]. Increased Ca^{2+} influx through voltage-operated calcium channels (VOCCs) is implicated in many forms of both apoptotic and necrotic cell death [34]. Wang and Xu [35] report a possible involvement of Ca^{2+} signalling in rotenone-induced apoptosis in human neuroblastoma SH-SY5Y cells.

There are several areas of future work that would improve the utility of cell-based biosensors. Numerous applications would benefit from the development of parallel systems that allow for simultaneous measurements on multiple cell lines. The development of a system utilizing multiple cell types will offer improvements to both the breadth of sensitivity and the ability to discriminate or classify analytes.

ABSTRACT

The Sonogel electrode was immersed in hemin solution to obtain the hemin–Sonogel-modified electrode by cyclic voltammetry (CV). It was applied to detect superoxide radicals produced by xanthine oxidase catalyzed hypoxanthine oxidation. The characterization of hemin–Sonogel was modified by impedance and CV.

1. Introduction

Hemin–iron protoporphyrin is the active center of the family of heme-proteins, such as cytochromes, peroxidase, myoglobin, and hemoglobin. In 1968, the electrochemical behaviour of hemin at a platinum electrode was already studied in a homogeneous solution by means of the coulostatic method [1]. Furthermore, the adsorption characteristics of hemin or hemin derivatives on carbon and mercury electrodes have been evaluated [2–6]. Hemin adsorbs strongly on the carbon electrode, especially on a pyrolytic graphite (PG) electrode. The adsorbed hemin remains fast electron transfer to the electrode surface. The adsorption of hemin on PG electrode can exceed the monolayer coverage, and thus, a higher amount of active species can be obtained [4,5]. The application of hemin electrodes in catalysis and the reduction of hydrogen peroxide and oxygen were also reported.

Superoxide is an oxygen-derived, potentially cytotoxic specie. Recently, there has been increasing evidence that superoxide is implicated in the pathology of many human diseases. The determination of superoxide has become a major interest to scientists from many fields. The electrochemical assay of superoxide has caused considerable attention during the past decade. There are two main types of electrochemical superoxide sensors. The work principle of the first type is based on the specific dismutation of superoxide by superoxide dismutase (SOD) [7–9]. In this case, hydrogen peroxide, the product of superoxide dismutation, is determined at the electrode surface. However, at the high electrode potential −0.5 V vs. Ag/AgCl, serious interferences appear from other substances in the medium. The selectivity of the electrode can be improved by using a superoxide permeable membrane, such as Teflon. However, the sensitivity and the response rate are decreased. The second group is based on the reduction of cytochrome *c* (cyt *c*) by superoxide. The reoxidation of cyt *c* on an electrode surface led to a current proportional to superoxide concentration. In order to establish electrochemical communication between the redox protein and the electrode, mediator-based configurations as well as configurations without mediator were used. Analytical application of cyt *c* for electrochemical assay of superoxide in a homogeneous solution was demonstrated with a promotor-modified electrode [10,11]. In the investigations carried out by Campanella et al. [12], hemin contained in a carbon paste electrode was used as electron mediator between cyt *c* and the carbon electrode in the detection of superoxide. Other attempts involved covalently immobilized cyt *c* on a 3,3-dithiobis-sulfosuccinimidylpropionate-modified gold electrode for the determination of superoxide [13]. Recently, the in vivo measurements have been successfully performed with cyt *c* covalently bound to an alkane thiol modified gold electrode [14,15].

The Sonogel–carbon electrode constitutes the novelty of the paper. The relative stability of these biosensors can be attributed to

doi:10.1016/j.talanta.2009.10.017

two factors. The first of them is the biocompatibility of the Sonogel electrode with hemin, probably because of the inorganic–organic structure of the Sonogel. The second is the inertness of this material. The shrinking phenomenon was avoided, thanks to the exclusion of the use of organic solvent in the sonogeling process, and the porosity and dry at room temperature. In this paper, a hemin-modified Sonogel–carbon electrode and its application for the electrochemical determination of superoxide is reported.

2. Experimental

2.1. Reagents

Xanthine oxidase (XOD) from cow milk (EC 1.1.3.22) was supplied by Boehringer-Mannheim. Hypoxanthine, catalase, and superoxide dismutase (SOD) were purchased from Sigma. All other products were of reagent grade and were used as received. Water purified by a Milli-Q system was used to prepare all the solutions. Stock solutions of 20 U XOD were prepared. The concentration of the hypoxanthine stock solution was 4 mM. The stock solution of hemin was prepared by dissolving hemin in 0.1 ml, 1 M NaOH, then diluted with 4.9 ml phosphate buffer solution (PBS) to acquire a final pH value of 7.5. A 0.1 M PBS containing 0.1 mM EDTA was prepared by mixing Na_2HPO_4, NaH_2PO_4, and EDTA with distilled water; the pH value was 7.5.

2.2. Apparatus

The measurements were performed in a stirred electrochemical cell. The three electrodes system consisted of Sonogel–carbon modified electrode as working electrode, an Ag/AgCl (3 M KCl) as reference electrode and a platinum wire as auxiliary electrodes. The formal potential values of hemin adsorbed on the electrode surface reported in the literature were recalculated vs. Ag/AgCl in 1 M KCl solution at pH 7.5. Cyclic voltammetry (CV) was performed using an Autolab system, Eco Chemie, the Netherlands.

2.3. Electrode preparation

The unmodified Sonogel–carbon electrode was prepared as described previously [16,17]. Before modification, the electrodes were polished with emery paper No. 1200 to remove extra composite material, wiped gently with weighing paper, thoroughly washed with deionised water and allowed to dry at room temperature. The prepared electrode was then immersed in 0.05 mM hemin solution to obtain the hemin-modified electrode by CV.

2.4. Superoxide measurement

In the electrochemical measurements, superoxide is generated by the reaction of hypoxanthine with XOD in the presence of dioxygen in PBS at room temperature. The reaction is:

$$\text{Hypoxanthine} + O_2 \xrightarrow{\text{XOD}} \text{uric acid} + O_2 + H_2O \quad (1)$$

$$H_2O_2 \xrightarrow{\text{catalase}} \frac{1}{2}O_2 + H_2O \quad (2)$$

The PBS containing hypoxanthine and 40 U ml^{-1} catalase was added to the electrochemical cell. The function of catalase was to remove the co-product H_2O_2. The reaction was started by adding XOD in the activity range of 10–90 mU ml^{-1}. The concentration of hypoxanthine in the electrochemical cell was 100 mM.

To test the effect of SOD, superoxide was generated by the use of 30 mU ml^{-1} XOD. The relative current decrease compared to the measurement without SOD was evaluated as the sensor signal.

2.5. Electrochemical Impedance Spectroscopy measurements

Electrochemical Impedance Spectroscopy (EIS) measurements were performed with a Voltalab 10 type PGZ 100 from Radiometer. The impedance spectra were recorded using the same three-electrode-cell setup described before. The initial frequency used was 100 KHz and the final one was 10 mHz with an AC amplitude of 5–10 mV. In order to insure the inert effect of hemin during the experiment, the potential of 0.15 V was chosen in the presence or in the absence of hemin.

3. Results and discussion

3.1. The effect of hemin concentration, scan rate, and number of scan cycles on the characteristics of the modified electrode

It was found that hemin concentration, scan rate, and number of scan cycles affect the formation of the electropolymerizate membrane. For low hemin concentration, the catalytic current decreased due to the lower degree of polymerization. The catalytic current increased with increasing hemin concentration due to the higher degree of polymerization. However, when the concentration of hemin reached 1×10^{-4} mol l^{-1}, the catalytic current became lower; therefore, 5×10^{-5} mol l^{-1} hemin concentration was used for subsequent experiments. The effect of scan rate is related to the hemin concentration and number of scan cycles. When the number of scan cycles is constant, the catalytic current increases with scan rate. The peak current was proportional to the potential scan rates, in the range of 10–700 mV s^{-1} (Fig. 1), as expected for a diffusion-controlled process.

When scan rate is constant, the catalytic current also increases with increasing number of scan cycles. However, when the scan rate or the number of cycles was too high, the catalytic current decreased slightly. This is because the electrochemical characteristics of the modified electrode are closely related to the thickness of the membrane at the surface of the modified electrode. When the membrane is thicker, more electro-active groups are linked to the membrane so the catalytic current is higher, but at the same time the resistance-to-charge transfer in the membrane also increases, which decrease the catalytic current to sum up. The optimum conditions for preparation of the hemin/Sonogel electrode used in subsequent studies are as follows: hemin concentration: 5×10^{-5} mol l^{-1}; scan rate: 50 m Vs^{-1}; number of scans: 60 cycles.

3.2. The selection of supporting electrolyte

For an organic system the proton is always involved in the electrode reaction, so a buffer solution is often used as the supporting

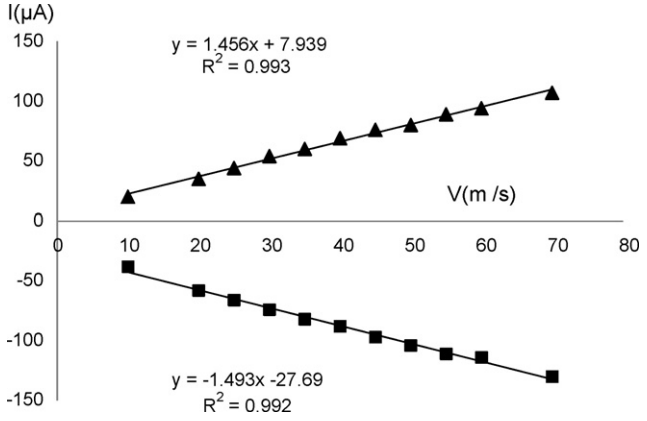

Fig. 1. Plots of cathodic (triangular) and anodic (square) current at the electrode as a function of scan rates in 0.2 M BR buffer, pH 6.

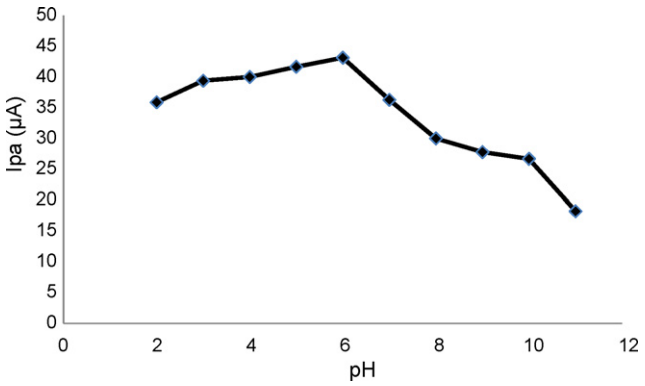

Fig. 2. Effect of pH, 0.2 M BR buffer.

electrolyte, and the peak shape and $E_{1/2}$ are closely related to the pH of the buffer solution. Therefore, selection of a suitable buffer solution is very important. The cyclic voltammetric behaviour of hemin in different media: HCl (pH 1.0–2.0) Britton–Robinson (BR) buffer solution (pH 2.0–10.0), HAc–NaAc buffer solution (pH 3.6–5.7), Michlaelis buffer solution (pH 5.2–8.3), and NH_3–NH_4Cl buffer solution (pH 7.5–11.0) were investigated. The results showed that the electrochemical responses of hemin were better in the acidic and neutral media. In NH_3–NH_4Cl buffer, the oxidation peaks of hemin were unsymmetrical, and their peak current was lesser. Symmetrical oxidation peaks were obtained in HCl, BR buffer, HAc–NaAc buffer and Michlaelis buffer, but the sensitivity is better for BR buffer, so it was used for subsequent experiments.

3.3. Effect of pH supporting electrolyte on hemin matrix

The pH of the supporting electrolyte affects directly the performance of the enzyme sensor due to the accumulation of protons. Fig. 2 shows the effect of pH on the anodic peak current of hemin. The best response is obtained at pH 6. All subsequent experiments were performed at pH 6.

3.4. Adsorption of hemin on Sonogel–carbon electrode

The preparation of hemin-modified Sonogel–carbon electrode is carried out by CV in a hemin solution; Fig. 3 shows the CV curve obtained. The formal potential estimated by $E^{\circ\prime} = (E_{pa} + E_{pc})/2$ is −0.34 V at pH 6. It is almost the same as that obtained with a hemin-modified basal plane PG [3], glassy carbon [2], and PG electrode [4]. It is about 20 mV more positive than the formal potential of hemin adsorbed on an edge plane PG electrode [5]. This shows that the formal potential of hemin is only slightly dependent on the characteristics of the electrode surface.

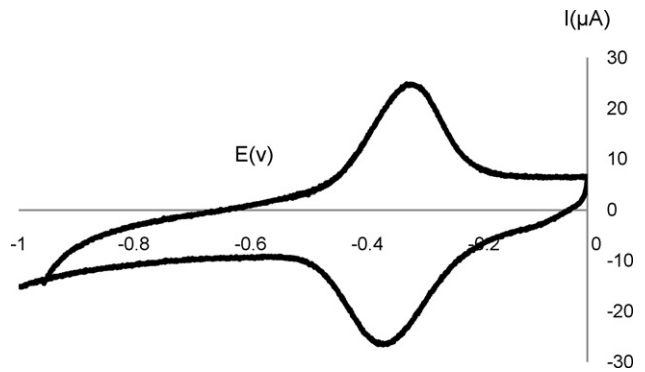

Fig. 3. Cyclic voltammograms of hemin/Sonogel–carbon electrode in 0.2 M BR buffer, pH 6.

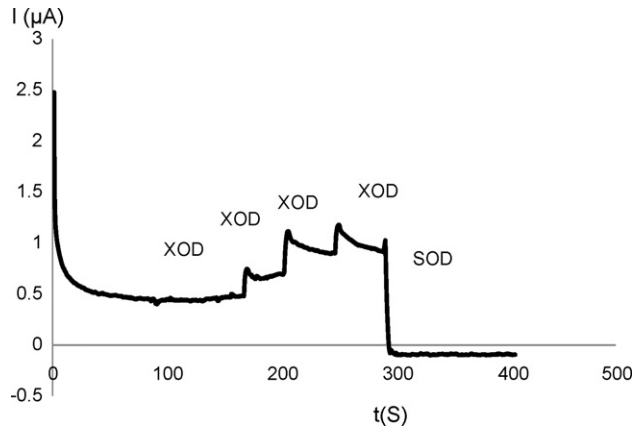

Fig. 4. Amperometric response of the hemin/Sonogel–carbon electrode on 30 mU ml^{-1} addition to a 100 mM hypoxanthine containing BR buffer and the effect of 2 U SOD, detection potential 0.15 V.

3.5. Oxidation of superoxide obtained with hemin–Sonogel–carbon electrode

For amperometric measurements of superoxide, the electrode was operated at a constant potential of 0.15 V [18]. The response of the hemin-modified Sonogel electrode to superoxide is shown in Fig. 4. Under the reaction conditions described here, a plateau response current was attained a few seconds after the addition of XOD in solution, i.e. at the start of the superoxide generation. The steady-state response current resulted from the counter balance between the enzymatic generation and the spontaneous dismutation of superoxide. It is a function of XOD concentration added in the solution. XOD obviously did not induce response in the absence

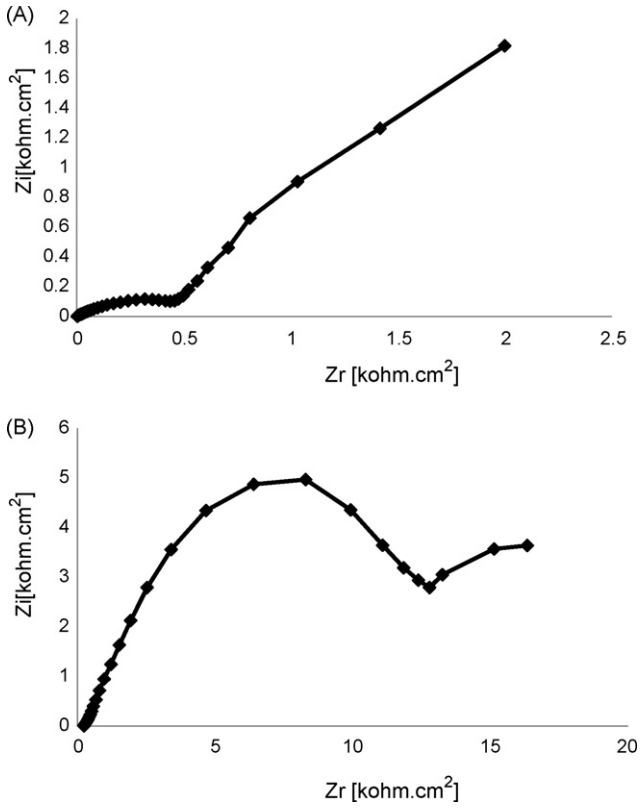

Fig. 5. Nyquist plot for (A) Sonogel–carbon electrode and (B) hemin/Sonogel–carbon.

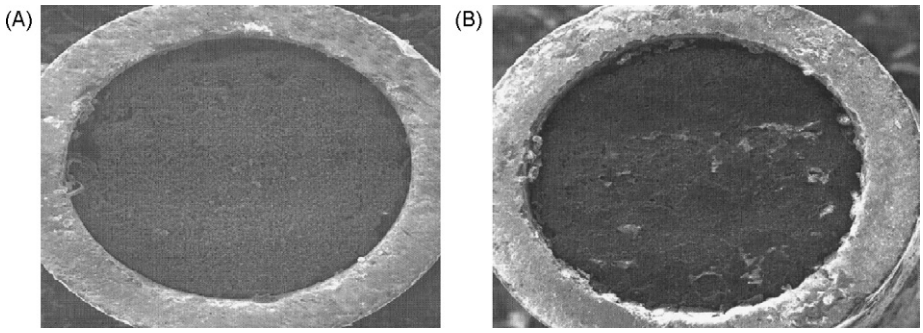

Fig. 6. SEM measurements obtained at 25.0 KV with a 500× zoom. (A) Sonogel–carbon electrode and (B) Hemin/Sonogel–carbon electrode.

of hypoxanthine. It is important to note that the response current could be eliminated immediately on the addition of SOD.

3.6. EIS measurements

In order to confirm the mechanisms suggested in the voltammetric part of this work regarding the hemin/Sonogel–carbon electrode interaction, we have performed EIS measurements. The impedance spectra in Fig. 5 were collected at 150 mV in a frequency range from 100 KHz to 10 mHz with an AC amplitude of 5 mV. Fig. 5A shows the Nyquist plot for the hemin-modified electrode. The high-frequency arc observed may be associated to charge transfer at the hemin–Sonogel–carbon electrode/solution interface. If we admit the randle equivalent circuit model, the calculated (Voltamaster® 4.0 software) charge transfer resistance (Rct) and the double layer capacitance Cd are, respectively: Rct = 14.22 kohm cm^2 and Cd = 27.97 $\mu F\,cm^{-2}$.

On the other hand, Fig. 5B also exhibited an arc like Nyquist plot for the Sonogel system; the electrical parameters calculated were: Rct = 619.2 kohm cm^2 and Cd = 25.68 $\mu F\,cm^{-2}$. It appears clearly from these data that the capacitance at the interface increases when the Sonogel–carbon electrode is modified with hemin. This observation is in agreement with literature. The observed decrease of the charge transfer resistance means also that Sonogel–Carbon/hemin system favors the electron transfer reaction at the electrode surface.

3.6.1. Reproducibility and stability

The reproducibility of the biosensors was evaluated by mean of 11 repetitive measurements with each electrode in 0.2 mol/l BR buffer, pH 7, 30 mU ml^{-1} XOD, 100 mM hypoxanthine. Relative standard deviation is 4.5%.

The hemin electrode responded quickly to superoxide, the hemin–Sonogel electrode could work stably for more than 22 h. The reproducibility of the hemin–Sonogel electrode is acceptable. The mean error of the amperometrie response of the amperometrie response of the hemin–Sonogel is within 5% for 10 measurements during more than 1 h.

3.6.1.1. SEM measurements. The results of morphological studies conducted on hemin/Sonogel–carbon are shown in Fig. 6. The SEM of Sonogel–carbon indicates that the film is uniform. The SEM of hemin/Sonogel–carbon shows the particle on the Sonogel carbon confirms the presence of hemin.

4. Conclusion

In this work, we have prepared a new modified Sonogel–carbon electrode based on the incorporation of hemin for detection of superoxide in aqueous solution. This method is very simple and offers a relative short analysis time. It is inexpensive and presents easy operability; and could be applicable for field-analysis use.

Flow-injection analysis

ABSTRACT

A sensitive and fast responding electrochemical sensor is described for the determination of free and total sulphur dioxide in wines and grape juices which prevents interferences coming from ethanol and other natural components. It consists of a cell provided with a porous gold working electrode supported on one face of an ion-exchange membrane, acting as a solid polymer electrolyte (SPE), which allows gaseous electroactive analytes to be detected. This sensor was used as an amperometric detector for a flow injection system in which controlled volumes of headspace equilibrated with samples were injected. This approach was adopted to make also possible the determination of total SO_2, avoiding drawbacks caused by the high relative humidity generated by the sample heating resulting from the neutralization reaction of excess NaOH, whose addition was required to release sulphur dioxide from its combined forms. Factors affecting the detection process were examined and optimised. Under the identified optimal conditions, SO_2 detection resulted in sharp peaks which allowed to infer detection limits for a signal-to-noise ratio of 3, referred to liquid samples, of 0.04 and 0.02 mg L^{-1} for free and total SO_2 which were determined at 20 and 35 °C, respectively. Moreover, the responses were found to be characterized by good repeatability (±2% and ±4%, respectively) and linear dependence on the SO_2 concentration over a wide range (0.2–500 mg L^{-1} for both free and total SO_2). Finally, the long-term stability of the sensor turned out to be totally satisfactory in that responses changed of ±9% alone even after long periods of continuous use. The application to some commercial wines and grape juices is also presented.

1. Introduction

Sulphur dioxide is extensively used in food and beverage making, not only in view of its profitable antioxidant properties but also because it displays a selective inhibitor effect on enzymatic and microbial activity. In particular, this compound is largely employed in grape processing for both selecting yeast strains in wines and preventing oxidative and fermentative processes in the storage of grape juices (as well as of other fruit juices) intended for the direct consumption. At a certain level, sulphur dioxide is toxic for human health since it can cause asthmatic attacks and allergic reactions [1,2], so that the excess added must be removed and its residual content must be controlled carefully.

In wine and grape juices, as well as in other several food products, the unremoved SO_2 can occur as both free and bound sulphur dioxide. Free SO_2, the actual active fraction, includes all unreacted species (typically HSO_3^- and SO_2) present at the specific pH, whereas bound SO_2 corresponds to its combined forms with different functional groups displayed by some of the constituents (mainly carbonyl groups, e.g. acetaldehyde, and pigments, e.g. anthocyanins). Such a combined sulphur dioxide can be released by promoting hydrolysis of its derivatives in basic media.

Residual sulphur dioxide represents a potential hazard, so that both the World Health Organization (WHO) and the Food and Agriculture Organization (FAO) have recommended a maximum daily intake (ADI) for adults of 0.7 mg kg^{-1} body weight, including all species containing S(IV) [3]. Moreover, in the European Community the presence of total sulphur dioxide is regulated by strict provisions which set legal limits for their maximum content in several foods, including wines (ranging from 160 to 400 mg L^{-1}, depending on wine quality) [4] and grape juices (10 mg L^{-1}) [5].

The standard method recommended for the determination of free SO_2 in wines or grape juices involves its transfer (with N_2 as a sweeping gas or with air aspiration) from acidified samples into a hydrogen peroxide trap where it is oxidized to H_2SO_4, which is then titrated with NaOH [6]. Total SO_2 is recommended to be determined by the same procedure, but after addition of NaOH and subsequent heating, so as to allow bound SO_2 to be released by hydrolysis of the relevant compounds [6]. This approach is tedious, time consuming, not easy to be automatized and suffers moreover from many possible interferences. This is the reason why several alternative methods have been proposed, mainly based on spectrophotometric

[7,8], chromatographic [9] electrophoresis [10], electroanalytical [11–13] and enzymatic [14,15] approaches. Even though some of these approaches are characterized by good selectivity and quite low detection limits, they are in general unsuitable for on-line and in situ monitoring. The sole exception is given by electroanalytical methods that, in principle, make possible in situ and instantaneous multicomponent measurements with on-line capabilities and low-cost instrumentation.

Unfortunately, conventional electroanalytical measurements performed directly in wines or grape juices are expected to be markedly interfered from other several reducing species present in these matrices (such as ascorbate ions and polyphenolics). Improved accuracy could certainly be attained by headspace analysis, by profiting of SO_2 volatility, but usual electroanalytical procedures cannot be directly applied to gaseous samples in which no supporting electrolyte is present and none can be added.

To overcome this obstacle, gas-permeable membrane electrodes have been developed, based on the diffusion of gaseous analytes through a membrane, so as to dissolve in an internal electrolyte solution where they diffuse to the working electrode. The performance of these devices is just conditioned by these diffusion steps which proves to be critical because they affect unfavourably sensitivity and response time [16,17].

A considerable amount of work has been performed in the last two decades on amperometric gas sensors of last generation which allow electroanalytical measurements to be performed in gas phase, without suffering from the drawbacks above. They are based on the use of moist ion-exchange membranes as solid polymer electrolytes (SPEs) [16–29] which are usually coated on one side (facing the analyte sample) with a porous conductive film (working electrode), while the other side contacts an electrolyte solution containing counter and reference electrodes. In these devices any membrane-permeation step is avoided since the membrane separating the sample from the internal electrolyte is not permeated by gaseous analytes but serves to ensure the transfer of charged species from the working to the counter electrode, thus playing the role usually played by supporting electrolytes [16].

In this paper we propose just the use of a SPE sensor allowing the selective detection of sulphur dioxide in the head-space in equilibrium with samples involved in grape processing, thanks to the appropriate choice of electrode material and internal electrolyte, as well as of the applied electrode potential. In particular, it prevents interferences coming from other volatile species (mainly ethanol) present in these real samples. Moreover, the optimised conditions of its use as a detector for a flow-injection system make possible very good performance to be achieved for the determination of both free and bound SO_2.

2. Experimental

2.1. Chemicals and instrumentation

All chemicals used were of analytical reagent grade quality and were employed without further purification. In all instances, high purity deionized water (resistivity $\geq$18 MΩ cm), purified with an Elgastat® UHQ-PS system ("Elgastat water"), was used as the solvent.

Stock standard solutions (0.05 M) of sodium sulphite were prepared daily by dissolving weighed amounts of the pure compound in Elgastat water and immediately deaerated by bubbling nitrogen, so as to minimize oxidation to sulphate caused by dissolved oxygen. Their standardization was conducted by the conventional iodimetric procedure involving slow addition of a controlled aliquot of sulphite sample to an acidified standard iodine solution, whose excess was back titrated with standard thiosulphate.

Synthetic samples were usually prepared by adding known amounts of sodium sulphite to Elgastat water containing or not 12% (v/v) ethanol for mimicking wine and grape juice samples, respectively. In some cases, to mimic better real samples, home-made musts were used, prepared by manual squeezing of different types of red and white table-grapes. They were filtered through sterilized gauzes and stored at 0 °C after addition of sodium benzoate, to inhibit bacterial growth. Soon before their use, either known amounts of sodium sulphite alone or Na_2SO_3 plus 12% (v/v) ethanol were added to these musts to mimic grape juices and wines, respectively. Sulphur dioxide was released from all these synthetic samples by addition of 85% (w/w) phosphoric acid, so as to achieve a 3 M final acid concentration.

Real grape juice and wine samples were purchased from local supermarkets and were used without preliminary treatments.

All voltammetric and amperometric experiments were performed by an EG&G PARC Model 273 potentiostat driven by an EG&G PARC Model 270 software installed on a Pentium IV computer. Flow-injection analyses were carried out by using nitrogen as carrier gas, whose rate was controlled in the range 70–200 mL min^{-1} by a micrometric valve Viton SS-22RS2.

2.2. Electrode assembly

The design of the SPE electrode used throughout this investigation is sketched in Fig. 1. Its core was the ion-exchange membrane, one surface of which (that facing the sample) was covered with a porous Au layer acting as the working electrode. The ion-exchange material used as SPE was a Nafion® 117 cationic perfluorinated membrane, 0.175 mm thick, supplied by Sigma–Aldrich, which was preliminarily cleaned by boiling in concentrated HNO_3 for 1 h and then in high purity deionized water for 1 h.

Au composite electrodes were prepared by pressing mechanically a close-mesh Au net (wire diameter 0.06 mm) onto one surface of a Nafion membrane, preliminarily coated with a very thin film of Nafion formed by droplet evaporation of a 5% (w/w) Nafion alcoholic solution (Aldrich). Au net and membrane were then placed one on another and tightened between two aluminium blocks suitably heated at 50 °C for 1.5 h.

Coated membranes were then cut into discs 1 cm in diameter, which were used to assemble SPE electrodes. To this end, one of the desired disc-shaped composites was clamped, with the conductive layer directed downward, at the bottom of a Pyrex cylinder, the end of which was threaded for connection to a drilled Teflon holder sealing the assembly by means of an elastic O-ring resistant to acids and bases. Electrical contact with the porous working electrode was made by inserting a thin Au ring in the shallow recession on the bottom of the inner side of the drilled holder, onto which the border of the electrode was pressed. A metallic wire contacting this ring and piercing through the holder permitted electrical connection. Such an assembly allowed ca. 0.5 cm^2 of covered membrane to be exposed to external media.

The uncoated side of the membrane was brought into contact with an aqueous electrolyte solution (1 M $HClO_4$) contained in an internal compartment which was equipped with a platinum counter electrode and an $Ag/AgCl,Cl^-_{sat}$ reference electrode, connected by a salt bridge containing 1 M $HClO_4$ either. This internal compartment was made out of the extension of the Pyrex cylinder which was sealed to the bottom of a suitable standardized hollow glass stopper, so as to can be used as a gas-tight stopper for containers in which measurements were conducted.

When the working electrode was held at an appropriate potential, sulphur dioxide oxidation became possible (see reaction (1)) just as SO_2 molecules from the gaseous sample reached the

metal/Nafion interphase.

$$SO_2 + 2H_2O \rightarrow {SO_4}^{2-} + 4H^+ + 2e^- \quad (1)$$

Hydrogen ions released by this anodic reaction were trapped in the membrane, coupled with an ionic migration through the membrane to maintain electroneutrality. Concurrently, hydrogen ions in the internal electrolyte were reduced at the counter electrode, thus restoring its ionic content.

2.3. Apparatus

Voltammetric and amperometric measurements by electroanalytical sensors described above were performed in gas phase under both static and flowing conditions.

Static measurements, were conducted by using SPE electrodes as gas-tight stoppers for a glass cell (ca. 110 mL) filled with 50 mL of either real or synthetic sample, this last containing variable but controlled Na_2SO_3 amounts, and provided with two additional holes and a thermostatic jacket connected to a Haake F3 thermostatic bath. One of the additional holes served for the addition of H_3PO_4 aimed at releasing SO_2, while in the other a thermometer was inserted. Electrodes were exposed to the headspace (ca. 50 mL) equilibrated with sulphur dioxide (and/or ethanol) released from the sample, by keeping it at controlled temperature (20–35 °C) in a thermostatic bath under stirring at a constant rate (100 rev min^{-1}) by an Amel (Milan, I) 291 Mast magnetic stirrer.

Flow-injection analyses were instead performed by employing the apparatus sketched in Fig. 2(A). It consisted of a glass cell, whose

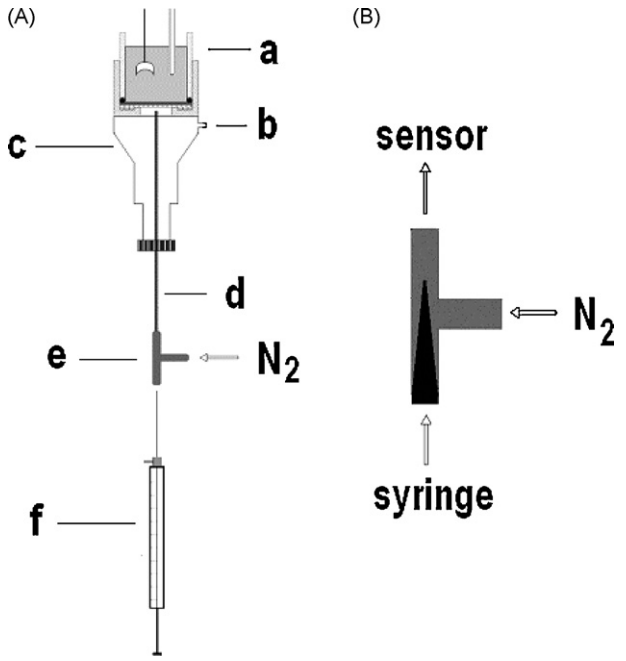

Fig. 2. (A) schematic view of the flow apparatus: (a) SPE sensor; (b) side exit for the carrier gas; (c) glass cell; (d) glass tube; (e) three-way injection device; (f) gas-tight syringe. (B) Enlarged view of the three-way injection device.

top was once again sealed by the SPE electrode acting as a gas-tight stopper, which was provided with a side exit for the carrier gas. The lower hole in the cell was sealed by a drilled stopper through which a thin glass tube (internal diameter 1.5 mm) was pierced, so as to allow flowing gas to be conveyed perpendicularly to the metal-covered Nafion surface (wall-jet configuration). The distance of the outlet of this tube from the sensing surface could be controlled by a Mitutoyo collimator microscope (Narishige, Japan). A suitable three-way connection (enlarged in Fig. 2(B)) was applied to the opposite end of the glass tube, for the carrier gas (nitrogen) supply and sample injection (by gas-tight microsyringes, through the septum covering the input opening).

An Eppendorf pipette tip was inserted into the arm for sample injection of this three-way connector (10 mm arm length; 4 mm internal diameter), to allow samples to be introduced in the same direction as that acquired by the carrier gas when its laminar flow is restored, after entrance in the connector and subsequent direction change. In such a way, a satisfactory flat baseline and well defined narrow peaks were recorded in a wide SO_2 concentration range.

All potentials are quoted versus an aqueous Ag/AgCl, $NaCl_{sat}$ reference electrode.

2.4. Analytical procedure

Free SO_2 determinations under static conditions were conducted by exposing SPE electrodes to the headspace (ca. 50 mL) in equilibrium with real or synthetic samples (50 mL) introduced in a glass cell (ca. 110 mL) thermostated at 20 °C and added with 10.2 mL of 85% (w/w) H_3PO_4 (3 M final acid concentration). After 5 min of equilibration under vigorous stirring, to attain phase distribution of released SO_2, a potential of 0.8 V versus Ag/AgCl,Cl^-_{sat} was imposed to the Au–Nafion composite electrode. Steady-state currents, recorded by keeping solutions stirred at constant rate (100 rev min^{-1}), were used to infer SO_2 contents by comparison with a calibration plot constructed for standard samples.

Total SO_2 under static conditions was instead determined after release from its combined forms by basic hydrolysis. With this aim, small amounts of a concentrated NaOH solution (19 M) were added to 50 mL of sample introduced in the thermostated glass cell, so as to achieve a 2 M final hydroxide concentration. After 7 min equilibration, 85% (w/w) H_3PO_4 was added to neutralize excess hydroxide and to achieve also in this case a 3 M final acid concentration. This neutralization caused a considerable solution heating (up to 45–50 °C) which was not counteracted quickly by water circulating into the cell jacket. Consequently, amperometric detection of total SO_2 was performed after a longer equilibration time (10 min, once again under vigorous stirring) which allowed the sample to attain a temperature of about 35 °C. The effect caused on current signals by small temperature fluctuations was accounted for by using a correction factor inferred by plotting the current signal recorded for standard SO_2 solutions against the temperature (about 3.5% signal increase per °C). The analysis was then conducted by following the procedure above for free SO_2.

Free and total sulphur dioxide determinations under flow conditions were performed on synthetic and real samples introduced once again into the 110 mL thermostated glass cell where they were subjected to all treatments described above. After equilibration, controlled headspace volumes (0.2–1.0 mL) were drawn by gas-tight syringes and injected in the flow apparatus sketched in Fig. 2(A). By applying at the Au–Nafion composite electrode a potential of 0.8 V versus Ag/AgCl,Cl^-_{sat}, narrow peaks were recorded, whose heights were related to SO_2 contents by exploiting calibration plots constructed by using standard samples.

3. Results and discussion

3.1. Voltammetric behaviour of SO_2 and C_2H_5OH at Au covered Nafion electrodes

In order to individuate the optimum operative potential for the amperometric detection of sulphur dioxide, preliminary voltammetric investigations were performed at gold covered Nafion electrodes, with 1 M aqueous perchloric acid as the internal electrolyte. They were conducted on headspaces in equilibrium with stirred aqueous solutions containing controlled amounts of sodium sulphite and/or ethanol introduced in the thermostated glass cell mentioned above and added with suitable amounts of H_3PO_4 (see above).

A single well formed and reproducible anodic wave was observed for SO_2, whose limiting current extended in a fairly wide potential range, as shown in Fig. 3. The height of this wave increased linearly with sulphur dioxide concentration and was located at potentials (ca. 0.45 V versus Ag/AgCl, Cl^-_{sat}) in full agreement with previous findings at SPE electrodes [28,30] and resembling closely those found at conventional Au electrodes for the oxidation of SO_2 dissolved in aqueous perchloric acid [31], i.e. the medium used as the internal electrolyte wetting the rear side of the Nafion membrane. When the 1 M $HClO_4$ internal electrolyte was replaced by solutions buffered at increasing pH up to 7, no appreciable potential shift could be detected, thus suggesting that the oxidation process is mediated by the low-coverage hydrous gold oxide species formed at potentials below those required to initiate regular monolayer gold oxide (or OH_{ads}) formation [32]. However, no progressive wave decrease was observed in the second and subsequent voltammetric scans, contrary to the results found at conventional electrodes for SO_2 dissolved in aqueous solutions [33], probably thanks to the ability of ion-exchange membranes of preventing electrode passivation, which was indeed observed previously [34].

Conversely, no signal for the oxidation of ethanol (up to contents of 20% (v/v) in the aqueous solutions assayed) could be detected at Au–Nafion electrodes with an acid internal electrolyte (see Fig. 3), while this process turned out to occur at about 0.2 V versus Ag/AgCl,Cl^-_{sat} only with strongly basic internal electrolytes. These

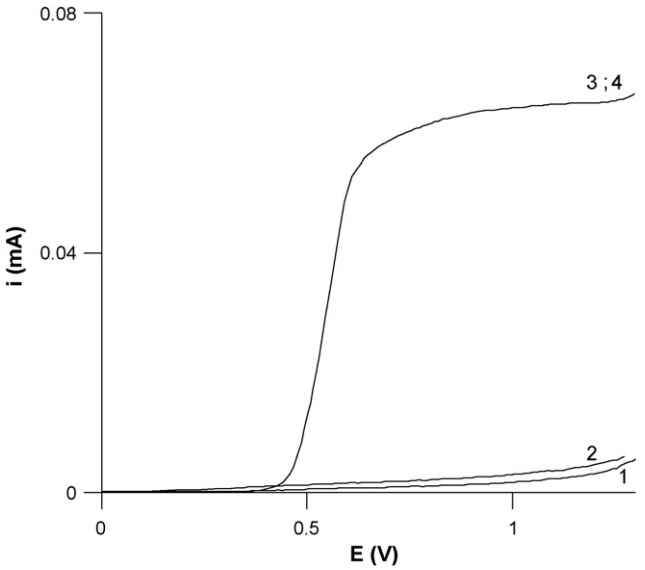

Fig. 3. Linear sweep voltammograms recorded at Au-SPE electrodes with aqueous 1 M $HClO_4$ internal electrolyte on the headspace in equilibrium with stirred: (1) Elgastat water (background profile); (2) Elgastat water containing 10% (v/v) ethanol; (3) aqueous 10^{-3} M Na_2SO_3 solution (126 mg L^{-1}, equivalent to 64 mg L^{-1} of SO_2) acidified with 85% (w/w) H_3PO_4 to achieve a 3 M final acid concentration; (4) as in (3), after addition of 10% (v/v) ethanol. Scan rate: 20 mV s^{-1}.

results agree well with previous reports on the anodic behaviour of this species at gold anodes for fuel cells [35], at gold microelectrodes [11] and at Au supported on Nafion membranes [36].

Consequently, an acid internal electrolyte was always used in the following because it proved to be suitable for the selective detection of sulphur dioxide even in the presence of ethanol, i.e. in environments like those present in the headspace of wines and grape juices.

3.2. Amperometric detection of SO_2 under static conditions

Amperometric measurements of SO_2 released by synthetic samples, consisting of either aqueous solutions or homemade musts with controlled concentrations of Na_2SO_3 and acidified with excess H_3PO_4, were first performed under static conditions. After 5 min of equilibration under vigorous stirring, the sulphur dioxide content was monitored by sampling for 2 min steady-state anodic currents recorded by applying a potential of 0.8 V to the Au working electrode. Recorded currents attained satisfactorily constant values in a fairly short time (about 15 s) and were reproducible within ±4% in replicate measurements. By plotting current signals versus SO_2 concentrations in acidified samples, a linear dependence over a wide range was found (from 0.5 to 100 mg L^{-1}) with a correlation coefficient of 0.998. From this plot, a detection limit of approximately 0.1 mg L^{-1} could be inferred for a signal-to-noise ratio of 3. Moreover, when these measurements were repeated after addition of increasing amounts of ethanol up to 20% (v/v) to synthetic sulphite samples, no appreciable change of the recorded signals was observed, thus proving that good selectivity could be achieved. Finally, when SPE electrodes were transferred from the cell to air, a rather rapid current decrease to the residual value was observed, as expected in the absence of memory effects.

Nevertheless, quite unsatisfactory results were found for the determination of total sulphur dioxide because anodic currents recorded after the equilibration time (10 min) attained acceptably constant values only after very longer times (ca. further 10 min). Moreover, these nearly constant currents turned out to be scarcely reproducible in replicate measurements (even ±25% relative standard deviations) and lacked accuracy (even – 30% recoveries were found in some cases). These very bad findings were due conceivably to the high relative humidity generated inside the cell by the solution heating caused by the neutralization reaction with H_3PO_4 of excess NaOH, required to release sulphur dioxide from its combined forms. In fact, as it could be visually observed, such a very moist atmosphere caused water condensation onto cold walls, including the Au net supported on the Nafion membrane acting as sensor probe, thus troubling markedly its basic operating mechanism. SPE electrodes are indeed effective fast-responding sensors, unlike conventional membrane electrodes, thanks to the fact that gaseous analytes undergo electrochemical reaction just as they reach directly the three-phase sites where the electrode, ion-exchange membrane and gas meet [16]. Instead, when a thick layer of condensed water is formed onto the sensor probe, the electrochemical reaction can occur only after two additional quite slow steps consisting in the dissolution of gaseous analytes into this water layer and their subsequent diffusion to the sensing surface. Consequently, under these conditions a lengthening of the response time, together with a decrease in sensitivity and a lack of signal constancy (owing to fluctuations with time of the water layer thickness) have to be expected. Moreover, changes with time of the swelling degree of the Nafion membrane are conceivably involved, which cause modifications of its area contacted by the Au net and hence of the effective electrode surface.

To overcome this drawback caused by the high humidity of the detection environment, the sensor was used as a flow-injection detector in a device separated from the vessel where hydrolysis and neutralization were let to occur, so as to minimize water condensation onto the sensor surface thanks to the use of small aliquots of the sample headspace.

3.3. Amperometric detection of SO_2 under flow-injection conditions

The performance of this detection approach is expected to be affected significantly by some important parameters, such as sample size, carrier gas flow rate and distance from the sensing surface of the outlet of glass tubing conveying gaseous samples (see Fig. 2(A)).

Sample size was first considered by injecting volumes ranging from 0.2 to 1.0 mL and keeping constant both carrier gas flow rate (150 mL min^{-1}) and distance between sample outlet and sensing surface (1 mm). As expected, the progressive increase of headspace volume injected caused improvement of sensitivity (a higher number of electroactive molecules reached the sensor surface), but also a concomitant shortening of the dynamic range (a progressively decreasing fractions of whole SO_2 molecules injected hit indeed the electrode surface, so as to undergo oxidation). The results found in these tests, which are summarized in Table 1, led to conclude that the most profitable performance was achieved by injecting 0.5 mL of sample, because this volume allows a satisfactory detection limit to be achieved concomitantly with a so wide linear range as to include even the maximum SO_2 legal limit set in wines (400 mg L^{-1}).

As to the effect of the carrier gas flow rate, which was evaluated in the range 50–200 mL min^{-1}, Table 2 compares some of the most

Table 1
Comparison of dynamic ranges and detection limits found by injecting different volumes of headspace in equilibrium with synthetic samples containing different SO_2 contents. Carrier gas flow rate: 150 mL min^{-1}; distance of the tube outlet from the sensing surface: 1 mm.

Sample volume (mL)	Dynamic range (mg L^{-1})	Detection limit (mg L^{-1})
0.2	0.5–700	0.10
0.5	0.2–450	0.05
1.0	0.2–200	0.03

Table 2
Comparison of peak width, dynamic range and detection limit found by using different carrier gas flow rates. Injected volume of headspace in equilibrium with synthetic samples containing different SO_2 contents: 0.5 mL; distance of the tube outlet from the sensing surface: 1 mm.

Flow rate ($mL\,min^{-1}$)	Base peak width (s)	Dynamic range ($mg\,L^{-1}$)	Detection limit ($mg\,L^{-1}$)
50	8	0.5–400	0.08
70	6	0.4–450	0.06
100	4	0.2–500	0.04
150	3	0.2–450	0.05
200	2	0.3–250	0.07

significant results found. These results suggested the use of a flow rate of 100 mL min^{-1}, in that higher rates led to lower sensitivities (because increasing fractions of analyte molecules are removed by the carrier gas before they find time to be oxidized), while lower rates led to progressively broader peaks whose height depended linearly on SO_2 concentration in progressively narrower ranges.

Finally, the distance between sample outlet and sensing surface, when varied in the range 0.5–2.0 mm, turned out to have a minimal effect upon stability of background currents, sensitivity and repeatability. Consequently, a distance of 1 mm was chosen arbitrarily and always adopted in further determinations.

It must be remarked that strictly similar results were found when all tests above were conducted on synthetic samples also containing increasing amounts of ethanol up to 20% (v/v), thus pointing out that also for this detection approach no interference was caused by this volatile component of wines and grape juices.

As shown in Fig. 4, which reports some typical signals recorded under the optimised conditions thus identified and reported in the relevant caption, detection of SO_2 by flow injection resulted in sharp peak readouts with rapid increases and decreases of the current that reflect the passage of the sample zone over the working electrode. On the basis of the results found for replicate measurements performed within about six months of continuous use on samples with different SO_2 contents, a very favourable performance was estimated (detection limit: 0.04 $mg\,L^{-1}$; dynamic range: 0.2–500 $mg\,L^{-1}$; regression equation: $i(\mu A) = 2.75\,C_{SO_2}(mg\,L^{-1}) + 1.03$; correlation coefficient: 0.998; repeatability: ±2% relative standard deviation; long-term stability: ±9%).

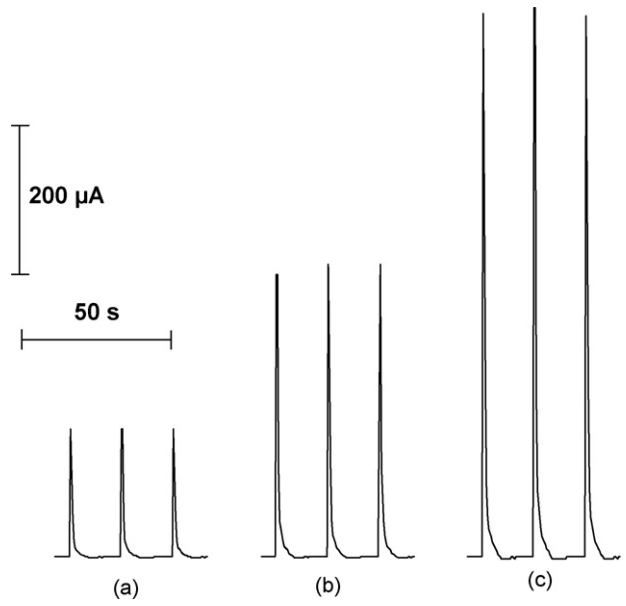

Fig. 4. Flow-injection peaks recorded at a gold–Nafion electrode with aqueous 1 M $HClO_4$ internal electrolyte for headspaces in equilibrium with aqueous Na_2SO_3 solutions reacted with 85% (w/w) H_3PO_4, so as to achieve SO_2 concentrations of: (a) 59 $mg\,L^{-1}$; (b) 142 $mg\,L^{-1}$; (c) 265 $mg\,L^{-1}$. Electrode potential: 0.8 V versus Ag/AgCl, Cl^-_{sat}; carrier gas flow rate: 100 mL min^{-1}; sample volume: 0.5 mL; distance of sample outlet from sensing surface: 1 mm.

This flow-injection approach, totally satisfactory for the selective determination of free SO_2, was subsequently also tested for the detection of total SO_2. Thus, known amounts of sodium sulphite and ethanol were added to synthetic samples consisting of home made musts, in order to verify whether sample heating caused by the mentioned neutralization of excess NaOH with H_3PO_4 allowed some possible interfering natural components of wines and/or grape juices to be transferred in the vapour phase.

Headspace samples to be injected in the flow apparatus were drawn from the reaction vessel after an equilibration time of 10 min, when the temperature (however always measured carefully) decreased to about 35 °C. Consequently, as expected on the basis of the Henry's law, higher SO_2 fractions were transferred in the vapour phase in comparison with those involved at 20 °C for free SO_2 measurements, so that a quite higher sensitivity became available. In agreement with our calibration displaying a ca. 3.5% signal increase per °C, about a 54% sensitivity increase was found, which allowed a lower detection limit (0.02 $mg\,L^{-1}$) to be inferred. Also for samples equilibrated just at 35 °C, the calibration plot was highly linear in a wide SO_2 concentration range which extended once again from 0.2 to 500 $mg\,L^{-1}$, with a good correlation coefficient (0.997). At times, after 10 min equilibration the temperature achieved in the reaction vessel differed from 35 °C, even though in a small range (±2 °C). In these cases, the current signal recorded was again referred to the calibration plot relative to 35 °C, but after correction by the suitable factor inferred from the plot of current signals against temperature (complying with the Henry's law).

No appreciable interference caused by components present in the homemade musts was observed and repeatability turned out to be satisfactory also at this temperature. In fact, replicate measurements allowed to estimate a repeatability of ±3% when performed within the same day and of ±8% when performed within one month of continuous use.

As expected, under these operative conditions no trouble was caused by the high humidity degree characterizing the headspace injected. This was because the small volume of moist atmosphere conveyed to the sensor surface was unable to cause appreciable condensation, also in view of the drying effect provided by the flowing carrier gas.

3.4. Analysis of real samples

The flow-injection apparatus above was also assayed for the determination of free and total SO_2 content in some real grape juice and red or white wine samples, all purchased from local supermarkets. These real samples were directly subjected to the analytical procedure above, without any sample pre-treatment.

Quantitative determinations of free and total SO_2 were performed by exploiting calibration plots constructed by using synthetic samples, since no appreciable matrix effect was observed for all drink samples analysed. This was checked by supplementing sulphite in each matrix considered and comparing the results found with those gained by using the mentioned calibration plots. The data obtained by these two approaches differed from each other by about ±6% at the most, thus indicating that a satisfactory recovery (and hence good accuracy) was achieved by the procedure adopted.

Table 3
Results found in the determination of free and total SO_2 contents in real samples, together with the recoveries achieved when they were spiked with 9.8 mg L^{-1} of sodium sulphite.

Real sample	Free SO_2 (mg L^{-1})[a]	Total SO_2 (mg L^{-1})[a]	Recovery (%)[a]	
			20 °C	35 °C
Red wine 1	13.1 ± 0.5	44.8 ± 1.4	98.6 ± 2.1	100.8 ± 0.7
Red wine 2	24.3 ± 0.9	81.2 ± 2.6	96.9 ± 3.6	99.7 ± 0.8
White wine 1	16.4 ± 0.6	55.6 ± 1.7	103.2 ± 3.8	102.3 ± 2.8
White wine 2	37.7 ± 1.2	122.6 ± 3.8	99.7 ± 0.8	102.4 ± 2.2
Grape juice 1	1.0 ± 0.0	3.2 ± 0.1	99.1 ± 3.8	101.8 ± 0.8
Grape juice 2	1.9 ± 0.1	5.5 ± 0.2	100.8 ± 3.1	98.9 ± 1.2
Grape juice 3	1.2 ± 0.0	4.1 ± 0.1	98.4 ± 2.7	100.2 ± 3.1

[a] Mean values calculated for five replicate measurements. The reported standard deviations were calculated accordingly.

In particular, sulphur dioxide recovery was evaluated in all cases from quintuplicate measurements performed on samples spiked with about 9.8 mg L^{-1} of sulphite (equivalent to about 5 mg L^{-1} of SO_2). The relevant results are summarized in Table 3.

We have preferred to check the reliability of these determinations by the recovery approach, instead of comparing our results with those found by the standard method [6] or other methods proposed previously [7–15]. This was because the standard method is characterized by a very poor repeatability (even standard deviations of ±15 mg L^{-1} are usually found), since it is affected by many drawbacks, such as interferences from reducing species frequently present in real samples and difficulties encountered both to recognize indicator colour changes in coloured media and to conduct some of the required experimental steps under standardized conditions. Similarly, also other methods proposed previously suffer in turn from some drawbacks making their findings scarcely reliable.

4. Concluding remarks

The results of this investigation point out that SPE electrodes make possible the selective detection of free and total SO_2 in wines and grape juices, thanks to the appropriate choice of electrode material and supporting electrolyte, as well as of the applied electrode potential. In particular, their use as detectors for flow-injection analysis performed under suitably optimised conditions leads to a very good performance, coming from quite attractive features such as: (i) high sensitivity; (ii) low detection limits; (iii) wide dynamic range; (iv) good repeatability; (v) long-term stability; (vi) absence of interferences. Moreover, it is worth highlighting that they are well suited for SO_2 on-line and in situ monitoring applications, since no real preliminary sample manipulation is involved and requires light weight, low cost and real-time instrumentation which also is simple compared to usual laboratory equipments. This approach appears to be particularly attractive when the acquirement of real-time analytical data are essential for the management of production plants, such as those designed for the removal of sulphur dioxide from stored fruit juices.

The detection of free and total SO_2 in wines and grape juices by SPE electrodes appears to be a very effective alternative not only to the standard method [6], requiring a complicated procedure unsuitable to be automatized and providing scarcely repeatable results, but also to other methods conventionally adopted as reference methods for sulphite determination in food. Thus, detection limits, repeatability and dynamic range found in our measurements (0.04 mg L^{-1}; ±2%; 0.2–500 mg L^{-1} for free SO_2 and 0.02 mg L^{-1}; ±4%; 0.2–500 mg L^{-1} for total SO_2, respectively) are undoubtedly better than those proper for the ion chromatographic method (0.05 mg L^{-1}; ±5%; 0.1–100 mg L^{-1}) which is one of the official methods for sulphite determination in food [37]. Moreover, they turn out to be advantageous even when compared with the same characteristics (0.05 mg L^{-1}; ±2%; 1–5 mg L^{-1}) of the conventional para-rosaniline-formaldehyde spectrophotometric method [38], whose advantageous application to food samples was recently proved [39].

ABSTRACT

Headspace single-drop microextraction has been investigated for the determination of chloride in conjunction with fibre optic-based cuvetteless micro-spectrophotometry which accommodates sample volume of 1 μL placed between the two ends of optical fibres. Method has been evolved for the determination of 0.025–4 mg L^{-1} of chloride involving its oxidation with permanganate in sulphuric acid medium, and reaction of chlorine with 2 μL drop of starch-iodide reagent suspended at the tip of microsyringe needle in the headspace of the reaction mixture. The limit of detection was found to be 2.8 μg L^{-1} of chloride which was better than obtained by existing methods. The method was highly selective and a number of ions which interfered severely in other methods did not affect the results. The method has been used to analyze water samples, inorganic compounds and cement when the overall recovery of chloride was 94.9% with a relative standard deviation of 3.9%.

1. Introduction

Miniaturization of analytical methods and instrumentation has resulted in precisely controlled trace level analyses, and their high environmental compatibility owing to insignificant amount of solvent and reagent consumption, low waste production, and low operational cost. Most of the current analytical procedures consist of a sample preparation step, and quantitation by chromatography and spectrometry.

Solvent extraction has been most widely used method for sample preparation. However, the classical mode of solvent extraction performed in a separatory funnel has inconveniences of unfavourable partition equilibria, formation of emulsions, necessity to use large volume of hazardous and ozone depleting organic solvents and difficulty in waste disposal. Miniaturization of extraction process by using microlitre volumes of the organic solvent has avoided many of these problems, allowed new ways in which the sample pre-treatment can be performed [1–3], and resulted in high sample throughput [4]. Thus, 50 or 200 μL portion of toluene, hexane or cyclohexane was used to extract the organic derivatives of nitrite, iodide, iodate and bromate in the standard flask, and a portion of extract settled in the neck of the flask was analyzed by gas chromatography [5–8]. Dispersive liquid–liquid microextraction in 70 μL of 1,2-dichlorobenzene of complexes of palladium and cobalt formed with 1-(2-pyridylazo)-2-naphthol (PAN) [9], or cloud point extraction of cobalt and nickel complexes with PAN [10] have been used along with fibre optic-linear array detection spectrophotometry that employed a 50-μL cylindrical cell of 1-cm pathlength. Extraction with microvolumes of ionic-liquids and dilution of extract with ethanol allowed the use of conventional 1-cm sample cell [11], but at the cost of sensitivity. A simple and robust microextraction method used 2–25 μL of solvent placed in the lumen of a hollow fibre that was previously impregnated with an organic solvent, and the device was placed in the sample solution [12–14]. Use of solvent drop represents further miniaturization of extraction, the early attempts were for ammonia and sulphur dioxide in air [15]. Methods involving use of microlitre drop at the tip of a capillary [16,17] or placed in a drop sized aqueous sample [18,19] or held at the end of polytetrafluoroethylene rod [20] had operational characteristics and theoretical background that appeared in a much simplified manner in the technique called single-drop microextraction (SDME) which used a 1–3 μL extraction solvent drop suspended from the tip of a microsyringe needle and held in the aqueous sample [21]. Since then, SDME has found extensive acceptance and applications in a wide variety of analyses [1–3].

Single-drop microextraction customarily results in high enrichment factor due to a large ratio (V_{aq}/V_o) of the volume of aqueous sample (V_{aq}) to that of organic phase (V_o), and this technique has mostly been used in conjunction with gas chromatography [22–25], high performance liquid chromatography [26], atomic absorption spectrometry [27–29], inductively coupled plasma mass spectrometry [30] and capillary electrophoresis [31]. However, the extracted volume is so small that SDME was not amenable to conventional UV–visible spectrophotometry. Advances in array detectors, fibre optic wave guides and high speed electronics has enabled the introduction of new generations of spectrometers that use charged couple device (CCD) or photodiode arrays as replacement to photomultipliers of classical spectrometers. NanoDrop® is a new generation of fibre optic-linear array detection spectrophotometer that is equipped to accommodate sample volumes as small as 1 μL for absorbance measurement with high accuracy and reproducibility. Utilizing the principle of surface tension, it holds the test solution in place between the two ends of optical fibres giving a sample path length of 0.2 and 1 mm. So far, only a few applications of NanoDrop® microspectrophotometry have been reported. Iodide was oxidized with hydrogen peroxide and the iodine liberated in the headspace (HS) was preconcentrated in a microdrop of dimethylformamide and its absorbance measured [32]. Hydrogen sulphide liberated by acid treatment of labile sulphide was absorbed in sodium zincate drop held in the headspace, and measured by turbidimetry [33]. Recently, a combination of HS-SDME and cuvetteless microspectrophotometry has been used for the determination of trimethylamine in fish [34]. The decreased path length (1 mm) used in cuvetteless NanoDrop® microspectrophotometry diminishes the sensitivity, however, methods for circumventing this inherent problem were illustrated for a number of analytes by using suitable reaction chemistry and enrichment of measurable species by liquid phase microextraction [35]. In this work further application of NanoDrop® microspectrophotometry is demonstrated for the simple and rapid determination of chloride in a variety of matrices.

For monitoring of water quality some components of water are controlled by non-enforceable regulations as they only cause cosmetic or aesthetic effects. One of aesthetic contaminants is chloride as it imparts a salty taste to water. The concentration of chloride in water is variable, normally low for ground water than for surface water, and quite elevated in wastewaters. Flow based methods using different detection systems are the most common procedures for the determination of chloride. Reaction between mercury thiocyanate and chloride leading to the displacement of thiocyanate, and thereafter, formation of an intensely coloured Fe(III)-thiocyanate complex and its spectrophotometry [36–39] is far more popular than the other methods that use displacement of chloranilate, and its spectrophotometry, by reaction of chloride with silver chloranilate [40]; reaction with silver(I) and measurement of turbidity caused by silver chloride precipitation [41]; or ion selective electrode based on Ag/AgCl [42,43]. The silver ion based methods principally aim to avoid the use of toxic mercury thiocyanate. The multi-syringe flow injection system was also proposed to minimize the consumption of mercury thiocyanate [39]. In using both reaction chemistries, ions which can interfere are several, and include bromide, iodide, sulphide, thiocyanate, cyanide, etc.; though the concentration level of these ions may be very low in natural waters. For analysis of such samples, ion chromatography is more versatile than spectrophotometric methods [44]. The features of diverse analytical methods for chloride are presented in Table 1. The limit of detection (LOD) of spectrophotometric methods is better (range 0.2–0.5 mg L^{-1}) than of potentiometric or turbidimetric methods (range 0.4–2 mg L^{-1}). Precipitation of chloride as silver chloride, and determination after its filtration by dispersive X-ray fluorescence [45], or oxidation of chloride to chlorine, air extraction and its chemiluminescence detection by reaction with luminol [46] give LOD of 25 μg L^{-1} and 4 μg L^{-1}, respectively. However, both methods are cumbersome to perform.

NanoDrop® microspectrophotometer allowed measurement of absorbance of a few microlitres of solvent, a volume that is commonly used for SDME. Headspace SDME (HS-SDME) is an efficient variation of the technique that is based on the transfer of volatile analytes from the sample matrix into the headspace, and thence into the solvent drop held in the headspace of the sample. In the proposed method chloride was oxidized to free chlorine using potassium permanganate in sulphuric acid medium which was then extracted into an aqueous drop of starch-iodide held in the headspace to form blue coloured starch-iodine complex. Finally, absorbance of the drop was measured at 553 nm using NanoDrop® microspectrophotometer. This simple and sensitive method, LOD of 2.8 μg L^{-1}, not only utilizes preferred reagents in terms of toxicity and cost but also has freedom from a number of potentially interfering materials.

2. Experimental

2.1. Equipment

All spectrophotometric measurements were made with a NanoDrop® ND 1000 full spectrum (220–750 nm) spectrophotometer (NanoDrop Technologies, Wilmington, DE, USA). It utilized surface tension of liquid sample to hold it in place between the two ends of optical fibres. This eliminated the need for cuvettes or other sample containment devices and allowed clean up by wiping. For absorbance measurement, a 1 μL sample was placed on to the one end of a fibre optic cable (the receiving fibre) and the second fibre optic cable (source fibre) was then brought into contact with liquid sample causing the liquid to bridge the gap between the two ends of optical fibres. The gap was controlled to both 1 mm and

[a] FI, flow injection; MSFI, multi-syringe flow injection; CFI, commuted flow injection; SI, sequential injection; EDXRF, energy dispersive X-ray fluorescence; HS-SDME, headspace single-drop microextraction; and ND, NanoDrop® microspectrophotometry.

0.2 mm paths, the former was used for absorbance measurement in the present work. The light source was a pulsed Xenon flash lamp, and the spectrophotometer utilized a 2048-element linear silicon CCD array detector to analyze the light after passing through the sample. The instrument was controlled by a software run from a PC.

Four millilitres vials, sealed by screw cap with PTFE-faced silicon septum (Supelco, New Delhi, India), were used for all HS-SDME measurements. A 10 μL Hamilton microsyringe (Supelco, New Delhi, India) with bevel tip was used for SDME. Thermostated magnetic heating plate (Kumars Equipments, Mumbai, India) was used for heating.

2.2. Reagents and samples

All aqueous solutions were prepared in HPLC grade water (Millipore-India, Mumbai, India). Potassium permanganate (Reanal, Hungary), 1 g was dissolved in 50 mL of HPLC grade water and mixed with 25 mL of 9 mol L^{-1} sulphuric acid. This solution was purged with nitrogen at the flow rate of 5 mL min^{-1} for 10 min to remove any chlorine that is formed from trace chloride impurity in the reagent, and finally diluted to 100 mL with HPLC grade water. Aqueous starch-iodide reagent was prepared freshly by dissolving 10 mg of potassium iodide (Qualigens, Mumbai, India) in 10 mL of 0.5% starch solution. Chloride solution, 1 g L^{-1} Cl was prepared by dissolving 210.0 mg of analytical reagent grade potassium chloride (Qualigens, Mumbai, India) in 100 ml of HPLC grade water. Less concentrated solutions were made by sequential dilution with water. All reagents and standards were kept refrigerated when not in use.

River water samples (the Ganga river, Kolkata, West Bengal, India; and the Narmada river, Jabalpur, Madhya Pradesh, India); Jabalpur city tap water; a Jabalpur city lake water were collected in amber glass bottles with polypropylene screw caps having PTFE septum. Commercial table salt and cement samples were purchased from local market. All aqueous samples were centrifuged (4000 rpm) to remove particulate matter, and stored at 4 °C before analysis. Solid samples were used without any treatment.

2.3. Determination of chloride

A 10 μL – 1 mL portion of sample solution containing 25 μg – 4 mg L^{-1} of chloride was placed in a 4 mL vial and capped. All subsequent additions were made by microsyringe through the septum in the vial cap. A 200 μL portion of potassium permanganate reagent solution, 500 μL of 9 mol L^{-1} sulphuric acid were added, and the total volume was made up to 2 mL by adding HPLC water. The reaction mixture was placed on a hot plate pre-heated to 50 °C (±5 °C). The needle of a 10 μL Hamilton syringe, containing 2 μL of starch-iodide reagent, was penetrated through the septum of the vial until the tip protruded 1 cm above the meniscus of the solution. The plunger was depressed to form a drop of the reagent at the tip which was then kept exposed in the headspace. After 15 min, the plunger was retracted back into the syringe, moved twice back and forth for uniform mixing of liquid, and the coloured drop was immediately transferred to the lower pedestal of the NanoDrop® spectrophotometer for absorbance measurement at 553 nm against the reagent blank. All steps of procedure are illustrated in Fig. 1.

3. Results and discussion

The basis of headspace in-drop reaction and NanoDrop® spectrophotometry for the determination of chloride was a set of oxidation reactions; first, the oxidation of chloride by potassium

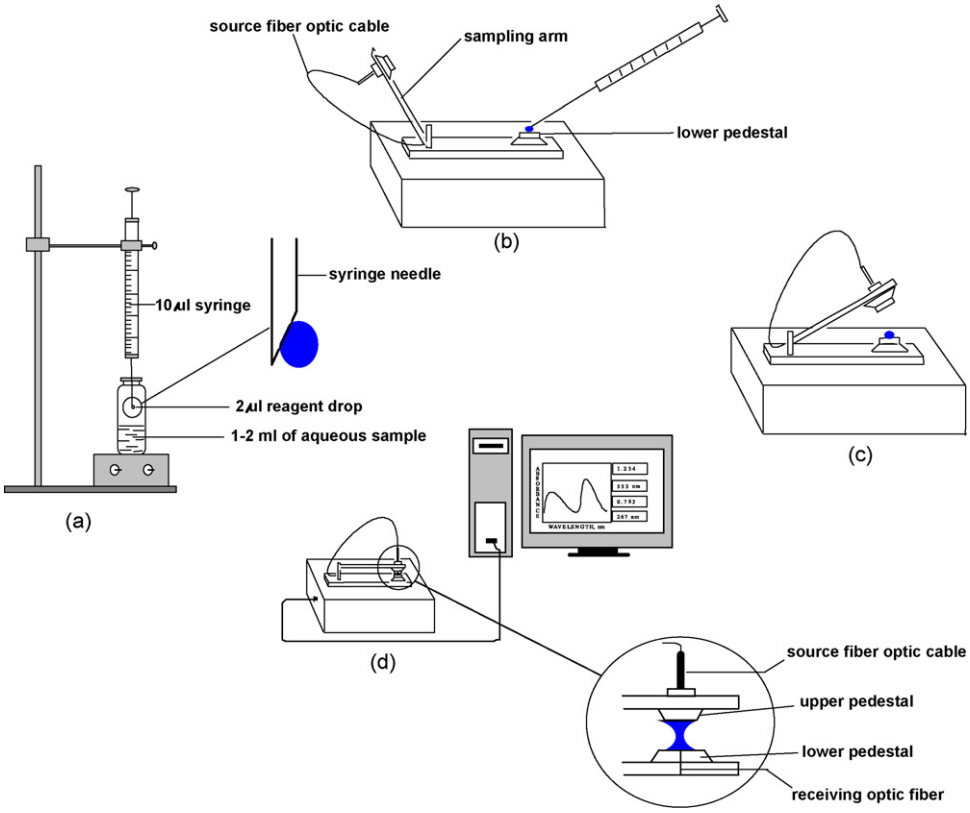

Fig. 1. Schematic representation of different steps involved in the determination of chloride by headspace in-drop extraction/reaction and absorbance measurement by NanoDrop® spectrophotometer. (a) Headspace single-drop microextraction and reaction of chlorine, showing 2 μL aqueous drop of starch-iodide suspended at the tip of a 10 μL microsyringe needle; (b) placement of drop on to the lower pedestal; (c) closing the sampling arm; and (d) spectral measurement using the operating software on the PC.

permanganate in sulphuric acid medium to form chlorine which was later released into the headspace of the reaction mixture, and secondly, oxidation of iodide to iodine by chlorine in the starch-iodide reagent drop held in the headspace. Immediately the drop acquired a blue colour due to the formation of starch-iodine complex. The uniformity of retracted extraction phase, that occurs due to parabolic flow profile, be ascertained by once or twice repeating drop formation and retraction. Headspace sampling has been found to have the benefit of preconcentration of measurable coloured species in the reagent drop, and freedom from interference of involatile oxidizing agents that happened to be present in the environmental and salt samples.

3.1. The oxidizing agent

The standard reduction potential (E°) [47] of chlorine-chloride system is 1.36 V, and many oxidizing agents (E° given in parentheses) that could be used in acid medium to oxidize chloride include peroxydisulphate (2.01 V), hydrogen peroxide (1.77 V), cerium(IV) (1.61 V) and permanganate (1.51 V). The higher reduction potential of peroxydisulphate may partly release chlorine from organo-chlorine compounds [48]. Hydrogen peroxide on heating was found to oxidize iodide in headspace reagent drop. Permanganate is a versatile and eco-friendly oxidizing agent [49,50]. A little higher reduction potential over chlorine-chloride system, non-volatility and ability to oxidize a large number of substances to give products which do not interfere in the present method made permanganate a reagent of choice for chloride oxidation.

To optimize the volume of the reagent, the variation in absorbance for the blue starch-iodine complex versus the volume of potassium permanganate was investigated. The absorbance reached optimum when the overall concentration of permanganate was 3.16 mmol L^{-1} in the reaction mixture, and then remained unaffected on further addition of reagent (Fig. 2). In the optimized method 0.2 mL of 63.2 mmol L^{-1} (1%) permanganate was used for 2 mL of reaction mixture giving 6.32 mmol L^{-1} of reagent concentration.

3.2. The headspace drop reagent

For the spectrophotometric detection of chlorine the three recommended standard methods are based on the oxidation of *N*,*N*-diethyl-*p*-phenylenediamine (also named as 4-*N*,*N*-diethylaminoaniline) (DPD), leuco crystal violet, and syringaldazine [51]. The stability of the coloured product of DPD was poor, the fading commencing almost immediately unless an excess of

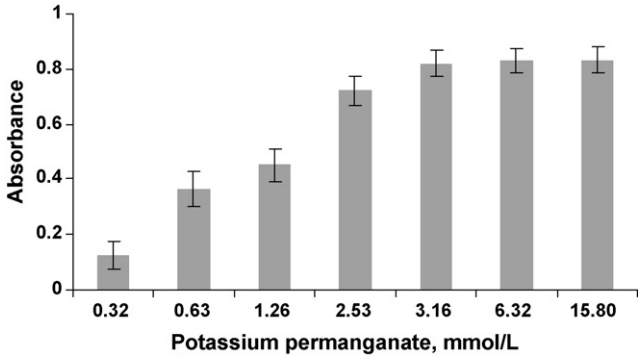

Fig. 2. Effect of permanganate concentration in the determination of 1.25 mg L^{-1} chloride. Other conditions include 0.2 mL of 9 mol L^{-1} sulphuric acid, reaction temperature 50 °C, equilibrium time 15 min, and 2 μL aqueous drop containing 6.0 mmol L^{-1} iodide in 0.5% starch. Absorbance measurement at 553 nm. The results are averages of 5 determinations. Error bars denote the standard error values.

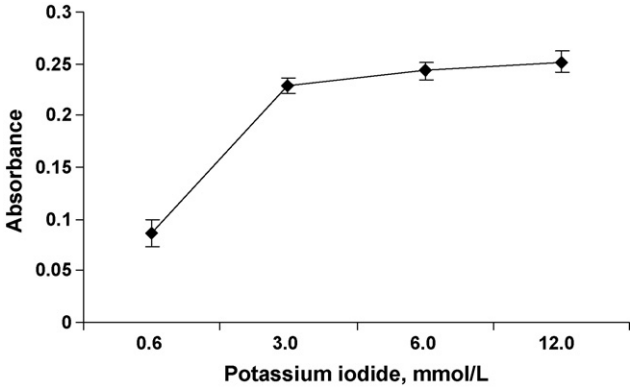

Fig. 3. Effect of iodide concentration in the headspace extraction/reaction drop in the determination of 0.125 mg L^{-1} chloride. Other conditions include 0.2 mL of 63.2 mmol L^{-1} permanganate, 0.2 mL of 9 mol L^{-1} sulphuric acid, reaction temperature 50 °C, equilibrium time 15 min, and 2 μL aqueous drop containing different concentrations of iodide in 0.5% starch. Absorbance measurement at 553 nm. The results are averages of 5 determinations. Error bars denote the standard error values.

reagent is used [52]. Other methods were found to be unsuitable since the coloured products were extremely unstable [53]. The other reagents which have been used are 4-nitrophenylhydrazine [54] or phenylhydrazine-4-sulphonic acid [55] together with *N*-(1-naphthyl)ethylenediamine dihydrochloride; *o*-dianisidine and *o*-tolidine [56]. However, the use of these reagents is restricted due to their carcinogenic nature. Aqueous starch-iodide reagent was selected in this work as it was eco-friendly and cost effective, and produced stable starch-iodine blue complex.

There were two equilibria in operation involving partitioning of chlorine. First, transfer of chlorine from aqueous sample to the headspace and, second, from headspace to aqueous drop. For the favourable position of first equilibrium, high temperature and excess of permanganate oxidized any traces of chloride to release molecular chlorine into the headspace. In the second equilibrium, the driving force for transfer of molecular chlorine from headspace to aqueous reagent was oxidation reaction giving tri-iodide anion and then starch-iodine complex within the drop. The concentration of iodide was very important parameter in the development of starch-iodine blue colour. A range of iodide concentrations from 0.60–30.0 mmol L^{-1} in 0.5% starch solution were studied. The absorbance increased till 6.0 mmol L^{-1} of potassium iodide was used and thereafter practically remained unaffected (Fig. 3). On increasing the iodide concentration beyond 12 mmol L^{-1}, the colour of the starch-iodine complex changed from blue to bluish brown, and some brownish precipitate appeared in the drop which impaired the analysis. Starch concentration did not play crucial role, and it was convenient to use its 0.5% aqueous solution. Thus, a 6.0 mmol L^{-1} (0.1%) iodide in 0.5% starch was used as reagent in subsequent studies.

3.3. Optimization of conditions

Since the extraction of analytes in headspace SDME is based on an equilibrium distribution process, the amount of analyte extracted at a given time depends on the mass transfer of the analytes from the headspace to the single-drop of extractant. One of the most important criteria of choosing the solvent for headspace extraction while heating is that the solvent drop must not evaporate during the process. Moreover, NanoDrop® spectrophotometer, which is based on the surface tension of the drop [57], imposes certain restrictions on the solvent that can be used for absorbance measurement. Solvent should be viscous enough so that it does not flow out of the pedestal, and should not be too volatile as to evaporate before measurement is completed. Hence, there should be a fair

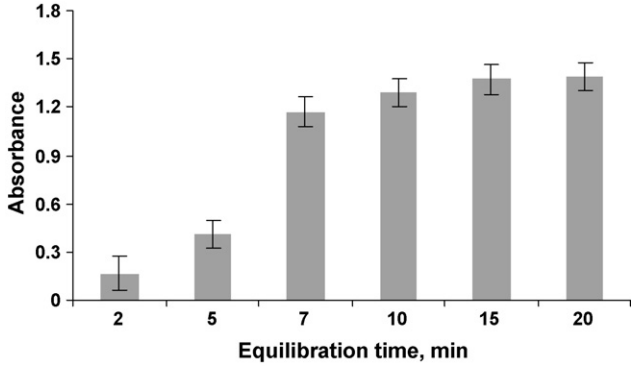

Fig. 4. Effect of equilibrium time for the extraction/reaction efficiency in the determination of 2.5 mg L^{-1} chloride. Other conditions include 0.2 mL of 63.2 mmol L^{-1} permanganate, 0.2 mL of 9 mol L^{-1} sulphuric acid, reaction temperature 50 °C, and 2 μL aqueous drop containing 6.0 mmol L^{-1} iodide in 0.5% starch. Absorbance measurement at 553 nm. The results are averages of 5 determinations. Error bars denote the standard error values.

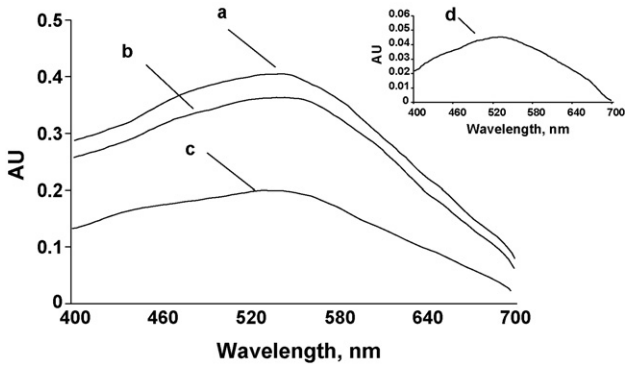

Fig. 6. Effect of drop volume in the determination of 0.25 mg L^{-1} chloride; (a) 3 μL drop (absorbance 0.401), (b) 2 μL drop (absorbance 0.373), and (c) 1 μL drop (absorbance 0.194). (d) Absorption spectrum for 0.025 mg L^{-1} chloride; 2 μL drop (absorbance 0.042). Other conditions include 0.2 mL of 63.2 mmol L^{-1} permanganate, 0.2 mL of 9 mol L^{-1} sulphuric acid, reaction temperature 50 °C, equilibrium time 15 min, and aqueous drop containing 6.0 mmol L^{-1} iodide in 0.5% starch. Absorbance measurement at 553 nm.

compromise in solvent selection for SDME and cuvetteless spectrophotometry. Water was indeed a good choice in present system as a medium for headspace extraction of chlorine, and its in-drop reaction with iodide leading to the formation of blue complex with starch.

The microdrop was kept exposed in the headspace of the reaction mixture for 2–20 min. A graph of extraction time versus absorbance of starch-iodine complex is shown in Fig. 4, which showed that the absorbance levelled at 15 min. Hence, 15 min was selected as the optimal extraction–complexation period.

For headspace SDME, the effect of sample temperature in range 30–90 °C was investigated. As shown in Fig. 5, the absorbance for the product was found dependent on the temperature. Generally, increasing the temperature would increase diffusion coefficient, so the vapour pressure and the concentration of analyte in the headspace increase [58]. As a result, the mass transfer of the analytes into the microdrop was also improved, and the equilibrium time would be shorter [59]. But, on increasing the temperature above 50 °C, the absorbance decreased significantly. Absorption of analytes in the microdrop is an exothermic process [60]. Thus, the depressive effect at higher temperature was due to decreased partition in the heated microdrop. All later experiments were conducted at 50 °C.

The effect of microdrop volume was investigated in the range 1–3 μL. The absorbance for the starch-iodine blue complex increased significantly with increase in the drop volume (Fig. 6) but drop bigger than 2 μL was more often prone to fall. Thus, the reagent drop of 2 μL was used.

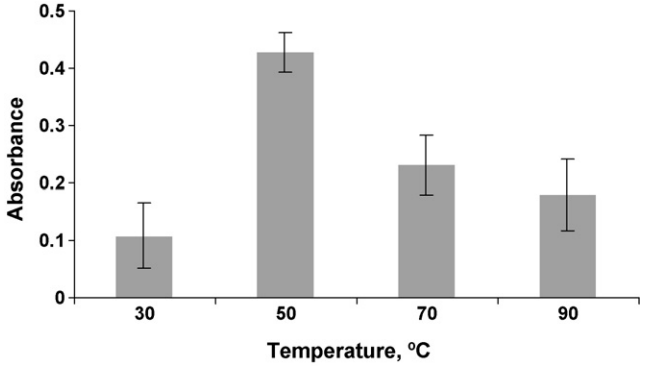

Fig. 5. Effect of reaction temperature in the determination of 0.5 mg L^{-1} chloride. Other conditions include 0.2 mL of 63.2 mmol L^{-1} permanganate, 0.2 mL of 9 mol L^{-1} sulphuric acid, equilibrium time 15 min, and 2 μL aqueous drop containing 6.0 mmol L^{-1} iodide in 0.5% starch. Absorbance measurement at 553 nm. The results are averages of 5 determinations. Error bars denote the standard error values.

Equilibrium between the aqueous and vapour phases can be achieved more rapidly by stirring the aqueous sample. For studying this effect, the aqueous reaction mixture was continuously agitated at 50 °C with stirring rates in range 200–500 rpm but this produced no significant increment in absorbance. Since the system without stirring was found to have adequate sensitivity, no attempts were made at higher stirring rate. All subsequent experiments were performed without stirring.

3.4. The interferences

In order to investigate the selectivity of the proposed method, the effect of diverse anions that are usually present in environmental aqueous samples was studied. The interferences were examined on 0.1 mg L^{-1} chloride standard spiked with 1–3 mg L^{-1} of each interferences. There was no influence of ions such as sulphate, nitrate, phosphate, iodate, bromate, chlorate, chromate, calcium(II), mercury(II), copper(II), iron(II) and nickel(II). Silver(I) precipitated with chloride and interfered. Lead(II) and thallium(I) also precipitated chloride, however, lead chloride was soluble at the reaction temperature (50 °C), and thallium(I) chloride was oxidized by permanganate in acidic medium to thallium(III) and chlorine. The tested reducing anions were iodide, bromide, thiocyanate, nitrite, sulphite, thiosulphate and sulphide. Except bromide, which produced a positive error, no other anion showed any interference. It was important to use excess of permanganate so that enough reagent was left for chloride oxidation. This was visually indicated by appreciable decolourization of the purple colour of permanganate. A 5% permanganate could be used for samples with high content of reducing ions.

Though iodide was smoothly oxidized to iodic acid (E° for iodic acid-iodine system, 1.20 V), bromide was oxidized mainly to bromine since oxidation to bromic acid was difficult using permanganate (E° for bromine–bromide system, 1.06 V; and for bromic acid-bromine system, 1.52 V). Bromine thus formed also behaved similar to chlorine in the present method. The only way to avoid the interference of bromide was to scavenge bromine by acetanilide, which showed rapid bromination reaction to form 4-bromoacetanilide [61], and had practically no reaction with permanganate in the present method. Chlorination of acetanilide was observed to be too slow in acidic medium. A 50 mg L^{-1} acetanilide was used along with other reagents for chloride determination in the presence of bromide.

Table 2
Determination of chloride in water samples.

Sample	Chloride found[a], mg L^{-1}	RSD (%)	Recovery[b] (%) at spiking level			
			1 mg L^{-1}	RSD (%)	2 mgL^{-1}	RSD (%)

[d] Chloride oxidation in the presence of 50 mg L^{-1} acetanilide.

3.5. Method validation

A rectilinear calibration graph was obtained for 0.025–4 mg L^{-1} of chloride, the correlation coefficient and limit of detection (LOD) were respectively 0.998 and 2.8 μg L^{-1}. The regression equation found was, $A = 0.6464C + 0.0673$, where A = absorbance, and C = concentration (mg L^{-1}) of chloride. The RSD in six replicate analyses of 0.025, 1.25 and 4 mg L^{-1} of chloride by the present method was 3.8%, 2.1% and 4.9%, respectively.

In order to investigate the applicability of the present method to real samples, chloride was determined in river, lake and tap waters (Table 2), inorganic compounds and cement (Table 3). Standard addition method was used to validate the method. In the analysis of spiked water samples, an average recovery of 95.4% (range 92–98%) was obtained with the average RSD of 3.8% (range 2.9–5.2%). An average recovery of 94.5% (range 82–106%) was obtained with the average RSD of 4.1% (range 2.3–5.8%) in the analysis of spiked inorganic compounds and cement.

The present method has distinct advantages over many of those reported in literature (Table 1) in terms of simplicity, sensitivity and selectivity. Methods based on mercury(II) thiocyanate [38,39], silver chloranilate [40] and silver chloride precipitation [41,45] are interfered by a number of anions. Some methods, such as based on energy dispersive X-ray fluorescence [45], make use of specialized instrumentation.

4. Conclusions

The proposed method for the determination of chloride is simple, sensitive, selective, eco-friendly and cost effective. The inherent drawbacks of low sensitivity of NanoDrop® spectrophotometry using cuvetteless 1 mm sample path length has been

avoided by headspace SDME leading to the enrichment of measurable species starch-iodine blue complex. The method requires low reagent consumption and produces minimal waste. Comparison of features of merit suggests that the proposed method has better sensitivity than conventional spectrophotometry, and flow injection analysis, and has less sensitivity to interferences.

Acknowledgements

The authors are very much thankful to reviewers for their kind suggestions to improve the manuscript. Thanks are due to the University Grants Commission, New Delhi, for financial support to this work.

Thermal oxidation

ABSTRACT

The aim of present study was to develop a simple method on UV spectrometer for the determination of peroxide value (PV) of the frying oil. The basis of the PV determination was the stoichiometric reaction of triphenylphosphine (TPP) with the hydroperoxides present in frying oil to produce triphenylphosphine oxide (TPPO), which exhibits a readily measurable absorption band at 240 nm by ultraviolet region. The PV ranged between 0.15 and 11.66 meq. of active oxygen per kilogram of oil as the canola oil was heated from 0 to 12 h in the fryer at 180 °C. The proposed method was correlated with official AOCS titration method and best correlation coefficient (R^2 = 0.99525) was achieved, proving that there is no significant difference in the results. Therefore, developed method could serve as an alternative to the titration method, for the determination of PV in frying oils.

1. Introduction

Basically frying is a cooking method in which food is submerged in hot oil. During frying thermo-oxidative or lipid oxidation and hydrolytic reactions take place that results in deterioration of the frying oil [1–3]. The primary oxidation products that develop in triacylglycerols are hydroperoxides, which may later break down to produce lower molecular weight compounds, such as free fatty acids, alcohols, aldehydes, and ketones, eventually leading to rancid product [4]. Lipid oxidation is a main deteriorative process which has an important implication in stipulations of the quality and value of fats and oils, particularly in relation to the off-flavors that develop as an outcome of autoxidation [5]. The level of hydroperoxides is commonly determined by using well-established standard AOCS iodometric procedure [6], and the resulting peroxide value (PV) is expressed as milliequivalents (meq.) of peroxide oxygen per kilogram of oil. Besides the sensitivity and reproducibility, the titrimetric methods are laborious and need a lot of chemicals and solvents, hence are associated with environmental issues. In the literature some other methods have been reported for PV determination that were based on both direct and indirect measurement of hydroperoxides by spectrophotometery [7,8] and infrared spectroscopy [9,10,11,5]. The common spectrophotometric method is very complex and involves numerous steps with the use of several chemicals and reagents [12]. Subsequently, a very useful and more accurate method was developed by Xiuzhu Yu et al. [5] on FT-IR spectroscopy using an established stoichiometric reaction of triphenylphosphine (TPP) with hydroperoxides developed in oil to form triphenylphosphine oxide (TPPO). Our present work was focused on to develop an effective UV spectrometric method based on a stoichiometric reaction involving hydroperoxides. According to well-recognized reaction (Fig. 1), hydroperoxides present in the oil react stoichiometrically with TPP to form TPPO and their respective alcohols.

2. Experimental

2.1. Reagents, standards and samples

All chemicals and reagents used were of analytical grade. Chloroform was purchased from Fischer scientific UK Ltd. Triphenylphosphine (TPP), Triphenylphosphine oxide (TPPO), potassium iodide, sodium thiosulphate and acetic acid were obtained from Sigma–Aldrich Chemie GmbH (Buchs, Germany). The concentrated stock solution for working standards was prepared by dissolving TPPO in the chloroform (40%). Fresh refined, bleached and deodorized canola oil was obtained from the local edible oil industry in Karachi, Pakistan.

2.2. Determination of peroxide value

Peroxide value, expressed in milliequivalents of active oxygen per kilogram of oil (meq./kg), was determined by standard procedure by a mixture of oil and chloroform/acetic acid which was

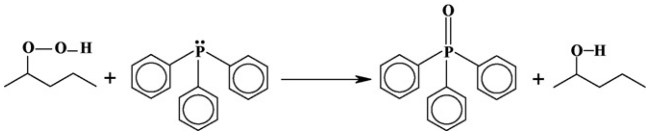

Fig. 1. Reaction of hydroperoxides with triphenylphosphine (TPP) to form triphenylphosphine oxide (TPPO) and alcohol.

left to react with a solution of potassium iodide in darkness; and then free iodine was titrated with a sodium thiosulfate solution [13].

2.3. Standard and sample preparation

Stock solutions (0.7 g) of TPPO (40% in chloroform) were mixed into 100 g of zero-PV canola oil to produce base oils which contained 50 PV equivalents of TPPO [9]. Calibration standards ranging from 0.5 to 50 PV were then prepared by gravimetrically mixing various amounts of stock oils of 30 PV in the chloroform. Just for 30 s, all the standard solutions were heated in the microwave oven to dissolve the TPPO completely. Furthermore, the PV values of standards were also confirmed by standard AOCS titration method. Similarly the preparation of oil samples involved the mixing of thermally oxidized canola oil (0.7 g) with TPP (40% in chloroform) in stoppered Erlenmeyer flask and kept in microwave oven for 30 s to complete reaction of peroxide of oil with TPP to form TPPO.

2.4. Instrumentation

2.4.1. UV–visible spectrophotometer

UV–vis spectra were recorded the respective absorbance value at specific wavelength on a PerkinElmer Lambda 35 UV/visible spectrophotometer, using standard 1.00 cm quartz cells.

2.4.2. Domestic microwave oven

A domestic microwave oven, Pell-PM 023 (Japan) with power settings range from 100 to 900 W was used in the present study. All standards of TPPO in canola oil and chloroform as well as samples with TPP in chloroform containing glass vial were subjected to full power (900 W) of microwave irradiation. After 30 s microwave heating the vial was taken out and shaken vigorously to cool. Then the UV spectra of each standard and sample were taken.

2.4.3. Heating procedure

The west point deep fryer (E-2016) was used for carrying out the thermal oxidation of canola oil at frying temperature. The capacity of fryer was 3 L with thermostatic temperature control up to 180 °C. 2 L pure canola oil was initially heated to about 180 °C, then kept at constant frying temperature i.e. 180 °C for 12 h. After each hour heating interval, about 10 mL of the heated canola oil was filtered into a screw cap vial and stored at 4 °C until analysis. The volume of oil was not refilled during the heating process.

2.4.4. Calculations and statistical analyses

Each standard and sample was analyzed twice. The data obtained were put into OriginPro 7.5 program and reported as mean ($n = 1 \times 2 \pm$ SD).

3. Result and discussion

3.1. General spectroscopy

The UV spectral characteristics of TPPO in canola oil at various concentrations were investigated by adding the TPPO to zero-PV canola oil. The recorded UV spectra of the standards for the calibration with 0, 0.5, 1, 2, 4, 6, 8, 10, 15, 20, 25, 30, 35, 40, 45 and 50 PV are shown in Fig. 2. Sophisticated chemometric technique i.e. PLS was used to achieve the regression equation for the quantification of PV in the thermally oxidized canola oil.

3.2. PLS calibration

A PLS calibration model was developed to predict PV based on the quantitation of TPPO using the absorbance at 240 nm. Excellent correlation coefficient of 0.99885 was achieved which proves the good accuracy of proposed method as shown in Fig. 3. Following regression equation was achieved from the plot of various PV of the standards versus UV absorbance at 240 nm (Fig. 3) by using OriginPro 7.5 program to predict the unknown PV in thermally oxidized canola oil.

$$Y = 0.03193 + 0.01385X$$

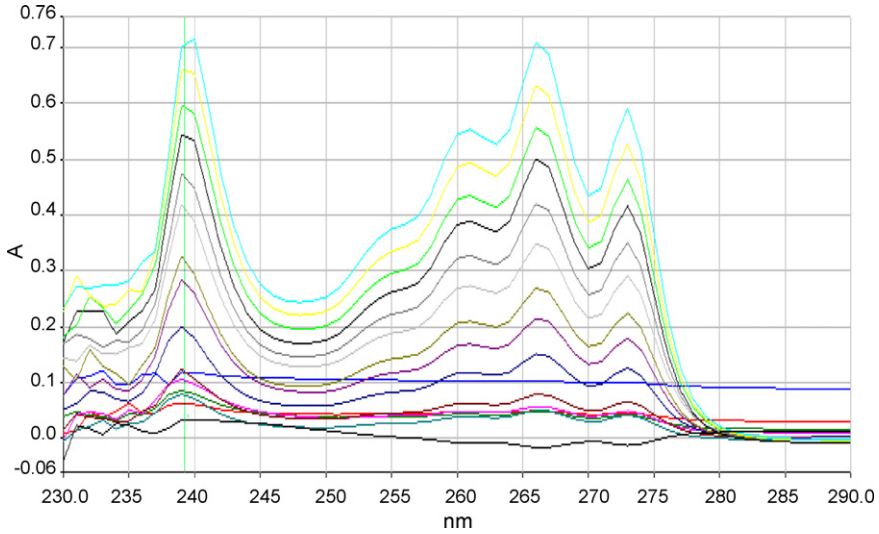

Fig. 2. Spectra showed the calibration range of TPPO concentration in canola oil vs absorbance for PV from 0, 1, 2, 4, 10, 15, 20, 25, 30, 35, 40, 45 and 50 PV.

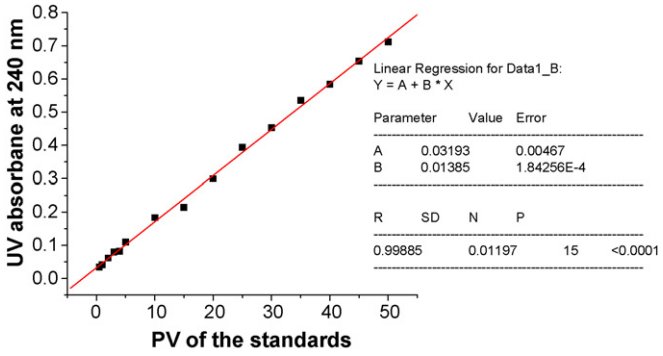

Fig. 3. Plot illustrating the various concentrations of TPPO calibration standards versus UV absorbance at 240 nm in the partial least squares calibration standards.

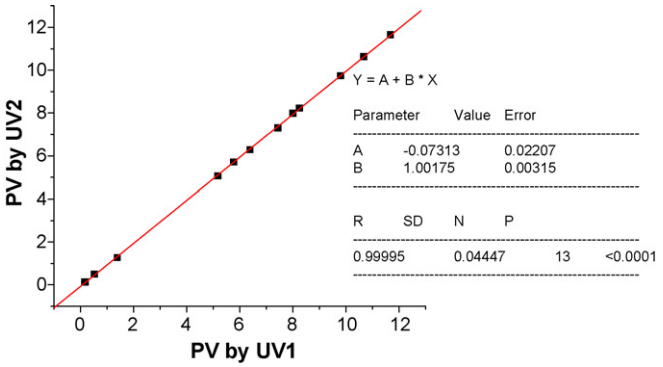

Fig. 6. Plot of PV data obtained from duplicate analysis by UV method.

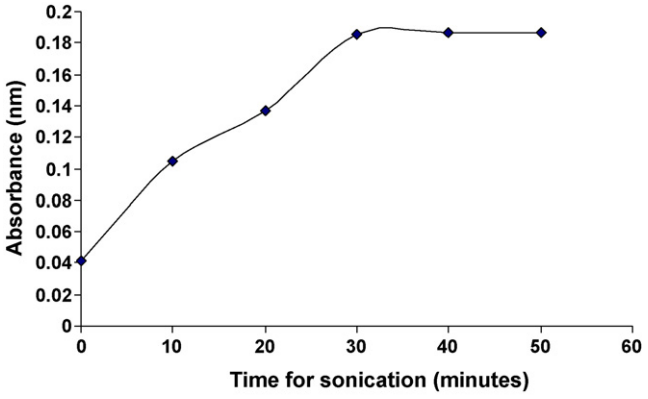

Fig. 4. Response of absorbance on reaction stability of TPP and oil at different sonication time.

3.3. Reaction stability of TPP and hydroperoxide of oil to form TPPO

The reaction stability between TPP and hydroperoxide in oil to form TPPO is very important for accurate determination of the PV content in thermally oxidized canola oil. The reaction was carried out by different methods such as ultrasonic waves, microwaves, hand shaking and electrical shaking on 12 h thermally oxidized canola oil samples. Each method was performed at different time intervals, to get the maximum response by conversion of TPP to TPPO in oil, each method has its own significance, but interestingly the only method that gave good results was the microwaves method through which we get the excellent response i.e. maximum UV absorbance with in only 30 s. As the sonication time increased the reaction between TPP and oil also increased, but it reached to plateau after 30 min as shown in Fig. 4. As there was no any significant change after 30 min reaction time, this time was considered for the complete reaction between the oil and TPP. Hand shaking and electrical shaking gave poor results as compared to ultrasonic and microwave method to determine the response of absorbance on reaction stability of TPPO. Therefore, domestic microwave oven was selected for all other samples due to quick reaction (30 s) and save enough time.

3.4. Validation

The PLS calibration model was validated by analyzing a series of thermally oxidized canola samples obtained after each hour heating from 0 to 12 h. 0.7 g of TPP was added to each sample and kept for 30 s in domestic microwave oven for a complete reaction between TPP and hydroperoxide of canola oil to form TPPO. UV spectra of

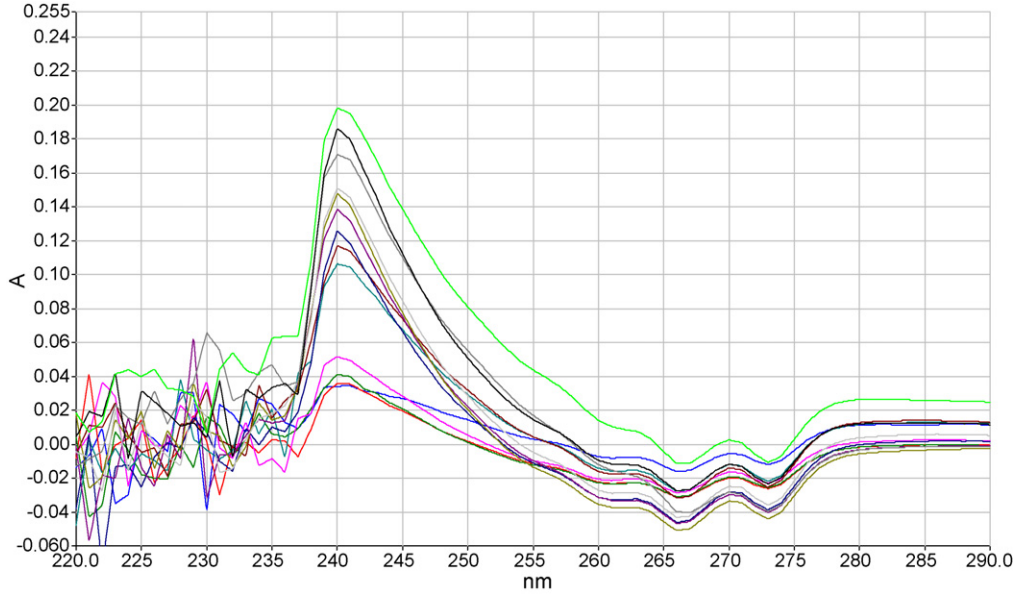

Fig. 5. UV spectra of the sample from 0 to 12 h thermally oxidized canola oil.

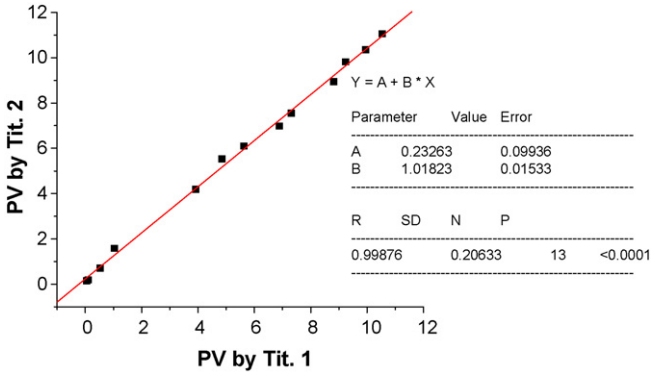

Fig. 7. Plot of PV data obtained from duplicate analysis by titration method.

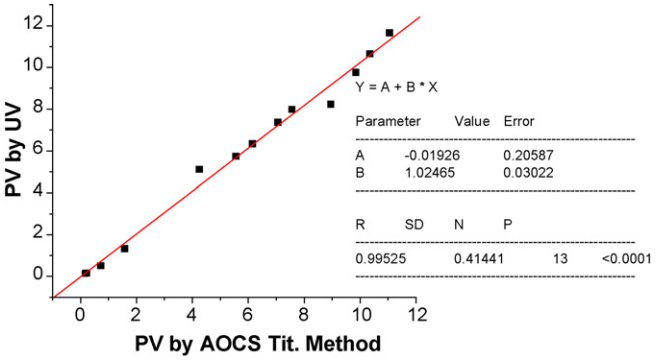

Fig. 8. Plot of mean UV-predicted PV versus mean titration PV values.

samples were recorded. The UV spectra of the sample (0–12 h) are shown in Fig. 5.

Duplicate analyses were performed and the mean difference for reproducibility (MD*r*) and the SD of the differences (SDD*r*) for the UV duplicate predictions were 0.06 PV and ± 0.04 PV units, respectively as shown in Fig. 6. These validation samples were also chemically analyzed by the AOCS PV method (Cd 86-90) (1).

A careful assessment of duplicate analyses by the AOCS chemical method indicated that the reproducibility of the chemical method was good but comparatively less from the proposed UV method, producing a mean difference for reproducibility (MD*r*) of 0.33 PV and SDD*r* of ± 0.21 PV. A plot of the duplicates against each other (Fig. 7) was linear ($r = 0.9986$), had a slope close to 1 (1.01823) and intercept close to zero (0.23263 PV).

Fig. 8 illustrates the validation plot of the mean UV-predicted PV values versus their mean AOCS titration PV values. The linear regression equation for the plot was $Y = A + BX$, with a correlation coefficient of 0.99525. The mean difference for accuracy (MD*a*) and the SD of the differences (SDD*a*) for the UV duplicate predictions were −0.12 PV and ± 0.41 PV units, respectively. The data of study clearly indicate that one can routinely reproduce PV results within SD ±0.50.

Although standard AOCS titration method is quite simple and reproducible but proved to be relatively insensitive at lower PV values as compare to UV method. Table 1 presents comparative results of mean PV values obtained from duplicate analyses by the AOCS titrimetric and UV method. No significant variation was observed in the results of PV values for all analyzed samples. The following equation deduced from the Fig. 8 could be used to match PV values

Table 1
Peroxide value (meq. of O_2/kg oil) obtained from duplicate analysis of a fresh and 12 thermally oxidized canola oil samples by spectrometer and titration and methods.

of UV and standard AOCS titration method.

$$\mathrm{PV(UV)} = -0.01926 + 1.02465 \times \mathrm{PVAOCS},$$

$$R = 0.99525; \quad \mathrm{SD} = 0.41$$

4. Conclusion

Due to a simple and rapid stiochometric reaction and excellent association to the AOCS titration method, the UV method could provide a simple and alternative means of measuring PV values in the edible oils. Also the instrumental method could provide UV spectra as a solid document for the PV results in contrast to AOCS titration method. The UV method has a major advancement over titration method in terms of reducing solvent and reagent, which not only cuts the cost but also avoids disposal and environmental problems associated with the toxic chemicals. Furthermore, the proposed UV method would reduce labor requirements in routine quality control analysis of edible fats and oils.

Acknowledgments

The authors would like to thank the management of Shujabad Agro Industries (Pvt.) Limited, Karachi, Pakistan for providing the oil samples and the National Centre of Excellence in Analytical Chemistry, University of Sindh, Jamshoro, Pakistan for the financial support to carry out this research work.

Silver(I)

ABSTRACT

A 4-(2-pyridylazo)-resorcinol (PAR)-modified carbon ceramic electrode (CCE) prepared by the sol–gel technique has been reported for the first time in this paper. By immersing the CCE in aqueous solution of PAR (0.001 mol L^{-1}), after a short period of time, a thin film of PAR was rapidly formed on the surface of the electrode due to its strong adsorption properties. A differential pulse anodic stripping voltammetric (DPASV) method was developed for determination of Ag(I) at the modified carbon ceramic electrode. The analysis procedure consisted of an open circuit accumulation step in a sample solution which was continuously stirred for 12 min. This was followed by replacing the medium with a clean solution where the accumulated Ag(I) was reduced for 15 s in −0.6 V. Then, the potential was scanned from −0.2 to +0.2 V to obtain the voltammetric peak. The detection limit of silver(I) was 0.123 μg L^{-1}, and for seven successive determinations of 10, 100 and 200 μg L^{-1} Ag(I), the relative standard deviations were 2.1, 1.4 and 1.03%, respectively. The calibration curve was linear for 0.5–300 μg L^{-1} silver(I). The procedure was applied to determine silver(I) in X-ray photographic films and super-alloy samples.

1. Introduction

Silver is a metal of commercial importance for use in high-strength and corrosion resistance alloys, and jewellery. For example, because of the marked antibacterial properties of silver, its compounds and alloys have been widely used in dental and pharmaceutical preparations, and in implanted prosthesis. In addition, for the increase in the use of highly pure materials [1–3], and as silver has enough potential to become a highly pure metal, it is one the most widely used metals in electronic devices. Also, it is extensively utilized in the photographic and imaging industry. Considering the wide use of silver, it can be discharged in to the environment from its industrial applications, and this may cause the aquatic and terrestrial organisms to be exposed to silver. The toxicity of silver ranges between several orders of magnitude depending on the silver forms. While the ionic form of silver has been shown to be toxic to a variety of aquatic organisms, the forms of silver other than ionic silver are significantly less toxic [4]. With due attention to the above, silver(I) determination in industrial and environmental samples is very important.

Several analytical techniques including flame atomic absorption spectrometry [5,6], spectrophotometry [7–9], ion chromatography [10], colorimetric solid-phase extraction [11] and discontinuous flow analysis (DFA) [12] were applied for the determination of silver(I) ion in food, water and real samples.

The above techniques, which are commonly used for trace measurement of silver(I) ion in laboratories, are not suitable for in situ testing and monitoring. Electrochemical methods are the most favorable techniques to determine metal ions due to their low cost, high sensitivity, easy operation and the ability to carry out speciation analysis.

A group of ion-selective electrodes have been used for Ag^+ measurements based on different ionophores including tetrakis (4-*n*-dodecylphenyl) porphyrin [13], 2,6-bis-methylsulfanyl-[1,3,5]-thiadiazine-4-thione [14], hexathia-18-crown-6 [15], *p*-*tert*butylcalix[4]arene derivatives [16], octahydroxy-calix[4]arene derivative [17] and trialkyl phosphorothioates [18].

These ion-selective electrodes are not sensitive enough for direct determination of trace amounts of silver. Stripping voltammetric analysis is one of the most sensitive methods to determine ion metals [19]. A number of articles discuss the determination of silver by stripping analysis at modified carbon paste electrodes. There are carbon paste electrodes modified by alizarin violet [20], Dowex 50 W-12 [21], EDTA [22], S_2O_2-donor dopant [23], vermiculite clay mineral [24], keratin [25], 2,3-dicyano-1,4-naphthoquinone (CYNQ) [26], 2-mercaptoimidazole [27], *N*,*N*-diphenyl oxamide [28], zeolites [29] and *N*-benzoyl-*N*,*N*-di-butylthiourea [30].

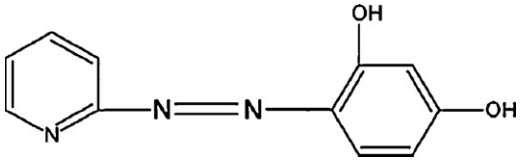

Fig. 1. Molecular structure of 4-(2-pyridylazo)-resorcinol (PAR).

In recent years, modification methods by adsorption have attracted considerable amount of attention because of their unique advantages such as surface renewal, easier preparation, low cost and high stability.

Sol–gel technology involves the fabrication of a material through the low temperature hydrolysis of a suitable monomeric precursor, followed by condensation and polycondensation to yield a polymeric oxo-bridged SiO_2 network. In 1994, Lev et al. [31] introduced the sol–gel derived carbon ceramic electrodes (CCEs) which are comprised of dispersion of carbon powder into the starting sol–gel solution. And, this new kind of electrode had been largely utilized to design electrochemical devices whose surfaces could be renewed by a simple polishing step [32,33]. Other than carbon (graphite) particles, gold [34] or glassy carbon particles [35] can also be incorporated into the sol–gel solution to construct new ceramic composite materials.

Zhu et al. [36] fabricated a MB-intercalated zirconium phosphate-modified CCE. This type of electrode has several advantages, including the convenience of surface renewal, preparation and bulk modification as well as the ability to control the surface wetness in aqueous solution, especially the high capacity for adsorption without any activation. Salimi et al. fabricated a surface-modified CCE by chlorogenic acid, and the resulting modified electrode was used for amperometric detection of NADH [37] and hydrazine [38].

The possibility of sol–gel method to prepare glassy materials at room temperature, which can support the immobilization of different reagents, was investigated earlier for electrochemical application [39]. The sol–gel method as a simple-handled method is well suited for thin-film fabrication in electrochemical studies since it provides excellent physical and chemical stability for the sensors [40–42]. The species embedded in the inert and stable solid matrices usually preserve their functional characteristics with no significant leaching in case an appropriate entrapment procedure is used. These properties will contribute to the long-term operational stability of the sol–gel-doping materials under storage conditions. The isolation of reagents from their surrounding by the bottle-neck structure of the pores makes their stability comparable to those of covalently bonded species but superior to adsorbed ones [40]. An interesting feature of the carbon ceramic electrodes, due to the brittleness of the sol–gel silicate backbone, is that the active section of the electrodes is not clogged upon successive mechanical polishing of its surface. The modified CCEs containing ruthenium metallodendrimer, manganese and nickel hexacyanoferrate were fabricated by the sol–gel technique and used for voltammetric and amperometric detection of insulin, l-methionine, l-cysteine, thiosulfate, sulfide and sulfur oxoanions [43–45].

4-(2-Pyridylazo)-resorcinol (PAR), with the structure shown in Fig. 1, is a sensitive and selective azo dye, widely used as a colorimetric reagent for metal ions as it forms very stable and highly colored complexes with some of transition metals [46–48]. Silver(I) reacts with PAR and gives an orange red chelate. The complex is stable and is not affected by light. The composition of the complex was found to be 1:1 by Job's and mole ratio methods [49].

The aim of the present investigation is to develop a new CCE modified by PAR, for selective preconcentration and determination of Ag(I) by differential pulse anodic stripping voltammetry. In addition, the PAR-modified CCE exhibited several advantages such as simple preparation, reproducibility of surface renewal by simple polishing, good stability and excellent ability to determine trace amounts of silver(I) in super-alloy samples and X-ray photographic films.

2. Experimental

2.1. Reagents

Methyltrimethoxysilane (MTMOS) and highly pure graphite powder were purchased from Fluka. PAR, of analytical grade, and methanol were purchased from Merck. Silver nitrate solutions were prepared in triply distilled deionized water and their concentrations were checked by an atomic absorption spectrometer (PerkinElmer model 2380). The silver solutions were placed in the dark and protected against light in amber bottles. The accumulation solution for silver(I) was a buffer solution containing sodium bicarbonate (0.1 mol L^{-1}) and NaOH (0.1 mol L^{-1}) (pH 9.5). Highly pure nitrogen was used for deaeration. PAR solutions (1 mmol L^{-1}) were freshly prepared just prior to use.

2.2. Apparatus

Voltammetric experiments were performed using a Metrohm electroanalyzer (Model 757 VA Computrace). The measurements were recorded using VA computrace version 2.0 (Metrohm) run under windows 98 operating system. All voltammograms were recorded with a three-electrode system consisting of an Ag/AgCl electrode as the reference electrode, a platinum wire as the auxiliary electrode, and the CCEs (modified or unmodified) as the working electrode. A Metrohm 710 pH meter was used for pH adjustments. All the electrochemical experiments were carried out under pure nitrogen atmosphere at room temperature.

2.3. Preparation of bare and PAR-modified CCEs

The bare CCEs were prepared according to the procedure described by the Lev et al. [31]. The real fabrication procedures were as follows: a mixture of 0.75 mL CH_3OH, 0.5 mL MTMOS and 0.05 mL HCl (11 mol L^{-1}) was prepared and sonicated for 2 min. Then, 1.20 g of graphite powder was added and the mixture was sonicated for another 2 min, until a homogeneous gel solution was obtained. Next, the mixture was packed into one end of the glass tubes (with 3 mm inner diameter and 5 cm length, the composite material in the tube was about 0.3 cm high), and the resulting electrode was dried for 48 h at room temperature. Electric contacts of the electrodes were made by a copper wire inserted from the other end of the electrodes. The prepared carbon ceramic electrode was polished with some polishing paper to remove any extra composite material. By immersing the bare CCE in 1.0 mmol L^{-1} aqueous solution of PAR for 1–15 s, a stable film of PAR was adsorbed on the surface of the electrode. The electrode was rinsed with ultra pure water and used for electrochemical experiments.

3. Results and discussion

3.1. The effect of the immersing time on voltammograms

Cyclic voltammograms of the modified electrode with different surface concentrations of PAR were recorded by immersing the bare electrode in 1.0 mmol L^{-1} PAR solution for different lengths of time (1–15 s). Results showed that a stable thin film of PAR adsorbed on the surface of the CCE had no well-defined voltammetric wave within the applied potential window. Further experiments showed

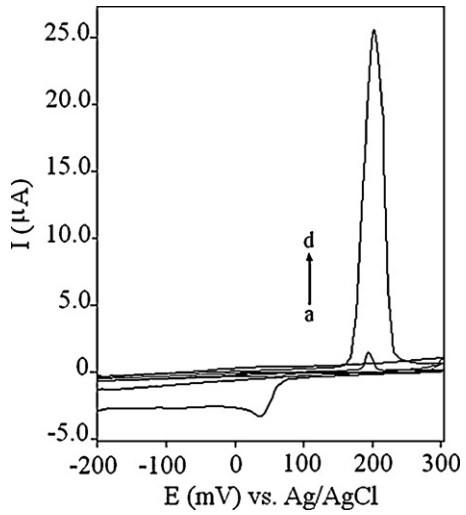

Fig. 2. Cyclic voltammograms in 0.1 mol L^{-1} HCl after open circuit accumulation in buffer solution (pH 9.5): (a) unmodified CCE, no Ag(I) in accumulation medium, (b) CCE, with 100 μg L^{-1} Ag(I) in accumulation medium, (c) PAR-MCCE, no Ag(I) in accumulation medium and (d) PAR-MCCE, with 100 μg L^{-1} Ag(I) in accumulation medium. Other conditions: accumulation time = 12 min and scan rate was 50 mV s^{-1}.

that the back current of the modified electrode increased with an increase in immersing time. A thin film of PAR was adsorbed on the electrode surface after immersing the bare CCE in 1.0 mmol L^{-1} PAR solution for only 2 s. Therefore, the 2 s length of time was selected as the optimum immersing time in all the following experiments.

3.2. General procedure

Cyclic voltammograms (CVs) were recorded after purging the solutions for at least 5 min with ultra pure nitrogen gas. After a 12 min preconcentration in open circuit condition the CVs were recorded within the potential window of −0.2 to +0.3 V (with a 50 mV s^{-1} scan rate). For differential pulse anodic stripping voltammetric experiments, the modified carbon ceramic electrode was immersed in a 10 mL of sample solution (pH 9.5) containing a known amount of Ag(I) and the solution was stirred for 12 min. This was followed by replacing the medium with a 0.1 mol L^{-1} HCl solution, where the accumulated silver(I) was reduced for 15 s in −0.6 V. Finally the differential pulse voltammogram was recorded from −0.2 to +0.2 V (with 30 mV s^{-1} scan rate, 100 mV pulse amplitude, and 4 ms pulse period). All the measurements were carried out at room temperature (23 ± 1°C).

3.3. Voltammetric behavior of silver(I) at PAR-MCCE

The ability of the PAR-MCCE to preconcentrate Ag(I) was investigated. Fig. 2(a) and (c) shows the CVs of CCE and PAR-MCCE in 0.1 mol L^{-1} HCl after preconcentration in the buffer solution as the accumulation medium. In the applied potential range only residual current was observed. Fig. 2(b) and (d) shows the CVs obtained from the same procedure at the CCE and PAR-MCCE, but with 100 μg L^{-1} Ag(I), in the accumulation medium. In CCE case, a small anodic peak at about +0.18 V indicates that some adsorption of Ag(I) occurred at the CCE surface. However, this miniscale peak provided an evidence for the absence of a significant preconcentration of Ag(I) at the unmodified electrode. In contrast, when PAR-MCCE was applied, a well-defined anodic stripping peak at +0.20 V appeared after accumulation in the medium containing 100 μg L^{-1} Ag(I). This peak was due to the reoxidation of elemental silver, produced by the reduction of accumulated Ag(I) at the negative potentials. On the reverse scan, a smaller cathodic peak with a peak potential at 0.03 V was also observed due to the reduction of Ag(I) (Fig. 2d). As it can be seen, the anodic peak current of silver at PAR-MCCE is several times larger than that of the unmodified electrode. A substantial enhancement in silver oxidation peak current was observed when the modified carbon ceramic electrode was applied. Hence, the anodic peak of silver(I) was systematically studied by differential pulse anodic stripping voltammetry for analytical applications.

3.4. Principle of the method

Regarding the above-discussed observations, and under the experimental conditions, the possible pathways for analysis cycle, from accumulation step to voltammetric scan, can be presented as follows:

Accumulation step via complex formation:

$$Ag^{+}_{aq} + PAR^{-}{}_{sur} \rightarrow [Ag\text{-}PAR]_{sur} \quad (1)$$

Reduction step in negative potentials:

$$[Ag\text{-}PAR]_{sur} + e + H^{+} \rightarrow Ag^{0}{}_{sur} + PARH_{sur} \quad (2)$$

Stripping step via positive scan:

$$Ag^{0}{}_{sur} \rightarrow Ag^{+}_{aq} + e \quad (3)$$

3.5. pH of accumulation medium

No voltammetric peaks were observed when acidic or neutral media were used to accumulate Ag(I). This can also be understood from the structure of PAR. When the pH decreases, PAR is protonated in the nitrogen and oxygen atoms reducing the complexing ability of the PAR. Therefore, we can expect that the most favorable conditions for complexation can be those with higher pHs. The influence of pH on the stripping peak current and potential was studied in buffer solutions (pH range 7.5–11). It was found that the greatest peak current was in the pH range of 9–10.5. As a result, pH 9.5 was used in all the measurements.

3.6. Stripping medium

0.1 mol L^{-1} of HCl, HNO_3, H_3PO_4, H_2SO_4 and CH_3COOH solutions were used as the stripping medium. The best solution, by which we achieved the most ideal shape and the highest current, was HCl. The effect of HCl concentration on the shape of voltammograms was also investigated, a small current was observed in 0.001 mol L^{-1} HCl, which gradually increased up to 0.1 mol L^{-1} HCl and then decreased at higher concentrations. Anodic peak also shifts to negative potentials due to the effect of H^{+} concentration which shown in Eq. (2). So the concentration, 0.1 mol L^{-1}, was used in all the measurements.

3.7. Accumulation time

The dependence of anodic peak current on the accumulation time for 100 μg L^{-1} Ag(I) was also investigated. The anodic peak current increases with the increase of accumulation time between 0 and 11 min above which it becomes nearly constant. Hence, for all the subsequent measurements accumulation time of 12 min was applied.

3.8. Reduction potential and reduction time

The influence of reduction potential on the anodic peak current of silver(I) was studied by varying the reduction potential from 0 to −1.6 V. When the potential was increased to −0.5 V, a well-defined peak with the highest peak current was obtained. Further

Table 1
The effect of co-existing metal ions.

Bi(III)	99
Fe(II)	98
K(I)	100
Cd(II)	95
Hg(II)	88
Cu(II)	86

Table 2
Determination of Ag(I) in super-alloy samples and X-ray photographic films ($n = 5$).

Sample	Serial no.	Certified ($\mu g\,g^{-1}$)	Found by this method ($\mu g\,g^{-1}$)	Found by AAS
Super-alloy	GBW01621	5.4	5.45 ± 1.8	–
Super-alloy	GBW01619	3.7	3.64 ± 1.5	–
X-ray film	–	–	4.5 ± 2.1	4.3 ± 1.5

increases in the reduction potential from −0.8 to −1.6 V led to a decrease in peak currents. This is mainly due to the cohydrogen evolution at such high potentials. Therefore, −0.6 V was applied as an optimum reduction potential for further studies. The effect of reduction time was also examined. The peak current of silver(I) was found to increase linearly by increasing the reduction time up to 15 s. So a time of 15 s was consequently used for all the measurements.

3.9. Calibration curve, detection limit and reproducibility

Standard solutions containing different amounts of Ag(I) were prepared in pH 9.5. And the general procedure was applied to these solutions. Voltammograms at these concentrations are shown in Fig. 3a. A linear calibration graph was obtained in the concentration range of 0.5–300 $\mu g\,L^{-1}$ (Fig. 3b). The detection limit was found to be 0.123 $\mu g\,L^{-1}$ Ag(I), and for seven successive determinations of 10, 100 and 200 $\mu g\,L^{-1}$ Ag(I), the relative standard deviations were 2.1, 1.4 and 1.03%, respectively.

(a–i): 0.5, 5.0, 20.0, 32.0, 70.0, 98.0, 123.0, 196.0, 270.0, 300.0. (b) The calibration graph of Ag(I) according to data in (a). Other conditions: accumulation time = 12 min, reduction potential = – 0.6 V, reduction time = 15 s and scan rate was 30 mV s^{-1}.

3.10. Interferences

The presence of other metal ions can interfere with Ag(I) determination if they compete for complexation in the PAR complexing sites. When the developed procedure was employed for the determination of 100 $\mu g\,L^{-1}$ Ag(I) in optimum conditions, no interference was seen for adding 10 mg L^{-1} of each of Ni(II), Pb(II), Zn(II), Mn(II), Co(II), Au(III), Na(I), Bi(III), Fe(II) and K(I). However,

the presence of 10 mg L^{-1} Cu(II), Hg(II) and Cd(II) caused a 14%, 12% and 5%—decrease in the Ag(I) peak, respectively (Table 1).

3.11. Analytical application

In order to evaluate the performance of the PAR-modified carbon ceramic electrode in practical analytical applications, determination of silver(I) in super-alloy samples and X-ray photographic films was attempted. The results are given in Table 2.

For X-ray photographic films analyses, the used films were washed with distilled water and were cut into small pieces after drying in an oven at 40 °C for 20 min. 20 mL of aqueous nitric acid (5 mol L^{-1}) was added to 2.0 g of the film. The mixture was filtered, and the solution was diluted to 500 mL and pH was adjusted to 7 by NaOH solution (2 mol L^{-1}). 100 μL of the solution was added to 10 mL of the buffer solution (pH 9.5), and the general procedure was applied to the resultant solution. Samples were also analyzed using an independent technique, atomic absorption spectrometry (AAS). The measured values are in agreement with the certified values or those obtained by atomic absorption spectrometry, as shown in Table 2.

4. Conclusions

We have demonstrated that carbon ceramic electrode modified by 4-(2-pyridylazo)-resorcinol can be used to determine trace amounts of silver(I). The ability of the PAR to extract silver(I) into the carbon ceramic leads to fabrication of an electrode that is precise and accurate. The analyte ion may be preconcentrated by chemical interaction with the electrode at open circuit potential. This method showed a high selectivity because of the complexation and the exchange of the medium. The calibration graph of Ag(I) showed an ideal linear relationship from 0.5 to 300 μg L^{-1}, with a slope factor of 0.2384 μA(μg L^{-1})$^{-1}$ and the correlation coefficient, R^2, of 0.9995.

The limit of detections for some modified electrodes to determine Ag based on 3-amino-2-mercapto quinazolin-4(3H)-one [50], ion-exchanger Dowex [21], DL-dithiothreitol [51], polythiophene [52], S_2O_2-donor podand [23], vermiculite clay mineral [24], 2-mercaptobenzoxazole [27] and zeolites [29] together with their reported linear ranges are also included in Table 3 for comparison. The data given in Table 3 indicate that the LOD associated with the proposed modified electrode for Ag(I) ion determination is undoubtedly superior to that of all the other modified electrodes. In addition, the PAR-modified CCE exhibited some advantages such as simple preparation, surface renewal, good stability, reproducibility and finally excellent ability towards the determination of trace amounts of silver(I) in X-ray photographic films and super-alloy samples with acceptable results.

ABSTRACT

The possibility provided by Chemometrics to extract and combine (fusion) information contained in NIR and MIR spectra in order to discriminate monovarietal extra virgin olive oils according to olive cultivar (Casaliva, Leccino, Frantoio) has been investigated.

Linear discriminant analysis (LDA) was applied as a classification technique on these multivariate and non-specific spectral data both separately and jointly (NIR and MIR data together).

In order to ensure a more appropriate ratio between the number of objects (samples) and number of variables (absorbance at different wavenumbers), LDA was preceded either by feature selection or variable compression. For feature selection, the SELECT algorithm was used while a wavelet transform was applied for data compression.

Correct classification rates obtained by cross-validation varied between 60% and 90% depending on the followed procedure. Most accurate results were obtained using the fused NIR and MIR data, with either feature selection or data compression.

Chemometrical strategies applied to fused NIR and MIR spectra represent an effective method for classification of extra virgin olive oils on the basis of the olive cultivar.

1. Introduction

Nowadays, one of the major issues regarding food products is to develop objective tools to determine the origin of raw materials as well as finished products in order to ensure their traceability. The application of spectroscopy which includes IR and Raman techniques combined with chemometric methods is a relatively new approach in food characterisation studies [1,2].

Extra virgin (e.v) olive oils come from many olive varieties which are generally grown on a specific soil type: both these factors (olive variety and soil type) confer specific sensory [3] and chemical properties on an oil. Often, olive cultivar and olive oil production area are linked together, but the main varieties are cultivated in many different geographical areas.

Recently, many applications of NIR and MIR spectroscopy for composition studies [4,5] and geographical characterisation (authenticity) have been reported [6–11].

In particular, there have been many studies attempting to elucidate the link between composition and geographical origin using NIR and MIR spectroscopy coupled with multivariate analysis.

For example, the results obtained by Downey et al. [6], Bertran et al. [7], Carazzolo et al. [8], Galtier et al. [9], Casale et al. [10] and Woodcock et al. [11] have suggested that near infrared spectroscopy has the potential to separate virgin olive oils coming from adjacent geographic regions with a high degree of accuracy and to discriminate olive oils bearing different denominations of origin.

With respect to MIR, Tapp et al. [12] investigated whether Fourier transform infrared spectroscopy (FTIR), in combination with multivariate analysis, could distinguish extra virgin olive oils from different producing countries. Both MIR and NIR spectra were considered for the characterisation and classification of Italian virgin olive oils by Sinelli et al. [13].

In this work, it is mainly the identification of the olive cultivar used for the oil production which is of interest.

Since the spectroscopic techniques provide multivariate and non-specific signals, Chemometrics is necessary to filter out the most relevant information from the data sets.

In this work, the data collected from a NIR and a MIR spectrometer, have been processed both separately and jointly, using chemometrical techniques, to demonstrate the synergistic effect of information obtained from the two instruments. In the literature, some examples of data fusion in food authentication problems are reported [14,15].

Linear discriminant analysis (LDA) [16] has been used as a classification technique in order to discriminate oil samples on the basis of the olive cultivar.

Because the number of variables (wavenumbers) was much greater than the number of training set objects in our data set, LDA was applied after feature selection or data compression.

Application of methods for variable selection or data compression is important since they enable variables with low information content to be discarded; inclusion of such variables may results in an overestimation of prediction ability during classification. Despite this advantage, the use of variable selection methods is still limited in practice. Most of the chemometrical software integrated into the commercial NIR and MIR instruments contains chemometrical modules for the development of classification models, which only permit that part of the spectrum without any significant absorption signal to be removed. In fact these software do not normally contain any tool able to discard the non-informative variables on the basis of a mathematical analysis.

This paper contains the results of a study designed to illustrate the advantage of using, first, such pre-treatment tools and, second, using fused spectroscopic data sets for a classification problem. For variable selection, the SELECT algorithm [17] has been used while for data compression, a wavelet transform [18] has been deployed.

2. Experimental

2.1. Oil sampling

A total of 82 monovarietal extra virgin olive oils were analysed. This sample set comprised oils from the cultivars Casaliva, Leccino and Frantoio (27 from Casaliva, 28 from Leccino and 27 from Frantoio). Each cultivar was grown in three different sites (Puegnago, Follonica and Mirto) representative of Italian olive growing regions. In particular, Puegnago is representative of the "Garda Bresciano" area (western shore of Lake Garda) in Lombardy (northern Italy); Follonica, of the "Tyrrhenian cost" area in Tuscany (central Italy) and Mirto of the "Ionian cost" area in Calabria (southern Italy).

The monovarietal extra virgin olive oil samples were obtained from 6 kg to 10 kg of olives, harvested in the harvest period of 2005–2006: a standard continuous procedure in a mini oil mill (Toscana Enologica Mori, mod. Mini 50 modified - Tavarnelle Val Di Pesa) was used within three days of picking the olives. Olives, collected at commercial maturity, were crushed with an hammer mill and the crushed olive pasta was then submitted to a malaxation (20 °C for 30 min) to allow the microscopic oil droplets to coalesce into larger globules. Oil was then extracted by hydraulic press (maximum 20 MPa) and separated by centrifugation for 10 min at 3000 rpm.

2.2. Instruments and procedures

2.2.1. NIR spectroscopy

NIR spectral data were collected in transmission mode using vials of 8 mm path length with an FT-NIR spectrometer (MPA, Bruker Optics, Ettlingen, Germany). Data were collected over the range 12,500–4500 cm^{-1} (resolution: 8 cm^{-1}, scanner velocity: 10 kHz, background: 64 scans, sample: 64 scans) at room temperature. Instrument control and initial data processing were performed using Opus software (v. 6 Bruker Optics, Milan, Italy).

2.2.2. MIR spectroscopy

ATR FT-IR experiments were performed on a spectrometer (VERTEX 70, Bruker Optics, Ettlingen, Germany) equipped with a deuterated triglycine sulfate (DTGS) detector.

For both background and sample, 16 cm^{-1} asymmetric interferograms with a spatial resolution of 4 cm^{-1} were co-added and Fourier transformed. Oil samples were spread out on a horizontal germanium crystal ATR plate with 11 internal reflections (Pike Technologies, Inc., Madison, USA) in order to cover the entire crystal. For each sample, spectral data were collected in the range 4000–700 cm^{-1} at 20 °C and stored as $\log(1/R)$ files. Opus software (v. 6, Bruker Optics, Ettlingen, Germany) was used for spectral acquisition, instrument control and preliminary file manipulation. In order to eliminate disturbing H_2O and/or CO_2 bands in the ratio spectra, the spectra were compensated with the Atmospheric Compensation command, using Opus software.

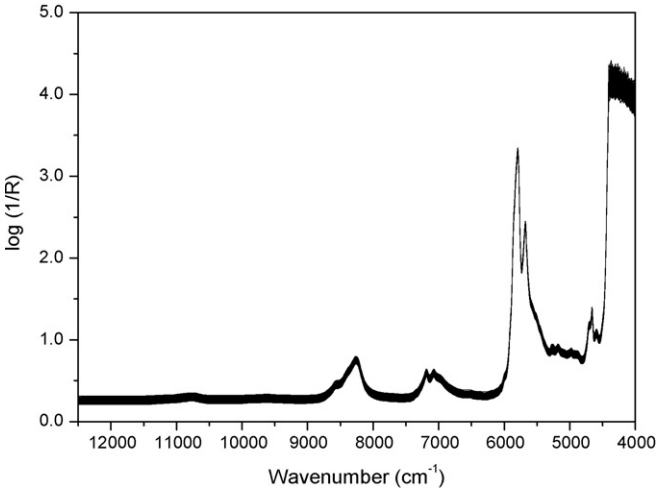

Fig. 1. Raw NIR spectra.

2.3. Data analysis

Figs. 1 and 2 show the raw NIR and MIR spectra respectively. As far as the NIR spectra are concerned, four segments of the signal without absorption were removed: 12,493–8650 cm^{-1}, 8000–7400 cm^{-1}, 6700–6000 cm^{-1}, 4400–4000 cm^{-1}. Therefore, the final NIR data matrix contained 82 rows (samples, olive oils obtained by different cultivars) and 766 columns (variables, absorbance at different wavenumbers). This data matrix will be identified by the notation $N_{82,766}$.

As far as the MIR spectra are concerned, three segments without absorption were removed: 3996–3040 cm^{-1}, 2650–1870 cm^{-1}, 1600–1490 cm^{-1}. So, the final MIR data matrix had 82 rows (sam-

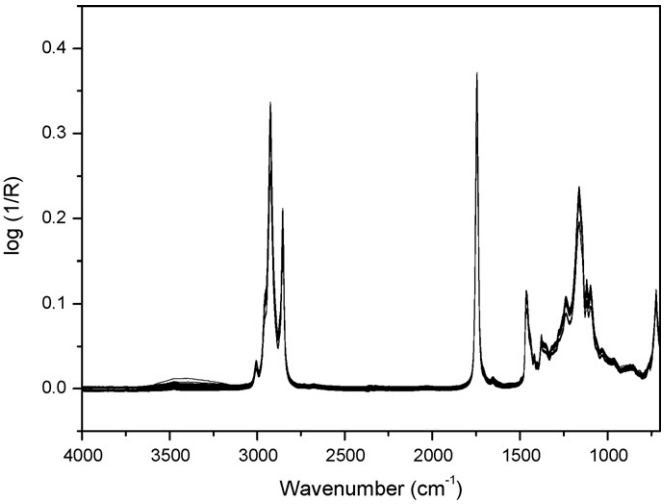

Fig. 2. Raw MIR spectra.

ples) and 753 columns. This data matrix will be identified by the notation $M_{82,753}$.

Subsequently, as first step, the NIR and MIR spectra were pre-treated separately, in order to eliminate differences due to base-line shift and scatter effects. A standard normal variate (SNV) transformation [19] and a first derivative were performed: the method of Savitzky and Golay [20] with third-order smoothing polynomials through eleven points was used to compute the first derivatives of the spectra that were used for all the data analysis.

These pre-treated matrices were as $Nt_{82,766}$ and $Mt_{82,753}$.

At the beginning, $Nt_{82,766}$ and $Mt_{82,753}$ were processed separately. After which the two matrices were joined to evaluate the synergistic effect of data recorded by these techniques. This unified matrix was called $U_{82,1519}$. In this case, the use of autoscaling was necessary to standardize the variable scale.

Linear discriminant analysis (LDA) was used as a classification technique in order to classify oil samples on the basis of olive cultivar. For classification analysis, the Casaliva olive oils were ascribed to class 1, the Leccino olive oils to class 2 and Frantoio olive oils to class 3.

LDA is a probabilistic classification technique which searches for directions (canonical variables) with maximum separation among categories; the first canonical variable is the direction of the maximum ratio between inter-class and intra-class variances. Although the transformation from the original variables to the canonical variables is non-orthogonal, nevertheless, the plots on the first canonical variables are useful display methods, widely applied in classification studies. An important restriction in the application of LDA concerns the ratio between the number of objects in the sample training set and the number of variables. From a strictly mathematical point of view, it is sufficient that the number of objects is one more than the number of variables. But, in practice, for a significant result, a total number of objects equal to at least three times, preferably five times, the number of variables is suggested. Thus, collecting a number of samples which is both reasonable and satisfactory for the above requirement could be very difficult or impossible when the number of variables is very large: in such cases, LDA should be applied after a reduction in the number of variables, performed either by means of feature selection or data compression.

Therefore, in this work, LDA was carried out, initially, after application of an algorithm for stepwise decorrelation of the variables (SELECT) as a feature selection techniques.

SELECT, introduced by Kowalski and Bender [21] is based on stepwise decorrelation of variables. In the application of this algorithm to classification problems, the first variable to be decorrelated, the first Z, is the predictor with the maximum Fisher weight (a measure of the between-class and within class variance ratio) [22]. Z_1 is copied as the first column of the matrix P of selected predictors and then it is decorrelated from all the other predictors. The second selected predictor, Z_2, will be that, from the non-selected predictors, with the maximum Fisher weight. It will be copied as the second column of the matrix P, and it will be decorrelated from all predictors. Decorrelation continues until the Fisher weight is lower than a fixed value or a fixed number of variables to retain is reached. The models obtained contain a minimum number of relevant predictors, and as a consequence of the stepwise decorrelation, these predictors are orthogonal. The algorithm permits the retention of either the decorrelated variables or the original ones.

In a second approach, LDA was applied after a data compression performed by means of the wavelet transform.

Wavelet transform is the name of a technique developed to study, as the Fourier transform, the frequency components of a signal with the main objective of compression. The compression is realized by replacing the original variables with a series of wavelet coefficients, the "basis", and discarding the irrelevant variables.

The problem studied in this paper involved not single independent signals, but matrices of signals, characterised by having as many rows as samples analysed and as many columns as variables measured (e.g., absorbance at different wavenumbers). For this reason, the compression of all signals was performed by keeping, for each of them, the same number of corresponding coefficients: the so-called "common basis" [23]. Many criteria to choose the best common basis exist: in this study, the cut-off value criteria was used [24].

Wavelets are based on the repeated use of low-pass and high-pass filters and there are many types of filters, constituting the families of wavelets. The Daubechies filters are the best known; they work progressively on an even number of points (windows).

In this study, the Wavelet Packet Transform (WPT) algorithm was applied using Daubechies filters working on eight points windows (D8).

In the case of both feature selection and data compression, the classification rules were evaluated on the basis of the predictive ability in cross-validation groups.

In order to obtain reliable classification rules, a rigid validation is necessary, but in this case the number of objects was too low to create an external test set; for this reason, we used a cross-validation procedure. In cross-validation, with N objects, the number of cancellation groups can range from 3 to N. Cross-validation with N cancellation groups is generally known as a leave-one-out procedure (LOO). LOO produces, in each validation cycle, a very small change in the training set and this small perturbation has the consequence that the measure of the predictive ability can be overly optimistic. On the contrary, with a small number of cancellation groups, the resulting training sets are very different, and the measure of the predictive ability is not optimistic, possibly pessimistic. So, we performed cross-validation many times, with a different number of cancellation groups, specifically with LOO, seven (7CV) and five (5CV) cancellation groups. Such a validation procedure required a little additional time, but it ensured a significant measure of the predictive ability.

All the above mentioned chemometrical techniques are implemented in the package V-PARVUS that was used for the data analysis [25].

3. Results and discussion

3.1. Feature selection by SELECT algorithm

The same processing strategy was performed on the three data sets $Nt_{82,766}$, $Mt_{82,753}$ and $U_{82,1519}$.

The stepwise decorrelation of the variables (SELECT) was applied on these three matrices in order to retain 15 variables. In both NIR and MIR regions the 15 wavenumbers selected are associated with the absorption bands of the most important compounds of olive oil, like fatty acids, phenols, triglycerides and tocopherols. In particular, regarding near infrared region, the principal wavenumbers selected are in the range 8500–6800 cm^{-1} and 5500–4900 cm^{-1} where there are the absorption bands of C–H (second overtone and combination bands) and C–H and C=O (first overtone and combination bands of stretching vibration), respectively. In the mid region the main variables selected (1330–1380 cm^{-1} and 1630–1811 cm^{-1}) correspond to CH_3 bending and C=O stretching vibration.

LDA was then performed on the three reduced data matrices. The results, reported in Table 1, show the ability of NIR and MIR spectroscopy to classify extra virgin olive oils on the basis of the olive cultivar. The prediction ability obtained using the MIR data ($Mt_{82,753}$) was better (overall rate of about 86%) than that obtained

Table 1
LDA results after feature selection (15 variables retained).

SELECT_LDA LOO	96.2	90.2	92.6	92.9	85.2

Cross-validation performed with 5, 7 and 82 (LOO) cancellation groups.

using the NIR data ($Nt_{82,766}$). The best results were obtained by combining information from NIR and MIR spectra: the mean rate of samples correctly predicted was about 88%.

Generally, the classification results are considered acceptable when the prediction rate is significantly larger than the null-model rate that is the probability of correct predictions only by chance. For three categories, the null-model rate is 33.3%, and its confidence interval with 82 objects is 22.9–44.2% [26]; the upper limit of the null-model rate confidence interval differed a lot from the lower limit of the confidence interval of the prediction rate.

Moreover, taking into account the chemical and physical nature of the samples of this study, the classification task was not easy, in effect the NIR and MIR spectra showed a high degree of overlap among the three categories and in this view, the results obtained were very satisfactory.

For both NIR and MIR spectroscopy, the Casaliva (class 1) and Leccino (class 2) olive oils were classified more accurately than the oils belonging to class 3 (Frantoio). In fact, in all cross-validation models performed with five, seven and LOO cancellation groups (CV), the prediction rates for categories 1 and 2 were higher than for class 3.

In particular, the LDA results obtained by joining NIR and MIR spectra ($U_{82,1519}$) showed the best prediction ability for category 2 (Leccino cultivar), with an overall rate of 93%: a graphical display of these results is shown in Fig. 3, in which samples are projected on the first two canonical variables of LDA. The figure highlights the ability of spectroscopic techniques to discriminate extra virgin olive oils on the basis of the olive cultivar.

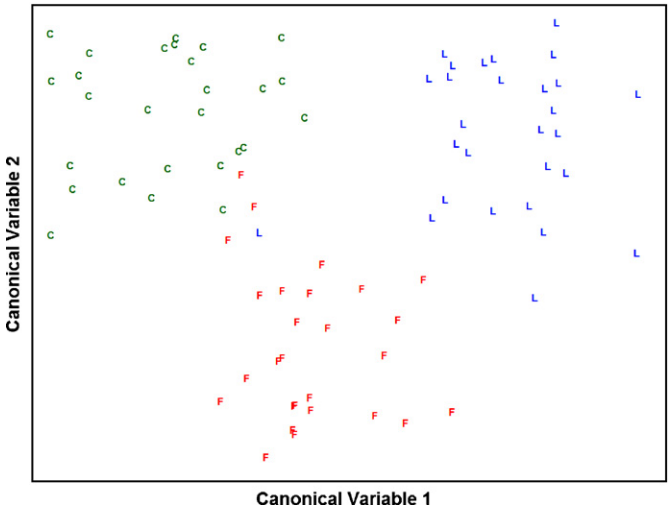

Fig. 3. NIR and MIR spectra fused. Projection on the first two canonical variables of LDA computed on 15 selected variables by SELECT. Samples are shown by their class symbol: C (Casaliva), L (Leccino) and F (Frantoio).

3.2. Data compression with wavelets transform

As above, the same processing strategy was performed on the three data sets $Nt_{82,766}$, $Mt_{82,753}$ and $U_{82,1519}$.

The WPT algorithm with Daubechies filters D8 was applied on the signals and the best common basis was obtained with the cut-off value criterion.

A number of wavelet coefficients corresponding to 75% of the total variance was retained and the LDA was performed on these selected coefficients.

To evaluate the prediction rate, the leave-one-out (LOO) and the usual cross-validation procedure with five and seven cancellation groups, were performed; the detailed results are listed in Table 2, with prediction rates reported for the three categories. Even though the results were worst than those obtained above by feature selection, data compression was helpful in extracting useful information from the NIR and MIR spectra and allowing a partial discrimination among cultivars. The prediction results for the compressed data were in agreement with the results obtained by SELECT algorithm, in fact they showed how the performances of the classification rules computed after the fusion of the NIR and MIR variables were better than those obtained using the separate data sets and how the samples of class 2 (Leccino) were better discriminated than the other two cultivars.

Fig. 4 shows the sample scores plot on the first two canonical variables of LDA for fused NIR and MIR spectra, after data compression using the wavelet transform.

In order to provide a benchmark against which to evaluate the merits of variable reduction and data compression with regard to classification performance, LDA was also performed using the complete NIR and MIR spectra, that is without reduction of the number of original variables. Since the high number of variables prevented the use of LDA, this classification method was performed working on the Principal Components. These results, listed in Table 3, were compared with those obtained after feature selection or data compression; they demonstrated that the application of strategies for discarding the not informative variables improved the classification performances.

Summarising, the LDA results showed that it is possible to discriminate the olive oils on the basis of the olive cultivar using NIR and MIR spectroscopy, in fact the prediction rates were generally satisfactory especially for category 2, the oils from cultivar 'Leccino'. The better classification of 'Leccino' cultivar could be due to its antioxidant profile. As demonstrated by Tura et al. [27], the olive

oil of this cultivar is characterised by an antioxidant pattern that differs from those of the other two cultivars. The authors showed that 'Leccino' had higher tocopherol content and higher ratio of saturated to polyunsaturated fatty acids in comparison to the two cultivars 'Casaliva' and 'Frantoio'.

Variable selection was more efficient than data compression in the elimination of useless information and the best LDA results were obtained after having used SELECT as a feature selection technique.

Moreover, there was a positive effect of the fusion of NIR and MIR spectra, in fact the prediction abilities always increased after coupling the two types of information, using either feature selection or data compression.

4. Conclusion

In this paper, in order to discriminate extra virgin olive oils according to the olive cultivar, the "fusion" of NIR and MIR variables was performed.

For high resolution methods such as MIR–NIR spectroscopy, a common problem is that the data are over determined in that there are more variables than objects. This case presents a problem for all supervised chemometrical methods in that models exist for fitting the data perfectly by modeling insignificant variations in the data (i.e., noise). Therefore, variable selection or data compression are important to extract the maximum useful information enclosed in the data.

In this study, an algorithm for variable selection (SELECT) and a method for data compression (wavelet transform) were applied on NIR and MIR spectra, both separately and after fusion.

The results of the classification analysis were acceptable and showed the potential of fused NIR and MIR spectra for the classification of extra virgin olive oils on the basis of the olive cultivar. LDA prediction abilities always increased after coupling the data obtained by the two analytical techniques.

However, this study presents some limitations and some work has still to be done: a higher amount of samples from many different

harvesting years and geographical areas should be analysed, aiming to obtain more robust classification rules, able to account in a better way both for the regional and for the time variability of the different classes. It could be surely useful and interesting to extend the study in this direction, considering not only Italian olive cultivars, but for example, cultivars coming from different Mediterranean areas.

ABSTRACT

The guanidinium salt of the new heteropolymolybdate 11-molybdobismuthophosphate $Gua_6PBiMo_{11}O_{40}$ (11-MBP) was synthesized, characterized and used as a reagent for batch spectrophotometric (SP) and sequential injection determination of ascorbic acid (AsA). When compared to other Keggin's heteropolyanions, the reduction of 11-MBP with AsA is both fast and maximal within a pH range of 1.6–2.0. The stoichiometry of the reaction was determined using molar ratio and continuous variation methods and was shown to be 1:1. The molar absorptivity of the reduced form of 11-MBP was 6.0×10^3 L mol^{-1} cm^{-1} at 720 nm. The reaction is also specific for AsA. Only cysteine, hydroquinone and hydroxyacids were found to interfere with the reaction, while no interference was observed with the common reducing agents, including reducing sugars, catecholamines, nitrite, sulfite and iron(II) ions. Batch SP and sequential injection analysis (SIA) systems were developed for the determination of AsA, with calibration ranges of the SP methods at 2×10^{-6}–8×10^{-5} M for a 10 mm cell and 5×10^{-7}–3×10^{-5} M for a 50 mm cell and a limit of detection at 3×10^{-7} M. The linear range of the SIA method was 6×10^{-6}–5×10^{-4} M, with a detection limit of 2×10^{-6} M and a sample throughput of 15 h^{-1}. The proposed methods were successfully used for the determination of AsA in both pharmaceuticals and fruit juices, and the results were consistent with those provided by the 2,6-dichlorophenolindophenol method.

1. Introduction

The widespread use of L-ascorbic acid (AsA) in medicine and the food industry is the reason why so many determination methods have been developed for this substance. The importance of AsA (vitamin C) for the human immune system and its use in the prevention of numerous diseases is well known. AsA is therefore a common ingredient of multivitamin preparations, food additives and pharmaceuticals, and because of its antioxidant properties, it is commonly added to foods, juices and beverages.

Due to its simplicity of use and low cost, spectrophotometry is considered one of the most effective and appropriate method for routine analysis of AsA. In addition, a great many colorimetric methods have been designed for determining AsA [1–3], based primarily on its oxidation–reduction properties or on its ability to couple with diazotized aniline derivatives. Some of these methods are quite time-consuming and lack either specificity or sensitivity, particularly when used for the analysis of beverages, fruits and certain pharmaceutical substances.

Most batch spectrophotometric (SP) and flow injection methods rely on AsA's ability to reduce Fe(III) or Cu(II) and the reaction of the resulting Fe(II) with 1,10-phenanthroline [4–6], ferrozine [7,8] or 2,2′-bipyridyl [9], or the reaction of Cu(I) with neocuproine [10,11]. Interference from PO_4^{3-}, SO_3^{2-} and S^{2-} is particularly strong due to their complexation or oxidation with Fe(III). However, most of these methods have either a limited range for upper determination [7,9,11,12], a prohibitively low sensitivity [4,13,14] or potential interferences have simply not been reported [6,13,14]. In addition, a washing step between sample injections is usually included in order to avoid the absorption of Fe(III) or Prussian blue [12] on the Teflon tubing and the walls of the flow cell. The reaction of AsA with hexacyanoferrate [1] or 2,2′-bipyridyl [15,16] requires a 10–60 min waiting period before measuring absorbance, while in the case of ferrozine and o-phenanthroline complex formation with Fe(II), the reaction is relatively fast but not selective enough [10,17]. These methods also have another disadvantage: the interference of

metal ions such as Co(II), Ni(II), Cu(II) and Fe(II), as well as interference from polyphenols, hydroxyacids, cysteine, nitrite, sulfite, thiosulfate, riboflavin and oxidants.

Heteropolycomplexes have long been known as useful reagents for the determination of organic reducing substances due to their ability to form highly colored reduction products, their stability, the reversibility of the reduction processes, as well as their low cost and easy availability. The substitution of Mo atoms in heteropolyanions (HPA) with a Keggin structure of $XMo_{12}O_{40}^{q-}$ (X = P(V), As(V), Si(IV), Ge(IV), Ga(III)) on the W or V atoms [18,19] leads to a continuous change in their oxidation–reduction properties. One of the molybdenum atoms in 12-HPA can be substituted by a metal ion, thus forming metal-substituted HPA $XMeMo_{11}O_{40}^{p-}$, which can also lead to valuable changes in the chemical–analytical properties.

A variety of reagents based on iso- or heteropolyanions have been reported for the determination of AsA. These include isopolymolybdate, 12-molybdophosphate, 12-molybdosilicate HPA in addition to others. The molybdate system requires 1 h for complete color development with AsA [20]. The method based on the reaction of AsA with Folin–Ciocalteu reagent [21] is almost equally time-consuming, requiring some 40–50 min to obtain full color intensity. In addition, these methods are not sufficiently sensitive and serious interferences caused by phenolic compounds, such as catechins, gallic acid, pyrogallol and gallotannins as well as thiosulfate ions and thiourea, are observed.

AsA [22] was determined, along with cystine or cysteine, using 18-tungsto-2-phosphate HPA $P_2W_{18}O_{62}^{6-}$ [23]. It can be determined by this reagent in mixtures with cysteine using the inhibition of color production of thiol compounds with $HgCl_2$, or, even better, formaldehyde. The reaction is fast and reproducible, but polyphenols and many inorganic reducers, including Fe(II), Cu(II), Sn(II) and SO_3^{2-}, interfere with it.

12-Molybdophosphate and 18-molybdo-2-phosphate HPA doped on xerogels were used for the determination of hydrazine and Sn(II), whereas reaction with AsA was very slow and required more than an hour of analysis [24]. The reaction was accelerated in the presence of Cu(II), however, finishing in 10–15 min. This method was therefore used for the development of the solid-phase SP and visual determination of AsA [25]. Molybdosilicate and molybdophosphate HPAs immobilized on polyurethane foam have been proposed for the sorption-photometric determination of AsA, but the reaction took 18–20 h to complete [26]. Intensification of the reduction process by microwave irradiation was used in another paper from the same authors [27], a process that complicated the procedure but shortened the reaction time to 6 min.

A procedure based on the reduction of AsA with the ternary Mo(VI)–Sb(III)–P(V) HPA was described [1,28]. The color in this case ($\varepsilon_{710} = 3.68 \times 10^3$ L mol^{-1} cm^{-1}) was produced in 35 min, and the linearity of the calibration plot remained within the limits of 6×10^{-6}–3×10^{-5} M. AsA was determined in the flow injection system using the reduction of vanadotungstophosphoric acid [29], with a detection limit of 6×10^{-6} M. Although the influence of many reducing agents was not evaluated, the peak did show a 67% increase at 100-fold weight excess of semicarbazide and an 8% decrease with an excess of sulfite. Molar absorptivity was estimated for this heteropolyblue (HPB) as 1×10^3 L mol^{-1} cm^{-1} [18].

In general, a number of shortcomings limit the broader application of HPAs to the determination of reducing agents. Such reactions, especially those involving Keggin-type HPAs, are usually slow and are sometimes not sufficiently sensitive or selective enough. As a result, overcoming such problems in a search for new HPAs and the investigation of their properties seems a potentially promising task.

Among the various detection techniques used in flow injection analysis (FIA), visible spectrophotometry has been the most predominant. FIA provides high sample throughput, high repeatability and easily automated operation. It is widely used for the determination of pharmaceuticals [30–32]. Sequential injection analysis (SIA) based on principles similar to FIA, but with the possibility of universal flow manipulation, was introduced in 1990 [33]. Among the major benefits of SIA systems are reduced consumption of reagents by at least one order of magnitude, robust hardware and flexible control software which enables the convenient optimization and operation of the system. Few papers have been published that used the SIA method for the determination of AsA [6,31,34–38], and these have shown few advantageous analytical parameters when compared to FIA procedures. SIA has allowed for the use of titrimetry [35,36] and kinetics study [6] as well as the simultaneous determination of AsA and other active substances [37].

It is clear from the preceding short description that the application of reactions between HPAs and AsA in flow analytical methods has, until now, been restricted by its limited selectivity and in particular by its prolonged reaction time. The purpose of this work was to develop a sufficiently sensitive, rapid, simple, selective batch SP and SIA method for the determination of AsA using the recently synthesized 11-molybdobismuthophosphate HPA.

2. Materials and methods

2.1. Reagents

All reagents used were of analytical-reagent grade, and deionized water (Millipore, USA) was used throughout. An AsA solution was prepared daily by dissolving 0.176 g of L-AsA (Fluka, Germany) in methanol and filling the flask up to the 100 mL mark. Pure grade $Na_2MoO_4 \times 2H_2O$ (Alfarus, Ukraine) was additionally re-crystallized from a water–alcohol solution, while 0.4 M bismuth nitrate solution was prepared by dissolving 2.5 g $Bi(NO_3)_3 \times 5H_2O$ in 2.5 mL of 5 M aqueous H_2SO_4 and diluting it to 25 mL with water. The guanidinium (Gua) nitrate (Applichem, Germany), potassium dihydrogen phosphate (Sigma–Aldrich, Ireland) and sulfuric acid (Alfarus, Ukraine) were used as purchased. A 2×10^{-3} M solution of 11-molybdobismuthophosphate HPA (11-MBP) was prepared by dissolving 0.230 g of re-crystallized $(Gua)_6PBiMo_{11}O_{40}$ in 50 mL of water. The 11-MBP solution is stable for at least one month after preparation but should be preserved from contact with reducing substances contained in water or air. Working solutions of samples and reagents were prepared by appropriate dilution with water.

2.2. Apparatus

2.2.1. Batchwise method

Absorbance measurements were made using SF-26 (LOMO, Sankt-Petersburg, Russia) and SPECORD M-40 (Carl Zeiss, Jena, Germany) spectrophotometers with 10 and 50 mm light-path cells. The IR spectra of the samples (2% sample in KBr) were recorded as KBr discs on a Nicolet Impact 410 FT-IR spectrophotometer (Thermo-Nicolet, Madison, WI, USA). The pH of the solutions was monitored using an EV-74 pH-meter with glass and silver/silver chloride reference electrodes. The ^{31}P NMR spectra were recorded with a Bruker Avance 300 spectrometer (Bruker Biospin, Rheinstetten, Germany) operating at 121.5 MHz. 7.55 s pulse (90°), pulse level on ^{31}P channel 0 dB, relaxation delay time of 2.0 s, an acquisition time of 0.8979s (AQ) were used. Chemical shifts are given on the δ-scale and were referenced to an external standard (phosphoric acid, 300 K).

2.2.2. SIA method

The commercially available FIAlab 3000 system (FIAlab Instruments, USA) having a microsyringe pump (syringe reservoir 5.0 mL) and an 8-port selection Cheminert valve (Valco Instrument Co.,

USA) was used. The manifold was equipped with a fibre optic UV–vis CCD detector USB 2000 (Ocean Optics Inc., USA) having an LS-1 tungsten lamp (Ocean Optics Inc., USA). The entire SIA system was controlled by the latest version of the FIAlab program for Windows 5.0. The SIA system was made of PTFE tubing 0.75 mm in diameter, and a 10 mm FIAlab fiber optic SMA-Z flow cell was used.

2.3. Synthesis of $(Gua)_6PBiMo_{11}O_{40}$

The guanidinium salt of 11-MBP was prepared and purified as follows: a solution of 2.662 g (11 mmol) $Na_2MoO_4 \times 2H_2O$ in 25 mL of water was prepared and 2 mL of 0.5 M KH_2PO_4 along with 2 mL of 5 M H_2SO_4 were added. Then 4 mL of a 0.4 M solution of $Bi(NO_3)_3$ in 0.5 M H_2SO_4 was added drop-wise. The pH of the yellow-orange solution was maintained at 1.5–1.8 by the addition of 1 M sodium acetate or 1 M H_2SO_4. For precipitation, 40 mL of a 0.2 M Gua nitrate was used. The resulting $(Gua)_6PBiMo_{11}O_{40}$ was filtered off, carefully washed with a small quantity of water, dried in air and purified by re-crystallizing from hot water at 80–90 °C.

2.4. Procedures for AsA determination

2.4.1. Batchwise procedure

Calibration solutions for batch SP determination of AsA were prepared as follows: 1 mL of 10^{-3} M 11-MBP, 3 mL of 0.05 M H_2SO_4 (pH 1.7 ± 0.1) and the required amount of AsA were mixed in a 25 mL volumetric flask. The flask was then filled with water to the mark. Absorbance was measured after 5 min at 720 nm against water in a 10 or 50 mm glass cell.

2.4.2. SIA procedure

The SIA manifold configuration employed for the determination of AsA is depicted in Fig. 1. The analytical cycle began by filling the piston pump syringe with 800 μL of the carrier solution (water acidified with sulfuric acid to pH 1.7 ± 0.1), which was drawn into the syringe at a flow rate of 50 $\mu L\,s^{-1}$. This was followed by 60 μL of reagent (2×10^{-3} M solution of 11-MBP) and 140 μL sample or AsA standard aspirated sequentially into the holding coil at 50 $\mu L\,s^{-1}$ through separate ports (ports no. 4 and no. 5, respectively) of the selection valve (Fig. 1). The end of the holding coil was filled through valve port no. 2 with 120 μL of carrier solution, used as a spacer. To achieve better mixing, the reaction mixture was moved back and forth in 40 μL steps. A delay of 90 s was used to prolong the reduction time of 11-MBP. Using port no. 6, the entire volume was then propelled at 20 $\mu L\,s^{-1}$ through the Z flow cell. The spectrometer reference scan was made after 2 s and then absorbance scanning began.

2.4.3. Determination of AsA in pharmaceuticals

The following three commercial ascorbic acid formulations available from local sources were subjected to the proposed analytical procedures: (1) tablets containing AsA (250 mg) as a single component (Celascon, producer «Zentiva», Praha, Czech republic); (2) tablets containing AsA (60 mg) together with ferrous sulfate (320 mg) (Durules, producer «Egis», Budapest, Hungary); (3) multivitamin tablets containing nicotinamide (18 mg), vitamin E (10 mg), vitamin A (0.8 mg), pantothenic acid (6.6 mg), vitamin B_1 (1.4 mg), vitamin B_2 (1.6 mg), vitamin B_6 (2 mg), vitamin D (5 μg) (Spofavit, producer « Zentiva », Praha, Czech republic). The tablets also contained inactive ingredients. Ten tablets were accurately weighed and crushed into a powder. An amount equivalent to one tablet was weighed, dissolved in water, transferred to a 100 mL volumetric flask and sonicated for 10 min. The solution was then filtered through a Whatman no. 41 paper filter to separate the insoluble sample matrix. The solution was then filled up with water. A known volume containing the appropriate weight needed to give approximately 2.5×10^{-4} M of AsA was further diluted to 20 mL and analyzed as described above.

2.4.4. Determination of AsA in fruit juices

Commercially available fruit juices were centrifuged at 3500 rpm for 4 min at 4 °C. The solution obtained was filtered through a Whatman no. 42 paper filter and diluted to an appropriate volume. Suitable aliquots (1–2 mL) of the clear juices were then immediately analyzed as described above.

3. Results and discussion

3.1. Synthesis and identification of $(Gua)_6PBiMo_{11}O_{40}$

11-Molybdobismuthophosphate HPA could be easily synthesized by the careful addition of a bismuth nitrate solution to an acidified mixture of sodium molybdate and potassium dihydrogen phosphate. Quantitative formation of 11-MBP in a dilute solution was observed in a pH range from 1.7 to 3.5 [39]. In order to prevent hydrolysis of BiO^+ cations during synthesis, the acidity of the solution must be maintained at pH < 1.8, or sometimes more acidic, using 1 M sodium acetate. For completion of the reaction, a small excess up to 1.6-fold of the Bi(III) nitrate should be used. The 11-MBP can also be obtained in an excess of molybdate ions [39], but this method is less suitable from a synthetic standpoint considering the very similar conditions needed for the precipitation of iso- and heteropolymolybdate ions.

The selective precipitation of 11-MBP occurred with a number of tetraalkylammonium or pyridinium salts, but the use of Gua nitrate was preferable because its salt was more soluble in water, making it easy to obtain a concentration of up to approximately 5×10^{-3} M. The Gua salt could also be easily purified by re-crystallization from hot water. The purity and composition of the 11-MBP obtained was confirmed by elemental analysis, vis–near-IR, FT-IR and ^{31}P NMR spectroscopy.

It is well known that no more than one molybdenum or tungsten atom in a Keggin HPA can be substituted by a metal ion [40,41]. Nevertheless, in most published papers, the HPA formed during the reduction of 12-molybdophosphate (12-MPA) with AsA in the presence of Sb(III) or Bi(III) was considered to have a formula of $PSb_2Mo_{10}O_{40}$ [42,43] or $PBi_2Mo_{10}O_{40}$ [44], respectively. Consequently, a series of syntheses altering the Bi(III):Mo(VI) ratio from 1:1 to 3:1 was undertaken. In all studies, the analysis of the Gua salt was consistent with the same composition, that is, close to the ratio P:Bi:Mo = 1:1:11. Thus, along with the results of CHN analysis, the formula of the heteropolycomplex as $(Gua)_6PBiMo_{11}O_{40}$ was confirmed. In addition, potentiometric titration of the heteropolyacid obtained from Gua salt by exchange on an ion-exchange resin in the form of H^+ confirmed a basicity equal to six.

The IR spectrum of the Gua salt of 11-MBP (Fig. 2) was similar to the spectrum of 12-molybdophosphate HPA, which is evidence of the structural identity of the anions. In general, four characteristic IR bands appeared in the spectra of the Keggin HPAs [45,46]. For the 11-MBP reported here, three bands were readily assigned upon comparison with values in the literature: Mo=O terminal, 937 cm^{-1}; Mo–O–Mo corner-sharing, 869 cm^{-1}; Mo–O–Mo edge-sharing, 789 cm^{-1}. The fourth band is associated with a stretching mode of the central PO_4 moiety. This band was split into two new bands at 1071 and 1032 cm^{-1} as the symmetry of the HPA decreased from T_d to C_s due to substitution of one of the molybdenum atoms in 12-MPA on the large Bi atom [47]. This part of the IR spectrum was thus useful for checking the purity of the obtained compound.

The structure and purity of the synthesized heteropolycomplex was confirmed by ^{31}P NMR spectroscopy. In the spectrum of

the 0.05 M solution of $(Gua)_6PBiMo_{11}O_{40}$ in dimethylformamide, only one signal, at −2.05 ppm, was observed with a chemical shift aside from the signals from the 12-molybdophosphate ($\delta = -3.79$ ppm), 18-molybdo-2-phosphate ($\delta = -3.01$ ppm) and 11-molybdophosphate ($\delta = -1.49$ ppm) HPAs. The formation and coexistence of 12-MPA and 11-MPA with mixed HPAs of Bi(III) and Fe(III) in the water solution had been found earlier using ^{31}P NMR spectroscopy [39,48].

3.2. Relation between the 11-MBP and HPB formed by the reduction of 12-molybdophosphate with AsA in the presence of Bi(III) ions. Optimization of the conditions for the batch SP method

Batch SP methods based on the reduction of 12-molybdophosphate by AsA in the presence of As(III), Sb(III) or Bi(III) were among the most widely used in procedures for the determination of phosphorus(V). The reaction was accelerated through the use of VA Group elements, resulting in a fast reduction at room temperature. In contrast, it had been reported that 24 h were required to complete the reaction in the absence of Bi(III) at room temperature [49]. Data concerning the nature of HPB and its spectrum, as well as the mechanism of the reaction in the P(V)–Mo(VI)–Bi(III)–H^+ system, are rare and conflicting [42,44,50–52]. Several quite different hypotheses concerning the position of Bi(III) in the complex formed were explored. It was supposed that Bi(III) takes a position in the center of the HPA [50], substitutes one [51] or two [43,44] of the Mo atoms in the polymeric ligand, or even forms an ion association complex [53].

In the system being investigated, reduction of the synthesized 11-MBP with AsA provided a much faster reaction than for the parent 12-MPA. The reaction rate was dependent on the temperature, and the reduction took about 5–7 min at 20–25 °C. The HPB obtained remained stable for at least 1 h.

Complete HPB formation was observed in a narrow pH range between 1.55 and 1.80 (Fig. 3). The mixed HPA was stable at pH > 1.80, but in this case the difference in redox potential between AsA and HPA was not large enough to shift the reaction to the HPB side. The decrease in absorbance at pH < 1.55 could be explained by the destruction of 11-MBP.

Stoichiometry for the 11-MBP-AsA reduction reaction was determined using the mole-ratio method and Job's method of continuous variation. In both cases, the intersection point of the extrapolated lines corresponded to the interaction of one mole of AsA with one mole of HPA. It was seen also from the plots that even in the big excess of AsA only one complex was formed. It could be concluded that two of the eleven Mo(VI) atoms present in the HPA were reduced to the five-valent state. If so, the equation of the reaction between 11-MBP and AsA could be presented as

$$P\mathrm{Bi}^{\mathrm{III}}\mathrm{Mo}^{\mathrm{VI}}{}_{11}O_{40}{}^{6-} + H_2AsA = H_2P\mathrm{Bi}^{\mathrm{III}}\mathrm{Mo}_2{}^{\mathrm{V}}\mathrm{Mo}_9{}^{\mathrm{VI}}O_{40}{}^{6-} + 2AsA$$

At the same time, the reduction of 11-MBP in a more acidic solution and other conditions typical to the standard method for phosphorus(V) determination leads to the formation of a more intensely colored HPB. In this case, stoichiometry of the reaction

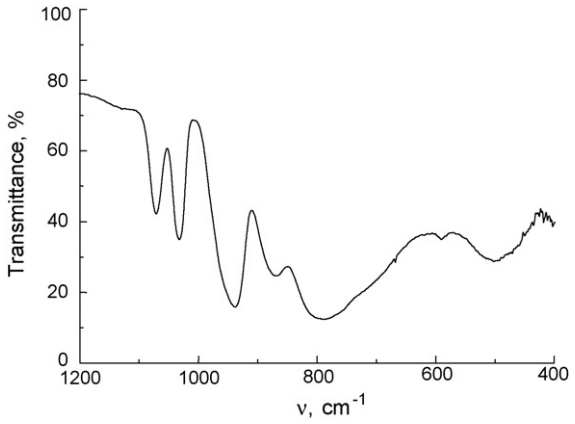

Fig. 2. IR spectrum of $(Gua)_6PBiMo_{11}O_{40}$.

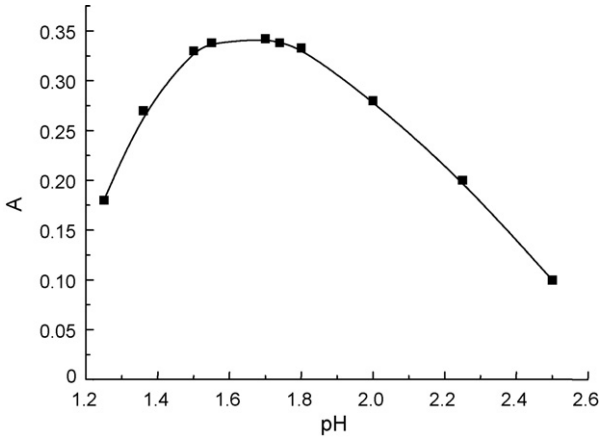

Fig. 3. Influence of medium acidity on the absorbance of reduced 11-MBP. C(11-MBP) = 4×10^{-5} M, λ = 720 nm, l = 10 mm, C(AsA) = 10^{-5} M.

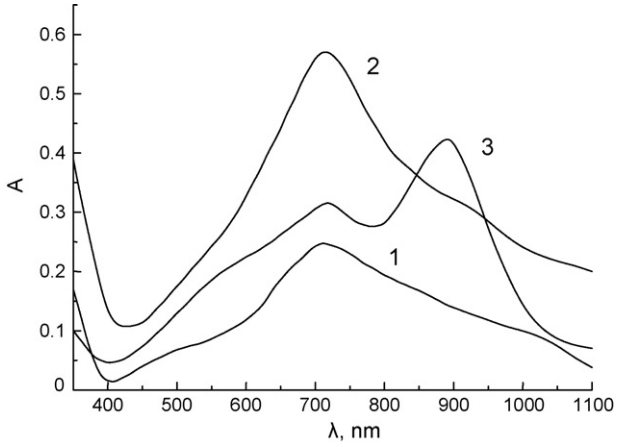

Fig. 4. Absorption spectra of metal-substituted HPBs prepared by reduction with AsA from synthesized 11-MBP (1) or obtained from components in the excess of molybdate and Bi(III) (2) or Sb(III) (3). 1–$C_{11\text{-MBP}} = 4 \times 10^{-5}$ M, $C_{AsA} = 4 \times 10^{-5}$ M, $C_{Sulfuric\ acid} = 7.0 \times 10^{-3}$ M; 2–$C_{P(V)} = 4 \times 10^{-5}$ M, $C_{AsA} = 8 \times 10^{-4}$ M, $C_{Sulfuric\ acid} = 0.1$ M, $C_{Mo(VI)} = 2.8 \times 10^{-3}$ M, $C_{Bi(III)} = 1.4 \times 10^{-4}$ M; 3–$C_{P(V)} = 2 \times 10^{-5}$ M, $C_{AsA} = 8 \times 10^{-4}$ M, $C_{Sulfuric\ acid} = 0.1$ M, $C_{Mo(VI)} = 2.8 \times 10^{-3}$ M, $C_{Sb(III)} = 1.6 \times 10^{-4}$ M, $l = 10$ mm.

between AsA and 11-MBP is equal to 2:1. Consequently, four-electron reduced specie was formed from 11-MBP in the excess of the AsA and Bi(III) ions.

Several intensive overlapping bands were present in the visible region in the absorption spectra of the two- and four-electron reduction products formed by the reaction of 11-MPB with AsA (Fig. 4). The most characteristic feature of each spectrum was the presence of a band with an absorption maximum near 720 nm. As was earlier pointed out [54], the band close to this wavelength appeared in the spectra of other metal-substituted HPBs with Sb(III), Ti(IV) and Sn(II). Unlike the behavior of other molybdenum HPBs, the position of the band did not actually depend on a change in pH [18]. Two absorption maxima appeared in the spectrum of the blue derived from the Sb(III) mixed complex, with the more intense band occurring at 890 nm [42]. The same feature also appeared in the spectrum of the blue formed in the presence of As(III) [53].

The four-electron reduced species obtained from 11-MBP in the excess of AsA, molybdate and Bi(III) had the same spectrum and molar absorptivity as the blue formed in the reaction used in the standard method for the determination of phosphate [53,55]. The identical character of the reduction process means the following can be suggested. When 12-MPA reacted with AsA in the presence of the Bi(III) or Sb(III) ions, mixed HPA was primarily formed. In the second step, a metal-substituted complex was quickly reduced with AsA. It is well known that both the three- and pentavalent states are stable in the case of VA Group elements. This feature, in addition to the ability of Bi(III) or Sb(III) to form complexes with AsA, could be responsible for facilitating the electron transfer in the reaction between AsA and the metal-substituted HPAs. It has often been claimed in the literature that Bi(III) or Sb(III) acts as a catalyst in the reaction discussed above. However, an excess of the metal ions was used in the formation of the intermediate complex, so we cannot consider their catalytic character.

The determination of AsA could be performed using mixed HPA obtained directly from the components in the solution, as was suggested for the analogous complex with Sb(III) [1]. However, in this case, high molybdate and acid concentrations should be used to ensure the complete formation of the complex. Therefore, the oxidation of AsA could not be carried out at the optimal pH. In addition, the use of synthesized compounds was well-suited for the development of different methods based on impregnated species, such as spot test determination. Their use in flow methods simplified the configuration of the system and the choice of optimal conditions.

3.3. Batch procedure. Calibration

Two calibration curves were obtained in the optimal conditions found for the determination of AsA. The two curves differed in the path lengths used. The concentration of 11-MBP should be increased to 8×10^{-5} M to extend the analytical range. In this case, absorbance was measured in a 10 mm cell. A linear relationship was observed over a range of 2×10^{-6}–8×10^{-5} M of AsA using a 10 mm cell and over a range of 5×10^{-7}–3×10^{-5} M using a 50 mm cell, respectively. The corresponding linear regression equations of the calibration plots were $A_{720} = [(6.0 \pm 0.2) \times 10^3]C_{AsA}$ ($R^2 = 0.9983$) and $A_{720} = (0.025 \pm 0.003) + [(2.71 \pm 0.05) \times 10^4]C_{AsA}$ ($R^2 = 0.9982$), where A is the absorbance, and C_{AsA} is the concentration of AsA in mol L^{-1}. The standard deviations of the intercept and slope are given in parentheses. The relative standard deviation (RSD) for five runs of 2×10^{-5} M AsA was 1.4%. The limit of detection (LOD), calculated using the equation LOD = $3 \times S_a/b$, where S_a is the standard deviation of the intercept a, was found to be 3×10^{-7} M.

3.4. SIA procedure. Optimization of the manifold parameters

As is shown above, 11-MBP was slowly reduced by AsA. Therefore, the use of this reaction for the development of a method using an FIA configuration would require a long flow line resulting in a high dispersion of the colored zone and a prolonged residence time. In an SIA manifold, the mixing of reagents and sample in the holding coil could be carried out by gentle flow manipulation.

In order to develop the final system, the SIA variables were studied using the above-mentioned optimal chemical variables. The concentration of the 11-MBP was kept at a value of 2×10^{-3} M, close to the maximum value needed to extend the analytical concentration range. The effect of pH changes on product absorbance was low in the range from 1.4 to 2.1, while in the pH range of 1.6–1.8, in direct relation to the results obtained in the batch method, absorbance was found to be independent of pH. Thus, a pH of 1.7 was selected as the optimal value.

Simple mixing of the reagents in the holding coil led to distorted or double peaks. Thus, additional moving of the reaction mixture back and forth through the holding coil was found to be sufficient to obtain symmetric signals with common shapes.

Compared to the batch method, SIA measurements were made under non-equilibrium conditions, when the signal has not yet reached its maximum value. This was the reason for the shorter delay time in comparison with the batch method. Investigation of the influence of the delay time on the absorbance of the HPB formed showed that the response reached a plateau at 90 s, and the decrease in the absorbance due to dispersion became significant after 200 s.

The effect of variation in the flow rate during the measurement stage with respect to the shape and intensity of the recorded peak was investigated. The signal intensity was independent of the flow rate in the range from 5 to 20 μL s^{-1}. Absorbance was slightly decreased when using faster flow rates. Thus, a flow rate of 20 μL s^{-1} was chosen as optimal to ensure a higher throughput value.

Under the above SIA optimized conditions, the effect of the volume of 2×10^{-3} M 11-MBP was studied in the range of 5–140 μL. As can be seen in Fig. 5, increasing the concentration of the reagent increased the signal intensity, which reached a plateau at a volume of 60 μL of 11-MBP. No difference was further observed; hence a 60 μL sample was selected as the most appropriate volume. The influence of the sample volume was investigated by injecting volumes in the range of 20–200 μL. A sample volume of 140 μL was

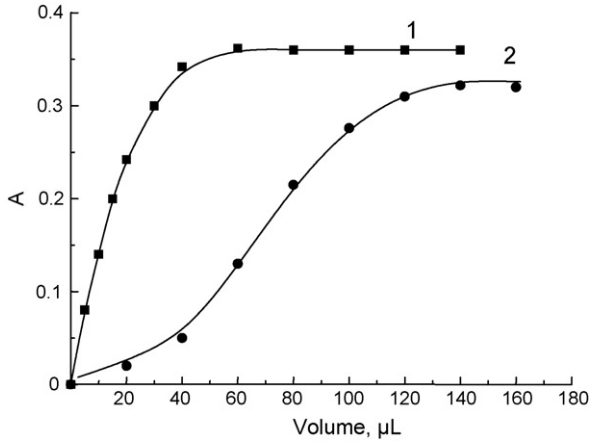

Fig. 5. Influence of reagent (1) and sample (2) injected volume on product absorbance.

then chosen as optimal, considering sample consumption and the fact that maximum absorbance was achieved at this value.

Aspiration of a series of standard AsA solutions resulted in the flow signals shown in Fig. 6. The equation of the calibration plot in the AsA concentration range from 6×10^{-6} to 5×10^{-4} M was as follows: $A_{720} = (-0.009 \pm 0.016) + [(1.49 \pm 0.08) \times 10^3] C_{AsA}$, ($R^2 = 0.998$). The precision of the proposed method was checked by repeated aspiration of the same standard AsA solutions. The relative standard deviations (R.S.D.) of 20 aspirations of each solution containing 12.5, 50, and 250 μM of AsA were 4.8%, 3.6% and 2.7%, respectively. The limit of detection obtained with a peak height by three-times of the signal-to-noise ratio (S/N = 3) was 2×10^{-6} M. Under the SIA optimized conditions, the throughput was calculated as 15 h^{-1}, with negligible carryover.

3.5. Interference study

In order to assess the possible analytical applications of the batch SP and SIA methods described above, the effect of interfering species on the determination of AsA in real samples was studied by analyzing a model sample solution containing AsA and various excess amounts of common interferents. The tolerance limit was set as the maximum amount causing an error of ≤± 5% in the absorbance.

It is easily seen in Table 1 that the reaction of 11-MBP with AsA was found to be highly selective. This could be explained by the optimal difference of the redox potentials and by favorable kinetic factors. The E^0_{red} for [Fe(III,II)-(phen)$_3$] (1.06 V in 1.0 M H_2SO_4 solution) and the E^0_{red} for [Cu(II,I)-(Nc)$_2$] (0.603 V, pH 7.0) [10] are higher than the E^0_{red} for 11-MBP$_{ox}$/11-MBP$_{red}$ (0.52 V, pH 2.0). The reaction rates of 12-MPA and 11-MBP with AsA differed greatly. At the same time, the reduction potentials of these HPAs were close to one another. Consequently, an additional factor—the presence of Bi atom in HPA—influenced the studied reaction. The 11-MBP reacted very slowly even with strong reducing agents, and a large excess of such compounds did not seriously interfere with the reaction. Thus, most organic and inorganic reducing agents did not influence the reduction of 11-MBP, including high concentrations of species such as the reducing sugars, norepinephrine, methyldopa, uric acid, sodium sulfite, hydrazine and ferrous sulfate.

In addition, no interferences were found for saccharose, acetylsalicylic acid, paracetamol, nicotinic acid, caffeine and other excipients at ratios [interferent]/[AsA] much higher than those found commonly in pharmaceuticals. A large excess of vitamins could be tolerated, excepting vitamin B_1. Sulfide as well as thiamine formed brown complexes with Bi atom in 11-MBP, and cysteine slowly reduced the 11-MBP. Cu(II) ions, in contrast to Fe(III) ions, were unable to oxidize the HPB. As for other HPAs, hydroxyacids were able to induce their destruction. For example, with citric acid at a concentration of 5×10^{-4} M, the color produced by the reaction between AsA and 11-MBP began to disappear, while increasing the concentration of citric acid to 2×10^{-3} M completely prevented the development of color. Hydroquinone appreciably interfered with the determination of AsA, resulting in a relative error of 8% at a 10-fold excess and 24% at a 50-fold excess.

Table 1
Influence of some interfering species on the determination of AsA ($C_{AsA} = 8 \times 10^{-6}$ M).

3.6. Application

The determination results of the AsA content in some pharmaceuticals obtained by the proposed and standard titrimetric

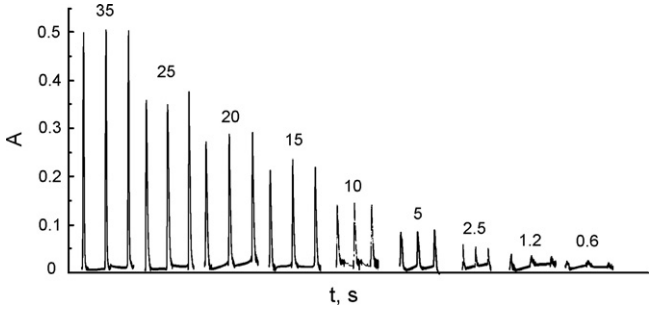

Fig. 6. Typical SIA signals obtained by construction of the calibration graph for the determination of AsA using standards in the range from 0.6×10^{-5} to 35×10^{-5} M.

Table 2
Results of the determination of AsA in pharmaceutical preparations by the proposed and reference methods (mg/tablet ± confidence intervals of the method for $n = 5$ and 95% confidence level).

Sample	Proposed method		Reference method [56]	Claimed value
	SIA	SP		
Celascon	247 ± 5	251 ± 2	251 ± 1	250
Durules	61 ± 2	59.5 ± 0.6	–	60
Spofavit	60.5 ± 0.7	60.3 ± 0.3	60.1 ± 0.3	60

Table 3
Results of the determination of AsA in juices (mg/100 mL ± confidence intervals for $n = 5$ and 95% confidence level).

Sample	Proposed batch SP method	Reference method [56]
Orange juice "Parmalat"	41 ± 2	40 ± 1
Orange juice "Sandora"	40 ± 1	40.2 ± 0.4
Pineapple juice "Parmalat"	12.5 ± 0.4	12.5 ± 0.1
Orange juice "FMG"	92 ± 2	90 ± 2

method based on the colorimetric titration of AsA with 2,6-dichlorophenolindophenol [56] are presented in Table 2 and were in good agreement with each other. The results of analyses of pharmaceuticals obtained using the proposed methods also agreed well with the claimed value of producers in all instances, thus confirming the accuracy of the developed methods. In addition, the developed procedures were easy to apply to the analysis of pharmaceuticals containing ferrous sulfate, which usually interferes strongly with AsA determination in other batch SP and FIA methods. Based on these results, it could be concluded that no interference was found in the presence of complex matrices such as multivitamin pharmaceutical formulations, common excipients and additives used in pharmaceutical preparations. It is thus possible to use this method for the direct determination of AsA in pharmaceuticals without separating potentially interfering materials.

The developed batch SP method was used for the determination of AsA in orange and pineapple juices produced by "Parmalat" (Belgorod, Russia), and orange juices from the "Frout Master Group" (Beregovo, Ukraine) and "Sandora" (Mykolayvske, Ukraine). Table 3 shows the AsA content in some of the analyzed fruit juices. No interference was found even in the presence of a very complex matrix of the samples. Fruit juices could be analyzed without any prior chemical treatment except dilution. The potential interference of iron(II) and hydrogensulfite, which could be present in fruit juices, was excluded using a selective reagent. Accuracy was assessed by comparing results with those obtained by the reference method [56]. No significant differences at 95% confidence level were observed.

4. Conclusions

The developed batch SP and SIA methods for the determination of AsA proved to be more rapid, more selective and sufficiently sensitive when compared with most of the reported methods. The reaction of AsA with 11-MBP is simple and direct. Unlike electrochemical procedures, the proposed methods are robust and relatively low cost in terms of equipment and operations when compared with methods involving enzymes and chromatography. Furthermore, the method eliminates many of the disadvantages of previously reported methods for batch SP and FIA/SIA determination of AsA, in particular those involving heteropolycomplexes. There is no need to use laborious and time-consuming washing or background correction steps. The reagent solution is stable and does not need to be standardized before use. The SIA procedure is characterized by small reagent consumption of just 0.08 mL, a good sampling frequency of 15 h^{-1} and a broad calibration range of 6×10^{-6}–5×10^{-4} M. In addition, 11-MBP is a milder, and therefore more selective, oxidant than Fe(III)-phenantroline or Cu(II)-neocuproine. The significant interference from catecholamines, polyphenols, vitamins, nitrite, sulfite, ferrous(II) and copper(II), frequently mentioned in many papers, is eliminated by using the proposed reagent.

The investigation of pure synthesized complex allowed us to elucidate its structure, its formula, its chemical properties, the extent of the reduction, and the spectrum of the HPB. The accelerating effect of Bi(III) on the reaction between AsA and 12-molybdophosphate has been explained by the intermediate formation of the mixed HPA, which is reduced by AsA much faster than 12-MPA. Due to the presence of a Bi atom, mixed HPA can coordinate AsA, thus facilitating a transfer of the electrons. The same behavior is proposed when using mixed complex containing Sb(III). A general feature of all the investigated molybdenum metal-substituted HPBs is the presence of the absorption band at approximately 720 nm. With a single exception—the analysis of beverages with very high citric acid content—the proposed methods have been successfully applied to the determination of AsA in complex matrices such as multivitamins, pharmaceutical formulations and fruit juices.

Metabolic disorder

ABSTRACT

Hereditary tyrosinemia type I is a serious metabolic disorder leading to liver failure. 2-(2-Nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) is a relatively new drug which is used to prevent the accumulation of toxic metabolites in patients with hereditary tyrosinemia type I. In the present study, we have developed a new, simple, fast, and cost-effective capillary electrophoresis method for the quantitative monitoring of this drug in serum samples. Micellar electrochromatographic separation of NTBC was performed using 20 mmol/L phosphate and 40 mmol/L sodium dodecylsulfate (SDS) at pH 12 as running electrolyte. Separation of NTBC was achieved in around 4 min. Reproducibilities of migration times and corrected peak areas of NTBC (as R.S.D.%) were found as 0.73 and 1.99, respectively. The detection limit was 3.17 and the quantification limit was 10.6 μmol/L for NTBC using UV detection at 278 nm. The utility of the method was demonstrated by the detection of NTBC in serum samples from patients with hereditary tyrosinemia type I using this drug.

1. Introduction

Tyrosinemia type I is a metabolic disorder caused by enzyme deficiency in tyrosine catabolism pathway, leading to liver failure [1]. Diagnosis is confirmed by increased tyrosine serum levels and large amounts of succinylacetone (SA) in urine. As the liver transplantation had been the only option, the introduction of NTBC in the treatment of tyrosinemia in 1992 [2] has reduced the need of liver transplantation and gave a good outlook for children with this disorder [3,4]. The use of NTBC is still under study. The clinical studies on the NTBC treatment have been steadily reported in different hospitals and in different countries. Every year, the European Medicines Agency (EMEA) reviews any new information on NTBC treatments. The current recommended starting dose is 1 mg/kg body weight/day and the dose is adjusted to the patient. In patients with poor response to NTBC treatment, the NTBC dose is increased to prevent the production of hepatotoxic metabolites, but keeping the serum NTBC concentration within the desired range of 40–50 μmol/l to prevent possible secondary NTBC effects [3,5–7]. A column liquid chromatographic method [8] and a LC–MS/MS method [9] were reported by now for the analysis of NTBC in plasma. Individual dose adjustment is based on the biochemical response and the plasma NTBC concentration. However, the analysis of plasma NTBC level is not routinely available for many laboratories. Following our first study on the rapid and easy capillary electrophoresis (CE) method for the determination of succinylacetone in urine samples from patients with hereditary tyrosinemia type I [10], the aim of present study is to develop an inexpensive and trustable capillary electrophoretic method for the detection and quantitative determination of NTBC in serum samples.

2. Experimental

2.1. Chemicals, standards and serum samples

Sodium dodecyl sulfate (SDS), and phosphoric acid were obtained from Merck (Darmstadt, Germany). Acetonitrile is from J.T. Baker (Deventer, Holland). All solutions were prepared with distilled water purified in an Elgacan C114 filtration system.

NTBC as Orfadin capsules with a purity of 99.8% (w/w) was supplied by Swedish Orphan AB, Stockholm, Sweden. Orfadin is a hard white-opaque capsule, marked as 2, 5, or 10 mg NTBC, plus pregelatinized starch. Orfadin capsules with a known amount of NTBC were dissolved in 5 mol/L NaOH. Starch was separated by centrifugation. After dilution to the desired concentration, solutions were filtered using 0.45 μm microfilter and injected directly to the capillary column.

doi:10.1016/j.talanta.2009.10.032

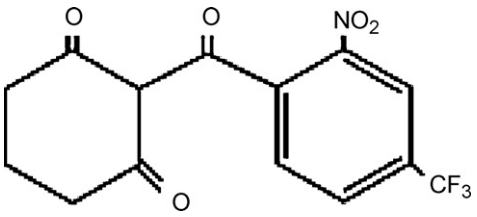

Fig. 1. Chemical structure of NTBC.

Serum samples were prepared by diluting the serum with acetonitrile (1/1.5, v/v) [11]. The solution was shaken for 5 min and centrifuged for 10 min. Before injection, the supernatant solutions were filtered using microfilter with a pore size of 0.45 μm. Buffer solution was prepared from H_3PO_4 stock solution by diluting it to 20 mmol/L by water and adjusting its pH with 0.1 M NaOH solution.

2.2. Apparatus and operating condition

Separations were performed with an Agilent capillary electrophoresis system (Germany) equipped with a diode-array detector. The data processing was carried out with the Agilent ChemStation software. The wavelength was set at 278 nm. The separation was performed at 28 kV. The fused silica capillaries used for the separation experiments were 75 μm i.d. and were obtained from Agilent. The total length of the capillary was 65 cm and the length to the detector was 56.5 cm. The new fused silica capillary was conditioned prior to use by rinsing with 1 mol/L NaOH for 30 min and with water for 10 min. The capillary was flushed by 0.1 mmol/L NaOH and water for 5 min each, in the beginning of every working day, and then the capillary was washed with buffer for 5 min. 5 min of flushing with buffer was performed between runs. Injections were made at 5×10^{-3} MPa for 5 s.

3. Results and discussion

NTBC is a triketone. The structure of molecule shown in Fig. 1 suggests that it could not be charged and separated in capillary zone electrophoretic conditions. In order to separate nonionic compounds in CE, an interaction with a charged carrier in the buffer must be provided. The most common technique to separate nonionic compounds is MEKC. By including a surfactant in the mobile phase, neutral molecules can be separated on the basis of their interaction with the micelles. The concentrations between 20 and 50 mmol/L in phosphate were tried as buffer and between 20 and 50 mol/L as surfactant. The optimal mixture was selected as 20 mmol/L phosphate and 40 mmol/L SDS. NTBC migrated in only 4 min with a good sensitivity using this buffer composition at pH 12. Fig. 2 A and B show the electropherograms of a serum sample and serum sample spiked with NTBC, respectively.

3.1. Method validation

3.1.1. Reproducibility

The precision of the method was checked by 5 successive injections of 100 μmol/L NTBC solution. The precision values for migration times and corrected peak areas (A/t) were 0.73 and 1.99% R.S.D., respectively. Between days precision values for peak areas ($n = 3$) were found as 2.43% R.S.D.

3.1.2. Linear range, LOD and LOQ

The calibration solutions were performed with NTBC solutions obtained by diluting standard NTBC solution with water. The calibration curve was plotted according to the corrected peak areas (A/t) between 25 and 200 μmol/L concentration ranges. The regression equation between this range was $y = 0.00101585x - 0.0006789$ and the correlation coefficients was found to be 0.99611 (r).

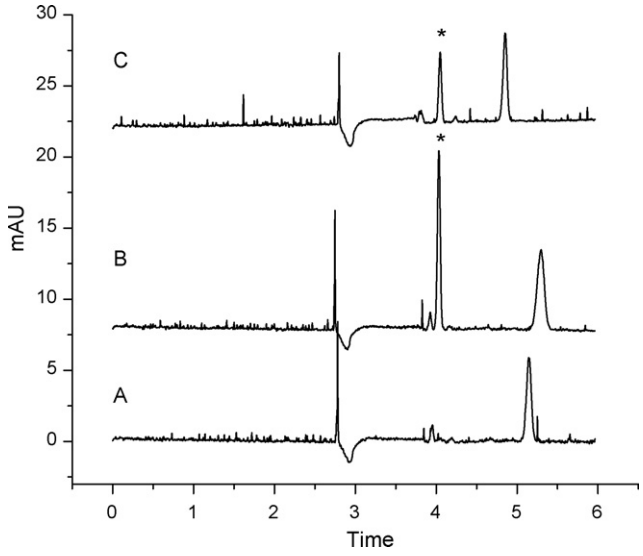

Fig. 2. Electropherogram of a serum sample (A); serum sample spiked with NTBC (B); serum sample from a patient with hereditary tyrosinemia type I (C), who was administrated NTBC. Injections: 5×10^{-3} MPa for 5 s. Running voltage: 28 kV. Capillary: 65 × 56.5 cm and 75 μm i.d. Detection: 278 nm. Separation electrolyte: 20 mmol/L phosphate and 40 mmol/L SDS at pH 12. *Shows NTBC peak, second peak is an unknown coming from serum.

The limit of detection was calculated as 3 times of the average noise taken for three different baseline areas and found to be 3.17 μmol/L for NTBC using UV detection at 278 nm. The limit of quantification is 10.6 μmol/L as 10 times of the average noise.

3.1.3. Accuracy of the method

Accuracy of the method was checked with the addition of NTBC to the serum samples for six measurements at three concentration levels, i.e., 50, 100, and 150 μmol/L NTBC. The recovery values were found between 74 and 84%.

Validation values are given all together in Table 1.

3.2. Application

The utility of the method was demonstrated by the detection of NTBC in serum samples from patients with hereditary tyrosinemia type I using this drug**.** The NTBC peak was identified by spiking with standard solution. Fig. 2C shows the electropherogram of a serum sample from a patient taken 1 mg NTBC/kg daily. The plasma concentration of this patient was found as 38.43 μmol/L NTBC.

Table 1
Validation values.

Run to run ($n = 5$) precision		
Corrected area (A/t)	1.99	
Day to day ($n = 5 \times$ 3 days) precision		
Corrected area (A/t)	2.43	
LOD (μmol/L)	3.17	
LOQ (μmol/L)	10.6	
Spiked to serum sample (μmol/L)		Recovery (%)
50		74 ± 7
100		84 ± 5
150		84 ± 4

4. Conclusion

In conclusion, NTBC level that is considered adequate in the treatment of tyrosinemia, is much higher than the LOD value in our developed method. Thus, capillary electrophoresis is highly recommended for the simultaneous control of both NTBC and succinylacetone, the latter with the use of the method that we have developed earlier [10] as an economic method both in time and money.

ABSTRACT

A new ultra high-performance liquid chromatography method with UV detection was examined for detection and separation of polychlorinated biphenyls. This included optimization of separation conditions for two model mixtures containing seven and fifteen most relevant congeners, comparison of three types of reversed phase sub-2-micron particle sized columns and assessment of system suitability under the optimized conditions. Calibration curves determined in the range from 0.5 to 50.0 μg/mL exhibited correlation coefficients ranging from 0.997 to 0.999. Lower limits of detection ranged from 0.1 to 0.5 ppm. The most efficient Grace C18 column filled with 1.5 μm particles was then tested to separate the complex commercial mixture Delor 103, where the elution order was confirmed by GC–MS. 13 individual congeners were separated and some of the other co-eluting congeners could be resolved using another separation dimension performed with a mass spectrometry detector. The developed method could be directly applied to the separation of less complex mixtures in aqueous sample matrixes, which are used in general for enzyme degradation studies.

1. Introduction

Although the industrial use and production of polychlorinated biphenyls (PCBs) has long been banned, the persistency of these compounds means they still represent a serious environmental problem. It has been widely reported that determination of PCBs in environmental samples is a difficult task [1,2].

The complexity of the chromatographic separation of PCBs consists in the number of possible congeners (209) and their physico-chemical similarities, together with the complexity of environmental matrices harboring the PCBs. For this reason, gas chromatography (GC) has always been the method of choice for determination of these compounds [3,4], since it allows the congener-specific analysis of PCBs and the routinely used detectors, ECD, MS and HRMS, to exhibit high sensitivity.

Two-dimensional gas chromatography [5,6] has been investigated by a number of researchers in order to solve certain co-elution problems inherent in single-column analysis. A number of GC column combinations have been used to resolve the co-elution of PCBs [7]. Several authors used two-dimensional chromatography with HPLC as the first separation dimension for fractionation. PCB atropisomers were partially separated using chiral stationary phases (beta-cyclodextrin derivatized silica) [8] and dioxin-like PCBs were fractionated on an activated carbon-based column [9,10], porous graphitic carbon [11], or (2-(1-pyrenyl)ethyl)dimethylsilylated silica [12]. Other applications of column liquid chromatography described in the literature include the use of various systems for PCB separations from the matrix or other compounds [13,14]. A limited number of publications are available on application of the HPLC technique for determination of PCBs. Andersson and Kaiser [15] tested several modified stationary phases including octadecylsilica for separation of commercial mixture Aroclor. A partial improvement of separation was observed with phenyl butano sulfide stationary phase [15].

Another new technique, ultra high-performance liquid chromatography (UHPLC), which has been introduced into practice, is based on the HPLC principle but provides separation efficiency attaining GC parameters. According to the Van Deemter equation, when the particle size of the chromatographic sorbent is decreased, the efficiency of the separation process increases and the efficiency does not diminish at higher flow rates or linear velocities [16]. The separation speed, resolution, sensitivity and peak capacity can be improved by using smaller particles. UHPLC technique offers both a high throughput of the analyzed samples and separation of complex mixtures like PCBs. The latter feature is caused by the large peak capacity mentioned above. Another advantage over common HPLC consists in the reduced time of analysis and solvent consumption. Sub-2-micron particle columns provide maximum efficiency, leading to back-pressures of more than 60 MPa, which cannot be achieved by using conventional liquid chromatographic systems or

doi:10.1016/j.talanta.2009.10.033

columns [17]. UHPLC systems can work at extreme pressures up to 100 MPa [18] due to hardware adjustments. While the separation of PCB derivatives using HPLC is probably not sufficient, the UHPLC application on special columns with sub-2-micron particle could lead to better separation. A number of producers currently offer reversed phase columns with sub-2-micron particle size sorbents with different properties that are suitable for UHPLC applications. In addition to the original columns provided by Waters that use octadecyl silica Bridged Ethyl Hybrid (BEH) particles with diameter of 1.7 μm, several other producers manufacture UHPLC columns e.g. Zorbax Rapid Resolution High Throughput 1.8 μm from Agilent or C18 Grace 1.5 μm from Alltech.

The aim of this study was to test the ability of liquid chromatography on reversed phase sub-2-micron particle columns, viz. BEH C18 (1.7 μm), Waters; BEH Phenyl (1.7 μm), Waters; Vision HT C18 Grace (1.5 μm), Alltech, for the separation of the most often monitored PCB congeners in two premixed mixtures and for the separation of the commercial mixture Delor 103.

2. Experimental

2.1. PCB model mixtures and other chemicals

Two model mixtures of PCBs were used to test the retention behavior and for a quantitative study. Mix A consisted of PCBs 18, 28, 52, 101, 153, 138, 180 (Dr. Ehrenstorfer GmbH, Augsburg, Germany). Mix B included the most toxic PCB congeners supplemented with several other congeners with three, four and five mainly ortho-chlorine substituents: 18, 28, 37, 45, 77, 81, 91, 101, 105, 114, 118, 123, 126, 156 and 169. The individual PCB congeners used for the preparation of this mixture were also obtained from Dr. Ehrenstorfer GmbH (Augsburg, Germany). Both of the mixtures contain the most relevant congeners that are commonly monitored [19,20]. The PCB commercial mixture used for the investigation, Delor 103, with an average of 3 chloro substituents, was obtained from a former Czechoslovak producer (Chemko Strážské, Slovakia). The congener composition of Delor 103 has been described in detail in previous investigations [21]. Acetonitrile (Biosolve) and water (Biosolve) used for UHPLC mobile phase preparation were of UHPLC–MS grade and were purchased from Chromservis (Prague, Czech Republic).

2.2. UHPLC analysis conditions

An Acquity UHPLC system (Waters, Milford, MA, USA), equipped with a 2996 photodiode-array detection (DAD) system detector operating at 202 nm, was used for PCB analysis. The data were processed with Empower 2 software (Waters). For elucidation of the UHPLC elution order and identification of the PCB congeners, the mobile phase of the best chromatographic run was collected (4 times per minute) using an automated fraction collector (Labio, Prague, Czech Republic). These fractions were subsequently analyzed using GC–MS to confirm the structures of the individual congeners.

For simplicity, PCBs were monitored at the same wavelength of 202 nm, where all of them display significant absorbance.

Three sub-2micron particle UHPLC analytical columns were compared for their efficiency in PCB separation: BEH C18 (50 mm × 2.1 mm I.D., particle size 1.7 μm), Waters; BEH Phenyl (50 mm × 2.1 mm I.D., particle size 1.7 μm), Waters; Vision HT C18 Grace (50 mm × 2.0 mm I.D., particle size 1.5 μm), Alltech.

The binary mobile phase consisted of solvent A, 100% acetonitrile, and solvent B, 10% acetonitrile in water was employed under the following linear gradient program (min/%A) 0/15, 6/40, 14/40, 20/45, 30/95, 35/95. This program was used for column comparison and later also for separation of Delor 103.

Each analysis was followed by a column equilibration step (5 min). The column temperature was maintained at 35 °C, and the flow rate was set at 0.4 mL/min. Sample volumes of 5 μL were injected. The total analysis time was 30 min, the data were collected at 20 Hz sample rate and the filter constant was set at 0.5.

2.3. UHPLC partial validation (calibration curves, LLOQ, LOD)

Calibration curves obtained with UHPLC technique were determined over a linear range from 0.5 to 50.0 μg/mL for the selected PCBs (Nos. 18, 28, 37, 45, 52, 77, 81, 91, 101, 105, 114, 118, 123, 126, 138, 153, 156, 169 and 180). Accurately weighted portions of each solid congener were dissolved in acetonitrile to prepare 50 μg/mL stock solutions. Then each stock solution was diluted stepwise with acetonitrile to prepare a series of standard solutions, with concentrations of 50.0, 25.0, 10.0, 5.0, 1.0, 0.5 and 0.1 μg/mL.

The lower limit of quantification (LLOQ) was determined as the lowest concentrations of PCBs quantified with precision (RSD) and accuracy lower than 20% [22]. For quality control (QC), six replicates of all the quantified PCB standards with the concentration 0.5 μg/mL (0.1 μg/mL in the case of PCB 101) were measured. At this concentration level, the signal-to-noise ratio was found to be greater than 10.

The limit of detection (LOD) was calculated as follows: LOD = LLOQ/0.33.

2.4. UHPLC system suitability

Both model mixtures (Mix A and Mix B) were injected 6 times into a UHPLC system under optimized conditions (Grace column, for chromatographic conditions see Section 2.2, UHPLC analysis conditions). The mean values and RSD (%) of the peak retention times and peak areas of the monitored congeners were calculated to obtain the repeatability. The other parameters to be determined included the peak symmetry, resolution and EP plate count.

2.5. GC–MS analysis conditions

The GC–MS system 450-GC with an ion trap 240-MS (Varian, Walnut Creek, CA, USA) was used for a qualitative PCB analysis. The Varian MS workstation 6.9.1. was used as data processing software.

The column used was a 30 m DB-5MS capillary column of 0.25 mm I.D. and 0.25 μm film thickness (C&W). One microliter of each sample was splitless injected at 240 °C. Helium was used as a carrier gas with a constant flow rate of 1 mL/min. The GC oven temperature program started at 60 °C, was held for 1 min and then increased at 25 °C/min to 120 °C. Further heating followed at 2.5 °C/min to 240 °C, which was finally maintained for 19 min. The transfer line, manifold and ion chamber temperatures were set at 240, 220 and 240 °C, respectively. The mass spectrometer operated under an external ionization mode and mass spectra were recorded under electron impact at 70 eV.

2.6. HPLC analysis conditions

In order to compare the efficiency of the HPLC technique an HPLC system was used for separation of D103, as well. Separation was tested on two conventional reversed phase columns: Xbridge C18 (250 mm × 4.6 mm I.D., particle size 3.5 μm), Waters and Synergy Polar RP (250 mm × 4.6 mm I.D., particle size 4 μm), Phenomenex. The HPLC system consisted of binary gradient pump 522, autosampler 465, and diode-array detector 540+, (Bio-tek Instruments, Italy). The binary mobile phase consisted of solvent A, 100% acetonitrile, and solvent B, 10% acetonitrile in water, was employed under the following linear gradient programs: Xbridge column (min/%A) 0/65; 30/100; 50/100 and Synergi column 0/65; 60/100; 70/100

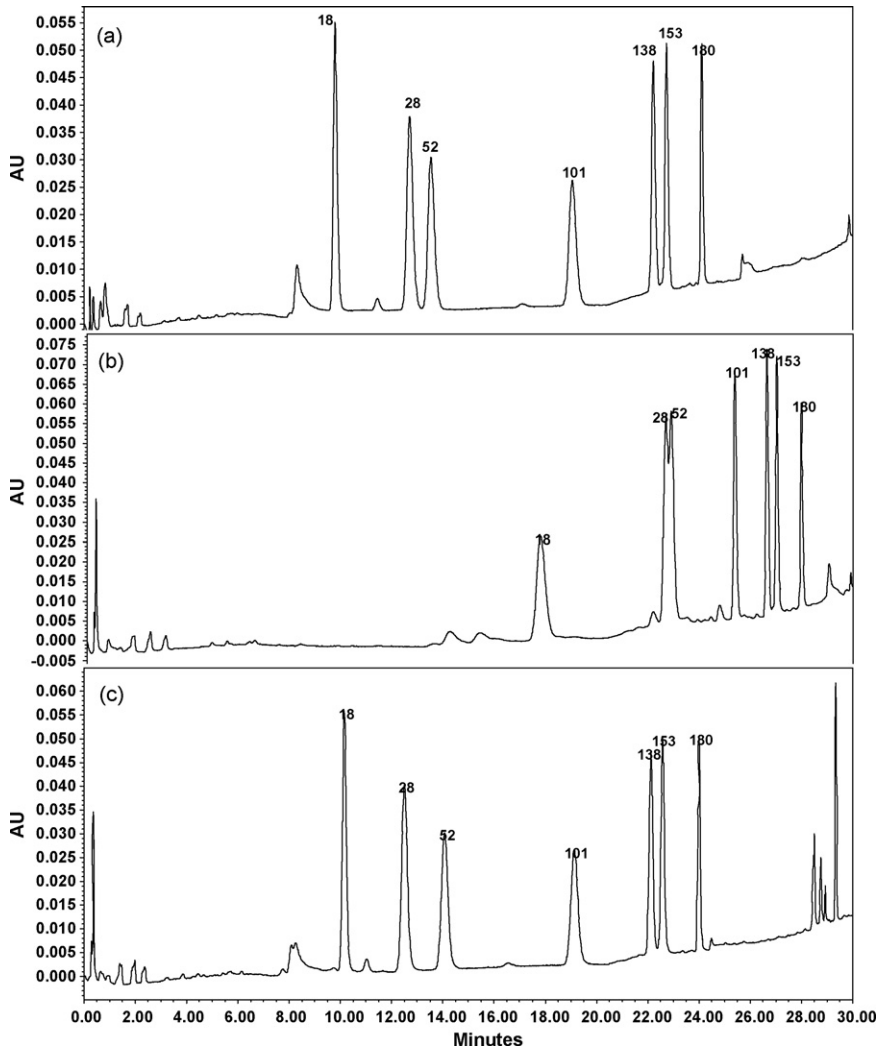

Fig. 1. Comparison of Mix A (4 μg/mL of each congener) separation with three various columns: Vision HT C18 Grace column (a), BEH C18 column (b), BEH Phenyl column (c). Chromatographic conditions: solvent A, 100% acetonitrile, solvent B, 10% acetonitrile, gradient program (min/%A) 0/15; 6/40; 14/40; 20/45; 30/95; 35/95, equilibration step (5 min), column temperature 35 °C, flow rate 0.4 mL/min, sample volume 5 μL.

Table 1
Verified values of LLOQ and LOD of the tested PCB congeners separated on the C18 Grace column.

PCB No.	LLOQ (μg/mL)	Accuracy (%)	RSD (%)	LOD (μg/mL)	Regression equations	R^2
18	0.5	104.1 ± 0.3	0.3	0.15	$y = 1.40 \times 10^5 x - 7.26 \times 10^3$	0.999
28	0.5	113.4 ± 2.4	2.1	0.15	$y = 1.11 \times 10^5 x - 1.33 \times 10^4$	0.999

(min/%A). The column temperature was maintained at 35 °C, and the flow rate was set at 1 mL/min. Sample volumes of 5 μL were injected and PCBs were monitored at the wavelength of 202 nm.

3. Results and discussion

3.1. UHPLC

Several gradient programs (approximately 20 for each column, data not shown) based on a multiple, stepwise increase of the acetonitrile ratio were applied to all of the three tested sub-2-micron particle columns in order to obtain the separation of the congeners in the premixed mixtures. All of the three columns yielded sufficient separation of Mixture A (Fig. 1). However, only the C18 Grace column exhibited the ability to separate more complex Mixture B (Fig. 2), while some congeners showed poor or no tendency to separate on columns BEH C18 (1.7 μm), and BEH Phenyl (1.7 μm) (Waters). The optimized gradient program (see Section 2.2) for the C18 Grace column was therefore used with the other columns to demonstrate their selectivity for the PCB congeners in the mixtures. The chromatograms presented in Figs. 1 and 2 show that, under these conditions, the Phenyl BEH column appeared to be almost as efficient in the separation of Mix A as the C18 Grace column while, in Mixture B, it was not able to separate the congeners 28 from 37, 91 from 77 and especially the later-eluting congeners (Nos. 114, 118, 123, 126) (see Fig. 1c). The C18 BEH column, which was the first one routinely used for UHPLC separations [23,24], yielded good separation of most of the peaks in the mixtures (Fig. 1b). However, it was necessary to substantially extend the chromatographic run to attain sufficient separation of congeners Nos. 123, 114, 118 and 126. Also in this case, the early eluting congeners Nos. 28 and 37 were not separated under any of the tested conditions.

The results in Fig. 1 also suggest that, in addition to different analyte–sorbent interactions among phenyl and the octadecylsilica columns, the size of the particles can probably play an important role in the efficacy of the separation [16]. Another explanation for the different selectivity of both C18 columns could be the silica end-capping technology used. Residual silica hydroxyl groups in the Grace column might probably cause higher specificity of this stationary phase for PCB congeners due to a different solute–sorbent interaction.

3.2. Calibration curves

The PCB (except for the congener No. 101) calibration curves were prepared over a linear range from 0.5 to 50.0 μg/mL at six concentration levels, 0.5, 1.0, 5.0, 10.0, 25.0, 50.0 with the C18 Grace column. The calibration curve of congener No. 101 was prepared in the range from 0.1 to 50.0 μg/mL at seven concentration levels, 0.1, 0.5, 1.0, 5.0, 10.0, 25.0, and 50.0. The relevant regression equations and determination coefficients R^2, which range from 0.997 to 0.999, are given in Table 1.

3.3. LOD, LLOQ

The LLOQ of the quantified congeners, except for congener No. 101, was 0.5 μg/mL with a precision (RSD) ranging from 0.3 to 5.7% and accuracy from 91.4 ± 3.3 to 117.9 ± 1.7% (n = 6). The LOD for these congeners were 0.15 μg/mL. The LLOQ of congener No. 101 was determined as 0.1 μg/mL with a precision (RSD) of 1.9% and accuracy of 107.3 ± 2.1%. The calculated LOD of congener No. 101 was 0.03 μg/mL.

3.4. System suitability

System suitability data are listed in Table 2. The retention time repeatability (RSD) is excellent (maximum of 0.01%). The peak area repeatability ranges from 0.4 to 5.0%. The maximal RSD values were observed for peaks that were not sufficiently separated. Part of this error can be attributed to use of the partial loop injection mode, which was discussed by other authors [25].

The peak symmetry, resolution and EP plate count were calculated for sufficiently separated peaks. Since the mixtures contain PCB congeners without any significant interferences, the resolutions were calculated only between the nearest congeners. The column efficiency expressed as the EP plate counts increases for compounds with higher retention times. This fact corresponds with the band broadening theory. As the content of acetonitrile is higher during the gradient, the later-eluting peaks are sharper since they are focused in a narrower zone. This phenomenon is also visible in the chromatograms depicted in Fig. 1. All the peaks had symmetrical shape with a symmetry factor ranging from 1.09 to 1.18.

Table 3
Delor 103 peak identification after separation on the C18 Grace column.

Peak No.	Retention time (min)	Congener No.	Peak No.	Retention time (min)	Congener No.
1	7.6	4	17	14.8	47,49, 84, 89, 92

16	14.1	52, 71, 64, 41,72			

3.5. Comparison of HPLC and UHPLC for the separation of Delor 103

The UHPLC C18 Grace column was subsequently tested for the separation of PCB congeners in the commercial mixture Delor 103. The chromatogram is depicted in Fig. 3 and the peak identification is given in Table 3. The results show that the UHPLC method was able to separate 13 individual congeners in the D103 mixture. Other compounds were co-eluted in clusters, but some of these co-eluting congeners could be resolved using another separation dimension performed with a mass spectrometry detector e.g. Nos. 37-42, 41, 91, 83, 148. Generally, the elution order of UHPLC is comparable with that of GC, suggesting participation of a similar hydrophobic retention mechanism.

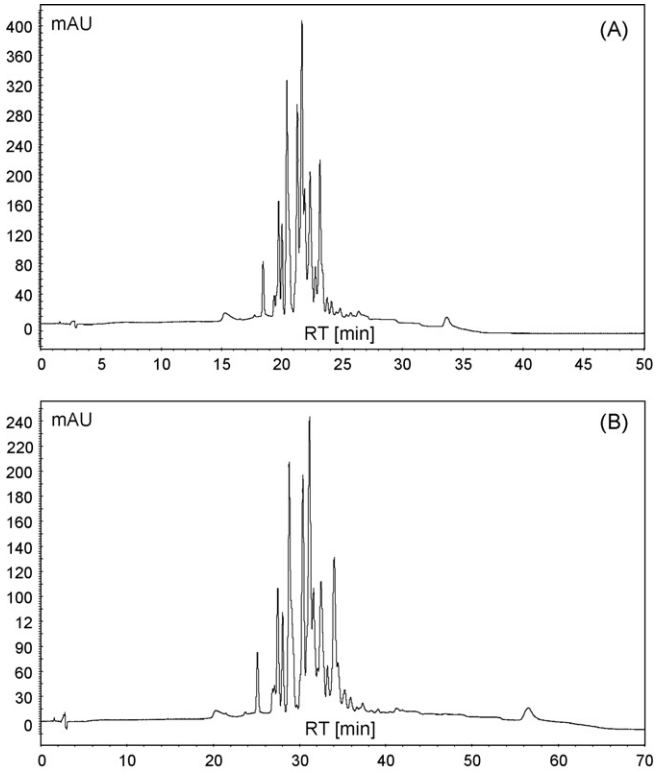

Fig. 4. Chromatogram of Delor 103 (100 μg/mL) HPLC separation with the C18 Xbridge (A) and Synergi (B) columns. For chromatographic conditions see Section 2.6.

In order to show the reasonability of this study of the UHPLC application we also briefly tested two conventional HPLC packed with 3.5 and 4.0 μm particles, respectively. Several various gradients were also applied in this case and the selected ones (see Section 2.6) were applied to separation of D103 mixture. The chromatograms are shown in Fig. 4. The figure documents substantially lower separation efficiency of the HPLC stationary phases comparing to sub-2-micron particle columns. This is mainly evident for the dominant trichloro congeners. The later-eluting tetra chlorinated representatives that are only partially separated from the main peak cluster.

The outcomes of this study imply that UHPLC separation of PCB mixtures cannot be for the meantime a real alternative to the classical GC determination. However, the results show that the technique could be used for specific experiments like biodegradation studies that are carried out with less complex mixtures of PCBs [26]. Another aspect to be pointed out is that the study was performed with commercial UHPLC columns and development of taylor made stationary phases for the separation of chlorinated aromatics could lead to further improvement of PCB separation.

4. Conclusion

In this article, three columns were compared under chromatographic conditions optimal for the most efficient column. Two premixed mixtures of PCBs often monitored for their abundance or high toxicity were successfully separated with the Grace C18 column filled with 1.5 μm particles. The fact that the best column was filled with the smallest particles indicates the importance of the sorbent particle size. The newly developed UHPLC method was partially validated and exhibited a linear range of detector response for quantification of PCBs with acceptable correlation coefficients. LLOQ was determined and verified at sub μg/mL concentrations. An attempt was made to separate the commercial PCB mixture Delor 103 under the selected conditions and the mixture was separated with some success. Individual PCB congeners were identified using comparison with standard retentions and also using GC–MS of collected UHPLC fractions.

To our knowledge, this is the first article dealing with UHPLC reversed phase separation of complex PCB mixtures suggesting a new potential direction in UHPLC applications. The combination of high throughput and efficiency of the UHPLC technique with the selectivity and sensitivity of mass spectrometry would be a promising way to enlarge the number of UHPLC applications in the environmental analysis.

The advantage of PCB determination with the liquid chromatography alternative to GC should be not only an enlargement of applications for UHPLC, but also it could be useful for specific sit-

uations such as performing PCB biodegradation experiments. For example enzymatic studies are carried out in liquid water systems and direct analyses of such samples allow to measure kinetics directly from one experimental sample avoiding extraction and purification steps that are necessary for GC and lead to termination of the particular sample [26].

Gas chromatography–atomic emission detection

ABSTRACT

A method based on solid-phase microextraction (SPME) followed by gas chromatography with microwave-induced plasma atomic emission detection for determining dimethylselenide (DMSe) and dimethyldiselenide (DMDSe) in milk and milk by-products is proposed. Parameters affecting the SPME, such as sample volume or mass, ionic strength, adsorption and desorption times and temperatures were optimized in the headspace mode. The matrix effect was evaluated for the different samples studied, concluding that standard additions calibration was required for quantification purposes. The detection limits ranged from 70 to 110 pg mL^{-1} for DMSe and from 80 to 400 pg mL^{-1} for DMDSe, depending on the sample under analysis. None of the twenty-three samples analyzed contained the studied compounds at concentrations above the corresponding detection limits.

1. Introduction

The selenium content in the milk of dairy cows from different countries has been reported to be in the 2–1270 $\mu g\,L^{-1}$ range [1], these values being directly related with the cow origin and feed, the amount of selenium in the soil and the season. Because of the role that selenium plays in cancer prevention, the supplementation of foods (including milk) has been gaining ground in the recent years, and it has been found that supplementing the cows' diet with selenium-enriched yeast is generally more effective than with inorganic selenium [2]. Selenoaminoacids and selenoproteins are the main forms in which this element appears in milk [3], whereas the appearance of alkyl volatile compounds dimethylselenide (DMSe) and dimethyldiselenide (DMDSe) in this sample matrix has not been reported in the literature. It is widely known that they are the most abundant organoselenium compounds in environmental and biological samples [4], and are considered to be 500 times less toxic than selenite. The production of both compounds by the biomethylation of inorganic selenium by microorganisms, as well as by the conversion of selenocystine and selenomethionine by various organisms, is well documented [4–6]. Bacteria cultures are used in milk fermentation to produce yogurt, *Lactobacillus bulgaricus* being the most widely used and sometimes others *Lactobacillus* like *acidophilus* or *casei* and *Streptococcus salivarius*. Since several milk by-products are enriched with lactic bacteria, the question of a possible appearance of volatile selenium compounds in these enriched dairy products could be posed.

Volatile organic selenium compounds are traditionally determined by gas chromatography because of its high sensitivity and the fact that no derivatization step has to be included in the whole procedure [6–19]. Plasma spectrometry has proved to be an interesting detection system to gas chromatography [4], with microwave induced plasma coupled to atomic emission detection (MIP-AED) [7,15–19] considered as a good alternative to the expensive detector based on inductively coupled plasma with mass spectrometry (ICP-MS) [10,13]; other detection techniques used in selenium speciation are atomic fluorescence spectrometry (AFS) [9], electrothermal atomic absorption spectrometry (ETAAS) [6,11], mass spectrometry (MS) [5,8] and photoionization detection (PID) [14].

The low concentration of the analytes here aborded and the complexity of the milk matrix make it necessary to include extraction and preconcentration steps in the analysis procedure. Solid-phase microextraction (SPME) is a simple and efficient alternative to the analysis of the organic substances present at trace concentration levels in complex matrices [20]. SPME, which brings together all the conditions necessary to be considered as a sample preparation technique in green analytical chemistry, since it avoids

doi:10.1016/j.talanta.2009.10.034

the use or generation of substances harmful to human health and the environment [21], has been used to preconcentrate alkylselenium compounds from different matrices [13,15–17,19,22].

The present work focuses on the determination of the low-molecular-weight volatile selenium compounds, DMSe and DMDSe, by means of SPME in headspace mode and GC–MIP–AED. The possibility of that organic or inorganic selenium compounds may be converted into DMSe and/or DMDSe in milk and milk by-products matrices is also considered.

2. Experimental

2.1. Chemicals

Dimethylselenide [$(CH_3)_2Se$, DMSe; 99% purity] and dimethyldiselenide [$(CH_3)_2Se_2$, DMDSe; 98% purity] were obtained from Fluka (Buchs, Switzerland) and Aldrich (Steinheim, Germany), respectively. Standard solutions of 1000 μg mL^{-1} of the volatile compounds were prepared by appropriate dilution in methanol and stored at 4 °C. Lower concentration stock solutions of the organocompounds were prepared daily in methanol and stored in the refrigerator. Working standard solutions of both analytes were prepared immediately before use by diluting with water obtained from a Milli-Q water purification system (Millipore, Bedford, MA, USA). Sodium chloride, casein powder from bovine milk and lactalbumin were provided by Sigma (St. Louis, MO, USA).

The plasma gas and carrier gas used for GC was helium. The reagent gas for the AED was hydrogen. Nitrogen was used for purging the AED system. All the gases (99.999% purity) were supplied by Air Liquide (Madrid, Spain).

It should be noted that DMSe and DMDSe have the following risk (R) [23] and safety (S) [24] notes: R23/25-33-50;S20/21-28-45-60-61, and should be handled with the appropriate caution.

2.2. Instrumentation

The SPME device for manual sampling consisted of a holder assembly and several replaceable fibers, all obtained from Supelco (Bellefonte, PA, USA). SPME fibers coated with non-bonded polydimethylsiloxane (PDMS) of 100 μm thickness, bonded polydimethylsiloxane/divinylbenzene (PDMS/DVB) of 65 μm, bonded stableFlex divinylbenzene/Carboxen/polydimethylsiloxane (DVB/CAR/PDMS) of 50/30 μm, bonded Carboxen/polydimethylsiloxane (CAR/PDMS) of 75 μm and bonded polyacrylate (PA) of 85 μm, were obtained from Supelco. The fibers were conditioned prior to use by heating in the injection port of the chromatographic system under the conditions recommended by the manufacturer for each fiber coating. Whenever needed, the conditioning step was repeated for fiber cleanup. All analyses were performed in 15 mL clear glass sealed vials. An RH-KT/C magnetic stirrer (IKA, Staufen, Germany) and a home-made heating system consisting of a drilled block provided with an electronic temperature control system were used for stirring and heating, respectively, during the extraction step. PTFE-coated magnetic stir bars (10 mm × 6 mm O.D.) were used for stirring the samples. The SPME experimental conditions appear in Table 1.

An Agilent 6890 gas chromatograph was directly coupled by a transfer line to a G2350A microwave-induced plasma atomic emission detector (Agilent, Waldbronn, Germany). The updated G2070AA ChemStation application with G2360AA GC–AED software was used to control the GC and AED systems, and for data acquisition and treatment. The experimental conditions for chromatographic separation and the detection system are summarized in Table 1. A SPME liner (Supelco) of 0.75 mm I.D. was used. The helium make-up flow-rate was set at 180 mL min^{-1}, and was measured with the window purge gas flow on. Filter and backamount adjustment in the AED were set according to Agilent default specifications.

2.3. Samples. SPME procedure

The twenty-three dairy products analyzed (four whole milk samples, four partially skimmed milk samples, four skimmed milk samples, two infant formula samples, one probiotic infant formula sample, three yogurt samples, two probiotic yogurt samples and three probiotic liquid yogurt samples enriched with bifidobacteries) were obtained from a local supermarket.

The infant formula samples were prepared by dissolving 12 g of sample in 100 mL of water, according to the manufacturer's recommendations. The yogurt was prepared by adding 1 mL of water to 2 g of the solid sample previously weighed; the rest of the samples were analyzed as received.

To carry out the extractions, 2 mL of sample were placed into a 15 mL SPME–vial, into which 0.6 g NaCl had been previously weighed. The vial was immediately sealed with the cap after introducing the magnetic stir bar and the mixture was homogenized for 0.5 min by inserting the vial in the home-made heating module previously programmed at 40 °C and setting the stirring speed at 1300 rpm. The SPME fiber was exposed for 5 min to the headspace sample solution. Next the fiber was placed into the GC injector, thermally desorbed for 1 min and then removed. Each sample was performed in duplicate. Table 1 shows the experimental conditions of the SPME–GC–AED system.

2.4. Recovery assays

Since no reference materials are available for the validation of the method, spiked samples were prepared. Samples were spiked by adding 25 and 50 μL of a working solution, containing DMSe and DMDSe at concentration levels of 100 and 250 ng mL^{-1} to 2 mL of milk sample and 2 g of yogurt, respectively, previously weighed in 15 mL SPME vials, these concentration levels corresponding to about 5 and 10-fold the corresponding quantitation limits. The spiked samples were set aside for 60 min in the closed vessels and analyzed as described above. The fortification procedure was applied to four different samples.

3. Results and discussion

3.1. Chromatographic and AED parameters

To proceed with the optimization of the chromatographic separation and detection steps, 0.2 μL of a methanolic standard solution containing the analytes at a concentration level of 250 ng mL^{-1} were injected in the splitless mode. With the polar-stationary phase DB-624 and the program finally selected (summarized in Table 1), the most volatile compound was eluted at about 90 °C and DMDSe at the beginning of the ramp from 140 to 300 °C. Separation was carried out at a 4 mL min^{-1} constant flow-rate, since this value reduced the analysis time needed and increased the sensitivity compared with lower flow-rates. Higher helium flow-rate values are not recommended by the manufacturer to preserve the stationary phase. The chromatographic conditions finally adopted elute DMSe and DMDSe at retention times of 3.03 and 4.96 min, respectively.

Hydrogen is the only reagent gas required for monitoring the selenium wavelength emission line. When hydrogen pressure was varied between 5 and 30 psi, the peak area of both compounds was maximum at 10 psi, so this value was selected. To study the supplementary helium required, a standard solution was injected using different make-up gas-flow rates ranging from 140

Table 1
Experimental conditions of the SPME–GC–AED system.

SPME conditions	Adsorption step	5 min at 40 °C (Headspace mode)
	Desorption step	1 min at 310 °C (splitless)
	Fiber material	CAR/PDMS, 75 μm
GC conditions	Capillary column	DB-624 (30 m × 0.32 mm I.D. × 1.8 μm)
	Carrier gas	Helium, 4 mL min^{-1}
	Oven program	40 °C (2 min)–140 °C at 50 °C min^{-1}, 140–300 °C at 60 °C min^{-1} (1 min)
GC–AED interface	Transfer line	DB-624
	Transfer line temperature	325 °C
AED conditions	Reagent gas	H_2 at 10 psi
	Spectrometer purge flow	Nitrogen, 2.5 L min^{-1}
	Helium make-up flow	180 mL min^{-1}
	Cavity temperature	325 °C
	Se wavelength	196.018 nm

to 200 mL min^{-1}. Maximum sensitivity was obtained for both analytes at 180 mL min^{-1}, which was selected. The transfer line and the cavity temperatures were optimized between 250 and 350 °C and best results were obtained at 325 °C.

3.2. Optimization of the SPME procedure

To optimize the SPME procedure a fortified sample was used considering the possibility that the sample matrix influences the extraction parameters. Seven mililiters of a partially skimmed milk fortified at a concentration level of 10 ng mL^{-1} for both analytes were used. All experiments were carried out in duplicate and, unless specified, in the headspace mode, considering the volatility of the studied compounds.

3.2.1. Selection of the fiber coating and the extraction mode

Five different fiber-coating materials were tested in order to obtain maximum sensitivity and repeatability by exposing the fiber to the sample for 20 min at 40 °C. Neither analyte was extracted when the polar polyacrylate and the non-polar polydimethylsiloxane materials were used. As can be observed in Fig. 1, the 65 μm PDMS/DVB extracted the compounds but to a very low extent. As regards the partially crosslinked 50/30 μm divinylbenzene/Carboxen/polydimethylsiloxane (DVB/CAR/PDMS) and the 75 μm Carboxen/polydimethylsiloxane (CAR/PDMS) fiber materials, although no significant sensitivity-related differences were obtained in the case of DMDSe, the CAR/PDMS fiber provided higher sensitivity for DMSe and higher repeatability in both cases, as can be observed in Fig. 1. Both immersion and headspace extraction modes were checked for each fiber coating, headspace providing higher sensitivity in all cases except for the preconcentration of DMDSe when using PDMS/DVB. The results obtained are in accordance with those previously reported by Dietz et al. [22].

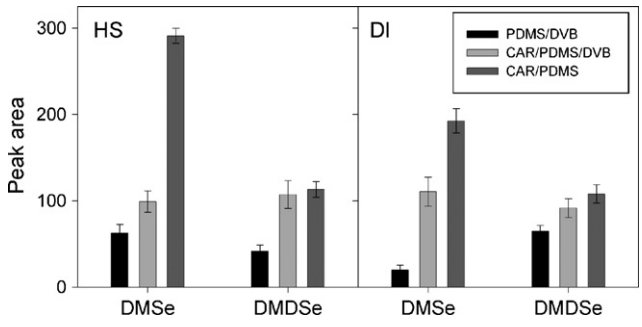

Fig. 1. SPME-extraction efficiencies for DMSe and DMDSe obtained using different fiber coating materials in the headspace (HS) and direct immersion (DI) mode, with temperatures of 40 and 300 °C and times of 20 and 2 min for the extraction and desorption steps, respectively. Vertical bars indicate the corresponding standard deviations ($n = 5$).

The influence of the ionic strength of the extraction solution was studied by incorporating different percentages from 0 to 30% (w/v) of sodium chloride to the extraction vial, and extracting the mixture for 20 min at 40 °C. The presence of salt in the sample matrix did not change the sensitivity in the case of DMDSe, while a 30% (w/v) salt concentration resulted in much higher sensitivity for DMSe. The addition of NaCl at this concentration level was therefore adopted.

3.2.2. Adsorption temperature and time

The adsorption temperature was varied between ambient and 98 °C for 7 mL of partially skimmed milk fortified with 2.5 and 5 ng mL^{-1} of DMSe and DMDSe, respectively, with an adsorption time of 20 min and the results are shown in Fig. 2A. Temperatures higher than 60 °C provided a decrease of sensitivity for both compounds probably due to a decrease in the partition coefficients between the fiber coating material and the sample headspace. A temperature of 40 °C was finally selected. The adsorption time was studied from 2 to 20 min, maintaining the vial at 40 °C. As can be observed in Fig. 2B, 5 min were enough to reach equilibrium, and this extraction time was adopted.

3.2.3. Extraction solution volume and stirring speed

The sample volume was studied in 15 mL SPME vials using volumes ranging between 1 and 10 mL of a fortified partially skimmed milk sample. Higher volumes were not assayed because they led to partial immersion of the fiber in the sample solution. The sensitivity of both selenium compounds was maximum for 2 mL, decreasing at higher volumes, especially in the case of DMDSe (Fig. 2C). Taking into account that sample dilution may lead to higher sensitivity [25,26], a study was carried out by diluting the fortified sample. The lowest detection limits were obtained by preconcentrating the analytes from 2 mL of non-diluted milk sample. In the case of solid samples, such as yogurts, different sample mass to water volume ratios were assayed, and best results were obtained for 2 g sample mass homogenized with 1 mL of water.

Stirring of the sample solution enhanced the sensitivity for both analytes, and when the effect of this parameter was studied by varying the stirring speed between 0 and 2000 rpm, maximum sensitivity for both alkyl selenium compounds was observed at 1300 rpm, which was selected.

3.2.4. Desorption parameters

The CAR/PDMS fiber was submitted to different temperatures in the injection port of the GC ranging from 250 °C and the highest temperature permitted by the coating, 310 °C, for 1 min. The sensitivity increased with temperature, 310 °C providing the best results for both compounds. The desorption time was varied at the temperature value selected, with 0.3 min being sufficient to desorb the analytes. 1 min was finally selected in order to ensure the des-

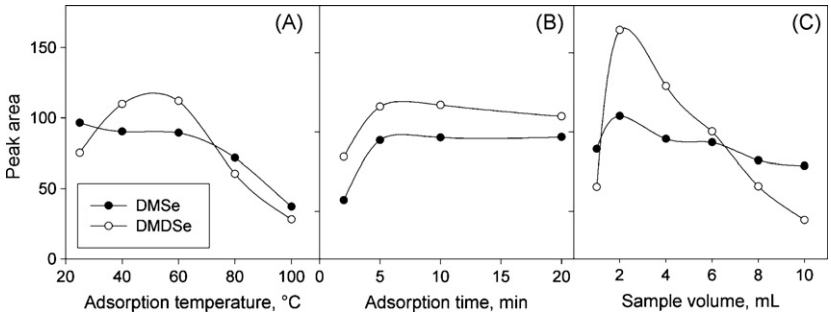

Fig. 2. Influence of (A) adsorption time, (B) adsorption temperature and (C) sample volume on the analytical signal of a partially skimmed milk sample fortified with 2.5 and 5 ng mL^{-1} of DMSe and DMDSe, respectively, by using a CAR/PDMS fiber in the HS mode.

orption of higher analyte concentrations and to remove possible carryover effects.

3.3. Analytical characteristics of the method

Different values for the calibration slopes were obtained when standard additions calibration graphs were constructed, the values depending on the sample. The calibration data obtained for five different samples under the optimized conditions, as well as those obtained with aqueous standards, are shown in Table 2. In all cases, six concentration spiking levels were used and two replicates for each level were measured. Correlation coefficients higher than 0.99 were obtained in all cases. When comparing the slopes for DMSe and DMDSe obtained by using aqueous standards, the sensitivity for each analyte depended not only on the number of the heteroatoms contained in the molecular formula, but also (and to a greater extent) on the volatility and the affinity of the compound for the CAR/DVB fiber material. Moreover, the influence of the sample matrix may lead to greater sensitivity to the analyte which contains only one heteroatom, although this effect was not observed in liquid yogurts. On the other hand, as expected, the sensitivity for both analytes decreased when the fat content in the milk samples increased, this effect being more pronounced in the case of DMDSe. Consequently, according to the obtained results, the use of the standard additions method is required for quantification.

In order to investigate other components of milk and milk by-products, in addition to fat, which could affect the sensitivity of the analytes under study, the effect of casein and lactalbumin concentrations was studied. Different percentages ranging between 0 and 10% (w/v) of casein and lactalbumin were added to aqueous DMSe and DMDSe standards. As shown in Fig. 3, the signal of DMSe was not affected by either of the two proteins. However, the sensitivity for DMDSe decreased with increasing concentration of both proteins, concluding that the less volatile and more heavy analyte is affected by the sample matrix in a higher extent than DMSe. The slopes of the calibration graphs obtained from aqueous standards in the absence of lactalbumin and casein were compared with those corresponding obtained of standards prepared in the presence of 2.7 and 3.5% (w/v) casein and lactalbumin, respectively, values which correspond to the average concentration of these proteins in real milk samples. As expected, the presence of the proteins did not change the slope value for DMSe, but decreased in the presence of lactalbumin and casein in the case of DMDSe (Table 2).

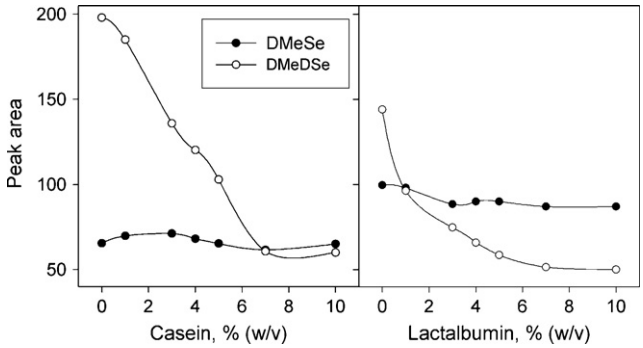

Fig. 3. Effect of the addition of casein and lactalbumin on the peak area obtained from aqueous standard solutions.

The detection limits calculated using a signal-to-noise ratio of three and considering the slopes of the standard additions calibration graphs obtained for skimmed-milk sample are shown in Table 3. Detection limits ranged from 70 to 110 pg mL^{-1} for DMSe, corresponding to a skimmed-milk sample and a liquid yogurt sample, respectively. For DMDSe, detection limits between 80 and 400 pg mL^{-1} were obtained, which corresponded to a skimmed milk sample and a whole milk sample, respectively. The quantification limits were calculated for the same milk sample using a signal-to-noise ratio of ten. These values must be considered as orientative as they are dependent on the sample matrix. The repeatability, calculated using the relative standard deviation for 10 successive injections of a fortified sample at 6 ng mL^{-1}, were 2.85 and 3.03% for DMSe and DMDSe, respectively. The analytical characteristics calculated for a yogurt sample also appear in Table 3. Detection limits obtained for the two other yogurts analyzed were similar.

3.4. Real samples and recovery studies

None of the samples analyzed contained the studied selenium compounds, at least above the stated detection limits. As no reference materials are available, recovery studies were carried out

Table 2
Comparison of the slopes of the standard addition method for different samples.

in order to verify the accuracy of the proposed method, fortifying four samples at two different concentration levels. An average recovery ± S.D. (n = 48) of 89.5 ± 15.5% was obtained.

On the other hand, a study on the stability of DMSe and DMDSe in different fortified sample matrices was carried out. Liquid yogurt and partially skimmed milk were fortified at concentration levels of 2.5 ng mL^{-1} for both analytes, and stored in the fridge and at 25 °C in open vessels. Fig. 4 shows the results obtained. As can be observed higher recovery values were obtained for both compounds when samples were stored at 4 °C, especially in the case of DMDSe.

Finally, 5 μg mL^{-1} of inorganic selenium were incorporated to a probiotic liquid yogurt enriched with bifidobacteria and a partially skimmed milk sample to check its possible methylation to produce DMSe and/or DMDSe, being the samples maintained in closed vessels. The analytical signals obtained after different storage intervals of time ranging between 0 and 36 h at the temperature values of 25 and 40 °C, showed no differences in the absence or in the presence of inorganic selenium.

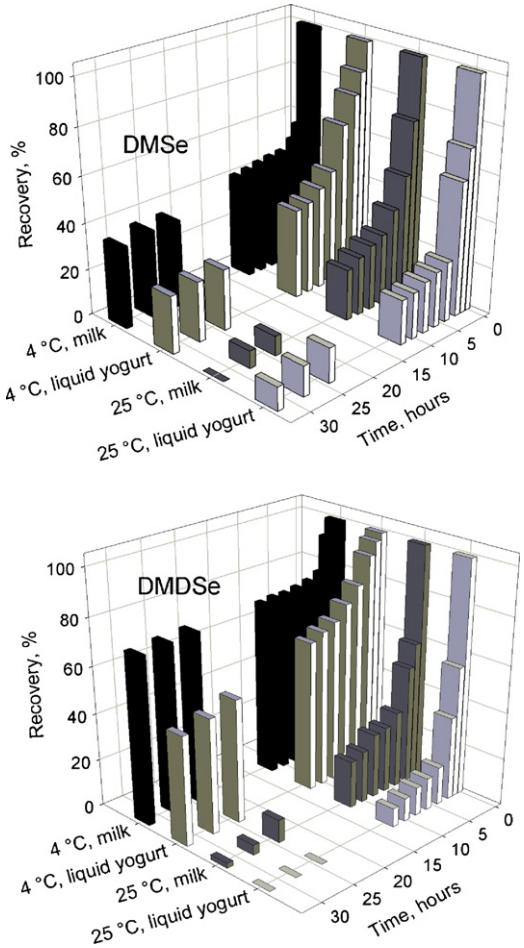

Fig. 4. Stability with time of DMSe and DMDSe incorporated in different sample matrices stored at different temperatures and analyzed using the finally selected SPME–GC–AED conditions.

4. Conclusion

DMSe and DMDSe can be preconcentrated from the sample headspace in only 5 min, an extraction mode that minimizes the coextraction of undissolved particles and non-volatile components from the sample matrix; it also prolongs the life time of the fibers. The analytical characteristics of the proposed method make it a useful tool for the monitoring of selenium volatile compounds in milk and milk by-products. Nevertheless, the complexity of this type of matrix makes it necessary to quantify the analytes using the standard additions method. No methylation of inorganic selenium was observed in the storage conditions assayed.

Powder
Matrix effect
Fractionation
Binder
Particle size distribution

ABSTRACT

A study of LA–ICP-MS analysis of pressed powdered tungsten carbide precursors was performed to show the advantages and problems of nanosecond laser ablation of matrix-unified samples. Five samples with different compositions were pressed into pellets both with silver powder as a binder serving to keep the matrix unified, and without any binder. The laser ablation was performed by nanosecond Nd:YAG laser working at 213 nm.

The particle formation during ablation of both sets of pellets was studied using an optical aerosol spectrometer allowing the measurement of particle concentration in two size ranges (10–250 nm and 0.25–17 μm) and particle size distribution in the range of 0.25–17 μm. Additionally, the structure of the laser-generated particles was studied after their collection on a filter using a scanning electron microscope (SEM) and the particle chemical composition was determined by an energy dispersive X-ray spectroscope (EDS).

The matrix effect was proved to be reduced using the same silver powdered binder for pellet preparation in the case of the laser ablation of powdered materials.

The LA–ICP-MS signal dependence on the element content present in the material showed an improved correlation for Co, Ti, Ta and Nb of the matrix-unified samples compared to the non-matrix-unified pellets. In the case of W, the ICP-MS signal of matrix-unified pellets was influenced by the changes in the particle formation.

1. Introduction

Laser ablation inductively coupled plasma mass spectrometry (LA–ICP-MS) has become a method commonly used for the direct analysis and microanalysis of solid samples with a very wide field of application. The main problems that still hinder LA–ICP-MS as an ideal method for any kind of direct analysis are fractionation and quantification [1].

The common term "fractionation" comprises non-stoichiometric effects observed with the LA–ICP-MS. A lot of works describe the influence of the laser parameters on the particle formation and consequently various "suggestions" on how to reduce the fractionation effects using an appropriate laser wavelength [2–6], pulse duration [7–15] or energy density [15–17] have been proposed. However most of these parameters are dictated by the construction of the ablation laser used and so their variability becomes strongly dependent on the available experimental setup.

Besides the ablation process itself, the transport of aerosol particles to the ICP [18–22,4,23] and vaporization and ionization in the ICP [24] are important and also contribute to the fractionation manifesting itself as matrix interference of the ICP-MS signal. During transportation, diffusion of the particles smaller than 2 nm and gravitational settling of particles in micrometric range (contingent on the particle density) takes place and, depending on the small and large particle representation, the mentioned factors occur [10]. In the ICP itself the main problem is that large particles cannot be completely vaporized and ionized. Some works determine 0.5 μm as a critical size for the particle vaporization [24,25], however the volatility of particles influences the limit of the maximum diameter of the particle evaporated in the ICP.

The "matrix effect" is another frequent and permanent problem arising during the LA–ICP-MS quantitative analysis. The "matrix effect" is a term for the variable ablation mechanism of materials in different matrices causing changes in volume and composition of the generated particles during the laser beam interaction with the various sample surfaces. To overcome the "matrix effect", it is necessary to create a suitable calibration strategy for the LA–ICP-MS quantitative analysis. To compensate for the matrix effect, matrix

doi:10.1016/j.talanta.2009.10.035

matched calibration has become the most common quantification technique relying on the use of a reference material with the same matrix as the analysed sample [1,26].

The analysis of powdered materials by LA–ICP-MS requires a preparative procedure resulting in a target with sufficient homogeneity, cohesion and stability during laser ablation. Plenty of different methods have been described for the target preparation such as melting with lithium borate [27–31], casting with a glue [32,33] or pressing into pellets [34–39]. The choice of a suitable method depends on the sample properties and laboratory facilities. Possible resulting problems must be taken into consideration like sample contamination, loss of volatile elements or sample dilution.

To press the powder into a pellet is the most common way because of its speed and simplicity. The pellets are pressed with or without other additives serving as a binder, matrix unifier or internal standard. The possibility of the matrix unification by using diverse powdered samples offers the LA–ICP-MS a great advantage in comparison to the analysis of naturally compacted samples where matrix unification is impossible. On the other hand, the presence of any kind of additive influences the ablation process. Therefore the choice of the additive should conform not only to the pellet's physical properties, but also to the suitability of the ablation mechanism providing successful quantitative analysis.

The purpose of this study is to show the effect of adding a matrix unifier into the powdered samples on the particle formation and the ICP-MS signals. Five powdered Co-cemented ceramic samples containing tungsten carbide (WC) as the main constituent were chosen as samples belonging to the same sort. The sample set selection gives a great opportunity to study particle formation behaviour of real samples with similar matrices but different main components giving the specific properties of each sample. Detailed description of the Co-cemented ceramic is made in work studying the particle formation of cemented WC samples [40]. As a matrix unifier powdered silver meeting also the criteria of the suitable binder such as easy homogenization with the sample, proper binding effect and positive price was used on the basis of previous experience with the silver as a binding material for the pellet preparation [36,38,39].

2. Experimental

2.1. Samples

2.1.1. Tungsten carbide precursors

The powdered precursors (WC/Co) for cemented carbides were obtained from Pramet Tools, L.L.C., Šumperk, Czech Republic, a subsidiary of Seco Tools AB, Fagersta, Sweden. Co-cemented carbide, or hardmetal as it is often called, is a material containing ceramic non-conductive constituent (tungsten carbide (WC)) and metal cobalt which plays the role of a binder during the sintering process, so the physical properties of both main constituents are very different (WC m.p. 2870 °C, b.p. 6000 °C, density 15.8 g cm^3; Co m.p. 1495 °C, b.p. 2877 °C, density 8.9 g cm^3). To obtain a hardmetal with specific properties, other constituents such as Ti, Ta, Nb or V are added in the form of carbides before sintering. By the addition of titanium carbide and tantalum carbide, the high temperature wear resistance, the hot hardness and the oxidation stability of hardmetals have been considerably improved, and the WC–TiC–(Ta,Nb)C–Co hardmetals are excellent cutting tools for the machining of steel [41]. The physical properties of TiC and TaC as the additives with the highest content in the final product are: TiC m.p. 3160 °C, b.p. 4820 °C, density 4.9 g cm^3; TaC m.p. 3880 °C, b.p. 5500 °C, density 13.9 g cm^3.

Five powdered precursors of hardmetals with a varied content of their main constituents were selected as representatives of a larger set of miscellaneous samples. Their properties were expected to vary over the whole sample collection. Samples were routinely analysed using XRF spectrometry in the laboratory of the Research Institute of Inorganic Chemistry, J.S.C., (VÚAnCh) Ústí nad Labem, Czech Republic. Details on the XRF instrumentation and analysis have already been described by Kanický et al. [42–44]. The composition of studied powdered tungsten carbide precursors is shown in Table 1.

Table 1
The chemical composition of the tungsten carbide precursor samples (wt%).

5124	22.5 ± 0.8	0.04 ± 0.01	–	–	72.3 ± 1.0

2.1.2. Sample preparation for LA–ICP-MS

The powdered samples were employed for the analysis as pressed pellets with and without the binder. In both cases, the first preparation step consisted of sample grinding to obtain a fine powder. The particle size distribution, measured by laser diffractometry, showed diameter values not exceeding 5 μm after 5 min of sample grinding in a ball mill (Planetary Micro Mill Pulverisette 7, FRITSCH, Germany). The 25 ml mortars as well as milling balls (Ø 12 mm) were from Sialon material (90% Si_3N_4). To obtain binderless pellets, ground samples were pressed without any additional material, while the binder-containing ones were prepared in the ratio of 1:1 ground sample (3 g) and the silver powder (3 g, 99.99% purity, particle size <15 μm; Safina Vestec Company, Czech Republic), which was homogenized in the ball mill for 10 min. Pellets of both types were made by pressing with a hydraulic press (Mobiko Company, Czech Republic) at 1.3 GPa for 30 s. The pellet diameter and thickness was 12 mm and 1–1.5 mm, respectively. The weight of the binderless pellets was in the range of 1.3–1.7 g whilst binder-containing pellets had a weight between 1.2 and 1.5 g.

2.2. Laser ablation system

The laser ablation was realized by a pulsed Nd:YAG laser operating at a wavelength of 213 nm with a pulse duration of 4.2 ns (UP 213, New Wave Research, Inc., Fremont, CA, USA). In order to generate a sufficient number of particles within the whole particle size range studied for all examined sample types, several optimization experiments were undertaken. Based on these experiments, the following parameters of the ablation laser system were employed: a laser spot diameter of 100 μm, a laser pulse repetition rate of 10 Hz and a fluence of 13 J cm^{-2}. Higher fluences (30 and 40 J cm^{-2}) were also tested for the experiments, but with the increasing fluence the reproducibility of the particle concentration measurements rapidly decreased (13 J cm^{-2} with 7% RSD, 40 J cm^{-2} with 23% RSD). Because the particle size distribution diagrams have the same shape differing only with the particle number, the fluency of 13 J cm^{-2} was employed for the rest of the experiments. The laser spot of 100 μm diameter was used because of its suitability for the bulk analysis of powdered material where the representative sampling is very important and so larger laser spot is required. The 33 cm^3 sample chamber (SuperCell, New Wave Research, USA) of the ablation system was specifically designed to enable rapid eluting of the aerosol in a large format cell. Using helium as a carrier gas under normal operating conditions with a flow rate of 1.0 l min^{-1}, the ablation-generated aerosol was transported from the chamber through a 1-m long polyurethane transport tube (i.d. 4 mm) to either an ICP-MS system or an aerosol spectrometer.

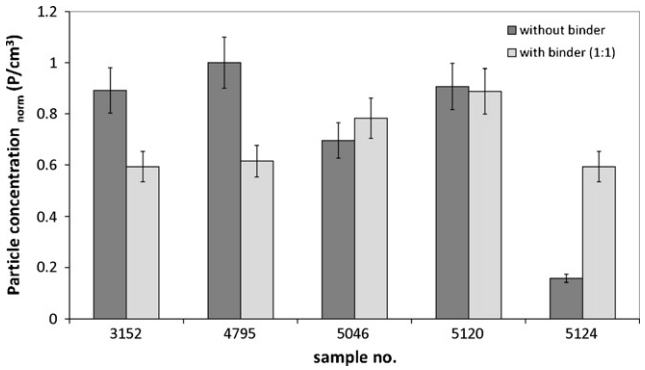

Fig. 1. Total concentration of particles (10 nm–17 μm) formed during the laser ablation of non-matrix-unified (without binder) and matrix-unified (with Ag binder) samples. The error-bars signify the standard deviation of three parallel measurements of each sample.

2.3. Inductively coupled plasma mass spectrometry

The aerosol was transported to the ICP discharge of the quadrupole mass spectrometer (ICP-MS Agilent 7500ce, Agilent Technologies, Santa Clara, CA, USA). The following isotopes were selected and used for the LA–ICP-MS analyses: ^{48}Ti, ^{51}V, ^{59}Co, ^{93}Nb, ^{181}Ta and ^{184}W.

2.4. Measurement of aerosol particles

The particle size and concentration of the laser produced aerosol particles was measured and evaluated on-line with an optical Aerosol Spectrometer Welas® 3000 Series (Palas, Germany). The Welas® operates on the principle of the single particle scattering of white light. The Welas® sensor 2200 provides a direct measurement of size distribution of particles in the size range 0.25–17 μm with a maximum concentration of 10^4 particles cm^{-3}. The particles are classified into 60 size channels on the basis of polystyrene-latex-equivalent diameters. Particles smaller than 250 nm are below the size limit for the detection by the Welas® sensors. To detect these small particles, their size is first increased by condensing 2-propanol vapor onto the small particles in the Condensation Nucleus Counter (CNC), to μm-sized particles that can be on-line detected with the Welas® sensor 2100. However, as a result of 2-propanol condensation, the former size distribution of small particles is lost and we can only count the total concentration of all particles larger than 10 nm up to 17 μm with a maximum concentration of up to 10^5 particles cm^{-3}. The number concentration of small particles (the size range 0.01–0.25 μm) was calculated as a difference between the total number concentration of all particles (measured with sensor 2100 as a result of 2-propanol condensation in the CNC; the size range 0.01–17 μm) and the number concentration of large particles (measured with sensor 2200; the size range 0.25–17 μm).

To avoid coincidence error of Welas sensors, high concentration of particles produced during the laser ablation was diluted at the output from LAS by mixing with stream of argon (5–15 l min^{-1}), part of formed mixture (5 l min^{-1}) was analysed in Welas and rest was wasted. Measuring of particles by CNC required higher dilution coefficient (12–15) than in case of sensor 2200 (dilution factor 5–7). Because of non-linear dependence of the dilution factor on the absolute particle concentration value for two types of sensors we prefer to demonstrate normalized values instead of absolute values of PC in Figs. 1 and 4. Dilution factor for PC measured by CNC was 15 (Fig. 1) while sensor 2200 used for the large particles determination worked with the dilution factor of 6 (Fig. 4).

2.5. Scanning electron microscopy and energy dispersive X-ray spectrometry

The structure and chemical composition of the laser-generated particles was studied *off-line* after their collection on a polycarbonate membrane filter (25 mm diameter, 0.2 μm pores, Cyclopore, Whatman). To collect a sufficient number of particles, the ablation was performed over a 5 min time period. The filter was placed behind the ablation cell at a distance equal to the ablated particle measurements conducted on the Welas® (0.5 m). The particles collected on the filter as well as the laser ablated craters were studied using an EDS instrument (INCA x-sight, Oxford Instruments Ltd., UK) of field emission SEM (JSM-6700F, JEOL, Japan). A secondary electron detector providing the topographical contrast was used. The acceleration voltage was 5 kV. The EDS analyses were performed at the electron acceleration voltage of 15 kV. A liquid nitrogen cooled Si(Li) detector of the INCA x-sight analyser guaranteed a stable output with a count rate.

The EDS allows analysis of W and Co as matrix elements. Method of EDS did not detect other elements as Ti, Ta and Nb due to the thickness of carbon coating used for sample conductivity that was approximately 30 nm. The carbon layer decreases the intensity of X-ray that leaves the sample for the reason of decreasing the primary electron flux and its own absorption of an output signal.

2.6. Optical profilometry

The ablation crater shape and volume was measured with 1-μm lateral and 3-nm vertical resolution by an optical profilometer MicroProf (FRT, Germany) [40]. In this device white light from a halogen lamp passes through the CHR 150 N lens with a high chromatic aberration. Different monochromatic light components are focused at different heights from a reference plane at the output of the optical fibre. The same optical fibre collects scattered light from the surface under study. This light is analysed by means of a spectrometer. The height of the surface irregularities is deduced by means of a calibration table from the wavelength of the spectral intensity distribution maximum.

3. Results and discussion

3.1. Matrix unification of different powdered samples

The real function of the silver binder as a matrix unifier was proved by two ways – by the particle concentration measurements and by the ablation crater studies. In both cases we presumed more similar results (smaller RSD) in the particle formation (measuring the particle concentration (PC)) as well as in the formation of ablation craters (more similar ablation rates and crater structure) – for samples prepared as matrix-unified pellets than for non-matrix-unified samples. The measurement of each pellet was done three times and the repeatability did not reach deviation of 10%. The RSD value used in the text as a criterion for the "level of unification" was calculated from mean values of the three repeated measurements of different samples. The matrix-unified samples represented pellets prepared by pressing of the sample and silver powder mixture as described in 2.1.2.

The total concentration of generated particles was monitored during the laser ablation of either non-matrix-unified or matrix-unified samples. The particle concentration of the five non-matrix-unified pellets differed from sample to sample very distinctly with a relative standard deviation (RSD) of 46%. It signifies a high influence of the sample composition on the particle production during laser ablation. Even if the tungsten content varies from sample to sample, the most important changes in elemental composition occur in the

Table 2
The coefficients of determination of the LA–ICP-MS signals dependent on the element concentration for the non-matrix-unified and the matrix-unified samples.

R^2	Without binder	WC + Ag (1:1)
Ti	0.9571	0.9860
Nb	0.9388	0.9782
Ta	0.9698	0.9862
Co	0.9356	0.9822
W	0.6976	0.0391

case other components such as Co, Ti and Ta (see Table 1). The RSD value, calculated from the PC values of all five samples, decreased to the value of 19% using the binder for the matrix unification. The results of PC measurements for both sets of samples are displayed in Fig. 1.

The observation of different ablation craters can also outline the similarity or difference in the laser ablation processes – the shape, structure and volume of the ablation crater can be used to explain the ablation process behaviour. One of the parameters that can be estimated from the crater depth is the ablation rate. Here the ablation crater depths were measured using the optical profilometer after 100 laser pulses. The crater depths on the non-matrix-unified samples fell in the range of 45–116 μm with the mean value of 93 μm and RSD of 36%. This result indicates the differences in the ablation rates for the samples with different compositions. The preparation of samples as matrix-unified matrix pellets caused a reduction in ablation rate differences – the depths of the ablation craters varied from 58 to 87 μm with a mean value of 70 μm. The RSD value decreased to 16%. The comparison of crater depths thus proved the results of particle formation. Both data sets confirmed our expectations that the binder unifies sample properties and consequently the ablation process.

3.2. LA–ICP-MS

The suitability of the matrix unification of the powdered hardmetal precursor for the LA–ICP-MS analysis was tested for Co, Ti, Ta, Nb and W using the conditions described above. On the basis of the LA–ICP-MS measurements, the appropriate isotope intensity (cps–count per second) dependence on the element content in the sample (simulated calibration curve) was created for each element and the regression lines were constructed. The following isotopes were used for analysis: ^{48}Ti, ^{51}V, ^{59}Co, ^{93}Nb, ^{181}Ta and ^{184}W. The measurements were done on both sets of pellets – (non)/matrix-unified samples. The coefficients of determination of the regression lines pertaining to the same element but different pellets (with or without binder) were compared.

For the matrix-unified samples, the results obtained show improved correlation of regression lines for all elements except W. It means that the Ag powder additive helps to unify the LA–ICP-MS conditions for Co, Ta, Ti and Nd while the possibility of the W quantification in the matrix-unified samples is unsatisfactory. The improvement of correlation is shown in Fig. 2, where the regression lines for Ti are displayed.

Coefficients of determination for all elements are summarized in Table 2.

3.3. Particle structure and composition

The information about the particle chemical composition can explain the behavior of the particle formation and consequently the estimation of the elemental fractionation degree during the ablation. The particle formation and elemental fractionation of Co-cemented tungsten carbides during ns laser ablation has already been described in detail elsewhere [40]. Single spherical particles with diameters in the size range of 0.25–2 μm and agglomerates

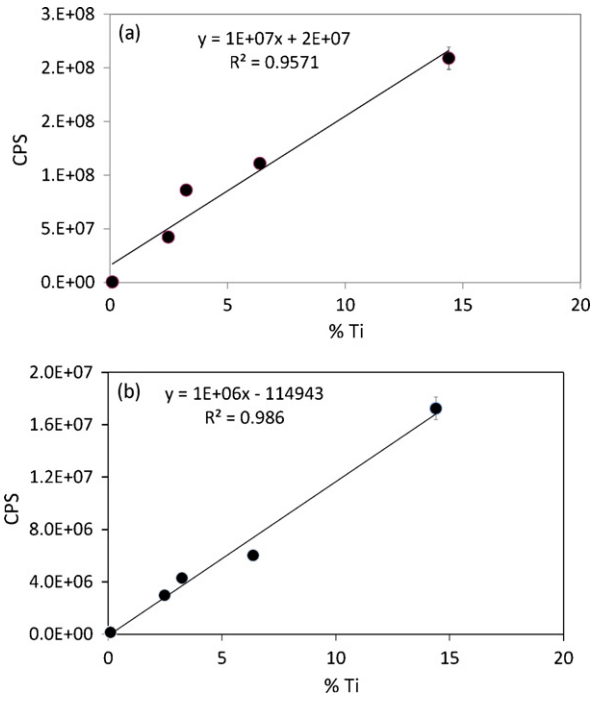

Fig. 2. The LA–ICP-MS signal dependence on the element content for 5 samples: (a) ^{48}Ti for non-matrix-unified samples and (b) ^{48}Ti for matrix-unified samples. The error-bars signify the standard deviation of three parallel measurements of each sample.

composed of primary particles of diameters ranging from tens to hundreds of nanometers were observed on the filter. The presence of tungsten (representing a low volatile element) entirely in the large spherical particles and the strong cobalt enrichment of the small particles proved the theory of particle formation: small particles, enriched with a more volatile constituent, can be formed by nucleation and condensation from the vapor, whereas larger particles rich in lowly volatile elements are ejected from the melted liquid due to hydrodynamic instability of the surface recoil pressure from the expanding vapor plume [45–47]. The elemental fractionation during ns ablation of non-matrix-unified powdered tungsten carbide precursors was identical with the above described Co-cemented samples. In the case of the matrix-unified samples, the influence of silver on the particle composition was studied. The particles were collected on the polycarbonate membrane filter during the 5 min ablation-time period. The particle structure and composition were then studied using SEM and EDS, respectively. The SEM images show, on the first sight, typical structures including single spherical particles and smaller agglomerates creating fibres and adhered to the large particle surface (Fig. 3a). With a higher magnification we can observe that the surface of the large spherical (tungsten) particle is covered by a non-homogenous layer (Fig. 3b). This is the layer where the agglomerates are bound. The EDS analysis showed the preferential presence of silver in the layer – the Ag/W mass ratio increased to the value of 25 from the declared 1.4. This finding clarifies the "destiny" of silver during ablation – the silver vapor condenses on the tungsten particle surface, which results from the much higher silver volatility than the volatility of other sample constituents (Ag melting point is 960 °C, boiling point is 2212 °C).

The EDS analysis did not allow the analysis of other elements such as Ti, Ta and Nb. On the base of the LA–ICP-MS results we can presume homogenous distribution of these elements in smaller particles. The agglomeration with the large tungsten particles seems to be logical especially for tantalum as an element with

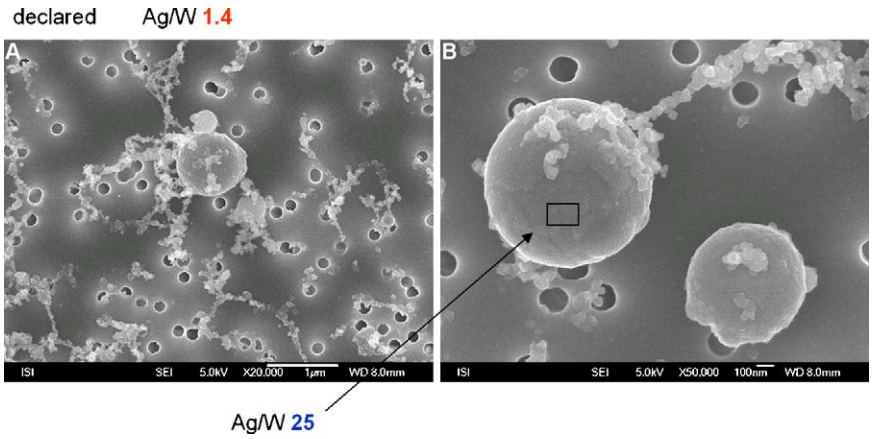

Fig. 3. The SEM images of laser-generated particles from matrix-unified sample no. 5124 after their collection on a polycarbonate membrane filter; (a) overall view, (b) detailed view with large spherical particles and surrounding clusters; a square label defines the area analysed by the EDS, the results of the EDS analysis are pasted together with the declared values.

similar physical properties to tungsten but no dependence of the analytical results on the particle formation was observed.

3.4. Particle size distribution

Silver condensation on the spherical tungsten particles leads to the growth of these particles. This fact was proved by the particle size measurements using the Welas spectrometer. The particle sizes were measured in the diameter range of 0.25–17 μm for the sample 3152 pressed in to 4 various pellets with differing amounts of the silver binder: without any added binder, 33%, 50% and 66% of the binder in the silver–sample mixture. The particle size distribution diagrams show changes in particle concentration with the increasing amount of Ag binder in the pellet (Fig. 4). For those particles with a diameter smaller than 0.31 μm the difference in the particle concentration is not significant, but the particles larger than 0.31 μm in diameter were formed in higher concentrations from the binder pellets. The dependence of particle concentration on the amount of added binder is also evident and the largest difference between the particle distribution diagrams was observed between the pellet without any binder and the pellet with the highest studied amount of added binder (i.e., 66% Ag).

Even if the analytical results of tungsten are surely influenced by the fractionation caused by the gravitational settling of the particles in the ablation cell and the transporting tube (because of the high density of W), the growth in volume of the tungsten particles caused by the Ag condensation most probably leads to another fractionation of laser formed particles inside the ICP. The incomplete particle vaporization/ionization in the inductively coupled plasma then results in problems with the tungsten quantitative analysis. The particle distribution graphs (Fig. 4) show that the concentration of the particles with a diameter larger than 0.5 μm (which can be the critical value for the particle vaporization [24,25]) increase very significantly.

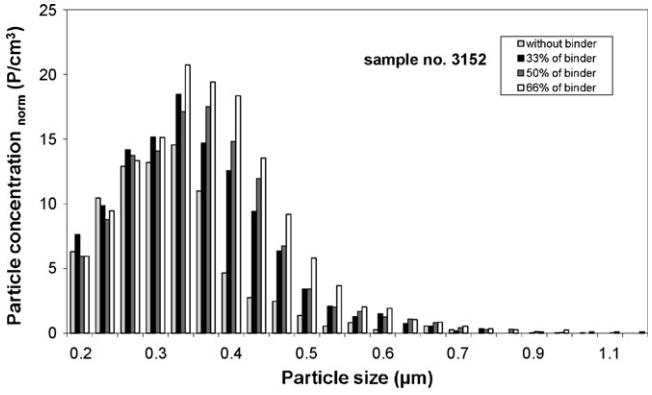

Fig. 4. Particle size distribution of the large particles (0.25–17 μm) for the sample 3152 prepared by pressing different amounts of binder. Histograms are based on a single measurement.

4. Conclusion

The reduction of the "matrix effect" by using a binder for the pellet preparation of powdered materials was investigated. Five samples representing Co-tungsten carbide precursors were prepared for ns laser ablation as pressed pellets without any binder and with the powdered silver serving as the binder and matrix unifier. The study of particle and ablation crater formation clearly demonstrated the function of the matrix unifier - the differences between studied samples in the particle concentration were reduced (RSD decreased from 46% to 19%) as well as the differences in the volumes of the ablation craters (the RSD decreased from 36% to 16%). The effect of the binder utilization on the LA–ICP-MS signals shows an improvement correlation of different samples in simulated calibration curve (increasing of the correlation coefficients of the isotope intensity *vs.* elemental content in the sample) for all elements of interest (Co, Ti, Ta, Nb) except W. In order to find a solution for the deterioration of the tungsten analytical response in the case of binder pellets, the structure and chemical composition of the particles formed during the laser ablation was investigated. The particle size distribution measurements showed an increase in the number of particles for the size range from 0.31 to 1.2 μm with the increasing binder content in the pellet. This effect was assigned to the condensation of vapor enriched by silver as a highly volatile component on the surface of the larger particles created from the melted material. It resulted in the production of large tungsten particles covered with a silver layer which was further proved by the SEM and the EDS measurements. Because the particle diameter is a critical parameter for the fractionation in the ICP, the increasing diameter of the silver-covered tungsten particle leads to their incomplete atomisation and ionization. The important role plays also the gravitational settling of W particles because of their extreme high density. Consequently, the W quantification in the matrix-unified samples is unsatisfactory.

This study shows that matrix unification can be a useful tool for the LA–ICP-MS quantitative analysis of powdered materials, but it can also cause changes in the particle formation during the ablation process leading to fractionation. The matrix unification of the Co-

tungsten carbide samples using the silver binder markedly reduced differences in the crater volumes as well as the evenly balanced concentration of generated particles during the laser ablation of different samples. On the other hand the matrix unification did not lead to complex improvement of analytical results. In general, the choice of the matrix unifier (binder) must therefore be done very carefully depending on the sample to be analysed and the ablation conditions.

Thrombin

ABSTRACT

An aptamer-based assay for thrombin with high specificity and sensitivity was presented. In the protocol, the aptamer for thrombin was immobilized on magnetic nanoparticle, and its complementary oligonucleotide was labeled with gold nanoparticles, then the aptamer was hybridized with the complementary oligonucleotide to form the duplex structure as a probe, this probe could be used for the specific recognition for thrombin. In the presence of thrombin, the aptamer prefer to form the G-quarter structure with thrombin, resulting in the dissociation of the duplex of the probe and the release of the gold labeled oligonucleotide. Upon this, we were able to detect thrombin through the detection of the electrochemical signal of gold nanoparticles. The strategy combines with the high specificity of aptamer and the excellent characteristics of nanoparticles. This assay is simple, rapid, sensitive and highly specific, it does not require labeling of thrombin, and it could be applied to detect thrombin in complex real sample. The method shows great potential in other protein analysis and in disease diagnosis.

1. Introduction

The detection of protein is of central importance for diagnosis and treatment of diseases and attracts increasing attention in the biomedical fields [1,2]. In most diagnosis application, specific protein recognition is often accomplished by antibodies [3–4]. Aptamers, the synthetic DNA/RNA selected from combinatorial libraries by SELEX, promise to replace antibodies for their small size, chemical simplicity and flexibility [5–7] and they are considered promising recognition elements for biosensor application. Aptamer-based protein detections have been illustrated such as colorimetric [8], fluorescence [9], quartz crystal microbalance [10] and electrochemical detection [11–13].

In the paper, human thrombin was chosen as the target analyte of interest. Thrombin (activated Factor II) is a specific serine protease involved in the coagulation cascade, which converts soluble fibrinogen into insoluble strands of fibrin and catalyzes many other coagulation-related reactions [14]. The concentration of thrombin in blood during the coagulation progress varies from nM to low μM levels [15], while the detection of thrombin is important for related diagnoses [16]. Therefore, it is necessary to develop an assay for thrombin with high sensitivity, selectivity, and simplicity. Recently, electrochemical [17,18] and optical techniques [19–21] were widely applied in the field of thrombin detection. However, the reliability, selectivity and the sensitivity of the assay should be improved. We show here an analytical strategy based on gold nanoparticles and magnetic nanoparticles that achieves both high specificity and the enhanced sensitivity.

Nanoparticles can be used as scaffolds for assembling nanoparticle-based biosensors [22]. Gold nanoparticles are excellent candidate for bioconjugation, owing to the fact that they are compatible, and bind readily to a range of biomolecules such as amino acids, protein, enzymes and DNA [23–25]. Gold nanoparticle-based DNA electrochemical detections have been reported due to the sensitivity and excellent electrochemical signal [26,27]. In addition, magnetic nanoparticles have been widely used in bioanalysis and pharmaceutical detection for the particular properties and magnetism [28].

An electrochemical protocol for detection of thrombin based on the gold nanoparticles and magnetic nanoparticles was proposed. As shown in Fig. 1, the aptamer for thrombin was immobilized on magnetic nanoparticles, and its complementary oligonucleotides was labeled with gold nanoparticles, and then the aptamer was hybridized with the complementary oligonucleotide to form the duplex structure as a probe (A). In the presence of thrombin, the aptamer prefers to bind with thrombin and cause the dissociation of the probe, liberating the gold nanoparticle-labeled complemen-

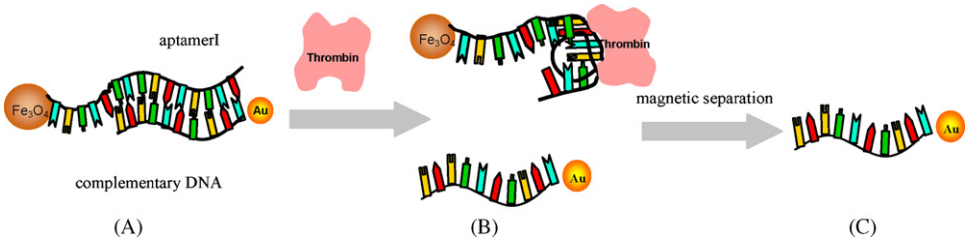

Fig. 1. Schematic representation of the assay. (A) The duplex structure of magnetic nanoparticle-aptamer/gold nanoparticle-oligonucleotide. (B) In the presence of thrombin, the dissociation of the duplex structure and the liberating of the gold nanoparticles labeled complementary oligonucleotides. (C) After the magnetic separation, the released gold nanoparticle-labeled complementary oligonucleotide to produce an electrochemical signal.

tary oligonucleotide (B). The basic principle for the strategy is that aptamers could form defined tertiary structure when binding to target protein, and also able to bind to complementary DNA sequence to form a duplex structure. Therefore, when the target protein and the complementary oligonucleotide are introduced, the aptamer is in a conformational equilibrium between the duplex structure and the tertiary structure [29,30]. It prefers to bind to the target protein and thus resulting in the specific recognition of the target [31,32]. Then after magnetic separation, high specific and sensitive detection of thrombin was achieved in connection to measurement of the electrochemical signal of the released gold nanoparticle-labeled complementary oligonucleotide (C). The electrochemical signal of gold is proportional to the amount of thrombin and the quantitative assay of thrombin was accomplished by using this proposed electrochemical sensor. In this strategy, gold nanoparticle offered excellent electrochemical signal and magnetic nanoparticle was used for separation. The assay responds rapidly and specifically to thrombin, which shows extensive application in protein monitoring, in disease diagnosis as well as other research fields.

2. Experimental

2.1. Apparatus and reagents

Differential pulse voltammetry (DPV) was performed using a CHI Instruments model 832 Electrochemical Analyzer (CHI Instrument Inc., USA). The electrochemical system comprised of a working electrode of glassy carbon electrode, an Ag/AgCl reference electrode, and a platinum wire counter electrode. SEM data were recorded using a JEOL JSM-6700F Field Emission Scanning Electron Microscope (JEOL, Japan).

The oligonucleotides used in this study were purchased from Sangon Biotechnology Inc. (Shanghai, China) with the following sequences: the oligonucleotide with amino-group at 5′ end (aptamer) : 5′ H_2N-$(CH_2)_6$–ATAGGTTGGTGTGGTTGG; complementary oligonucleotide with mercapto-group at 5′ end: (5′SH-$(CH_2)_6$CCAACCACACCAACC); thrombin, bovine plasma albumin (BSA) and lysozyme were purchased from Sigma–Aldrich. Magnetic nanoparticle (50 mg/mL, carboxyl functionalized, average diameter 100 nm) was purchased from Chemicell Inc. (Berlin, Germany). Sodium citrate, $AuCl_3HCl{\cdot}4H_2O$, ethyl-3-(dimethylaminopropyl)-carbodiimide hydrochloride (EDAC), imidazole, PBS (0.1 M, pH 7.3), Tris–HCl buffer and other reagents were commercially available and were all of analytical reagents grade, and ultrapure water was used from Aquapro system (specific resistance is 13 MΩ cm).

2.2. Immobilization of the aptamer onto magnetic nanoparticles

The immobilization of the aptamer onto magnetic nanoparticles was carried out on, briefly, magnetic nanoparticles were washed three times with PBS buffer (pH 7.3) and resuspended in 500 μL of PBS buffer, then ultrasonicated for 30 min after 4.3 mg imidazole was added. After 2.0 OD of aptamer was dissolved in 100 μL of PBS buffer solution and 4.6 mg of EDAC was added. The resulting mixture was stirred for 8 h for the amidation between amino aptamer and carboxyl functionalized magnetic nanoparticles. After magnetic separation, the magnetic nanoparticles with immobilized aptamer was washed three times with 500 μL of PBS, unbounded aptamer was removed by using a magnet, the resulting solution was resuspended in 500 μL of PBS buffer and stored at 4 °C.

2.3. Preparation of the gold nanoparticles

Gold nanoparticles were prepared according to the literature [33]. All glassware used in the following procedure was cleaned in a bath of freshly prepared 3:1 HNO_3–HCl, rinsed thoroughly in twice-distilled water and dried in air. $HAuCl_4$ and sodium citrate solution needs to be filtered through a 0.22 μm microporous membrane filter prior to use. Gold nanoparticles were prepared by adding 2.5 mL of sodium citrate solution to 100 mL of boiling aqueous solution containing 1 mL of 1% (w/w) $HAuCl_4$, and stirred for 30 min; within the time, the color of the solution changed from grey, blue, purple, to wine red. The mixture continued to stir for 10 min after removal from the heater. The preparation was stored in dark glass bottles at 4 °C for further use.

2.4. Preparation of gold nanoparticle-labeled oligonucleotide

Gold nanoparticle-labeled oligonucleotide was prepared as literature [23], briefly, gold nanoparticle solution was mixed with 1 OD of mercapto-oligonucleotide for 16 h, and the solution was centrifugated for at least 25 min at 16,128 × *g* to remove the excess oligonucleotide. The wine red precipitate was washed with 0.1 M PBS and redispersed in 0.1 M PBS. Then, the resulting solution was stored in the refrigerator for further use.

2.5. Preparation of the probe of magnetic nanoparticle-aptamer/gold nanoparticle-oligonucleotide

The probe of magnetic nanoparticle-aptamer/gold nanoparticle-oligonucleotide was prepared as follows, after 600 μL of the gold nanoparticle-labeled oligonucleotides were added in the solution containing 40 μL of magnetic nanoparticle-aptamer in PBS buffer, then 0.585 g of NaCl was added to retain a certain salinity for hybridization, and the volume was adjusted to 1000 μL by adding PBS buffer. The hybridization was carried out for 1 h at 37 °C. The final magnetic nanoparticle-aptamer/gold nanoparticle-oligonucleotide were washed five times with 200 μL of PBS buffer and resuspended in 300 μL of PBS buffer for further use.

2.6. Experimental method for the recognition of thrombin

The specific recognition for thrombin was carried out in an electrochemical cell containing 15 μL of the probe, adding 10 μL of definite concentration of thrombin and the volume was adjusted

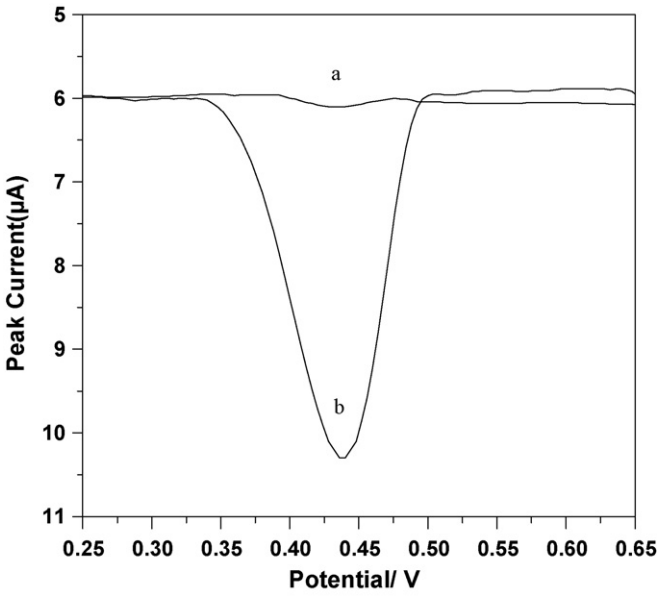

Fig. 2. DPV response of (a) in the absence of thrombin; (b) in the presence of 3.36×10^{-11} M thrombin.

to 100 μL by adding PBS buffer (pH 7.3) containing Mg^{2+} (1 mM Mg^{2+}). The incubation was carried out for 20 min at 37 °C, after the magnetic separation, the supernatant fluid was dissolved in 0.1 M HCl solution for detection.

2.7. Electrochemical measurements

All electrochemical experiments were directly performed in an electrochemical cell, with a glassy carbon working electrode (diameter = 5.0 mm), an Ag/AgCl (saturated KCl) reference electrode and a platinum auxiliary electrode. The supernatant fluid was dissolved in 1 mL of 0.1 MHCl solution and the electrochemical oxidation of gold was performed at +1.25 V for 120 s in the solution. Immediately after the electrochemical oxidation, differential pulse voltammetry was performed with the scan range from +0.65 V to 0.25 V (scan rate 20 mV/s, pulse width 0.05), resulting in an analytical signal due to the reduction of $AuCl_4^-$, which relates to the amount of the gold nanoparticle-oligonucleotide released upon the target protein. The DPV peak height at a potential of +0.43 V of the reduction of $AuCl_4^-$ was used in all of the measurements.

3. Results and discussion

3.1. The recognition for thrombin

Upon the presence of the target protein, the probe of magnetic nanoparticle-aptamer/gold nanoparticle-oligonucleotide dissociated and cause the release of the gold nanoparticle-labeled oligonucleotide, which can be investigated by the DPV responses of the gold nanoparticles. As shown in Fig. 2(a), without thrombin for incubation, the peak current of DPV at +0.43 V (vs Ag/AgCl) could be neglected. For that without thrombin, gold nanoparticle-oligonucleotide would not dissociate from the duplex structure, therefore no DPV response of gold was observed. When 3.36×10^{-11} M of thrombin was added, 4.2340 μA of peak current of DPV was observed (Fig. 2(b)). Because the aptamer is in a conformational equilibrium between duplex structure and the G-quarter structure, it prefers to bind with thrombin to form the G-quarter structure, and liberate the gold nanoparticle-labeled oligonucleotide.

3.2. The SEM identification for the displacement assay

Two samples were prepared according to the protocol, sample a contains thrombin, sample b contains no thrombin as a control experiment. After the incubation, wash, the samples were diluted by 600 μL distilled water respectively. 30 μL of the resultant solution was used for SEM. Fig. 3(b) shows apparently that gold nanoparticle adhered on the magnetic nanoparticles, owing to the fact that the magnetic nanoparticle-aptamer bind to the gold nanoparticle-oligonucleotide through the hybridization. While no gold nanoparticles was observed in sample a (Fig. 3 (a)), which has identified that in the present of the target protein, the aptamer prefers to bind to thrombin, and therefore the gold nanoparticle-labeled oligonucleotide released from the duplex structure.

3.3. Optimization for the assay

3.3.1. Effect of the temperature and time

The temperature of the incubation has an influence on the dissociation of the probe of magnetic nanoparticle-aptamer/gold nanoparticle-oligonucleotide and the displacement reaction in the presence of thrombin. According to the experimental scheme, two samples were prepared, one contained 1.12×10^{-11} M of thrombin, another contained no thrombin as control. The effect of the temperature was investigated in the range of 17–57 °C and the interval is 5 °C. The experimental results were shown that in the absence of thrombin (Fig. 4A (curve a)), the peak current could be neglected in the range of 17–42 °C, for the probe would not dissociate during the range of 17–42 °C, and it began to dissociate at 45 °C. While in the presence of thrombin (Fig. 4A (curve b)), during the range of 17–37 °C, the peak current gradually increased with the increase of the temperature, and a higher response was obtained at 37 °C, thus 37 °C was chosen in the experiment for the determination. Afterwards, the peak current increased swiftly with the increase of the temperature, owing to the fact that the probe may dissociate after 45 °C, resulting in the rapid increase of the peak current. These experimental results showed that the specific recognition for thrombin at 37 °C was induced by thrombin, not by the dissociation of the complex.

The time dependence of the assay was also studied in the range of 5–30 min at 37 °C (Fig. 4B), the electrochemical signal we obtained increased swiftly with the time increased, reached at a platinum at 20 min, then decreased after 25 min. We deduced from the experiments that 20 min will assure the fully dissociation of the duplex and the formation of the G-quarter structure. The probable reason of the signal decreased after 25 min is that the activity of thrombin may decreased after 25 min, therefore affect the binding affinity toward aptamer. Therefore 20 min was chosen in the experiment.

3.3.2. Effect of the buffer

The effect of buffer in the assay was compared by carrying out the assay in Tris–HCl, PBS and PBS containing MgCl. The experimental results revealed that the signal obtained in PBS buffer was significantly higher than in Tris–HCl, which indicates that PBS buffer was more favorable for the incubation. This is consistent with the report that PBS buffer is suitable for the incubation of thrombin [34]. The results also showed that the signal achieved in PBS containing MgCl was higher than in PBS because Mg^{2+} could stabilize the G-quarter structure of the aptamer-protein. It was reported that Mg^{2+}, Ca^{2+}, Na^+, K^+ have a great influence on the formation of the G-quarter structure of the aptamer [35], thus PBS containing 0.001 M Mg^{2+} was chosen as the reaction buffer.

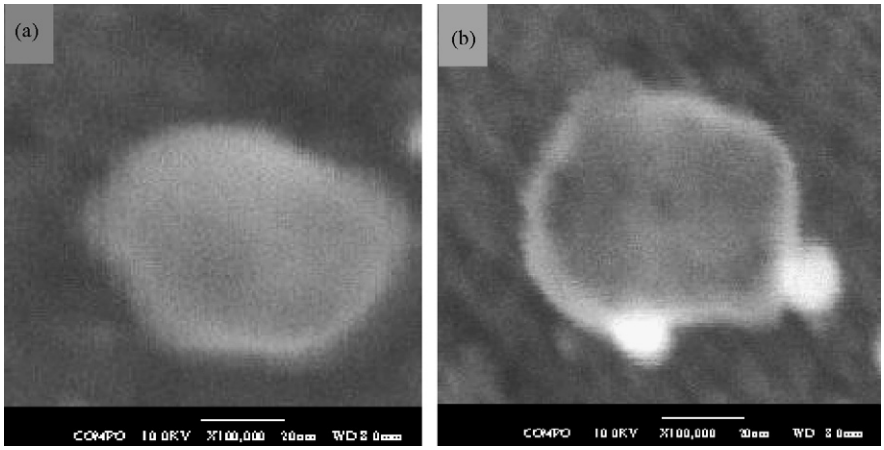

Fig. 3. SEM of the specific recognition for thrombin. (a) In the presence of thrombin; (b) in the absence of thrombin.

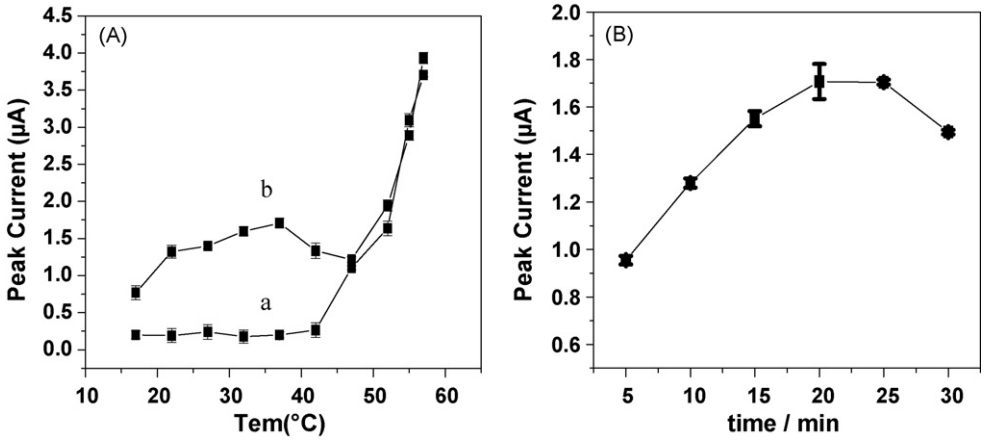

Fig. 4. (A) Effect of the temperature (a) on the dissociation of the probe, (b) on the displacement assay in the presence of thrombin; (B) effect of the time on the displacement assay, the temperature applied in the experiments is 37 °C. The error bar indicates the RSD of five independent experiments, the concentration of thrombin applied in the experiments is 1.12×10^{-11} M.

3.4. Specificity of the assay

As signaling is based on a specific, binding-induced conformational change, the sensor should be relatively insensitive to nonspecific binding, such as adsorption. In order to test this, we have shown that 1.49×10^{-6} M of BSA and 3.13×10^{-6} M of lysozyme did not exhibit any measurable signal (Fig. 5(a) and (b)). Similarly, when thrombin coexisted with other protein, 1.49×10^{-6} M of BSA (Fig. 5(d)) or 3.13×10^{-6} M of lysozyme (Fig. 5(e)), did not exhibit any apparent signal change compared with thrombin (Fig. 5(c)). These results imply that the dissociation of the duplex, and the subsequent increase of the peak current require the formation of a specific aptamer–thrombin complex. Therefore the sensor is highly selective, quite affinity toward the target protein. It is quite insensitive to nonspecific binding and thus readily detects physiological thrombin levels, even in complex sample such as blood serum.

3.5. Quantitative detection of thrombin

The illustrated error bars represent the RSD of five measurements conducted at each thrombin concentration.

To assess the sensitivity and the linear range of the optimized assay, the target thrombin was serially diluted and analyzed. In Fig. 6, the increased electric current generated by gold was observed depending on the increased concentration of thrombin.

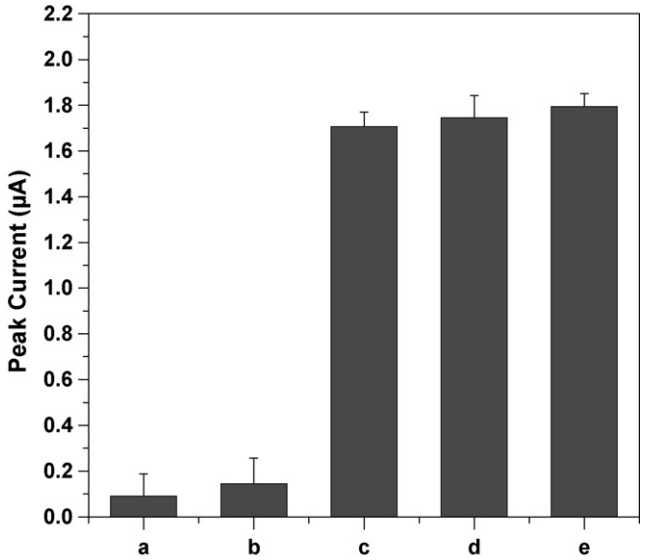

Fig. 5. Specificity of the assay (a) with 1.49×10^{-6} M BSA (b) with 3.13×10^{-6} M lysozyme (c) with 1.12×10^{-11} M thrombin (d) with 1.12×10^{-11} M thrombin and 1.49×10^{-6} M of BSA coexisted (e) with 1.12×10^{-11} M thrombin and 3.13×10^{-6} M lysozyme coexisted. The error bars indicates the RSD of five independent experiments.

Table 1
Assay results of thrombin in plasma.

Sample	Thrombin amount found after dilution (M)	Added amount (M)	Found amount (M)	Recovery (%)	Thrombin amount in plasma (M)
1	7.47×10^{-12}	5.60×10^{-12}	13.45×10^{-12}	106.8	
2	7.48×10^{-12}	5.60×10^{-12}	12.58×10^{-12}	91.07	7.76×10^{-7}
3	8.33×10^{-12}	5.60×10^{-12}	13.52×10^{-12}	92.70	

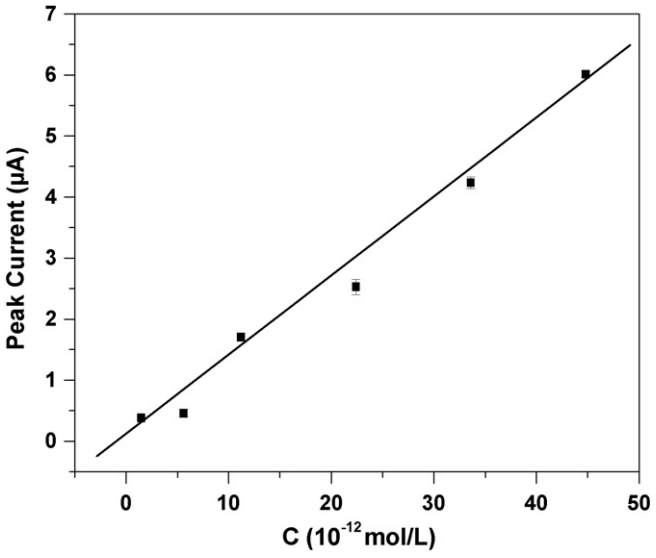

Fig. 6. Dependence of the peak current on the concentration of target thrombin, the concentration of the thrombin is 1.47×10^{-12} M to 4.48×10^{-11} M. The illustrated error bars represent the RSD of five measurements conducted at each thrombin concentration.

The dynamic range of the assay covers physiologically relevant concentrations, which range from 1.47×10^{-12} M to 4.48×10^{-11} M. The resulting linear regression is $Y = 0.12427 + 0.12958X$ (X stands for the value of the 10^{-12} M, and Y is the value of the DPV current, unit: μA), with a correlation coefficient of 0.997. As low as 6.616×10^{-13} M of the target thrombin can be detected with a signal-to-background ratio of 2.7 with the proposed assay. The reproducibility of the assay assessed by analyzing samples containing 4.48×10^{-11} M of target thrombin was 4.87% ($n = 5$).

The amount of thrombin in real plasma sample was detected. Thrombin is a plasma protein, and all of the thrombin in plasma is present in the form of its precursor, prothrombin. Trypsin was added in 100 μL of the plasma to convert the prothrombin to thrombin. Calcium ion was added to retain 1 M. After proper dilution, the electrochemical detection were carried out as the procedure mentioned above. Three different plasma samples were detected, the amount of thrombin found in plasma and the recovery were presented in Table 1. Data show that the concentration of thrombin in plasma is 7.76×10^{-7} M.

4. Conclusion

In conclusion, the present study described a novel and efficient detection procedure for thrombin. In the sensing system, the electrochemical signals with the concentration of thrombin over a range from 1.47×10^{-12} M to 4.48×10^{-11} M were detected and the detection limit obtained was 6.616×10^{-13} M. This aptamer-based assay demonstrated several advantages. Gold nanoparticles and magnetic nanoparticles exhibit excellent electrochemical characteristics to assure the high sensitivity. The simplicity and the selectivity were achieved by the aptamer-based structure switch system. On the other hand, it is fit for the detection of real sample, as a result of the high specificity to human thrombin, even in a complex blood serum.

The assay provides a new platform for the specific recognition of other proteins. It is also believed that the facile method developed will find more potential biological applications due to its simple, fast, specificity and stability.

ABSTRACT

In this paper, a solid-phase extraction (SPE) method based on mixed hemimicelles of cetyltrimethyl ammonium bromide (CTAB) on silica-coated magnetic nanoparticles (MNPs) is developed for extraction and preconcentration of compounds from the biological samples. We selected rhein and emodin which are the major active anthraquinones of rhubarb as model analytes. A high performance liquid chromatography–fluorescence detection (HPLC/FLD) method was developed for the determination of rhein and emodin in urine and serum samples. The main factors influencing the extraction efficiency including the amount of surfactant, the concentration of MNPs, the shaking time and the desorption ability of organic solvents were investigated and optimized. No interferences were caused by proteins or endogenous compounds in urine and serum samples. Good linearities ($r^2 > 0.9995$) for all calibration curves were obtained, and the limits of detection (LODs) for rhein and emodin were 0.2 and 0.5 ng/mL in urine samples and 7 and 10 ng/mL in serum samples, respectively. Satisfactory recoveries (92.76–109.90% and 97.53–107.72% for rhein and emodin) in the biological matrices were achieved.

1. Introduction

Rhei Rhizoma (rhubarb) is a well-known traditional Chinese herbal medicine. Anthraquinone components are the main effective ingredients of rhubarb, which have many pharmacological activities including anti-bacterial [1,2], anticancer [3,4], antifungal [5], antioxidative actions [6,7] and protection of the damaged liver [8,9]. Therefore, it is necessary to determine the content of anthraquinones in biological samples for their pharmacological studies. Rhein and emodin are the major active anthraquinones [10,11]. Several analytical methods have been reported for the quantification of them in biological matrices, such as TLC [12], HPLC/UV [1], LC/MS [12], etc. Generally, for chromatographic analysis of pharmaceutical compounds in biological matrices such as urine, serum and plasma, sample pretreatment is required to clean up the sample before injection. A literature survey reveals that there have been a number of pretreatment methods for analysis of bioactive components in rhubarb, e.g., protein precipitation [12–14], liquid–liquid phase extraction (LLE) [10,15], column-switching [16], etc. However, these methods still have some limitations or shortcomings, for example, need of sample dilution, incomplete protein precipitation, drug co-precipitation, etc. Compared with LLE, solid-phase extraction (SPE) has many obvious advantages including high preconcentration factors, low consumption of organic solvents and ease to operate.

The absorption of ionic surfactants on metal oxides such as alumina, silica, titanium dioxide and ferric oxyhydroxides can form hemimicelles and admicelles [17–21]. Recently, new SPE methods based on mixed hemimicelles assembles has been proposed for the extraction and preconcentration of ionic [19], non-ionic [22,23], amphiphilic [18] compounds. In these methods, the sorbents were produced by the adsorption of ionic surfactants such as sodium dodecyl sulfate (SDS) or cetyltrimethyl ammonium bromide (CTAB) on the surface of mineral oxides [24]. Compared with the normal sorbents, one feature of these sorbents is that the outer surface of hemimicelles is hydrophobic and the admicelles is ionic, which offers different mechanisms for extraction. Moreover, the number of commercially available surfactants is very large, hence the degree of hydrophobicity and the charge of the sorbent can be easily modified according to the nature of analytes. Therefore, using mixed hemimicelles in SPE has many advantages, such as high extraction yields, high breakthrough volumes, and rapid elution of analytes. However, to our knowledge, mixed hemimicelles have not yet been applied in the analysis of biological samples.

Recently, many research groups have explored the application of several nanosized SPE adsorbents such as nanoparticles (NPs) and nanotubes. Magnetic nanoparticles are one of the most popular materials in analytical biochemistry, medicine, and biotechnology, and they have been increasingly applied to immobilize proteins, enzymes, and other bioactive agents [25]. Fe_3O_4 nanoparticles have

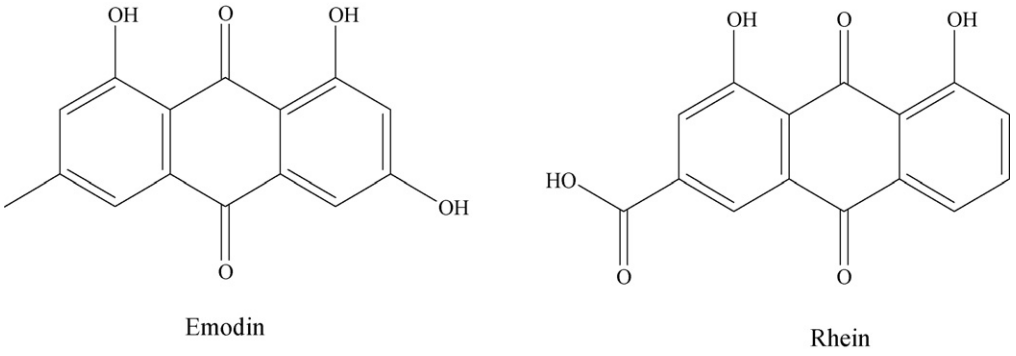

Fig. 1. The chemical structures of rhein and emodin.

attracted particular interest in separation science, for they can be easily isolated by using an external magnetic field placed outside of the extraction container. However, pure magnetic particles are prone to form aggregates and their magnetic properties can be altered in complex environmental and biological systems. To solve the above problems, a suitable protective coating on a magnetic core is often used. The core–shell magnetic nanoparticles have high surface areas. Silica has been considered as one of the most ideal shell materials due to its reliable chemical stability, biocompatibility and versatility in surface modification [26]. Hence, silica-coated Fe_3O_4 nanoparticles could be used for rapid separation. Mixed hemimicelles based silica-coated magnetic nanoparticles were proposed to preconcentrate phenolic compounds from environmental samples [27].

In this work, we combine the advantages of both mixed hemimicelles and silica-coated magnetic nanoparticles, and a mixed hemimicelles based nanosized SPE sorbent is proposed for the extraction and preconcentration of the two active components (rhein and emodin) of rhubarb from the serum and urine samples. We synthesized the Fe_3O_4/SiO_2 core/shell nanoparticles and modified them by coating with cationic surfactants (CTAB) to form the nanosized SPE sorbents. The factors influencing the formation of mixed hemimicelles and the recoveries of the analytes in biological samples were investigated. We found that, for the analysis of rhein and emodin in biological samples, the proposed mixed hemimicelle based nanosized SPE method is more sensitive than the conventional method.

2. Experimental

2.1. Instrumentation and chromatographic conditions

Liquid chromatographic system (Shimadzu, Kyoto, Japan) was consisted of two LC-20AT pumps, a CTO-10AS VP column oven and a RF-10A XL FLD system. They were connected via a communication bus module (Model CBM-20A), and controlled by a Shimadzu LC Solution workstation. A Shimadzu Shim-pack vp-ODS column (5 μm, 4.6 mm × 150 mm) was utilized. When methanol or acetonitrile/water was used as the mobile phase, the peaks of analytes showed band broadening and tailing. In order to improve the peak shape, acetic acid was used to modify the mobile phase. Acetic acid solution (0.1%, 0.3%, 0.5%, 0.8%)–methanol was tested as mobile phases. When the concentration of acetic acid solution was increased to 0.5%, narrow peaks, good symmetry and smooth baselines were obtained. So the mobile phase was composed of A (0.5% acetic acid, v/v)–B (methanol) with the gradient elution (0–5 min, isocratic conditions with 65% of methanol; 5–20 min, linear gradient from 65% to 90% of methanol). The other analysis

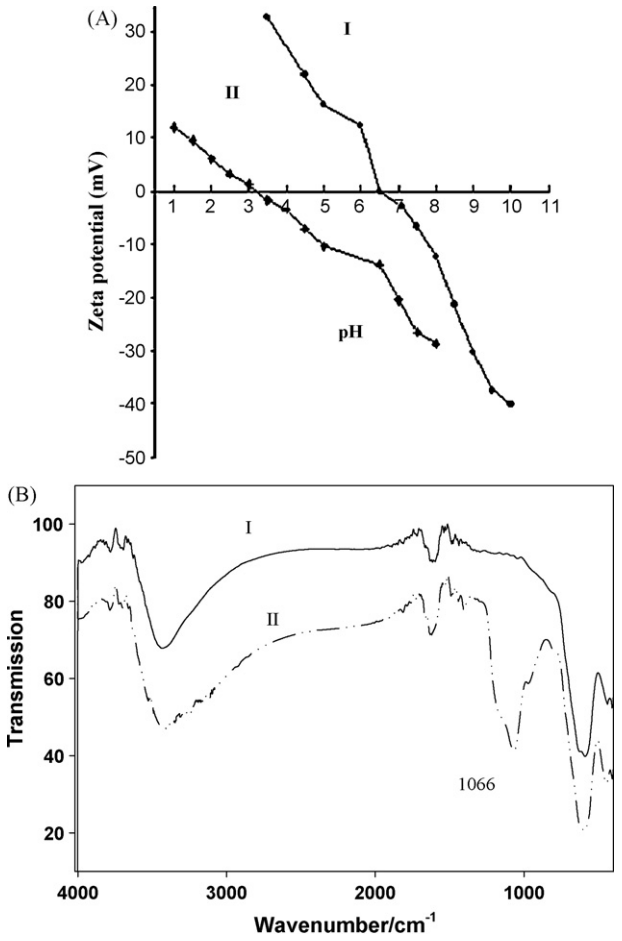

Fig. 3. Zeta-potential at different pH (A) and the infra-red spectrogram (B) of Fe_3O_4 MNps (I) and Fe_3O_4/SiO_2 MNPs (II).

conditions were as follows: column temperature, 30 °C; flow rate, 1.0 mL/min; injection volume, 20 μL. The detection wavelengths were selected at 435 and 515 nm for excitation and emission, respectively. Samples were filtered through 0.45 μm membrane prior to injection.

Zeta-potential measurements of Fe_3O_4 NPs and Fe_3O_4/SiO_2 NPs were performed with Zetasizer 3000 HAS apparatus (Malvern, United Kingdom).

2.2. Chemicals and reagents

The standards of emodin and rhein were purchased from Herbwide Scientific and Technical Development Center (Beijing, China). Their structures are shown in Fig. 1. HPLC-grade methanol (E. Merck, Darmstadt, Germany) was used for HPLC analysis. Ultrapure water was prepared using an Aike purification system (Chengdu, China). Other reagents were of analytical grade, including CTAB, ferric chloride ($FeCl_3{\cdot}6H_2O$), ferrous chloride ($FeCl_2{\cdot}4H_2O$), hydrochloric acid (HCl), aqueous ammonia and tetraethyl orthosilicate (TEOS).

2.3. Preparation of silica-coated magnetite nanoparticles

Fe_3O_4 magnetite was prepared by the coprecipitation method [28]. 1.08 g $FeCl_3{\cdot}6H_2O$ and 0.376 g $FeCl_2{\cdot}4H_2O$ were dissolved in 6 mL 1 mol/L hydrochloric acid. The resulted clear yellowish green solution was then added into 50 mL (5%, v/v) ammonia solution. Upon addition, the solution turned black and was then stirred magnetically at 1000 rpm for 1 h. The Fe_3O_4 magnetite was then washed three times with ethanol and suspended in the ethanol.

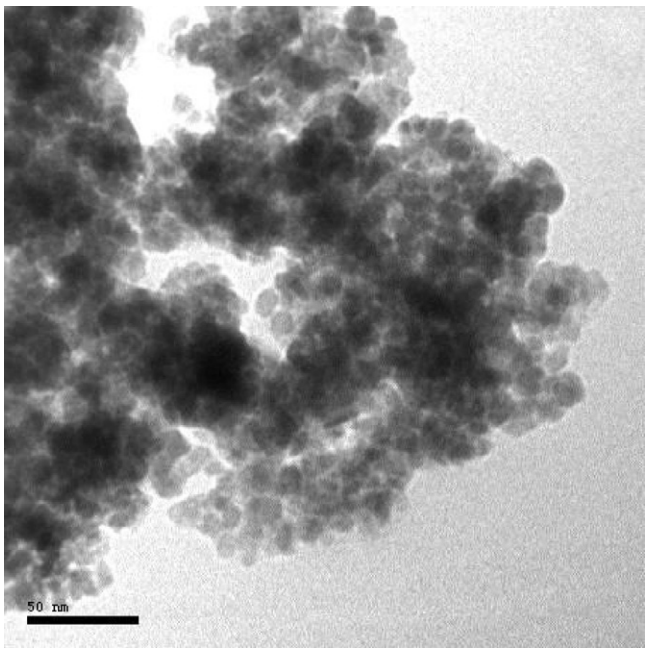

Fig. 4. TEM image of Fe_3O_4/SiO_2 MNPs.

The Fe_3O_4 nanoparticles (0.2 g) were suspended in ethanol (40 mL) under sonication for 1 h. Aqueous ammonia (4.5 mL), deionized water (3.75 mL) and TEOS (0.1 mL) were added in sequence to the suspension. The mixture was sonicated for 1 h followed by vortex mixing for another 8 h. The silica-modified nanoparticles were isolated by magnetic separation and were rinsed with deionized water three times and then resuspended in deionized water (10 mL). The concentration of the generated nanoparticles was estimated to be 20 mg/mL.

2.4. Serum and urine sampling

A mixed stock solution containing rhein (50 μg/mL) and emodin (100 μg/mL) was prepared in methanol. Blank serum and urine samples were collected from volunteers in the Hospital of Hunan University (Changsha, China) and stored at 4 °C. Appropriate milliliters of stock solution of rhein and emodin were added to the blank urine and human serum solutions. The urine samples were prepared with 0.5–250 ng/mL of rhein and 1–500 ng/mL of emodin, respectively. While the serum solutions were prepared with 5–2500 ng/mL of rhein and 10–5000 ng/mL of emodin, respectively.

2.5. Solid-phase extraction procedure

For the extraction and preconcentration of analytes in urine samples, 10 μL MNPs solution (10 mg/mL), 10 μL CTAB solution (4 mg/mL) and 1 mL urine samples were added into a 2 mL centrifuge tube in sequence. For serum samples, 80 μL MNPs solution (10 mg/mL), 70 μL CTAB solution (4 mg/mL) and 100 μL serum samples were added into a 2 mL centrifuge tube, and then was diluted by ultrapure water to 1 mL. To form CTAB-coating on magnetic particles and to trap the targets completely, the above-mentioned centrifuge tube was equilibrated for 5 min in an oscillator. After equilibrium, the MNPs were isolated by placing a strong magnet at the side of the tube and the supernatant

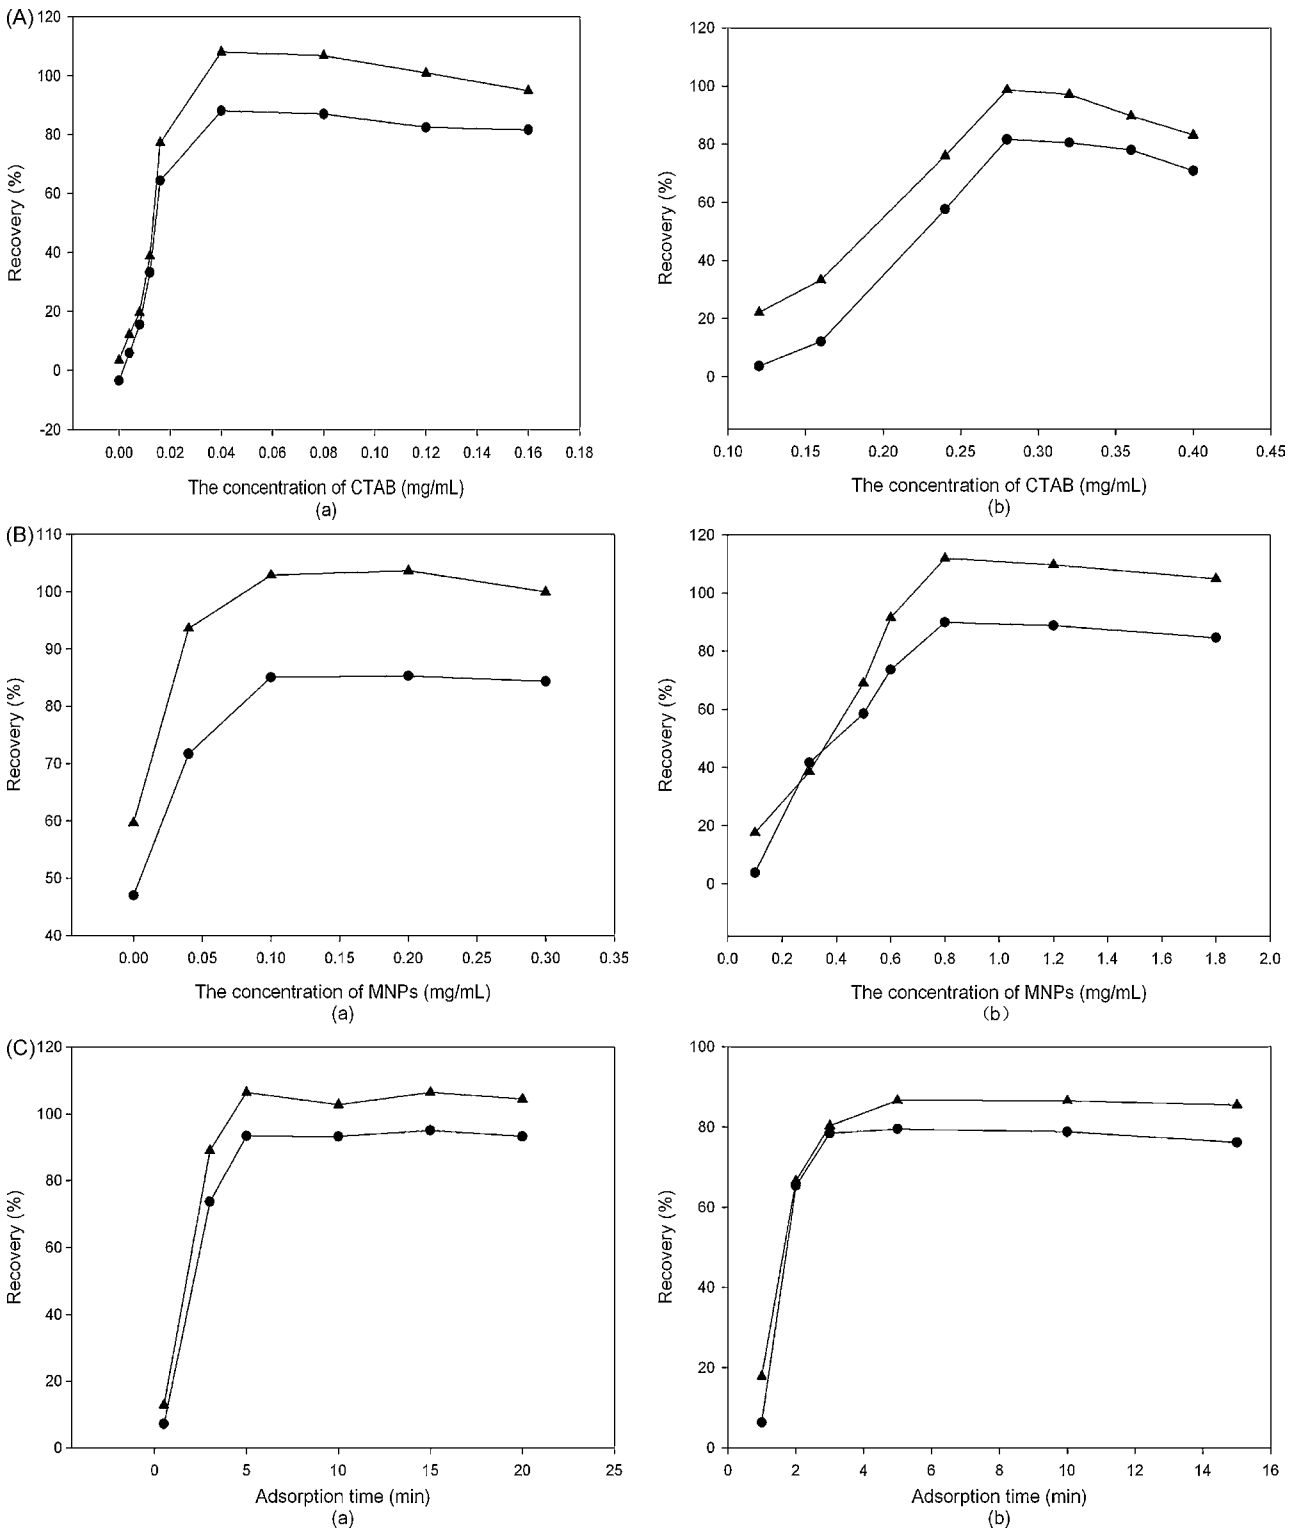

Fig. 5. Effects of the amount of CTAB (A), the concentration of MNPs (B), and the shaking time (C) on the adsorption of rhein (●) and emodin (▲) performed in urine samples (a) and serum samples (b). Performed in batch mode. Concentrations of analytes: 25 ng/mL for rhein and 50 ng/mL for emodin, respectively. (A) The concentration of MNPs was 15 mg/mL. (B) The concentration of CTAB was 4 mg/mL. (C) The concentration of MNPs was 10 mg/mL and the concentration of CTAB was 4 mg/mL.

was discarded. To the isolated NPs, acetonitrile containing 1% acetate acid was added to desorb the analytes (washed twice, 0.5 mL each time). The acetonitrile solution was collected and then dried under a stream of nitrogen at 60 °C and redissolved in 100 μL methanol. After filtration through 0.45 μm membrane, 20 μL of this solution was injected into the HPLC system for analysis. After the nanoparticles were totally isolated by strong magnet, we proved that the nanoparticles can be reused at least for three times, with recoveries of analytes around 90% for each time, and the RSD of the recoveries were 4.98% and 2.56% for rhein and emodin, respectively. Fig. 2 shows the procedure of such a SPE.

3. Results and discussion

3.1. Characterization of CTAB-coated Fe_3O_4/SiO_2 NPs

3.1.1. Characterization of Fe_3O_4/SiO_2 NPs

The isoelectric point (iep) is an important characteristics of metal oxides. In this study, the iep was determined by zeta-potential of NPs under different pH (Fig. 3A). The iep of Fe_3O_4 NPs is consistent with the reported value at pH 6.5. The iep of silica-coated magentic NPs was 3.23, and it approached to the reported value of natural silica which is 3 [29,30]. The infra-red spectrogram of the silica-coated magentic NPs is shown in Fig. 3B. The characteristic band of Si—O is at 1066 cm^{-1}. Therefore, the results confirm that the Fe_3O_4 NPs were protected by silica coating.

Fig. 4 shows the TEM image of the nanoparticles. We can see that the diameters of most particles are around 10 nm, and most of the particles are quasi-spherical in shape. Besides, we made nitrogen adsorption experiments using Autosorb-6 of Quantachrome and found that the specific area was 157.33 m^2/g when p/p_0 was 0.25897 and the total pore volume was 0.1625 cm^3/g when p/p_0 was 0.99513.

3.1.2. Evaluation of magnetic ability of the sorbent

For practical application of MCT (magnetic carrier technology), it is important that the CTAB-coated Fe_3O_4/SiO_2 NPs should possess sufficient magnetic attraction. We have tested three different cases, using three vials each containing 0.01 mg/mL Fe_3O_4 MNPs (a), 0.01 mg/mL Fe_3O_4/SiO_2 MNPs (b) and 0.01 mmol/L CTAB and 0.01 mg/mL Fe_3O_4/SiO_2 MNPs (c), respectively. It is found, when the magnet was placed beside the three vials, all NPs were quickly attracted to the walls of the vials within a few seconds, leaving the solution transparent. The results indicate that the CTAB-coated Fe_3O_4/SiO_2 nanoparticles as sorbents can be completely aggregated by an external magnetic field.

3.2. Mixed hemimicelle-based SPE

As we know that when the micelles concentration is less than critical micelle concentration (CMC), the micelles will form hemimicelles and admicelles spontaneously on the surface of the metal or non-metal. So the absorption of ionic surfactants on metal oxides such as alumina, silica, titanium dioxide and ferric oxyhydroxides can form hemimicelles and admicelles which is used as sorbents for the SPE of organic compounds. In this study, we tested CTAB-coated Fe_3O_4/SiO_2 NPs, where the analyte retention mechanism is mainly based on electrostatic interaction and lipophilic interaction. The predominant factors affecting the SPE of bioactive analyte with CTAB-coated NPs were investigated.

3.2.1. Influence of the amount of CTAB on the adsorption of the analytes

The influence of CTAB concentration on the adsorption of the analytes from the urine and serum samples was studied in batch mode. The experimental results are shown in Fig. 5A. It can be seen that, without CTAB, the analytes hardly adsorb onto the surface of Fe_3O_4/SiO_2 NPs. However, with the increase in CTAB concentration, the adsorption amount of targets increases remarkably. While surfactant concentration is above the CMC, the adsorption of analytes decreases gradually. The increase in adsorption can be explained by the gradual formation of hydrophobic mixed hemimicelles and admicelles on the surface of NPs. And the adsorption amount decreased when micelles were formed in the bulk aqueous solution, because the micelles caused the analytes to redistribute into the solution again. Comparing Fig. 5A a and b, more CTAB is needed for serum samples than urine samples because more protein or endogenous compound is presented in the former. Therefore, 0.04 and 0.28 mg/mL of CTAB were used for extraction of the analytes from urine and serum samples, respectively.

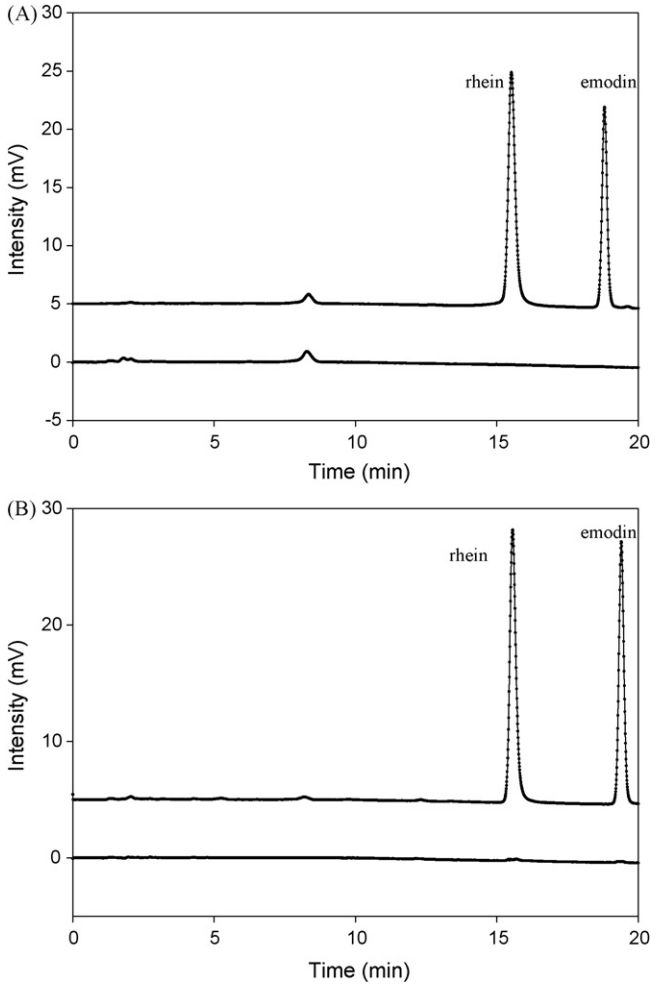

Fig. 6. (A) Comparison of chromatogram of blank urine sample and chromatogram of spiked urine sample for rhein (250 ng/mL) and emodin (500 ng/mL), respectively. (B) Comparison of chromatogram of blank serum sample and chromatogram of spiked serum sample for rhein (2.5 μg/mL) and emodin (5 μg/mL), respectively.

3.2.2. Effect of the concentration of Fe_3O_4/SiO_2 NPs

Nanoparticles have been used as better sorbents for their high surface areas than conventional sorbents. Therefore, fewer amounts of nanoparticle sorbents can achieve satisfactory results. In this work, we found that 0.1 and 0.8 mg/mL were adequate for extracting the analytes from urine and serum, respectively. The results are shown in Fig. 5B.

3.2.3. Shaking time for adsorption

In the SPE process, the shaking time is one of the prime factors influencing the target analytes extraction. As shown in Fig. 5C, when the NPs were isolated immediately without a shaking process into the urine or serum samples, the analytes were hardly adsorbed. However, when the samples were shaken for 5 min, as shown in Fig. 5C, the peak areas of analytes all achieve their maximums both in urine and serum samples. Therefore, a short shaking time of 5 min was selected for adsorption, which enables the targets to be completely absorbed on the CTAB-coated Fe_3O_4/SiO_2 NPs.

3.2.4. Desorption conditions

Organic solvents can rapidly and completely disrupt the mixed hemimicelles. In this paper, acetonitrile and methanol were stud-

Table 1
Linear range, slope, intercept, correlation coefficients (r^2) and limits of detection (LOD) of the investigated compounds.

Compound (n = 6)	Linear range (ng/mL)	Slope	Intercept	r^2	LOD (ng/mL)
Rhein					
Urine	0.5–2500	1366.1	1193.6	0.9999	0.2
Serum	10–2500	148.48	1859.6	0.9997	7
Emodin					
Urine	1–5000	427.37	−746.58	0.9997	0.5
Serum	20–5000	52.24	−3399	0.9996	10

ied for the desorption of analytes from the CTAB-coated Fe_3O_4/SiO_2 NPs. We found that the desorption ability of acetonitrile was superior to that of methanol. Furthermore, while acetic acid was added into the organic solvent, the recoveries of the targets were improved. We studied acetonitrile containing 0.5%, 0.8%, 1%, 1.2% acetic acid as the solvent. When acetonitrile containing 1% acetic acid was used, the analytes can be fully desorbed (washed twice, 0.5 mL each time).

3.3. Method validation

Based on the above results, the conditions of the SPE were as follows: 0.04 mg/mL CTAB and 0.1 mg/mL NPs were added into the urine samples while 0.28 mg/mL CTAB and 0.8 mg/mL of NPs were added into the serum samples, shaking time was 5 min, and acetonitrile containing 1% acetic acid was used for the desorption. Fig. 6A shows the chromatograms of blank and the spiked urine samples, respectively. Fig. 6B shows the chromatograms of blank and the spiked and serum samples. All the samples were dealed with the proposed SPE method before injection. The urine samples can be preconcentrated by ten times. The retention times of rhein and emodin were 15.56 and 19.12 min, respectively. No interferences from the proteins and endogenous components of the urine and serum samples were observed, which shows the excellent specificity for the determination of rhein and emodin with this mixed hemimicelles coated MNPs SPE method.

3.3.1. Linearity, limit of detection and comparison with other methods

The linearities of the analytes were studied in urine and serum samples, respectively. Three injections were examined at each level. Limits of detection (LODs) of the investigated compounds were estimated as the minimum concentration determined with a signal-to-noise ratio of 3. The linear range, slope, intercept, correlation coefficients (r^2) and LODs are listed in Table 1. The results show good linearity ($r^2 > 0.9995$) of the calibration curves. The LODs of rhein and emodin were 0.2 and 0.5 ng/mL in urine samples and 7 and 10 ng/mL in serum samples, respectively.

The extraction efficiency of this proposed method was compared with the protein precipitation method. 1 mL Sample (with spiked given concentration analytes) was added to 3 mL acetonitrile. After vortex-mixing for 1 min, the solution were centrifuged

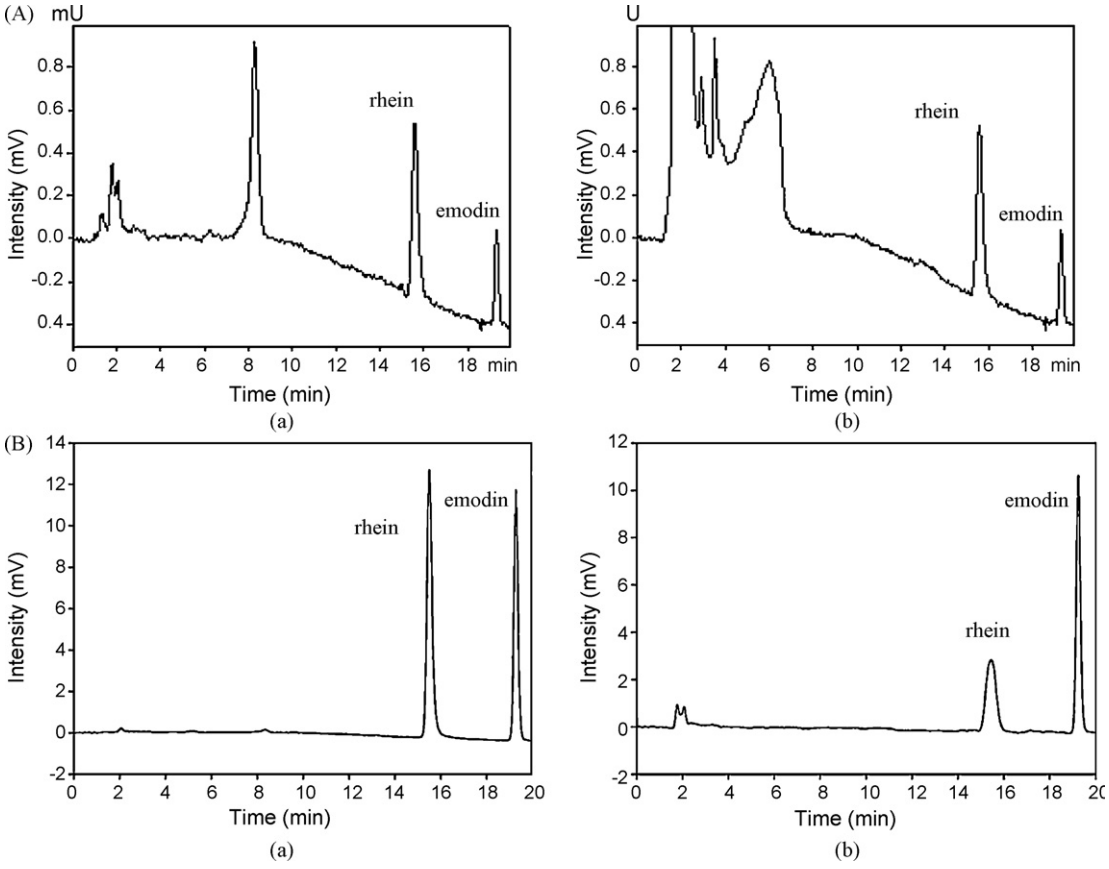

Fig. 7. The chromatograms of the urine (A) and serum (B) samples with the proposed sample pretreatment method (a) and protein precipitation method (b). The concentrations in urine sample are 10 ng/mL for rhein and 20 ng/mL for emodin, and that in serum sample are 2.5 and 5 μg/mL, respectively.

	2000	108.49	5.36	4000	103.36	3.55

at 5000 rpm for 10 min, the supernatants were evaporated to dryness under a stream of nitrogen flow at 60 °C, then the residue was treated with 100 μL methanol solution. An aliquot (20 μL) was injected into the LC system for analysis. Fig. 7 shows the chromatograms of the samples with the proposed method (left) and the classical method (right). It can be seen from Fig. 7 that no interference was caused in both methods, but while using the mixed hemimicelles coated MNPs method, the background noise was less.

Compared with the previously reported method, wider linear ranges, lower LODs and better recoveries were obtained for rhein (no data were reported for emodin in [10]). The comparison result is given in Table 2.

3.3.2. Precision and accuracy

The intra-day and inter-day precision and accuracy of the method were evaluated by assaying five replicate spiked urine and serum samples at three different concentration levels (low, middle and high quantification concentrations) of the targets in the same day and in three consecutive days, respectively. The relative standard deviations (RSDs) of the intra-day and inter-day precision and accuracy values for spiked biological samples are summarized in Table 3. The RSDs of the intra-daily tests are less than 5.5%, and the RSDs of inter-daily tests (three consecutive days) are less than 6.8%. These results indicate that the present method has good accuracy and precision.

3.3.3. Recovery

The recovery of the method was studied using the standard addition method. The reference standards were added at three different concentration levels (low, middle and high concentrations of the matrix) with five parallels at each level. The recoveries of rhein and emodin in urine and serum samples are shown in Table 4. It can be seen that satisfactory recovery (92.8–109.9%) was obtained using the proposed method. Thus it is suitable for analyzing the biological samples.

4. Conclusion

A rapid, sensitive and simple SPE method which combined the advantages of mixed hemimicelles and silica-coated magnetic nanoparticles was applied in extraction and preconcentration of the active compounds in biological samples firstly. Rhein and emodin which are the major active anthraquinones of rhubarb were selected as the example. This method was proved to be feasible. The analytes were extracted and preconcentrated by this SPE method before HPLC/FLD analysis. Compared with the classical pretreatment method (protein precipitation), the amount of the analytes found in the biological samples are superior. Also we obtained good linearities and recoveries with serum and urine samples, which indicates that this proposed method can be successfully applied in the sample preparation of biological samples.

Thin mercury film rotating disk electrode (TMF-RDE)
Absence of gradients and Nernstian equilibrium stripping (AGNES)
Heavy metals speciation

ABSTRACT

In the present work, the applicability of thin mercury film on a rotating disk electrode (TMF-RDE), to assess the free metal ion concentration by the absence of gradients and Nernstian equilibrium stripping (AGNES), is evaluated. The thickness of the mercury film and several AGNES parameters has been optimized. A nominal 16 nm film is chosen due to the higher signal (faradaic current) relative to the value of the noise (capacitive current). Due to the smaller volume to area ratio, the deposition time needed to reach a certain preconcentration factor (Y) is much shorter than in larger electrodes, like the HMDE. The limit of detection (3σ) for lead(II) is 7.4×10^{-9} M and 7.2×10^{-8} M for a Y of 5000 (deposition time of 150 s) and 1000 (deposition time of 100 s), respectively. A specific mathematical treatment is developed in order to subtract a corrected blank taking into account the degradation of the thin film (presumably, falling down of drops). The couple TMF-RDE/AGNES is successfully applied for speciation purposes in the systems Pb(II)–latex nanospheres and Pb(II)–IDA (iminodiacetic acid), where the stability constants calculated for both systems agree with values reported in the literature.

1. Introduction

Absence of gradients and Nernstian equilibrium stripping (AGNES) was recently proposed for the determination of the free metal ion concentration of amalgamating elements [1]. The key idea in this technique is that during the deposition step the metal within the mercury electrode is allowed to proceed until reaching Nernstian equilibrium without concentration gradients. Therefore, the concentrations of amalgamated metal and the faradaic stripping current are proportional to the free metal ion concentration in the bulk solution [1,2].

Recently, instead of using the conventional HMDE, AGNES was applied with Hg–Ir microelectrodes. Due to a reduction of the drop size in the latter case, the amount of deposited metal for a given preconcentration is much less and the deposition time can be reduced. Because of the larger ratio of the accessible area over the volume of the amalgam, shorter times will be required to attain the target conditions (Nernst equilibrium). Despite of these advantages, the preparation procedure of the microelectrode is time consuming and the mechanical resistance of this electrode still needs to be improved. Moreover, the large capacitive current only allowed a modest decrease in the limit of detection [3].

In a previous work, the thin mercury film rotating disk electrode (TMF-RDE) proved to be suitable in stripping chronopotentiometry and scanning stripping chronopotentiometry (SCP/SSCP) studies of metal cations, due to the high sensitivity and resolution attained [4]. A relatively stable, homogeneous and reproducible *ex situ* thin mercury film (TMF) could be easily plated, with a single electrodeposition step of high overpotential, in acidic solutions [4,5].

The aim of the present work is to evaluate the TMF-RDE to perform AGNES. For that, the evolution of the film electrode is taken into account by means of a mathematical treatment. The TMF-RDE thickness is optimized in order to obtain a stable film coating that could be used for one day, without recasting the electrode. The key parameters of the technique, such as deposition time, deposition potential and also the rotation speed applied to the rotating disk electrode (RDE) are also investigated. The main goal is to shorten the time of analysis while obtaining a low detection limit.

Additionally, the speciation capability of the TMF-RDE coupled with AGNES is assessed, evaluating the interaction of lead(II) cation with two ligands: (i) iminodiacetic acid (IDA) and (ii) 40.0 nm radius carboxylated latex nanospheres (P(S/V–COOH)).

2. Theoretical background

We now summarize the principles of AGNES and its application with non-evolving electrodes (fixed area and fixed volume).

AGNES consists of two conceptual steps or stages: deposition or first stage, and stripping or second stage. The aim of the deposition step is to attain a special situation without concentration gradients (both inside the mercury film electrode and in the solution in contact with the electrode), while a constant ratio is kept between the concentrations of the electroactive couple due to the Nernstian equilibrium [1]. This ratio is called gain or preconcentration factor Y, and depends on the applied potential, E_1:

$$Y = \frac{c^*_{M^0}}{c^*_M} = \exp\left[\frac{-nF(E_1 - E^{0'})}{RT}\right] \quad (1)$$

where $E^{0'}$ stands for the standard formal potential of the redox couple of the metal M and $c^*_{M^0}$ and c^*_M correspond to the final homogeneous metal concentrations inside the mercury electrode and the bulk solutions, respectively. The duration of the deposition stage is denoted as t_1. The gain Y for a given applied potential E_1 is determined from the peak potential of a differential pulse polarography (DPP) experiment, E_{peak} [6]:

$$Y = \sqrt{\frac{D_M}{D_{M^0}}}\exp\left[-\frac{nF}{RT}\left(E_1 - E_{peak} - \frac{\Delta E_{DPP}}{2}\right)\right] \quad (2)$$

where D_{M^0} is the diffusion coefficient of the reduced metal, and ΔE_{DPP} is the modulation amplitude of the DPP experiment.

In the second (or quantification) step, a sufficiently less negative potential, E_2, is applied in order to produce a stripping current under diffusion limited conditions. The measured response function is the current I at a certain time t_2. The faradaic component of this current is linearly related with $c^*_{M^0}$, due to the linear features of the metal diffusion inside the mercury film. So, the free metal ion concentration is directly proportional to the faradaic current with a proportionality factor h (which can be obtained from the calibration), since, according to Eq. (1) [1], $c^*_{M^0}$ is Yc^*_M. So

$$I_f = hc^*_M \quad (3)$$

The measured current contains other components apart from the faradaic current; therefore it is necessary to subtract a blank from the total current.

3. Experimental

3.1. Reagents

All chemicals were of analytical reagent grade and all solutions were prepared with ultra-pure water (18.3 MΩ cm, Milli-Q systems, Millipore-waters). Sodium nitrate, potassium chloride, nitric acid 65% (Merck, suprapur), hydrochloric acid 37% (trace select, Fluka) and 1000 ppm Hg and Pb AA-Spectrosol metal ion standards (Merck) were also used. Ferricyanide standard solution (1.929×10^{-3} mol dm^{-3}) in 1.0 mol dm^{-3} KCl was used for chronoamperometry. Nitric acid (1 M) and sodium hydroxide solutions (1 M) were used for pH adjustments. Stock solution of MES 2-(N-morpholino-ethanesulfonic acid) buffer (0.1 M) was prepared from the solid (Merck). Solutions of ammonium acetate (NH_4Ac 1.0 M/0.5 M HCl) pH buffer and ammonium thiocyanate 1.0 M were prepared monthly and used without further purification. Biohit Proline pipettes equipped with disposable tips were used for appropriate dilutions. All measurements were carried out at room temperature (20 °C).

3.2. Apparatus

An EcoChemie Autolab PGSTAT12 potentiostat (controlled by GPES 4.9 software from EcoChemie, the Netherlands) was used in conjunction with a Metrohm 663 VA stand (Metrohm, Switzerland). The three electrode configuration was used comprising a TMF plated onto a rotating glassy carbon (GC) disk (1.9 mm diameter, Metrohm) as the working electrode, a GC rod counter electrode and a double junction $Hg|Hg_2Cl_2|KCl$ (3 M) encased in a 0.1 M $NaNO_3$ solution, as the reference electrode. The electrochemically active surface area of the glassy carbon electrode (3.098 ± 0.015) mm^2, was measured by chronoamperometry (in 1.929×10^{-3} M ferricyanide/1.0 M KCl solution; two polishing experiments, each with four replicate determinations).

A combined glass electrode (Radiometer Analytical pHC3006-9) connected to a pH meter (Thermo Electron Corporation, Model Orion 3-Start) was used for pH measurements.

The microscope examinations were carried out with an optical inverted microscope Zeiss Axiovert 40 MAT connected to a digital camera Cannon Powershot A620 and an AxioVision LE Canon Module software.

3.3. Preparation of the thin mercury film electrode

Prior to coating, the GCE was conditioned following a reported polishing/cleaning procedure [7]. The GCE was polished with an alumina slurry (grain size 0.3 μm, Metrohm) and sonicated in pure water for 60 s, to obtain a renewed electrode surface. Then, an electrochemical pre-treatment was carried out with a multicycle voltammetric scanning (50×) between −0.8 and +0.8 V at 0.1 V s^{-1}, in NH_4Ac–HCl solution. These polishing and electrochemical pretreatments were repeated daily.

The thin mercury film was then *ex situ* prepared in 0.12 mM mercury(II) nitrate and adjusted to pH ~ 1.9, with a 1 M nitric acid solution, by electrodeposition at −1.3 V for different deposition times (240 s and 480 s) and a rotation rate of 1000 rpm [5,8].

The charge associated to the deposited mercury (Q_{Hg}) was calculated by electronic integration of the linear sweep stripping peak of mercury, for $\nu = 0.005$ V s^{-1}. The electrolyte solution was ammonium thiocyanate 5 mM (pH 3.4). The stripping step began at −0.15 V and ended at +0.6 V [8]. All charges quoted are mean values of 6 replicate measurements (RDS < 7%). The thickness of the TMF-RDE was estimated using this mean value of Q_{Hg} and assuming a uniform spread of the mercury on top of the entire disk surface [5,8]. Assuming a thin-film condition, the volume of the mercury electrode, $V_{Hg,dep}$, can be estimated from the amount of deposited mercury measured as the charge, Q_{Hg}, using the Faraday law and assuming the Hg atomic radius (r_{Hg}) as 1.44×10^{-10} m [7]. For the thin mercury film used in this work, the Q_{Hg} was 1.28×10^{-3} C (mean value of 6 replicate measurements with an RDS < 7%), leading to a $V_{Hg,dep}$ 5.01×10^{-14} m^3.

When not in use, the GCE was stored dry in a clean atmosphere [5].

3.4. AGNES procedures

AGNES experiments for optimization of parameters and for calibration were carried out in 20 mL 0.01 M $NaNO_3$ solutions spiked with lead(II) at pH of *ca.* 4. The potential program used consists in applying one potential step along the first stage ("1 pulse" or "1P" strategy) [6].

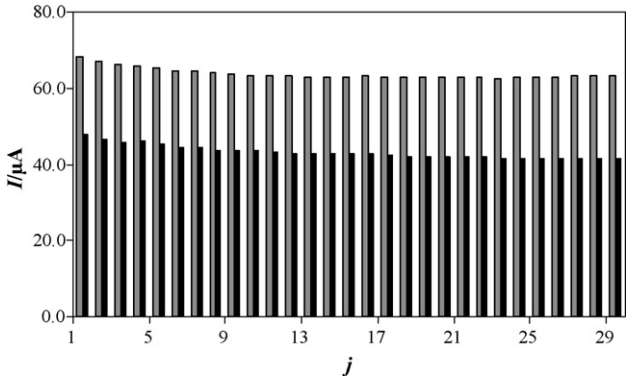

Fig. 1. Evolution of the measured current I (grey bars) and the current of the shifted blank I_{sb} (black bars) over 29 consecutive measurements. Parameters $t_2 = 2$ ms, $Y = 2000$ and $t_1 = 150$ s. The experiments were performed in 0.01 M $NaNO_3$ media, at a pH *ca.* 4 and for a total concentration of lead(II) of 3.96×10^{-7} M. The RDE was rotated at 500 rpm.

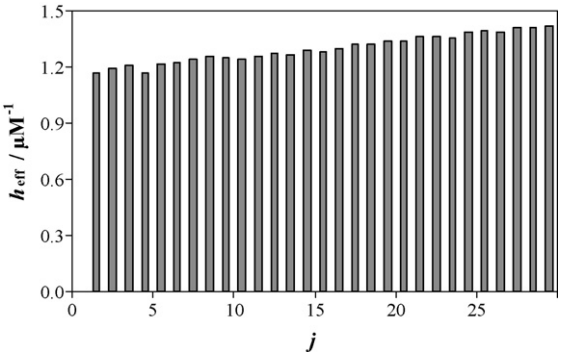

Fig. 2. Variation of the h_{eff} throughout 29 consecutive measurements. The current was measured at t_2 of 2 ms and the other experimental parameters used were: $Y = 2000$ and $t_1 = 150$ s. The experiments were performed in 0.01 M $NaNO_3$ media, at a pH *ca.* 4 and for a total concentration of lead(II) of 3.96×10^{-7} M. The RDE was rotated at 500 rpm.

The measured response is the current I at a certain time t_2. To this current we have to subtract a blank to remove the contributions other than the faradaic one. The synthetic blank [1,2,9] (obtained applying the same potential program in a solution with the same composition of the sample but no metal) is not suitable in case of presence of traces of contaminants or when dealing with natural samples with complex matrices. So, we developed a new kind of blank, the "shifted blank" [3,6,10–12]. The "shifted blank" is applied to the solution containing the metal but with a potential program shifted with respect to the main measurement; the deposition potential $E_{1,sb}$ corresponds to a very low gain ($Y_{sb} = 0.01$) and a $E_{2,sb}$ is applied keeping the same potential jump ($\Delta E = E_{1,sb} - E_{2,sb}$) of the main measurement. To avoid the effects caused by the presence of residual oxygen in the test solution, all of the current values (of the main and the shifted blank measurements) are corrected with the residual current (I_∞), which is obtained at very large stripping time (usually 20 s) [3].

All solutions were purged for 60 min at the beginning of each series of AGNES experiments and 60 s (assisted by mechanical stirring of the rotating GCE for the experiments performed using the rotation of the electrode) after each measurement.

Prior to the addition of the ligand (latex nanospheres or IDA) for the speciation assays, a calibration plot was performed using the optimized experimental parameters (t_1, t_2, Y and rotation speed of the rotating disk electrode).

4. Results and discussion

4.1. AGNES with evolving electrodes

4.1.1. Mechanical stability of the TMF-RDE

One of the problems reported with the use of the TMFE, especially when applied in the rotating mode of the electrode, is its mechanical degradation due to the coalescence or falling of the small drops of Hg. The stability of the mercury coating was assessed by evaluating the repeatability of the current measured at t_2 of 2 ms and for a Y of 2000. A set of 29 consecutive AGNES measurements, each of them immediately followed by a measurement of the shifted blank (a total of 58 measurements in 29 pairs of main measurement and shifted blank), is shown in Fig. 1. A "synthetic blank" with just background electrolyte ($NaNO_3$ 0.01 M solution, pH *ca.* 4) in the solution was run prior to the addition of the metal to the electrolyte solution.

Despite of this slight drift, we accept that this electrode can be used for a maximum of 58 AGNES experiments. A strategy (not essayed here) could be to discard the first few AGNES measurements, since the highest current deviations occur along these initial values.

4.1.2. Mathematical treatment

One interpretation of the observed decrease of the main measurements and blank currents is the falling down of some of the small drops that make up the film. Up to date, AGNES technique has only been used with electrodes whose area and volume remained fixed during the experimental course. Given that the shifted blanks could not be used because of their anomalously high values, we develop next a new mathematical treatment for this electrode with non-fixed area and volume.

We assume that AGNES principles apply to each individual drop, so that the *faradaic* current of a drop ($I_{f,j}^{drop}$) is proportional to the free metal concentration c_j at that moment or addition. j denotes a given configuration in the life of the evolving film, e.g. the electrode situation for a pair of main measurement and shifted blank in Fig. 2. So,

$$I_{f,j}^{drop} = h^{drop} c_j \tag{4}$$

where h^{drop} depends on the area of the drop. For the sake of simplicity, we assume that all drops are identical.

Assuming that the capacitive current (e.g. via the area) is proportional to the number of drops:

$$I_{sb,j} = n_j I_{sb,j}^{drop} \tag{5}$$

we can divide the previous equation applied to a general j with respect to a fixed (selected) "reference" moment or addition:

$$\frac{I_{sb,j}}{I_{sb,ref}} = \frac{n_j I_{sb,j}^{drop}}{n_{ref} I_{sb,ref}^{drop}} = \frac{n_j}{n_{ref}} \tag{6}$$

We assume that, for each j, we can use a certain synthetic blank, which denoted $I_{NaNO_3,j}$. This value cannot be experimentally measured for each moment j, but rather is estimated from the initial measurement $I_{NaNO_3,0}$ (synthetic blank with just background electrolyte):

$$\frac{I_{NaNO_3,j}}{I_{NaNO_3,0}} = \frac{n_j}{n_0} \Rightarrow I_{NaNO_3,j} = \frac{n_j}{n_0} I_{NaNO_3,0} = \frac{I_{sb,j}}{I_{sb,0}} I_{NaNO_3,0} \tag{7}$$

Thus, the faradaic component of one main measurement is:

$$I_{f,j} = I_j - I_{NaNO_3,j} = I_j - \frac{I_{sb,j}}{I_{sb,0}} I_{NaNO_3,0} = n_j I_j^{drop} = n_j h^{drop} c_j \tag{8}$$

where I_j is the total current of the main measurement.

Let us divide the previous equation applied to a general moment or addition j with respect to a fixed (selected) "reference" moment or addition:

$$\frac{I_j - (I_{sb,j}/I_{sb,0})I_{NaNO_3,0}}{I_{ref} - (I_{sb,ref}/I_{sb,0})I_{NaNO_3,0}} = \frac{n_j \bar{h}^{drop} c_j}{n_{ref} \bar{h}^{drop} c_{ref}} = \frac{n_j c_j}{n_{ref} c_{ref}} \quad (9)$$

We can isolate the faradaic component as

$$I_{f,j} = I_j - \frac{I_{sb,j}}{I_{sb,0}} I_{NaNO_3,0} = \left(I_{ref} - \frac{I_{sb,ref}}{I_{sb,0}} I_{NaNO_3,0} \right) \frac{I_{sb,j}}{I_{sb,ref}} \frac{c_j}{c_{ref}} \quad (10)$$

which, by defining a dimensionless or normalized current as

$$I_{norm,j} \equiv \frac{I_j - (I_{sb,j}/I_{sb,0})I_{NaNO_3,0}}{I_{sb,j}} = \frac{I_j}{I_{sb,j}} - \frac{I_{NaNO_3,0}}{I_{sb,0}} \quad (11)$$

the relationship can be simply written as

$$I_{norm,j} = h_{eff} c_j \quad (12)$$

with h_{eff} being the "effective" proportionality between concentration and the ratio between the faradaic and the shift blank currents:

$$h_{eff} \equiv \frac{(I_j/I_{sb,j}) - (I_{NaNO_3,0}/I_{sb,0})}{c_j} \quad (13)$$

From the calibrations, we compute h_{eff} as the slope of $(I_j/I_{sb,j}) - (I_{NaNO_3,0}/I_{sb,0})$ *vs* c_j and then we use this h_{eff} in Eq. (12) to determine the free metal concentration in a speciation experiment.

As a simple verification of this proposal, we have computed h_{eff} with Eq. (13) for the experiments shown in Fig. 1 and plot the results in Fig. 2. The variation of h_{eff} is around 20% from $j = 1$ to $j = 29$, but is around 10% if we go from $j = 1$ to $j = 15$ (30 experiments). This variation in h_{eff} is reasonably acceptable for the small number of experiments performed by us in one day (e.g. in the speciation experiments). We speculate (with the support of a simple model based on the proportionality between capacitive current with area and the functional dependence for h given in Eq. (A9) of ref. [1]) that the increase with time of h_{eff} could be due to the falling down of the smallest droplets, while the largest ones would remain attached.

4.2. Selection of the mercury film thickness in AGNES

The TMF-RDE is subject to mechanical deterioration of the electrode surface during the experimental course. To improve the electrode stability, the electrodeposition of mercury was performed in very acidic solutions (pH *ca.* 1.9) as in [5]. The result was the formation of highly reproducible thin mercury films, consisting of a collection of very small radius mercury droplets, as can be seen in the optical microphotographs (Fig. 3). The performance, i.e. reproducibility, stability/durability, of the TMF-RDE prepared by this procedure is similar to that achieved for the mercury films, *ex situ* prepared in thiocyanate media [7], as reported in a previous work [4].

The capacitive currents exhibited by microelectrodes [3] and by the TMF-RDE (probed in this work) are relatively large (i.e. of the same order of magnitude as the main measurement, so that the faradaic component is less well-defined). Here, the thickness of the mercury coating has revealed as key to reduce the charging currents [3]. Indeed, for the TMF-RDE of 9.1 nm the current obtained in the main experiment was practically the same as the capacitive current (provided by the shifted blank and for a concentration of lead(II) of 2.0×10^{-7} M) and so, a thicker, of *ca.* 16 nm, TMF-RDE was used in this work.

4.3. Optimization of AGNES parameters

Now we evaluate the impact of the different AGNES experimentally controlled parameters, such as the interval time used to measure the current (t_2) during the stripping step, the deposition time (t_1) and the rotation speed applied to the disk electrode, on the performance of the TMF-RDE.

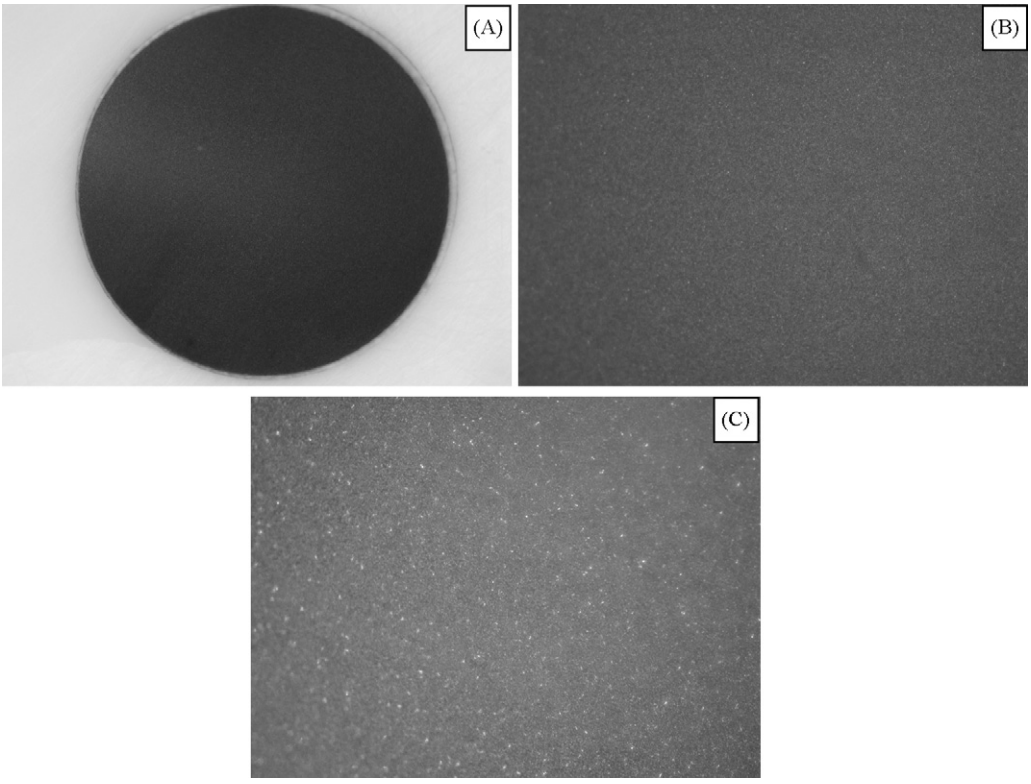

Fig. 3. Optical micrographs: ×50 (A), ×100 (B) and ×500 (C) of a TMFE (16 nm of nominal thickness), plated on a glassy carbon electrode.

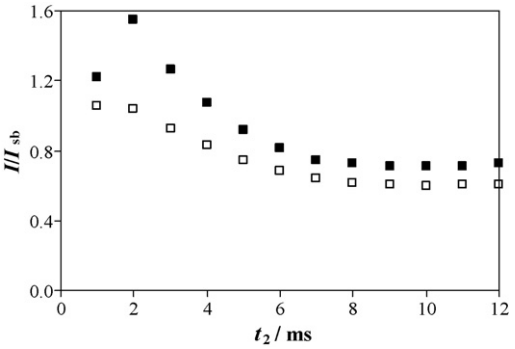

Fig. 4. Ratio between the measured current and the current of the shifted blank along the second stage of AGNES, within the t_2 interval 1–12 ms, in a given moment of the life of the evolving electrode (i.e. same *j*). The experiments were performed in 0.01 M $NaNO_3$ medium at a pH *ca.* 4 and for a total concentration of lead(II) of: (□) 1.99×10^{-7} M and (■) 5.99×10^{-7} M. Other experimental conditions: $Y = 2000$ and $t_1 = 150$ s; no rotation speed of the RDE was used.

4.3.1. Selection of t_2

The new mathematical treatment for evolving electrodes relies on the application of Eq. (12). The faradaic current $I_{f,j}$ (see Eq. (10)) is obtained by subtraction of the corrected synthetic blank Eq. (7)) from the main measurement of the current, being all currents measured at the same fixed t_2.

The selection of the measuring time t_2 stems from the idea of minimizing the relative importance of the capacitive current (estimated with the corrected synthetic blank) in the total current, which can be reformulated as obtaining larger values for the normalized current). In order to look for the ideal t_2, the ratio of the measured current over the shifted blank was plotted (Fig. 4) within the time interval of 1–10 ms, for a *Y* of 2000 and for two concentrations of lead(II).

The results point out that the suitable t_2 values are within the interval of 1–3 ms, where the I/I_{sb} ratio goes through a maximum around 2 ms. Therefore, 2 ms was the time chosen as the standard t_2 for the present work, representing a time neither too short (where large initial capacitive current arise) nor too long (where the gradual extinction of the faradaic current proceeds). Of course that, depending on the experimental set-ups, the optimum t_2 might suffer slight variations, but they can be easily followed given that the stripping current is recorded for a large number of t_2 values.

4.3.2. Effect of the deposition time, t_1

The deposition time is a key parameter in AGNES experiments. Higher t_1 values will favour the approach to the Nernst equilibrium, although too long deposition times would render the technique less useful. Therefore, using a one pulse strategy (i.e. the simplest potential program, that consists in applying only one deposition potential), the effect of the deposition time t_1 on the reaching of the sought equilibrium was evaluated. The deposition gain (*Y*) used in this experiment was 5000 and the total lead(II) concentration selected was 1.49×10^{-7} M. In the first stage (see Fig. 5A), no rotation was applied to the rotating disk electrode during the deposition step. The results reveal that for a gain (or preconcentration factor) of 5000, deposition times (t_1) longer than *ca.* 1600 s at the AGNES first stage, are required to reach the equilibration with flat profile.

Previous works of AGNES with the HMDE have systematically used stirring as a means of improving the efficiency of the mass transport, this resulting in a reduction of the required deposition time (t_1) [1]. This feature is particularly relevant to measure trace levels of free metal ions, where high preconcentration factors are frequently required. Therefore, the effect of the rotation speed in the experimental time of AGNES first stage under the same experimental conditions, i.e. using a *Y* of 5000, was evaluated (Fig. 5B).

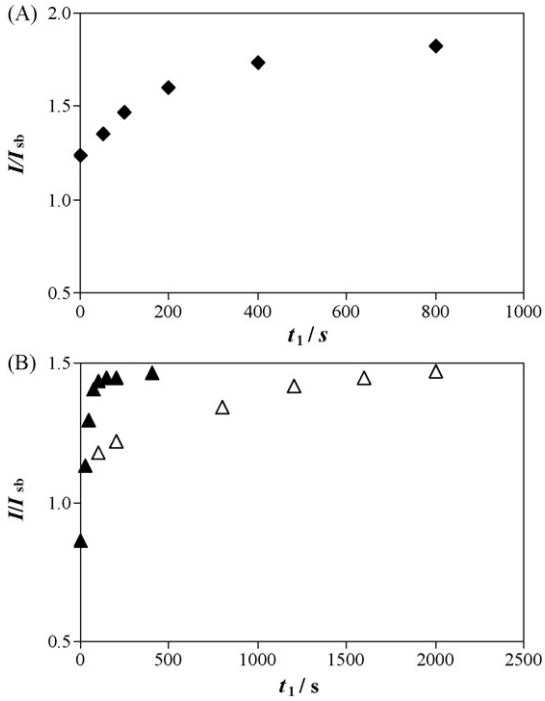

Fig. 5. Variation of the normalized current (I/I_{sb}) as a function of the deposition time (t_1), measured at t_2 of 2 ms and for: *Y* of 2000 for a rotation speed of the RDE of 0 rpm (A) and *Y* of 5000 for a rotation speed of the RDE of 0 rpm (white triangles) and 500 rpm (black triangles), respectively (B). The experiments were performed in 0.01 M $NaNO_3$ media, at a pH *ca.* 4 and for a total concentration of lead(II) of 4.99×10^{-7} M (A) and 1.49×10^{-7} M (B).

As expected, Nernst equilibrium is attained much faster with the rotation of the electrode, during the application of the potential deposition E_1. For the *Y* of 5000 used in this experiment, the plateau is reached for a deposition time of 100 s with a rotation speed of 500 rpm, which is sixteen times less the time needed without the rotation of the RDE (1600 s). In both cases, a stabilized faradaic current of *ca.* 2×10^{-5} A is achieved. The small t_1 values needed to reach the equilibrium at the TMF-RDE allow the use of higher preconcentration factors, thus lowering the limit of detection (LOD) of the technique.

Comparing the performance of the TMF-RDE with that of the Hg–Ir microelectrode [3], apart from the differences in the composition of the test solution used in the set-ups of experiments (the measurements using the microelectrode were made in 0.1 M KNO_3 media, at a pH 6.1), the results reveal that shorter t_1 values are required for the film electrode to reach AGNES conditions. For a gain of 5000, the microelectrode requires a t_1 of 400 s and reaches a LOD of 3.43×10^{-8} M, while the TMF-RDE for the same *Y*, reaches a lower LOD of 7.20×10^{-9} M with a shorter t_1 (150 s) for a rotation speed of 500 rpm.

The thin mercury film electrode is considered to be morphologically characterized not as a true film, but as a collection of small mercury droplets (*cf.* Fig. 3). The increased efficiency of the TMF-RDE with respect to the Hg–Ir microelectrode is a combination of a favourable ratio accessible area over volume and to the possibility of enhancing the mass transport via rotation [1,3,13].

In this work, other experiments were performed using a rotation speed of the RDE of 1000 rpm. The results were quite similar to the ones obtained with a rotation of 500 rpm, i.e. the time needed to obtain the plateau was basically the same. Since higher rotation speeds promote the faster mechanical degradation of the TMFE, the rotation speed of 500 rpm was selected as the more adequate, being applied in the subsequent studies.

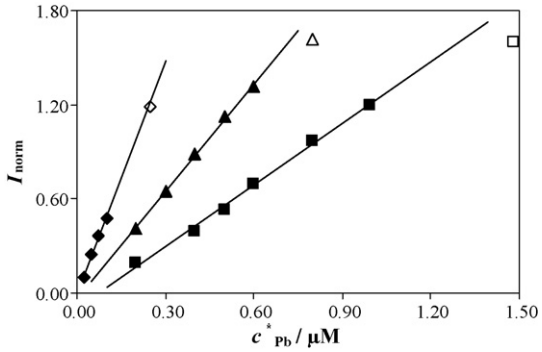

Fig. 6. Plot of I_{norm} (see Eq. (11)) *vs* the free metal concentration of lead(II) (c^*_{Pb}), for different *Y* values: 1000 (■ and □), 2000 (▲ and △) and 5000 (♦ and ◊). Full markers are related to the linear interval of concentrations and the open markers to the concentration range where the TMF-RDE stripping current deviates from the linear behaviour. The experiments were performed in 0.01 M $NaNO_3$ media, at a pH *ca.* 4. The current was measured at a t_2 of 2 ms and the deposition times used were: t_1 = 150 s for a *Y* of 5000 and t_1 = 100 s for a *Y* of 1000 and 2000. The RDE was rotated at 500 rpm.

4.4. Determination of the working concentration range for AGNES at the TMF-RDE

The proportionality between I_{norm} and c^*_{Pb} (given by Eq. (12)) on the TMF-RDE of 16 nm of thickness was evaluated. The calibration curves for three *Y* values (1000, 2000 and 5000) are displayed in Fig. 6. Before the additions of the metal to the electrolyte solution ($NaNO_3$ 0.01 M solution, pH *ca.* 4), a "synthetic blank" was made.

The interval of linearity between the faradaic current and the concentration of the free lead(II) ion clearly depends on the gain applied in the experiment. A higher gain produces higher faradaic current and as a result, the deviation to the linearity occurs at lower metal ion concentrations. Fig. 7 shows the chronoamperograms obtained in the second stage of AGNES for several concentrations of the total lead(II) and for a *Y* of 5000. The distortion in the AGNES signals for a concentration of the total lead(II) above 5×10^{-7} M is clearly seen. The anomalous stripping behaviour of Zn and Cd in AGNES experiments has been recently described in [14] and mostly attributed to a low ratio of the electroactive to background electrolyte concentrations [15]. One strategy, to avoid these distortions in the current values consists in increasing the ionic strength (provided this change or selection is allowed in the specific study undertaken, e.g. in many titrations of humic acids with metals). Alternatively, one can use the stripped charge (by integration of the stripping current all along the second stage) as response function, thus, increasing the range of linearity of the response function with the reduced metal concentration quite close to the saturation conditions.

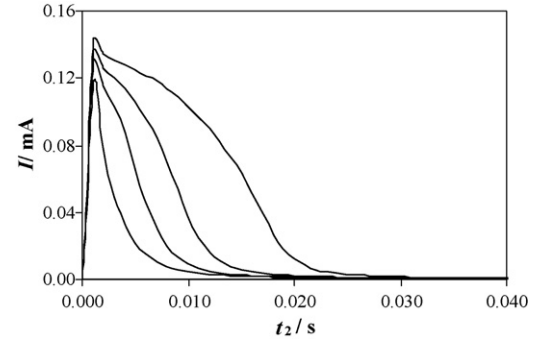

Fig. 7. Stripping signals along the first 40 ms of the AGNES second stage after reaching a *Y* of 5000. The concentrations of the total lead(II) used are (from lower curves to upper curves): 1.0×10^{-7} M, 5.0×10^{-7} M, 9.9×10^{-7} M and 20×10^{-7} M.

Table 1
Maximum workable concentration ($c_{Pb\,max}$) values and the corresponding LOD and calibration data (h_{eff} and *r*) for three gains at the 16 nm thick TMFE (plots presented in Fig. 6) for a rotation speed of 500 rpm.

Y	$c_{Pb\,max}$ (M)	Calibration data		LOD (M)
		h_{eff} (M^{-1})	*r*	
1000	1.0×10^{-6}	1.32×10^{6}	$0.995_{(N=5)}$	7.4×10^{-8}
2000	6.0×10^{-7}	2.28×10^{6}	$0.999_{(N=6)}$	2.1×10^{-8}
5000	2.0×10^{-7}	4.97×10^{6}	$0.998_{(N=4)}$	7.2×10^{-9}

Table 1 presents the interval of operational concentration values (expressed by the total lead(II) concentration) at this ionic strength, the limit of detection (LOD) and the calibration data, i.e. the slope (the proportionality factor, h_{eff}) and the correlation coefficient (*r*).

By applying a *Y* of 1000 it is possible to work with higher concentrations, but impossible to go below 7.4×10^{-8} M of lead(II), since the metal current is mainly capacitive current. The analytical window can be lowered applying a *Y* of 5000. Though, at this preconcentration factor it is not possible to go above a total lead(II) concentration of 2.0×10^{-7} M, due to the anomalous behaviour of the stripping currents at high reduced metal concentrations (for this ionic strength), but further work could take advantage of the wider analytical window available with the charge as response function [14]. The limit of detection (LOD) of this technique at the TMFE was 7.4×10^{-8} M and 7.2×10^{-9} M for a *Y* of 1000 and 5000, respectively. Lower LOD can – in principle – be achieved increasing the preconcentration factor applied in the experiment, though – in practice – the degradation with the required increased deposition times might pose restrictions. AGNES with the TMF-RDE and the essayed selection of the preconcentration gains, has measured the free metal concentration within a wide range of metal concentrations, i.e. from 7.2×10^{-9} M to 1×10^{-6} M, depending on the chosen conditions.

The factor h_{eff}, that represents the direct proportionality between the normalized current measured and the free metal concentration (Eq. (3)), when plotted as a function of the preconcentration factor *Y*, confirms the direct proportionality between these two parameters by the linearity attained (slope = 9.13×10^2 and correlation factor: 0.9999).

4.5. AGNES for metal speciation studies

4.5.1. Labile system

Monodisperse carboxylated latex nanospheres (P(S/VCOOH)) with 40.0 nm radius constitute a good model for macromolecular and particulate binding. The interaction of lead(II) with the latex nanospheres was studied with AGNES and the values obtained were compared with the experimental values obtained at the HMDE [11]. The experiments were performed for a total concentration of lead(II) of 6.0×10^{-7} M, at ionic strength 0.01 M in $NaNO_3$, and a MES 2-(N-morpholino-ethanesulfonic acid) buffer concentration of 2.0×10^{-3} M to fix the value of the pH to 5.5 and 6.1. The experiment at the TMF-RDE was carried out using a *Y* of 5000 and 2000, a deposition time of 150 s and a rotation speed of 500 rpm. Prior to the addition of the ligand to the test solution, the calibration plots for both preconcentration factors were obtained (pH *ca.* 4), see Table 2.

To compare with existing literature, we have computed the conditional stability constant as

$$K = \frac{c_{ML}}{c_M c_L} = \frac{c_{M,t} - c_M}{c_M(c_{L,t} - c_{M,t} + c_M)} \quad (14)$$

(i.e. by assuming that M only forms the complex ML with L, and neglecting other forms of species M and L, such as $PbNO_3^+$). We include these retrieved values of *K* in the last column of Table 2.

Table 2
Values of the logarithm of the free metal ion concentration and bulk stability constant value obtained for two measurements for the lead(II)–latex nanospheres (40 nm radius latex and 0.08 and 0.1%, w/w) at the TMF-RDE. Total concentration of lead(II) 6.0×10^{-7} M.

pH	Y	c_L (M)	$\log c_M^*$	$\log K$
5.51	5000	1.6×10^{-5}	−6.56	4.77
6.12	5000	1.6×10^{-5}	−7.06	5.46
5.50	2000	1.8×10^{-5}	−6.59	4.87
6.12	5000	1.8×10^{-5}	−7.00	5.37

Table 3
Values of the logarithm of the free metal ion concentration and bulk stability constant value obtained for the lead(II)–IDA system for N measurements at the TMF-RDE. Total concentration of lead(II) 2.49×10^{-7} M.

c_L (M)	N	$\log c_M^*$	$\log K$
2.5×10^{-5}	2	−6.75	8.63
4.9×10^{-5}	2	−6.86	8.62
9.8×10^{-5}	2	−7.00	8.58
2.5×10^{-4}	1	−7.54	8.63

The calculated values perfectly agree with the values of [4.9–5.0] and [5.3–5.6] for pH 5.6 and 6.1, respectively, obtained with the HMDE by Domingos et al. [11].

4.5.2. Quasi-labile system

The interaction of lead(II) with iminodiacetic acid (IDA) was studied with AGNES at the TMFE. In order to assess this, a titration was performed by adding different concentrations of IDA to a test solution, containing a total concentration of lead(II) of 2.49×10^{-7} M and a MES 2-(N-morpholino-ethanesulfonic acid) buffer concentration of 2.0×10^{-3} M to fix the value of the pH to 5.5. The experiment was performed using a Y of 5000 and the other AGNES parameters (deposition time and rotation speed of the RDE) were the same as in Section 4.5.1. The results are presented in Table 3.

For the Pb–IDA system, the values obtained for $\log K$, mean value of 8.61 ± 0.06 for 0.01 mol dm^{-3} ionic strength, are in reasonable agreement with the $\log K$ value of 8.48 dm^3 mol^{-1} computed with Davies correction from the reported value in references [16,17]. However, one obtains an average $\log K$ value 8.1 from works reported in MiniSCD where Davies correction [18–20] is applicable.

5. Conclusions

The free metal determination with AGNES using a TMF-RDE has been implemented. The thickness of the film (16 nm) and the rotation of the electrode (500 rpm) have been optimized, as well as the parameters of AGNES technique (deposition time, gain and reoxidation measuring time). A specific mathematical treatment (*cf.* Section 4.1.2 and Eq. (12)) has also been developed to take into account the degradation suffered with time and stirring with this kind of film electrodes.

Lower LOD, in comparison with the conventional dropping mercury electrode or the Ir–Hg microelectrode, can be attained with this electrode for comparable times. Special care has to be taken to avoid anomalous stripping currents for higher metal ion concentrations (relative to the background electrolyte) which lead to a loss of linearity in the calibration plot. The measurement of the charge is expected, in further work, to allow access to higher concentrations.

Good results have also been obtained with TMF-RDE when performing speciation determinations. The free metal concentration, and, thus, the conditional stability constants, determined with AGNES for the two systems considered (the complexation of Pb(II) with monodisperse carboxylated latex nanospheres and the complexation of Pb(II) with iminodiacetic acid (IDA), are in reasonable agreement with values reported previously.

ABSTRACT

Triethyltin, tributyltin, diphenyltin and triphenyltin were selected as model compounds. The method is based on in situ ethylation and simultaneous headspace-solid-phase microextraction (HS-SPME) and gas chromatographic-mass spectrometry analysis (GC–MS). The extraction procedure was optimized studying some variables such as reaction time, salinity, sample volume and headspace volume. SPME–GC–MS and SPME–GC–FID techniques were compared; quality assurance parameters such as sensitivity, selectivity and precision were established. The proposed procedure showed limits of detection between 0.025 and 1 ng/L. The linearity was in the 0.025–5000 ng/L range. The precision expressed as relative standard deviations (RSD), were below 20%. Real wastewaters and seawaters were analyzed. The method permits controlling legislated annual average values.

1. Introduction

In the 1980s, organotin compounds were recognized for the first time as being responsible of very serious environmental contamination, and consequently the European Union listed them as priority pollutants. The Directive 2000/60/EC (Water Framework Directive, WFD) is probably the most significant international legislation to be introduced in the field of water from many years [1]. WFD includes and protects different kinds of water in Europe (surface water, subterranean, transitional and coastal) with the aim to achieve and ensure a good quality for all of them. WFD includes as a priority and hazardous substance the tributyl compounds among others substances. Furthermore, Directive 2008/105/EC lays down environmental quality standards (EQS) for priority substances and certain other pollutants as provided for in WFD. The Directive 2008/105/EC establishes the extent permitted of tributyl compounds (tributyltin-cation) in inland and other surface waters, expressed as an annual average value (0.0002 μg/L) or as maximum allowable concentration (0.0015 μg/L).

Organotin compounds have been extensively used in recent decades. Several monoalkyl tins have been used as PVC stabilizers, catalysts, water repellents and fire retardants. Some dialkyl tins have been used as catalysts, stabilizers against heat and light effects in construction industry, anthelmintics in poultry management, insecticides for sheep and cattle and for packaging of food, beverages, pharmaceuticals and cosmetics. Trialkyl tins have been used as biocides in marine antifouling paints, fungicides, insecticides, mosquito larvicides, wood preservatives and industrial circulation water disinfectant [1,2].

Organotins toxicity is dependent on the size and number of organic groups attached to the tin atom. Trialkyltins are generally more toxic than the corresponding dialkyl or monoalkyl derivatives. Within the trialkyltin compounds, the lower homologues, triethyltin and trimethyltin, have the greatest acute toxicity. Various dialkyltin and trialkyltin compounds have an immunotoxic effect. Tributyltin is particularly toxic in gastropods and molluscs. It can produce chronic toxic effects on oysters (shell deformation), mussels (growth inhibition) and marine gastropods (sterilization of females) [3,4].

Analytical methods for organotin compounds determination wearing in mind WFD must be highly sensitive. Determination of trace organotins in water requires the combination of a separation method, usually gas chromatography (GC) or liquid chromatography (LC), coupled with highly selective and sensitive detectors, such as mass spectrometry [5–9], atomic absorption spectrometry [10], flame photometry [11–13] and flame ionization detection [14,15].

Solid phase microextraction (SPME) was developed as a useful alternative to liquid–liquid extraction (LLE) [16,17] or solid phase extraction (SPE), as it reduces extraction time, and no organic solvent is necessary. This technique is based on equilibrium between

[a] Estimated value. STEB: sodium tetraethyl borate. STPB: sodium tetrapropyl borate.

the analyte concentration in the solution matrix and that in the solid-phase fibre; the fibre is coated generally with a polymeric organic stationary phase. SPME has been used to extract organotins from water samples [18] and from sediments [19]. The SPME sampling can be carried out in direct mode, immersed in liquid or in the headspace mode [13].

Organotins due to its low volatility need to be derivatized before being injected into the gas chromatograph. The methods of derivatization used include hydride generation with sodium borohydrate [12] or alkylation by Grignard reagent [20]. These methods have been used for long time, however, requires a strictly aprotic medium for the derivatization [21]. In the last years sodium tetraethylborate [11,13] or sodium tetrapropylborate (STPB) [21–23] have been used. These compounds can be used directly in aqueous phase. Derivatization with sodium tetraethylborate (STEB) converts ionic organotins compound into non-polar volatile derivates in situ, removing the problems associated with extracting ionic compounds into an organic solvent from an aqueous matrix. In Table 1 several analytical studies about organotins analysis by using STEB and STPB are compared, any method used HS-SPME–GC–MS for water analysis. Any method could detect TBT at the legislated annual average concentration.

The aim of this work was to develop a cost-effective method to detect in several water matrices the organotins compounds at the levels required by the legislation. HS-SPME–GC–MS is the best option as this manuscript demonstrates. Figures of merit were established and some samples of wastewater and seawaters were analyzed by the optimized HS-SPME–GC–MS procedure to test the reliability of the method.

2. Experimental

2.1. Reagents and solutions

All the reagents were of analytical grade, Triethyltin bromide (TET, 97% purity), tributyltin chloride (TBT, 96% purity), diphenyltin dichloride (DPT, 96% purity), triphenyltin chloride (TPT, 97% purity) and sodium tetraethylborate (STEB, 97% purity) were purchased from Sigma–Aldrich (Steinheim, Germany). Sodium chloride and sodium acetate were obtained from VWR International Eurolab (Barcelona, Spain).

Individual standard solutions of the organotins (200 mg/L) were prepared in methanol and more diluted aqueous solutions were prepared from the most concentrated solutions. Methanol was of spectrophotometric grade (Sigma–Aldrich, St. Louis, MO, USA) and pure water was obtained by means of a Milli-Q water purification system (Millipore).

A 2% (w/v) aqueous solution of STEB was used for derivatization. STEB was kept in desiccators into a glove bag under dry nitrogen and was always manipulated in the glove bag inside of an extractor hood. The STEB solution was prepared every day taking certain amount of reagent and adding the necessary volume of pure water into a dark and sealed vial.

Sodium chloride solutions and sodium acetate buffer solution were used to adjust the salinity and the pH in the derivatization process. The buffer solution was prepared by dissolving the necessary amount of sodium acetate in pure water to get 0.1 M concentration and then adding acetic acid (98% purity) to adjust the pH to 5. Solutions were kept in darkness at 5 °C.

2.2. Apparatus and chromatographic conditions

Analysis by GC–FID was performed with a gas chromatographic system (Agilent Tecnologies 6890N, Palo Alto, CA, USA) coupled with a flame ionization detector and operated by the Chemstation Software (Agilent Tecnologies).

Analysis by GC–MS was conducted using a mass spectrometer (Agilent Tecnologies 5973 inert), a gas chromatograph (Agilent Tecnologies 6890N) and a split/splitless injection port and operated by MSD Chemstation Software (Agilent Tecnologies).

A 30 m × 0.250 mm i.d. capillary column HP-5MS (Agilent Tecnologies) with a stationary phase with a thickness of 0.25 μm was used for analytes separation in both systems. The carrier gas was helium.

Both gas chromatographs were operated in splitless mode and the injection port temperature was held isothermally at 260 °C. The temperature program used was as follows: initial temperature of 50 °C, 15 °C/min to 190 °C, 10 °C/min to 240 °C, 30 °C/min to 290 °C, held for 4 min, for a total run time of 19 min.

A SPME holder with replaceable extraction fibres was used for extraction of organotin compounds from water samples. The fibre used in the study was coated with 100 μm thickness polydimethyl-

siloxane (PDMS). The SPME holder and the fibres were obtained from Supelco (Bellefonte, PA, USA). A magnetic stirrer and stir bars (VWR International Eurolab) were used for the extraction.

2.3. Extraction procedures

The GC–FID system was used for optimizing variables. In all assays, the fibre was introduced in the headspace of a glass vial containing the standard samples of the organotins. Afterwards, the SPME device was placed into the GC interface and the organotins were desorbed from the fibre under static mode during 2 min.

Sodium chloride concentration was changed from 0% to 7% (w/v) of salt. The volume of STEB 2% (w/v) solution assayed was 0.3 mL and 1 mL. The derivatization time (i.e., time since the STEB was added until the fibre was introduced in the chromatograph inlet port) was varied between 15 and 60 min. 30 and 45 min were also assayed by using MS detection.

The sample volume was optimized testing both miniaturized (2.54 mL) and normal volumes (12.7 mL) using different total volumes (2.8 and 14 mL, respectively) and different vial sizes (5 mL and 22 mL, respectively). The headspace volume was tested for 22 mL vial size employing 14 mL and 7 mL of mixture solution. Higher volumes of mixture solution cannot be tested considering the SPME device.

All the experiments were performed in duplicate at ambient temperature.

2.4. Analytical performance

The retention times of all organotins were determined using aqueous standard solutions up to 150 μg/L of each organotin for the SPME–GC–FID system and aqueous standard solutions up to 50 ng/L of each organotin for the SPME–GC–MS system. The mass spectrums were obtained at a mass ratio scan range from 100 to 400 m/z to determine the appropriate masses for selected ion monitoring (SIM). SIM mode was used for quantification.

Solutions of 1, 2 and 5 μg/L for TPT; 0.1, 0.5, 1, 2 and 5 μg/L for TET, TBT and DPT were prepared for detection limits determination in the SPME–GC–FID system. Solutions of 0.5, 1, 2, and 5 ng/L for TET and TPT; 0.025, 0.05, 0.1, 0.25, and 0.5 ng/L for TBT and DPT were prepared to calculate detection limits in the SPME–GC–MS system.

Linearity and precision were determined in SPME–GC–FID system using solutions of 1, 5, 10 and 15 μg/L of TET, TBT and DPT, and solutions of 10, 15, 30 and 40 μg/L of TPT. Moreover, in SPME–GC–MS system, linearity and precision were determined using solutions between 5 and 5000 ng/L for TET and TPT and solutions between 1 and 5000 ng/L for TBT and TPT.

2.5. Analysis of real water samples

Wastewater samples and seawater samples were use to validate the developed methods. Grab wastewater samples were collected at 7 wastewater treatment plants effluents located in close proximity to the Comunidad Valenciana coast (East of Spain). Seawater samples were collected at 24 different geographical sites along the Comunidad Valenciana coast. Samples were introduced into amber bottles and kept in the fridge at 4 °C till the analysis. Each sample was analyzed in duplicate at all assays were carried out at ambient temperature.

Real sample analysis was carried out with 12.7 mL of water sample in a 22 mL vial. Then, 1 mL of acetate buffer and 0.3 mL of STEB were added into the vial and finally the sample was extracted in headspace for 45 min with constant stirring. Wastewater and seawater samples were analyzed by SPME–GC–MS. The found concentration is always characterized by the expanded uncertainty ($K = 2$) estimated with EURACHEM/CITAC Guide Quantifying Uncertainty in Analytical Measurement [24].

3. Results and discussion

3.1. Optimization of the extraction process

Fig. 1 shows the salinity effect employing normalized chromatographic signals for each compound. For all organotins studied, the signal percentage steeply decreases with salt concentration increase. The sodium chloride addition in the standard solution, within the 0–7% (w/v) range, revealed that the salinity negatively affects the analyte extraction efficiency. Therefore, the salt addition is not advisable. However, a final sodium chloride concentration of 3.3% (w/v), similar to that of Mediterranean waters, was used in the standards when this kind of samples was processed.

The variation of the STEB volume added did not produce any improvement in the extraction efficiency (data not shown), achieving the same results for the two volumes studied (a t-test was applied and no significant value was obtained at 95% confidence level). Therefore, it seems more suitable to work with the lower amount in order to optimize the cost of the procedure (see experimental section). The use of STEB could generate tetraethyltin, affecting on the analysis of TET [22]. Nevertheless, this possible interference in TET analysis was not observed in this study.

Standard solutions containing a mixture of the organotins evaluated (15 μg/L of each compound, wearing in mind that the detector used was FID) were prepared in a 22 mL vial as follows: 12.7 mL of water, 1 mL of acetate buffer, 0.3 mL of STEB, 0.5 g of sodium chloride for sea water and the necessary amount of the organotin concentrated solutions (no correction volume was necessary). Samples were extracted during 15, 30, 45 and 60 min in order to get the optimum reaction time. The extraction started in headspace just after adding the STEB and with constant stirring (750 rpm) due to liquid sample agitation improves the kinetics of the derivatizing reaction and the analytes transport towards the fibre [19]. As Fig. 2 shows, the optimum reaction time changes for each compound. The signal increases with the reaction time for TET, DPT and TPT but not for TBT, for which the signal drops off after reaching an optimum at 30 min. The same pattern was obtained for all derivatives by employing smaller concentrations by use of MS detection (30 and 45 min were tested). The reasons for TBT-derivative behaviour could be mainly explained by its affinity by the fibre and its stability. Finally, within the time range considered, a 45 min value was considered as optimum reaction time for further work.

Other sample volume was assayed in order to minimize reagents and sample consumptions: in a 5 mL vial were placed 2.54 mL of water, 0.2 mL of acetate buffer, 0.06 mL of STEB, and the necessary

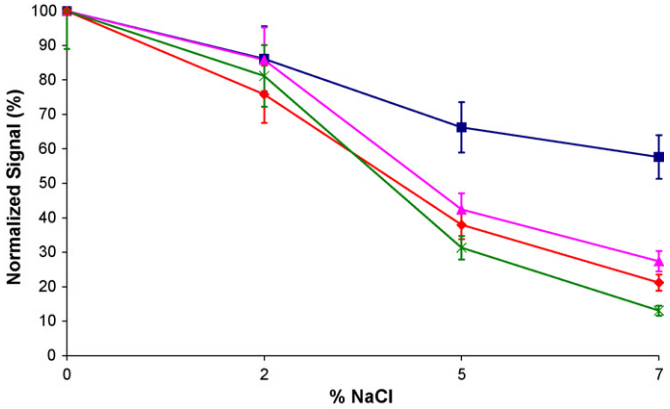

Fig. 1. Effect of salinity in the GC–FID system. TET (■), TBT (▲), DPT (♦) and TPT (×).

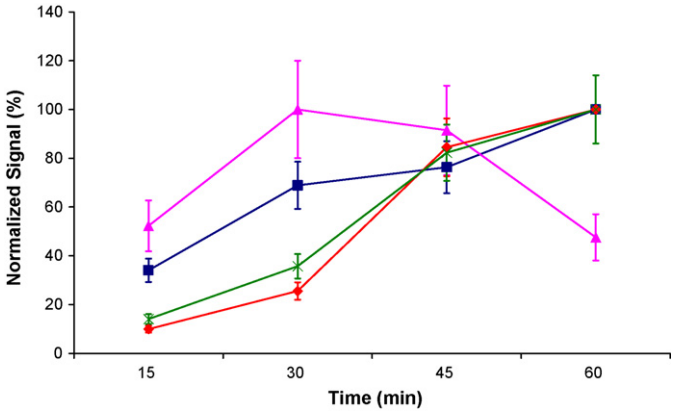

Fig. 2. Effect of reaction time between analytes and STEB. TET (■), TBT (▲), DPT (♦) and TPT (×).

amount of standard solution (no correction volume was necessary) in order to get 15 μg/L concentration for each organotin being the final volume 2.8 mL. Similar signals than those obtained with 22 mL vials were achieved. Then, if necessary less volume of sample could be used.

Regarding headspace volume optimization, two solutions volumes were prepared in a 22 mL vial size: a 14 mL solution (maximum volume of mixture solution permitted considering SPME device and consequently minimum headspace volume) was prepared adding, 12.7 mL of water, 1 mL of acetate buffer, 0.3 mL of STEB and the necessary amount of standard solution in order to get a concentration of 15 μg/L (of each organotin); and a 7 mL solution adding, 6.35 mL of water, 0.5 mL of acetate buffer, 0.15 mL of STEB, 0.2 g of sodium chloride for sea water and the necessary standard solution so to get 15 μg/L concentration (of each organotin). Once the solutions were prepared, the fibre was exposed in the headspace solution during 45 min. Higher analytical signals were obtained with the smallest headspace volume of 8 mL assayed

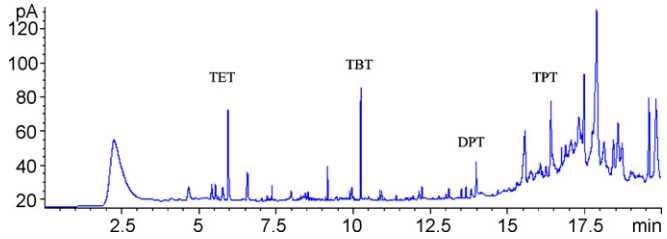

Fig. 3. FID chromatogram for a solution containing 15 μg/L of each organotin.

considering the response for all organotins tested, being the preconcentration factor the highest one.

3.2. Analytical parameters

Fig. 3 shows an organotins chromatogram in the optimized conditions by use FID detection. Figures of merit achieved from this detector are given in Table 2. The detection and quantification limits were determined experimentally as the lowest concentration giving a chromatographic peak three times the signal/noise ratio and ten times the signal/noise ratio, respectively. The detection limits in the GC–FID system are above the environmental quality standards established for TBT by Directive 2008/105/EC.

The first study undertook with the GC–MS system was in full scan mode in order to find the characteristic ions and the abundance of each organotin (Fig. 4). The mass spectra obtained were similar to mass spectra showed by NIST library [25]. Each organotin had different number of characteristic ions depending on its structure. TBT showed more fragmentation than TET since its molecule is bigger and it is more easily fragmented than DPT or TPT.

Selected quantification ions were chosen for each organotin and other characteristic ions were also selected in order to identify each compound. Table 3 shows quantification and identification ions used for the studied organotins.

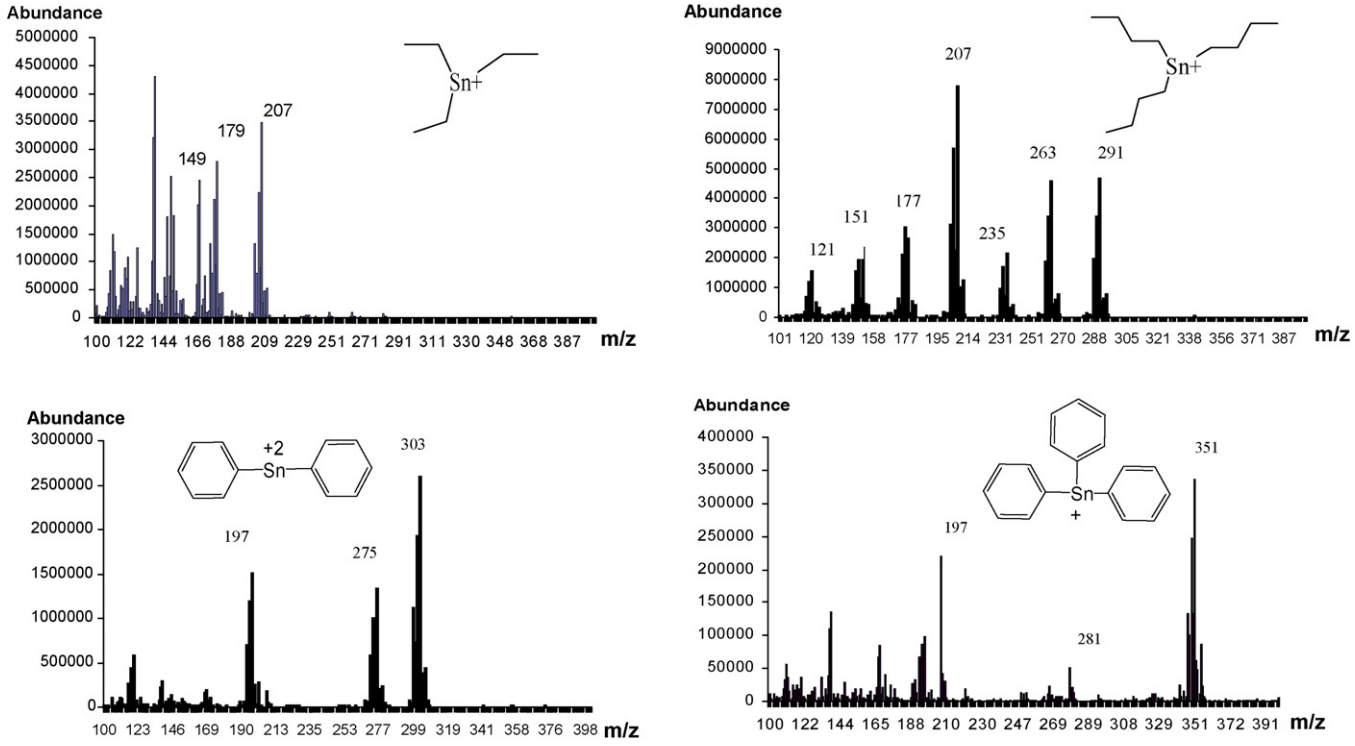

Fig. 4. Mass spectra for TET, TBT, DPT and TPT in scan mode at 10 μg/L.

			281	$SnEt_3Ph$

Table 4
SPME–GC–MS analytical parameters.

Compound	LODs (ng/L)	$b_0 \pm s_0$ (μg/L)	$b_1 \pm s_1$ (μg/L)	r^2	RSD (%)
TET	1	$(3 \pm 3) \times 10^5$	$(5.6 \pm 0.1) \times 10^6$	0.9967	11
TBT	0.025	$(4 \pm 4) \times 10^4$	$(2.3 \pm 0.1) \times 10^6$	0.9940	9
DPT	0.025	$(3 \pm 5) \times 10^4$	$(1.0 \pm 0.1) \times 10^6$	0.9831	20
TPT	0.5	$(1 \pm 1) \times 10^4$	$(0.5 \pm 0.1) \times 10^6$	0.9971	12

LOD: detection limits. b_0 and b_1: parameters of calibration curve *peak area* vs *concentration*. r^2: determination coefficient. RSD: relative standard deviation for 5 ng/L ($n = 3$).

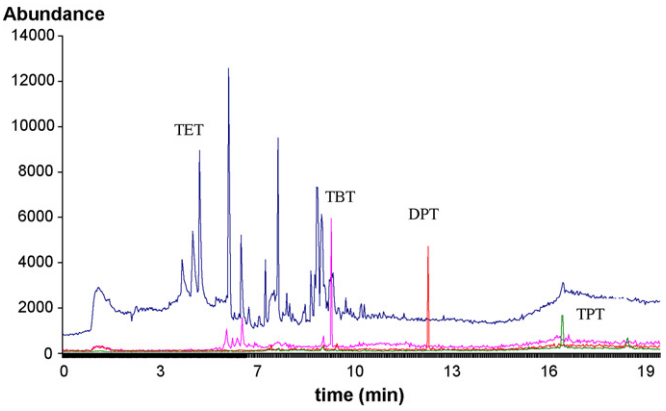

Fig. 5. Selected ion monitoring for studied organotins at 5 ng/L for TET, TBT and DPT and at 10 ng/L for TPT. See Table 3.

The SIM mode analysis was used to determine the quality assurance parameters such as detection and quantification limits, precision and linearity. All determinations were carried out in the optimized conditions: 3.3% of salinity (for sea water), 0.3 mL of STEB, 45 min for extraction, 14 mL of solution and 22 mL total volume vials. Fig. 5 shows the chromatograms obtained in the SIM mode for each compound and Table 4 the figures of merit obtained.

The detection and quantification limits were determined as described for the GC–FID. The detection limits in the GC–MS system are quite lower than the environmental quality standards established for TBT by Directive 2008/105/EC.

3.3. Real samples

The accuracy of method was evaluated by analyzing fortified seawater and wastewater samples. The obtained recoveries were 90 ± 20 ($n = 12$) being independent of the organotin assayed.

Wastewater sample analysis revealed the presence of DPT at detection limit level in two samples. Detection of DPT in wastewater could be derived from its use as plasticizer.

The analysis of seawater samples revealed the presence of DPT and TBT. DPT was detected and quantified in one sample, reaching a concentration of 0.14 ± 0.04 ng/L. TBT was found at detection limit level in 11 samples. Moreover, TBT was detected and quantified in a sample grabbed in close proximity to a harbour. The TBT concentration in this sample was 1.3 ± 0.3 ng/L. This value is below the maximum allowable concentration permitted by Directive 2008/105/EC but is above the annual average value permitted. Hence, periodical sampling campaigns should be needed in order to evaluate, in the long term, the water chemical status regarding TBT.

4. Conclusions

The HS-SPME–GC–MS method is a cost-effective method with adequate figures of merit for the study of the presence of organotins in environmental water samples. The detection limits achieved with the proposed method are far below of concentration levels established in Application of EU Water Framework Directive (DMA 2000/60/EC).

The proposed method allows detect organotin compounds in water samples at concentration of pg/L with low sample volume (12.7 or even 2.54 mL) compared with those required by other methods (see Table 1). The method also avoids the use of organic solvents for the treatment of the sample. Table 1 shows that this method offers the best detection limits with the less time and volume for all studied organotins.

ABSTRACT

Mycophenolic acid (MPA) is an immunosuppressant drug which powerfully inhibits lymphocyte proliferation. Since the early 1990s it has been used to prevent rejection in organ transplantation. The requirement of therapeutic drug monitoring shown in previous studies raises the necessity of acquiring accurate and sensitive methods to measure MPA and its major metabolite mycophenolic acid glucuronide (MPAG).

The authors developed a sample cleanup-free, rapid, and highly specific method for simultaneous measurement of MPA and MPAG in human plasma and serum using the novel technology of ultra-performance liquid chromatography–electrospray ionization tandem mass spectrometry. MPA- and MPAG-determinations were performed during a 2.0-min run time. Multiple calibration curves for the analysis of MPA and MPAG exhibited consistent linearity and reproducibility in the range of 0.05–100 ($r > 0.999$) mg L^{-1} and 4–4000 mg L^{-1} ($r > 0.999$), respectively. Limits of Detection were 0.014 mg L^{-1} for MPA and 1.85 mg L^{-1} for MPAG. Lower Limits of Quantification were 0.05 mg L^{-1} for MPA and 2.30 mg L^{-1} for MPAG. Interassay imprecision was <10% for both substances. Mean recovery was 103.6% (range 78.1–129.7%) for MPA and 111.1% (range 73.0–139.6%) for MPAG. Agreement was good for MPA and MPAG between the presented method and a validated HPLC-MS/MS method. The Passing-Bablok regression line for MPA and MPAG was HPLC-MS/MS = 1.14 UPLC-MS/MS—0.14 [mg L^{-1}], $r = 0.96$, and HPLC-MS/MS = 0.77 UPLC-MS/MS + 0.50 [mg L^{-1}], $r = 0.97$, respectively. This sample cleanup-free and robust LC-MS/MS assay facilitates the rapid, accurate and simultaneous determination of MPA and MPAG in human body fluids.

1. Introduction

Mycophenolic acid (MPA) is an immunosuppressant drug which is derived from the fungus *Penicillium stoloniferum*. The pharmacological effect of MPA is based on the selective inhibition of the inosine-monophosphate dehydrogenase, the enzyme that controls the synthesis rate of guanine monophosphate in the *de novo* pathway of purine synthesis used in the proliferation of T- and B-lymphocytes [1]. Therefore, MPA was used as an immunosuppressive drug after organ transplantation to prevent acute rejection of the transplant. Furthermore, MPA was increasingly used as part of a multiple-drug regime to prevent acute rejection of the transplant because the mode of action of MPA differs from that of cyclosporine, tacrolimus, and sirolimus. The large interindividual variation in the pharmacokinetic profiles for MPA, as well as the effort to achieve both increase efficacy and decrease toxicity, has promoted the monitoring of MPA concentrations [2–5]. In general, 97% of MPA is bound to albumin and more than 90% of MPA is metabolized in the liver by glucuronidation to mycophenolic acid glucuronide (MPAG), an inactive compound that is excreted in the urine and feces [5].

For the purpose of therapeutic drug monitoring (TDM) different routine assays like enzyme-multiplied immunoassay technique (EMIT), HPLC with UV-detection and liquid chromatography–tandem mass spectrometry (LC-MS/MS) have been developed to measure total MPA in blood serum or plasma [6–26]. The EMIT assay for MPA, which shows some cross-reactivity

with acyl-MPAG and used expensive antibodies, has the advantage of being less laborious and time-consuming than chromatography technology and was therefore often used for routine drug monitoring. Using ultra-performance liquid chromatography–electrospray ionization tandem mass spectrometry (UPLC-ESI-MS/MS), we combined the advantage of both technologies and developed an assay for MPA and MPAG which not only shows high analytical sensitivity and specificity and which uses inexpensive reagents, but which also needs nearly no sample preparation and is very fast.

2. Materials and methods

2.1. Reagents, internal standards, calibrators, and quality-control samples

HPLC-grade water and methanol were purchased from Fisher Scientific GmbH (Schwerte, Germany). MPA, ammonium acetate, sodium acetate and formic acid were obtained from Sigma–Aldrich (Deisenhofen, Germany). MPAG was obtained from Analytical Services International Limited (London, UK).

To identify appropriate internal standards, eligible compounds like ascomycin, cyclosporine D, indomethacin, indole-3-butric acid, indole-3-propionic acid, napropamide, naphthalane, naproxen, N-phthaloyl-L-phenylalanine (PPA), phthalide, and phenolphthalein-β-glucuronic acid (PPG), which were obtained from Fluka (Taufkirchen, Germany), were tested.

Stock solutions of MPA, MPAG, PPA, and PPG, each at a concentration of 10 g L^{-1}, were prepared separately in acetonitrile/water (90:10) and stored at −20 °C. Internal standard solution including 5 mg L^{-1} PPA and 25 mg L^{-1} PPG was prepared by mixing 50 μL PPA stock solution, 250 μL PPG stock solution and 99.7 mL methanol/water (5:95) containing 0.1% formic acid and 2 mmol L^{-1} ammonium acetate.

Using drug-free serum or EDTA plasma, we prepared several calibrators and in-house quality-control samples as described previously [25]. In addition, commercially available calibrators and quality-control samples for MPA purchased from Chromsystems (Munich, Germany), as well as from Siemens Medicals Solutions Diagnostics (Tarrytown, NY), were used.

2.2. Serum samples

Venous blood samples from blood donors and patients were collected in EDTA sample tubes, as well as in serum monovettes from KABE Labortechnik GmbH (Nümbrecht-Elsenroth, Germany). All samples were anonymized prior to inclusion within the study.

2.3. Sample preparation for UPLC-MS/MS

Sample preparation was performed in a 1.5-mL polypropylene microcentrifuge tube. 10 μL each of EDTA plasma, serum, calibrator or quality-control sample were added to 990 μL internal standard solution (see above). After vortex-mixing for 10 s, the final solution was transferred to the autosampler vessel and 1.5 μL were injected into the UPLC-MS/MS system.

2.4. UPLC-MS/MS analysis

For measurement of MPA and MPAG, a 2.1 × 50-mm reverse phase column (Waters, Acquity UPLC BEH C8, 1.7 μm) maintained at 55 °C was used for separation by an UPLC system (Waters Acquity UPLC Basissystem) directly coupled to a Waters TQ tandem mass spectrometer fitted with Z Spray ion source. A 1.5-μL sample was injected at a flow rate of 0.35 mL min^{-1}. The gradient program was 95%/5% water/methanol containing 0.1% formic acid and 2 mmol L^{-1} ammonium acetate for 0.70 min, followed by a step gradient of 5%/95% water/methanol containing 0.1% formic acid and 2 mmol L^{-1} ammonium acetate. After additional 1.1 min, the mobile phase was reverted to the initial state, and the run was terminated at 2.0 min. The mass spectrometer was operated in electrospray positive ionization mode, and the system control and data acquisition were performed using MassLynx NT 4.1 software, with automated data processing by the MassLynx QuanLynx program provided with the instrument. Nitrogen was used as the nebulizing gas. Argon was used as the collision gas. Instrument settings were as follows: capillary voltage, 3.8 kV; source temperature, 120 °C; desolvation temperature, 400 °C; sample cone energy for MPA ammonium adduct, MPAG ammonium adduct, PPA, and PPG, 13, 20, 29, and 38 eV, respectively; and collision energy for MPA ammonium adduct, MPAG ammonium adduct, PPA, and PPG, 23, 34, 13, and 16 eV, respectively. The collision gas pressure was 3.4×10^{-3} mbar. Sample analysis was performed in the multiple reaction monitoring mode (MRM) of the instrument, with a dwell time of 0.10 s for all compounds and the mass transitions for MPA ammonium adduct, MPAG ammonium adduct, PPA, and PPG m/z 338.0 → 207.1, m/z 514.2 → 207.1, m/z 296.1 → 250.1, and m/z 495.1 → 319.1, respectively.

2.5. Ion suppression

Ion suppression was investigated by a post column infusion experiment as described previously [25].

2.6. Validation

2.6.1. Linearity studies

A matrix-based calibration curve for MPA, as well as MPAG using drug-free serum, was constructed as described elsewhere [25]. In addition, commercially available calibrators for MPA were used for linearity studies.

2.6.2. Limit of Detection (LOD) and Lower Limit of Quantification (LLOQ)

The minimum of detectable concentration was assessed as 3 SD_0, where SD_0 is the value of the standard deviation as the concentration of the analyte approaches 0. The LOD was determined by performing 25 replicates measurements in a single UPLC-MS/MS assay with drug-free serum as a sample. LLOQ was the value for which the interassay CV reached <20%.

2.6.3. Imprecision

The intraassay imprecision was determined by analyzing 20 replicates of a low (0.53/48.5 mg L^{-1}), medium (3.28/96.5 mg L^{-1}), and high (6.31/255 mg L^{-1}) MPA and MPAG sample, respectively, on the same day. The interassay precision was also obtained by measurement of a low (0.79/55.9 mg L^{-1}), medium (3.36/114 mg L^{-1}), and high (6.44/230 mg L^{-1}) MPA and MPAG sample, respectively, on 20 different days over 1 month.

2.6.4. Stability

The stability of MPA, as well as MPAG in serum, was investigated by measurement of these compounds in a freshly collected patient sample and the measurement of the same sample at RT after 1 day, 1 week and 1 month.

2.6.5. Recovery

The recovery efficiency of the assay was established by measuring the MPA, as well as MPAG concentration in serum, before and after enrichment with different amounts of MPA and MPAG, respectively. Analytical recoveries were calculated as the mea-

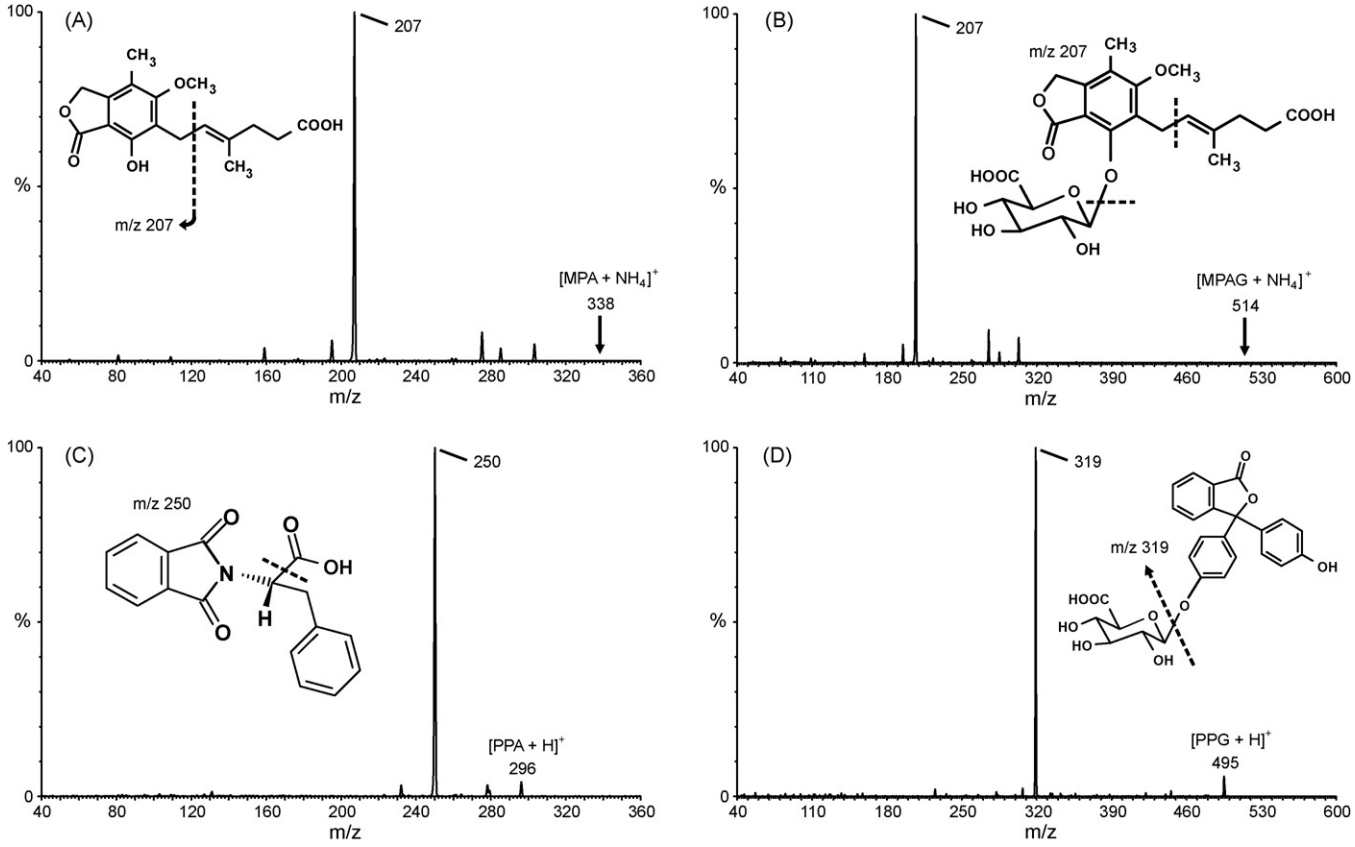

Fig. 1. Product ion spectrum of MPA (A) and MPAG (B), as well as its internal standards PPA (C) and PPG (D). The arrow at *m/z* 338 and *m/z* 514 shows the position of the $[MPA+NH_4]^+$ and the $[MPAG+NH_4]^+$ precursor ion, respectively (A and B). Both precursor ions were not detected in the product ion spectra because the ions were completely fragmented under experimental conditions. The other precursor ions $[PPA+H]^+$ and $[PPG+H]^+$ at *m/z* 296 and 495, as well as the fragment ions of MPA ammonium adduct, MPAG ammonium adduct, PPA and PPG at *m/z* 207, 207, 250, and 319 are shown. The chemical structures of the molecules are depicted and the fragmentation positions are shown (dotted arrows and dotted lines).

sured concentrations divided by the expected concentrations and expressed as a percentage.

2.6.6. Comparison of MPA and MPAG concentrations in EDTA plasma and serum

We used 96 serum and 96 EDTA plasma samples from the same patient from routine MPA monitoring to compare the MPA and MPAG concentrations in the different materials.

2.7. Method comparison

The UPLC-MS/MS method proposed here was compared with a validated LC-MS/MS assay described previously [25] using the same set of clinical samples. The resulting data were analyzed by Passing-Bablok regression.

3. Results

3.1. General approaches of the UPLC-ESI-MS method

N-phthaloyl-L-phenylalanine (PPA) and phenolphthalein-β-glucuronic acid (PPG) were detected as appropriate internal standards for MPA and MPAG, respectively, as a result of intensive investigation of potential compounds like ascomycin, cyclosporine D, indomethacin, indole-3-butric acid, indole-3-propionic acid, napropamide, naphthalane, naproxen, PPA, phthalide, and PPG. As shown in Fig. 1, MPA and the referable internal standard PPA, as well as MPAG and the referable internal standard PPG, have not only same structure similarities but also as shown in Fig. 2 nearly the same retention time. Therefore, quantitative errors of both MPA and MPAG resulting from potential ion suppression during measurement will be compensated via its internal standards PPA and PPG, respectively.

In-source fragmentation of MPAG was detected by measuring $[MPA+H]^+$, but not by measuring the MPA ammonium adduct $[MPA+NH_4]^+$ (Fig. 2). Thus, determination of MPA concentration in blood samples by measuring $[MPA+NH_4]^+$ was not interfered with in-source fragmentation of MPAG. Furthermore, the MPA peak resulting from in-source fragmentation of MPAG was clearly separated from the original MPA peak, which was apparent by measuring $[MPA+H^+]$ (Fig. 2). Maximum sensitivity was achieved by monitoring the fragmentation of single-charged molecule ions $[MPAG+NH_4]^+$, $[PPA+H]^+$, $[PPG+H]^+$, and the MPA ammonium adduct $[MPA+NH_4]^+$, respectively. 1.5 μL of 100-fold diluted sample (see sample preparation) gave clean chromatograms with no interfering components present (Fig. 2). All compounds were clearly separated from the void volume (0.3 min) and elute in <2 min, allowing an injection-to-injection cycle time of <3 min. Loss of sensitivity resulting from the contamination of the sample cone of the mass spectrometer was tested by 100 repeated injections of 1.5 μL of a pooled sample. No systematic loss in sensitivity was observed in the absolute peak areas measured, and the CV for peak-area ratio (analyte/internal standard) was 3.7%.

3.2. Validation

The MPA calibration curve was linear between 0.05 and 100 mg L^{-1} ($r > 0.999$), and the MPAG calibration curve was linear

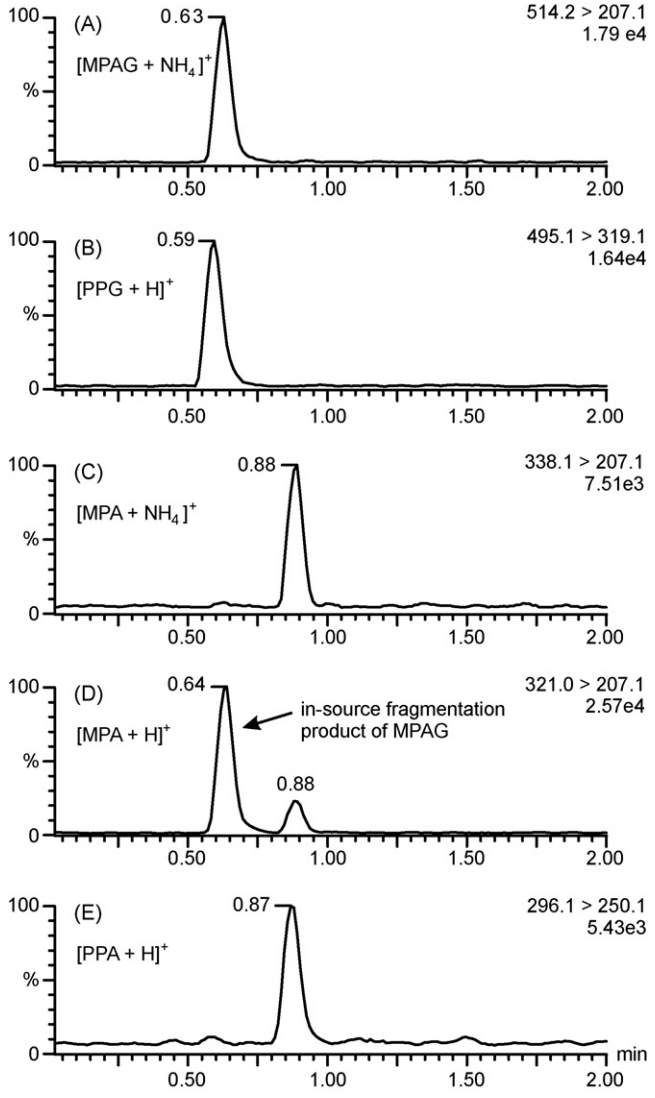

Fig. 2. MRM chromatograms of a serum sample diluted 100-fold with internal standard solution from a patient under treatment with MMF. (A) MRM transitions for the ammonium adduct of MPAG, m/z 514.2 > 207.1, (B) MRM transitions for the internal standard of MPAG which is the protonated adduct of PPG, m/z 495.1 > 319.1, (C) MRM transitions for the ammonium adduct of MPA, m/z 338.1 > 207.1, (D) MRM transitions for the protonated adduct of MPA, m/z 321.0 > 207.1, and (E) MRM transitions for the internal standard of MPA which is the protonated adduct of PPA, m/z 296.1 > 250.1.

between 4 and 4000 mg L^{-1} (r = 0.999). The LODs were 0.014 mg L^{-1} for MPA and 1.85 mg L^{-1} for MPAG, using an injection volume of 1.5 μL. The LLOQ were 0.05 mg L^{-1} for MPA and 2.30 mg L^{-1} for MPAG which is comparable with other MPA-, MPAG-assays [25]. The within-run and between-run CVs which were measured for different concentrations of MPA and MPAG, respectively, were all <10% (Table 1). The mean recovery for MPA at a concentration of 0.4–10.0 mg L^{-1} was 103.6% (range: 78.1–129.7%) and that for MPAG at a concentration of 10–100 mg L^{-1} was 111.1% (range: 73.0–139.6%). MPA and MPAG were stable in EDTA plasma or serum at 4 °C for at least 21 days, as well as RT which was found by systematical testing over a period of 1 month.

To estimate the importance of sample material, we compared the MPA, as well as the MPAG measurements of serum and EDTA plasma samples, each from the same patients (n = 96), in a side-by-side assay on the same day and analyzed them by least-square linear regression. The resulting regression line was y (plasma) = 0.92 (serum) + 0.05 [mg L^{-1}]; r = 0.99 for MPA and y (plasma) = 0.95 (serum) + 1.32 [mg L^{-1}]; r = 0.99 for MPAG, respectively.

Table 1
Analytical imprecision of LC-MS/MS assay.

Concentration	Intraassay (n = 20)		Interassay (n = 20)	
	Mean ± SD, mg/L	CV, %	Mean ± SD, mg/L	CV, %
MPA				
Low	0.53 ± 0.03	5.4	0.79 ± 0.08	9.6
Medium	3.28 ± 0.16	4.9	3.36 ± 0.27	7.9
High	6.31 ± 0.23	3.7	6.44 ± 0.44	6.6
MPAG				
Low	48.5 ± 2.3	4.7	55.9 ± 2.8	5.1
Medium	96.5 ± 3.0	3.1	114 ± 4.7	4.1
High	255 ± 9.7	3.8	230 ± 14.2	6.1

3.3. Method comparison

Method comparison analysis was performed using samples from 121 heart transplantation patients who used MMF as part of a multiple-drug regime to prevent acute rejection of the transplant. As shown in Fig. 3 the correlation between the validated LC-MS/MS assay and our novel UPLC-MS/MS assay was good.

4. Discussion

Recent developments in high performance liquid chromatography using columns packed with smaller particles with superior resolution and sensitivity have yielded an improved technology, termed ultra-performance liquid chromatography, or UPLC [26]. Here we could demonstrate that the combination of UPLC technology with the sensitivity of mass spectrometry facilitates a direct measurement of MPA, as well as MPAG in human serum or plasma. Apart from a simple dilution step with the internal standard solution, no sample preparation was necessary. Therefore, the method was less labor-intensive and the need of chemicals was limited. In addition, the application of the small sample size used in the method should prove useful when monitoring pediatric patients and will spare expensive calibrators and quality-control materials. Furthermore, it might be possible to validate MPA- and MPAG-determination in capillary blood finger prick collection.

The use of ammoniated MPA, as well as MPAG species increases the assay sensitivity by effectively concentrating all the usual fragment ions resulted from the fragmentation of the precursor ion into a single product ion species. Both $[MPA+NH_4]^+$ and $[MPAG+NH_4]^+$ ions produced the major product ion species at m/z 207 whereas both precursor ions were not detected in the product ion spectra because the ions were completely fragmented under experimental conditions (Fig. 1). PPA, the internal standard of MPA, and PPG, the internal standard of MPAG, produced, in contrast to the mycophenolate compounds, no ammonium adducts and show high sensitivity as single ion species which effectively fragmented to a major product ion at m/z 250 and 495, respectively. Our method conception in combination with the sensitivity and the specificity of the MS/MS detector makes lengthy sample preparation such as solid-phase or liquid–liquid extraction unnecessary and is, therefore, eminently suitable for the measurement of MPA and MPAG in routine samples.

The method was very fast in comparison to other MPA assays [16–19]. The run time was only 2 min which limited on the one hand solvent consumption and made the assay on the other hand much more suitable for the analysis of large number of clinical samples, where a fast turnaround time is required. Loss of sensitivity as a result of a potential contamination of the sample cone of the mass

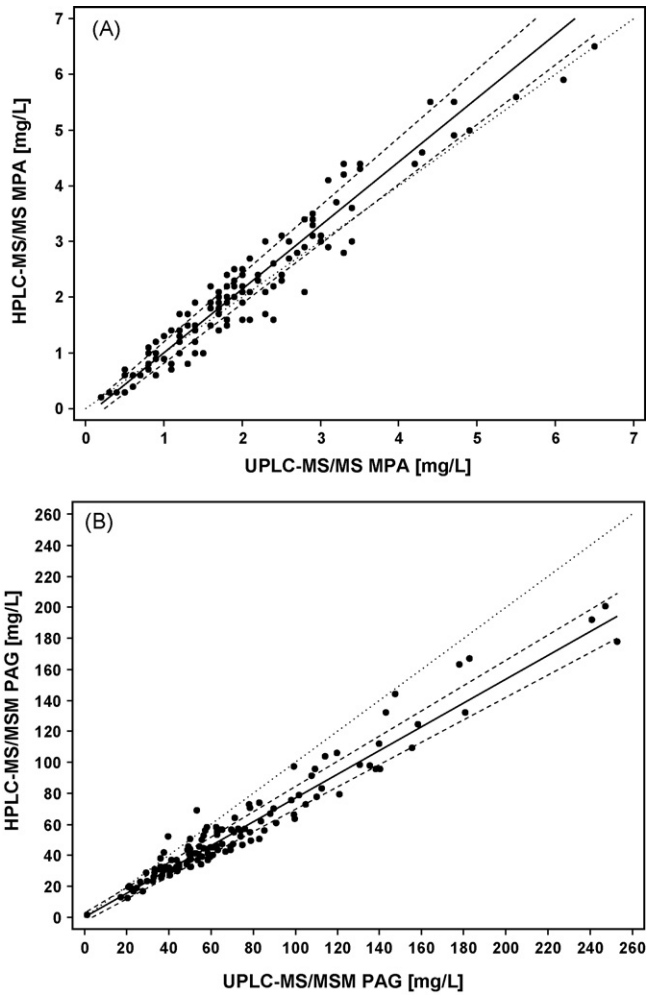

Fig. 3. (A) Comparison of MPA results obtained by UPLC-MS/MS assay and a validated LC-MS/MS assay by Passing-Bablok regression. HPLC-MS/MS = 1.14 UPLC-MS/MS—0.14 [mg L^{-1}] (r = 0.96; n = 121; 95% CI for slop, 1.07–1.22; 95% CI for intercept, −0.26 to −0.03). (—), PBR; (- - -), 95% CI; (···), line of equality. (B) Comparison of MPAG results obtained by UPLC-MS/MS assay and a validated LC-MS/MS assay by Passing-Bablok regression. HPLC-MS/MS = 0.77 UPLC-MS/MS + 0.50 [mg L^{-1}] (r = 0.97; n = 125; 95% CI for slop, 0.72–0.82; 95% CI for intercept, −2.60 to 2.71). (—), PBR; (- - -), 95% CI; (···), line of equality.

spectrometer was not detected even after 100 repeated injections of a pooled sample.

The LOD and the LLOQ were, at 0.014 and 0.050 mg L^{-1} for MPA and 1.85 and 2.30 mg L^{-1} for MPAG, comparable with other MPA-, MPAG-assays [25]. The intra- and inter-assay imprecision for MPA and MPAG, respectively, was, at <10% for all CVs, very good. MPA and MPAG were measured in parallel from the same injection in 2 min. The comparison between our UPLC-MS/MS and a validated LC-MS/MS assay [25] was good which is shown in Fig. 3.

Ion suppression will be compensated via the internal standards PPA and PPG for MPA and MPAG, respectively, showing certain structural similarity and having nearly the same retention time as its corresponding analyte. In-source fragmentation of MPAG was clearly detected as a single-charged molecule ion $[MPA+H]^+$ (Fig. 2D), but not as an MPA ammonium adduct $[MPA+NH_4]^+$ (Fig. 2C) which we used for quantification of MPA in our assay. In addition, MPA was chromatographically separated from MPAG, which prevented interfering effects of MPAG (Fig. 2D).

In summary, the advantages of this method over existing LC-MS/MS methods, including a direct measurement of MPA and MPAG from a diluted serum or plasma sample without any other sample preparation step, couplet with a shorter analysis time on the UPLC-MS/MS which allow a faster throughput of samples.

5. Conclusion

The combination of UPLC and MS/MS with an ESI interface facilitates a rapid method for measuring MPA, as well as MPAG in serum and plasma, with minimum sample consumption and without the need for sample cleanup or other purification steps.

Wine compounds thresholds

ABSTRACT

An electronic nose (e-nose) based on thin film semiconductor sensors has been developed in order to compare the performance in threshold detection and concentration quantification with a trained human sensory panel in order to demonstrate the use of an e-nose to assess the enologists in an early detection of some chemical compounds in order to prevent wine defects. The panel had 25 members and was trained to detect concentration thresholds of some compounds of interest present in wine. Typical red wine compounds such as whiskeylactone and white wine compounds such as 3-methyl butanol were measured at different concentrations starting from the detection threshold found in literature (in the nanograms to milligrams per liter range). Pattern recognition methods (principal component analysis (PCA) and neural networks) were used to process the data. The results showed that the performance of the e-nose for threshold detection was much better than the human panel. The compounds were detected by the e-nose at concentrations up to 10 times lower than the panel. Moreover the e-nose was able to identify correctly each concentration level therefore quantitative applications are devised for this system.

1. Introduction

Electronic noses have aroused in last years as a powerful tool in many applications mainly in food [1–3]. Their performances are usually compared with respect to analytical methods as gas chromatography–mass spectrometry or human sensory panels. Comparison with human panels has been performed mostly in food quality applications [4–6] with a qualitative approach. There are few examples of quantitative applications [7] and are outside this field. Electronic noses have been applied to wine related measurements since last decade for several purposes: varietal origin [8], oak toasting levels [9], regional characterization [10–12], ageing [13], defects detection [14–16] and sensory properties prediction [17,18] among others.

A sensory panel can provide information about the sensory properties of consumer products that is far richer than can be provided by instrumental devices alone, but significant training is required before the panel becomes a reliable sensory instrument [19] specially dealing with wine, a very complex product.

In the present work a sensory panel and an electronic nose (e-nose) based on semiconductor oxide sensors have been trained in parallel with several aromatic compounds present in wine in order to compare their performances in threshold detection and concentration quantification. This threshold is the minimum concentration of an aroma in water perceived for at least 50% of the members of a sensory panel. Other term related to the olfactory threshold detection is the difference threshold detection, the minimum amount of an aroma that has to be added to a product already containing this aroma in order to produce an appreciable sensory change. This concept is especially useful in dealing with compounds in wine. Usually this threshold is evaluated in an artificial wine [20] but in the present case we used real wines.

The great influence of water and ethanol in the response of semiconductor oxide sensors is known [21,22]. We have employed two sampling methods, headspace and purge and trap in order to elucidate the influence of these interferents in the e-nose performance.

The aim of this work is to assess if the sensory panel can be substituted by an electronic nose for some specific tasks such as threshold detection. This experimental method may eventually replace current sensory evaluation techniques, with a simpler qualitative and quantitative technique, offering better reliability and reproducibility of results, faster operation and lower cost.

2. Materials and methods

2.1. Aromatic compounds

Thirty-eight aromatics compounds of white and red wines belonging to different chemical families and grouped under nine aromatic descriptors of wine quality were used in the training and initial selection of the members of a sensorial panel. These descriptors were: fruity-like, herbaceous, spicy, phenolic, microbiologic, oxidation, chemical, woody-like and off-flavours (Table 1). Standard solutions were diluted with water and/or ethanol (adjusting final ethanol content to 12%, v/v) at concentrations typically found in wine. All solutions were added with 5 g/l tartaric acid and the pH was adjusted at 3.2 with 1 M NaOH [23].

Last, a set of eight typical compounds of white and red wines have been measured at increasing levels from the olfactory detection threshold. The compounds chosen were whiskeylactone, nonalactone, decalactone and diacetyl for red wines and 3-methyl butanol, 4-vinyl guaiacol, butyric acid and damascenone for white wines. Table 2 shows these volatile compounds with their odor descriptors and their threshold values (*T*) found in literature [24–26]. These threshold values were used in the initial phases of the training of the panel, in which solutions of pure chemical compounds at different concentrations were presented to the panel.

Table 1
Aromatics compounds used in the training and selection of members of the sensorial panel.

Descriptor	Pure standard compounds
Fruity-like	Ethyl octanoate Isoamyl acetate Hexyl acetate Ethyl cinnamate Ethyl-isobutyrate Ethyl hexanoate Ethyl isovalerate 2-Methylethyl butyrate
Herbaceous	1-Hexanol c-3-Hexenol Benzaldehyde
Spicy	Eugenol 2-Methyl-3-methoxy-pyracine
Phenolic	Guaiacol 4-Vinylguaiacol 4-Ethylguaiacol Vanillin
Microbiologic	Diacetyl Butyric acid Isovaleric acid Octanoic acid Acetoine Acetic acid
Oxidation	Acetaldehyde
Chemical	Isoamyl-alcohol 3-Methyl butanol Decanoic acid Sulphur dioxide Ethanol
Woody-like	β-Damascenone γ-Octolactone γ-Nonalactone δ-Decanolactone (E)-whiskeylactone 2-Furan-methanothiol
Off-flavour	Ethyl acetate Ethanethiol 2,4,6-Trichloroanisol (TCA)

Table 2
Odor thresholds, odor descriptions and concentrations in the test wines of the studied compounds.

Compound	Odor threshold (μg/l)	Odor description	Concentration (μg/l)
Whiskeylactone	67	Wood, sweet fruit	8.5
Nonalactone	30	Coconut	16.2
Decalactone	88	Sweet fruit	0.5
Diacetyl	100	Creamy, milk	350
3-Methyl butanol	29,930	Oil	185,000
4-Vinyl guaiacol	1,146	Phenolic	900
Butiric acid	173	Cheese	500
Damascenone	0.05	Fruit, mulberry	1.8

Sample sets with the aromatics compounds were prepared at three different concentrations: *T*, 2*T* and 4*T*. When the panel did not perceive the 4*T* concentration, 6*T* and 8*T* and 10*T* concentrations were used in the next session of training. All compounds were of analytical quality and were provided by Sigma–Aldrich and Merck.

2.2. Sensory panel

Initially 36 voluntary subjects from both investigation groups IMIDRA, IFA and staff cellars took part in the training program during several months. Sensory evaluations were realized under ISO standards related to methodology (ISO 3972:1991), sensory analysis vocabulary (ISO 5492:1992), tasting room (ISO 8589:1988), selection and formation of tasters (ISO 8586-1 and 2: 1993). Sample sets of synthetic wines added with the 38 aromatic compounds (Table 1) were given to the panellist at threshold concentration (*T*). 30 subjects that were able to correctly classify the 80% of the compounds continued with the training. In a second stage an experimental young white wine from Airén variety and a young red wine of Tempranillo variety were used as control wine. Vinyl guaiacol, butyric acid, 3-methyl butanol and damascenone, typical of white wines, were added one to one to the Airén wine. Whiskeylactone decanolactone, nonalactone and diacetyl generally more characteristic of red wines, were presented in the Tempranillo wine. First, the original concentration of the aromatic compounds in these wines was quantified by CG–MS [27]. The results showed that all compounds were under threshold human detection with the exception of 3-methyl-butanol that presented an odor activity value (OAV) > 1. Finally, four experimental white wine sample sets and four experimental red wine sample sets were obtained and the only difference with their corresponding test wine was the concentration of one aromatic compound. Each sample set was made of six levels of concentration *T*, 2*T*, 4*T*, 6*T* 8*T* and 10*T*. These concentrations correspond to 1, 2, 4, 6, 8 and 10 times the threshold value of detection of the volatile compounds.

In a second selection operation ANOVA analysis ($p < 0.05$) was applied to the rate of the correct panellist responses after they arranged the six levels of concentration of diacetyl and β-

Table 3
Percentage of panel members that recognized the compounds at each concentration level.

Compound	*T*	2 × *T*	4 × *T*	10 × *T*
Whiskeylactone	16.7	25	41.7	45.8
Nonalactone	29.2	33.3	45.8	41.7
Decalactone	8.3	41.7	45.8	62.5
Diacetyl	22.2	44.4	55.6	81.5
3-Methyl butanol	11.1	14.8	29.6	77.8
4-Vinyl guaiacol	10.7	32.1	60.7	75
Butiric acid	3.6	17.9	35.7	56.5

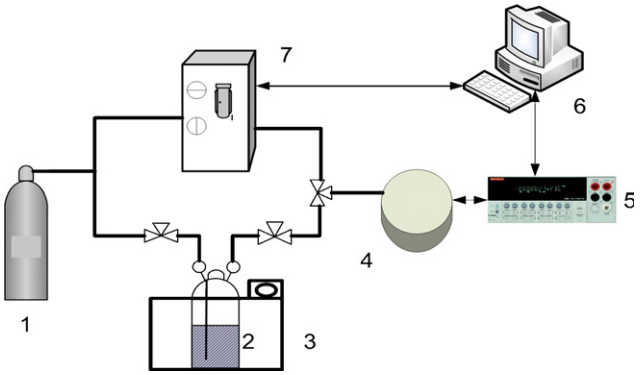

Fig. 1. Measurement setup: (1) nitrogen bottle, (2) Dreschell bottle with sample, (3) thermostatic bath, (4) sensors cell, (5) multiplexer and DMM, (6) personal computer, (7) purge and trap.

damascenone sample sets and 25 people were selected to take part in the human sensory panel.

The trial of the selected sensory panel consisted in the determination of the perception threshold by triangular probe (ISO 4120:1983) of each aroma when it was added to experimental wines. To avoid a saturation effect in tasters, the training was carried out along four sessions in different days. Six concentration levels of two different aromas were evaluated in each session.

2.3. Electronic nose

An electronic nose based on a tin oxide array has been employed. The array was composed by 16 thin film tin oxide sensors with thickness between 200 and 800 nm doped with small amounts of chromium and indium (both as surface or intermediate layer) to increase their selectivity. Sensors were deposited by reactive sputtering onto an alumina substrate. Details of the preparation can be found elsewhere [28]. The array was place in a 20 cm^3 stainless steel cell kept at 300 °C.

Two sampling methods were used: headspace and purge and trap. In the first case 10 ml of sample was kept in a Dreschell bottle at 30 °C for 20 min. The headspace was carried by an inert gas for 10 min to the sensor cell. The carrier used gas was nitrogen 99.998% purity at a constant flow of 200 ml/min. We used an inert, no oxidizing gas to ensure the stability of the wines during the experiments. With the purge and trap method 1 ml of sample were placed in the vessel of a Tekmark 3000 purge and trap concentrator. The sample was purged with pure helium into a Tenax trap for 10 min and then desorbed at 250 °C with a nitrogen flux. With this adsorbent water and ethanol content of the sample are minimized.

The resistance of the sensors were measured with a Keithley 2001 digital multimeter (DMM) connected to a Keithley 7001 multiplexer controlled by a personal computer. The sensor responses were calculated as the relation between the equilibrium resistance value in pure nitrogen, R_N, and the equilibrium resistance value in

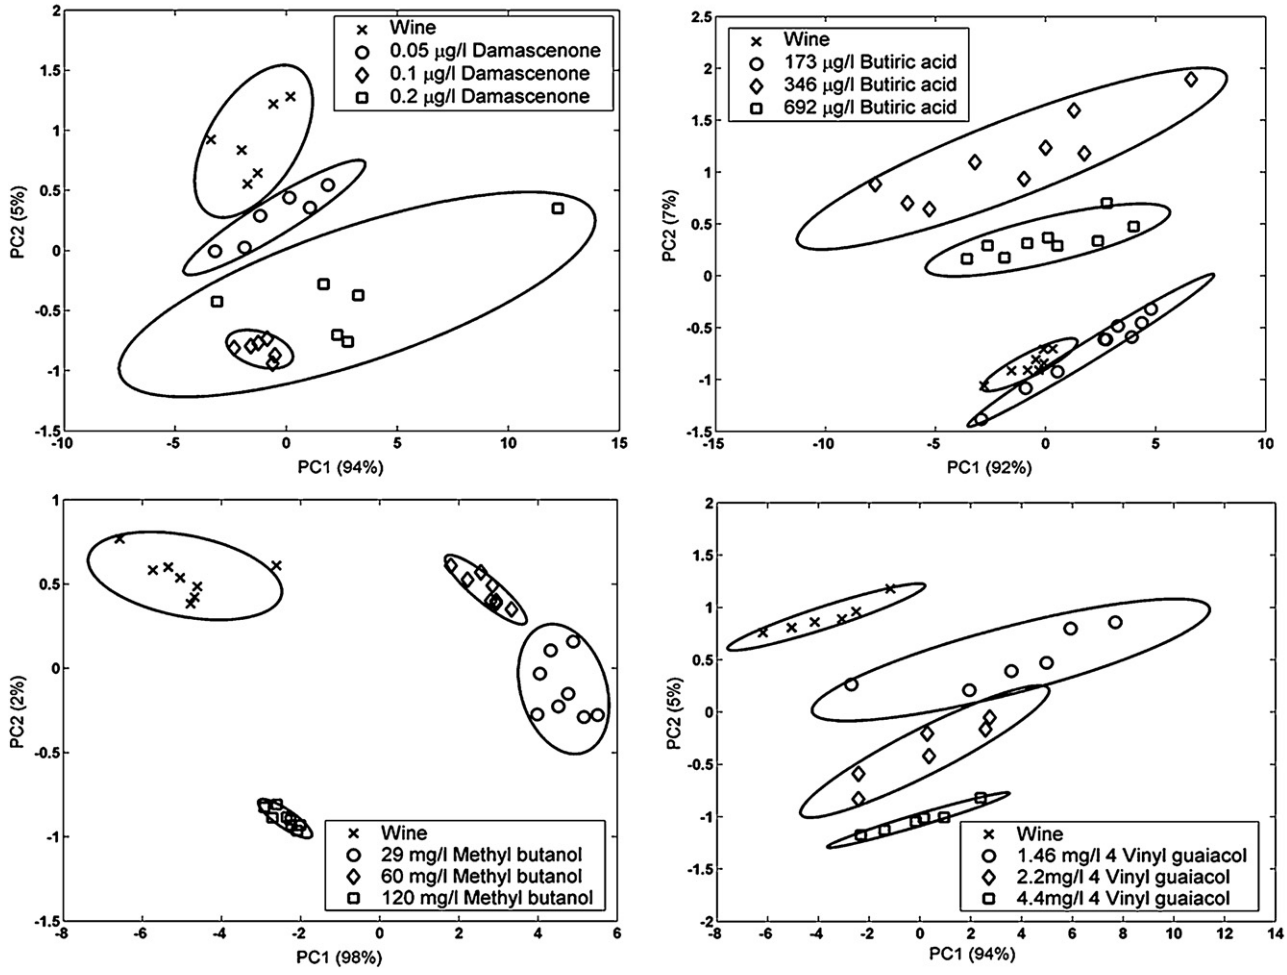

Fig. 2. PCA score plot for white wine compounds with headspace sampling.

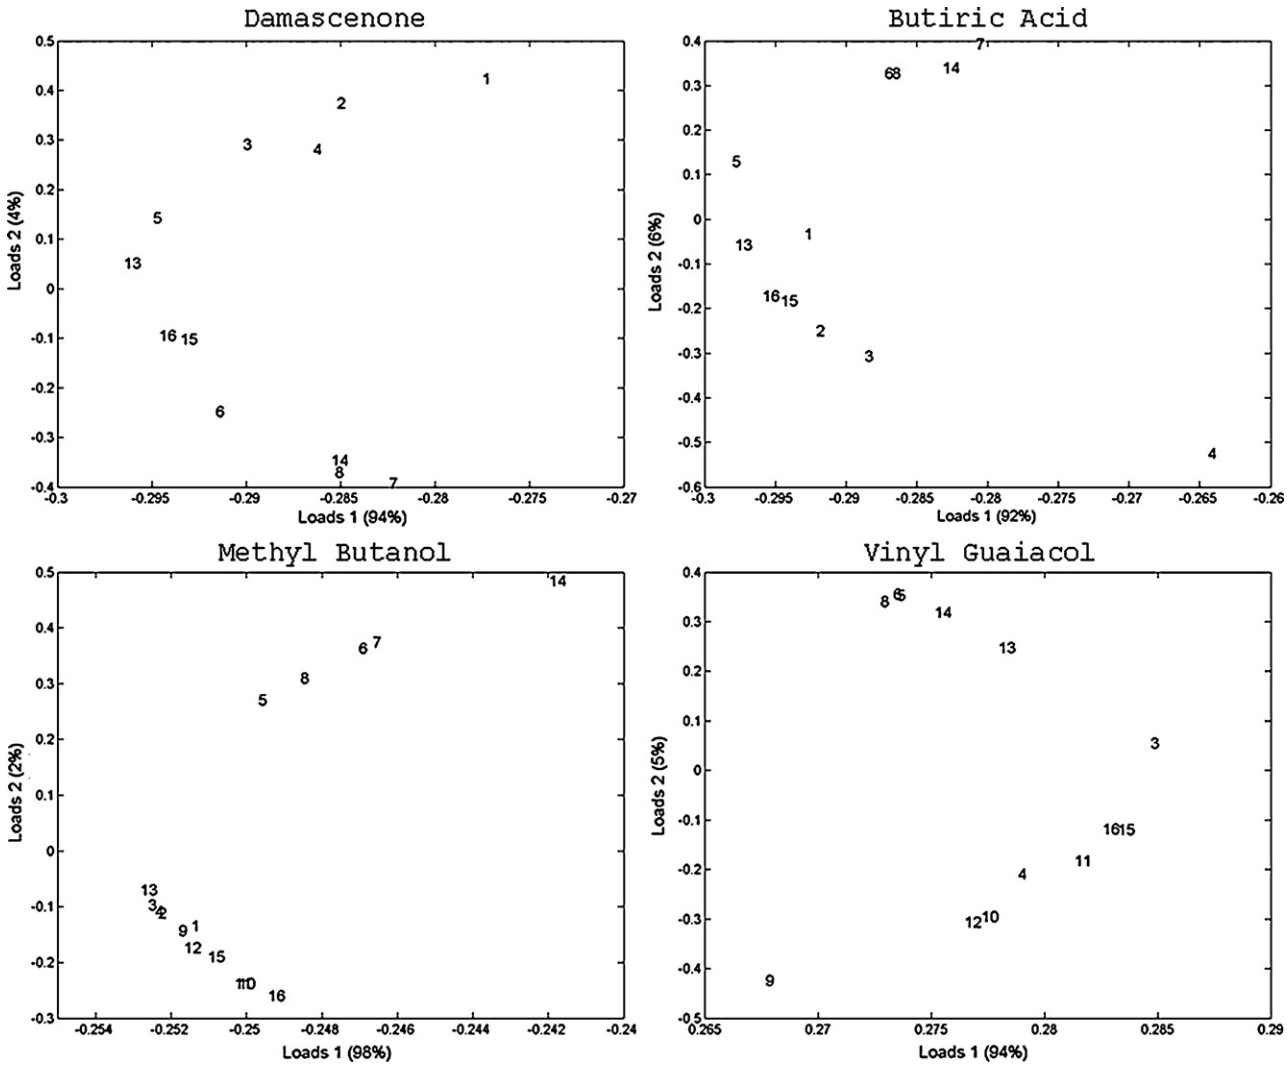

Fig. 3. PCA loadings plot for white wine compounds with headspace sampling.

the presence of the sample R_S:

$$r = \frac{R_N}{R_S} \quad (1)$$

The sensors were calibrated with ethanol in a weekly basis to compensate for drift. The experimental setup is shown in Fig. 1.

2.4. Data analysis

Two multivariate data processing techniques have been used: a linear unsupervised one, principal component analysis (PCA) and a nonlinear supervised one, a probabilistic neural network (PNN) [29].

Principal component analysis (PCA) is a chemometric linear, unsupervised and pattern recognition technique used for analyzing and reducing the dimensionality of numerical datasets in a multivariate problem. This method extracts the features from a data matrix in terms of a complementary set of scores (coordinates of the data in the new base) and loadings (contribution of the sensors to the components) plots. This method applies a linear transformation to the data and result in a new space of variables called principal components. The scores plot is usually used for studying the distribution of the data clusters. In the loading plot sensors with similar contributions will be close together. Sensors close to the origin have comparably small contribution.

The scores of the three first principal components were used in the training of the neural network.

The PNN was used for classification purposes. This network was composed by three layers. In the input layer there were three elements that corresponded with the first three components of the PCA. The hidden layer had the same number of neurons as the number of training vectors with radial basis transfer functions. The purpose of this layer is to measure and weight with a radial function the distance of the input layer vector with each training set element. The output layer was a competitive one with four neurons, one for the test wine and the others for the samples with added compounds (T, $2T$ and $4T$). In this third layer we add up the weighed distances for each class and the neural network select the highest one as the classification result. As we did not have many measurements leave one out cross validation was applied to check the performance of the network [30]. This method consists of training N distinct nets (in this case, N is number of measurements) by using $N-1$ training vectors, while the validation of the trained net is carried out by using the remaining vector, excluded from the training set. This procedure is repeated N times until all vectors are validated. Both PCA and PNN were performed in Matlab (version 6.1, Mathworks Inc., Natick, MA, USA).

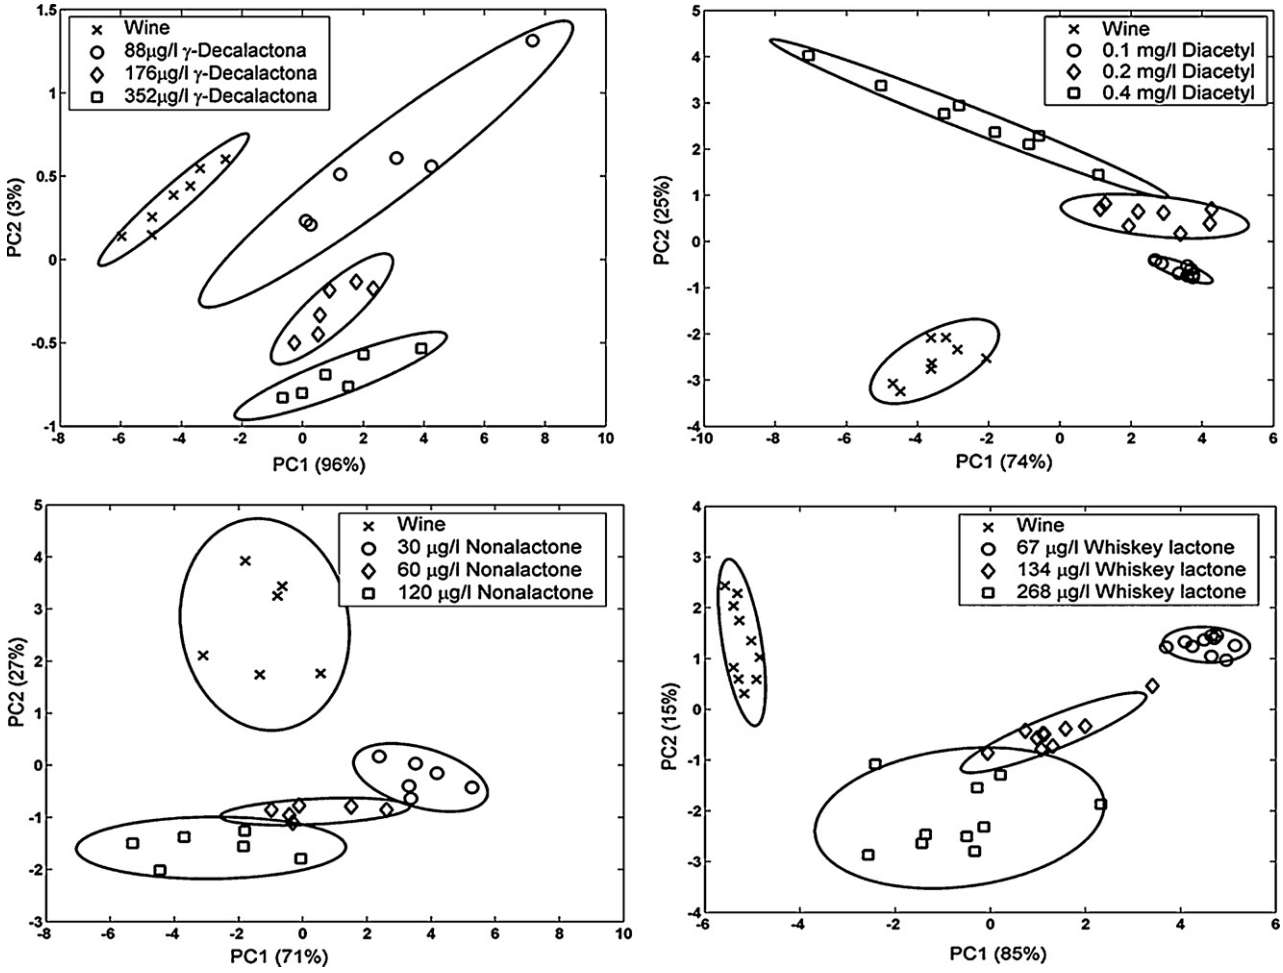

Fig. 4. PCA score plot for red wine compounds with headspace sampling.

3. Results

3.1. Sensory panel

The analysis of the sensory panel is summarized in Table 3. The table gives the percentage of panel members that detects each compound at each concentration. No compound was detected at the olfactory detection threshold. Only two compounds (diacetyl and 4-vinyl guaiacol) were detected by at least 50% of the panel at four times the threshold although more than 40% of the panelists recognized the rest of the compounds except 3-methyl butanol and butiric acid. The other compounds were detected at or above 10 times the threshold.

3.2. Electronic nose

After feature extraction using equation 1 data were preprocessed before PCA analysis. The preprocessing involved autoscaling and centering:

$$r_i = \frac{(r - \bar{r}_i)}{\sigma_i} \quad (2)$$

where $\bar{r}_i$ is the mean and σ_i is the standard deviation of sensor i response over the input data. The distribution of values for each sensor across the entire database is set to have zero mean and unit standard deviation.

The first three principal components accounted for more than 98% of the cumulative variance. Ellipsoids in the score plots are drawn assuming a Gaussian data distribution and represent the curve with a 90% probability.

3.3. Headspace

The PCA score plot for compounds in white wine is shown in Fig. 2. The variance explained by each principal component is in brackets. Only the datasets corresponding to methyl butanol are clearly separated. For the other compounds datasets showed partial overlapping. The corresponding PCA loadings plot is shown in Fig. 3. Sensors are well distributed around the loadings plane although there are some sensors close to each other for several compounds such as sensors 15 and 16 (indium doped sensors) for damascenone, butyric acid and vinyl guaiacol. This implies colinearity and redundancy of these two sensors. However their contribution to methyl butanol are more differentiated. For this last compound sensors 2, 3, 4 (undoped sensors), 8 and 13 (chromium doped sensors) are redundant and also 10 and 11 (indium intermediate layer doped sensors) are very close.

The PCA score plot for compounds in red wine is shown in Fig. 4. Although there is overlapping between datasets corresponding to nonalactone and whiskeylactone the wine datasets are clearly separated for every compound. The loadings plot showed a similar distribution than in the previous case. There was as well colinearity for some sensors but not for the same ones. For example sensors 7 and 8 (chromium intermediate layer doped sensors) gave similar information for decalactone, but differentiated contributions for the other three compounds. As in the previous

Table 4
Success rates of the PNN for headspace sampling for white wine compounds.

Compound	Qualitative	Quantitative
3-Methyl butanol	100	100
4-Vinyl guaiacol	96	83
Butiric acid	89	74
Damascenone	92	83

Table 5
Success rates of the PNN for headspace sampling for red wine compounds.

Compound	Qualitative	Quantitative
Whiskeylactone	100	100
Nonalactone	100	96
Decalactone	100	75
Diacetyl	100	83

case no sensor appears to be redundant for the whole compound dataset.

In general the output of the neural network is given as a confusion matrix. From the confusion matrix a success rate is defined as the number of correct classified measures in each class over the total number of measures in this class. In our case we have two success rates: a qualitative success rate and a quantitative success rate. In the quantitative case each compound concentration is considered a separated class. In the qualitative case we have only two classes: test wine and wine plus added compound. For headspace sampling the success rates are shown in Table 4 for white wine and Table 5 for red wine. For white wine compounds qualitative success rates are near 100% but only for 3-methyl butanol the neural network is able to classify correctly all classes both qualitatively and quantitatively. For red wine compounds test wine are correctly separated from wine added compounds measurements. A 100% quantitative success rate is achieved for whiskeylactone samples.

3.4. Purge and trap

The PCA score plot for compounds in white wine is shown in Fig. 5. Datasets for all compounds appear clearly separated except for the high concentration levels of damascenone. The PCA loadings plot showed similar trend tan in the headspace case except for damascenone. For this compound most sensors contributed in a similar way to PC1 and there was more variation in the contributions to PC2. For the other compounds the loadings of the sensors are more separated although there is a similar contribution from the sensors 2, 4 and 5.

The PCA score plot for compounds in red wine is shown in Fig. 6. In this case the separation between datasets is less clear but the test wine dataset is always separated from the wine with added compounds datasets. Datasets are better separated for compounds in white wine than for compounds in red wine as in the case of headspace extraction. The PCA loadings plot showed two group of sensors with similar contribution to the first principal component for nonalactone: sensors 9–12 (indium doped in an intermediate layer sensors) and the rest of the array. For the rest of the com-

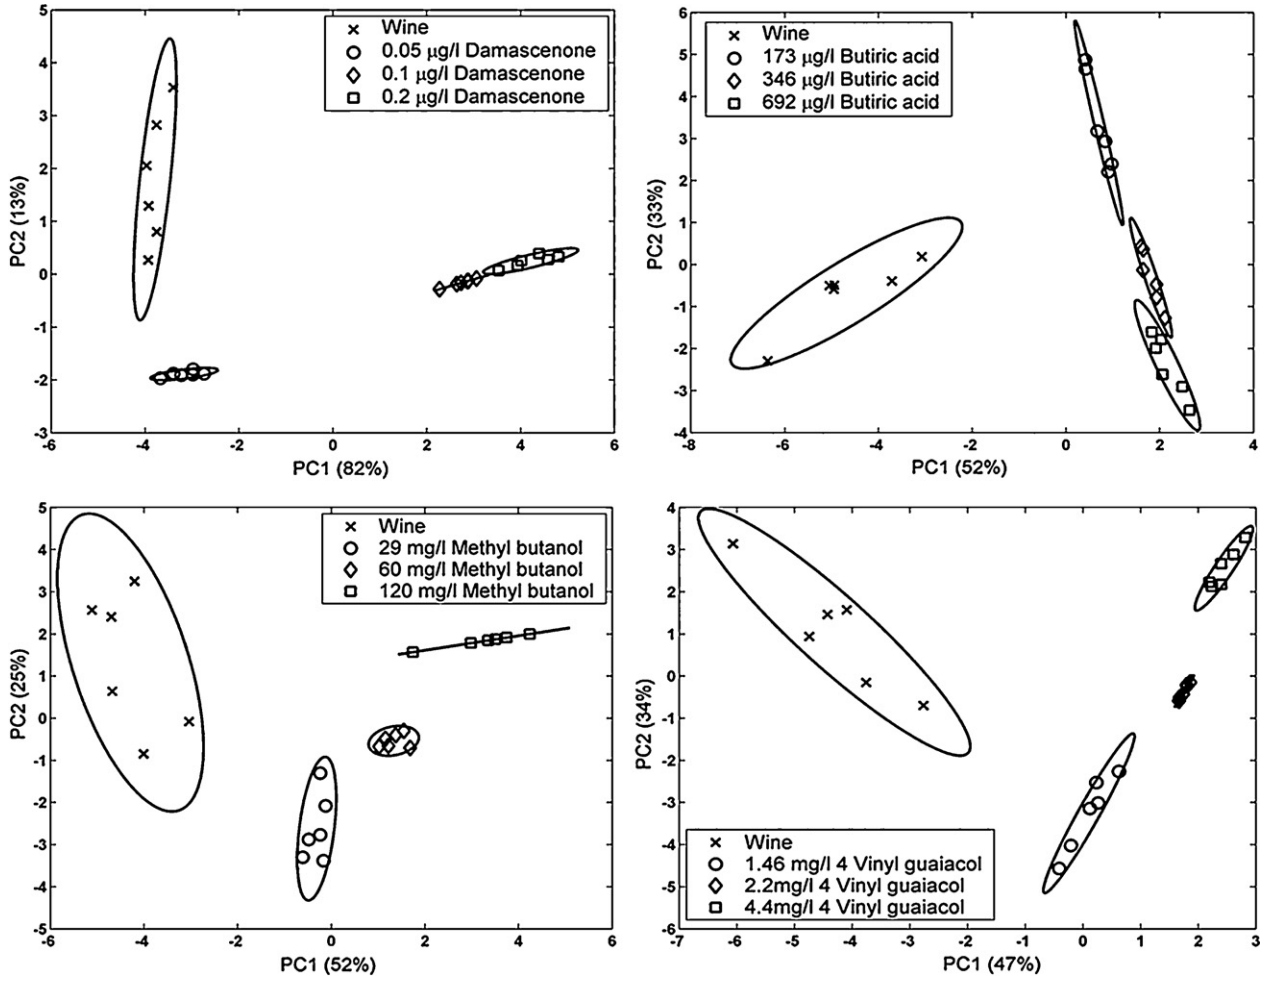

Fig. 5. PCA score plot for white wine compounds with purge and trap sampling.

Table 6
Success rates of the PNN for purge and trap sampling for white wine compounds.

Compound	Qualitative	Quantitative
3-Methyl butanol	100	100
4-Vinyl guaiacol	100	100
Butiric acid	100	96
Damascenone	100	100

pounds the sensor loadings are more separated. It can be noted that sensors 13 and 14 (chromium surface doped sensors) have the greatest contribution to PC2 for all compounds.

The success rates of the probabilistic neural network are shown in Table 6 for white wine compounds and Table 7 for red wine compounds. Success rates are 100% qualitative both for white and red wine compound. We obtain better quantitative success rates for the compounds in white wine just as in the PCA analysis.

The separation is better for purge and trap sampling method than for headspace as expected. Purge and trap is especially successful for the compounds in white wine with a minimum of 96% correct quantitative classifications.

Table 7
Success rates of the PNN for purge and trap sampling for red wine compounds.

Compound	Qualitative	Quantitative
Whiskeylactone	100	93
Nonalactone	100	92
Decalactone	100	80
Diacetyl	100	96

4. Discussion and conclusions

In every case the electronic nose exhibited a better performance than the human sensory panel in the discrimination of aromatic compounds. The first threshold data are correctly separated from wine data for all compounds with purge and trap method. Higher concentration datasets are separated as well but in most cases there is confusion between the different concentrations tested. In the case of the sensory panel the compounds are detected only at concentrations four times higher than the threshold for diacetyl and 4-vinyl guaiacol and 10 times higher than the threshold for decalactone, 3-methyl butanol and butiric acid.

Whiskeylactone and nonalactone are not recognized even at the maximum concentration. The electronic nose, however, performed very well with a 100% quantitative success rate with purge and trap extraction for white wine compounds. On the other hand decalactone gave the poorest response. In the case of the damascenone only detected by the panel even at 10 times the threshold, the electronic nose performed well both qualitative and quantitative despite the low concentrations involved (the first odor threshold is only 0.05 μg/l). It appears evident that the performance of the electronic nose is not directly related either to the odor threshold concentration of a compound or to the ratio of its real concentration in wine to its threshold concentration. From the loading plots we

can conclude that none of the 16 sensors appears to be redundant for the whole compound dataset for both sampling methods.

On the other hand, despite the strong ethanol and water interference the electronic nose performs well with headspace sampling method due to the saturation of the sensors to low levels of ethanol although purge and trap gives better results. This result confirms previous results in compounds discrimination in wine and ethanol [31].

We can conclude that the use of electronic noses in the determination of compound thresholds is advantageous over the human sensory panel in terms of training time and accuracy.

ABSTRACT

The eggshell membrane (ESM) contains several surface functional groups such as amines, amides and carboxylic groups with potential as SPE adsorbent for the retention of target species of interest. In this paper, the potential use of ESM, a typical biomaterial, as solid-phase extraction (SPE) adsorbent is evaluated for analysis of trace arsenic(V) in environmental water samples in combination with hydride generation atomic fluorescence spectrometry (HG-AFS). In order to obtain the satisfactory recovery of arsenic(V), various parameters including the desorption and enrichment conditions such as pH, the flow rate and the volume of sample solution, the amount of ESM and the content of sodium chloride were systematically optimized and the effects of co-existed ions were also investigated in detail. Under the optimal conditions, arsenic(V) could be easily extracted by the ESM packed cartridge and the breakthrough adsorption capacity was found to be 3.9 $\mu g\,g^{-1}$. The favorable limit of detection (LOD) for arsenic(V) was found to be 0.001 $\mu g\,L^{-1}$ with an enrichment factor of 33.3, and the relative standard deviations (R.S.Ds) was 2.1% for 0.6 $\mu g\,L^{-1}$ arsenic ($n = 11$). The reproducibility among columns was satisfactory (R.S.D. among columns is less than 5%). The proposed method has been successfully applied to analysis of arsenic(V) in aqueous environmental samples, which suggests the ESM can be an excellent SPE adsorbent for arsenic(V) pretreatment and enrichment from real water samples.

1. Introduction

Up to now, the world-wide consumption of arsenic compounds in pesticides, wood preservatives, glassware production, electronics industries, waste incineration and the amounts derived from volcanic emissions, fossil fuels have made arsenic be one of the abundant elements in environment [1–3]. Thus, the arsenic was inevitably brought into the environment [4] and accumulated especially via food chains in vegetables, milk and rice [5]. Arsenic is a highly toxic pollutant. In general, the inorganic forms of arsenic are more toxic than its organic ones; the toxicity of trivalent forms of arsenic is greater than that of pentavalent forms [6]. Arsenic have caused a potential threat for environment safety, human health owing to its carcinogenic effects on hematopoietic system, lungs, kidneys, liver, bladder and the central nervous system, cardiovascular diseases, and dermal changes [7–10]. Recently, the contamination incidents of arsenic were reported in groundwater [11,12]. Therefore, the residual level of arsenic in drinking water is restricted by some the major world governments' health policies. For example, the United States Environment Protection Agency (US EPA) regulates arsenic maximum contaminant level (MCL) of 10 $\mu g\,L^{-1}$ [13], the World Health Organization (WHO) and Japanese restrict it to be 10 $\mu g\,L^{-1}$ [3]. Meanwhile, the European Community has limited the concentrations of arsenic in superficial waters to be 1.6 and 1.4 $\mu g\,L^{-1}$ from 2008 to 2015 [14]. Hence, it is particularly important to develop effective and reliable analytical techniques for arsenic determination.

In recent years, many analytical methods have been developed to determine arsenic in surface water, ground water and wastewater including hydride generation atomic absorption spectrometry (HG-AAS) [15], inductively coupled plasma atomic emission spectrometry (ICP-AES) [16], inductively coupled plasma mass spectrometry (ICP-MS) [17], hydride generation atomic fluorescence spectrometry (HG-AFS) [18], etc. Among above-mentioned methods, HG-AFS was widely used as a routine method for arsenic analysis due to its adequate sensitivity and selectivity, wide linear dynamic range and easy operation [19–21].

doi:10.1016/j.talanta.2009.10.042

Due to low concentration level of arsenic in natural water, preconcentration is necessary piror to determination. Among various pretreatment methods, SPE has several merits of short extraction time, high enrichment factor, low consumption of eluent, easy automation and has been used for arsenic preconcentration. Literature survey demonstrated that some new materials including ion exchange resins [16,22], carbon nanofibers [17], surfactant modified silica [23], nanometer titanium dioxide [24], the PTFE turnings for retention of As(III)–PDC (pyrrolidine dithiocarbamate) complex [25], activated alumina [26], etc., have been adopted as SPE adsorbent for preconcentration of arsenic from water samples. Recently, our group has induced a novel SPE format based on MWCNTS functionalized with CTAC hemimicelle as adsorbent for arsenic in environmental waters [27].

Due to having abundant of functional groups such as carboxyl, hydroxyl, sulfhydryl and amino groups, the exploitations of biomaterials or cells as solid substrates for solid-phase extraction of analytes have attracted extensive attentions recently [28–31]. ESM is a cheap, green and easily achieved biological material. It is mainly composed of a thin inner and a thick outer membrane including typical collagen protein, amino acids, saccharides and lipids [32,33] with a complex lattice network composed of stable and water-insoluble protein fibers. So, it could be considered as a promising candidate for SPE adsorbent due to attractive features such as the high specific surface area, excellent chemical stability and high density of surface functional groups including amines, amides and carboxylic [34]. In the previous research, the ESM which has been applied as an effective adsorbent for removing various heavy metals including Au, Pt, Cu, Cr, Pd [33–35] and the textile dyes [36]. In the study by Ishikawa et al., eggshell membrane and broiler chicken feathers were evaluated for the removal of the oxyanions selenium [Se(IV) and Se(VI)] and arsenic [As(III) and As(V)] from aqueous solutions in batch mode [37]. Recently, the batch removal of arsenic from aqueous solution using powdered eggshell was also reported [38]. However, to the best of our knowledge, there is no report on natural biomaterial ESM-based adsorbent for arsenic enrichment as SPE format. The goal of this study is to develop an analytical method for the determination of arsenic(V) by using ESM as SPE adsorbents to enrich arsenic(V) from water samples. The off-line SPE followed by HG-AFS method were chosen for monitoring arsenic in aqueous environmental samples.

2. Experimental

2.1. Chemicals and reagents

The stock standard solution of 1000 mg L^{-1} arsenic(V) was purchased from the national standard material center (National Center for Standard Material, Beijing, China). Working standard solutions of arsenic(V) (100 μg L^{-1}) were further prepared by serial dilution of the arsenic(V) stock standard solution with ultrapure water. All reagents used in the experiments were of analytical-reagent grade, except that the hydrochloric acid was guarantee reagent. 0.01 mol L^{-1} HCl and 0.01 mol L^{-1} NaOH solutions were prepared by adequate dilution of concentrated HCl and adequate amount of NaOH, respectively. The 2% (m/v) of sodium borohydride ($NaBH_4$) was freshly prepared by dissolving the sodium borohydride (Tianjin Institute of Chemical Reagents, Tianjin, China) in 0.5% (m/v) NaOH solution. The 5% (m/v) ascorbic acid and 5% (m/v) sulfocarbamide mixture solution were freshly prepared daily. The water used in this study is ultrapure water. All the glassware and polyethylene bottles used in experiments were firstly soaked with 10% (v/v) nitric acid for at least 24 h and cleaned with ultrapure. The glassware and polyethylene bottles were dried in a clean oven before use.

Table 1
Parameters and operating condition of AFS-230E.

Parameters	Settings
Lamp current	60 mA
Auxiliary lamp current	30 mA
Atomizer height	8 mm
Atomization temperature	250 °C
High negative voltage of photomultiplier	300 V
Carrier argon flow rate	400 ml min^{-1}
Shield gas flow rate	1000 ml min^{-1}
HCl carrier solution	5 (%, v/v)

Fresh eggs were purchased form the Chongqing local supermarket, and the ESM of hen eggs was obtained by opening the eggshell, then emptying the albumen and yolk and thoroughly washed with ultrapure water. The ESM was carefully peeled off the emptied fresh eggshell by hand. The cleaned ESM was finally immersed in 1 mol L^{-1} nitric acid for 12 h and rinsed with ultrapure water several times. Then the membrane was placed in a clean beaker, and dried at 80 °C for 2 h and cut into a small piece (about 0.5 mm × 0.5 mm). The as-treated ESM was used as SPE adsorbent material.

2.2. Instrumentation

A model AFS-230E hydride generation, double-channel atomic fluorescence spectrometer (Beijing Haiguang Instrument Ltd., Beijing, China) was used throughout for arsenic determination. The arsenic high-intensity hollow cathode lamp (General Research Institute of Non-Ferrous Metals, Beijing) was employed as the radiation sources. The working conditions of HG-AFS were listed in Table 1.

2.3. SPE procedure

An ESM packed cartridge was organized by modifying a C18 cartridge (1 g, 6 mL, popropylene) purchased from SUPELCO Cooperation, USA. The C18 packing material was evacuated and a proper amount of ESM was packed into the cartridge. The popropylene upper frit was reset at the upper end of the column to prevent the ESM leaching. Then the outlet tip of the column was connected to a model SHZ-3 (III) vacuum pump (Yuhua Instrument Co. Ltd., Zhengzhou, Henan), and the inlet end of column was connected to PTFE suction tube whose other end was inserted into sample solution. In order to reduce the possible interferences of metal ions, the entire SPE assembly needed to be preconditioned by washing with 5 mL of 2 mol L^{-1} nitric acid and 150 mL of ultrapure water before the pretreatment procedure. Next, sample solution was passed through cartridge at a flow rate of 3 mL min^{-1} by a vacuum pump. After the cartridge was washed with 5 mL of ultrapure water and dried under a certain negative pressure (20 mmHg) for 5 min, then arsenic(V) retained on the ESM column was eluted with an optimal volume of nitric acid. Finally, the eluent was used for arsenic(V) analysis. After finishing the elution process, 5 mL of 2 mol L^{-1} HNO_3 were employed to pass through the mini-column to regenerate the column for the next run and then washed with water until neutral pH was reached. The recovery was used as criterion to optimize the parameters for ESM-based SPE. The recovery was calculated as the ratio of the amount of arsenic(V) with and without preconcentration.

2.4. Analytical application

In this work, several types of environment water samples were selected for investigation the potential of ESM-based SPE for arsenic(V) enrichment. Tap water sample was collected from our laboratory after flowing for 10 min. River water sample was

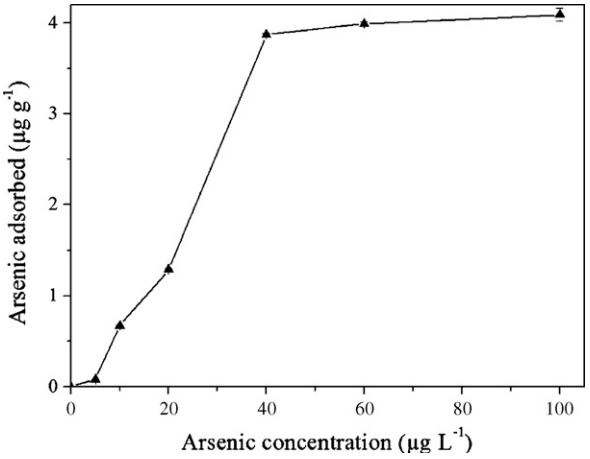

Fig. 1. The breakthrough curve of arsenic on the ESM. Sample volume: 40 mL; pH: 11. ESM: 500 mg, flow rate: 3 mL min^{-1}. Error bars represent one standard deviation for three measurements.

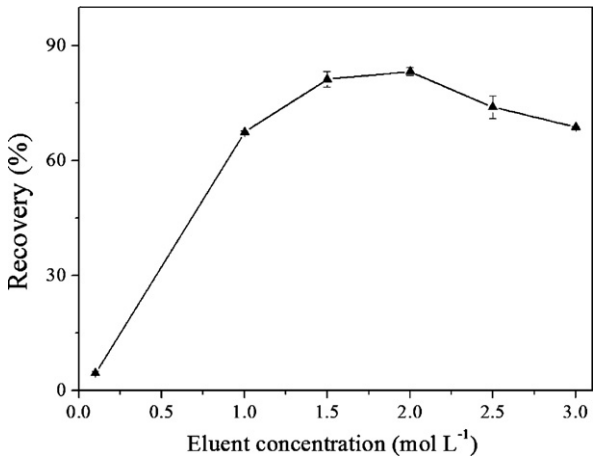

Fig. 2. Effect of nitric acid concentration on recoveries of arsenic. Arsenic(V) concentration in sample solution: 0.5 μg L^{-1}; volume of sample solution: 40 mL; the amount of ESM: 500 mg; sample flow rate: 3 mL min^{-1}; sample pH: 6.0. Error bars represent one standard deviation for three measurements.

collected from Jialingjiang River water. Lake water was collected from ChongDe Lake located in Southwest University. Wastewater samples were from sewage and effluent of the constructed wetland system. Before analysis, all the water samples were filtered through 0.45 μm membrane filters to remove suspended solids and stored in acid-cleaned polyethylene bottles at 4 °C in refrigerator. For real water sample analysis, 8 mL of 0.5 mol L^{-1} sodium fluoride as masking agent was added to 200 mL (adjusted to pH 11) of the environmental water samples for eliminating the interference of metal ions. Note that if the precipitation takes place after addition of sodium fluoride, the sample should be filtered through 0.45 μm membrane filters, then used for arsenic analysis.

3. Results and discussion

3.1. Adsorption capacity of eggshell membrane

In order to study the adsorption capacity of ESM-based SPE column for arsenic(V), according to the method by Maquieira et al. [39], 40 mL of sample solutions containing different concentrations (0–100 μg L^{-1}) of arsenic(V) were extracted by the SPE. Then, the amount of arsenic(V) adsorbed by ESM packed cartridge at the each concentration level was calculated. The dynamic adsorption curve for arsenic(V) was obtained by plotting the concentration (μg L^{-1}) of sample solution versus the microgrammes of arsenic(V) adsorbed on per gram of the ESM (μg g^{-1}), and shown in Fig. 1. As can be seen that the breakthrough capacity of the ESM biosorbent materials for arsenic(V) was found to be 3.9 μg g^{-1}. So, ESM shows good retention ability for arsenic(V) and can be used as adsorbent for arsenic(V) enrichment.

3.2. Optimization for the solid-phase extraction

3.2.1. Effects of the desorption reagent

Desorption of arsenic(V) from the ESM packed cartridge was investigated using different concentrations of nitric acid between 0.1 and 3 mol L^{-1}. The results presented in Fig. 2 indicated that the recoveries increased with the increase of nitric acid concentration to 2.0 mol L^{-1}, above which the recovery decreased. Then, the volume of nitric acid for desorption of arsenic(V) from the ESM was also investigated in the range of 2–10 mL. The experimental results shown that 6 mL of nitric acid was enough to desorb arsenic(V) from the ESM column. In order to obtain a higher preconcentration factor and satisfactory recovery, 6 mL of 2 mol L^{-1} nitric acid was selected for further experiments.

3.2.2. Effect of pH

The effect of pH on recovery was investigated in the range of 4–12. Results shown in Fig. 3 revealed that the recoveries of arsenic(V) were not significantly affected by the pH value from 5 to 9. It was worth noticing that the maximum recoveries were obtained between pH 10 and 11, above which, it decreased. Hence, a pH value of sample solution adjusted to 10–11 was adopted as the optimum pH value for in the present study. The pH effect was somewhat similar to that by Ishikawa et al. [37] who discovered that the adsorption efficiency of arsenic on the ESM increased gradually with the increase of pH from 8 to 11, and the maximum adsorption amount was generally found at pH 11. The adsorption of metal ions such as Cr(VI) and As(V) onto the surface of organic substrates such as eggshell membrane is a complicated process. It has been demonstrated by Zou et al. [35] that ESM shows good retention ability for Cr(VI) due to the presence of the positively charged functional groups such as $-NH_3^+$ and $-CO\text{-}NH_2^+-$. Therefore, the adsorption processes of As(V) onto the ESM surface might be similar to that of Cr(VI), which is electrostatic interaction between the As(V) and ESM surface due to the fact that As(V) is in the forms of oxyanions in surface water [40]. According to Zou et al., the N-acetyl group might contribute to the bio-sorption of As(V) on the surface of ESM [35]. When performing arsenic analysis, pH adjustment should be

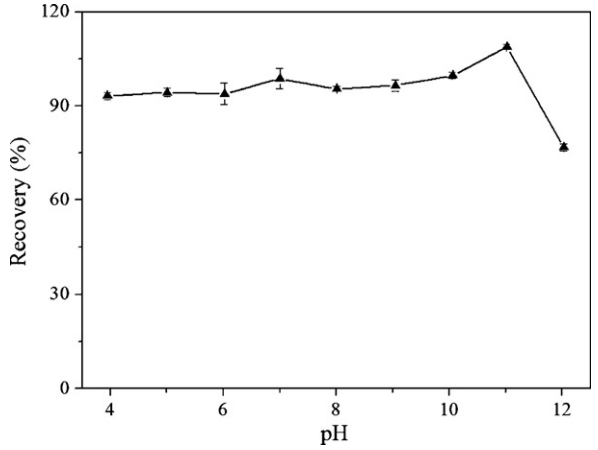

Fig. 3. Effect of sample pH on recoveries of arsenic. Arsenic(V) concentration in sample solution: 0.5 μg L^{-1}; volume of sample solution: 40 mL; the amount of ESM: 500 mg; sample flow rate: 3 mL min^{-1}; eluent: 6 mL of 2.0 mol L^{-1} nitric acid. Error bars represent one standard deviation for three measurements.

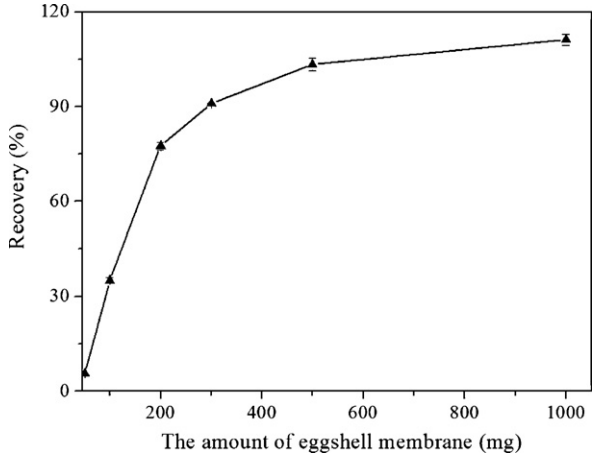

Fig. 4. Effect of amount of the ESM on the recoveries of arsenic. Arsenic(V) concentration in sample solution: 0.5 μg L^{-1}; volume of sample solution: 40 mL; sample flow rate: 3 mL min^{-1}; sample pH: 11; eluent: 6 ml of 2.0 mol L^{-1} nitric acid. Error bars represent one standard deviation for three measurements.

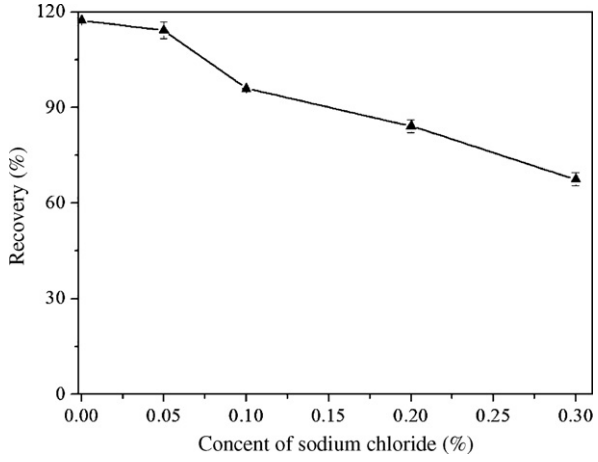

Fig. 5. Effect of the content of sodium chloride on the recoveries of arsenic. Arsenic(V) concentration in sample solution: 0.5 μg L^{-1}; volume of sample solution: 40 mL; the amount of ESM: 1000 mg; sample flow rate: 3 mL min^{-1}; sample pH: 11; eluent: 6 ml of 2.0 mol L^{-1} nitric acid. Error bars represent one standard deviation for three measurements.

an important step to ensure quantitative retention of As(V) onto ESM due to the fact that it not only determined the present state of analytes in solution as ionic or molecular state, but also the sorbent surface properties [35]. The effect of solution pH can be tentatively explained by considering the surface charge of the ESM and the distribution of As(V) species. As indicated previously, the adsorption processes of As(V) onto the ESM surface might be the electrostatic interaction between the As(V) and ESM surface due to the presence of the positively charged functional groups such as $–NH_3^+$ and $–CO\text{-}NH_2^+$–. The majority of As(V) is present in neutral molecular H_3AsO_4 at pH below 2, the lower adsorption of arsenic can be obtained. At pH values of 2.24–6.76, and 6.76–11.60, the major forms of As(V) are $H_2AsO_4^-$ and $HAsO_4^{2-}$, respectively [40], the arsenic adsorption tends to increase, suggesting that ESM can more easily adsorb $H_2AsO_4^-$ and $HAsO_4^{2-}$. However, the competition phenomena with hydroxides could tend to reduce the arsenic adsorption at higher pH (pH 12).

3.2.3. Effect of sample solution flow rate and volume

The effect of flow rate on retention of arsenic(V) was studied from 1.0 to 8.0 mL min^{-1} (the maximum flow rate of the vacuum pump). The experimental results demonstrated that the recoveries decreased with the increase of the flow rate. Finally, 3 mL min^{-1} was chosen as the flow rate for subsequent experiments. The effect of sample solution volume was determined for achieving higher enrichment factor by using different volume of sample solution (100, 150, 200, 300 and 500 mL) through the ESM packed cartridge. The results exhibited that the satisfactory recovery of arsenic(V) was obtained from 100 to 200 mL. Further increase of the solution volume led to significantly decrease for the recovery of arsenic(V). When 200 mL was selected, an enhancement of 33.3 based on calculation of preconcentration factor (PF) was obtained for arsenic(V) because 6 mL of 2.0 mol L^{-1} nitric acid was chosen as optimal eluent. Therefore, 200 mL of sample volume was selected as the optimal sample volume for further investigation.

3.2.4. Effects of ESM amount

Effect of the ESM amount on SPE efficiency of arsenic(V) was shown in Fig. 4. As can be seen that the recovery of arsenic(V) increased remarkably with increase of the amount of ESM when packed ESM was lower than 300 mg. The recovery of arsenic(V) increased gradually with increase of the ESM amount in the range from 300 to 1000 mg. To gain high enrichment efficiency and provide more adsorption sites, 1000 mg of ESM was selected as the optimal amount of ESM for the subsequent works.

3.3. Effect of sodium chloride and other co-existing substances

In this study, the content of sodium chloride ranging from 0 to 0.3% (w/v) was evaluated. The experimental results shown in Fig. 5 indicated that addition of sodium chloride would lead to decrease of arsenic(V) retention. It should be easily observed that the recovery of arsenic(V) was lower than 95% at the sodium chloride concentration above 0.1% (w/v), corresponding to 393 and 607 mg L^{-1} for Na^+ and Cl^-, respectively. A previous study reported that the electrolytes (e.g. sodium chloride) caused the adsorption capacity of arsenic decrease on an activated carbon with an increase of sodium chloride concentration [14]. This phenomenon may be caused by the competitive adsorption between chloride anion and the oxyanions of arsenic at the same active sites on the ESM surface. In order to evaluate the analytical applications of developed method, the effect of other co-existing substances were investigated under the optimized conditions. The effect of foreign substances was tested by enrichment a standard solution of As(V) (0.5 μg L^{-1}) according to SPE procedure described in experimental section to which increasing amounts of interfering substances was added. The tolerable concentration ratios with respect to 0.5 μg L^{-1} arsenic(V) for interference at less than 10% level were listed in Table 2. As can be seen that Fe, Mn and Pb are the main interferences for arsenic(V) retention. In fact, less than 5% recoveries were obtained when performing direct arsenic preconcentration without considering the elimination of cation ions. In order to eliminate the interferences derived from Fe, Mn, Pb and other co-existing transient metals, different chelate reagents such as EDTA, triethanolamine, 8-hydroxyquinoline and NaF were tested. Experimental results indicate that quantitative recoveries of arsenic(V) were obtained when NaF was added to the water samples. Hence, for real sample analysis for arsenic(V), NaF was selected.

3.4. Analytical performance

Analytical parameters for the quantitative analysis of arsenic(V) such as linear range, limit of detection (LOD), correlation coefficient (R^2), and the relative standard deviation (R.S.D.) were evaluated under the optimal conditions. According to experimental results, the calibration curves were in the range of

Table 2

[a] Mean value ± standard deviation (n = 3).

0.005–2.0 μg L^{-1} arsenic(V) standards by HG-AFS detection. The calibration equation was $\Delta I = 2611.5c + 190$ with a correlation coefficient of 0.9947 (n = 11), where ΔI being the net fluorescence intensity, c being the arsenic(V) concentration (μg L^{-1}). The linear calibration plot for arsenic(V) was shown in Fig. 6. The LOD (3σ) and limit of quantitation (LOQ) (10σ) was found to be 0.001 and 0.0033 μg L^{-1}, respectively. The present method was compared to the analytical methods previously published in literatures [16–20,22,23,25,27,41–43] using solid-phase extraction for arsenic analysis in terms of the detection limits (LODs). And the LODs were listed in Table 3. As can be seen, the LOD of this work was at least one order of magnitude lower than the reported SPE-ICP method [16,17,41,42], showing high sensitivity of the proposed method. Also, the LOD of this method was comparable with that obtained by functionalized MWCNTS and cigarette filter-based SPE methods [27,43]. The R.S.D. was 2.1% for 0.6 μg L^{-1} arsenic level (n = 11), indicating favorable precision of the proposed method.

three columns. The R.S.Ds were 2.6 and 4.3% for day-to-day and column-to-column, respectively. As can be seen, R.S.D. (precision) of day-to-day and column-to-column is less than 5%, suggesting the reproducibility among columns is satisfactory.

3.5. Application to environmental water samples

In order to validate the proposed method, a certified reference material was analyzed for arsenic(V) concentration (CRM GBW(E) 080391, environmental water sample) (Institute of Reference Materials, Beijing, PR China). The result was listed in Table 4. As can be seen, the analytical result of the certified reference was satisfactorily in agreement with the certified value.

The developed method was also applied to arsenic determination in several environmental water samples. In order to eliminate the possible interferences from metal ions, NaF was used as masking reagent. As can be seen from Table 4 that the recoveries of arsenic(V) in the spiked environmental water samples ranged from 98 to 113%, which demonstrated that the proposed method was satisfactory for arsenic analysis. It should be indicated that the extraction recoveries above 100% for some water samples were probably caused by the experimental errors and matrix effects.

4. Conclusion

In summary, we propose a natural biomaterial ESM-based adsorbent for arsenic(V) enrichment as SPE format coupled with HG-AFS in this study. The current investigation has demonstrated well the potential of ESM as SPE adsorbent for enriching of arsenic(V) in environmental aqueous samples by adsorption capacity test, desorption test and real sample application. The proposed method promises high sensitivity and good reproducibility for arsenic(V) determination. In addition, the ESM-based adsorbent promises to be cheap, environmentally benign and biodegradable. It is believed that the eggshell membrane may be useful a SPE adsorbent for other pollutants.

ABSTRACT

A microwave-assisted extraction used to extract trace triorganotin from aquatic organisms and a sensitive analytical method for the determination of ultratrace triorganotin (namely trimethyltin, triethyltin, tripropyltin and tributyltin) with capillary electrophoresis–inductively coupled plasma mass spectrometry were firstly described in this study. The extraction method is simple, effective and can be used to extract trace triorganotin in aquatic organisms within several min. The analytical method has a much lower detection limit of 0.2–0.7 ng Sn/mL for triorganotin compounds, and can be used to determine trace triorganotin in aquatic organisms directly without any derivatization and preconcentration. Using above methods, we have successfully determined trimethyltin, triethyltin, tripropyltin and tributyltin in dried *Mya arenaria Linnaeus* and *Corbicula fluminea* within 17 min with a recovery of 93–104% and a RSD (relative standard deviation, $n = 6$) of 2–5%. Our results showed that dried *M. arenaria Linnaeus* contained an extremely high tributyltin of 5.1 μg Sn/g dried weight, indicating that it may be a good biomarker for the organotin pollution in ocean.

1. Introduction

For environmental studies, speciation is of major interest in organotin analysis, since the organotin's toxicity is strongly dependent on the species [1]. Especially, environmental concern about organotin compounds (OTCs) has increased considerably in recent years owing to the extensive use of these compounds as active components in antifouling paints (mainly tributyltin, TBT) and in pesticide formulations (mainly triphenyltin, TPhT) [2]. It is well known that TBT and TPhT are one of the endocrine disruptors and have a harmful influence on "non-target" marine organisms even at the ng/L level [3]. Their direct introduction into the marine environment has caused environmental and economic damage [4]. Therefore, in many countries, the use of triorganotin compounds such as TBT and TPhT has been prohibited or restricted by law. In order to control the effectiveness of these legal provisions and to evaluate the distribution and the fate of triorganotin compounds in the marine environment, it is very important to develop a sensitive and accurate analytical method for the quantification of ultratrace triorganotin compounds in aquatic organisms including *Mya arenaria Linnaeus* and *Corbicula fluminea*.

So far, main techniques employed to the speciation analysis of OTCs are based on the combination of separation techniques such as gas chromatography (GC) or liquid chromatography (LC) and sensitive, element-selective detectors such as flame photometric detection (FPD) [5–7], atomic absorption spectrometry (AAS) [8], atomic emission spectrometry (AES) [9,10], mass spectrometry (MS) [11–13] and inductively coupled plasma mass spectrometry (ICP-MS), etc. [14–18]. However, GC-based techniques require a previous derivatization step due to the low volatility of OTCs, and the derivatization is one of the most critical steps in organotin analysis. Low yield as well as degradation phenomena in derivatization can heavily affect the quality of the results [2]. LC-based methods do not require previous derivatization, however, LC-based techniques often suffer from one or more of the following deficiencies: lower resolution, poor sensitivity (combined with UV, AES, AAS and so on), inadequate stability due to much organic solvent (combined with ICP-MS) and so on [19].

In comparison with GC and LC, capillary electrophoresis (CE) offers higher separation efficiency, requires much smaller sample and has various separation modes [20]. Combined with different detectors such as UV-spectrometry, atomic fluorescence spectrometry (AFS) and so on, CE has been used in the analysis of various OTCs [21–24]. However, the combination of CE and UV or AFS has obvious limitations such as lower sensitivity, poorer stability

and so on. On the other hand, ICP-MS possesses several inherent advantages such as extremely high sensitivity for metallic ions, wide linear dynamic range, high speed analysis and the ability to perform isotopic analysis. These advantages make it an attractive CE detector for elemental speciation analysis [25]. Therefore, the coupling of CE and ICP-MS has received considerable attention due to the potential benefits offered by the combination of these two methodologies [26], and has been used in the speciation analysis of some elements [27]. However, the simultaneous determination of trimethyltin (TMT), triethyltin (TET), tripropyltin (TPT) and tributyltin (TBT) with CE–ICP-MS has not been reported up to date, because these four triorganotin compounds have very similar chemical structure and are difficult to be separated by CE.

The main aim of the present study is to develop a novel method for the simultaneous determination of ultratrace level of TMT, TET, TPT and TBT by using CE–ICP-MS, in hope of providing a realistic approach for the evaluation of organotin pollution in aquatic organisms.

2. Materials and methods

2.1. Reagents

The analytical grade of four triorganotin compounds including TMT, TET, TPT and TBT were purchased from Tianjin Alfa Aesar Co. Ltd. (Tianjin, China). The 1000 μg/mL stock standard solutions of TMT, TET, TPT and TPT were prepared by dissolving appropriate amounts of above drugs in methanol (HPLC grade, Shanghai Reagents Co. Ltd., Shanghai, China). The stock standard solutions were stored at 4 °C, and the working standard solutions were prepared by diluting stock standard solutions to the desired concentration with buffer solution just before use.

The super-pure sodium dodecyl sulfate (SDS) was obtained from Sigma company (USA), analytical grade sodium tetraborate ($Na_2B_4O_7{\cdot}10H_2O$) and boric acid (H_3BO_3), super-pure nitric acid and sodium hydroxide were purchased from Shanghai Reagents Co. Ltd. (Shanghai, China). The running buffer solution of 50 mmol/L H_3BO_3–12.5 mmol/L $Na_2B_4O_7$–20 mmol/L SDS was prepared by dissolving above reagents in Milli-Q water. All solutions were treated with ultrasonic agitation and filtered through a 0.22 μm membrane filter before use. All experiments were performed at room in which the temperature was regulated in 23–25 °C by air conditioners, and water used in this experiment is Milli-Q water (18.2 MΩ).

Dried *M. arenaria Linnaeus* sample, a marine bivalve molluscs, was offered by The Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences. Dried *C. fluminea* sample, a species of fresh water clam, was purchased in local market. All samples were lyophilized and grinded into powder, and then were stored in a desiccator.

2.2. CE–ICP-MS system

The CE–ICP-MS system used in this study is the same as that reported in our previous paper, which consists of a home-made CE unit and an Agilent 7500ce ICP-MS system (Agilent Technologies, USA) [28]. The home-made CE was coupled to ICP-MS with a home-made interface. Sample solution was injected into CE–ICP-MS for determination with electro-migration injection. The CE capillary was conditioned daily by purging with Milli-Q water for 10 min, 0.1 mol/L NaOH solution for 10 min, Milli-Q water for 10 min and running buffer solution for 10 min, respectively. Between each run, the CE capillary was flushed with Milli-Q water and running buffer solution for 2 min, respectively.

2.3. Determination of TMT, TET, TPT and TBT in dried M. arenaria Linnaeus and C. fluminea

OTCs in dried *M. arenaria Linnaeus* and *C. fluminea* was extracted with the modified method of Wang et al. [11]. Firstly, about 0.2 g sample was accurately weighed and put into a 15 mL polyethylene centrifuge tubes, and 4.0 mL of methanol solution was added. Then, the tube was put into a 250 mL beaker in which has 100 mL water and the beaker was put into microwave digester (Sineo Microwave Chemical Technology Co. Ltd., Shanghai, China). The microwave system was programmed to heat the whole at 90 °C for 3 min under 500 W power. After the whole in the centrifuge tube was cooled to room temperature, the extract was separated by filtering it through a 0.22 μm membrane filter. Then, the extract was evaporated to near dryness using moderate N_2 stream and the residue was diluted to the appropriate volume (12.0 mL for *M. arenaria Linnaeus* and 2.0 mL for *C. fluminea*) with buffer solution again. The final solution was used for the CE–ICP-MS analysis with continuous sample-introduction mode.

3. Results and discussion

3.1. The optimum CE–ICP-MS conditions for the separation and detection of TMT, TET, TPT and TBT

In CE-based analysis, the buffer solution including its chemical components, pH and concentration greatly affected the separation of analytes by affecting the electroosmosis flow (EOF). In this study, we firstly try to separate TMT, TET, TPT and TBT with CZE (capillary zone electrophoresis), and several different buffer solutions including HAc–NaAc, H_3PO_4–NaH_2PO_4, NaH_2PO_4–$Na_2B_4O_7$, H_3BO_3–$Na_2B_4O_7$, strong inorganic acid and tartaric acid were used to separate TMT, TET, TPT and TBT. The experimental results showed that TET, TPT and TBT can not be completely separated under each of above buffer solution by CZE. It was reported that micelle capillary electrophoresis has many advantages for the separation of OTCs [29]. In this study, we also try to separate TMT, TET, TPT and TBT with micelle capillary electrophoresis by adding different surfactant such as SDS and sodium cholate into each of above buffer solution. The experimental results showed that TMT, TET, TPT and TBT can be completely separated when the H_3BO_3–$Na_2B_4O_7$ solution ($H_3BO_3/Na_2B_4O_7$ = 4/1, mole concentration) containing a 10 mmol/L SDS (critical micellar concentration of SDS) was used as buffer solution. Therefore, the H_3BO_3–$Na_2B_4O_7$ solution (4:1, mole concentration) containing a certain concentration of SDS was chosen as running buffer solution in this study.

The effect of the concentration of SDS on the separation and migration time of TMT, TET, TPT and TBT was studied in range of 10–40 mmol/L at 50 mmol/L H_3BO_3–12.50 mmol/L $Na_2B_4O_7$ buffer solution (pH 8.0) in detail, and the results indicated that higher concentration of SDS is favorable to prolong the migration time of all four triorganotin compounds and improve the electrophoretic resolution (see Fig. 1), however, higher concentration also increased background. Considered all of analytical time, background and resolution, 20 mmol/L was selected as the optimal SDS concentration.

The pH of the running buffer solution strongly affects the electrophoretic resolution and sensitivity. The relationship between migration time/resolution and pH was studied in detail with a 50 mmol/L H_3BO_3–12.5 mmol/L $Na_2B_4O_7$–20 mmol/L SDS buffer solution in the range of 7.50–8.50, and the results are shown in Fig. 2. From Fig. 2, we found that higher pH is favorable to improve the separation of TPT and TBT, TPT and TBT can be base line separated when pH is higher than 7.75. However, when pH is higher than 8.5, TMT and TET can not be completely separated. The electropherogram shown in Fig. 2 indicated that all four triorganotin

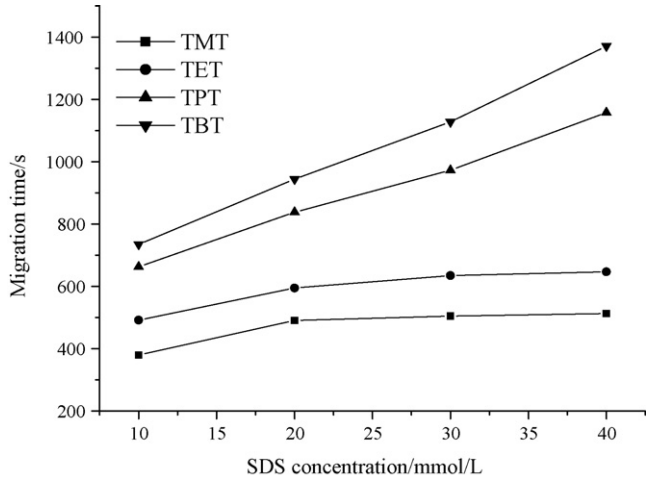

Fig. 1. The effect of SDS concentration on the separation of TMT, TET, TPT and TBT. The data was obtained by determining a 100 ng/mL mixed solution of TMT, TET, TPT and TBT with CE–ICP-MS under conditions of Table 1 except SDS concentration.

compounds can be base line separated with symmetrical peak shape when pH was in range of 7.75–8.25. Finally we chose pH 8.00 as the optimum pH for the separation of TMT, TET, TPT and TBT.

The effect of the concentration of running buffer solution on the separation and migration time was studied by using different concentration of H_3BO_3–$Na_2B_4O_7$ solution (H_3BO_3:$Na_2B_4O_7$ = 25.0:6.25, 37.5:9.38, 50:12.50, 75:18.75 and 100:25.00 mmol/L) containing 20 mmol/L SDS at pH 8.00 and +15 kV voltage, and the results are shown in Fig. 3A. From Fig. 3A, we found that the migration times of all four triorganotin compounds became longer with the increase of the concentration of H_3BO_3–$Na_2B_4O_7$ solution, however, higher concentration also led to a higher current and finally resulted in a bigger noise and a poorer reproducibility. The experimental results showed that when 50 mmol/L H_3BO_3–12.50 mmol/L $Na_2B_4O_7$ containing 20 mmol/L SDS (pH 8.00) was used as running buffer solution, the resolution and the peak shapes of four triorganotin compounds were the best. Therefore, 50 mmol/L H_3BO_3–12.50mmol/L $Na_2B_4O_7$ containing 20 mmol/L SDS (pH 8.00) was selected as the running buffer solution.

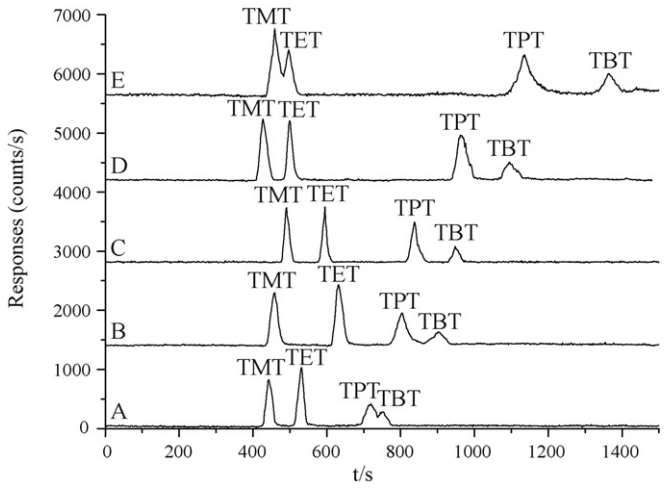

Fig. 2. The electropherograms of TMT, TET, TPT and TBT under different pH. The data was obtained by determining a 100 ng/mL mixed solution of TMT, TET, TPT and TBT with CE–ICP-MS under conditions of Table 1 except pH. (A) pH 7.50; (B) pH 7.75; (C) pH 8.00; (D) pH 8.25; and (E) pH 8.50.

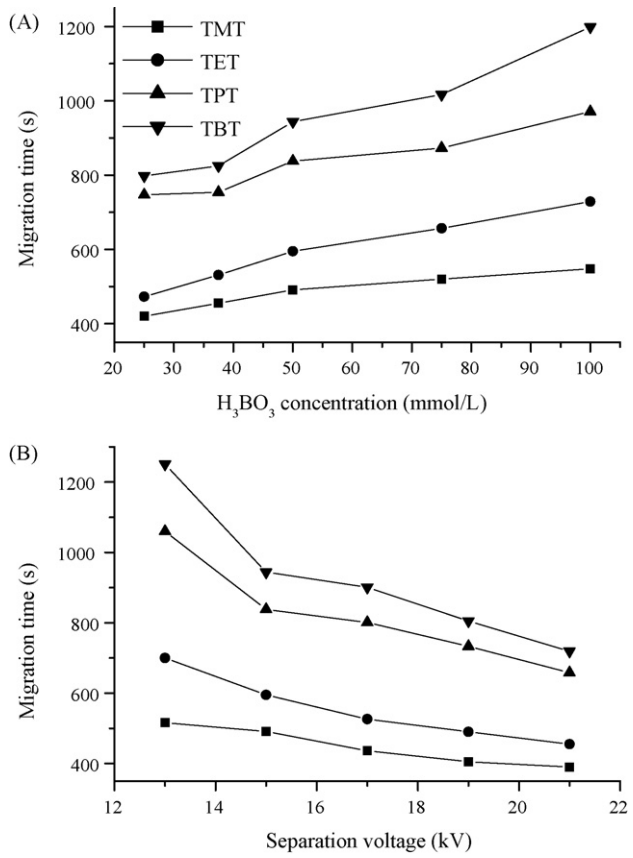

Fig. 3. The effect of buffer solution concentration and separation voltage on the separation of TMT, TET, TPT and TBT. The data was obtained by determining a 100 ng/mL mixed solution of TMT, TET, TPT and TBT with CE–ICP-MS under conditions of Table 1 except buffer solution concentration (A) and separation voltage (B). (A) Buffer solution concentration and (B) separation voltage.

The effect of the separation voltage on the migration time and electrophoretic resolution was investigated in the range of 13–21 kV, the results indicated that higher voltage is favorable to shorten the migration time, improve the sensitivities and the peak shapes (especially for TPT and TBT) (see Fig. 3B). However, higher voltage led to poorer reproducibility due to Joule heating effect. Considered all of reproducibility, analytical time and peak shape, +15 kV was selected as the separation voltage.

Different injection times (5, 10, 15, 20 and 25 s) were tested in this experiment, and the results showed that the sensitivities of four triorganotin compounds become higher with the increase of injection time. However, longer injection time will degrade electrophoretic resolution and broaden the peaks. Considering both sensitivity and separation efficiency, we selected 10 s as sample's injection time.

As we mentioned in our previous paper [28], the flow rate of pump 1, which was used to transport the analyte solution eluted out of the CE capillary to three-way PEEK and introduce a tiny sheath-flow into the outlet of CE capillary, will influence the peak shape and the sensitivity. By change the rate of pump 1 from 1.5 rpm (3 μL/min) to 7.5 rpm (15 μL/min), we found that 6.0 rpm of pump 1 (12 μL/min) provide a better peak shapes and sensitivity. The optimum rate of pump 2, which was used to pump Milli-Q water to ICP-MS nebulizer in order to achieve stable atomization and ionization efficiency, was selected by change the rate from 0 rpm (0 μL/min) to 10.0 rpm (400 μL/min), and the results showed that the flow rate of pump 2 = 5.0 rpm (200 μL/min) is the best choice.

At above optimum CE–ICP-MS conditions (see Table 1), four triorganotin compounds were completely separated within 17 min,

Table 1
Optimal running parameters of CE–ICP-MS.

Parameter	Value
CE voltage	+15 kV
Sample injection time	10 s
CE capillary	i.d. 75 μm; o.d. 365 μm; 60 cm long
Lab temperature	23–25 °C
Running buffer solution	50 mmol/L H_3BO_3–12.5 mmol/L $Na_2B_4O_7$ (pH 8.0) containing 20 mmol/L SDS
Flow rate of pump 1	12 μL/min
Flow rate of pump 2	200 μL/min
RF power	1300 W
Outer plasma gas	15 L/min
Intermediate plasma gas	0.90 L/min
Carrier gas	0.75 L/min
Makeup gas	0.30 L/min
Monitored isotope (m/z)	^{118}Sn, ^{120}Sn
Nebulizer type	MCN (optimum flow is 50–200 μL/min)

and their electropherograms are shown in Fig. 4 together with the electropherogram of reagent blank.

3.2. Reproducibility, linear relationship and detection limits

At the optimal CE–ICP-MS conditions shown in Table 1, the determination of 100 ng/mL mixed standard solution was repeated for six times in order to investigate the reproducibility of our method. The RSD ($n = 6$) of migration time was calculated to be 1.3%, 2.1%, 2.2% and 3.2% for TMT, TET, TPT and TBT, respectively, and that of peak area is 3.4%, 4.2%, 4.4% and 5.8% for TMT, TET, TPT and TBT, respectively. A series of different concentrations of mixed standard solutions (10, 20, 30, 50, 75, and 100 ng/mL) were determined in order to obtain calibration curves. The linear correlation coefficients between counts (peak area) and concentrations were better than 0.995 for all TMT, TET, TPT and TBT in the concentration range of 10–100 ng/mL (see Table 2). The instrument detection limits ($3\sigma/S$, the concentration necessary to yield a net signal equal to three times the standard deviation of the background) were calculated to be 0.2, 0.2, 0.3 and 0.7 ng/mL for TMT, TET, TPT and TBT, respectively, much lower than those obtained with other CE-based techniques [22,24].

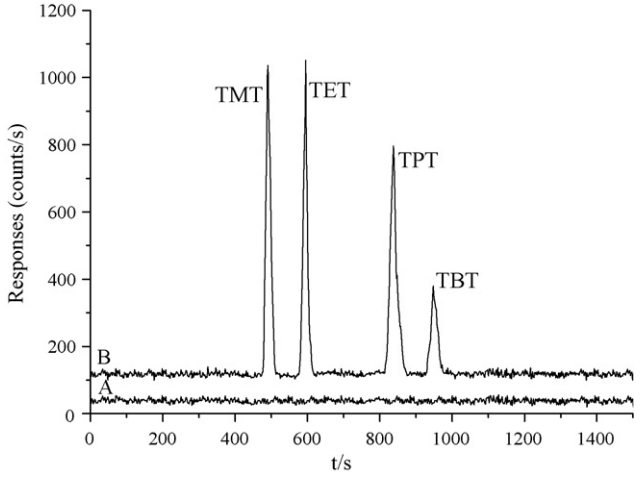

Fig. 4. The electropherograms of TMT, TET, TPT, TBT under the optimal CE–ICP-MS conditions shown in Table 1. The data was obtained by determining a 100 ng/mL mixed solution of TMT, TET, TPT and TBT and a reagent blank with CE–ICP-MS, respectively. (A) Blank and (B) mixed standard solution.

Table 2
Linear relationship and detection limits of our method.

Analyte	Regression equation[a]	Correlation coefficient	Liner range (ng/mL)	Detection limit[b] (ng/mL)
TMT	$y = 1133x + 301$	0.998	10–100	0.2
TET	$y = 1080x + 251$	0.997	10–100	0.2
TPT	$y = 923x + 337$	0.995	10–100	0.3
TBT	$y = 380x + 272$	0.996	10–100	0.7

[a] x = concentration (ng/mL), y = counts.

3.3. The extraction of triorganotin compounds in M. arenaria Linnaeus and C. fluminea samples

To perform the speciation analysis of triorganotin compounds in aquatic organisms, the extraction of each triorganotin is another key point. The extraction method must be capable of quantitatively extracting each triorganotin species from samples without altering the individual organotin species during extraction process. So far, several kinds of organic solvent such as toluene, acetic acid–methanol, methanol–water have been used to extract OTCs in environmental and biological materials [11,30,31] and microwave-assisted extraction was reported to be an effective method for element species in marine plant and animal tissues [11,32]. Considering that methanol has a good solubility for all of TMT, TET, TPT and TBT and has a lower toxicity than toluene, in this study, a microwave-assisted extraction with methanol as solvent was used to extract triorganotin compounds in *M. arenaria Linnaeus* and *C. fluminea*. The effect of extracting temperature on the extracting efficiency was also investigated in 70–100 °C with *M. arenaria Linnaeus* as target, and the results showed that microwave-assisted extraction have a highest and most stable extracting efficiency in 90–100 °C (see Fig. 5). In this study, we selected 90 °C as the optimum temperature.

The power of microwave digester, ratio of extracting solvent volume to the mass of sample and extracting time are also important factors for the extraction of OTCs. In our experiments, a 500 W microwave digester was used for the extraction, and the effect of power on the extracting efficiency was not studied in detail since the power of microwave digester cannot be adjusted. The ratio of extracting solvent volume to the mass of sample was also optimized in this study, and the experimental result showed that the best ratio was 20. Higher ratio will increase the background of reagent blank and harm the detection limit of the method, whereas, lower

[c] Unit is μg Sn/g dried weight.
[d] $n = 6$.

ratio will decrease the extracting efficiency of TMT, TET, TPT and TBT. Under 90 °C, 500 W and 20 times of solvent, OCTs in the dried *M. arenaria Linnaeus* and *C. fluminea* can be completely extracted within 3 min.

3.4. Determination of TMT, TET, TPT and TBT in dried M. arenaria Linnaeus and C. fluminea samples

In order to verify the reliability of our methods, the TMT, TET, TPT and TBT in dried *M. arenaria Linnaeus* and *C. fluminea* were extracted by the above method and their concentrations were determined with CE–ICP-MS under the conditions of Table 1. The analytical results are shown in Table 3 and their electropherograms are shown in Fig. 6.

The recoveries were also obtained by determining dried *M. arenaria Linnaeus* samples spiked with 3.0 μg Sn/g dried weight of TMT, TET, TPT and TBT and dried *C. fluminea* samples spiked with 0.50 μg Sn/g dried weight of TMT, TET, TPT and TBT with the same procedure described as above. The recoveries are also shown in Table 3 together with RSD. From Table 3, we found that the recovery is 93–104% and RSD ($n = 6$) is smaller than 5% for all four triorganotin compounds.

It was well known, if all OTCs in samples were completely extracted and if each triorganotin species keep no change during extraction process are two key points to the speciation analysis of triorganotin. From the results shown in Table 3, we found that the sum of the concentrations of each triorganotin species is consistent with the total concentration of tin (the concentration determined with ICP-MS after sample was completely decomposed with 7 mol/L HNO_3), indicated that all tin had been completely extracted using our method. The approximately 100% of recovery for all TMT, TET, TPT and TBT obviously indicated that each triorganotin species kept no change during extracting and analytical process, since the recovery of at least one triorganotin species should excessively deviated from 100% if any triorganotin species was changed during extracting and analytical process. The detection limits of analytes in samples can be calculated according to the detection limits of instrument and the preconcentration times of sample. In the case of dried *M. arenaria Linnaeus* and *C. fluminea*, 2 mL extracting solution of 0.2 g sample can be directly analyzed using our method without any pretreatment, therefore the method detection limits of each triorganotin in dried *M. arenaria Linnaeus* and *C. fluminea* were calculated to be 2.0, 2.0, 3.0 and 7.0 ng Sn/g dried weight (or 0.2, 0.2, 0.3 and 0.7 ng Sn/g fresh weight) for TMT, TET, TPT and TBT, respectively, equal to those obtained with GC-based technique [33]

From the electropherograms shown in Fig. 6, it was clearly found that TBT was detected in dried *M. arenaria Linnaeus*, and TMT was detected in dried *C. fluminea*. It was well known that TBT was deadly toxic to bivalve molluscs [34]. Zhou et al. reported that *M. arenaria Linnaeus* may have stronger ability to accumulate or lower rate to metabolize TBT than other marine organisms, and can become a more sensitive bio-monitor to effectively evaluate tributyltin con-

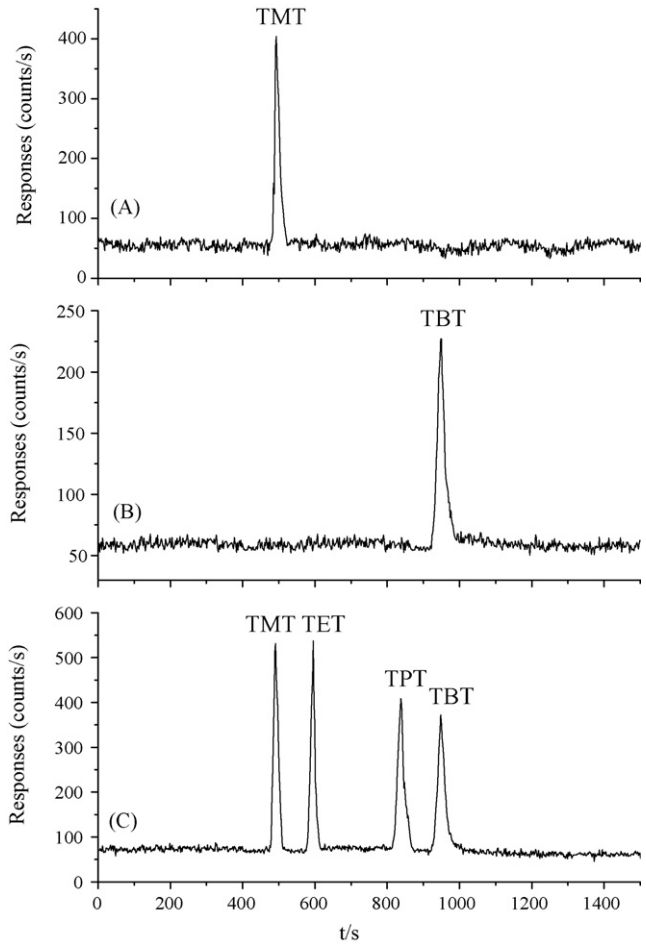

Fig. 6. The electropherograms of TMT, TET, TPT and TBT under the optimal CE–ICP-MS conditions shown in Table 1. (A) *Corbicula fluminea*; (B) *Mya arenaria Linnaeus*; and (C) *Mya arenaria Linnaeus* spiked with 3.0 μg Sn/g dried weight of TMT, TET, TPT and TBT.

tamination in ocean [35]. Our results also verified that *M. arenaria Linnaeus* had a much higher accumulation for TBT, the concentration of TBT in dried *M. arenaria Linnaeus* up to 5.1 μg Sn/g dried weight or 510 ng Sn/g fresh weight. While, no TBT was detected in *C. fluminea*, the major triorganotin species in *C. fluminea* was TMT and the concentration of TMT in dried *C. fluminea* was about 0.43 μg Sn/g dried weight or 43 ng Sn/g fresh weight.

According to the average seafood consumption (68.8 g/day, FAO, 1997–1999), the tolerable average residue level (TARL) for TBT in Chinese seafood was estimated to be 90.8 ng Sn/g for a common person with a weight of 60 kg [36]. The 510 ng Sn/g fresh weight of TBT in *M. arenaria Linnaeus* was much higher than TARL, implied that some people with *M. arenaria Linnaeus* preference may be at a high risk to organotin exposure. As for *C. fluminea*, the content of OTCs is much lower than TARL, and its predominant OTC was TMT. The potential danger of *C. fluminea* to the consumers should be further investigated.

4. Conclusion

An effective microwave-assisted extraction used to extract trace triorganotin compounds in aquatic organisms and a sensitive analytical method for the determination of ultratrace TMT, TET, TPT and TBT with CE–ICP-MS were firstly described in the study. The extraction method is simple, effective and can be used to extract trace triorganotin compounds in aquatic organisms with a satisfactory recovery within several minutes. The CE–ICP-MS analytical method have a much lower detection limit of 0.2–0.7 ng Sn/mL for TMT, TET, TPT and TBT, and can be used to simultaneously determine trace TMT, TET, TPT and TBT in aquatic organisms directly without any derivatization and preconcentration. With the help of above extraction and analytical method, we have successfully determined TMT, TET, TPT and TBT in dried *M. arenaria Linnaeus* and *C. fluminea* with detection limits of 2–7 ng Sn/g dried weight, RSD ($n = 6$) of 2–5% and recovery of 93–104%. About 5.1 μg Sn/g dried weight of TBT was detected in dried *M. arenaria Linnaeus*, whereas only about 0.43 μg Sn/g dried weight of TMT was detected in dried *C. fluminea*, indicating that *M. arenaria Linnaeus* is a good biomarker for TBT.

Iodine-adlayer
Palladium modified electrode
Anodic stripping

ABSTRACT

The self-assembled iodine-adlayer was fabricated at the palladium (Pd) electrode surface throughout a spontaneous oxidative chemisorption of iodide ions contained in an alkaline supporting electrolyte. It enhances the electron transfer kinetics for the oxidation of dopamine (DA) and ascorbic acid (AA) and was important to separate the peak current of both species with a practical potential difference compared with that occurred at the unmodified electrode. The anodic peak currents of both species were linearly increased with their respective concentrations using linear square stripping voltammetry. The activity of the electrode system was further investigated applying chronoamperometry method. The steady–state amperometric signal for the oxidation of DA in the presence of iodide ions was five times greater than that in its absence. The current–time response was also used to evaluate the diffusion coefficient of DA based on Cottrell plot that results with a value of 4.19×10^{-8} m^2 s^{-1}. The proposed method was successfully applied to detect DA and AA in human serum.

1. Introduction

The determination of DA and AA in biological fluids of humans is important in clinical analysis. The concentration of DA in the fluids of brain tissues is in the range of 10–1000 nmol L^{-1} [1,2], while the concentration of AA in biological systems is as high as 100 μmol L^{-1} [3]. Both species are vitally related to the diagnosis of various kinds of diseases. For instance, abnormal levels of DA are diagnostic to Parkinson's disease, Schizophrenia and neuroendocrine disorder [4–6]. Similarly, the content of AA in biological samples has been taken as an index for oxidative stress in human metabolism [7,8] which is related to cancer and hepatic disease.

Electrochemically, both compounds are active and known to be oxidized at very close potentials at most unmodified electrodes causing a great interference, unselective identification and poor current peak separation [9,10]. In order to address such a problem, considerable efforts have been devoted including surface modification of electrode substrates with conducting polymeric films [11–15], self-assembled monolayer films [16–18], electrodes based on ion exchange membrane coated film [4,19–22] and composite electrode based on methylene blue entrapped in a sol–gel matrix film [23,24]. Also, nanomaterials have received considerable interest due to their remarkable physical and chemical properties. Therefore, many approaches were based on the fabrication of metal or metal oxide nanoparticles modified electrodes as biochemical sensors [25–30]. Others combined conducting organic polymers and inorganic porous metal oxides to form nanocomposite materials that showed unique mechanical and electrical properties [31,32] and used successfully for the above important applications.

Another area of interest concerning electrode modification is the formation of anion adlayer by oxidative chemisorptions. Of the various systems studied, halide adsorption (mostly bromide and iodide) on metal electrodes [33–36] has been of central significance in surface electrochemistry. The structure and the composition of the adsorbed layer were thoroughly characterized by many ex situ and in situ techniques such as low-energy electron diffraction (LEED) [37,38], scanning tunneling microscopy (STM) [39–42] and surface X-ray scattering (SXRS) [43,44]. Iodide is chemically stable anion forming a compact iodine-adlayer on electrode surface due to its strong adsorption affinity. Iodine-adlayer modified electrodes were employed successfully for numerous applications and studies such as catalytic anodic stripping of metallic films [45,46], catalytic oxidation of hydrogen peroxide [36] and uric acid [47], and test of the catalytic activity by active site blocking method [48].

In this work, the in situ fabrication of potentially dependent iodine-adlayer at Pd-electrode surface in alkaline solution assigned as (I_{ad}/Pd-modified electrode) is described and tested for electrochemical measurements of DA and AA.

2. Experimental

2.1. Reagents

All solutions were made from high purity chemicals prepared in Millipore water. A phosphate buffer solution (PBS) of 0.100 mol L^{-1} (pH = 7.28) was used to prepare the standard solutions of DA and AA (Aldrich–Chemie) as well as the serum sample. All electrochemical measurements were carried out in 0.100 mol L^{-1} sodium hydroxide (NaOH) solution at ambient temperature in the presence of 10 mM KI (BDH Limited Poole England). The electrolyte was degassed with stirring by purging oxygen-free nitrogen gas for 10 min and blanketed throughout the experiment.

2.2. Electrodes

The electrochemical measurements including cyclic voltammetry (CV), chronoamperometry (CA) and linear square stripping voltammetry (LSSV) experiments were conducted using a BAS 50W work station (Bioanalytical System, West Lafayette, IN, USA). The three electrode cell consisting of a Pd-electrode with geometric area of 0.0707 cm^2, a platinum coil with geometric area of 1.90 cm^2 and an $Ag/AgCl/KCl_{(sat.)}$ (Bioanalytical System, West Lafayette, IN, USA) were used as the working, counter and reference electrodes, respectively.

Prior to each experiment, the working electrode was polished using a polishing cloth and alumina slurry (5.0 and 1.0 μm), rinsed thoroughly with distilled water, ultrasonicated for 5 min using (JAC Ultra Sonic, 1505, LABKOREA INC, Korea) and finally rinsed with distilled water. The electrode was then pretreated electrochemically by scanning the potential reversibly between −400 mV and +1000 mV for 25 cycles at 100 mV s^{-1} and terminating at the anodic potential limit in PBS to establish a reproducible electrode surface and avoid any previous fouling effect.

The CV experiments were utilized mainly to study the electrode behavior in iodide containing solution and characterize the adsorption/desorption of iodine-adlayer by scanning the potential reversibly between +800 mV and −1000 mV at particular scan rates.

CA measurements were made by stepping the electrode potential from −500 mV to 0 mV over a range of pulse widths (2000–30,000) in milliseconds (ms). The last 50 digitized data points were averaged for each experiment and the mean value and standard deviation were also verified. In other separate experiments, the above anodic potential step was held for 20,000 ms at which the current had approached the steady-state value, averaged as above and collected as a function of [DA] in the presence and absence of KI solution.

For LSSV experiments, the electrode potential is scanned in one direction from −800 mV to +200 mV at 100 mV s^{-1} and the deposition time at the initial electrode potential was 60 s.

2.3. Treatment of the serum sample

The serum was obtained form the University Hospital. A 1.0 mL of the sample was mixed with 5.0 mL of methanol and then centrifuged (Centaur 2, MSE, UK) at 1500 rpm for 20 min. The supernatant was diluted for 4 times with 0.100 mol L^{-1} of PBS (pH = 7.28) before analysis. The contents of DA and AA in the serum were evaluated using the regression data obtained from the calibration plots (current density vs. concentration) of artificial samples.

3. Results and discussion

3.1. Chemisorption of iodide ions at palladium electrode

Fig. 1 shows the cyclic voltammograms obtained at Pd-electrode in alkaline solution in the absence (dotted line, scan rate = 100 mV s^{-1}) and the presence of 10 mmol L^{-1} KI solution (solid lines for a range of scan rates). The voltammogram in the absence of KI is characterized by the potential induced partial oxidative adsorption and reductive desorption of hydroxyl ions (OH^-) [49,50] observed at −450 and −380 mV vs. Ag/AgCl, respectively.

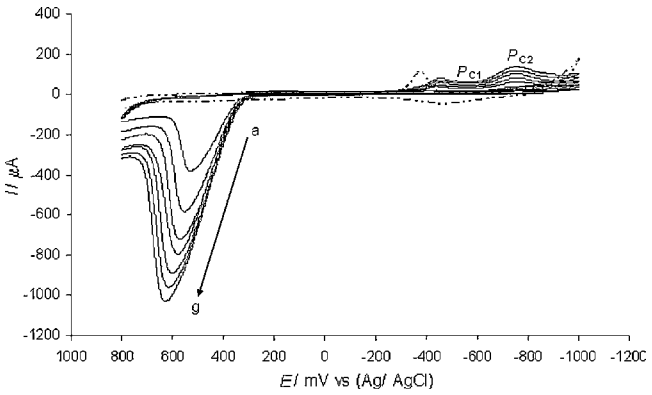

Fig. 1. Cyclic voltammograms at the unmodified electrode (dotted line, ν = 100 mV s^{-1}) and at the I_{ad}/Pd-modified electrode (solid lines) for a range of scan rates; (a) 25, (b) 50, (c) 75, (d) 100, (e) 150, (f) 200, and (g) 300 mV s^{-1}.

The presence of 10 mmol L^{-1} KI generates quite significant change in the cyclic voltammogram obtained in which a significant suppression of OH^- adsorption due to blocking of the Pd-electrode surface by preferential chemisorption of I^- ions [51]. Instead, a couple well-defined cathodic peaks assigned as P_{C1} and P_{C2} appeared at −430 and −770 mV vs. Ag/AgCl, respectively, corresponding to reductive desorption of iodine-adlayer that previously produced due to oxidative adsorption of strongly adsorbed I^- ions characterized by a sharp anodic peak obtained at +530 mV vs. Ag/AgCl (ν = 25 mV s^{-1} and shift to a more positive potential with increasing ν). It should be noted, that the structure and surface coverage of the iodine-adlayer were studied and characterized using different techniques and all agrees that it is potential dependent [34,48,52].

The position and less intensity of the reductive desorption peaks were obtained at extremely negative potential compared with that of the oxidative adsorption peak. This difference may be attributed to (i) reconstruction of the electrode surface structure since the surface coverage of adsorbed OH^- ions manipulate this kind of kinetic transition [53,54], and (ii) the presence of a competitive adsorption between OH^- and I^- species since the surface coverage of iodine-adlayer is pH-independent (because H^+ and OH^- ions are not involved in the adsorption step of I^-), while the adsorption of OH^- is pH− dependent. Accordingly, the kinetics of reductive desorption of iodine is expected to be sluggish and its peak potential shifted to a more negative value.

The couple reductive desorption peaks and the oxidative adsorption peak increases with ν as demonstrated in Fig. 1. The cathodic peak currents (P_{C1} and P_{C2}) were increased linearly with ν and extrapolated to the origin as shown in Fig. 2A indicating a surface confined process at which the cathodic reaction is associated with iodine-adlayer desorption. Similarly, a linear relationship was obtained for the plot of the anodic peak current as a function of the square root of scan rates ($\nu^{1/2}$) which also extrapolated to the origin as shown in Fig. 2B. Therefore, stepping the electrode potential to more positive value enhances the formation of iodine-adlayer (I^- ions adsorbed and potentially oxidized) where the electrode reaction is controlled mainly by mass transport process.

The deposition charge density, σ, in μC cm^{-2} of the adsorbed iodide ions was determined by integrating the area under the

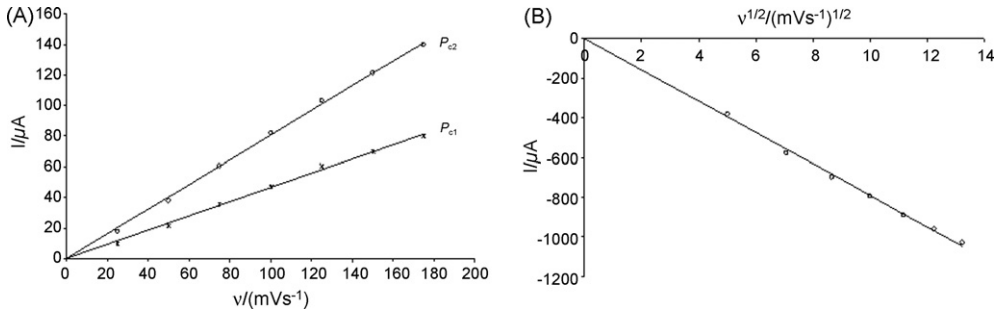

Fig. 2. (A) The cathodic peak currents (P_{C1} and P_{C2}) as a function of scan rate and (B) the dependence of anodic peak current on the square root of scan rates. Data collected from Fig. 1.

oxidative adsorption peak current, while the surface coverage of iodine-adlayer, Γ, was estimated to be 5.69×10^{-8} mol cm^{-2} applying the following equation:

$$\sigma = nF\Gamma \quad (1)$$

The number of electrons transferred during the deposition of iodine-adlayer was 1.96 calculated from the slope of the peak current (I_p) vs. (ν) (for the data presented in Fig. 1) using Eq. (2) [55,56].

$$I_p = \left(\frac{n^2F^2A\nu}{4RT}\right)\Gamma \quad (2)$$

The surface coverage of iodine-adlayer mean value was equal to 5.91×10^{-8} mol cm^{-2} applying Eq. (2) at different (ν) and considering (n = 2).

It should be noted that the present system was tested for electrolyte composition dependency, i.e. pH and the amount of KI. In acidic and neutral media, a deep yellow color was observed during the progress of catalysis which may be related to a partial solubilization (much faster in acidic medium) of iodine-adlayer in excess iodide ions to form tri-iodide ion (I_3^-). Also, it was found that the LSSV voltammetric signal for the oxidation of DA and AA increases with [KI] in the range 2–10 mmol L^{-1}, but approximately attains a steady value up to 16 mmol L^{-1}. Therefore, the electrode system for the present work is defined experimentally by dipping Pd-electrode in alkaline solution containing 10 mmol L^{-1} of KI as described above in Section 2.1.

3.2. Electrochemical oxidation of DA and AA at I_{ad}/Pd-modified electrode

Electrochemical measurements based on LSSV have been conducted instead of differential pulse voltammetry (DPV) for simultaneous determination of DA and AA. For the present system, DPV technique was found to posses a weak separation capability particularly at concentration lower than 10 μmol L^{-1}. At higher concentration levels, the voltammetric peak of AA splits as a peak shoulder on DA, thus the system demonstrating less sensitivity and weak resolution facility that can be utilized for analytical applications. Therefore, LSSV was selected as an alternative and sensitive technique for better resolution and deprive concurrent peak overlapping.

Fig. 3 demonstrates the electrochemical oxidation of an equivalent concentration (25 μmol L^{-1}) of both DA and AA at bare Pd-electrode in 0.100 mol L^{-1} NaOH solution using LSSV method. The anodic peak of both species appeared at approximately similar potential, viz. E_{DA} = −60 mV and E_{AA} = −83 mV, indicating a poor selective property at which the simultaneous determination of these species is prohibited. The narrow peak-to-peak separation as well as low current responses are practically referred to a weak and inactive electrochemical system. Apparently, the electrocatalytic surface of the unmodified system suffers interference process and slow electron transfer reaction. The nature of the electrode system and the electroactive species undergoes surface reaction may play the major role for such a trend. It should be noted that the oxidation of DA and AA is associated with the coadsorption of OH$^-$ ions which occurred at more negative potential (about −450 mV as shown in Fig. 1). Also, the surface coverage of the oxidative adsorption of OH$^-$ ions at the electrode surface is known to be potential dependent [57] which may promote a negatively charged film. It excludes and weaken the adsorption of negatively charged ascorbate ions (pK_a = 4.30) and hence the oxidation of AA occurs at a potential more positive than expected.

On the other hand, the cationic DA species (pK_a = 8.91) may experience a larger electrostatic attraction with the hydroxyl layer and hence produce a greater electrical signal. Apparently, the strong adsorption of cationic DA at the electrode surface may play a significant role in the inhibition process in addition to that caused by the adsorption of oxidation products.

Fig. 4A shows LSSV anodic current density in (μA cm^{-2}) for a range of [AA] at the I_{ad}/Pd-modified electrode. The peak current arises at about −168 mV vs. Ag/AgCl is linearly related to [AA] in the range 1.0×10^{-6} to 1.0×10^{-4} mol L^{-1}, resulting with the following regression data; slope = 6706.2 (±108.9) A cm mol^{-1}, intercept = 1.7760 (±0.5814) μA cm^{-2}, and R^2 = 0.9979. As can be seen from Fig. 4A, the anodic peak of AA increases significantly and shifts to a more negative potential, ca. 85 mV, compared with that typically obtained at the unmodified electrode. The electrode sensitivity and selectivity were improved with the simple modification of the electrode surface provided by the compact iodine layer. Increasing the current response of AA is associated with electrode kinetics in which the electron transfer process becomes more favored at the modified surface [27]. Also, the electrode surface modification decreases the chemisorption of OH$^-$ ions and hence eliminates electrostatic repulsion with anionic AA

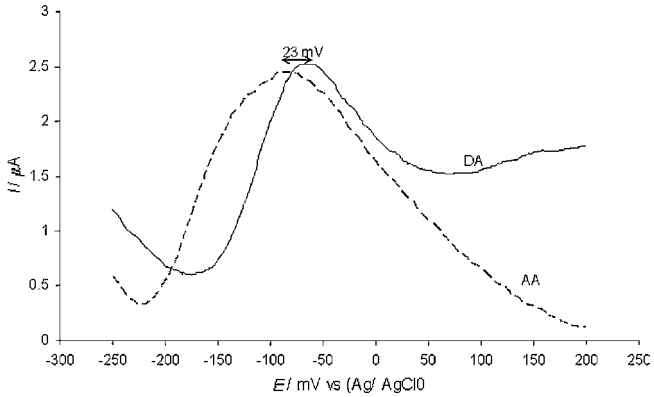

Fig. 3. LSSV curves of equivalent [DA] and [AA] at the unmodified Pd-electrode in (0.100 mol L^{-1}) NaOH solution (ν = 100 mV s^{-1}).

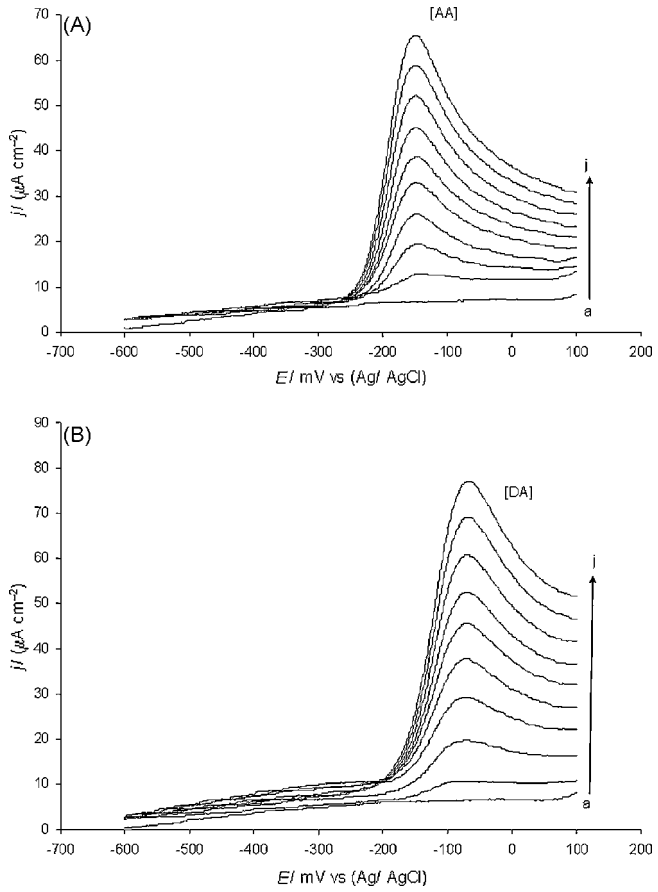

Fig. 4. LSSV curves for (A) AA and (B) DA at the I_{ad}/Pd-modified electrode as a function of their concentrations from (a to j); (0 μmol L^{-1}), (1 μmol L^{-1}), (2 μmol L^{-1}), (3 μmol L^{-1}), (4 μmol L^{-1}), (5 μmol L^{-1}), (6 μmol L^{-1}), (7 μmol L^{-1}), (8 μmol L^{-1}) and (9 μmol L^{-1}).

species that has been shown to occur at the unmodified electrode surface.

Similarly, Fig. 4B shows LSSV signals for the oxidation of DA at the modified electrode where the anodic peak current occurred at about −68 mV increases significantly and linearly with [DA] in the range 1.0×10^{-7} to 1.0×10^{-4} mol L^{-1}. The regression data for the linear relationship of the peak current as a function of [DA] are given by; slope = 8855.4 (±186.7) A cm mol^{-1}, intercept = − 1.6059 (±0.5719) μA cm^{-2}, and R^2 = 0.9955. The estimated slope ratio of DA to AA (S_{DA}/S_{AA} = 1.32) suggests that the modified electrode is relatively much sensitive towards DA than AA. The above trend can be attributed to the nature of iodine-adlayer during oxidative chemisorption which may present as atomic iodine bearing a partial negative charge [57]. The applied negative potential (relevant to the deposition potential conducted in this work by LSSV) promotes and stabilizes the negative charge of iodine-adlayer which has greater affinity for cationic DA and repels anionic AA species. When the electrode potential is stepped linearly to the positive region (typical for DA and AA oxidation), the iodine-adlayer may be considered as a neutral bearing no charge diminishing electrostatic attractions or/and repulsions with DA and AA. Therefore, the anionic AA species, which apparently has less adsorption affinity during the deposition time, becomes more accessible and adsorptive at the modified electrode surface resulting with a reasonable negative potential difference.

Moreover, the remarkable enhancement of the electrode activity towards the oxidation of DA and AA indicates that the electron transfer process is faster and much feasible at the modified electrode surface. It is important to elucidate that the electron transfer

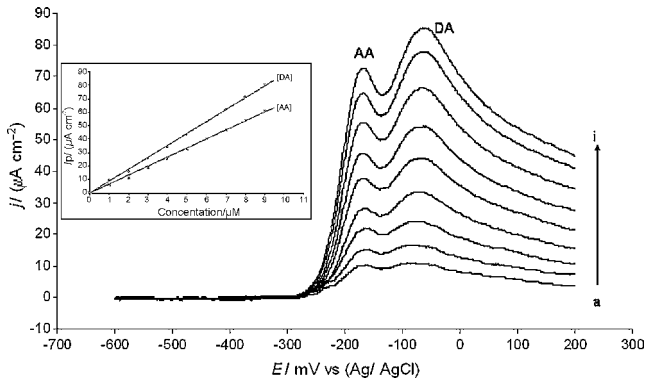

Fig. 5. LSSV curves for a binary mixture containing equal concentrations of DA and AA at the I_{ad}/Pd-modified electrode. Concentrations from (a to i); (1 μmol L^{-1}), (2 μmol L^{-1}), (3 μmol L^{-1}), (4 μmol L^{-1}), (5 μmol L^{-1}), (6 μmol L^{-1}), (7 μmol L^{-1}), (8 μmol L^{-1}) and (9 μmol L^{-1}). Insert shows the calibration curves for DA and AA.

process is occurred at the iodine-adlayer/electrolyte interface rather than at the electrode substrate surface for the following reasons; (i) the formation of a stable and compact iodine-adlayer at relatively large anodic potentials in the presence of high [I^-], (ii) the iodine-adlayer is very thin and free of pinhole [36], thus not accessible by the large cationic DA (or anionic AA) species. Therefore, the mutual electron transfer kinetics is believed to take place by the electron tunneling through the iodine-adlayer to the Pd surface [58]. Accordingly, the most feasible active site for the present electrochemical system is characterized mainly by the iodine-adlayer/electrolyte interface.

3.3. Simultaneous determination of DA and AA

To further investigate the applicability of the system for simultaneous determination of both analytes in a mixture, LSSV was employed to record the anodic peak under conditions similar to those described above. Fig. 5 depicts the simultaneous determination of a binary solution containing equal concentrations of DA and AA species at the I_{ad}/Pd-modified electrode. A well-defined two voltammetric peaks at potentials −170 and −65 mV, corresponding to the oxidation of AA and DA, respectively, are resolved and increased simultaneously as a function of species concentration. The anodic peak current of DA and AA arises at potentials fairly similar to those observed in the individual analysis indicating that the electron transfer process incorporated with the oxidation of each species is not altered by the presence of the other. Moreover, the electrode fouling due to adsorption of oxidation products such as DA-semiquinone from DA or/and dehydroascorbate from AA [59] was negligible and has no major effect on the activity of the modified electrode even at relatively high concentrations of DA and AA.

The regression data of the linear relationship between the peak current as a function of species concentration along with the estimated detection limit (DL) were collected and presented in Table 1. The system maintained the same sensitivity towards DA even in the presence of AA which can be evaluated by means of the slope

Table 1
Analytical parameters and regression data obtained from the plot of peak current against [DA] and [AA] in their binary mixtures.

Species	Slope (A cm mol^{-1})	Intercept (μA cm^{-2})	R^2	DL (3σ) (μmol L^{-1})
DA[a]	9613.1	−1.8292	0.9934	0.57
AA[b]	7258.1	−1.6664	0.9947	0.69

[a] Linear range between 1.0×10^{-6} and 5.0×10^{-5} mol L^{-1}.
[b] Linear range between 1.0×10^{-6} and 1.0×10^{-4} mol L^{-1}.

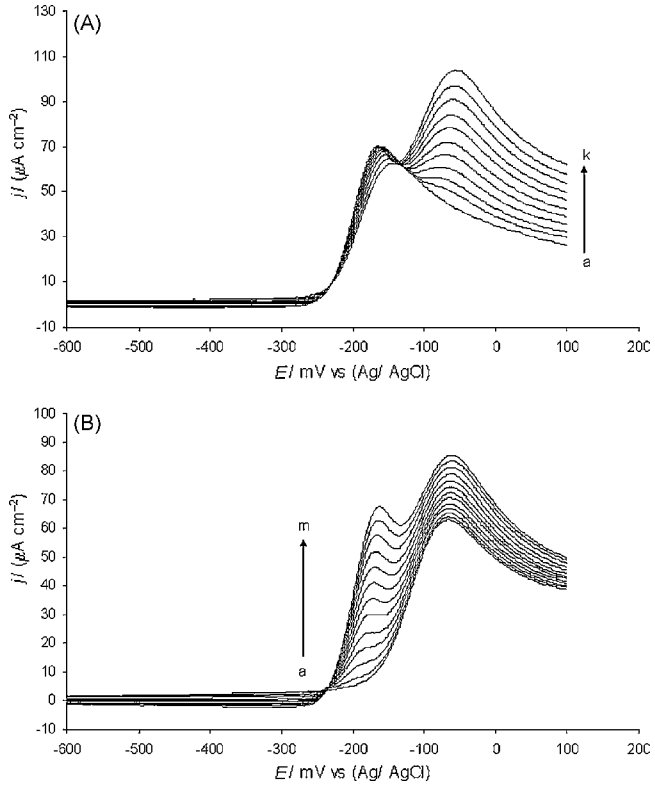

Fig. 6. LSSV curves for the selective determination of (A) DA in the presence of (100 μmol L^{-1}) of AA as a function of [DA]; (a) (0 μmol L^{-1}) increases by (1 μmol L^{-1}) each time to a final (k) (10 μmol L^{-1}). (B) AA in the presence of (100 μmol L^{-1}) of DA as a function of [AA]; (a) (0 μmol L^{-1}) increases by (1 μmol L^{-1}) each time to a final (m) (12 μmol L^{-1}).

value differences of both species. Moreover the slope ratio (DA/AA) obtained by this experiment is equal to 1.32 similar to that evaluated by experiments of individual samples given above. This may reveal a high sensitivity, selectivity and stability of the present system at the above applied concentration range. In a similar electrolytic system using poly crystalline gold electrode, it was found that the peak potentials of uric acid (UA) and AA were well separated. The current responses of both species were also highly reproducible and the system was greatly stable due to the presence of the compact iodine-adlayer.

The stability of the electrode was checked by repeating the electrolysis of sample containing 50 μmol L^{-1} of both species for 12 times at 5 min interval. The peak-to-peak separation was successfully maintained indicating a good stability of the iodine-adlayer. The current variation was estimated mathematically and found to be 4.3% suggesting that the electrode reactivity is not affected critically by the adsorption of analytes or their oxidation products.

3.4. Selective determination of individual component in the presence of a fixed concentration of the other

Fig. 6A depicts the determination of DA in the presence of 100 μmol L^{-1} AA at I_{ad}/Pd-modified electrode using LSSV method. The current response for the oxidation of DA increases with increasing [DA] disregard of interfering tendency that may come up by the presence of large [AA]. Furthermore, the peak current of DA is well separated and occurred as close as to −60 mV, while the peak current for the oxidation of AA arose with no significant change in its intensity. The above experimental data indicates that the working system is able to measure selectively DA at sub-micro-molar levels in the presence of high [AA], mimicking situation in biological fluids.

Table 2
Analytical parameters and recovery percentage (n = 3) for AA and DA species in the serum sample using standard addition method and regression data obtained by Fig. 4A and B, respectively.

	(j) (μA cm^{-2})	[Actual] (μmol L^{-1})	[Found] (μmol L^{-1})	Recovery (%)
AA				
(1)	15.3	2.50	2.55	102
(2)	31.5	5.00	4.96	99
(3)	48.0	7.50	7.42	99
DA				
(1)	16.8	2.00	2.08	104
(2)	34.6	4.00	4.09	102
(3)	52.5	6.00	6.11	102

The same trend can be seen also in Fig. 6B, where the peak current of AA increases with increasing [AA] in the presence of 100 μmol L^{-1} DA. The peak potential of both species unchanged and occurs at the same potential for the one of pure solution containing only AA or DA shown in Fig. 4A and B, respectively. One important point to be addressed here is the slight increase in the current response of DA with increasing [AA]. It might be explained due to convolution of DA peak current with the electrical signal obtained by AA oxidation which occurred at potential more negative than that of DA. Therefore, deconvolution process would be imperative to correct the peak intensity and gain much accurate analysis [60].

For the present electrolytic system, the presence of AA has no major interference property that may catalyze DA oxidation to some extent as described for other modified systems [61,62] since the electrode sensitivity, i.e. the slope ratio, sustained approximately a similar value as that obtained in the individual and mixture analysis described above. Also, such an assumption should be associated with a decrease in the anodic current of AA (which is not observed here) as long as some of AA is consumed to reduce the oxidized form of DA (DA-semiquinone) into DA.

According to the above results, it is believed that the I_{ad}/Pd-modified electrode can be effectively employed for the electrochemical measurements of trace amounts of either DA or AA in the presence of high concentrations of the other species.

3.5. Determination of individual component in real samples

The electrode system was applied for the determination of AA and DA in real samples such as human serum. The pretreated sample was injected in the alkaline iodide solution contained in an electrochemical cell with a dilution ratio of 100 times. The LSSV voltammogram show nil detection for AA and DA species. A standard addition method was applied to measure the [AA] and [DA] using the above method while the regression data obtained in Fig. 4A and B were used to calculate the recovery percentage of both species, respectively.

The electrode system recovers excellently all spikes of both species as described in Table 2 achieving a higher sensitivity and selectivity.

3.6. Amperometric analysis

The catalytic activity of the electrode system towards the oxidation of DA was further investigated using CA technique. The steady-state current responses recorded as a function of [DA] or pulse width has been achieved according to the experimental conditions described above in Section 2.2. Fig. 7 shows the anodic current responses for the oxidation of 50 μmol L^{-1} DA

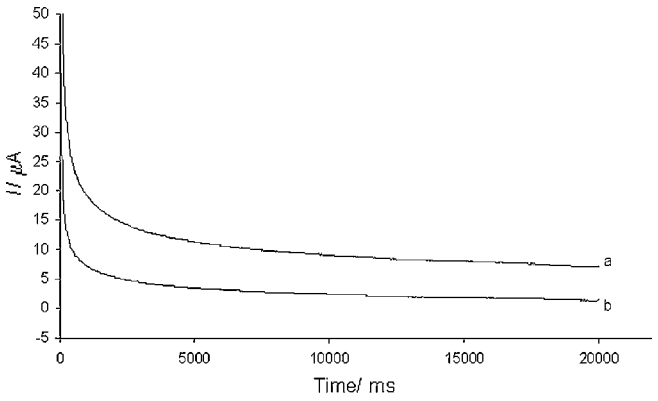

Fig. 7. The current–time responses for the oxidation of (50 μmol L^{-1}) DA obtained at 0.0 mV in the presence (a) and absence (b) of (10 mmol L^{-1}) KI solution.

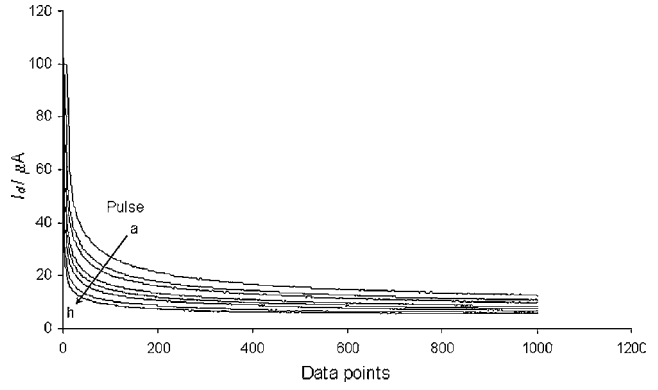

Fig. 8. The steady-state diffusion currents obtained at the I_{ad}/Pd-modified electrode in the presence of (50 μmol L^{-1}) DA as a function of pulse widths: (a) 2, (b) 4, (c) 6, (d) 8, (e) 10, (f) 12, (g) 20 and (h) 30 s.

in 0.100 mol L^{-1} NaOH in the presence (a) and absence (b) of 10 mmol L^{-1} KI solution. The observed current in the presence of iodide ions is significantly five times greater than in its absence. This suggests that the formation of iodine-adlayer at the electrode surface enhances the catalytic oxidation of DA. Moreover, the above method is used successfully to study the electrode reaction under diffusion control process by recording the current–time response for a range of pulse widths at constant species concentration.

The diffusion current (I_d) given by Eq. (3) as a function of electrolysis time can be used to evaluate the diffusion coefficient of DA (D_{DA}).

$$I_d = \frac{nFD^{1/2}C}{\pi^{1/2}t^{1/2}} \quad (3)$$

Equation (3) is known as the Cottrell equation [55] where the plot of (I_d vs. $t^{-1/2}$) must be linear and extrapolated to the origin. Fig. 8 demonstrates the current–time response in the presence of 50 μmol L^{-1} DA, where the anodic diffusion current decays to a lower value with electrolysis time consistent with the form of Cottrell equation. The Cottrell plot was linear with a positive slope resulting with D_{DA} value equals to 4.19×10^{-8} m^2 s^{-1}.

4. Conclusions

A chemically modified electrode was fabricated via the in situ formation of iodine-adlayer at the Pd-electrode surface in alkaline solution containing iodide ions. The modified electrode exhibited a high electrocatalytic activity towards the oxidation of DA and AA. The anodic peak currents of both species in their (1:1), (100:1) or/and (1:100) mixtures were well separated and increased linearly with the respective concentration of each species. Interference effect due the presence of one species at concentration 100 times greater than the other was not practically observed. Also, electrode fouling due to the accumulation of oxidation products was not identified as the electrode system sustain good activity and stability even at high initial concentrations of both species. The present system may be utilized for developing biological sensors to detect DA at sub-nano-molar levels in the presence of other physiological species using microelectrodes. Moreover, the construction of bromine-adlayer modified electrode is another area of research that may produce advantageous results for the above task.

HPLC
Multivariate optimization

ABSTRACT

A reversed-phase dispersive liquid–liquid microextraction (RP-DLLME) method was developed for the preconcentration and direct HPLC determination of oleuropein in olive's processing wastewater (OPW) and olive leaves extracts. In conventional DLLME, the sedimented phase is a micro-drop of a chlorinated organic solvent that is not compatible with RP-HPLC. Therefore, solvent evaporation and reconstitution with an appropriate solvent is often required. In RP-DLLME, this problem was overcome by overturning the solvent polarity in the ordinary DLLME and replacing the organic solvent with water. A central composite chemometrics design was used for multivariate optimization of the effects of five different parameters influencing the extraction efficiency of the method. In the optimized conditions, a mixture of 1.4 mL of an ethyl acetate extract of sample and 40 μL water (pH 5.0) was rapidly injected into 5.3 mL of cyclohexane. After centrifugation of the formed cloudy mixture, a micro-drop of the aqueous phase was sedimented at the conical bottom of the centrifuge tube. This phase, that contained the preconcentrated and partially purified analyte, was directly injected into an RP-HPLC column for analysis. A mean extraction recovery of 102.5 (±4.5) % with enrichment factors exceeding 38, was obtained for five replicated analysis. The detection limit of the method (3σ) for OE was 0.02 $\mu g\,L^{-1}$ for OPW and 2×10^{-3} $mg\,kg^{-1}$ for olive leaves samples. The results showed that, RP-DLLME is a promising technique which is quick, easily operated and can be directly coupled to HPLC.

1. Introduction

Oleuropein (OE) is the main glycoside in olive and is responsible for the bitter taste of olive products [1,2]. OE is known as a strong antioxidant and it has shown to have important human health benefits [3–6]. Olive leaves are whilst and cheap sources of OE. The OE level in olive leaves varies with olive variety, time of collection, climate, etc. [7]. Therefore, the development of simple and effective extraction methods for the preconcentration and accurate determination of OE is of great importance.

Ordinary solvent extraction, solvent extraction assisted by ultrasound [7,8] or microwave [9] energies and extraction with superheated solvents [10] are among the methods extensively used for the extraction of OE and related compounds from olive leaves before their GC or HPLC analysis. Methanol, ethanol, water and ethyl acetate have been among the most commonly used solvents for this purpose. Washing the extracts with non-polar solvents such as hexane [11], cyclohexane [12] and petroleum ether [13] for removing the heavy lipids has been sometimes recommended.

In the production process of table olives, a large quantity of wastewater is produced. The main purpose of this procedure is partial removal of the natural bitterness of the fruit that is mainly related to OE. However, OE is essentially hydrolyzed in the alkaline treatment stages of this procedure [14,16]. Extraction of OE and other biophenols from olive's processing wastewater (OPW) and olive mill wastewater has been performed by different organic solvents such as *tert*-butyl methyl ether, diethyl ether and ethyl acetate, with the last one being the most efficient [14–16].

Microextraction methods have attracted much attention in recent years as alternatives for classic extraction procedures [17]. These techniques are simple and fast, miniaturize sample pretreatment processes and minimize the use of organic solvents. A microextraction method can often be directly coupled to an analytical instrument. Dispersive liquid–liquid microextraction (DLLME) is a promising alternative to the classic liquid-liquid extraction (LLE) and was recently pioneered by Assadi and coworkers [18]. DLLME is simple, rapid and inexpensive and provides high enrichment factors. This method has been used for the extraction of several biochemicals and organic and inorganic compounds

doi:10.1016/j.talanta.2009.10.051

followed by their determination with GC [18,19], AAS [20,21] and HPLC [22–24] techniques. DLLME is based on a ternary component solvent system. In this method, generally, a small volume of a chlorinated, heavier than water organic solvent (e.g. carbon tetrachloride and chlorophenol) is dispersed into fine droplets in the sample solution by the aid of a water miscible solvent as disperser. After phase separation followed by centrifugation, the organic solvent is sedimented at the conical bottom of centrifuge tube as a micro-drop that can be withdrawn by a microsyringe. However, the organic solvent used in this procedure is not directly compatible with HPLC or AAS techniques. Therefore, evaporation of the organic solvent in a concentrator and reconstitution by an appropriate solvent is often required before analysis [20–24].

In this paper, a new generation of DLLME, termed as reversed-phase DLLME is presented that is directly compatible with HPLC. The proposed RP-DLLME method overturns the solvent polarity in the ordinary (normal-phase) DLLME and replaces the chlorinated, toxic solvents with water. In this technique, a small volume of water (or aqueous buffer solution) is dispersed in a lighter than water organic solvent with the aim of a moderately polar solvent as disperser. Therefore, the sedimented phase will be an aqueous micro-drop that can be directly injected into an RP-HPLC column. In this way, the time required for the solvent evaporation and reconstitution is saved. The capability of the method is demonstrated by its application to the preconcentration of oleuropein from OPW and olive leaves extracts.

A central composite design (response surface) is used for efficient optimization of the microextraction conditions. This method is a multivariate optimization technique that produces a detailed quantitative model for the response(s). The model can predict how a response relates to the values of various factors and it usually requires less number of experiments compared to a one-at-a-time procedure [25].

2. Experimental

2.1. Reagents and materials

Oleuropein (OE) was purchased from Indofine Chemical Company (Hillsbrough) and Hydroxytyrosol was prepared from Extrasynthesise (Genay, France). HPLC grade acetonitrile, ethyl acetate, cyclohexane and other chemicals were purchased from Merck (Darmstadt, Germany) and used as received. Double-distilled water was used throughout. A solution of 540 μg mL^{-1} OE in ethyl acetate was prepared and used as stock solution for the preparation of working standard solutions.

2.2. Apparatus

HPLC analysis of the samples was conducted using a Shimadzu (model L-10AD) instrument consisting of two reciprocating pumps, a DGU-14A in-line degasser, a model CT10-10AC oven, a high pressure manual injection valve (20 μL injection loop) and a UV/VIS (model SPD-10A) detector. The software used for the data acquirement and processing was Class-vp v.R 6.1. The analytical column was a 25 cm × 4.6 mm i.d. RP-8 column (Shim-Pack CLC-C8) packed with 5 μm particles and equipped with a 1 cm guard column (C8-B197) packed with 10 μm particles of the same type.

A 25 μL HPLC microsyringe (F-LC, SGE, Australia) was used for the sample withdrawal and injection. A variable automatic pipette (ISOLAB, Gmbts) was used for the RP-DLLME procedure.

A totally glass Fisons (UK) double distiller was used for preparation of doubly distilled water.

For ultrasonic irradiation of the samples, an ultrasonic water bath (22 kHz, model 5RS, Sonica, Italy) was used. An Eppendorf AG centrifuge (model 5810, Hamburg) was used for centrifugation of the extracts.

2.3. Field samples

Olive leaves of *Mary Zeitoon, Sevillana* and *Amphisis* varieties were collected from T-57 Agricultural Research Garden, Khoramabad, Iran, in July 2008. The leaves were dried in shadow and ground into approximately 1 mm pieces before analysis.

OPW was obtained from a green olive production plant in Khoramabad, Iran.

2.4. Procedures

For the preliminary extraction of OE from olive leaves, a static ultrasound assisted solvent extraction method was used [7]. To 0.10 g portion of the ground sample, 10 mL ethyl acetate was added in a glass test tube. The test tube was capped, thermostated at 40 °C, and sonicated for 30 min in the ultrasonic water bath. The supernant solution was decantated and filtered through 0.45 μm membrane filter and stored at 4 °C before further extraction by the RP-DLLME method. This extract was also directly injected into the HPLC column after 5 times dilution by ethanol.

For the preliminary extraction of OE from OPW a known LLE method [16] was used with some modifications. To 5 mL of acidified sample (pH 2), 5 mL ethyl acetate was added and the mixture was sonicated for 10 min. After the phase separation, the supernatant solution was decantated and the aqueous phase was extracted with a second 5 mL portion of ethyl acetate and the two extracts were added together.

The RP-DLLME method was performed as follows: A 1.4 mL portion of the ethyl acetate extract of the sample was mixed with 40 μL of water (pH 5.0). This mixture was rapidly injected into 5.3 mL cyclohexane in a centrifuge test tube using a variable pipette. A cloudy solution was formed that was centrifuged at 4000 rpm for 5 min. The sedimented aqueous tiny droplet at the conical bottom of the test tube was carefully withdrawn by a 25 μL syringe and directly injected into the HPLC column for analysis.

For HPLC separation of OE and other co-extracted compounds, a gradient elution with a mixture of solvents A (0.05 mol L^{-1} acetate buffer pH 5.0 in water) and B (acetonitrile) with a flow rate of 1.0 mL min^{-1} was used. The elution program was as follows: 0–8 min, 20–80% B; 8–11 min, 50–70% B; 11–13 min 70% B and 13–15 min, 70–20% B. The chromatograms were acquired at 240 nm.

Optimization of the effects of different parameters affecting the extraction by the RP-DLLME method was performed by a half-fraction central composite design (response surface method) using Minitab statistical software [26]. Table 1 depicts the abbreviation and levels of each factor included in the design.

Extraction recovery (ER%) was calculated from 100 times of the initial amount (μg) of OE in the sample, divided by its amount extracted into the aqueous phase. For calculation of the enrichment factor (EF), the OE concentration in the receiving phase was divided by its initial concentration in the sample.

Table 1
The factors included in the central composite design and the levels for each of them.

Parameter	Abbreviation	Factors' levels	
		Low	High
Cyclohexane volume (mL)	CV	5	3
Ethyl acetate volume (mL)	EV	1.5	0.5
Water volume (μL)	WV	70	50
Water pH	pH	8	6
Centrifuge time (min)	CT	6	4

3. Results and discussion

Preliminary extraction of OE and related compounds into an appropriate solvent for the RP-DLLME method was a critical requirement. Since, methanol, ethanol and ethyl acetate have been the most frequently used solvents for the extraction of OE from olive products [7–13], the possibility of using them as the disperser phase in the RP-DLLME procedure was examined. By using cyclohexane as the bulk organic solvent, it was found that methanol and ethanol tend to sediment together with water and this increases, drastically, the volume of the sedimented phase. Furthermore, the volume of the sedimented micro-drop was quite sensitive to the initial water volume. In an experiment, increasing the water volume from 40 to 45 μL, increased the sedimented aqueous phase volume from zero to about 430 μL. This may be explained by the high tendency of the alcohols to water that causes co-sedimentation of them with water. The volumes of cyclohexane and the dispersers were 5.0 and 1.0 mL, respectively, in these experiments. Ethyl acetate, on the other hand, was found to be quite an appropriate disperser as it produced reasonable and repeatable sedimented phase volumes, and stable cloudy solutions. Therefore, ethyl acetate was selected as an appropriate solvent for the preliminary extraction of OE from olive samples, and an appropriate disperser for the subsequent RP-DLLME procedure.

Using ethyl acetate as the disperser, cyclohexane, petroleum ether, diethyl ether and a 1:1 mixture of cyclohexane and petroleum ether were examined as the organic solvent for the RP-DLLME system. In comparison with the toxic chlorinated solvents usually used in DLLME, these solvents are relatively non-toxic, cheap and have been commonly used for the removal of heavy lipids from olive extracts before their HPLC analysis [11–13]. No considerable differences were observed in the extraction efficiencies of the studied solvents. However, since more stable cloudy solutions and more reproducible volumes of the sedimented phase was obtained by using cyclohexane, this solvent was selected in subsequent experiments. By using cyclohexane, the extraction recoveries were in the range of 91–99%, depending upon the experimental conditions. The mean volume of the sedimented micro-drop was 31.7 (±1.5) μL for three replicates.

3.1. Optimization by the central composite design

After performing some preliminary experiments, optimization of the extraction conditions by the proposed RP-DLLME method was conducted using a half-fraction central composite design. Five factors of cyclohexane (organic solvent) volume, ethyl acetate (disperser) volume, water (extraction solvent) volume, pH of the aqueous phase and centrifugation time (with 3000 rpm) were included in the design (see Table 1). Two dependent variables of extraction recovery (ER%) and enrichment factor (EF) were optimized with the model.

In each experiment, a mixture of the extracting solvent (water with an adjusted pH) and ethylacetate (containing 0.1 mg L^{-1} OE) was rapidly injected into the organic phase. The formed cloudy solution was then centrifuged and the sedimented aqueous phase was directly injected into the HPLC column for subsequent analysis.

The data given in Table 2 show the ER% and EF responses obtained for 28 experiments designed by using the MINITAB software [26]. Table 3 contains the regression coefficients for each term in the model and the analysis of variance (ANOVA) of the effects. The *R*-squared statistic indicated that the model explains 94.25% and 98.83% of the variability in ER% and EF, respectively. The adjusted *R*-squared statistic was 0.7782 for ER% and 0.9549% for EF. The standard error of the estimate showed the standard deviation of the residuals to be 4.27 and 2.13 for the dependent variables, respectively. The Durbin–Watson (DW) statistic showed that there is probably not any serious autocorrelation in the residuals.

Table 2
The conditions of the central composite design experiments and the responses.

No	Parameter*					ER%	EF
	CV	EV	WV	pH	CT		
1	3	0.5	70	6	4	83	7.6
2	5	1.5	70	6	4	106	28.5

28	4	1.0	60	7	5	101	22.0

* For the full names of the parameters, see Table 1.

A *p*-value less than 0.05 in the ANOVA table, indicates the statistical significance of an effect at 95% confidence level. The data in Table 3 indicate that ethyl acetate (EV) and cyclohexane (CV) volumes have significant effects on both ER% and EF, but pH influences only ER%. Water's volume, on the other hand, has considerable effect only on EF. The centrifuge time (CT) did not show any significant influence on the responses. The interactions of EV with both CV and WV are significant. As shown in Table 3, quadratic terms of EV^2 and CV^2 also show significant effects on ER%.

Table 3

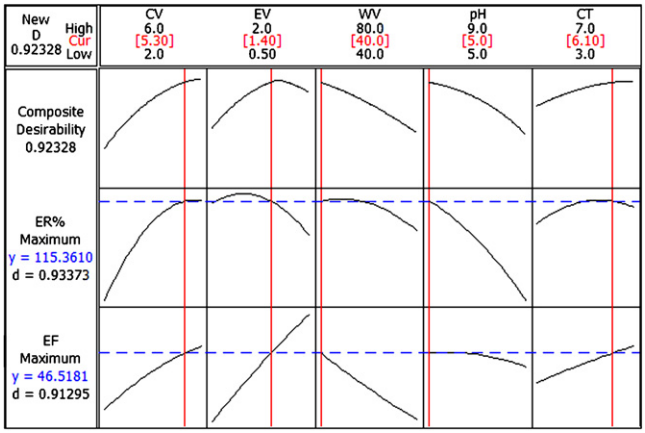

Fig. 1. The optimization plot for the central composite design, including five independent and two dependent variables.

The response surface model with the estimated regression coefficients (see Table 3) was used for the response optimization, including all the factors. The optimization plot (Fig. 1) indicates the predicted conditions for the optimum point and the desirability of the prediction. Each individual plot in the figure shows the way each factor influences the ER%, EF and their composition. Decreasing the extraction efficiency with pH is evident. It is expected that increasing EV should increase the recovery, but in higher EV values no stable cloudy solution is formed and the solution approaches a uniphase at too high ethyl acetate volumes.

Fig. 2 depicts the response surface plots of extraction recovery modeling for some of the significant factors. The curvatures of the plots indicate the interaction between the factors.

3.2. Analytical performances

Five replicated experiments were performed at the predicted optimum conditions by the response surface model (i.e. 1.4 mL ethyl acetate, 5.3 mL cyclohexane, 40 μL water at pH 5.0 and 6.1 min centrifugation time). The extraction of 0.1 mg L^{-1} OE under the optimal conditions resulted in an extraction recovery of 102.5% with a relative standard deviation of 4.5% and an enrichment factor of 38. It can be concluded that the prediction of the model is desirable and the recovery is quantitative. The calibration curve was linear over a range of 0.07–4 mg L^{-1} of OE, with a R^2 of 0.999. The detection limit of the method for OE determination was calculated from 3σ to be 0.02 μg L^{-1} for OPW samples and 2×10^{-3} mg kg^{-1} for olive leaves samples.

3.3. The RP-DLLME of olive leaves samples

The RP-DLLME method was applied for extraction of OE from the ethyl acetate extracts of olive leaves from three different olive varieties. Table 4 indicates the more or less quantitative extraction recoveries for the samples. Fig. 3 compares the chromatograms of *Mary Zeitoon* variety, before (a) and after (b) preconcentration by the proposed method. In Fig. 3(a) only a small peak is observed for

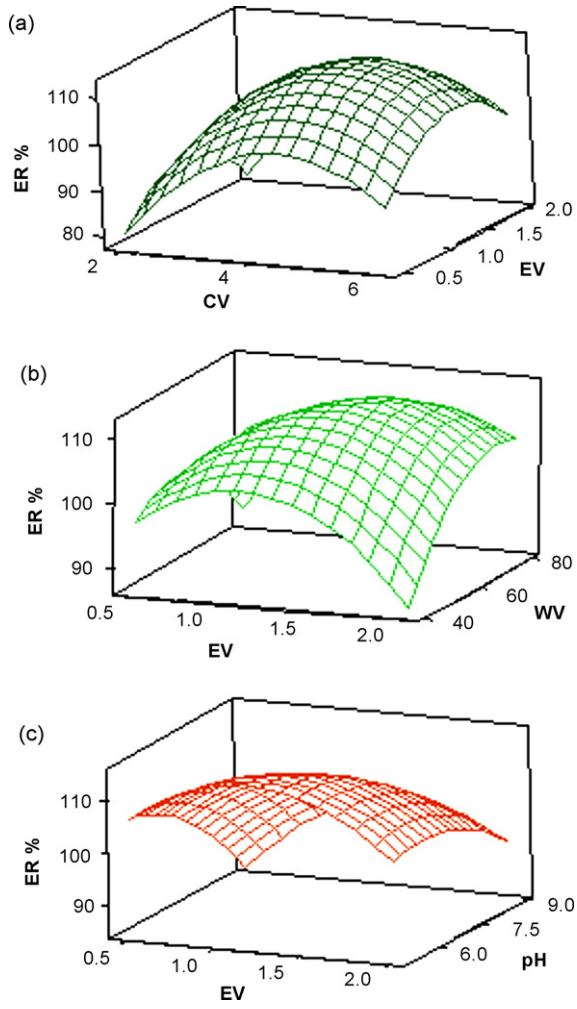

Fig. 2. The response surface plots for extraction recovery (ER%) as a function of CV and EV (a), EV and WV (b) and EV and pH (c).

OE with a signal height of only about 0.03 absorbance units. On the other hand, a sharp OE peak with a height of about 2.4 absorbance units is observed in Fig. 3(b). For direct injection of the ethyl acetate extracts, they were diluted, five times, by ethanol. Evidently, the RP-DLLME method has not only preconcentrated, but also purified the analyte in a considerable extent. Evidently, the system shows a high selectivity towards the extraction and preconcentration of OE into fine droplets of the aqueous phase. Furthermore, the role of the organic phase for removal of heavy lipids and high molecular weight phenolic compounds should not be forgotten [11–13].

3.4. The RP-DLLME of spiked OPW samples

Separation and preconcentration of OPW by the RP-DLLME method resulted in no detectable signal for OE. It has been reported that during the alkaline treatment of olive, OE is essentially hydrolyzed to hydroxytyrosol and other metabolites [14,16].

Table 4
The results of the RP-DLLME-HPLC analysis of the extracts of three olive leaves under the optimized experimental conditions.

Olive variety	OE (mg g^{-1}), direct injection	OE (mg g^{-1}), RP-DLLME	ER%	EF

[a] Limit of detection, in mg Kg^{-1} (for olive leaves) or μg L^{-1} (for OPW samples).
[b] Long = The time is longer than 1 h (the exact time is not reported).
[c] NR = Not reported.

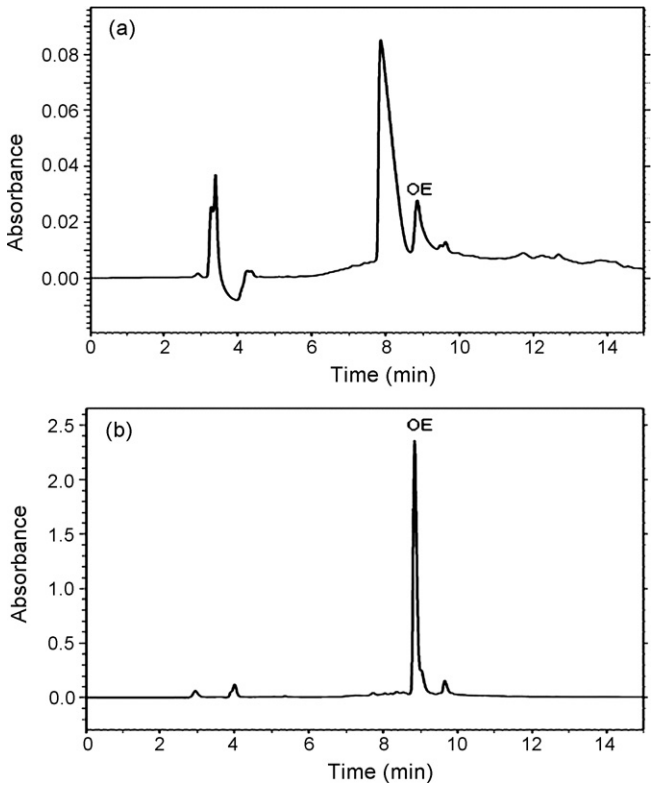

Fig. 3. The chromatograms of the extract of *Mary zetoon* leaves before (a) and after (b) preconcentration by the RP-DLLME method, under the optimized conditions.

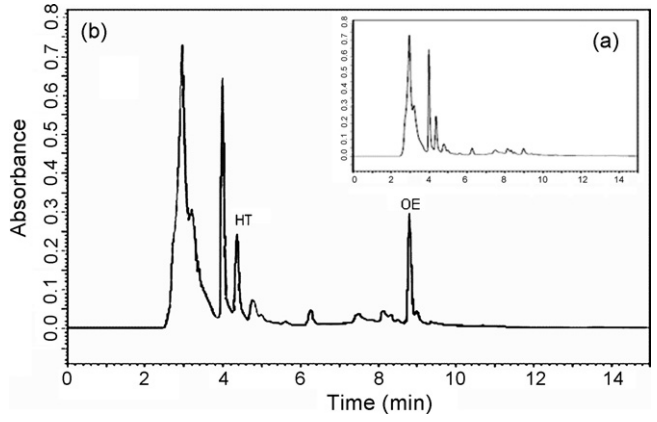

Fig. 4. The chromatograms of non-spiked (a) and spiked (b) OPW by 0.054 mg L^{-1} OE after undergoing the RP-DLLME, under the optimized conditions.

Therefore, the wastewater sample was spiked by OE before the extraction. The results shown in Table 5 indicate a good agreement between the added and found OE which indicates that the proposed method is appropriate for quantitative extraction of OE from such complicated matrices. Fig. 4 shows a chromatogram for one of the spiked samples. The higher area peaks at the beginning of the chromatogram indicate that hydroxytyrosol (HT) and some other biophenols may also be extracted and preconcentrated by the method. Optimization of the RP-DLLME method for the extraction of these compounds will be the subject of our research group future studies.

4. Conclusion

RP-DLLME is a simple and rapid extraction technique with large enrichment factors and low detection limits. In contrast to the conventional DLLME, the extraction phase in the proposed method is a micro-drop of water or an aqueous solution that can be directly injected to HPLC for analysis. The organic phase in this method is lighter than water and is used as the bulk solvent. The solutes distribute between this phase and the aqueous phase and therefore, macromolecules and heavy lipids are removed from the sample. The only disadvantage of RP-DLLME is the relatively high volume of organic solvent used in this method. However, this volume is still far beyond the volumes used in classic LLE techniques. Table 6 compares the proposed method with some other extraction techniques used for the extraction of OE from olive leaves or olive processing wastewater. The much lower detection limits of the RP-DLLME and its small extraction volumes and high enrichment factors are evident.

ABSTRACT

CdTe quantum dots (QDs), capped with mercaptopropionic acid (MPA), were synthesized and the variation of their fluorescence properties (steady state and lifetime) with pH was assessed in solution and when immobilized in a sol–gel host. Three different sizes of CdTe QDs with excited state lifetimes ranging from 42 to 48 ns and with emission maximum at 540 nm (QD_{540}), 580 nm (QD_{580}) and 625 nm (QD_{625}) were selected. The solution pH affects the maximum emission wavelength (shifts to higher wavelengths of 23, 24 and 27 nm for QD_{540}, QD_{580} and QD_{625}, respectively), the excited state lifetime and the fluorescence intensity in a reversible way. Linearization of the maximum emission wavelength variation with the pH allows the estimation of an apparent ionization constant (pK_a) for each QD: 6.5 ± 0.1 (QD_{540}), 6.1 ± 0.5 (QD_{580}) and 5.4 ± 0.3 (QD_{625}). The variation of the QDs fluorescence properties was further explored using confocal laser scanning microscopy allowing the implementation of a new calibration method for pH imaging in solution. QDs were successfully immobilized on the tip of an optical fiber by dip-coating using sol–gel procedure. The immobilized QDs showed a similar pH behaviour to the one observed in solution and an apparent lifetime of 80, 68 and 99 ns, respectively. The proposed QDs based methodology can be successfully used to monitor pH using wavelength encoded data in imaging and fiber optic sensing applications.

1. Introduction

Semiconductor nanoparticles, or quantum dots (QDs), are presently a widely used tool in the field of biomedical imaging. In addition, their outstanding luminescent properties make them a very appealing alternative to organic dyes in traditional fluorescence based analytical techniques. Their high photostability and quantum yields, together with the ability to tune their absorption and emission properties, simply by changing the size or composition of the nanoparticles, give them superior performance in many applications [1–3]. For these reasons, in the last few years the use of QDs has been demonstrated in a growing range of chemical and biosensing applications [4–6]. While the majority of these applications has been demonstrated in solution assays, the use of quantum dots in combination with optical fibers and other waveguide platforms is a promising emerging field and an essential step towards the implementation of advanced analytical tools [7].

A necessary condition towards the applications of QDs in biological media is the ability to make them stable in aqueous media. The most common strategies to obtain QDs water soluble involve the modifications of their surface with hydrophilic capping ligands [8,9]. Further functionalization of the QD surface with a given ligand can enable its use as a specific indicator for a variety of analytes [10]. A great diversity of sensing applications has been reported where different capping strategies have been used to detect widely different analytes from a diversity of metallic and non-metallic ions [11,12], gases [13] or explosive molecules [14].

Functionalization of the dots surface with ligands containing ionizable groups can render nanoparticles sensitive to pH. The functionalization of CdSe/ZnS QD with a chromophore whose absorption spectrum shifted according to the surrounding pH has been reported [15]. The absorption shift changed the relative overlap with the QD emission, modulating the fluorescence resonance energy transfer (FRET) efficiency according to the pH. Using this method the authors demonstrated an approximately linear variation of the QD luminescence intensity within the pH range 3–11. A potential problem of this strategy lies in the fact that purely intensity based measurements are prone to be affected by

doi:10.1016/j.talanta.2009.10.048

several sources of optical power drift. Although the QD luminescence lifetime was shown to be pH dependent, average values in the order of 15 ns were reported. Therefore the implementation of intensity independent lifetime or frequency domain interrogation techniques would require very fast optoelectronic devices. Other authors implementing similar strategies have used pH sensitive QDs to detect glucose or an avian influenza virus [16,17]. Although the pH sensitivity of CdTe QDs has been studied by many authors [18], in most of the reported applications detection was based in simple intensity quenching measurements, few observations were made on QDs wavelength behaviour.

In a more elaborated approach, a QD based ratiometric probe has been designed [19]. This was achieved by conjugating CdSe/ZnS TOPO overcoated with a NIR luminescent squaraine dye. pH modulated FRET resulted in a luminescent emission displaying an isobestic point at 640 nm, which allowed the implementation of ratiometric detection schemes. The generalization of this approach to sensing different biochemical species is possible because the narrow, size-tunable emission spectrum of QD, acting as donors, can be matched with the acceptor absorption features of an analyte sensitive dye, thereby maximizing FRET efficiency.

In this work, the synthesis of thioglycolate capped CdTe QDs is described and their luminescence properties (excitation and emission wavelengths and lifetimes) obtained as function of the reaction time, concentration and pH presented. It is shown, in a confocal microscopy application, that the spectral behaviour of the QDs with pH enables ratiometric pH imaging without the need of combination with organic indicators. Furthermore, the CdTe QDs were immobilized in sol–gel and their pH sensing properties in fiber optic probes assessed.

2. Experimental

2.1. Reagents

Reagents and the respective percentages of purity were the following: tellurium powder (99.997%); cadmium chloride (99.99%); sodium tetrahydroborate (96%); MPA (99%). Deionized and deoxygenated water was used during the synthesis. Water deoxygenating was accomplished by boiling followed by cooling under nitrogen. An inert nitrogen atmosphere was maintained during the synthesis.

A diluted solution of each QD was prepared in a proportion of 1:25 mL in water. The pH of this diluted solution was reversibly changed in the pH range 4–9 with sodium hydroxide (0.1 M) and hydrogen chloride (0.1 M).

TEOS (tetraethoxysilane) (≥99%), TMOS (tetramethyl orthosilicate) and Ph-TriEOS (phenyltriethoxysilane) were obtained from Sigma–Aldrich Química S.A. (Spain).

2.2. Synthesis of CdTe QD

The QDs synthesis was based on well known previously described work [20–22] with the following particular method: (i) 50 mg of sodium tetrahydroborate were mixed with 2 mL of water followed by 75 mg of tellurium—this solution was left to stabilized for about 24 h; this solution was carefully decanted into 100 mL of water; (ii) 230 mg of cadmium chloride was dissolved in 500 mL of water and mixed with 250 μL of MPA—the pH of this solution was rigorously fixed to 6.5 by the addition of sodium hydroxide 1 M; (iii) the tellurium solution was transferred quickly and vigorously into the cadmium solution and the mixture was refluxed up to 27 h. 50 mL samples were removed at selected reaction times (15, 30, 45, 60, 90, 120 and 180 min, 11, 19 and 27 h) for analysis.

By this method the CdTe nanoparticles were capped with mercaptopropionic acid (MPA) becoming water soluble and pH sensitive. One end of the hydrophilic capping ligands contains a thiol group that binds with the QDs surface. The other polar end contains a carboxylic group that makes them water soluble. Because the carboxylic acid group has acid–base properties the optical fluorescence properties of these QDs can be used as pH sensitive indicators.

To evaluate the behaviour of the QDs when submitted to pH changes, three sets of nanoparticles were selected with peak emission at 540 nm (QD_{540}), 580 nm (QD_{580}) and 625 nm (QD_{625}). The fluorescence measurements were performed during the pH titration of the QDs solution. The titration started at pH 6.3 and small amounts of NaOH (0.1 M) were added until the following pH was achieved. After pH 9, small amounts of HCl (0.1 M) were then added to obtain more acidic solutions down to pH 3.0.

2.3. Preparation of optical fiber probes

Silica optical fibers with core/cladding diameters of respectively 550 and 600 μm were purchased from Thorlabs. The fiber tips were carefully polished and their protective coating removed with acetone followed by rinsing with deionized water. To enhance the efficiencies of excitation and collection of luminescence the fiber tips were reshaped by chemical etching. By slow and controlled immersion (using a step motor) of the tip in 40% HF tapered probes with conical shape were obtained (in a 2 cm fiber length the diameter was reduced from 600 μm to approximately 200 μm). To obtain the luminescent probes the fibers were then dip-coated with the QD-doped sol–gel solutions and left to dry in a clean environment at ambient temperature.

2.4. Immobilization of QD in sol–gel matrix and optical fibers

Two sol–gel preparations were tested for the immobilization of the QDs, one based on TMOS and the other, a hybrid sol–gel, based on TEOS and Ph-TriEOS.

(Sol–gel A—TMOS) TMOS was partially hydrolyzed by mixing with an equal amount of HCl (0.1 M), with vigorous stirring for 2 h at room temperature. The resulting solution became a clear and homogeneous sol–gel. At this point equal amounts of the sol–gel was thoroughly mixed with a water solution of the QD, and poured into 1 cm plastic cells. The sol–gel was left in the dark at room temperature for a day and left to dry in a form of a parallelepiped before making the measurements.

(sol–gel B—TEOS/Ph-TriEOS) 1 mL of TEOS and 50 μL Ph-TriEOS were mixed with 250 μL of hydrogen chloride 0.1 M and shaken for 20 min. 2.50 mL of the raw QD solution was added and the mixture shaken for 5 min. Films were immobilized in glass plates and optical fibers by dip-coating [23].

2.5. Instrumentation

A Spex 3D Spectrofluorimeter with a 75 W xenon lamp and a CCD detector was used. Excitation emission matrices of fluorescence (EEM) were acquired, in an excitation wavelength range from 250 to 550 nm, and in an emission wavelength range from 250 to 710 nm, with a resolution of 5 nm. UV–vis spectra were acquired with a Hewlett-Packard HP8452A diode-array spectrophotometer using 1 cm quartz cells in a wavelength range from 240 to 800 nm with a 2 nm interval and an integration time 0.5 s.

The apparent lifetimes of QD doped solutions and sol–gel membranes were estimated using a frequency domain interrogation set-up. The excitation source was a violet LED, and its current modulated with a function generator (Wavetek) and a voltage/current converter (Analog Modules 775). Silica optical fiber bundles were used to guide the excitation radiation to the samples and also to collect the luminescent emission back to detection which was made

using a silicon photodiode (PDA36A). A lock-in amplifier (SRS844) was then used to evaluate the phase difference between the LED emission and the luminescent signals. By performing a phase scan as function of frequency and fitting the acquired data to well known analytical relations between the phase shift and the modulation frequency [24], the samples average lifetime could be estimated.

Using the same excitation source/fiber bundle combination, the spectral characterization of the solutions and of the sol–gel samples was made using a CCD spectrometer (OceanOptics USB4000).

Confocal microscope images were acquired with a Leica SP2 AOBS SE (Leica Microsystems, Germany). The excitation of QDs was made with the Ar laser lines of 458 and 476 nm. A filter-free prism spectrophotometer head with a set of 3 photomultiplier tubes (PMT) allowed the addressing of distinct detection channels in three user-defined spectral ranges. All the image processing operations were done with MATLAB and ImageJ software [25].

3. Results and discussion

3.1. QD fluorescence properties

Table 1 resumes the photophysical properties of the synthesized QDs. These results show that, considering the relative positions of the absorption and emission peaks, all QDs have relatively large apparent Stokes shifts ranging between 230 and 310 nm. It was also observed that the maximum of the excitation wavelength shows a blue shift of about 30 nm when the concentration of the QDs aqueous solution decreases about ten times—at small dilutions the wavelength is kept almost constant and a marked decrease in the excitation wavelength is observed for dilutions higher than 40% the raw concentration. This result may be explained by the aggregation/disaggregation of the QD or a filter effect.

The emission band and the apparent Stokes shift are sensitive to the reaction time, suffering a deviation for the red and an increase, respectively. The increase in the reaction time leads to a shift of the emission wavelength of the CdTe QDs to longer wavelengths (from yellow/green up to red). Longer reaction times result in bigger nanoparticles and, consequently, to a decrease in the carriers' confinement energy and an increase in emission wavelength. The size of the nanoparticles was estimated using the simple model of Bawendi et al. [26], considering a bandgap energy for bulk CdTe of 1.56 eV [27]. The results shown in Table 1, confirm the increasing size of QD_{540}, QD_{580} and QD_{630} which was approximately 6, 7 and 8 nm, respectively. Therefore, by changing the reaction time the size of the nanoparticles can be adjusted and their emission wavelength tuned. Once the reaction is stopped, the resulting nanoparticles are stabilized in water solutions, showing no significant changes in their spectral properties. Therefore, stable nanoparticles can be obtained with different emission characteristics. In addition, by choosing an appropriate wavelength range, all the nanoparticles can be excited using a single excitation source. The full width of half maximum (FWHM) increases with reaction time (from 42 to 62 nm in the range tested), indicating an increase in the dispersion of the size distribution of the nanoparticles.

Table 1
Photophysical and acid–base properties of CdTe QD.

Property	QD_{540}	QD_{580}	QD_{625}
Excitation wavelength (nm)	307	309	316
Emission wavelength (nm)	540	580	625
Estimated size (nm) [26]	6	7	8
FWHM (nm)	42	44	62
pH sensitivity range (ΔpH)	5.7–8.0	4.6–7.5	3.5–8.1
Variation of the emission wavelength with the pH ($\Delta\lambda_{acid/base}$) (nm)	23	24	27
$\Delta\lambda/\Delta$pH (nm)	9.6	8.3	5.9
pK_a	6.5 ± 0.1	6.1 ± 0.5	5.4 ± 0.3
Variation of the lifetime with the pH ($\Delta\tau_{acid/base}$) (ns)		30–90	
τ_{water} (ns)	42	48	44
$\tau_{sol-gel\ based\ TMOS}$ (ns)	80	68	99

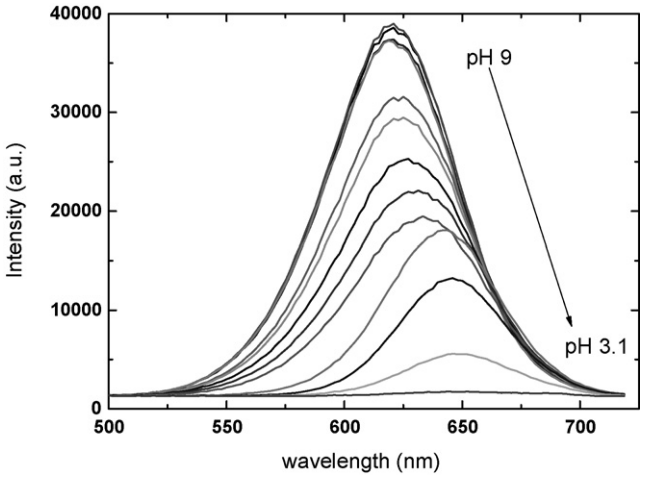

Fig. 1. Emission spectra as function of the pH for QD_{625}.

The emission wavelength of the QDs could be easily tuned between 520 and 630 nm, by increasing the reaction time from 15 min to 27 h. Longer reactions times could result in longer emission wavelengths; however, as the particles grow the effect of quantum confinement starts to decrease, strongly impacting the quantum yield. For smaller nanoparticles the emission efficiency increases with reaction time, however, for reaction times longer than 12 h, the quantum yield decreases. The bandgap energy of bulk CdTe is 1.56 eV [27], which corresponds to an emission wavelength of approximately 795 nm, therefore, to obtain QDs with, longer emission wavelengths different semiconductor materials with smaller bandgap energy must be used (e.g., PbS, PbSe or InAs [28,29]).

The lifetime of the different QDs was also evaluated in water solutions by frequency domain spectroscopy. The decay dynamics of CdTe QD is known to be complex and most often dual or multi-exponential behaviours have been observed. Nevertheless, it is always possible to estimate an average apparent lifetime. The apparent lifetimes of the three QDs were very similar ranging from 42 to 48 ns (Table 1). These values are in agreement with those reported in literature where values ranging from 6 to 125 ns were observed, depending on the QD microenvironment [30,31].

3.2. pH effect on the QD fluorescence properties

The QDs fluorescence intensity, emission spectrum and excited state lifetime in the pH range from 3 to 9 were measured. All QDs exhibited similar behaviour, i.e. as the solution pH was increased, the luminescence intensity increased, the lifetimes decreased and the emission peak was shifted towards shorter wavelengths. The titration procedure was repeated several times, going up and down on the pH scale, and it was observed the changes in the emission peak, the luminescence intensity and the lifetime, were all fully reversible with no observable hysteresis.

Fig. 1 shows an example of the emission spectra variation with the pH of QD_{625}. From this data it can be estimated a wavelength shift of 25 nm for a pH change of 6 units. In the same range the luminescence intensity was quenched by 89%. Similar features were obtained for QD_{540} and QD_{580} and the results are summarized in Table 1.

The presence of a pH dependent wavelength shift suggests that the protonation/deprotonation of the carboxylic ligands of the MPA may influence the QDs bandgap energy. As the pH is increased and the carboxylic ligands ionize, a negatively charged shell builds up in the dots surface that increases the confinement of the charge carriers in the semiconductor core. The increased confinement results in a higher bandgap energy, shorter emission wavelengths and higher quantum yields.

A closer analysis of the data presented in Table 1 reveals that depending on their size, each set of nanoparticles was sensitive to a different pH range. The range of pH sensitivity is 5.7–8.0 for QD_{540}, 4.0–7.0 for QD_{580} and 3.0–8.0 for QD_{625}. The pH dependence of the peak wavelength for the three sets of QDs can be observed in Fig. 2a–c, respectively. Each of the curves obtained are the result of three independent measurements (standard deviation of the average wavelength in each measurement was less than 0.1%), further confirming the reversibility of the changes in the luminescence properties. In addition, these results show that bigger nanoparticles have a pH dependence in an extend range. This happens because, as the average size of particles grows, so does the number of carboxylic ligands on the nanoparticles surface, thereby increasing the number of possible ionization states.

On the other hand, it can also be observed that the shift induced in the emission wavelength is more pronounced for smaller particles. In fact, although the absolute wavelength change increases with particle size, the relative change by pH unit, considering the corresponding sensitive ranges, decreases with growing particle size. This happens because a given change in acidity corresponds to a certain number of ionized carboxylic ligands and the relative change is more pronounced in smaller QDs. In addition, the solutions containing larger nanoparticles have a wider size distribution. This results in a sharper pH response for smaller dots, corresponding to a well defined pK_a and a more broad response for larger QDs, corresponding to a wider pH sensitivity range.

The lifetime of each sample was determined as a function of pH and the corresponding graphical representation is shown in Fig. 3. The analysis of this figure shows that different QDs have different lifetimes, that the lifetime change is relatively small and that this variation occurs in different pH ranges. It can be seen that the lifetime change with pH of bigger QDs has a broader sigmoidal response. This correlates well with the behaviour observed for the wavelength response. In addition, it is also observed that the apparent lifetime decreases as the pH increases. QDs are known to have complex decay dynamics with multi-exponential behaviours. Typically, the shorter lifetime contributions can be attributed to intrinsic recombination of populated core states. Long lived contributions on the other can be associated with the involvement of surface states in the carrier recombination process [32]. Therefore, the behaviour observed could be explained by the increased confinement that enhances the recombination dynamics of surface states. Nevertheless, a more detailed study of the decay dynamics is necessary to better understand the mechanisms involved.

3.3. Confocal microscope imaging

Obtaining analytical information from fluorescent images is a very powerful tool in many applications from biomedical to environmental fields. In particular, self-referenced techniques where the influences of different sources of signal drift are compensated are highly attractive [19,33,34]. If different probes are available, the identification of multiple analytes can be made simultaneously [35]. However, the multiplexing ability of broad emitting organic dyes is quite limited. Therefore, the possibility to use ratiometric analytical imaging methods with the readily multiplexable QDs is highly attractive. To assess the possibility to use these pH sensitive QDs as ratiometric pH probes in imaging applications, different

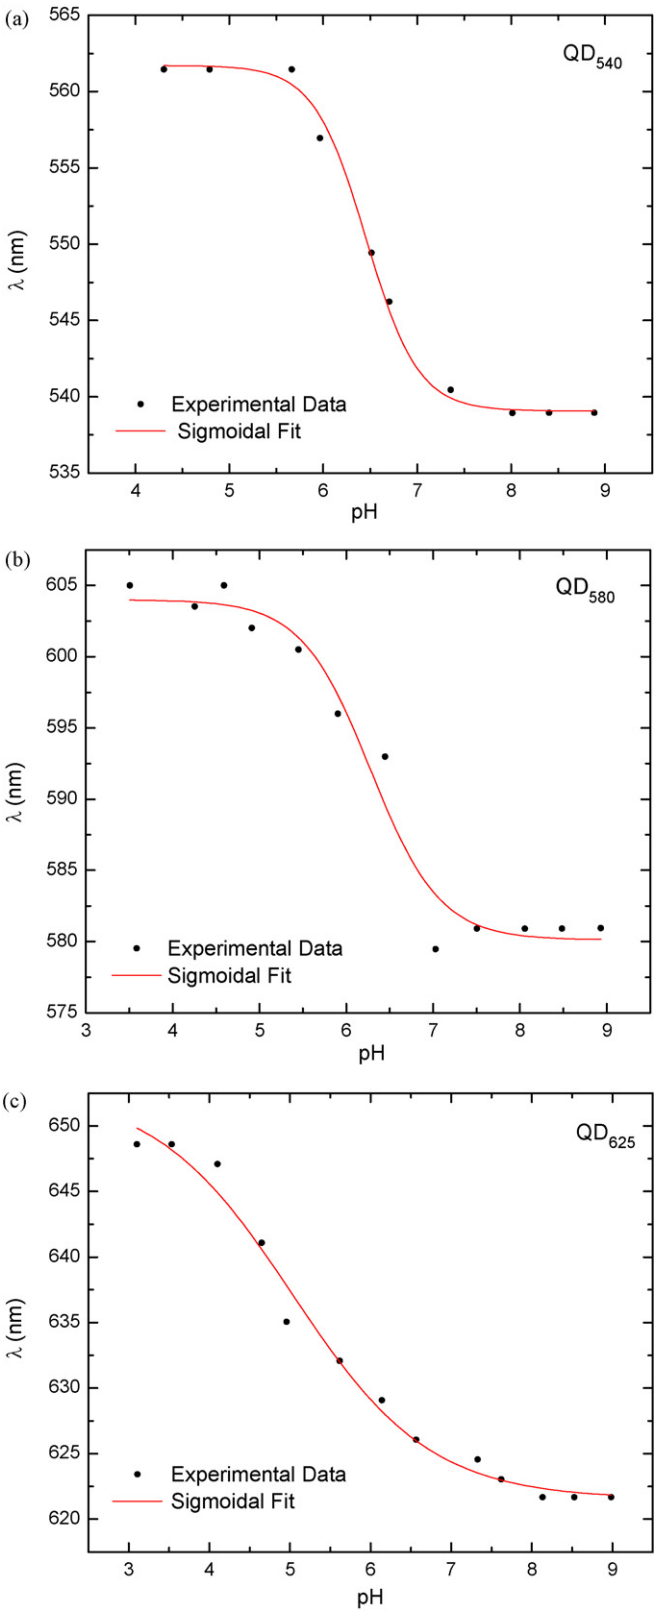

Fig. 2. Variation of the maximum emission wavelength with the solution pH for: (a) QD_{540}; (b) QD_{580}; and (c) QD_{625}. Each curve results from three independent measurements. Standard deviation of measurements is smaller than 0.1%.

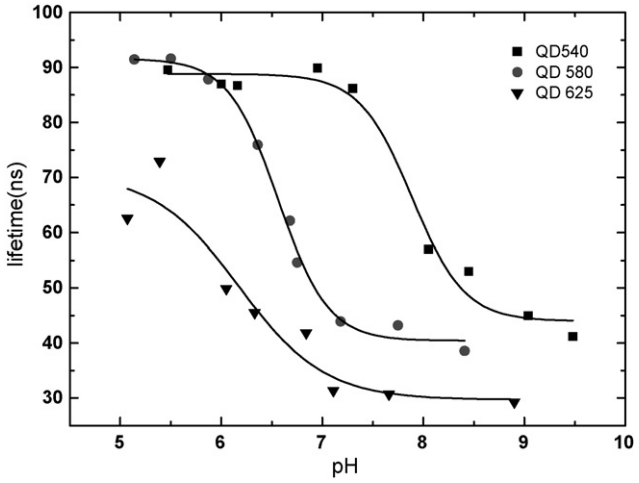

Fig. 3. Dependence of the excited state lifetime with the solution pH.

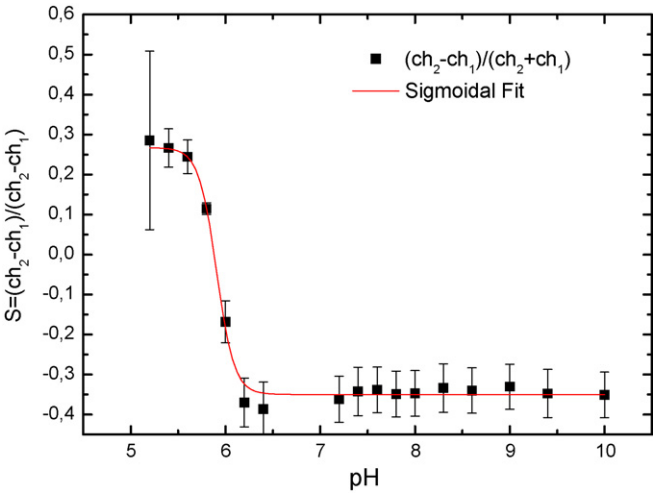

Fig. 4. Ratiometric calibration curve.

buffer solutions doped with pH sensitive QD580 were analysed by confocal laser scanning microscopy.

Using the possibility of the confocal microscope to simultaneously address independent spectral channels a ratiometric detection scheme can be implemented. In particular, if the integrated intensity of two narrow wavelength ranges (channels Ch_1 and Ch_2), chosen in opposite sides of the QDs emission band are recorded, the ratio calculated by $S = (Ch_1 - Ch_2)/(Ch_1 + Ch_2)$ is independent of the intensity and proportional to the wavelength of the emission peak which, in this particular case, is proportional to pH.

This scheme was previously applied for temperature sensing using CdSe–ZnS QDs immobilized in non-hydrolytic sol–gel hosts [36]. This technique can be applied to microscopy by acquiring simultaneously two images of each sample, one through acquisition Ch_1 and another through acquisition Ch_2, each corresponding to the integral of distinct spectral intervals [Ch_1 (540–560 nm) and Ch_2 (620–640 nm)]. By performing the ratiometric scheme described (pixel by pixel), a matrix can then be obtained where each pixel yields a numerical value, given by S, proportional to pH. A false colour scheme can then be applied to obtain images with analytical information.

To calibrate this imaging procedure, several samples corresponding to different pH buffers doped with QDs (ranging from pH 3.2 to 10.0), were analysed. In the pH range between 3.2 and 4.7 the QDs coagulated and precipitated as an orange solid and the images obtained in this pH range were discarded. For the remaining pH range, for each sample, two images with uniform grey level were obtained (one per acquisition channel). The mean value of the grey level intensity (16 bit) of the images was computed, yielding numerical values corresponding to Ch_1 and Ch_2 and ratio S was then calculated. From these operations a sigmoidal calibration curve could be obtained as shown in Fig. 4. In the figure, each data point corresponds to the calculated value of S. The errors bars were calculated considering the standard deviation associated to the values of Ch_1 and Ch_2 and considering error propagation in the calculation of S. The experimental data could be fitted by a four parameter sigmoidal curve with adjusted $R^2 = 0.997$. In the range, pH 5.6–6.2, a linear fit could be obtained with $R^2 = 0.919$.

To demonstrate the feasibility of this method, samples with QDs in different pH buffers were mixed. In particular, a microemulsion was obtained by mixing a few microliters of a QD solution in pH 5.6 and 8 into a drop of silicon oil. Hand shaking of the mixture resulted in a micro-bubbles containing QD solution inside the silica oil droplet.

In Fig. 5, two separate micro-droplets with pH 5.6 (left) and pH 8 (right) are shown. All the images were pre-processed in order to reduce noise (3×3 median filter) and eliminate the non-luminescent background by defining a threshold. The ratiometric scheme and the application of a false colour map using the sigmoidal calibration resulted in images that can be used to estimate the pH. The false colour palette was set between 5 and 6.2 which is the pH range where the wavelength variation took place (all image points with pH higher than 6.2 are represented by the same colour—dark red).

The different stages of the mixing process of two droplets with distinct pH are shown in Fig. 6. The processed images allow seeing clearly that, as the droplets mix, intermediate pH values (between the two extremes 5.4 and 6.2) start to appear. This demonstrates the ability of the ratiometric processing scheme to yield images where a pH value can be ascribe to each pixel.

This technique is therefore promising for pH mapping in bioimaging applications. Similar techniques have been reported using organic dye molecules such as SNARF or phorphyrins (see Ref. [37] and references therein). However, the possibility to implement such analytical imaging techniques using QD introduce several advantages such as increased photostability, narrow emission and tunability of emission wavelength. Such characteristics opens the possibility of using multiple QD probes, each sensitive to a specific analyte (e.g., heavy metals [38,39]), all excited by the same optical source, enabling multianalyte imaging and sensing.

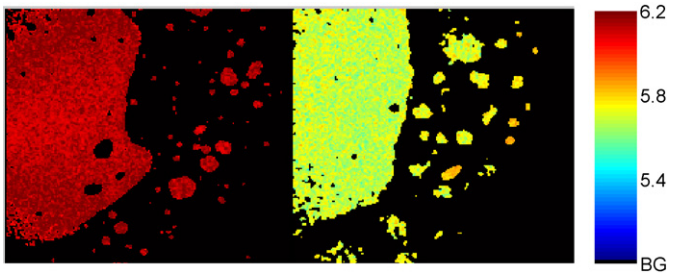

Fig. 5. Image of QDs in pH buffer 5.6 (right) and 8 (left). pH information is given by false colour scale (obtained by application of ratiometric processing and sigmoidal calibration to the original images). Black pixels correspond to background (BG).

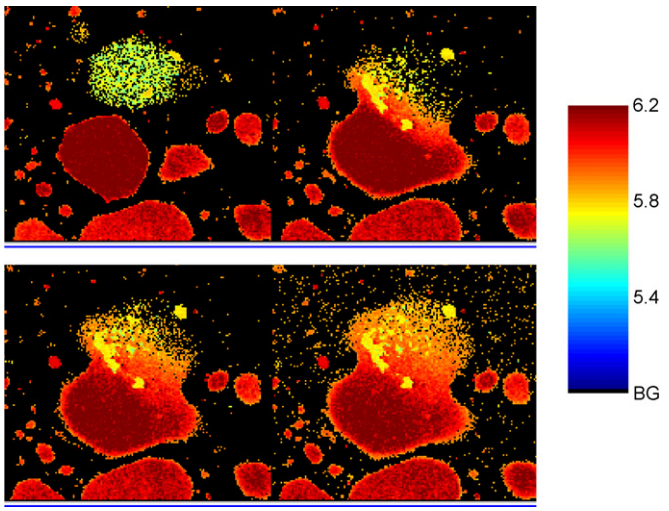

Fig. 6. Sequence of images (from left to right and top to down) showing the mixing process of two droplets with pH values at extremes of the sigmoidal response (8 and 5.6). Black pixels correspond to background (BG).

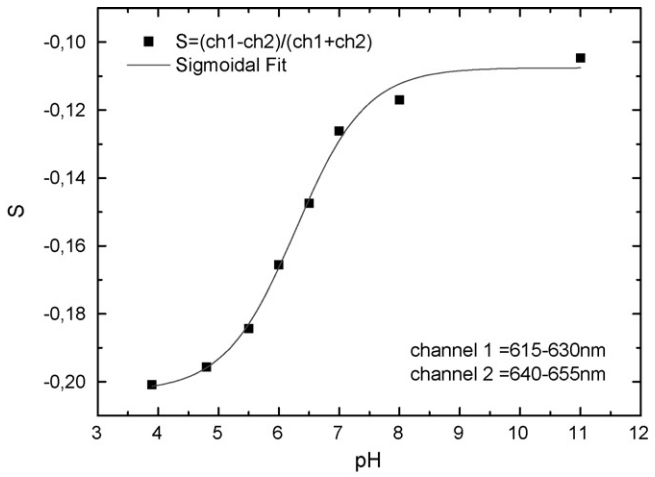

Fig. 7. Ratiometric output of the QD doped fiber probe as function of the solution pH.

3.4. Immobilization of QDs in sol–gel

The QDs were successfully immobilized in TMOS based sol–gel and highly luminescent glass parallelepiped could easily be obtained. The analysis of the emission properties of the monoliths show that the fluorescence intensity of the QDs in the sol–gel based TMOS matrix is enhanced when compared to the one in solutions. This is mostly due to the increase in QDs concentration as a consequence of a volume reduction due to shrinking. Also, the fluorescence emission bands of the different samples are changed from water to sol–gel. All the immobilized QDs showed a shift in their emission peak towards the red, of approximately 14 nm. The immobilization of QDs, introduces changes in their surrounding microenvironment. This is bound to impact mostly their surface states. In particular, the red shift observed indicates that the confinement potential of the immobilized nanoparticles was reduced.

The effect of confinement is also observed in the lifetime behaviour of the QDs. This can be seen in Table 1 where the lifetimes of the QDs in aqueous solutions and in sol–gel matrixes can be compared. In sol–gel the observed lifetimes are higher, by roughly a factor of 2, than those measured in aqueous solutions. The increased lifetimes indicate that the surrounding microenvironment is more favourable to radiative recombination of the long lived surface states when the QDs are immobilized in a sol–gel host. This shows that, while the nanoparticles are very stable in aqueous environments, water may be responsible by partially quenching their luminescence.

When the luminescent glass monoliths entered into contact with different pH aqueous solutions the lifetime and steady state properties of the immobilized QDs did not change significantly and, consequently this sol–gel host was not considered as suitable for sensor applications.

A different immobilization strategy was followed by doping TEOS with Ph-TriEOS. The resulting sol–gel films successfully immobilized the QDs in glass plates and in the tip of optical fibers showing good response to the solution pH. A red shift of approximately 12 nm was observed in the immobilized QDs emission. In this particular case the lifetime was not measured due to reduced signal to noise ratio of the probes obtained. Nevertheless, wavelength ratiometric measurement could be made with the CCD spectrometer.

3.5. Optical fiber probes

The optical fiber probes coated with the TEOS/Ph-TriEOS based films, doped with QD with emission peak at ~635 nm, were tested. When in contact to different pH buffers it could be observed that both luminescence intensity and wavelength were pH dependent, with similar behaviours to the ones observed in solution (Sections 3.2 and 3.3). However, the changes were much smaller indicating that the host matrix had still a significant interference on the QDs behaviour.

In order to evaluate the possibility of using the fiber probes as pH sensors a ratiometric detection scheme, similar to that used above in Section 3.3, was implemented. This scheme was applied to an optical fiber probe doped with QD_{580} setting Ch_1 and Ch_2 for the wavelength intervals of [615, 630 nm], and [640, 655 nm], respectively.

While the wavelength shift observed when the fiber was immersed in pH buffers ranging from pH 4.8 to 11 was barely observable in the spectrometer, it could be easily quantified using the ratiometric scheme. The results obtained are shown in Fig. 7, where the processed output of the fiber probe displays a sigmoidal dependence with pH that is in agreement with the behaviour observed in solution.

These results show the feasibility of pH sensitive QD based optical fiber sensors. However, it was observed that the sensing layer had poor long term stability. The thin film was slowly degrading losing its physical integrity and luminescent capability. This way, although the reversibility of the wavelength response could be observed, a relatively fast degradation of the luminescent intensity was taking place that limited the usefulness of the probes to a small number of essays. Further work is in progress to understand the causes of degradation and to optimize the immobilization procedures.

4. Conclusions

CdTe QDs synthesized and functionalized with MPA were shown to be pH sensitive. The nanoparticles displayed a reversible variation of their peak emission wavelength, emission intensity and lifetime with the pH. The results showed that the emission wavelength changes are more pronounced for smaller particles, which are thus more sensitive to pH. However, it was seen that increasing the particle size lead to sensitivity in a wider range spanning into more acidic pH.

A practical application of these QDs was performed using confocal laser scanning microscopy. A ratiometric scheme was successfully applied to acquired images enabling analytical imaging where pH values could be estimated.

The synthesized QDs were immobilized in different sol–gel hosts. The pH fluorescence behaviour of the nanoparticles immobilized in a TEOS/Ph-TriEOS sol–gel matrix was similar to the one observed in solution. Nevertheless, increased lifetimes and luminescence emission intensities were observed in the solid phase. Also the variations in wavelength and luminescence intensity induced by pH changes were less pronounced in the sol–gel. Nevertheless, it was shown that applying a ratiometric signal processing it was possible to measure pH using a QDs doped optical fiber probe. Work is in progress to improve the long term stability of the fiber probes.

Overall the results obtained show QD as promising labels with analytical capabilities without the need for intermediate indicator dyes and with strong potential for the development of chemically sensitive fluorescent fiber probes. Further functionalization of the quantum dots will enable to apply the same techniques to perform optical fiber sensing or analytical imaging of different chemical analytes, e.g., heavy metals. The use of QDs with different sensitivities together with their multiplexing ability will allow the application of the results obtained in this work in multipoint/multiparameter biochemical sensing and imaging techniques.

ABSTRACT

The supramolecular interaction of a homologous series of cucurbit[*n*]uril (CB[*n*], *n* = 5, 6, 7, 8) hosts and coptisine (COP) was studied by spectrofluorimetry. All of the CB[*n*]s were found to react with COP to form 1:1 host–guest stable complexes and the fluorescence intensity of the complexes was greatly enhanced. The apparent association constants of the complexes were 1.44×10^4, 1.28×10^4, 1.86×10^4 and 1.26×10^4 L mol^{-1} for CB[5], CB[6], CB[7] and CB[8], respectively. In addition, CB[5] and CB[7] exhibited a higher fluorescence signal than CB[6] and CB[8]. The fluorescence intensity of the complex with CB[7] was enhanced 70-fold compared to that of the studied drug itself. Based on the significant enhancement of fluorescence intensity of supramolecular complex, a simple, rapid, highly sensitive, and selective spectrofluorimetric method was developed for the determination of COP in aqueous solution in the presence of CB[7]. At the optimum reaction conditions, a linear relationship was obtained in the range from 0.05 to 1700 ng mL^{-1} with a detection limit of 0.012 ng mL^{-1}. The proposed method was successfully applied for the determination of the drug in urine and serum samples.

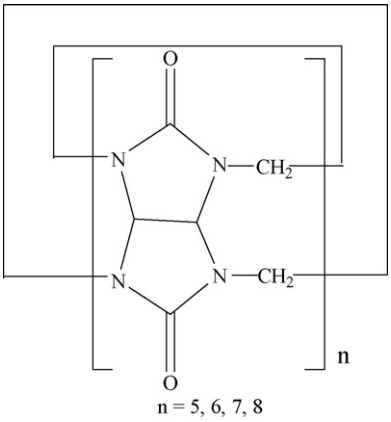
1. Introduction

The cucurbit[*n*]urils (CB[*n*], *n* = 5, 6, 7, or 8) are a relatively new family of pumpkin-like macrocyclic host molecules comprised of five, six, seven, or eight methylene-bridged glycoluril units, which possess a hydrophobic cavity accessible through portals surrounded by polar carbonyl groups capable of including a variety of hydrophobic or/and positively charged guest molecules [1–5]. Confinement in the cucurbituril macrocycle can alter the chemical and spectroscopic properties of guest molecules [6,7], enhance photostability [8,9] or facilitate stereoselective photodimerization [10,11]. Despite CB[*n*]s (Scheme 1) have become widely used in studies of general inclusion phenomena of guest molecules, little attention has been devoted to their fluorescence properties.



Coptisine (COP) (Scheme 2), an isoquinoline alkaloid originally isolated from rhizome of *Coptis japonica*, has extensive pharmacological actions, including anti-bacterial activity towards antimicrobial, anti-diarrhoea, anti-diabetic, and anti-cancer [12–15]. It also inhibits proliferation of vascular smooth muscle cells [16]. Several methods have been reported for the determination of COP including high performance liquid chromatography (HPLC) [17–20] and capillary electrophoresis (CE) [21–24]. However, most of these methods require the use of organic solvents, complicated extraction processes, expensive instruments, strictly controlled reaction conditions and time-consuming operating steps.

Spectrofluorimetry is a highly sensitive, selective, easily operated, and economical method that is widely used in the determination of pharmaceutical compounds [25–29]. COP possesses a low fluorescence emission in aqueous solution, which means that it cannot be determined directly by normal fluorimetric methods. To the best of our knowledge, fluorimetric determination of COP has not been reported. Therefore, the development of a rapid, simple, highly sensitive, and selective spectrofluorimetric method for the determination of COP in aqueous solution is highly desirable.

In this report, a comparative study of the inclusion interactions of CB[*n*] (*n* = 5, 6, 7, 8) with COP has been carried out on the basis of results obtained by spectrofluorimetry. A significant increase in the fluorescence intensity was observed when CB[*n*] was added to an aqueous solution of COP. In particular, CB[7] exhibited strong binding ability compared with the other CB[*n*]s tested. Based on the significant enhancement of fluorescence intensity of the supramolecular complexes, a spectrofluorimetric method with high sensitivity and selectivity was developed for the determination of COP in aqueous solution in the presence of CB[7]. The method is simple, accurate, and practical. Its detection limit is 0.012 ng mL^{-1}, which is lower than any other method reported thus far in the literature. The proposed method had been applied to the determination of COP in human urine and plasma samples

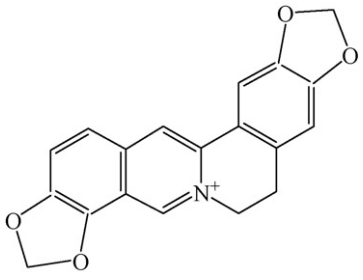
with satisfactory results. This method shows promising potential for therapeutic drug monitoring, pharmacokinetics, and clinical applications.



2. Experimental

2.1. Instruments

Fluorescence spectra and intensity measurements were obtained with a Hitachi F-4500 spectrofluorimeter equipped with a 150 W xenon lamp (Tokyo, Japan). All measurements were performed at 25 ± 0.5 °C using a thermostated cell holder and a thermostatically controlled water bath. Values of pH were measured with a pHS-3C digital precision pH meter (Shanghai, China).

2.2. Reagents

All chemicals were of analytical reagent grade and doubly distilled water was used throughout. COP was obtained from China Chengdu Scholar Bio-Tech Co. Ltd. A standard stock solution of 1.0×10^5 ng mL^{-1} was prepared with ethanol. Working solutions were obtained by appropriate dilution of the stock solution with doubly distilled water. CB[*n*] (*n* = 5, 6, 7, or 8) was prepared and characterized according to reported procedures [2]. CB[*n*] (*n* = 5, 6, or 7) stock solutions of 1.25×10^{-3} mol L^{-1} were prepared by dissolving CB[5, 6, or 7] in 3.0 mL hydrochloric acid and diluting to the mark in a 100 mL volumetric flask with doubly distilled water. CB[8] stock solution of 1.25×10^{-3} mol L^{-1} was prepared by dissolving CB[8] in 60 mL formic acid and diluting to the mark in a 100 mL volumetric flask with doubly distilled water. Working solutions were obtained by dilution of the stock solution. All four types of stock standard solutions were stable for several weeks at room temperature. Britton–Robinson buffer solution of pH 1.80 was prepared by mixing 100 mL of 0.04 mol L^{-1} acid (3.92 g of H_3PO_4 + 2.40 g of HAc + 2.47 g of H_3BO_3) with appropriate volumes of 0.2 mol L^{-1} NaOH, and adjusting to pH 2.0.

Scheme 2. The structure of coptisine.

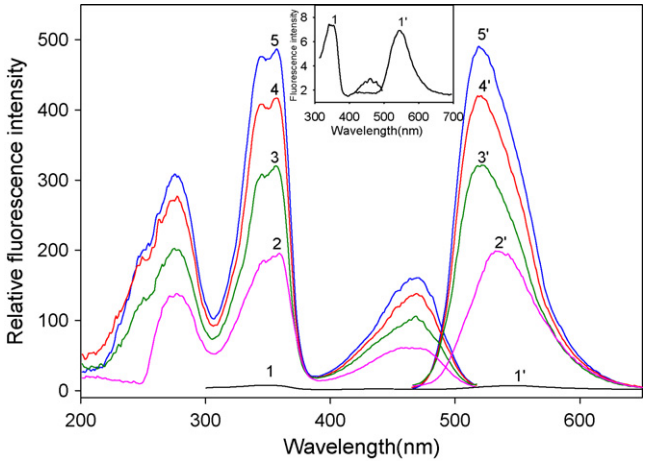


Fig. 1. Excitation and emission spectra. Excitation and emission spectra of: (1, 1′) COP (1.0×10^3 ng mL^{-1}) with $\lambda_{ex}/\lambda_{em}$ = 342/544 nm; (2, 2′) CB[8] (4.375×10^{-4} mol L^{-1})–COP (1.0×10^3 ng mL^{-1}) with $\lambda_{ex}/\lambda_{em}$ = 359/533 nm; (3, 3′) CB[6] (4.5×10^{-4} mol L^{-1})–COP (1.0×10^3 ng mL^{-1}) with $\lambda_{ex}/\lambda_{em}$ = 357/523 nm; (4, 4′) CB[5] (3.0×10^{-4} mol L^{-1})–COP (1.0×10^3 ng mL^{-1}) with $\lambda_{ex}/\lambda_{em}$ = 357/521 nm; (5, 5′) CB[7] (4.6875×10^{-5} mol L^{-1})–COP (1.0×10^3 ng mL^{-1}) with $\lambda_{ex}/\lambda_{em}$ = 358/520 nm; (1, 2, 3, 4, and 5) excitation spectra; (1′, 2′, 3′, 4′, and 5′) emission spectra.

2.3. Procedure

2.3.1. General procedure

A suitable amount of COP solution was transferred into a 10 mL volumetric flask and 2.0 mL of 1.25×10^{-3} or 3.125×10^{-4} mol L^{-1} CB[*n*] solution was added, followed by 5.0 mL of Britton–Robinson buffer of pH 2.0. After dilution to the mark with doubly distilled water, the mixture was shaken and equilibrated at room temperature for 10 min. The relative fluorescence intensity of the solution of the drug with CB[5], CB[6], CB[7] and CB[8] was then measured at 521, 523, 520 and 533 nm with excitation at 357, 357, 358 and 359 nm against a reagent blank, respectively. All measurements were performed using 1.0 cm quartz cells. Both excitation and emission slit widths were set at 2.5 nm. The fluorescence spectra were recorded at scan rate of 1200 nm min^{-1}.

2.3.2. Analysis of plasma and urine samples

5.0 mL of plasma was deproteinized by the addition of 10 mL acetonitrile and centrifuging at 4000 rpm for 5 min. 3 mL volume of the clear supernatant was pipetted into a 50 mL volumetric flask, then 2.0 mL of the drug stock solution was added. The mixture was diluted to the mark with doubly distilled water and the general analytical procedure was followed.

Urine samples were centrifuged at 4000 rpm for 5 min, then 1 mL of the clear supernatant was pipetted into a 50 mL volumetric flask, then 2.0 mL of the drug stock solution was added. The mixture was diluted to the mark with doubly distilled water. The standard additions method was used in the sample analysis procedure.

3. Results and discussion

3.1. Excitation spectra and emission spectra

The spectral characteristics of COP and its complexes were studied. As shown in Fig. 1, an aqueous solution of COP had a weak native fluorescence and the maximum excitation and emission wave-

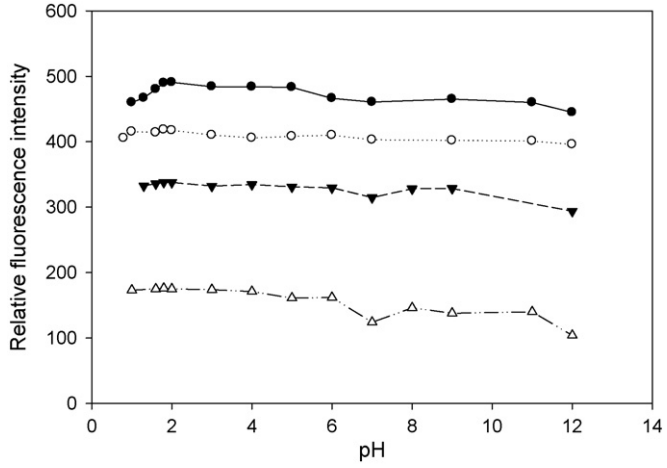

Fig. 2. Influence of pH on the fluorescence intensity. Experiment conditions: COP: 1.0×10^3 ng mL^{-1}; CB[5] (○): 3.0×10^{-4} mol L^{-1}; CB[6] (▼): 4.5×10^{-4} mol L^{-1}; CB[7] (●): 4.6875×10^{-5} mol L^{-1}; CB[8] (△): 4.375×10^{-4} mol L^{-1}.

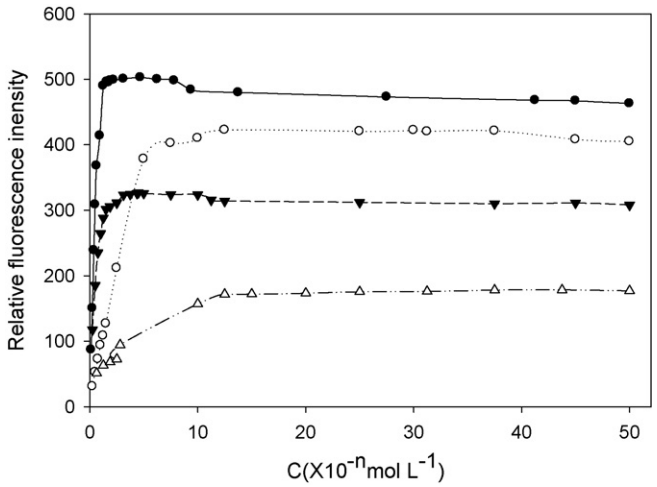

Fig. 3. Influence of CB[n] on the fluorescence intensity. Experiment conditions: COP: 1.0×10^3 ng mL^{-1}, pH 2.0; CB[5] (○): ($C \times 10^{-5}$ mol L^{-1}); CB[6] (▼): ($C \times 10^{-4}$ mol L^{-1}); CB[7] (●): ($C \times 10^{-5}$ mol L^{-1}); CB[8] (△): ($C \times 10^{-5}$ mol L^{-1}).

lengths were located at 342 and 544 nm, respectively. However, significant increases in the fluorescence intensity were observed when CB[5], CB[6], CB[7], or CB[8] were added to the aqueous solution of COP. In addition, the excitation and emission wavelengths of their complexes moved to wavelengths of 357, 357, 358, 359 nm and of 521, 523, 520 and 533 nm, respectively. These modifications of the features of the fluorescence spectra were considered to be a result of inclusion complex formation between the investigated drug and CB[n]. This is most probably due to the combination of ion–dipole interactions and hydrophobic effect contributes to the binding forces. There is coulomb attraction between the positive charge of the heterocyclic nitrogen of the guest and the high electron density of the carbonyl oxygen of the CB[n] (Scheme 1), whereas the apolar part of COP enters the interior of CB[n], displacing solvent water molecules from within the CB[n] and from the solvation sheath of the guest, thereby contributing a hydrophobic effect to the stability of the complex [6,30,31]. In addition, CB[5] and CB[7] exhibited higher signals than CB[6] or CB[8]. The fluorescence intensity of the drug was enhanced 70-fold in the presence of CB[7]. For this reason, further studies used CB[7] as the host for drug determination.

3.2. Influence of pH

The influence of pH on the relative fluorescence intensity of formed CB[n]–COP inclusion complex was therefore studied at their respective maxima using buffer solutions in the pH range of 1.0–12.0 in order to establish an optimal experimental condition. As shown in Fig. 2, the fluorescence intensity was maximal and almost constant over the pH range of 1.0–4.0 for all the studied CB[n]s tested with COP. The fluorescence intensity decreased with any further increases in pH. This behavior was probably attributable to CB[n] preferentially binding cations. Therefore, a pH of 2.0, prepared in the form of aqueous Britton–Robinson buffer solutions, was used for all subsequent experiments.

3.3. Influence of CB[n] concentration

The effect of CB[n] concentration on the fluorescence intensity of COP was examined in the range from 1.25×10^{-6} to 5×10^{-4} mol L^{-1}. As shown in Fig. 3, the fluorescence intensity of COP was rapidly enhanced as the amount of CB[n] was increased. When the concentration of CB[5], CB[6], CB[7] or CB[8] was increased up to 1.25×10^{-4}, 3.75×10^{-4}, 1.56×10^{-5} and 2.5×10^{-4} mol L^{-1}, respectively, the fluorescence intensities were maximal and leveled off at higher concentrations. Thus, the final CB[5], CB[6], CB[7] or CB[8] concentration used in further experiments was 3.0×10^{-4}, 4.5×10^{-4}, 4.6875×10^{-5} or 4.375×10^{-4} mol L^{-1}, respectively.

3.4. Influence of temperature and reaction time

The effect of temperature on the formed complexes was investigated in the range of 5–90 °C as shown in Fig. 4. All of the formed complexes were stable up to 40 °C. At temperature higher than 40 °C, the fluorescence intensity greatly decreased due to dissociation of the complexes at high temperatures. Based on these findings, all further measurements were performed at room temperature.

The fluorescence intensity reached a maximum within 10 min after the reagents had been added and remained constant for at least 5 h as shown in Fig. 5. For this reason, room temperature for 10 min was selected as a standard reaction condition.

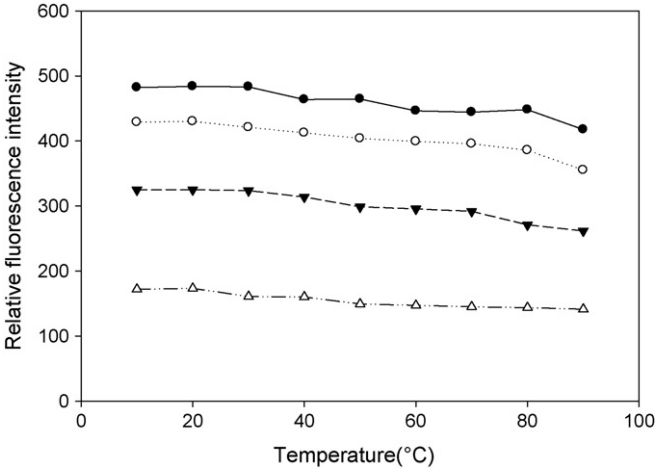

Fig. 4. Influence of temperature on the fluorescence intensity. Experiment conditions: COP: 1.0×10^3 ng mL^{-1}, pH 2.0; CB[5] (○): 3.0×10^{-4} mol L^{-1}; CB[6] (▼): 4.5×10^{-4} mol L^{-1}; CB[7] (●): 4.6875×10^{-5} mol L^{-1}; CB[8] (△): 4.375×10^{-4} mol L^{-1}.

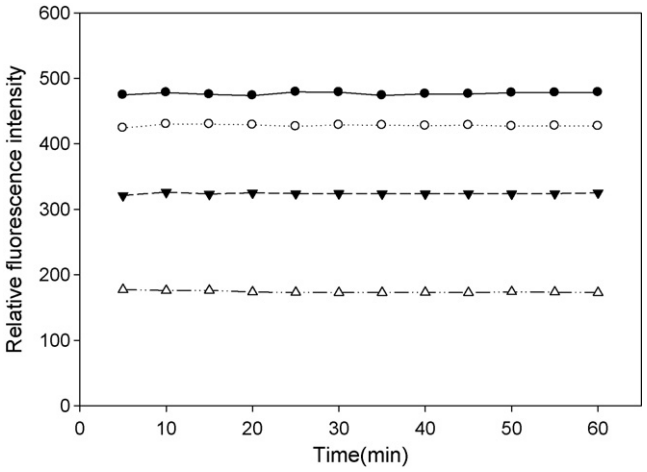

Fig. 5. Effect of reaction time on fluorescence intensity. Experiment conditions: COP: 1.0×10^3 ng mL^{-1}, pH 2.0; CB[5] (○): 3.0×10^{-4} mol L^{-1}; CB[6] (▼): 4.5×10^{-4} mol L^{-1}; CB[7] (●): 4.6875×10^{-5} mol L^{-1}; CB[8] (△): 4.375×10^{-4} mol L^{-1}.

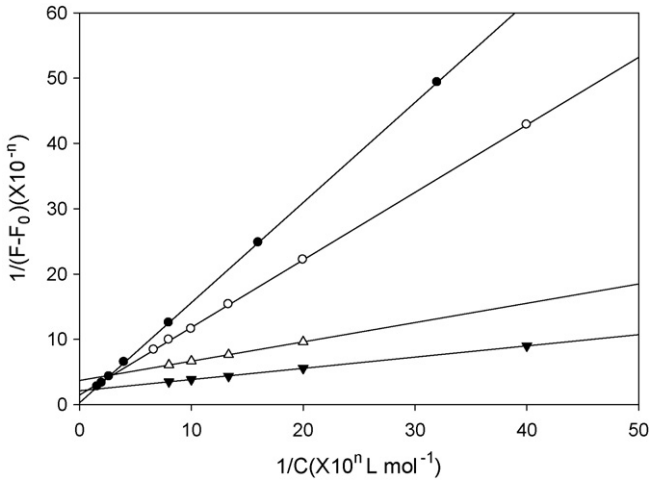

Fig. 6. Plot of $1/(F-F_0)$ vs. $1/C_{CB[n]}$. Experiment conditions: COP: 1.0×10^3 ng mL^{-1}, pH 2.0; CB[5] (○): $(1/C \times 10^4\ \mathrm{L\,mol^{-1}},\ 1/(F-F_0) \times 10^{-4})$; CB[6] (▼): $(1/C \times 10^3\ \mathrm{L\,mol^{-1}},\ 1/(F-F_0) \times 10^{-4})$; CB[7] (●): $(1/C \times 10^5\ \mathrm{L\,mol^{-1}},\ 1/(F-F_0) \times 10^{-4})$; CB[8] (△): $(1/C \times 10^3\ \mathrm{L\,mol^{-1}},\ 1/(F-F_0) \times 10^{-4})$.

3.5. Stoichiometry and association constant of the inclusion complex

The magnitude of the association constant is usually taken as a measure of the strength of the interaction between the two molecules forming the complex. For this study, 1000 ng mL^{-1} of COP solution and varying amounts of 1.25×10^{-3} mol L^{-1} CB[n] solution were prepared. Aliquots of each solution were added in different ratios to a series of 10 mL calibrated flasks, then the general procedure was followed for determination of the association constant.

The stoichiometry and association constant of the inclusion complex were studied under the established experimental conditions by the following method:

Assuming that the composition of the complex was 1:1, the expression can be written as follows:

$$\mathrm{COP} + \mathrm{CB}[n] \leftrightarrow \mathrm{CB}[n]\text{–}\mathrm{COP} \quad (1)$$

The apparent constant of the complex (K) is given by

$$K = \frac{C_{\mathrm{CB}[n]\text{–}\mathrm{COP}}}{C_{\mathrm{COP}} \times C_{\mathrm{CB}[n]}} \quad (2)$$

where C_{COP}, $C_{\mathrm{CB}[n]}$, and $C_{\mathrm{CB}[n]\text{–}\mathrm{COP}}$ are equilibrium concentrations. The association constant value for the inclusion complex can be determined by the typical double reciprocal (or Benesi–Hildebrand) plots:

$$\frac{1}{F - F_0} = \frac{1}{(F_\infty - F_0)KC_{\mathrm{CB}[n]}} + \frac{1}{F_\infty - F_0} \quad (3)$$

where F_0 is the fluorescence intensity of COP in the absence of CB[n], F_∞ is the fluorescence intensity when all of the COP molecules are essentially complexed with CB[n], and F is the observed fluorescence intensity at each CB[n] concentration tested.

A good linear relationship was obtained when $1/(F-F_0)$ was plotted against $1/C_{\mathrm{CB}[n]}$, which supported the existence of a 1:1 complex (R = 0.9998, Fig. 6). The apparent association constants for these 1:1 complexes were determined to be 1.44×10^4, 1.28×10^4, 1.86×10^4 and 1.26×10^4 L mol^{-1} in the presence of CB[5], CB[6], CB[7] and CB[8], respectively. These values were determined by dividing the intercept by the slope of the corresponding lines. It is evident that both CB[5] and CB[7] exhibited stronger binding ability than did CB[6] and CB[8].

3.6. Calibration graph and sensitivity

Under the experimental conditions described, standard calibration curves of the complexes for four CB[n]s with COP were constructed by plotting fluorescence intensity vs. concentration. The linear regression equation for each method is listed in Table 1. The correlation coefficients ranged from 0.9997 to 0.9999, indicating good linearity. The small value for the variance confirmed the small degree of scatter in the experimental data points around the regression line.

The increase in sensitivity obtained with the proposed method, compared with other methods, is very substantial. This comparison (Table 2) showed an improvement of about three orders of magnitude vs. a previous HPLC method [17]. Spectrofluorimetry through supramolecular interaction, as performed in the present study, had the main advantages over HPLC methods [17] of rapidity and sim-

plicity. The proposed method was highly sensitive when compared with spectrophotometric methods.

3.7. Effects of interferences

A systematic study of interference by the usual excipients and the main constituents of plasma and urine in the determination of COP were carried out. A 3000-fold mass excess of these over 1.0×10^3 ng mL^{-1} of COP was first tested. If interference occurred, the ratio was reduced gradually until the interference ceased. The criterion for interference was fixed at a ±5% variation in the average fluorescence intensity calculated for the established level of COP. As shown in Table 3, this method had high selectivity and it was obvious that the determination of COP was free from interference due to substances in plasma and urine samples. The emission wavelength of COP itself was 544 nm, however, in the presence of CB[*n*], the emission wavelengths of resultant complexes moved to wavelengths of 521, 523, 520 and 533 nm for CB[5], CB[6], CB[7], or CB[8], respectively. This effectively removed the interference for the determination of COP at pharmaceutical dosages in plasma and urine samples.

4. Analytical application

4.1. Analysis of spiked human plasma and urine

The high sensitivity of the proposed method allows the determination of COP in biological fluids. Therefore, spiked samples of

[a] Average of five determinations.

human urine and plasma were also analyzed, as shown in Table 4. The accuracy was assessed by calculating the recovery of COP at five concentration levels covering the specified range (five replicates at each concentration). Excellent recoveries with S.D. less than 2.0% were obtained, indicating both good accuracy and precision.

5. Conclusion

The proposed method is rapid, simple, reproducible, economical, highly sensitive, and selective. It can be used for determination of COP in its corresponding dosage forms, without interference from commonly used excipients. The proposed procedure is so sensitive that 0.012 ng mL^{-1} of COP could be determined with satisfactory accuracy and precision. The method also permits the determination of the studied drug in biological fluids.

ABSTRACT

The toxicity and bioaccumulation of organotin compounds (OTCs) led to the development of sensitive and selective analytical methods for their determination. In the past much attention was assigned to the study of OTCs in biological samples, water and sediments, coming mostly from marine environment. Little information about OTCs pollution of terrestrial ecosystems is available. In order to optimise the extraction method for simultaneous determination of butyl-, phenyl- and octyltin compounds in sewage sludge five different extractants (tetramethylammonium hydroxide, HCl in methanol, glacial acetic acid, mixture of acetic acid and methanol (3:1), and mixture of acetic acid, methanol and water (1:1:1)), the presence or not of a complexing agent (tropolone), and the use of different modes of extraction (mechanical stirring, microwave and ultrasonic assisted extraction) were tested. Extracted OTCs were derivatised with sodium tetraethylborate and determined by gas chromatography coupled with mass spectrometer. Quantitative extraction of butyl-, phenyl- and octyltin compounds was obtained by the use of glacial acetic acid as extractant and mechanical stirring for 16 h or sonication for 30 min. The limits of detection and quantification for OTCs investigated in sewage sludge were in the ng Sn g^{-1} range.

1. Introduction

Organotin compounds (OTCs) are organometallic derivatives of tin that have the highest number of commercial applications than any other element [1]. Mostly they have been used as stabilizers and catalysts in the production of poly(vinyl chloride) (PVC), polyurethanes and silicones, as antifouling paints for ship hulls, and as agricultural and wood preservative fungicides [2–4]. Due to their widespread use, OTCs may be found in different ecosystems. Today, their high toxicity for aquatic and terrestrial organisms is well documented [3,4]. Moreover, because of their toxicity and bioaccumulation potential, OTCs have been registered as priority pollutants by the European Union in the Pollutant Emission Register (2000/479/EC) and in the Water Framework Directive (2000/60/EC).

During last decades, a variety of analytical methods for the speciation of OTCs has been developed. Analytical procedures for OTCs speciation generally attempt to preserve only the organic radical during extraction, whereas the counterion and other tin heteroatomic bonds are cleaved during extraction or derivatisation [5]. Sample preparation techniques for speciation analyses of OTCs in solid samples consist of several steps: solid–liquid extraction, simultaneous derivatisation and extraction into an organic solvent, separation and detection. One of the most difficult parts of the analysis of OTCs in sewage sludge is their extraction from the complex matrix. Extraction of OTCs from solid matrices keeping their speciation preserved is not straightforward because the binding forces between OTCs and matrices are species and matrices dependant [6,7]. In addition, some OTCs are not stable during extraction. Species transformation can be considered to be one of the most serious problems during phenyltin speciation analysis [8–10].

From the discovery of the toxicity of OTCs towards numerous marine species in late 1970s, most efforts have been devoted to the development of analytical methods for their determination in marine environments (seawater, sediments and biota) [5,11,12]. There are few studies concerning tin speciation in samples from terrestrial ecosystem [10,13,14]. OTCs are entering the terrestrial environment via the leaching from products made of PVC and silicone, by the use of pesticides and the amendment of cultivated soil with contaminated sewage sludge [15,16]. OTCs were also found in leachates from landfills [17,18].

Sewage sludge is an important source of OTCs in the terrestrial ecosystems [15,16]. Thus, reliable analytical methods are needed in order to evaluate the contribution of contaminated sewage sludge to the OTCs pollution of terrestrial environment. The aim

of our investigation was to set up an analytical procedure for the speciation of OTCs in sewage sludge by gas chromatography mass spectrometry (GC–MS). The influence of the extractant, extraction technique and the presence of complexing agent on the extraction efficiency of butyl-, phenyl- and octyltin compounds from sewage sludge have been studied. The selected methods encompass five different extractants (tetramethylammonium hydroxide (TMAH), hydrochloric acid (HCl) in methanol, glacial acetic acid, mixture of acetic acid and methanol (3:1), and mixture of acetic acid, methanol and water (1:1:1)), the presence or not of a complexing agent (tropolone), and the use of different modes of extraction (mechanical stirring, microwave and ultrasonic assisted extraction). Extracted OTCs were derivatised with sodium tetraethylborate ($NaBEt_4$) and determined by GC–MS.

2. Experimental

2.1. Instrumentation

For the separation and detection a Hewlett-Packard 6890 gas chromatograph (GC) (Hewlett-Packard, Waldbronn, Germany) coupled to a Hewlett-Packard 5972A mass spectrometer (MS) was used. The GC was equipped with a 30 m × 25 mm HP-MS5 polydimethylsiloxane capillary column (film thickness 0.25 μm). The following temperature program was applied for the separation of OTCs: the column temperature was held at 80 °C for the first 4 min, raised to 180 °C at the heating rate of 10 °C min^{-1}, then to 220 °C at 20 °C min^{-1}, and to 270 °C at 30 °C min^{-1} (held at this temperature for 6 min). The splitless injector port was kept at a temperature of 240 °C and the transfer line at 280 °C. Helium (He) was used as a carrier gas (1 mL min^{-1}). The volume of injected sample was 1 μL. The MS operated with the electronic impact (70 eV) ion source at a temperature of 180 °C in the total ionization mode. Selected Ion Monitoring signals (SIM) were recorded. In Table 1 are presented the mass/charge (m/z) ratios of OTCs and their retention times. For the quantification the most abundant ions were used.

Mechanical shaking during the extraction procedure was performed on an elliptical table Vibramax 40 (Tehtnica, Železniki, Slovenia). Microwave assisted extraction was performed with a CEM MARS 5 Microwave Acceleration Reaction System, CEM Corporation (Matthews, NC, USA). Ultrasonic-assisted extraction of samples was performed with an ultrasonic bath Model 550D, VWR International (West Chester, PA, USA). Centrifugation of sample extracts was performed on a Heraeus (Osterode, Germany) Model 17S Sepatech Biofuge centrifuge and on a LC 320 centrifuge (Tehtnica, Železniki, Slovenia).

2.2. Reagents

Monobutyltin trichloride (MBT, 95%), monophenyltin trichloride (MPhT, 98%) and diphenyltin dichloride (DPhT, 96%) were purchased from Aldrich (Milwaukee, WI, USA). Dibutyltin dichloride (DBT, 97%), tributyltin chloride (TBT, 96%), triphenyltin chloride (TPhT, 95%) and tripropyltin chloride (TPrT, 98%) were obtained from Merck (Darmstadt, Germany). Monooctyltin trichloride (MOcT, 98%), dioctyltin dichloride (DOcT, 98%) were obtained from LGC Promochem (Wesel, Germany) and trioctyltin chloride (TOcT, 95%) from Fluka (Buchs, Switzerland). Organotin standard stock solutions (1000 mg Sn L^{-1}) were prepared in methanol. Working standard solutions (10 mg Sn L^{-1}) were prepared weekly from stock standard solutions by dilution in Milli-Q water (18.2 MΩ cm) (Millipore, Bedford, MA, USA). Standard solutions of 100 μg Sn L^{-1} were prepared daily. All the standards were stored in the dark at 4 °C.

Glacial acetic acid, ammonia solution and nitric acid were obtained from J.T. Baker (Phillipsburg, NJ, USA). Methanol was purchased from Merck (Darmstadt, Germany). Sodium tetraethylborate ($NaBEt_4$) was purchased from Strem Chemicals (Newburyport, MA, USA). $NaBEt_4$ was dissolved in Milli-Q water to provide a 2% (m/v) ethylating solution.

2.3. Sample preparation

Sewage sludge samples were dried at 50 °C in the dark for 3 days, homogenised and sieved through a 0.2 mm sieve. The samples were then frozen at −20 °C.

2.4. Analytical procedure

2.4.1. Extraction from the sample

Approximately 1 g of dried sewage sludge was weighted in a polyethylene (PE) extraction tube. Based on our previous experiences 0.2 μg of TPrT in methanol was added as internal standard [19]. After 15 min the samples were subjected to different extraction methods.

2.4.1.1. Method 1. 20 mL of tetramethylammonium hydroxide (TMAH) was added to the sample. The tubes were subjected to ultrasound assisted extraction for 2 h and centrifuged for 15 min at 4200 rpm.

2.4.1.2. Method 2. Samples were supplemented with 15 mL of 0.1 mol L^{-1} HCl in methanol. The closed tubes were firstly mechanically shaken on an elliptic table for 2 h and then subjected to ultrasonic assisted extraction for 1 h and centrifuged for 15 min at 4200 rpm.

2.4.1.3. Method 3. Samples were supplemented with 20 mL of glacial acetic acid. The tubes were subjected to closed vessel microwave assisted extraction for 4, 7 and 16 min. Microwave extraction conditions were as follows: 1200 W, 1 min ramp to 50 °C, hold at that temperature for 3, 6 and 15 min. After the extraction, the suspension was centrifuged for 15 min at 4200 rpm.

2.4.1.4. Method 4. To the solid sample 5 mL of methanol and 15 mL of glacial acetic acid were added. The tubes were subjected to closed vessel microwave assisted extraction for 7 min. The microwave extraction conditions were as described in Section 2.4.1.3. After the extraction, the suspension was centrifuged for 15 min at 4200 rpm.

2.4.1.5. Method 5. Samples were supplemented with 20 mL mixture of acetic acid, methanol and water (1:1:1). The tubes were subjected to closed vessel microwave assisted extraction for 7 min. The microwave extraction conditions were as described in Section 2.4.1.3. After the extraction, the suspension was centrifuged for 15 min at 4200 rpm.

2.4.1.6. Method 6. To the solid sample 5 mL of 0.02% (w/v) tropolone in methanol and 15 mL of glacial acetic acid were added. The tubes were subjected to closed vessel microwave assisted extraction for 7 min. The microwave extraction conditions were as described in Section 2.4.1.3. After the extraction, the suspension was centrifuged for 15 min at 4200 rpm.

2.4.1.7. Method 7. Samples were supplemented with 20 mL of glacial acetic acid. The closed tubes were subjected to ultrasound assisted extraction for 5, 10, 20, 30 and 60 min. After the extraction, the suspension was centrifuged for 15 min at 4200 rpm.

2.4.1.8. Method 8. As Method 7. Acetic acid–methanol mixture (3:1) instead of glacial acetic acid as extractant was applied to the samples.

2.4.1.9. Method 9. To the solid sample 20 mL of glacial acetic acid was added. The closed tubes were mechanically shaken on an elliptic table for 1, 5, 15 and 24 h in the dark. Then, the suspension was centrifuged for 15 min at 4200 rpm.

2.4.2. Derivatisation and extraction

Aliquots (1–4 mL) of the extract described above, 0.5 mL 2% (w/v) solution of $NaBEt_4$ for the derivatisation and 1 mL of isooctane for the extraction of ethylated organotin species were added to 20 mL of sodium acetate-acetic acid buffer (pH 4.8). The mixture was shaken for 45 min at 300 rpm. The same procedure, with the exception that no sample was added, was applied to determine blanks. All the analyses were made in triplicate.

2.4.3. Spiking protocol

The recovery of the studied OTCs from sewage sludge was investigated by spiking known amount of OTCs into samples of relatively low OTCs contents. For spiking of sewage sludge samples OTCs as chlorides dissolved in methanol were used. The equilibration step was carried out by shaking (350 rpm) the samples for 30 min.

For each extraction three different spikes were prepared. One aliquot of the sewage sludge was spiked with 1000 ng Sn g^{-1} of monosubstituted butyl-, phenyl- and octyltin compounds (MBT, MPhT, MOcT). The second one was spiked with 1000 ng Sn g^{-1} of disubstituted butyl-, phenyl- and octyltin compounds (DBT, DPhT, DOcT) and the third with 1000 ng Sn g^{-1} of trisubstituted butyl-, phenyl- and octyltin compounds (TBT, TPhT, TOcT). The differences between recoveries depend only on the differences in extraction procedure, as the post-extraction steps of the analytical method remained the same.

3. Results and discussion

Sewage sludge consists of a complex matrix. In order to release the molecular and ionic OTCs from organic matter in sewage sludge an appropriate digestion/extraction must be applied. In any speciation procedure, the extraction procedure must be carefully chosen so as to destroy the matrix but not to affect the authentic forms of the analyte molecules [20].

The removal of OTCs in wastewater treatment plants takes place in two steps. First, in the primary treatment mostly by sorption onto particulate matter of the wastewater [21]. Second, in the secondary biological treatment by sorption onto particulate organic sludge material and by assimilation of carbon from OTCs by microorganisms [15]. In bio-tissue the OTCs are strongly bound to the cellular structure [9]. Usually, for the extraction of OTCs from bio-tissues 25% water solution of TMAH or 0.1 mol L^{-1} HCl in methanol are applied [5,22,23]. Since sewage sludge from wastewater treatment plant is mostly composed of organic matter (dead biomass), those two extractants (Methods 1 and 2) were considered. On the other hand, the bonds between OTCs and particulate organic matter are strong. So, extraction solvents that are usually applied to sediment samples were also verified. As glacial acetic acid and mixtures of acetic acid and methanol have been the most widely reported in the literature for the extraction of OTCs from sediments and soil [12,14,24], their performance on sewage sludge was examined (Methods 3–9). All the tested methods (1–9) are precisely described in Section 2. In Table 2 a schematic description of the selected methods is presented.

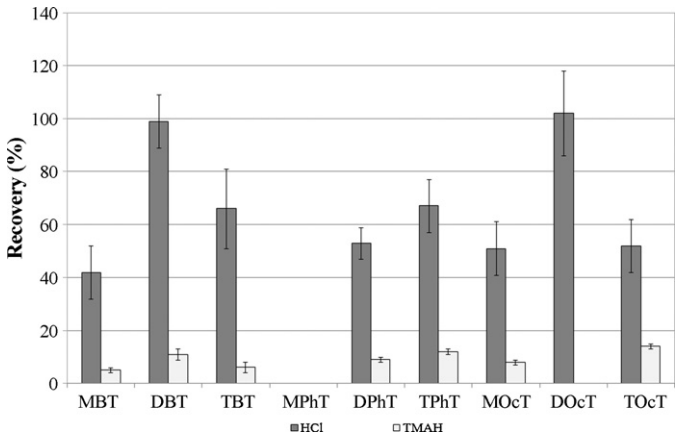

Fig. 1. Extraction recoveries of butyl-, phenyl- and octyltin compounds from spiked sewage sludge sample (1000 ng Sn g^{-1}) applying the extraction with 25% water solution of TMAH and 0.1 mol L^{-1} HCl in methanol.

3.1. Methods 1 and 2

25% water solution of TMAH and 0.1 mol L^{-1} HCl in methanol are the most frequently applied solvents for the extraction of OTCs from biological samples [5,24]. As sewage sludge is mostly composed by organic matter, the extraction efficiency of those two solvents for the extraction of OTCs from sewage sludge was tested. In Fig. 1 the extraction recoveries of both solvents are presented.

When TMAH was applied as extractant, an emulsion disturbing the analytical process during the derivatisation was formed. 25% water solution of TMAH was not efficient for the extraction of butly-, phenyl- and octyltin compounds from sewage sludge. The recoveries for all OTCs were around 10% (Fig. 1). As can be also seen from Fig. 1, when 0.1 mol L^{-1} HCl in methanol was used, the recoveries for butyltins, octyltins, DPhT and TPhT were between 40 and 60%, while MPhT was not extracted at all. High recovery values for DBT and DOcT, 100 and 105%, respectively, were observed.

If OTCs in sewage sludge is bound to the cellular structure of the biomass TMAH would efficiently solubilise the matrix in order to release OTCs (as in fish and mussel tissue). From the results it may be deduced that OTCs present in the sewage sludge are not bound to the cellular structure of the biomass but are sorbed onto the particulate organic matter. Since the binding to particulate organic matter is stronger than that to biological tissue, TMAH was too weak for the extraction of OTCs from the complex matrix of sewage sludge.

As highly polar mono- and disubstituted OTCs need acidification to increase the efficiency of extraction from the sample [7], the use of 0.1 mol L^{-1} HCl in methanol would favour their extraction. The results in Fig. 1 did not confirm that. It can be seen that monosubstituted OTCs were not efficiently extracted most probably due to too low acid concentration. Contrary, 0.1 mol L^{-1} HCl turned out to be too strong for trisubstituted OTCs provoking their degradation.

Table 2
Schematic description of tested extraction methods.

Method	Extractant	Complexing agent	Mode of extraction
1	25% water solution TMAH	–	Ultrasound assisted extraction
2	0.1 mol L^{-1} HCl in methanol	–	Mechanical stirring and ultrasonication
3	Glacial acetic acid	–	Microwave assisted extraction
4	Glacial acetic acid:methanol (3:1)	–	Microwave assisted extraction
5	Glacial acetic acid:methanol:water (1:1:1)	–	Microwave assisted extraction
6	Glacial acetic acid:methanol (3:1)	Tropolone	Microwave assisted extraction
7	Glacial acetic acid	–	Ultrasound assisted extraction
8	Glacial acetic acid:methanol (3:1)	–	Ultrasound assisted extraction
9	Glacial acetic acid	–	Mechanical stirring

Table 3
Extraction recoveries (%) of butyl-, phenyl- and octyltin compounds for spiked sewage sludge (1000 ng Sn g^{-1}) applying MWAE with glacial acetic acid.

OTCs	Extraction times		
	4 min	7 min	16 min
MBT	99 ± 6	107 ± 5	44 ± 5
DBT	105 ± 6	105 ± 6	81 ± 9
TBT	102 ± 6	97 ± 4	78 ± 7
MPhT	81 ± 8	100 ± 11	101 ± 10

TOcT	90 ± 7	100 ± 4	98 ± 6

3.2. Methods from 3 to 6

Microwave assisted extraction (MWAE) was investigated in order to substantially reduce the extraction time for the determination of OTCs in sewage sludge. Extraction times of 4, 7 and 16 min were tested. Glacial acetic acid was used as extractant (Method 3). The results are presented in Table 3.

It is evident from Table 3 that butyltin compounds were efficiently extracted with acetic acid after 4 and 7 min of MWAE. At longer extraction time the extraction efficiency of butyltin compounds was appreciably reduced. In order to find out whether the degradation of butyltin compounds took place, an additional experiment was done. Two sewage sludge samples were spiked with DBT and TBT (1000 ng Sn g^{-1}), respectively, and subjected to MWAE with glacial acetic acid for 16 min. Results are presented in Fig. 2(A) and (B).

Data from Fig. 2(A) and (B) indicate that no degradation processess occured during the course of the experiment. In addition, no increase of the Sn(IV) peak was observed. Therefore, the degradation of MBT or DBT and TBT direct to Sn(IV) may be excluded. From the results, it may be presumed that lower extraction efficiencies of butyltin compounds after 16 min of MWAE are most probably related to more efficient extraction of the organic matter from sewage sludge. The co-extracted organic matter inhibits ethylation/extraction steps, resulting in poor butyltin compounds recoveries.

It can be seen from Table 3 that MPhT was efficiently extracted after 7 min. The recoveries for DPhT and TPhT were about 20% after 4 min and below 10% at longer extraction times.

To check if the degradation of phenyltin compounds occurred, two aliquots of sewage sludge were spiked with DPhT and TPhT (1000 ng Sn g^{-1}), respectively, and subjected to MWAE with glacial acetic acid for 4 min, Fig. 3(A) and (B).

From data of Fig. 3, it is obvious that TPhT was almost completely degraded via DPhT to MPhT. Also 90% of DPhT was degraded to MPhT.

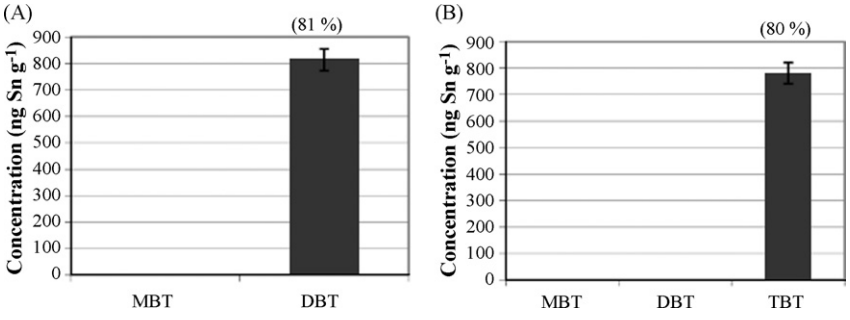

Fig. 2. Degradation of (A) TBT and (B) DBT in spiked sewage sludge (1000 ng Sn g^{-1} of TBT and/or DBT) during MWAE with glacial acetic acid (16 min).

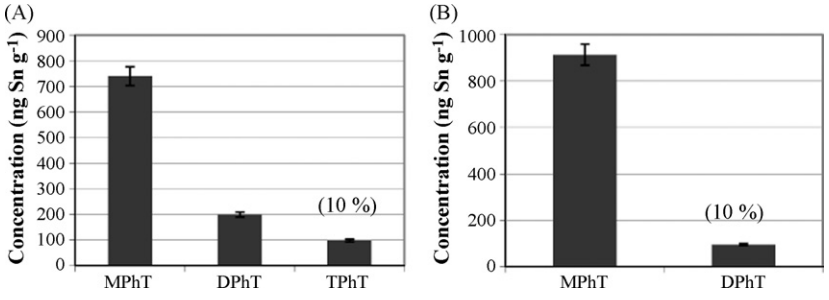

Fig. 3. Degradation of (A) TPhT and (B) DPhT in spiked sewage sludge (1000 ng Sn g^{-1} of TPhT and/or DPhT) during MWAE with glacial acetic acid (4 min).

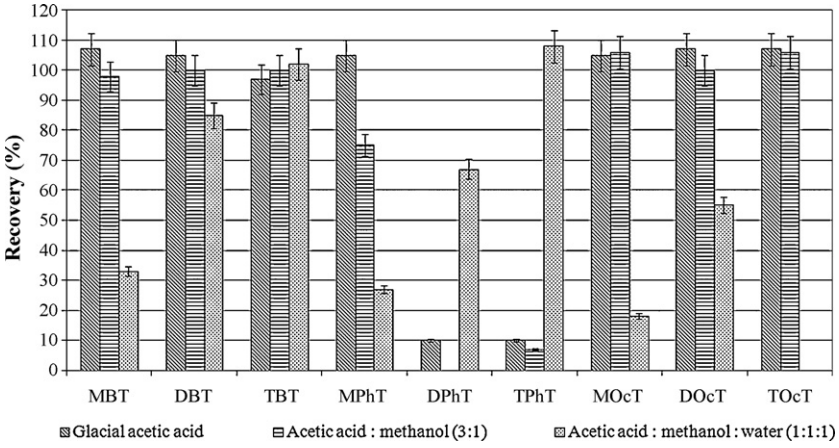

Fig. 4. Extraction recoveries for spiked sewage sludge with OTCs (1000 ng Sn g^{-1}) applying MWAE with glacial acetic acid, acetic acid and methanol (3:1), and acetic acid, methanol and water (1:1:1).

Organometallic degradation during MWAE has been previously reported by Abalos et al. [5] and Huang et al. [10]. The fast temperature increase of extracting solution induces dealkylation and dearylation of analytes [14], especially the most thermolabile, i.e. trisubstituted ones, which is in agreement with the presented data.

Octyltin compounds were efficiently extracted after 7 min (Table 3). When subjected to longer extraction times only DOcT exhibits slightly lower extraction efficiency. Since there was no evidence of the degradation of DOcT, the lower extraction efficiency for DOcT after 16 min of MWAE may be related to the influence of the co-extracted organic matter.

Based on results from Table 3 and Figs. 2 and 3, the optimal extraction time for butyl- and octyltin compounds applying MWAE and glacial acetic acid as extractant was found to be 7 min. The exceptions were phenyltin compounds, for which MWAE was not applicable.

To examine the potential of other extractants, mixtures of acetic acid and methanol (3:1) as well as acetic acid, methanol and water (1:1:1), were subjected to MWAE for 7 min. The comparison between extraction efficiencies of OTCs from spiked sewage sludge samples (1000 ng Sn g^{-1}) of the above-mentioned extractants is given in Fig. 4.

Namely, the addition of methanol to the glacial acetic acid should enhance the extraction efficiency for TBT [6], while the extraction efficiency of phenyltin and octyltin compounds should not be affected [14,25]. From comparison of results (Fig. 4) it can be seen that, as expected, the extraction recovery of TBT using acetic acid–methanol (3:1) was slightly higher than with glacial acetic acid. For MBT, DBT and octyltin compounds the addition of methanol had no great influence on the extraction efficiency, while the extraction efficiency for phenyltin compounds was even worse.

When water was added to glacial acetic acid and methanol quantitative extraction efficiency for TBT and moderate (85%) for DBT was obtained. The addition of water seemed to severely reduce the extraction efficiency of MBT, MPhT and octyltin compounds, most probably due to lower extractant strength. The most beneficial influence of water addition was observed for TPhT, where the extraction recovery raised to 100%. The addition of water and methanol to glacial acetic acid decreased the strength of the acid. This resulted in optimal condition for the extraction of TPhT, while for the efficient extraction of DPhT and MPhT the acid strength was too low.

It was experimentally proven that MWAE using 0.02% tropolone as a component of the extractant solution (Method 6) was not appropriate for OTCs analyses. Tropolone enhanced the extraction of organic matter that resulted in significant increase of the background signal during the chromatographic separation of OTCs (see data from Fig. 5).

3.3. Methods 7 and 8

Ultrasound assisted extraction (USAE) has become a widely used extraction technique. In combination with glacial acetic acid and acetic acid and methanol, high recoveries for sediment and soil samples were obtained [12,14].

For the simultaneous extraction of butyl-, phenyl- and octyltin compounds from sewage sludge sample glacial acetic acid USAE was applied for 5, 10, 20, 30 and 60 min. In Table 4 the obtained extraction efficiencies are presented.

It can be observed from Table 4 that the time of sonication has a great influence on the extraction efficiency. MBT and DBT were quantitatively extracted after 30 min, while for TBT 20 min of sonication gave quantitative recoveries. Longer extraction times did not have significant influence on the recovery of butyltin compounds.

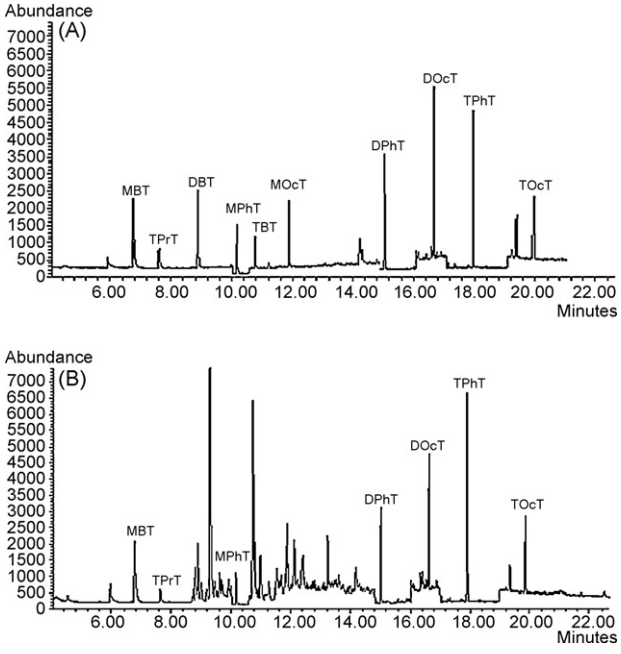

Fig. 5. Chromatograms of butyl-, phenyl- and octyltin compounds from spiked sewage sludge sample (1000 ng Sn g^{-1}) using MWAE with (A) methanol and acetic acid and (B) 0.02% (w/v) tropolone in methanol and acetic acid.

Table 4
Extraction recoveries of butyl-, phenyl- and octyltin compounds for spiked sewage sludge sample (1000 ng Sn g^{-1}) applying USAE with glacial acetic acid.

OTCs	Extraction time				
	5 min	10 min	20 min	30 min	60 min
MBT	31 ± 6	80 ± 7	63 ± 6	100 ± 5	98 ± 9
DBT	86 ± 8	83 ± 6	85 ± 9	97 ± 4	101 ± 10
TBT	89 ± 7	99 ± 10	100 ± 10	100 ± 7	99 ± 10
MPhT	44 ± 10	67 ± 12	63 ± 5	93 ± 5	86 ± 12

MOcT	54 ± 8	82 ± 7	80 ± 8	92 ± 5	102 ± 17
DOcT	83 ± 7	83 ± 6	108 ± 10	99 ± 4	100 ± 15
TOcT	89 ± 9	100 ± 9	99 ± 9	96 ± 5	100 ± 16

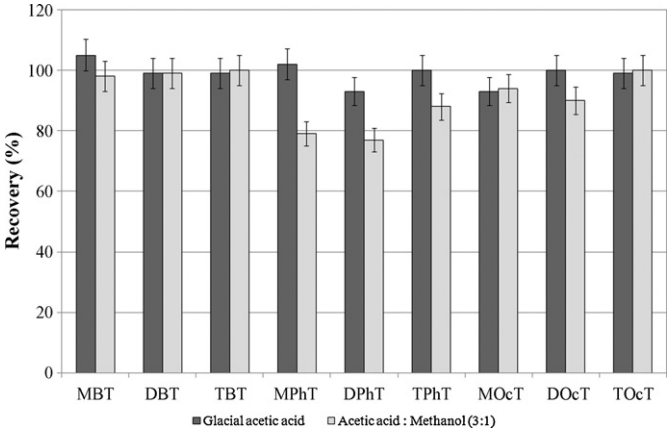

Fig. 6. Extraction recoveries of butyl-, phenyl- and octyltin compounds from spiked sewage sludge sample (1000 ng Sn g^{-1}) applying USAE with acetic acid and methanol (3:1).

Phenyltins are also efficiently extracted after 30 min of USAE. The extraction recoveries for phenyltin compounds remained constant after 30 min of sonication. MOcT showed the same behaviour as phenyltin compounds, while DOcT was efficiently extracted after 20 and TOcT after 10 min. The extending of extraction time did not significantly influence the recoveries of these two octyltin compounds.

The studied OTCs in the spiked sewage sludge sample were extracted also with a mixture of acetic acid and methanol (3:1) and subjected to USAE. The results are presented in Fig. 6.

As it was the case of MWAE, the mixture of acetic acid and methanol lowered the extraction efficiencies for phenyltin compounds by USAE, while it did not have significant influence on the extraction of butyl- and octyltin compounds.

Table 5
Extraction recoveries (%) of butyl-, phenyl- and octyltin compounds from spiked sewage sludge sample (1000 ng Sn g^{-1}) applying MSAE with glacial acetic acid.

OTCs	Extraction time			
	1 h	5 h	16 h	24 h
MBT	67 ± 7	74 ± 7	97 ± 5	82 ± 8
DBT	68 ± 10	79 ± 1	92 ± 4	80 ± 4
TBT	71 ± 8	75 ± 4	109 ± 5	75 ± 3
MPhT	59 ± 6	67 ± 7	100 ± 6	40 ± 3
DPhT	58 ± 7	74 ± 6	98 ± 5	28 ± 4
TPhT	74 ± 10	78 ± 4	97 ± 6	62 ± 6
MOcT	72 ± 7	84 ± 8	104 ± 4	90 ± 9
DOcT	75 ± 15	80 ± 2	97 ± 3	87 ± 2
TOcT	72 ± 10	80 ± 3	95 ± 5	85 ± 3

3.4. Method 9

The most frequently used extraction mode for OTCs determination in solid samples is mechanical stirring (MSAE). For the simultaneous extraction of butyl-, phenyl- and octyltin compounds from sewage sludge sample MSAE using glacial acetic acid as extractant was applied for 1, 5, 16 and 24 h. In Table 5 the obtained extraction efficiencies are presented.

As can be seen from Table 5 the extraction time has a significant influence on the extraction efficiency of MSAE. It is evident that butyl-, phenyl- and octyltin compounds are quantitatively extracted after 16 h and no degradation occurred. At longer extraction time (24 h) lower extraction efficiencies of butyl- and octyltin compounds are observed. Additional experiments where sewage sludge sample was spiked either with TBT and TOcT or with DBT and DOcT confirmed that no degradation occurred. Therefore, lower extraction efficiencies are related most probably to re-adsorption on particulate matter and/or highest amount of co-extracted matter from the sample. From Table 5, it is further evident that poor extraction recoveries after 24 h are obtained for phenyltin compounds. In the additional experiment sewage sludge sample was spiked with either TPhT or DPhT. Under these conditions important degradation of TPhT and DPhT occurred. In addition, no increase of the Sn(IV) peak was observed. Therefore, the degradation of MPhT to Sn(IV) may be excluded. Lower extraction recovery for MPhT after 24 h of MSAE with glacial acetic acid may be due to the influence of the co-extracted matter from the sample and re-adsorption on particulate matter.

Since glacial acetic acid applying MSAE for 16 h quantitatively extracted butyl-, phenyl- and octyltin compounds from sewage sludge other extracting agents (acetic acid and methanol (3:1), and acetic acid, methanol and water (1:1:1)) were not tested.

Table 6
Limits of detection (LOD), quantification (LOQ) and repeatability (as RSD) for MSAE and USAE of butyl-, phenyl- and octyltin compounds in sewage sludge.

OTCs	MSAE			USAE		
	LOD[a] (ng Sn g^{-1})	LOQ[b] (ng Sn g^{-1})	RSD (%)	LOD (ng Sn g^{-1})	LOQ (ng Sn g^{-1})	RSD (%)
MBT	27	53	8	24	49	6
DBT	28	54	3	26	53	5
TBT	40	73	4	39	71	3

[b] Limits of quantification.

3.5. Analytical performances of MSAE and USAE

Limits of detection (LOD) and quantification (LOQ) for MSAE and USEA were calculated on the basis of the standard addition method calibration curves [26]. The results for LOD, LOQ and repeatability (as relative standard deviation, RSD) for both methods are presented in Table 6.

Based on results from Tables 4 and 5 it can be concluded that quantitative extraction of butyltin compounds (MBT, DBT, TBT), phenyltin compounds (MPhT, DPhT, TPhT) and octyltin compounds (MOcT, DOcT, TOcT) is obtained by the use of glacial acetic acid as extractant and MSAE for 16 h or USAE for 30 min. As can be seen from Table 6, LOD and LOQ for the two methods are similar. Therefore, the choice of the extraction mode depends on the availability of the laboratory equipment. The experiment also confirmed that MWAE and extractants as TMAH, 0.1 mol L^{-1} HCl in methanol, mixtures of acetic acid and methanol (3:1) and acetic acid, methanol and water (1:1:1) were not applicable for the simultaneous determination of butyl-, phenyl- and octyltin compounds in sewage sludge.

4. Conclusions

For the extraction of OTCs from sewage sludge five extraction solvents (TMAH, HCl diluted with methanol, glacial acetic acid, acetic acid with methanol (3:1), and acetic acid, methanol and water (1:1:1)), the use of complexing agent (tropolone), and three extraction modes (MSAE, USAE and MWAE) were tested. Regardless of extractants applied, MWAE was not appropriate for simultaneous determination of butyl-, phenyl- and octyltin compounds in sewage sludge. Quantitative extraction of butyl-, phenyl- and octyltin compounds was obtained by the use of glacial acetic acid as extractant and MSAE for 16 h or sonication for 30 min. Both extraction procedures represent reliable analytical tool for the determination of the content of OTCs in sewage sludge.

ABSTRACT

A novel fluorescence turn-on detection method of human serum albumin (HSA) and bovine serum albumin (BSA) in aqueous solution is investigated using 2,4-dihydroxyl-3-iodo salicylaldehyde azine (DISA). Upon the addition of DISA to HSA/BSA solution, a fluorescence turn-on effect at 529 nm can be observed with a large stokes shift of ~129 nm based on hydrophobic binding-mode between protein and dye. Under the optimal condition, the linear ranges of fluorescence intensity for HSA and BSA are 0.1–30 μg mL^{-1} with the relative correlation coefficient of R^2 = 0.991 (n = 10) and 0.3–50 μg mL^{-1} with R^2 = 0.997 (n = 10); and the detection limits for HSA and BSA based on IUPAC ($C_{DL} = 3S_b/m$) are 20 ng mL^{-1} and 50 ng mL^{-1}, respectively.

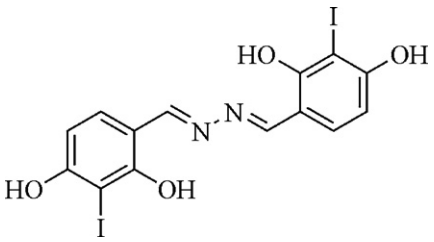
1. Introduction

Protein detection is of profound importance in a wide range of investigations such as biochemistry and immunodiagnostics. Traditional ways of detecting proteins are generally based on absorption spectrometry, such as Bradford method [1], Lowry method [2] and Biuret method [3]. However, these detecting methods usually suffered limitations like complicated steps, limited sensitivity and narrow linear range.

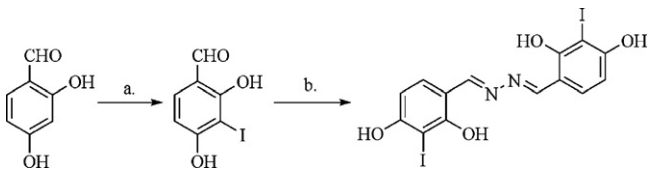
As a conventional and highly sensitive analytical method, fluorometric detection of proteins [4] depending on covalent and noncovalent-labeling has attracted increasing interests [5]. The covalent-labeling fluorescent methods are generally of high sensitivity through the reaction between the fluorophore and the primary amine in proteins [6–8]. Nevertheless, disadvantages such as multi-steps, inefficiency and rigorous conditions-needing have blocked further applications of these measurements. Compared to covalent-labeling, low-cost and fast noncovalent-labeling methods treated with relative facile manipulations are attracting more focuses [9,4,10–15].

Notably, most fluorometric detection of proteins via noncovalent-labeling are based on electrostatic interaction between proteins and dyes [16–19], which might be probably interfered by electrolyte in body fluid when actual sample measurements are processed, or fluorescence-quenching effect of protein endogenous fluorescence by the addition of organic molecules, which would have a negative effect on the detection sensitivity. In this paper, we report a novel fluorescence turn-on bioprobe, 2,4-dihydroxyl-3-iodo salicylaldehyde azine (DISA, Scheme 1), which can facilely, sensitively and selectively detect human serum albumin (HSA) and bovine serum albumin (BSA) in aqueous solution through hydrophobic binding-mode. The application of the proposed method in actual sample detection is also studied.



2. Experimental

2.1. Materials, methods, and instrumentation



Unless otherwise noted, all reagents and solvents used in this paper are analytical grade without further purification. Proteins (BSA, HSA, ·γ-globulin, ovalbumin and lysozymn) are purchased from Sigma Chemical Co., USA. The stock solutions of proteins are 0.1, 1, and 10 mg mL^{-1}, prepared by dissolving proteins in aqueous phosphate buffer (PB) at pH 6.0 and stored at 4 °C. Other reagents are purchased from Alfa Aesar Co., Tianjin, China. Doubly distilled deionized water is used throughout the experiment. PB solutions with different pH values are prepared by mixing appropriate volumes of Na_2HPO_4 and NaH_2PO_4 to obtain 20 mM stock solution. 1 mM stock solution of DISA is prepared by dissolving appropriate product in ethanol. The determinations of cmc (critical micelle concentration) of SDS, CTAB and Triton X-100 are conducted by plotting the conductivity against the concentration of surfactants in 1:9 ethanol/water buffered by 10 mmol L^{-1} PB at pH 6.0. The curve shows two good linear regions, and cmc is the intersection point obtained by extrapolating the linear region of plots. Samples

of people serum and bovine serum are bought from Beijing Solarbio Science & Technology Co. Ltd.

Absorption spectra are carried on JASCO V-550 UV–vis spectrophotometer. Fluorescence spectra and intensities are recorded on JASCO FP-6500 spectrofluorimeter equipped with a xenon discharge lamp, 1 cm quartz cells. All pH measurements are performed with a pHS-3C pH meter (Shanghai Precision & Scientific Instrument Co. Ltd., Shanghai, China). ^{1}H and ^{13}C NMR spectra are measured using a JOEL JNM-ECA300 spectrometer operated at 300 MHz. ESI-MS spectra are operated on a HP 1100 LC–MS spectrometer. Elemental analyses are performed on an Elementar Vario EL (Germany). X-ray crystal structure data collection is controlled by XSCANS program. Computations are performed using the SHELXTL NT ver. 5.10 program package on an IBM PC 586 computer. Analytic expressions of atomic scattering factors are employed, and anomalous dispersion corrections are incorporated. Crystal drawing is produced with Windows XP. Unless otherwise mentioned, all measurements are operated at room temperature of about 293 K.

2.2. Synthesis of DISA

As shown in Scheme 2, the synthesis of DISA begins with 3-iodation of 2,4-dihydroxylbenzaldehyde [20], in which K_2CO_3 (1.7 g, 12.5 mM) and I_2 (3.2 g, 25.0 mM) are added to a solution of 2,4-dihydroxylbenzaldehyde in CH_3CN (25.0 mL) and react for 24 h at 50 °C. Above synthetic route affords iodated compounds with a yield of 21% after purification by flash chromatography (petroleum ether:ethyl acetate = 1:1). Immediate product is then reacted with hydrazine hydrate (85%) at molar ratio of 2:1 in ethanol at room temperature overnight to precipitate [21–23]. After that, the resulting precipitations are filtered and washed by 30.0 mL cold ethanol/water (1:1, v/v) for three times. After drying in vacuo and recrystallization in DMSO/ethanol (1:1, v/v), DISA is obtained with a high yield of 80%.

2.3. Characterization

DISA is characterized by ^{1}H, ^{13}C NMR, ESI-MS and elemental analysis. ESI mass spectrometry for DISA: m/z 522.83 ([M−H]$^-$); M$^-$ calculated: 523.87. ^{1}H NMR (DMSO-d_6), δ (ppm): 6.59 (d, 2H, Ar-H, J = 8.4 Hz), 7.38 (d, 2H, Ar-H, J = 8.4 Hz), 8.85 (s, 2H, –CH=N), 11.18 (s, 2H, Ar-OH), 12.65 (s, 2H, Ar-OH). ^{13}C NMR (DMSO-d_6) δ (ppm): 75.8, 107.8, 110.3, 134.4, 160.8, 162.1, 163.5. Elemental analysis: C 32.02%, H 1.99%, I 48.47%, N 5.39%, O 12.13%, calculated for $C_{14}H_{10}I_2N_2O_4$: C 32.09%, H 1.92%, I 48.43%, N 5.35%, O 12.21%. From the crystal structures of DISA in Fig. 1, intramolecular hydrogen bonds of salicylaldamine moieties and stacking of molecules can be clearly observed, which are accordant with analogous compounds in our previous work [21].

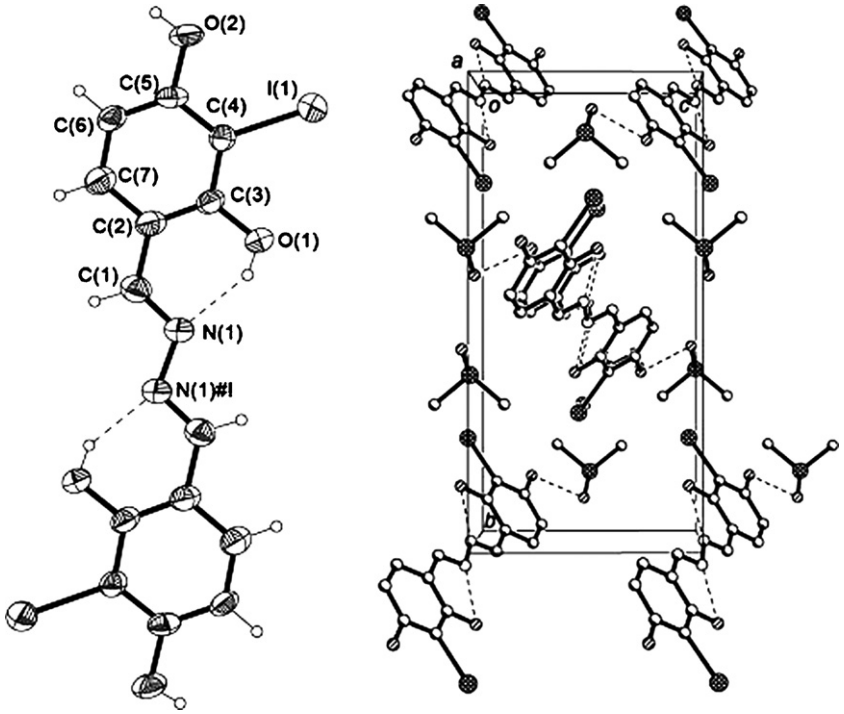

Fig. 1. Crystal structure of compound DISA. Left: ORTEP drawing with 35% probability ellipsoids. Right: A packing view along the *a* direction. The crystal structure is obtained as $C_{14}H_{10}I_2N_2O_4 \cdot 1.5(CH_3)_2SO$ to get reasonable thermal parameters as the mixed solvents of 9:1 ethanol/DMSO is used.

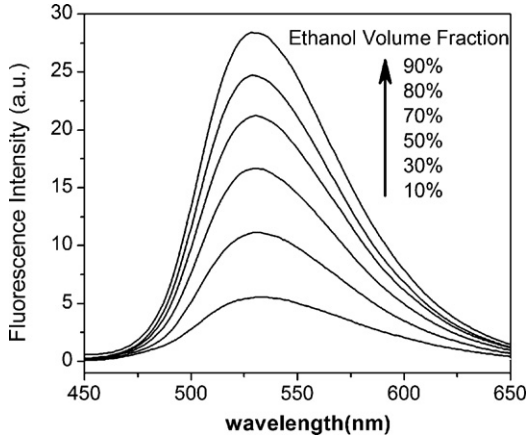

Fig. 2. Fluorescence spectra of DISA (10 μM) with the increasing of ethanol volume fraction from 10% to 90% buffered by 10 mM PB at pH 6.0. Excitation is performed at 400 nm.

3. Results and discussions

3.1. Fluorescence turn-on detection of DISA·HSA and DISA·BSA

For HSA and BSA, these two proteins have been virtually proved to be with very similar protein structure [24], which are mainly composed of α-helices lined with several hydrophobic pockets [25–27]. The presence of surface hydrophobicities in serum albumin underlies effective binding sites with a number of organic and inorganic molecules, especially those compounds with aromatic and heterocyclic ligands [28–31]. As shown in Fig. 2, the fluorescence intensity of DISA increases with the increasing of the solution hydrophobicity as the ethanol volume fraction is from 10% to 90%, predicting the application of DISA in the detection of HSA and BSA [32,33].

Interactions between DISA and proteins are first investigated by fluorescence spectra in aqueous PB (pH 6.0) at room temperature. Fluorescence spectra are performed at λ_{em}(DISA·HSA/BSA) = 529 nm with λ_{ex}(DISA·HSA/BSA) = 400 nm. As shown in Fig. 3, DISA shows little fluorescence in 10 mM PB solution at pH 6.0, while the fluorescence intensity of DISA is greatly enhanced by interacting with HSA and BSA.

In this study, interactions between DISA and HSA/BSA are greatly influenced by pH of the solution. The effect of pH on the fluorescence intensity of DISA·HSA/BSA is investigated in 10 mM PB at pH 5.5–8.0. As illustrated in Table 1, both fluorescence intensity ratio of $I_{HSA·DISA}/I_{DISA}$ and $I_{BSA·DISA}/I_{DISA}$ reach maxima around pH 5.5–6.0 and significantly decline after pH further increasing. That is because DISA might undergo deprotonation at high pH (observed from Fig. 4, pK_a values of DISA are 6.2 and 8.1, respectively) and negatively charged ions of DISA would weaken the hydrophobic force between DISA and proteins. Considering pH 6.0 is closer to physical environment pH, it is set as the optimum pH to detect proteins in this paper.

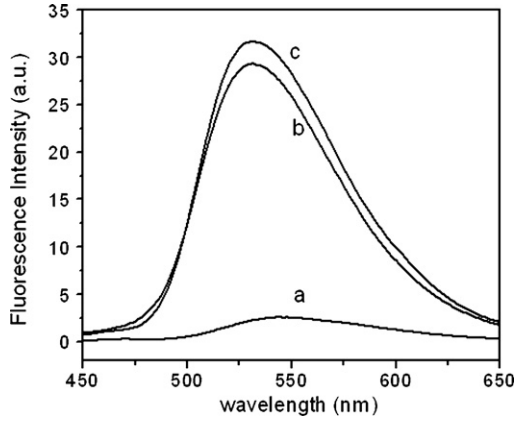

Fig. 3. Fluorescence spectra of DISA·HSA and DISA·BSA. (a) 10 μM DISA; (b) DISA + 0.1 mg mL^{-1} BSA; (c) DISA + 0.1 mg mL^{-1} HSA in 10 mM PB at pH 6.0. Excitation is performed at 400 nm.

Table 1
The pH effect on the fluorescence intensity ratio of $I_{DISA·HSA}/I_{DISA}$ and $I_{DISA·BSA}/I_{DISA}$.

pH	5.5	6.0	6.5	7.0	7.5	8.0
$I_{DISA·HSA}/I_{DISA}$	21.0	21.4	15.9	6.9	3.4	2.8
$I_{DISA·BSA}/I_{DISA}$	15.4	18.3	13.5	7.5	4.3	3.5

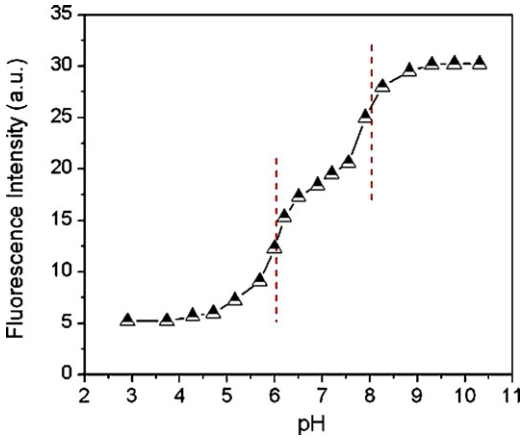

Fig. 4. pH effect on the fluorescence intensity of DISA (10 μM) in 1:9 ethanol/water buffered by 10 mM PB. Excitation is performed at 400 nm.

The dynamics of the reaction between DISA and HSA/BSA is investigated by operating time-dependent fluorescence spectra. As shown in Fig. 5, it takes about 5 min to produce more than 95% of the total fluorescence intensity. Therefore, each sample is laid for 5 min before analyzing procedures.

3.2. The binding modes of DISA·HSA and DISA·BSA

According to previous literatures, iodo-compounds can react with proteins by covalent binding of iodine atom and active residues on proteins, such as thiolate of cyc-34 residues in HSA and BSA [34,35]. To further investigate the interaction between DISA and serum albumin, the possibility of the covalent binding

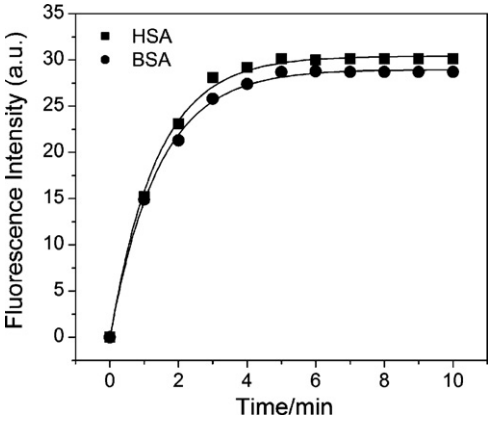

Fig. 5. Kinetic behavior of the fluorescence of DISA·HSA and DISA·BSA in 10 mM PB at pH 6.0. Excitation is performed at 400 nm.

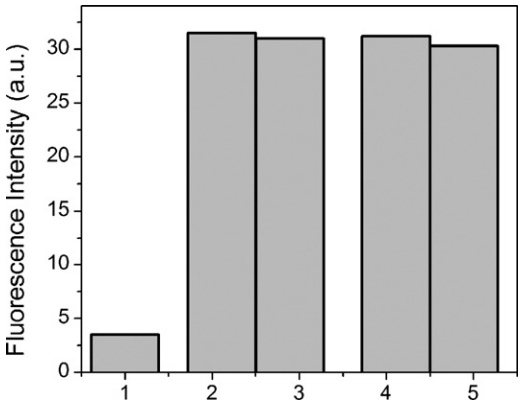

Fig. 6. Comparison between DISA·HSA/BSA and DISA·blocked HSA/BSA in 10 mM PB at pH 6.0. Column 1: DISA; Column 2: DISA·HSA; Column 3: DISA·BSA; Column 4: DISA·blocked HSA; Column 5: DISA·blocked BSA. Excitation is performed at 400 nm.

should firstly be eliminated as there are two iodine atoms on DISA. Hence, HSA and BSA (1 mg mL^{-1}) in 10 mM PB are incubated with a 100-fold molar excess of iodoacetamide for 20 h in the dark [36,37] to block active residues. As demonstrated in Fig. 6, fluorescence intensity of DISA·blocked HSA/BSA show almost no difference from DISA·HSA/BSA, eliminating the possibility of the covalent binding between DISA and HSA/BSA.

To further confirm the noncovalent interaction between DISA and HSA/BSA, several protein-unfolding agents like surfactants and urea are utilized. The protein-structure-unfolding ability for different surfactants below cmc follow the order of anionic > cationic > non-ionic surfactant [38–40]. As shown in Fig. 7, the fluorescence intensities of DISA·HSA and DISA·BSA are dramatically weakened by adding 0.1 mM sodium dodecyl sulphate (SDS, cmc = 0.3 mM), 0.1 mM cetyltrimethyl ammonium bromide (CTAB, cmc = 0.9 mM) and 0.1 mM Triton X-100 (cmc = 8.1 mM) [41] following the order of $I_{\text{DISA·HSA/BSA+SDS}} < I_{\text{DISA·HSA/BSA+CTAB}} < I_{\text{DISA·HSA/BSA+Triton X-100}}$. In the study of urea-induced unfolding of HSA and BSA [42], the fluorescence intensity of DISA·HSA/BSA is also stepwisely weakened by the addition of urea (Fig. 8). These two results both explicate the folding-structure-sensitive interaction between DISA and HSA/BSA; in other words, DISA is confirmed to serve as a noncovalent-labeling bioprobe in protein detection.

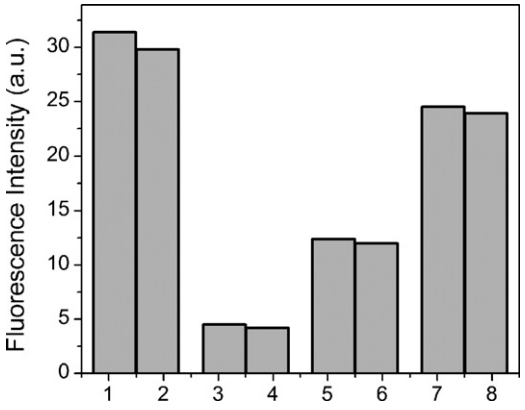

Fig. 7. The effect of different surfactants on the fluorescence intensity of DISA·HSA/BSA in 10 mM PB at pH 6.0. Column 1: DISA·HSA; Column 2. DISA·BSA; Column 3: DISA·HSA + SDS; Column 4: DISA·BSA + SDS; Column 5: DISA·HSA + CTAB; Column 6: DISA·BSA + CTAB; Column 7: DISA·HSA + Triton X-100; Column 8: DISA·BSA + Triton X-100. The concentrations of added surfactant are all 0.1 mM, below the cmc of 8.1, 0.9 and 0.3 mM for SDS, CTAB and Triton X-100, respectively. Excitation is performed at 400 nm.

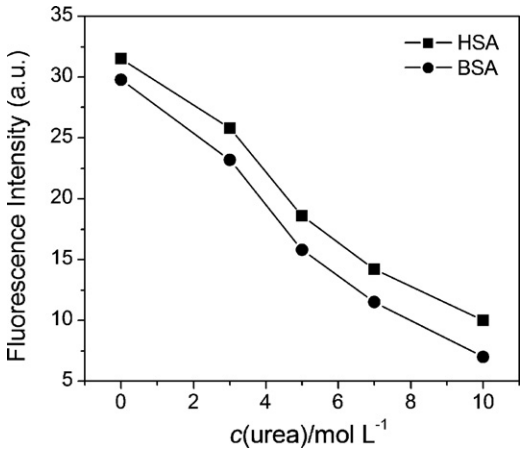

Fig. 8. The effects of different concentrations of urea on the fluorescence intensity of DISA·HSA/BSA in 1:9 ethanol/water buffered by 10 mM PB at pH 6.0. Excitation is performed at 400 nm.

To determine the maximum binding site number of DISA·HSA/BSA, job's plot [43] is constructed by utilizing fluorescence enhancement characteristics of DISA·HSA/BSA while maintaining the total concentration of DISA plus HSA/BSA at a constant value of 10 μM. There are three structurally homologous domains (I–III) in HSA/BSA molecules, each containing two subdomains (A and B) stabilized by disulfide bonds. Particularly, subdomains IIA and IIIA (also called as Sudlow site I and Sudlow site II) are termed to be the predominant binding sites with the foreign compounds [44–47]. This is indeed the case as shown in Fig. 9. The inflection points of job's plot give the value of 0.63 and 0.65 for DISA·HSA and DISA·BSA respectively, indicating a stoichiometric ratio of 2:1 and two noncovalent binding sites for each protein.

Taking into consideration of binding mode for the complex formation, the determination for thermodynamic parameters of enthalpy change (ΔH) and entropy change (ΔS) are carried out. Generally for the noncovalent interactions of DISA·HSA/BSA, hydrogen bonds ($\Delta H < 0$, $\Delta S < 0$), van der Waals forces ($\Delta H < 0$, $\Delta S < 0$), hydrophobic ($\Delta H > 0$, $\Delta S > 0$) and electrostatic interactions ($\Delta H < 0$, $\Delta S > 0$) all play potential roles [48–51]. To obtain these thermodynamic parameters, the temperature dependence of binding constant K is studied by fluorimetric tritration of DISA with

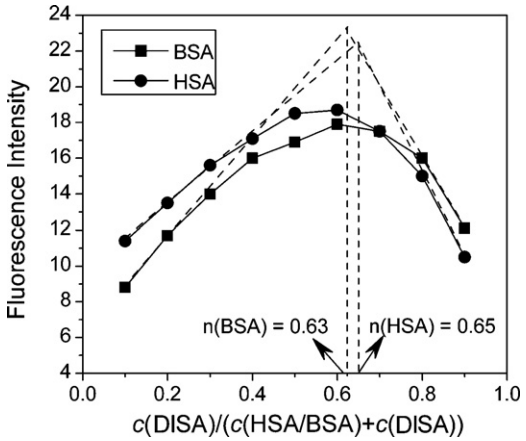

Fig. 9. Job's plots of fluorescence intensities as functions of the molar fraction of HSA/BSA in 10 mM PB at pH 6.0. The total concentration c(HSA/BSA) + c(DISA) is kept constant at 10 μM. The inflection points of job's plot give a value of 0.65 (for HSA) and 0.63 (for BSA) respectively, which correspond to the stoichiometric ratio of n(DISA:HSA/BSA) = 2:1. Excitation is performed at 400 nm.

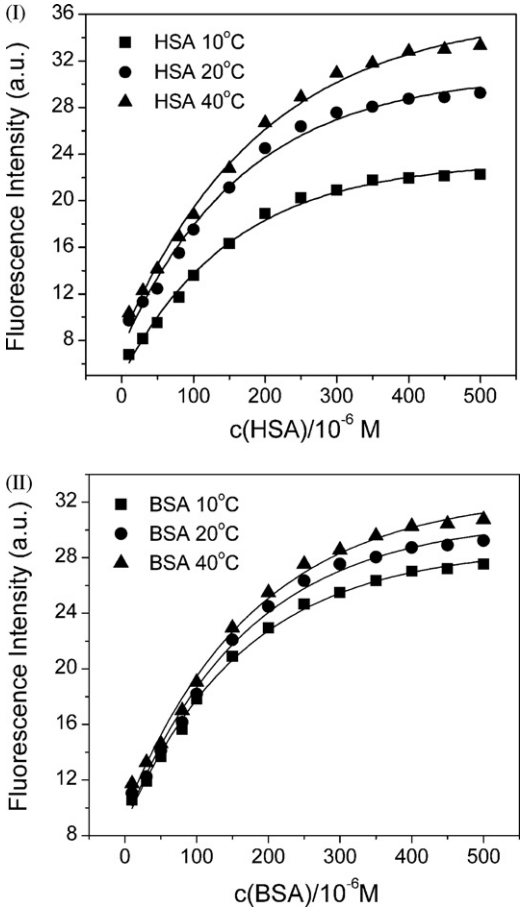

Fig. 10. The binding curve of DISA·HSA (10-I) and DISA·BSA (10-II) at different temperatures of 10 °C, 20 °C and 40 °C in buffered 10 mM PB at pH 6.0. Excitation is performed at 400 nm.

HSA/BSA at three different temperatures, 10 °C, 20 °C and 40 °C, under which HSA and BSA are structure-stable (Fig. 10). The binding constants K for DISA·HSA and DISA·BSA complexes are determined according to the following equation:

$$\Delta I_s = \frac{C[\mathrm{P}](K_1[\mathrm{DISA}] + K_1K_2[\mathrm{DISA}]^2)}{(1 + K_1[\mathrm{DISA}] + K_1K_2[\mathrm{DISA}]^2)}$$

where ΔI_s is the margin of fluorescence intensity ($\Delta I_s = I_s - I_{\mathrm{DISA}}$); [P] is the concentration of protein; K_1 and K_2 are the first and second binding constants, respectively; C is the constant of the equation. Calculations are refined through nonlinear least-squares analysis by origin program. After obtaining fitting K values (Table 2), ΔG, ΔH and ΔS are acquired according to the van't Hoff equation and thermodynamic formulas. As shown in Table 3, the binding reaction of DISA·HSA and DISA·BSA are both spontaneous accompanied by positive ΔH and ΔS values, generally revealing the hydrophobic binding modes mechanism. Consequently, the hydrophobic interaction should probably be the main binding force for DISA·HSA and DISA·BSA complexes.

For comparison, ovalbumin, γ-globulin, and lysozymn are selected, which are of different hydrophobicities following the order HSA > BSA > γ-globulin > lysozymn > ovalbumin (if the hydrophobicity of ovalbumin is set as 1, those of lysozymn, γ-globulin, BSA and HSA are 1.7, 5.5, 181.9 and 182.1, respectively) [52,53]. As demonstrated in Column 1–6 of Fig. 11, the fluorescence intensity of DISA·proteins follow the similar order to that of hydrophobicity: DISA·HSA > DISA·BSA > DISA·γ-globulin > DISA·lysozymn > DISA·ovalbumin, demonstrating selective detection of HSA/BSA due to stronger hydrophobic interactions between DISA and HSA/BSA than other proteins accordant with previous literature [52]. To investigate the potential application of this method to other hydrophobic protein, the fluorescence intensity of gluten (a very hydrophobic protein) [54] upon the addition of DISA is also measured as shown in column 7 of Fig. 11, which is nearly as strong as HSA and BSA. The difference between gluten and HSA/BSA is that HSA/BSA are basically hydrophilic with several hydrophobic pockets in them, while the surface of gluten is mostly composed by hydrophobic amino acids, which can interact with DISA by hydrophobic interaction. Therefore, this method can also be applied in the detection of other hydrophobic proteins.

3.3. Effect of foreign substances

Interference of foreign substances is carefully tested and demonstrated in Table 4. It is found that most of metal ions, amino acids or nucleic acid displayed no or little interference on HSA/BSA detection.

Table 3
Thermodynamic parameters of DISA·HSA and DISA·BSA at 20 °C[a].

	ΔG_1 (kJ/mol)	ΔH_1 (kJ/mol)	ΔS_1 (J/K mol)	ΔG_2 (kJ/mol)	ΔH_2 (kJ/mol)	ΔS_2 (J/K mol)

[a] Conditions: 20 μg mL^{-1} HSA/BSA, 10 μM DISA, 10 mM PB solution at pH 6.0, 30 min reaction time at room temperature. Excitation/emission is performed at 400/529 nm.
[b] Determination of protein in solution by the absorption of Tyr and Trp at 280 nm; and 1 mg mL^{-1} BSA is set as a protein standard of $A_{280\,nm}$ = 0.66. In analytical procedures, 5.0 mL PB stock solution at pH 6.0 is transferred to a 10.0 mL flask; then 200 μL of a sample solution are subsequently added. The solution is diluted to the mark with water and well mixed in the shaking bed (120 rpm^{-1}, 298 K) for 5 min and then absorbance at 280 nm was recorded.

4. Analytical applications

4.1. Calibration curve and detection limits

Calibration curve is studied for the determination of HSA and BSA. Under optimum conditions (10 mM PB at pH 6.0, 10 μM DISA, 5 min reaction time, $\lambda_{ex}/\lambda_{em}$ at 400/529 nm at room temperature), the linear range for HSA and BSA are 0.1–30 μg mL^{-1} with a relative correlation coefficient of R^2 = 0.991 (n = 10) and 0.3–50 μg mL^{-1} with R^2 = 0.997 (n = 10), respectively. The detection limits for HSA and BSA based on IUPAC ($C_{DL} = 3S_b/m$) are 20 ng mL^{-1} and 50 ng mL^{-1} according to 10 black measurements. The relative standard deviation (R.S.D.) for five repeated measurements of 10 μg mL^{-1} HSA and BSA are 1.3% and 1.5%, respectively.

4.2. Application in real sample detection

This proposed method is applied for detecting HSA in human serum and BSA in bovine serum. In analytical procedures, 50.0 mL PB stock solution at pH 6.0 is transferred to a 100.0 mL flask; then 1.0 mL 0.1 mol L^{-1} DISA stock solution and 50 μL of sample solutions are subsequently added. The solution are diluted to the mark with water and well mixed in the shaking bed (120 rpm, 298 K) for 5 min. Afterwards, the fluorescence spectra are examined at excitation/emission wavelength of 400/529 nm. As shown in Table 5, satisfactory recovery and R.S.D. values are both achieved. Furthermore, a comparison method using UV detection is also applied, which is commonly utilized for analyzing serum album in blood; and experimental results of the proposed method are valid and effective as illustrated in Table 5.

5. Conclusion

In conclusion, we described a novel fluorescence turn-on method for protein detection with facility, selectivity, wide linear range and good sensitivity. A large Stokes shift of ~129 nm is observed for DISA, which serves as a noncovalent fluorescence bioprobe, compared to traditional molecular bioprobes after the addition of HSA/BSA. The binding mode between protein and DISA is proved to be hydrophobic interaction. In addition, the detection of other hydrophobic proteins by DISA is also workable. This method can be successfully used for the determination of HSA in people serum and BSA in bovine serum; and further biological applications for DISA are still in progress in our laboratories.

ABSTRACT

This work exploited a sequential injection lab-on-valve (LOV) system for the determination of cadmium by anodic stripping voltammetry (ASV). A miniaturized electrochemical flow cell (EFC) was fabricated in LOV, in which a nafion coated bismuth film electrode was used as working electrode. The cadmium was electrodeposited on the electrode surface in bismuth solution, and measured with the subsequential stripping scan. Under optimal conditions, the proposed system responded linearly to cadmium concentrations in a range 2.0–100.0 $\mu g\,L^{-1}$. The detection limit of this method was found to be 0.88 $\mu g\,L^{-1}$. By loading a sample volume of 800 μL, a sampling frequency of 22 determinations h^{-1} was achieved. The repeatability expressed as relative standard derivation (R.S.D.) was 3.65% for 20 $\mu g\,L^{-1}$ cadmium ($n = 11$). The established method was applied to analysis of trace cadmium in environmental water samples and the spiked recoveries were satisfactory.

1. Introduction

Cadmium is one of the most dangerous elements in environmental and biological system. Cadmium can accumulate in the bones, liver and kidneys of human body, where it damages the immune system and the central nervous system, and causes psychological disorders. Besides, it takes a very long time for cadmium to be excreted from there. Therefore, accurate determinations for cadmium in environmental and biological samples are highly demanded [1–3].

Anodic stripping voltammetric methods have been widely developed for the determination of trace metals owing to its high sensitivity, relatively inexpensive instrument and multi-element detection ability [4,5]. In traditional stripping voltammetry analysis, mercury film and hanging mercury drop have been used as electrode materials [6,7], because of its favored analytical properties in the negative potential range. However, the environmental regulations and health considerations restrict its continuous application. Bismuth, regarded as an 'environmentally friendly' material, is considered as a substitute for the mercury. The bismuth film electrodes have been applied for anodic stripping voltammetric analysis of metal ions [8–10] and their electrochemical properties were further enhanced by using modified electrode with polymeric materials. Especially, the bismuth film electrode coated with nafion not only exhibited high sensitivity for metals detection, but also alleviated the influence of the surface-active compounds [11,12].

The increasing need to develop more rapid and automatic analytical systems with minimal sample volume for metals determination is of high interest to date. Flow injection (FI) and sequential injection (SI) systems coupled with voltammetric techniques have been developed as an advantageous alternative to the traditional electrochemical analytical systems working in batch mode [13–15], among which, bismuth film electrodes were used as working electrodes for stripping voltammetric determination. These on-line schemes exhibited excellent stripping performance with the features of rapidity, accuracy, low sample and reagents cost in the analysis. SI lab-on-valve (SI–LOV), the third generation of flow injection, has unique sample handing potential due to the combined use of a LOV unit and a dual-directional propulsion system [16–19]. The LOV unit, integrating a set of microchannels and all necessary laboratory facilities for different analytical schemes, such as sampling conduit and flow cell, was placed atop a conventional multiposition valve. The central channel was connected with the syringe pump for precise sample and reagent arrangement. All the manipulations were carried out in a closed system, and the fluidic manipulation in the LOV was at the level of microlitre range. These characteristics were especially beneficial for downscaling the level of sample cost and avoiding solutions contaminations. In previous work, using SI–LOV manifold coupled with stripping voltammetry has been firstly reported for the on-line determination of Pb [20], which was based on the measurement of the stripping current intensity generated on the mercury film

coated glassy carbon electrode. This investigation has highlighted the advantages of electrochemical detection technique with SI–LOV system.

Taking into account the excellent electrochemical activity of bismuth film, the analytical performance and device stability provided by the SI–LOV system, this work described the development of a nafion coated bismuth electrode for the determination of cadmium in a SI–LOV system. To the best of our knowledge, currently there was only a few related work dealing with SIA, and mainly LOV methods with electrochemical detection techniques in literatures. The method involved the formation of the bismuth film and its subsequent application to heavy metal analysis. We further validated the feasibility of the proposed method for its applications in different environmental water samples.

2. Experimental

2.1. Apparatus

The SI–LOV electrochemical analytical system consisted of the following components: a FIAlab-3000 sequential injection system (FIAlab Instruments, Bellevue, WA, USA), a home-made LOV unit, and a CHI660A electrochemical workstation (Chenhua Instrument, Shanghai, China), as shown in Fig. 1. The sequential injection system equipped with a 2.5 mL syringe pump (Cavro, Sunnyvale, CA, USA) was employed for sample and reagent delivery. FIA software for Windows 5.0 was used to control the instrument. The LOV unit, incorporating an electrochemical flow cell (EFC) with a volume of 200 μL, was mounted on the multiport valve. The EFC comprised a three-electrode system with a 2 mm i.d. nafion–bismuth film coated glassy carbon as working electrode, a 0.5 mm platinum wire as counter electrode and a 1.0 mm Ag/AgCl as reference electrode. The three-electrode system was assembled into the LOV unit and the working electrode was placed in the middle. All measurements were carried out using the differential pulse technique and the signals were recorded in the peak height mode. All externally used tubes were made of 0.8 mm i.d. PTFE tubing (Upchurch Scientific, OakHarbor, WA, USA).

2.2. Reagents and chemicals

All the reagents used were at least of analytical reagent grade and purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China) unless otherwise stated. Double de-ionized water (18 MΩ) was used throughout the experiments.

The bismuth (III) standard stock solutions were prepared by dissolving $Bi(NO_3)_3$ (Sinopharm Chemical Reagent Co., Ltd., Shanghai, China) in 0.1 mol L^{-1} acetate buffer solution (pH 4.5). The working standard solutions served as the plating solutions were obtained by step-wise dilution in the same medium. The cadmium working solution was prepared by dilution commercial standard solution (1000 mg L^{-1}). Nafion (5%, w/v solution in a mixture of water and lower alcohols) was purchased from Aldrich (St. Louis, MO). The dilution nafion solutions were prepared with absolute ethanol. Triton X-100, CTAB, SDS were used as surface-active compounds. Acetate buffer solution (0.1 mol L^{-1}, pH 4.5) was employed as carrier stream. All the experiments were carried out at room temperature without removing the oxygen.

2.3. Preparation of the nafion coated glassy carbon electrode

The glassy carbon electrode surface was polished manually to obtain a fresh surface, then, a drop of the nafion solution (1%, approximate 10 μL) was placed on the surface of electrode. Prior to assembling into the EFC, the coated membrane was left to evaporate at room temperature for 10 min and cured with a hot air stream for 1 min and then left to cool at room temperature.

2.4. Operating procedure

Cadmium solution from port 5 and bismuth plating solution from port 4 were sequential aspirated by syringe pump and stored in the holding coil, where they were subject to overlap (steps 1–2 in Table 1). Then the solution was reversed, and dispensed into the electrochemical flow cell at a flow rate of 17 μL s^{-1} from port 6 while a potential of −1.3 V was subsequently applied to the nafion coated glassy carbon electrode for 100 s to form alloys (step 3 in Table 1). After a rest period of 5 s, the cadmium-bismuth deposits

were stripped from −1.1 to −0.6 V (steps 4–5 in Table 1). Finally, the electrode was directly to be electrochemically cleaned for 10 s at a potential of 0.3 V for the next run (step 6 in Table 1). The completely operational sequence was listed in Table 1.

3. Results and discussion

3.1. Optimization of experimental parameters

Nafion coated electrode was widely employed to enhance sensitivity in ASV determination, which exhibited ideal properties for electrochemical analysis and increased the resistance of electrode against fouling by co-existing surface-active compounds compared with the bare electrode [12]. Fig. 2 illustrated the typical cadmium stripping voltammetric signals at the nafion/bismuth film electrode (a), bismuth film electrode (b), and bare glassy carbon electrode (c). It can be seen that a much narrower and higher peak was obtained at the nafion/bismuth film electrode compared with the bare glassy carbon electrode and the bismuth film electrode. At the same time, the peak potential shifted in the negative direction, which was similar to the previous investigation [14,21]. In this experiment, nafion concentration in a range from 0.1 to 2% was carefully investigated in order to obtain more insights in the cadmium analysis procedure and the experimental results were shown in Fig. 3. The peak current considerably increased with the nafion concentration increased from 0.1 to 1%. This can be attributed to the fact that the polymer film helps confine the stripped species close to the electrode surface where repetitive replating—stripping cycling to cause the signal to amplify. However, with further increasing the nafion concentration up to 2%, the mass transport and charge transfer rate maybe conversely decrease, leading to the current intensity declined. Thus, a nafion concentration of 1% was selected as the optimum condition in the subsequential experiments.

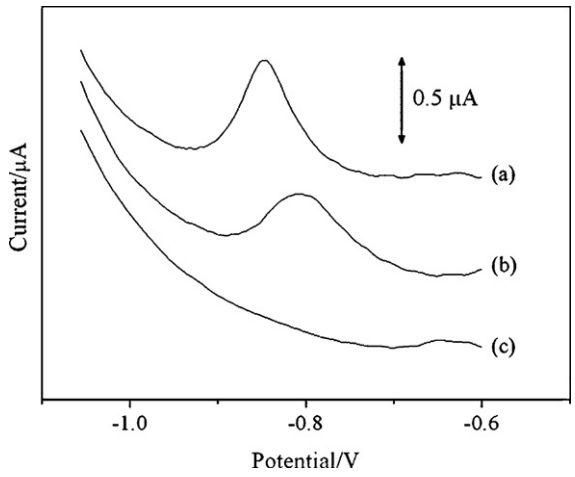

Fig. 2. Stripping voltammetric signals of 20 $\mu g\,L^{-1}$ cadmium at the bismuth/nafion film electrode (a), the bismuth coated electrode (b), the bare glassy carbon electrode (c) in acetate buffer solution (0.1 $mol\,L^{-1}$, pH 4.5).

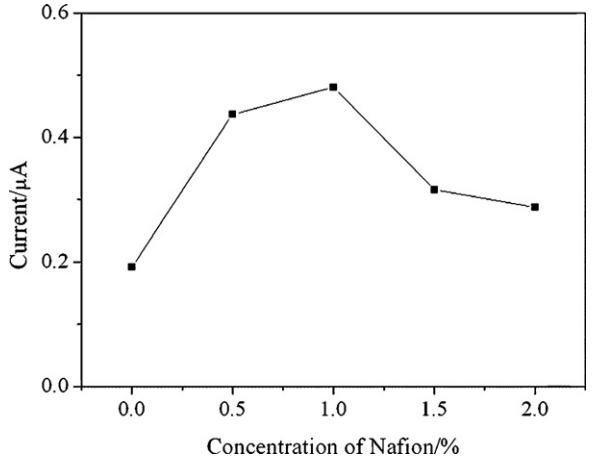

Fig. 3. Effect of the nafion concentration on cadmium stripping signals.

In this work, bismuth solution was utilized for the in situ formation of bismuth film on the nafion modified electrode with target metal ions [22]. The bismuth and cadmium solution were aspirated into the holding coil in sequence and delivered to the EFC for cadmium preconcentration with a potential of −1.3 V, then the stripping signals were recorded with potential scan from −1.1 to −0.6 V. The thickness of bismuth film had a significant effect on the cadmium stripping signals, which were controlled by the bismuth solution concentration. Fig. 4 demonstrated the influence of the bismuth solution concentration on the cadmium stripping signals in the range from 0.25 to 4.0 mg L^{-1}. As can be clearly seen, the signal became narrower and higher gradually with the concentration up to 1.0 mg L^{-1} while the peak position did not shift in the whole concentration range. Such phenomenon may be contributed to the fact that lower concentration cannot form multi-component "fusing" alloys with cadmium completely. When the concentration

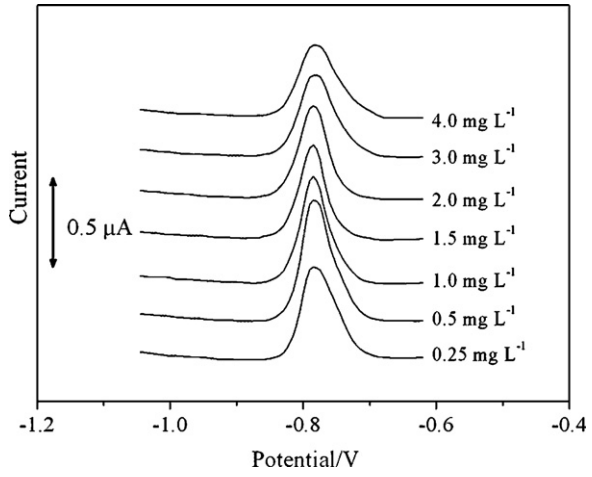

Fig. 4. Effect of the bismuth concentration on cadmium stripping signals.

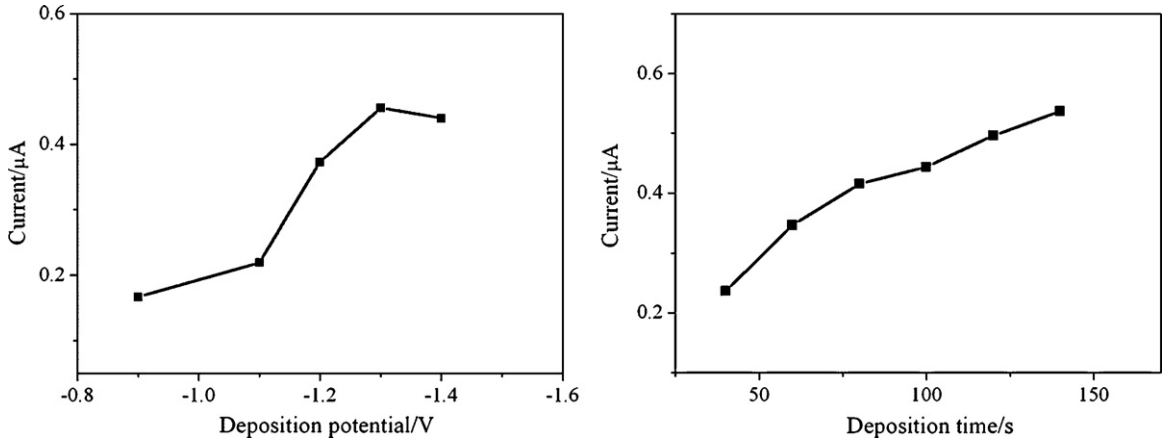

Fig. 5. Effects of the deposition potential (a) and deposition time (b) on cadmium stripping signals.

of bismuth solution varied from 1.0 to 2.0 mg L^{-1}, a thicker bismuth film would be obtained, which would hold back the target metals, with the result that the peak currents decreased and the peak shape became broad [23,24]. Hence, a bismuth concentration of 1.0 mg L^{-1} was employed due to the good sensitivity and well defined peak shape. The formation procedure of bismuth film was finished in the acetate buffer supporting electrolyte, and the effect of acetate buffer concentration on the stripping signals was also investigated in the presence of 1.0 mg L^{-1} bismuth solution. The peak currents increased rapidly with increasing the concentration of buffer solution within the range from 0.01 to 0.1 mol L^{-1}, while higher concentration would keep the signal intensity unchanged. Subsequently, 0.1 mol L^{-1} acetate buffer solution was selected.

Deposition variables, including deposition potential and deposition time, have significant influence on the cadmium stripping performance. In this work, the effect of deposition potential on the stripping peak current was investigated in the range from −0.9 to −1.4 V. As shown in Fig. 5(a), when more negative deposition potential was employed, the current intensity became lower slightly and the stability of peak current was deteriorated, owing to some reduced procedures arose by some other chemicals in the solution. On the contrary, when the more positive deposition potential was employed, the peak current decreased and the background current became higher. This phenomenon can be explained that the applied potential was not sufficient for cadmium to be reduced. Therefore, the deposition potential of −1.3 V was selected for further determinations due to sensitivity and reproducibility. The influence of the deposition time on the peak current was studied at a fixed deposition potential of −1.3 V. As can be seen from Fig. 5(b), the peak current intensity was systematically improved with the increasing of deposition time within the range of 40–140 s. Although a good sensitivity could be achieved with much longer deposition time, the analytical frequency would decrease. From this point of view, 100 s was selected for the ensuing experiments as a compromise between analysis frequency and signal intensity.

The influence of the flow rate on the analytical signal was evaluated with various solution volumes when the sample solution passed through the EFC. It was found that the stripping signals were enhanced with the flow rate increased in a range from 7 to 17 μL s^{-1}. Afterwards, peak current gradually decreased with increasing flow rate. It is probably because higher flow rate may destroy the bismuth film on the electrode surface. Consequently, 17 μL s^{-1} was selected as the optimal flow rate in the following experiments, corresponding to the 1700 μL sample and bismuth mixed solution.

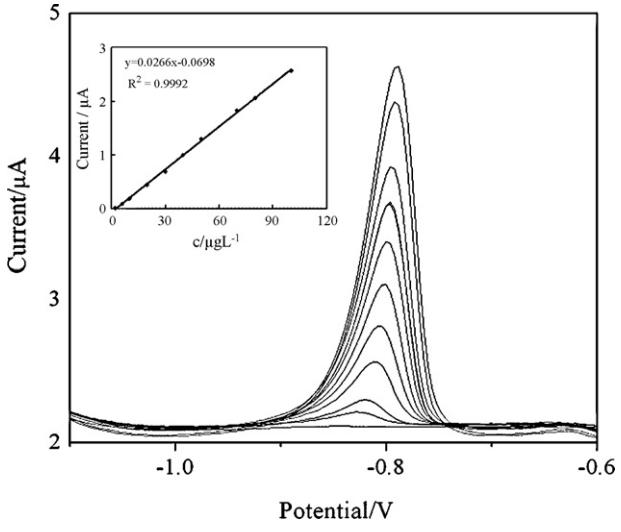

Fig. 6. Voltammograms for the determination of cadmium in the range 2–100 μg L^{-1} using nafion coated bismuth film electrode coupled with SI–LOV system (inset calibration curve). Nafion concentration: 1%; bismuth concentration: 1.0 mg L^{-1}; deposition potential: −1.3 V; deposition time: 100 s; flow rate: 17 μL s^{-1}.

3.2. Interferences

The common existing interferences of various foreign metal ions were investigated to test for sensitivity, as well as the influence of some other surface-active compounds [25,26]. They were added to the sample alone with a cadmium concentration of 20 μg L^{-1}, and the tolerable limit of the foreign substance was defined as the relative error produced by concomitant species not higher than ±5%. No changing of the cadmium voltammetric signals occurred in excess of the following ions: Na^+, K^+, Mg^{2+}, Ca^{2+}, Co^{2+} and Ba^{2+}. The tolerated ration of the other foreign substances were 100-fold for Fe^{3+} and Zn^{2+}, 20-fold for Pb^{2+}, 4-fold for Cu^{2+}. The results showed that most of the metal ions studied had no interference for the determination of cadmium except for Cu^{2+}, which suppressed the peak current intensity down to 50% at a 6-fold excess. The reason for Cu^{2+} interference could be that there was the competition between the bismuth ions and copper ions at the active sites of the nafion coated electrode surface. The surface-active compounds of Triton X-100, CTAB, SDS were also studied as the model compounds to study the potential interferences, which can cause the bismuth film to deactivate by fouling the electrode surface. They exhibited an obviously depressed effect on the cadmium determination and the stripping peak current was decreased drastically with the enhancement of surface-active compounds concentration. If the sample solution

contained more than 2.0 mg L^{-1} Triton X-100, 0.5 mg L^{-1} CTAB, and 1.0 mg L^{-1} SDS, respectively, the signal intensity would be declined to 50%. The similar result has been reported for cadmium by ASV quantification. Fortunately, the interferences caused by Cu^{2+}, Triton X-100, CTAB and SDS could be negligible in the real environmental samples analysis, because their concentration was low.

3.3. Analytical figures of merit

Under the optimal conditions, the analytical characteristics of the established sequential injection LOV–ASV system were evaluated by examining the linear range, precision, detection limit and sampling frequency. A series of voltammograms for the determination of cadmium at nafion coated bismuth electrode with increasing concentrations were illustrated in Fig. 6. A linear range 2.0–100 $\mu g L^{-1}$ was obtained with the regression equation $i_p = 0.0266C_{Cd} - 0.0698$ (i_p: 10^{-6} A, C: $\mu g L^{-1}$) and the correlation coefficient of 0.9992. The detection limit, defined as the concentration of the analyte giving signals equivalent to three-time the standard deviation of the blank signals, was 0.88 $\mu g L^{-1}$, which was compatible with those of the published values [27–30]. The R.S.D., evaluated by eleven repetitive determinations of 20 $\mu g L^{-1}$ cadmium solution, was 3.65%. A sampling frequency of 22 determinations h^{-1} was achieved with low solutions consumption.

3.4. Application to water samples

In order to demonstrate the applicability of the proposed method for the direct determination of cadmium, the proposed method was validated by analyzing environmental water samples. Prior to being introduced in the LOV–ASV system, the samples were filtered through a 0.45 μm membrane filter after collection. The results were summarized in Table 2, and the accuracy was checked by analyzing the samples spiked with different cadmium concentration levels in the range of 5.0–15.0 $\mu g L^{-1}$. Higher recoveries, in the range of 97.1–103.4% were obtained.

4. Conclusions

The stripping voltammetric technique using bismuth glassy carbon electrode implemented in a SI–LOV system was successfully carried out for cadmium analysis. The system not only provided sufficient stability and reliability for long term operation under the well-controlled conditions, but also offered high sensitivity and anti-interference ability with the use of nafion coated electrode. More importantly, the unused ports in the LOV unit may serve as micro-column to perform beads renewable on-line matrix elimination manipulation, through which the complicated sample solution could be purified and enriched before dispensed into EFC for stripping voltammetric detection. The practical analysis was applied to the rapid measurement of cadmium at low levels in water samples.

Fluorescence ratio

ABSTRACT

This study presents a high-performance ratiometric pH optode based on the fluorophore 6,8-dihydroxypyrene-1,3-disulfonic acid (DHPDS). The two pH-sensitive terminal hydroxy groups of DHPDS facilitated dual excitation/dual emission (F_1: $\lambda_{1,ex}$ = 420 nm, $\lambda_{1,em}$ = 462 nm; F_2: $\lambda_{2,ex}$ = 470 nm, $\lambda_{2,em}$ = 498 nm) properties for ratiometric ($R_{F1,F2} = F_1/F_2$) normalization of sensor signal. The sensor demonstrated an exponentially decreasing ratiometric response with increasing pH, with a linear correlation (R^2 = 0.9936) between $^{10}\log(R_{F1,F2})$ and pH within the pH interval 6–9. Precision determined as the IUPAC pooled standard deviation for the pH values 6.00, 7.01 and 9.01, was 0.0057 pH units for the fluorosensor and 0.0054 for a commercially available pH electrode used for comparison. Between the end-points of calibration at pH 7.01, the precision of the sensor was 0.0037 pH units. Effects from changes in ionic strength (I_{tot}, 10–700 mM) were more pronounced for the electrode, with a linear (R^2 = 0.9976) increase in response ($\delta E/\delta pH$) with increasing I_{tot}. The DHPDS-based fluorosensor, however, retained sensitivity ($\delta^{10}\log(R_{F1,F2})/\delta pH = 0.8024 \pm 0.0145$), though with an overall increase in ratiometric signal with increasing I_{tot}. The preserved sensitivity despite changes in ionic strength was possibly a consequence from the dual photo-acidic properties of DHPDS. Analytical characteristics of immobilized DHPDS therefore not only facilitated high-performance measurements over a wide pH range, but also opened for straightforward simultaneous measurements of pH and ionic strength.

1. Introduction

The activity of hydrogen ions is a master analytical parameter to understand and predict electron transfer and general dynamics during multiple reactions in natural environments [1]. Consequences and feedbacks from changes in pH may have local, regional and global importance. For example, pH of seawater has received particular attention in current characterizations of the oceanic response to anthropogenic emissions of CO_2, in part due to the recently demonstrated acidification of the world's oceans [2]. Although ion-selective electrodes are commonly used for pH measurements [3,4], optical sensors (optodes) have since 1980 frequently been used for pH measurements [5–9]. Optodes are also suitable for high-resolution imaging of pH distributions in complex environments such as aquatic sediments [5,10,11], and there are exciting possibilities for multi-parameter and multi-analyte sensing [9,12–14].

The dynamic range for quantification using optical sensors is normally set by the dependence between the associated and dissociated form of the indicator, and restrictions inherent to the optical instrumentation used during measurements (e.g. [15,16]). For conjugate pairs of acid–base compounds, one compound is often considered undetectable in the presence of the other when relative color intensity is less than ~one-tenth. These traditional limits also tend to fix the dynamic range of fluorescence based sensors to ±1 pH units surrounding the apparent pK_a (pK_a') of the acid–base indicator [17]. In response to biological activities such as intense photosynthesis, bioturbation and organic matter mineralization, pH of natural environments frequently varies by several pH units even on short time-scales [3,18,19]. Such large variation (>2 pH units) in pH is likely to hamper the analytical performance of acid–base indicators and optical sensors in general. Further, an often conveyed limitation of optical sensors is the sensitivity to changes in ionic strength (I_{tot}) of the sample matrix [20]. According to the Debye–Hückel theory, optical sensors for pH normally suffer from a decreased pK_a' with increasing I_{tot} [21]. Despite theoretical and model predictions, there are few, if any, investigations specifically designed to experimentally verify and quantitatively compare the relative dependence to changes in I_{tot} between optodes and ion-selective electrodes available for pH measurements. Overall, the analytical performance of optical pH sensors is due to progressive improvements considered comparable to that of pH electrodes (e.g. [22,23]).

8-Hydroxypyrene-1,3,6-trisulfonate (HPTS; Fig. 1) is one of the most widely used fluorescence indicators for pH measurements in near-neutral samples [8,24,25]. HPTS is a fluorophore used not only

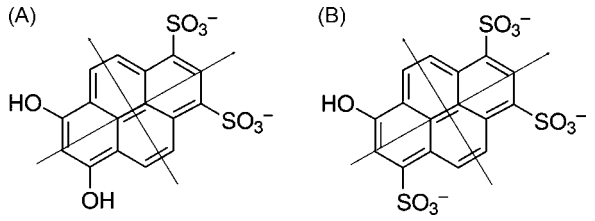

Fig. 1. Chemical structures of (A) 6,8-dihydroxypyrene-1,3-disulfonic acid (DHPDS) and (B) 8-hydroxypyrene-1,3,6-trisulfonate (HPTS) (pH > pK_a of the sulfonate groups, i.e. pH > 1). The arrows represent through atom (excited energy state ^1L_a, arrow through atoms) and through bond (^1L_b) excitation light directions.

to quantify pH in various solutions, but also in more sophisticated applications such as cellular imaging [26] and imaging optodes for both microscopic [23] and macroscopic use [5,11]. General patterns of HPTS fluorescence are essentially governed by the protonation/deprotonation equilibrium of the hydroxyl hydrogen and the photo-acidic properties of HPTS [22]. HPTS is normally considered highly photo-acidic, i.e. the fluorophore is more acidic in the electronically excited state (HPTS*; Fig. 1) than in the ground state [27]. Frequently, pK_a' of excited photo-acidic compounds is 6–7 pH units lower than in the ground state. For example, pK_a' of HPTS in solution is ~7.3 while in excited state it can be as low as 1.0 [28]. Photo-acidic properties therefore govern the dual excitation (~405 and 450 nm) single emission (~520 nm) ratiometric sensing scheme observed for HPTS in solution. Further, HPTS have intrinsic ratiometric properties that provides signal normalization and amplification. The ratiometric approach has been demonstrated to be as effective as lifetime measurements to reduce artifacts [29].

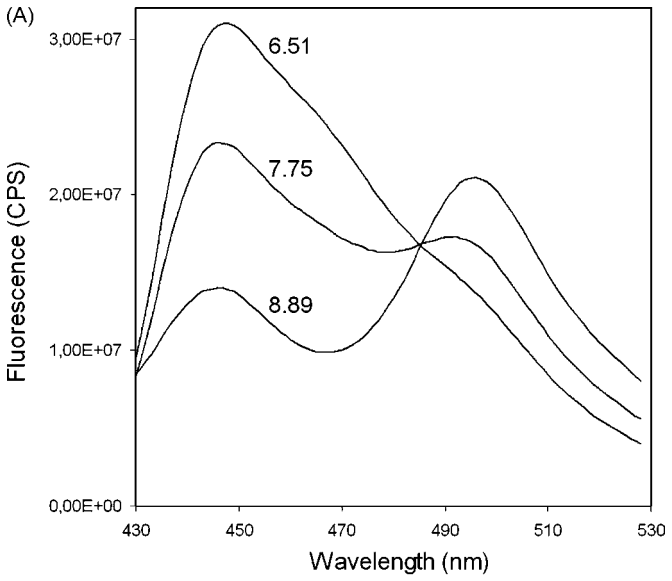
In contrast to the wide range of pH measurements that include HPTS, there are only few studies that have utilized the di-hydroxylated analogue 6,8-dihydroxypyrene-1,3-disulfonate (DHPDS; Fig. 1) [30,31]. DHPDS shares most of the advantageous properties of HPTS, such as high quantum yield, excellent water solubility, ratiometric properties and lack of toxicity. The objective of this study was to reassess the suitability of DHPDS as a fluorophore for pH measurements and to experimentally evaluate fluorescence properties of DHPDS immobilized in a sensing membrane. As the structure of DHPDS includes two hydroxyl groups with overlapping (within 2 pH units) pK_a'-values (7.33 and 8.53; [24]), we hypothesize that, while retaining essential spectroscopic signatures, the analytical characteristics of the two acidic protons provide the basis for a significantly improved sensor dynamic range compared to, for example, HPTS-based sensors.

2. Experimental

2.1. Materials

The sensing film was prepared in a similar manner as was originally described in [10]. A prefabricated transparency film (Hewlett Packard, HP C3835A) consisting of a 100 μm thick polyester foil with a 10 μm cellulose acetate coating was used for the immobilization of DHPDS. In brief, the sensing foil was immersed over night in a high ionic strength (NaCl 1.0 M) solution with 75 μM of the fluorophore 6,8-dihydroxypyrene-1,3-disulfonic acid (DHPDS; >98%, Fluka). The high ionic strength is intended to provide thin double layers, which allows short range fluorophore–foil interactions. These close interactions are the basis for the immobilization mechanism through, e.g. hydrogen bonds, ion-dipole and hydrophobic interactions. The cellulose acetate provides a convenient platform for DHPDS association by these interactions as the ζ-potential is close to zero for ionic strength above 3 mM [32]. Before use, the sensor film was treated in Milli-Q water (deionized water further purified by a Milli-Q system, Millipore Corp., to a resistivity of >18 MΩ cm^{-1}) for 12 h and finally immersed in a sample-like matrix for 12 h. Phosphate buffers ($[H_3PO_4]_{tot}$ = 4 mM) were prepared from appropriate amounts of 40 mM NaH_2PO_4 and Na_2HPO_4 (p.a., Merck) stock solutions in Milli-Q water. Total ionic strength of solutions was adjusted by proper additions of NaCl (p.a., Merck). Buffer solutions for calibration were certified traceable to NIST Standard Reference Material (pH 6.00, 7.01 and 9.01 at 20 °C, Merck).

2.2. Instrumentation



The sensor with immobilized DHPDS was mounted onto a plexiglass support and secured in a plastic cuvette (3 mL), placed in the spectrofluorometer (Fluoromax-3, SPEX Instruments Int., Inc.). To minimize background noise and reflection from incident light, the angle of incidence for the excitation light was set to 30°. Excitation and emission scans were performed at 1.00 nm resolution, 0.25 s time of integration and slit widths corresponding to 2.00 nm bandpass. Matrix scans (Fluoromax-3, SPEX Instruments Int., Inc.) at pH 9.01 and 6.00 were prior to experiments divided to determine the optimum pairs of ratiometric wavelengths for this particular setup. Here, F_1 ($\lambda_{1,ex}$ = 420 nm, $\lambda_{1,em}$ = 462 nm) and F_2 ($\lambda_{2,ex}$ = 470 nm, $\lambda_{2,em}$ = 498 nm) were used for ratiometric ($R_{F1,F2} = F_1/F_2$) detection of fluorescence. The pH electrode (model 6.0232.100, 780 pH meter; Metrohm Ltd.) was calibrated in NIST buffers by a two-point calibration procedure (pH 6.00 and 9.01). Temperature was kept constant (20 ± 1 °C) during all experiments.

2.3. Procedures

Repeatability of the DHPDS-based sensor was analytically evaluated to obtain a quantitative measure of sensor precision within the pH interval 6–9. The repeatability experiment was designed to include four replicates at the end-points of calibration (i.e. two replicates at pH 6.00 and two at pH 9.01) and four at the intermediate pH 7.01 (i.e. n_{tot} = 8). Calibrations were performed before and again repeated after sample measurements (i.e. two-point calibrations were performed at pH 6.00 and 9.01). The ratiometric signal, $R_{F1,F2}$, was linearized ($^{10}\log(R_{F1,F2})$) for visualization purposes and to simplify quantifications. Time-dependent calibration functions were applied on the linearized response function to provide a unique set of calibrations for each individual repetition [22,33]. Replicate measurements were analytically evaluated for repeatability according to IUPAC's definition of pooled standard deviation [34]. The repeatability experiment encompassed 11 consecutive ratiometric measurements, including calibrations and replicate samples. Measurements were performed using NIST traceable standards, 5 min equilibrium time, 0.5 s time of integration.

To evaluate the sensitivity towards changes in ionic strength, the response from the DHPDS-based optical sensor was compared to that of a commercially available pH electrode (model 6.0232.100, 780 pH meter; Metrohm Ltd.). Comparisons were made at pH 6.246 and 8.026 in phosphate buffers ($[H_3PO_4]_{tot}$ = 4 mM) in which the ionic strength was adjusted to 10, 355 and 700 mM with appropriate additions of NaCl (p.a., Merck).

For comparison, the fluorescence response of dissolved DHPDS and HPTS was individually evaluated by titrating 3 μM of each fluorophore in 0.0667 M phosphoric acid with 2 M NaOH. Photobleaching of DHPDS and HPTS was assessed using 3 μM of each fluorophore in NIST buffer (pH 7.00). The experiment was performed in the mode of constant illumination (excitation at 420 and 470 nm for DHPDS, and at 405 and 455 nm for HPTS) for 2 h.

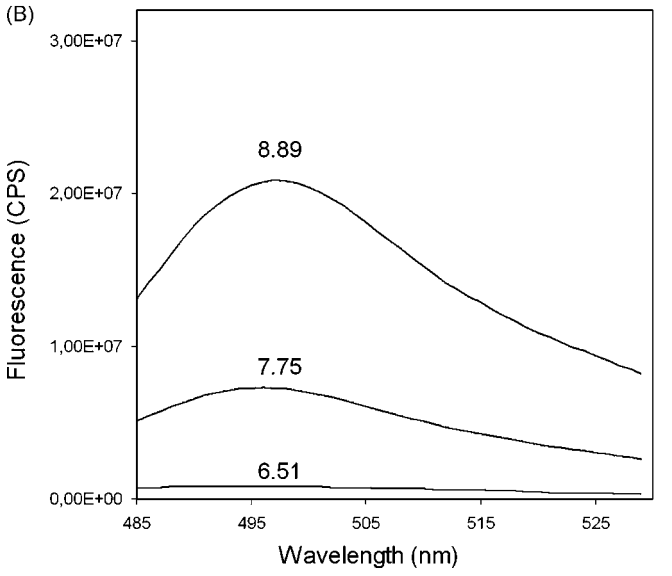


Fig. 2. Emission spectra of DHPDS immobilized in the sensor film at pH 6.51, 7.75 and 8.89 (I_{tot} = 700 mM). Excitation was performed at 420 nm (A) and 470 nm (B). Excitation at 420 nm demonstrated an isosbestic point at ~485 nm.

3. Results and discussion

3.1. General sensor characteristics and sensor response

Fluorescence matrix scans (excitation and emission) were divided to evaluate and optimize pairs of wavelengths for maximum relative response in fluorescence with changing pH. Within the excitation range 340–480 nm and the corresponding emission range 430–550 nm, F_1 ($\lambda_{1,ex}$ = 420 nm, $\lambda_{1,em}$ = 462 nm) and F_2 ($\lambda_{2,ex}$ = 470 nm, $\lambda_{2,em}$ = 498 nm) were associated with the largest relative response. These pairs of excitation and emission wavelengths (F_1 and F_2) were therefore consecutively used for ratiometric ($R_{F1,F2} = F_1/F_2$) normalization of sensor signal (Fig. 2). Procedures of dual excitation and dual emission were used to significantly increase the dynamic range and sensitivity of measurements. Immobilized DHPDS demonstrated double emission maxima at ~450 and ~500 nm (excitation at 420 nm), and a single emission at ~500 nm as a response to the excitation at 470 nm (Fig. 2). The fluorescence observed at 450 nm (excitation

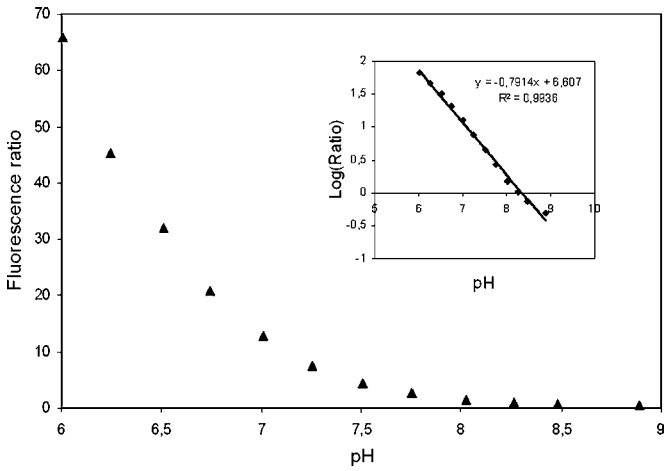

Fig. 3. The ratiometric response ($R_{F1F2} = F_1/F_2$) of immobilized DHPDS as a function of pH. Inserted is the logarithmic response from pH 6 to 9. I_{tot} = 700 mM.

at 420 nm; F_1) decreased, while the fluorescence at 500 nm (excitation 470 nm; F_2) increased with increasing pH. Maximum relative response used for quantification of pH (from the matrix scans) did not exactly match the maximum fluorescence obtained following single-wavelength excitation at 420 nm ($\lambda_{max,em1}$ = 447 nm) and 470 nm ($\lambda_{max,em2}$ = 495 nm; Fig. 2), which is not uncommon during fluorescence detection [35]. The relatively large shift observed for excitation at 420 nm ($\lambda_{1,em}$ = 462 nm rather than 447 nm; Fig. 2) may be caused by a broad overlap of energy levels associated with the fluorescence measured. The ratiometric response ($R_{F1,F2}$; I_{tot} = 700 mM) decreased exponentially from pH ~ 6 ($R_{F1,F2} \approx 65$) to pH ~ 8.9 ($R_{F1,F2} \approx 0.5$) (Fig. 3), with a significant linear correlation between the logarithmic signal ($\delta^{10}\log(R_{F1,F2})$) and pH ($(\delta^{10}\log(R_{F1,F2})/\delta\text{pH}) = -0.7914$; $R^2 = 0.9936$; $n = 12$). Similarly, as was also observed for immobilized DHPDS, the ratiometric response of dissolved DHPDS followed a decreasing exponential function with pH (Fig. 4). The logarithmic ($\delta^{10}\log(R_{F1,F2})$) response of dissolved DHPDS from three independent titrations followed a linear function ($(\delta^{10}\log(R_{F1,F2})/\delta\text{pH}) = -1.01$; $R^2 = 0.9974$; $n = 22$) between pH ~ 5 and pH ~ 10. For comparison, the logarithmic response from a similar titration of HPTS in solution was linear between pH 5 and 8, with a slope ($\delta^{10}\log(R_{F1,F2})/\delta$pH) of −0.82

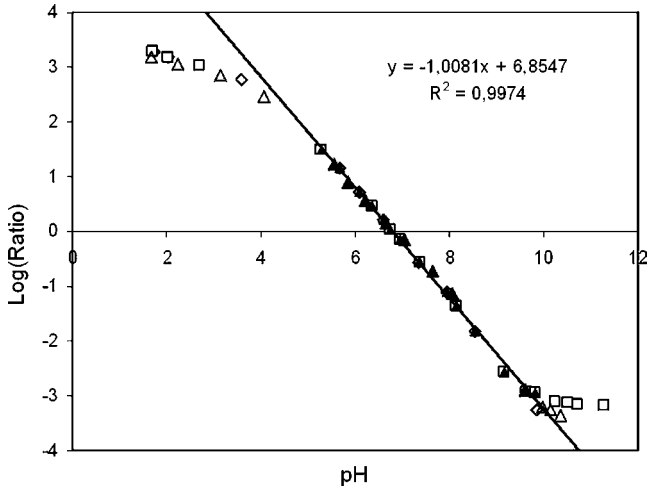

Fig. 4. Logarithmic sensor response ($\delta^{10}\log(R_{F1,F2})$) as a function of pH for 3 μM DHPDS in 0.067 M phosphoric acid titrated with 2 M NaOH (three independent titrations; n_{tot} = 41). Black triangles denote data points used to calculate the linear correlation (n = 22).

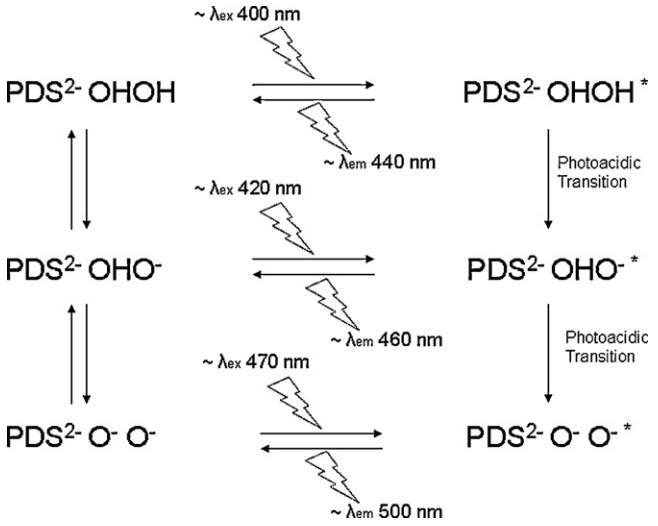

Fig. 5. Suggested proton dynamics for DHPDS. PDS^{2-} denotes the pyrene-disulfonate group to which the hydroxyl groups with the two acidic protons are attached. (*) Indicates electronically excited DHPDS.

($R^2 = 0.9974$; $n = 7$) (not shown). The response of dissolved HPTS and DHPDS not only indicated a significantly larger (close to 2 pH units) dynamic range of DHPDS compared to HPTS. The steeper slope of the response function also suggested an improved sensitivity (>20%) for DHPDS.

Overall, the response of an optical pH sensor is determined by the acid–base equilibria of the immobilized dye, with a classical sigmoidal calibration having an inflection point that corresponds to the pK_a' of the immobilized indicator [10]. The analytical sensitivity is most pronounced close to this pK_a' where the derivative (δ(signal)/δ(pH)) is maximized. An apparent dissociation constant of $10^{-6.4}$ (i.e. $pK_a' = 6.4$) was observed for HPTS immobilized onto cellulose acetate in seawater [10]. As the pH of open seawater is slightly above 8, and even higher in environments of intense primary production (e.g. [19]), the analytical performance of HPTS-based sensors is normally hampered for use in such systems (e.g. [5]). The large dynamic range of DHPDS-based sensors observed in this study, including pH values up to ~9, support the preferential use of DHPDS rather than HPTS for pH measurements in e.g. seawater.

Based on the obtained fluorescence response, a simplified scheme for proton and excited state dynamics of DHPDS is presented (Fig. 5). Fluorescence transitions are not infinitely narrow and there are often significant overlaps between excitation and emission bands. The closely coupled energy levels corresponding to excitations at 400 and 420 nm are particularly likely to be associated. At 500 nm (excitation at 420 nm), the fluorescence of DHPDS in solution was more pronounced (not shown) compared to that observed for DHPDS immobilized onto the sensor film (Fig. 2A). This observation indicated that immobilization of DHPDS onto the sensor support caused a reduced photoacidity by obstructing proton dynamics. The effect following immobilization was, however, not as pronounced as previously demonstrated for HPTS where the complete photoacidity was removed upon immobilized in ethyl-cellulose [22]. Excitation and emission properties for DHPDS demonstrated in this study also support that excited state dynamics of DHPDS may include a double deprotonation (Fig. 5), as 400 nm excitation at pH < 6.5 resulted in a substantial fluorescence at 500 nm (data not shown).

The photobleaching experiment demonstrated that upon constant illumination for 2 h, the emission decreased by 8.5% for DHPDS and 1.5% for HPTS. The corresponding ratiometric signals changed by 0.4% for both DHPDS and HPTS. The combination of ratiometric normalization and time-correlated calibration protocols would thus completely cancel out this potential artifact as well as the plausible leaching of the fluorophore.

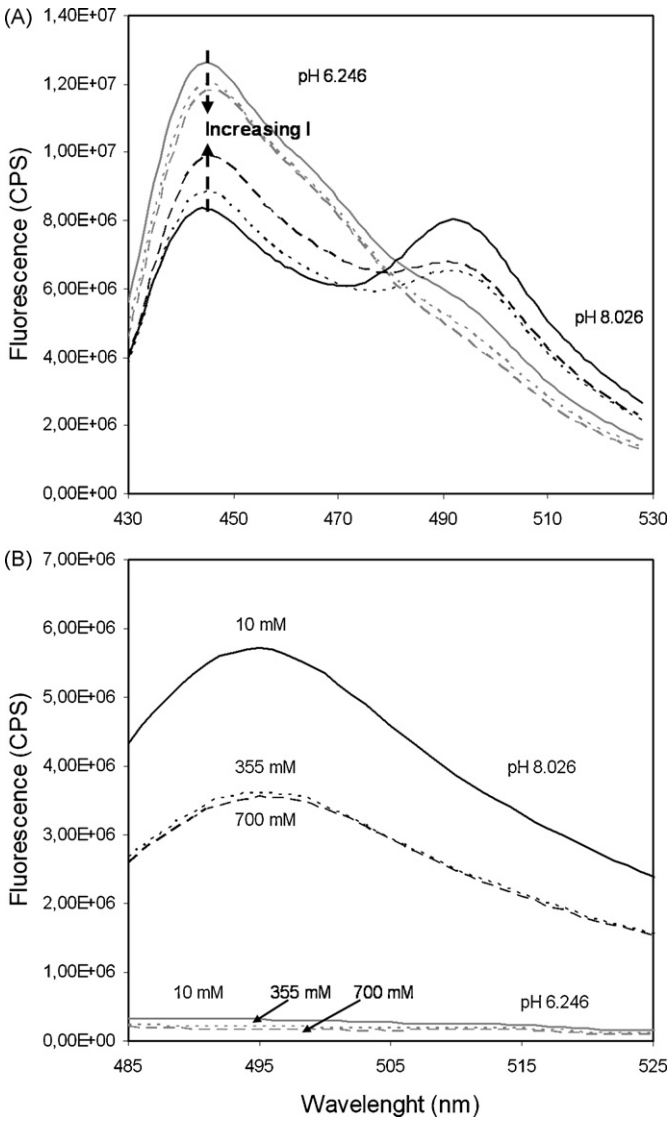

Fig. 6. Emission spectra of immobilized DHPDS at 10 mM (solid), 355 mM (dotted) and 700 mM (dashed) ionic strength. Measurements were performed at pH 8.026 (black) and 6.246 (grey) using excitation at 420 nm (A) or 470 nm (B).

3.2. Effects of ionic strength

Fluorescence spectra for the sensor exposed to pH 6.246 and 8.026 in solutions of 10, 355 and 700 mM total ionic strength (I_{tot}) are shown in Fig. 6. Fluorescence intensity at 450 nm (excitation at 420 nm) was shifted in opposite directions at low and high pH with increasing ionic strength (Fig. 6A). At pH 6.246, the fluorescence decreased, while at pH 8.026 measured fluorescence increased with increasing I_{tot}. In contrast, emission at 500 nm (excitation at 420 nm) decreased progressively with increasing I_{tot} for both pH values. This experimental observation is quite opposite to the Debye–Hückel theory that under conditions of high pH would predict a decrease in pK_a'. As a consequence, fluorescence emission would be significantly reduced with increasing I_{tot} [21]. We suggest that a decreased solvent acceptance of protons, with a subsequent reduction in photoacidity, caused the increase in flu-

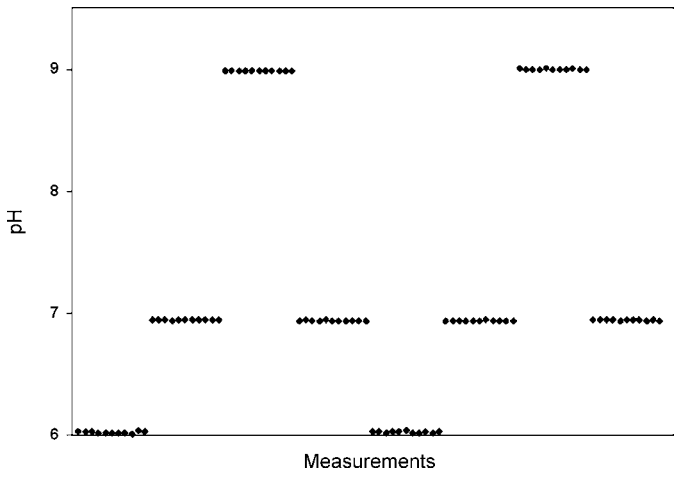

Fig. 7. Repeatability of the DHPDS-based sensor at pH 6.00, 7,01 and 9.01 ($n = 11$). The pooled standard deviation (IUPAC) was 0.0057 ($n = 8$). Time between each data point was 5 s, and the time between sampling occasions was 5 min.

orescence observed at ~450 nm with increasing I_{tot}. A reduced photoacidity may also explain the decrease in F_1 ($\lambda_{1,ex} = 420$ nm, $\lambda_{1,em} = 462$ nm) with increasing I_{tot} observed at pH 6.246. The overlap in energies associated with the excitation at 420 and 400 nm is likely more decoupled as photoacidity decreases, i.e. the reduction of fluorescence observed at 462 nm (excitation at 420 nm; Fig. 6) is generated by the first photo-acidic transition of DHPDS (Fig. 5).

Optodes are normally considered highly sensitive to changes in I_{tot} as the solute activity coefficient of the indicator and the surface potential are partly controlled by changes in I_{tot} (e.g. [20,21]). Further, properties of the surface itself are vital for local fluorescence via acid-base characteristics and changes in the ζ-potential [20]. In this study, samples of variable ionic strength ($I_{tot} = 10$, 355 and 700 mM) demonstrated that the DHPDS-based pH fluorosensor was significantly less sensitive to changes in I_{tot} than the commercially available electrode used for comparison. While the optode seemed to maintain the sensitivity of the ratiometric signal ($\delta^{10}\log(R_{F1,F2})/\delta\text{pH} = 0.8024 \pm 0.0145$) within the pH interval 6.246–8.026, there was a positive linear correlation in electrode response to I_{tot} ($R^2 = 0.9976$; $n = 6$). For comparison, the linear correlation (R^2) between I_{tot} and pH was 0.065 ($n = 6$) for the optode. The quantitative errors related to changes in I_{tot} (10–700 mM) rather than pH correspond to 0.322–0.338 pH units for the optode and 0.528–0.725 for the electrode, respectively. However, as a solution of NaCl was used to moderate ionic strength of samples, effects associated with changes in I_{tot} may at least partly be caused by the linear increase in sodium concentration induced by NaCl additions. Nevertheless, the comparably low sensitivity towards changes in I_{tot} demonstrated for the DHPDS-based pH sensor may open up for simultaneous measurements of pH and ionic strength over wide ranges using DHPDS-based optical sensors. Ideally, fluorescence at the isosbestic point ($\lambda_{ex} = 420$ nm, $\lambda_{em} = 485$ nm, Fig. 2) where sensor response is insensitive to pH, could be used for such dual measurements. Unfortunately, there was only a small response to changes in ion strength at the isosbestic point (Fig. 6).

3.3. Analytical performance

The precision (IUPAC's definition of pooled standard deviation; $n = 8$) of the DHPDS-based optical sensor was within the pH interval 6–9 comparable to that of the electrode used for comparison (Fig. 7). With a linear time-dependent two-point calibration, the precision over three pH values (6.00, 7.01 and 9.01) was 0.0057 pH units for the optical sensor, compared to 0.0054 for the electrode. The accuracy, defined as mean systematic deviation (absolute value) from the NIST pH values, was 0.037 for the optode ($n = 8$) and 0.023 for the electrode ($n = 8$), respectively. Between the end-points of calibration at pH 7.01, the precision of the optode was 0.0037 pH units ($n = 4$). Using a similar experimental set-up, a precision of 0.0029 (IUPAC, $n = 8$) was demonstrated for a HPTS-based ratiometric fluorosensor between pH 6.64 and 7.76 [23]. Optode standardizations were made in relation to a commercially available pH electrode using multi-point ($n = 4$–7) time-dependent sigmoidal calibrations. In the present study, however, NIST buffers were exposed directly to the optode for calibrations and measurements to eliminate limitations inherent to the analytical performance of the electrode. Calibrations were made using time-dependent linear functions linked within a two-point calibration. The comparably large systematic errors (0.037) of the optode response were likely explained by insufficient exchange of sample volume during the analytical procedure, and the dead volume associated with sensor configuration.

Further developments of the DHPDS-based sensing scheme are suggested to include metal enhanced fluorescence (MEF) and plasmonics to further enhance fluorescence characteristics [36]. Properly arranged, the sensor system would benefit from surface plasmon enhancement and lossy surface wave quenching as the fluorophore moves toward the plasmon active nanoparticles [35]. Additionally, constructive scattering effects have the potential to further enhance the signal.

4. Conclusions

DHPDS is a double excitation and double emission (F_1: $\lambda_{1,ex} = 420$ nm, $\lambda_{1,em} = 462$ nm; F_2: $\lambda_{2,ex} = 470$ nm, $\lambda_{2,em} = 498$ nm) ratiometric ($R_{F1,F2} = F_1/F_2$) fluorophore with similar analytical characteristics as HPTS. Due to the dual photo-acidic properties of immobilized DHPDS, the fluorescence dynamic range encompassed pH 6–9, i.e. the range for pH measurements was significantly larger for the DHPDS-based sensor than that previously observed for HPTS-based optical sensors. The precision of the DHPDS sensor was 0.0057 over the investigated pH range. The sensitivity to changes in ionic strength was significantly better for the DHPDS sensor than that of a commercially available pH electrode used for comparison. The DHPDS-based sensor retained sensitivity between 10 and 700 mM ionic strength.

ABSTRACT

Twenty nine phenolic compounds comprising nine phenolic acids, sixteen flavonoids (including eight tea catechins, glycosides and aglycones), four coumarins plus caffeine were analysed within 20 min using ultra high performance liquid chromatography (UHPLC) with PDA detection. UHPLC system was equipped with C18 analytical column (100 mm × 2.1 mm, 1.7 μm), utilising 0.1% formic acid and methanol mobile phase in the gradient elution mode. The developed method was tested for the system suitability: resolution, asymmetry factor, peak capacity, retention time repeatability and peak area repeatability. The method was fully validated in the terms of linearity ($r^2 > 0.9990$ for all 30 compounds), range (typically 1–100 mg L^{-1}), LOD, LOQ, inter/intra-day precision (<3% and <9% respectively) and inter/intra-day accuracy (typically 100 ± 10%). Subsequently the method was applied to the identification (spectral information and peak purity calculations were profited) and quantification of phenolic compounds and caffeine present in tea infusions and extracts.

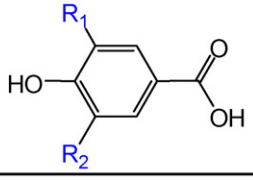
1. Introduction

Phenolic compounds attract the attention of research laboratories and literature especially due to their biological and physiological importance. They are able to scavenge free radicals [1,2], specifically reactive oxygen species (ROS) and reactive nitrogen species (RNS, e.g. nitric oxide). The oxidative stress, caused by the excess ROS/RNS, can damage cellular lipids, proteins or DNA inhibiting their normal function [3]. In this way it is implicated in various pathological conditions involving cardiovascular disease, cancer, neurological disorders, diabetes, ischemia, aging and other diseases [4]. Flavonoids and phenolic acids are two main groups of phenolic compounds with antioxidant activity.

Flavonoids form a large group of structurally related compounds with a chroman-type skeleton and with a phenyl substituent in the C_2 or C_3 position. They are often hydroxylated in positions 3, 5, 7, 3′, 4′ or 5′ and their hydroxylic groups are frequently modified (methylated, acetylated, prenylated or sulphated). In plants are flavonoids often present as *O*- or *C*-glycosides [5]. They are further divided into classes depending on the oxidation degree of the central pyran ring [6]. More than 6500 different flavonoid products of secondary plant metabolism, mainly responsible for the colour of flowers, fruits and sometime leaves, have been characterized in various plant species, but their real number may exceed 8000 [7].

The *phenolic acids* are secondary plant metabolites derived from either benzoic or cinnamic acid (Fig. 1). For instance gallic acid, caffeic acid, vanilic acid, ferulic acid and chlorogenic acid with esters can be frequently found in tea, wine and herbal infusions [8].

Coumarins are often found in phenolic fraction of plant extracts. Presently over 1000 coumarins have been described in the plant families *Fabaceae* (sweet clover, tonka bean), *Apiaceae* (khella, angelica) and *Rubiaceae* (sweet woodruff). Antioxidant activity of these 2H-1-benzopyran-2-ones (Fig. 1) is in general lower [9,10].



Tea is a rich source of antioxidant phenolic compounds, especially polyphenols, and it is after water the most often consumed beverage worldwide. Therefore it was chosen as matrix for validation in our study. Tea is made by steeping processed leaves, buds, or twigs of *Camellia sinensis* (L.) *Kuntze* (*Theaceae*) in hot water for a few minutes. Tea infusion is a rich natural source of alkaloids (caffeine, theobromine, theophylline, theacrine, adenin, xanthine), phenolic compounds (phenolic acids, flavanols, flavonols), amino acids (L-theanine), metals and vitamins (ascorbic acid) [11,12].

The polyphenolic fraction of tea contains flavanols (catechins), flavonols (myricetin, quercetin, kaempferol) and products

of condensation (proanthocyanidins). Namely (+)-catechin (C), (−)-epicatechin (EC), (−)-epigallocatechin (EGC), (−)-epicatechin gallate (ECg), (−)-epigallocatechin gallate (EGCg) are the most abundant phenols in tea leaves, constituting up to 30% of the dry mass [13]. The representation of particular catechins in the tea infusion is dependent on the processing of tea leaves. EGCg is the major component of unfermented green tea [14], making up to about 10–50% of the total green tea catechins. Its antioxidant activity is 100 times more effective than that of vitamin C and 25 times more effective than that of vitamin E [15]. After the fermentation process the major catechin is GC, while the content of EGCg is decreased approximately 10× [16]. Besides catechins also small amounts of flavonols 3-*O*-glycosides occurs in tea leaves.

Analytical methods employed in analysis of flavonoids and phenolic acids were summarized in recently published review articles [5,17]. Basically all conventional separation methods are used such as capillary electrophoresis and chromatographic methods including HPLC, GC as well as TLC. Although HPLC was a method of choice, none of published works concerning with analysis of phenolic compounds in tea gave satisfactory results for separation of catechins [18–25]. The weak point of all published methods was limited separation efficiency, which press on to compromise separation time or resolution. The methods, which provided sufficient resolution for all peaks were extremely time-consuming, which means analysis time about 25–40 min for typically 7–12 analytes. For instance 15 analytes within 92 min [25] or 24 analytes within

LOD: limit of detection, LOQ: limit of quantification.

40 min [21]. An overview of HPLC methods used in analysis of phenolics with the emphasis to catechin analysis is displayed in Table 1b.

Recently, Ultra high performance liquid chromatography (UHPLC) has become widely spread technique and new trend in separation sciences. Higher separation efficiency of sub-2-μm particle sorbents allows faster chromatographic separation keeping the same resolution compared to HPLC sorbents with conventional particle size [26]. This is expressed by Knox curves, where lower height equivalent of theoretical plate indicates improved separation efficiency and higher optimum linear velocity, which means decrease in analysis time [27]. Generated back pressure of particle sorbents is inversely related to the cubed particle size, therefore UHPLC system is necessary (back pressures up to 100 MPa). A higher sensitivity is achieved using column with small internal diameter (typically 2.1 mm) and a low volume optical cell for UV detection. UHPLC systems have been demonstrated to be beneficial in the pharmaceutical development [28], drug monitoring [29], metabolite profiling [30], proteomics [31], environmental chemistry [32] or food chemistry [33].

Several new UHPLC methods for the determination of flavonoids and phenolic acids in various matrices have been recently developed [33–39]. An overview is displayed in Table 1a. These methods have typically analytical runs shorter than 10 min, in extremes they are able to separate 19 analytes in 2 min [34]. High applicability is of value especially in work of Gruz et al. [33], who determined 17 common phenolic acids or the work of Klejdus et al. [34], who determined common phenolic acids together with some flavonoids. The main drawback of latter method lays in determination only of vanillic and caffeic acid without chlorogenic acid, as these three phenolic acids typically cause coelutions in real matrices and they are often present together. Kumar et al. developed UHPLC-DAD and UHPLC–ESI-MS/MS method only for determination of phenolic acids and flavonoids [38].

In our previous work four individual methods were developed for four groups of phenolics (catechins, less polar flavonoids, coumarins and phenolic acids) using UHPLC-UV [39]. The aim was to stress the benefit of UHPLC above HPLC analysis in analysis of phenolic compounds. The four newly developed methods used various four completely different gradient elution profiles and temperatures. The convenience of UHPLC was clearly proven in terms of speed of analysis and separation efficiency however previously reported UHPLC methods might be excessively rapid not providing enough peak capacity for separation of all structurally similar compounds. Also selectivity issue was not addressed as single UV detection does not provide sufficient confirmatory results.

The aim of this work was to develop and fully validate fast, efficient routine UHPLC method with PDA detection for the simultaneous qualitative and quantitative analysis of a wide range of the most commonly occurring phenolic compounds of various structures plus caffeine (to exclude the interference) in plant matrices or dietary supplements. Structures have been chosen based upon the occurrence of phenolic compounds in plant material – see Fig. 1, to represent important examples from each group of phenolic compounds of various polarities. Tea infusions and tea extracts were selected in order to demonstrate sufficient separation efficiency, selectivity and sensitivity. The proposed method can be used in other applications, e.g. for the quantification of phenolic compounds in other plant extracts. Notably dietary supplements with contents of phenolic compounds are potential field for application, since their popularity is growing. Manufactures have not been required to demonstrate declared amount of active ingredients of their products so far [40] however, this may change soon. Therefore, commercial dry tea extracts were also included in our study.

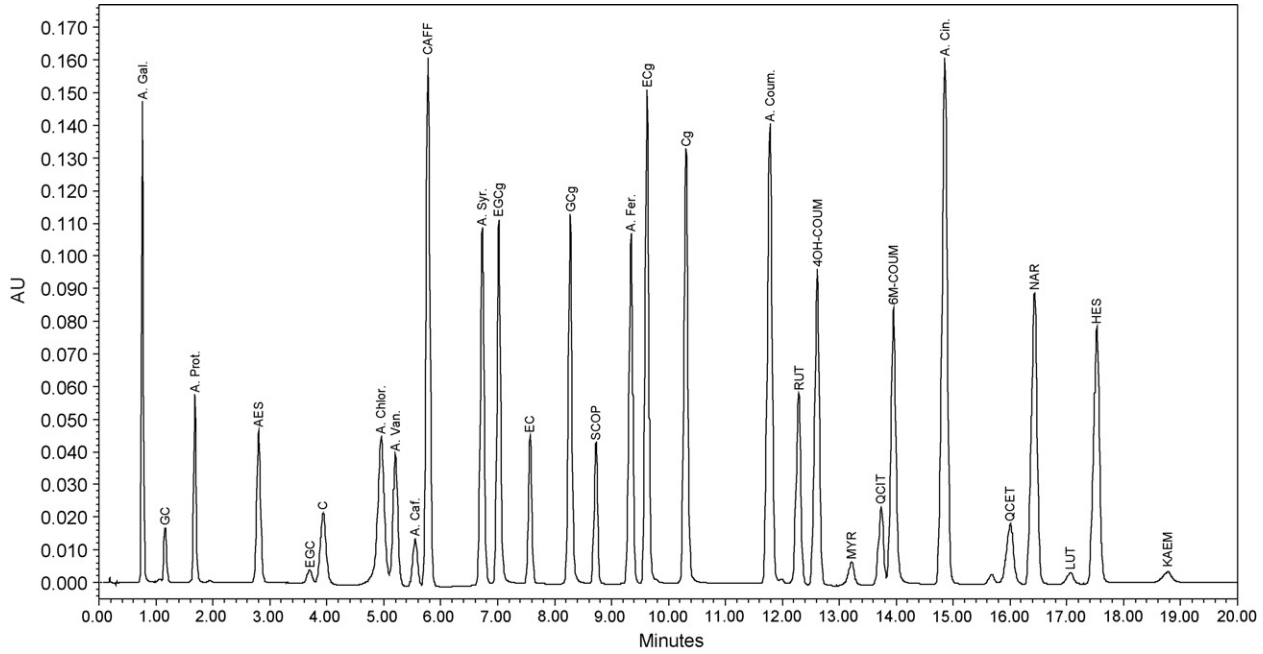

Fig. 2. Chromatogram of a standard mixture of 29 phenolic compounds and caffeine. (UV 280 nm, 0.1% formic acid–methanol from 88.5:11.5 to 50:50 (v/v), 0.45 mL min^{-1}).

2. Experimental

2.1. Chemicals and reagents

Reference standards of phenolic compounds were used in this study. They were purchased from Sigma–Aldrich (Prague, Czech Republic) as follows: phenolic acids: gallic (A. Gal.), protocatechuic (A. Prot.), chlorogenic (A. Chlor.), vanillic (A. Van.), caffeic (A. Caf.), syringic (A. Syr.), ferulic (A. Fer.), o-coumaric (A. Coum.), cinnamic (A. Cin.); flavonoids: catechin (C), catechin gallate (Cg), epicatechin (EC), epicatechin gallate (ECg), epigallocatechin (EGC), epigallocatechin gallate (EGCg), gallocatechin (GC), gallocatechin gallate (GCg), rutin (RUT), myricetin (MYR), quercitrin (QCI), quercetin (QCE), naringenin (NAR), luteolin

(LUT), hesperetin (HES), kaempferol (KAEM); coumarins: aesculin (AES), scopoletin (SCOP), 4-hydroxycoumarin (4OH-COUM), 6-methylcoumarin (6M-COUM) and caffeine (CAFF).

The non-fermented teas Kokaicha and Formosa Gunpowder, the fermented teas Pu-Erh and Nepal SFTGFOP-Maloom, the mixture of non-fermented and fermented tea leaves "Festival", the fruit teas "Messina" and "Cinnamon-Apple" were all obtained from OXALIS (Slušovice, Czech Republic). The non-fermented Vietnam tea with jasmine was purchased from a specialized tea shop. The green tea extracts "GT ex. p." (min. 80% catechins, max 8% caffeine) and "Ethyl Acetate Free Green Tea extract" (80% catechins/50% EGCg) were obtained from PORTA s.r.o (Prague, Czech Republic).

The mobile phase additive formic acid 98% p.a. as well as HPLC grade methanol and acetonitrile were obtained from Sigma–Aldrich. HPLC grade water, prepared by Milli-Q reverse osmosis Millipore (Bedford, MA, USA), was additionally filtrated through a 0.22 μm membrane filter immediately before use.

2.2. Instrumentation

Acquity UPLC system (Waters, Prague, Czech Republic) consisted of Acquity binary solvent manager (BSM), Acquity sample manager (SM), Acquity column manager and Acquity PDA detector. All UPLC analyses were performed on a BEH C18 analytical column (100 mm × 2.1 mm, 1.7 μm, Waters, Czech Republic).

The mobile phase consisted of 0.1% formic acid (solvent A) and methanol (solvent B). The following gradient program was employed: 0–4 min isocratic elution (88.5% A:11.5% B) and 4–20 min linear gradient elution from 88.5% A:11.5% B to 50% A:50% B. The initial flow rate 0.45 mL min^{-1} was reduced to 0.42 mL min^{-1} in the time interval from 4.1 to 20 min. Column oven temperature

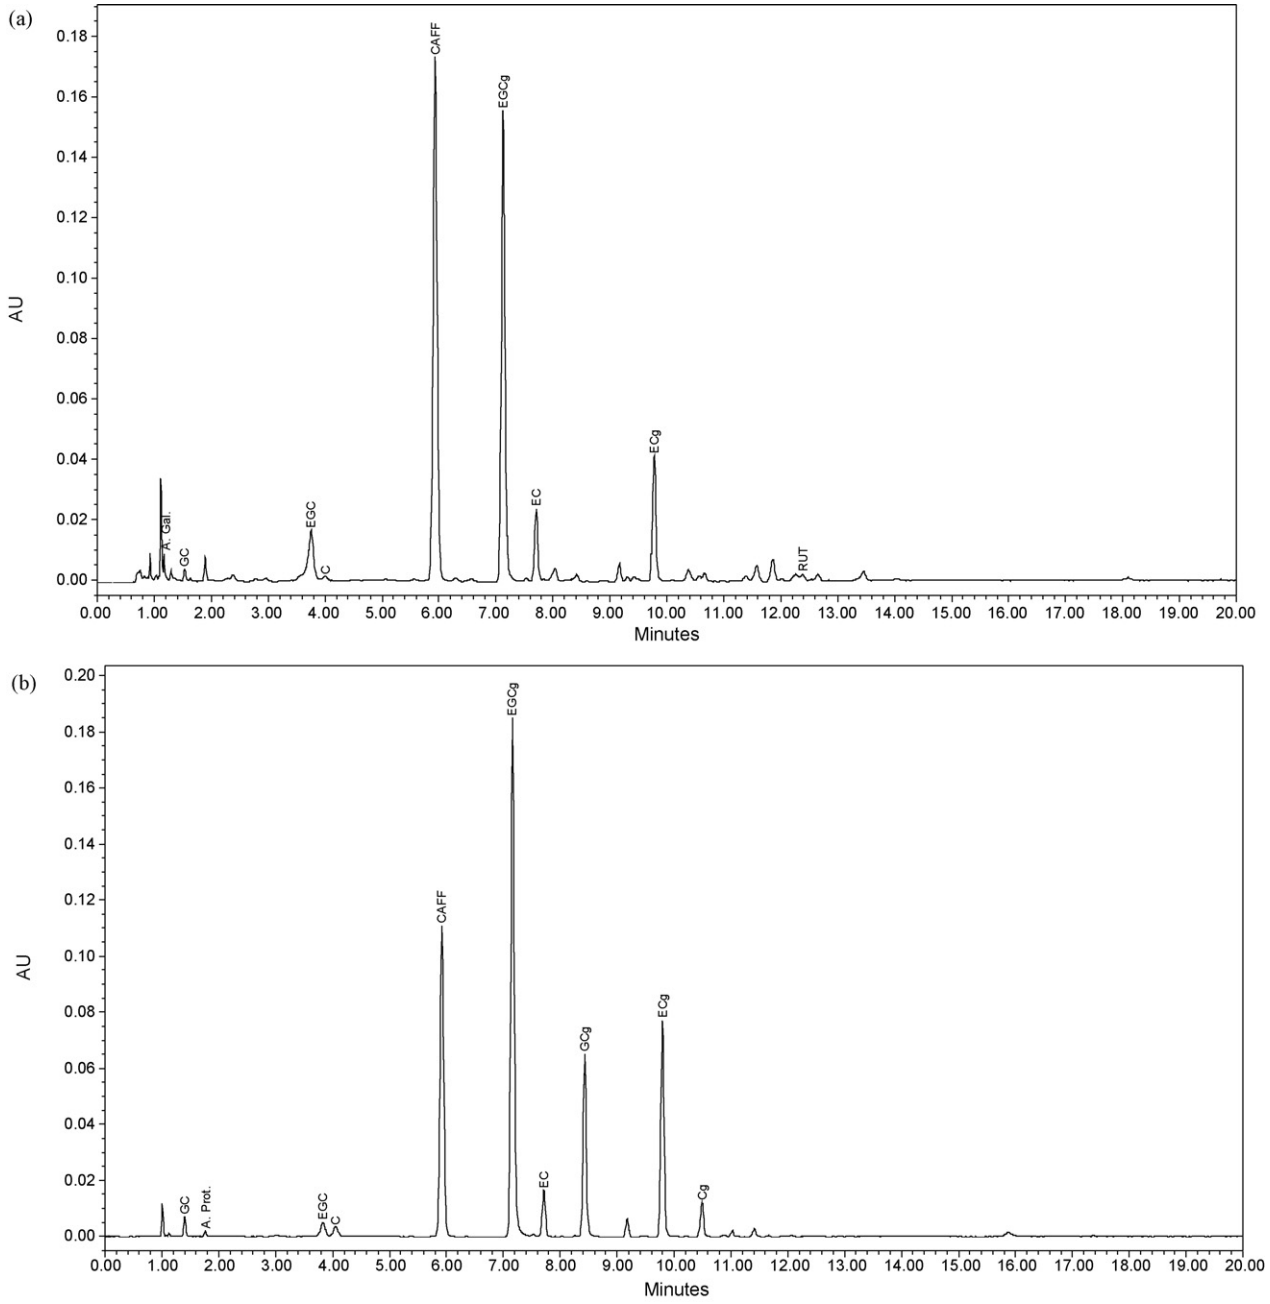

Fig. 3. Chromatograms of Kokaicha (water infusion) (a) and GT ex. p. extract (b).

was set up to 25 °C and the samples were kept at 4 °C in the sample manager. The partial loop injection mode with needle overfill injected a volume of 2.0 μL using 5 μL injection loop. Methanol was used as a strong wash solvent and 20% methanol as a weak wash solvent. The PDA detection was conducted at 280 nm for quantitative purposes with data acquisition rate of 20 Hz. Spectral data and peak purity calculation were used for identity confirmation. Chromatographic software Empower 2 was used for gathering data and processing of the chromatograms. This software enables a calculation of peak purity and operation with spectral data. Two UV absorbance maxima (if available) were used for identity confirmation of all analytes. Peak purity calculations uses two variables – peak purity angle and peak purity threshold. The criteria of peak purity are fulfilled when peak purity angle value is lower than the value of peak purity threshold.

2.3. Stock solutions and tea samples pre-treatment

The *stock solutions* of phenolic acids, flavonoids, catechins, coumarins and caffeine were prepared in methanol at the concentrations ranging from 1 to 5 g L^{-1}, keeping approximately equimolar ratios. All 30 stock solutions were combined into one mixed working solution and further diluted by mobile phase.

The *tea infusions* were prepared by pouring 100 mL of hot water (90 °C) over 1 g of dry tea mixture and 5 min of maceration with mild stirring. Then the cooled down tea infusion was filtrated through 0.20 μm membrane filter and further 2.5 times diluted by the mobile phase. The diluted tea infusions were used for injections immediately.

The *methanolic tea extracts* were prepared by pouring 50 mL of methanol over 1 g of tea mixture and sonication for 20 min. The following steps were the same as in the case of water infusion; the solutions were filtrated and stabilized by low pH of the mobile phase.

The *tea extract samples* prepared from commercially available powder extracts were diluted by methanol, filtrated and further diluted by the mobile phase prior to analysis. Fresh samples prepared daily were used for the analysis.

2.4. System suitability test and validation

A mixed standard solution of all phenolic compounds at the concentration corresponding to the middle of the calibration range was injected in ten replicates for the system suitability test (SST) measurements. Evaluated parameters were the mean values of resolution, asymmetry factor and peak capacity. The repeatability of retention time and peak area expressed as %RSD were checked and they should meet the requirement of RSD < 1%. The rules for measurement and the limits for the acceptance are given by official pharmacopoeias [41,42].

Determined validation parameters were following: range, linearity, LOD, LOQ, precision, accuracy and selectivity. Linearity was established using mixed standard solutions at seven calibration levels for each compound. Method precision was tested at three concentration levels in three replicates using tea samples to calculate RSD of the determination, which describes the closeness of agreement between series of measurements. Tea samples spiked with standard solution at three concentration levels were used for determination of method accuracy and recovery. Spiked samples were run in three replicates and agreement between theoretical and measured value was confronted with appropriate guidelines [43]. Both accuracy and precision were determined as intra-day and inter-day measurements (measurements were performed on three different days). Method selectivity was confirmed by calculation of peak purity and spectral data. Peak purity was calculated using two variables (calculated by software) – peak purity angle and peak purity threshold. The value of peak purity angle must be lower than the value of peak purity threshold. Formosa gunpowder tea was used as tea matrix for precision and accuracy experiments.

3. Results and discussion

3.1. Method development

The different portions of organic modifier present in mobile phase were tested in order to achieve optimal separation. The key issue was to achieve separation between peaks of chlorogenic, vanillic and caffeic acid, due to very similar retention properties. A sufficient separation was obtained eluting 0.1% formic acid and methanol isocratically in the ratio 88.5:11.5 (v/v) for 4 min. Consequently gradient curves of convex and concave profile and several target ratios were tested in order to achieve satisfactory separation of later eluted analytes. The final gradient profile with the target ratio 50:50 (v/v) enabled quick elution of relatively low polar flavonoid aglycons. A less steep gradient profile prolonged the analysis and undesirably affected symmetry of late eluting peaks. Finally the slightly convex gradient curve was performed to optimize the resolution.

The choice of wash liquids and standard/sample dissolution media is of special importance in UHPLC. Concerning wash liquids – weak wash solvent participate on injection procedure, therefore

it was necessary to use one corresponding to initial gradient conditions (20% methanol). The same applied to dissolution media as using narrow diameter columns the choice of dissolution solvent can influence chromatographic separation significantly more than in conventional HPLC analysis.

3.2. System suitability test and validation

SST parameters including resolution – R_s, peak asymmetry, repeatability of retention time and peak area were measured for all 30 compounds. The values of the resolution were in the range specified by pharmacopoeias (>1.5) corresponding to baseline separation, except of the values for the three pairs of substances (EGC and C, chlorogenic and vanillic acid, quercitrin and 6-methylcoumarin, where R_s was around 1.3). The asymmetry factor values varied between 0.84–1.17 fully meeting the criteria for symmetric peaks (0.8–1.5) according to EP [41]. The average peak capacity was 67.7, which is fully acceptable by general recommendations.

RSD for the retention time ranged from 0.09 to 0.52% and for the peak area from 0.17 to 0.91%, respectively. This is again in agreement with the requirements of EP [41]. Details of SST results are given in Table 2 and a typical chromatogram of standard mixture separation is shown in Fig. 2. The developed gradient method met all claims obligatory for SST.

To demonstrate method selectivity, spectral data were acquired and peak purity was calculated – data are displayed in Table 3. Two UV maximum absorbance wavelengths (if available) were compared in measurement of standard mixture and real sample. UV spectra matched for all maximum absorbance wavelengths ± 1 nm. These criteria for the peak purity were met for all 30 compounds in standard mixture, however only for 28 compounds in spiked real tea sample in spite of seeming agreement in UV spectra. Thus it could be concluded, that peak of Cg and 4-hydroxymethylcoumarin probably co-eluted with some interfering compound from matrix and quantitative results will not be reliable.

The calibration curves were measured using mixed standard solutions in a wide concentration range, typically from 1 to 100 mg L^{-1}, details are given in Table 2. The response was linear in tested range with correlation coefficients >0.9990 for all analytes. The last point of calibration curve was considered to be method LOQ (S/N = 10). LOD were calculated by extrapolation (S/N = 3). Typical LOD and LOQ were 0.06 mg L^{-1} or 0.2 mg L^{-1} respectively. Intra-day method precision for all thirty compounds expressed as RSD was less than 3%, while inter-day precision was less than 9%, the results are displayed in Table 4. Intra-day method accuracy expressed as recovery was within the range 77–110%, while inter-day method accuracy within 76–111% with typical values 100 ± 10%. The results are shown in Table 5.

3.3. Quantification of tea samples and extracts

In fact a cup of tea is a simple water infusion. Hence we used the extraction by hot water to study concentrations of polyphenolic tea components available for common tea consumers. Results achieved using the hot water extraction were compared to those achieved by sonication in cold methanol. Although compared to water methanol is theoretically more preferable solvent for polyphenols, the extraction by methanol appeared to be less efficient in case of non-fermented teas than the hot water infusion. Typical chromatogram is given in Fig. 3a. Results of the tea samples quantification can be seen in Tables 6 and 7. The indicated numbers represent the milligram content of tea components in 1 g of dry tea mixture. Excellent sensitivity of proposed UHPLC method allowed quantification of phenolic compounds present even in trace concentrations such as C, Cg, GCg, protocatechuic acid or rutin however, the care must be taken with each sample to verify its selectivity using peak purity calculation and spectral data.

According to the expectations, high content of catechins was found in non-fermented teas, typically ranging from 7 to 9% (w/w). The highest total quantity of catechins at all was found in Formosa gunpowder (93 mg g^{-1}), while very similar quantities were reported by Wang et al. in gunpowder tea [18]. Content of caffeine in the non-fermented teas was around 2% (w/w). Apart from catechins and caffeine also other phenolic compounds were quantified in tea samples. Phenolic acids (gallic, chlorogenic, protocatechuic, vanillic, caffeic and ferulic acid) were present at concentrations around 1 mg g^{-1}. Myricetin, quercetin and kaempferol-3-glycosides were also previously reported in tea infusions [44], although only quercitrin and rutin were found in our samples in detectable concentration. The fermented teas and fruit mixtures contained much lower quantities of monitored phenolic compounds.

The commercially available green tea extracts were tested in order to verify correct quantification of phenolic compounds by UHPLC – see Fig. 3b. Determined quantities were compared to the quantity guaranteed by the producer (>80%) and good agreement between both values was found (Table 7).

4. Conclusions

A newly developed UHPLC method with PDA detection enables simultaneous determination of 29 commonly occurring phenolic compounds and caffeine in tea matrices within only 20 min.

Apart from catechins (the most common antioxidant phenolic compounds abundant in tea and many other plant materials) also other natural phenolic compounds from groups of flavonoids, phenolic acids and coumarins were chosen in order to extend the utilization of this method to a number of various applications. High separation efficiency predestines this analytical method to be, e.g. useful screening tool in pharmaceutical botany or fingerprinting for the quality control of tea and tea extracts. The system suitability test and validation parameters were meeting requirements for all thirty compounds and thus the method was convenient for use in the quantitative analysis. Method selectivity was enhanced using spectral data from PDA detector and peak purity information. Furthermore it is important to highlight the minimal consumption of time and solvents when UHPLC is used contrary to conventional HPLC methods.

ABSTRACT

A number of recent studies have utilised ferricyanide as a respiratory mediator for microbial-based assays for determining water quality parameters such as biochemical oxygen demand (BOD) and toxicity. The majority of assays published to date obtain a result by determining the difference in ferrocyanide accumulation between a test sample and one or more control samples. However, a validation of the relationship between ferrocyanide accumulation and standard measures of cell density or viability has not yet been performed. To this end, a rapid microbially catalysed ferricyanide-mediated respiration (FM-RES) assay was compared with standard plate count (SPC) and spectrophotometer (OD_{600}) measurements on a growing batch culture of *Escherichia coli*. Good agreement was observed between all techniques, with predictable deviations noted in different phases of the growth curves. Standardised FM-RES assays showed excellent correlations with the SPC method under controlled conditions, indicating that short-term changes in microbial activity are due to a change in per-cell respiration, rather than changes in cell numbers. The FM-RES assay was then used to observe the changes in the respiration of *E. coli* induced by the addition of a glucose–glutamic acid (GGA) mixture, 3,5-dichlorophenol (3,5-DCP) and Ag^+ in various combinations and concentrations. Stimulation of respiration was pronounced in the presence of GGA while both 3,5-DCP and, in particular, Ag^+ demonstrated inhibitory respiratory effects. The results highlight the validity and suitability of ferricyanide-mediated respiration bioassays, with appropriate modification, to monitor either stimulatory effects on microbial populations, such as occurs with BOD, or inhibitory effects, such as occurs with toxicity assays.

1. Introduction

The accurate quantification of microbial populations or microbial respiration is important for the monitoring of water and food supplies, determining the effectiveness of wastewater treatment and for use in rapid microbial-based bioassays. However, due to their microscopic size and large population, direct quantification of the viable micro-organism population in a sample can be difficult and time-consuming. This is especially the case for techniques that involve directly counting bacteria, either via staining or culturing. These include the 4′-6-diamidino-2-phenylindole (DAPI) staining method [1], the standard membrane filtration method and the spread plate count (SPC) methods [2]. Additionally, assays relying on culturing bacteria require suitable growth media upon which the target bacteria are capable of growing rapidly enough in the incubation time to produce a measurable response.

The utility of micro-organisms for a range of rapid bioassays has long been recognised and a variety of techniques that aim to enumerate [3–5] or quantify the activity of [6–8] the microbial population in a sample have been developed. Many of these microbial assays attempt to indirectly measure changes in the activity of a microbial population by quantifying changes to the activity of the micro-organism's electron transport system (ETS), either instantaneously or over a time period. This is useful as the ETS is intrinsically linked to the essential cellular functions of metabolism and respiration and therefore represents an index of the overall integrity of cellular components and functions. Examples of such assays include the quantification of bioluminescence in the Microtox assay [7,9], measurement of respiration inhibition in the OECD 209 activated sludge test [10] or the accumulation of ferrocyanide in rapid, ferricyanide-mediated BOD assays [6,11].

Abbreviations: APHA, American Public Health Association; BOD, biochemical oxygen demand; CFU, colony forming units; ETS, electron transport system; FM-BOD, ferricyanide-mediated biochemical oxygen demand; FM-RES, ferricyanide-mediated respiration; GGA, glucose–glutamic acid; OECD, Organisation for Economic Co-operation and Development; PB, phosphate buffer; SPC, standard plate count.

Ferricyanide has been used as a redox mediator for studying cellular processes for a considerable time [12], but only recently has research interest into the use of ferricyanide-mediated (FM) microbial reactions focused on rapid analytical bioassays [13–15] or biosensors [11]. Ferricyanide is approximately five orders of magnitude more soluble than oxygen in water and can be used as an alternative terminal electron acceptor by a range of bacterial species, including the commonly studied *Escherichia coli* [6]. This enables the use of high microbial populations in small sample volumes without the electron acceptor limiting the rate of respiration, in turn reducing the incubation time required to achieve a measurable response. An example of this FM approach has been in the development of rapid BOD assays. There are several advantages of this approach over the conventional BOD_5 method, which have been discussed in more detail elsewhere [6]. In short, the FM-BOD assay can be completed in hours rather than days, has a greater linear range and measures the accumulation of the reduced respiration product, ferrocyanide, from a zero background [13]. Minor modification of the assay to quantify the inhibition of FM respiration due to toxicity has also been the subject of several recent studies [16–18].

A number of bacterial species, including *E. coli*, *Pseudomonas putida* and mixed consortia have been investigated as biocatalysts in the FM assays [11,19]. The most recently published versions of the FM-BOD technique have incubation times of 1–4 h [6,20], though some FM biosensors utilising immobilised cells have shorter incubation times [21]. A single FM incubation cannot differentiate changes in overall activity due to individual cell growth, net population size, metabolic activity or substrate availability. However, controlling parameters such as incubation time and the choice of biocatalyst can facilitate investigation into degradation efficiencies of various compounds and provide more insight into the processes occurring during the incubation [19].

All of these studies have assumed that the measured production of ferrocyanide is quantitatively related to cell growth and/or cell activity. In support of this assumption, Morris et al. [13] described the relationship between microbial density and ferrocyanide production, through a dilution process of a homogeneous bacterial culture. However, the ability of an FM bioassay to sensitively monitor changes in a dynamic microbial population has not yet been validated. This study aims to explore the relationship between respiration, as measured by the production of ferrocyanide by a bacterial culture, and quantification by two common, widely used bacterial enumeration methods. The utility of the assay for sensitively describing changes in the activity of bacterial populations will be demonstrated with an example of stimulatory and inhibitory responses to various mixtures of a GGA solution with either 3,5-dichlorophenol (3,5-DCP) or silver ions.

2. Methods

2.1. Bacterial cultures

E. coli K12 was obtained from the University of New South Wales Culture Collection. Cultures were maintained on nutrient agar plates (Oxoid) and re-plated regularly to ensure viability. A 1.5 L solution of autoclaved tryptone soy broth (Gibco) was inoculated with a colony of *E. coli* and grown aerobically at 37 °C for 16–18 h on an orbital shaker.

2.2. Microbial culture growth experiment

At the desired sampling times (either 30 or 60 min intervals), a representative 10 mL subsample was withdrawn from the 1.5 L broth culture and divided into three sub-samples. Each of the sub-samples was analysed concurrently using spectrophotometric analysis of the optical density, the standard spread plate count method and the ferricyanide-mediated respiration rate. For the purposes of this paper, the incubation of bacteria in the presence of ferricyanide is referred to as an FM-RES assay.

For the FM-RES assay, ferricyanide was made up to 600 mM in PB solution comprising 0.08 M K_2HPO_4/0.12 M KH_2PO_4. The ferricyanide-mediated cellular respiration technique consisted of immediately adding 100 μL of freshly prepared ferricyanide to 1 mL aliquots of the batch culture sub-sample, to give a final ferricyanide concentration of 55 mM. The sub-samples were then incubated for 15, 30 and 60 min at 37 °C, after which the biochemical reaction was terminated by centrifugation (13 200 rpm). Determination of microbially produced ferrocyanide in the supernatant was carried out by chronoamperometry using a 25 μm Pt microelectrode, as described in Morris et al. [13].

Optical density measurements of the batch culture sub-samples were taken in 1 mL quartz cuvettes at 600 nm (OD_{600}) using a Shimadzu UV-1601 UV-Vis spectrophotometer. To avoid deviations of linearity in the measurement, when the OD_{600} reached approximately 0.5, the sample was diluted with the remaining reference solution. Reference solution was prepared by centrifuging the remaining sample at 13 200 rpm and then filtering the supernatant through a 0.2 μm cellulose filter. This ensured that, as far as practically possible, the sample and the reference solution were matrix matched.

Standard plate counts were carried out as described by the APHA standard methods [2]. In brief, a serial decimal dilution series was prepared in 3% sterile peptone solution. Following dilution, duplicate 100 μL aliquots were pipetted onto sterile agar plates and spread over the surface of the agar plate using a sterile glass spreader. Following inoculation, the plates were incubated at 37 °C for 24 h and the numbers of colony forming units (CFUs) were counted. As recommended by the APHA standard methods, only dilutions producing counts between 30 and 300 CFUs were considered to be valid to be used in the calculation of population density (CFU/mL).

2.3. Standardised FM-RES and SPC test

An *E. coli* culture was prepared as described above and harvested by centrifugation (4000 rpm) in the late exponential phase of growth, as determined by a growth curve. The cells were washed twice and resuspended in a minimal amount of PB to give a concentrated suspension of cells in their endogenous state.

Serial dilutions (no dilution, 20%, 40%, 60%, 80%, 90%, 98%) of the cell solution were then prepared using PB as the diluent. These solutions were then concurrently analysed employing the SPC and FM-RES techniques described above. As the washed cells contained little exogenous organic substrate, the FM-RES method was slightly altered to supply the bacteria with a carbon source. In this case, 100 μL of the standard GGA mixture (300 mg L^{-1} each of glucose and glutamic acid, giving a BOD_5 equivalent of 396 mg L^{-1}) was added to the FM-RES matrix.

2.4. Microbial response to substrates and toxicants

Cells were harvested as described for the standardised test and resuspended in PB to an OD_{600} of 8.8. Samples were then prepared by adding 1.00 mL of cell suspension, 1.00 mL of test sample, and 0.20 mL of 600 mM potassium ferricyanide solution. Test samples comprised GGA and one of either 3,5-DCP or Ag^+. 3,5-DCP was tested at concentrations of 0, 5, 15 and 40 mg L^{-1}, Ag^+ at concentrations of 0, 2.5, 7.5 and 20 mg L^{-1} and GGA at BOD_5 equivalent concentrations of 0, 25, 100 and 400 mg L^{-1}. Test samples were prepared in a matrix format, in which each toxicant concentration was

tested against each GGA concentration. Each of the three substances was also tested alone at the concentrations described.

Samples were incubated at 37 °C for 15, after which the biochemical reaction was terminated by centrifugation. Samples were then decanted into new sample containers and analysed for ferrocyanide production as described above.

3. Results and discussion

3.1. Batch culture dynamics and effect of FM-RES duration

The growth of an *E. coli* culture was monitored over an 18 h period using three concurrent measurement techniques, the FM-RES assay, the SPC and the spectrophotometric technique. The FM-RES assay, which involves a secondary incubation in the presence of ferricyanide, was carried over three different times to identify whether time exposure to ferricyanide was a significant factor in the FM-RES assay. The net ferrocyanide production at each time point was predictably larger at longer FM-RES assay times (Fig. 1a).

The growth curves shown in Fig. 1 assist in the validation of the FM-RES technique as an indicator of microbial activity for several reasons. First, the curves depict the classic stages of bacterial culture growth, including an initial lag phase, an exponential growth phase, a brief stationary phase and the onset of death phase. Second, the average respiration rate was similar for the three FM-RES incubation times, though the rate in the 60 min incubations peaked lower and dropped more quickly after 14 h than the 15 or 30 min incubations (Fig. 1b). This indicates the respiration rate in a 60 min incubation tapers off in the last 30 min, potentially due to limitation by substrate, electron acceptor or waste product accumulation. The peak rate of ferrocyanide production was highest for 15 min FM-RES assays, which suggests that the 15 min data is the most accurate indicator of the activity of the microbial population at the time the sample is withdrawn from the batch culture. Therefore, data from the 15 min FM-RES assay was used for further comparisons in the study. Most importantly, it is clear that by quantifying cellular respiration with the FM-RES assay, discrete and sensitive changes of the microbial culture population dynamics can be rapidly and readily determined.

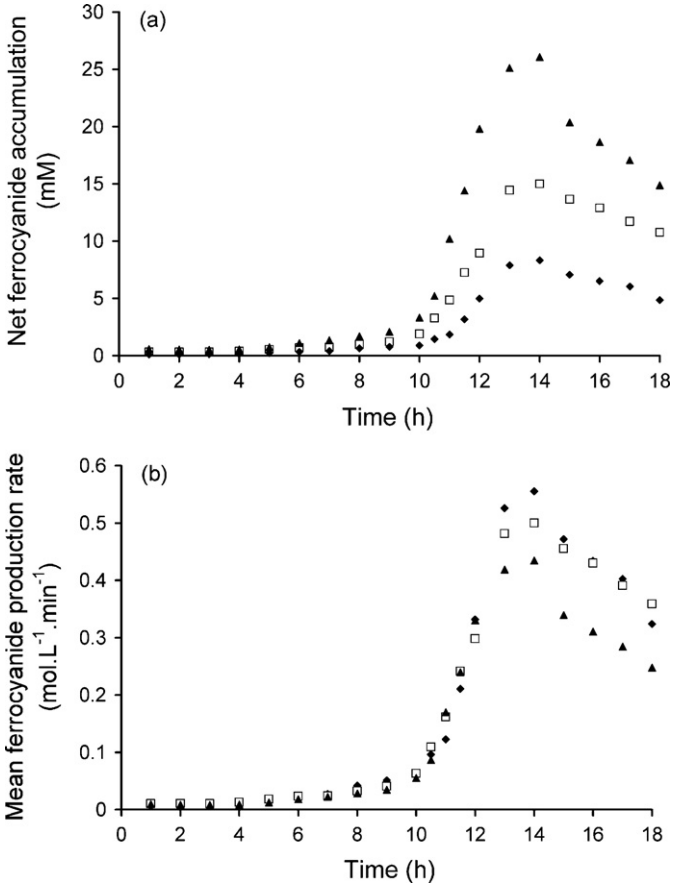

Fig. 1. *E. coli* growth curve as measured by FM-RES incubations of three different durations, 15 min (diamonds), 30 min (open squares) and 60 min (triangles). The data is presented as (a) absolute values of ferrocyanide accumulation and (b) the rate of ferrocyanide accumulation, normalised by assay time.

3.2. Comparison of FM-RES, OD_{600} and SPC assays

There was generally close agreement between the spectrophotometric measurement of culture optical density and the FM-RES measured values, as shown in Fig. 2. The largest deviation between the techniques occurred between hours 14 and 18, in which the OD_{600} values remained relatively constant while the FM-RES values dropped substantially, indicating a decrease in cellular activity. This highlights an advantage of the FM-RES method over optical measurements of cell density. The spectrophotometric analysis, while rapid, is not an accurate measure of cell activity, as both living and non-living cells (and potentially other material, such as membrane fragments and extracellular polymers) are part of the analytical signal. Further, attempts to use spectrophotometry as an enumeration method can be confounded by changes in cell size at different growth stages. Therefore, the observed deviation in the OD_{600} and FM-RES curves between 14 and 18 h as the culture passed through stationary phase and into death phase would be expected. The FM-RES assay, by measuring changes in population and per-cell activity directly, avoids problems with optical interferences such as dead cells or debris and provides a more accurate representation of the state of the microbial population.

In contrast to the spectrophotometric technique, the SPC method followed the same general trend as the FM-RES method throughout the growth curve (Fig. 3), including the lag phase, growth phase and death phase. This confirms the previously discussed shortcomings of the spectrophotometric technique, and emphasises the importance of an assay being capable of distinguishing between viable and non-viable cells.

Despite the similarities in the curves between the SPC and FM-RES assay, there are important differences in the nature of the techniques which were evident at different phases of the growth curve. The SPC only measures cells that are capable of growing fast enough on the growth medium to produce a visually identifiable

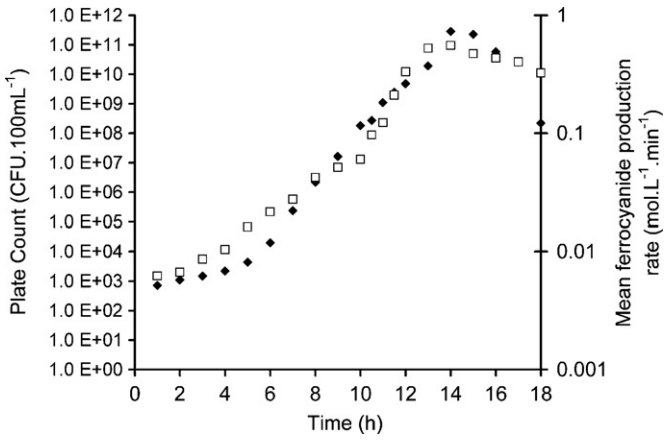

Fig. 3. Plot of growth curve displaying log CFU/mL from the standard SPC (diamonds) and log mean ferrocyanide production rate (open squares) from the FM-RES assay.

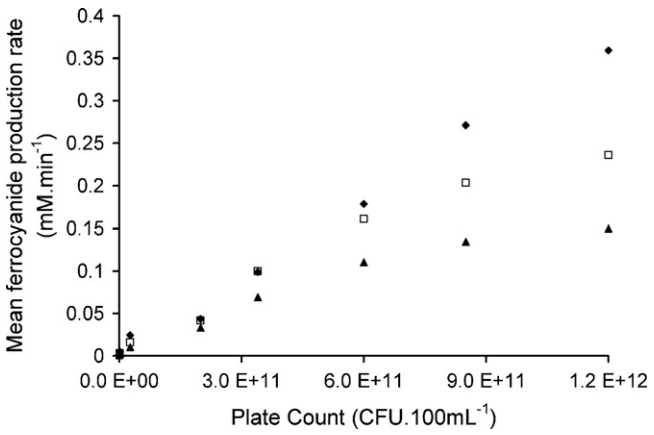

Fig. 4. Linear relationships between the rate of ferrocyanide production and quantity of colony forming units for three FM-RES incubation times, 15 min (diamonds), 30 min (open squares) and 60 min (triangles). Samples comprised *E. coli* harvested from the late exponential phase, standardised at OD_{600} and serially diluted to generate a curve.

colony, which are defined as viable cells. By contrast, the FM-RES signal comprises the net activity of all cells in the population, whether they are respiring at maximal capacity or only a fraction of their potential. This is an important distinction, as microbial activity can change with factors such as the cell size or substrate availability, without necessarily changing the number of viable cells. For example, increasing cell size in the early exponential phase would lead to increasing activity without a proportional increase in viable cell numbers. Conversely, in the death phase, the proportion of cells that are viable may decline rapidly, but these cells may still be respiring and hence contributing to the FM-RES signal. Importantly, the FM-RES assay can provide information about the changing bacterial population in just over 15 min, as opposed to 24 h required for the SPC method.

3.3. Comparison of SPC and standardised FM-RES assay

As there were differences in the growth curves measured by the FM-RES and SPC assays, the final validation experiment standardised the FM-RES and SPC assays for growth stage, by using cells in the late exponential phase of growth, as well as population density, as measured by OD_{600}. In other words, bacteria were harvested at a point when the culture contained the largest number of highly active cells. The cells were then washed to remove exogenous carbon sources and standardised for optical density. Fig. 4 depicts the correlation between the FM-RES and SPC methods for three FM-RES assay incubation times. There was a strong linear trend for all incubation times, most notably the 15 min assay, for which a Pearson product moment correlation analysis gave an r-value of 0.997 ($p < 0.001$, $n = 7$). The 30 and 60 min assays appeared to level off slightly at the highest cell counts, but correlation values of 0.993 for the 30 min assay ($n = 6$) and 0.991 for the 60 min assay ($n = 6$) were achieved by omitting the highest point in each curve.

The excellent correlation between FM-RES and the SPC method when growth phase and optical density were controlled is important for the development of FM bioassays for two reasons. Firstly, it validates the experimental principle behind FM microbial bioassays by showing, for the first time, a strong and significant relationship with a standard viable cell enumeration technique. Second, it has been determined that, under controlled conditions with a standardised biocatalyst and optical density, any change in the analytical response is due to a change in activity per cell. In other words, the control respiration in a 15 min FM-RES assay is directly related to the number of viable cells present. Deviations from this control value in samples exposed to a test substance are therefore due to a change in per-cell respiration, rather than a change in population size or other factors.

However, there were deviations in linearity at higher cell densities for the 30 and 60 min incubations, with values starting to plateau. This result reinforces the previously discussed idea that longer FM-RES incubations may be more susceptible to variability compared to shorter incubations. The deviation in linearity indicates that, above a threshold CFU population, the kinetics of the FM-RES biochemical reaction are limited by factors other than cell population, such as electron acceptor concentration and/or carbon source availability.

For the purposes of a bioassay, standardising the biocatalyst prior to the assay is necessary to ensure the results are comparable and reproducible between assays. While the previous FM-RES tests on a growing bacterial population are promising, it is important to determine if a standardised bacterial population will respond predictably in the presence of different compounds. Washing the bacteria in phosphate buffer solution prior to testing ensures they are suspended in a simple, controlled medium. This will be especially relevant if different biocatalysts are employed in FM assays, as the culture media required to grow the bacteria may differ.

The duration of the FM-RES assay is an important aspect to consider when using the method to assess the activity of a microbial population. FM-BOD assays use longer deployment times, such as 1–4 h [6] to ensure a high percentage of substrate degradation, with the accumulated ferrocyanide used to gauge this value. During the course of such an assay, the rate of accumulation of ferrocyanide can change [20]. Therefore, the information obtained from an FM-RES assay must be interpreted in the context of the incubation time and the presence of other factors, such as exogenous substrates. Non-BOD techniques may require a rapid snapshot of microbial population and/or activity, in which case a shorter incubation is much more desirable, as the result will more closely reflect the activity of the test population at the start of the FM-RES incubation.

3.4. Effect of substrates and toxicants on FM-RES assay

To demonstrate the suitability of the standardised *E. coli* biocatalyst for bioassays, a range of metabolic responses to test samples were studied. Assays were conducted at four fixed GGA levels with varying toxicant concentrations to investigate the interaction between stimulatory and inhibitory influences. Stimulation of respiration in the presence of GGA was pronounced (Fig. 5a), with a rate of ferrocyanide production in the sample

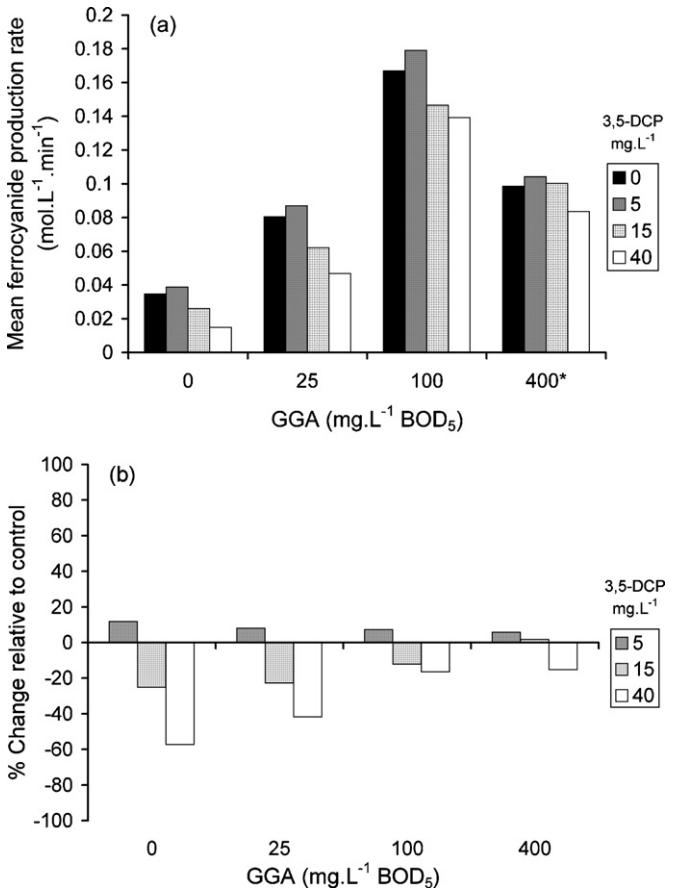

Fig. 5. The (a) rate of ferrocyanide production in samples containing 3,5-DCP at 0, 5, 15 and 40 mg L^{-1} at differing concentrations of GGA (*x*-axis, in terms of mg L^{-1} BOD_5) and (b) the normalised effect of the 3,5-DCP relative to the control (i.e. no 3,5-DCP) samples, as calculated by Eq. (1). **Note*: values for 400 mg L^{-1} GGA were divided by 5 for ease of display in (a).

containing 400 mg L^{-1} BOD_5 (as GGA) an order of magnitude above the endogenous (i.e. no added GGA or toxicant) respiration rate observed. This is in keeping with the observed rapid increase in *E. coli* metabolism with GGA, reported by Morris et al. [13].

In the concentration ranges tested, the stimulatory effect of GGA dominated the inhibitory effect of 3,5-DCP (Fig. 5a). However, despite the differences in magnitude of the control responses (i.e. no toxicant), the effect of the 3,5-DCP can still be measured by normalising the response of each toxicant sample (I_{lim} Sample in Eq. (1)) to the control sample with the corresponding GGA concentration (I_{lim} GGA control in Eq. (1), and the black columns in Fig. 5a). In other words, we can compare the FM-RES response at different toxicant concentrations (5, 15, 40 mg L^{-1} 3,5-DCP) to the FM-RES response at zero toxicant concentration and report the comparison as a percent change in ferricyanide-mediated respiration (Eq. (1)):

$$\%\text{Change} = \left(\frac{I_{\text{lim}}\text{Sample} - I_{\text{lim}}\text{GGA control}}{I_{\text{lim}}\text{GGA control}}\right) \times 100 \quad (1)$$

Therefore, while the production of ferrocyanide was greater in absolute terms for samples with higher GGA, the relative effect on microbial metabolism by the toxicants is still comparable across GGA treatments (Fig. 5b). Change in metabolism, calculated using Eq. (1), can indicate inhibition, as negative percentage values up to −100%, at which point no activity remains in the sample. Conversely, positive percent changes indicate stimulation of respiration, which can be higher than 100%.

The inhibition of respiration by each of the two toxicants tested, when corrected for the effect of added GGA, contrasted strongly

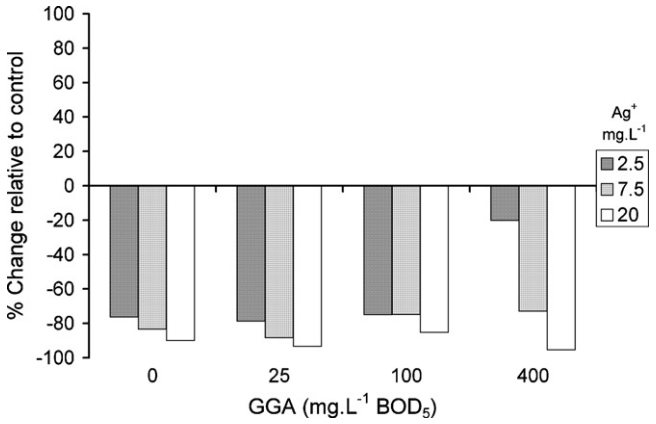

Fig. 6. Changes in ferrocyanide production relative to control samples for three Ag^+ concentrations, as calculated by Eq. (1).

(Fig. 5b vs. Fig. 6). It is apparent that microbial respiration was not completely inhibited by 3,5-DCP in any sample, even at a concentration of 40 mg L^{-1}, which is substantially higher than the EC_{50} values of 3.73 mg L^{-1} for *Vibrio fischeri* in the Microtox test and 13 mg L^{-1} for *E. coli* in the 15 min micredox toxicity assay [16]. This is likely to be due to the experimental conditions, which are not optimised for sensitive toxicity testing.

At low 3,5-DCP concentrations, there was a stimulation of respiration which may be associated with a stress response of the bacteria, as has been reported in other studies [22]. The responses in Figs. 5b and 6 show a range of stimulatory and inhibitory effects on a timescale too small to be detected by either the spectrophotometric method or the SPC technique. This emphasises the importance of measuring cell activity, as opposed to surveying cell numbers or the number of culturable cells in a population, if a rapid, accurate determination of the influence of a test sample on a microbial population is desired.

A key finding from the stimulation and inhibition experiment is that the toxicity of 3,5-DCP was substantially greater when GGA was omitted from the incubation mixture (Fig. 5b). Comparison of the inhibition induced by 40 mg L^{-1} 3,5-DCP on microbial populations shows that the percent change was almost four times greater in the presence of zero GGA (57% inhibition) than with 400 mg L^{-1} BOD_5 GGA added (15% inhibition). Fig. 6, on the other hand, shows that Ag^+ was highly toxic at all concentrations tested irrespective of GGA concentration. All but one sample containing Ag^+ produced ferrocyanide at a rate 75–100% lower than the corresponding controls. The presence of GGA at a concentration of 400 mg L^{-1} BOD appeared to mitigate the inhibitory effect of 2.5 mg L^{-1} Ag^+, as inhibition was only 20%.
