The general trend here is relatively simple, in that the presence of exogenous carbon substrate mitigates the inhibitory effect of toxicants. However, the interrelationship between combinations of substrates and toxicants can be highly complex [23]. It is unclear whether the GGA simply allows the cells to metabolise more rapidly despite the inhibition by the toxicants, or whether the presence of the GGA directly interrupts the mode of action of the toxicant, or if a combination of factors is responsible for the changes. Such interpretations are even more difficult if the biocatalyst is capable of metabolising the toxicant, in which case the response induced by a toxicant could change from inhibition to stimulation over the course of an incubation. At a simplistic level, the result in Fig. 5 clearly shows that the addition of exogenous carbon is undesirable if FM-RES methods are to be used in toxicity assays, as toxic effects are more pronounced when there is little or no exogenous carbon. The most recently published ferricyanide-mediated direct toxicity assessment assays include GGA mixture as a substrate, which may

reduce the sensitivity of the assays for some samples and confound comparisons of toxicants [16,18].

Finally, an important consideration for any assay based on the FM-RES technique is that the test sample and the presence of ferricyanide may have time-dependent effects on the microbial population. For example, this study shows that, for a rapid FM-BOD assay, simple substrates such as glucose will have a pronounced effect in a short period of time, whereas recalcitrant substrates will not affect short-term assays but will be a consideration in longer incubations. More thorough investigation of the role of time is required when optimising the FM-RES assay for a particular technique [19]. In the use of FM-BOD assays, clearly a longer incubation time would be desirable, as the microbial population would require a longer period of time to degrade both labile and more recalcitrant organic compounds in the test sample and therefore provide a representative measurement of the potential biochemical oxygen demand. However, in the case of assays which require a rapid assessment of cell activity, such as direct toxicity assays, this study suggests that a shorter time period for incubation in the presence of ferricyanide may be desirable. A 2-step incubation approach, in which the microbial cells are first exposed to a test sample followed by a secondary incubation in the presence of ferricyanide to determine cell activity, may serve to reduce interference by short-term stimulatory stress effects, as observed in Fig. 5b, and the presence of labile carbon compounds. Future development of ferricyanide-mediated direct toxicity assessment assays should proceed with these considerations in mind.

4. Conclusions

The analytical principle of ferricyanide-mediated quantification of the activity of microbial populations has been validated against two commonly used microbial enumeration techniques. The agreement between the FM-RES, OD_{600} and SPC methods was generally very good, with predictable deviations consistent with the nature of each technique. The shortest FM-RES incubation time, 15 min, provided reproducible and sensitive measurements of changing population size and activity across a substantial linear range of cell population. The FM-RES approach is faster and requires fewer resources than the SPC, though the type of information obtained is different. FM-RES also provides much more information than measurements of optical density using a spectrophotometer, as it can distinguish between live and dead cells, as well as changes in per-cell activity, and is less likely to suffer interferences from non-living material in the matrix.

Both stimulation and inhibition of microbial activity was observed in mixtures containing GGA and either 3,5-DCP or silver, varying between almost complete inhibition of ferrocyanide production to a stimulation of approximately fourteen times the endogenous response. This demonstrated the ability of FM-RES methods to sensitively and rapidly investigate changes in the activity of standardised microbial populations in synthetic solutions at a time scale comparable to the fastest available alternatives. Importantly, the addition of exogenous carbon was found to decrease the toxic effect of 3,5-DCP on *E. coli*, which suggests a closer examination of the experimental design of existing rapid, ferricyanide-mediated toxicity assays are required to ensure consistent and sensitive responses across a range of toxicants.

ABSTRACT

Progesterone (P4) is a steroidal hormone with a vital role in the maintenance of human and animal health. This paper describes the development of an immunosensor coupled to glassy carbon (GC) electrode and integrated to a microfluidic system to quantify P4 from bovine serum samples in a fast and sensitive way. The serum samples spiked with a given P4 concentration and a given P4 concentration bound to horseradish peroxide (HPR) were simultaneously added and, therefore, they competed immunologically with sheep monoclonal anti-P4 antibodies that were immobilized at a rotating disk. HRP in the presence of hydrogen peroxide (H_2O_2) catalyzes the chatecol (H_2Q) oxidation to benzoquinone (Q). Its reverse electrochemical reduction to H_2Q can be detected at a GC electrode surface at −0.15 V by chronoamperometric measurements. These current responses are proportional to the enzyme activity and inversely proportional to the P4 amount present in bovine serum samples. This P4 immunosensor showed a linear working range from 0.5 to 12.5 ng mL^{-1}. The detection (DL) and quantification (QL) limits were 0.2 and 0.5 ng mL^{-1}, respectively. The electrochemical immunosensor had a higher sensitivity than the ELISA method using conventional spectrophotometric detections. However, both methods allowed us to obtain similar detection limits. The immunosensor allowed us to make up to 100 determinations on different samples without any previous pre-treatment. This behavior proved to be suitable to detect P4 in routine veterinary, clinical, biological, physiological, and analytical assays.

1. Introduction

Nowadays, the use of electrochemical immunosensors as efficient analytical tools in the fields of clinical diagnosis and environmental monitoring is well established [1,2]. These immunosensors have excellent analytical applications, such as higher sensitivity and reproducibility. Their construction and use is very simple. These important advantages allow the electrochemical immunosensors be able to perform immunoreagent immobilizations, be more efficient in transduction events as well as work in a small scale.

Progesterone (P4) (pregn-4-ene-3,20-dione) is an α,β unsaturated ketone, a steroid hormone with a vital role in the maintenance of human and animal health. Its imbalance can cause malformations in the reproductive system as well as infertility problems [3,4]. P4 is secreted by the uterus to prepare it for pregnancy and maintain the pregnancy after conception secretes P4. Therefore, P4 is adequate to diagnose an early pregnancy [5]. P4 levels should be at sufficiently high values in the organism to assure the embryo development [6]. Thus, monitoring of P4 levels is important to reproductive system. A periodic control of P4 level is used to determine the next most fertile ovulation time and to program the animal's service or the artificial insemination, which would help to improve the percentages of pregnancy [7,8].

The most common methods to quantify P4 in animal serum are those based on enzyme-linked immunosorbet assay (ELISA) and radio immuno assay (RIA). These methods are applied using commercial kits [8,9,10]. However, immobilized antibodies have to be discarded immediately after the first use in these assays. HPLC is another technique used to quantify P4, where ethanol–water solvent binary mixtures are employed as the mobile phase and the column should be thermostatized to 40 °C [11]. Hart et al. [12] have designed a carbon paste amperometric biosensor to detect P4 indirectly in milk through determinations of products involved in the enzymatic-substrate reaction. Another biosensor has also been designed by Claycomb et al. [13,14], which uses the same enzymatic immunoassay method to detect P4 in milk. Recently, an amperometric immunosensor was developed using a colloidal gold–graphite–Teflon–tyrosinase composite to determine P4 in milk [15]. Nevertheless, the implementation of sensitive, fast and

low cost methodologies to quantify P4 in bovine serum samples is still a challenge to carry out further studies.

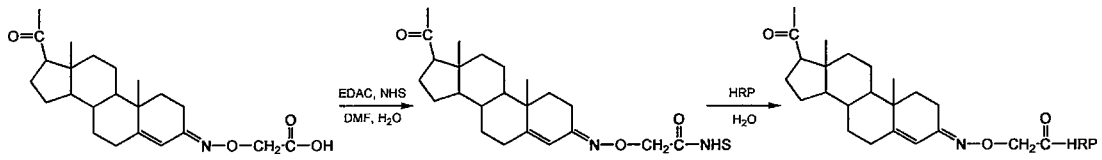
Heterogeneous enzymatic immunoassays, coupled with amperometric detection flow injection (FI) system, represent a powerful analytical tool to determinate low levels of different analytes, such as hormones, antibodies, drugs, tumor markers, and viruses [16]. The amperometric detection offers a good sensitivity combined with a simple and low-cost instrumentation [17,18]. One approach used is to employ a labeled enzyme which generates an electrochemically active product [19–22].

In this paper, we study the development of an immunosensor coupled to a glassy carbon (GC) electrode integrated to a microfluidic system to quantify P4 in bovine serum samples previously spiked with a known P4 concentration. A fast and sensitive method based on the use of a monoclonal antibody (mAb), which was immobilized on a rotating disk. Bovine serum samples containing P4 were added to the reactor with a known concentration of enzyme-labeled antigen (i.e., the "conjugated"). Therefore, labeled and unlabeled antigens compete with antibody binding sites bound at the rotating disk. The enzyme used to label the antigen was horseradish peroxidase (HRP) and chatecol (H_2Q) was the enzymatic redox mediator. HRP in the presence of hydrogen peroxide (H_2O_2) catalyzes the oxidation of H_2Q to benzoquinone (Q). Its reverse electrochemical reduction to chatecol can be detected on the GC electrode surface at −0.15 V through chronoamperometric measurements. These amperometric responses are proportional to the activity of the enzyme and inversely proportional to the amount of P4 in bovine serum samples.

2. Experimental

2.1. Chemicals

All reagents used were of analytical reagent grade. P4, progesterone–3-carboxymethyloxime (P4–3-CMO), 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDAC), sheep monoclonal antibody (mAbP4) and horseradish peroxidase (HRP) were obtained from Sigma Chemical Company and *N*-hydroxysuccinimide (NHS) from Fluka. Anhydrus dimethylformamide (DMF), Glutaraldehyde (25% aqueous solution) and pH 7.00 phosphate buffer solutions (PBS) as well as H_2O_2 were purchased from Aldrich and Merck (Darmstadt, Germany), respectively. H_2Q was obtained from BDH Chemicals Ltd. (Poole, England). All reagents were used as received. 3-Aminopropyl-modified controlled pore glass, 1400 Å mean pore diameter and 24 $m^2\,mg^{-1}$ surface areas, was obtained from Electro Nucleonics (Fairfield, NJ, USA) and contained 48.2 $\mu mol\,g^{-1}$ of amino groups. The School of Agriculture and Veterinary from Universidad Nacional of Río Cuarto gently supplied bovine serum samples. The ELISA test kits for P4 quantitative determination were obtained from Abbott Axsym System®, Reagent Pack, Abbott Japan Co., Ltd. The manufacturer's instructions were taken into account to perform these assays. Aqueous solutions were prepared using purified water from a Milli-Q system.



2.2. Apparatus

The main body of the cell was made of Plexiglas. Both the design of the flow through chamber containing the microfluidic immunosensor and its detection system are shown in Fig. 1a.

The volume of the cell was 5 μL. The GC electrode was on the top of the sensor. The rotating reactor was a disk of Teflon (3 mm diameter) where a miniature magnetic stirring bar was incorporated. 0.3 mg of controlled-pore glass is stuck on its surface. The reactor rotation was performed by a magnetic stirrer (Metrohm E649 from Metrohm AG, Herisau, Switzerland) and controlled with a variable transformer of an output between 0 and 250 V and maximum amperage of 7.5 A (Waritrans, Argentina). Chronoamperometry and cyclic voltammetry measurements were performed by using a BAS LC4C and a BAS 100 B (electrochemical analyzer from Bioanalytical Systems, West Lafayette, IN, USA), respectively.

The potential applied to the GC electrode for performing amperometric measurements was −0.15 V *vs* Ag/AgCl, 3.0 $mol\,L^{-1}$ NaCl reference electrode (BAS RE-6). A Pt wire was the counter electrode. A catalytic current was established at this potential. The inner diameter (i.d.) of flow channels was 0.100 mm and the length of flow channels was 10 mm. Pumps (Baby Bee Syringe Pump, Bioanalytical System, West Lafayette, IN) were used for pumping, introducing samples and stopping the flow.

The pH measurements were carried out with an Orion Expandable Ion Analyzer (model EA 940, Orion Research, Cambridge, MA, USA) equipped with a glass combination electrode (Orion

Scheme 1. Synthesis of P4–3-CMO with HRP to form the labeled P4.

Research). Absorbance measurements were performed by Bio-Rad Benchmark microplate readers (Japan) and Hewlett-Packard spectrophotometer, Model 8452A, equipped with a temperature controller.

2.3. Preparation of P4–HRP conjugate

P4 was bound to HRP by following a synthesis of activated ester to generate the P4 labeled. Thus, 7.9 mg of P4–3-CMO were dissolved in 600 μL of DMF containing 400 μL of distilled water and 18 mg of NHS. Then, 33 mg of EDAC were added. Reaction mixture was stirred to 4 °C in the darkness for 5 h to activate the carboxyl group of the steroid. HRP (1 mg) was dissolved in 1 mL of distilled water. Steroid activated solution was added to HRP aqueous solution and then stored and shaken overnight at 4 °C. The solution was then dialyzed in water for 5 days by using a cellulose dialysis membrane (cut-off molecular weight 12 kDa). Finally, it was stored at 4 °C (see Scheme 1).

Concentrations of synthesized P4–HRP conjugated (P4–HRP) were determined spectrophotometrically by measuring absorbance changes at 252 and 402 nm in 0.01 mol L^{-1} PBS (pH 7.0), considering that P4–3-CMO and HRP show absorption maximum at those wavelength, respectively. The synthesized conjugated P4–HRP had 8 mol of P4 per HRP mole as it was determined spectrophotometrically. This ratio showed that there was unbound P4 in the solution. The true synthesized P4–HRP conjugated concentration was unknown. Therefore, different known dilutions were prepared for convenience.

2.4. Progesterone immunoassay

The ELISA test kits with standard series covering the relevant range (0–25 ng mL^{-1}) were supplied by the company, as mentioned before [23]. The manufacturer's protocol was followed to perform standard calibration curves from spectrophotometric measurements. Therefore, P4 concentrations were calculated measuring absorbance changes at 405 nm.

2.5. mAbP4 immobilization

The rotating disk reactor (bottom part, Fig. 1a) was prepared by immobilizing mAbP4 on a controlled pore glass modified by 3-aminopropyl (APCPG), which was smoothly spread on one side of a double-coated tape attached to the disk surface. Then, it was allowed to react with a 5% (w/w) glutaraldehyde aqueous solution of pH 10.0 (0.20 mol L^{-1} carbonate) for 2 h at room temperature. After different washing steps with both purified water and 0.01 mol L^{-1} PBS (pH 7.0), 30 μL of mAbP4 different dilutions were allowed to react with aldehyde residual groups overnight at 5 °C. Then, 30 μL of 0.1 mol L^{-1} glycine solution was added to block the remaining reactive groups for 2 h at room temperature after being thoroughly rinsed with water. Then, these groups were reduced with 30 μL of 0.5% $NaBH_4$ solution for 2 h at room temperature. Finally, the immobilized antibody was washed with 0.01 mol L^{-1} PBS (pH 7.0) and stored in the same buffer at 4 °C between measurements. Immobilized antibody preparations remained stable for at least 1 month.

2.6. Amperometric analysis of P4 in serum bovine samples

The amperometric measurements were applied for P4 determination through a competitive assay in different bovine serum samples, which had been previously spiked with a known P4 concentration. The experimental procedure was performed at a constant rotation speed of 180 rpm and at a flow rate of 50 μL min^{-1}. Unspecific bindings were blocked through a treatment at 37 °C with 3% low-fat milk in a 0.01 mol L^{-1} (pH 7.0) under stopped flow conditions, during 10 min. After that, the immunoreactor was washed with 0.01 mol L^{-1} PBS (pH 7.0) at a flow rate of 50 μL min^{-1} and serum samples and P4–HRP conjugated were then injected into the 0.01 mol L^{-1} PBS (pH 7.0) carrier stream and incubated at 37 °C under stopped flow conditions for 15 min (competitive assay). Then, the immunoreactor was washed by using a 0.01 mol L^{-1} PBS (pH 7.0) at a flow rate of 50 μL min^{-1} in order to eliminate any traces of unbound P4 and P4–HRP. Finally, a substrate solution (10 μL 0.1 mol L^{-1} phosphate–citrate buffer, pH 5.0 + 1×10^{-3} mol L^{-1} H_2O_2 + 1×10^{-3} mol L^{-1} H_2Q) was injected and the enzymatic reaction product was detected through amperometric FI measurements for 2 min under stopped flow conditions.

For the next analysis, the immunoreactor was reconditioned by desorption. First, buffer injections (0.1 mol L^{-1} glycine–HCl, pH 2.0) were applied for 2 min and then, the immunoreactor was washed with 0.01 mol L^{-1} PBS (pH 7.0). The desorption efficiency was checked by the absence of the reduction current of the enzymatic reaction product at GC electrode at −0.15 V after the addition of H_2O_2 and H_2Q, which is a consequence of the absence of P4–HRP.

A standard amperometric curve was generated by employing concentrations which covered the clinically relevant range supplied with ELISA test kits (0–20 ng mL^{-1}). The following protocol was used: amperometric measurements were performed at GC electrode at a potential of −0.15 V at room temperature in 0.1 M phosphate–citrate buffer (pH 5.0) solutions containing 1×10^{-3} mol L^{-1} H_2O_2 + 1×10^{-3} mol L^{-1} H_2Q. The corresponding cathodic peak currents were recorded in the potentiostat meter. The immunoreactor was stored in 0.01 mol L^{-1} PBS (pH 7.0) at 4 °C when it was not used.

3. Results and discussion

3.1. Study of the enzymatic process

Reactions catalyzed by enzymes have been largely used for analytical purposes in determinations of different substrates, inhibitors, etc. Gorton [24] has explained the HRP catalytic mechanism. Therefore, it is well known that in the presence of H_2O_2 the enzyme catalyzes the oxidation of H_2Q to Q [25], which at a potential of −0.15 V can be electrochemically reduced to H_2Q, providing a reduction current peak which can be related to substrate concentration [26]. Fig. 1b shows a schematic representation of this process.

3.2. Optimization of the experimental variables involved on antigen–antibody reaction

mAbP4 concentration is not provided by the Sigma commercial reactive. The synthesized P4–HRP concentration is also unknown,

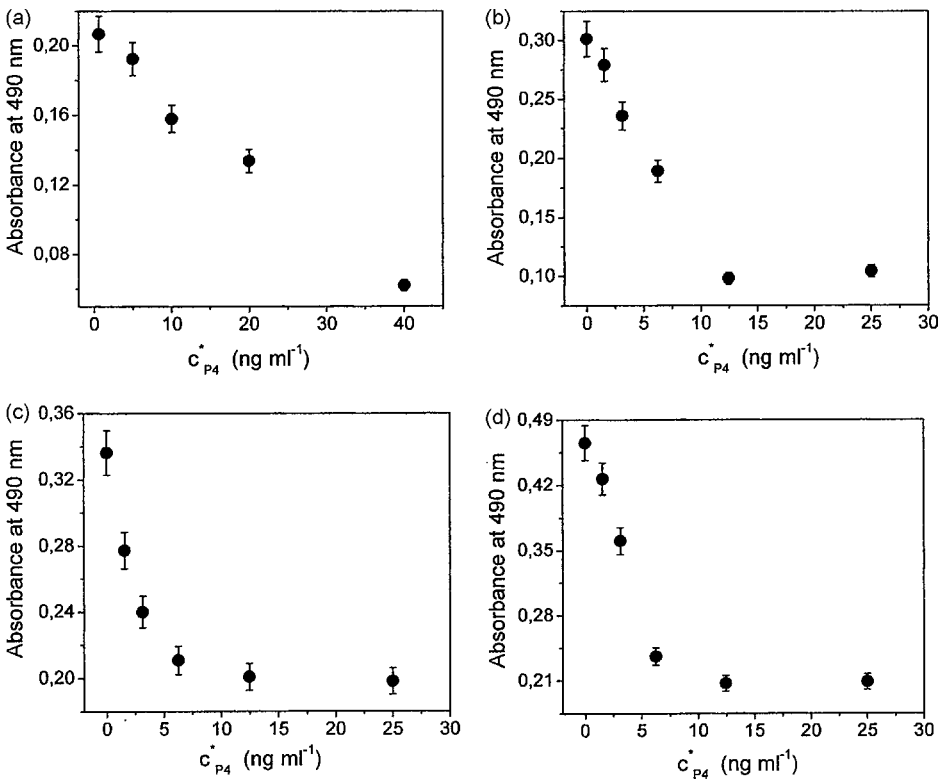


Fig. 2. Optimization of P4–HRP. ELISA assay for different P4–HRP dilution factors. (a) 1/190; (b) 1/100; (c) 1/75 and (d) 1/55. Dilution factor of mAbP4 = 1/50.

so different dilutions were prepared for both. In this study, optimal dilutions for mAb and P4–HRP were studied by using an ELISA test kit. Optimal responses were proved from 1/50 to 1/4000 and 1/10 to 1/1200 dilution ranges for mAb and P4–HRP, respectively.

Curves for each mAbP4 dilution were obtained at different P4–HRP dilutions. It was experimentally observed that the smaller the mAbP4 dilution factor was, the higher the absorbance value was (results not shown). The chosen value for the dilution factor was 1/50 in order to achieve the best sensitivity.

In addition, at a mAbP4 constant dilution factor of 1/50, an increase of P4–HRP concentrations produced also an increase in absorbance values (results not shown). P4–HRP dilution factors smaller than 1/10 produce the saturation of mAbP4 immobilized, since constant absorbance signals were observed when the P4–HRP amount was greater [27]. Different competitive assays between P4–HRP and P4 were carried out in order to know the best dilution factor. Competitive assays for different P4–HRP factor dilutions are shown in Fig. 2.

Absorbance values increased as P4–HRP concentration was increased (lower dilution) but the linear range of P4 concentration decreased due to saturation of mAbP4 adsorbing sites to high P4 concentrations.

The highest linear range with very good responses was obtained by using a 1/100 P4–HRP dilution factor, which coincides with veterinary relevant range (0–15 ng mL^{-1}) [7].

3.3. Effect of reactor rotation and continuous flow/stopped flow operation

The implementation of continuous flow/stopped flow programming was followed by the location of an independent two-phase reactor with two different surfaces, which are facing each other, one is the sensing element itself (GC electrode) and the other is the one where the immune reaction takes place (Teflon disk) (Fig. 1). This design allows for: (I) the use of relatively low immunoreaction loading conditions, (II) an instantaneous operation under high initial rate conditions, (III) the easy detection of accumulated products, and (IV) the reduction of apparent Michaelis–Menten constant K_M'. It is possible to get a complete reagent homogenization because the cell works as a mixing chamber facilitating the arrival of immunoreactants at the specific mAbP4 and enzymatic substrate at active sites as well as the release of products from the same sites [28]. This procedure allows us to obtain higher current values. The main advantages of this system are its simplicity and the convenience to determine P4 in serum samples.

The rotation velocity effect was studied in a range from 60 to 250 rpm under stopped and continuous flow conditions. A linear relationship between the electrical signal and rotation velocity in the range from 60 to 180 rpm under stopped flow conditions was found, showing a response maximum rate for rotation velocities higher than 180 rpm (Fig. 3a). The electrical signal decayed when the reactor operated under continuous flow conditions (Fig. 3b), probably because the reaction product (benzoquinone) escaped from the reactor chamber. When the reactor rotation in the cell stopped, the current response was lower because controlled diffusion reactions were too slow for being detected at the time scale of amperometric measurements, operating under stopped or continuous flow conditions (Fig. 3c and d, respectively). Thus, a rotation velocity of 180 rpm was chosen to be administered to the reactor located at the bottom of the cell under stopped flow conditions (with mAbP4 immobilized and the already formed immunocomplex between P4 of bovine serum samples + the P4–HRP). The sample volume was studied in the range 2–20 μL. Sensitivity was almost tripled in the range between 2 and 10 μL. Insignificant differences were obtained for greater sample size. A sample size of 10 μL had to be injecting in order to minimize convective and dispersive effects that characterize the FI system characteristic as well as to obtain a complete filling of the chamber.

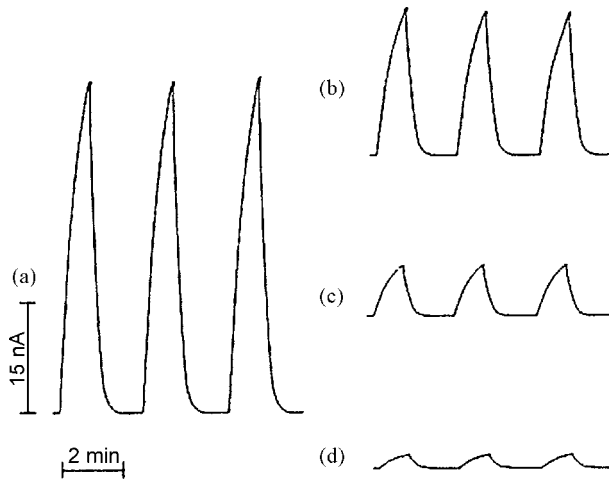

Fig. 3. Effect of reactor's rotation under continuous and stopped flow conditions. (a) Stopped flow with rotation (180 rpm). (b) Continuous flow with rotation (180 rpm). (c) Stopped flow without rotation. (d) Continuous flow without rotation. c^*_{P4} = 3 ng mL^{-1}. Flow rate = 50 μL min^{-1}, cell volume = 5 μL. 0.1 mol L^{-1} phosphate–citrate buffer, pH 5.0 solution containing 1.0×10^{-3} mol L^{-1} H_2O_2 and 1.0×10^{-3} mol L^{-1} H_2Q. The flow was stopped for 2 min during measurement.

3.4. Optimal conditions for the determination of the enzymatic products

The rates of the enzymatic reaction under stopped-flow conditions have been previously studied [28]. These responses showed a maximum value at pH 5.0 in 0.1 mol L^{-1} phosphate–citrate buffer. As it is well known, the optimal temperature of immunoreactions is about 37 °C. Therefore, in this study all experimental measurements were performed at this temperature. The effect of varying H_2O_2 concentration from 7.0×10^{-4} to 5.0×10^{-3} mol L^{-1} at a given H_2Q concentration (1.0×10^{-3} mol L^{-1}) as well as the effect of varying H_2Q concentration from 1.0×10^{-4} to 3.6×10^{-2} mol L^{-1} at a given H_2O_2 concentration (1.0×10^{-3} mol L^{-1}) was evaluated on bioreactor responses. The optimal H_2O_2 and H_2Q concentrations found were 1.0×10^{-3} mol L^{-1} and 1.0×10^{-3} mol L^{-1}, respectively. Those concentrations were, then, used for all experiments.

3.5. Detection and competitive immunoassay on the immunoreactor

Under the previously described selected conditions, amperometric measurements obtained for the reduction of Q in 0.1 mol L^{-1} phosphate–citrate buffer (pH 5.0) were proportional to enzyme conjugated (P4–HRP) activity and, consequently, indirectly proportional to the amount of P4 in serum bovine samples bound to mAbP4 immobilized on the rotating disk. A linear calibration curve for detection of P4 in PBS 0.01 mol L^{-1} (pH 7.0) was obtained. For convenience, sampling times of 2 min at different P4 concentrations were used, considering that longer sampling times than 2 min produced a loss of linear relationship between current responses and P4 concentrations. A good linear calibration curve was found between 0.5 and 12.5 ng mL^{-1} (Fig. 4). For greater concentrations than 12.5 ng mL^{-1}, the saturation of the immobilized mAbP4 took place. The linear regression equation was:

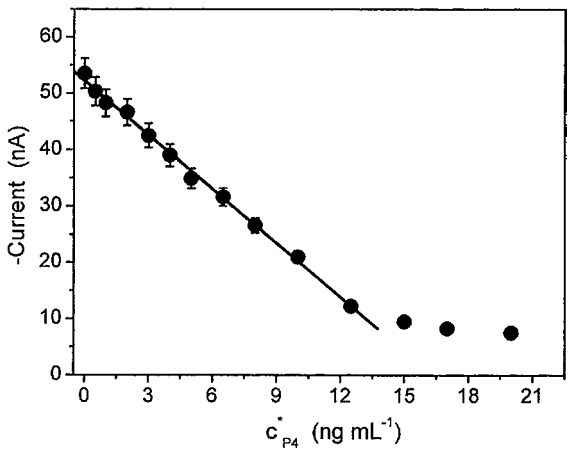

Fig. 4. Calibration curve for P4 determination by amperometric FI immunoassay. Amperometric measurements were performed at −0.15 V *vs* Ag at 37 °C in a 0.1 mol L^{-1} phosphate–citrate buffer (pH 5.0) solution containing 1.0×10^{-3} mol L^{-1} of H_2O_2 and 1.0×10^{-3} mol L^{-1} H_2Q. Current sampling time: 2 min.

$$\text{Current [nA]} = (52.2 \pm 0.9)\,[\text{nA}] - (3.0 \pm 0.1)\,[\text{nA ng}^{-1}\text{ mL}]\,c^*_{P4}\,[\text{ng mL}^{-1}]$$

being the correlation coefficient, $r = 0.998$. Each experimental point shown in Fig. 4 is the average of three replicated measurements.

The precision between the assays of amperometric measurements was tested with three measurements in 5 ng mL^{-1} P4 + 0.01 M PBS (pH 7.0). The percentage variation coefficient (%VC) was 4.5%, showing a good precision. The detection (DL) and the quantification (QL) limits were 0.2 and 0.5 ng mL^{-1}, respectively. The sensitivity was (3.0 ± 0.1) nA ng^{-1} mL in the range from 0.5 to 12.5 ng mL^{-1}.

The determination of P4 was carried out under the best experimental conditions found from bovine serum samples. Considering that serum samples did not contain P4, they were spiked with a known P4 concentration prepared in BPS 0.01 mol L^{-1} (pH 7.0) at a low buffer concentration (≤1%) in order to avoid a dilution effect. Therefore, two samples of serum containing 1 and 5 ng mL^{-1} of P4 were prepared. A given amount of P4–HRP was then added to both serum samples, with a dilution factor of 1/100 for P4 labeled to carry out competitive assays. Serum samples were introduced in the immunoreactor without any previous pretreatment. Obtained results are shown in Table 1, where current values represent an average of three replicated measurements, Recovery percentage values obtained were very good. Concentration values obtained by the ELISA method for the same samples are also shown in Table 1. The results obtained using both methods are very good.

The biosensor stability was tested for nearly 25 days at a P4 constant concentration in the inmunoreactor system. Current responses were practically constant during this period.

Table 1
Statistical analysis of inmunoreactor responses for two samples of serum with different amounts of spiked P4.

c^*_{P4} [a] (ng mL^{-1})	Current[b] (nA)	c^*_{P4} [c] (ng mL^{-1})	%VC[d]	Recovery (%)	c^*_{P4} [e] (ng mL^{-1})
1	50.0	1.03	4.02	103	0.995

[a] P4 concentration in samples of bovine serum.
[b] Current values represent an average of three measurements.
[c] Average value of P4 concentration determined by the immunosensor.
[d] Percentage variation coefficient.
[e] Average value of P4 concentration determined by ELISA method.

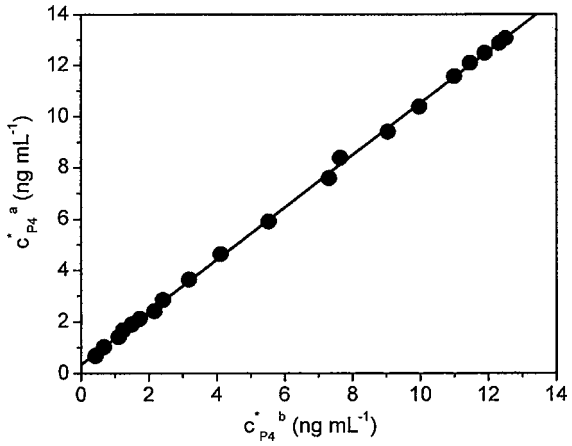

Fig. 5. Correlation between amperometric and commercial photometric assays. Slope = (1.019 ± 0.005), intercept = (0.34 ± 0.04) and r = 0,9997. (a) P4 concentration determined by ELISA method; (b) P4 concentration determined by the electrochemical immunosensor.

The immunoreactor was regenerated by injection of desorption buffer (0.1 mol L^{-1} glycine–HCl, pH 2.0) for 2 min and then washed with 0.01 mol L^{-1} in PBS (pH 7.0), which allowed us to use the reactor with about 100 determinations. For these measurements, P4 standard solutions as well as serum samples were employed alternatively. The reproducible current values that were found showed that the antibody activity loss was not observed. Then, the immunoreactor could be used for performing further analysis.

3.6. Correlations with ELISA assay procedure

The ELISA method was applied in accordance with the manufacturer's protocol. A calibration curve using the absorbance changes was constructed (figure not shown). The expression obtained using a least square procedure was:

$$\text{Absorbance} = (0.993 \pm 0.007) - (0.055 \pm 0.001)\,[\text{ng}^{-1}\,\text{mL}]\,c^{*}_{P4}\,[\text{ng mL}^{-1}] \quad r = 0.995$$

The %VC for the determination of 1 and 5 ng mL^{-1} P4 in bovine serum samples was 4.02 and 5.80% (three replicates), respectively. Results obtained by using the two methods are shown in Fig. 5.

Results of the linear correlation between the two methods render a slope of (1.019 ± 0.005) and an intercept of (0.34 ± 0.04) indicating a very good agreement between both methods (Fig. 5).

P4 ELISA assay kits for in-clinic uses allow P4 concentration to be determined either qualitatively or quantitatively. These results are usually obtainable within 45 to 60 min of sample collection. Most kits are modifications of kits marked for P4 assays used in the dairy industry [9]. The DL obtained for the ELISA procedure is similar to that determined with the electrochemical immunosensor (see Section 3.6). However, the ELISA method requires longer times of analysis. In a conventional ELISA test kit, 96 samples can run simultaneously. We did not compare the number of samples with this electroanalytical method but we just compared the general time of assays. This electroanalytical method could work with more immunosensors simultaneously. The determined number of samples analyzed with this methodology was greater than that obtained with the commercial ELISA test kits. Furthermore, ELISA test kit can be used only for one assay while the immunosensor we described can be used for up to 100 determinations.

Other electrochemical immunosensors to determine P4 in milk have been recently proposed [13–15]. Although the DL is comparable, most of them have higher variation coefficients (6–9%) as well as a longer analysis time. In addition, an important advantage of the immunosensor described in this paper is that it can perform up to 100 determinations before it is regenerated in a very simple way.

4. Conclusions

In this study an electrochemical immunosensor was developed to determine P4 at trace levels in the concentration range of interest in animal sera, particularly of bovine origin. These determinations performed without any pretreatment of samples would indicate the great selectivity of the antibody used. The immunoreactor developed can operate as a fast, selective, and sensitive detector when it is incorporated into a flow injection analysis system. The immunoreactor also minimizes the use of expensive antibodies and other reagents. It also shows physical and chemical stability, a wide working potential range and accuracy. It does not require highly skilled technicians or expensive and dedicated equipments. The electrochemical detection was carried out within 2 min and the total analysis time does not exceed 30 min. Moreover, the bonding between two biological molecules (P4 and HRP) was performed successfully, which allowed us to carry out competitive assays. Immunosensors based on specific reactions between antibodies and antigens seem to be promising alternative tools for the routine veterinary, clinical, biological, physiological assays and analytical practices.

ABSTRACT

In this work, the effect of the serum protein, bovine serum albumin (BSA), on the detection of propranolol in artificial serum by ion-transfer voltammetry at an array of micro-interfaces between two immiscible electrolyte solutions (μITIES) is presented. Cyclic voltammetry (CV), differential pulse voltammetry (DPV), and differential pulse stripping voltammetry (DPSV) were examined for the detection of low concentrations of propranolol. Both CV and DPV had an interference effect from BSA, manifested as lower currents in the presence of the protein. DPSV proved to be the most effective technique, enabling the detection of 0.05 μM propranolol in the presence of BSA. The DPSV method employed a preconditioning step as well as a preconcentration step followed by the analytical signal generation step. The latter was based on the back-transfer of the drug across the μITIES. The preconcentration step was crucial to prevention of the adverse effects of BSA on the voltammetric detection. These results demonstrate that serum-protein effects on drug detection at low concentrations can be eliminated by use of DPSV at arrays of μITIES. CVs of propranolol with increasing concentrations of BSA revealed the influence of the drug–protein binding interaction, with decreases in current but no change in transfer potential. Therapeutic concentrations of propranolol were detected, demonstrating the viability of this approach for bioanalytical investigations.

1. Introduction

Blood and blood-derived samples remain the most investigated physiological matrices for the direct detection of drugs as it provides information on the circulating concentration of the analyte of interest. However, drug detection can be hindered due to drug–protein binding. The most abundant protein in blood is serum albumin, which comprises *ca.* 60% of the total albumin [1], and exhibits a high affinity towards drugs [2–4]. The pharmacological activity of drugs is a function of their free (i.e. non-protein bound) concentration in plasma. One drug with a high affinity for plasma protein binding is propranolol. It has been reported that 90–95% of propranolol, which is the most widely used adrenergic α-receptor blocking agent, binds to plasma proteins [5]. Reports in the literature indicate that propranolol binds to both serum albumin and to α-acid glycoprotein in blood [6–8]. Paxton and Calder [9] investigated the effect of propranolol binding in serum as a function of drug concentration, pH, and temperature using dialysis and ultrafiltration methods and found that an increase in pH and a decrease in temperature reduced the percentage of free (unbound) propranolol. Changes in propranolol concentrations were found to have no effect. It was found that the maximum serum concentration of propranolol (260 ± 80 nM) occurred 1 h after its oral administration (80 mg) [10]. The parameters of propranolol binding to human serum albumin have also been investigated, with a binding constant of $\sim 1000\ M^{-1}$ at 37 °C estimated by capillary electrophoresis [11]. Propranolol has been detected in serum using various analytical techniques, encompassing solid phase microextraction [12,13], capillary electrophoresis [14] and high-performance liquid-chromatography [15]. It is known that interactions between drugs and proteins are extremely important for drug development, with the binding affecting absorption, distribution and metabolism of many common drugs [16,17]. Serum albumin itself is chiefly responsible for the maintenance of blood pH [18]. In this work, bovine serum albumin (BSA) was selected as a model protein because of its abundance, low cost, ease of purification and stability [19,20]. BSA is a water-soluble globular protein comprised of a single 582 amino acid chain containing 17 cystine residues. These cystine residues provide eight disulfide bonds and one free thiol. In contrast to human serum albumin, BSA contains two tryptophan residues, placed in positions 134 and 212 [21]. It has well-known surfactant properties, a molar mass of 69,000 amu, a hydrodynamic radius of *ca.* 3.25 nm [22] and an isoelectric point (p*I*) of 4.7. Shi et al. [23] reported the net charge of BSA at pH 7.4 was

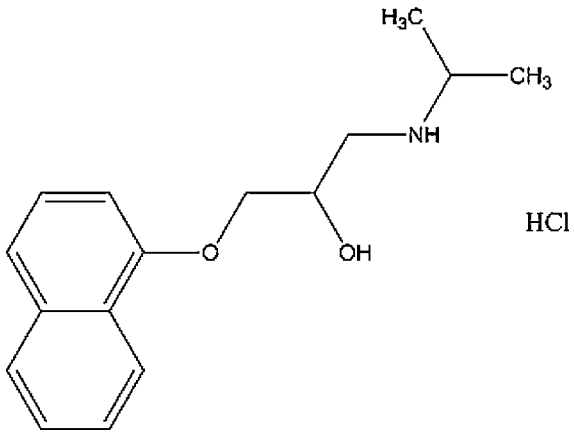
−17. This negative charge and the positive charge of propranolol at physiological pH contribute to drug–protein binding.

Electrochemistry at the interface between two immiscible electrolyte solutions (ITIES) [24–27] has been of growing interest over recent decades due to the opportunities it offers for label-free detection of various bioactive substances including peptides, proteins [28,29] and drug molecules [30–33]. Studies have found that proteins adsorb at this liquid–liquid interface [34,35], with some protein behaviours depending on the aqueous phase pH and the nature of the electrolyte anion in the organic phase [28,36,37]. BSA was also found to adsorb at the liquid–liquid interface. Vanysek et al. [22,38] have studied BSA adsorption at the water–nitrobenzene interface using AC impedance measurements and found that adsorption caused the transfer properties of the interface to be altered.

In this paper, the effect of BSA in an artificial serum matrix on the detection of propranolol at an array of miniaturised ITIES was investigated. Such micro-interface (or μITIES) arrays were previously prepared by laser-ablation of holes in thin polymer sheets [39]. These microhole-based ITIES were shown to behave like inlaid microdisc electrodes [40] and had advantages over regularly sized interfaces due to reduced ohmic drop, reduced charging current, enhanced mass transport, and improved sensitivity [41–43]. Liquid–liquid micro-interface arrays have been typically fabricated within thin polymer sheets such as poly(ethylene terephthalate), PET [41,44–48]. Recently, micropore silicon membranes prepared by photolithography and silicon etching processes were introduced [49] and shown to be useful for detection of dopamine and oligopeptides by facilitated ion transfer [28,50,51] and propranolol in an artificial saliva matrix [52].

The aim of the work was to examine the effect of serum protein on the detection of low concentrations of propranolol by voltammetry at the μITIES array. Therefore, propranolol detection in artificial serum with and without BSA was examined and compared using cyclic voltammetry (CV), differential pulse voltammetry (DPV), and differential pulse stripping voltammetry (DPSV).



2. Experimental

2.1. Reagents

All chemical reagents were purchased from Sigma–Aldrich and used as received unless indicated otherwise. 1,6-Dichlorohexane (1,6-DCH) (Merck) was purified according to the published procedure [53]. For studies of drug detection at the μITIES array, the aqueous phase was artificial serum [54,55], composed of KCl (1.5 mM), $CaCl_2$ (5 mM), $MgCl_2$ (1.6 mM), D-(+)-glucose (4.7 mM), NaH_2PO_4 (1 mM), KH_2PO_4 (1 mM), urea (2.5 mM, from Qiagen) and bovine serum albumin (0.6 mM). The organogel organic phase was prepared using bis(triphenylphosphoranylidine)ammonium tetrakis(4-chlorophenylborate) (BTPPATCB, 10 mM) in 1,6-DCH and low molecular weight poly(vinyl chloride) (PVC) [28,56]. The BTPPATCB salt was prepared by metathesis [41,57] of bis(triphenylphosphoranylidene)ammonium chloride (BTPPACl) and potassium tetrakis(4-chlorophenyl-borate) (KTCB, Fluka). Propranolol (commercial name: DL-Propranolol hydrochloride, (±)-1-Isopropylamino-3-(1-naphthyloxy)-2-propanol hydrochloride) was purchased from Sigma–Aldrich, relative molecular mass 295.8 g mol^{-1} (see Scheme 1). All aqueous solutions were prepared in purified water from an Elgastat Maxima-HPLC (Elga, UK), with a resistivity of 18 MΩ cm.

2.2. Apparatus

All experiments were performed using a CHI660B electrochemical analyzer (CH Instruments, TX, USA). The micropore arrays were fabricated in silicon using photolithographic patterning and a combination of wet and dry silicon etching [49]. The fabrication procedure provided micropores with hydrophobic walls so that the organic phase filled the pores [49,51]. The micropore array consisted of eight micropores arranged in a hexagonal close-packed arrangement, each with a diameter of 52 μm and a pore center-to-center distance of 500 μm. The microporous silicon membranes were sealed onto the lower orifice of a glass cylinder using a silicone rubber (RS 555-588 silicon rubber compound). The gellified organic phase solution was introduced into the silicon micropores via the glass cylinder, and the organic reference solution was placed on top of the gellified organic phase. The silicon membrane was then immersed into the aqueous phase (artificial serum) and voltammetric experiments performed, as previously described [28,51,52].

Scheme 1. Chemical structure of DL-Propranolol hydrochloride, (±)-1-Isopropylamino-3-(1-naphthyloxy)-2-propanol hydrochloride.

2.3. Electrochemical measurements

The waveform parameters used for DPV and DPSV were as follows: pulse amplitude: 0.05 V; sampling width: 0.055 s; step height: 4 mV. These were applied for all differential pulse voltammetry experiments. For double layer capacitance measurements both a μITIES array and a macro-ITIES electrochemical cell was used. The latter was a four-electrode liquid–liquid cell, with 1,2-dichloroethane containing BTPPATCB (10 mM) as the electrolyte. The interfacial potential difference was applied between a pair of Ag|AgCl reference electrodes. The current was measured by two platinum counter electrodes (one in each phase). The geometric area of the interface in the macro-ITIES cell was 0.95 cm^2.

3. Results and discussion

3.1. Effect of serum albumin on voltammetry at the μITIES array

At physiological pH, BSA bears an overall charge of ∼−17 and propranolol (pK_a 9.23) has a charge of +1. This makes it likely that albumin–propranolol binding will occur, although shielding of the charges by the electrolyte ions will decrease this to some extent. As discussed in Section 1, not only does BSA bind to propranolol [5] but it also adsorbs to the liquid–liquid interface [22,38]. As a result, BSA may hinder the detection of propranolol at the μITIES array by either binding to propranolol and preventing its transfer across the interface or by adsorbing at the μITIES and preventing propranolol transfer. To investigate the effect, two separate artificial serum solutions were prepared: one without BSA and the other containing a physiological concentration of BSA. CV and DPV analyses were carried out on these matrices spiked with 100 μM propranolol (Fig. 1).

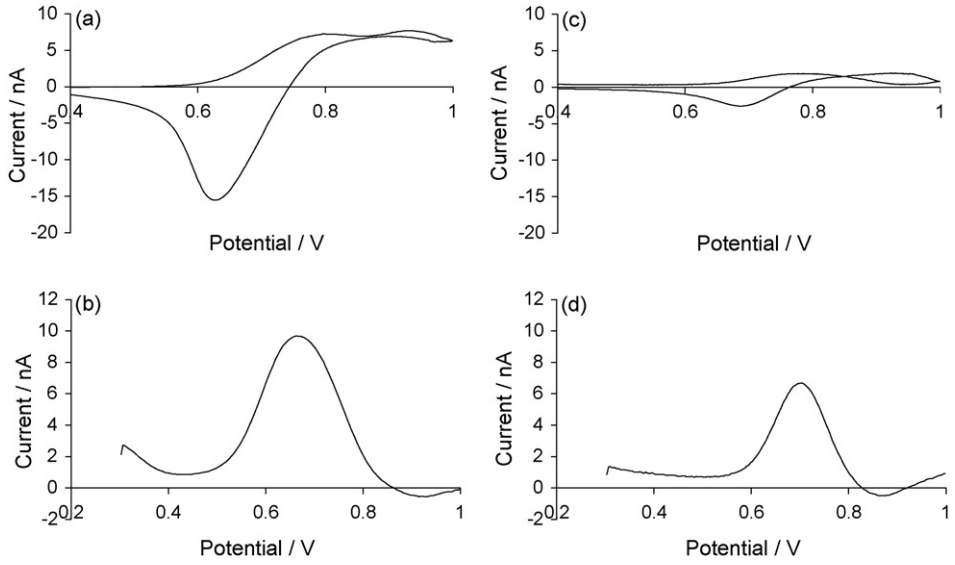


Fig. 1. Electrochemistry of 100 μM propranolol in artificial serum at the μITIES array using (a) cyclic voltammetry (background-subtracted), scan rate, 10 mV s^{-1} (serum without BSA); (b) differential pulse voltammetry (background-subtracted) (serum without BSA); (c) cyclic voltammetry (background-subtracted), scan rate, 10 mV s^{-1} (serum with BSA); (d) differential pulse voltammetry (background-subtracted) (serum with BSA) [the loops in the higher potential regions of (a) and (c) are artifacts of the background subtraction].

The background-subtracted CVs exhibited an asymmetric shape, with an apparent steady-state curve on the forward sweep and a peak-shaped response on the reverse sweep (Fig. 1(a) and (c)). This is due to spherical diffusion of propranolol to the micropores as the controlling mass-transport process occurring on the aqueous side of the interface during the forward sweep. The back-transfer of propranolol from the organogel phase (negative sweep) was controlled by linear diffusion within the micropores, producing a peak-shaped current response, as identified previously by Shao et al. for μITIES formed at micropipettes [58]. It was observed that the peak current magnitudes of the forward and reverse sweeps for propranolol in artificial serum without BSA were almost four times greater than for propranolol in artificial serum with BSA. The forward peak for propranolol transfer from the artificial serum (containing BSA) into the organogel phase was extremely small. This indicated that a lower concentration of free propranolol was present in the aqueous phase, as current signals are proportional to the concentration of the transferring analyte. This reduction in current signal due to the presence of BSA was also seen with background-subtracted DPV (Fig. 1(b) and (d)). For DPV, the potential was scanned in the positive direction only, corresponding to a transfer of the positively charged propranolol from the aqueous phase into the organogel phase. Higher current values were recorded for DPV in comparison to CV values, a feature of its increased sensitivity, thus allowing for better detection of propranolol in artificial serum containing BSA. However, as seen with the CVs, higher peak currents were recorded for propranolol detection in artificial serum without BSA.

These results suggested that BSA has a major influence on the detection of propranolol in artificial serum. Although detection of propranolol in the presence of BSA was possible, peak currents were severely diminished. DPV was shown to provide a more sensitive detection signal for low concentrations of propranolol in the presence of BSA in comparison to CV. As a result, DPV was further investigated.

3.2. Differential pulse voltammetry at the μITIES array

The DPV method consisted of a preconditioning step and a voltammetric step. The preconditioning step may be employed prior to a subsequent voltammetric step in a series of repeated measurements in order to remove any detectable residue of target analyte from the organogel phase remaining after the previous electrochemical measurement step. This ensures that the organogel phase is cleaned. This step is essentially the application of a potential more negative than the transfer potential of the analyte for a given period of time. The optimum preconditioning time for this μITIES arrangement was found to be 90 s [52] and was employed in all DPV experiments at a preconditioning potential of 0.35 V. Increasing concentrations of propranolol were added to two separate artificial serum solutions (without and with BSA) as shown in Fig. 2(a) and (b), respectively. The lowest concentration of propranolol detected when added to serum without BSA was 1 μM; however the lowest concentration detected for propranolol in the presence of BSA was 4 μM.

On examination of both sets of voltammograms it was apparent that BSA caused a reduction in the propranolol detection peak currents. Nevertheless, the currents increased linearly with propranolol concentration both in the absence and in the presence of BSA, as summarized in Table 1. The peak current responses for propranolol were higher in artificial serum without BSA. The precision of the measurements at any single concentration was assessed by the relative standard deviations. These were in the range of 2.8–4.9% and 0.5–23.2% across the concentration ranges studied (as listed in Table 1) for propranolol in artificial serum in the absence and in the presence of BSA, respectively.

Different analytical sensitivities (calibration line slopes) were obtained in the absence and presence of BSA. This may be due to a change in the double layer capacitance upon adsorption of BSA at the interface [22]. When molecular or ion adsorption occurs at the ITIES, both the double layer capacitance and the ion transfer properties will be altered [22]. Since the lowest concentration of propranolol detected in the presence of BSA was 4 μM, an improvement was necessary. DPSV, which has proven to offer improved detection capability [52], was thus investigated.

3.3. Differential pulse stripping voltammetry at the μITIES array

The DPSV method employed consisted of a preconditioning step, a preconcentration step and a voltammetric detection step. The preconditioning step (previously discussed) was employed for 90 s at

Table 1
Linearity data for propranolol in artificial serum in the absence and presence of BSA.

Artificial serum	Slope (±S.D.)[a]/nA μM^{-1}	Intercept (±S.D.)[a]/nA	Concentration range/μM	*n*
Without BSA	0.09 ± 0.01	−0.09 ± 0.24	1–35	8
With BSA	0.07 ± 0.01	−0.11 ± 0.002	4–35	7

[a] S.D., standard deviation.

a potential of 0.35 V. The preconcentration step is crucial in DPSV because it is the factor which enables lower detection limits to be achieved. It was implemented by applying a potential more positive than the transfer potential of the analyte to be detected but at a potential more negative than the transfer potentials of the supporting electrolytes. This ensured only the transfer of the analyte into the organogel phase, where it is preconcentrated prior to the subsequent detection scan. The preconcentrated analyte, in this case propranolol, was then stripped out of the organogel phase using a negative-direction DPV scan. A preconcentration time of 180 s at potentials 0.82 V and 0.88 V was employed for artificial serum with and without BSA, respectively.

As illustrated in Fig. 3(a) and (b), as the concentration of propranolol increased the stripping peak current also increased. The peak currents for propranolol detection in artificial serum with and without BSA were similar, indicating that the presence of albumin did not influence the detection capabilities. In fact a concentration of 0.05 μM was detected for propranolol in the presence of BSA, a vast improvement on the 4 μM detected using DPV. A reason for this may be that the preconcentration step in DPSV was potential-controlled, thus allowing for the selective preconcentration of propranolol and the prevention of BSA interaction at the interface. It may be possible that BSA does not adsorb at the interface, thereby not inhibiting propranolol transfer. As discussed previously, it has been reported that 90–95% of total propranolol in serum is bound to serum albumin [5], however since the peak currents in Fig. 3(a) and (b) are very similar, it seems that the preconcentration step induced the dissociation of propranolol from its complex with BSA and allowed it to transfer across the interface. However, propranolol detection can also be influenced by BSA adsorption at the liquid–liquid interface.

The adsorption of large molecules at the ITIES can lead to a change of its capacitance, which in turn can influence the sensitivity of electroanalytical measurements there. Since adsorption of a protein will effect the charge distribution at an ITIES, a change in the interfacial capacitance is expected. Vanysek and Sun [22] reported that the impedance of the ITIES changed on addition of BSA to the cell, which implied that the interfacial structure had changed, most notably in the capacitance of the interface. It was noted that this was because the amino acid residues of BSA consisted of hydrophobic and hydrophilic regions, making it possible for an adsorbed interfacial layer to form at the interface.

3.4. CV of drug–protein interaction

CV can provide useful information on the kinetics of a reaction, the mass-transport process and the electrochemical reversibility of a reaction. In the present experimental system, the following

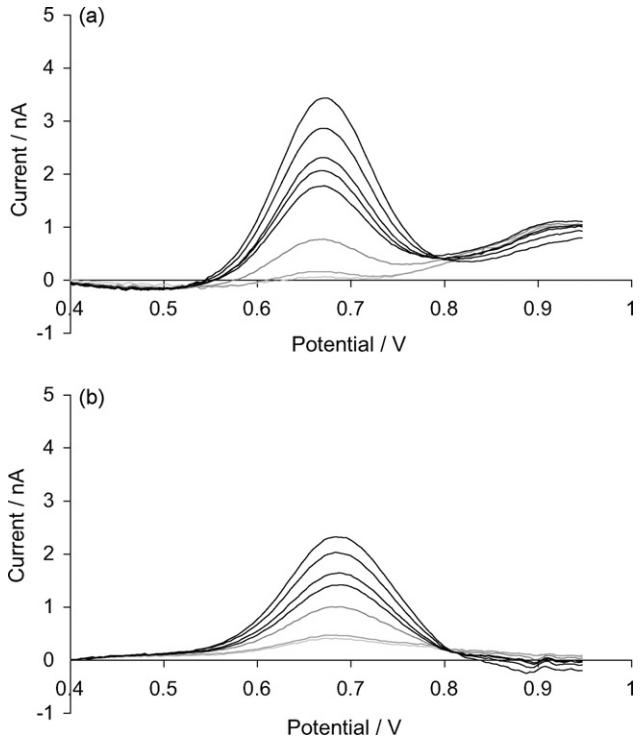

Fig. 2. DPV of increasing propranolol concentrations in artificial serum at the μITIES array. DPV (background-subtracted) (DPV_{bs}) response of (a) artificial serum without BSA for 1 (light gray), 4, 10, 15, 20, 25, 30, and 35 μM (black) and (b) artificial serum with BSA for 4 (light gray), 10, 15, 20, 25, 30, and 35 μM (black) propranolol.

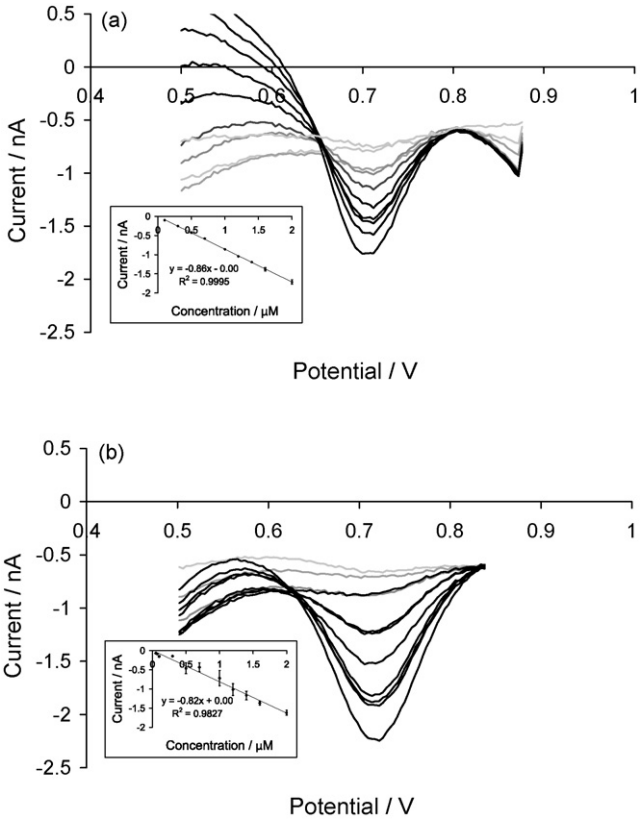

Fig. 3. Electrochemistry of increasing propranolol concentrations in artificial serum at the μITIES using differential pulse stripping voltammetry. DPSV (background-subtracted) (DPV_{bs}) response of (a) artificial serum without BSA and (b) artificial serum with BSA for 0.05 (light gray), 0.1, 0.3, 0.5, 0.7, 1, 1.2, 1.4, 1.6, and 2 μM (black). Inset: calibration curve of current vs concentration.

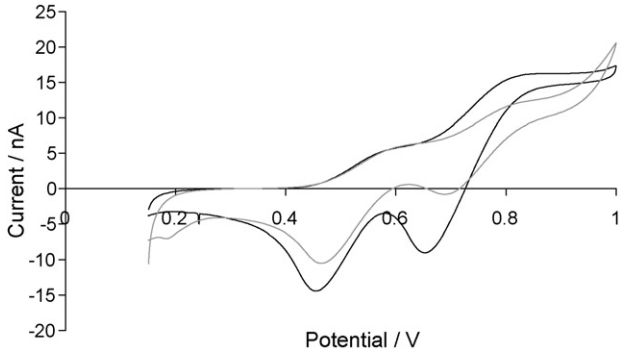

Fig. 4. Cyclic voltammetry of an artificial serum solution of 0.1 mM TPA^+ and 0.2 mM propranolol in the presence of 0 mM BSA (black line) and 1 mM BSA (gray line). Scan rate 10 mV s^{-1}.

reactions occur in solution:

$$[\text{Prop}_{\text{free}}]_{(\text{aq})} + [\text{BSA}_{\text{free}}]_{(\text{aq})} \leftrightarrow [\text{PropBSA}_{\text{complex}}]_{(\text{aq})} \quad (1)$$

$$[\text{Prop}_{\text{free}}]_{(\text{aq})} \rightarrow [\text{Prop}_{\text{free}}]_{(\text{org})} \quad (2)$$

where Prop is propranolol, and the subscripts free and complex refer to non-complexed and complexed propranolol, respectively, and (aq) and (org) refer to locations of the species in the aqueous phase and organic phase, respectively. The binding of drugs to blood plasma is reversible (Reaction (1)) with a rate in the millisecond range [59]. The system is in equilibrium between complexed and free propranolol. To understand the effect of BSA on propranolol transfer, CVs of propranolol transfer at the μITIES array in the absence and presence of different concentrations of BSA were recorded.

CV of these mixtures (Fig. 4) revealed steady-state currents on the forward sweeps, but these were decreased relative to that in the absence of BSA. The relationship between the steady-state current measured on the forward sweep with increasing concentration of BSA was also investigated. The current response for propranolol transfer decreased from ~9.7 nA to ~6.4 nA in the absence and presence (1 mM) of BSA, respectively. Fig. 4 also shows that the half-wave potential for propranolol transfer on the forward sweep was shifted only slightly (Fig. 4). No shift occurred for the reference ion tetrapropylammonium TPA^+ (half-wave potential at ~0.52 V). Neither did a change occur in the transfer current for TPA^+ in the presence of BSA. As BSA concentration increased, the current for propranolol transfer decreased, due to lower concentrations of free drug in solution available for transfer, as expected from Reactions (1) and (2) above. A similar result was obtained for propranolol in the presence of human serum albumin (HSA), with the peak current decreasing from 13 nA (absence) to 8.8 nA in its presence. BSA and HSA have the same effect on propranolol detection. In comparison to BSA, however, the half-wave potential for propranolol transfer on the forward sweep was shifted only slightly, but in the negative direction. No shift occurred in the presence of HSA for the reference ion, TPA^+. These results confirm that complexation of propranolol by serum albumin is an interference mechanism in the detection of propranolol in serum by ion-transfer voltammetry.

4. Conclusions

The effect of BSA on the detection of propranolol by voltammetry at the ITIES was investigated. There was a decrease in the detection signal for propranolol when CV and DPV were employed, however no effect was observed when DPSV was used. As a result, lower concentrations of propranolol were detected with DPSV (0.05 μM) in comparison to DPV (4 μM) in an artificial serum sample matrix. This improvement may be due to the preconcentration step which specifically targets only the transfer of propranolol across the interface. As well as the intended well-known preconcentration effect for stripping voltammetry methods, this option of selectivity may contribute by removing propranolol from its complex with BSA into the organic phases, from where it is subsequently stripped back into the aqueous phase, with this step being seemingly unaffected by complexation with the protein. The interference effect of BSA on propranolol detection is the complexation of the target analyte, making it unavailable for the interfacial charge transfer step.

It was found that propranolol detection at the μITIES array was achievable down to a concentration of 0.05 μM or *ca.* 15 ng mL^{-1}. Blood serum concentrations of propranolol are within the range 46–91 ng mL^{-1}, depending on various health factors [60]. These results demonstrate that propranolol detection in artificial serum in the presence of a globular protein is possible at the μITIES array, with the preconcentration step of DPSV playing a crucial role.

Boron-doped diamond electrode

ABSTRACT

A boron-doped diamond (BDD) electrode was used for the electroanalytical determination of estriol hormone in a pharmaceutical product and a urine sample taken during pregnancy by square-wave voltammetry. The optimized experimental conditions were: (1) a supporting electrolyte solution of NaOH at a pH of 12.0, and (2) a frequency of 20 Hz, a pulse height of 30 mV and a scan increment of 2 mV (for the square-wave parameters). The analytical curve was linear in the concentration range of 2.0×10^{-7} to 2.0×10^{-5} mol L^{-1} ($r = 0.9994$), with a detection limit of 1.7×10^{-7} mol L^{-1} and quantification limit of 8.5×10^{-7} mol L^{-1}. Recoveries of estriol were in the range of 98.6–101.0%, for the pharmaceutical sample, and 100.2–103.4% for the urine sample, indicating no significant matrix interference effects on the analytical results. The accuracy of the electroanalytical methodology proposed was compared to that of the radioimmunoassay method. The values for the relative error between the proposed and standard methods were −7.29% for the determination of estriol in the commercial product and −4.98% in a urine sample taken during pregnancy. The results obtained suggest a reliable and interesting alternative method for electroanalytical determination of estriol in pharmaceutical products and urine samples taken during pregnancy using a boron-doped diamond electrode.

1. Introduction

Estriol (1,3,5,(10)-estratriene-3,16α,17β-triol) (Fig. 1) is by far the most abundant estrogen present in pregnant mammals. Estriol is produced by placental syncytiotrophoblasts from dehydroepiandrosterone sulfate and its 16α-derivatives produced by fetal adrenals and the liver, respectively. Since the production of estriol relies on fetal and placental reactions, estriol determinations in blood and urine can be used to monitor the fetus-placental unit and indicate fetal well being. Free estriol is hydrophobic but it is conjugated to hydrosoluble glucuronides and sulfates (70–80% as 16α-glucuronides) by the maternal liver and excreted in the urine [1–2]. The conjugated forms of estriol in urine are quickly hydrolyzed after excretion, leaving estriol in the free form. Oral estriol tablets have been used with good results, primarily for the treatment of local urogenital complaints in postmenopausal women, for over 40 years. One of its product characteristics is that it does not stimulate the endometrium and can, therefore, be used uninterrupted without the cyclical addition of a progestogen to protect the endometrium. Although all available data confirm the endometrial safety of oral estriol tablets, it is considered relevant to update the existing long-term data on this topic [3–4].

Estriol levels in urine, serum and amniotic fluid have been measured by HPLC using various detectors including UV [5,6], fluorescence [7,8] and electrochemical (EC) [9], and different methods such as GC–MS [10,11], micellar electrokinetic chromatography [12], enzyme immunoassay (EIA) [13–15], and radioimmunoassay (RIA) [16]. However, most of these methods require sample preparation steps such as extraction from biological fluids, enzymatic hydrolysis or acidic solvolysis and derivatization. These procedures are tedious and time-consuming, require high-cost equipment and sometimes adversely affect the analytical results. In the case of immunoassays, for example, it is necessary to obtain a specific antibody for this steroid. RIA is currently considered to be the screening method of choice for routine measurements of estriol. Although this method is sensitive and reliable, there are drawbacks associated with the use of radioisotopes, for example, the cost of scintillation fluids, radioactive waste disposal, and its use being restricted to institutes granted permission to handle radioisotopes. Electrochemical studies on alkyl phenols with estrogenic properties have been reported. Vega et al. [17] developed a methodology using a carbon nanotube-modified electrode for amperometric detection of phenolic estrogenic compounds, including estriol, by HPLC. The determination of estriol was obtained in the range of 1.0–100 μmol L^{-1} with a detection limit of 0.340 μmol L^{-1}. The

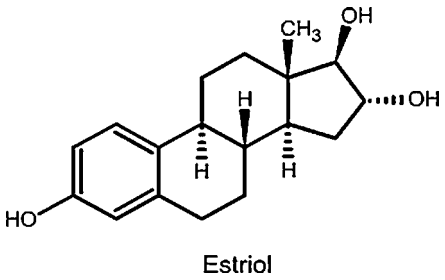

Fig. 1. Chemical structure of estriol.

method was successfully applied to determine estriol in tap water. At the present time, there are no other publications reporting the electrochemical determination or behavior of estriol. Some articles have described the use of chromatographic methods with amperometric detectors to investigate hormones like bisphenol A [18,19], or to develop biosensors for the determination of the hormones 17β-estradiol and estrone [20–24].

In the present study a boron-doped diamond (BDD) electrode was used to develop an electrochemical methodology for determination of estriol. Diamond is an electrical insulator, but conducts heat even more effectively than copper and can withstand very high electric fields. With these physical properties, diamond is an attractive material for electronic applications, particularly when it is rendered conductive through the introduction of charge carriers [25]. Boron has one less electron than carbon and because of its small atomic radius it is relatively easily incorporated into diamond. BDD electrodes have been extensively studied in recent years, in relation of their fundamental electrochemical properties [25] and also in terms of their applications [25,26]. BDD electrodes have high stability and hardness, inert surfaces and very low capacitive background currents. Thus, they have been extensively used in electrosynthesis, electroanalysis, electrochemical combustion, and as electrocatalyst supports [25–27]. Recent reports in the literature have shown that several bio-molecules can be satisfactorily determined using BDD electrodes. Souza et al. [28] quantified sulfonamides in pharmaceutical products and obtained an analytical curve in the concentration range of 8.01×10^{-6} to 1.19×10^{-4} mol L^{-1}. Lourenção et al. [29] developed an electrochemical method for the single or simultaneous determination of paracetamol and caffeine; the calibration curves for the simultaneous determination showed an excellent linear response, ranging from 5.0×10^{-7} to 8.3×10^{-5} mol L^{-1} for both compounds. A methodology to determine perfloxacin in pharmaceuticals and serum presented a linear range for concentrations between 2.0×10^{-6} and 2.0×10^{-4} mol L^{-1} [30]. Many other bio-molecules, including pentachlorophenol, 4-nitrophenol, lincomycin, purine and pyrimidine, dopamine and ascorbic acid, aspartame and cyclamate [31–36], have been determined using BDD electrodes and in all cases the methodologies presented good selectivity, repeatability, reproducibility, precision and accuracy. However, BDD electrodes have not yet been used for the electroanalytical determination of hormones. Thus, the objective of this study is to develop a cost-effective, single-use, feasible, accurate, and reliable method to detect estriol in a complex matrix (urine) and in a drug sample using a boron-doped diamond electrode by square-wave voltammetry.

2. Experimental

2.1. Chemicals and solutions

All reagents used in this study were of analytical grade purchased from Sigma. The solutions were prepared with water purified using a Milli-Q system manufactured by Millipore (Bedford, MA, USA). Sodium hydroxide (pH 12.0) and five buffer solutions were tested as supporting electrolytes: Britton–Robinson (pH 2.0–12.0), acetate (pH 4.5), ammonium (pH 9.4) and Ringer's solution (pH 12.0). All of these solutions had a concentration of 5.0×10^{-3} mol L^{-1}. A solution of 0.1 mol L^{-1} NaOH was used to adjust the pH of the 5.0×10^{-3} mol L^{-1} NaOH supporting electrolyte to 12.0. Progesterone, urea, uric acid, albumin and creatinine were evaluated as potential interferents for estriol determination in urine. The excipients present in the pharmaceutical preparation used in this study (Ovestrion®) are amido, lactose, magnesium stearate and amilopectine. They were tested as potential interferents for estriol determination in the commercial product. Stock solutions of 1.4×10^{-2} mol L^{-1} estriol dissolved in methanol were prepared daily and less concentrated solutions were prepared by dilution. For the recovery studies, standard solutions of the hormone were added to samples of urine and tablets of a commercial product (Ovestrion®). The urine sample was obtained from a woman in the third trimester of pregnancy and no pretreatment was necessary to determine its estriol levels. Commercially available estriol contained 1 mg of estriol. Ten tablets of the medicament were finely macerated in a mortar with a pestle. The powder was weighed in the quantity necessary to prepare the sample solutions, diluted using methanol and mixed for 5 min. The non-dissolved excipients were left to settle and a sample was then withdrawn from the clear supernatant liquor.

2.2. Cell and electrodes

Linear scan, cyclic and square-wave voltammograms were recorded using a 25-mL three-electrode electrochemical cell. The electrochemical detection of estriol was initially tested on five electrodes: copper, platinum, gold, glassy carbon and boron-doped diamond. The electrodes (with the exception of the BDD electrode) were hand-polished before each experiment with 0.05 μm alumina paste and ultrasonically rinsed in deionized water. The BDD working electrode ($A = 0.23$ cm^2) employed for the development of the electroanalytical methodology was a BDD film with around 8000 ppm of boron. A pretreatment procedure was initially applied to the BDD electrode to achieve reproducible results. The procedure consisted of the polarization at −3.0 V of the BDD electrode in 0.5 mol L^{-1} H_2SO_4 for 3 min in a separate cell, as recommended in the literature [27]. Afterwards, the electrode was transferred to the measuring cell containing the supporting electrolyte and estriol, and polarized under stirring at −3.0 V for 30 s between each run. Following this method, excellent electrode response and reproducibility were systematically observed for estriol determination. Platinum wire and Ag/AgCl electrodes were used as auxiliary and reference electrodes, respectively. All potentials were measured versus this reference electrode.

2.3. Instruments

Voltammetric measurements and surface pretreatment of the BDD electrode were performed on a Voltalab PGZ 100 potentiostat/galvanostat interfaced with a computer using the Voltamaster 4.0 software. Linear scan and cyclic voltammmetry were employed for preliminary studies on the electrochemical behavior of the estriol compound. Square-wave voltammetry was used for the development of the electroanalytical methodology and estriol determination in urine and in a commercial drug sample. The accuracy of the proposed method was compared to the standard radioimmunoassay method [37].

3. Results and discussion

3.1. Electrode selection

In order to compare the electrochemical oxidation of estriol, copper, platinum, gold, glassy carbon and BDD were tested as catalyst electrodes. In this study, linear scan voltammetric measurements were carried out from 0.0 to +0.63 V at 50 mV s^{-1} using 2.0×10^{-5} mol L^{-1} estriol in NaOH (pH 12.0) solution. Under these experimental conditions, estriol was electrochemically inactive on copper, platinum and gold electrodes, since no oxidation current was observed. On the other hand, as can be seen in Fig. 2, the voltammograms obtained with the glassy carbon (a and c) and BDD (b and d) electrodes without (a and b) and with (c and d) 2.0×10^{-5} mol L^{-1} estriol solution show that the electrochemical oxidation of estriol produced a good, sensitive and well-defined anodic current peak. However, the current at the BDD electrode was almost 10 times higher than at the glassy carbon electrode. Similar behavior has been systematically observed by other authors for this type of electrode and for other bio-molecules [26,30]. The good performance of BDD electrodes as electrochemical catalysts is due to properties such as low sensitivity to dissolved oxygen and low background currents. The capacitive background current, for example, is ten times lower than that at glassy carbon electrodes [38], making BDD electrodes highly sensitive toward the oxidation/reduction of organic molecules. This study confirms, therefore, that the BDD electrode also offers excellent electrocatalytic properties for the oxidation of hormones, in particular estriol, which is here under study for the first time using this type of electrode surface. Accordingly, the BDD electrode was selected to develop the methodology for the electrochemical determination of estriol.

3.2. Selection of supporting electrolyte

The choice of the supporting electrolyte is an important stage in electroanalytical studies because its composition and pH affect the properties of the solution as well as the electrode–solution interface, modifying the thermodynamics and kinetics of the charge transfer process and the adsorption at the electrode surface [39]. In this study, solutions with different compositions and pH values were tested as the supporting electrolyte to investigate the estriol oxidation at a BDD electrode. Therefore, the buffers Britton–Robinson (pH 2.0–12.0), acetate (pH 4.5), ammonium (pH 9.4) and Ringer's solution (pH 12.0), and the NaOH (pH 12.0) solution, were evaluated. All of these solutions had a concentration of 5.0×10^{-3} mol L^{-1}. Fig. 3A shows the cyclic voltammograms obtained for 5.0×10^{-5} mol L^{-1} estriol in different supporting electrolytes. In all voltammograms, just one oxidation peak was observed when the potential was swept from 0.0 to +1.2 V and back to 0.0 V at a scan rate of 100 mV s^{-1}. As can be seen, estriol oxidized at a high potential of 0.90 V in Britton–Robinson (pH 2.0) solution (Fig. 3A(a)), and a well-defined oxidation peak and analytical signal, i.e. the anodic current density, were observed. In acetate (pH 4.5) buffer (Fig. 3A(b)), the estriol oxidation was observed at 0.75 V with a small current being produced. A very poorly defined current peak was generated at 0.64 V in Britton–Robinson (pH 7.0) buffer (Fig. 3A(c)). The estriol oxidation in ammonium (pH 9.4) (Fig. 3A(d)) and Ringer's solution (pH 12.0) (Fig. 3A(e)) buffers was observed at almost the same potential of 0.45 V. In spite of the well-defined peaks, the analytical signals were also poor. In Britton–Robinson (pH 12.0) solution, a peak with low current and ill-defined peak was observed at 0.40 V (Fig. 3A(f)). The most well-defined oxidation peak and the highest anodic current density were obtained in NaOH (pH 12.0) solution (Fig. 3A(g)). Under this experimental condition the hormone estriol oxidized at 0.38 V, the lowest oxidation potential observed. The relatively high peak current found for estriol oxidation in solutions of pH 12.0 suggests that the electrochemical reaction follows a different mechanism to that in solutions of lower pH and also with a different number of electrons involved. As can be seen in Fig. 3A, the cyclic voltammograms shifted to less positive potentials as the solution pH increased. As a consequence, the water oxidation reaction was anticipated and a narrower cyclic voltammogram was

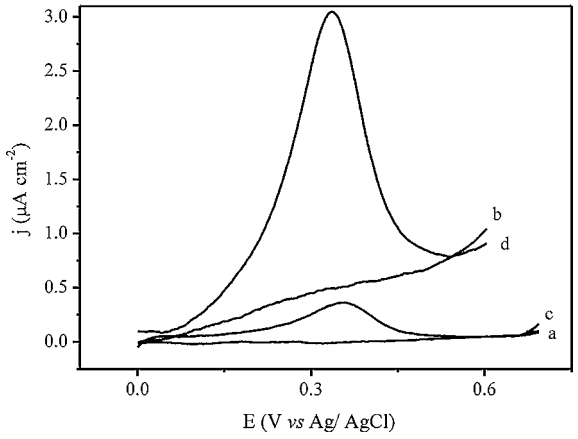

Fig. 2. Linear scan voltammograms for (a) glassy carbon and (b) BDD electrodes in NaOH (pH 12.0) solution and (c and d) in the presence of 2.0×10^{-5} mol L^{-1} estriol, $\nu = 50$ mV s^{-1}.

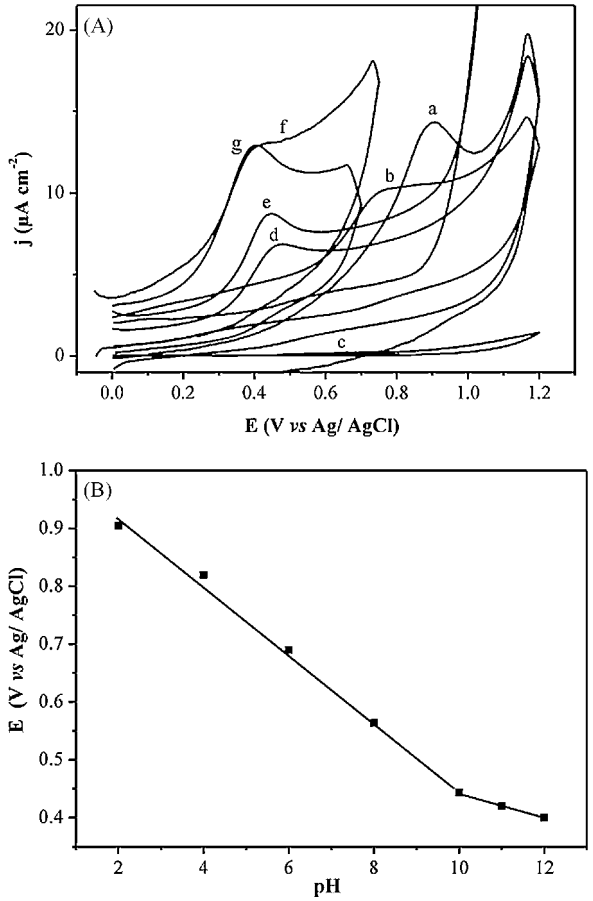

Fig. 3. (A) Cyclic voltammograms for 5.0×10^{-5} mol L^{-1} estriol at a BDD electrode immerse in (a) Britton–Robinson (pH 2.0), (b) acetate (pH 4.5), (c) Britton–Robinson (pH 7.0), (d) ammonium (pH 9.4), (e) Ringer's (pH 12.0), (f) Britton–Robinson (pH 12.0), and (g) NaOH (pH 12.0) solutions, $\nu = 100$ mV s^{-1}. (B) Influence of Britton–Robinson solution pH on the estriol oxidation peak potential.

obtained since the initial potential was the same for all experiments.

The influence of the pH on the oxidation peak of 5.0×10^{-5} mol L^{-1} estriol in Britton–Robinson solutions of pH 2.0–12.0 is shown in Fig. 3B. The increase in pH shifted the estriol oxidation potential to less positive values. This is a typical behavior for the oxidation of phenols and was also observed by Vega et al. [17] for the oxidation of phenolic estrogenic compounds. The intersection of the two straight lines observed in Fig. 3B matches the pK_a of the phenolic group present in the estriol chemical structure. The value found (10.0) is very close to 10.3–10.4, the value reported in the literature [40].

As demonstrated, a good compromise between low detection potential and high peak current was achieved using NaOH (pH 12.0) solution as the supporting electrolyte, which was chosen for further experiments and development of the methodology.

3.3. Electrochemical behavior of estriol at BDD electrode in NaOH (pH 12.0) solution

The cyclic voltammograms shown in Fig. 4 show the electrochemical behavior of 2.0×10^{-5} mol L^{-1} estriol in NaOH (pH 12.0) solution at a BDD electrode. The influence of the potential scan rate on the estriol oxidation was studied over the range of 10–200 mV s^{-1}. The potential was swept from 0.0 to +0.7 V and back to 0.0 V. The cyclic voltammograms are characteristic of an electrochemically irreversible reaction showing just one oxidation peak potential at 0.365 V for a scan rate of 20 mV s^{-1}.

The peak potential shifted to more positive values as the scan rate increased, also in agreement with an irreversible electrochemical behavior. Furthermore, a linear $j \times v^{1/2}$ plot was obtained indicating a diffusion-controlled process of the oxidation reaction. The $\log j \times \log v$ plot showing a slope of 0.64 ($r = 0.999$) confirmed this finding with a small contribution from the adsorption process. Finally, interdependence between the current function ($jv^{-1/2}$) and the potential scan rate indicated that the chemical reaction was coupled to the electrode process, i.e. the reaction followed an EC mechanism. The data collected on the influence of the solution pH and potential scan rate on the electrochemical behavior of estriol at the BDD electrode allow some speculations regarding its oxidation mechanism. The mechanism for the electrochemical oxidation of estriol seems to follow the typical oxidation of phenolic compounds having just one hydroxyl group in their structure [41–43]. Additionally, the cyclic voltammograms of estriol (Fig. 4) are similar to that of β-estradiol [22], a hormone with similar chemical structure.

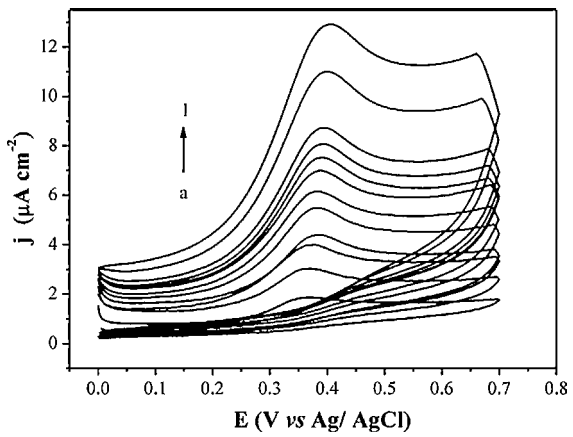

Fig. 4. Cyclic voltammograms for 2.0×10^{-5} mol L^{-1} estriol at a BDD electrode immerse in NaOH (pH 12.0) solution, v (a) 10 mV s^{-1}, (b) 20 mV s^{-1}, (c) 30 mV s^{-1}, (d) 40 mV s^{-1}, (e) 50 mV s^{-1}, (f) 60 mV s^{-1}, (g) 70 mV s^{-1}, (h) 80 mV s^{-1}, (i) 90 mV s^{-1}, (j) 100 mV s^{-1}, (k) 150 mV s^{-1} and (l) 200 mV s^{-1}.

The electrochemical behavior of both hormones shows one oxidation peak and characteristics of an electrochemically irreversible charge transfer.

Hence, we propose that the electrochemical oxidation of estriol forms a phenoxonium ion, the electrochemical step of the EC mechanism, in a two-electron reaction process. Such an oxidation reaction is diffusion-controlled, as indicated by the data obtained at different scan rates. The phenoxonium ion can undergo homogeneous chemical reactions in the sequence, the chemical step of the EC mechanism. The reactions are fast, dependent on the solution pH and irreversible in alkaline media. The resulting products vary according to the rearrangements in the oxidized molecule. In acetonitrile medium, for example, the final identified product was the ketone derivative of β-estradiol [22].

The stability of estriol in NaOH (pH 12.0) solution was initially studied over 6 h by cyclic voltammetry. The cyclic voltammograms obtained over time were reproducible indicating that the estriol solution was stable. The same behavior was observed for a solution studied over 10 days. These experiments indicated that the determination of estriol can be carried out in NaOH (pH 12.0) solution without modifying the composition of the solution containing the analyte.

3.4. Optimization of square-wave voltammetry parameters

Square-wave voltammetry is a pulse technique that offers the advantages of fast speed and good sensitivity for reversible as well as irreversible reactions. The excitation signal is obtained applying a series of forward and reverse pulses superimposed onto a constant-height potential staircase to the working electrode. The current is sampled twice in each wave cycle: once at the end of the forward pulse and once at the end of the reverse pulse. The signal is given by the difference between these two currents. As a consequence, an important step in the development of the electroanalytical methodology is the optimization of the parameters that can influence the voltammetric response. Hence, the dependence of the SWV responses on parameters such as frequency (f), pulse height (PH) and scan increment (ΔE_s) was analyzed in order to optimize the experimental set-up for estriol determination. The SWV parameter optimization was carried out in solutions of 2.0×10^{-5} mol L^{-1} estriol in NaOH (pH 12.0) solution as the supporting electrolyte. The ranges studied were 5–100 Hz for frequency, 10–50 mV for pulse height and 1–5 mV for scan increment. The frequency is one of the most important parameters of SWV since it determines the intensity of the signals and, consequently, the sensitivity of the method. The anodic current density increased with the increase in the frequency at constant PH and ΔE_s values, as shown in Fig. 5A. At higher frequencies, a broadening and a distortion in the voltammograms were observed (data not shown). An excellent compromise between voltammetric profile and sensitivity was obtained at a frequency of 20 Hz. As a consequence, the frequency of 20 Hz was chosen for use in subsequent experiments. For totally irreversible redox systems, analytical sensitivity in the SWV is greatly influenced by variations in the pulse height [44]. It is observed in Fig. 5B that the current density values increased linearly up to 30 mV and for higher values remained almost constant. Thus, a pulse height of 30 mV was selected for further experiments. The scan rate in SWV is the result of the product of the f and ΔE_s. Therefore, a higher ΔE_s can increase the analytical signal and, thus, improve the sensitivity of the method [44]. However, with higher scan increments a broadening of the peak can occur, and thus the resolution of the voltammograms can be affected. Consequently, this is a parameter which also has to be analyzed. In Fig. 5C, it can be seen that the anodic current density remained almost constant for ΔE_s values higher than 2 mV and therefore this ΔE_s value was selected. The optimized values were also used to validate the methodology

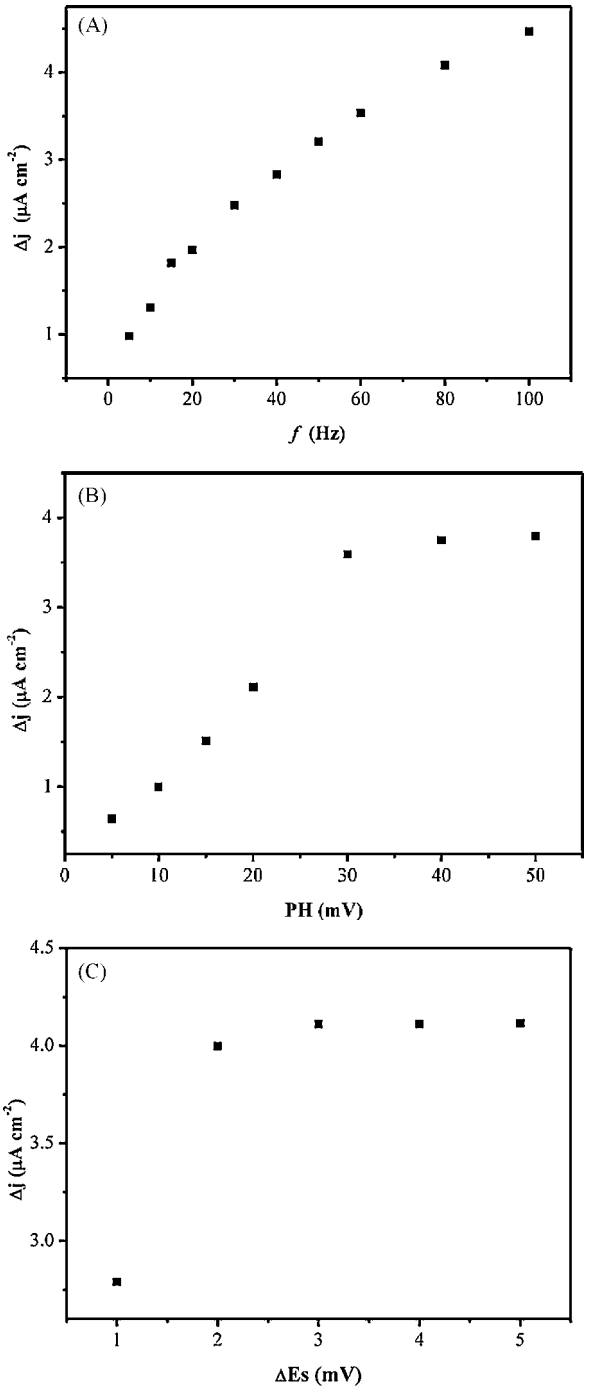

Fig. 5. Dependence of the anodic current density on (A) frequency at PH = 40 mV and ΔE_s = 2 mV, (B) pulse height at f = 60 Hz and ΔE_s = 2 mV and (C) scan increment at PH = 40 mV and f = 60 Hz obtained by square-wave voltammetry for 2.0×10^{-5} mol L^{-1} estriol at a BDD electrode immerse in NaOH (pH 12.0) solution.

proposed as well as for estriol determination in a pharmaceutical product and in urine.

3.5. Analytical curve and validation parameters of the method proposed for estriol determination

The previously optimized SWV parameters were employed to record the analytical curve for estriol in NaOH (pH 12.0) solution as the supporting electrolyte using the BDD electrode. The square-wave voltammograms were collected from 0.0 to 0.7 V and the resultant anodic current density was registered

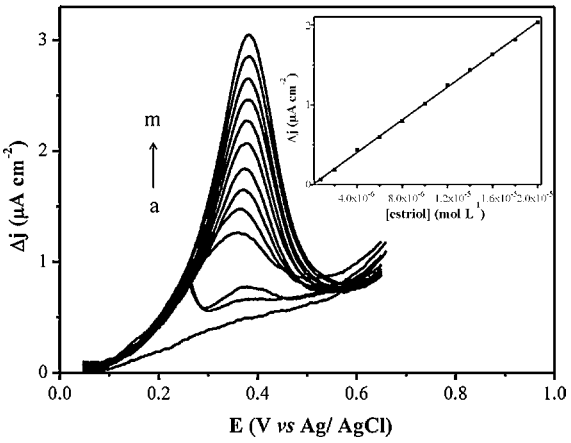

Fig. 6. Square-wave voltammograms for estriol using NaOH (pH 12.0) solution at a BDD electrode: (a) blank; (b) 2.0×10^{-7} mol L^{-1}; (c) 8.0×10^{-7} mol L^{-1}; (d) 2.0×10^{-6} mol L^{-1}; (e) 4.0×10^{-6} mol L^{-1}; (f) 6.0×10^{-6} mol L^{-1}; (g) 8.0×10^{-6} mol L^{-1}; (h) 1.0×10^{-5} mol L^{-1}; (i) 1.2×10^{-5} mol L^{-1}; (j) 1.4×10^{-5} mol L^{-1}; (k) 1.6×10^{-5} mol L^{-1}; (l) 1.8×10^{-5} mol L^{-1}; (m) 2.0×10^{-5} mol L^{-1} (f = 20 Hz; PH = 30 V; ΔE_s = 2.0 mV). Inset: the analytical curve.

at the peak potential. Fig. 6 shows the SWV voltammograms for estriol obtained after successive additions of the respective standard solution and the inset depicts the corresponding analytical curve. For the construction of the analytical curve, the currents shown in the square-wave voltammograms were subtracted from the background current. Table 1 shows some of the validation parameters for the proposed method for estriol determination. As can be seen, a well-defined irreversible oxidation peak was obtained, with the current density increasing proportionally to the estriol concentration. The analytical curve shows a linear response in the range of 2.0×10^{-7} to 2.0×10^{-5} mol L^{-1}. The equation for the straight line can be expressed according to $\Delta j/\mu A\,cm^{-2} = 1.02 \times 10^5$ [estriol]/mol $L^{-1} - 0.0044$. From this plot, the detection limit (DL) was calculated according to the equation: DL = 2 Sb/B, where Sb is the standard deviation of the y-coordinate from the line of best fit (linear coefficient) and B the slope (angular coefficient) of this line. The calculated DL for estriol was 1.7×10^{-7} mol L^{-1}. Additionally, the quantification limit (QL) was calculated using the equation: QL = 10 Sb/B. The calculated QL for estriol was 8.5×10^{-7} mol L^{-1}. The repeatability for five measurements of the current peak for solutions of 5.0×10^{-7} mol L^{-1} estriol, under optimized conditions, was very good, with a relative standard deviation of 0.64%. The reproducibility of the

current peak was tested using two methodologies: interday, over 5 days using different solutions prepared in the concentration of 5.0×10^{-7} mol L^{-1} and intraday, using five different solutions prepared on the same day and using the same concentration of estriol (5.0×10^{-7} mol L^{-1}). The relative standard deviations ($n = 5$) were 0.98 and 0.78%, respectively. Good data were also obtained for the repeatability and reproducibility of peak potential, as can be seen in Table 1. These results demonstrate that the measurement of the current density and peak potential, as well as of the method proposed, show excellent accuracy, precision, reproducibility, repeatability and sensitivity for estriol determination.

3.6. Estriol determination, recovery and potential interferent studies on a commercial pharmaceutical product

The electroanalytical methodology described above and the standard radioimmunoassay method for estriol determination were applied in pharmaceutical dosage for the hormone quantification. The electroanalytical determination is shown in Fig. 7A. The mean results for three determinations ($n = 3$) of both techniques were very close to the declared value of 1.00 mg; the confidence limits were calculated for a significance level of 0.05. Table 2 summarizes the results obtained. The standard method resulted in a higher value for estriol determination than the value labeled on the commercial pharmaceutical product, while the electroanalytical method resulted in lower values. The relative error between the standard method and the labeled value was 2.91%, while for the method proposed it was −4.17%. The relative error between the method proposed and the radioimmunoassay was −7.29%. The performance of the two methods (proposed and standard) was verified using the Student's *t*- and *F*-tests. The *t*-test was carried out to check the validity of the data obtained using the standard and proposed methods. At the 95% confidence level both results for t_{value} calculated were lower than the result for $t_{theoretical}$ (5.99), indicating no significant differences between the data obtained using the two methods and the true (labeled) values. The precision of the proposed method was compared to that of the standard method through statistical examination of the values obtained from *F*-tests, also at the 95% confidence level. The F_{value} was 0.032, which is lower than the $F_{theoretical}$ (19), indicating excellent performance of the electroanalytical method when compared to the standard method. Taking into consideration that other components of the matrix of the pharmaceutical dosage may interfere with the analysis or accurate quantification of the analyte, potential effects from matrix components must be investigated. If no adequate placebo can be prepared, a known amount of drug substance can also be added to an authentic batch of a drug product (standard addition). In this case, recovery experiments are performed in the presence of the real matrix. The acceptable range of recovery for the analysis of residues is generally between 80 and 120% [45]. As demonstrated in Table 3, the estriol recovery ranged from 98.6 to 101.0%. Furthermore, the slope of 1.09×10^5 μA L mol^{-1} cm^{-2} ($r = 0.9982$) obtained from the curve shown in Fig. 7A, is very close to that obtained from the analytical curve (Table 1), which indicates the excellent selectivity of the method proposed. The results shown in Fig. 7A were converted in order to obtain the same units for the slope of both

curves. Finally, amido, lactose, magnesium stearate and amilopectine (the excipients present in the pharmaceutical preparation used in this study) were also tested as potential interferents. The studies showed that all of them are insoluble in methanol, the solvent used to prepare the solutions. The experiments carried out in the presence of these potential interferents did not change significantly the results described above. These results showed that the proposed method could be applied with great success to assays of estriol in tablet form without any significant matrix interference effects.

3.7. Study of potential interferents for estriol determination in urine

It is well known that urine is a complex matrix and the determination of its components is not an easy task. Urine is composed essentially of water, salts, proteins, principally albumin and creatinine, and uric acid. During pregnancy, it is common for glucose and progesterone concentrations to increase. Most of these compounds could hinder the electrochemical determination of estriol, therefore, studies on interferents were carried out to identify any such influence. The major components of urine, progesterone, urea, uric acid, creatinine and albumin were tested as interferents in a 5.0×10^{-7} mol L^{-1} estriol solution. The estriol:interferent ratios studied were 1:0.01, 1:0.1, 1:1, 1:10 and 1:100. The results for the determination of the anodic current density obtained from the voltammograms recorded for estriol oxidation in the absence and in the presence of the potential interferents are listed in Table 4. As can be seen, the current density generated by the estriol oxidation was almost the same in the absence and presence of the potential interferents. This signifies that progesterone, urea, uric acid, albumin and creatinine did not significantly interfere in the analytical signal produced by the electrochemical oxidation of estriol. Thus, we can extrapolate this observation to a real urine sample and consider that the components of the urine will not significantly interfere in the determination of estriol in urine samples taken during pregnancy.

Table 4
Study of potential interferents for determination of estriol in urine.

	Estriol:interferent ratio					
	(1:0)	(1:0.01)	(1:0.1)	(1:1)	(1:10)	(1:100)

Creatinine	0.14	0.14	0.13	0.14	0.14	0.15
Albumin	0.15	0.15	0.16	0.16	0.16	0.17

[a] $n = 3$.

3.8. Estriol determination and recovery studies in urine sample taken during pregnancy

Without any sample preparation, extraction, filtration or evaporation step other than an adequate dilution of the sample, the electroanalytical methodology developed was successfully applied to the determination of estriol in a urine sample taken during pregnancy (Fig. 7B). Table 2 summarizes the results obtained. As can be seen, the value found for estriol determination in urine (8.03×10^{-5} mol L^{-1}, $n = 3$) was lower than that of the comparative radioimmunoassay method (8.43×10^{-5} mol L^{-1}). Both values found were in good agreement with the values published in the pertinent literature [4]. The relative error for the mean of three determinations was −4.98% considering the electroanalytical and radioimmunoassay methods. The precision of the proposed method was compared to the radioimmunoassay method through statistical examination of the values obtained from the *F*-test, considering a 95% confidence level (Table 2). The value for F_{value} (1.0) was lower than that for $F_{theoretical}$ (19.0), indicating excellent performance of the electroanalytical method using the BDD electrode when compared to the radioimmunoassay method. Recovery experiments were performed in the presence of the real matrix in order to check the matrix interference effects. As demonstrated in Table 3, the recovery ranged from 100.2 to 103.4% for estriol, indicating that the composition of the matrix does not significantly interfere in the analytical response of the method proposed. This behavior, i.e. the selectivity of the proposed method, was confirmed by comparing the slopes of the analytical curve (Table 1) and that obtained in Fig. 7B (1.04×10^5 μA L mol^{-1} cm^{-2}, $r = 0.9991$), which were very close. The linearity and slope of the analytical curve and that obtained by the standard addition method, the repeatability and reproducibility of the data and the recovery results obtained for estriol determination using the optimized parameters for SWV and a suitable surface pretreatment for the BDD electrode indicated that the proposed electroanalytical methodology can be successfully applied in control processes and estriol determinations in urine samples taken during pregnancy. The direct determination of estriol in urine here reported is comparable to the existing radioimmunoassay methodology, but with clear advantages, as no preliminary separation steps or pretreatment of the matrix are required.

4. Conclusions

According to the results obtained in this study, it can be concluded that the electroanalytical methodology proposed using a BDD electrode and the SWV technique presented a concentration range and detection limit compatible with the conventional techniques of urine analysis for estriol determination and can also be applied to routine analysis for quality control in the pharmaceutical industry. Another positive aspect observed was the total absence of interferences in the determination of this hormone in a complex sample, in this case urine. The determination of estriol in a urine sample taken during pregnancy was successfully achieved without sample pretreatment. Therefore, this confers credibility and feasibility to the methodology proposed for the determination of estriol in urine samples taken during pregnancy. In addition, due to the simplicity of the preparation procedures, fast routine determinations can also be achieved in the direct electrochemical analysis of estriol and other hormones in pharmaceutical preparations.

Partial least-squares
Chemometrics
Densitometry

ABSTRACT

Simple, accurate, sensitive and validated UV spectrophotometric, chemometric and HPTLC-densitometric methods were developed for determination of oxybutynin hydrochloride (OX) in presence of its degradation product and additives in its pharmaceutical formulations. Method A is the first derivative of ratio spectra (DD^1) which allows the determination of OX in presence of its degradate in pure form and tablets by measuring the peaks amplitude at 216 nm. Method B and C are principal component regression (PCR) and partial least-squares (PLS) for determination of OX in presence of its degradate in pure form, tablets and syrup. While, the developed high performance thin layer chromatography HPTLC-densitometric method was based on the separation of OX from its degradation product, methylparaben and propylparaben followed by densitometric measurement at 220 nm which allows the determination of OX in pure form, tablets and syrup. The separation was achieved using HPTLC silica gel F_{254} plates and chloroform:methanol:ammonia solution:triethylamine (100:3:0.5:0.2, v/v/v/v) as the developing system. The accuracy, precision and linearity ranges of the developed methods were determined. The results obtained were statistically compared with each other and to that of a reported HPLC method, and there was no significant difference between the proposed methods and the reported method regarding both accuracy and precision.

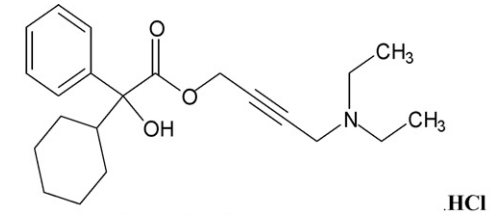
1. Introduction

Oxybutynin hydrochloride OX, Fig. 1 is an antispasmodic, anticholinergic agent which is commonly indicated for the treatment of overactive bladder with symptoms of urge urinary incontinence and frequency [1]. It is chemically designated as [4-(diethylamino)-2-butynyl (±)-α phenylcyclohexane-glycolate hydrochloride] [2]. The official methods for determination of OX are non-aqueous titration and potentiometric acid–base titration according to USP [3] and BP [4], respectively. A survey of the literature revealed that few methods have been reported for the determination of OX such as UV spectrophotometry [2], RP-HPLC [2,5], HPLC determination of OX in presence of its degradation product [6], an enantioselective method using liquid-phase microextraction (LPME) followed by an HPLC analysis was developed for the determination of OX and its major metabolite N-desethyloxybutynin in rat liver [7], gas chromatography in serum [8], Polymeric matrix membrane sensors were used for stability-indicating potentiometric determination of OX and flavoxate hydrochloride urogenital system drugs [9] and voltammetric technique [1].

So the aim of this work was to develop a comparative study of recent, simple, sensitive, validated stability indicating methods that are of lower cost than the reported HPLC method. Also to develop spectrophotometric methods able to determine the studied drug in presence of methyl and propyl parabens inspite of their high absorptivity. These methods include spectrophotometric, chemometric and HPTLC-densitometric ones for the determination of OX in presence of its degradate in pure form, laboratory prepared mixtures and in its pharmaceutical preparations.

2. Experimental



2.1. Samples

2.1.1. Pure samples

Standard oxybutynin hydrochloride OX with claimed purity of 100.02% according to a reported HPLC method [6] was kindly donated by the Egyptian Co. for chemicals and pharmaceuticals, ADWIA, 10th of Ramadan city, Egypt.

Fig. 1. Chemical structure of oxybutynin hydrochloride.

2.1.2. Pharmaceutical formulations

- Uripan tablets batch no. 0811106, were labeled to contain 5 mg of OX per one tablet, were manufactured by the Egyptian Co. for chemicals and pharmaceuticals, ADWIA, 10th of Ramadan city, Egypt.
- Detronin tablets batch no. 710907, were labeled to contain 5 mg of OX per one tablet, were manufactured by Pharaonia pharmaceuticals, Alexandria, Egypt.
- Uripan syrup batch no. 080470 was labeled to contain 100 mg OX per 100 mL syrup were manufactured by the Egyptian Co. for chemicals and pharmaceuticals, ADWIA, 10th of Ramadan city, Egypt.
- Detronin syrup, batch no. 4038005 and were labeled to contain 100 mg OX, 100 mg methylparaben and 20 mg propylparaben per 100 mL syrup were manufactured by Pharaonia pharmaceuticals, Alexandria, Egypt.

2.2. Chemicals and reagents

- Methanol, ammonia solution, diethylether, ethyl acetate, triethylamine and chloroform (El-Nasr Pharmaceutical Chemicals Co., Abu-Zabaal, Cairo, Egypt).
- HCl and NaOH solutions (0.1N and 1N aqueous solution, respectively). (El-Nasr Pharmaceutical Chemicals Co., Abu-Zabaal, Cairo, Egypt).
- Degraded sample: 0.3 gm of oxybutynin hydrochloride was refluxed with 30 ml of 1N NaOH for three hours. The solution was cooled and then the pH of the solution was adjusted to two pH units for complete precipitation of the degradate then the degradate was extracted with multiple fractions of diethylether (6 mL × 20 mL). The course of the reaction was followed by TLC using plates of silica gel 606F_{254} and using methanol:ethyl acetate:chloroform (1.5.2:7, v/v/v) as a mobile phase. The prepared degradate was subjected to IR and mass spectrometry, where IR spectrum of OX showed a characteristic band at 1741 cm^{-1} indicating the presence of carbonyl group.

2.3. Apparatus

- A double beam UV–vis spectrophotometer (SHIMADZU, Japan) model UV-1601 PC with quartz cell of 1 cm pathlength, connected to IBM compatible computer. The software was UVPC personal spectroscopy software version 3.7.
- Camag TLC scanner 3 S/N 130319 operated with winCATS software.
- Linomat 5 autosampler (Switzerland).
- Camag microsyringe (100 μL).
- Precoated silica gel aluminium Plates 60 F254, ALLUGRAM® SIL G/UV 254 (Machenary-Nagel, Germany) 20 cm × 20 cm with 0.2 mm coating thickness.

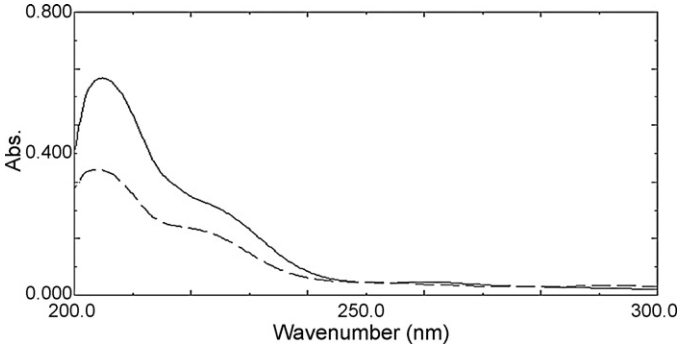

Fig. 2. Zero order absorption spectra of 15 μg/mL of oxybutynin hydrochloride (——) and 15 μg/mL of its degradate (------) using 0.1N HCl as a solvent.

2.4. Software

All computations were performed in Matlab for Windows™ version 6.5 [10]. The PLS procedure was taken from PLS_Toolbox [11] for use with Matlab® 6.5.

2.5. Spectral characteristics

The absorption spectra of OX and its degradate in 0.1N HCl were recorded over the range 200–400 nm using 0.1N HCl as blank, Fig. 2.

2.6. Chromatographic condition

HPTLC was performed using precoated silica 20 cm × 10 cm HPTLC aluminium sheet; the plates were pre-washed with methanol and dried at 60 °C for 15 min prior to sample application. Samples were applied in the form of bands in the length of 4 mm. Linear ascending development was performed in a chromatographic tank previously saturated using chloroform:methanol:ammonia solution:triethylamine (100:3:0.5:0.2, v/v/v/v) as mobile phase for one hour at room temperature.

The mobile phase was allowed to develop 90 mm from the lower edge. The developed plates were air dried and scanned at 220 nm.

2.7. Standard solutions and calibration

For (DD^1) spectrophotometric method

- Stock standard solution of OX and stock solution of the degradate 1 mg/mL were prepared by accurately weighing 100 mg of pure powder of each into two separate 100-mL volumetric flasks dissolved in and diluted to the volume with methanol.
- Working standard solution of OX and working solution of the degradate 100 μg/mL were prepared by transferring 10 mL of stock standard solution of OX and stock solution of the degradate each of 1 mg/mL into two separate 100-mL volumetric flasks dissolved in and diluted to the volume with methanol.

Aliquots equivalent to 60–280 μg OX were accurately transferred from its working standard solution (100 μg/mL) into a series of 10-mL volumetric flasks the volume was completed to the mark with 0.1N HCl to obtain final concentration range of 6–28 μg/mL.

The zero order absorption spectra of the resulting solutions were scanned and divided by the absorption spectrum of 20 μg/mL degradate solution. The peak amplitudes of the first derivative of ratio spectra at 216 nm were differentiated with respect to wavelength with $\Delta\lambda = 4$ and scaling factor = 10) were plotted vs. the corresponding concentration, and regression equation was computed.

2.8. Assay of laboratory prepared mixtures

Solutions containing different ratios of OX and its degradate were prepared to contain 10–90%. The absorption spectra of different laboratory prepared mixtures were divided by the absorption spectrum of 20 μg/mL degradate solution .The DD^1 values were recorded at 216 nm. The concentrations of OX were calculated from the computed regression equation.

For chemometric method

- Stock standard solution of OX and stock solution of the degradate 1 mg/mL were prepared as mentioned previously under (DD^1) spectrophotometric method.
- Working standard solution of OX and working solution of the degradate 100 μg/mL were prepared as mentioned previously under (DD^1) spectrophotometric method.

Multilevel multifactor design was used for the construction of the calibration and validation sets [12]. A five-level, five-factor calibration design was used .The concentrations details are given in Table 1. The absorption spectra of the prepared mixtures were recorded and transferred to Matlab® for subsequent data manipulation. Sixteen mixtures were used for building the calibration model, while seven mixtures were chosen to be used as an external validation set.

For spectrodensitometric method:

Aliquots equivalent to 2–14 mg OX were accurately transferred from its stock standard solution (1 mg/mL) into a series of 10-mLvolumetric flasks dissolved in and diluted to the volume with methanol, 10 μL of each solution was applied on the HPTLC plates. The calibration curve was constructed relating the integrated area under the peak in triplicates to the corresponding concentrations as μg/band.

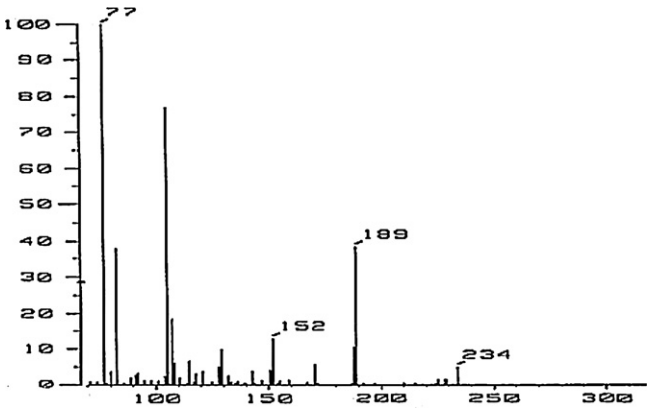

Fig. 4. Mass spectrum of oxybutynin degradate.

2.9. Application to pharmaceutical preparations

The contents twenty tablets were accurately weighted and powdered. An accurate weight of the mixed sample was transferred into a beaker, 50 mL methanol were added with continuous magnetic stirring for about 10 min. The solution was filtered into a 100-mL volumetric flask, and the volume was completed with methanol.

Accurate volume of syrup was transferred, measured and diluted to 100 mL methanol, filtered. Then the procedure detailed under linearity and construction of calibration curve for each method was followed.

3. Results and discussion

The main task of this work was to establish simple, sensitive and accurate analytical methods for the determination of OX in presence of its degradation product in its bulk powder and pharmaceutical dosage forms with satisfactory precision for good analytical practice (GAP). Also, to statistically compare and evaluate the efficiency of the developed methods for determination of the studied compound.

Upon refluxing OX with acid or alkali, the carboxylic acid degradate was obtained, so the determination of OX in presence of its alkaline (or acidic) degradate was essential. The structure of the alkaline (also obtained by acid hydrolysis) degradate was elucidated by IR and mass spectrometry where the IR spectrum of the degradate showed the band of carbonyl group shifted to 1726 cm^{-1} and a new broad band at 3420 cm^{-1} indicating the presence of a hydroxyl group of carboxylic acid resulting from hydrolysis. The mass ion peak of the degradate was at m/z 234 as shown in Figs. 3 and 4. Therefore one can conclude that carrying out the alkaline (or acidic) hydrolysis of OX may proceed as shown in Fig. 5.

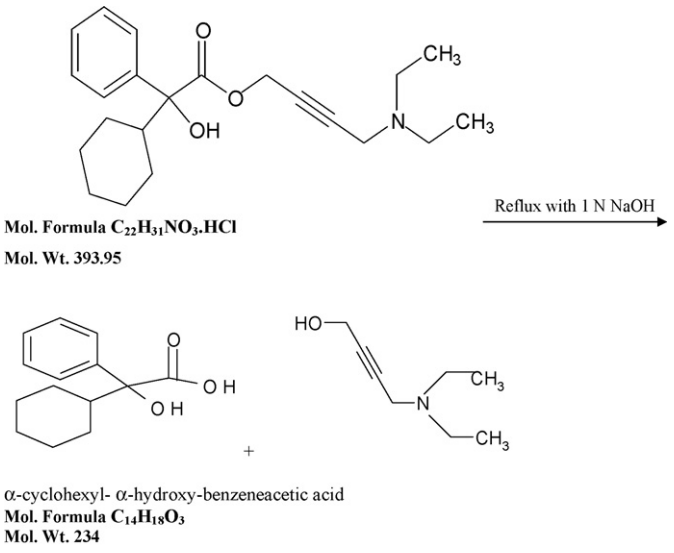

Fig. 5. Scheme of hydrolysis of oxybutynin hydrochloride.

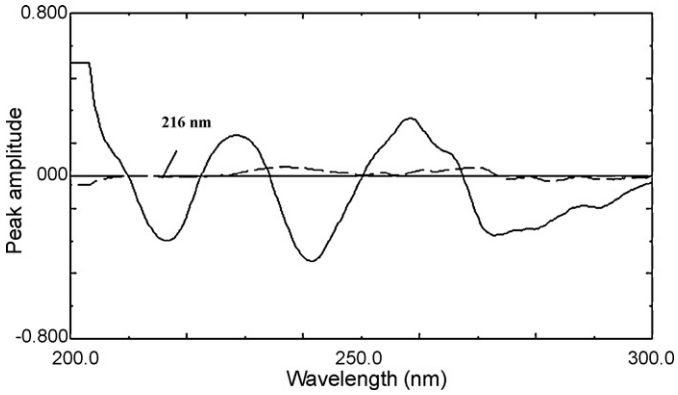

Fig. 6. First derivative of the ratio spectra of 15 μg/mL of oxybutynin hydrochloride (——) and 15 μg/mL of its degradate (------) using 20 μg/mL of the degradate as a divisor and 0.1N HCl as a blank.

3.1. DD^1 spectrophotometric method

OX can be assayed by dividing the absorption spectra of its different concentrations in the range (6–28 μg/mL) by the absorption spectrum of degradate (20 μg/mL), the obtained ratio spectra were differentiated with respect to wavelength ($\Delta\lambda = 4$, scaling factor = 10) (Figs. 6 and 7).

DD^1 values showed good linearity and accuracy at $\lambda = 216$ nm. The linear regression equation was found to be:

$$Y = 0.0196C - 0.0351, \qquad r = 0.9997$$

where Y is the peak amplitude at 216 nm, C is the concentration in μg/mL and r is the correlation coefficient.

To optimize this method, it was necessary to test the influence of variables:

(a) The divisor and its concentration: it was found that the degradate of OX as a divisor could solve the overlap of OX, and give high selectivity. Different concentrations of the degradate were tested, but concentration of (20 μg/mL) gives the best results.

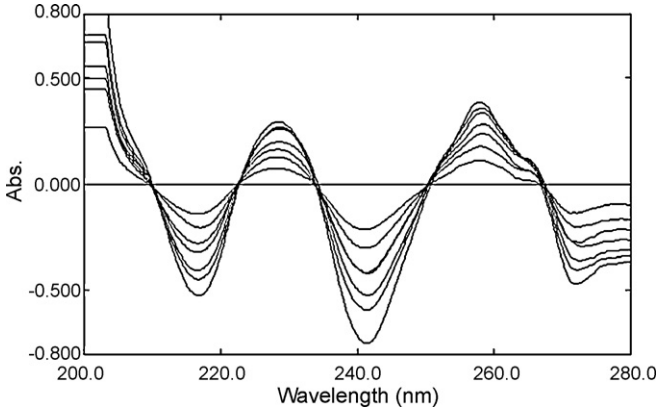

Fig. 7. First derivative of ratio spectra of different concentrations of oxybutynin hydrochloride using 20 μg/mL of its degradate as a divisor.

Table 2
Determination of oxybutynin hydrochloride in presence of its degradate in laboratory prepared mixtures by the DD[1] method.

Degradate %	Recovery[a] % of OX by DD[1] method at 216 nm
10	98.30
20	97.31
30	100.24
40	102.29
50	101.60
60	99.50
70	101.97
80	103.37
Mean ± SD	100.57 ± 2.099

[a] Average of 3 experiments.

(b) Different smoothing factors ($\Delta\lambda$) values were tried where a smoothing factor = 4 showed a suitable signal to noise ratio and the spectra showed good resolution. Different scaling factor values were tried where scaling factor 10 was suitable to enlarge the signal of OX to facilitate its measurement and to diminish error in reading signal.

Different synthetic laboratory prepared mixtures were made to give evidence to this proposal, where OX could be determined in presence of up to 80% of the degradation products without interference with mean percentage recovery100.57 ± 2.099 (Table 2).

The DD[1] spectrophotometric method was applied successfully for the determination of OX in Uripan® tablets and Detronin® tablets and the validity of the method was further assessed by applying the standard addition technique (Table 3). for Uripan® and Detronin® syrup, the preservatives methylparaben and propylparaben were interfered with the determination as they possess high absorbance bands at 256 nm.

3.2. Chemometric methods

3.2.1. Principal component regression (PCR)

The principal component regression method combines the principal component analysis (PCA) with an inverse least square (ILS) regression to create a quantitative model for complex samples. The eigenvectors resulting form the data decomposition represent the spectral variations that are common to all of the spectroscopic calibration data. Therefore, using the new data to calculate a regression model instead of straight spectral responses will produce a robust model for predicting concentrations of the desired constituents in very complex samples [13].

3.3. Partial least-squares (PLS)

Partial least-squares is a quantitative spectral decomposition technique that is closely related to (PCR). However, in PLS, the decomposition is performed in a slightly different fashion. In PCR method only the information in the matrix is used during data decomposition, but in the PLS method, the concentration data matrix is also used in this step. When the decomposition and regression are made at the same time, for all components, the type is named PLS-2, but if the decomposition and regression are made separately for each component the name given is PLS-1. The main advantage of PLS-2 is the higher speed and less complexity, but these advantages have become less important owing to the increase in calculation speed of computers so PLS not only has the advantage of PCR, but also it produces more robust model as it removes noise from both absorbance and concentration data [14,15].

The first step in the determination of the cited drug by multivariate calibration methods involves constructing the calibration matrix for the binary mixture. The calibration set was obtained by using the absorption spectra set of 16 mixtures of OX and its degradate with different ratios of each component. The initial model was

Table 6
Summary of results obtained by applying the diagnostic tools for model validation of the chemometric methods.

Validation parameters	PCR	PLS
(a) Predicted vs. known concentration plot		
1-Slope	0.9762	0.9759
2-Intercept	0.1625	0.1963
3-Correlation coefficient	0.9995	0.9996
(b) Residual vs. actual concentration plot ± error in prediction	0.31	0.32
(c) RMSEP	0.17	0.15

found to give bad results so the regions from 200 to 207 nm and above 340 nm were rejected.

Selection of the optimum number of factors is very important step before constructing the models, because if the number of factors retained is more than the required, more noise will be added to the data. On the other hand, if the number retained is too small meaningful data that could be necessary for the calibration may be discarded. In this study, the data was autoscaled as a pre processing step, leave one out cross validation method was applied and the root mean squared error of calibration RMSEC values of different developed models were compared. The selected model was that with the smallest number of factors such that RMSEC for that model was not significantly greater than RMSEC from model with an additional factor. Five factors were found suitable for both PCR and PLS.

To assess the prediction ability of the suggested models, an external validation set was used. The root mean squared error of prediction (RMSEP) values were calculated and found to be 0.17 for PCR method and 0.15 for PLS method. The percentage recoveries of the validation samples are shown in Table 4.

The two chemometric PCR and PLS methods were successfully applied for the determination of OX in Uripan® tablets, Detronin® tablets.

In order to apply the developed methods for determination of OX in Uripan® syrup and Detronin® syrup, model updating was performed in order to remove the interference of both methylparaben and propylparaben.

[b] Average of 3 experiments.

3.4. Model updating

Multivariate calibration models can be updated by including samples containing the new sources of data variance, $\mathbf{X}_{new}$, to the existing calibration set, **X**, and the concentrations of the new samples $\mathbf{Y}_{new}$ is added to the existing concentration matrix **Y**. This can be represented as follows:

$$\mathbf{X}_{upd} = \begin{bmatrix} \mathbf{X} \\ \mathbf{X}_{new} \end{bmatrix} \qquad \mathbf{Y}_{upd} = \begin{bmatrix} \mathbf{Y} \\ \mathbf{Y}_{new} \end{bmatrix}$$

The updated model was capable of predicting the concentrations of the OX of the syrup with good accuracy and precision without reconstruction of the calibration set, the minimum number of samples necessary to update efficiently the developed model was also studied.

Models updating was applied to predict the concentration of OX in Uripan® and Detronin® syrup formulation which containing different spectral characteristics. The minimal number of samples needed to efficiently update the developed models must be accurately determined. The influence of the number of samples added to the calibration set on RMSEP was studied for each developed multivariate calibration model. One to six samples containing OX in the concentration ranges of 6–18 μg/mL were added to the initial calibration set. The predictive ability of the updated models was checked using external validation samples of syrup dosage form. For Uripan® syrup six samples are necessary to perform an efficient update of the PCR and PLS models while four samples from Detronin® syrup are necessary to perform an efficient update of the PCR and PLS models for Detronin® syrup Table 5.

3.4.1. Validation of PCR and PLS models

The validation of the developed PCR and PLS models was assessed using several diagnostic tools, Table 6. These tools were grouped into two categories in model diagnostic tools that are used to determine the quality of the model and sample diagnostic tools which are used to study the relationship between the samples and to identify unusual samples.

The predicted concentrations of the validation samples were plotted against the true concentration values. This was used to determine whether the model accounted for the concentration variation in the validation set. All plots had a slope of nearly one and an intercept close to zero Table 6.

The RMSEP was another diagnostic tool for examining the errors in the predicted concentrations, it indicates both the precision and accuracy [16]. The results in Table 6 indicating the high predictive abilities of the two models.

3.4.2. HPTLC-densitometric method

The TLC-densitometric method was successfully applied for the determination of OX in pure form, in presence of its degradate and in tablets and syrup. The TLC-densitometric method was characterized by separation OX from methylparaben and propylparaben successfully and efficiently separates from its degradation product. This method offers a simple way to quantify directly on TLC plate by measuring the optical density of the separated bands. The amounts of compounds are determined by comparing to a standard curve from reference materials chromatographed simultaneously under the same condition [17].

Studying the optimum parameters for maximum separation was carried out by trying different developing systems with different ratios but complete separation of the drug, its degradate and parabens was achieved by using chloroform:methanol:ammonia solution:triethylamine (100:3:0.5:0.2, v/v/v/v) as a mobile phase which gave good resolution, sharp and symmetrical peak of OX as shown in Fig. 8.

Table 8
Regression parameters and results of determination of pure samples of OX by DD[1] spectrophotometric and spectrodensitometric methods.

Parameters	DD[1] spectrophotometric method	Spectrodensitometric method
Calibration range	6–28 μg/mL	2–14 μg/band
Slope	0.0196	0.0476
Intercept	−0.0351	0.0782
Mean	100.15	99.77
SD	1.592	1.069
Coefficient of variation	0.016	0.011
Correlation coefficient	0.9997	0.9997
RSD%[a] **	1.279–1.498–1.095	1.157–1.325–0.766
RSD%[b] **	1.184–1.684–1.584	1.417–1.114–1.076
LOD[c]	3.5 μg/mL	0.56 μg/band
LOQ[c]	5.5 μg/mL	1.85 μg/band

RSD%[a] ** and RSD%[b] **; the intra- and inter-day relative standard deviation of concentrations (8, 10, 12 μg/mL) for DD[1] spectrophotometric method and (4, 8, 10 μg/band) for spectrodensitometric method.

[c] Limit of detection and quantitation are determined via calculations [18]. LOD = 3.3 × SD/slope LOQ = 10 × SD/slope. And determined experimentally for spectrodensitometric method.

Table 9
Parameters of system suitability of the TLC-densitometric method.

parameters	OX	Methylparaben	The degradate
Symmetry factor	1.25	1.3	0.98
Resolution (R_s)[a]	1.7	1.5	
Capacity factor (K′)	0.41		
Selectivity (α)[a]	2.107		

[a] The parameters were calculated using OX as reference.

Table 10
Statistical analysis of the proposed methods and the reported method [6] for determination of OX in its pure powdered form.

Items	DD[1] method	Spectrodensitometric method	PCR method	PLS method	Reported method
Mean	100.15	99.77	99.32	99.66	100.02
SD	1.592	1.069	1.632	1.603	2.538
n	11	9	7	7	6
Variance	2.534	1.143	2.663	2.57	6.441
Student's *t*-test (2.23)[a]	0.131	0.02	0.599	0.599	
F-Value (5.05)[a]	2.54	1.033	2.419	2.507	

[a] Figures between parentheses represent the corresponding tabulated values of *t* and *F* at $p = 0.05$.

Table 11
One-way ANOVA testing for the different proposed methods used for the determination of OX.

	Source of variation	DF	Sum of squares	Mean square	*F*-Value
OX	Between exp.	8	3.536	0.442	0.0986
	Within exp.	31	138.888	4.48	

There was no significance difference between the methods using one-way ANOVA (*F*-test), where *F* tabulated = 2.254 at $p < 0.05$.

Different scanning wavelengths were tried; on using 220 nm the separated peaks were more sharp and symmetrical with minimum noise. The R_f values was as follows OX (0.59) parabens (0.28) and the degradate (0.12) as shown in Fig. 8.

The calibration curve was constructed by plotting the integrated peak area $\times 10^{-4}$ versus the corresponding concentration in the concentration range of 2–14 μg/band for OX. The regression equation was calculated and found to be:

$$Y = 0.0476C + 0.0782, \qquad r = 0.9997$$

where, *Y* is the integrated peak area, *C* is the concentration of OX in μg/band and *r* is the correlation coefficient.

The suggested methods are valid and applicable for the analysis of OX in Uripan® tablets, Detronin® tablets, Uripan® and Detronin® syrup. The validity of the proposed methods was assessed by applying the standard addition technique, which showed accurate results and specific for the determination of OX in presence of other excipients as shown in Tables 3, 5 and 7.

Method validation was performed according to USP guidelines [3] for DD1 spectrophotometric and spectrodensitometric methods.

4. Method validation

4.1. Linearity

The linearity of the methods was evaluated by analyzing eleven concentrations of OX ranging between 6–28 μg/mL for DD1 and nine concentrations of OX ranging between 2–14 μg/band for TLC-densitometric. Each concentration was repeated three times. The assay was performed according to the experimental conditions previously mentioned Table 8.

4.2. Accuracy

The accuracy of the results was checked by applying the proposed method for determination of different blind samples of OX. The concentrations were obtained from the corresponding regression equations. From, which the percentage recoveries were calculated with mean percentage recovery 99.75 ± 0.704 for DD1 method and 99.53 ± 1.692 for TLC-densitometric.

Accuracy of the method was further assured by the use of the standard addition technique, it was performed by addition of known amounts of pure OX to known concentrations of the pharmaceutical preparations the resulting mixtures were assayed, and the results obtained were compared with the expected results, Tables 3 and 7. The good recoveries of standard addition technique suggested good accuracy of the proposed methods.

4.3. Precision

4.3.1. Repeatability

Three concentrations of OX (8, 10, 12 μg/mL) for DD1 spectrophotometric method and (4, 8, 10 μg/band) for spectrodensitometric method were analyzed three times intra – daily using the proposed methods. The percentage recoveries and relative standard deviation were calculated, Table 8.

4.3.2. Reproducibility (intermediate precision)

The previous procedures were repeated inter – daily seven times on four different days for the analysis of the three chosen concentrations. The percentage recoveries and relative standard deviation were calculated, Table 8.

4.4. Range

The calibration range was established through considerations of the practical range necessary according to adherence to Beer's law and the concentration of OX present in the pharmaceutical preparations to give accurate precise and linear results Table 8.

4.5. Detection and quantitation limits

According to the ICH recommendations [18], the approach based on the SD of the response and the slope was used for determining the detection and quantitation limits, Table 8.

$$\text{LOD} = 3.3 \times \text{SD/slope} \qquad \text{LOQ} = 10 \times \text{SD/slope}$$

4.6. Selectivity

Selectivity of the methods was achieved by the analysis of different laboratory prepared mixtures of OX and its degradation product for DD1 spectrophotometric within the linearity range. Satisfactory results were shown in Table 2.

4.7. Stability

OX working solution showed no spectrophotometric changes for one week when stored at room temperature (25 °C).

4.8. TLC system suitability

Parameters including resolution (Rs), peak symmetry, capacity factor (K′) and selectivity (α) were calculated (Table 9).

Table 10 shows statistical comparison of the results obtained by the proposed methods and the reported HPLC method [6]. The calculated t and F values are less than the theoretical ones indicating that there is no significant difference between the proposed methods and the reported HPLC method with respect to accuracy and

precision. One-way ANOVA was applied for the purpose of comparison of developed methods Table 11 shows that there was no significant difference between them for the determination of OX.

5. Conclusion

The present work is concerned with the determination OX in presence of its degradate. In this paper simple, sensitive and rapid methods were described for determination of OX in pure form or in pharmaceutical formulations.

DD[1] spectrophotometric method is simple, more convenient, less time consuming and economic stability indicating method compared to other published LC methods.

OX was successfully determined in Uripan® and Detronin® syrup by densitometric and chemometric methods without any interference from excipients.

The suggested methods showed high sensitivity, accuracy, reproducibility and specificity and can be used as stability indicating methods. Moreover, these methods are simple and inexpensive, permitting their application in quality control laboratories.

ABSTRACT

A new type of amperometric glucose biosensor based on silicon dioxide coated magnetic nanoparticle decorated multiwalled carbon nanotubes (Fe_3O_4@SiO_2/MWNTs) on a glassy carbon electrode (GCE) has been developed. MWNTs have been synthesized by catalytic chemical vapour decomposition (CCVD) of acetylene over rare earth (RE) based AB_3 alloy hydride catalyst. The as-grown MWNTs have been purified and further functionlized. Functionalized MWNTs have been decorated with magnetic Fe_3O_4 nanoparticles which have been uniformly coated with biocompatible SiO_2 using a simple chemical reduction method. The characterization of magnetic nanoparticle modified MWNTs have been done by X-ray diffraction (XRD), Fourier transform infra red spectroscopy (FT-IR), scanning electron microscope (SEM), transmission electron microscope (TEM), vibrating sample magnetometer (VSM), energy dispersive X-ray analysis (EDX) and UV–vis spectroscopy. Amperometric biosensor has been fabricated by the deposition of glucose oxidase (GOD) over Nafion-solubilized Fe_3O_4@SiO_2/MWNTs electrode. The resultant bioelectrode retains its biocatalytic activity and offers fast and sensitive glucose quantification. The performance of the biosensor has been studied using cyclic voltammetry and amperometry and the results have been discussed. The fabricated glucose biosensor exhibits a linear response from 1 μM to 30 mM with an excellent detection limit of 800 nM indicating the potential applications in food industries.

1. Introduction

Magnetic core–shell Fe_3O_4@SiO_2 nanoparticles as specially immobilizing carrier of biomolecules have aroused great interest in current researches. The inner iron oxide core with outer shell of silica not only stabilizes the nanoparticles in solution but also provides sites for surface modification with various biomedical ligands in biomedical applications. The coating of silica on the magnetic nanoparticles facilitated the dispersion of nanoparticles [1,2]. Due to their unique physical, chemical, and mechanical properties, superparamagnetic composite nanoparticles (NPs) hold much promise for biosensor applications [3–5]. Superparamagnetic iron oxide core of individual NPs becomes more efficient at dephasing the spins of surrounding water protons, enhancing spin–spin relaxation times (T_2 relaxation times) so that the NPs act as magnetic relaxation switches (MRS) [6]. Carbon nanotubes (CNTs) are one of the most studied nanomaterials for application in biosensor technologies, by immobilizing bioactive molecules on their surfaces through covalent or non-covalent bonds. The nanodimensions of CNTs guarantee a very large active surface area and are especially suited for the conception of miniaturized sensors. In addition to this, high porosity and reactivity makes them ideal candidates for the storage of neutral species as well as electron donors when used as electrodes in electrochemical reactions [7–9].

Compared with the corresponding CNTs-free biosensor, the CNTs-doped counterpart exhibited enhanced stability and sensitivity. Surface functionalization aids CNTs to become biocompatible, improving their solubility in physiological solutions and selective binding to biotargets. CNTs functionalization with biomolecules may occur by adsorption, but covalent tethering provides better stability, accessibility, selectivity and reduced leaching, and usually occurs by an amidation reaction [10]. CNTs are also used for dramatically amplifying enzyme-based bioaffinity electrical sensing of proteins and DNA [11]. Compared with single walled nanotubes (SWNTs), much cheaper multiwalled nanotubes (MWNTs) produced by chemical vapour deposition have more structural defects and thus provide more sites for biomolecule immobilization [8]. Non-covalently functionalized CNTs may also immobilize glucose and small molecules [12].

Nanocomposite materials may play an important role for improving functionalized electrodes envisaging commercial applications. Nanoparticles, especially metal nanoparticles, are an emerging issue in biosensor design, and they have been combined with CNTs to modify a glassy carbon electrode, thus improving the

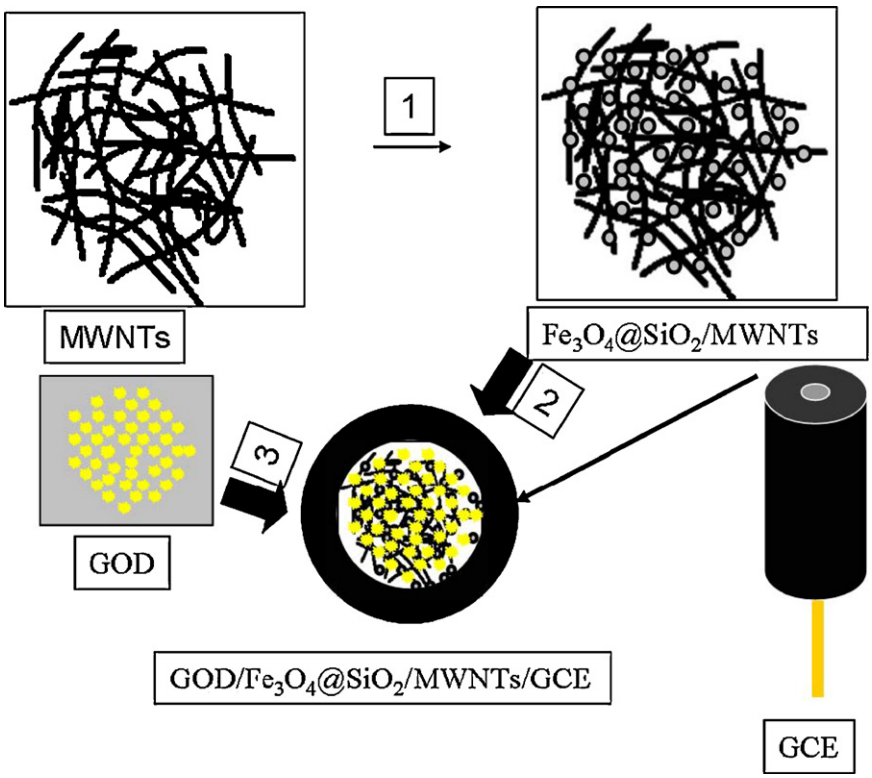

Fig. 1. Schematic of fabricated GOD/Fe_3O_4@SiO_2/MWNTs/GC electrode.

electroactivity and selectivity for glucose [13]. Metal nanoparticles have been applied as catalysts in numerous biosensor applications, due to their superior stability and complete recovery in biochemical redox processes. However, other groups showed that immobilization of the Au nanoparticles (or other metal nanoparticles) on the electrode surface would also cause similar catalytic effect on the electrochemical responses. Amperometric detection of glucose was developed using Au nanoparticles and CNT-multilayer membranes [14].

An electrochemical study with cyclic voltammetry and impedance analysis confirmed that glucose oxidase molecules suffer minimal structure changes after being immobilized on the surface of CNTs, retaining the ability to interact with small biomolecules (e.g., ethidium bromide) [7]. In this present study, MWNTs functionalized with nitric acid, in order to introduce carboxylic acid groups, have been used for the preparation of Fe_3O_4@SiO_2/MWNTs-based electrodes. Prior to immobilization, glucose oxidase (GOD) was physically adsorbed on these modified electrodes. Here, we show a good performance, fast response, nice stability and reproducibility, and a low detection limit of Fe_3O_4@SiO_2/MWNTs nanocomposite based on the reduction of H_2O_2 by immobilizing glucose oxidase on the composite.

2. Experimental

2.1. Materials

Glucose oxidase (GOD, from *Aspergillus niger*), tetraethoxysilane (TEOS) were purchased from Sigma. 0.1 M phosphate buffer solution (PBS, pH 7) prepared using potassium phosphate dibasic anhydrous and potassium dihydrogen orthophosphate. Ferric chloride ($FeCl_3{\cdot}6H_2O$), ferrous sulphate ($FeSO_4{\cdot}7H_2O$), ethanol and ammonium hydroxide (25%) were of analytical grade and deionised (dI) water was used throughout.

2.2. Sample preparation

Carbon nanotubes were synthesized by catalytic chemical vapour deposition over an alloy hydride catalyst. Rare earth based AB_3 alloy hydride was made by arc melting followed by several cycle of hydrogen absorption/desorption process. The catalyst was kept inside a furnace and acetylene (carbon precursor) was allowed at a temperature range 650–750 °C, in an inert atmosphere. Pyrolysis of acetylene was taken place at that temperature and MWNTs start growing. The as-grown MWNTs were purified before using for any applications. The amorphous carbon can be removed by heating the as-grown sample in oxygen atmosphere. Refluxing in concentric acids has been shown to be an

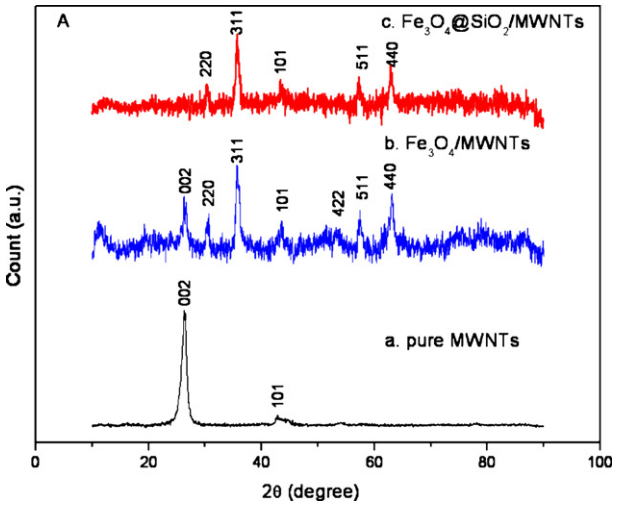

Fig. 2. X-ray diffractograms of (a) pure MWNTs, (b) Fe_3O_4/MWNTs and (c) Fe_3O_4@SiO_2/MWNTs.

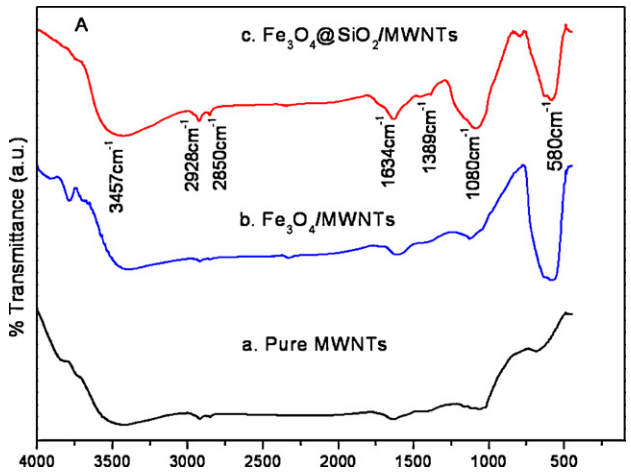

Fig. 3. FT-IR spectrum of (a) pure MWNTs, (b) Fe_3O_4/MWNTs and (c) Fe_3O_4@SiO_2/MWNTs.

effective method for the separation of the catalytic impurities [15].

Hydrated ferric chloride and ferrous sulphate precursors were dissolved in 100 ml water and heated to 90 °C, and then two solutions, 10 ml of ammonium hydroxide (25%) and 0.5 g of functionalized MWNTs dissolved in 50 ml of water, were added rapidly and sequentially. The mixture was stirred at 90 °C for 30 min and then cooled to room temperature. The black precipitate was collected by filtrating and washed to neutral with water. The obtained black precipitate was Fe_3O_4/MWNT nanoparticles and was ready for use.

Core–shell Fe_3O_4@SiO_2/MWNT nanoparticles were prepared by growing silica layers onto the surface of the Fe_3O_4/MWNTs as described by Lu et al. [16]. Twenty-five milliliters of ethanol, 1 ml water, 1 ml ammonium hydroxide and 150 μl of TEOS were added in a 250 ml three neck flask in a 40 °C water bath. Add Fe_3O_4/MWNTs to the above solution under mechanical stirring. Aliquots of the mixture were takes out after 12 h by centrifugation and washed with dI water and vacuum-dried at 50 °C overnight.

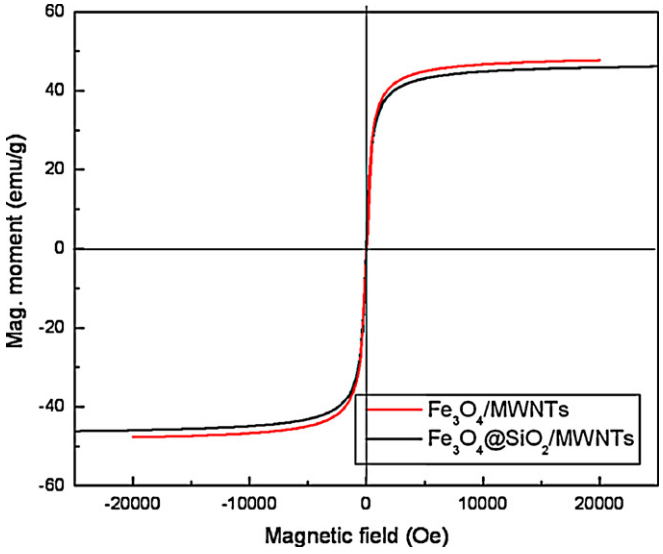

Fig. 4. VSM study of Fe_3O_4/MWNTs (red line) and Fe_3O_4@SiO_2/MWNTs (black line). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

2.3. Fabrication of the amperometric immunosensor

The GCE (3-mm diameter) was first polished on chamois leather with 0.05-μm alumina slurry and then washed ultrasonically in doubly distilled water, anhydrous ethanol, and doubly distilled water, respectively. The cleaned GCE was allowed to dry at room temperature.

Fe_3O_4@SiO_2/MWNTs was sonicated in 0.5% Nafion solution to give a concentration of ~1 mg/ml. For example, four microliters of the Fe_3O_4@SiO_2/MWNTs suspension was film-cast onto the surface of the GC electrode and allowed to dry slowly. Films formed from Nafion-solubilized MWNTs are more uniform and stable than those cast from organic solvents. Nafion assists the dispersion of Fe_3O_4@SiO_2/MWNTs, whereby the Fe_3O_4@SiO_2/MWNTs remains well dispersed on prolonged standing. 16 μl of 100 U GOD solution was film-cast onto the surface of the Fe_3O_4@SiO_2/MWNTs/GC electrode and allowed to dry slowly at 4 °C. The obtained Fe_3O_4@SiO_2/MWNTs/GC electrode was washed carefully with DI water and dried at less than 4 °C. Fig. 1 shows the schematic of fabrication of Fe_3O_4@SiO_2/MWNTs/GC electrode. These Fe_3O_4@SiO_2/MWNTs/GC electrodes were coated with an extra 2.5 μl layer of 0.5% Nafion. The electrodes were rinsed with pH 7 phosphate buffer solution (PBS) and stored in the buffer at 4 °C prior to use.

2.4. Characterization methods

The electrochemical measurements were performed with CH Instruments CHI 608C Electrochemical Analyzer/Workstation. A platinum wire counter electrode, Ag/AgCl (3 M KCl) reference electrode and glassy carbon electrode (GCE, diameter 3 mm) were inserted into a modified 5–10 ml glass cell for the measurement. All potentials are referred to the Ag/AgCl reference electrode. The samples were characterized using different techniques. Powder X-ray diffraction studies were carried out using a X'Pert PRO, PANalytical diffractometer with nickel-filtered Cu Kα radiation as the X-ray source. The sample was scanned in steps of 0.016° in the 2θ range 10–90°. Identification and characterization of functional groups were carried out using PerkinElmer FT-IR spectrometer in the range 300–4000 cm^{-1}. The surface morphology of the sample was done by using scanning tunneling microscope (SEM) (FEI; QUANTA scanning electron microscope) with EDX system. The EDX system attached with the SEM enables the elemental analysis of the samples. The TEM images were obtained on a transmission electron microscope (TEM, JEOL JEM-2010F). UV absorption spectra of the samples in deionized water were recorded on JASCO Corp., V-570 spectrophotometer. Magnetic study of the samples had been done by vibrating sample magnetometer (VSM).

3. Results and discussion

3.1. XRD and FT-IR studies of the samples

The XRD pattern in Fig. 2 indicates that the crystal structure of magnetic nanocomposites comprises MWNTs, two phases of cubic Fe_3O_4/MWNTs and Fe_3O_4@SiO_2/MWNTs. Well-resolved diffraction peaks reveal the good crystallinity of the Fe_3O_4 specimens, which are located at 2θ of 30.28°, 35.56°, 43.3°, 53.68°, 57.36° and 62.72°, respectively. These data matched well with the peer Ref. [17]. The peaks in the Fe_3O_4@SiO_2/MWNTs reveal that even after the SiO_2 coating the sample retains its crystallinity [18]. The absence of SiO_2 peak in the XRD pattern in the composite is due to its amorphous structure coated on the Fe_3O_4 nanoparticles. The diffraction peak at 2θ = 26.4° is the typical Bragg peak of pristine MWNTs and can be indexed to the (0 0 2) reflection of graphite. Judging from the pat-

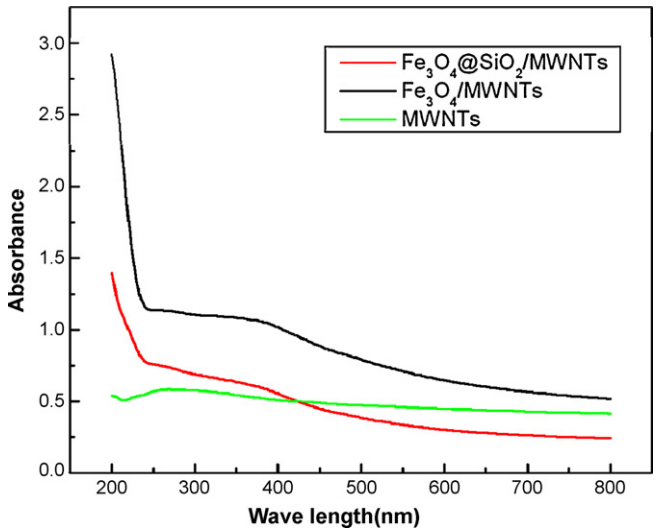

Fig. 5. UV–vis absorbance study of pure MWNTs (green), Fe_3O_4/MWNTs (black) and Fe_3O_4@SiO_2/MWNTs (red). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

tern, the third phase does not exist. The average grain size (D) of the Fe_3O_4 particles was calculated using Scherrer's formula described by

$$D = \frac{0.9\lambda}{\beta \cos(\theta)} \quad (1)$$

λ is wave length of X-ray used, β is FWHM of diffraction peak and θ angle corresponding to the peak. The calculated average grain sizes using 35.56° diffraction peak were ~25 nm. Moreover, the diffractive peaks of Fe_3O_4 are broadened, implying that the crystalline size of Fe_3O_4 particles is quite small.

Selectivity of MWNTs-based biosensors may be introduced by anchoring on the MWNTs surface, specific functional groups that selectively bind specific target molecules. All types of MWNTs show peaks between 1300 and 1100 cm^{-1}, which are ascribed to the phenyl-carbonyl C–C stretch bonds (Fig. 3(a)). The peak between 3300–3500 cm^{-1} is normally due to stretching vibration mode of OH and NH group. The peak at 3457 cm^{-1} in curve (a) and curve (b) is due to OH group (due to oxidation with HNO_3) and in curve (c) it is due to both OH and –NH (from ammonia solution). One can see a small broadening of this peak in the case of curve (c). As seen from Fig. 3(b), the peak at 568 cm^{-1} is the stretching vibration due to the interactions of Fe–O–Fe in Fe_3O_4 and the peaks at 1383, 2850 and 2928 cm^{-1} are attributed to the in-plane bending vibration of methyl ($-CH_3$) and the symmetric and asymmetric vibration of methylene ($-CH_2-$). Compared with the two spectra (b and c), the existence of the characteristic Si–O–Si peak at 1080 cm^{-1} in Fig. 3(c) is direct evidence to verify the formation of the silica shell. From Fig. 3(b) and (c), we can also see that the characteristic Fe–O–Fe peak of Fe_3O_4/MWNTs at 568 cm^{-1} shift to 580 cm^{-1} in the spectrum of SiO_2 coated magnetic nanoparticles. It is inferred that the silica shell is linked to the surface of the magnetic nanoparticles by a Fe–O–Si chemical bond [19]. It is generally accepted that the interpretation of surface groups can only be qualitative, as they cannot be expected to behave as isolated functional groups [20].

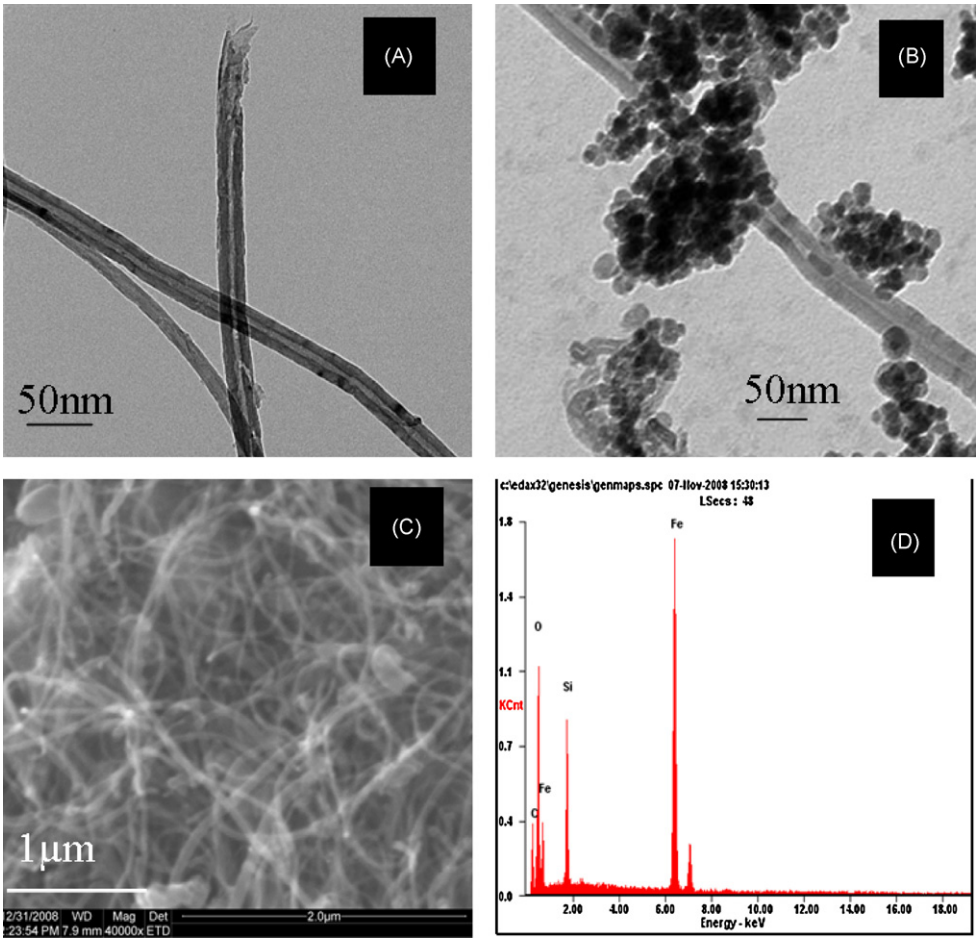

Fig. 6. TEM image of (A) pure MWNTs, (B) Fe_3O_4@SiO_2/MWNTs, (C) SEM image of pure MWNTs and (D) EDX for Fe_3O_4@SiO_2/MWNTs.

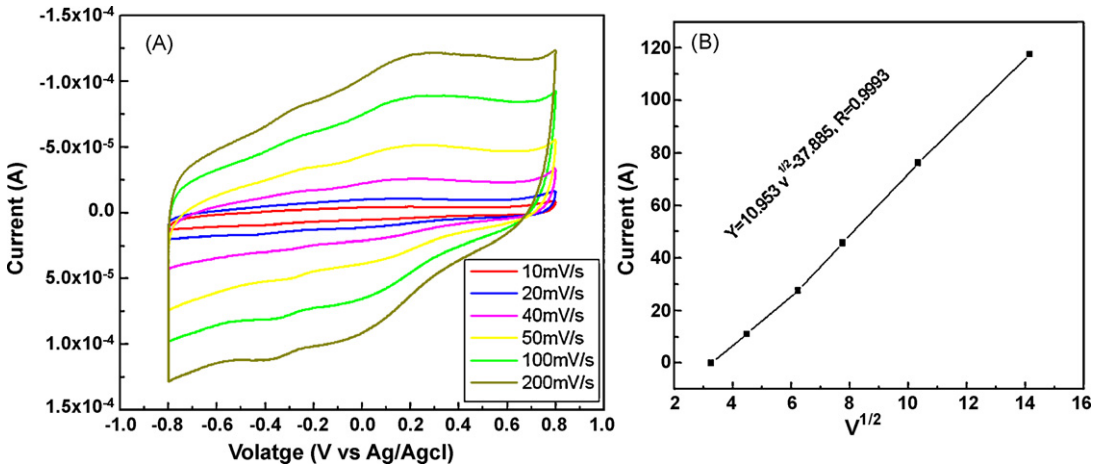

Fig. 7. (A) Fe_3O_4@SiO_2/MWNTs modified electrode at different scan rates in PBS (0.1 M, pH 7) and (B) the plot of peak anodic peak current vs. $v^{1/2}$.

3.2. Magnetic and optical studies of samples

Fig. 4 exhibits the hysteresis loop of the as-prepared sample at room temperature. It can be seen that the saturation magnetization of Fe_3O_4@SiO_2/MWNTs (~44 emu/g) is almost comparable to that of Fe_3O_4/MWNTs (~46 emu/g), which indicates that Fe_3O_4 nanoparticles covered by a silica network can preserve their superparamagnetic properties.

The UV–vis absorption spectrum of different samples in deionized water is illustrated in Fig. 5. A very broad absorption peak appeared at about 267 nm, which originated from the C=C structure of MWNTs [21]. The optical properties of all the magnetic nanoparticles used (with or without silica coating) are dominated by a broad featureless absorption tail characteristic of indirect band gap semiconductors. In the wavelength of >330 nm region, a broad featureless adsorption could be observed in the curves with SiO_2 and without SiO_2 originates primarily from the absorption and scattering of light by magnetic particles, which is in accordance with the previous literatures [22], and is the characteristic of indirect band gap semiconductors [23].

3.3. SEM and TEM analysis of the samples

The morphology of the purified MWNTs is clearly visible from the SEM image shown in Fig. 6(C). Fig. 6(A and B) illustrates the TEM images of the synthesized MWNTs and prepared Fe_3O_4@SiO_2/MWNTs core–shell nanoparticles. The open end of the MWNTs are clearly visible from the TEM image. The diameter of the MWNTs is ~25 nm. With the help of references [24,25] and the TEM and EDX shown in Fig. 6(B and D) we can see that the sample is nearly in core–shell structures, with black color shows Fe_3O_4 and ash color is the SiO_2 shell. This indicates the successful coating on the surface of the magnetic particles with silica. The EDX shown in Fig. 6(D) confirms the presence of iron and silicon in the sample. Inorganic compound functionalized iron oxide NPs can greatly enhance the antioxidation properties for naked iron oxide NPs, and its corresponding scope of application has been greatly extended. Moreover, inorganic compounds functionalized iron oxide NPs are very promising for application in catalysis, biolabeling, and bioseparation [26].

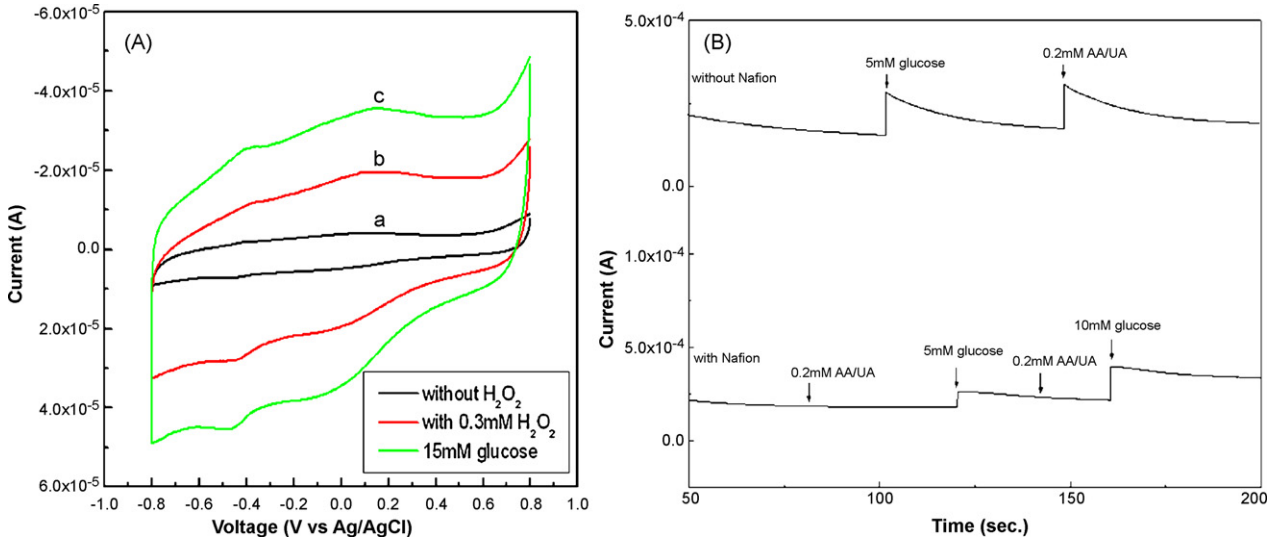

Fig. 8. (A) displays the CV of the Fe_3O_4@SiO_2/MWNTs modified electrode (a) in PBS (b) with 0.3 mM H_2O_2 and (c) 15 mM glucose solution and (B) study of interference due to ascorbic acid and uric acid with and without a selective Nafion film on the GOD/Fe_3O_4 @SiO_2/MWNTs modified electrode.

3.4. Cyclic voltammetry and electrocatalytic properties of the GOD/Fe_3O_4@SiO_2/MWNTs modified electrode toward hydrogen peroxide

Cyclic voltammetry peak currents of the GOD/Fe_3O_4@SiO_2/MWNTs modified electrode increased with scan rate and the peak separation (ΔE_p) was nearly independent of the scan rate (Fig. 7(A)). The anodic peak currents increased linearly with the increase of the square root of scan rate, suggesting that the electrochemical reaction is a diffusion-controlled process (Fig. 7(B)).

Fig. 8(A) shows the cyclic voltammograms of the GOD/Fe_3O_4@SiO_2/MWNTs/GC electrode in the absence (curve a), in the presence of 0.3 mM H_2O_2 (curve b) and in 15 mM glucose solution (curve c). The GOD/Fe_3O_4@SiO_2/MWNTs/GC electrode exhibits significant electrocatalysis to the oxidation and reduction of H_2O_2 starting around 0.1 V, which is even lower than that obtained with the GOD/MWNTs electrode by covalent binding immobilization (0.2 V) [27]. The good performance of the fabricated GOD/Fe_3O_4@SiO_2/MWNTs/GC electrode toward the oxidation of H_2O_2 makes it attractive for glucose sensing applications. When MWNTs were treated with the acid solution, the carboxylic acid functional groups introduced at the end points and surface of MWNTs allow them to adsorb the enzyme of GOD. Since this adsorption was fulfilled through a covalent bond, the link between MWNTs and GOD was more close and stable. Moreover, because the MWNTs have large surface area, they could enhance a large amount of GOD to be immobilized within the nanotubes. The more quantity of GOD made the biosensor possible to engender high response current and expand the detectable range when in a glucose solution.

3.5. Effect of electroactive interferents

The interference of some electroactive compounds to the glucose response was examined. To study this we added 0.2 mM of ascorbic acid (AA) and uric acid (UA) to the solution and checked the GOD/Fe_3O_4@SiO_2/MWNTs/GC electrode with Nafion coating and without Nafion coating. The upper curve in Fig. 8(B) which had been done without Nafion shows the presence of AA and UA. The lower curve in Fig. 8(A) shows the interference study with Nafion coated GOD/Fe_3O_4@SiO_2/MWNTs/GC electrode. There is not much change in the current due to AA and UA. Which clearly shows that 2.5 μl of 0.5 wt% Nafion on the surface of GOD/Fe_3O_4@SiO_2/MWNTs/GC electrode prevent the interference.

3.6. Study of amperometric i–t and calibration curve

The amperometric responses at the GOD/Fe_3O_4@SiO_2/MWNTs/GC electrode for successive addition of different concentration of glucose are presented in Fig. 9 (inset). Well-defined current responses for glucose were obtained at the GOD/Fe_3O_4@SiO_2/MWNTs/GC electrode. The reaction occurring at the biosensor is very fast in reaching a dynamic equilibrium upon each addition of the sample solution, generating a steady-state current signal within 3–6 s. Using the optimum conditions established in the above studies, the calibration of the GOD/Fe_3O_4@SiO_2/MWNTs/GC electrode is depicted in Fig. 9. The steady-state currents gradually increased with increasing concentration of glucose, and exhibited a linear relationship with the concentration of glucose in the range from 1 μM to 30 mM with a detection limit of 800 nM (estimated at S/N = 3) with a correlation coefficient of 0.9994. The performance of GOD/Fe_3O_4@SiO_2/MWNTs/GC electrode is superior than the reported value of GOD/Fe_3O_4@SiO_2/GC electrode which is having

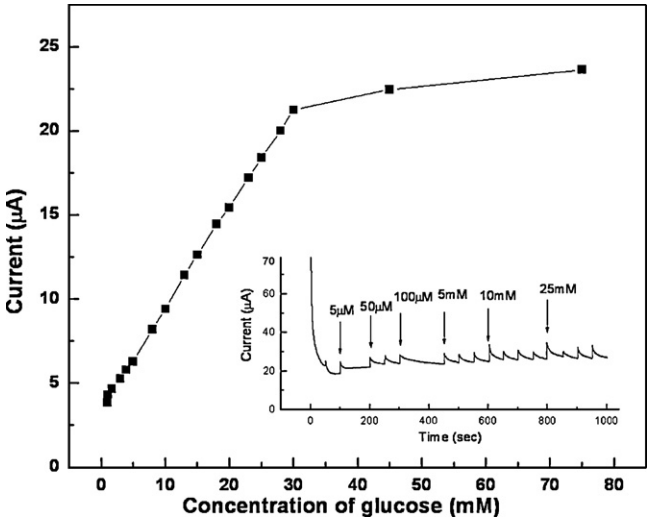

Fig. 9. The calibration curve of the fabricated GOD/Fe_3O_4@SiO_2/MWNTs/GC electrode. Amperometric *i–t* curve with addition of different concentration of glucose solution (inset).

a linear range 1.0×10^{-5} to 4.0×10^{-3} M with a detection limit of 3.2 μM [28].

From Fig. 9, it was observed that the biosensor response gradually deviates from the linear feature as the glucose concentration up to 30 mM. This is the characteristic of a typical Michaelis–Menten kinetics. The apparent Michaelis–Menten constant $K^{app}m$, which depicts the enzyme–substrate kinetics of biosensor, can be calculated from the Line weaver–Burk equation:

$$\frac{1}{I_{ss}} = \left(\frac{K^{app}m}{I_{max}}\right)\left(\frac{1}{C}\right) + \frac{1}{I_{max}} \quad (2)$$

where C is the concentration of substrate, I_{ss} is the steady-state current and I_{max} is the maximum current measured under substrate saturation [29]. Therefore the values of the $K^{app}m$ and I_{max} in this work can be calculated to be 13 mM and 25 μA, respectively. The lower $K^{app}m$ means the higher enzymatic activity of immobilized GOD thus the above result further indicates that the Fe_3O_4@SiO_2/MWNTs modified biosensor possesses a high affinity to glucose [30].

Since MWNTs have excellent electrical conductivity, MWNTs as well as iron oxide dispersed MWNTs attached to the protein shell of enzyme could improve the transfer of electrons between the active redox center of the enzyme. This effect could accelerate the regeneration of GOD and increase the relative activity of the enzyme finally. It is thought to be the mean reason of why the current response of MWNTs and iron oxide dispersed MWNTs modified glucose biosensor was higher than that of the other biosensors.

4. Conclusion

Fe_3O_4 nanoparticles can be successfully stabilized by SiO_2 and Fe_3O_4@SiO_2/MWNTs can be deposited on GCE. GOD can be effectively immobilized on Fe_3O_4@SiO_2/MWNTs/GC electrode to produce a fast direct electron transfer. The immobilized GOD maintains its bioactivity and native structure. Its reduced form can be oxidized by dissolved oxygen to cause an electrocatalytic reaction, which is restrained by glucose due to the reaction between the oxidized form of GOD and glucose. Based on the decrease of electrocatalytic response, a novel glucose sensor has been developed and the resulting sensor displays a high sensitivity (58.9 μA/mM cm^2) and a linear range from 1 μM to 30 mM for glucose determination, and can efficiently exclude the interference of commonly coexisted uric and ascorbic acid. Because of its convenient preparation and

good properties, this biosensor can be used for glucose determination in food industries.

Selective Pb^{2+} determination
Fluorescence quenching

ABSTRACT

A novel fluorescence chemical sensor for the highly sensitive and selective determination of Pb^{2+} ions in aqueous solutions is described. The preliminary potentiometric and spectrofluorimetric complexation studies in solution revealed that the lipophilic ligand 5,8-bis((5′-chloro-8′-hydroxy-7′-quinolinyl)methyl)-2,11-dithia-5,8-diaza-2,6-pyridinophane (**L2**) forms a highly stable and selective $[Pb\mathbf{L2}]^{2+}$ and $[Pb(\mathbf{L2})_2]^{2+}$ complexes which results in a strong fluorescence quenching of the ligand. Thus, a novel fluorescence Pb^{2+} sensing system was prepared by incorporating **L2** as a neutral lead-selective fluoroionophore in the plasticized PVC membrane containing tetrakis(*p*-chlorophenyl) borate as a liphophilic anionic additive. The response of the sensor is based on the strong selective fluorescence quenching of **L2** by Pb^{2+} ions. At pH 5.5, the proposed sensor displays a calibration curve over a wide concentration range of 3.0×10^{-7} to 2.5×10^{-2} M with a relatively fast response time of less than 5 min. In addition to high stability, reversibility and reproducibility, the sensor shows a unique selectivity towards Pb^{2+} ion with respect to common coexisting cations. The proposed fluorescence optode was successfully applied to the determination of lead in plastic toys and tap water samples.

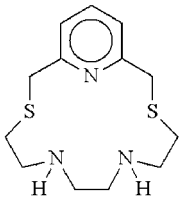
1. Introduction

Forty years of coordination chemistry of macrocylic ligands, after the first discoveries of crown ethers [1] and cryptands [2], have introduced a large number of macrocylic receptors including metal free ligands and coordinatively unsaturated metal complexes, suitable for selective binding and recognition of a wide variety of cationic, anionic and neutral substrates [3–6]. Many of these interesting macrocylic receptors are still waiting to be engineered via linking to a light emitting fragment to act as luminescent sensors for given ions or molecules of prominent interest in biological, medical, environmental and industrial analyses. Due to their interesting coordination chemistry and wide analytical applications, such conjugated chemosensors consisting of a fluorogenic fragment (signaling unit) covalently linked, via an appropriate spacer, to a platform of a macrocyclic or chelating ligand (receptor unit), have attracted the increasing interest of many research groups throughout the world [7–10].

It is worth mentioning that the development of optical sensors has now become a rapidly expanding area of analytical chemistry, because they offer the advantages of simple preparation, reasonable selectivity and sensitivity and no need for separate reference devices [11–13]. Fluorescence is particularly a suitable optical sensing method for designing these optical sensors. This is mainly due to its inherent sensitivity, its almost complete inertness to turbidity and its flexibility with respect to geometric arrangements [11]. The increasing interest in this field is mainly due to the growing demand for highly selective analytical tools for the detection and monitoring of ions in environmental, biological and industrial effluent samples.



Lead poisoning is one of the most common environmental child health threats which can cause brain and kidney damage, mental retardation, behavior problems, development delays, and other physical and mental problems [14]. Due to increased industrial use of lead on one hand and its serious hazardous effects, on the other [14,15], the preparation of lead ion-selective membrane electrodes by using a wide variety of active materials have been extensively

doi:10.1016/j.talanta.2009.11.011

studied. Only in the past 5 years, more than 30 lead ion-selective electrodes have been reported in the literature, some of the most sensitive and selective of which are described in Refs. [16–24]. However, compared with Pb^{2+} selective potentiometric sensors, work on ion-selective bulk optodes for lead(II) ion has been quite sparse [25–29].

In recent years, we have been involved in the synthesis and coordination chemistry of mixed thia–aza macrocycles containing heteroaryl moieties [30,31] and their widespread analytical applications as selective ion carriers for transition and heavy metal ions in solid phase extraction, ion transport and ion-selective electrode studies [30,32,33]. We have recently reported the successful use of some thia–aza macrocyclic ligands with different fluorogenic subunits for the preparation of selective fluorescent optical sensors for some heavy metal ions [34–37]. In this work, we found that the strong fluorescence of the new chemosensor 5,8-bis((5′-chloro-8′-hydroxy-7′-quinolinyl)methyl)-2,11-dithia-5,8-diaza-2,6-pyridinophane, **L2**, quenched considerably, and in a selective manner, upon complexation with Pb^{2+} ions. Thus, we decided to probe the fluoroionophore in plasticized PVC-membranes for sensing of traces of lead in aqueous solutions. 2,11-Dithia-5,8-diaza-2,6-pyridinophane, **L1**, is the mother macrocycle of **L2**.

2. Experimental

2.1. Reagents

Reagent-grade *o*-nitrophenyloctylether (NPOE), dioctyl phthalate (DOP), bis(2-ethylhexyl) sebacate (EHS), potassium tetrakis(*p*-chlorophenyl) borate (KTpClPB), high relative molecular weight high molecular weight poly(vinyl chloride) (PVC), tetrahydrofuran (THF) and acetonitrile were purchased from Fluka chemical company and used as received. Reagent-grade nitrate salts of all cations used (all from Merck) where of the highest purity available and used without further purification except for vacuum drying. All other chemicals and solvents needed were of reagent-grade and used as received. Doubly distilled deionized water was used throughout. *N*,*N*′-bis(2-chloroethyl)ethylendiamine hydrochloride and 2,6-dithiomethylpyridine were synthesised according to the literature [38,39].

2.2. Synthesis of *N*,*N*′*(t-butoxycarbonyl)-bis(2-chloroethyl)ethylendiamine*

Bis(2-chloroethyl)ethylendiamine dihydrochloride (6.5 g, 25 mmol) was added to a cooled solution of sodium hydroxide (8 g, 200 mmol) in 120 mL of water. Di-*tert*-butyl dicarbonate (11.8 g, 54 mmol) was carefully added and the reaction mixture was stirred overnight at room temperature. The product was extracted with ethyl acetate (4× 70 mL), dried over Na_2SO_4 and concentrated in vacuo to obtain the protected diamine as a pale yellow oil (8.2 g, 85% yield).

^{1}H NMR (300 MHz, $CDCl_3$), δ_H 1.42 (s, 18H, C(CH_3)$_3$), 3.36–3.41 (4H, m, NCH_2CH_2Cl), 3.47–3.59 (8H, m, $CH_2NCH_2CH_2Cl$). ^{13}C NMR (75 MHz, $CDCl_3$), δ_C 28.2 (C(CH_3)$_3$), 41.5 (NCH_2CH_2Cl), 49.7 (NCH_2CH_2Cl), 52.6 ($CH_2NCH_2CH_2Cl$), 80.3 ($C(CH_3)_3$), 154.9 (C=O).

2.3. Synthesis of *N*,*N*′*-t-butoxycarbonyl-2,11-dithia-5,8-diaza-2,6-pyridinophane*

A solution of *N*,*N*′-(*t*-butoxycarbonyl)-bis-(2-chloroethyl) ethylendiamine (2.1 g, 13.0 mmol) and 2,6-dithiomethylpyridine (4.7 g, 12.0 mmol) in dry DMF (100 mL) was added, under N_2 over 24 h, to a well stirred suspension of Cs_2CO_3 (6.6 g, 20.3 mmol) in dry DMF (300 mL) maintained at 55 °C. The resultant mixture was stirred for 1 h at 55 °C and left for 24 h at room temperature and subsequently concentrated under vacuum. The residue was taken up in CH_2Cl_2 (150 mL) and the organic extract washed with water, dried over Na_2SO_4 and concentrated under vacuum. The resulting brown residue was purified by crystallization from petroleum ether 40–60° to give a pale white product. (1.57 g, 30% yield). mp: 142–144 °C. Elemental analysis: *Anal.* Calc. for $C_{23}H_{37}N_3O_4S_2$: C, 55.3; H, 7.5; N, 8.4; S, 12.8. Found: C, 55.6; H, 7.7; N, 8.7; S, 12.5%. ^{1}H NMR (300 MHz, $CDCl_3$), δ_H 1.41 (18H, s, C(CH_3)$_3$), 2.41–2.60 (12H, m, $SCH_2CH_2NCH_2$), 3.76 (4H, s, $ArCH_2S$), 7.21 (2H, d, J = 6.0 Hz), 7.62 (1H, t, J = 5.7 Hz). ^{13}C NMR (75 MHz, $CDCl_3$), δ_C 28.3 (C(CH_3)$_3$), 29.6 ($ArCH_2S$), 37.1 (SCH_2CH_2N), 46.6 (SCH_2CH_2N), 48.1 ($SCH_2CH_2NCH_2$), 79.1 ($C(CH_3)_3$), 121.4, 137.7, 154.8, 157.8.

2.4. Synthesis of 2,11-dithia-5,8-diaza-2,6-pyridinophane (*L1*)

Trifluoroacetic acid (20 mL) was added to a solution of *N*,*N*′-t-butoxycarbonyl-2,11-dithia-5,8-diaza-2,6-pyridinophane (1.7 g, 3.51 mmol) in CH_2Cl_2 (20 mL) and the resulting solution was stirred at room temperature under N_2 for 2 h. The solvent was removed under reduced pressure and the residue taken up in water. The pH value was adjusted to 14 by adding 6 M NaOH and the product extracted into CH_2Cl_2. The organic layers were dried over Na_2SO_4, filtered and concentrated under reduced pressure to give a white solid. (0.66, 67% yield). mp. 135-138 °C. Elemental analysis: *Anal.* Calc. for $C_{13}H_{21}N_3S_2$: C, 55.1; H, 7.5; N, 14.8; S, 22.6. Found: C, 54.8; H, 7.8; N, 14.5; S, 22.7%. ^{1}H NMR (300 MHz, $CDCl_3$), δ_H 2.26 (2H, s br, NH) 2.64–2.67 (8H, m, SCH_2CH_2N), 2.74–2.78 (4H, m, $SCH_2CH_2NCH_2$), 3.82 (4H, s, $ArCH_2S$), 7.21 (d, 2H, J = 6.0 Hz), 7.61 (1H, t, J = 5.7 Hz). ^{13}C NMR (75 MHz, $CDCl_3$), δ 32.1 ($ArCH_2S$), 38.0 (SCH_2CH_2N), 47.6 ($SCH_2CH_2NCH_2$), 48.2 (CH_2NCH_2), 121.2, 137.3, 158.7 (aromatic carbons).

2.5. Synthesis of 5,8-bis((5′-chloro-8′-hydroxy-7′-quinolinyl) methyl)-2,11-dithia-5,8-diaza-2,6-pyridinophane (*L2*)

5-Chloro-8-hydroxyquinoline (0.47 g, 2.41 mmol) and paraformaldehyde (0.10 g, 3.34 mmol) were added to a mixture of **L1** (0.30 g, 1.06 mmol) in dry benzene (30 mL). The solution was heated to reflux for 12 h under nitrogen. The solution was filtered off and the solvent was evaporated under reduced pressure. The residue was washed with Et_2O to give a light brown solid (0.45 g, yield 64%). mp: 153–155 °C. Elemental analysis: *Anal.* Calc. for $C_{33}H_{33}O_2N_5S_2Cl_2$: C, 59.5; H, 5.0, N, 10.5; S, 9.6. Found: C, 59.3; H, 4.9, N, 10.3; S, 9.4%. ^{1}H NMR (300 MHz, $CDCl_3$): δ_H 2.60–2.65 (8H, m, SCH_2CH_2N), 2.75–2.81 (4H, m, $SCH_2CH_2NCH_2$), 3.80 (4H, s, $ArCH_2S$), 3.85 (4H, s, NCH_2Q), 7.29 (2H, d, J = 7.2 Hz), 7.45–7.48 (2H, m), 7.70 (1H, t, J = 7.6 Hz,), 8.43 (2H, d, J = 8.4 Hz), 8.84 (2H, d, J = 8.0 Hz). ^{13}C NMR (75 MHz, $CDCl_3$): δ_C 27.0 ($ArCH_2S$), 37.0 (SCH_2CH_2N), 51.0 (NCH_2Q), 54.0 (SCH_2CH_2N), 55.3 ($SCH_2CH_2NCH_2$), 119.4 (C–Cl, Q), 121.5 (Py), 121.9 (Q), 122.5 (Q), 125.7 (Q), 127.5 (Q), 133.1 (Q), 137.9 (Py), 139.2 (C–OH, Q), 148.6 (Q), 151.1 (Q), 158.7

(Py); [Py = pyridine framework, Q = 5-chloro-8-hydroxyquinoline framework].

2.6. Apparatus

All melting points are uncorrected. Microanalytical data were obtained using a Fison EA CHNS-O instrument (T = 1000 °C). The ^{1}H and ^{13}C NMR spectra were recorded on a Varian VXR300 spectrometer (operating at 75.4 MHz). All fluorescence measurements were carried out on a JASCO FP 6200 fluorometer. A Jeneway 3345 Ion Meter calibrated against two standard buffer solutions at pH 4.0 and 7.0 was used for the pH measurements.

2.7. Membrane preparation

The membrane solution was prepared by dissolving 3 mg of fluoroionophore **L2**, 30 mg of powdered PVC, 61 mg of plasticizer NPOE and 6 mg of additive KTpClPB in 1.5 mL THF. A volume of 0.1 mL of this solution was pipetted and uniformly spread onto a 24 mm × 13 mm dust-free glass plate by using a spin on device (at a rate of 2000 rpm). The resulting membrane, thickness of ca 2–3 μm, was then placed in a THF saturated desicator for 2 h, and was allowed to stand in ambient air before use.

2.8. Fluorescence measurements

The film was first soaked for more than 20 min in an acetate buffer solution of pH 5.5 until the membrane had a stable fluorescence value before the first lead measurement was made. During its use the membranes were placed diagonally inside the sample cuvette of the instrument containing 2 mL buffer solution of pH 5.5. The fluorescence intensity, at an excitation wavelength of 388 nm was measured at 515 nm. Then the sample was titrated with standardized lead ion solutions and the fluorescence intensity of the system was measured after ~5 min, required to reach the equilibrium.

2.9. Potentiometric measurements

The pH-metric measurements (pH = −log[H$^+$]) employed for the determination of ligand protonation and metal complex stability constants were carried out in the case of ligand **L1** in 0.10 mol L^{-1} NMe_4Cl aqueous solutions and, in the case of **L2** in 0.10 mol L^{-1} NMe_4Cl water–MeCN (1:1, v/v) solution at 298.1 ± 0.1 K by using equipment and procedure described elsewhere [40]. The choice of such solvent mixture was dictated by the low solubility of the complexes with **L2** in pure water. The combined Ingold 405 S7/120 electrode was calibrated as a hydrogen concentration probe by titrating known amounts of HCl with CO_2-free NaOH solutions and determining the equivalent point by Gran's method [41] which allows one to determine the standard potential E^o and the ionic product of water (pK_w = 13.73 in 0.10 mol L^{-1} NMe_4Cl aqueous solutions, pK_w = 14.99 in 0.1 M NMe_4Cl water–MeCN (1:1, v/v) solution). At least three measurements (about 100 data points each one) were performed for each system in the pH ranges 2.5–10.5. In all experiments the ligand concentration was about 1.0×10^{-3} mol L^{-1}. In the complexation experiments the metal ion concentration was varied from 0.3:1 to 0.9:1. The computer program HYPERQUAD [42] was used to calculate the equilibrium constants from e.m.f. data. In the case of Hg^{2+}, under the experimental conditions employed, the formation of metal-chloride complexes is expected to occur. For the determination of the stability constants of the Hg^{2+} complexes with **L1** in aqueous solution, the formation of Hg^{2+} complexes with chloride was taken into account and their stability constants were taken from Ref. [43]. The stability constants of the Hg^{2+} complexes with chloride in 0.10 mol L^{-1} NMe_4Cl water–MeCN (1:1, v/v) solution are not known and the formation of such complexes was not considered in calculations. Hence, the stability constants of Hg^{2+} complexes with **L2** must be referred to the specific composition of the medium employed (0.10 mol L^{-1} NMe_4Cl water–MeCN (1:1, v/v)).

2.10. Procedure for determination of lead content in children plastic toys

About 10.0 g of plastic toy was placed in a crucible and it heated by flame and then kept in a furnace at 700 °C until it changed into white powder. Then 6 mL of HNO_3/HCl, 1:3 (v/v) solution was added. The mixture was heated until dissolution was complete. The sample solution was further heated to reach a volume of 0.5 mL. The solution was then cooled and completely transferred to a calibrated 100.0-mL volumetric flask. The pH was adjusted to 5.5 by acetate buffer and diluted to volume with doubly distilled water. Proper sample solutions were prepared by appropriate dilution of the mother solution. The lead content of sample was determined by the proposed optical sensor, using the calibration method.

3. Results and discussion

3.1. Solution studies

3.1.1. pH-metric studies

In order to obtain a clue about the stoichiometry and stability of the transition metal complexes of some selected metal ions with 5,8-bis((5′-chloro-8′-hydroxy-7′-quinolinyl)methyl)-2,11-dithia-5,8-diaza-2,6-pyridinophane, **L2**, and its mother macrocycle 2,11-dithia-5,8-diaza-2,6-pyridinophane, **L1**, protonation and metal complexation with ligands was studied by means of potentiometric measurements carried out in aqueous solution, in case of **L1** or in acetonitrile/water 1:1 (v/v) solution, in case of **L2**. The use of the latter solvent mixture is due to very scarce solubility of the metal complexes of **L2** in water. Fig. 1 displays the distribution diagrams for the protonated ligands. The calculated stepwise protonation constants of the ligands are also included in the legend of Fig. 1.

Considering ligand protonation, **L1** and **L2** can bind up to three and two acidic protons in solution, respectively. The values of the constants for both the protonation equilibria of **L2** and for the first two of **L1** range between 9.37 and 6.0 log units, accounting for protonation of the aliphatic amine groups of the macrocycles [44]. In fact, pyridine and 5-chloro-8-hydroxyquinoline are featured by lower basicity constant (for instance log K = 5.22 and 4.22 for protonation of pyridine in water and in CH_3CN/H_2O 1:1 (v/v) medium, respectively) [45]. In the case of **L1**, a third protonation step takes place at more acidic pH values, as expected considering that protonation occurs on the weakly basic nitrogen atom of the pyridine unit. Conversely, in the case of **L2** no further protonation step is observed in the pH range investigated (2.5–10.5). On the other hand, **L2** displays also a deprotonation step, with the formation of the anionic species [**L2**(H_{-1})]$^-$ at alkaline pH values; this process can be attributed to deprotonation of one 5-chloro-8-hydroxyquinoline moiety, in agreement with the known ability of 5-chloro-8-hydroxy-quinoline to deprotonate at strongly alkaline pH values (pK_a = 10.64 in water–dioxane 60:40 mixture) [46]. Deprotonation of the second 5-chloro-8-hydroxy-quinoline was instead not observed in our experimental conditions (pH range 2.5–10.5).

Considering metal complexation, in the case of **L1** the potentiometric studies were generally carried out in the pH range 2.5–10.5, with the only exception for Cu^{2+}, where the pH range

Table 1
Stability constants of the Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+} and Hg^{2+} complexes with **L1** (NMe_4Cl 0.1 mol L^{-1} aqueous solution, 298.1 K) and **L2** (0.1 mol L^{-1} NMe_4Cl water–MeCN (1:1, v/v) solution).

was only 2.0–7.0, due to complex precipitation at alkaline pH values. Similarly, in the case of **L2** the measurements were limited to the pH range 2.0–7.0 for all metal cations, due precipitation of hydroxo-complexes or metal hydroxides in the alkaline region. The formation constants of the complexes are listed in Table 1, while Figs. 2–4 display the distribution diagrams for the complexes with **L1** and **L2**.

Table 1 shows that **L1** forms only 1:1 complexes with all the metal cations investigated. As often found in metal complexation with ligands containing nitrogen atoms, Cu^{2+} and Hg^{2+} form the most stable $[M\mathbf{L1}]^{2+}$ complexes, due to the stabilizing effect of CFSE in the case of Cu^{2+} and to the high affinity of Hg^{2+} for nitrogen donors. The most interesting finding in Table 1, however, is the remarkable higher stability of the $[Pb\mathbf{L1}]^{2+}$ complex with respect to the $[Zn\mathbf{L1}]^{2+}$ and $[Cd\mathbf{L1}]^{2+}$ ones. In fact, it is known that polyamine ligands often form Zn^{2+}, Cd^{2+} and Pb^{2+} complexes with similar stability [47]. In this case, the Pb^{2+} complex is *ca.* 5 orders of magnitude more stable than the Zn^{2+} and Cd^{2+} ones. This selectivity can be interpreted considering the presence of a couple of soft sulfur donors, which generally display a higher binding ability towards the softer Pb^{2+} ion. At the same time, the 15-membered macrocyclic cavity may have the optimal dimensions to host the larger Pb^{2+}.

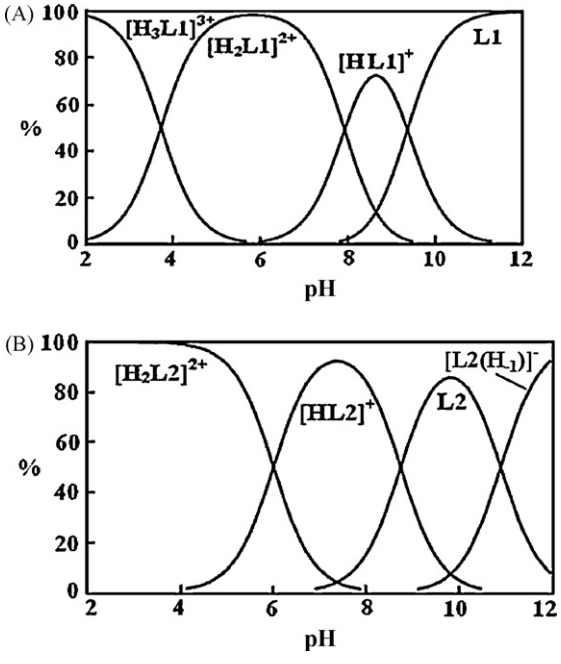

Fig. 1. Distribution diagrams of the protonated species of **L1** (A) and **L2** (B) ($[\mathbf{L1}] = [\mathbf{L2}] = 1.0 \times 10^{-3}$ mol L^{-1}, 298.1 K, 0.1 M NMe_4Cl aqueous solution (**L1**) or 0.1 mol L^{-1} NMe_4Cl water–MeCN (1:1, v/v) solution (**L2**)). In the case of **L1**, the constants (log *K*) for the equilibria $\mathbf{L1} + H^+ = [H\mathbf{L1}]^+$, $[H\mathbf{L1}]^+ + H^+ = H2\mathbf{L1}]^{2+}$ and $[H2\mathbf{L1}]^{2+} + H^+ = [H3\mathbf{L1}]^{3+}$ were respectively 9.37(5), 7.93(9) and 3.7(1), while in the case of **L2** the constants (log *K*) for the equilibria $\mathbf{L2} = [\mathbf{L2}(H^{-1})]^- + H^+$, $\mathbf{L2} + H^+ = [H\mathbf{L2}]^+$ and $[H\mathbf{L2}]^+ + H^+ = [H2\mathbf{L2}]^{2+}$ were respectively 10.9(1), 8.75(9), and 6.00(9).

From this point of view, it can be of interest to compare the stability sequence of the complexes in the present case ($Pb^{2+} > Cd^{2+} \approx Zn^{2+}$) with that previously found in the case of the complexes with macrocycle 2,8-dithia-5-aza-2,6-pyridinophane (**L3**) [47], characterized by an overall structure similar to that of **L1**, but containing a smaller macrocyclic cavity and featuring a N_2S_2 set of donors, instead of the N_3S_2 one of **L1**. Actually **L3** shows a higher affinity for Cd^{2+} over Zn^{2+} and Pb^{2+}. This observation may suggest that the smaller Cd^{2+} cation has the optimal dimension to fit the macrocyclic cavity of **L3**, while the cavity of **L1** is best sized for the larger Pb^{2+} ion.

All the $[M\mathbf{L1}]^{2+}$ complexes show a marked tendency to bind acidic protons affording mono-protonated complexes and, in the case of Pb^{2+} and Hg^{2+}, also diprotonated species (Table 1 and Fig. 2). It is noteworthy that the constants for the addition of the acidic proton to the $[Zn\mathbf{L1}]^{2+}$ and $[Cd\mathbf{L1}]^{2+}$ complexes are remarkably high (log *K* = 8.9 and 9.3 for the equilibrium $[M\mathbf{L1}]^{2+} + H^+ \rightleftharpoons [M\mathbf{L1}H]^{3+}$ with $M = Zn^{2+}$ and Cd^{2+}, respectively). These values are similar to the first protonation constant of the ligand alone (9.37 log units), suggesting that in the $[Zn\mathbf{L1}]^{2+}$ and $[Cd\mathbf{L1}]^{2+}$ complexes protonation occurs on an amine group not involved in metal binding. This observation further supports the hypothesis that the macrocyclic cavity of **L1** is too "large" to optimally host Zn^{2+} and Cd^{2+}.

Finally, deprotonation of a coordinated water molecule affords hydroxo-complexes of the type $[ML(OH)]^+$ at alkaline pH values ($M = Zn^{2+}$, Cd^{2+}, Pb^{2+} and Hg^{2+}; Cu^{2+} coordination was not studied in the alkaline pH region).

The coordination behavior of **L2** is remarkably different with respect to that of **L1**. In fact, while Cu^{2+} and Zn^{2+} forms only 1:1 complexes, at least in the pH range investigated, the larger and softer Cd^{2+}, Pb^{2+} and Hg^{2+} cations give not only 1:1 species, but also complexes featuring a 1:2 metal-to-ligand molar ratio (see Table 1).

Considering Cu^{2+} and Zn^{2+}, metal coordination occurs at acidic pH values (Fig. 3A and B) to give the $[Cu\mathbf{L2}]^{2+}$ or $[Zn\mathbf{L2}]^{2+}$ complexes. Unfortunately, the use of a different solvent in the measurements does not allow reliable comparisons with the stability constants of the corresponding complexes with ligand **L1**. However, the potentiometric titrations also show that the $[Cu\mathbf{L2}]^{2+}$ and $[Zn\mathbf{L2}]^{2+}$ complexes release an acidic proton to form $[Cu\mathbf{L2}(H_{-1})]^+$ and $[Zn\mathbf{L2}(H_{-1})]^+$ species. This process takes place, once again, in the acidic pH region, with pK_a values of 3.5 and 6.9 for the Cu^{2+} and Zn^{2+} complexes, respectively, and it can be reasonably attributed to a metal-assisted deprotonation of the hydroxyl group of one of the 5-chloro-8-hydroxy-quinoline moieties.

Similarly to Cu^{2+} and Zn^{2+} cases, Cd^{2+}, Pb^{2+} and Hg^{2+} form simple $[M\mathbf{L2}]^{2+}$ complexes above pH 2.5 (Figs. 3C–E, 4A–C). In this case, however, this process is followed, at slightly higher pH values by the formation of $[M(\mathbf{L2})_2]^{2+}$ complexes, containing two ligands bound to a single metal. Although the potentiometric data do not allow in this case to infer hypothesis on the structural features of these complexes, it is worth noting that the smaller and more acidic Cu^{2+} and Zn^{2+} ions seem to prefer a binding mode involving deprotonation of the 5-chloro-8-hydroxy-quinoline upon metal coordination, while the larger Cd^{2+}, Pb^{2+} and Hg^{2+} ions appear to be able not only

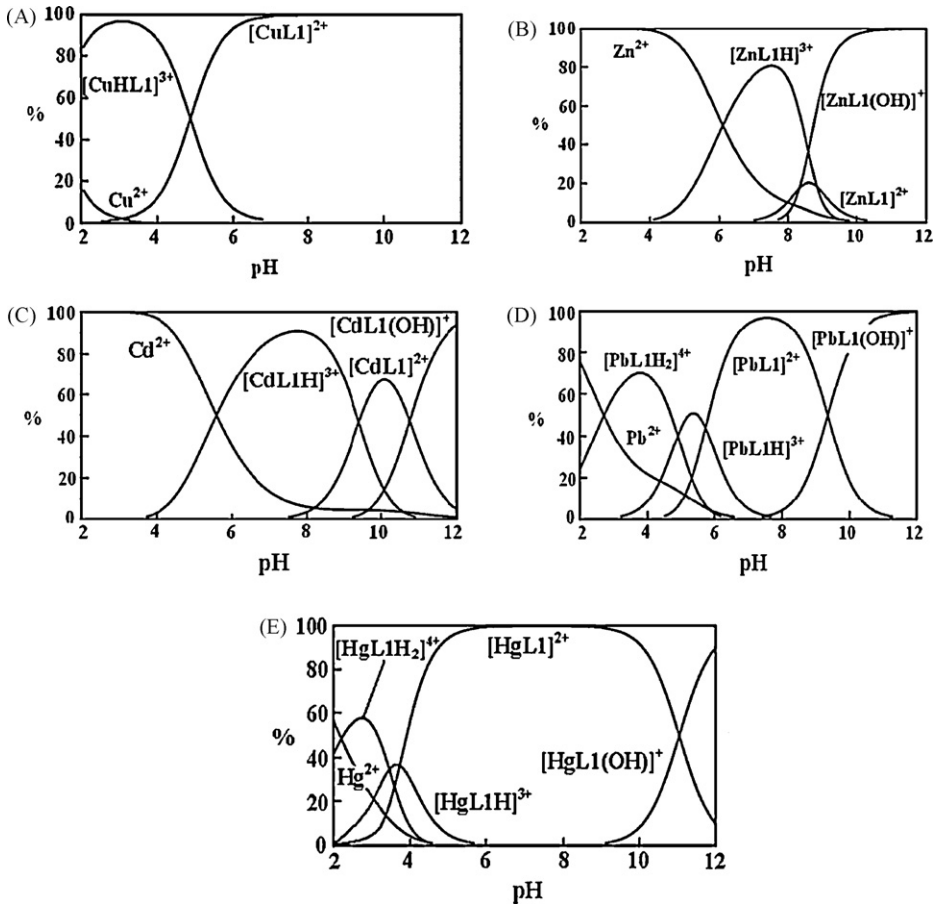

Fig. 2. Distribution of the complexed species of **L1** in the presence of 1 equiv. of Cu^{2+} (A), Zn^{2+} (B), Cd^{2+} (C), Pb^{2+} (D) and Hg^{2+} (E) ([**L1**] = [Cu^{2+}] = [Zn^{2+}] = [Cd^{2+}] = [Pb^{2+}] = [Hg^{2+}] = 1.0×10^{-3} mol L^{-1}, 298.1 K, 0.1 mol L^{-1} NMe_4Cl aqueous solution).

to form "common" 1:1 complexes, but also to arrange two ligand moieties within their coordination sphere.

3.1.2. Fluorescence studies

In order to evaluate whether **L2** could be used as a suitable fluorescent chemosensor for Pb^{2+} ion, we recorded the excitation and emission fluorescence spectra variations that occur upon addition of increasing amount of selected metal cations, and in particular Pb^{2+}, to a MeCN solution of the ligand (8.0×10^{-6} mol L^{-1}) at 25.0 ± 0.1 °C (Fig. 5). As seen from Fig. 5, the excitation and emission spectra of the ligand show sharp bands at 340 nm and 506 nm, respectively, both of which significantly decreased as a function of Pb^{2+}/**L2** molar ratio. The corresponding Pb^{2+}/**L2** plots at maximum excitation (340 nm) and emission (506 nm) wavelengths, shown in Fig. 6, indicate two distinct inflection points at metal ion to ligand mole ratios of 0.5 and 1.0 due to the formation of both [Pb(**L2**)$_2$]$^{2+}$ and [Pb**L2**]$^{2+}$ complexed adducts in solution. It is noteworthy that because of very short fluorescence lifetimes and low concentration conditions used the effect of concentration quenching should be negligible. As is also obvious from Fig. 5, an interesting point about the change in stoichiometry from the 1:2 complex to a 1:1 species upon further addition of the metal is the appearance of new excitation and emission bands at about 375 and 405 nm, respectively, at a Pb^{2+}/**L2** molar ratio of about 0.5 in MeCN solution. These results are nicely in agreement with those obtained from pH-metric study results given in Section 3.1.1.

The resulting fluorescence intensity-molar ratio data for the case of Co^{2+}, Cu^{2+}, Fe^{3+}, Ag^{+}, Hg^{2+}, Y^{3+}, Cd^{2+} and La^{3+} ions are also shown in Fig. 6. As is obvious from Fig. 6, in Y^{3+}, Cd^{2+} and La^{3+} cases, a rather pronounced chelation enhancement of quenching of the fluorescence (CHEQ effect) is observed for **L2** upon addition of increasing quantity of the metal ions, with two more or less pronounced inflection points at metal/**L2** molar ratios of 0.5 and 1.0, similar to that observed for the case of Pb^{2+} ion, but with lower extent of intensity changes. However, in the case of Y^{3+}, Cd^{2+} and La^{3+} ions, a CHEQ effect is observed up to a metal/ligand molar ratio of about 0.5 which is followed by a remarkable enhancement of the fluorescence intensity upon further addition of the metal ions with a more or less pronounced inflection point at a molar ratio of 1.0, clearly indicating the subsequent formation of 1:2 and 1:1 metal-to-ligand complexes. The observed increased fluorescence intensity of the ligand **L2** upon addition of the metal ions should be due to the increased rigidity of the complexed ligand, as already reported [48].

3.2. Ab initio calculations of structure of Pb^{2+} complexes with fluoroionophore *L2*

In order to obtain further information about the optimized structures of the fluoroionophore **L2** and its 1:1 and 1:2 metal-to-ligand complexes with Pb^{2+}, the molecular structures of the uncomplexed ligand and its lead ion complexes were built with the Hyperchem program [49]. The structure of free ligand was optimized using the 6.31 G* basis set at the restricted Hartree-Fock (RHF) level of theory. The optimized structure of the ligand was then used to find out the initial structures of its lead complexes. Finally, the structures of the resulting 1:1 and 1:2 metal-to-ligand complexes were optimized using the Lan12mb basis set at the RHF level of theory. No molecular symmetry constraint was applied; rather, full optimization and frequency option of all bond lengths,

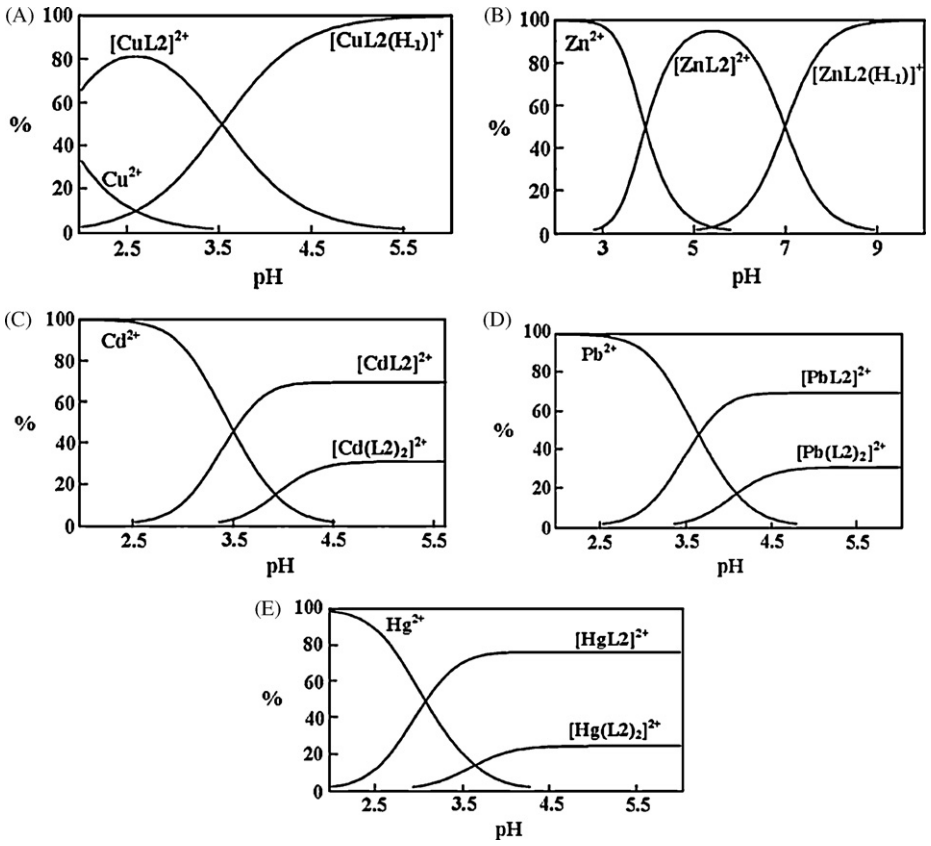

Fig. 3. Distribution of the complexed species of **L2** in the presence of 1 equiv. of Cu^{2+} (A), Zn^{2+} (B), Cd^{2+} (C), Pb^{2+} (D) and Hg^{2+} (E) ([**L2**] = [Cu^{2+}] = [Zn^{2+}] = [Cd^{2+}] = [Pb^{2+}] = [Hg^{2+}] = 1.0×10^{-3} mol L^{-1}, 298 K, 0.1 mol L^{-1} NMe_4Cl water–MeCN (1:1, v/v) solution).

bond angles and torsion angles were carried out using the Gaussian 98 program [50].

The optimized structures of **L2**, [Pb**L2**]$^{2+}$ and [Pb(**L2**)$_2$]$^{2+}$ are shown in Fig. 7. It should be noted that, only real frequency values were observed, indicating that the structural geometries shown in Fig. 7 are quite acceptable [51]. As it is obvious from Fig. 7A, in the case of free ligand, the two (5-chloro-8-hydroxy-7-quinolinyl)methyl groups (as the signaling moieties) are pointing away from plane of the ionophore ring containing a pyridine nitrogen, two donating sulfur atoms and two nitrogens (as the recognition moiety), via proper spatial twisting of the carbon atoms of the ethyl groups, to result in the lowest conformational energy. In this conformation, the ligand benefits from maximum fluorescence intensity. Meanwhile, in the optimized structures of the 1:1 complex (Fig. 7B), the cation is well incorporated inside the twisted ligand cavity and coordinated to all five donor atoms of the ligand molecule, in a more or less square-based pyramidal geometry, as previously reported for the lead(II) complexes with pentadentate ligands, in the corresponding crystal structures [30]. In this case, the two (5-chloro-8-hydroxy-7-quinolinyl)methyl groups are now situated in line with the central lead ion so that it may facilitate the photoinduced electron transfer (PET) from the amino groups to the signaling groups, thus affording a strong fluorescence quenching of the ligand system.

Finally, in the optimized structure of [Pb(**L2**)$_2$]$^{2+}$ complex (Fig. 7C), the Pb^{2+} ion coordinates to one of the amine nitrogens, one of the donating sulfur atoms and the pyridine nitrogen of the ring of each of the two **L2** ligands participating in the complex formation to form an octahedral structure. Here, one of the two (5-chloro-8-hydroxy-7-quinolinyl)methyl groups in each ligand molecule are located too far from the metal centre and, thus, are not able to be involved in any photoinduced electron transfer process in the complexed structure. However, each one of the remaining (5-chloro-8-hydroxy-7-quinolinyl)methyl groups in each ligand molecule are nicely situated in line with the central lead ion to easily facilitate the photoinduced electron transfer (PET) from the amino groups to the signaling groups, thus affording a further fluorescence quenching of the two ligand systems involved. It is interesting to note that the corresponding ΔE values for the resulting lead complexes, i.e., −267.080 kcal mol^{-1} for [Pb**L2**]$^{2+}$ and −283.844 kcal mol^{-1} for [Pb(**L2**)$_2$]$^{2+}$ complexes, clearly revealed that the 1:2 sandwich complex of lead ion is significantly more stable than the 1:1 adduct, and most probably is the one involved in the response mechanism of the lead sensor, as will be discussed later.

Thus, based on the results obtained from preliminary solution studies and from ab initio theoretical calculations discussed above, as well as the high lipophilicity of **L2** and its diminished fluorescence intensity brought about upon complexation with Pb^{2+} (static quenching), the PVC-membrane incorporated **L2** was investigated for low level sensing of lead ion in aqueous solutions.

3.3. Operation principle

The fluorescent optode membrane proposed in this work is based on the incorporation of a lipophilic chromoionophore **L2** in a plasticized PVC containing KTpClPB, as a lipophilic anionic additive. The chromoionophore possesses selective binding properties to Pb^{2+} ions and changes its strong fluorescence intensity as a result of the binding event. Since the chromoionophore is neutral and, therefore, cannot function as an ion-exchanger, the presence of a lipophilic anionic site is necessary to provide the optode membrane with the ion-exchange properties. Under the experimental conditions used and supposing the formation of a 1:2 metal-to-ligand

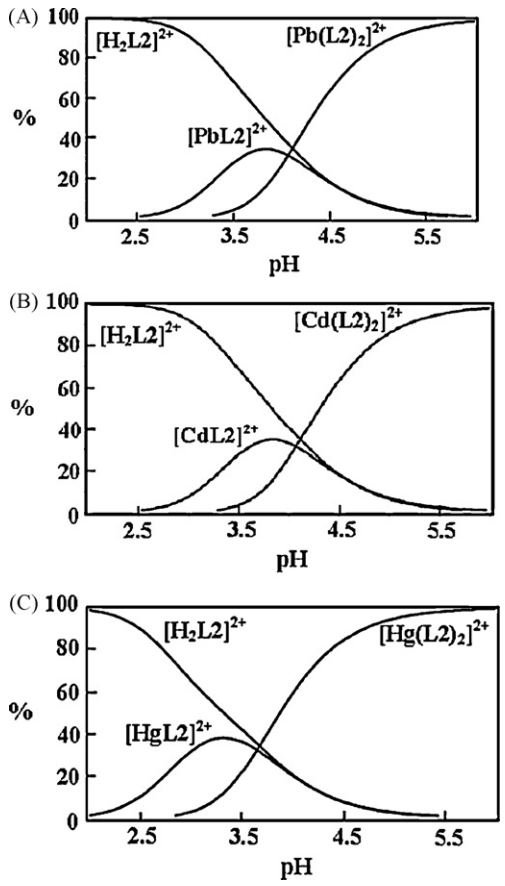

Fig. 4. Distribution of the complexed species of **L2** in the presence of 0.5 equiv. of Pb^{2+} (A), Cd^{2+} (B) and Hg^{2+} (C) ($[\mathbf{L2}] = 1 \times 10^{-3}$ M, $[Pb^{2+}] = [Cd^{2+}] = [Hg^{2+}] = 5.0 \times 10^{-4}$ mol L^{-1} 298.1 K, 0.1 M NMe_4Cl water–MeCN (1:1, v/v) solution).

complex between **L2** and Pb^{2+} ion in the organic phase, the response mechanism of this optical system can be described by the following ion-exchange mechanism [35–37]:

$$2\mathbf{L2}_{(org)} + 2K^{+}_{(org)} + 2TpClPB^{-}_{(org)} + Pb^{2+}_{(aq)} \rightleftharpoons [Pb(\mathbf{L2})_2]^{2+}_{(org)} + 2TpClPB^{-}_{(org)} + 2K^{+}_{(aq)} \quad (1)$$

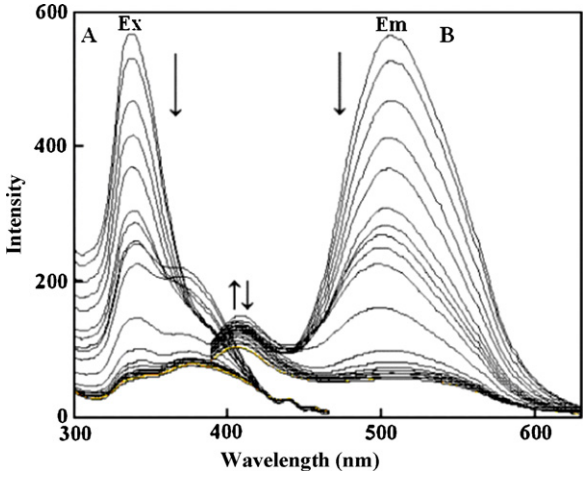

Fig. 5. (A) Excitation, Ex, and (B) emission, Em, spectra of **L2** (8.0×10^{-6} mol L^{-1}) in MeCN in the presence of increasing concentration of Pb^{2+} ion.

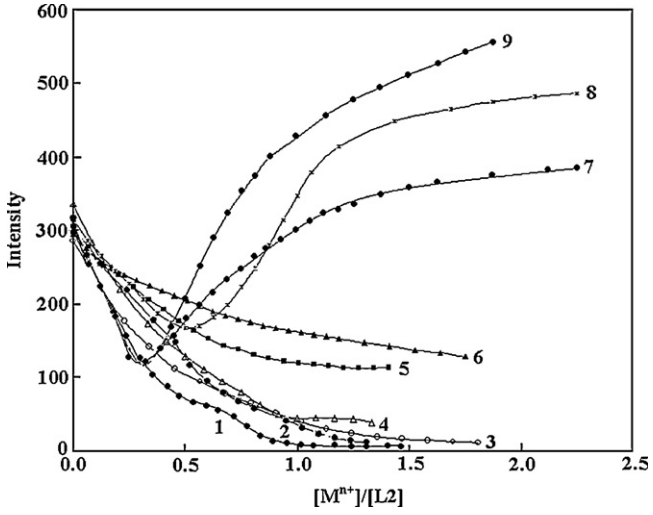

Fig. 6. Fluorescence intensity vs. $[M^{n+}]/[\mathbf{L2}]$ molar ratio plots in MeCN solution for different transition metal ions: (1) Pb^{2+}, (2) Co^{2+}, (3) Cu^{2+}, (4) Fe^{3+}, (5) Ag^{+}, (6) Hg^{2+}, (7) Y^{3+}, (8) Cd^{2+}, and (9) La^{3+}.

The fluorescence excitation and emission spectra of the fluorescent optode membrane in an acetate buffer solution of pH 5.5 and in the presence of increasing concentration of Pb^{2+} ion are shown in Fig. 8. As is obvious, as a result of a strong and selective quenching effect of Pb^{2+}, both the excitation and emission intensities are decreased considerably upon increasing concentration of lead ion in the buffer solution, indicating no measurable spectral position shifts. It is noteworthy that, as expected, the excitation and emission wavelengths observed for the membrane sensor are quite different from those observed in MeCN solution (Section 3.1.2). Here, the maximum intensities for the excitation and emission of **L2** in the membrane are observed at 388 and 515 nm, respectively.

Thus, based on the response mechanism of the proposed fluorescent sensor outlined above, its measuring principle can be explained as follows. Owing to the establishment of a complexation equilibrium between Pb^{2+} ion (M) in the aqueous sample solution and the fluoroionophore **L2** (L) in the organic membrane phase, a M_mL_n complex can be formed as

$$mM_{(aq)} + nL_{(org)} \overset{K}{\rightleftharpoons} M_mL_{n(org)} \quad (2)$$

with

$$K = \frac{[M_mL_n]_{(org)}}{[M]^m_{(aq)}\,[L]^n_{(org)}} \quad (3)$$

where m and n designate the complexing ratio between lead ion and **L2**, and K is the equilibrium constant of the overall reaction.

By definition, the relative fluorescence intensity α, as the ratio of uncomplexed L in the membrane phase, $[L]_{(org)}$, to its total amount, $[L_t]_{(org)}$, is given as

$$\alpha = \frac{[L]_{(org)}}{[L_t]_{(org)}} \quad \text{and} \quad [M_mL_n]_{(org)} = \frac{[L_t]_{(org)}(1-\alpha)}{n} \quad (4)$$

In practice, the α-value during the titration of **L2** with Pb^{2+} ions can be evaluated by measuring the fluorescence intensity of the optical sensor, FI:

$$\alpha = \frac{FI - FI_o}{FI_n - FI_o} \quad (5)$$

where FI_o and FI_n are the limiting fluorescence intensities of the membrane sensor at $\alpha = 0$ (i.e., totally complexed L) and $\alpha = 1$ (i.e., uncomplexed L), respectively. Thus, the relationship between the α-value and the concentration of Pb^{2+} ion in aqueous sample solu-

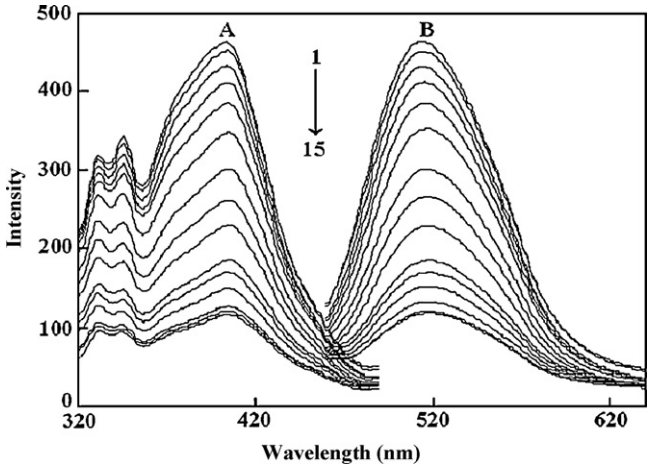

Fig. 8. Excitation (A) and emission (B) spectra of the lead-selective optical sensor in the presence of varying concentrations of Pb^{2+} ion: (1) in acetate buffer of pH 5.5, (2) 5.0×10^{-7} mol L^{-1}, (3) 1.0×10^{-6} mol L^{-1}, (4) 5.0×10^{-6} mol L^{-1}, (5) 1.0×10^{-5} mol L^{-1}, (6) 5.0×10^{-5} mol L^{-1}, (7) 1.0×10^{-4} mol L^{-1}, (8) 2.0×10^{-4} mol L^{-1}, (9) 4.0×10^{-4} mol L^{-1}, (10) 8.0×10^{-4} mol L^{-1}, (11) 1.25×10^{-3} mol L^{-1}, (12) 2.0×10^{-3} mol L^{-1}, (13) 4.0×10^{-3} mol L^{-1}, (14) 8.6×10^{-3} mol L^{-1}, (15) 2.5×10^{-2} mol L^{-1}.

tion, $[M]_{(aq)}$, can be obtained by combining Eqs. (4) and (5), as follows:

$$\frac{\alpha^n}{1-\alpha} = \frac{1}{n\mathrm{K}[\mathrm{L}_t]^{n-1}_{(org)}[\mathrm{M}]^m_{(aq)}} \quad (6)$$

Eq. (6) could be used as a basis for the quantitative determination of lead ions, using the proposed optical membrane sensor.

3.4. Effect of optode membrane composition

It is well documented that the membrane composition may largely influence the response characteristics and working concentration range of the optical sensors [7,52]. Thus, in this work, five PVC-membranes with plasticizer/PVC ratios in the range1.7–2.1, but with varying nature and amount of other ingredients were prepared (Table 2). It is known that the plasticized PVC-membranes used in ion sensors will usually result in the best response membrane characteristics at a plasticizer/PVC ratio of about 2 [52]. As is obvious from Eq. (1), since the bulk membrane optodes must be in thermodynamic equilibrium with the sample, the mass transfer of analyte into the membrane is required [53]. Thus, in the proposed lead-selective optical sensor containing **L2** as a neutral chromoionophore, the presence of a lipophilic additive such as KTpClPB is necessary to facilitate the ion-exchange equilibrium. The absence of KTpClPB was found to affect not only the working concentration range of the sensor (Table 2), but also resulted in the prolonged response time and reduced selectivity of the sensor [54]. The presence of 60–63% plasticizer in the PVC-membranes resulted in optimum physical properties, as well relatively high mobilities of their constituents [55,56]. The nature of plasticizer also influences considerably the measuring range of the solvent polymeric membrane sensors and their selectivity coefficients [57,58]. As is obvious from Table 3, the use of DOS as plasticizer resulted in a large widening of measuring range of the proposed optical sensor (i.e., some two orders of magnitude) over the membrane based on DOP and NPOE. As is seen from Table 2, the presence of 3% chromoionophore **L2** and 6% of additive KTpClPB in the PVC-membrane resulted in the best optical response of the lead-selective sensor. Thus, the membrane number 4 (Table 3) with an optimized PVC:NPOE:KTpClPB:**L2** wt.% ratio of 30:61:6:3 was used for further studies.

Table 2
Optimization of membrane ingredients.

Membrane number	Composition (%)				Working range (mol L^{-1})
	PVC	Plasticizer	KTpClPB	**L2**	
M1	35	60, NPOE	3.5	1.5	1.0×10^{-1} to 7.0×10^{-5}
M2	30	60, NPOE	7.0	3.0	1.0×10^{-1} to 4.0×10^{-5}
M3	31	62, DOP	5.5	1.5	1.0×10^{-3} to 1.0×10^{-4}
M4	30	61, DOS	6.0	3.0	2.5×10^{-2} to 5.0×10^{-7}
M5	30	63, DOS	4.0	2.0	1.0×10^{-2} to 1.0×10^{-6}

Table 3
SSM selectivity coefficients of the optode membranes M4 in acetate buffer of pH 5.5.

Ion	log K^{opt} at $\alpha = 0.5$
Ag^{+}	−1.20
Fe^{3+}	−1.31
Hg^{2+}	−1.23
Mo(VI)	<−4
Mn^{2+}	<−4
Cd^{2+}	−1.95
Cu^{2+}	−0.69
Ni^{2+}	−3.01
Tl^{+}	−3.05
Zn^{2+}	−2.77
Al^{3+}	−2.84
As^{3+}	<−4
Bi^{3+}	−1.50
Sr^{2+}	<−4

3.5. Effect of pH

The influence of pH values on the fluorescence response of the proposed Pb^{2+}-selective optical sensor was studied in the presence of 1.0×10^{-5} mol L^{-1} solution of Pb^{2+}over the range of 1–9, and the results are illustrated in Fig. 9. The pH of solution was adjusted by either HNO_3 or NaOH. As is obvious from Fig. 9, the fluorescence intensity increases with increasing pH of solution and reaches a maximum value at a pH 5.5, and then decreases. The decreased intensity at lower pH might be due to the extraction of H^{+} from the aqueous sample solution into the PVC-membrane, via protonation of the nitrogen atoms of **L2** molecule, which results in an expected change in the mobility of electrons of the system.

On the other hand, the reduced optical response of the sensor at pH >6.0 could be due to a possible slight swelling of the polymeric film under alkaline conditions, as well as the hydroxide formation of lead ions, resulting in decreased concentration of free Pb^{2+} ions in sample solution. Thus, in subsequent experiments, a solution of pH 5.5 adjusted by a 0.05 mol L^{-1} acetate buffer solution, was used for further studies.

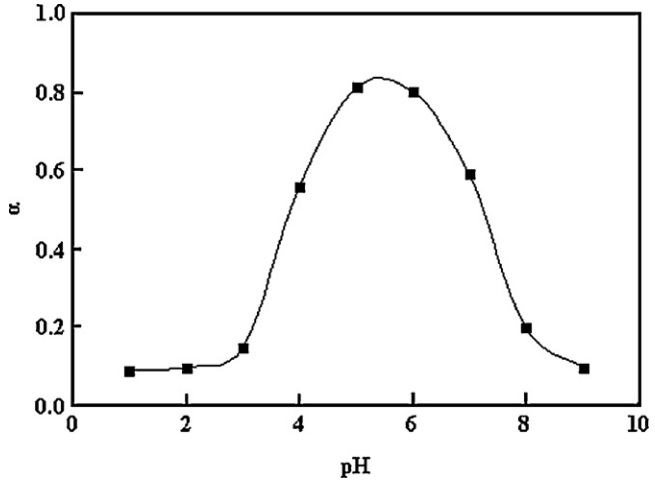

Fig. 9. Effect of pH of the test solution on the optical response of the lead ion-selective sensor in the presence of 1.0×10^{-5} mol L^{-1} Pb^{2+}.

3.6. Measuring range and dynamic response time

Fig. 10 displays the optical response of the proposed Pb^{2+}-selective fluorescent optode to various concentrations of Pb^{2+} ion under optimal experimental conditions at pH 5.5. As is obvious, this curve can be suitably used as a calibration curve for the determination of Pb^{2+} ions in a concentration range of 5.0×10^{-7} to 2.5×10^{-2} mol L^{-1}. The limit of detection (LOD) based on 3σ of the blank was 2.0×10^{-7} mol L^{-1}. The three curves shown in inset of Fig. 10 are calculated based on Eq. (6) with different *m*:*n* ratios. As is quite clear, the curve with *m*:*n* of 1:2 stoichiometric ratio and a reasonable *K* value (2.0×10^{6}) fits the best to the experimental data, while its fitting to other *m*:*n* values of 1:1 and 2:1 was not successful. The results thus obtained further support the formation of a 1:2 $[Pb(\mathbf{L2})_2]^{2+}$ complex in the membrane phase.

The dynamic response time of the present optode, as an important characteristic for any membrane sensor, it is controlled by the time required for the analyte to diffuse from the bulk of the solution toward the membrane interface to associate with ligand. In the case of the proposed fluorescence membrane sensor, the membrane response found to be relatively fast so that the fluorescence intensity of the corresponding signal reached equilibrium within 5 min, over the entire calibration concentration of lead ion.

3.7. Reproducibility, reversibility, short-term stability and life time

The regeneration of the proposed membrane sensor was studied in by the use of different reagents including HCl, HNO_3,

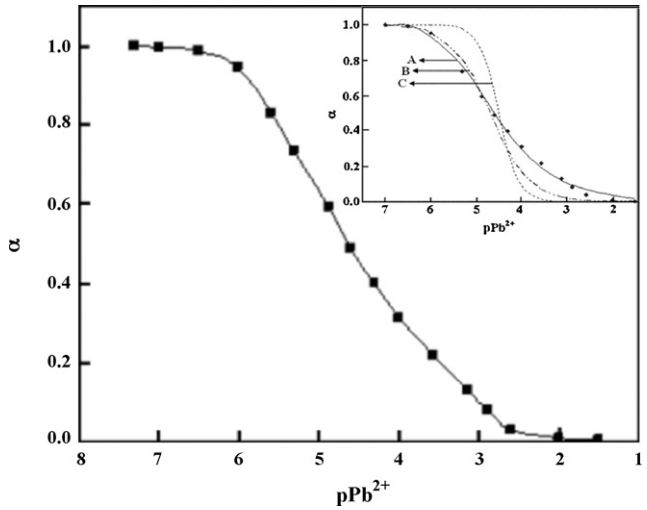

Fig. 10. Relative fluorescence intensity vs. pPb^{2+}. Inset shows the curve fitting of the experimental data based on Eq. (6) for different *m*:*n* and *K* values: (A) *m*:*n* = 1:2, $K = 2.0 \times 10^{6}$; (B) *m*:*n* = 1:1, $K = 5.0 \times 10^{4}$; (C) *m*:*n* = 2:1, $K = 1.0 \times 10^{9}$.

Table 4
Results of three replicate determinations of lead in different real samples.

Sample	Amount of lead		
	Proposed sensor	AAS	Relative error (%)
Toy 1 (China)	37.35 (±1) μg g^{-1}	35.95 (±0.9) μg g^{-1}	3.9
Toy 2 (Iran)	52.65 (±1)	51.50 (±0.9)	2.2
Tap water	Not found	8 ng mL^{-1} [a]	–
Tap water +0.5 μg mL^{-1} Pb^{2+}	0.51 (±0.03) μg mL^{-1}	–	102% recovery

[a] GFAAS was used.

H_3PO_4, NaF, bis(aminoethyl)-glycoether-*N*,*N*,*N*,*N*-tetraacetic acid (EGTA), sodium citrate, nitrilotriacetic acid (NTA), ethylenediaminetetraacetic acid (EDTA), 5-sulfosalicylic acid, thiourea and dithiotritol. It was found that, in the presence of 0.001 mol L^{-1} dithiotritol, the optode membrane will be regenerated completely within a short regeneration time period of 10–20 s. After regeneration and for the next Pb^{2+} ion concentration measurement, the membrane should be kept in a buffer solution of pH 5.5.

The reproducibility and reversibility are two important characteristics in evaluating the suitability of an ion-selective optical sensor for selective determination of ion of interest. These characteristics were studied by fluorescence intensity measurements of the same membrane sensor when it was exposed to repeated concentration step changes between 1.0×10^{-6} and 1.0×10^{-5} mol L^{-1} at pH 5.5. The coefficient of variation of 5 determinations for the 1×10^{-6} and 1.0×10^{-5} mol L^{-1} lead were found to be ±1.5 and ±0.95, respectively. The results indicated that the proposed sensor possess good repeatability and reversibility.

The difference in the response of individual membrane was evaluated by preparing seven membranes from the same mixture and the reproducibility was obtained by determining the fluorescence signal of the membrane to 1.0×10^{-5} mol L^{-1} solution of Pb^{2+}. The standard deviation of response between membranes found to ±0.90. The results show that the reproducibility is satisfactory.

To study the short-term stability of the optode membrane, the fluorescence intensity of the membrane in contact with 1.0×10^{-5} mol L^{-1} Pb^{2+} at pH 5.5 acetate buffer was recorded over a period of 5 h with an interval of 30 min. The membrane exhibited good stability with a relative standard derivation of less than 2.0. In addition, it was found that the membrane sensor could be stored in wet conditions without any measurable change in its fluorescent intensity for at least 2 months, which implies that the fluoroionophore **L2** is quite stable in a membrane contacting with water. The membrane was stable over a period of several months when was not in use (membrane was kept in air) and the signal value of the membrane did not change.

3.8. Selectivity

The selectivity behavior, which is the relative optode response for the primary ion over other ions present in solution, is one of the most important characteristics of an ion-selective optical sensor. The optical selectivity of optical membrane sensor over several interfering ion was investigated by separate solution method (SSM) [36] from the corresponding α vs. pM plots at α value of 0.5, and the results are summarized in Table 3. As it is obvious, the proposed optical sensor possesses good selectivity for Pb^{2+}, so that the disturbance produced by the other cations tested in the functioning of the proposed Pb^{2+} optical sensor is negligible.

3.9. Analytical applications

To test the practical applications of the proposed sensor, it was successfully applied to the determination of lead at micromolar concentration levels in children toys and tap water samples, and the results are summarized in Table 4. Toys samples were prepared as described in Section 2.6. As is obvious from Table 4, the result obtained, for the lead content of the real samples by the proposed sensor correlate well with those from atomic absorption spectrometry (AAS) [19].

4. Conclusions

This work demonstrated that **L2** can be used as a suitable fluoroionophore in the development of a novel optode membrane for Pb^{2+} ion determination at low concentration levels. It is based on the considerable selective quenching of the strong fluorescence of **L2** upon complexation with lead ions. It is fully reversible and can be easily regenerated with 0.001 mol L^{-1} dithiotritol. The sensor is characterized by good response characteristics with respect to stability, reproducibility, reversibility, calibration range detection limit and selectivity. The proposed fluorescent sensor was successfully applied to the direct determination of lead content in different real samples.

Lead
Single-drop microextraction

ABSTRACT

A highly efficient single-drop microextraction (SDME) procedure using a low-cost room temperature ionic liquid (RTIL), i.e., tetradecyl(trihexyl)phosphonium chloride (CYPHOS® IL 101), for Pb determination at trace levels in real water samples was developed. Lead was chelated with 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol (5-Br-PADAP) reagent and extracted into a 4 μL microdrop of CYPHOS® IL 101. The RTIL drop was directly injected into the graphite furnace of the electrothermal atomic absorption spectrometer (ETAAS). Under optimal microextraction conditions, a preconcentration factor of 32 was achieved with only 1.5 mL of sample resulting in a phase-volume ratio of 375. The limit of detection (LOD) obtained was 3.2 ng L^{-1} and the relative standard deviation (RSD) for 10 replicates at 0.5 μg L^{-1} Pb^{2+} concentration level was 4.9%, calculated at peak heights. The calibration graph was linear from concentration levels near the detection limits up to at least 4.5 μg L^{-1} with a correlation coefficient of 0.9996. The accuracy of the methodology was evaluated by analysis of a certified reference material (CRM). The method was successfully applied to the determination of Pb in tap, mineral, well and river water samples.

1. Introduction

Lead is one of the metals considered as a major threat to human health. This heavy metal is characterized by its toxic effects on the gastrointestinal tract, renal system and central or peripheral nervous system [1]. The main sources of lead in humans are inhaled air, diet and drinking water [2]. Lead could be present in water due to general environmental contamination. Polluting sources are quite varied, ranging from industrial and traffic emissions to the use of purification mud and agricultural excipients [3]. The World Health Organization (WHO) has established a maximum permissible limit of 10 μg L^{-1} Pb in drinking water [4]. Therefore, evaluation of Pb at levels close to this limit and in presence of relatively high amounts of other ions and organic matter makes straight determination of Pb a difficult task for quality control of waters.

In general, the most widely used techniques for trace determination of Pb are electrothermal atomic absorption spectrometry (ETAAS) [5,6], inductively coupled plasma optical emission spectrometry (ICP-OES) [7,8] and inductively coupled plasma-mass spectrometry (ICP-MS) [9,10]. Among these, ETAAS and ICP-MS are the most sensitive techniques. Despite the great potential of ICP-MS for trace Pb determination, this technique often involves a greater cost, higher sample volume requirements and increased instrumentation complexity, limiting its widespread application to routine analytical work. ETAAS is still being used as it shows several advantages including, fast analysis time, relative simplicity, reduced cost, low sample volume requirements and low detection limits. All of these features have been responsible for its broad application to trace and ultratrace elemental analysis of different samples. However, the low levels of lead in some types of water samples are not compatible with ETAAS detection limits, hence a preconcentration step is needed prior to ETAAS determination [11].

MeOH volume (washing solution)	20 μL			

Several sample preparation methods such as solid phase extraction [12], liquid–liquid extraction [13], co-precipitation [14] and knotted reactor separation [15] have been employed for traces lead preconcentration. Conventional liquid–liquid extraction (L–L) is a very effective analytical technique to extract and preconcentrate metallic and organometallic species as well as organic compounds from liquid samples [16]. Recently, considerable interest has been appeared in solvent microextraction procedures based on room temperature ionic liquids (RTILs) [17–19], in which the volume of solvent required is significantly reduced while achieving high extraction efficiency. Single-drop microextraction (SDME) is a simple procedure where analytes are extracted into a single-drop of solvent suspended from the tip of a microsyringe needle [20] that can be directly immersed in the aqueous sample (DI-SDME) or in its headspace (HS-SDME). Due to their high viscosity, thermal stability and undetectable volatility in comparison with conventional solvents, ILs are very suitable for single SDME and HS-SDME. Moreover, larger and more reproducible extracting volumes can be used as well as higher stability of the drop and better precision levels are obtained. ILs have been proposed in SDME and HSME for organic compounds determination [21,22]. Very recently, Manzoori et al. have proposed the use of SDME-ETAAS for determining trace amounts of Mn and Pb in water and food samples [23,24].

Ionic liquids (ILs) have been recognized as alternative solvents for a diversity of chemical applications, such as analytical and separation chemistry [25–28]. Among the various IL families, most of the current research has been focused on 1-alkyl-3-methylimidazolium, tetraalkylammonium and alkylpyridinium based ionic liquids [29,30]. Tetraalkylphosphonium-based ILs are also known for their unique solvent properties, and consequently, they have been considered as alternative solvents for separation chemistry in some publications [31–34].

In this work, a phosphonium-containing RTIL tetradecyl(trihexyl)phosphonium chloride (CYPHOS® IL 101) (Fig. 1) is proposed for extraction and preconcentration of Pb with SDME technique. A suitable chelating reagent, such as 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol (5-Br-PADAP), was used to increase extraction efficiency of the metal ion [35]. To our knowledge, the combination of CYPHOS® IL 101 and 5-Br-PADAP chelating agent for developing a SDME and preconcentration procedure to determine Pb has not been reported before. Furthermore, the determination of metals in phosphonium-based ionic media by ETAAS has not been so far studied. The method was applied for evaluating trace levels of Pb in tap, mineral, well and river water samples.

2. Experimental

2.1. Instrumentation

Elemental detection was performed using a Perkin-Elmer 5100 atomic absorption spectrometer (Perkin-Elmer, Norwalk, CT, USA) equipped with a pyrolytic graphite tube (Perkin-Elmer) and a transversely heated graphite atomizer Zeeman-effect background

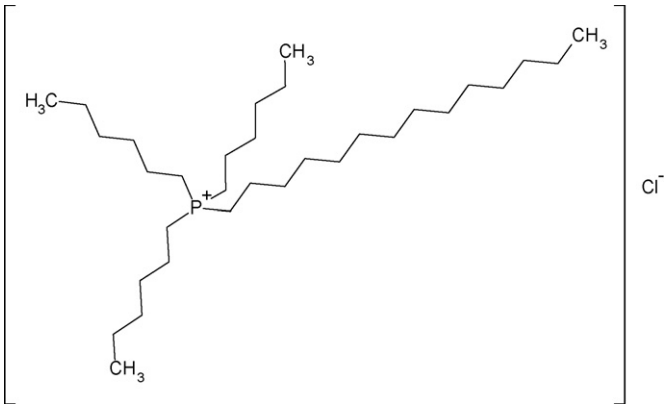

Fig. 1. Molecular structure of the RTIL CYPHOS® IL 101 used in this work.

correction system. A Pb electrodeless discharge lamp (Perkin-Elmer, Norwalk, USA) operated at a current of 360 mA (modulated operation) and a wavelength of 283.3 nm with a spectral band pass of 0.7 nm was used. All measurements were made based on absorbance signals with an integration time of 5 s. The temperature vs. time program for the atomizer is fully depicted in Table 1.

2.2. Reagents

All the reagents were of analytical grade and the presence of Pb was not detected within the working range.

The IL, CYPHOS® IL 101, was provided by CYTEC and molecular structure of this compound is shown in Fig. 1.

A 10^{-2} mol L^{-1} 5-Br-PADAP (Aldrich, Milwaukee, WI, USA) solution was prepared in ethanol (Merck, Darmstadt, Germany). Lower concentrations were prepared by serial dilution with ethanol.

A 1000 mg L^{-1} Pb^{2+} stock standard solution was prepared from $Pb(NO_3)_2$ (Merck) in 0.1 mol L^{-1} nitric acid (Merck). Lower concentrations were prepared by diluting the stock solution with 0.1 mol L^{-1} nitric acid.

The buffer solution was 2.0 mol L^{-1} ammonia (Merck) adjusted to pH 9.0 with hydrochloric acid (Merck).

A 150 mg L^{-1} $Mg(NO_3)_2$ (Merck) and 2500 mg L^{-1} $NH_4H_2PO_4$ (Merck) stock solution was used as chemical modifier. This solution was prepared in 3×10^{-3} mol L^{-1} HNO_3.

A 2 mol L^{-1} $NaNO_3$ (Merck) solution was used to adjust ionic strength.

Ultrapure water (18 MΩ cm) was obtained from a Millipore Continental Water System (Bedford, MA, USA).

2.3. Sample collection and conditioning

For tap water samples collection, domestic water was allowed to run for 20 min and approximately a volume of 1000 mL was collected in a beaker. Tap water samples were analyzed immediately after sampling. Mineral water was a commercial product.

River and well water samples were collected in cleaned bottles rinsed three times with water sample prior to collection. Water samples were conditioned by adding nitric acid until ca. pH 4, filtered through acid cleaned 0.22 μm pore size membrane filters (Millipore Corporation, Bedford, MA, USA) and stored in polypropylene bottles (Nalgene; Nalge, Rochester, NY, USA) at 4 °C [36]. The used sampling material was previously washed overnight with a 1.5 mol L^{-1} HNO_3 water solution and rinsed with ultrapure water.

2.4. General extraction and preconcentration procedure

A 1.5 mL sample volume was placed in a 2 mL glass vial containing a magnetic stirring bar. Then, 30 μL of buffer solution, 30 μL of EtOH and 4 μL of 1×10^{-4} mol L^{-1} 5-Br-PADAP solution were added. A 3 mm long polytetrafluoroethylene (PTFE) tube (0.35 mm I.D.) with a collar of 0.4 mm was fitted to the blunt needle tip of a 50 μL microsyringe (Perkin-Elmer) for maximizing the contact area between the drop and the needle tip. A microsyringe, containing a known volume of CYPHOS® IL 101 as an acceptor phase, was clamped above the vial and its needle was immersed into the sample. The plunger was depressed and a microdrop of the RTIL phase was exposed to the sample under constant stirring at room temperature. After an extraction time of 15 min, the remainder volume of RTIL acceptor phase was retracted into the microsyringe, and then the extract was injected into the graphite furnace of ETAAS instrument. Further washing with 20 μL of MeOH solution served to remove any remaining of analyte still present in the microsyringe. This solution was also injected into graphite furnace followed by 20 μL of chemical modifier mixture ($NH_4H_2PO_4$ + $Mg(NO_3)_2$). ETAAS determination was performed under the conditions showed in Table 1. Calibration was performed against aqueous standards submitted to the same preconcentration procedure. Likewise, blank solutions were analyzed in the same manner as standard and sample solutions.

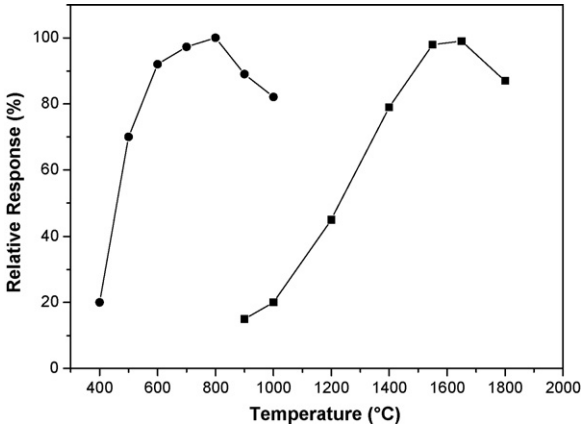

Fig. 2. Pyrolysis (●) and atomization (■) temperature curves for 15 μg L^{-1} of Pb in RTIL-methanol using 50 μg of $NH_4H_2PO_4$ and 3 μg of $Mg(NO_3)_2$ as modifier. Other conditions were as indicated in Table 1.

3. Results and discussion

3.1. RTIL phase analysis by ETAAS

Initial studies were performed for evaluating thermal and spectral behavior of CYPHOS® IL 101 during Pb measurements by ETAAS. With the aim of reducing interferences and increasing accuracy, the use of a chemical modifier or a mixture of modifiers has become indispensable in ETAAS measurements. Two modifiers, $NH_4H_2PO_4$ and $Mg(NO_3)_2$, were investigated. Common used chemical modifiers, such as $NH_4H_2PO_4$ and $Mg(NO_3)_2$, could not be individually used, as high background and poor thermal stabilization were observed. On the other hand, sharp and well-defined signals were obtained with both modifiers. Therefore, a modifier mixture containing 50 μg of $NH_4H_2PO_4$ and 3 μg of $Mg(NO_3)_2$ was injected for each measurement.

An increased background signal was observed during the atomization step in presence of CYPHOS® IL 101 and 5-BrPADAP, due to their organic nature. To eliminate the matrix effect, an *in situ* digestion step was developed by injecting different amounts of HNO_3 and applying diverse temperature ramps during the pyrolysis step [37]. Optimal results, with reduced background, were obtained when 10 μL of 10% (v/v) HNO_3 were injected before the evaporation step. Furthermore, it was very important to select an appropriate pyrolysis temperature for efficient organic matter removal due to RTIL phase while preventing the pyrolysis loss of Pb prior to atomization (Fig. 2). The influence of pyrolysis temperature on the absorbance was studied within a range of 400–1000 °C. The maximum absorbance was observed within a range of 600–800 °C. Therefore, 600 and 800 °C were selected as the working pyrolysis temperature in the two pyrolysis steps. A ramp time of 15 s was chosen as it allowed gradual elimination of organic matrix while avoiding Pb losses. Once selected these pyrolysis conditions, the effect of atomization temperature on Pb absorbance signal was studied within the range of 900–1800 °C. The highest signal was obtained from 1550 °C and remained constant up to 1650 °C. An atomization time and temperature of 5 s and 1600 °C were selected, respectively.

A significant experimental observation was made regarding the injection of the RTIL phase into the graphite furnace of ETAAS. The high viscosity of the resulting RTIL phase compromised quan-

titative and reproducible injection of the RTIL phase. Therefore, the application of an additional injection step using a proper solvent was considered to overwhelm this drawback. After microdrop injection into the furnace, further washing with methanol served to remove any sample still present in the microsyringe. Methanol was assayed in volumes ranging from 5 to 50 μL. A volume of 20 μL was suitable to obtain quantitative elution of the RTIL phase from the syringe. Smaller volumes did not remove completely the RTIL and caused loss of analytical sensitivity. Thus, the resulting alcoholic RTIL phase was successfully analyzed by ETAAS under the conditions showed in Table 1.

3.2. Study of SDME conditions using CYPHOS® IL 101

RTILs are gaining increasing attention due to their promising role as alternative media for developing preconcentration methodologies. The aim of the current work was the evaluation of a new ionic liquid as an efficient and stable media for extraction and preconcentration methods development. Recently, CYPHOS® IL 101 was reported to be chemically stable and remain inert with Grignard reagents such as phenylmagnesium bromide under strongly basic conditions (i.e., the phosphonium cation was not deprotonated to produce the corresponding phosphorane). Several ionic liquids, especially those based on imidazolium ions, such as 1-butyl-3-methylimidazolium ([C_4mim]), have shown to have some degree of chemical reactivity. On the other hand, quaternary phosphonium salts are more stable at high temperatures and longer periods of time than nitrogen-based cations as those present in imidazolium-containing RTILs.

Tetraalkylphosphonium salts do not have such acidic protons or aromatic rings like imidazolium salts, and consequently there is little potential for direct interaction with solutes [31]. Thus, a possible extraction of solutes with phosphonium-ILs would be dominated by polarity affinity. In view of the possibility of Pb chelation with 5-Br-PADAP, this pyridylazo reagent was used to improve affinity of the metal for the RTIL phase. The complexation phenomenon is strongly conditioned by pH value of solutions and it subsequently affects the extraction efficiency of Pb-5-Br-PADAP complex. Therefore, the effect of pH on analyte complexation and extraction of Pb-5-Br-PADAP was studied in the range of 1.5–12. The results illustrated in Fig. 3(a) show that the highest extraction efficiency was achieved between pH 8.1 and 10.5. It has been demonstrated, that this pH region is also the best for optimal Pb chelation with the 5-Br-PADAP reagent. A neutral complex is thus obtained within this pH interval, as it can be deduced from the dissociation constants of 5-Br-PADAP reagent (pK_{a1} = 0.1, pK_{a2} = 2.02, and pK_{a3} = 11.30) [38] and the stoichiometry of Pb-5-BrPADAP complex (1:2) [39]. This finding supports our hypothesis that extraction mechanism involved in this system is based on polarity affinity, as it was early mentioned in this work. A pH value of 9 was chosen for further experiments. This working pH was obtained with a 4×10^{-2} mol L^{-1} ammonia buffer concentration.

Concentration is a critical variable to be optimized in extraction methods based on a chelating agent such as 5-Br-PADAP. Thus, it is highly important to establish the minimal reagent concentration that leads to total complex formation while achieving the highest extraction. The results in Fig. 3(b) show 8×10^{-8} mol L^{-1} 5-Br-PADAP as the minimum concentration required to achieve the highest extraction efficiency, while a drop of extraction performance was observed when 5-Br-PADAP concentration exceeded 3.5×10^{-7} mol L^{-1}. This can be attributed to excessive 5-Br-PADAP concentration in the sample solution, which could be co-extracted along with the complex into CYPHOS® IL 101, thus diminishing extraction efficiency of the proposed method. Thus, a concentration of 2.7×10^{-7} mol L^{-1} was chosen as the optimum.

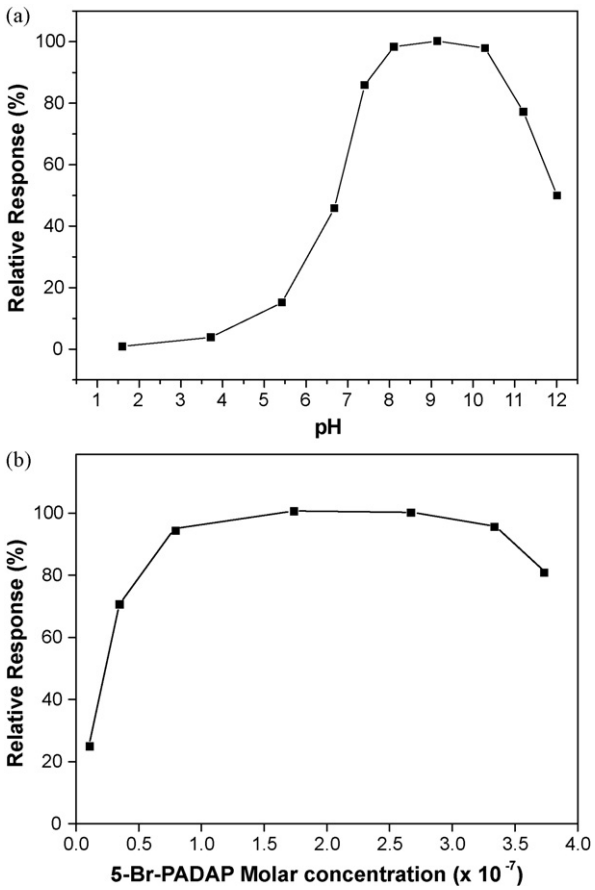

Fig. 3. (a) Effect of pH on Pb preconcentration. Each desired pH was obtained by adding suitable amounts of diluted HCl or NaOH, respectively. (b) Effect of 5-Br-PADAP concentration on Pb preconcentration. Other conditions were as indicated in Table 1.

In order to avoid the precipitation of the complexing agent and Pb-5-Br-PADAP complex in aqueous medium, concentration of ethanol in sample solution was evaluated. The study revealed that both, complexing agent and metal complex remained in solution within an ethanol concentration range of 1.5–5% (v/v). Higher ethanol concentrations led to solubilization of the ionic liquid and hence non-reproducible results. A 2% (v/v) ethanol concentration was chosen for further experiments. No effect on the kinetics of phase separation and extraction was observed with ethanol.

Generally, the addition of a salt in traditional liquid–liquid extraction using conventional organic solvents increases extraction performance due to salting out effect. This effect was investigated using $NaNO_3$ in a concentration range of 0–5% (w/v). As expected, the response was slightly increased by 5% as a result of salting out effect in the range of 0–1% (w/v) of $NaNO_3$. However, background signal was also increased during the atomization step. Since metal determination by ETAAS is more accurate when background absorption is small as compared to atomic absorption, salt addition was not adopted as it would negatively affect to the performance of the system.

One of the most important factors in SDME is the volume of the microdrop as it has deep influence on extraction efficiency. The effect of CYPHOS® IL 101 drop volume on lead signal was investigated in the range of 1–5 μL. The results illustrated in Fig. 4 show an enhancement of the analytical response by increasing the microdrop volume. Obviously, surface area of the microdrop is significantly increased when higher RTIL volumes are used, resulting in higher mass transfer from the bulk aqueous solution to the RTIL drop. However, when volumes larger than 4 μL were used, the

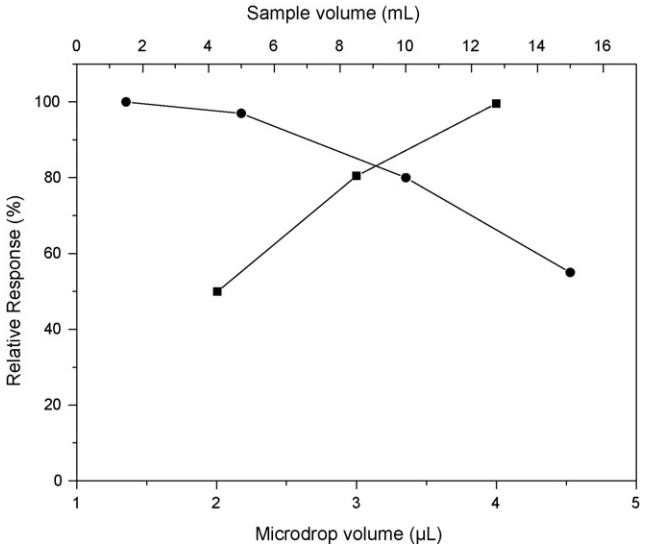

Fig. 4. Effect of the amount of RTIL on the extraction efficiency of the system (■) influence of sample volume on the performance of the extraction system (●) (a microdrop volume of 4 μL was used for this experiment). Other experimental conditions are listed in Table 1.

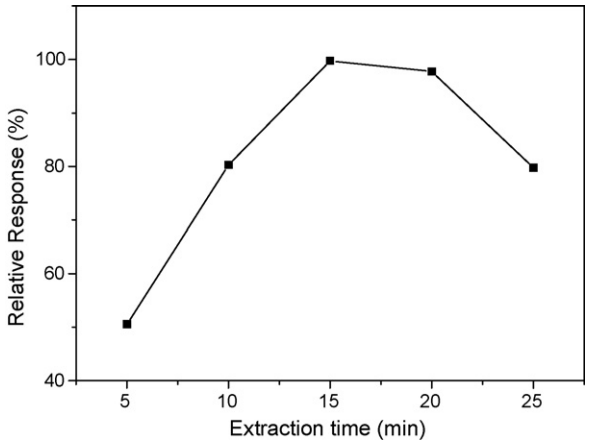

Fig. 5. Effect of the extraction time on the efficiency of the system. Experimental conditions are listed in Table 1.

microdrop became unstable, and it was easily dislodged from the syringe needle tip. Therefore, a 4 μL volume of the RTIL microdrop was selected for next experiments.

Sample volume is critical to be studied, since it strongly conditions the enhancement of analytical sensitivity obtained with preconcentration techniques. The effect of sample volume was examined in a range of 1–15 mL with a 0.5 $\mu g\,L^{-1}$ Pb standard solution (Fig. 4). Due to the minimal volume of the IL microdrop, a high enhancement factor was obtained even with a low sample volume. Thus, a volume of 1.5 mL was sufficient to obtain an appropriate enhancement factor and simplicity in sample treatment. Higher sample volumes negatively affected the extraction efficiency probably due to higher solubility of the RTIL microdrop.

Stirring of the sample is another important parameter which has impact on extraction efficiency and a reduction of the extraction time in SDME. According to film theory, convective–diffusive mass transfer at high stirring rate diminishes the thickness of static solution layer around drop, leading to a better mass transfer between the sample solution and the extracting microdrop [40,41]. Although high stirring rates improve the enrichment factors considerably with SDME technique, the stability of the microdrop at the needle tip could be affected dramatically. This was especially observed for extended stirring times and a microdrop volume of 4 μL were applied. Thus, a stirring rate of 700 rpm was used for all further experiments. Temperature also affects the extraction kinetics. At high temperatures, diffusion coefficient of the analyte increases and viscosity of the organic membrane decreases, therefore the time required to achieve equilibrium decreases [42]. On the other hand, higher temperatures result in some practical difficulties, such as microdrop instability and reduction of its volume due to higher solubility of RTIL in aqueous phase. In order to avoid these drawbacks, all studies were performed at room temperature.

Since analyte mass transfer is a time-dependent process, the effect of extraction time on the analytical signal was investigated and the experimental results are shown in Fig. 5. It can be seen that extraction efficiency of analyte increased within 15 min interval. Extraction time longer than 20 min, led to RTIL microdrop dissolution and thereby to reduce extraction efficiency. An extraction time of 15 min was thus chosen for further studies.

3.3. Potential interfering species

The effect of concomitant ions regularly found in natural water samples was also evaluated in this work. The study was performed by analyzing 1.5 mL of 0.5 $\mu g\,L^{-1}$ Pb solution containing concomitant ions at different concentrations, according to the recommended extraction procedure. A concomitant ion was considered to interfere if it resulted in an analytical signal variation of ±5%. Thus, Cu^{2+}, Zn^{2+}, Ni^{2+}, Co^{2+}, Mn^{2+} and Fe^{3+} could be tolerated up to at least 100 $\mu g\,L^{-1}$. Commonly encountered concomitant ions, such as alkaline and alkaline earth elements, do not form stable complexes with 5-Br-PADAP at working pH. Therefore, they are not extracted from the aqueous solution. Additionally, their contribution to the ionic strength of the system is insignificant and does not affect the extraction efficiency. Analytical signal of the blank was not modified in presence of the concomitant ions assayed. On the other hand, it is expected that humic substances do not produce interference effects on lead extraction with RTILs [43]. In fact, it has been already reported in the literature that stability constants of metal complexes formed with pyridylazo-type reagents [39] are higher than those reported for metal-humates [44].

3.4. Analytical performance and determination of lead in water samples

An extraction efficiency of 45% was achieved when the procedure was developed under optimum experimental conditions (Table 1). It has to be mentioned that, despite the relatively low extraction efficiency obtained with the proposed IL-based SDME method, a sensitivity enhancement factor of 32 was obtained. This was to due to the low volume of CYPHOS® IL 101 phase (4 μL) compared to the sample volume required for the analysis. Thus, significant volume ratio (375) between CYPHOS® IL 101 and sample yielded an acceptable enhancement of the analytical sensitivity. The preconcentration factor was obtained from the ratio of the calibration curve slopes for Pb with and without application of the preconcentration step.

The relative standard deviation (RSD) resulting from the analysis of 10 replicates of 1.5 mL solution containing 0.5 $\mu g\,L^{-1}$ Pb^{2+} was 4.9%. The calibration graph, obtained by analysis of 6 standards with different known concentrations of Pb, was linear with a correlation coefficient of 0.9996 at levels near the detection limits and up to at least 4.5 $\mu g\,L^{-1}$ [$A = 0.0021(\pm 0.002) + 0.25068(\pm 0.0021)C$], where A is the absorbance and C is Pb^{2+} concentration in $\mu g\,L^{-1}$. The limit of detection (LOD), calculated as the concentration of lead required to yield a net peak equal to three times the standard

deviation of the blank signal (3σ), was $3.2\,ng\,L^{-1}$. The calibration graph obtained without the preconcentration method was $A = 6.1 \times 10^{-4} + 0.0078\,C$.

In order to study analyte recovery, 15 mL of tap, mineral, well and river water samples were divided into 10 portions of 1.5 mL each. The proposed method was applied to six portions and the average concentration of Pb^{2+} found was taken as the base value. The remaining aliquots were spiked with increasing quantities of Pb^{2+} and were analyzed by the proposed method. The results are shown in Table 2. The method was applied in different water samples taken from Mendoza province (Argentina). Lead concentrations were 0.42 and $0.53\,\mu g\,L^{-1}$ for river water, 0.29 and $0.38\,\mu g\,L^{-1}$ for well water, 0.12 and $0.18\,\mu g\,L^{-1}$ for tap water and n.d. and $0.05\,\mu g\,L^{-1}$ for mineral water; 95% confidence interval ($n = 6$). Additionally, the accuracy of the proposed methodology was evaluated by analyzing a certified reference material (CRM) described as natural water NIST SRM 1643d, with a Pb^{2+} content of $18.15 \pm 0.64\,\mu g\,L^{-1}$. Using the method developed in this work, the Pb^{2+} content found in the CRM was $18.14 \pm 0.59\,\mu g\,L^{-1}$ (95% confidence interval; $n = 6$).

Finally, a comparison of the proposed method with others reported in the literature for Pb determination in water is shown in Table 3. Our method shows good LOD and a high enhancement factor, considering the low volume of sample required to perform the analysis. Regarding the frequency of analysis, although preconcentration of the analyte for a single sample could take more than 15 min, the extraction procedure can be applied in as many samples as possible at a time, substantially increasing the number of samples analyzed. Considering that CYPHOS® IL 101 is a low-cost ionic liquid, the proposed method could be generally applicable for routine analytical laboratories.

4. Conclusion

In this work, an efficient method for extraction and preconcentration of Pb has been developed based on SDME technique using 4 μL of RTIL tetradecyl(trihexyl)phosphonium chloride prior to ETAAS determination. This methodology combines the advantages of single-drop microextraction (i.e., miniaturization and low solvent consumption) with the use of an ionic liquid as extrac-

tant. SDME technique was particularly useful to overcome those problems associated with separation of low density RTIL, such as CYPHOS® IL 101, from aqueous systems. This work shows that 5-Br-PADAP-CYPHOS® IL 101 system is suitable for trace level determination of Pb. Furthermore, quantitative extraction and a preconcentration factor of 32 were achieved. Direct analysis and accurate determination of Pb by ETAAS is demonstrated even in the presence of complex organic matrix originated from RTIL. The preconcentration method was successfully applied to Pb determination in water samples in the low $\mu g\,L^{-1}$ range, with good accuracy and reproducibility.

Radiello®

ABSTRACT

Semipermeable membrane devices (SPMDs) were evaluated as passive samplers for the determination of 26 volatile organic compounds (VOCs) in contaminated air of occupational environments. A direct methodology based on the use of head-space-gas chromatography–mass spectrometry (HS-GC–MS) was developed for VOCs determinations in SPMDs, without any sample pre-treatment and avoiding the use of solvents. A desorption temperature of 150 °C for 10 min was sufficient for a sensitive VOCs determination providing limits of detection in the range of 15 ng SPMD^{-1} for 21 of 26 studied compounds. Linear and equilibrium uptake models were established for each VOC from compound isotherms. Highly volatile compounds were slightly absorbed and moderately volatile compounds were strongly absorbed by SPMDs. This study is the first precedent of the use of SPMDs for the simultaneous sampling of a wide number of VOCs. The use of SPMDs is a simple and low cost alternative to ordinary sampling devices such as Radiello® diffusive samplers or badge-type solid-phase supports.

1. Introduction

Volatile organic compounds (VOCs) constitute a wide group of chemicals that evaporate easily at room temperature and which are usually found in air. Their sources are numerous and diverse, such as: traffic pollution, paints, cleaning supplies, pesticides, building materials and furnishings, fragrance products or office equipment [1].

Some VOCs can cause sore throats, increase the risk of asthma, or affect the nervous, immune and reproductive systems [2]; other VOCs cannot be considered hazardous to human health in the short-term, but they are mutagenic or carcinogens at long-term exposures [3]. This is the case of benzene and tetrachloroethene that have been recognized by the World Health Organization (WHO) as carcinogenic. Usually, benzene, toluene, ethylbenzene and xylenes (BTEX) are common markers for human exposure to VOCs, but nowadays the monitoring of more compounds are required to obtain an improved evaluation of the risks to human health.

Moreover, the European Commission Regulation No. 1907/2006 established in 2006 the norms for the "Registration, Evaluation, Authorisation and Restriction of Chemicals" (REACH) that are produced in Europe at amounts of more than 1 tonne/year, in order to improve the protection of human health and the environment from the impact of more than 34 millions of chemical substances [4].

The reference procedure, suggested by the U.S. Environmental Protection Agency, for the air measurement of VOCs is based on an active sampling by using sorbent tubes [5] or specially prepared canisters [6]. In spite of this, air pollution measurements with passive samplers have been increased in the last few years due to their simplicity, low prize and ease of use [7]. Passive samplers frequently employed for the sampling of VOCs are: Radiello®, Organic Vapours Monitor (OVM), ORSA passive sorbent sampling badges, PerkinElmer tubes, SKC diffusive samplers, polyurethane foam (PUF), solid-phase microextraction (SPME) or semipermeable membrane devices (SPMD) [8]. In fact, the passive sampling of BTEX compounds [9], polychlorinated biphenyls and polycyclic hydrocarbons [10] and pesticides [11–13] in air by means of SPMDs has been previously studied by our group with excellent results.

A SPMD is made of a low-density polyethylene (LDPE) layflat tube filled with triolein and sealed at both ends. Hydrophobic compounds go easily from air through the LDPE tube and accumulate both in triolein and LDPE. Pollutants bonded to particles will not pass the membrane, so we are only evaluating the time-weighting average (TWA) of pollutants present in the air as gases or vapours and not other sources, such as dust or particulate matter [14].

The uptake kinetics of a pollutant sampled with a SPMD is mediated by its physico-chemical properties and certain environmental factors, mainly temperature and air flow [15]. Thus, if there are not big changes in temperature and air flow, the sampling rate (R_S) can be theoretically calculated by using octanol–water partition coefficient (K_{OW}) and the Henry's law constant (H). Sampler–air partition

coefficient (K_{SA}) and sampling rates (R_S) can be also experimentally calculated for each considered compound by the establishment of uptake isotherms, as it was shown in previous studies [9].

The aim of this study was focussed in the evaluation of SPMDs as passive samplers of a wide group of VOCs, commonly found in working environments. Analytical parameters were established for the determination of each studied compound in air. Experimentally calculated R_S values were established for each studied compound, and they were compared with the theoretical ones. Finally, the occupational exposure to VOCs in air of a paint factory was estimated by the use of SPMDs and compared with Radiello® diffusive samplers used as a reference methodology.

2. Experimental

2.1. Apparatus and reagents

VOCs accumulated in SPMDs were determined with the use of an HS2000 head-space (HS) injector from Finnigan (Waltham, MS, USA). A Finnigan Trace gas chromatograph equipped with low bleed column HP-5MS (30 m × 0.32 mm, 0.25 μm) capillary column and Finnigan Polaris Q ion trap mass spectrometer detector were used for VOCs determinations.

Glass vials, with an internal volume of 10 mL, capped with PTFE-butyl rubber seals were employed for HS measurements.

LDPE layflat tubing, 2.9 cm wide, was obtained from Garciplast (Barcelona, Spain). A Rovebloc sealer (Barcelona, Spain) was employed to heat-seal the membranes. Triolein 99% was obtained from Sigma Chemicals Co. (St. Louis, MO, USA).

The Radiello® sampler, provided by Supelco, consists of a microporous polyethylene cylindrical diffusive body (RAD120) that contain a stainless steel coaxial cylindrical cartridge filled with 530 ± 30 mg activated charcoal adsorbent (RAD130), supported by a triangular plate (RAD121).

Studied VOC standards (see Table 1) and hexadecane were obtained from Scharlau (Barcelona, Spain), Fluka Chemie (Steinheim, Germany), Merck (Darmstadt, Germany) and Aldrich (Steinheim, Germany). A 3.85% (w/w) VOCs standard solution was prepared by mixing 1 g of all considered analytes and it was stored at −20 °C. Working standard solutions were prepared by dilution of that in hexadecane. Hexadecane was employed due to its high boiling point. Benzene-free carbon disulphide from Acros organics (Barcelona, Spain) was employed for the extraction of VOCs from Radiello® cartridges.

Glass containers, 2.85 ± 0.01 L volume, were appropriately decontaminated and cleaned-up using a 5 min nitrogen flow before being used to study the absorption isotherms of considered compounds in SPMDs. Several blank studies (sampling the clean containers with SPMDs for 24 h) were performed in order to assure the complete release of VOCs from containers.

2.2. General procedure

2.2.1. Preparation of SPMDs

A standard SPMD is 90 cm long, 2.54 cm wide and contains 1 mL triolein inside, with a surface area–triolein volume ratio of 460 $cm^2\ mL^{-1}$. In this study short SPMDs (10 times smaller) were made with LDPE layflat tubing cut into segments of 10 cm, with one end heat-sealed, then 0.1 mL triolein were introduced into the membrane, squeezing to form a continuous film and the other end was also heat-sealed. The effective length was 8 cm and the obtained surface area–triolein volume ratio was 464 $cm^2\ mL^{-1}$. SPMDs were wrapped in separate aluminum foils and stored in a closed vessel at −20 °C to avoid contamination before in-field deployment. After deployment, the devices were rolled, placed inside 10 mL HS vials, capped hermetically, and stored at −20 °C until the HS-GC–MS measurement.

Calibration curves were prepared with SPMDs spiked by adding 5 μL VOC standards at different concentrations (0.003, 0.015, 0.03, 0.15, 0.3 and 3 $g\ L^{-1}$ of each compound in hexadecane). Standard solutions were directly introduced inside the layflat tube with a glass syringe. The spiked SPMDs were also placed in hermetically capped HS vials and stored at −20 °C or directly measured by HS-GC–MS.

Table 1
GC–MS measurement parameters and physico-chemical properties of the studied VOCs.

	Compound	Retention time (min)	Ions measured (m/z)	Boiling point (°C)	Vapor pressure (mm Hg)	log K_{OA}[a]

[a] Octanol–air partition coefficient (K_{OA}) [16,17].
[b] Overlapped peaks, but well-resolved by MS.
[c] Selected K_{OA} values were estimated with KOAWIN v1.10 software.

2.2.2. Determination of absorption rates

In order to achieve the corresponding calibration parameters (R_S and K_{SA}) for each studied VOC, 5 μL of 3 g L^{-1} VOC standard dissolved in hexadecane was added to a 2 cm^2 piece of filter paper and placed inside closed 2.85 ± 0.01 L glass bottles. After complete VOC evaporation, air concentration of each VOC in the containers was 5.2 mg m^{-3}. Then one SPMD was placed inside each container for variable exposure times of 1–7, 9, 12, 18, 24 and 48 h. These experiments were carried out by triplicate in a clean room with controlled temperature at 25 ± 0.5 °C. SPMDs and the spiked filter papers were placed in 10 mL HS vials and measured by HS-GC–MS.

2.2.3. Field studies

Time weighted average (TWA) concentration of VOCs was measured simultaneously with SPMD and Radiello® devices. Both samplers were deployed in several places of a paint factory, 2 m above the ground during 48 h, to determine the concentration of VOCs in the air. After sampling time both samplers were properly kept, labeled and stored under refrigeration at −20 °C, awaiting their measurement. The corresponding blanks were also analyzed to confirm the absence of contamination in the manufacture, trip or storage of samplers.

2.2.4. HS-GC–MS determination

VOCs vaporization from SPMDs was carried out at 150 °C for 10 min, with a syringe temperature of 150 °C and a constant air flow purge. A volume of 0.1 mL HS fraction was injected in split mode (1:10) at 200 °C, employing 1 mL min^{-1} constant flow of helium as carrier gas. The GC oven temperature program was 40 °C, held for 9 min, increased at a rate of 20 °C min^{-1} up to 200 °C, and finally held for 2 min. The transfer line and source temperatures were 300 and 250 °C, respectively. Electron impact ionization at 70 eV was employed and a mass scanning range from 40 to 180 *m*/*z* was used for full scan acquisitions. The measured *m*/*z* ions employed for each compound are shown in Table 1 together with their chromatographic retention times and their physico-chemical parameters.

2.2.5. VOC determination in Radiello® sampler

Each Radiello® cartridge was extracted as recommended by the supplier, with 2 mL of CS_2 directly in a closed glass tube without drawing out the cartridge, stirring from time to time for 30 min [18]. Then, 1 μL extract was injected employing the same chromatographic and MS conditions than those employed for HS-GC–MS determinations.

3. Results and discussion

3.1. HS-GC–MS measurement

HS desorption has been previously employed for the determination of BTEX compounds from SPMDs [9]. In that study, it was established that longer volatilization times did not increase the obtained recoveries, so a maximum evaporation temperature of 150 °C for 10 min was employed for the determination of BTEX in SPMDs. Thus, the same conditions were assayed for the quantification of VOCs, but a reduced injection volume (100 μL) has been employed in order to improve chromatographic resolution.

To evaluate the use of VOC solutions for external calibrations, signals obtained for SPMDs spiked with different amounts of VOCs were analyzed. As indicated in Fig. 1, slopes of the calibration curves obtained in the presence of the SPMD (LDPE membrane and triolein) varied from 30 to 84% of those found for external calibration. Fig. 1 inset shows the relationship between the obtained relative slope and the boiling point of each VOC. Thus, SPMDs spiked with the correspondent standard were employed to quantify unknown samples.

Fig. 2 shows the HS-GC–MS chromatograms obtained for one SPMD deployed in sampling site number 2 for 48 h and a SPMD spiked with 15 μg $SPMD^{-1}$ VOC standard. As it can be seen the peak

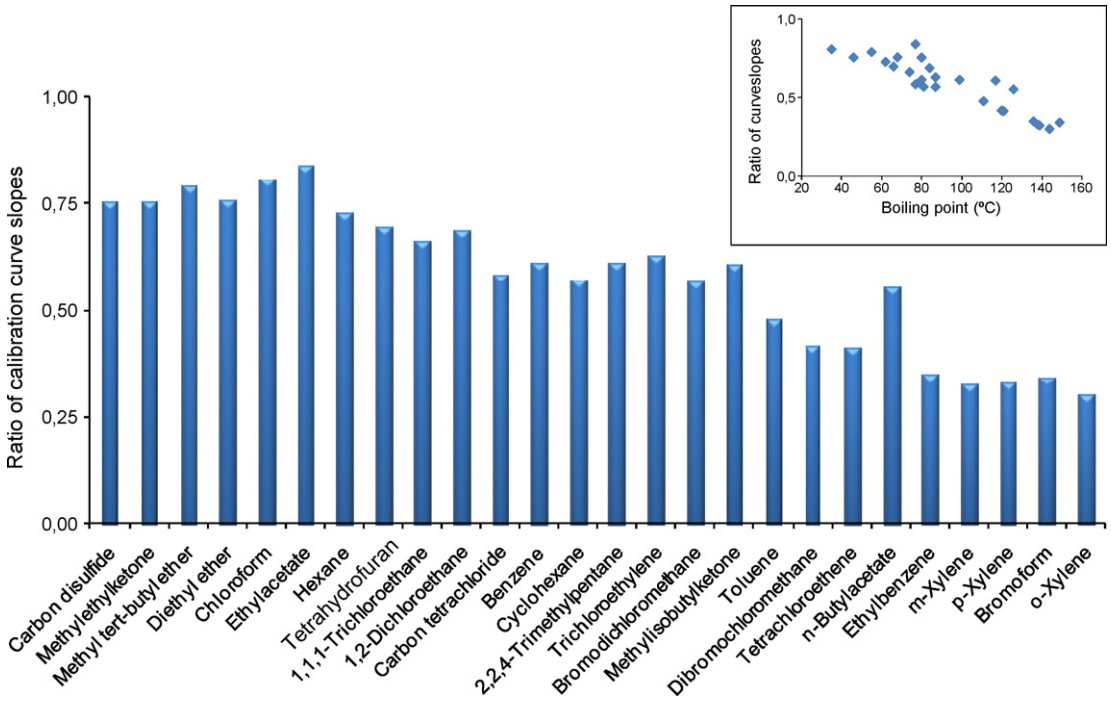

Fig. 1. Relative slope of the VOCs calibration curves obtained in the presence/absence of the SPMD by HS-GC–MS. Inset: relationship between the relative slope and the boiling point of the considered compounds.

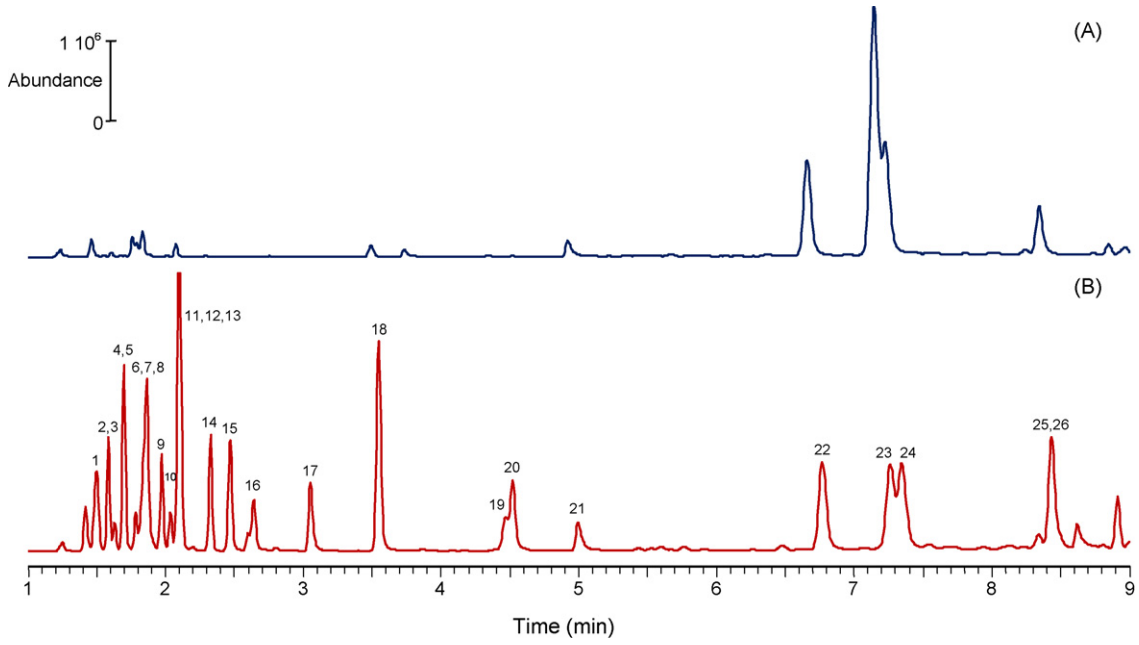

Fig. 2. Total ion chromatogram obtained for SPMD deployed in sampling site 2 for 48 h (A) and a SPMD spiked with 15 μg SPMD^{-1} VOC standard (B). Note: carbon disulfide (1); methylethylketone (2); methyl tert-butyl ether (3); hexane (4); diethyl ether (5); ethylacetate (6); chloroform (7); tetrahydrofuran (8); 1,1,1-trichloroethane (9); 1,2-dichloroethane (10); carbon tetrachloride (11); benzene (12); cyclohexane (13); 2,2,4-trimethylpentane (14); trichloroethylene (15); bromodichloromethane (16); methylisobutylketone (17); toluene (18); dibromochloromethane (19); tetrachloroethene (20); n-butylacetate (21); ethylbenzene (22); m-xylene (23); p-xylene (24); bromoform (25); o-xylene (26).

resolution achieved was adequate to analyze the 26 considered VOCs with enough sensitivity.

3.2. Analytical features

Calibration curves were established with SPMDs spiked with different VOC standards dissolved in hexadecane. Hexadecane was employed for their similarity with triolein (non-polar long-chain alkane) and for its low viscosity. The detector response was linear over a wide concentration range from 0.015 to 15 μg VOCs, with correlation coefficients ranging from 0.9996 to 0.9999.

Limit of detection (LOD) was established as the VOC concentration that provided a signal-to-noise ratio higher than three, which was calculated using Xcalibur software from Thermo-Finnigan. The obtained LOD were 15 ng SPMD^{-1} for most of the compounds, except for carbon disulfide, diethyl ether, chloroform, ethylacetate and n-butylacetate with values of 75 ng SPMD^{-1} (see Table 2).

Precision was established as the relative standard deviation (RSD) of three independent measures of three SPMDs spiked with 750 ng VOCs, each of them in their own HS vial. Repeatability was established as the RSD of 3 and 5 sequential injections of the same spiked SPMD, with 20 min of cooling time between every injection to avoid sample overheating, in order to know the possibility to do replicate analysis of a same sample. It is in fact a great advantage of the HS-GC–MS determination of VOCs in SPMDs, in front of active sampling procedures, that usually involves a total thermal desorption where replicate analysis is not allowed. Precision of the HS-GC–MS method was from 1.6 to 8.6% and repeatability for three sequential injections were satisfactory for all compounds except for some halogenated VOCs, see Table 2. So, triplicate measurements of a same SPMD could be done with the proposed methodology, in the case it was required.

3.3. Experimental estimation of R_S and K_{SA}

The establishment of absorption isotherms with SPMDs allows to calculate the uptake parameters (R_S and K_{SA}) to estimate TWA concentration of VOCs during the sampling of air. The VOCs standard was placed on a paper filter, to increase the volatilization area and to ensure the whole evaporation. SPMDs were placed in the containers and removed after several times and later on the absence of VOCs in the paper filters was checked in order to assure the whole evaporation of the studied compounds.

Fig. 3 shows the VOCs amount absorbed with each SPMD at 25 °C at different uptake times, from air contaminated with 5.2 mg m^{-3} VOCs. As it can be seen, the absorption of dibromochloromethane,

Table 2
Analytical features for the determination of VOCs in SPMDs by HS-GC–MS.

	Compound	LOD (ng SPMD^{-1})	RSD (%, $n=3$)	Repeatability (%)	
				($n=3$)	($n=5$)

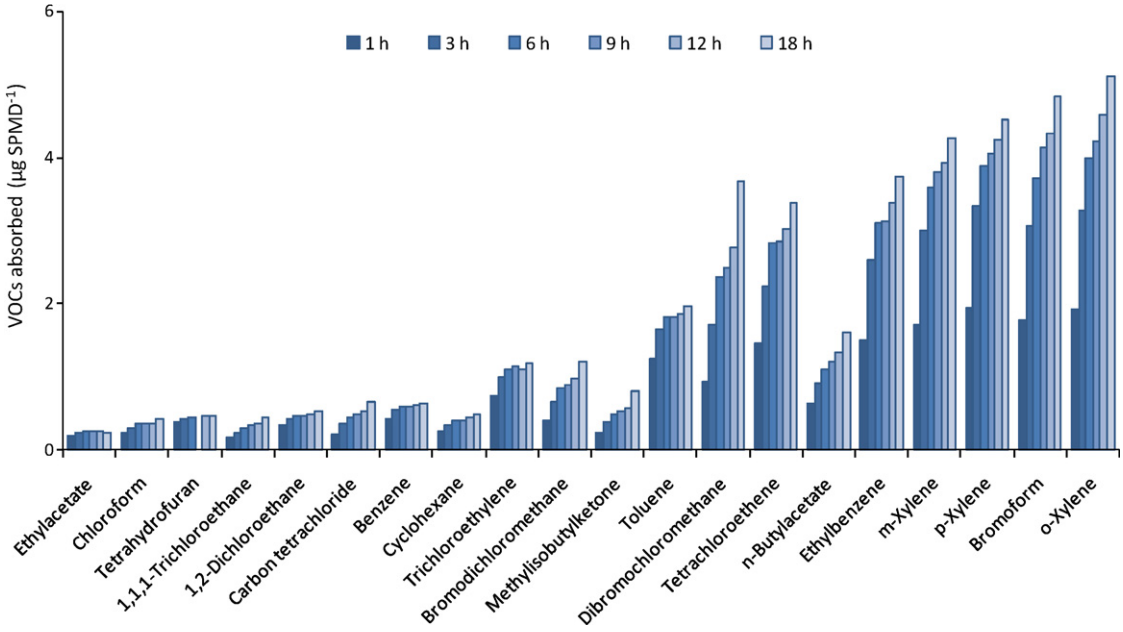

Fig. 3. SPMD absorption isotherms for VOCs at 25 °C in air spiked at 5.2 mg m^{-3} level.

tetrachloroethene, ethylbenzene, xylenes and bromoform was very high, compared with the very volatile compounds evaluated, while toluene and n-butylacetate show an intermediate absorption pattern.

Table 3 shows the time required to reach the equilibrium for each VOC sampled with SPMD in the isotherm study made. This equilibrium time was different for each considered VOC, few hours was enough for most of them, but in the case of 1,1,1-trichloroethane, carbon tetrachloride and n-butylacetate equilibrium was not reached until 18 h. Thus, a specific model was employed for each compound. However, the equilibrium model was used in all cases when a 24 h sampling is performed and linear models were mandatory for 1 h sampling.

As it was well established, the pollutant uptake by the SPMD passive sampler can be explained in three stages: first a linear absorption, later a curvilinear stage, and finally an equilibrium state [19]. Linear and equilibrium models are easy to use with the previous establishment of R_S and K_{SA} parameters, respectively.

For sampling times equal or longer than the equilibrium time (e.g. 24 h), K_{SA} can be used to estimate the TWA concentration of pollutants in air from the amount of VOCs determined in the SPMD, as explained by Eq. (1).

$$C_{AIR} = \frac{N_S}{K_{SA}V_S} = \frac{N_S}{K'_{SA}} \quad (1)$$

where C_{AIR} (mg m^{-3}) is the TWA concentration of a VOC dissolved in air; N_S (mg) is the VOC amount found in SPMD; K_{SA} is the sampler–air partition coefficient; V_S (m^3) is the sampler volume and K'_{SA} (m^3) is the pseudo sampler–air partition coefficient. The K'_{SA} value can be considered as the equivalent volume sampled with SPMD in equilibrium conditions.

In the case of short sampling times (e.g. 1 h), when the VOC amount absorbed by the SPMD is very small and the desorption rate from the SPMD is relatively insignificant, the uptake behavior can be explained by Eq. (2) [20].

$$\frac{dN_{SPMD}}{dt} \approx R_S C_{AIR} \quad (2)$$

where t (days) is exposure time; and R_S (m^3 day^{-1}) is sampling rate. If C_{AIR} is considered to remain constant, it is equivalent to the TWA concentration, then this equation integrates to Eq. (3).

$$N_S = R_S C_{AIR} t \quad (3)$$

Absorption data from laboratory isotherms of SPMDs at 25 °C and Eq. (3) can be used to calculate experimentally R_S values in the linear uptake.

Table 3 shows the corresponding R_S and K'_{SA} values for all the considered VOCs. These values have been expressed as equivalent for standard SPMDs (90 cm × 2.54 cm × 1 mL triolein) in order to be comparable to others found in the literature. As it can be seen R_S values varied from 0.008 to 0.12 m^3 day^{-1} and K'_{SA} values from 0.0003 to 0.0085 m^{-3}. R_S was not calculated for carbon disulfide, methylethylketone, methyl tert-butyl ether, hexane, diethyl ether, hexane and 2,2,4-trimethylpentane because the equilibrium state was reached very fast, in less than 1 h.

There are air R_S values available in the literature for a few number of semi-volatile pollutants. These values varied from 3.6 to 11 m^3 day^{-1} for polychlorinated biphenyls (PCBs) [21], from 0.7 to 15 m^3 day^{-1} for polycyclic aromatic hydrocarbons (PAHs) [20,22] and from 1.5 to 28 m^3 day^{-1} for some pesticides [12,23]. As it can be seen, the above cited R_S values were higher than those obtained for VOCs, but this result is reasonable, taking into account the enormous differences between their physico-chemical properties: such as boiling point, vapor pressure or octanol–air partition coefficient (K_{OA}) (see Table 1).

Sampling LODs were calculated for the determination of VOCs in air, from the LOD values for the SPMD analysis (showed in Table 2), the experimental R_S and K'_{SA} values (Table 3), and a selected sampling time (e.g. 1 and 24 h). Table 3 shows the LOD for each VOC for both considered sampling times and as it can be seen they range between 0.03 and 2.18 mg m^{-3} and between 0.02 and 1.90 mg m^{-3} for 1 and 24 h of sampling time, respectively.

3.4. Theoretical estimation of R_S

A theoretical estimation of R_S values was performed in order to assure the trueness of values that were experimentally calculated. The dependence between the R_S and the K_{OA} of 75 semi-volatile pollutants (over a K_{OA} range from 6 to 12), such as PCBs, PAHs, polychlorinated naphthalenes (PCNs) and several pesticides has been

Table 3
Sampler–air partition coefficients (K_{SA}), sampling rates (R_S) and limits of detection (LOD) for VOCs in sampled air with SPMDs.

	Compound	Experimental data from isotherms			Theoretical R_S[a] ($m^3\ d^{-1}$)		LOD ($mg\ m^{-3}$)

[a] K_{SA} and R_S values have been calculated as equivalent for standard SPMDs (90 cm × 2.54 cm × 1 mL triolein).
[b] When equilibrium is reached in less than 1 h, R_S and $LOD_{1\,h}$ were not calculated.

fitted by Huckins et al. as explained in Eq. (4) [20].

$$\log R_S = 0.154 \log K_{OA} - 0.80 \quad (R^2 = 0.64,\ \ n = 75) \tag{4}$$

Experimentally calculated K_{OA} values are easy to be found in the literature for many solvents and volatile compounds [16,17]. Thus, R_S values for the considered VOCs can be easily estimated by substitution of their K_{OA} values (Table 1) in Eq. (4). Table 3 also shows the theoretical R_S for the studied VOC with values ranging between 0.32 and 0.67 $m^3\ day^{-1}$.

Theoretical and experimental R_S values differ considerably, in a factor from 3 to 50 times, depending on the considered compound. This discrepancy can be attributed to the different physico-chemical properties between VOCs and semi-volatile compounds, principally due to the different boiling temperature, vapour pressure and K_{OA} values. Thus, a new mathematical model was proposed to explain the dependence between the R_S and the K_{OA}, equivalent to Eq. (4), but appropriate for very volatile compounds (with K_{OA} values lower than 5), such as those chosen in this study. Fig. 4 shows the linear relationship between the logarithm of experimental R_S and theoretical K_{OA} values (Table 1) and it corresponds to Eq. (5), with a slope of 0.75 ± 0.08 and an intercept of −4.0 ± 0.3.

$$\log R_S = 0.75 \log K_{OA} - 4.0 \quad (R^2 = 0.83,\ \ n = 20) \tag{5}$$

3.5. Comparative study between SPMD and Radiello® samplers

Five sampling sites inside a paint factory were selected to be sampled with SPMDs due to the high use of solvents in the painting industry. A double sampling was performed in each site with one SPMDs and one Radiello® sampler. After a deployment time of 48 h, each sampler was measured by the corresponding methodology: direct HS-GC–MS determinations for SPMDs and CS_2 extraction followed by GC–MS measurement for Radiello® samplers.

Air temperature was monitored in the sampling sites and it ranged from 8 to 19 °C. If we assume that changes in temperature during the sampling step did not affect significantly to the uptake parameters, R_S values could be used together with data of the VOCs amount accumulated in the SPMD to estimate TWA concentration of VOCs in air, as explained in Eq. (3).

Calibration model and other parameters for Radiello® samplers were obtained from the corresponding Technical sheet provided by the supplier, with R_S values ranging between 54 mL min^{-1} for cyclohexane and 75 mL min^{-1} for toluene [18].

Table 4 shows the description of each sampling site and the corresponding air concentration of VOCs sampled with Radiello® and SPMD samplers. Results obtained by both devices were equivalent, taken into account the big differences between the samplers and their corresponding mathematical models used to evaluate the air concentration from the pollutant amount found in each sampler.

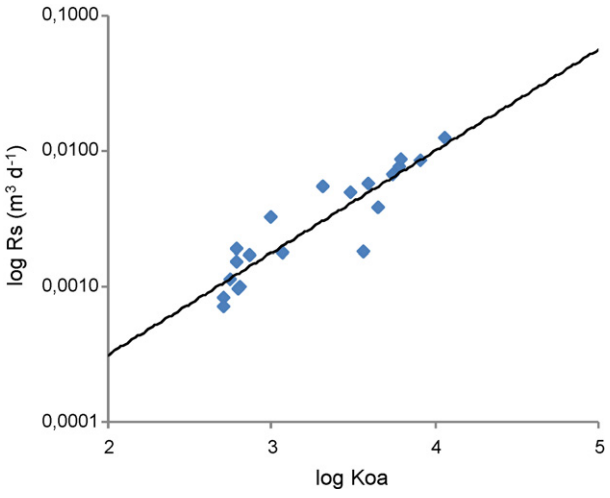

Fig. 4. Dependence between the experimental sampling rates (R_S) and the octanol–air partition coefficient (K_{OA}) of the studied VOCs.

Table 4
Air concentration of VOCs found in different sites of a paint industry by using one SPMD and one Radiello® diffusive sampler in each site.

Sample	Site description	Compounds founded	Air concentration ($mg\,m^{-3}$)	
			Radiello®	SPMD
1	Application laboratory	Methylisobutylketone	7.2	4.1
	Poor ventilation	Ethylbenzene	9.5	2.8
	Temperature range 12–19 °C	(m + p) xylene	14.2	9.8
		o-Xylene	4.4	1.2
2	Colorimetric laboratory	Methylisobutylketone	0.67	1.9
	Poor ventilation	Ethylbenzene	36.8	24.8
	Temperature range 12–19 °C	(m + p) xylene	37.9	41.8
		o-Xylene	16.4	8.0
3	Industry plant (paint mixer)	Methylisobutylketone	12.7	8.6
	Well ventilated	Ethylbenzene	9.7	4.2
	Temperature range 8–18 °C	(m + p) xylene	15.2	15.6
		o-Xylene	4.9	1.7
4	Industry plant (corridor)	Methylisobutylketone	14.6	8.2
	Well ventilated	Ethylbenzene	9.8	3.3
	Temperature range 8–18 °C	(m + p) xylene	15.5	12.9
		o-Xylene	4.8	1.4
5	Industry plant (tin seal)	Methylisobutylketone	10.0	8.8
	Well ventilated	Ethylbenzene	4.0	5.2
	Temperature range 8–18 °C	(m + p) xylene	6.0	19.2
		o-Xylene	1.9	2.0

When concentrations found by SPMDs were correlated with those obtained by Radiello® samplers and adjusted by a least squares regression, the fitted equation was C_{SPMD} ($mg\,m^{-3}$) = (-2 ± 2) + (0.91 ± 0.09)$C_{Radiello}$ ($mg\,m^{-3}$) with a correlation coefficient of $R^2 = 0.86$ ($n = 19$). In this equation, the intercept and slope values were statistically comparable to 0 and 1, respectively, for a probability level of 95%. Thus, it can be concluded that results obtained with SPMDs were statistically comparable with those found using Radiello® samplers.

Concentration of VOCs in indoor air of several places have been reviewed in a recent paper and it ranged from 0.1 to 8.3 $\mu g\,m^{-3}$ in laboratory hospitals; from 0.01 $\mu g\,m^{-3}$ to 4.3 $mg\,m^{-3}$ in social places (restaurant, bar, pub, cinema, theatre, and museum); from 0.01 to 11 $\mu g\,m^{-3}$ in transport environments (car, truck, garage, petrol station, mechanic shop, public transport, station, airport); and from 0.02 $\mu g\,m^{-3}$ to 150 $mg\,m^{-3}$ in other workplaces and indoor environments [7]. In this study, TWA concentration of VOCs found in air of the studied paint industry ranged from 0.7 to 42 $mg\,m^{-3}$. Thus, we can conclude that VOC levels found can be considered as quite high. Lamentably, these results are often found in studies performed in industrial workplaces and indoor environments. So, the VOCs concentration found was reasonable for an industry with intensive use of solvents, but it must be drastically minimized taken into account the today's legal frame.

4. Conclusions

The use of SPMDs for the passive sampling of VOCs has been confirmed as a real alternative to other passive samplers, generally based on solid supports. The HS treatment of SPMDs allowed direct and rapid determinations of VOCs in only 20 min without the use of any extraction solvent, thus providing an environmentally friendly analytical tool [24]. Linear and equilibrium models have been proposed for the passive sampling of the studied VOCs with SPMDs, by using a simple and easy procedure based on the establishment of uptake isotherms in laboratory studies. Finally, a comparative sampling was performed on a paint industry by using SPMD and Radiello® samplers and the obtained results were comparable.

Water hardness

ABSTRACT

In this work, a rapid assay of water hardness is presented based on the formation of a coacervate phase made up of multilamellar vesicles and close bilayers produced upon the reaction of alkaline earth metals with a carboxylate anionic surfactant in the presence of a co-surfactant (methanol). The procedure exploits the light scattering abilities of the coacervate phase which can be logarithmically linked to total hardness as $CaCO_3$ equivalents via spectrophotometric detection at 350 nm. The method, abbreviated as HALC, stemming from hardness by alkaline earth metal coacervation, is straightforwardly applicable overcoming the requirement for regulation of the experimental parameters involved in the determination procedure. In total, 28 water samples with various matrix compositions and hardness contents were analyzed with satisfactory accuracy as evidenced by comparison of the results with EDTA complexometric titration. The method is free from interferences from environmentally significant metal cations and inorganic anions affording detection limits as low as 13.5 mg L^{-1} $CaCO_3$ with the aid of a correction factor, which is determined by the non-linear absorbance properties of the solution mixture, and satisfactory reproducibility (RSD = 4.21–8.08%).

1. Introduction

Real time monitoring of water quality parameters is of critical importance in environmental and industrial fields, including the water quality control in drinking water treatment plants. Among these parameters, total hardness, defined as the total content of calcium (Ca^{2+}) and magnesium (Mg^{2+}) in water, is one of the most popular indicators of water quality since it is not only related to the deposition of mineral deposits in water pipes but it is also reported to affect the toxicity of certain metal ions in aquatic ecosystems [1]. Furthermore, water hardness contributes to the daily uptake of Ca^{2+} and Mg^{2+} which are physiologically important elements for the human body with significant negative effects encountered in cases of deficiency [2].

The most popular methods for the determination of water harness are those based on complexometric titration [3], flame atomic absorption spectrometry [4] and ion-selective electrodes [5,6]. Complexometric methods are probably the most popular methods due to their simplicity but they are prone to the analysts' efficiency unless an automated system is used that can accurately determine the end point of the titration. On the other hand, flame AAS methods are highly accurate for benchtop analysis but they cannot be used for outdoor studies. Potentiometric ion-selective electrodes (ISEs) are the technique of choice when continuous in situ measurements in an automatic manner are required combining simplicity of operation and low analysis cost. However, the selectivity of measurements is not often sufficient to enable the primary ion to be directly determined; interferences arising from other species with similar size and charge, matrix effects and mediocre day-to-day reproducibility may have serious repercussions in the accuracy of the analysis [5]. To overcome these problems, several techniques have been employed based on physical separation of sample components (i.e., chromatography), modeling the potentiometric response of the analytes in the presence of interferences (Nikolskii–Eisenman equation) or chemometric procedures [5,7].

In the pursue of combining the advantages of the above methods in the determination of water hardness, the phenomenon of coacervation may offer a convenient alternative. By definition, coacervation is the separation of colloidal systems into two liquid phases, a colloid-rich and a colloid-poor phase [8]. In that sense, coacervates can be defined as colloid-rich liquids immiscible with the colloid-poor aqueous equilibrium solution from which it is separated. In this context, if appropriate interactions between the coacervate phase and the analytes of interest can be established, coacervation can be efficiently employed as an alternative to the solvent-free extractions. Up to date, several such systems have appeared in the literature enabling the determination of organic

doi:10.1016/j.talanta.2009.11.003

and inorganic analytes via hydrophobic, electrostatic and hybrid interactions [9–13].

The coacervation of organic macromolecules induced by metallic ions is a well-known phenomenon and several studies have been devoted to the characterization of the morphological changes induced upon their interaction [14]. In this direction, alkaline earth metals, and especially Ca^{2+}, have received considerable attention due to their high reactivity with anionic surfactants leading either to the formation of well-known lime soaps or to complex vesicle and lamellar phases with interesting properties [14,15]. Nevertheless, the analytical utility of these interactions towards the determination of alkaline earth metals has not been reported despite the fact that vesicle-based extractions of metal ions exploiting their attraction with the anionic head group of anionic surfactants have been described [9,16,17].

Considering the high reactivity of alkaline earth metals with anionic surfactants, this work describes the first analytical application of the phenomenon of coacervation for the determination of water hardness. The proposed method is based on the formation of a lamellar colloid-rich phase induced by alkaline earth metals with sodium dodecanoate in the presence of a co-surfactant (water miscible organic solvent). This reaction results in the formation of a dispersed vesicular phase which scatters visible light in manner related to metal ion concentration. Based on this principle, the absorbance of the coacervate phase formed by Ca^{2+} and Mg^{2+} with sodium dodecanoate was monitored spectrophotometrically yielding a concentration depended response to metal ion concentration. To the best of our knowledge, this is the first time that metal ion induced coacervation is being exploited directly towards the determination of water hardness whish is one of the most popular water quality parameters.

2. Experimental section

2.1. Reagents

All reagents were of analytical-grade and they were used without further purification. Standard metal solutions used for the experiments were prepared by sequential dilution of 1000 mg L^{-1} stock solutions prepared by dissolving appropriate amounts of $Ca(NO_3)_2$ (Merck, Darmstadt, Germany) and $Mg(NO_3)_2{\cdot}6H_2O$ (Fluka, Buchs, Switzerland). Metal standard solutions used for the interference study were prepared by sequential dilution of 1000 mg L^{-1} of Titrisol stock solutions (Merck). Lauric acid in the form of Sodium dodecanoate (Sigma grade, 99–100%, Sigma–Aldrich, Greece) was dissolved in HPLC grade methanol (Labscan, Dublin, Ireland.) to prepare a 5% (w/v) stock solution.

2.2. Instrumentation

Absorbance measurements were performed with matched quartz cells of 1-cm path length in a Jenway 6405 UV–vis spectrophotometer. A pH meter, WTW 552 model glass electrode was employed for the pH measurements for the solutions.

2.3. HALC analytical procedure

In 10 mL of water sample previously equilibrated at room temperature, 1 mL of Lauric acid solution (5% (w/v) in methanol) is added. The mixture is agitated and its absorbance is directly recorded at 350 nm against reagents blank.

2.4. Real samples

In total, 28 water samples of various matrix composition and hardness content were assessed. Bottled waters (9 samples) purchased from local stores, surface waters (6 samples) collected from Acherontas river (N.W. Greece) in various locations from springs to estuary and water samples from six (6) springs used for water supply in Thesprotia region were collected in HNO_3-cleaned glass containers, filtered through a Whatman No. 40 filter (0.45 μm) and stored at room temperature. Tap water was collected directly form the drinking water network supply, filtered and analyzed directly without storage.

A series of samples from underground water aquifers were collected along the coastal line (≤2 km from sea) of north Corfu Island (N.W. Greece) from four (4) different drillings. Infiltration of seawater was qualitatively determined by the addition of $AgNO_3$ leading to the formation of white AgCl precipitate. Two (2) seawater samples were collected from the coastal line of Thesprotia (N.W. Greece). The first sample was collected in the estuaries of Kalamas River and the other by direct sampling of seawater 10 m from the coast.

3. Results and discussion

3.1. Optimization of experimental conditions

The optimization of the experimental conditions that enable the determination of water hardness with the proposed coacervation scheme is not a straightforward objective. That is because Ca^{2+} and Mg^{2+} upon reaction with sodium dodecanoate, in the presence of methanol as a co-surfactant (which affects aggregates size) [18], yield different lamellar structures [17]. According to the SEM micrographs of Fig. 1, Ca^{2+} favours the formation of spongelike phases (Fig. 1b) and Mg^{2+} the formation of bilayer structures (Fig. 1c) while mixtures of alkaline earth metals lead to the formation of a complex network of organized surfactant assemblies containing both multilamellar and bilayer vesicular aggregates (Fig. 1d). From a technical standpoint, these phenomena can be explained taking into consideration the organization phenomena occurring in the oriented molecular layers and the different radii of the hydrated cation condensation [9,17]. However, in the context of the analytical application intended in this study, these structural diversifications of the coacervate phase bring about significant changes in the absorption of each solution. According to the results of the calibration curves of Fig. 2, Ca^{2+} yields a linear response up to a concentration of 100 mg L^{-1} while Mg^{2+} response is rectilinear only up to 15 mg L^{-1}, above which absorbance values gradually reaches a plateau. In the linear range of the calibration curves, the ratio of slopes (Mg^{2+}/Ca^{2+}) is approx. 8 which means that Mg^{2+} induces, on average, 8 times more intense absorption than Ca^{2+} at the same concentration level at 350 nm.

Beyond ion type and concentration, the measured signal strongly depends on other parameters related to the formation and stability of the vesicular (coacervate) phase, like sodium dodecanoate concentration, ionic strength, hydroxyl or hydrogen concentration and temperature [9,10,17]. To this end, we decided to prepare a set of model solutions containing a high variety of Ca^{2+} and Mg^{2+} concentrations and use them as workings solutions for the optimization of the working conditions. The composition of these samples, gathered in Table 1, covers a wide range of Ca^{2+} and Mg^{2+} concentrations (as well as their ratio) so as to provide a representative evaluation of most natural waters. All samples had a total volume of 10 mL and measurements were performed at 350 nm.

3.2. Effect of sodium dodecanoate concentration

The first parameter assessed was sodium dodecanoate concentration in the range of 0.1–2% (w/v). Aqueous solutions (10 mL) were spiked with 0.1–2 mL of 5% (w/v) sodium dodecanoate and the

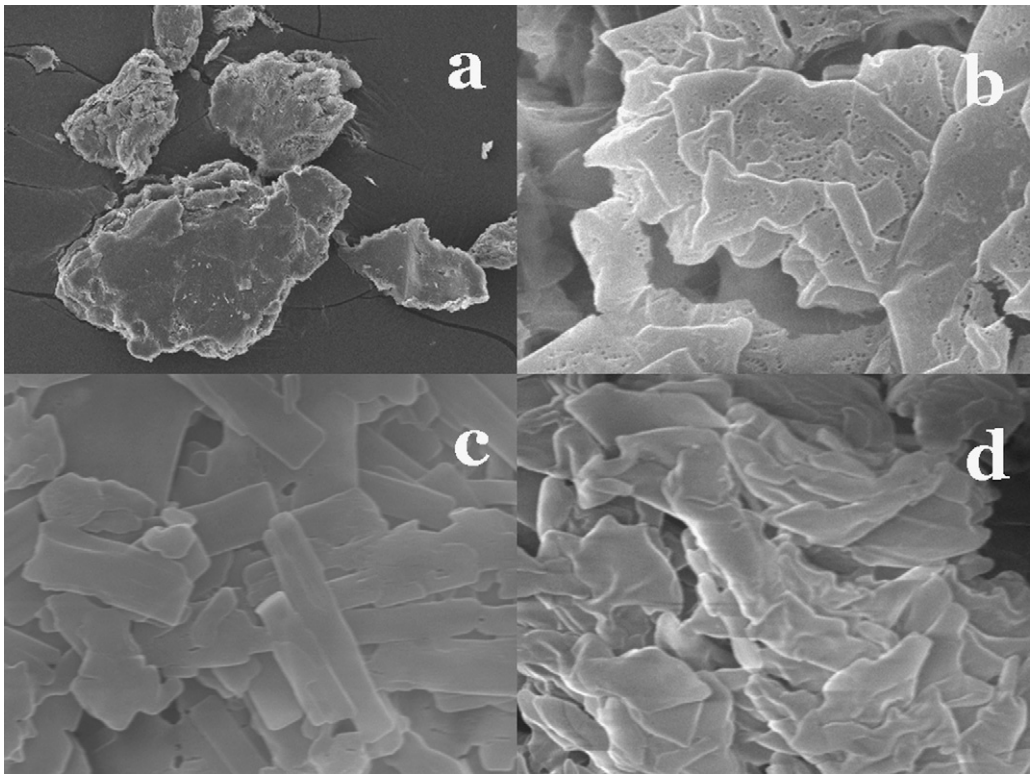

Fig. 1. SEM micrographs of the coacervate phase formed by sodium dodecanoate, methanol and various cations. (a) Na^+ (50 μm at 10 kV), (b) Ca^{2+} (5 μm at 20 kV), (c) Mg^{2+} (5 μm at 20 kV) and (d) Ca^{2+} and Mg^{2+} (1 μm at 20 kV).

absorbance was immediately recorded at 350 nm. According to the data presented in Fig. 3, 0.5% (w/v) sodium dodecanoate provides the optimum absorption for a wide variety of water hardness ranging from soft to very hard water. For lower sodium dodecanoate concentrations, the vesicle's charge was probably counterbalanced due to inadequacy of reactive sites and in combination with the respective low amounts of co-surfactant content did not favour the formation of a lamellar phase. On the other hand, with increasing sodium dodecanoate and co-surfactant concentrations, the precipitate swelled, increasing the absorbance of the solution, either due to transition from vesicles to stacked membranes [17], or due to the increase of surfactant concentration above cmc which complicates solubilization and dispersion of the alkaline earth metal coacervates due to the presence of micellar aggregates. In either case, the analytical signal is deteriorated either due to low UV absorption or due to intense turbidity that reduces the working and measuring range of the method. Therefore, the concentration of 0.5% (w/v) was selected for the remaining work.

It is worth mentioning that at the optimum sodium dodecanoate concentration, sample volume did not have any significant effect on the absorbance of the solutions (±6%). However, to minimize uncertainty it is advisable to maintain a constant sample volume throughout method application.

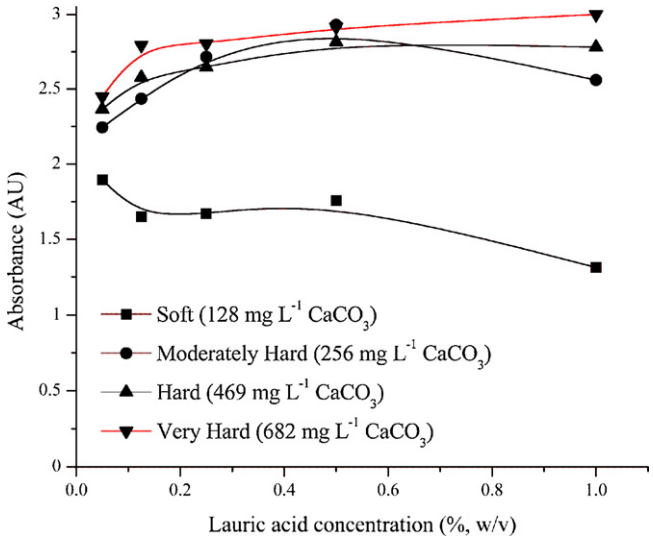

Fig. 3. Effect of sodium dodecanoate concentration in the absorbance of aqueous solutions containing various levels of water hardness.

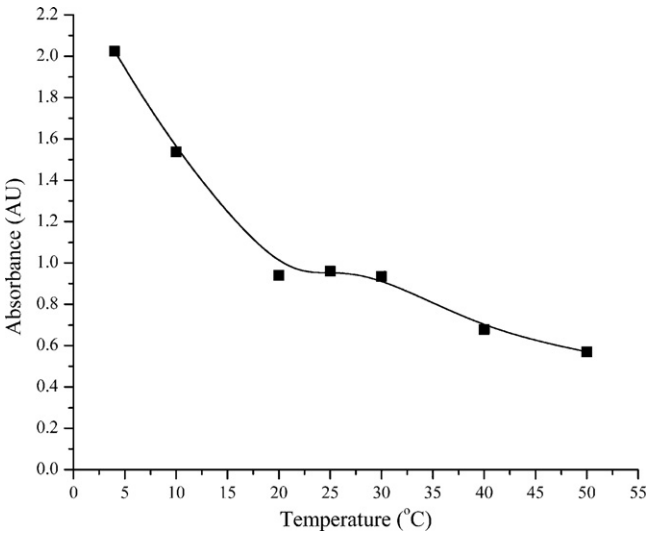

Fig. 5. Absorbance signal as a function of temperature in soft water.

3.3. Reaction kinetics

The incubation time necessary for sodium dodecanoate to react with alkaline earth metals towards the formation of a lamellar structure was the next parameter assessed for its influence on the analytical signal in terms of intensity, measuring range and reproducibility. Absorbance values recorded over the range of 0–240 min showed an increasing absorbance pattern with reaction time. From the data of Fig. 4 it can be inferred that absorbance increases with increasing water hardness gradually limiting the applicability of the method in hard waters since the signal eventually soared up to "out-of-range" absorbance values (not shown). Furthermore, the reproducibility of the measurements was deteriorated probably because vesicle membranes were not homogeneously dispersed in the vial which increases uncertainty. On the other hand, samples analyzed immediately after sodium dodecanoate addition gave the best reproducibility. Based on this observation, samples were measured after addition of sodium dodecanoate followed by vortex agitation to facilitate the reaction of sodium dodecanoate with alkaline earth metals and improve dispersion of the lamellar phase.

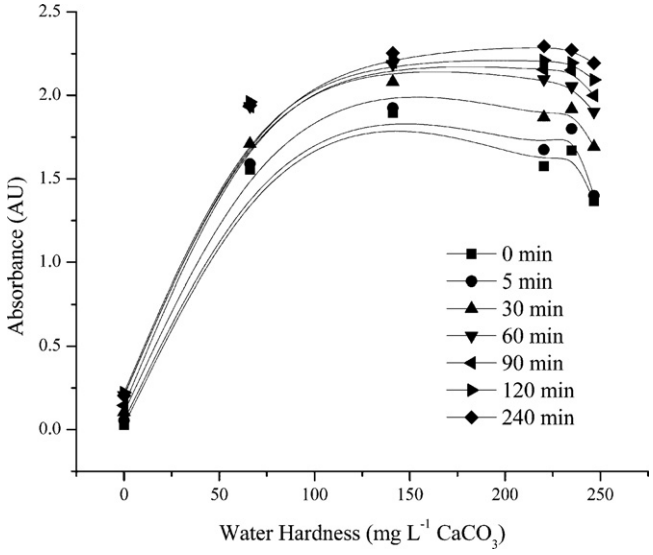

Fig. 4. Effect of incubation time on the absorbance of sodium dodecanoate-alkaline earth cation coacervates.

3.4. Effect of temperature

Temperature was the next parameter assessed for its effect on the analytical response (Fig. 5). Cold conditions (<10 °C) induced significant signal amplification due to the formation of a viscoelastic phase while warm conditions reduced the absorbance due to increased solubility of the lamellar phase and dehydration of the amphiphile head group inducing thermo-sensitive transformations [16,17]. A stable and reproducible response was obtained between 20 and 30 °C, therefore room temperature (approx. 25 °C) was selected for the analysis of real samples.

3.5. Effect of solution pH

The influence of hydrogen or hydroxyl concentration present in the sample was assayed by addition of increasing amounts of dilute HCl or NaOH. At acidic pH values sodium dodecanoate is protonated which increases competition with alkaline earth metals while the opposite is observed in alkaline media where the anionic group of sodium dodecanoate is deprotonated which aids complexation with metal species. In either case, the concentration of Ca^{2+} and Mg^{2+} in the sample was found to be an important factor in the absorbance of the solution as a function of pH. At acidic media higher Ca^{2+} and Mg^{2+} concentrations were necessary to compete for the reactive sites of sodium dodecanoate while in alkaline conditions complexation was favoured with increasing pH and water hardness. In this context, a priori knowledge of total hardness is necessary in order to decide on the appropriate regulation of the solution pH which has no practical meaning since the determination of hardness is of concern. Furthermore, the pH of the solution upon addition of sodium dodecanoate was close to 6.5 which is not far from the usual pH of most natural waters and far less than the solubility limit of both Ca^{2+} and Mg^{2+} in aqueous solutions. Therefore it was decided to apply the method in an unregulated pH environment.

3.6. Calibration procedure

The calibration procedure was performed with a series of model solutions (10 mL sample volume) containing various amounts of water hardness and Ca^{2+}/Mg^{2+} ratios, by extending the

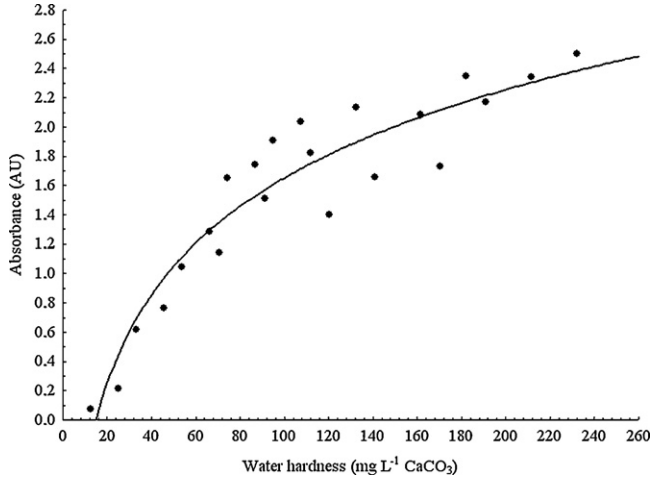

Fig. 6. Logarithmic calibration curve at 350 nm.

experimental data of Table 1, in an unregulated ionic strength environment to simulate the composition of natural waters. The concentration vs. absorbance line plotted in Fig. 6 shows that the absorbance is linearly depended on water hardness up to 60 mg L^{-1} (as $CaCO_3$) but above this value a logarithmic relationship is blatantly observed. This is reasonable since Mg^{2+}-sodium dodecanoate coacervates scavenge the light more intensely than the respective Ca^{2+}-sodium dodecanoate coacervates. As a result, the same absorbance value can be produced by at two combinations, the first involving high Ca^{2+} levels and the second low Mg^{2+} levels. From the concentration curves of Fig. 2 it is inferred that an absorbance value of 1 (a.u.) can be obtained by either 56.7 mg L^{-1} Ca^{2+} or 5 mg L^{-1} Mg^{2+}. In order to account for all occasions (samples with different water hardness giving similar absorbance values analyzed in the same batch) the overall fit to the experimental data was logarithmically expressed as a function of total water hardness. The calibration data were fitted to the expression

$$A = 0.9347 \times \mathrm{Ln}_{(\text{total hardness})} - 2.6626 \quad r = 0.9765 \qquad (1)$$

which was considered satisfactory considering the large number of data points and the high variability in the concentration of the individual data points included in the calibration curve. This equation was therefore applied to the analysis of real samples and the results were evaluated from a qualitative, semi-quantitative and quantitative perspective. It is conceivable that appropriate dilution can bring the sample within the linear range of the calibration curve, provided that an a priori assessment of total hardness has been undertaken.

Starting already from the first attempts to apply HALC method to the analysis of real samples it was revealed that a correction factor (C_f) to the calculated concentration was necessary. This came as no surprise considering the aforementioned discussion regarding the influence of Mg^{2+} in comparison to Ca^{2+}. Despite the fact that in most real samples situations were Ca^{2+} is totally absent or Mg^{2+} significantly surpasses Ca^{2+} concentration are rather scarce, we persisted on accounting for all cases, irrespectively of their scarcity and appearance rate in the natural environment. The calculated values of total hardness were multiplied by a factor of 1.80 ± 0.41 when the absorbance lied within the range $0.31 < Abs_{350} < 2$ and by a factor of 0.70 ± 0.13 when $2 < Abs_{350} < 0.31$. By using this approach the total hardness of real samples was calculated and the results are presented below in more detail. In is conceivable that if another calibration curve equation is used then a re-examination of the correction factors should be applied although no significant differences were observed in model solutions examined for that purpose. The following classification was used according to the level of total hardness: very soft (0–70 mg L^{-1} $CaCO_3$), soft (70–140 mg L^{-1} $CaCO_3$), slightly hard (140–210 mg L^{-1} $CaCO_3$), moderately hard (210–320 mg L^{-1} $CaCO_3$), hard (320–530 mg L^{-1} $CaCO_3$) and very hard (>530 mg L^{-1} $CaCO_3$).

3.7. Analytical characteristics of the method

Due to the lack of linearity of the calibration curve the determination of method detection limit and the quantitation limit as multiples of the signal-to-noise ratio cannot be calculated because of the non-linear properties of the calibration curve which results in variable slope and, as previously discussed, similar responses to more than one combination of Ca^{2+} and Mg^{2+} levels. Therefore, the lower limit of detection (LLD), which is the lowest amount or concentration of analyte which can be distinguished from the blank with a reasonable confidence, was determined by the mean absorbance of the blank sample plus k times the standard deviation of the absorbance obtained on the blank sample, i.e., $A_{LLD} = A_{\text{mean blk}} + k \times A_{SDblk}$, where k is a constant related to the statistical level of confidence [19]. This approach is similar to that proposed in DG SANCO decision were the detection capability (CC_a) is defined "the lowest concentration level at which a method can discriminate with a statistical certainty of $1 - \alpha$ whether the identified analyte is present" [20]. For $k = 3$, the LLD is 19.4 mg L^{-1} $CaCO_3$ and corresponds to the uncorrected concentration determined directly by equation (1). Since the absorbance at this concentration is below 0.31, multiplication by the respective $C_f = 0.70$, results in a final detection limit of 13.5 mg L^{-1} $CaCO_3$.

The reproducibility of the method, expressed by the relative standard deviation (RSD) of repeated assays was 4.21–8.08% ($n = 7$) from very soft to very hard waters, which satisfies the requirements for the application intended in this study.

3.8. Interferences

In view of the low selectivity of the spectrophotometric detector and the competitive reaction ambience where other metallic ions may react with sodium dodecanoate, various metallic cations and inorganic anions were investigated for their effect on the absorbance signal. The tolerance limit of a foreign species was defined as the concentration that causes a relative error greater than ±5%. Trace elements like Pb^{+2}, Cd^{+2}, Sb^{+3}, As^{+3}, Co^{2+}, Ni^{+2} and Cr^{3+} had no effect on the analytical response at concentrations up to 50 μg L^{-1}, which is well above the usual concentration levels. Important elements like Fe^{3+}, Al^{3+} and Zn^{2+} had no effect up to the maximum concentration levels examined (500 μg L^{-1}), while Cu^{2+} could be tolerated up to 200 μg L^{-1}.

Regarding the interference by anions, phosphates (25 mg L^{-1}), chloride (250 mg L^{-1}), nitrates (50 mg L^{-1}), nitrites (0.5 mg L^{-1}), fluoride (1.5 mg L^{-1}) and sulphate (250 mg L^{-1}), which are the indicative values proposed by the 98/83/EC directive, did not interfere with the determination of water hardness. Furthermore, organic matter in the form of humic acids (10 mg L^{-1}) did not exhibit any adverse effects on the analytical response of HALC.

4. Method application

4.1. Qualitative analysis

As previously discussed the reaction of sodium dodecanoate with alkaline earth metals yields a coacervate phase depending on the total water hardness which is further determined by the relative abundance of Ca^{2+} and Mg^{2+}. In most natural waters where Mg^{2+} is less or equal to Ca^{2+} the coacervate phase yields a response similar to that of Fig. 7. As we can observe, although the visual

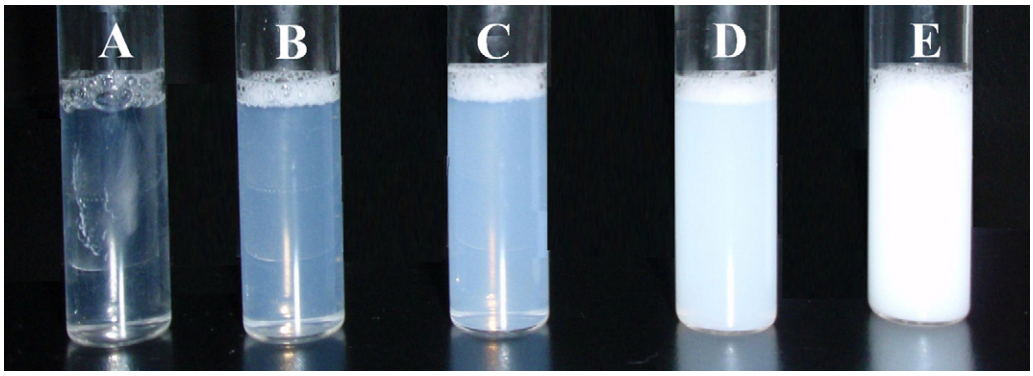

Fig. 7. A photograph of real samples taken after the addition of sodium dodecanoate in the presence of various water hardness content. (A) Very soft water at 35 mg L^{-1} $CaCO_3$, (B) soft water at 105 mg L^{-1} $CaCO_3$, (C) moderately hard water at 265 mg L^{-1} $CaCO_3$, (D) hard water at 425 mg L^{-1} $CaCO_3$ and (E) very hard water at 600 mg L^{-1} $CaCO_3$. Experimental conditions as defined in the text.

differentiation between soft to moderately hard and hard to very hard water requires some degree of familiarization, the classification to soft, moderately hard and hard water can be accomplished by direct visual inspection even without any previous experience in the method. Therefore, the method is directly applicable to the qualitative assay of water hardness by visual inspection which is not offered by any of the usual methods for the determination of water hardness.

4.2. Semi-quantitative analysis

The method was then applied to the classification of water hardness based on the concentration ranges assigned to each type of water adopted in this work (very soft to very hard). The data gathered in Table 2 show that method application successfully assigned almost all samples to the correct concentration range thus providing a good classification of water samples based on the level

of total hardness. This is advantageous when a fast estimation of water hardness is of concern, thus minimizing experimental effort.

4.3. Quantitative analysis

The ability of the method to provide an accurate measure of total water hardness is also shown in Table 2. The average relative error ranges, in terms of absolute values, from 0.87 to 29.7% with an average value of $10.7 \pm 7.9\,mg\,L^{-1}$ $CaCO_3$ and a standard error of $1.58\,mg\,L^{-1}$ $CaCO_3$. The distribution of relative experimental error shows that the method affords a satisfactory assessment of water hardness. The relative average deviation (ARD) of all samples, which is a measure of precision, was $0.11 \pm 0.08\%$ to $0.13 \pm 0.1\%$ which is very satisfactory. It is also worth mentioning that the lowest error was observed in bottled waters where the concentrations of both Ca^{2+} and Mg^{2+} were known thus enabling an accurate calculation of total hardness as $CaCO_3$ equivalents, using the equation:

$$[CaCO_3] = 2.497 \times [Ca^{2+}] + 4.117 \times [Mg^{2+}] \quad (2)$$

which derives from the ratio of the molar masses of $CaCO_3$, Ca^{2+} and Mg^{2+}. On the other hand, all other samples were analyzed with the EDTA titration method with visual inspection of the end point of the EDTA titration procedure.

4.4. Analysis of salt containing samples

The analysis of real samples containing inorganic salts was further considered. It is well known that inorganic electrolytes decrease the electrostatic repulsion among adjacent sodium dodecanoate molecules leading to the formation of planar or bent structures (Fig. 1a) while they compete Ca^{2+} and Mg^{2+} for the available reactive sites [9,17]. Therefore the applicability of the method in the presence of NaCl, which is the most common inorganic salt in the environment, was investigated. Considering the competition of Na^+ counter-ions for Ca^{2+} and Mg^{2+} the influence of increasing NaCl was investigated at concentrations from 0 to 0.75 M which is higher than the usual value of seawater (35‰) by direct spiking in salt-free water samples (bottled waters) with variable total hardness content. However, values above 0.5 M could not be employed because the coacervate phase became insoluble forming a thick membrane that remained on the top of the vial especially with increasing total hardness. The analysis of salt containing samples revealed that the absorbance signal soars up to 0.1 M NaCl irrespectively of water hardness, but above this value it descents, increases or reaches a plateau depending on total hardness (Fig. 8), which is attributed to the relative competition of Na^+ with Ca^{2+} and Mg^{2+} for the reactive sites of sodium dodecanoate. From a practical standpoint, the presence of salt deteriorated the relative experimental error between EDTA titration and the proposed method providing no improvement in the measured concentrations. Furthermore, no specific relationship between salt concentration and water hardness could be established. Empirically, it was observed that the influence of ionic strength is related to the relative abundance of individual alkaline earth metals to that of salt counter-ion but the wide distribution of the experimental measurements did not enable the provision of a mathematical expression that could account for these phenomena.

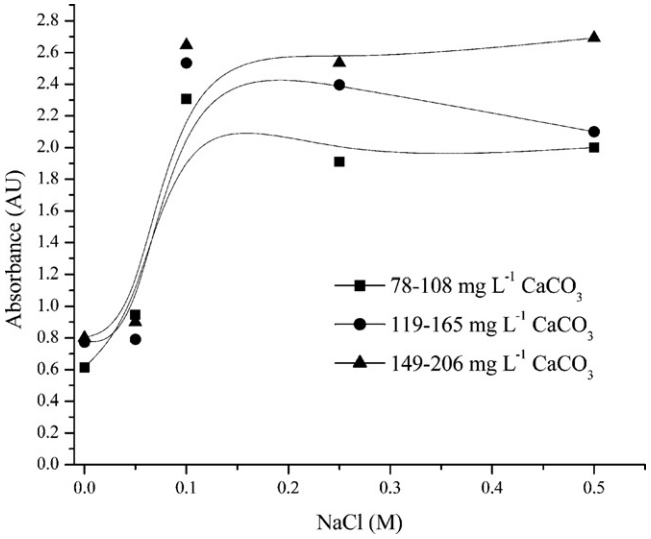

Fig. 8. Influence of ionic strength on the absorbance yield of HALC in variable water hardness.

Since no clear relationship between ionic strength and water hardness was found, it was decided to investigate the influence of NaCl on the analytical response of HALC method empirically by employing real rather than artificial samples. A series of four NaCl-containing samples from different drillings located along the coastal line of north Corfu (<2 km from sea) and two (2) seawater samples from the Thesprotia region were analyzed for that purpose applying various dilution factors (Table 3). The optimum results were obtained at 2-fold dilution of underground water samples and 50-fold for seawater while for higher dilution the relative error deteriorated significantly and was attributed to the high Mg^{2+} content of seawater, compared to Ca^{2+} [21]. Therefore, although the proposed method may provide a fair approximation of water hardness to salt containing samples after appropriate dilution, its application is not a straightforward task and requires the experimental validation of the results before a secure conclusion can be reached. In this sense, samples that contain appreciable amounts of salts should be analyzed in parallel with another method in order to decide on the best dilution factor which enables HALC method to provide an accurate estimate of total hardness. In the same direction, Mg^{2+}-rich waters could be treated in a similar manner in order to reduce the influence of Mg^{2+} in the final measured signal. However, once this is done, the HALC method can be routinely applied to monitor water hardness in salt containing and/or Mg^{2+}-rich samples.

4.5. Speciation of water hardness

Despite the non-selective determination of Ca^{2+} and Mg^{2+} ions afforded by HALC, further development towards the individual determination of water hardness components, which may is of interest especially in biological samples, can be pursued. As previously discussed, both Ca^{2+} and Mg^{2+} yield a linear response with increasing concentration suggesting that the method can be conveniently applied to their separate determination. Since most samples of environmental, biological and food origin contain both species, the selective removal or determination of one species must precede the speciation protocol, the other being determined as the difference between total hardness and known ion concentration according to Eq. (2). Ion-selective electrodes or flame atomic absorption spectrometry could be employed towards this direction [4,5,7,22].

5. Conclusions

A rapid and facile method abbreviated as HALC (hardness by alkaline earth metal coacervation) is described in this study for the determination of water hardness exploiting the phenomenon of coacervation of alkaline earth metals in aqueous solution upon their reaction with an anionic surfactant (sodium dodecanoate). Investigation of the experimental conditions that afford the optimum analytical performance was elucidated suggesting that the method is straightforwardly applicable by measuring the absorbance of the solutions at 350 nm, without the need for any adjustment of the usual analytical parameters like pH, ionic strength, temperature and incubation time. Due to the different response of Mg^{2+} and Ca^{2+} in the final absorbance signal, a non-linear calibration curve based on the logarithmic expression of absorbance vs. concentration was constructed and a concentration correction factor was established. The method was successfully applied to various natural water samples yielding a fair estimation of water hardness in terms of qualitative, semi-quantitative and quantitative analysis. The interference from salts (above 0.1 M) or too high Mg^{2+} concentrations can easily be overcome by simple dilution, enabling method application in a wide variety of samples, including seawater.

Water analysis

ABSTRACT

A new and fast equilibrium-based solvent microextraction technique termed vortex-assisted liquid–liquid microextraction (VALLME) has been developed and used for the trace analysis of octylphenol, nonylphenol and bisphenol-A in water and wastewater samples. According to VALLME, dispersion of microvolumes of a low density extractant organic solvent into the aqueous sample is achieved by using for the first time vortex mixing, a mild emulsification procedure. The fine droplets formed could extract target analytes towards equilibrium faster because of the shorter diffusion distance and larger specific surface area. Upon centrifugation the floating extractant acceptor phase restored its initial single microdrop shape and was used for high-performance liquid chromatographic analysis. Different experimental parameters were controlled and the optimum conditions found were: 50 μl of octanol as the extractant phase; 20 ml aqueous donor samples; a 2 min vortex extraction time with the vortex agitator set at a 2500 rpm rotational speed; centrifugation for 2 min at 3500 rpm; no ionic strength or pH adjustment. The calculated calibration curves gave high levels of linearity yielding correlation coefficients (r^2) greater than 0.9935. The repeatability and reproducibility of the proposed method were found to be good and the limits of the detection were calculated in the low $\mu g\,l^{-1}$ level ranging between 0.01 and 0.07 $\mu g\,l^{-1}$. Matrix effects were determined by applying the proposed method to spiked tap, river water and treated municipal wastewater samples. The proposed method was finally applied to the determination of target pollutants in real wastewater effluent samples using the standard addition method.

1. Introduction

Analytical microextractions represent an important development in the field of sample preparation, addressing issues of simplicity, miniaturization and time efficiency [1]. Although different types of microextraction techniques were initially reported, it was the introduction of solid-phase microextraction (SPME) in 1990 [2] that initiated intensive research efforts in the area. Few years later, solvent microextraction (also known as liquid-phase microextraction or LPME) appeared in the literature [3–6], representing a miniaturization of the traditional liquid–liquid extraction (LLE) procedure whereby the solvent to aqueous phase ratio was greatly reduced. The general requirements for LPME were the use of an acceptor phase immiscible to the aqueous sample donor solution and analytes that were more soluble in the extractant phase than in the sample solution. Hitherto, different methodologies evolved from this approach including amongst others immersion [7] and headspace [8] single-drop microextraction, static and dynamic LPME [9] or even hollow fiber LPME [10,11].

Recently, a new LPME method termed dispersive liquid–liquid microextraction (DLLME), based on a ternary component solvent system similar to the one found in homogeneous liquid–liquid extraction and cloud point extraction, appeared in the literature [12]. For DLLME, a water-immiscible extractant solvent dissolved in a water-miscible dispersive solvent was rapidly injected into an aqueous donor solution leading to the formation of a cloudy solution consisting of fine droplets of the extractant solvent dispersed entirely in the aqueous (continuous) phase. Target analytes were extracted into these fine droplets, which could be subsequently separated by centrifugation and used for analysis. The main drawbacks associated with DLLME were the difficulty to automate and the necessity of using a third component (disperser solvent), which commonly decreased the partition coefficient of analytes into the extractant solvent [13]. Recently, dispersion of the extractant phase into the sample solution was also achieved using the so-called temperature-controlled ionic liquid DLLME method [14]. The method was based on the ability of an ionic liquid drop to disperse in an aqueous phase at higher temperatures, yet return to phase separation upon cooling and centrifugation. Although the method yielded high enrichment factors, analyte losses due to volatilization at higher temperatures were reported. Finally, the possibility of using ultrasound as a mean for dispersing the

doi:10.1016/j.talanta.2009.11.005

extractant acceptor phase (organic solvent [13,15] or an organic solvent/ionic liquid mixture [16]) into an aqueous donor phase was recently explored. In general, heterogeneous liquid–liquid systems are known to become uniform when subjected to ultrasonic irradiation. The process is also known as "homogenization" or "emulsification" and has been used as an alternative to the conventional LLE method [17]. Moreover, ultrasound was found to speed up this homogenization/emulsification step given that the formation of submicron size droplets greatly increased the contact surface between the two liquids, yielding fast and efficient analyte transfer. Nevertheless, in many cases analytical chemists have been reluctant to test ultrasound as a mean for improving liquid–liquid extraction given that it most often produces stable emulsions that result in long phase separation times. Problems were also encountered due to the use of cleaning baths as ultrasound irradiation production equipment which are notorious for their tendency to decline in power with time and their lack of uniformity in the transmission of ultrasound irradiation [18]. It should also be mentioned that even at these low frequencies and relatively short application times, analyte degradation may occur through large pressure and temperature gradients, high shear forces, or even by free radicals generation [19,20].

The aim of this research was to introduce a new and fast microextraction method whereby dispersion of the extractant phase into the aqueous is achieved for the first time using vortex mixing, a mild emulsification procedure. The resulting methodology was termed vortex-assisted liquid–liquid microextraction (VALLME) and was used for the extraction of trace amounts of alkylphenols (namely: octylphenol (OP) and nonylphenol (NP)) and bisphenol-A (BPA) used here as model compounds from water and wastewater samples. In general, alkylphenols are considered as degradation products of alkylphenolpolyethoxylates, a widely used class of nonionic surfactants with industrial and household applications [21,22]. OP and NP have been classified as endocrine disruptive compounds by several organizations, and are listed as a priority substance in the Water Framework Directive [23]. BPA on the other hand is commonly used as an intermediate in the production of polycarbonate and epoxy resins, flame retardants and other specialty products [24] and was found to exhibit weakly estrogenic activity as well as antiandrogenic activity [25]. Hitherto, different reports based on SPME or LPME coupled to high-performance liquid chromatography (HPLC) deal with the trace analysis of environmental samples containing these target analytes [21,26–32]. For the purpose of the present investigations, several experimental parameters affecting the extraction process (namely: organic solvent, agitation time, rotational speed of the vortex agitator, acceptor phase volume, aqueous sample volume, pH and salt addition) were initially controlled and optimized and the performance of the proposed method was then assessed. Matrix effects upon extraction were evaluated by analyzing spiked tap and river water as well as effluent water samples taken from a municipal wastewater treatment plant.

2. Experimental

2.1. Chemicals and samples

BPA and OP were purchased from Aldrich (Sigma–Aldrich, Gillingham, Dorset, UK). 1-octanol and NP Pestanal® (94% purity) were purchased from Riedel-de Haën (Seelze, Germany). All organic solvents used here were of pesticide grade. Deionized water was prepared on a water purification system (EASYpure®RF) supplied by Barnstead/Thermolyne Corporation (Dubuque, IO, USA). Stock solutions were prepared in methanol and stored at 4 °C in the dark when not in use. Working standards were prepared daily at the concentration levels of interest.

A 100 μl Hamilton (Bellefonte, BA, USA) HPLC 710 SNR model microsyringe was used to introduce the organic solvent into the aqueous sample and then collect it and inject it into the HPLC system for analysis.

River water samples were collected from the River Koiliaris situated in Chania-Crete (pH 7.5; chemical oxygen demand (COD) = 20 mg/l; total dissolved solids (TDS) = 100 mg/l). Wastewater effluent samples were collected from the municipal wastewater treatment plants of Chania (pH 7.6; COD = 15 mg/l; TDS = 508 mg/l) and Rethymno (pH 8.0; COD = 68 mg/l; TDS = 780 mg/l) situated in the North-West part of Crete, serving approximately 70,000 and 25,000 habitants, respectively. All samples were collected the day before being analyzed and were stored in the dark at 4 °C.

2.2. VALLME

Unless otherwise stated within the text, 20 ml aqueous samples spiked at a known concentration with all target analytes were placed in a round-bottom glass vial (diameter: ~2 cm) and 50 μl of octanol were then slowly introduced acting as the extractant solvent. The mixture was then vigorously shaken using a vortex agitator (Reax Control, Heidolph, Germany) for 2 min at 2500 rpm (maximum setting). As a result fine droplets were formed facilitating mass transfer of the target analytes into the organic acceptor phase. Separation of the two phases occurred upon centrifugation at 3500 rpm for 2 min (Labofuge 400 Heraeus, Kendro Laboratory Products, Germany). The floating octanol phase could thus restore its original single microdrop shape and 30 μl could be easily collected with the help of a microsyringe and used for HPLC analysis. During optimization, all experiments were run at least in duplicate.

2.3. HPLC analysis

Separation and quantification was carried out using an HPLC system, manufactured by Shimadzu (Shimadzu Corporation, Kyoto, Japan), equipped with a fluorescence detector (FLD) and two solvent delivery pumps. A Nucleosil 100-5 C18 (250 mm × 4.6 mm × 5 μm; Macherey-Nagel, Duren, Germany) was used to separate the target analytes at 27 °C. The mobile phase was acetonitrile:water (80:20) with a flow rate of 1.0 ml min^{-1}. The excitation and emission wavelengths of the FLD were set at 277 and 300 nm respectively. The total analysis time was 15 min.

3. Results and discussion

3.1. Optimization of VALLME

Initially, several water immiscible solvents (namely: 1-octanol, toluene, *n*-hexane, octane and cyclohexane) were tested, having densities lower than that of water and differing in polarity and water solubility. Each time, 50 μl of the organic solvent to be tested was slowly added to a 20 ml aqueous sample spiked at 1 μg l^{-1} with BPA and OP and 10 μg l^{-1} with NP. Given that all solvents tested had densities lower than that of water, they resided in the top surface of the water sample in the form of a single microdrop. The mixture was then vigorously agitated using a vortex agitator (2 min; 2500 rpm) leading to drop breakage into fine droplets. In the present studies centrifugation (2 min at 3500 rpm) was chosen as a viable mean for separating the two phases of this liquid–liquid dispersion. Amongst the low density solvents tested, 1-octanol had the ability to "restore" its initial single microdrop shape and as such could be easily collected and used for HPLC analysis. Under the present experimental conditions, coalescence of the fine droplets into a coherent phase did not occur for the rest of the tested solvents which were left scattered on the top surface of the aqueous solution in the form of smaller satellite microdrops hindering thus

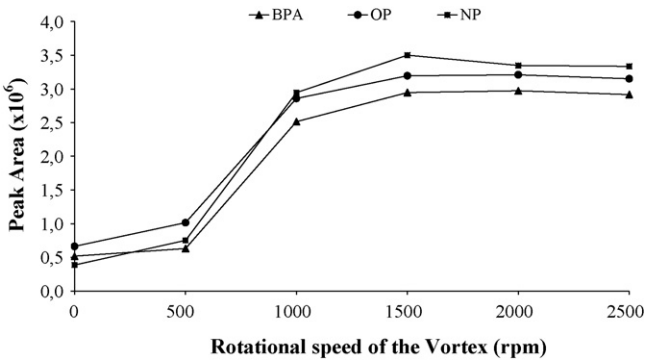

Fig. 1. Effect of the rotational speed of the vortex agitator upon VALLME. Other experimental conditions: 50 μl octanol; 20 ml aqueous samples spiked at 1 μg l^{-1} with BPA and OP and 10 μg l^{-1} with NP; 2 min agitation using a vortex agitator; centrifugation for 2 min at 3500 rpm.

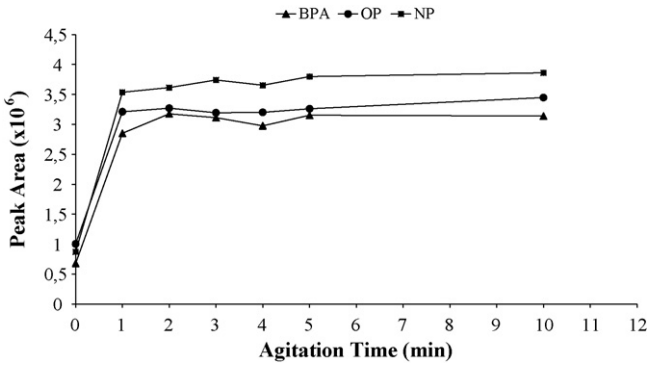

Fig. 2. Effect of vortex extraction time upon VALLME. Other experimental conditions: 50 μl octanol; 20 ml aqueous samples spiked at 1 μg l^{-1} with BPA and OP and 10 μg l^{-1} with NP, vortex agitator set at 2500 rpm rotational speed; centrifugation for 2 min at 3500 rpm.

their collection. Despite the numerous studies in the field separation processes driven by gravity or centrifugal forces are not yet completely understood [33]. In addition the mechanisms involved during drop breakage and formation are rather complex and form part of many ongoing investigations. Nonetheless, they appear to be greatly influenced (amongst others) by the physicochemical properties of the phases involved and the geometry of the apparatus used [34]. It should be mentioned here that the ability of 1-octanol to efficiently extract alkylphenols (NP and 4-*tert*-OP) when compared to ionic liquids and carbon tetrachloride has been demonstrated in the past [27]. Based on the above, 1-octanol was used as the acceptor organic phase for the rest of the experiments.

In general, the effect of a vortex agitator is to swirl the fluids and create a vortex, the size and shape of which depend upon the rotational speed of the rotor. In the case of immiscible liquids and at elevated speeds this generally results into the breakup of one of the two phases into fine droplets. Although such unstable fluid fields would seem unfavorable for operation, solvent microextraction methods are equilibrium methods and mass transfer within the organic acceptor phase is a limit step [6]. These fine droplets could extract analytes towards equilibrium faster because of the shorter diffusion distance and larger specific surface area [35]. Accordingly, in a separate set of experiments, the effect of the rotational speed of the vortex agitator upon VALLME was investigated and the results are depicted in Fig. 1. The "0 rpm" experimental point corresponded to the extraction where the water–octanol mixture was not subjected to vortex agitation and preconcentration of the target analytes was solely due to diffusion during the centrifugation step [36]. Fig. 1 demonstrates the beneficial effect of vortex agitation over centrifugation alone and it appears that the final analyte concentration of the microextract is nearly uniform for speeds greater than 1500 rpm where equilibrium conditions appear to be attained within the 2 min agitation time applied. Based on these observations it was decided to use the maximum speed setting of the vortex agitator (2500 rpm) for all subsequent experiments.

Fig. 2 depicts the results obtained whilst investigating the effect of vortex extraction time upon VALLME. At the experimental point "0 min", samples were only centrifuged and preconcentration was once again solely due to diffusion during centrifugation [36]. As can be seen extraction rates increased for increased vortex extraction times and it appears that equilibrium is attained for all target analytes after only 2 min. Based on the above, a 2 min vortex extraction time was chosen, enabling extraction at equilibrium conditions and resulting in increased precision and sensitivity.

Next, the effect of the acceptor phase volume upon extraction was investigated for volumes ranging between 50 and 80 μl. Octanol volumes lower than 50 μl were avoided, given that final collection of at least 30 μl which could be used for analysis was not always possible. It was assumed that although octanol had the ability to "restore" its initial microdrop shape, the formation of smaller satellite microdrops that could not coalesce with the mother drop was unavoidable. Octanol dissolution into the aqueous phase may have partially contributed to the reduced volumes of the final microdrops used for analysis. In the present investigations an overall 36, 38 and 42% decrease in the response of the instrument was recorded for BPA, OP and NP, respectively, whilst increasing the acceptor phase volume from 50 to 80 μl. This was due to the decreased final concentrations of target analytes in the octanol phase [6]. Thus, for all subsequent extractions, 50 μl octanol volumes were used.

The effect of aqueous sample volume upon VALLME was then investigated. As expected, increasing the volume of the spiked aqueous solution from 5 to 20 ml, increased the total mass of analytes available for extraction [37], resulting in a net increase in the response of the analytical instrument for BPA, OP and NP and the recorded signals were found to be 1.5, 2.4 and 3.4 times higher, respectively. It should be mentioned here that larger volumes were not tested given that the sensitivity of the instrument was found to be satisfactory. Based on the above, 20 ml aqueous samples were used each time for extraction.

It is well known that pH can significantly influence the partitioning of ionizable hydrophobic chemicals to octanol. The pollutants investigated here are considered to be weak acids and are expected to be found mainly in their molecular form for pH values below 8.0 and in their deprotonated form for pH values over 11 [24,27]. During the present studies, a non-significant negative effect of the pH upon VALLME was recorded for pH values ranging from 4 to 8. This is in agreement with a recent report published by Liu et al. [27], who concluded that altering the pH of sample solutions containing 4-*tert*-OP and NP, had a significant effect on the uptake kinetics into the 1-octanol film supported on a hollow fiber, yet no pH effect was observed for the equilibrium distribution, which is the case here. Given that no significant changes in extraction efficiency were observed in the environmentally relevant pH range, it was decided not to alter the pH of the aqueous samples.

Finally, the effect of salt for NaCl concentrations ranging from 0 to 15% (w:v) upon VALLME was investigated and the results are given in Fig. 3. As can be seen the presence of salt restricted the extraction of OP and NP, and was found to be beneficial for BPA. Similar results were obtained by Cai et al. [30], whilst developing an SPME method coupled to HPLC-FLD for the analysis of BPA, NP, and 4-*tert*-OP. In their work, increasing the ionic strength of the samples (up to 20% (w:v) NaCl) resulted in an increase of the extraction efficiency for BPA and a decrease for NP. In the case of 4-

Table 1
Selected method parameters (linear concentration range, r^2 and LOD) and average relative recoveries ($n = 3$) for different samples (namely tap water, river water and wastewater (WW)) spiked at 1 μg l^{-1} with BPA and OP and 10 μg l^{-1} with NP (RSD values given in parentheses).

Compound	Conc. range	r^2	LOD	Relative recoveries (% (RSD))		
				Tap	River	WW effluent
BPA	0.05–100	0.9992	0.02	94 (3)	105 (3)	75 (2)
OP	0.05–100	0.9996	0.01	101 (3)	111 (3)	63 (6)
NP	0.50–100	0.9935	0.07	104 (4)	109 (4)	67 (7)

tert-OP, extraction increased reaching a maximum at 5% (w:v) NaCl and then decreased for increased salt concentrations. Recently, Braun et al. [38] developed a method based on SPME coupled to gas chromatography–mass spectrometry. During optimization the authors reported that the response for 4-*tert*-NP decreased significantly as the salt concentration increased, whereas for BPA a slight increase in extraction yield was recorded for increased NaCl concentrations, which was hardly lowered up to the saturated condition. Finally, Rezaee et al. [31] whilst developing a sample preparation method based on DLLME coupled to HPLC-UV reported a non-significant effect on the extraction recovery of BPA when sodium chloride up to 8% (w:v) was added in the sample solution. The authors in this study took into account for their calculations the increase in volume of the sedimented extractant solvent phase. Given that in the present investigations the presence of salt did not result in significant positive changes in the extraction yields of all target analytes, it was decided not to alter the ionic strength of the aqueous samples destined for analysis.

Overall, the optimized experimental conditions found here were: 50 μl octanol; 20 ml aqueous samples; 2 min vortex extraction time; vortex agitator set at 2500 rpm rotational speed; centrifugation for 2 min at 3500 rpm; no ionic strength or pH adjustment.

3.2. Analytical performance of VALLME

The linearity of the proposed method was determined by extracting under the optimized extraction conditions, aqueous solutions spiked at concentrations ranging from 0.05 to 100 μg/l for BPA and OP and 0.5–100 μg/l for NP. The calculated calibration curves gave a high level of linearity, yielding correlation coefficients (r^2) 0.9992, 0.9996 and 0.9935 ($n = 5$) for BPA, OP and NP, respectively (Table 1). The repeatability of the method, expressed as relative standard deviation (RSD), was evaluated after extracting at two concentration levels five consecutive aqueous samples each time. Spiking aqueous samples at 1 μg l^{-1} with BPA and OP and 10 μg l^{-1} with NP yielded RSD values of the order of 2.4, 2.1 and 2.2%, respectively. For samples containing 0.1 μg l^{-1} BPA and OP and 1 μg l^{-1} NP, the RSD values found were 5.9, 4.6, 8.0%, respectively. The limits of detection (LOD) defined for a signal-to-noise of three (S/N = 3) were found in the low μg l^{-1} level (Table 1), lower or similar to the ones reported when coupling a liquid- or solid-phase microextraction method coupled to HPLC (Table 2). Enrichment factors defined as the ratio between the final analytes concentration in the organic acceptor phase and the initial aqueous sample concentration were found to be approximately for 450, 690 and 150 for BPA, OP and NP, respectively.

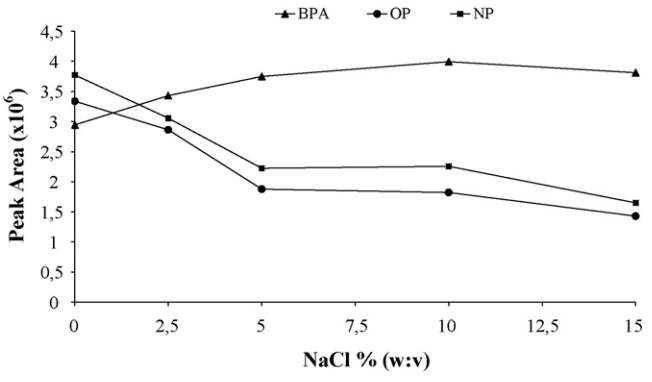

Fig. 3. Effect of ionic strength (% NaCl, w:v) upon VALLME. Other experimental conditions: 50 μl octanol; aqueous samples spiked at 1 μg l^{-1} with BPA and OP and 10 μg l^{-1} with NP; 2 min vortex extraction time; vortex agitator set at 2500 rpm rotational speed; centrifugation for 2 min at 3500 rpm.

It is well known that the efficiency of microextraction methods can be affected by the composition of the sample matrix. Accordingly, tap, river and municipal sewage effluent water samples were spiked at 1 μg l^{-1} with BPA and OP and 10 μg l^{-1} with NP and analyzed under the optimized experimental conditions. The relative recoveries found (defined as the ratio of the concentrations found in environmental and deionized water samples spiked with the same amount of analytes) are given in Table 1. As can be seen, in the case of tap and river water matrix did not affect extraction. However, in the case of effluent wastewater a decrease in extraction yield and as a consequence in sensitivity was observed. A similar observation has been reported in the past [39] and it was decided that for quantification in more complex environmental samples (such as wastewater effluents) the standard addition method should be used. Typical HPLC chromatograms obtained after VALLME of wastewater effluent samples before and after spiking at 1 μg l^{-1} with BPA and OP and 10 μg l^{-1} with NP are given in Fig. 4.

Table 2
Comparison of LOD obtained with VALLME and other published liquid- or solid-phase microextraction methods coupled to HPLC.

Method	LOD (μg l^{-1})	Reference
DLLME coupled to HPLC-UV	BPA: 0.07	[31]
Ionic liquid LPME coupled to HPLC-FLD	4-NP: 0.3 4-*tert*-OP: 0.7	[21]
1-Octanol Thin Film supported on a hollow fiber coupled to HPLC-FLD	4-NP: 0.06 4-*tert*-OP: 0.1	[27]
SPME coupled to HPLC-FLD	BPA: 0.9	[29]
SPME coupled to HPLC-FLD	BPA: 0.43 4-*tert*-OP: 0.16, NP: 0.29	[30]

VALLME coupled to HPLC-FLD	BPA: 0.02 OP: 0.01 NP: 0.07	Present studies

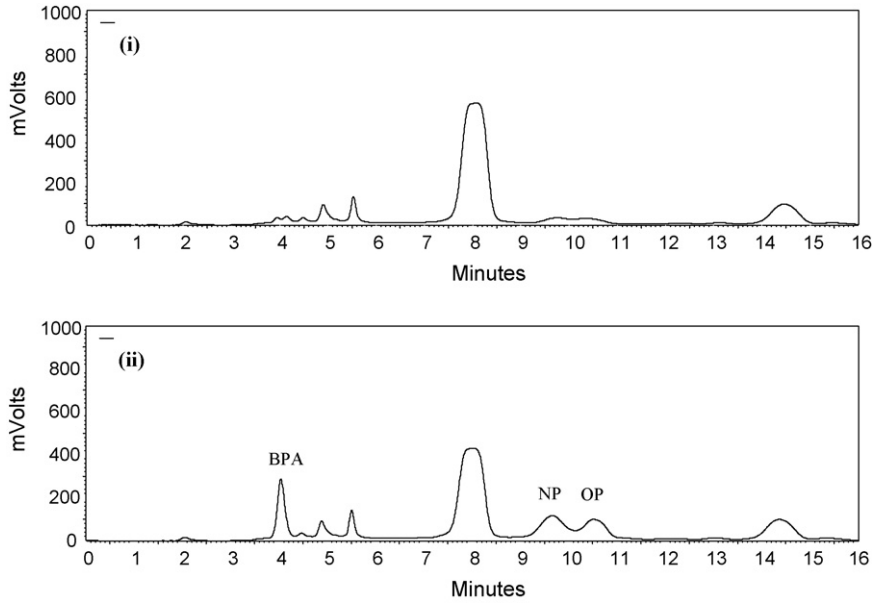

Fig. 4. Typical HPLC chromatograms obtained after VALLME of wastewater effluent samples (i) before and after spiking at 1 $\mu g\,l^{-1}$ with BPA and OP and 10 $\mu g\,l^{-1}$ with NP.

Table 3
Concentrations of target pollutants in wastewater effluent samples originating from two municipal wastewater treatment plants situated in the north part of Crete (Chania and Rethymno). The standard deviations of the measurements are also included.

Compound	WW effluent from Chania ($\mu g\,l^{-1}$)	WW effluent from Rethymno ($\mu g\,l^{-1}$)
BPA	0.14 ± 0.01	0.28 ± 0.03
OP	0.39 ± 0.07	0.21 ± 0.04
NP	3.20 ± 0.25	0.67 ± 0.10

3.3. Analysis of effluent wastewater samples

The presence of BPA, OP and NP in real treated samples taken from two municipal wastewater treatment plants was then quantified using the VALLME. The standard addition method was chosen and samples were multiply extracted. As can be seen (Table 3) the presence of all target pollutants was confirmed, demonstrating the inability of this treatment process to efficiently remove these contaminants [25]. In addition, the contamination levels found in the treated wastewater samples examined here were similar to the ones found in different Mediterranean countries. Gómez et al. studied the contamination levels of effluents samples taken from two municipal wastewater treatment plants located in south-eastern Spain (Almeria), reported a 0.38 $\mu g\,l^{-1}$ mean value for BPA after a 1 year monitoring study [39]. Gonzalez et al., whilst comparing the efficiency of a pilot plant membrane bioreactor working in parallel to a full-scale wastewater treatment plant situated in Rubí (Barcelona-Spain), reported a 2 $\mu g\,l^{-1}$ average value for NP in the effluent samples [40]. Finally, Stasinakis et al. reported 0.18 and 0.15 $\mu g\,l^{-1}$ mean values for NP and BPA respectively for effluent samples taken from six different wastewater treatment plants in Greece [25].

4. Conclusions

A new and fast sample preparation method termed vortex-assisted liquid–liquid microextraction is presented here having the inherent advantage of achieving equilibrium conditions within only a few minutes. For the first time dispersion of the extractant phase into the aqueous was achieved using vortex mixing, a mild emulsification procedure, avoiding thus problems associated with the application of ultrasound. The proposed method was successfully applied to the determination of BPA, OP and NP at trace levels in water samples. For more complicated matrices the standard addition method was found to be suitable for quantification. Overall, this is a promising and fast sample preparation method that can be used for the trace analysis of organic pollutants in aqueous environmental samples.

ABSTRACT

Polychlorodibenzo-*p*-dioxins, polychorodibenzofurans and "dioxin-like" polychlorinated biphenyls are widespread persistent organic pollutants sharing a similar toxicological pathway mediated by the aryl-hydrocarbon receptor (AhR). Since the confirmatory method for their measurement at trace levels in complex matrices (using isotopic dilution and gas chromatography–high resolution mass spectrometry) remains time and cost-consuming, growing efforts of the scientific community have been focused on the development of screening approaches, including AhR mediated assays. Unfortunately, AhR ligands are highly diverse and agonistic/antagonistic effects can be observed on procedural blanks and/or sample extracts. In this study, the influence of solvent grade quality on the response of a DNA-binding AhR mediated assay used for screening dioxins has been investigated. Our results demonstrated a very critical impact of this parameter with both strong agonistic and antagonistic effects observed for any tested solvent lot. A small silver nitrate silica column removed partly these interfering compounds and then can be recommended as final purification step. Some preferable grades can be identified and selected in order to guarantee the best possible performances. However, it appears necessary to test every new lot, even if a grade appeared previously compliant.

1. Introduction

Polychlorodibenzo-*p*-dioxins (PCDD), polychorodibenzofurans (PCDF) and polychlorinated biphenyls (PCB) are widespread persistent organic pollutants. Among these 3 classes of compounds, 29 specific congeners (7 PCDD, 10 PCDF and 12 "dioxin-like" PCB or dl-PCB) are of particular concern for their shared toxic effects at trace level. Most countries have implemented regulations aiming to reduce their impact on public health, which led to appropriate survey control plans and monitoring programs dedicated to environmental matrices as well as foodstuff and biological samples. In this last case, the extremely low residual concentration levels (down to sub-ppt) placed the isotopic dilution method with gas chromatography coupled to high resolution mass spectrometry on electromagnetic sector instruments as the reference analytical method. Since this approach remains time and cost-consuming [1], growing efforts of the scientific community have been focused on the development of analytical alternatives, especially for screening strategies. Various approaches have been described, including the use of (1) alternative GC–MS based instruments [2–5], (2) regression models [6–8], (3) immunoassays [9–11], (4) DNA-binding assays or (5) cell-based bioassays.

All developed cell-based and DNA-binding assays are based on aryl-hydrocarbon receptor (AhR) activation, a ligand-activated transcription factor that mediates the biologic and toxicological effects of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and the 28 related chemicals [12]. The AhR is a member of the basic-helix–loop–helix (bHLH)–Per-ARNT-Sim (PAS) nuclear receptor superfamily. In dioxin-sensitive organisms, the AhR can be found in the cytosol in a complex with Hsp90 (2 units), XAP2 and p23 proteins. Upon binding to a ligand, the complex translocates to the nucleus and dissociates. Thus, the released ligand/AhR complex forms a heterodimer with the aryl-hydrocarbon receptor nuclear translocator (ARNT), its partner bHLH–PAS protein. The resulting heterodimeric complex shows high affinity to the dioxin response element (DRE), a GCGTG DNA sequence located upstream to the target genes, in the promoter region [13–16].

Cell-based bioassays measure the expression of a marker protein resulting from an exposure to a ligand. One popular example of such test used for routine analysis is the Chemically Activated LUciferase gene eXpression assay (CALUX). The luciferase gene and the DRE have been introduced in the cell line genome. The expres-

sion of luciferase is then measured by recording the emitted light after contact with the luciferine substrate [17–21].

Conversely, DNA-binding assays measure the activated AhR by quantifying the bound DNA *in vitro*. More precisely, a rodent hepatic cytosolic fraction containing AhR, ARNT and co-factors, is mixed with the ligand extract and a synthetic DNA sequence containing the DRE sequence. A first technique, the gel retardation of AhR binding (GRAB), consists in an electrophoretic separation of ^{32}P-labeled DNA complexes, followed by an autoradiography [22]. The GRAB assay is poorly compatible with routine screening analysis. A second technique, namely Procept®, involves quantitative polymerase chain reaction (qPCR), a more suitable technique for high throughput screening. The ligand/AhR/ARNT/DNA complex is trapped on the surface of the qPCR well by a specific antibody. Thus, the bound DNA is amplified after removal of any excess reagents [23–26].

Whatever considered AhR mediated assay, and for regulatory purpose, a TCDD calibration curve allows to express the measured response as a bioanalytical equivalent quotient (BEQ), a TCDD equivalent correlated to the regulatory defined toxic equivalent quotient (TEQ) [12,27,28]. Unfortunately, AhR ligands are highly diverse, including halogenated and polycyclic aromatic hydrocarbons and many other naturally occurring compounds [14]. Consequently, these screening assays still require relatively substantial sample extraction and purification. Indeed, interfering compounds may come from the matrix but also from the analytical procedure itself (*e.g.* stationary phases, glassware and solvents) [21,29]. The volumes of solvents considered are usually in the 10–200 mL range. Working with a cell-based bioassay, Windal et al. [29] reported that in their lab, when just one column of acidic silica is used for the cleanup, the response of a spiked procedural blank is only about half of the expected response, indicating that some inhibitors occur in procedural consumables. Miniaturizing the sample preparation process might be helpful for both saving time/cost and improving performances, but the sensitivity usually achieved with cell-based and DNA-binding assays does not permit such reduction of sample size to a large extend. Consequently, procedural blanks responses are often higher than background level, in the linear range of assays. This impacts negatively on the detection limit by reducing the working range, and necessitates blank correction of the results.

Usually, high attention is paid to the cleanup of glassware and stationary phases, and to the quality of solvents as well. Some laboratories specialized in bioassays usually characterize all solvent lots (toluene, hexane, dichloromethane) since they identified it as a possible source of inhibition and/or signal interference. However, this kind of study has to be conducted for each specific test considered. In the present work, the impact of different toluene grades on the Procept® DNA-binding assay was evaluated, taking into account both agonistic and antagonistic effects, for different target concentration levels.

2. Materials and methods

2.1. Solvents

The six tested toluene grades were: LGC Promochem Picograde lot 811902 (Wesel, Germany), Biosolve Dioxins & PCB's Analysis lot 639871 and Biosolve Pesti-S lot 595921 (Leenderweg, The Netherlands), Carlo Erba Reactifs SDS Atrasol lot D8M052248 M, Carlo Erba Reactifs SDS Pestipur lot D8G002088I (Val de Reuil, France) and JT Baker Ultra Resi-Analyzed lot 0829600025 (Deventer, The Netherlands). Available information regarding these different products, as attested by the joined analysis certificates, is reported in Table 1.

2.2. TCDD dilution series

TCDD was purchased from Wellington Laboratories (Guelph, Canada). For calibration curves, three times TCDD dilution series, from 59,049 down to 27 fg/μL, were prepared in *n*-heptane (Picograde, lot 701228, LGC Promochem) using dedicated syringes.

2.3. Toluene concentration

Each toluene grade was concentrated by a factor of 2000 and re-suspended in *n*-heptane. All used glassware was heated prior to use at 400 °C for 4 h. More precisely, 200 mL of each toluene grade was concentrated to ~2 mL using a Rotavapor®, transferred to a test tube using a Pasteur pipette and then concentrated to 500 μL under a gentle nitrogen stream (Class I, Air Liquide, Paris La Défense, France). The solvent volume was split into 4 equal aliquots in glass vials and evaporated to dryness under a gentle nitrogen stream. Dried extracts remained sealed one night and were re-suspended in 25 μL of *n*-heptane or 25 μL of TCDD solution from the TCDD dilution series (81, 729 or 6561 fg/μL) just prior to AhR contact. These fortification levels corresponded to lower and medium part of linear range, and to a value close to the saturation plateau, respectively. These four toluene extracts with increasing TCDD concentrations can be directly compared to the assay calibration curve plots.

2.4. Silver nitrate treatment

Because a major negative impact of raw toluene extracts was initially observed on the assay, the addition of a purification step applied to the extract was considered, in order to remove most part of these interferences. Indeed, silver nitrate is known to degrade or retain numerous sensitive interfering compounds, including polycyclic aromatic hydrocarbons. Then, alternatively, 200 mL of each toluene grade was concentrated to ~2 mL using a Rotavapor®, transferred to a test tube using a Pasteur pipette and then evap-

orated to dryness under a gentle nitrogen stream. 150 mg of silica gel coated with 10% (w/w) of silver nitrate (Sigma–Aldrich, St Louis, USA) previously activated one night at 200 °C were packed in a glass column (7 mm i.d.) and pre-washed with 10 mL of *n*-hexane. The extract was re-suspended and loaded in 1 mL of *n*-hexane (Picograde, lot 808405, LGC Promochem) and eluted fractions of 6 mL (corresponding to 2,3,7,8-substituted PCDD/F and dl-PCB) were collected and submitted to the same concentration and split than previously described in *n*-heptane.

2.5. Procept® immuno-qPCR assay

The Procept® assay was performed according to the indicated instructions of use. All solution dispensing and measuring was performed using delivery pipets and plastic barrier pipet tips. Plastic 96-well plates for PCR were prepared as follows: (1) washing on a plate washer (ELx50, BioTek, Winooski, USA) using the manufacturer supplied wash solution to remove the protective coating, (2) adding the thawed and diluted antibody solution to each well, (3) equilibrating on a plate shaker (Titramax 100, Heidolph, Schwabach, Germany) for 90 min and (4) washing on the plate washer to remove non-coated excess antibody. While the plastic wells were equilibrating, activation of the AhR was performed in a 96-well plate of glass vials as follows: (1) addition of 25 μL of the manufacturer supplied assay buffer solution, (2) addition of 5 μL of corresponding prepared TCDD standard and/or toluene extract, (3) addition of 25 μL of activation solution diluted by 2 with the assay buffer and containing the AhR, the co-factors, the ARNT and the DNA sequence (stored at −80 °C and thawed immediately prior to use) and (4) equilibration on the plate shaker for 60 min. During the equilibration time, *n*-heptane evaporates and target compounds go to AhR contact in aqueous phase. Following AhR activation, binding of complexed DNA was realized as follows: (1) transfer of 25 μL of complexation solution from each glass vial to corresponding prepared plastic PCR well, (2) equilibrating for 30 min on the plate shaker to bind the ligand/AhR/ARNT/DNA complex to the specific antibody and (3) removal of excess AhR, ARNT, and DNA by washing on the plate washer. The templates included 8 duplicate wells for TCDD standard curve (including assay blank) and 8 duplicate wells for each tested solvent (blank and 3 TCDD spike levels, with/without $AgNO_3$ treatment).

2.6. Quantitative polymerase chain reaction (qPCR)

PCR reagent was prepared according to the manufacturer's instructions by blending 40% Sterile water (Biosolve), 50% TaqMan 2X Universal PCR Master Mix (No AmpErase UNG, Applied Biosystems, Branchburg, USA) and 10% primer/probe solution (included in kit). 40 μL of PCR reagent were added to each well. The plates were sealed using optically clear adhesive film (Applied Biosystems) and placed in the real-time PCR instrument (Gene Amp 5700, Applied Biosystems). The PCR protocol included 2 min at 50 °C, 10 min at

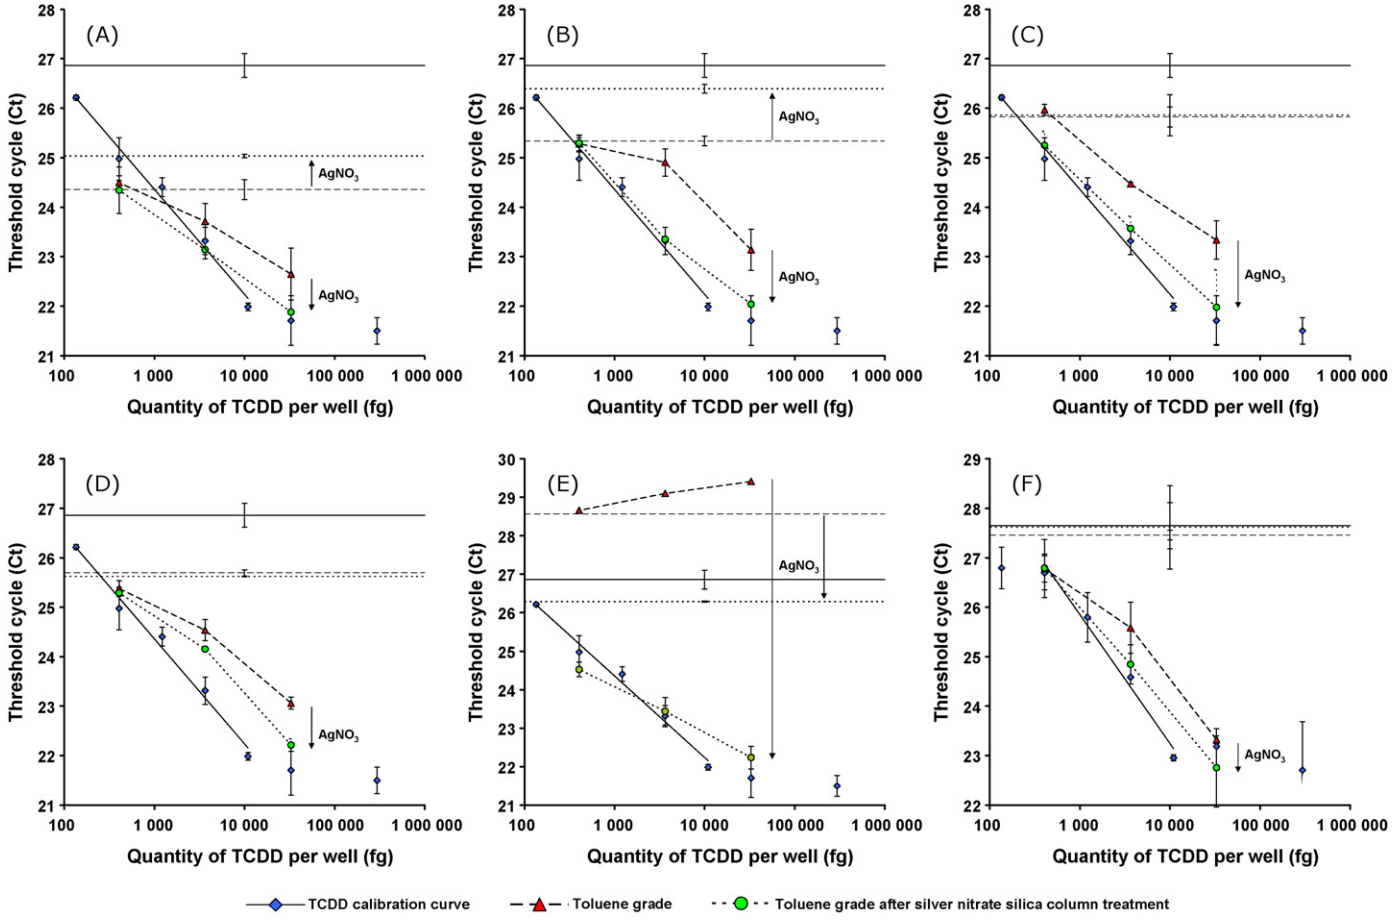

Fig. 1. Threshold cycle obtained for calibration curve (blue diamond, full line) and each tested toluene (A to F), without (red triangle, discontinuous line) or with (green circle, dashed line) silver nitrate silica column purification at background level (no TCDD, symbolic line at corresponding threshold level) and TCDD levels (plots). Standard deviation bars are from 2 assay measurement replicates. Arrows highlight the effect of silver nitrate silica column purification. Nota benne: procedural blanks on silver nitrate silica column showed no significant difference compared to assay TCDD calibration curve. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

95 °C and then 40 cycles of 15 s at 95 °C and 60 s at 60 °C. The output from the PCR instrument for each sample is a threshold cycle (Ct). The Ct is the number of real-time PCR temperature cycles at which the fluorescence measurement exceeds a threshold level chosen in the exponential part of amplification curves. *X*-Axis is usually set as logarithmic scale. Indeed, background level Ct appears higher than saturation plateau Ct, leading to a decreasing sigmoid curve.

3. Results and discussion

3.1. TCDD calibration curve

Two 96-well plates were used in this study. Fig. 1 shows results for the 6 toluene grades. Typically, calibration curve has a sigmoid shape. Its three parts correspond to background level, linear or working range and saturation plateau (defined by AhR concentration and well surface binding capacity). The ΔCt between the background level (assay blank) and the saturation plateau (5.36 and 4.95 Ct) were compliant, according to the manufacturer recommendations. The linear parts of the curves ranged from 135 to 10,935 fg/well (5 points, curve 1) or from 405 to 10,935 fg/well (4 points, curve 2). Coefficients of determination (R^2) were higher than 0.98, which appeared compliant with the European guidelines on screening bioassays for PCDD/F and DL-PCB. The obtained EC50 (concentration corresponding to the median response between the background level and saturation plateau) were 1214 and 1811 fg, respectively, these values being considered as usual.

3.2. Background levels

Four of the six toluene extracts (solvents A, B, C and D) gave higher background responses, reducing the Ct range with TCDD calibration saturation plateau by 20–50%. Such a result suggests that these toluene lots bring some agonistic compounds. Then, the sensitivity of the assay significantly decreases when toluene is used for sample preparation. Interestingly, solvent E showed the singularity to give a background level ~1.7 Ct higher than the calibration curve background. This could be interpreted as an inhibitory effect. Since the antibody is specific to the ARNT and that it is suspected that most of the background level is due to some "auto-activated AhR" (e.g. AhR Repressor or naturally occurring agonist in the rodent cytosolic liver extract), this result suggests that it is the antibody binding mechanism which is affected. This hypothesis is supported by the fact that the resulting solvent E background level is corresponding to a response level obtained when no antibody is added in the plastic wells. In such case, the obtained response is coming from unwashed free DNA (adsorption). Finally, solvent F showed the best behavior since no significant deviation was observed.

When concentrated extracts were submitted to a further purification step using a silver nitrate treatment before applying to the assay, the deviations of background levels significantly decreased for 3 of the solvent lots (solvents A, B and E). This purification step appeared to be partially efficient for selected grades only, suggesting that agonistic compounds can differ from a grade to another and that some are not sensitive to $AgNO_3$ treatment.

3.3. TCDD measurements

For each toluene grade, the concentrated extract was resuspended in *n*-heptane with 3 different TCDD concentrations (81, 729 and 6 561 fg/μL). For most of the results, responses were lower, up to −50%, compared to TCDD calibration curve. For lower spike level, solvent A gave a higher response compared to calibration curve, in accordance to the background level (similar signal) which is also higher than the calibration curve for this TCDD level. The singularity of solvent E persisted for spiked levels, with obtained responses also ~1.7 Ct higher than the calibration curve background. This corroborates the fact that there is a negative effect of this grade on the assay response as if no complex with DNA was bound to the antibody and or captured to the surface of the well.

When concentrated extracts were submitted to the silver nitrate purification, the deviations decreased in most of the cases, but not completely. These results suggest that antagonistic compounds occurring in different toluene grades are generally sensitive to $AgNO_3$ treatment but are not completely removed.

3.4. Discussion

The present study investigated the occurrence of both agonistic and antagonistic compounds as impurities in various toluene grades. From this point of view, no toluene grade behaved like the other one, suggesting that each manufacturing process lead to a distinct qualitative and quantitative profile in terms of impurities and interferences. One might suppose that involved compounds and their proportions also differ from one lot to another. Comparing the results with the information available in analysis certificates (Table 1) did not lead to pertinent trend concerning the identification of involved compounds in observed interferences.

Taking into account agonistic and antagonistic effects, the most suitable studied solvent grade appeared to be toluene B (Fig. 1). Starting from 50 mL and without silver nitrate silica column treatment, the working range was significantly reduced and a high inhibitory effect was observed. But after the silver nitrate silica column treatment, the diminution of ΔCt range (agonistic effect) and the inhibition effect on spiked levels appeared to be lower than 10%. This additional purification step appeared to be partially efficient for selected grades and should be adopted as final purification step of sample preparation just prior to assay measurement.

The present work shows that the performances of screening methods are not only depending on extraction/purification strategy but also to given solvent lots. Similar experiments were conducted with *n*-hexane and dichloromethane, with equivalent results and conclusions (data not shown). In order to obtain the best possible analytical performances, the control of each solvent lot before its use on "real" samples is highly recommended. Then, the question is what criteria should one respect to declare a lot compliant. A consensus should be to be defined by all the cell-based/DNA-binding assay and screening method experts.

4. Conclusion

In this study, we clearly demonstrated that the solvent grade has a major impact on the response of an AhR mediated assay. Both strong agonistic and antagonistic effects were observed for any studied lot. A small silver nitrate silica column partly removed these interfering compounds and is recommended as final purification step. Some "better" grades can be identified and selected in order to guaranty the best possible performances. However, it appears necessary to test every new lot, even if a grade previously appeared compliant.

Acknowledgment

The authors want to express their special thanks to the solvent manufacturers who provided free test samples.

ABSTRACT

A fast method for direct multi-element analysis of non-digested biological samples is presented. The only sample preparation needed is 1 min homogenization with a Polytron mixer in a small volume of neutral phosphate buffer saline solution (PBS). The total time for analysis (sample preparation and measurement) is 4 min only. This "mix and measure" method can handle large sample loads of biological samples and thus minimize dilution of trace elements. For example 100% whole blood was introduced without any clogging of the introduction system or extinguishing of the plasma. In 70% (v/v) whole blood reference material 14 of 16 analytes were quantified within ±10% (Al, B, Ba, Ca, Cu, Fe, Mg, Mn, P, Pb, S, Sr, Ti and Zn) and two semi-quantified within ±20% (Cd and K). Fresh bovine liver was also analyzed with the same method and 7 of 9 analytes were quantified in 5% (w/v) liver slurry. Three different nebulizers were tested, Glass Expansion Concentric (GEC) of Meinhard type, Cross Flow and Burgener T2100 and they performed roughly equally well in giving quantitative results for the slurries but the sensitivity was better with the GEC. The stability of the plasma was studied by evaluating the ratio of Mg 280.270 nm and Mg 285.213 nm lines. When increasing the sample load from 20 to 100% (v/v) of whole blood and from 0.5 to 10% (w/v) of bovine liver the Mg ratio was constant within a few percent for all of the nebulizer tested. The ratio of the sensitivity between GEC and Burgener T2100 was studied and the ratio increased with the energy sum for atomic and ionic lines separately.

1. Introduction

Fast and accurate analytical methods are the aim for both analytical chemists and the assigners. Therefore a lot of research is performed on reducing the total analysis time needed. In multi-element analysis of different biological materials by inductively coupled plasma-atomic emission spectrometry (ICP-AES) or inductively coupled plasma-mass spectrometry (ICP-MS), like in many other analytical techniques, the most time consuming step is the sample preparation. For ICP-AES and ICP-MS methods there is almost always a digestion or dissolution step involved prior to measurement, which in the worst case could last for several hours or days. By excluding this step not only the time of the total analysis is reduced substantially, but also, it leads to less risk for contamination of the sample from digestion reagents and to reduce consumption of destructive chemicals, which is of concern both environmentally and for occupational health. Moreover, losses of analytes especially volatile ones are minimized by using the slurry technique compared to the more aggressive acid digestion. Analysis of non-dissolved material, i.e. slurries, of both inorganic and organic materials by different plasma techniques, is of great concern due to additional reasons. The limited dilution in slurry analysis is beneficial because it enables analysis of elements present at low concentrations in the sample, which after a digestion procedure would have ended up in concentrations below the detection limit of the instrument. It is also advantageous when the amount of sample is limited, which could be important in analysis of samples with, for example, medical or forensic origin.

The basic concept of slurry analysis is that it is possible to quantify any element as long as the behaviour of the element in the slurry samples resemble the behaviour in the calibration solutions concerning nebulization, transport efficiency, atomization, ionization and excitation. Some of the differences that might occur due to matrix effects from the sample, could however be compensated for by evaluation with internal standard or sometimes with inter element correction (IEC) [1–3].

To bring a solid sample into a sprayable liquid without any tedious digestion there are several options described in the literature, for example, a short semi-digestion procedure including addition of nitric acid [4] and sometimes followed by ultra sonication [5–7]. Also grinding [8–10] or sieving [11] followed by dilution with dilute nitric acid (1–2%) has been tried with varying success on different types of samples. Moreover, carbonisation (ashing) of the organic part of the sample prior to slurry analysis has been

reported [7,12]. Most of these methods require a total time of more than 5 min and in some cases hours for successful homogenization to a particle size that is possible to transport to the plasma and to be atomized properly. Ebdon et al. [1] concluded, for example, in their comprehensive review of slurry nebulization in plasmas in 1997, that particles larger than 5 μm do not reach the plasma. In addition, Goodall et al. [12] mention that the maximum size of a particle that reaches the plasma depends on the density.

A crucial point after homogenization of the sample is to keep the slurry homogeneous during introduction into the ICP. In a macro point of view some kind of stirring is used like magnetic stirrer or shaker. In a micro-point of view the particles must be prevented from forming too large aggregates. This is successfull and almost always performed by adding different amounts of the detergent Triton X-100 (0.001–1%) [6,7,9,11,13–15]. However, concern must be taken since using a too large amount of Triton causes foaming in the spray chamber.

When it comes to calibration procedure the calibration solution matrix is in most cases closely matched to the samples. According to the literature published, nitric acid seems to be the preferable choice probably because the slurry samples often are treated or diluted with nitric acid and due to the fact that an acidic matrix prevents precipitation and adsorption of the analytes onto the walls of vessels and tubing. There are however some indications of precipitation of proteins in the slurry sample when using nitric acid [6]. Also some reports are published using alkaline [16] or neutral matrices [14] and then EDTA is added to prevent metal ions to precipitate or to adsorb onto container walls. When working with slurries of organic materials, the general approach seems to be dilution of samples and carrying out quantification without internal standard [5,7–9,12,13,17]. However, internal standards mentioned in the literature when analyzing slurries with ICP-AES are Y [15,18], Sc [6,19] and Lu [14].

For screening purposes, a method including a simple homogenization of cell pellets or biological samples prior to direct measurement by ICP-AES and ICP-MS, has initially been tested in our laboratory for semi-quantification of Gd or B in cultured cells and for determination of Mn in mouse brain [20]. In this method a Polytron mixer was used for fast homogenization of the fresh biological sample followed by dilution by the physiological solution phosphate buffered saline (PBS) to prevent precipitation of proteins. The slurry was then immediately introduced into the ICP-AES and evaluated with aqueous calibration solutions. Total analysis time was only a few minutes.

In this work extremely high sample loads of non-digested biological material were introduced into the plasma. The aim was to investigate the possibilities for a simple "mix and measure" method to accurately quantify some elements of toxic, environmental, and/or physiological concern with the lowest possible dilution. By increasing the sample load, both the inorganic and the organic content are increased at the same time, giving rise to many possible influences on the emission signals of the analytes. The samples also contain fragments of cells that may affect the plasma conditions. The behaviour of the plasma when increasing the sample load was studied by measuring the ratio of Mg 280.270 nm and Mg 285.213 nm lines [21–23] and the effect on emission lines with different ionization and/or excitation energies (energy sum) was investigated [2,22,23]. Also the signal precision [24] of repeated measurements was followed when increasing the sample load. The purpose was to use the equipment most commonly used in ICP-AES with ordinary settings. Three different nebulizers were tested; Glass Expansion Concentric (GEC), Cross Flow and Burgener T2100 and their performance are discussed. As a suitable test sample a whole blood reference material was used since analytical values of the elements of interest are at hand, and the fact that whole blood contains a lot of cells, cell-membranes and other ingredients that are expected in a biological sample. Others have analyzed whole blood by ICP-AES or ICP-MS but for digested [17,25,26] or more diluted samples [27–29]. Since the whole blood reference material is freeze dried and there might be differences concerning cell consistency from fresh biological samples that might affect the behaviour in the ICP, a fresh bovine liver sample was also analyzed.

2. Experimental

2.1. Chemicals and solutions

All chemicals were of analytical grade and solutions diluted with Milli-Q purified water (Millipore, Billerica, MA, USA). In the following the abbreviation MQ will be used. Multi-element standard stock solution and multi-internal element standard stock solution were obtained by dilution of commercial standards (Teknolab A/S, Drobak, Norway, and Referensmaterial AB, Ulricehamn, Sweden). The phosphate buffered saline, PBS (BioChemika, Fluka, Buchs, Switzerland) was prepared according to instructions from the manufacturer. Nitric acid solutions were obtained by dilution of concentrated nitric acid (Merck, Darmstadt, Germany). A stock solution of 5% (v/v) Triton X-100 was prepared by gentle dilution of Triton (Sigma Aldrich, Steinheim, Germany) to avoid foaming. Triton was added to all solutions and slurries measured by ICP-AES to a final concentration of 0.05% (v/v). Multi-element calibration standards (with sample matched concentrations of the analytes) including internal standards (Sc and Y), were prepared by dilution of stock solutions by either PBS or nitric acid to a final concentration of 10% PBS (13.7 mM NaCl, 2.7 mM KCl and 1 mM phosphate buffer) or 1% nitric acid (0.14 M) respectively. Calibration solutions in PBS were freshly prepared prior to measurement.

The solution added to the slurry samples prior to homogenization was prepared from PBS solution, Triton and appropriate amounts of internal standards. In the following text this solution is referred to as the "mixing solution". The concentration of PBS, Triton and internal standards were in all measurements the same in the samples as in the calibration standards. The concentration of each internal standard was 1 mg/l.

The samples analyzed were one reference material, Seronorm^{TM} Trace Element whole blood L-3 REF 102405, LOT 0512627 (Sero AS, Billingstad, Norway) and a fresh bovine liver from a one year old animal purchased at a supermarket nearby.

2.2. Instrumentation

The ICP-AES instrument used was a Spectro Ciros^{CCD} EOP (Spectro Analytical Instruments, Kleve, Germany), equipped with a Glass Expansion Concentric nebulizer of Meinhard type (Glass Expansion, MA, USA), Burgener T2100 nebulizer (Burgener Research Inc., Ontario, Canada) or Cross Flow nebulizer (supplied by the manufacturer of the ICP instrument) followed by a Scott double-pass spray chamber. The ICP operating conditions are presented in Table 1. The

instrumental settings for each nebulizer were optimized by measuring Mn 257.611 nm in aqueous solution (recommendation from the manufacturer of the instrument). Appropriate background correction for each sample type and element was performed. Lines measured are listed in Tables 2 and 3. The software used was Smart Analyzer Vision (version 2.11) supplied by the manufacturer of the instrument.

A Polytron PT 1200 mixer (Kinematica, AG, Lucerne, Switzerland) was used for homogenization of samples (down to 20 μm particles according to manufacturer) and for the continuously stirring during introduction to the ICP-AES a Heidolph R2R No. 50111 attached with a Teflon tube (1/4″) as stirring tool was used. To increase the stirring efficiency half of the Teflon tube was removed by cutting along the tube at the lower part in contact with the slurry.

For acid digestions stainless steel bombs with Pyrex tubes and Teflon seals were used.

2.3. Sample preparation and measurement procedure

The freeze dried blood (1.21 g) was reconstituted by adding 5.00 ml MQ according to the instructions given by the manufacturer. Different amounts of the reconstituted whole blood were

weighed directly into 15 ml plastic tubes. A volume of 2.00 ml of mixing solution was added and followed by 3× 15 s homogenization with the Polytron mixer at 14,000 rpm. After mixing, the samples were diluted with MQ to a final volume of 10.00 ml. The procedure was somewhat different when preparing samples of 100% whole blood; 4.00 ml MQ and 1.00 ml mixing solution was directly added to the freeze dried sample for reconstitution, followed by homogenization.

The bovine liver was roughly homogenized with a household mixer and stored in the freezer prior to analysis. Duplicates of different amounts of defrosted liver (50, 100, 200, 500, 750, 1000 mg) were accurately weighed into 15 ml plastic tubes and then treated in the same way as the blood samples.

The measurement sequence was started by aspirating the slurry for 45 s followed by measuring the emission (3× 25 s). After measurement of the slurry the introduction system was washed by aspirating 0.05% Triton for 30 s followed by MQ for at least 1 min. The stability of the emission signals and the possibility of memory effects were checked by frequently measuring the zero calibration solution and one of the multi-element standards.

For the acid digestion about 0.3 g of the bovine liver was weighed into three tubes. 100 μl Yttrium (1000 mg/l) and 4 ml conc. nitric acid was added to each tube and to two empty tubes used as blanks. The tubes were put into bombs and sealed with a Teflon seal, closed with a moment of 32 N m and then heated for 2.5 h at 160 °C. After cooling to room temperature the solutions were transferred to 25 ml volumetric flasks and diluted with MQ. Multi-element standards with sample matched concentrations of the analytes in nitric acid were used for evaluation.

The concentrations were evaluated by calibration with and without internal standards and when necessary, polynomial evaluation (2nd order) was used.

3. Results and discussion

3.1. Whole blood analysis

It is possible to aspirate samples with up to 100% of whole blood into the plasma without clogging of the introduction system or extinguishing the plasma, with GEC, Cross Flow and Burgener nebulizer. This is possible due to the non-acidic matrix, PBS, in the samples. Similar attempts with this high biological sample load in an acidic matrix resulted in immediate precipitation of proteins in the introduction system which has also been reported by others [17]. All three nebulizers gave good recoveries within ±20% for 10–70% (v/v) of whole blood for most elements when evaluated with internal standard (Y 371.030 nm or Sc 361.384 nm), examples shown in Figs. 1 and 2. Without internal standard, the recoveries leveled off at higher sample loads. In Table 2 typical recoveries of analytical values for elements in 40 and 70% (v/v) of whole blood for GEC are shown. The recoveries were evaluated both with and without internal standard. Results in white field are within ±10%, results in light grey field ±20% and dark grey field show results worse than ±20%. Of the 16 analytes measured, 14 could be quantified (±10%) and 2 semi-quantified (±20%) in 70% (v/v) whole blood. Mn and Ti could be quantified despite the low analytical concentration given by the producer; 12.5 and 16 μg/l respectively. Simultaneously with the determination of Mn and Ti in the low μg/l range, Fe, P and S at levels of several hundreds of mg/l could be quantified. With GEC it is also possible to quantify Fe (259.941 nm) in 100% (v/v) whole blood. The too large recovery of K could be explained by signal enhancement caused by the increased amount of easily ionized elements (EIE) in the blood

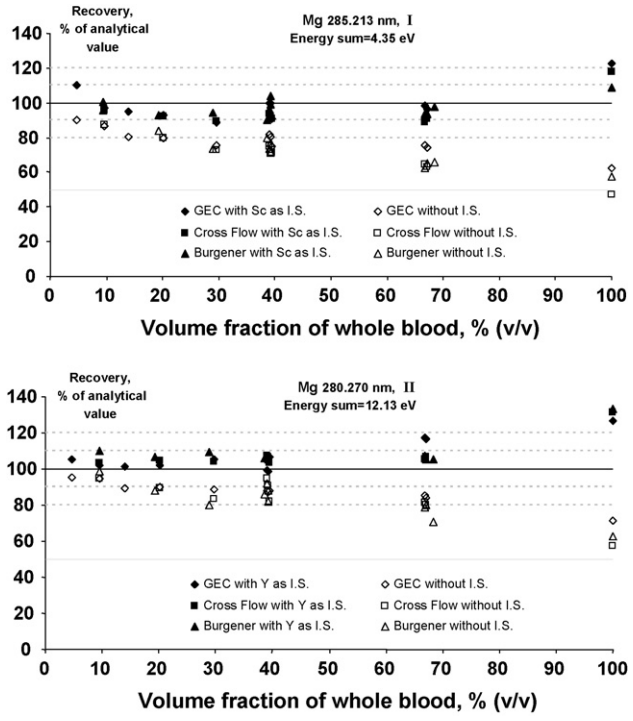

Fig. 1. Recovery of analytical value of Mg (21.7 (±0.6) mg/l) for one atomic and one ionic line in different dilutions of Seronorm Trace Element in whole blood L-3 with Glass Expansion Concentric (GEC), Cross Flow and Burgener T2100 nebulizer respectively.

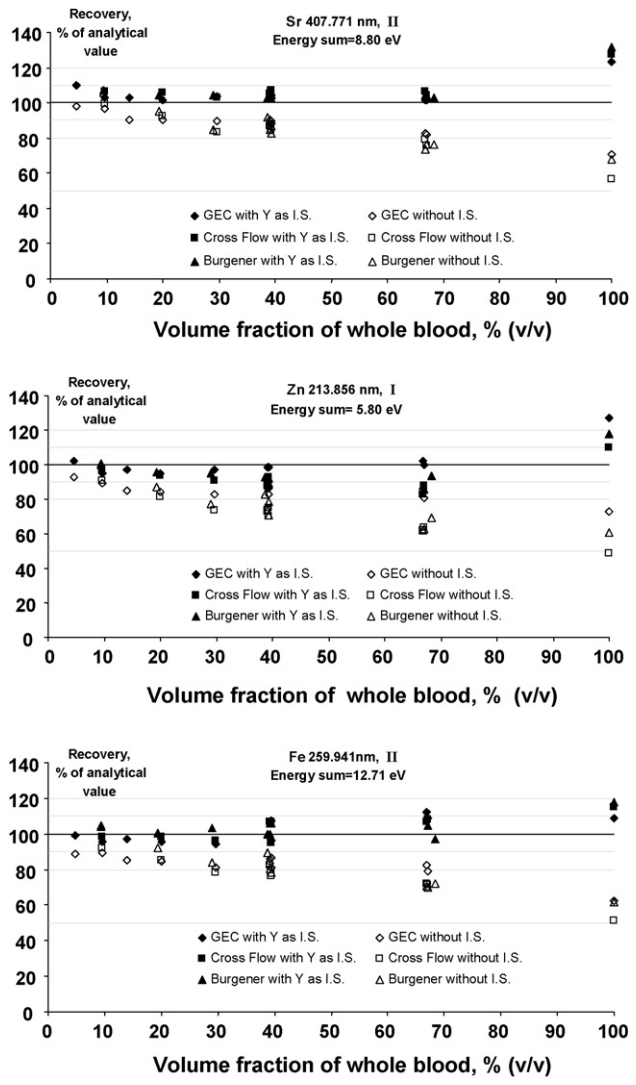

Fig. 2. Recovery (%) of analytical value for Sr (205 (±7) μg/l), Zn (8032 ± 512 μg/l) and Fe (468 (±11) mg/l) in different dilutions of Seronorm Trace Element in whole blood L-3 for Glass Expansion Concentric (GEC), Cross Flow and Burgener T2100 nebulizer respectively. The behaviour is the same for all three elements despite large concentration ranges and differences in energy required for emission.

sample (Table 3). The recoveries with Burgener and Cross Flow nebulizer are both very close to the results with GEC for most elements, which can be seen by the examples given in Figs. 1 and 2. Results with Cross Flow were not as reproducible as GEC and Burgener. Recoveries for Mg with the three nebulizers evaluated with and without internal standard are presented in Fig. 1. The upper diagram shows results for the atomic line (285.213 nm) and the lower for the ionic line (280.270 nm). Using internal standard improved the recoveries generally. Sc gave slightly better results than Y as internal standard for the atomic line but Y was slightly better for the ionic line. The trends were similar for both internal standards giving recoveries <100% for Mg (285.213 nm) and >100% for Mg (280.270 nm), but since most of the recoveries were within ±10% no general conclusions could be drawn from this. In Fig. 2 examples are given for analytes with different concentration levels in the whole blood, as well as different energy sum. The similarity between all the diagrams is striking. It is also clearly demonstrated in the diagrams mentioned above; that the higher the volume percent of whole blood in the sample the more severe are the matrix effects and using internal standard is more important for accurate results. This of course could be expected since both the inorganic and organic contents are increased. For example, Burkowska et al. [23] show similar trends when studying the change in line intensity for several emission lines with increasing Ca + Mg concentration in the matrix and the same trend is also seen in a work by Ioannidou et al. [30] when increasing the carbohydrate concentration. Since the decrease in recovery for all elements (Figs. 1 and 2) are about the same when increasing the blood content in the sample, regardless of their energy sum and/or whether atomic or ionic lines are considered, the decrease could not be explained by reduction of the energy available in the plasma caused by the heavy sample load. This has also been seen by others analyzing dissolved matrices with increasing concentration of NaCl [24]. More likely, decreased nebulization and transport efficiency of the sample to the plasma [2] contribute to the declining recoveries. By using Y or Sc as internal standard the recoveries are improved for all the analytes presented in Figs. 1 and 2 and also for several of the analytes presented in Table 2. Worth notifying is that in 100% (v/v) of whole blood the internal standard is not able to accurately correct for the matrix effects in the same extent as in samples with lower blood content. In this case this is probably due to a too large discrepancy between the physical properties of the 100% (v/v) blood and the calibration solutions, which severely affects the transport efficiency and spray formation. However, even in dissolved matrices it has been verified that the internal standard fail to provide accurate result when the sample matrix is increased [2,31,32] since the analyte and internal standard are differently affected by the matrix (see more detailed discussion about internal standards below).

The stability of the sample introduction system, i.e. transport efficiency and spray formation for a given sample solution could by followed by studying the signal precision [24], i.e. the fluctuations in repeated measurements of the emission signal. When introducing 70% (v/v) whole blood the relative standard deviation (RSD) varied between 0.5 and 2% for triplicate measurements. This is slightly higher than for the calibration solutions which most often gave a RSD below 1%, but still this could be regarded as stable and acceptable values for quantitative analysis.

The conditions in the plasma could be studied by monitoring the ratio between Mg II (280.270 nm) and Mg I (285.213 nm) [21–23]. This ratio gives a measure of the energy available for ionization and excitation in the plasma and a value of eight is reported to indicate a robust plasma [21]. However, the ratio can differ from instrument to instrument due to the type of monochromator and signal collection system. No obvious change in the ratio was seen for any of the three nebulizers tested when 20, 30, 40, 70 and 100% (v/v) of whole blood was introduced into the plasma. For GEC the average ratio (±S.D.) was 8.0 (±0.1), for Cross Flow 6.6 (±0.3), and for Burgener 7.3 (±0.1). Obviously the energy available in the plasma does not change with increased concentration of whole blood. The Mg ratio varied somewhat between different runs but the trend, with no change of the ratio within a run when increasing the blood concentration, was consistent. It should be noted that the emission of Mg at 280.270 nm in 100% blood is close to the upper limit of the linear range. However, the results for Mg, Al and Sr, which all have been evaluated both by an atomic line and an ionic line giving similar results, thus further support that the energy in the plasma is not altered by the sample matrix with the instrumental settings used.

All elements were evaluated both with Y (371.030 nm, II, 9.62 eV) and Sc (361.384 nm, II, 10.03 eV) as internal standards. These lines have been used for analysis of digested [33] or diluted [17,34] serum and digested whole blood [17,35]. In the present study also other emission lines for Y (324.228, 360.073 and 224.306 nm) and Sc (335.374 nm) were studied when increasing the concentration of whole blood. They showed, however, the same behaviour as the commonly used lines mentioned above. In Table 2 results with and without Y as internal standard are presented for all elements. Results evaluated with Sc are only presented for the

elements that gave better recoveries with Sc, namely; B, Ba, Cu, Mg, and S. Elements giving best recoveries with Y were; Al (167.08 nm), Ca, Fe, Pb and Sr. Only Al (396.152 nm), P and Mn yielded best recoveries without internal standard. Since Mn has higher energy sum than both Y and Sc, while Al and P have lower, the failure of the internal standards is not explained by differences in energy sum. Nor is it explained by the different distribution of the elements in either the cellular fraction of the whole blood or in the blood plasma. This could be seen by the quantitative recoveries of Fe evaluated with internal standard. Since Fe almost totally exists in the red blood cells [36] this means that the atomization and excitation is not affected by whether the element exists inside or outside a cell. Further support to this is the quantitative recoveries of Mg, Zn and P, which also predominantly exist in the cellular fraction of whole blood [36]. However, it must be mentioned that in addition to the homogenization of the blood sample by the Polytron, the tested reference blood has been freeze dried, which could contribute to the disruption of the blood cells and thus facilitate the atomization of elements coming from within the cells.

3.2. Analysis of bovine liver

It is possible to aspirate at least up to 10% (w/v) of the fresh bovine liver sample into the plasma without clogging of the introduction system or extinguishing the plasma, both with GEC and with Burgener nebulizer. Cross Flow was not used for the liver analysis due to somewhat more irreproducible performance. Both nebulizers gave recoveries within ±20% for most elements for 0.5–5% (w/v) liver (Table 4). The recovery was calculated by using the analytical value received from analysis of acid digested bovine liver as the true value. Ca, Fe, K, Mg, P and Zn were quantified within ±10% in 10% (w/v) with GEC, and with Burgener Cu and Zn were quantified while Ca, Fe, K, Mg, Mn and P were semi-quantified (±20%). At the lower concentration 5% (w/v) of slurry liver sample it was possible to quantify seven of the nine elements measured with both nebulizers. Most of these elements were quantified with external calibration, and only Cu and Mn gave good and stable recoveries with Y as internal standard. All the examined lines of Y; 371.030, 324.228, 360.073 and 224.306 nm, showed similar behaviour in the liver matrix and thus Y solely is not a good choice as a multi-element internal standard. The fairly good recoveries of elements evaluated with external calibration could probably be improved by using other elements appropriate as internal standards. Since it is shown in this study that quantification is possible with external calibration and the aim was to evaluate the limits for the suggested method no further attempts to improve the recoveries were made.

The liver sample matrix gives a lower sample load than the blood sample, both concerning the total ion concentration and the carbon content (Table 3). This could explain the need of an internal standard for quantitative recoveries in the blood matrix (Table 2) and the fairly good recoveries received without internal standard for the liver samples (Table 4). This also implies that the liver slurries are efficiently nebulized and transported into the plasma, in roughly the same extent as the calibration solutions. The signal precision for 5% (w/v) liver sample varied between 0.5 and 3% for triplicate measurement (average 1.2%) which further verify a quite efficient transport and excitation of the analytes. However, for Y the signal precision was 3.5% and it also varied more between the samples than for the analytes. This could indicate that Y is not uniformly distributed in the liver slurry despite thorough mixing with the Polytron and hence giving erroneous results as an internal standard. In the blood samples the signal precision for Y was equal to the ones for the analytes averaging around 1%.

The condition in the plasma was followed by the Mg ratio mentioned above and there were no change observed when the higher concentrations of liver samples were introduced. The average ratio was 7.6 (±0.1) for both Burgener nebulizer and GEC.

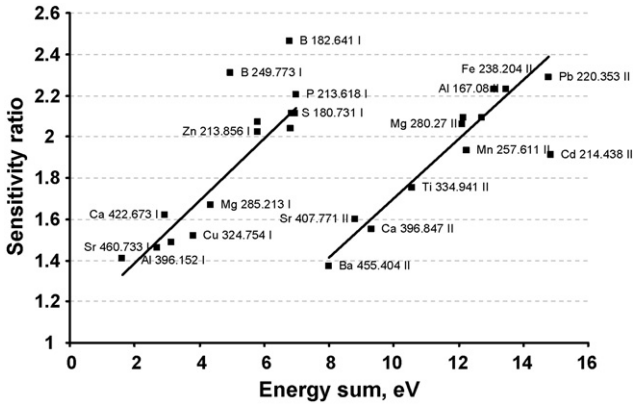

Fig. 3. Sensitivity ratio (slope/slope) for Glass Expansion concentric (GEC) and Burgener T2100 nebulizer from calibration curve as a function of energy sum.

Initially slurry analysis of the reference material NIST SRM 1577a bovine liver (NIST, Boston, MA, USA) was performed. However, the suggested sample preparation method with homogenization by the Polytron mixer did not manage to homogenize some aggregates in the freeze dried liver sample that could be residues of vessel tissue. These aggregates caused frequent clogging in all the sample introduction systems tested and only a few results were obtained. Others have succeeded better with slurry analysis of 1577a probably due to a better homogenization procedure or addition of nitric acid to the freeze dried liver [9] which could disrupt the aggregates properly before introduction to the ICP. Nitric acid is not an option in this work since protein precipitation and leaching from the Polytron mixer must be prevented. Since the method is useful for fresh bovine liver and the aim of this study was not slurry analysis of freeze dried samples, no further effort was made to analyze 1577a.

3.3. Additional comparison of the nebulizers

GEC nebulizer gave superior sensitivity (larger slope from calibration curve) for all elements, while Cross Flow and Burgener T2100 gave about the same with the instrumental settings used. Compared to Burgener, GEC gave from 1.4 to 2.5 times higher sensitivity, Fig. 3. GEC nebulizer is known to create a very fine mist with small droplets while Burgener, due to its wider inner diameter, allows larger droplets to form. These larger droplets are partly filtered by the spray chamber and thus less analyte reaches the plasma which could explain the lower sensitivity in general. In the case of Cross Flow the slightly lower Mg ratio indicates a higher matrix plasma load than for GEC and Burgener. The more heavily loaded plasma has a lower temperature and thus decreased sensitivity due to decreased atomization and excitation. Also the ability of a certain nebulizer to form a well shaped spray of as much sample as possible influences the sensitivity [24] and Cross Flow is not known to give a high sensitivity but for being suitable for slurry analysis [37].

In Fig. 3 the sensitivity ratio between GEC and Burgener for several emission lines, is plotted against the energy sum for each line (values are given in Table 2). There is an obvious trend for atomic lines and for ionic lines separately. In both groups the sensitivity ratio increases with the energy sum. This means that, within each group, the larger the energy sum of an element the larger difference there is in sensitivity between GEC and Burgener nebulizer under the conditions used. However, rather than the energy sum, the wavelength of the emitted radiation seems more important for the difference between the nebulizers. All emission lines that yield

a sensitivity ratio higher than 1.8 are in the UV-region from 167 nm for Al up to 280 nm for Mg. Emission lines with a lower ratio range from 285 nm for Mg to 766 nm for K. One explanation could be a higher degree of absorption and/or scattering of these low UV lines and these effects seem to be more severe when using Burgener than GEC. The reason for this is not fully understood but the finer mist from GEC might reduce absorption and scattering and thus contribute to the higher sensitivity.

It should be mentioned that the sensitivity also could be influenced by changing the spray chamber. In this work the same one (Scott double pass) was used in all experiments to focus solely on the nebulizer performance.

More information concerning the change in intensity for different elements as a function of energy sum when altering the plasma power, sample transport efficiency, matrix components, electron density, observation height could be found elsewhere [2,3,21–24,32].

4. Conclusions

By this fast and simple "mix and measure" multi-element method it is possible to quantify macro, micro and trace elements in non-digested biological samples with a total analysis time of 4 min (one for homogenization and three for measurement). In 70% (v/v) whole blood reference material 14 of 16 analytes were quantified within ±10% (Al, B, Ba, Ca, Cu, Fe, Mg, Mn, P, Pb, S, Sr, Ti and Zn) and two semi-quantified within ±20% (Cd and K). In 5% (m/v) fresh bovine liver slurry 7 of 9 elements were quantified; Ca, Cu, K, Mg, Mn, P and Zn, while Fe and S were semi-quantified.

Introduction of these amounts of biological samples do not alter the plasma stability but the analyte signals are frequently suppressed. Evaluation by internal standard is then necessary and both Y (371.030 nm) and Sc (361.384 nm) are suitable for several of the evaluated emission lines.

It is possible to use both GEC and Burgener nebulizers for quantitative analyses in whole blood and liver slurries. Cross Flow could be used for blood analysis but was not tested for liver sample. To obtain highest sensitivity GEC should be used, especially when measuring emission lines in the low UV-region since, according to this study, these lines are more affected by the choice of nebulizer. In sample matrices where there might be residues of larger particles, not sufficiently homogenized by the Polytron, Burgener T2100 could be recommended since the inner diameter is almost four times larger than in GEC and hence problems with clogging would be reduced.

Acknowledgements

The authors gratefully acknowledge Louisa Eriksson and Mattias Brodin for their assistance with the analysis of the fresh liver samples.

Oil matrices

ABSTRACT

A solvent-free analytical approach based on headspace solid-phase microextraction (SPME) of oil matrices heated at high temperatures coupled to gas chromatography with mass spectrometry detector (GC-ion trap) has been developed for the determination of phthalic acid esters (PAEs) in oil matrices without sample manipulation. For this study, three fibers, i.e., 85 μm-polyacrylate (PA), 50/30 μm-divinylbenzene–carboxen–polydimethylsiloxane (DVB/CAR/PDMS) and 100 μm-polydimethylsiloxane (PDMS) were tested. Variables affecting the SPME headspace composition such as incubation sample temperature, sample incubation time and fiber exposition time were optimized. The optimal values found were 250 °C for sample incubation temperature and 30 min for incubation and extraction time. PA fiber was not suitable for the lightest polar phthalates which showed poor extraction and repeatability values. PDMS fiber had very poor response for some of the heavier and non-polar phthalates, whereas DVB/CAR/PDMS fiber showed the best response and repeatability values for the majority of the phthalates studied. The main benefit of the analytical method proposed is the absence of sample manipulation and hence avoidance of possible contamination coming from glassware, environment, solvents and samples.

1. Introduction

Worldwide production of phthalic acid esters (PAEs) and their common application in different products of everyday use has resulted in their widespread presence in environment and foods. PAEs are used extensively as plasticizers in different materials, especially polivinyl chloride, polyvinyl acetate, polystyrene, polyamide and polyester materials. Bis-(2-ethylhexyl) phthalate (DEHP) and benzylbutylphthalate (BBP) are the most abundant phthalate esters due their wide use in many industrial sectors like cosmetics and paints. As plasticizers are not chemically bound to the polymer, migration of PAEs in significant amounts is possible.

Some research papers have been published recently about the impact of PAEs on wild animals and human beings [1,2]. It is suggested that increasing exposure to PAEs might be partially responsible for some diseases. Furthermore, it was found that PAEs might persist in human body tissues [2]. Since foods are the major source of exposure to PAEs, it is important to monitor their levels in foods to provide data for human exposure assessment. The US Environmental Protection Agency (EPA) and several other agencies classified the commonly occurring PAEs as priority pollutants. Due to such health implications, there is increasing demand for reliable analytical methods that allow their detection and quantification at very low levels in different environmental, biological and food matrices.

Several analytical methods have been developed for determining PAEs in food samples and fatty matrices [3,4], and recently an interesting application to olive oil has been published [5]. Either adsorption chromatography on Florisil or alumina [6,7] or codistillation of PAEs [8] is usually applied. Quantification of low levels using solid-phase extraction (SPE) with C18 [9], C8 [10], polystyrene [11] and multi-walled carbon monotubes to concentrate PAEs [12] has been also proposed prior to analysis by either liquid or gas chromatography. These options have been preferred to solvent extraction due to lower consumption of organic solvents.

Several studies applying direct SPME extraction of PAEs have been proposed. This procedure significantly reduces the risk of secondary contamination and substantially simplifies the overall analytical process. It has been already applied to the determination of phthalates in wine [13,14], cow milk [15], vegetable oil using solvent-based matrix modification [16], and plastic for foods [17].

Cross contamination from chemicals, materials and laboratory equipment are common problems in all PAEs analysis methods

[18]. For example, di(2-ethylhexyl) phthalate and dibutyl phthalate are usually detected in blank samples. In addition, the difficulty for separating co-extracts as lipids, pigments, etc., makes the determination of low levels of PAEs in food matrices very difficult.

The aim of this work was to develop an analytical procedure to detect and quantify the phthalate levels in oil matrices without sample manipulation and thus avoiding external contamination from air, solvents, labware, etc. The novelty of this method consists of adsorption by SPME of the headspace of the oil heated at high temperature (250 °C) in a sealed vial followed by subsequent analysis by gas chromatography ion trap MS–MS. For the first time, high temperature is here used for determination of phthalates in oil matrices.

2. Materials and methods

2.1. Reagents and materials

Virgin olive oil purchased locally was used as oil matrix for experiments. A standard mixture solution of phthalates (EPA 8061 Mix Analytes) and benzyl benzoate containing 1 mg mL^{-1} of each compound in 95:5 hexane:acetone (v/v) (Cromlab, Barcelona, Spain) was used for setting instrumental conditions and spiking the olive oil samples. The standard mixture solution contained 1 mg mL^{-1} of methyl phthalate (DMP), diethyl phthalate (DEP), benzylbenzoate as internal standard (IS), di-isobuthyl phthalate (DIBP), di-n-buthyl phthalate (DBP), bis-2-methoxyethyl phthalate (MEP), bis-1,2-(4methyl-2pentyl) phthalate (1,2MPP), bis-1,3(4methyl-2pentyl) phthalate (1,3MPP), bis-2ethoxyethyl phthalate (EEP), di-n-amyl phthalate (DAP), di-n-hexyl phthalate (DHP), benzyl buthyl phthalate (BBP), bis-2-buthoxyethyl phthalate (BBEP), dicyclohexyl phthalate (DCHP), bis 2-ethylhexyl phthalate (DEHP), di-n-octyl phthalate (DOP) and di-n-nonyl phthalate (DNP). Five spiked levels of 0.05, 0.1, 0.5, 1.0 and 2.0 mg kg^{-1} were prepared. Initial olive oil used for experiments and the solvents for preparing spiking solutions were tested previously to verify absence of phthalates.

Six samples of virgin olive oils, purchased locally, were stored at room temperature (23 ± 5 °C) for 12 months, either in glass bottles or in PET (polyethylene terephthalate) bottles. Duplicate samples were taken at 8, 10 and 12 months.

Special care was taken with glassware, vials, caps and septa before use. All materials were dried and kept at 200 °C until use. To avoid phthalate contamination, all glassware used was soaked in acetone for at least 30 min, then washed with acetone, rinsed with hexane, and dried at 200 °C for at least 4 h. All the solvents, chromatographic system, standards and spiked samples were subjected to similar extraction and analysis procedures. Blank extraction was routinely performed. Also, the chromatographic system was initially and regularly checked for absence of phthalates by running blank injections.

2.2. SPME fibers

SPME fibers were purchased from Supelco (Bellefonte, PA, USA). Three types of fiber coating were tested, i.e., 85 μm-polyacrylate (PA), 50/30 μm-divinylbenzene–carboxen–polydimethylsiloxane (DVB/CAR/PDMS) and 100 μm-polydimethylsiloxane (PDMS), previously conditioned in accordance with manufacturer's instructions. Fibers were thermally cleaned in the injection port before sampling. Each ten extractions, fibers were cleaned by immersion with vigorous shaking in a mixture of 20:70:10 water:acetonitrile:acetic acid (v/v/v) for 1 h, dried under nitrogen and conditioned at 260 °C for 30 min.

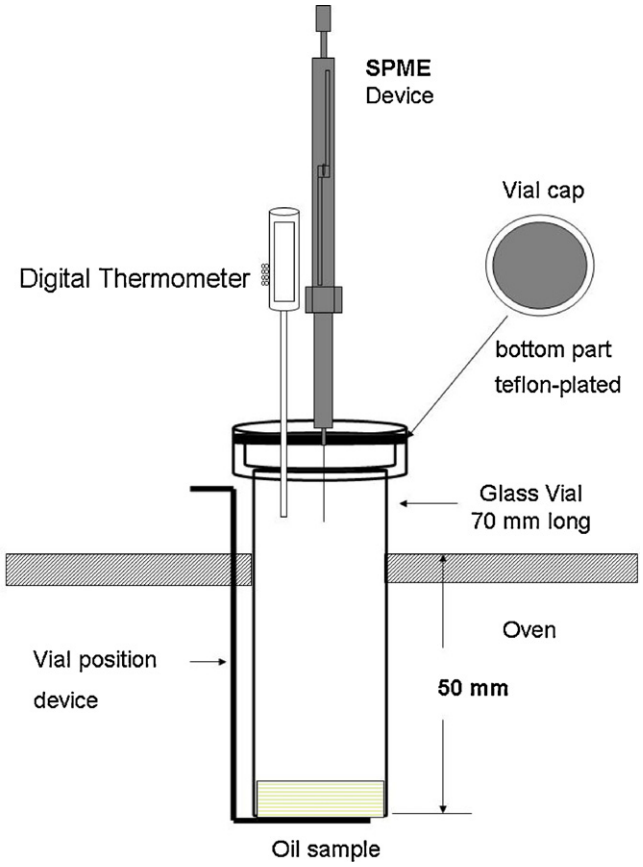

Fig. 1. Schematic representation of the extraction procedure.

2.3. SPME procedure

Samples of 1 g olive oil were weighed into glass vials (70 mm long and 22 mm diameter) and tightly capped. The bottom part of the caps was Teflon-plated to avoid plastic contact with headspace. Then, vials were heated at different temperatures (200–275 °C) and time periods (10–40 min) in order to promote release of the semivolatile compounds to headspace. Sampling was performed by exposing the SPME fiber to headspace for 30 min at the upper part of vial positioned outside the oven-heating zone (20 mm long), as shown in Fig. 1. After sample extraction, the SPME fiber was introduced into the GC injection port (260 °C) operating in splitless mode for 5 min. Samples were extracted only once from vial.

2.4. GC ion trap–MS analysis

The GC ion trap–MS experiments were performed using a Finnigan Trace-GC 2000 gas chromatograph coupled to a Polaris-Q Ion trap mass spectrometer (ThermoFinnigan, Austin, TX, USA) operating in fullscan and MS/MS mode. The column used was a Zebron ZB-5 ms (Phenomenex, Torrance, CA, USA) fused silica capillary column (30 m long × 0.25 mm i.d × 0.25 m film thickness). The GC conditions included helium as carrier gas at 1 mL min^{-1} in constant flow mode. The initial temperature of 70 °C was kept for 2 min, then raised to 200 °C at a rate of 6 °C min^{-1} and held for 5 min, then raised to 295 °C at a rate of 4° C min^{-1} and held for 8 min. Injector temperature was 260 °C and a 0.8 mm ID liner was used for SPME injection port.

The MS operating conditions were as follows: ion source and transfer line temperatures were 200 and 290 °C, respectively. The electron energy was 70 eV, resolution was unit and the emission current was 250 μA.

Abbreviations: DMP, Methyl phthalate; DEP, diethyl phthalate; IS, internal standard (benzylbenzoate); DIBP, di-isobuthyl phthalate; DBP, di-n-buthyl phthalate; MEP, bis-2-methoxyethyl phthalate; 1,2MPP, bis-1,2-(4methyl-2pentyl) phthalate; 1,3MPP, bis-1,3(4methyl-2pentyl) phthalate; EEP, bis-2ethoxyethyl phthalate; DAP, di-n-amyl phthalate; DHP, di-n-hexyl phthalate; BBP, benzyl buthyl phthalate; BBEP, bis-2-buthoxyethyl phthalate; DCHP, dicyclohexyl phthalate; DEHP, bis 2-ethylhexyl phthalate; DOP, di-n-octyl phthalate and DNP, di-n-nonyl phthalate.

The Xcalibur version 1.4 software was used for data acquisition and processing of the results.

3. Results and discussion

3.1. Mass spectrometry scanning method

Full scan and MS/MS (MS^2) were used alternately and consecutively for MS operations. The MS/MS method development was carried out in two steps. The first one was to set the retention time of the compounds of interest and to slice the chromatogram into 17 segments corresponding to specific PAEs and benzyl benzoate. First, the standard mixture (EPA 8061 Analytes) was injected in fullscan mode. Maximum excitation energy (Q) and CID excitation voltage were optimized for each individual standard compound and precursor ion in order to get the best isolation efficiencies and ensure maximum production or transmission of collision fragments.

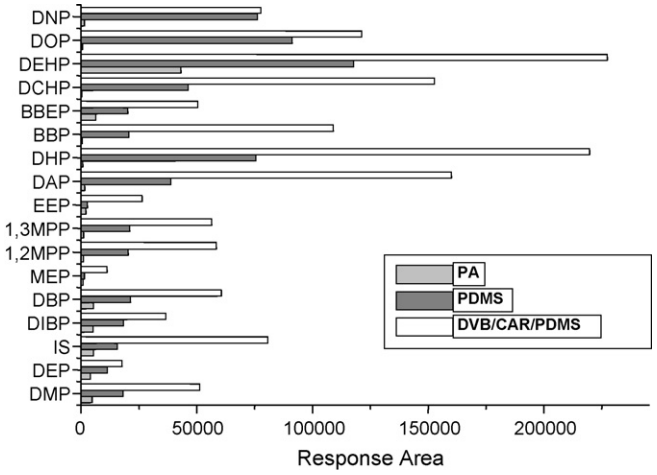

Fig. 2. Response areas obtained with the fibers tested. Means of five determinations. Coefficients of variation were lower than 10%. Abbreviations for fibers: PA, 85 μm-polyacrylate; PDMS, 100 μm-polydimethylsiloxane and DVB/CAR/PDMS, 50/30 μm-divinylbenzene–carboxen–polydimethylsiloxane. Abbreviations for phthalates: DMP, Dimethyl phthalate; DEP, diethyl phthalate; IS, internal standard (benzylbenzoate); DIBP, di-isobuthyl phthalate; DBP, di-n-buthyl phthalate; MEP, bis-2-methoxyethyl phthalate; 1,2MPP, bis-1,2-(4methyl-2pentyl) phthalate; 1,3MPP, bis-1,3(4methyl-2pentyl) phthalate; EEP, bis-2ethoxyethyl phthalate; DAP, di-n-amyl phthalate; DHP, di-n-hexyl phthalate; BBP, benzyl buthyl phthalate; BBEP, bis-2-buthoxyethyl phthalate; DCHP, dicyclohexyl phthalate; DEHP, bis 2-ethylhexyl phthalate; DOP, di-n-octyl phthalate and DNP, di-n-nonyl phthalate.

Each scan was subdivided into two events. The first one was performed in fullscan mode in the 50–600 amu scan range, and the second one in MS/MS mode with the precursor ion selected. The total scan time for each couple of segments was 0.38 s and the system performed 3 microscans per second. Table 1 shows precursor ions for each segment of MS/MS experiments and quantification ions for the PAEs studied.

Upon data acquisition, analysis of data was based on the following criteria: retention time for each peak should be within a 1% range, and integration of ion chromatograms was done with the Xcalibur Software using ICIS Peak Detection with ion ratio confirmation parameter, selecting each peak area for the base peak corresponding with the quantification ion selected. For all of PAEs, except DMP and internal standard, two ions were considered as

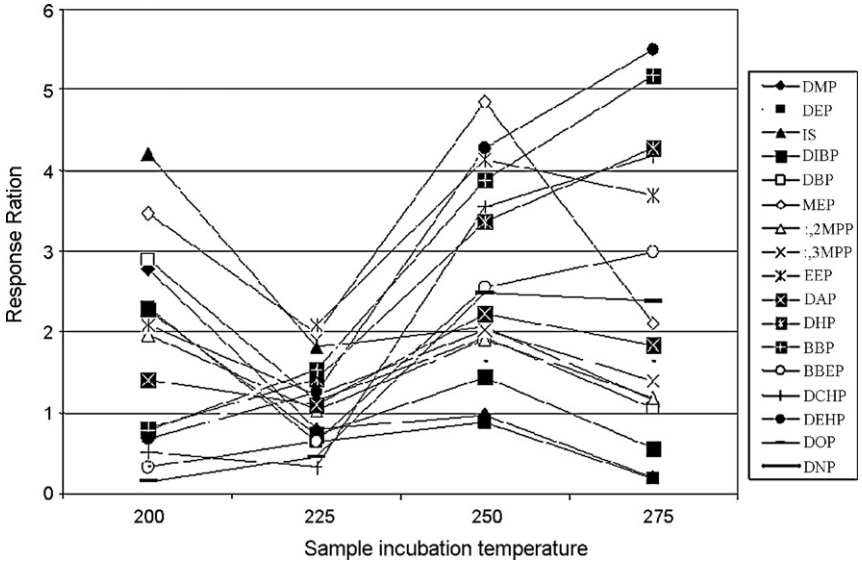

Fig. 3. Phthalate responses as a function of incubation temperature. Sample: EPA Mix 8061A standard mixture in olive oil (1 mg kg^{-1}).

quantification ions when relation of *m/z* 121 and *m/z* 93 was between 2.5 and 2.7 (±5%), as found for the standard compounds. For DMP and IS, single ions were selected for quantification due to their specificity.

3.2. Fiber and sample temperature optimization

Fiber type and sample temperature play an important role in the amounts of compounds absorbed and both have to be controlled separately. Three types of fiber coating were tested: PA, DVB/CAR/PDMS and PDMS fibers. PA and PDMS fibers, at headspace temperatures tested here, were not suitable for dimethyl and diethyl phthalates extraction and showed poor repeatability for the rest of PAEs studied (data not shown). As listed in Fig. 2, DVB/CAR/PDMS fiber showed the best response values for all of the phthalates studied from di-methyl phthalate (DMP) to di-nonyl phthalate (DNP).

Sample incubation temperature was tested between 200 and 275 °C since it was preliminarily observed that presence of the least volatile phthalates in headspace was reduced below 200 °C. Fig. 3 shows response ratios obtained between SPME of 1 g of olive oil spiked with 1 μg g^{-1} of each compound of the standard mixture (EPA 8061 Analytes) and direct liquid injection (in splitless mode) of 1 μL of standard solution (1 mg L^{-1}). The best results were obtained at 250 °C, with good SPME/direct liquid injection response ratio for all the compounds studied. This intermediate incubation temperature selected was a compromise between those most specifically suitable for compounds of lowest and highest volatility.

Vials were placed so as to leave their upper part (20 mm long) out of the heating system (Fig. 1). Thus, such upper parts of vials were not directly heated and temperature could be established between 80 and 115 °C to allow optimal response for all the PAEs tested. As headspace composition can vary depending on temperature, the SPME needle was punched through the cap and septum into the headspace and introduced at different depths (3.0, 2.0, 1.5 and 1.0 cm under cap bottom). Temperature was measured at the different depths using a digital microtermometer. For each point headspace temperature varied only less than ±3 °C during extraction time (30 min), as shown in Fig. 4. By using the internal standard, possible variations derived from lack of fiber thermostation or influence of glass surface characteristics [19] could be corrected.

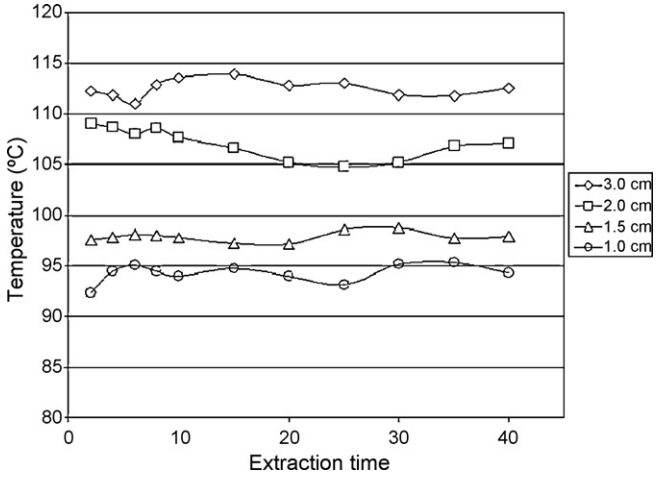

Fig. 4. Stability of headspace zone temperature during 40 min extraction period. Means of three analyses. Coefficients of variation were lower than 10%.

Fig. 5 shows response areas for phthalates absorbed from 1 g of oil sample containing 1 μg of each compound of the standard mixture (EPA 8061 Analytes) in function of the fiber position inside the headspace and the temperature on each position. The operating fiber position in the headspace selected was 1.0 cm under cap bottom, corresponding to 94 °C in headspace, according to the highest response areas obtained under such conditions.

Incubation time was studied from 10 to 40 min. Fig. 6 shows the results obtained, expressed as normalized response (% of each PAEs on total PAEs). Beyond 20 min of incubation time, this parameter was not critical, probably because the headspace equilibrium is reached relatively soon. However, it is important to stabilize the headspace zone temperature and that is why 30 min was selected as extraction time.

Fig. 7 shows the SPME–gas chromatogram ion trap MS/MS profile of an olive oil sample spiked with 1 μg g^{-1} of each compound of EPA 8061A Analytes compared with the profile corresponding to direct liquid injection of 1 μL of 1 mg L^{-1} EPA 8061A Analytes solution, in splitless mode. As can be observed, chromatograms were similar, which indicates that all phthalates were extracted without any distinctive suppression or promotion.

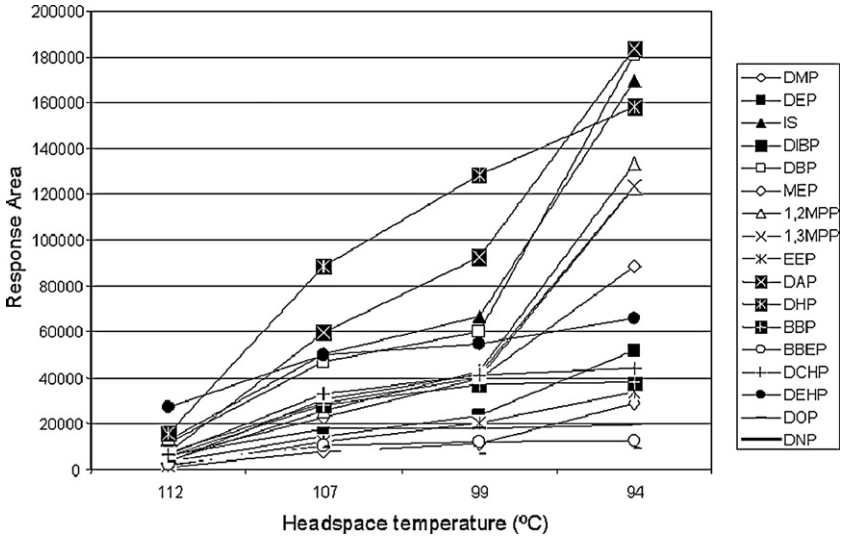

Fig. 5. Phthalate responses as a function of fiber sampling position (position 3, 2, 1.5 and 1 cm under the cup corresponds to 112, 107, 99 and 94 °C, respectively). Means of two analyses. Coefficients of variation were lower than 10%.

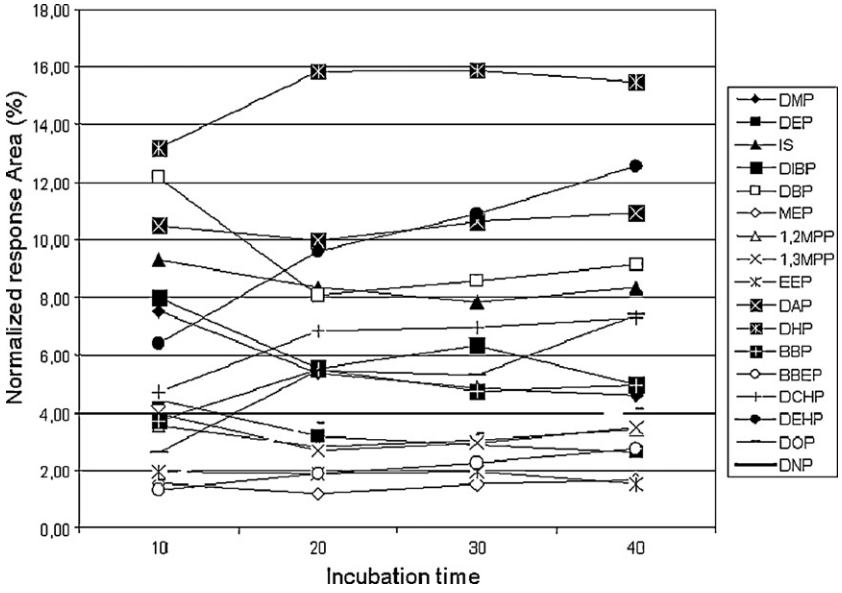

Fig. 6. Phthalate responses as a function of extraction time. Means of two analyses. Coefficients of variation were lower than 10%.

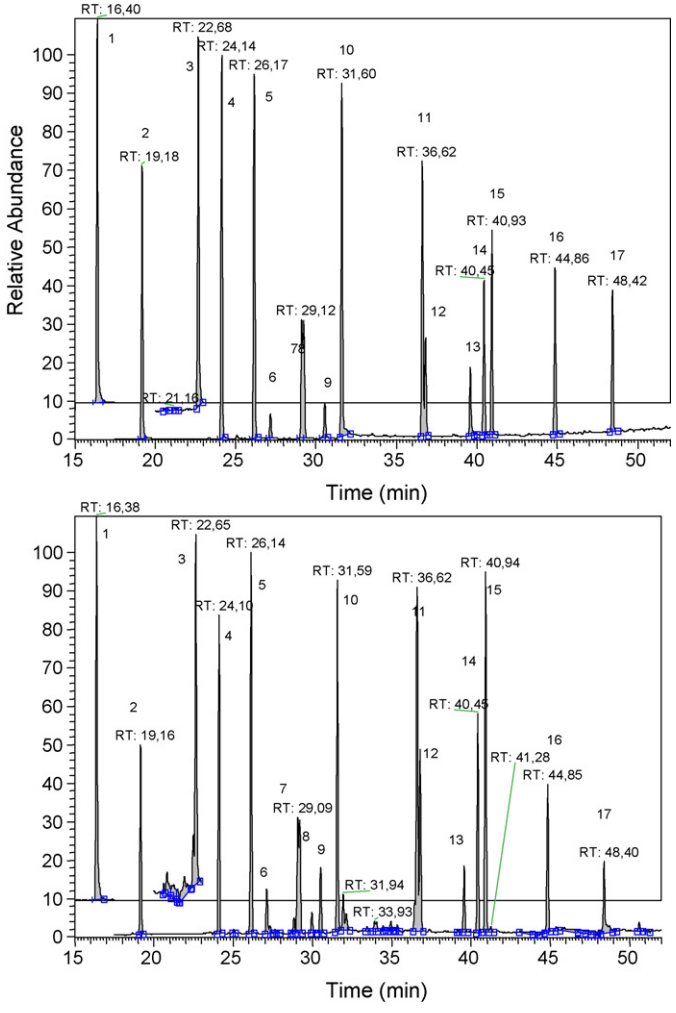

Fig. 7. Comparison of chromatograms obtained after: top, injection of 1 μL of phthalates standard solution (EPA 8061 standard mixture in acetonitrile, concentration 1 mg L^{-1}); bottom, HS-SPME of 1 g of olive oil (spiked with EPA 8061 standard mixture at the level of 1 μg g^{-1}). For peaks identification, see Table 1.

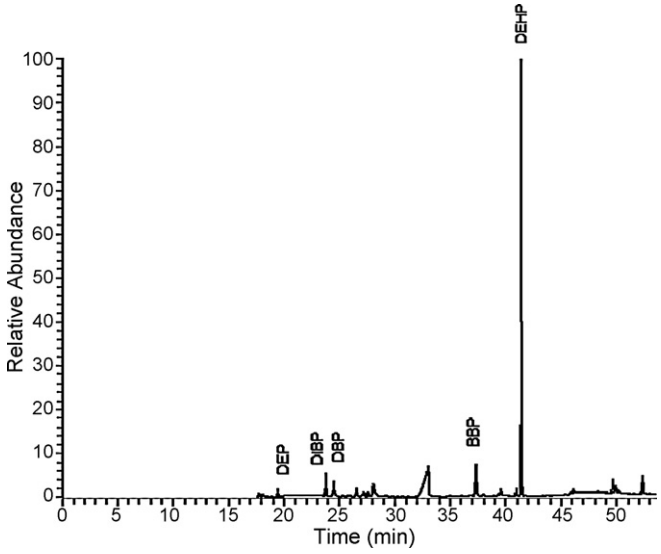

Fig. 8. Headspace GC-ion trap–MS/MS chromatogram of olive oil sample 1 (PET container) after applying the quantification layout.

Fig. 8 shows a representative example of the chromatographic profile obtained for a real sample by applying the method proposed. In this case, sample olive oil 1 (PET container), only DIBP, DBP, BBP and DEHP were detected in significant amounts.

3.3. Method performance

Repeatability of the SPME method was determined by five replicate analyses of olive oil spiked at levels of 0.1, 0.5 and 1.0 mg kg^{-1}. Linearity testing was carried out using olive oil spiked at levels of 0.05, 0.1, 0.5, 1.0 and 2.0 mg kg^{-1}. The resulting performance characteristics are summarized in Table 2.

Linearity of the analysis and extraction procedure of oil samples spiked with 0.05–2.0 mg kg^{-1} showed good correlation values for all of the compounds studied. The relative standard deviations (RSDs) for samples spiked with 0.1, 0.5 and 1.0 mg kg^{-1} were always below 20%. It is important to note that particularly low RSD, below 8.5%, were obtained for benzyl butyl phthalate (BBP)

and bis(2-ethylhexyl) phthalate (DEHP), which are the most widely found PAEs. Relatively high RSDs for some of the PAEs were found, especially the most volatile ones. Such results could be expected under the conditions used, which favor overall extraction and absence of contaminants during the extraction process but may otherwise lead to overestimated values [18].

3.4. Determination of PAEs in olive oil samples

As an example of application of the method to real samples, three samples of olive oils packed in plastic (PET, polyethylene terephthalate) bottles and three of olive oils packed in glass containers were analyzed for PAEs. As only few of the phthalates studied in this work may really be encountered in edible oils, namely DBP, DEP, DIBP, DBP, BBP, DEHP, DOP and DNP only those, if detected, are shown in real sample results. Analyses were done in duplicate and, if any, levels in blank were substracted.

Samples kept in PET containers shown presence of DIBP, DBP, BBP and DEHP but in samples kept in glass containers only significative BBP and DEHP were detected in the samples analyzed as it is shown in Table 3.

4. Conclusions

The analytical method described in the present work is simple and highly selective for quantification of PAEs in oil matrices. As compared with the conventional clean-up process based on liquid–liquid extraction or solid-phase extraction, the present approach is faster and more economical. Furthermore, the main benefit of the method is the suppression of the main contamination sources, especially in relation to sample manipulation. Due to complexity of the headspace of heated oils, however, there are certain limitations as to fiber durability. Degradation of fibers gives rise to poor recovery of the least volatile PAEs, such as DNOP and DNP, thereby special care should be taken to control recovery values and reject fibers when necessary.

ABSTRACT

Simultaneous analysis of 24 carbonyl compounds (alkanals, unsaturated, dicarbonylic and aromatic aldehydes and ketones) derivatized with 2,4-dinitrophenylhydrazine and 16 polycyclic aromatic hydrocarbons (PAHs) using a photodiode-array (PDA) and a fluorescence (FL) detector in series is proposed.

The separation is carried out with a reversed-phase column and gradient elution using four solvents (acetonitrile, water, tetrahydrofuran and methanol) in less than 35 min. Several critical pairs of carbonyl compounds with 3 and 4 carbon atoms and different functional groups, isomers of tolualdehyde, aromatic and aliphatic aldehydes were conditional on the gradient elution. Common pre-treatment for two groups of compounds consists in a step of extraction and derivatization in aqueous medium and a further clean-up using a polymeric phase SPE and concentration in a mixture of dichloromethane:methanol. A pre-concentration factor of 50 was achieved by this procedure. Acetone and formaldehyde blanks were minimized and remain controlled with a specific cleaning of glass material and washing the SPE cartridge.

The limits of detection (LOD) ranged from 0.006 to 0.18 ng mL^{-1} for PAHs and from 2.4 to 10.1 ng mL^{-1} for carbonyl compounds and method precision was $\leq$15% for all analysed compounds. Recoveries were within the range of 95–104% for PAHs except for more volatile compounds (acenaphthene and fluorene) and within the range of 72–113% for carbonyl compounds. The method was applied in water-soluble fraction of PM_{10} (atmospheric particulate matter with an aerodynamic diameter less than 10 μm) and the spectral contrast technique was used in the identification of carbonyl compounds.

1. Introduction

Polycyclic aromatic hydrocarbons (PAHs) and carbonyl compounds (aldehydes and ketones) are two groups of ubiquitous pollutants in the environment. PAHs have carcinogenic and mutagenic activities [1,2] and they become more toxic as a result of nitration reactions (nitro-PAHs). Some carbonyl compounds (e.g., formaldehyde, acetaldehyde, acrolein, and methyl ethyl ketone) may even have adverse effects on human health [3].

PAHs are produced from incomplete combustion (automobile traffic, industrial plants, domestic use, cigarette smoke. . .) and lots of emission sources, such as road traffic emissions, that are also common sources for carbonyl compounds. In addition, the latter play an important role in secondary atmospheric reactions. They can be produced by addition of ozone to unsaturated hydrocarbons or photooxidation of hydrocarbons or volatile organic compounds with OH radicals. But carbonyl compounds may also be degraded by photochemical reactions [4].

The particulate matter is a complex atmospheric matrix which has an influence on the atmospheric chemistry and also an adverse health impact due to its ability to penetrate into the respiratory tracts and be absorbed by mucous membranes. Water-soluble fraction is a part of particulate matter which contains inorganic ions and water-soluble organic compounds (WSOC) such as carbonyl compounds. Water-soluble fraction has an influence on the cloud condensation nuclei activity, particulate matter size and toxicity. Consequently, water-soluble compounds act as surface-active reagents, increasing the solubility of toxic organic compounds such as PAHs [5].

High-performance liquid chromatography (HPLC) separation of PAHs may be carried out using normal or reversed-phase chromatography but a major number of applications use

reversed-phase with fluorescence or UV detection. Although the separation of 16 Environmental Protection Agency (EPA) priority PAHs may be possible using an octadecylsilane stationary phase and a gradient elution, the best results for ring-isomeric pairs are obtained with a polymeric C_{18} column [1]. These special columns for PAHs separation are employed with a mobile phase containing mixtures of water/acetonitrile [6], water/methanol [7] or water/methanol/acetonitrile [8], at a programmed temperature of 30–40 °C [6]. In order to carry out an environmental analysis, fluorescence detection is most frequently chosen under programmed fluorescence conditions (excitation and emission wavelength pairs programme).

Chromatographic separation of carbonyl compounds, with prior derivatization to form the 2,4-dinitrophenylhydrazones derivatives, has been used for the last twenty years and nowadays it is applied in air monitoring programmes [9,10]. The separation is carried out on octadecylsilica column and binary mixture of water/acetonitrile or water/methanol. Aliphatic aldehydes (C_1–C_4) and aromatic aldehydes (benzaldehyde) have been separated with water/acetonitrile under isocratic conditions [11]. Binary gradients of water/acetonitrile [12] and water/methanol [13] have been used to separate unsaturated aliphatic, aromatic aldehydes, ketones and dicarbonyls compounds. A ternary gradient of water/acetonitrile/tetrahydrofuran has been effective in specific problems such as separation of carbonyl compounds with 3 carbon atoms: aliphatic, olefinic and ketone [14]. Dye and Oehme [15] have proposed another alternative using two columns in series and a ternary gradient of water/methanol/acetonitrile. Only one column and this ternary mixture have separated ketone, olefinic and aliphatic aldehydes in isocratic [16] and gradient conditions [4]. Quaternary gradients of water/acetonitrile/tetrahydrofuran/methanol may be recommended for mixtures of aliphatic, aromatic and unsaturated aldehydes, aliphatic and unsaturated ketones and dicarbonyl compounds [9]. The updating of this analytical method is focused on the study of interferences and isomers, the use of analytical column with smaller dimensions, mobile phase changes (nature and composition solvent) and a simultaneous analysis with other organic compounds.

Frequently, each group of organic compounds in atmospheric matrices is analysed by different analytical techniques after several pre-treatments of samples. Organic acids and aldehydes have been analysed separately in air using ionic chromatography and HPLC [4] or gas chromatography (GC) and HPLC [17], respectively. These two classes of compounds have been determined in rainwater using capillary electrophoresis (CE) and HPLC [18] or GC/MS and HPLC [19]. Therefore, in ambient air, carbonyl compounds have been analysed together with other groups of compounds such as alkanes using two GC methods [20] and volatile organic compounds (VOC) using HPLC and GC [21] respectively. Nevertheless, Komenda et al. [22] have quantified isoprene, methacrolein and methylvinylketone (degradation products of isoprene) using a common GC method. Simultaneous analysis of carboxylic acids and aldehydes has been achieved using GC–MS with two-step derivatization [23] for air samples and one step for atmospheric aerosol [24]. Moreover, HPLC after DNPH derivatization has been a suitable technique for the simultaneous analysis of these two groups in indoor air [25]. Two HPLC methods for determination of carbonyl compounds and PAHs in rainwater have been used [26]. Ho and Lee [2] analysed carbonyl compounds, PAHs and VOC using three methods (HPLC for carbonyl compounds and GC/MS for PAHs and VOC) in atmospheric samples.

Due to the nature and complexity of environmental matrices, the development of an analytical method ought to consider a multicomponent analysis (with the greatest number of pollutant classes) and a simultaneous extraction and determination of these pollutant classes, if possible, from sampling to measurement.

In this work, the aim pursuits the simultaneous determination of this two pollutant groups from pre-treatment (extraction, clean-up, derivatization, concentration) to chromatographic separation using two detectors in series (photodiode-array (PDA) detector for carbonyl compounds and fluorescence detector for PAHs). In this way, the sample manipulation is simplified, the time operation, solvents and chemicals employed are reduced and, consequently, the analysis expenses. In comparison to the determination of these pollutants using two methods, the method proposed improves the analysis throughput for a large number of analytes of two different classes.

In addition to the improvement in the methodological aspects of the PAH and carbonyl compounds determination, novelties in the environmental application are proposed since the method is applied to the water-soluble fraction of PM_{10} (atmospheric particulate matter with an aerodynamic diameter less than 10 μm). The determination of organic compounds present in particulate matter is frequently performed by extraction with relatively non-polar organic solvents. In this way, most polar and water-soluble compounds are not analysed and an important fraction of organic compounds cannot be characterized well enough. Information on their nature and amount in particulate matter could be useful to know their sources and to understand their formation process [27].

Carbonyl compounds have been mainly determined in air [3,4,9–12,15–17,20–22,25] but scarcely in particulate matter [14,24]. Kiss et al. analysed 15 carbonyl compounds derivatized with DNPH by HPLC but the extraction is performed with organic solvent [14]. Only Wang et al. have measured two dicarbonylic compounds by GC–MS in water-soluble fraction [24]. This fraction is more easily absorbed by the body and therefore, the toxicity of particulate matter is increased [5,28]. The identification of individual carbonyl compounds present in particulate matter and their concentration levels are incomplete in the literature. Their determination can provide information about their potential chemistry. The method proposed allowed the determination of 24 carbonyl compounds in water-soluble fraction.

Moreover, PAHs are slightly water-soluble compounds which could be present in water extracts although in smaller concentrations [27]. To our knowledge, there are no published methods which determine PAHs in water-soluble fraction of particulate matter although the analysis in organic fraction has been extensively studied [1–2,7,8]. Their determination in water-soluble fraction would be useful for their correlation with atmospheric aqueous matrices, or with other pollutants.

2. Experimental

2.1. Standards and reagents

Tetrahydrofuran, methanol and acetonitrile were of HPLC grade (Merck, Darmstadt, Germany; Romil, Cambridge, UK; and Panreac, Barcelona, Spain, respectively). Dichloromethane, super purity solvent, was purchased from Romil (Cambridge, UK) and perchloric acid 69–72% from J.T. Baker (Pillipsburg, USA). Ultra-pure water was obtained by water ultrafiltration with a Direct Q 5 system (Millipore, Bedford, UK). 2,4-Dinitrophenylhydrazine (DNPH) (50% in water) was obtained from Fluka (Steinheim, Germany).

Two derivatized carbonyl compounds mixtures in acetonitrile (DCC8315-1JM and DCC8315-2JM, ChemService (West Chester, USA) (100 μg mL^{-1} of each derivatized carbonyl) containing altogether 20 carbonyl compounds, as follows: formaldehyde, acetaldehyde, acetone, acrolein, propionaldehyde, butyraldehyde, crotonaldehyde, valeraldehyde, isovaleraldehyde, hexaldehyde,

heptaldehyde, octyl alcohol, nonanaldehyde, decyl aldehyde, cyclohexanone, benzaldehyde, 2,5-dimethylbenzaldehyde, *o*-tolualdehyde, *m*-tolualdehyde, *p*-tolualdehyde were used. Also 2-butanone-DNPH and methacrolein-DNPH (Supelco, Bellefonte, PA, USA) (350 μg mL^{-1} of each derivatized carbonyl) and glyoxal 40% in water Fluka, methylglioxal 40% in water Sigma (Steinheim, Germany).

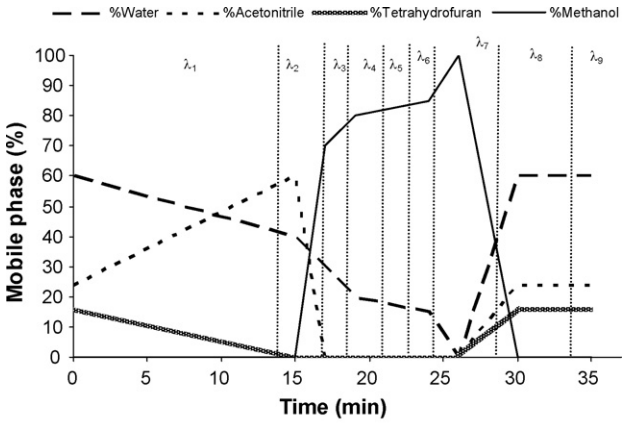
SRM 1647d 'Priority PAHs pollutant in acetonitrile' (NIST, Gaithersburg, MD, USA), which contains 16 EPA PAHs: naphthalene, acenaphthene, fluorene, phenanthrene, anthracene, fluoranthene, pyrene, benzo[*a*]anthracene, chrysene, benzo[*b*]fluoranthene, benzo[*k*]fluoranthene, benzo[*a*]pyrene, dibenzo[*a*]anthracene, benzo[*g*,*h*,*i*]perylene, indeno[1,2,3-*cd*]pyrene, was used. Acenaphthylene was omitted since it is only weakly fluorescent.

Oasis® HLB 60 cartridges (200 mg, 6 mL) (Waters Corporation, Mildford, MA, USA) and Albert® no. 135 ashless filter paper were used for manual solid-phase extraction and for filtration of aqueous extract of atmospheric particulate matter, respectively.

2.2. Materials and instrumentation

A Waters chromatographic system (Waters, Milford, MA, USA) was composed by a 2690 Alliance™ Separations module, UV–visible diode array and fluorescence detector in series (Waters 996 PDA and Waters 474) and Millenium 32® software. The tested analytical column was C_{18} Symmetry® 3.5 μm particle size (150 mm × 3.0 mm ID) with a precolumn 3.5 μm (10 mm × 2.1 mm ID).

2.3. Cleaning of glass material



To achieve suitable procedure blanks, it is necessary to submit the glass material to an exhaustive cleaning process which starts with its immersion in an ultrasonic bath with an alkaline detergent (Derquim LA13, Panreac, Barcelona, Spain) during 1 h. After that, the different pieces of glass material were rinsed with fresh milli-Q water and again immersed in the ultrasonic bath filled with fresh milliQ-water during 15 min. This latter part of the process was repeated twice. Then, it is dried in an oven covered with aluminium foils and introduced in a muffle furnace at 350 °C during 12 h, or 500 °C during 6 h. The material is cooled down to 100 °C into muffle and keeps cooling down by gentle stream nitrogen. Finally, it is stored in sealed polyethylene bags.

2.4. Sampling and sample preparation

PM_{10} samples were collected over 24 h periods simultaneously from two sites by EN-12341 reference high volume sampler (Digitel) on 15 cm diameter QF20 Schleicher and Schuell quartz fibre filters. All filters were pre-backed at 400 °C overnight before use in order to remove organic compounds and they were stored in baked aluminium foil. Subsequently, sampling filters were conditioned at 20 ± 1 °C and 50 ± 5% relative humidity during 48 h according to the EN-12341 gravimetric determination of particulate matter. After that, the filters were stored at −18 °C until analysis. An eighth portion of PM_{10} samples were twice ultrasonically extracted with 10 mL milli-Q water at ambient temperature in 15 min.

2.5. Derivatization and pre-concentration SPE procedures

Briefly, 200 μL of DNPH in acetonitrile (7 mg mL^{-1}) and two drops of $HClO_4$ (2 M) were added to 25 mL of aqueous extract. Once derivatization reaction takes place at ambient temperature during 1 h, OASIS HLB cartridges 0.2 g are conditioned with 5 mL dichloromethane, 5 mL methanol and 5 mL milli-Q consecutively. Next, samples are loaded and cartridges are washed with 10 mL milli-Q water and 1.5 mL methanol. Compounds are eluted with 20 mL of dichloromethane/methanol (85:15). This eluate is concentrated to 0.2 mL and then to dryness under a gentle stream of nitrogen. Finally, the residue is solved in 0.5 mL acetonitrile previous chromatographic determination.

Fig. 1. Elution gradient conditions, UV conditions and fluorescence programme of the method proposed.

2.6. Chromatographic conditions

The chromatographic conditions are shown in Fig. 1. Initially, the mobile phase flow was 0.5 mL min^{-1} at 0 min, increasing lineally at 0.55 mL min^{-1} in 15 min. This flow was maintained until minute 30 and decreased lineally to 0.5 mL min^{-1} at minute 35. Hydrazones of carbonyl compounds were detected in the wavelength interval 200–600 nm and quantified at 365 nm and a programme of nine excitation and emission wavelength was employed for PAHs [32]. The temperature of the pre-column and analytical column was maintained at 29 °C. The injection volume was 10 μL.

3. Results and discussion

3.1. Optimization of chromatographic separation

Firstly, separation of 24 carbonyl compounds: 11 aliphatic aldehydes C_1–C_{10} with an isomer of C_5 (isovaleraldehyde), 3 insaturated aldehydes (acrolein, C_3 and methacrolein, crotonaldehyde, C_4), 2 aliphatic ketones (acetone, 2-butanone) and 1 cyclic ketone (cyclohexanone), 5 aromatic aldehydes (benzaldehyde, 2,5-dimethylbenzaldehyde and *o*-,*m*-, *p*-tolualdehyde) and 2 dicarbonylic compounds (glyoxal and methylglioxal) is achieved. Next, PAHs separation is reviewed and adjusted with carbonyl conditions in order to achieve simultaneous analysis.

Last improvements in column technology allow working with columns of smaller dimensions and particle size. A review of some columns used in the literature for carbonyl compounds and PAHs is shown in Table 1. In this work, a column of octadecylsilica with dimensions of 3.5 μm particle size (150 mm × 3.0 mm ID) is chosen. These characteristics can provide a decrease of analysis time, a less solvent consumption and a sensitivity increase compared to a stan-

dard column (250 mm, 5 μm). Three critical separations in tested compounds that limit gradient peak capacity are found.

One of the critical pairs which is tackled in the literature are the carbonyl compounds with three carbon atoms (an unsaturated aldehyde, acrolein and acetone). In environmental matrices, acrolein is determined at low concentration with high levels of acetone, which makes difficult the separation [15]. Acrolein and acetone have been separated using the binary mixture water/acetonitrile, gradient elution and two reversed-phase columns in series although they are not baseline separated [10]. The same as in C_4 series, whose separation of an unsaturated aldehyde, methacrolein and a ketone, 2-butanone is difficult [16].

In this work, acrolein and acetone were separated for binary mixtures of water/acetonitrile as 65/35, but with higher retention times and peak broadening. Neither binary mixtures of methanol/water in interval 65–85% nor isocratic ternary mixtures (methanol/water/acetonitrile) were effective for the separation of this critical pair. Ternary mixtures (water/acetonitrile/THF), which gave good results in literature [11], were tested using percentages of water among 50–65%. The introduction of a third solvent, as tetrahydrofuran, which has less polarity, produces a decrease on the retention time for all compounds related to binary mixtures. The effect of THF on system C_3 and C_4 was studied as the first step of the gradient, establishing a lineal relation between retention time and %THF (Fig. 2). For 60% water, 10% tetrahydrofuran was sufficient for the resolution of acetone-acrolein. Elution order of three carbonyl compounds was acetone, acrolein and propanal according to other authors that used this mixture [11]. Elution order to C_4 compounds was crotonaldehyde, 2-butanone, methacrolein and butanal. The separation close to the baseline of critical peak pair

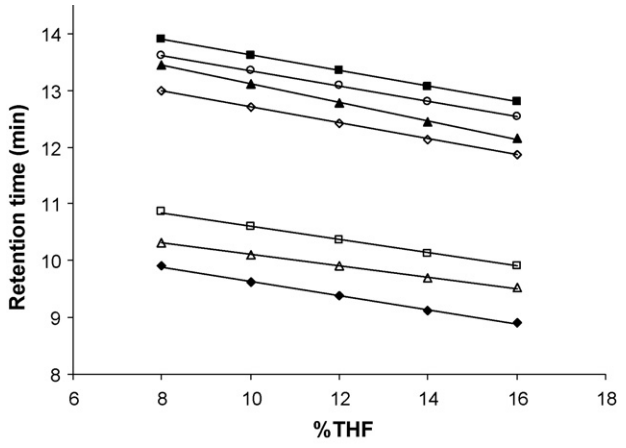

Fig. 2. Effect of tetrahydrofuran (THF) on the retention time of carbonyl compounds with three carbon atoms, system C_3 (♦ acetone, △ acrolein and □ propanal) and with four carbon atoms, system C_4 (◊ crotonaldehyde, ▲ 2-butanone, ○ methacrolein and ■ butanal).

(2-butanone and methacrolein) was reached using 16% tetrahydrofuran. The slope of the straight line is very similar for C_4 system except for 2-butanone which has a greater slope and therefore this fact makes selectivity possible with methacrolein. Concerning the system C_3, acetone also showed a higher slope in the studied interval. For the separation of C_4 compounds, 16%THF produces a worse selectivity between acrolein and propanal but a better selectivity between acrolein and acetone than 10%THF.

The separation of three isomers (*ortho*, *metha* and *para*) of tolualdehyde is another critical separation under a variety of tested conditions. In the literature, partial separation of three isomers is obtained or only one isomer (frequently *metha*-tolualdehyde) is determined. According to Kolliker et al. [12] the column had to contain high organic carbon content in order to obtain a separation with a valley of maximum 30–40%. In our case, the best conditions were achieved with binary mixtures water/acetonitrile using Symmetry column with a 19.5% of total carbon. For 45–50% percentages of acetonitrile, *ortho* and *metha* isomers have a resolution close to the baseline, and *metha* and *para*-tolualdehyde are separated partially. Higher values of acetonitrile make the separation worse. A first step of the gradient elution which starts with a ternary mixture (water/acetonitrile/tetrahydrofuran, 60/24/16) and finishes with a binary mixture (water/acetonitrile, 40/60) is a compromise between the elution of all compounds in a reasonable retention time and the partial separation of *metha* and *para* isomers.

Elution order of aromatic aldehydes was benzaldehyde after C_4 carbonyl compounds, tolualdehyde isomers after C_5 aldehydes, and 2,5-dimethylbenzaldehyde after hexaldehyde. These latter have revealed to be other critical pair of peaks. In the literature there are some separation systems that resolved satisfactorily two compounds with water/acetonitrile mixtures [10] and other authors have not obtained a baseline resolution [11]. A second step of the gradient elution includes 60% acetonitrile elutes hexaldehyde and 2,5-dimethylbenzaldehyde to higher retention times and broadening peaks. It was necessary a lineal increase of % acetonitrile but under these conditions the separation of these two compounds is partial (Fig. 3a). If the water/acetonitrile mixtures in the second step of the gradient elution are replaced by water/methanol (30/70), the separation of hexaldehyde and dimethylbenzaldehyde is total (Fig. 3b).

Other compounds such as glyoxal and methylglyoxal elute during the binary mixture of methanol with water, glyoxal between two isomers of pentanal, overlapping with one of them, isovaleraldehyde, and methylglioxal between tolualdehyde isomers and hexaldehyde. Moreover, in the separation proposed by Grosjean et al. [29], an overlapping between cyclohexanone and glyoxal occurred. In the proposed method, the cyclic ketone, cyclohexanone was eluted between benzaldehyde and C_5 compounds. Finally, the homologous series of semi-volatile C_7–C_{10} aldehydes elutes gradually according to the increasing values of alkyl chain length. Twenty-four carbonyl compounds are separated in less than 30 min analysis time.

Under conditions of separation for carbonyl compounds, the PAHs separation using fluorescence detection is reviewed. Using nine pairs of excitation and emission wavelengths and the same analytical column, the retention times of PAHs are found between 11 and 34 min. These retention times are within the interval of retention times of carbonyl compounds, making possible the simultaneous separation by dual detection (Fig. 4a).

Two compound pairs did not get separated: acenaphthene/fluorene and benzo[*a*]anthracene/chrysene. Fluorene and acenaphthene are separated with this column and binary mixtures water/acetonitrile (20/80) and water/methanol (25/75); however, these conditions are incompatible with the separation of carbonyl compounds of identical number (C_3 and C_4) carbon atom. A special stationary phase, containing a polymeric C_{18} or phenyl group

Concentration of hexaldehyde 304 ng mL^{-1} and 2,5-dimethylbenzaldehyde 185 ng mL^{-1}. The concentration of carbonyl compounds is in the range of 103–304 ng mL^{-1}.

[1], may be necessary for the other pair of 4 ring isomers. Also, the selectivity between benzo(g,h,i)perylene and indene(1,2,3-*cd*)pyrene is low because fluorescence conditions must be changed (Fig. 4b).

3.2. Pre-treatment (extraction, derivatization, clean-up and concentration)

Pre-treatment steps (extraction, derivatization, clean-up and concentration) to process atmospheric solid samples were studied. Filters of particulate material were extracted with 10 mL of water using ultrasound bath. A second extraction (10 mL of water) was necessary to achieve a recovery of 85% for PAHs since with one extraction only less than 50% of PAHs was extracted.

Extracted solid samples were derivatized with DNPH at ambient temperature during 1 h according to the procedure described in the literature, just as Tsai et al. [30] point out. Clean-up step is carried out by a SPE reversed-phase with a poly(divinylbenzene-co-N-vinylpyrrolidone copolymer and with characteristic lipophilic and hydrophilic which allow to retain polar and non-polar compounds. In our case, only one eluate containing two groups of pollutants is pursued. Acetonitrile (3–4 mL), used like elution solvent for Zwiener et al. [31], with this SPE phase, obtained good results in the case of C_1–C_5 carbonyl compounds and low recovery for aromatic carbonyl compounds and PAHs. Another solvent of great relative elution strength, tetrahydrofuran was suitable for carbonyl compounds but did not improve PAHs recovery. Dichloromethane is a solvent frequently used for extraction and [30] concentration of PAHs but incompatible with aqueous medium. In order to make compatible dichloromethane with aqueous medium, 1.5 mL of methanol is eluted before that the sample without carbonyl compound and PAHs are eluted. Methanol was also used to increase the polarity of the eluent in a mixture of dichloromethane and methanol (85:15). Finally, the eluate was evaporated easily due to the low boiling point of the mixture and re-dissolved in acetonitrile achieving a concentration factor of 50. Recoveries were greater than 90% for carbonyl compounds and PAHs except for the more volatile PAHs (naphthalene was lost and recovery of acenaphthene and fluorene was around 65%).

Nevertheless, this procedure of pre-concentration led to a high acetone blank and other interferences. In order to minimize blanks, washing was necessary to remove acid medium before elution to methanol. It was verified that pH of wash water arises around 3.

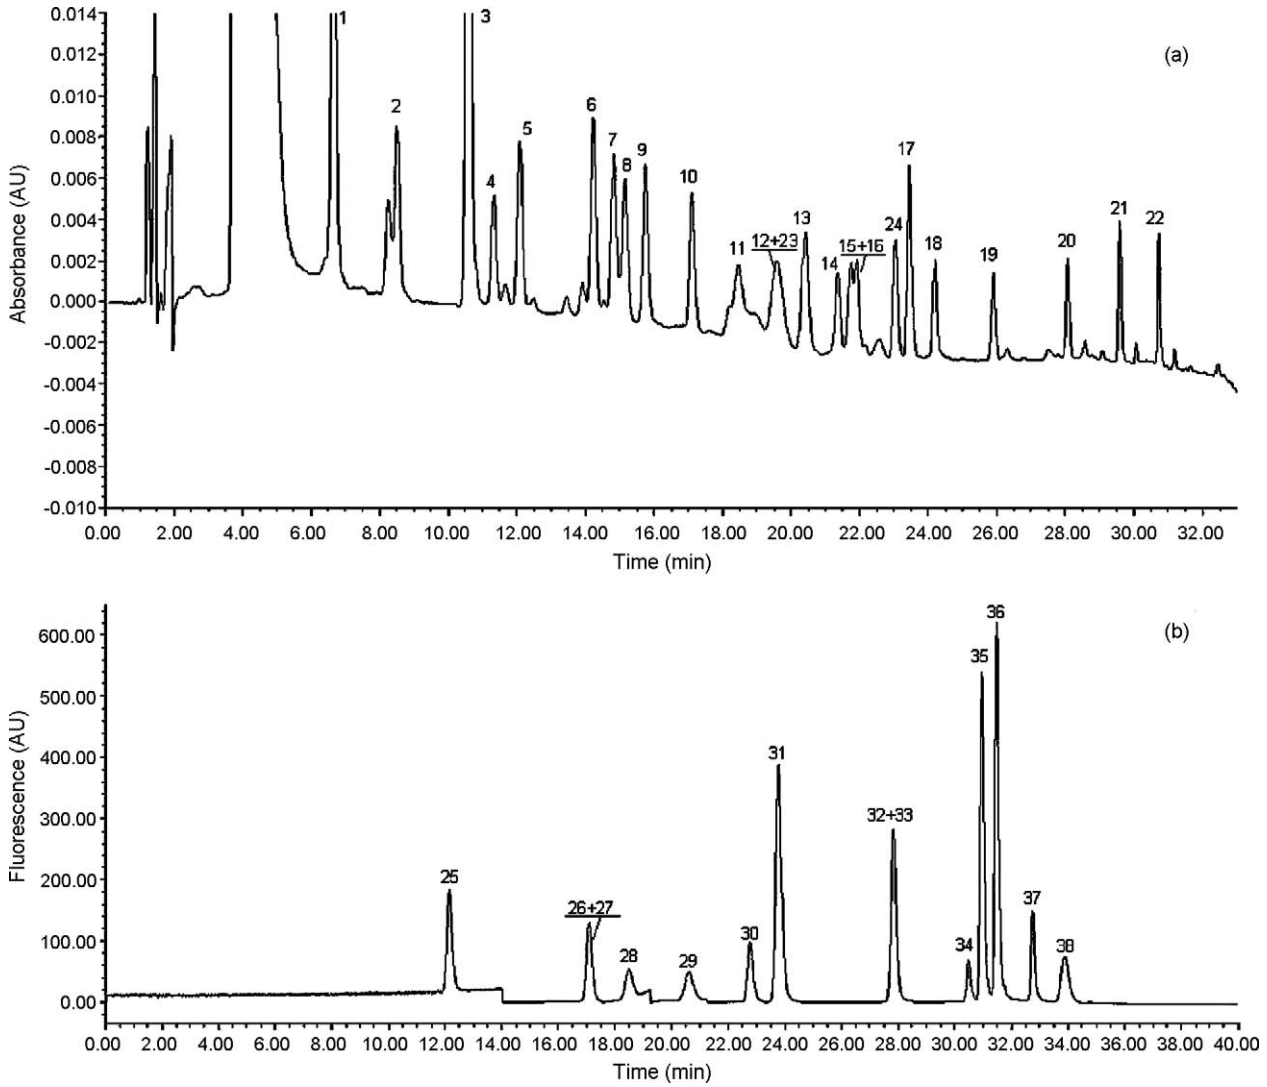

Fig. 4. Simultaneous separation of carbonyl compounds (a) and PAHs (b). (12 + 23) Isovaleraldehyde + glioxal, (24) methylglioxal, (25) naphthalene, (26 + 27) acenaphthene + fluorene, (28) phenanthrene, (29) anthracene, (30) fluoranthene, (31) pyrene, (32 + 33) benzo[*a*]anthracene + chrysene, (34) benzo[*b*]fluoranthene, (35) benzo[*k*]fluoranthene, (36) benzo[*a*]pyrene, (37) dibenzo[*a,h*]anthracene, (38) benzo[*g,h,i*]perylene. The concentration of PAHs is in the range of 5.9–191 ng mL^{-1}.

Thus, high blanks of acetone were minimized but a poor reproducibility to formaldehyde, acetone, benzaldehyde and nonanaldehyde in water blanks was observed. Several unidentified compounds with spectra similar to hydrazones and with retention times from volatile aldehydes to semivolatile aldehydes were also detected. The control of blanks and the reduction of background contamination was achieved by treatment of non-volumetric material (i.e., Pyrex glass tubes). This was heated in muffle furnace and cooled by a nitrogen stream. Glass Pyrex tubes with screw-top obtained the best results in all different materials tested for extraction. Also, 2,4-dinitrophenylhydrazine solution was prepared freshly prior to derivatization and acetone was not used like solvent in laboratory when the samples were processed. In this way, values around (6 ± 2) ng mL^{-1} of acetone, (9.5 ± 2.5) ng mL^{-1} of formaldehyde, (1.9 ± 0.7) ng mL^{-1} of benzaldehyde, (1.7 ± 0.5) ng mL^{-1} of nonanaldehyde, (0.5 ± 0.2) ng mL^{-1} of acetaldehyde for $n = 47$ were achieved.

3.3. Spectral validation

In this work, PDA has been employed to identify and classify hydrazone derivatives, to integrate with peak purity and detect interferences and to verify peak identification by comparing with a standard spectrum library.

All carbonyl compounds were identified initially by retention time and then by applying spectral contrast technique (incorporated in Millenium^{32} software), peak spectral homogeneity is confirmed. Finally, a spectral identification is carried out, contrasting the spectrum with a standard library.

A library was created with spectrums in wavelength interval of 210–600 nm at two different concentration levels of standards. One of them is close detection limit because the spectrum, at a low concentration, has a greater solvent contribution and noise and other level around 700 ng mL^{-1} derivative. Treatment of spectrum was carried out for standards and samples at a level concentration below 700 ng mL^{-1} of derivative by a mathematical process, Savitsky-Golay filters, that allow reducing spectrum noise [33]. In this way, the number of carbonyl compounds possible to identify by spectral contrast increased considerably (Fig. 5).

3.4. Performance of the analytical method

Calibration curves at five levels were prepared and each calibration level was injected twice. Good linearities with correlation

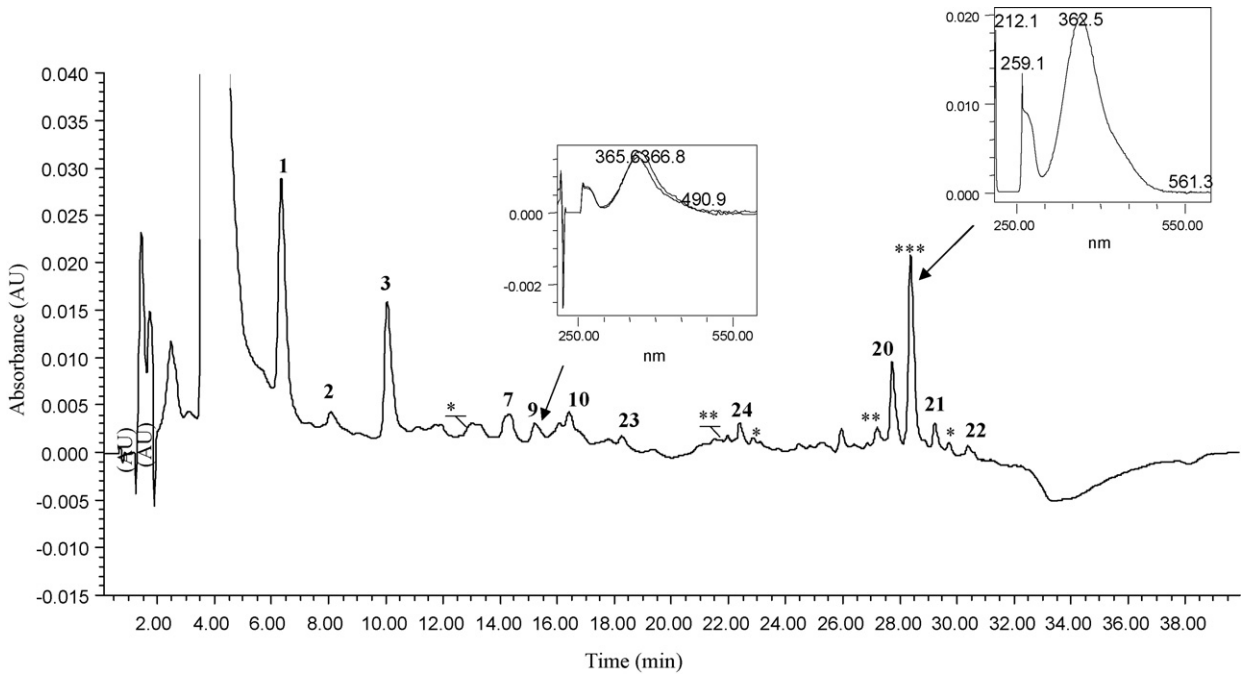

Fig. 5. Chromatogram of carbonyl compounds in PM_{10} sample at industrial site. Unidentified carbonyl compounds (*aromatic aldehydes/ketones, **aldehydes/ketones with conjugated double bounds, ***other aliphatic aldehydes/ketones).

coefficients (R^2) ranging from 0.9971 to 0.9999 for carbonyl compounds and from 0.9958 to 0.9987 were obtained. Table 2 summarizes concentration interval of calibration equations, precision, and detection and quantification limit [34]. Reproducibility was assessed on different days ($n = 10$) at a concentration in the range of 62–203 ng mL^{-1} for carbonyl compounds and 1.5–48 ng mL^{-1} for PAHs and relative standard deviation (%RSD) is reported in Table 2. Valeraldehyde isomers which elute on drift of gradient have had higher relative standard deviations.

Recoveries were determined by spiking portions of the filter from PM_{10} samples. The values obtained varied between 72 and 113% range for carbonyl compounds and higher than 95% (except acenaphthene and fluorene) for PAHs with relative standard deviations lower than 15 and 8% respectively (see Table 3).

3.5. Application to real samples

The method proposed was applied to samples of particulate matter of PM_{10} in order to analyse its water-soluble fraction. The samples were collected between January 2005 and March 2005 at two sites in A Coruña-Galicia (Northwestern Spain), with industrial and rural typologies. The results obtained for PAHs and carbonyl compounds are shown in Table 4. The level of concentration of PAHs was of pg m^{-3} excepting February 2005, when fluoranthene and chrysene/benzo[*a*]anthracene reached 1 ng m^{-3}. The total concentration of the PAHs at the industrial site was 4.9 times higher than at the rural site during the period studied. An increase in February for the two sites was observed, but this is more significant in the industrial site. High correlation coefficients among them in the range 0.87–0.99 were observed when the two sampling sites were accounted. Also, Alves et al. [35] obtained high correlations of PAHs but in organic fraction of PM_{10}. The comparison between water-extractable PAHs and organic solvent extractable PAHs according to their concentration level, individual compounds, and particulate size could be carried out in the next step of this study.

In the samples analysed, 10 carbonyl compounds (aliphatic, unsaturated and aromatic aldehydes and C_3–C_4 ketones), those which can be separated for the method proposed, were determined and other unidentified compounds with a spectrum similar to hydrazones were detected (Fig. 5). These unidentified compounds can be classified in different groups of carbonyl compounds (unsaturated with double or triple bonds, aromatic or aliphatic aldehydes or ketones), according to Potter and Karst [36], using ratios of areas peaks at two wavelength (300 and 360 nm). Although a LC–MS method could improve the identification and to confirm the structure of the carbonyl compounds found in water-soluble fraction; for the quantitative analysis, it would be necessary obtain standards of the identified carbonyl compounds.

The concentration of carbonyl compounds at ng m^{-3} levels was 100–1000 times higher in the case of PAHs. The total concentration is slightly higher in the rural site than in the industrial site. The concentrations of acetaldehyde, crotonaldehyde and decanaldehyde reached a higher value only in the industrial site. The main carbonyl compounds found were formaldehyde and octanaldeyde in both sampling sites. Due to the limited number of data, further studies are necessary for a more complete evaluation.

4. Conclusions

The method described showed the following advantages:

- The use of HPLC–PAD–FLD allowed to obtain two chromatograms, correspondent to each class of pollutants. DNPH-derivatized carbonyl compound can be detected only in UV region and PAHs are fluorescent but also exhibit UV absorption. Nevertheless, the latter do not interfere to UV wavelength and concentration used. Two different detection modes simplified the separation and reduced the analysis time since a smaller peak capacity is necessary.
- Spectral analysis of carbonyl compounds with diode-array detection was an adequate tool for verifying the identity of compounds and for detecting co-elutions. Its application to particulate material samples shows that a greater number of carbonyl compounds could be determined by the proposed method if other standard carbonyl compounds were available.
- The simultaneous pre-treatment prior to the chromatographic separation which involves sonication-assisted extraction, derivatization, clean-up and concentration reduced the analysis time and the sample manipulation with regard to the methods which carried out the pre-treatment separately. Therefore, good recoveries were obtained.
- Monodimensional chromatography was sufficient to separate the two kinds of organic compounds. In this way, the chromatographic system was simpler than if a bidimensional chromatography with two columns were used. However, it was necessary to study chromatographic behaviour of the two kinds of compounds to make compatible the chromatographic conditions required for each one of them.
- PAHs and carbonyl compounds were found in water-soluble fraction of PM_{10} at levels of pg m^{-3} and ng m^{-3} respectively. In future works, the application of the method to a greater number of samples will allow to establish the correlations between both kinds of organic compounds and their emission sources.

Rhodamine

ABSTRACT

An "off–on" rhodamine-based fluorescence probe for the selective signaling of Fe(III) has been designed exploiting the guest-induced structure transform mechanism. This system shows a sharp Fe(III)-selective fluorescence enhancement response in 100% aqueous system under physiological pH value and possesses high selectivity against the background of environmentally and biologically relevant metal ions including Al(III), Cd(II), Fe(II), Co(II), Cu(II), Ni(II), Zn(II), Mg(II), Ba(II), Pb(II), Na(I), and K(I). Under optimum conditions, the fluorescence intensity enhancement of this system is linearly proportional to Fe(III) concentration from 6.0×10^{-8} to 7.2×10^{-6} mol L^{-1} with a detection limit of 1.4×10^{-8} mol L^{-1}.

1. Introduction

The development of fluorescent chemical devices is a promising field [1–3]. An important area within this field is the design of fluorescent probes for various metal ions [4–8]. Ions play a fundamental role in a wide range of chemical and biological processes, and numerous efforts have been made to the development of effective fluorescent probes. Sensors based on ion-induced changes in fluorescence appear to be particularly attractive due to their simplicity, high sensitivity and instantaneous response [1–8]. The trivalent form of iron is an essential element in man. It provides the oxygen-carrying capacity of heme and acts as a cofactor in many enzymatic reactions involved in the mitochondrial respiratory chain. On the other hand, iron deficiency chlorosis is a widespread agricultural problem that affects the development and decreases the yield of many susceptible crops growing on calcareous and alkaline soils [9]. Thus, there is an urgent need to develop chemical sensors that are capable of detecting the presence of iron ions in environmental and biological samples at physiological pH value. Considerable efforts have been devoted to developing fluorescent probes for various metal ions over the last few decades [10–13]. To date, some Fe(III)-selective fluorescent probes have been achieved [14–17], since paramagnetic Fe(III) is described as one of the most efficient fluorescence quenchers among the transition metal ions, the signal transduction occurrence via chelation enhanced fluorescence (CHEF) with these inherent quenching metal ions is a challenging task. The rhodamine framework is an ideal mode to construct CHEF OFF–ON fluorescent probes due to its particular structural property, i.e. it undergoes equilibrium between non-fluorescent spirocyclic ("off" signal) and strongly fluorescent ring-open ("on" signal) forms and the two forms always behave with completely different fluorescent properties [18]. Heretofore, some studies on rhodamine-based probes have been reported [13,19–24]. We synthesized a rhodamine-based probe (RC) able to recognize and determine Fe(III) at biological pH value in aqueous solution, depending on a fluorescence "off–on" mode.

Furthermore, the real samples contain lots of impurities, which influence the determination. Hence, an appropriate sample pretreatment method is necessary before the determination. Solid-phase extraction (SPE) techniques have recently been among the most popular separation methods for the enrichment of metal ions prior to their determination. The basic principle of SPE is the concentration and purification of analytes from solution by sorption on a solid sorbent [25]. This has several advantages over other techniques, namely conservation of species, good enrichment factors, and ease of automation [25,26]. Accordingly, the choice of the solid sorbent is the most crucial factor. According to previous research, activated carbon-bound ethylenediamin (AC-EDA) showed an excellent adsorption capacity toward Fe(III). And, the application of AC-EDA for the separation, preconcentration and

doi:10.1016/j.talanta.2009.11.013

elution of trace Fe(III) from real samples was performed with satisfactory results [27].

In this study, firstly, we applied AC-EDA to pretreat aqueous samples for the purification and Fe(III) enrichment. Secondly, based on the high selective response to Fe(III) of the fluorescent probe RC, a fluorescence method was establish to determine Fe(III) in aqueous solution with satisfactory result.

2. Experimental

2.1. Apparatus

Fluorescence spectra measurements were performed on an F-4500 spectrofluorimeter (Hitachi, Japan). The absorption spectra were observed by a UV-Cary100 spectrophotometer (Varian, Australia). Infrared spectra (4000–400 cm^{-1}) in KBr were recorded on a Nicolet NEXUS 670 FT-IR spectrometer, Nicolet (Madison, WI, USA). A VarioEL element analyzer (Elementar Analysensysteme, Hanau, Germany) was used for elemental analysis. An YL-110 peristaltic pump (General Research Institute for Non-ferrous Metals, Beijing, China) was used in the column process. A PTFE (polytetrafluoroethylene) column (50 mm × 9.0 mm i.d., Tianjin Jinteng Instrument Factory, Tianjin, China) was used. A pH-10C digital pH meter was utilized to measure the pH values of aqueous solutions. ^1H and ^{13}C NMR spectra were taken on a Varian mercury-300 spectrometer with TMS as an internal standard and $CDCl_3$ as solvent. HRMS were determined on a Bruker Daltonics APEXII 47e FT-ICR spectrometer.

2.2. Reagents and chemicals

All reagents were of analytical grade or the best grade commercially available, and were put into use without further purification. Activated carbon (AC, gas chromatographic grade, 40–60 mesh) (Tianjin Guangfu Fine Chemical Research Institute, Tianjin, China), ethylenediamine (EDA) (Dong Feng Biochemical Reagent Factory, Shanghai, China), Rhodamine 6G (Shanghai Chemical Reagent Company, Shanghai, China), diethylenetriamine (Tianjin The Second Reagent Factory, Tianjin, China), and *N*,*N*′-dicyclohexylcarbodiimide (DCC) (Sinopharm Chemical Reagent Co. Ltds., Shanghai, China) were used in this work. The solutions of metal ions were prepared from their nitrate salts (The First Reagent Factory, Shanghai, China). HEPES buffer solutions (0.2 mol L^{-1}, pH = 7.2) were prepared in water. Deionized water was used as solvents throughout.

2.3. Synthesis procedure

Activated carbon powder was first purified with 10% (v/v) hydrochloric acid solution for 24 h so as to remove the metal ions and other impurities sorbed on it. Then 10 g of purified activated carbon was suspended in 300 mL of 32.5% (v/v) nitric acid solution under stirring and heating for 5 h at 60 °C. The mixture was filtered and washed with deionized water to neutral and dried under vacuum at 80 °C for 8 h. The product was carboxylic derivative of activated carbon (AC-COOH).

For the synthesis of activated carbon-bound ethylenediamin (AC-EDA), a 5.0 g amount of AC-COOH was suspended in 150 mL of ethylenediamine under stirring and heating, then 5.0 g of *N*,*N*′-dicyclohexylcarbodiimide (DCC) was added into the suspension and refluxed at 120 °C for 48 h [28]. The product (AC-EDA) was filtered off, washed with ethanol and dried under vacuum at 80 °C for 8 h. The synthetic pathways of AC-EDA is illustrated in Fig. 1.

The modified activated carbon was confirmed by IR analysis. Comparison of the IR spectrum of AC-COOH with activated carbon, a new bang (1710.17 cm^{-1}) appeared in AC-COOH due to $\nu_{C=O}$ of the carboxylic acid group, which indicated the carboxylic derivative of activated carbon was prepared successfully. When AC-COOH was modified by EDA, several new peaks appeared in the spectrum. According to the literature [29,30], the new peaks can be assigned as follows: the peak at 1658.17 cm^{-1} is due to $\nu_{C=O}$, the peak at 1528.56 cm^{-1} is caused by ν_{C-N} and δ_{N-H}. The bands around 3379.73 cm^{-1} can be assigned to ν_{N-H}. Elemental analysis indicated 59.10% carbon, 7.818% nitrogen and 2.904% hydrogen in AC-EDA. It could be calculated that 1 g activated carbon contained 0.154 g EDA. Consequently, the above experimental results suggest that activated carbon is successfully modified by ethylenediamine.

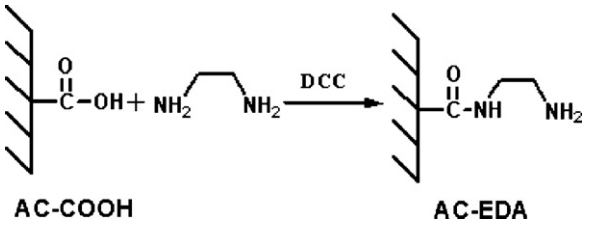

Fig. 1. synthetic pathways of AC-EDA.

The compound (RC) was prepared according to a minor modification of the literature procedure [21]. Rhodamine 6G (958 mg, 2 mmol) was dissolved in 20 mL of hot methanol, followed by the addition of diethylenetriamine (0.67 mL, 10 mmol). The reaction mixture was refluxed for 10 h till the fluorescence of the solution was disappeared. After cooling to the room temperature, the solvent was evaporated *in vacuo*. CH_2Cl_2 (100 mL) and water (200 mL) were added, and the organic layer was separated, washed twice with water and dried over anhydrous sodium sulfate. After filtration of sodium sulfate, the solvent was removed under reduced pressure. Then the resulting pink solid was purified by column chromatography (CH_2Cl_2:CH_3OH = 5:1, v/v) to give 148 mg of RC (pink solid) in 14.8% yield. ^1H NMR (300 MHz, $CDCl_3$): δ 7.90 (t, 1H), 7.43 (t, 2H), 7.01 (t, 1H), 6.32 (s, 2H), 6.22 (s, 2H), 3.52 (t, 2H), 3.20 (t, 4H), 2.54 (t, 2H), 2.31 (m, 4H), 1.85 (s, 6H), 1.36 (t, 6H) ppm; ^{13}C NMR (75 MHz, $CDCl_3$) δ 168.2, 153.3, 151.4, 147.1, 132.1, 130.7, 127.9, 127.7, 123.4, 122.3, 117.4, 105.6, 96.1, 64.7, 51.3, 47.3, 41.3, 39.9, 38.0, 16.4, 14.3 ppm; HRMS (ESI) *m*/*z* obsd 500.3025 ($[M+H]^+$ calcd 500.3020 for $C_{30}H_{37}N_5O_2$).

2.4. Sample pretreatment procedure

A total of 50 mg adsorbent AC-EDA was packed in the PTFE column (50 mm × 9.0 mm i.d.) plugged with a small portion of glass wool at both ends. Before use, HCl (0.5 mol L^{-1}) solution and doubly distilled deionized water were successively passed through the microcolumn in order to equilibrate, clean and neutralize it. Portions of aqueous standard or sample solutions containing metal ions were prepared. Each solution was passed through the column at a flow rate of 4.0 mL min^{-1} controlled by a peristaltic pump. Afterwards, the metal ions retained on column were eluted with a 3 mL of 0.5 mol L^{-1} HCl solution. The elution was collected for the fluorescence determination procedure.

2.5. Fluorescence determination procedure

The elution was adjust to pH 7.0 by NaOH solution and transferred into a 20.0 mL colorimetric tube. The solutions were added in the following order: 2.0 mL 0.2 mol L^{-1} HEPES buffer solutions (pH 7.2), 2.0 mL 1.0×10^{-4} mol L^{-1} RC solution. The mixture was diluted to 20.0 mL with water, and was allowed to stand for 5 min at 25 °C before a fluorescence measurement was made. The intensity of the fluorescence was measured at 552 nm (λ_{ex} = 500 nm) in a 1 cm quartz cell with a slit width of 5 nm for both excitation and emission.

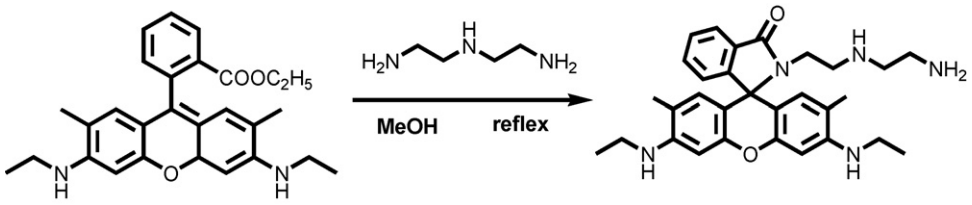

Fig. 2. Synthetic pathways of RC.

3. Results and discussion

3.1. Optical characteristics of the probe RC

As depicted in Fig. 2, compounds RC was facilely synthesized from the reaction of rhodamine 6G with triethylenetetriamine. Although RC is a derivative of rhodamine 6G, it form nearly colorless solutions in HEPES aqueous buffer solution (pH = 7.2), indicating that the spirocyclic forms exist predominantly. The characteristic peak near 64.7 ppm (9-carbon) in the ^{13}C NMR spectra of RC also supports this consideration [31].

When no metal ion was added to the solution of RC, almost no fluorescence signal in the range from 520 to 600 nm could be observed at pH 7.2 in water (Fig. 3 bottom line), whereas a significant enhancement of the characteristic fluorescence of rhodamine 6G emerged soon after Fe(III) was injected into the HEPES solution of RC. Besides, the fluorescence intensity at 552 nm enhanced as the Fe(III) concentration increased. Furthermore, the enhanced extents were in good proportion to the Fe(III) concentrations in a certain range, and other physiologically important cations, even if their concentrations were 50 times higher than that of Fe(III), and only Fe(III) ion can effectively enhance the fluorescence of RC. It was interesting that the enhanced extents of the fluorescence were in good proportion to the concentrations of Fe(III), indicating that an assay of Fe(III) in this way to be good practice. And, the distinct discrimination between Fe (III) and other ion made it possible for the RC to be used for the analysis of Fe (III) in the presence of other ions in aqueous system.

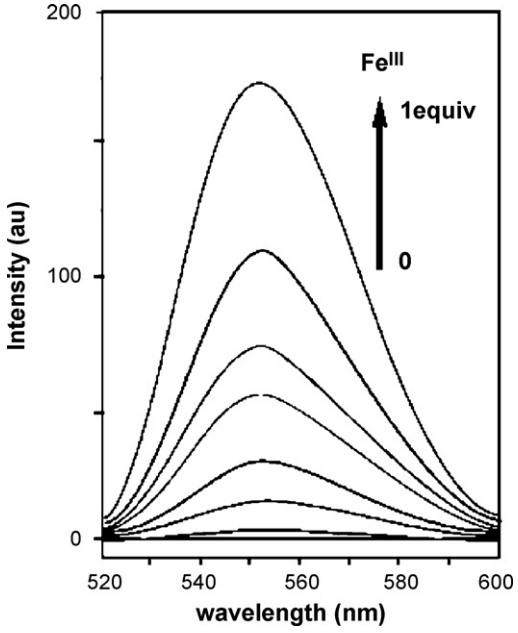

Fig. 3. Fluorescence spectra of RC (1.0×10^{-5} mol L^{-1}) with the addition of increasing concentrations of Fe(III) in HEPES buffer solution (pH = 7.2) with an excitation at 500 nm.

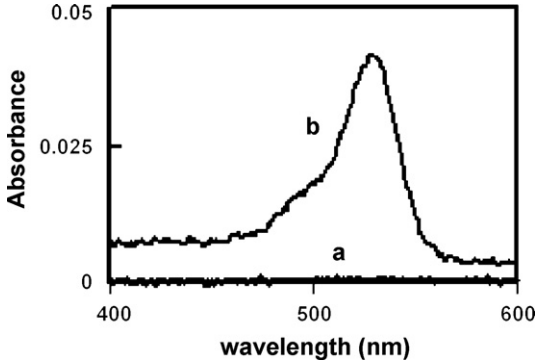

Fig. 4. Absorption spectra of RC (a) and RC with Fe(III) (b) [RC, 1.0×10^{-5} mol L^{-1}; Fe(III), 2.0×10^{-5} mol L^{-1}].

It is showed that RC had no rhodamine framework typical absorbance from 400 to 600 nm (Fig. 4a), which was in the visual range. For that reason, the aqueous solution of RC was colorless. However, with addition of Fe(III) the rhodamine typical absorbance at 527 nm appeared (Fig. 4b), which indicated rhodamine particular structure formed. Meanwhile, the job's plot indicated that a 1:2 stoichiometry for the binding mode of Fe(III) and RC (Fig. 5), and the binding constant was 6.43×10^3 mol^{-1}. It has been reported that many rhodamine derivatives are colorless and non-fluorescent substances due to their stable 'spirolactam form' [13,19,20]. In our study, RC is also colorless and non-fluorescent in aqueous solution for the same reason. If the 'spirolactam form' is opened, the fluorescence could be recovered due to substantially different spectral characteristics of spirocyclic and ring-open forms of rhodamine framework. The fluorescence spectra of RC in aqueous solution in the absence and presence of Fe(III) are shown in Fig. 3. It can be seen that RC displays almost no obvious spectral characteristics in either its absorbance or emission spectrum from 400 to 600 nm. However, a significant enhancement of fluorescence with an absorbance maximum at 527 nm and an emission maximum at 552 nm was observed when Fe(III) was added. We speculated that the spiro-

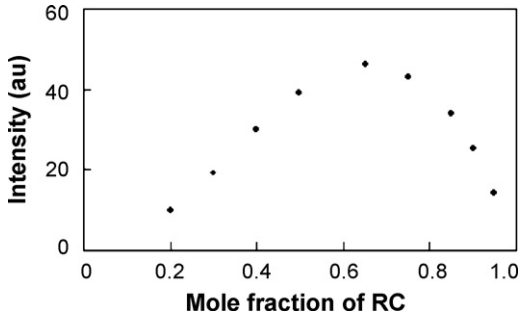

Fig. 5. Job's plot according to the method for continuous variations, indicating the 1:2 stoichiometry (Fe(III)/RC) [the total concentration of RC and Fe(III) is 2.0×10^{-5} mol L^{-1}].

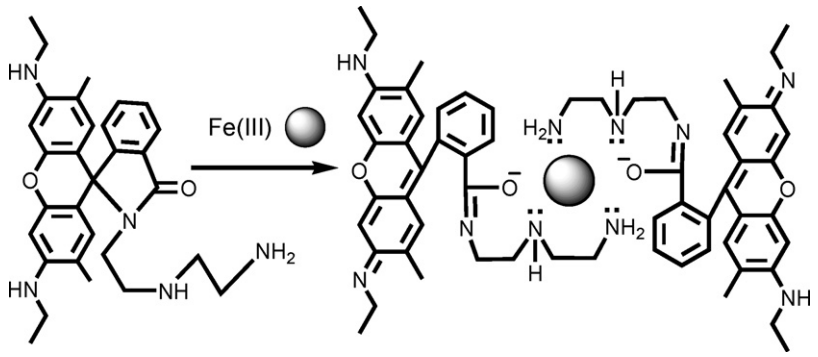

Fig. 6. Mechanism for the fluorescence enhancement of RC upon the addition of Fe(III).

lactam form was opened upon the addition of Fe(III) to RC, and a highly delocalized π-conjugated structure of RC was formed (Fig. 6) [13,19]. Thus, a significant enhancement of absorbance and fluorescence occurred. With this special coordinate mode, Fe(III) was able to enhance the fluorescence of RC, though the other ions failed, indicating the coordinate moiety of RC match perfect with Fe(III) instead of other ions.

3.2. Optimization of the analytical procedures

3.2.1. Effect of RC concentration

The concentration of RC influenced the Fe(III) determination. If the concentration of RC was too high, the sensitivity for the detection of Fe(III) would be decreased. On the contrary, the linear range would become narrow if the concentration was too low. For a balance between the sensitivity and the linear range, the optimum concentration of RC for the Fe(III) determination was 1.0×10^{-5} mol L^{-1}.

3.2.2. Effect of the pH

The effect of pH on the fluorescence intensity of RC in the system is shown in Fig. 7. It can be seen that the fluorescence kept constant tiny intensity between pH 5.5 and 8.5 in water. However, the fluorescence intensity increased sharply when pH value below 5.0 and became even more acidic. Finally, a physiological pH value 7.2 was chosen for the fluorescence intensity determination.

3.2.3. Effect of temperature

Under a temperature series, the fluorescence intensity of RC almost kept constant. For that reason, we could know that this system possessed stability to temperature for Fe(III) determination in aqueous solution. But considering the convenience and maneuverability, all the fluorescence measurements were conducted under 25 °C.

3.2.4. Effect of time

Under the optimum conditions, the effect of time on the Fe(III) determination was studied at room temperature. The fluorescence intensity changed soon after Fe(III) added into RC aqueous solution and remained stable from 1 min to 10 h. After all reagents had been added they were left standing for 5 min ahead of a measurement. In this study, 5 min was set as the standard for all fluorescence intensity measurements.

3.3. Tolerance of foreign substances

The effect of substances, including common metal ions was examined for interference. The results are summarized in Fig. 8 and Table 1. It is showed in Fig. 8 that other ions but Fe(III) failed to arouse fluorescence response of RC system. And, Table 1 shows that the influence of metal ions in biological systems, such as K^+, Ca^{2+}, Na^+, and Zn^{2+} though with much higher concentration compared with Fe(III), was tiny to the RC-Fe system. Consequently, it is clear that other ions' interference is slight to this system.

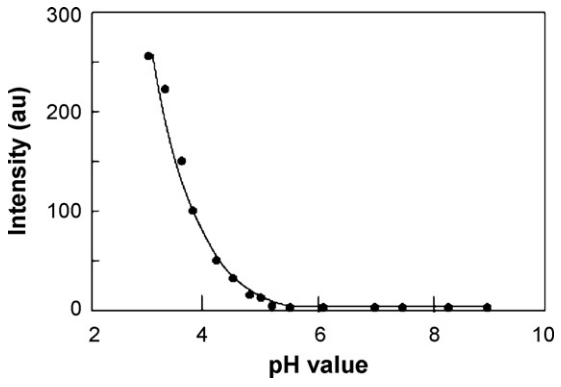

Fig. 7. Evaluation of the fluorescence intensity (at 552 nm) of RC (1.0×10^{-5} mol L^{-1}) under different pH values with an excitation at 500 nm.

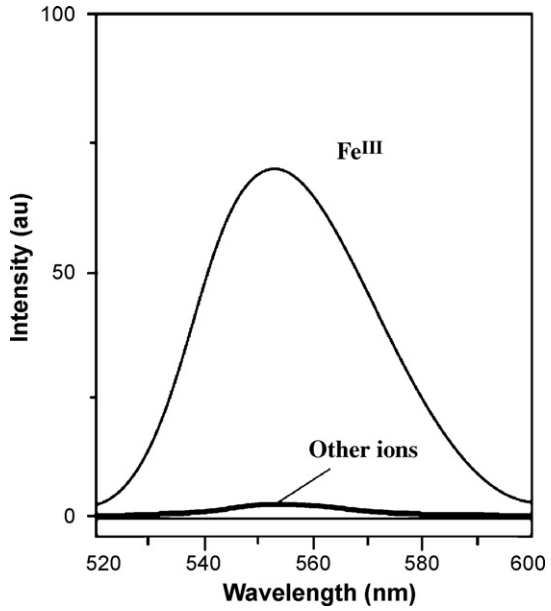

Fig. 8. Fluorescence spectra response of RC (1.0×10^{-5} mol L^{-1}) under the optimum conditions with different ions (4.0×10^{-6} mol L^{-1}) with an excitation at 500 nm. Other ions including K(I), Ca(II), Na(I), Mg(II), Zn(II), Pb(II), Co(II), Ba(II), Cu(II), Al(III), Cd(II), and Ni(II).

Table 1
Interference of potentially interfering ions.

Co-existing substance	Co-existing concentration ($\times 10^{-6}$ mol L^{-1})	Change in intensity of fluorescence (%)
K(I)	100	−1.95
Ca(II)	100	4.31
Na(I)	100	−0.40
Mg(II)	100	1.78
Zn(II)	100	−2.41
Pb(II)	100	−4.15
Co(II)	100	2.47
Ba(II)	100	−3.30
Cu(II)	50	3.63
Al(III)	50	4.32
Cd(II)	50	−2.1
Ni(II)	50	3.37
Fe(II)	50	4.83

Note: Determination conducted under the optimum conditions, samples contain 1.0×10^{-6} mol L^{-1} Fe(III) and other ions.

Table 2
Analytical parameters for the determination of Fe(III).

Sample	Linear range ($\times 10^{-8}$ mol L^{-1})	Linear regression equation (c, ng mL^{-1})	Detection limit (3σ, mol L^{-1})	Correlation coefficient
Fe(III)	6.0–720	$\Delta F = 1.67 \times 10^7 c + 3.25$	1.4×10^{-8}	0.998

Table 3
Results of the sample analysis.

[b] Standard Fe(III) solution addition.
[c] Detected by the method of this paper.
[d] The result found by the method of this paper.

3.4. Analytical characteristics

Under the optimum conditions, the relationship between ΔF [the fluorescence intensity enhancement of RC upon the addition of varying concentrations of Fe(III)] and the concentration of Fe(III) was obtained. The analytical parameters are given in Table 2, which demonstrates a linear relationship between ΔF and the concentrations of Fe(III) over a wide range, and the limit of detection reaching the 1.4×10^{-8} mol L^{-1}.

3.5. Analytical applications

The present method was applied to determine real samples, tap water and industrial waster water (the samples were supplied by gansu center for disease prevention and control). Table 3 shows the analysis results which were very close to those detected by ICP-AES method, which were 78.5×10^{-8} and 189.3×10^{-8} mol L^{-1} in the determination of samples, respectively (the result was supplied by Analytical Chemistry Institute of Lanzhou University). Therefore, the present method could be applied for the analysis of Fe(III) in aqueous system.

4. Conclusions

In conclusion, we have developed a novel fluorescent probe RC for Fe(III) based on the enhancement of fluorescence intensity of RC after adding Fe(III). Under the optimum conditions, the relative fluorescence intensity increase was linearly proportional to the concentration of Fe(III) in a wide range, and the limit of detection was 14 nmol L^{-1}. The probe RC had remarkably high selectivity and sensitivity. Moreover, the analytical results of real samples were satisfactory. Fluorescence enhance mechanism is presumably due to the chelation of Fe(III) with the oxygen atoms of the amide groups of RC results in the formation of the open-ring form, which leads to the enhancement of fluorescence signals of RC.

Fishery sample

ABSTRACT

The combination of molecular imprinting and solid-phase microextraction (SPME) technique provides a powerful sample preparation tool in terms of selectivity, simplicity, and flexibility. This paper reports a novel molecularly imprinted polymer (MIP) coated SPME fiber with 17β-estradiol as template by improved multiple co-polymerization method. The obtained fiber exhibits excellent characteristics such as high porosity, good thermal and chemical stability. Extraction performance shows that the MIP-coated fiber has stronger affinity to the template molecule as compared with the commercial SPME fibers and the control polymer-coated fiber without addition of template. Owing to the shape and structural compatibility, the obtained fiber also demonstrated specific selectivity to the structural related compounds of 17β-estradiol, such as estriol, estrone and 17α-ethynylestradiol, and thus can be applied to simultaneous determination of these estrogens from complex samples coupled with high performance liquid chromatography. The variables that influence extraction were investigated. The MIP-coated fiber demonstrated its efficiency for extraction of estrogens in fishery samples. The detection limits were in the range of 0.98–2.39 μg L^{-1}, and the recoveries were 80.0–83.6% and 85.0–94.1% for fish and shrimp tissue samples, respectively.

1. Introduction

Estrogens are a group of strong endocrine-disrupting compounds that are of particular interest due to their high estrogenic activities. For example, 17β-estradiol, a natural steroid estrogen, has been shown to cause the feminization of male fish at much lower concentrations (pg mL^{-1}) in aquatic environment [1]. Over the last few decades, there has been a steady increase in estrogen consumption for human medicine and animal farming. The excretion into the environmental water may cause accumulation of the estrogens in fish bodies. In addition, illegal application of estrogens to promote growth rate of fishes or as repartitioning agents in fishery production became a main hazard to human health, because of their potential carcinogenic properties and other adverse effects. Therefore, a selective, accurate and sensitive analytical method for detecting estrogens in fishery samples is important for the investigation of potential use of estrogens in food-safety area.

Several methods for the determination of estrogens have been reported, including immunoassay [2], chemiluminescence [3], gas chromatography–mass spectrometry (GC–MS) [4,5], liquid chromatography (LC) with ultraviolet detection (UV) [6], fluorescence detection (FD) [7], and mass spectrometry (MS) [8–10]. Each method has its advantages and limitations in terms of sensitivity, selectivity and convenience of operation. Among these, chromatographic methods are the most widely used. However, their sensitivity and selectivity limit their direct use for determination of these contaminants at trace concentration with complex matrix. Therefore, a sample preparation step prior to chromatographic analysis is usually necessary.

Such sample preparation procedures as liquid–liquid extraction (LLE) [11] and solid-phase extraction (SPE) [12,13] have been usually applied for the determination of estrogens. However, these methods require large volumes of organic solvents or time-consuming operation. Recently, newly developed sample pretreatment method, including cloud point extraction [14], stir bar sorptive extraction (SBSE) [15,16], membrane extraction [17] and solid-phase microextraction (SPME) [18,19] have been reported for monitoring estrogens either in pharmaceutical formulation, in environment matrices or in biologic samples. Among these methods, SPME is advantageous due to its convenience, less consumption of solvent and easiness to couple with chromatographic instruments [20]. For the polar characteristics of the estrogenic compounds, recent developed novel SPME coatings for determination of estrogens were focused on the preparation of polar coatings

doi:10.1016/j.talanta.2009.11.015

to improve the extraction capability, including both in-tube and fiber coatings [21,22]. However, those SPME coatings were mostly applied to environmental water samples which have relatively simple matrices. For analysis of those complex samples, such as biological samples, SPME coatings with higher selectivity are expected to develop in order to enrich the target molecules from these complex matrices.

Molecularly imprinted polymers (MIPs) are highly cross-linked and organized polymer aiming to mimic biological recognition. Removal of the template yields imprinted cavity capable of recognizing template molecule under appropriate conditions. The most common form of MIPs' application in sample pretreatment is solid-phase extraction (SPE) [23–25]. Recently, MIP was combined with simplicity and flexibility of SPME to develop novel recognition coatings in our and other laboratory, including using clenbuterol [26], prometryn [27,28], propazine [29], propranolol [30], diacetylmorphine [31], tetracycline [32] and propranolol [33] as template, respectively. The resulting MIP-SPME fiber showed specific selectivity towards the template molecules and their structural analogues in complex sample matrices such as food, soil and biological fluids. The preparation approaches were based on multiple co-polymerization method with repeated coating procedure on a silica fiber [26–28,32,33] or direct synthesis of MIP monoliths using silica capillaries as molds [29,31].

In this study, a novel MIP-coated SPME fiber with 17β-estradiol as template for selective extraction of estrogenic compounds in fishery samples was prepared by improved multiple co-polymerization method. Its characteristics, extraction capability and selectivity were investigated as compared with the commercial fiber and the non-imprinted polymer (NIP) coated SPME fiber. The MIP-coated SPME fiber has been coupled directly with HPLC for simultaneously multi-residue monitoring of four residual estrogens in fish and shrimp tissue samples.

2. Experimental

2.1. Instrumentation

A magnetic stirrer was obtained from Supelco (Bellefonte, PA, USA) for SPME procedure. A SPME–HPLC coupling device (Supelco, Bellefonte, PA, USA) was used for desorption. A XL-30 scanning electron microanalyzer (Philips, Eindhoven, The Netherlands) was employed to investigate the coating surface. A thermal gravity (TG) analyzer (Netzsch TG-209, Bavaria, Germany) was used to investigate the thermal stability of the coating.

The HPLC system assembled from Shimadzu LC-20A (Shimadzu, Japan) consists of a model LC 20AB pump and a model SPD-20A UV detector. A LC-solution workstation (Shimadzu, Japan) was utilized to control the system and also for data analysis.

2.2. Chemicals

Estrone, 17β-estradiol, estriol and 17α-ethynylestradiol with the purity >99% were purchased from Zizhu Tiangong Tech. (Beijing, China). Methacrylic acid (MAA), 4-vinylpyridine (4-VP) and azo(bis)-isobutyronitrile (AIBN) were obtained from Damao Reagent Plant (Tianjin, China). Trimethylolpropane trimethacrylate (TRIM) were purchased from Shenda Chemical Plant (Beijing, China). Acetonitrile and methanol of HPLC grade were purchased from Merck (Darmstadt, Germany). Water was doubly distilled. All other reagents were of analytical grade. All solutions used for HPLC were filtered through a nylon 0.45 μm filter before use. Fibers were kindly provided by FiberHome Telecommunication Technologies (Wuhan, China).

2.3. Preparation of molecularly imprinted polymer-coated silica fiber

The 17β-estradiol molecularly imprinted polymer-coated silica fiber was prepared by a modified procedure of our previous work [27,32]. Firstly, the silica fibers with diameter of 140 μm were etched with sodium hydroxide and then activated with hydrochloric acid. Prior to the coating procedure, the fibers were silylated for 1 h by immersing them into a 10% (v/v) 3-(methacryloxy) propyltrimethoxysilane solution in acetone at room temperature. Then the fibers were washed with methanol and dried with a stream of nitrogen. Pre-polymer solution for molecularly imprinted polymer (MIP) was prepared with 136.2 mg of 17β-estradiol and 0.34 mL MAA dissolved in 15.5 mL acetonitrile. This solution was incubated for 12 h at room temperature, and then 1.6 mL TRIM and 81.2 mg AIBN were added. Subsequently 1.5 mL of the mixture was transferred into a small glass tube and deoxygenized with a stream of nitrogen for 5 min. The silylated fiber was inserted in the tube and the whole reaction system was sealed immediately to perform the polymerization at 65 °C. When the polymerization solutions were transferred to semi-solid state about 2 h, the fiber was cautiously pulled out with a thin layer of MIP coating on the surface. The coating procedure was repeated for eight times. Subsequently the fiber was kept in nitrogen environment and heated at 150 °C for 3 h. In order to remove the template molecules, the fibers were soaked in 5 mL of 10% (v/v) acetic acid solution in methanol for 30 min. This procedure was performed repetitiously until 17β-estradiol could not be detected in the soaking solution. The NIP-coated silica fiber was prepared following the same procedure except for the addition of 17β-estradiol. The obtained coatings were kept for 1 cm long by scraping the unwanted coatings from the top. Then the uncoated end of fiber was adhered into the inner tube of the commercially SPME setup.

2.4. SPME procedure

In a typical assay, 4-mL estrogens standard solution in n-hexane was added into a 5-mL glass vial. An MIP-coated fiber was immersed into the solution to extract analytes for 40 min at stirring rate of 750 rpm. The six-way valve of the SPME–HPLC coupling device was switched to the LOAD position, and methanol, as the desorption solvent, was injected into the desorption chamber by syringe. The SPME fiber was then inserted into the chamber to desorb the analytes for 15 min. Subsequently, the six-way valve was switched to the INJECT position, all desorption solution was injected into the chromatographic system for analysis.

The commercial SPME fiber used for comparison study consists of the polydimethylsiloxane (PDMS), polydimethylsiloxane–divinylbenzene (PDMS/DVB) and Carbowax–Templated Resin (CW/TPR) fiber which were obtained from Supelco (Supelco, Bellefonte, PA, USA). The extraction was performed in 20 $\mu g\,L^{-1}$ of 17β-estradiol aqueous solution for 40 min at stirring rate of 750 rpm, and then desorbed by methanol for 15 min. The extraction ability of the NIP-coated fiber was compared with that of the MIP-coated fiber at the same extraction conditions.

2.5. Chromatographic conditions

A Diamonsil C18 (250 mm × 4.6 mm, 5 μm particle size, Dikma) column was used. The mobile phase consisted of acetonitrile and 0.12% acetate buffer. The acetonitrile composition was set at 25.5% initially and increased linearly from 15 min to 30 min till 45%. The mobile phase flow-rate through the column was 1.0 $mL\,min^{-1}$ at room temperature. UV wavelength was set at 225 nm. The injection volume was 20 μL.

2.6. Calibration and sample preparation

Calibration was made by the standard curve method. Stock solutions of estrogens were prepared at concentration of 1000 mg mL^{-1} in methanol. Diluting the stock solution serially with methanol yielded standard solutions. All solutions were sealed and refrigerated at 4 °C until use. Extraction of estrogens was performed by diluting standard solution with n-hexane to give the corresponding solution for calibrations, limits of detection (LODs) and linearity tests.

The fish and shrimp tissue samples were stored at −18 °C before analysis. The tissue samples were chopped and triturated in a blender. A portion of 5 g sample was mixed and homogenized with 100 μg L^{-1} estrogen standard solutions to obtain the spiked samples at the concentration of 0.010 μg g^{-1} of 17β-estradiol, estriol, and 0.020 μg g^{-1} of estrone, 17α-ethynylestradiol, respectively. Then 10 mL of acetonitrile was added in the samples, and the mixture was ultrasonicated for 30 min at room temperature. Then the sample was centrifuged at 3600 rpm for 15 min, and 4 mL of the supernatant was subjected to MIP-SPME procedure and HPLC analysis.

3. Results and discussions

3.1. Preparation and characterization of the MIP-coated fibers

The 17β-estradiol imprinted fiber coating was prepared by the multiple co-polymerization method according to our previous work [27,32] but with some modification. Usually, the silica fiber should be coated for several times to obtain the wanted film thickness. In our previous work, for the purpose of achieving higher cross-linked degree, the fiber was placed in tubes filled with N_2 and heated at 60 °C for 24 h after each coating procedure. In this work, the heating procedure between each coating was eliminated to reduce the preparation time. That is, the fiber was coated continuously for eight times. However, an additional heating step after accomplishment of the final coating under nitrogen at an elevated temperature at 150 °C for 3 h is essential to make the coating more robust. Therefore, the whole coating procedure for preparing a batch of fibers was accomplished within only 24 h. By comparison of the coating thickness, homogeneity and stability of the fiber prepared by two different coating methods, it was found that there was no obvious variation, but the preparation time was significantly reduced. Due to the multiple component structure of MIPs, any change in the nature and ratio of composition may change the mechanical and chemical characteristics of prepared fiber. Therefore, the optimization of experimental parameters such as functional monomer, polymerization solvent, time and temperature is indispensable. In view of the solubility for estrogens, acetone, chloroform, acetonitrile and toluene was selected as the possible polymerization solvent. A homogeneous surface was observed for MIP coating in each of these four solvents. Nevertheless, the thickest MIP film of 2.8 μm was obtained on naked fiber for a single coating procedure when acetonitrile was used as the polymerization solvent, and there was a good linearity between coating times and thickness of MIP coating. MAA and 4-VP were used for monomer optimization, and the coating with MAA as monomer had better homogeneity and morphological structure. TRIM, the most frequently used cross-linkers in the MIP preparation, were investigated with serial molar ratio of template: monomer: cross-linker from 1:8:10 to 1:8:40. The polymer became more and more dense and solid with the increase of cross-linker, which would make pulling out of fiber difficult. Finally, the molar ratio of 1:8:16 was selected owing to the best morphological coating with the large thickness of 3.2 μm obtained for a single coating. Under the optimized condition, the polymerization time was 2 h at 65 °C to obtain a semi-solid state of the polymer, and was shorter as compared to our previous study [32].

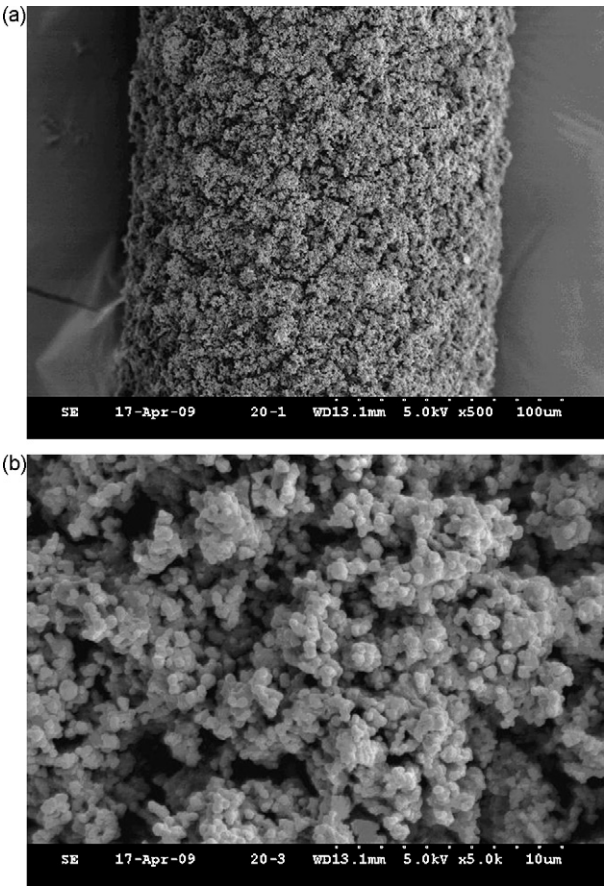

Fig. 1. The scanning electron micrographs images of the MIP-coated fiber under the magnifications of 500 (a) and 5000 (b).

The morphology and thickness of the coating was investigated by scanning electron micrograph after eight repeated polymerization, as illustrated in Fig. 1. The total diameter of the MIP-coated fiber is 160 μm from Fig. 1(a), therefore the absolute thickness of the MIP coating can be calculated by subtracting the diameter of the naked silica fiber, and is 20 μm. The relative standard deviation (RSD) for the thickness of a batch of different coatings is 6.5% (n = 7). Fig. 1(b) exhibits the morphological structure of the coating under the magnification of 5000. It can be seen that the MIP coating is composed of small and interconnected globules that form a porous structure. The morphology is benefit for increase of specific surface area, resulting in sufficient adsorption of solutes. The thermogravimetric analysis proved that the coating was stable within the temperature of 400 °C, and the solvent-resistance study showed a high chemical stability of the coating when immersed in conventional solvents, such as n-hexane, chloroform, toluene, methylene dichloride and acetonitrile.

3.2. Extraction ability

The extraction ability of the MIP-coated fiber was evaluated by comparison with that of the commercially available SPME fiber including PDMS, PDMS/DVB and CW/TPR fiber. Fig. 2 shows the extraction amounts of 17β-estradiol by the MIP fiber and three commercial SPME fibers at the initial concentration of 20.0 μg L^{-1}. The extraction procedure of the commercial SPME fiber was performed in aqueous solution owing to their distinct extraction mechanism from the MIP extraction procedure. The results reveal

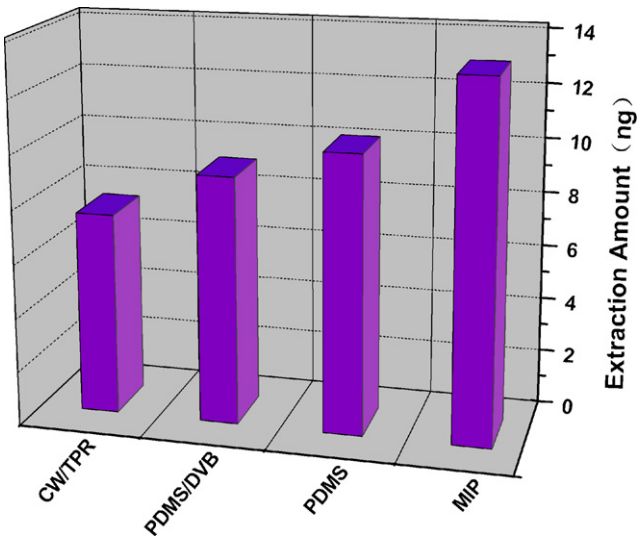

Fig. 2. The concentration of 17β-estradiol extracted on the prepared MIP-coated fiber with the initial concentration of 20 μg L^{-1} in n-hexane, and on the commercial PDMS, PDMS/DVB and CW/TPR fiber with the initial concentration of 20 μg L^{-1} in aqueous solution.

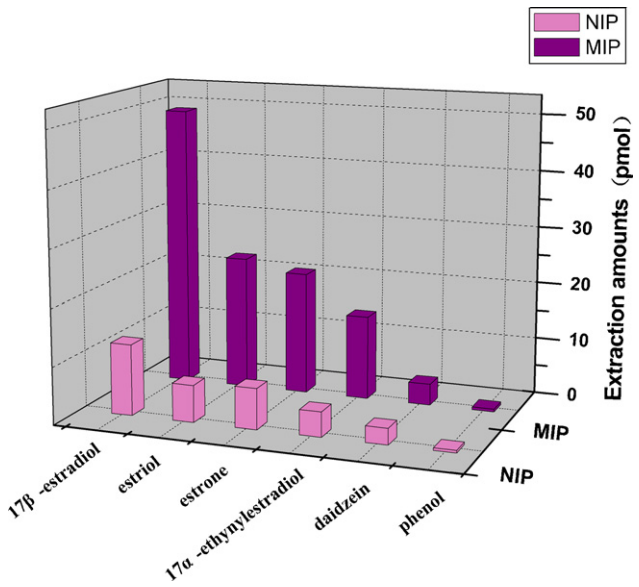

Fig. 4. Selectivity investigation of the MIP-coated fiber. SPME was performed in 4 mL of n-hexane standard solution containing 10 μg L^{-1} estrogens at room temperature for 40 min with desorption time of 15 min.

that the MIP-coated fiber possesses higher extraction ability than the three commercial SPME fiber investigated. It should be noted that the thickness of the MIP coating is much thinner as compared with that of the commercial fibers (100 μm for PDMS, 60 μm for PDMS/DVB, 50 μm for CW/TPR). Therefore, the extraction ability is even higher if the amounts of 17β-estradiol per extractant volume are considered. This high extraction ability is mainly owing to the specific adsorption of MIP to the template molecule and the hydrogen bonding interactions between the carboxylic groups in the MIP coating and hydroxyl groups in 17β-estradiol at corresponding positions.

The extraction ability of the MIP-coated fiber was further investigated by comparison with that of the NIP-coated fiber prepared in the same procedure except for the addition of the template molecule. Fig. 3 shows the binding amounts of the 17β-estradiol on the MIP- and NIP-coated fibers at different initial concentration of the template. It is clear that both the fibers show an increase in binding amounts as the initial concentration increases. However, the MIP-coated fiber generally binds more of the added 17β-estradiol

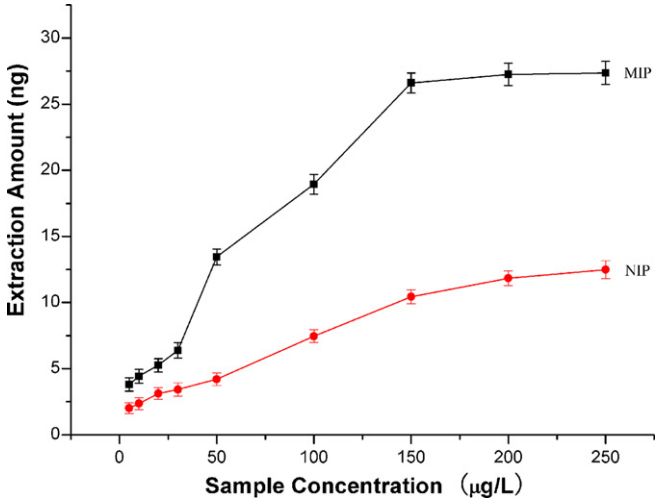

Fig. 3. The binding isotherms of 17β-estradiol on the MIP- and NIP-coated fibers. SPME was performed in 4 mL of n-hexane standard solution containing different concentration of 17β-estradiol at room temperature for 40 min.

than the corresponding NIP-coated fiber. This data is indicative of a true molecular imprinting effect being observed with the MIP-coated fiber.

3.3. Cross-selectivity

Successful imprinting cannot solely be evaluated on the ability of the MIP to rebind the template but also on its discrimination between analogue molecules. The selectivity test results among different compounds may also show some aspects of molecular recognition mechanisms. Therefore, the ability of the MIP-coated fiber to discriminate between other structural-related steroid compounds and reference compounds was investigated. The NIP-coated fiber was used for comparison. Fig. 4 shows the extraction amounts of 17β-estradiol, estriol, estrone, 17α-ethynylestradiol, daidzein and phenol with the MIP- or NIP-coated fiber. Their molecular structure is illustrated in Fig. 5. The results proved that the prepared MIP-coated fiber exhibited high selectivity for estrogenic compounds with the steroid structure, while other structurally unrelated compounds such as daidzein and phenol were poorly extracted. Moreover, 17β-estradiol exhibited the largest extraction amounts as compared with the other tested estrogens such as estriol, estrone and 17α-ethynylestradiol. However, NIP-coated fiber exhibited similar extraction ability towards these four estrogens. The minor extraction difference is approximately based on

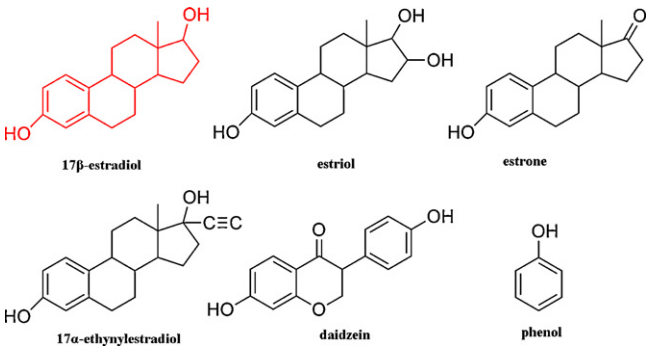

Fig. 5. The molecule structure of the compounds for selectivity investigation.

Table 1
Effect of solvent polarity on the extraction amounts of 17β-estradiol.

Extraction solvents	n-Hexane	Toluene	Methylene dichloride	Chloroform	Acetonitrile
Snyder polarity index [34]	0.06	2.4	3.4	4.4	6.2
Extraction amounts (ng)	19.829	0.992	0.222	0.106	0.085

their hydrophobic nature. For these reasons, it can be concluded that the selectivity of the prepared MIP fiber for estrogens was clearly induced during the imprinting process. This induction recognition ability is particularly noteworthy because the tested estrogenic compounds have only small structural differences. The structure of daidzein is similar to 17β-estradiol but lack of the steroid segment, which results in poor extraction. The obtained results show that the distance and angle of the hydroxyl groups is important for effective recognition of certain molecules with the 17β-estradiol imprinted fiber. On the other hand, the size and shape recognition by the imprinted polymer network possibly accounts for the poor extraction of phenol, which was almost not extracted by the MIP-coated fiber. The above results strongly support the conclusion that the obtained MIP-coated fibers are highly selective, and can be applied to enrichment of trace estrogenic compounds in complex samples.

3.4. Effective variables on the extraction performance

In SPME experiments, the extraction efficiency depends on the different variables such as time of extraction, stirring rate of the solution, the extraction and desorption solvent.

The solvent matrix of extraction usually plays the most important role on the extraction performance of the MIP-coated fiber. Consequently, the effect of solvents was investigated and illustrated in Table 1. Results show that the extraction amounts of 17β-estradiol have close relationship with the polarity of the solvent, increasing the solvent polarity leads to dramatic decrease of the extraction amounts of template. Best extraction capability was obtained with n-hexane as extraction solvent. This happens because n-hexane decreases to a minimum the non-specific hydrophobic interactions and creates the suitable environment for electrostatic interactions, which play a very important role in molecular recognition. The solute desorption is the reversed procedure of extraction, and was conveniently conducted with the commercial SPME–HPLC coupling device. The desorption solvent, in contrary to the extraction solvent, should effectively destroy the hydrogen interaction between the template solutes and the binding sites. Consequently, acetonitrile, methanol and their acetic acid mixtures were selected for investigating the effect of the desorption solvents (Fig. 6). Methanol and its mixture with acetic acids showed relative good desorption ability because these solvents could form hydrogen bonds with the binding sites, and finally methanol was chosen as desorption solvent.

The adsorption and desorption kinetics was investigated with 10.0 μg L^{-1} 17β-estradiol. As shown in Fig. 7, the extraction and desorption reach equilibrium at about 30 min and 10 min, respectively. This short equilibrium time was mainly ascribed to the thin thickness of the MIP coating. Highly porous structure of the MIP coating was another contributing factor, by which diffusion speed for the analytes into or out of the coating could be increased.

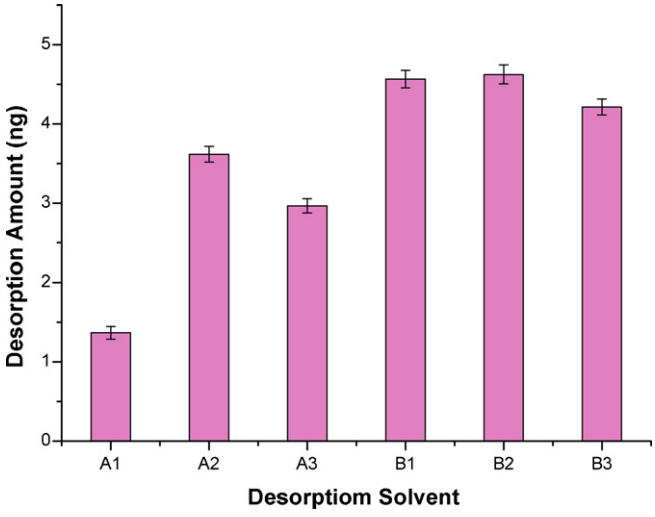

Fig. 6. Variations of 17β-estradiol amounts with the desorption solvents. SPME was performed in 4 mL of n-hexane standard solution containing 10 μg L^{-1} 17β-estradiol at room temperature for 40 min. A1, acetonitrile; A2, acetonitrile:0.12% acetic acid (45:55, v:v); A3, acetonitrile:acetic acid (99:1, v:v); B1, methanol; B2, methanol:0.12% acetic acid (45:55, v:v); B3, methanol:acetic acid (99:1, v:v).

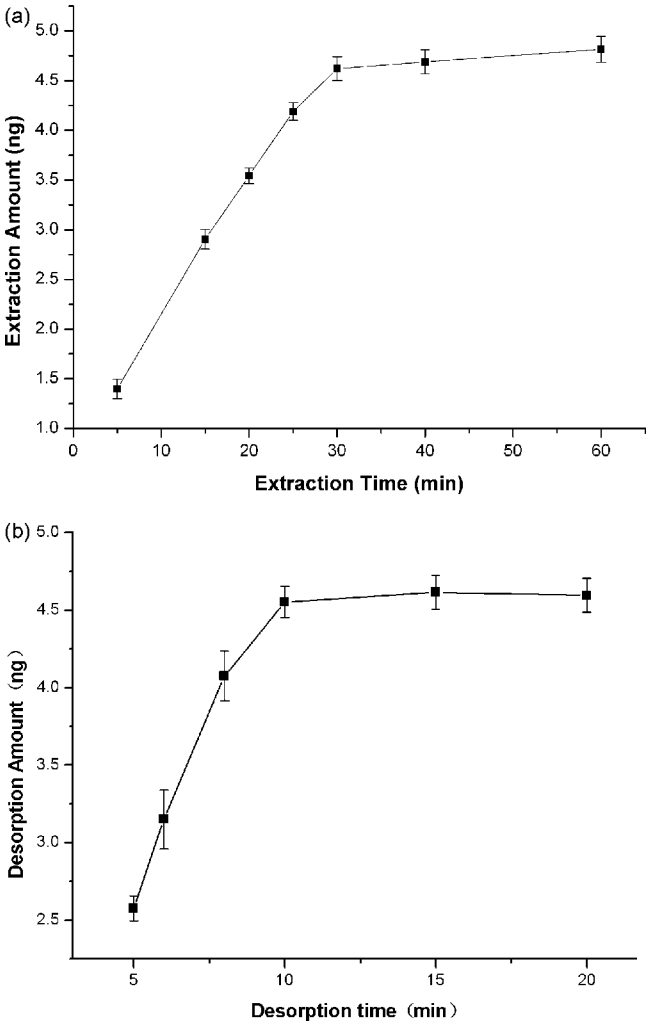

Fig. 7. Adsorption (a) and desorption (b) dynamics of the MIP-coated fiber for 10 μg L^{-1} 17β-estradiol.

Table 2
The linearity, precision and detection limit of the method.

Compounds	Calibration curve			Linear range ($\mu g\,L^{-1}$)	LOD ($\mu g\,L^{-1}$)	RSD[b] (%) ($n=6$)	
	Slope	Intercept	R^2			Intra-day	Inter-day
17β-Estradiol	3.15×10^2	11.6	0.9991	5.0–30.0	0.98	2.2	5.6
Estriol	1.48×10^2	16.9	0.9988	5.0–30.0	1.28	7.6	8.7
17α-Ethynylestradiol	1.40×10^2	15.6	0.9975	15.0–40.0	2.21	6.8	5.8
Estrone	3.27×10^2	39.2	0.9986	15.0–40.0	2.39	7.7	7.6

3.5. Method validation and comparison with other sample preparation techniques

The obtained MIP-coated fiber was coupled with HPLC and UV detection to establish a method for simultaneous determination of 17β-estradiol, estriol, estrone and 17α-ethynylestradiol under the optimized extraction conditions. The MIP-SPME procedure was performed in n-hexane for 40 min and then desorbed by methanol for 15 min. To validate the analytical methodology, the linearity, precision and detection limit of estrogens was investigated (Table 2). The MIP-SPME–HPLC procedure showed linear ranges of 5.0–30.0 $\mu g\,L^{-1}$ for 17β-estradiol and estriol, 15.0–40.0 $\mu g\,L^{-1}$ for estrone and 17α-ethynylestradiol. The square of correlation coefficients was above 0.9975. The linear range of the method is relatively short as compared with analytical methods based on conventional SPME technology. This can be ascribed to the limited interaction sites of the specific imprinted cavity on the MIP coating. For the conventional SPME coating, such as PDMS, the analytes absorb or adsorb on the coating by non-specific interaction, and the larger interaction sites result in a wider linear range. For calculation of the detection limits (LOD), we used three times standard deviations of calibration curves divided by their slopes. The LODs obtained for the studied estrogenic compounds are in the range 0.98–2.39 $\mu g\,L^{-1}$. These values are indicative of good performance of the prepared fiber. The precision of method for six replicate analyses of model solutions is also presented in Table 2 for a solution containing 10 $\mu g\,L^{-1}$ of each compound. The relative standard deviations for the compounds were below 10% for both inter- and intra-day precision study. The precision is acceptable by taking into account the low concentration levels of the analytes.

Some methods including cloud point extraction, stir bar sorptive extraction, SPE, and SPME coupled to HPLC with UV detection, diode array detection and fluorescence detection have been compared with the current method concerning the determination of estrogens, and are summarized in Table 3. The sensitivity of the proposed MIP-SPME–HPLC method was comparable with most of the other analytical methods. However, those sample preparation methods are usually not highly selective, and were applied to the water sample with relative simple matrix. For determination of estrogens in biological samples, interference could not be avoided for the reason of the complex sample matrix. Extraction methods based on MIP are very desirable for its high selectivity. As compared with the reported detection limits for 17β-estradiol with MIP-SPE–HPLC method [24], lower detection limits were obtained in the current study. In addition, the method based on MIP-SPME has the advantages of less solvent consumption, reduced operation procedure, and no requirement to add further purification procedure to remove co-extractant.

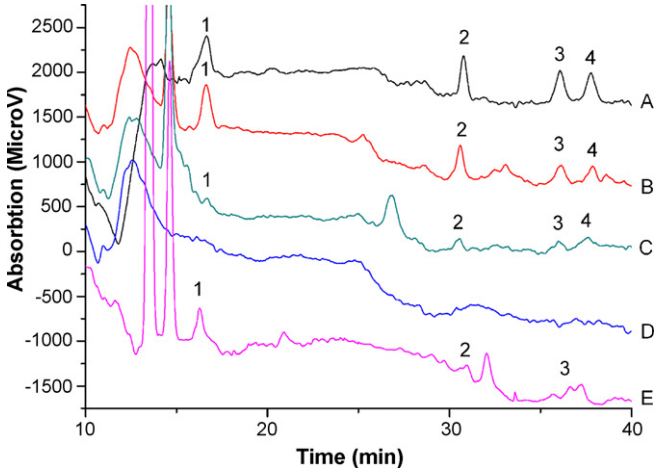

Fig. 8. Chromatograms of fish samples using MIP-SPME–HPLC method. (A) 500 $\mu g\,L^{-1}$ estrogens mixed standard solution; (B) fish samples spiked with 0.010 $\mu g\,g^{-1}$ estriol, 17β-estradiol, 0.020 $\mu g\,g^{-1}$ estrone and 17α-ethynylestradiol extracted by MIP-coated fiber; (C) fish samples spiked with 0.010 $\mu g\,g^{-1}$ estriol, 17β-estradiol, 0.020 $\mu g\,g^{-1}$ estrone and 17α-ethynylestradiol extracted by NIP-coated fiber; (D) blank samples extracted by MIP-coated fiber; (E) acetonitrile extracts of the spiked fish samples. Peaks: 1: estriol, 2: 17β-estradiol, 3: 17α-ethynylestradiol, and 4: estrone.

3.6. Sample analysis

The established MIP-SPME method was applied to analysis of trace amounts of estrogens in spiked fish and shrimp tissue samples. Firstly, acetonitrile which had good ability for precipitating protein, lower solubility of lipids than other solvents and could penetrate biological tissues after homogenization was selected to extract estrogens from fish and prawn samples with ultrasonication. After centrifugation, the supernatant was collected and directly subjected to a MIP-SPME procedure. Fig. 8 showed the chromatogram of the 500 $\mu g\,L^{-1}$ mixed standard estrogen solution (curve A), the blank fish sample by MIP-SPME (curve D), the spiked fish sample extracted by the MIP-SPME protocol (curve B), the NIP-SPME protocol (curve C) and direct injection of acetonitrile extracts (curve E). The results revealed that the chromatogram was complex for the acetonitrile extracts, showing large peaks at approximately 10 min, but was significantly cleaner after the MIP-SPME cleanup

Table 3
Comparison with other sample preparation methods for the determination of estrogens and analyzed by HPLC.

Extraction method	Analytical method	Sample type	LOD (μg/L)	Selective	References
Cloud point extraction	HPLC-UV	Waste water	0.23–5.0	No	[14]
Stir bar sorptive extraction	HPLC-DAD	River and lake water	0.04–0.11	No	[16]
Ultrasonic assisted extraction	HPLC-UV	Topic gel	10.3–19.8	No	[6]
SPME	HPLC-UV	River water	0.3–1.1	No	[35]
MIP-SPE	HPLC-FL	Fish and prawn	23.0	Yes	[24]
MIP-SPME	HPLC-UV	Fish and shrimp	0.98–2.39	Yes	This article

Table 4
Recoveries and RSD of the estrogens in the spiked fish and shrimp tissues ($n = 3$).

Compounds	Fish			Shrimp		
	Spiked ($\mu g\,g^{-1}$)	Recovery (%)	RSD (%)	Spiked ($\mu g\,g^{-1}$)	Recovery (%)	RSD (%)
Estriol	0.010	81.4	6.7	0.010	82.0	6.2
17β-Estradiol	0.010	83.6	5.1	0.010	85.1	5.7
Estrone	0.020	80.0	3.8	0.020	85.0	7.1
17α-Ethynylestradiol	0.020	81.9	8.0	0.020	94.0	8.3

protocol. Moreover, the sensitivities of four estrogens in the spiked samples were greatly enhanced with the MIP-SPME–HPLC analysis. The NIP-coated fiber possessed extraction capability much lower than that of the MIP-coated fiber for the four estrogens investigated. Owing to the specific recognition of the MIP-coated fiber to the structure-related estrogens, the method could be applied to selective and sensitive monitoring of trace estrogenic compounds in biological samples. As shown in Table 4, the recoveries for the spiked fish and shrimp samples were 80.0–83.6% and 85.0–94.1% with RSD from 3.8–8.0% and 5.7–8.3%, respectively. The MIP-coated SPME fiber was very stable, and can be repeatedly used for more than 100 times for standard solutions. For real sample analysis, the lifespan of the fiber was related with the degree of sample complexity, and an interval clean step by methanol and then heating at 120 °C would help regenerate the fibers. Owing to the selective characteristics of the MIP extracts, the proposed MIP-SPME–HPLC method is sufficiently accurate and precise for determination of estrogens in fishery tissue samples.

4. Conclusions

The novel SPME fiber based on MIP using 17β-estradiol as template was fabricated with an improved multiple co-polymerization method. The fabricated fibers were porous on surface, thermal and chemical stable, and can be directly coupled with chromatographic instruments. Under the optimized conditions the fabricated fiber showed better molecular recognition abilities for 17β-estradiol and the structure-related compounds, such as estriol, estrone and 17α-ethynylestradiol. Efficiency of the prepared fiber to extract and analyze these four estrogens has been investigated by implementation of SPME in fishery samples. The detection limits were in the range of 0.98–2.39 $\mu g\,L^{-1}$, and the recoveries were 80.0–83.6% and 85.0–94.1% for fish and shrimp tissue samples, respectively. The MIP-SPME–HPLC method was proved to be selective, sensitive, fast and convenient for determination of estrogens in complex samples.

Mercury

ABSTRACT

In this study we firstly report a new electrolytic cold vapor generation system for mercury determination on Pt/Ti cathode in the presence of organic acid catholyte. Comparing with the traditional inorganic acid, formic acid increased the signal intensity of Hg vapor from electrolytic generation on Pt cathode and reduced the impact of cathode erosion on the stability of signal intensity. Moreover, formic acid has better interference tolerance. The introduction location for carrier gas is probably the most important factor that influences the signal intensity of Hg from electrolytic vapor generation. The effects of the electrolytic conditions and interference ions on the ECVG have been studied. Under the optimized conditions, the detection limit (3σ) of Hg (II) in aqueous solutions is 1.4 ng L^{-1}; a relative standard deviation of 2.3% for 1 μg L^{-1} Hg was obtained. The accuracy of this method was verified by the determination of mercury in the certified reference materials. This system has been applied satisfactorily to the determination of Hg in Traditional Chinese Medicines samples.

1. Introduction

Traditional Chinese Medicines (TCMs) as natural medicinal materials have attracted much attention because of their outstanding therapeutic effects. One of the major problems in TCMs is the safety problem relating to the presence of high concentrations of toxic metals, including arsenic, mercury and lead [1,2] in some products. For instance, mercury could accumulate easily in the human bodies after long-term use of TCMs. Mercury accumulation induced an autoimmune ability in genetically susceptible mice, which characterized by lymphoproliferation, hypergammaglobulinemia and IgG antinucleolar antibodies [3]. Hence, there is a great demand for an accurate rapid analytical technique to monitor Hg in TCMs.

The most common procedure for the determination of mercury, namely chemical cold vapor generation (CVG) technique, involves the reduction of the analyte to its elemental form in an acidified solution; the reducing agent usually is $NaBH_4$ under ambient conditions [4–6]. The detection is normally carried out using inductively coupled plasma optical emission spectrometry (ICP-OES) [7], atomic absorption spectroscopy (AAS) [8] and special atomic fluorescence spectrometry (AFS) techniques [9]. Comparing with other technique, CVG technique has some merits such as high sensitivity, wide linear dynamic range, low noise level, fast analysis speed, ease of operation, and low cost. However, the drawbacks are also serious and remarkable. The $NaBH_4$ aqueous solution is expensive and unstable, the risk of contamination by reagents is high [10]. Therefore, it is necessary to develop a new method to reduce the use of chemical reagents.

Since 1990s a new sample introduction technique, electrochemical hydride generation (Ec-HG) for hydride forming-elements determinations, has drawn more and more attention. The analytes are reduced to vapors or hydrides on the surface of cathode in the electrolytic cell [11,12]. Most of the hydride forming elements was reported successfully by Ec-HG, such as As [13,14], Sb [15], Se [16,17], Ge [18,19], Bi [19], Sn [11,19] and Te [20], recently. In the past 19 years, the technique was also applied for analysis of water, medicines and biological samples [21]. Fundamental principles and the application of Ec-HG could be found in some review papers [22–23].

The electrolytic cold vapor generation (ECVG) for mercury determination has been reported by some groups. Červený et al. [24] developed a technique for determination of inorganic mercury in water samples by electrochemical mercury cold vapor generation and in situ trapping in a commercial graphite furnace covered with a gold foil. Pt and HCl were used as cathode and catholyte, respectively, and the LOD was 0.33 ng mL^{-1}. Arbab-Zavar et al. [25] described the ECVG technique for the determination of Hg, in which the batch mode electrolytic cell and a pre-activated graphite rod were used as generator and cathode, respectively, and the LOD was 2 ng mL^{-1}. Li and Wang [26] reported the detection of the mercury by AFS coupled with ECVG. The glassy carbon and H_2SO_4 were used

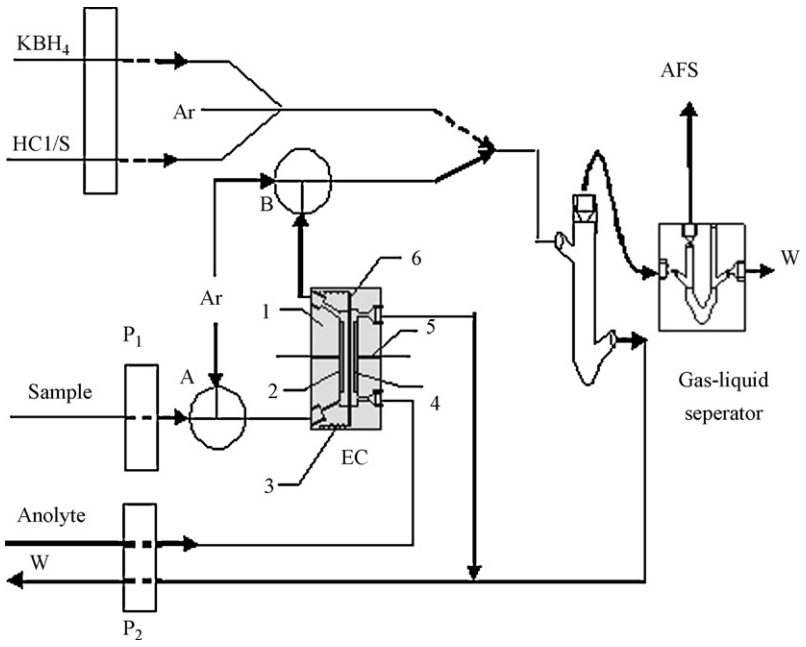

Fig. 1. Schematics of the Ec-HG system. A and B position of carrier gas imported, P: pump, EC: electrolytic cell, S: sample, W: waste, AFS: atomic fluorescence spectroscopy, 1: PTFE body, 2: Pt cathode, 3: sealing by screw thread, 4: Pt anode, 5: Pt wire, 6: ion-exchange membrane and gasket.

as cathode and catholyte, respectively, and the LOD was 1.2 ng L^{-1}. Comparing with CVG, however, the LOD of Hg by ECVG technology is poor.

The aim of this work is to develop a new ECVG system for the determination of Hg. The effects of catholytes and cathode on the signal intensity of Hg were evaluated and the reasons for the signal enhancement were also discussed. The influences of several factors on ECVG were investigated. The analytical figures of merit of the technique and its susceptibility to interferences were evaluated. The proposed method has been successfully applied to the determination of Hg in TCMs.

2. Experimental

2.1. Apparatus

A double-channel non-dispersive atomic fluorescence spectrometer (model AFS-230, Beijing Haiguang Instrument Co., Beijing, China) was employed throughout the experiment. A high-intensity mercury hollow cathode lamp (General Research Institute for Nonferrous Metals, Beijing, China) was used as the radiation source, which has advantages over electrode-less discharge lamps in both the stability and lifetime. A quartz tube (7 mm i.d. × 14 mm length) was used as the atomizer, into which the volatile species was carried by an argon flow. Two sequential gas–liquid separators were used for getting better hydrides transfer efficiency in our work, which depended on the gravity to separate the gas and liquid phases.

2.2. Vapor generation system

The electrolytic flow-through cell [21] was used to evaluate the ECVG of Hg. The polytetrafluoroethylene (PTFE) body of the cell consists of the cathodic and anodic compartments (both 55 mm × 11 mm × 2 mm, inner volumes of 1.2 mL). The cathode and the anode are embedded in them, separated by two slotted PTFE gaskets with an ion-exchange membrane (Huanyu Company of Beijing, Beijing, China) in between. The two compartments are held together with screw thread for easy dismounting the cell. A Pt foil anode was fixed on channel bottom of the anode cell. Some materials such as Pb foil, Ti foil, graphite and Pt foil were used as cathode and the surface area of the cathode was about 5 cm^2. Power supply for the electrolytic cell was DH1719A-3 constant current and constant voltage unit (Beijing Da Hua Wireless instrument Co, Beijing, China) working in the constant current mode.

A schematic of the ECVG–AFS system is shown in Fig. 1. The auto sampling device consisting of a peristaltic pump (IFIS-C, Xi'an Ruimai Electronic Technology Co., Ltd., Xi'an, China) was used to transport the samples. This system was controlled by a personal computer installed with lab-compiled software.

2.3. Chemical reagents

All reagents used in our experiment were of highest available purity, and of at least analytical grade. Doubly deionized water (DDW) was used throughout. The mercury standard solution was prepared by serial dilution of a 1000 mg L^{-1} mercury stock solution (Shanghai Institute of Measurement, Shanghai, China). The potassium tetrahydroborate (III) solution was prepared daily by dissolving the reagent in 0.5% (m/v) sodium hydroxide solution. High-purity HCOOH, HAc, HCOONa, NaAc, HCl, H_2SO_4 and HNO_3 were used to test the effects of the electrolytic solutions. Argon of 99.99% purity was used as the carrier gas (Nanjing special gases factory Co,. Ltd., Nanjing, China). All of the chemical reagents are buying from the Sinopharm Chemical Reagent Co. Ltd., except those indicated otherwise.

2.4. Analytic procedures

The analytical procedures of ECVG and CVG of Hg are schematically shown in Fig. 1. Firstly, the anolyte and catholyte/analyte were continuously pumped into the anode and cathode chambers of the cell, respectively. After the anode and cathode chambers were filled, changed the flow rate to 7.0 mL min^{-1} and started to electrolyze at current 1.4 A. The anolyte was reclaimed and recycled. At the same time, Hg vapor and hydrogen were generated on the cathode surface, and then the reaction products were mixed with Ar, delivered to a cross-tube. After gas–liquid separating, the gas containing Hg

Table 1

Flow rate of carrier gas (Ar) ($mL\,min^{-1}$)	300
Flow rate of shield gas (Ar) ($mL\,min^{-1}$)	1000

vapor were directed to the atomizer and determined by AFS. The operating programs of the system are listed in Table 1, except those indicated otherwise. A complete cycle of the procedure lasts ca. 60 s.

As a reference method, CVG was used in our work. Here, 2% HCl and 0.5% $NaBH_4$ prepared within 0.5% NaOH were used as carrying solution and reductant. Sample flow rate was set to 7.0 $mL\,min^{-1}$.

2.5. Sample preparation

TCM samples and reference materials were weighed accurately and transferred into PTFE containers, respectively. Pre-digestion was performed by mixing 5 mL of ultra pure HNO_3 with the sample. The mixture was allowed to stand overnight. On the next day, the pre-digested samples were further digested in a microwave oven. The pressure of the oven was 15 MPa and the digestion time was 5 min. After cooling to ambient temperature, 1 mL H_2O_2 was added to the sample, which was then digested again at the pressure of 10 MPa for another 3 min to ensure complete dissolution. Finally, the samples were transferred into a 25 mL calibrated flask and made up to the volume with 1.0 $mol\,L^{-1}$ HCOOH.

3. Results and discussion

3.1. The effect of catholyte on the signal intensity of Hg

In general, catholyte can be divided into four types: acid (including inorganic acid and organic acid), alkali, salt and buffer solution. The inorganic acid catholyte is usually used; other catholytes have also been used under special circumstances, e.g. for improving the signal strength and stability [21]. The organic acid as reaction medium is usually used by other vapor generation techniques such as ultraviolet irradiation-VG (UV-VG) [27], solution cathode glow discharge (SCGD) [28] and ultrasound-assisted-VG (UA-VG) [29], however, its are not be used as catholyte in ECVG technique.

Firstly, we studied the effects of some organic acids and buffer solutions including HCOOH, HCOONa, HAc, NaAc, HCOOH–HCOONa buffer solution and HAc–NaAc buffer solution on the signal intensity of Hg by ECVG. Form Fig. 2 it was found that the signal intensities of Hg from ECVG within inorganic acid medium were 30–40% of that from CVG. The signal intensity of Hg from ECVG under HCOOH medium increased remarkably. The signal obtained by ECVG for 1.0 $mol\,L^{-1}$ HCOOH reached 75% of that by CVG for 1.0 $mol\,L^{-1}$ HCl under best conditions. Comparing with HCOOH, HAc caused fluorescence signal of Hg decrease about 30–40%. Moreover, the signal intensity of Hg in HCOOH–HCOONa and HAc–NaAc was about 80–90% of that in HCOOH medium.

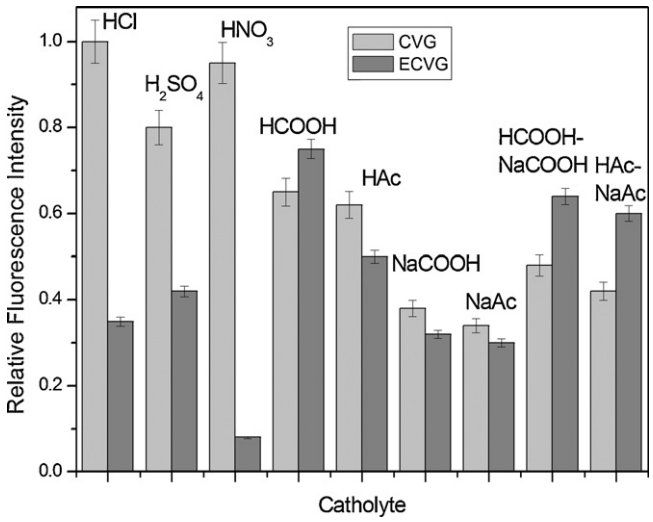

Fig. 2. The effects of the different catholyes on the fluorescence intensity of 1 $\mu g\,L^{-1}$ Hg. All of concentration of catholytes are 1 $mol\,L^{-1}$; Pt cathode. Catholyte flow rate of 7.0 $mL\,min^{-1}$; electrolytic current 1.4 A; 300 $mL\,min^{-1}$ Ar.

Comparing with inorganic acid medium, the major source of blank appears to arise from the use of the HCOOH catholyte. However, the signal intensities of Hg (II) in HCOOH by ECVG increased about 1–2 times. Moreover, the stability of signal intensity in HCOOH was better than that in inorganic acidic medium like H_2SO_4. The use of HCOOH is a good selection in view of the stability of signal intensity.

3.2. The effect of cathode on the signal intensity of Hg

The cathode material should have higher hydrides generating efficiency and good suppressing interference capability. It is generally believed that the efficiency of hydride forming by electrolysis depends primarily on the reducing ability of the cathode material under the operating conditions [22]. The higher the negative potential, the higher the reducing ability and the efficiency of hydride generation are, so lead and carbon cathode with high hydrogen over-voltage can bring higher hydride generating efficiency under the same conditions. However, the interference resulted from transition ions is an unavoidable problem. On the contrary, platinum is a good cathode material with suppressing interference capability and low hydride over-voltage, so it can only be applied to analyzing lower oxidation state of As, Sb and Se [23].

In present work, some materials including Pb, graphite, Pt and Ti were considered as cathode for Hg ECVG. The hydrogen over-voltage of Ti is higher than that of Pt, of course, lower than that of Pb and graphite under the same conditions.

Fig. 3 illustrates the effects of concentration of catholytes and cathode materials on signal intensity of Hg. Based on the above-mentioned reasons, the hydride generating efficiency and the signal intensity of Hg should change in this order: Pb > C > Ti > Pt. On the contrary, as shown in Fig. 3, the hydride generating efficiency and the signal intensity of Hg changed in the following sequence: Pb < C < Ti < Pt. Therefore, the electrolytic reduction mechanism of mercury may be different with those of other elements. At the same time, some authors thought that the graphite or glassy carbon was a good cathode material for Hg ECVG [25]; however, Ti and Pt were selected as cathode material for the Hg ECVG in our study based on the preliminary results obtained with this material, and the results were similar to those reported by Červený et al. [24].

Effects of HCOOH concentration on the signal response of Hg were examined as shown in Fig. 3. It was found that the intensity of Hg on Pt cathode remarkably increased with HCOOH concentration

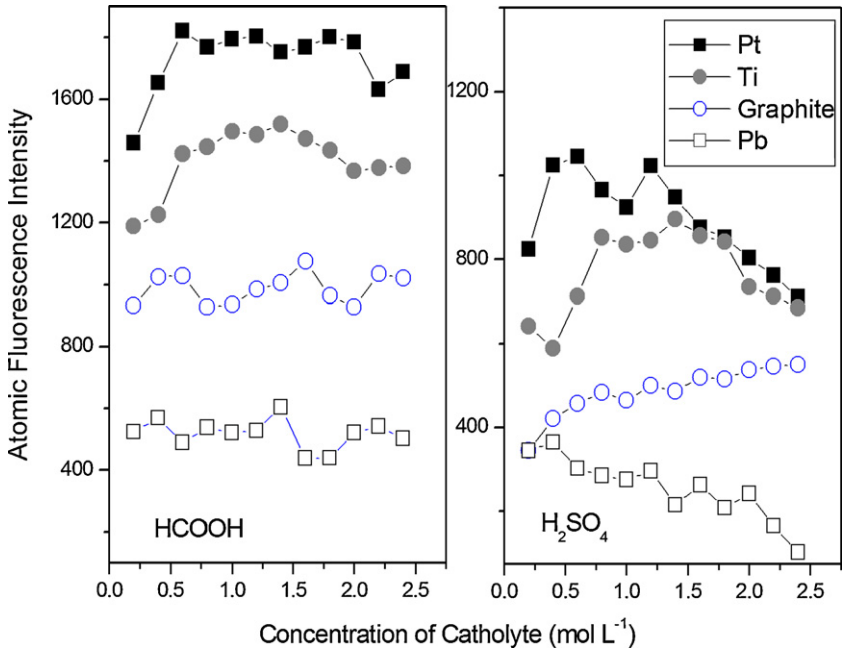

Fig. 3. The effects of the different cathodes and concentration of catholytes on the fluorescence intensity of 1 μg L^{-1} Hg. Catholyte flow rate of 7.0 mL min^{-1}; electrolytic current 1.4 A; 300 mL min^{-1} Ar.

increasing from 0.1 mol L^{-1} to 0.5 mol L^{-1}, and then leveled off, so 1.0 mol L^{-1} HCOOH was chosen as catholyte.

3.3. Interference study

Transition metals (Fe, Co, Cu and Ni) ions are easily reduced to their metallic states or colloidal forms by KBH_4 or $NaBH_4$, which scavenge or decompose the volatile analyte forms before the accomplishment of phase separation in CVG methods. In this study, the effects of these transition metal ions on the generation and determination of Hg were investigated. The effect is expressed as the recovery in the presence of interfering ions relative to the interference-free response. These metal ions concentration is about 100–1000 times Hg concentration in our choosing samples. Therefore, interference of these metal ions whose concentration was 500–20,000 times Hg concentration was investigated and the data were shown in Fig. 4.

Comparing with inorganic acid medium, the effect of transition metal ions on the signal intensity of Hg in HCOOH medium is slightly. On the Pt cathode, the Hg signal suppressions were observed to be 86% (Fe (III)), 76% (Co (II)), 63% (Ni (II)) and 37% (Cu (II)) when the 0.5 mol L^{-1} H_2SO_4 was used as catholyte, respectively, the Hg/metal weight ratios were 1:20,000 (20 mg L^{-1} metal ions). However, no significant interferences were observed in the presence of these transition metal ions (20 mg L^{-1}) for determination of Hg by the proposed method. Based on these results, the use of HCOOH is a good selection.

The effect of hydride-forming elements on the determination of 1 μg L^{-1} Hg (II) was also studied. The results were listed in Table 2. It was found that the hydride-forming elements, 0.5 mg L^{-1} Bi (III), Cd (II), Ge (IV), Pb (II), Se (IV), Sn (II), Zn (II) and As (III) had no significant influence on the measurement of 1 μg L^{-1} Hg (II). Moreover, large amounts of alkali and alkaline earth metal ions did not interfere with the determination. In addition, nitric acid and H_2O_2 are usually used in the digestion of sample. So the effect of nitrate ion and H_2O_2 were evaluated here for Hg determination. No interferences were observed in the presence of HNO_3 and H_2O_2 even the concentrations were 0.1 mol L^{-1}.

3.4. Effect of the carrier gas

Ar is usually used as carrier gas to transfer the product to detector. Traditionally, the introduction place of carrier gas is not taken into consideration because it does not influence the signal intensity of analytes. In our experiment, the effect of the introduction place of carrier gas on the signal intensity of Hg was studied. It was found that Hg response was low when Ar was introduced from sample outlet B (shown in Fig. 1); but a big signal intensity of Hg was detected by ECVG when the carrier gas was introduced from sample inlet A (shown in Fig. 1).

The reason for this phenomenon may be that the lifetime of Hg vapor is short and the vapor cannot transfer to the detector if the distance between the detector and introduction place; another possible cause is the deposition of the Hg vapor on the cathode surface and the walls of the transportation lines during the transferring process. When the 300 mL min^{-1} Ar was introduced from B point, in which the carrier gas did not go through the cathode compartment of the cell, the signal intensity of Hg

Table 2
Effect of coexisting ions on determination of Hg (1 μg L^{-1}).

Species	Concentration (mg L^{-1})	Concentration *M*/Hg	Signal change (%) ECVG
Ag (I)	0.1	100	−14
Ag (I)	0.5	500	−22
K (I)	10	10000	0

Sb (III)	0.5	500	+3
Bi (III)	0.5	500	0
Ge (IV)	0.5	500	−3
Zn (II)	0.5	500	+5

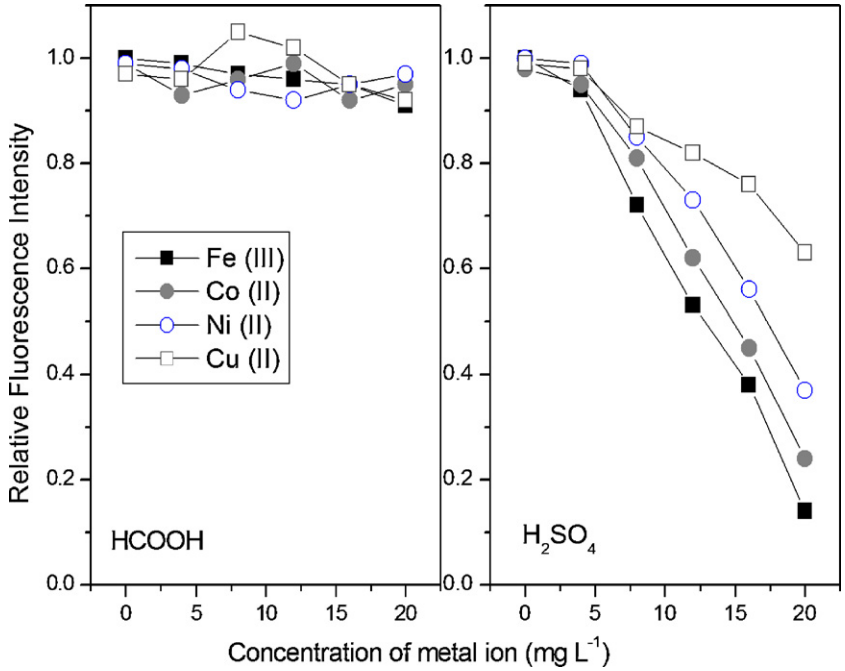

Fig. 4. Influence of the transition metal ions on the fluorescence intensity of 1 μg L^{-1} Hg involving HCOOH and H_2SO_4 catholyte. Pt cathode; catholyte concentration is 1 mol L^{-1}; catholyte flow rate of 7.0 mL min^{-1}; electrolytic current 1.4 A; 300 mL min^{-1} Ar.

was only about 5% that of CVG. When Ar entering the cathode cell (from A point) with a flow rate of 300 mL min^{-1}, the signal intensity of Hg increased remarkably and achieved about 75% that of CVG. These date suggest that the Hg vapor cannot be transported efficiently due to adsorption on the cathode surface of the cell. The result was similar to that reported by Ding and Sturgeon [14].

When the Ar flow rate increased continually, the signal intensity of Hg decreased remarkably, which is probably due to a significant dilution effect. Similar curves were also observed when graphite and Pb were used as cathode materials. Therefore, the Ar flow rate at 300 mL min^{-1} which was the smallest flow rate for our equipment was selected for the next experiments and the result was shown in Fig. 5.

3.5. Optimum conditions

It is well known that the rate of hydride formation is proportional to the electrolytic current. The dependence of fluorescence signals on Pt cathode was recorded for 1 μg L^{-1} Hg (II), at different electrolytic currents in the range of 0–1.6 A. The signal intensity increased proportionally with the electrolytic current from 0.0 to 1.2 A for 1 μg L^{-1} Hg solution, increased slightly in the range of 1.2–1.4 A, and then decreased after the current was higher than 1.4 A. Similar phenomena were observed when graphite and Pb were utilized as cathode materials. Based on these results, 1.4 A was selected as operating current.

The hydride generating efficiency is strongly affected by sample flow rate. The signal intensity of Hg (II) on Pt cathode increased remarkably along with sample flow rate varying from 1.5 to

Peach leaves (GBW08501)	0.046 ± 0.006	0.044 ± 0.005	4.3

7.0 mL min^{-1}, then decreased slowly with further increase of the flow rate. At the same time, the hydride generating efficiency of Hg (II) on Pt cathode decreased from 98% to 57%. The decrease of the fluorescence intensity at low flow rate was caused by the slow mass transfer of the analyte to the cathode surface, while at high flow rate the reduction of the residence time of the analyte in the cathode chamber was responsible for the decrease of the signal intensity. Similar results were found when Ti, graphite and Pb were used as cathode materials. As a consequence, 7.0 mL min^{-1} sample flow rate was chosen in our work and the detailed data are plotted in Fig. 6.

3.6. Discuss on the reduction mechanism

On the cathode material, the reaction mechanism of electrochemical hydride generation could be divided into two types: the electrocatalytic mechanism (cathode with low hydrogen over-voltage) and the electrochemical mechanism [22]. For example, the low hydrogen over-voltage of Pt is affected by the large hydrogen adsorbing ability and by the high catalytic activity of these metals [11]. Moreover, Milss et al. [30] thought that neither formic acid nor formate ion is the reduced electroactive species. They claimed that the solution exited the following ionization equilibrium.

$$HCOOH + H_2O \rightarrow HCOO^- + H_3O^+ \quad (1)$$

H_3O^+ is reduced to hydrogen atoms and the nascent hydrogen is adsorbed on the cathode surface [22]. This reaction is characterized by the Volmer-reaction.

$$M + H_3O^+ + e^- \rightarrow M - H + H_2O^+ \quad (2)$$

In reaction (2), M means cathode surface. Hg ion may be reduced stepwise to produce Hg vapor by the adsorbed hydrogen atoms.

$$2M - H + Hg^{2+} + 2e^- \rightarrow M + M - Hg(\text{adsorbed}) + H_2 \quad (3)$$

$$M - Hg(\text{adsorbed}) \rightarrow M + Hg(\text{vapor}) \quad (4)$$

Milss et al. [30] thought that formic acid molecules served as a conveyor of protons to the electrode surface despite being electrochemically inactive towards reduction. The HCOOH maybe affects the hydrogen adsorbing ability and the catalytic activity of Pt, and then influences the rate of reaction (3).

Moreover, Denkhaus et al. [11] deemed that the whole process of the Ec-HG could be described as an electrodeposition step in which the electrodeposition yield was mainly controlled by the design of the electrolytic cell and the working medium. According to this opinion, HCOOH maybe affects the electrodeposition yield of Hg, and then influences the rate of Hg vapor formation.

Table 5
Analytical results of Hg in TCMs sample.

Sample	Found value (μg g^{-1})	R.S.D. (%)	Recovery (%)
Huang qi	0.070 ± 0.009	3.2	105
Dan shen	0.068 ± 0.010	2.0	103
Dang shen	0.023 ± 0.004	3.5	97
Shen sha shen	0.215 ± 0.036	2.9	96
Liu wei de huang wan	0.725 ± 0.077	4.5	106

3.7. Analytical figures of merit

Linear calibration graph is obtained in the range 0.05–5 μg L^{-1} with the linear regression equations: $I_F = -28.74 + 1821.26C_{Hg}$. C in the equation is the Hg concentration (μg L^{-1}). The regression coefficient R is 0.9973. Detection limits based on three times the standard deviation of the blank (3σ) was 1.4 ng L^{-1} for Hg. Under the optimum condition, the precisions (R.S.D.) for 11 replicate determinaitons of 1 μg L^{-1} Hg was 2.3%. The R.S.D.s obtained for the real TCM samples were 2.0–4.5%, the R.S.D.s were slightly higher than those for the peach leaves due to the highly heterogeneous nature of the TCMs. The contrasts between the principal analytical parameters in our experiment and those reported by several other authors are shown in Table 3.

In comparison to the traditional inorganic acid system, despite the LODs were comparable, the advantage of the proposed method is obviously. Firstly, the signal intensity increased 1–2 times. Secondly, the stability of signal intensity in HCOOH was better. Moreover, the interference from the transition ions was suppressed totally.

3.8. Analytical results of samples

The proposed method was successfully applied to the analysis of different types of certificated reference materials and TCM samples. The result showed a good agreement with the certified values and the results are listed in Tables 4 and 5, and their recoveries are satisfying.

The content of Hg in TCM samples is higher than in the leaf certificated reference materials because the measured TCM samples are the root of plant in which the Hg is usually accumulated in them. The content of Hg in TCM pills (Liu wei di huang wan) is very high due to the concentrating and the pollution in the production process.

4. Conclusion

The novel technique of electrochemical vapor generation of Hg was developed. The organic acid was firstly used as catholyte, the signal intensity of Hg by ECVG markedly increased in organic acid.

The proposed method is sensitive and suitable for the determination of inorganic Hg. Under optimum conditions, this method can totally replace the traditional CVG method in the determination of mercury. The detection limit (3σ) of Hg (II) in aqueous solutions is 1.4 ng L^{-1}. A relative standard deviation of 2.3% for 1 μg L^{-1} Hg was obtained.

HCOOH maybe affect the hydrogen adsorbing ability and the catalytic activity of Pt, comparing with inorganic acids, and then affects the electrodeposition yield of Hg. In the present study, the formic acid is able to restrain the interference from the transition ions. Moreover, the introduction location of carrier gas is found to be an important factor that influences the signal intensity of Hg by ECVG. The Hg vapor cannot be transported efficiently due to adsorption on the cathode surface of the cell.

ABSTRACT

A novel electrochemical biosensor is described for detection of breakpoint cluster region gene and a cellular abl (BCR/ABL) fusion gene in chronic myelogenous leukemia (CML) by using thiolated-hairpin locked nucleic acids (LNA) as the capture probe. The hairpin LNA probe was immobilized on the nanogold (NG)/poly-eriochrome black T (EBT) film-modified glassy carbon electrode (GCE). The immobilized LNA probe could selectively hybridize with its target DNA on LNA/NG/EBT/GCE surface. The immobilization and hybridization of the LNA probe were characterized with cyclic voltammetry and electrochemical impedance spectroscopy. The hybridization of the immobilized LNA probe with the target DNA was detected by differential pulse voltammetry with the electroactive methylene blue as an indicator. The results indicated this new method has excellent specificity for single-base mismatch and complementary after hybridization, and a high sensitivity. This novel electrochemical biosensor has been used for assay of PCR real sample with satisfactory result.

1. Introduction

CML is a clonal myeloproliferative disorder, resulting from the neoplastic transformation of the primitive hemopoietic stem cell [1–3]. The chimeric oncogene breakpoint cluster region gene and a cellular abl gene (BCR/ABL) is the traditional gene existed in almost all cases of CML patients [4,5]. Thus, detection of BCR/ABL fusion gene will afford an early diagnosis and monitor of the disease. In recent years, there has been significant progress in developing nucleic acid hybridization biosensors for the rapid and accurate detections of specific gene sequence [6,7]. As with other types of biosensors, high selectivity is crucial for the success of hybridization biosensors [8]. The selectivity of nucleic acid hybridization assays depends primarily on the selection of the probe and then of the hybridization conditions. Thus, the design of the probe is the most important pre-analytical step. Recently, some reports described the synthesis and hybridization of a novel nucleotide termed LNA [9,10].

LNA is a nucleic acid analogue of RNA, in which the furanose ring of the ribose sugar is chemically locked by the introduction of a methylene linkage between 2′-oxygen and 4′-carbon. The covalent bridge effectively 'locks' the ribose in the N-type (3-endo) conformation that is dominant in A-form DNA and RNA. This conformation enhances base stacking and phosphate backbone pre-organization and results in improved affinity for complementary DNA or RNA sequences, with each LNA substitution increasing the melting temperatures (T_m) by as much as 3.0–9.6 °C [11,12]. LNA bases can be interspersed with DNA bases, allowing binding affinity to be tailored for individual applications. Due to the very high affinity of the LNA molecules, it demonstrates that LNA probes hybridize with very high affinity to perfectly complementary targets, and at the same time shows an extraordinary specificity to discriminate the targets that differ by a single-base.

Moreover, sensitive detection of specific gene sequence on the basis of the hybridization reaction is another key issue. Increasing the immobilization amount and controlling over the molecular orientation of probe oligonucleotides would improve the detection sensitivity [13,14]. In the DNA sequence detection, the nanogold not only can act as the immobilizing carrier to increase the immobilization amount of the DNA probe but also can serve as the signal particle to magnify the detection signal and lower the detection limit [15,16]. Therefore, in this article, we introduce a method of immobilizing the LNA probe with nanogold bound to the poly-EBT film on the GCE. Due to the rich electroactive center and three-dimensional available field potential, the polymerized film-modified electrode has stable performance with good infusible and insoluble capability. EBT has been used in the biological electro-

analysis [17]. Nanogold can integrate with the biological active components. LNA probe can form a powerful Au–S covalent bond with hydrosulfuryl and the excellent biocompatibility of nanogold with LNA. So a novel electrochemical DNA biosensor based on the NG/EBT/GCE was developed for recognition of target DNA by using hairpin LNA as the capture probe for hybridization with BCR/ABL fusion gene in CML.

2. Materials and methods

2.1. Reagents and apparatus

Methylene blue (MB) and $HAuCl_4{\cdot}4H_2O$ were purchased from Sigma (USA). Sodium dodecyl sulfate (SDS), sodium citrate and eriochrome black T (EBT) was purchased from Shanghai Chemical Reagents Company (China). The oligonucleotides were synthesized by Shanghai Shenggong Biotechnology Co. (Shanghai, China), and it has the following sequences:

Thiolated-hairpin LNA probe: 5′-SH-C**T**$^{\mathbf{L}}$G**C**$^{\mathbf{L}}$AG**A**$^{\mathbf{L}}$GT**T**$^{\mathbf{L}}$CA**A**$^{\mathbf{L}}$AA **G**$^{\mathbf{L}}$CC **C**$^{\mathbf{L}}$TT CGC AG-3′, (L: 2′-*O*,4′-*C*-methylene·(D-ribofuranosyl) nucleotides LNA. LNA probe is a DNA–LNA chimera, but for brevity it will be called LNA probe [18]. Bold letters represent LNA bases. Underlined letters are bases for stem). Complementary target: 5′-GAA GGG CTT TTG AAC TCT-3′, single-base mismatch: 5′-GAA GGG ATT TTG AAC TCT-3′, non-complementary: 5′-ACG TAA TCC CCA GCT CTC-3′.

The oligonucleotide stock solutions (100 μM) were prepared with 20 mM Tris–HCl, 10 mM $MgCl_2$, pH 8.0 and kept frozen. Real samples were kindly donated by Fujian Institute of Hematology, the Affiliated Union Hospital of Fujian Medical University. Millipore Milli-Q water was used in all experiments. Unless otherwise indicated, all reagents and solvents were purchased in their highest available purity and used without further purification.

A CHI 660C electrochemical analyzer (CH Instrument, USA), which was in connection with a GCE (3 mm diameter) as the working electrode, a Ag/AgCl reference electrode and a platinum wire auxiliary electrode, was used for the electrochemical measurement.

2.2. The preparation of surface of biosensor and its immobilization with LNA probe

The scheme for preparation of the electrochemical DNA biosensor is illustrated in Fig. 1. The surface modification of the GCE was performed by procedure reported in Ref. [17]. Before surface modification, the GCE was polished in sequential order with 1.0, 0.3 and 0.05 μm alumina (AlfaAesar, USA). The electrode was thoroughly washed with water, sonicated in ethanol, and finally dried thoroughly under N_2 flow. Then, GCE was polarized in 0.1 M H_2SO_4 by cyclic scanning between −0.40 and +1.50 V for 25 cycles and scanned in 0.1 M NaOH under the same conditions for 25 times to obtain the pretreated electrode. The poly-EBT was electropolymerized onto pretreated GCE in the presence of 0.1 M NaOH containing 0.5 mM EBT on the same conditions. The obtained electrode was donated as EBT/GCE. The EBT/GCE was immersed into 1% NG solution prepared by the citrate reduction of $HAuCl_4$ for 4 h [19,20]. NG was electro-deposited on the surface of EBT/GCE for 100 s at 0.15 V to prepare NG/EBT/GCE. Apparently a mount of nanogold provides an easier way to immobilize the probe LNA with thiol groups at the 5′ end [21].

Immobilization of the LNA probe on the NG/EBT/GCE surface is described as follows. 10 μl of 1.0 μM probe LNA was dropped on the surface of NG/EBT/GCE and air-dried to dryness. Then the electrode was washed with 0.1% SDS solution for 5 min to wash out the unimmobilized LNA probe. The probe modified electrode was donated as LNA/NG/EBT/GCE.

Table 1
Melting temperatures of the LNA and DNA capture probe against complementary and single-base-mismatched DNA targets.

Probe type	T_m (°C)		ΔT_m (°C)
	Complementary target	Single-base mismatch	
DNA	50.3	44.7	5.6
LNA	78.8	38.1	40.7

The hybridization was performed by pipetting 10 μl of different concentrations of complementary target (cDNA) onto the LNA/NG/EBT/GCE for 1 h at 60 °C. Thus, a double-stranded LNA-cDNA (dsDNA)/NG/EBT/GCE was obtained. The electrode surface was then washed with 0.1% SDS for 5 min to remove the unbound oligonucleotides. The same protocol as above-mentioned was applied to LNA/NG/EBT/GCE for hybridization with one-base mismatch and also with non-complementary sequences.

2.3. MB accumulation and voltammetric transduction

MB for DNA hybridization detection is illustrated in Fig. 1. MB was accumulated onto the surface of hybrid-modified NG/EBT/GCE by immersing the electrode into stirred 20 mM Tris–HCl (pH 7.0) containing 20.0 μM MB with 50 mM NaCl for 5 min without applying any potential. In the optimal condition, the concentration of MB was chosen as 20.0 μM and the accumulation time of MB was chosen as 5 min for optimum analytical performance. After accumulation of MB, the electrode was rinsed with 0.1 M PBS to remove the non-specific MB and subjected to electrochemical measurement.

3. Results and discussion

3.1. Spectrophotometric characterization of DNA and LNA probes

Melting temperature (T_m) is the temperature at which double-stranded DNA is changed (50%) to single-stranded DNA. The denaturation of double-stranded DNA can be conveniently monitored by the sharp increase in absorbance at 260 nm (the absorbance maximum for DNA) using the spectrophotometer UV–Vis Varian Cary 100 (Varian). T_m for the hybridization of LNA with their complemental DNA were examined to confirm their potential for selective recognition of complementary sequences. From Fig. 2 and Table 1, the T_m value of the LNA probe (78.8 °C) was greatly higher than that of its corresponding DNA probe (50.3 °C). Comparing with the analogous DNA–DNA hybrids, T_m value for LNA binding to DNA was increased 28.5 °C, which was equivalent to 4.1 °C per LNA compared to DNA duplexes [22,23]. T_m value for LNA binding to single-base mismatch was decreased to 38.1 °C. Therefore, the affinity and specificity of the LNA probes can be confirmed by measurement of duplex T_m.

Theoretically, the optimum hybridization temperature was about 20 °C lower than T_m. The T_m value of the LNA probe binding to complementary target was 78.8 °C, while for single-base mismatch was decreased to 38.1 °C, Therefore, the theoretical hybridization temperature was 58.8 and 18.1 °C for the complementary target and single-base mismatch, respectively. Accordingly, 60 °C was selected as hybridization temperature [10]. At this temperature, hybridization could be occurred only for the complementary target strand but not for the single-base mismatch. Therefore, the hybridization specificity was dramatically increased.

3.2. Covalent modification of GCE with EBT

The covalent modification of the GCE was performed by repeated cyclic voltammograms scanning over the range of −0.4

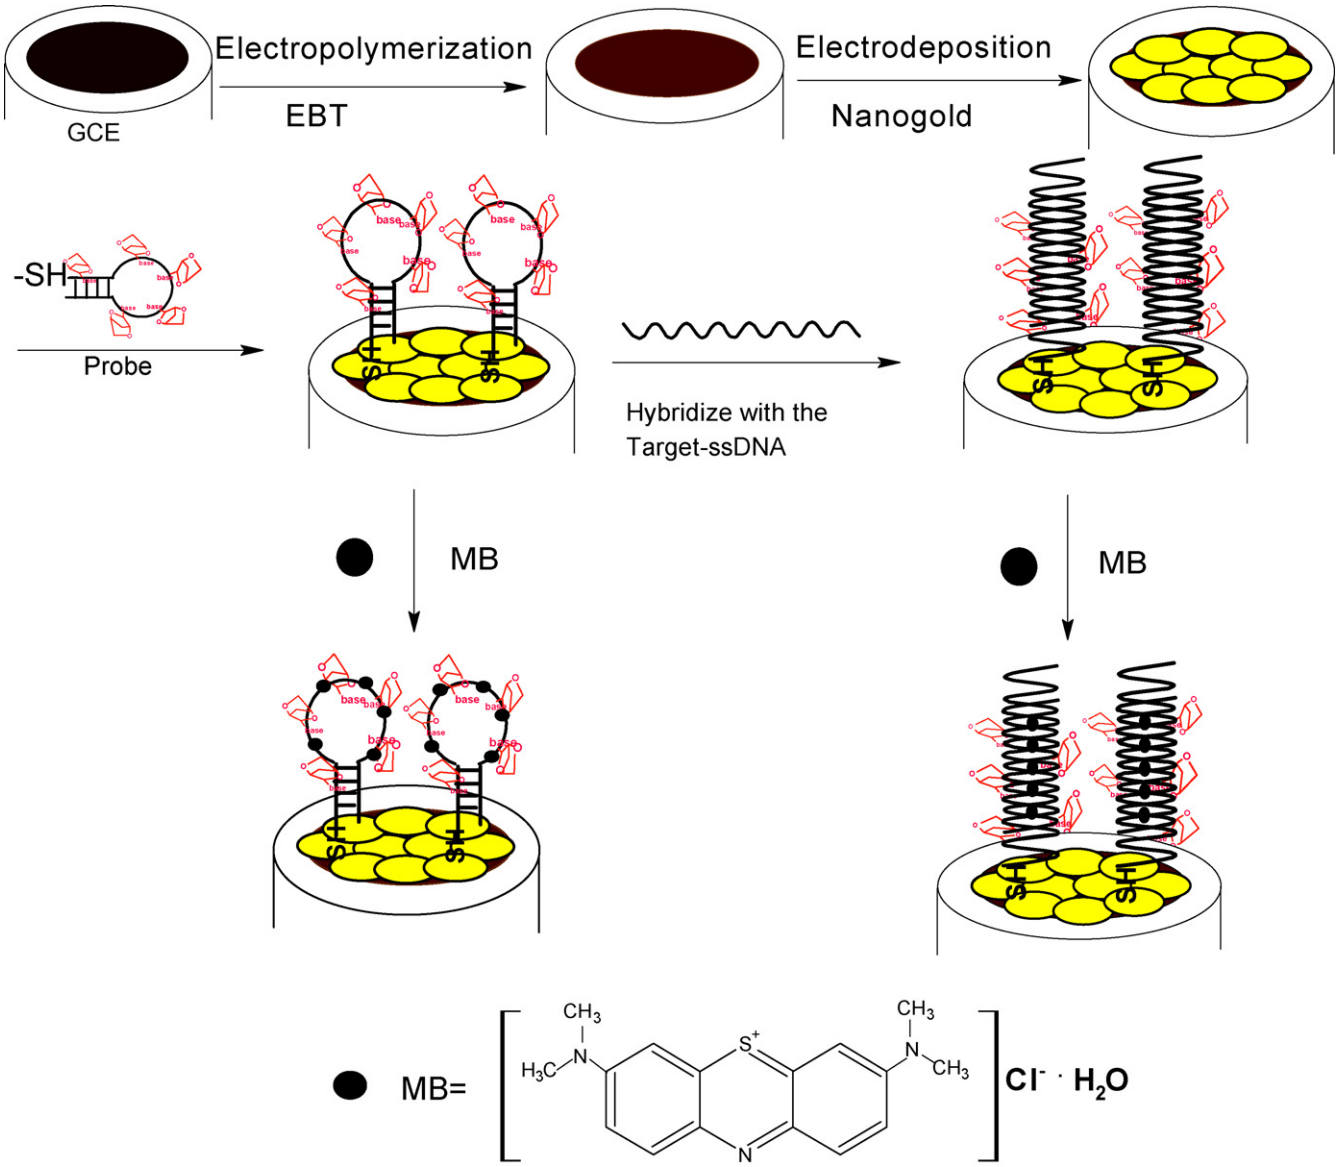

Fig. 1. Scheme of the procedure for the fabrication of DNA biosensor.

to 1.5 V at 100 mV/s for 25 cycles in 0.1 M NaOH containing 0.5 mM EBT. Typically, it was found that when cyclic time was increased, the peak currents gradually decreased. This phenomenon implies the formation of poly-EBT membrane on GCE [17]. The electrodeposited behavior of EBT at the GCE was similar to some reports referring to the electrochemical responses of a few azo compounds at solid electrode [24]. The reaction mechanism could be explained as follows: (1) EBT was first deposited at the surface of GCE and oxidized to form a benzoquinone diimine structure; (2) and then the benzoquinone diimine structure was reduced to EBT at the surface of GCE. The peak currents trended to be stable after 20 scans, which indicated that the GCE surface has been modified with a sulfonic-terminated monolayer to form the EBT/GCE.

3.3. *Electrochemical characterization of different modified electrodes*

Cyclic voltammograms (CV) of 10 mM $[Fe(CN)_6]^{3-/4-}$ redox couple in 0.1 M phosphate buffer solution at a bare GCE (a), EBT/GCE (b), NG/EBT/GCE (c), LNA/NG/EBT/GCE (d) and dsDNA/NG/EBT/GCE (e) were shown in Fig. 3A. Curve a shows that a symmetric, reversible

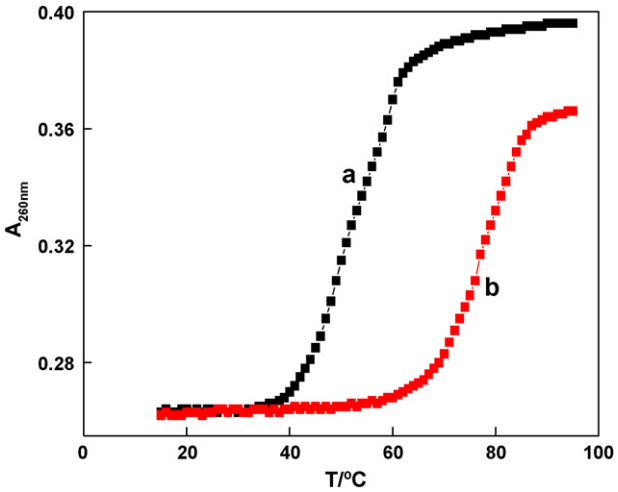

Fig. 2. Melting curves of DNA–DNA (a), LNA–DNA duplex (b).

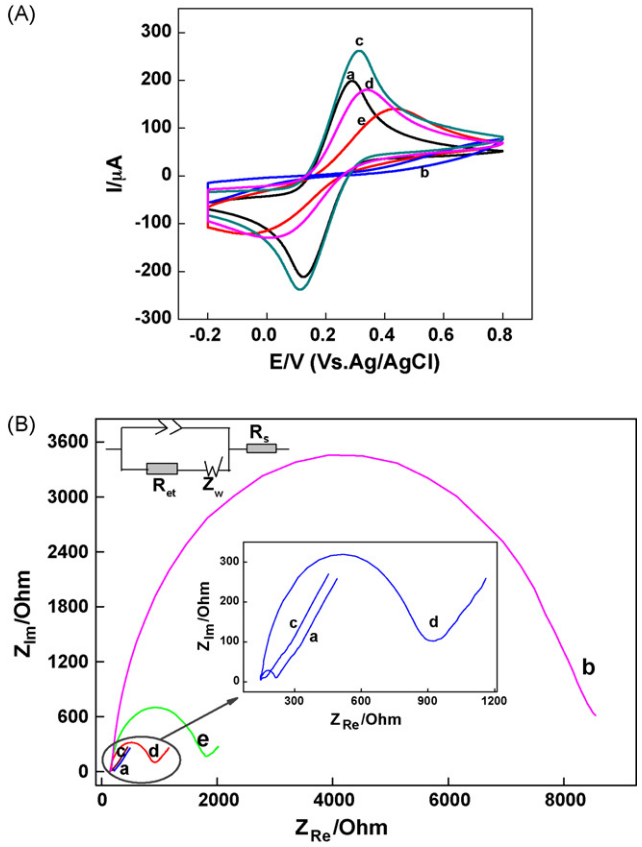

Fig. 3. (A) CV of 10 mM $[Fe(CN)6]^{3-/4-}$ for bare GCE (a), EBT/GCE(b), NG/EBT/GCE (c), LNA/NG/EBT/GCE (d) and dsDNA/NG/EBT/GCE (e). (B) Impedance plots on bare GCE (a), EBT/GCE (b), NG/EBT/GCE (c), LNA/NG/EBT/GCE (d) and dsDNA/NG/EBT/GCE (e) in 10 mM $[Fe(CN)6]^{3-/4-}$.

voltammogram was obtained for a bare GCE. Curve b clearly shows that the electron transfer of $[Fe(CN)_6]^{3-/4-}$ is completely blocked on the EBT/GCE. It can be explained by the electrostatic interactions between the modified surface and $[Fe(CN)_6]^{3-/4-}$. As it known, the pK_a value of R–SO_3H (R: alkyl or aryl groups) is usually between 3 and 4. When the solution pH was equal to 7, the –SO_3Na group of poly-(EBT) film could dissociate favorably into a negative charge group –SO_3^-. Thus, on the negatively charged EBT film, the electrostatic repulsion resists access of $[Fe(CN)_6]^{3-/4-}$ to the electrode surface and blocks its electron-transfer on the electrode surface. Curve c is the CV curve of the NG/EBT/GCE electrode in the same solution as above. The CV peak of curve c was much higher than that of curve b. This implies that NG had been successfully modified onto EBT film, resulting in the electrode having a larger electroactive surface and higher conductivity. When the LNA probe immobilized on the NG/EBT/GCE, compared with bare GCE and NG/EBT/GCE, the peak current decreased and the potential deviation increased (curve d). That is, the LNA probe had negative charge, so hampered $[Fe(CN)_6]^{3-/4-}$ to participate the electrode reaction. These results suggest that the NG/EBT/GCE surface is well covered with the LNA probe. After hybridization, there were more negative charges on the surface and the dsDNA modified layer became thicker. These two factors provide an effective barrier to electron-transfer of $[Fe(CN)_6]^{3-/4-}$ in solution (curve e).

Electrochemical impedance spectroscopy (EIS) can give information on the impedance changes of the electrode surface in the modification process. So EIS was also used to evaluate the interfacial electron-transfer efficiency at different stages of biosensor preparation [25]. Fig. 3B shows the typical EIS results of the bare GCE (a), EBT/GCE (b), NG/EBT/GCE (c), LNA/NG/EBT/GCE (d) and dsDNA/NG/EBT/GCE (e), respectively, which were obtained in a solution of 10 mM $[Fe(CN)_6]^{3-/4-}$ at a potential of 0.22 V (versus Ag/AgCl) in the frequency range of 0.1–10^5 Hz. The electron-transfer resistance (R_{et}) of the bare GCE was estimated to be 63 Ω (curve a). When a bare GCE was electropolymerized with EBT for 25 cyclic times, the electron transfer resistance increased significantly (R_{et} = 8386 Ω). The surface coverage (θ) of EBT film on a bare GCE can be calculated from the EIS in terms of the equation [26]

$$\theta = \frac{1 - R_{et}^{Bare}}{1 - R_{et}^{EBT}} \quad (1)$$

Using Eq. (1), the coverage was calculated to be 99.28%. When the gold nanoparticles was assembled on the EBT/GCE, the R_{et} value was found to be 16 Ω (curve c). As compared with curve a, the R_{et} value of the curve c reduced obviously. This might be due to the presence of nanoparticles playing an important role in accelerating the transfer of the electrons, thus decreasing the resistance of the NG/EBT/GCE to $[Fe(CN)_6]^{3-/4-}$. After the LNA probes were immobilized on the NG/EBT/GCE, its R_{et} value was 758 Ω (curve d), which was much larger than that of the curve c. The negatively charged phosphate backbone of the LNA probe prevented $[Fe(CN)_6]^{3-/4-}$ from reaching the electrode surface during the redox process, and therefore led to the obvious increase of R_{et} value. After hybridization, there were more negative charges on the surface and the DNA modified layer became thicker. These led to the further increase of R_{et} value. These results are in agreement with the CV data.

3.4. Hairpin LNA probe versus hairpin DNA probe

To clarify the role of the DNA sequence with locked nucleic acids modified probe (LNA probe), we tested the same sensing scheme immobilizing a DNA sequence that has no locked nucleic acids as probe (DNA probe) on the surface of NG/EBT/GCE. The experiment was performed with single-base mismatch sequences to investigate whether or not LNA probe improves the selectivity of the assay. Using DNA probe, the voltammetric signal obtained for single-base mismatch was found to be only about 1.42 times higher than the signal obtained for the same concentration of complementary target (see Fig. 4A). At the same time, the signal for the single-base mismatch was significantly increased when LNA was used as probe (see Fig. 4B). These data clearly show the high selectivity of LNA probe for the complementary target and single-base mismatch sequences compared with DNA probe. So in this study, we study the hybridization specificity by using LNA as the capture probe for detection of BCR/ABL fusion gene. The enhanced selectivity can be attributed to the LNA, LNA monomer contains a methylene bridge that connects the 2′-oxygen with the 4′-carbon of the ribose ring of RNA. This bridge results in a locked 3′-endo conformation, reducing the conformational flexibility of the ribose and increasing the degree of local organization of the phosphate backbone [27]. This entropic constraint leads to improving the binding to complementary RNA and DNA sequences.

3.5. The CV study of MB interacted with the LNA/NG/EBT/GCE along with change of scan rate

It had been reported that MB interacted in a different way with ssDNA and dsDNA [15,28]. So MB was used as an electrochemical indicator to study hybridization between LNA and target DNA. LNA modified NG/EBT/GCE electrode immersed in pH 7.0 Tris–HCl containing 20.0 μM MB and CV were collected with the scan rate of 50, 100, 200, 300, 400, 500, 600, 700 and 800 mV s^{-1}. As shown in Fig. 5A, a pair of evident oxidoreduction peak appeared, and the peak current increased along with the increasing of the scan rate. The plot of cathodic peak current (I) versus scan rate (v) is linear

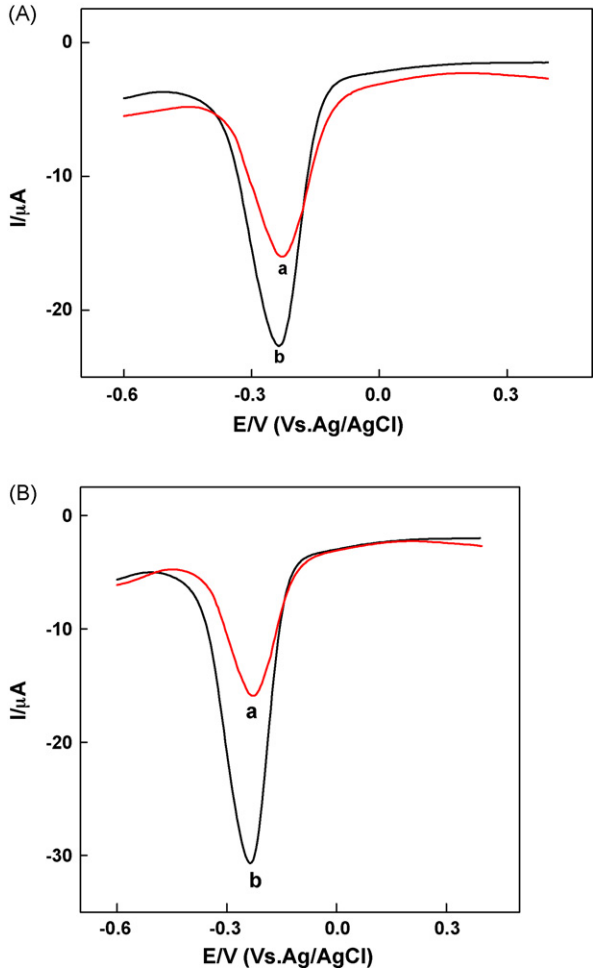

Fig. 4. (A) DPV of 20 μM MB at a DNA/NG/EBT/GCE hybridization with the complementary target (a) and single-base mismatch (b). (B) DPV of 20 μM MB at a LNA/NG/EBT/GCE hybridization with the complementary target (a) and single-base mismatch (b).

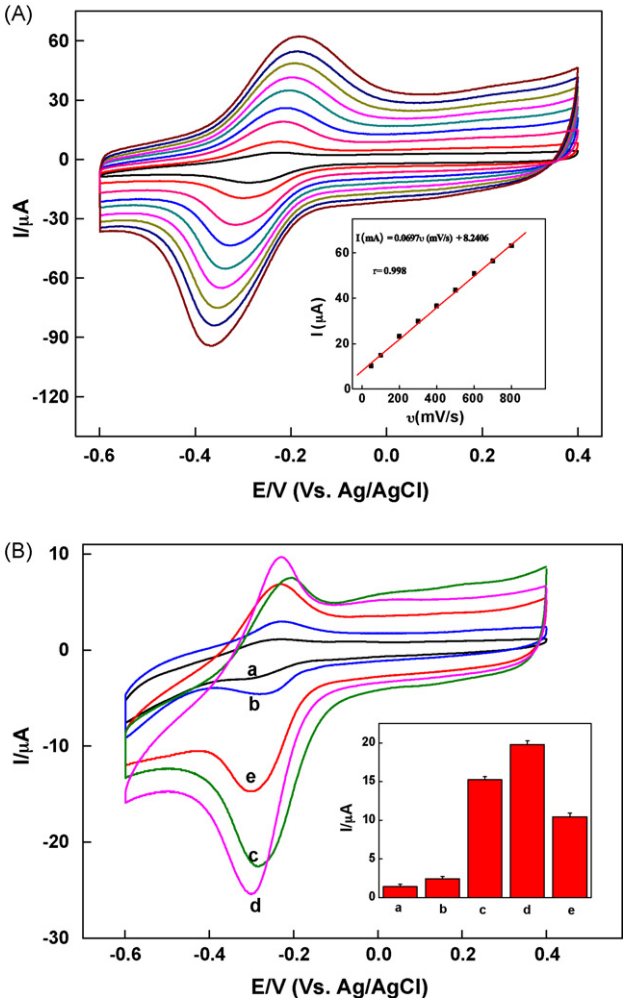

Fig. 5. (A) CV of 20 μM MB in 20 mM Tris–HCl buffer (pH 7.0) at the LNA probe modified NG/EBT/GCE surface with increasing scan rate from inner to outer: 50, 100, 200, 300, 400, 500, 600, 700, 800 mV s^{-1}. Inset shows plot of reduction peak current versus scan rate. (B) CV of 20 μM MB at the bare GCE (a), EBT/GCE (b), NG/EBT/GCE (c), LNA/NG/EBT/GCE (d) and dsDNA/NG/EBT/GCE (e). scan rate: 100 mV s^{-1}. Insert: corresponding histograms of the reduction peak currents.

(see Fig. 5A inset), indicating that MB was strongly bound to the LNA modified NG/EBT/GCE surface. Because MB could bind specifically to the LNA probe guanine bases [10,15]. The LNA probe was immobilized on the NG/EBT/GCE. So MB was strongly bound to the LNA modified NG/EBT/GCE surface.

3.6. Electrochemical behavior of MB on different electrodes

Fig. 5B shows the CV signals at different electrodes in 20 mM pH 7.0 Tris–HCl buffer solution containing 20.0 μM MB. It can be seen that a pair of weak redox peaks of MB was observed at the bare GCE (curve a) and EBT/GCE (curve b). For NG/EBT/GCE (curve c), the redox peak currents of MB were greatly enhanced. In addition, the immobilization of LNA probe on the NG/EBT/GCE modified electrode surface resulted in an increase in the peak currents of MB (curve d). It was attributed to nanogold thin film could provide a well platform for LNA probe immobilization and the electrostatic interaction between the negatively charged phosphate backbone of LNA and MB cation. At the same time, many more free guanine bases of LNA molecules were exposed out and had a strong affinity with MB, hence the greatest amount of MB accumulation occurs at this surface [29]. Therefore, the highest MB oxidoreduction signal was observed with LNA probe on NG/EBT/GCE. However, a significant decrease in the voltammetric peak current of MB was observed after complementary target sequence was allowed to hybridize with the LNA/NG/EBT/GCE (curve e). The decrease of current signal after hybridization was due to the inaccessibility of the guanine bases in dsDNA. This decrease is attributed to the steric inhibition of the reducible groups of MB packed between the bulky double helix of the hybrid. MB could bind specifically to the guanine bases and readily intercalate into dsDNA as well. Different binding modes of MB with LNA modified ssDNA and dsDNA resulted in variation in electrochemical responses.

3.7. Hybridization specificity of hairpin LNA probe

Hairpin LNA has high hybridization specificity because of its LNA and loop-stem structure [30], which can easily discriminate complementary oligonucleotide from single-base mismatch oligonucleotide. The selectivity of this assay was investigated by using the hairpin LNA as the capture probe to hybridize with various DNA sequences related to BCR/ABL fusion gene. Fig. 6A shows the differential pulse voltammetry (DPV) signal of MB at LNA/NG/EBT/GCE (d) and after hybridization with complementary target (a), single-base mismatch (b) and non-complementary (c). It is clear that curve d shows the highest peak current of MB on the LNA/NG/EBT/GCE, and after hybridization with complementary oligonucleotide, the peak current of MB is dramatically

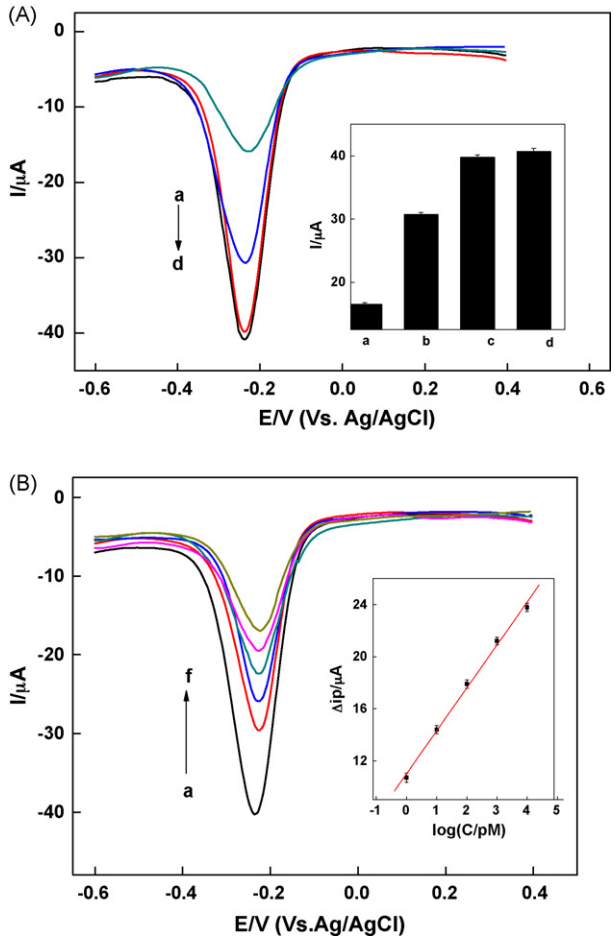

Fig. 6. (A) DPV of 20 μM MB at LNA/NG/EBT/GCE (d) and after hybridization with the complementary target (a), single-base mismatch (b) and non-complementary (c). Inset shows the bar graph of the peak current of MB when the LNA probe hybridized with different gene fragments. Error bars = ±relative standard deviation. (B) DPV of MB accumulated on the LNA after its hybridization with different concentration of the target sequence. Target concentration (*M*): (a) probe; (b) 1.0×10^{-12}; (c) 1.0×10^{-11}; (d) 1.0×10^{-10}; (e) 1.0×10^{-9}; (f) 1.0×10^{-8}. Inset shows the plot of the peak current of MB as a function of the target concentration. Error bars = ±relative standard deviation.

decreased (curve a). It can also easily discriminate the complementary oligonucleotide from single-base mismatch oligonucleotide. In the presence of oligonucleotide containing a single-base mismatch, significantly increased voltammetric signal can be observed (curve b), which indicates that the complete hybridization is not accomplished due to the base mismatch. So the hairpin LNA has high hybridization specificity for the complementary oligonucleotide and single-base mismatch oligonucleotide. In addition, as expected, no significant difference of peak current can be observed for the hairpin LNA probe and its hybridization with non-complementary (curve c), since no successful hybridization occurs due to the sequence mismatch between the hairpin LNA probe and non-complementary.

The sensitivity of this electrochemical biosensor for the target DNA was investigated by varying the target oligonucleotide concentration according to the procedure described in Section 2. The different current value obtained in the DPV response of MB after hybridization of LNA probe with target was recorded with three repetitive measurements. The current response decreased in proportion to the amount of the target sequence. The average current response shows excellent correlation with the amount of the complementary oligonucleotides in the range of 1.0×10^{-12}–1.0×10^{-8} M (Fig. 6B). The regression equation is

$$\Delta ip(\mu A) = 3.30(\log C/pM) + 11.0 \quad R = 0.9983$$

A detection limit of 1.0×10^{-13} M for the target DNA can be estimated using 3σ (where σ is the standard deviation of the blank solution, $n = 7$). The reproducibility of the biosensor for detection of 1.0×10^{-11} M target DNA is 7.35% ($n = 7$).

3.8. Detection of PCR products

This novel electrochemical biosensor based on the LNA probe on the NG/EBT/GCE has been used for assay of PCR product of real sample. When the hairpin LNA probe for BCR/ABL was immobilized and hybridized with real PCR samples in the hybridization step. The DPV signals of MB obtained from the LNA probe modified NG/EBT/GCE gave a mean average of 40.8 μA with a RSD of 5.12%. The DPV signals of MB obtained from the hybridization of the LNA probe with the positive and negative real samples gave mean average of 16.5 μA with RSD of 6.72% and 40.1 μA with RSD of 7.34%, respectively. The signal of MB for the LNA probe modified NG/EBT/GCE was much higher than that of LNA probe modified NG/EBT/GCE after hybridization with positive real sample. The decrease of DPV signals with positive real samples showed that the hybridization at the NG/EBT/GCE surface occurred and MB could not interact with the bound guanine base of the hybrid. The decrease in the reduction signal of MB was attributed to the steric inhibition of the reducible groups of MB because of the formation of hybrid at the NG/EBT/GCE surface. If the blood sample was negative, the negative real sample would not contain a target sequence complementary to the specific LNA probe. The hybridization between these negative real samples and the immobilized probe would not occur, so the signal of MB was higher than that of the positive real samples.

A gel electrophoresis method was performed. Fig. 7 shows the result of electrophoresis of PCR products. The PCR amplification products from a positive real sample (lane 3) show the light brands about 300 bp in the 1.5% agarose gel; however, the PCR amplification products from negative real sample (lane 2) do not present any brands in the gel. Thus, we can extrapolate that the primers have amplified specific band to discriminate the positive real sample

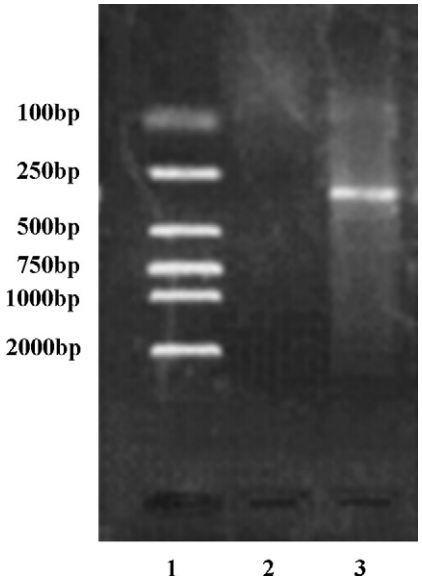

Fig. 7. Electrophoretogram of PCR amplified products. The lanes from left to right: lane 1: DL2000 DNA marker (the brands from up to down: 100 bp, 250 bp 500 bp, 750 bp, 1000 bp and 2000 bp); lane 2: negative real sample; lane 3: positive real sample.

from the negative real sample well. The results obtained from the gel electrophoresis are in good agreement with the ones obtained from the electrochemical DNA biosensor.

4. Conclusion

A novel electrochemical biosensor for detection of BCR/ABL fusion gene using hairpin LNA based on NG/EBT/GCE was fabricated. The hairpin LNA capture probe could selectively hybridize with its target DNA to form double-stranded DNA on NG/EBT/GCE surface. Since the quantities of LNA probe immobilized on the electrode surface can be greatly improved by nanogold-modified poly-EBT film approach. This novel DNA biosensor has higher sensitivity and better hybridization efficiency. The LNA probe was shown to be an effective biosensor for the detection of hybridization by using MB as the electrochemical indicator. This new method demonstrates its excellent specificity for single base mismatch and complementary after hybridization, and this method has been used for assay of PCR real sample with satisfactory result. The proposed method provided a simple, rapid tool for detection of DNA species in CML. It might have a promising future for investigation of DNA hybridization and solve the actual problem of the early diagnosis and prognosis monitor of CML and other diseases.

ABSTRACT

Speciation analysis of aluminium in the presented system of HPLC–FAAS hyphenated technique lasts 4 min. Using the bifunctional column in model analysis and using the calculation methods for modelling using the Mineql program enabled the authors to presume that particular forms will be subjected to elution in the following order: (1) AlF_2^+ and AlF_4^-, (2) AlF^{2+} and AlF_3^0 and (3) Al^{3+}. Based on the obtained results for model solutions, the presented method enables the determination of aluminium fluoride complexes and Al^{3+} speciation form. The study compares the tendency of occurrence variability of aluminium fluoride complexes and Al^{3+} form, determined based on the results obtained using the HPLC–FAAS hyphenated technique with the trend defined based on the Mineql program calculation method. The method was successfully applied to soil samples.

1. Introduction

Characterised by high reactivity and amphoteric properties, aluminium in the natural environment shows strong tendency to create complex bonds, both with organic and inorganic ligands. Aluminium complexes with fluorides (AlF_2^+, AlF^{2+}, AlF_3^0, AlF_4^-, AlF_5^{2-}, AlF_6^{3-}) belong to the strongest ones and they significantly influence the increase in solubility of aluminium compounds. According to Martin [1], both elements show strong relationship to one another in forming stable complex compounds. The fraction of monomeric/labile inorganic aluminium responsible for toxic impact of aluminium on particular components of the natural environment consists of a free Al^{3+} ion, bonds of aluminium with fluorides, sulfates and hydroxy groups. Among these, Al^{3+}, $Al(OH)^{2+}$ and $Al(OH)_2^+$ are considered to be the most toxic aluminium forms. Aluminium and fluoride form soluble complexes, mainly AlF^{2+}, AlF_2^+, AlF_3^0, AlF_4^-, both in water and soil. They are less toxic than hydroxy forms and the Al^{3+} form. Stevens et al. [2] observed that the presence of aluminium fluoride complexes defined by the author as $AlF_x^{(3-x)}$ increases phytotoxicity of aluminium. Stevens's research showed that forms such as AlF^{2+} and AlF_2^+ are also toxic, but to a lesser extent than Al^{3+}, $Al(OH)^{2+}$ and $Al(OH)_2^+$ forms [2]. Based on his research, Martin [1] stated that the occurrence of fluorides will reduce the toxicity of Al^{3+} in relation to plants, fish and people. Similarly to Radić and Bralić [3], who relate the occurrence of fluoride and citrate ions in water to the decrease of aluminium toxicity in fish. However, according to Strunecká et al. [4], simultaneous activity of fluorides and aluminium both in water and the food chain, as well as their broad use in industry, medicine and agriculture, contributes to causing various diseases resulting in changes in metabolism, growing processes and homeostasis of living organisms. The negative influence of aluminium and fluorides, considering their ability to form AlF_x complexes, initiated research on the toxicity of these compounds, mainly at the intracellular level [5–8]. Strunecká and Potočka [4,9] showed that it is not only aluminium which is responsible for the Alzheimer disease etiology, which was confirmed in the studies by other authors [10–15]. Pathological changes in brain may also be caused by the aluminium fluoride complexes [9,16]. The increasing acidification of the natural environment and industrial development causes the increase of aluminium concentration in the environment. High aluminium concentration and low pH values are favourable conditions for forming soluble aluminium complexes, including aluminium fluoride complexes. For this reason, quantitative and qualitative determination of aluminium and the Al^{3+} form using speciation analysis is an important analytical task. The use of aluminium, including the aluminium fluoride complexes of chelating reagents [17–21] and ion-exchange resins [17,22–25] along with the following detection techniques: spectrophotometric and fluorometric in the aluminium determinations, does not enable the full separation of inorganic and organic forms of aluminium [26–29]. In order to determine stable AlF_x complexes, Bertsch and Anderson

doi:10.1016/j.talanta.2009.11.018

used the HPLC technique (Dionex CS3 column) with UV detection along with the post-column reaction with Tiron (4,5-dihydroxy-m-benzene disulfonic acid). The determination conditions were used in the model solutions analysis in order to isolate Al^{3+} from fluoride, citrate and oxalate complexes. Forms AlF^{2+} and Al^{3+} were separated [30]. Willet used the CG2 guard column in his research along with post-column reagent PCV (Pyrocatechol Violet) and 1.10-phenanthroline, hydroxylamine. However, despite the quick separation, he did not obtain the full separation between the AlF^{2+} and AlF_2^+ forms [31]. Jones also used in his research the CG2 guard column, thermostated in 50 °C and fluorometric detection with post-column HQS (8-hydroxyquinoline-5-sulfonic acid) condensation in order to directly determine monomeric hydroxy aluminium forms [32]. Willet and Jones did not obtain the separation between the AlF^{2+} and AlF_2^+ forms, which were eluted close to the solvent front. Motellier and Pitsch used the cation CS2 analytical column with CG2 guard column and detection with post-column reaction with 3×10^{-4} M Tiron (4,5-dihdroxy-1,3 benzene disulfonic acid, di sodium salt monohydrate) in 3 M ammonium acetate. They did not get the full separation of AlF^{2+} and AlF_2^+ forms [33]. For speciating Al and its fluoro, oxalate and citrate complexes, Borrmann and Seubert used post-column reaction with Tiron (4,5-dihdroxy-1,3 benzene disulfonic acid, di sodium salt monohydrate) with UV detection and atomic spectrometry ICP-AES (for Al–citrate–oxalate complexes). Depending on the proportion of ligands in model solutions, in the case of Al–F complexes in the amount of 1:1 (Al:F), the obtained signals were related to the following forms: AlF_2^+, AlF^{2+} and Al^{3+} (for UV detection 310 nm following post-column reaction with Tiron) [34]. Previous solutions involved combining HPLC with ICP: mass spectrometry and atomic emission spectrometry (ICP-MS, ICP-AES) in the on-line [27,34–39] and off-line system [40,41] using the atomic absorption spectrometry with electrothermal atomisation as the detector in the off-line system [42,43]. Only the combination of HPLC with flame atomic absorption spectrometry (FAAS) detection enabled the full separation of aluminium fluoride complexes [44]. In the study by Zioła-Frankowska et al. [44], model analyses of synthetic solutions were presented and qualitative analysis of fully separated AlF_2^+, AlF^{2+} and Al^{3+} forms was performed. The use of HPLC and FAAS techniques brings along problems related to the quantitative analysis in order to perform speciation analysis of aluminium fluoride complex and the Al^{3+} form.

The main aims of this study were: (1) investigate qualitative and quantitative analysis of aluminium fluoride complexes and toxic form of aluminium Al^{3+}, (2) investigation of cation and anion forms of aluminium fluoride complexes in model system, (3) application of Mineql program to calculate and modelling occurrence of particular forms of aluminium, (4) evaluation and comparison between results obtained by calculated method with results of model solution from analytical system HPLC–FAAS, and (5) application of new system to speciation analysis of aluminium fluoride complexes and Al^{3+} in soil samples.

2. Materials and methods

2.1. Instrumentation

The chromatographic separation was performed by liquid chromatography system consisting of: Shimadzu solvent delivery module LC-10 ADVP liquid chromatograph (Shimadzu Corporation, Japan) and low pressure gradient flow control valve Shimadzu FCV-10 ALVP (Shimadzu Corporation, Japan), degasser DGU-20A5 (Shimadzu Corporation, Japan), column oven CTO-10ASvp (Shimadzu Corporation, Japan) with Rheodyne Model 7725i Injection Valve (Rheodyne LLC, USA) and with ion-exchange column—Dionex IonPac CS5A (analytical column, 250 mm, 4.0 mm i.d., particle size 9.0 μm, containing mixed anion and cation beds with sulfonic acid and alkanol quaternary ammonium functional groups) (Dionex, USA) and IonPac CG5A (guard column, 50 mm, 4 mm i.d., particle size 9.0 μm) (Dionex, USA). The chromatographic run was gradient at 2 ml min^{-1} with an injection volume of 500 μL. HPLC/IC system was controlled by CBM-20A (Shimadzu Corporation, Japan) communication bus module with LC Solution software. The gradient elution program is shown in Table 1.

Table 1
Gradient elution program with comments.

Time (min)	(A) H_2O	(B) NH_4Cl	Comment
0	100	0	Inject
1.00	100	0	Start linear gradient
1.30	0	100	Increase in eluent strength
1.30	0	100	Burner turn on
2.00	0	100	Return to initial conditions
2.01	100	0	Flame stabilization
2.30	100	0	Data collecting (value 0 on chromatograms)
4.00	100	0	Data collected (90 s)
4.00	100	0	Burner turn off

The species of aluminium were determined by the technique of atomic absorption spectrometry with acetylene–nitrous oxide flame atomisation (F-AAS) with the use of a SpectraAA 280FS spectrometer (Varian, Australia) with flame atomisation. Data capturing and peak analysis were performed with the use of Spectraa software ver. 5.1 pro (Varian, Australia). The analytical chromatographic column was directly connected to the nebulizer system simultaneously working type of atomic absorption spectrometer.

2.2. Reagents

All chemicals used were of high-purity grade. Deionised water from Milli-Q RG water unit (Millipore, France) was used for dilution of stock solutions as well as for any reagent preparation. All stock solutions of aluminium were obtained by dissolving standard solution 1000 mg L^{-1} from Merck (Darmstadt, Germany). Stock standard solutions of fluorine 1000 mg L^{-1} were prepared from Merck (Darmstadt, Germany). Working solutions were prepared daily just before measurements by appropriate dilution. The eluent used for gradient elution consisted of A: deionised water, B: ammonium chloride (1.8 M pH about 3). The eluent was made by dissolving a weighted portion of NH_4Cl (Merck, Darmstadt, Germany) in deionised water and finally diluted to 1000 ml by deionised water. The solution of NH_4Cl was acidified by 1 mM hydrochloric acid (Merck, Darmstadt, Germany) to pH about 3 in a volumetric flask. A series of standards mixtures of Al–F were prepared by the appropriate dilution of solutions containing aluminium and fluoride ions in various concentrations.

2.3. Modelling by Mineql 4.5+

The program for chemical modelling of the environment, Mineql 4.5+ (ERS, USA), was used to model and simulate the conditions in model solutions and in real samples. The program settings were as follows: for model solutions Al:F only the concentration of Al (1.85e-04, 9.27e-04, 1.85e-03, 2.78e-03 and 3.71e-03 M) and F (2.63e-04, 1.32e-03, 2.63e-03, 3.95e-03 and 5.26e-03 M) was taken into account, concentration of [H+] was 10^{-3}, temperature 25 °C, ionic strength correction was off.

3. Results and discussion

3.1. Results of model solution obtained by HPLC–FAAS hyphenated technique

Reaching the aims of the study involved preparing a series of model solutions with the concentration proportions Al:F in all possible combinations for Al (1.85e-04, 9.27e-04, 1.85e-03, 2.78e-03 and 3.71e-03 M) and F (2.63e-04, 1.32e-03, 2.63e-03, 3.95e-03 and 5.26e-03 M). The solutions analysis was performed in the system of HPLC–FAAS hyphenated technique. The speciation aluminium forms, separated in the chromatographic column, were directed to the flame atomic absorption nebulizer. Fig. 1 presents the obtained results in the form of overlapping chromatograms for a given stable concentration of aluminium and variable concentration of fluorides.

Based on the results obtained from the HPLC–FAAS system, the qualitative analysis is possible in the first place. On the other hand, the quantitative analysis is a more difficult task. The spectrometers and software available on the market produce certain limitations in terms of too short signal integration time, which is not long enough to perform a full analysis in the system using the said separation technique. The additional difficulty is the lack of possibility to calculate the surface area under particular analytical signals obtained under the peaks. The Spectraa (Varian, Australia) software was used in the research. The software enables obtaining the value repetitiveness and the continuity of signal counting, in spite of the short signal counting time: 30 s. The signal was received within 3× 30 s in one sequence (90 s). Based on the chromatograms obtained from the Spectraa software, absorbance values were counted manually every 0.5 s and recorded in a text file (*.txt). The text values were next deleted from the text file and moved to the Excel program, into the previously prepared columns with the values of time and absorbance respectively. The *.xls file prepared in this way for each signal separately was then imported to the Grapher program, where a typical linear diagram (time/absorbance) was drawn. Based on the diagram, using the calculate area function, the area under a peak was calculated. The surface area under particular signals was calculated for all model solutions and all data were collected for quantitative analysis. Qualitative analysis was initially based on literature data [33,37,44–50] and the property of the mixture components separation according to increasing charge of these forms. It was assumed that the first component (aluminium form) subject to elution was form AlF_2^+, then AlF^{2+} and finally Al^{3+}. The occurrence of a given form in the investigated model solutions at the constant aluminium concentration was dependent on the changing concentration of F^- ions. However, the research focused on the column type. The use of the bifunctional column poses a problem connected with the interpretation difficulties in relation to the obtained results in the case of aluminium fluoride complexes. In order to verify the speciation aluminium forms, which may be subject to elution (AlF_2^+, then AlF^{2+} and finally Al^{3+}), a simulation using the Mineql 4.5+ program was performed for the particular model solutions.

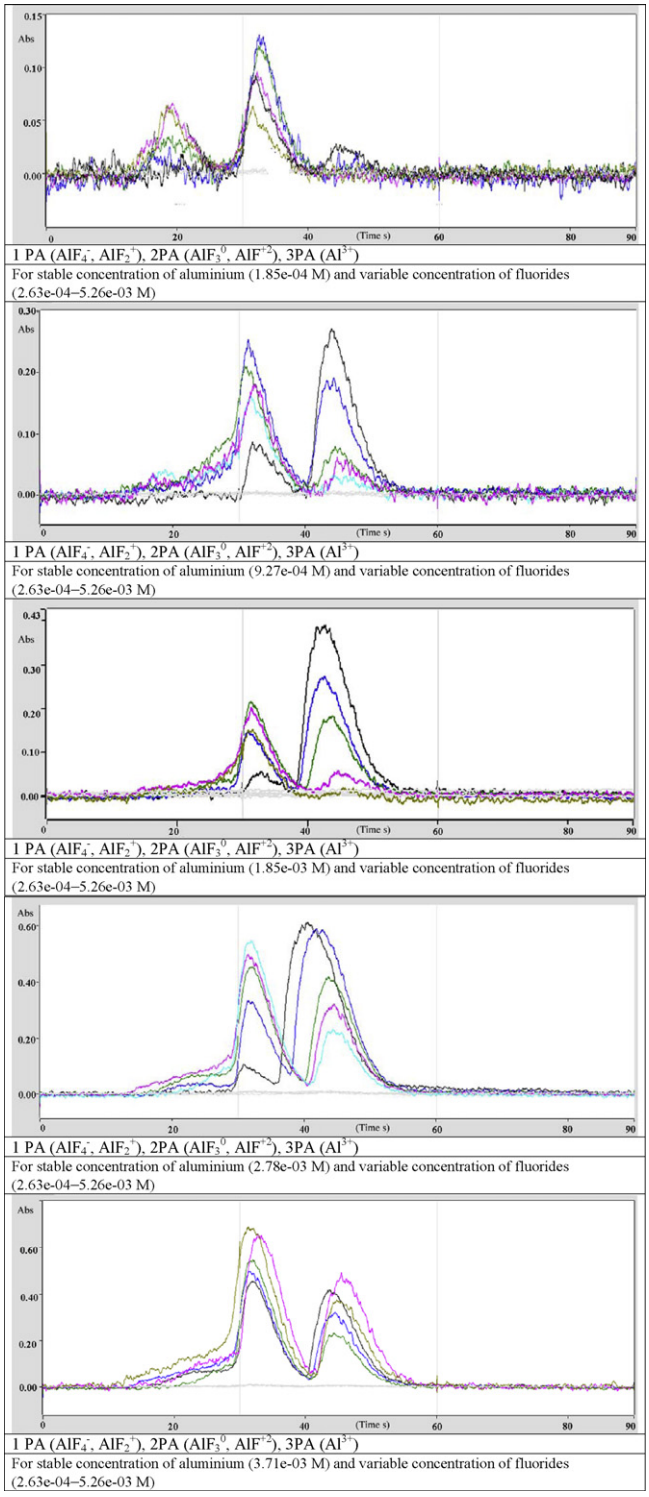

Fig. 1. Results in the form of overlapping chromatograms for a given stable concentration of aluminium and variable concentration of fluorides.

3.2. Results from Mineql+

The model analyses took into consideration both cation and anion forms of aluminium fluoride complexes: AlF_2^+, AlF^{2+}, AlF_3^0, AlF_4^-, and Al^{3+}. The obtained results were presented as the percentage participation of a given form [%], as a occurrence variability of these forms in relation to the variable concentration of aluminium and fluorides (Fig. 2).

Based on the obtained results it was observed that when the molar ratio Al/F is ≥0.7, three main forms of aluminium are formed: AlF_2^+ and AlF^{2+}, Al^{3+}. For the molar ratio Al/F = 0.01, these forms occur in the order according to the [%] concentration $AlF^{2+} > Al^{3+} > AlF_2^+$. On the other hand, for the concentration of Al/F = 0.003, Al^{3+} is the dominating form, and then $AlF^{2+} > AlF_2^+$. At the fluoride concentration higher than the aluminium concentration, AlF_3^0 forms and anion AlF_4^- form also begin to be formed. When the molar ratio Al/F = 0.035, AlF_3^0, AlF_4^- and AlF_2^+ forms are formed. The occurrence of these forms, when Al/F = 0.035, changes from $AlF_3^0 > AlF_4^- > AlF_2^+$ to $AlF_2^+ > (AlF^{2+}) > AlF_3^0 > AlF_4^-$

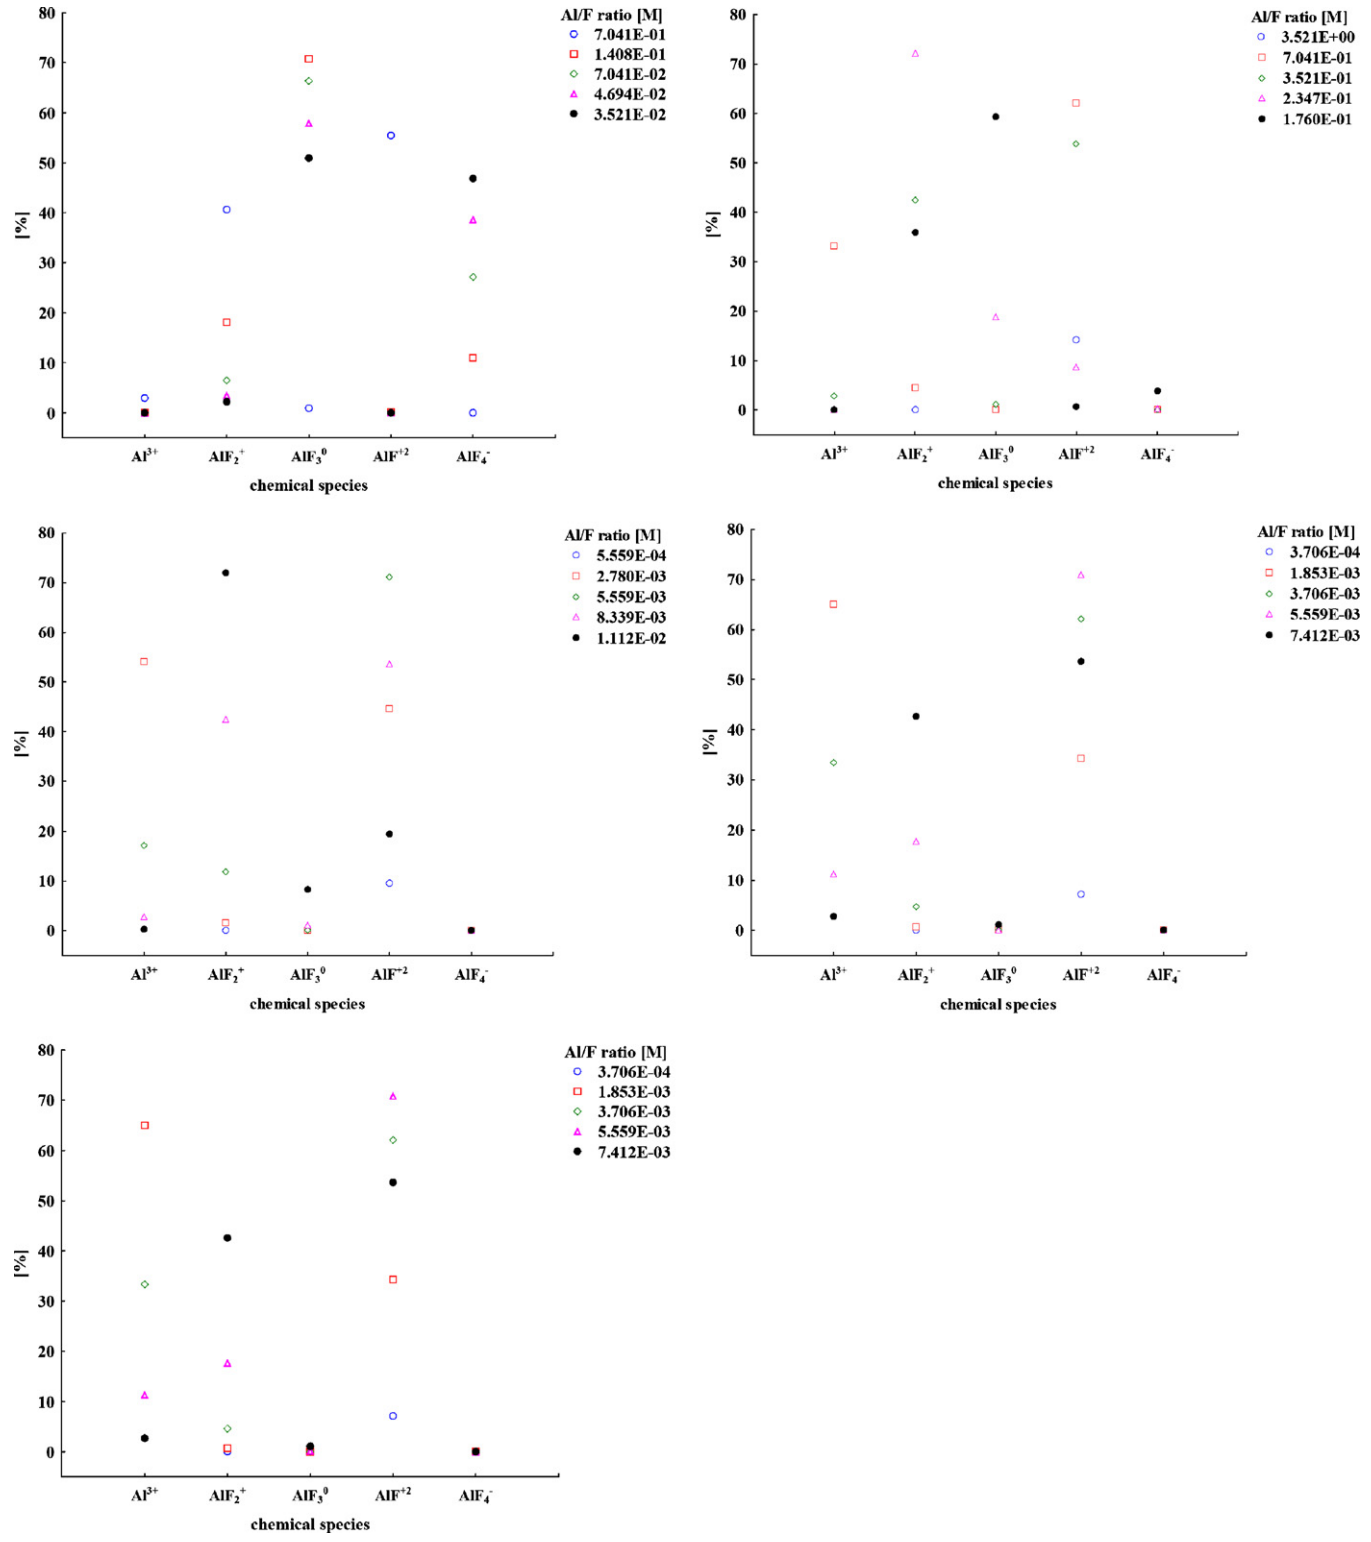

Fig. 2. Data obtained by Mineql program (all aluminium fluoride complexes and Al^{3+}).

when the proportion of molar ratio Al/F = 0.14. At the concentration value of Al/F = 0.14, strong formation of the AlF^{2+} form was observed. It should be underlined that in the case of bifunctional column one should expect such forms as: AlF_2^+, AlF^{2+}, AlF_3^0, AlF_4^-, Al^{3+}. The sequence of the particular signals was assumed based on the literature data and on the basis of the Mineql program calculations (Table 2).

Table 2
Proposed elution sequence forms: AlF_2^+, AlF^{2+}, AlF_3^0, AlF_4^-, Al^{3+}.

1PA—first signal AlF_2^+ and/or AlF_4^-	2PA—second signal AlF^{2+} and/or AlF_3^0	3PA—third signal Al^{3+}

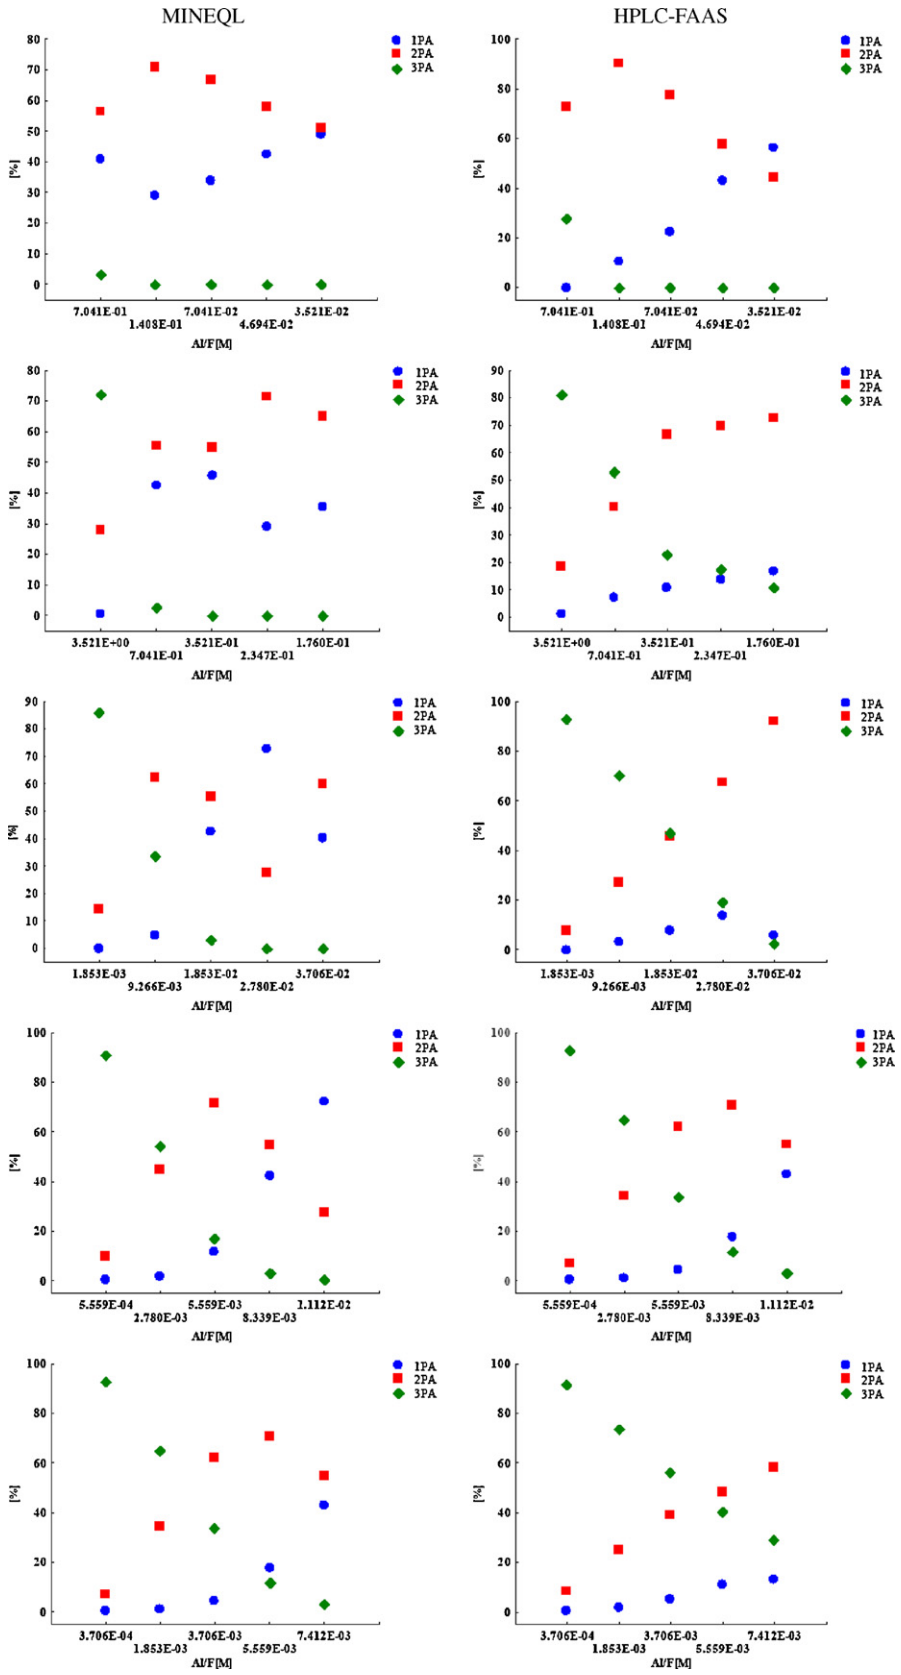

Fig. 3. Results obtained by Mineql program and by a new method of HPLC–FAAS hyphenated technique.

Then, in order to compare the results obtained from the Mineql program and the HPLC–FAAS system, the 1PA (AlF_2^+ and/or AlF_4^-), 2PA (AlF^{2+} and/or AlF_3^0), 3PA(Al^{3+}) forms were added respectively for better visualisation of the results (Fig. 3).

The results obtained for the model solutions in the HPLC–FAAS system and from the Mineql program calculations show significant similarity. For the diagrams (Mineql) with constant concentration of aluminium (1.85e-04 M) and variable concentration of fluorides (2.63e-04–5.26e-03 M), one can observe the participation shift towards the AlF^{2+} and/or AlF_3^0 (2PA) complex forms in relation to AlF_2^+ and/or AlF_4^- (1PA) at the decreasing fluoride concentration. On the other hand, together with the increasing concentration of fluorides, the balance shift towards the 1PA forms was observed. A similar tendency between the 1PA, 2PA and 3PA forms was observed for the HPLC–FAAS, 1.85e-04 M Al system results. It should be underlined that in the case of 1PA results for model solutions, % participation was much lower than for the Mineql results, and the 2PA and 3PA results stayed at the similar % level. The % increase to Al^{3+} of both 1PA and 2PA forms participation was observed, along with the increasing level of fluorides. In the case of the results obtained in model solutions, a similar tendency for 2PA forms was observed. A lower % participation for the 1PA form was recorded at a higher % participation of the Al^{3+} form. A growth tendency in 1PA of up to molar ratio 0.03 was observed at the aluminium concentration of 1.85e-03 M for the Mineql results. The similar tendency occurred in model solutions. In the case of 2PA this tendency is differential, in contrast with the HPLC–FAAS system results, where the proportional % increase was observed. Although the % participation of the Al^{3+} form in model solutions is higher, the 3PA in both cases show a similar tendency. In the solutions of aluminium concentration of 2.78e-03 and 3.71e-03 M, the distribution tendency of particular 1PA, 2PA, 3PA forms is similar. The differences between the Mineql and HPLC–FAAS results are related to the % participation, especially in the 1PA form (the values are lower) and 3PA (the values are higher). In the case of Al^{3+} form, the results obtained through the Mineql calculation method are lower in comparison with those obtained for model solutions, which in consequence explains the lower concentration of the AlF_2^+ and AlF_4^- forms. Moreover this difference can be connected with partly disintegrated during the chromatographic process [30,34–36].

3.3. Application to environmental samples

The environmental samples were taken in the area of Chemical Plants situated in Luboń (Poland). The soil samples of surface layer (0–1 m) were collected in two places located in the area of Chemical Plants (S1: N 521932.3 E 165344.6; S2: N 521932.7 E 165347.0). The samples lithology was medium sand. The research material was collected in polyethylene bags. Samples were dried at room temperature. The hygroscopic water and the substances dissolved in it were treated as an integral component of the sample. After drying a sample was passed through sieves with mesh sizes of 2.0, 1.0, 0.5, 0.25, 0.1, and 0.063 mm, according to the Polish Norms PN-ISO 565:2000 and PN-ISO 3310-1:2000, using a sieve shaker LAB-11-200/UP (EKO-LAB, Brzesko, Poland). Grain size fraction 0.125–0.25 mm was dominating and this fraction was used to prepare soil water extracts. In order to isolate the most environmentally available fraction, 5 g of a sample was collected and extracted in 50 ml of deionised water (1:10) for 1 h using a magnetic stirrer. The samples were then centrifugated (4000 rpm) for 15 min. The solution was decanted in 50 ml volumetric flasks. The pH H_2O determinations were performed in water extracts prepared for the HPLC–FAAS analysis using the ProfiLine Multi 197i (WTW, Germany) meter with Blueline pH electrode (Schott, UK). Furthermore, determinations of fluorides using an ion selective fluoride electrode (Orion, USA) were conducted. Aluminium water soluble

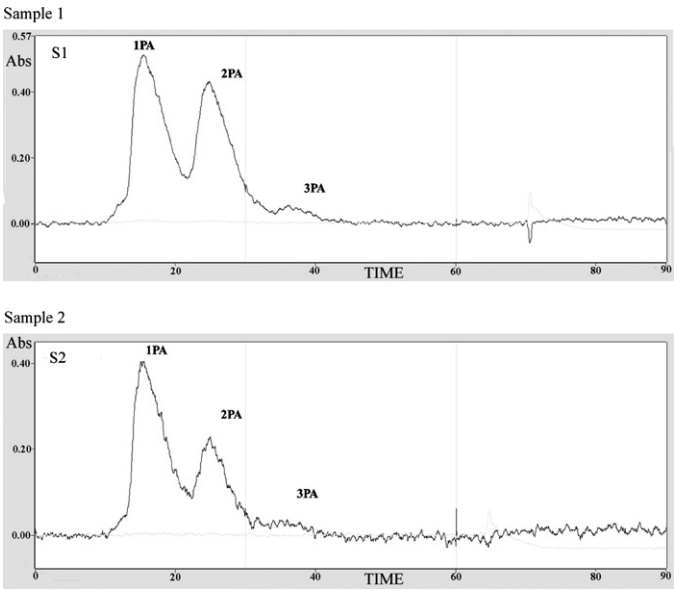

Fig. 4. Chromatograms obtained by HPLC–FAAS system in speciation analysis of aluminium in soil water extracts.

fraction determinations were performed directly in the solutions using the FAAS technique (Fig. 4).

Total concentration of aluminium and fluorides was: for S1 (Al = 458 mg kg^{-1} and F = 1325 mg kg^{-1}) for S2 (Al = 828 mg kg^{-1} and F = 2260 mg kg^{-1}). The reaction values were 3.81 and 4.08 respectively. Calculated values of aluminium fluoride complexes and Al^{3+} were compared between Mineql program and results obtained by HPLC–FAAS system. For S1 and S2 we obtained results for real samples S1: 231, 206, 20.9 and S2: 517, 258, 52.8 mg kg^{-1} for 1PA (AlF_2^+ and/or AlF_4^-), 2PA (AlF^{2+} and/or AlF_3^0) and 3PA (Al^{3+}) respectively. For results obtained by Mineql program S1: 334, 125, <0.05 and S2: 587, 241 and <0.05 mg kg^{-1} respectively.

4. Conclusions

The determination method of inorganic aluminium forms in the HPLC–FAAS hyphenated techniques system is a new solution in the analysis of this element. The use of the IonPac CS5A bifunctional column enabled the isolation of both anion and cation bonds this element forms with fluorides (AlF_2^+, AlF_4^-, AlF^{2+}, AlF_3^0), as well as the Al^{3+} form. Based on the modelling performed using the Mineql program, three groups of eluting components/forms were isolated in the following order: AlF_2^+ and AlF_4^-, AlF^{2+} and AlF_3^0, and Al^{3+}. It should be underlined that the method enables obtaining the most toxic aluminium form Al^{3+} as a single analytical signal. Moreover, the presented method enables both qualitative and quantitative determination of the Al^{3+} form and aluminium fluoride complexes (4 min). In addition, the analytical system in the presented method of aluminium determination operates in the on-line mode and it is not necessary to use derivatization reagents. The result analysis for model solutions along with the use of the supplementary tool (Mineql) to interpret the participation of the particular forms, showed the domination of the aluminium fluoride complexes in comparison to the Al^{3+} form, along with the increase in fluoride concentration. The participation of the Al^{3+} form was significantly reduced at the high concentrations of fluorides. It should be underlined that the analysis of the results obtained both from the Mineql program and the one performed for the model solutions using the HPLC–FAAS hyphenated technique, showed similarities in the occurrence variability tendency between the analysed aluminium forms. The quantitative analy-

sis of model solutions performed using both methods (HPLC–FAAS and Mineql), indicates higher concentration of the Al^{3+} form and lower concentration of AlF_2^+ and AlF_4^- forms. The suggested system of HPLC–FAAS hyphenated technique was successfully applied to speciation analysis of soil water extract.

Bismuth
On-line preconcentration
Lewatit TP-207

ABSTRACT

An on-line preconcentration procedure for the determination of bismuth by flame atomic absorption spectrometry (FAAS) has been described. Lewatit TP-207 chelating resin, including iminodiacetate group, packed in a minicolumn was used as adsorbent material. Bi(III) was sorbed on the chelating resin, from which it could be eluted with 3 mol L^{-1} HNO_3 and then introduced directly to the nebulizer-burner system of FAAS. Best preconcentration conditions were established by testing different resin quantities, acidity of sample, types of eluent, sample and eluent solution volumes, adsorption and elution flow rates, and effect of interfering ions. The detection limit of the method was 2.75 μg L^{-1} while the relative standard deviation was 3.0% for 0.4 μg mL^{-1} Bi(III) concentration. The developed method has been applied successfully to the determination of bismuth in pharmaceutical cream, standard reference materials and various natural water samples with satisfactory results.

1. Introduction

Determination of bismuth is important in environmental chemistry, cosmetic industry, medicine, semiconductors, alloys, metallurgical additives, recycling of uranium nuclear fuels and fabrication of catalysts. Since the use of bismuth and its compounds in different areas of life increased and this element started to be considered toxic for humans, animals and plants [1–3]. Although intestinal absorption of bismuth is limited in humans, because of its low solubility and its propensity to form insoluble oxychloride salts, some absorption must occur to produce measurable concentrations in body fluids and tissues [4]. As the use of bismuth in medicine increases, it has spread in the environment and the chance of exposure of organisms to bismuth has increased. A number of toxic effects in humans have been attributed to bismuth compounds [5–7]. Therefore, new methods are required for the low cost and rapid determination of Bi(III) in the pharmaceutical manufacture and quality control process. Cui et al. have proposed a new method for the determination of bismuth in pharmaceutical products using methyltriphenylphosphonium bromide as a molecular probe by resonance light scattering technique [8].

Several methods have been reported for the determination of Bi(III) in rock, water, alloy and biological samples. Some spectrophotometric methods have been applied for the determination of bismuth [9–11]. The extraction, in the presence of masking agents, with dithizone in chloroform or carbon tetrachloride is a selective spectrophotometric method for separating traces of bismuth [9]. 2,6-Dichloroarsenazo as chromogenic reagent has been used by Zhang et al. in the spectrophotometric determination of bismuth, in aqueous 0.6 mol L^{-1} $HClO_4$ solution, forming a deep blue complex with a maximum absorption at 631 nm [10]. Also, Hoshi et al. have used thiourea as a complexing agent in the spectrophotometric determination of bismuth after collection and elution of Bi(III) –thiourea complex on chitin [11]. Tzanavaras et al. reported a spectrophotometric method for the determination of bismuth in pharmaceutical products using sequential injection analysis [12]. Methylthymol blue (MTB) was used as a color forming reagent and the absorbance of the Bi(III)–MTB complex was monitored at 548 nm. On the other hand, hydride generation atomic absorption spectrometry (HG-AAS) [2,3,13], hydride generation inductively coupled plasma atomic emission spectrometry (HG-ICP-AES) [14], electrothermal vaporization ICP mass spectrometry (ETV-ICP-MS) [15], potentiometric stripping analysis (PSA) [16], anodic [17,18] and cathodic [19] stripping voltametry have also been applied in determination of bismuth in various samples. In another work made by Wang et al., the preconcentration and voltammetric behavior of Bi on a sodium humate modified carbon paste electrode were studied using cyclic voltammetry and differential pulse stripping voltammetry for the determination of bismuth in medicine for stomach [18].

Conventional off-line preconcentration procedures, although effective, are usually time consuming and tedious, require large quantities of sample and reagents, in consequence are vulnerable to contamination and analyte losses. Flow injection (FI) methods

doi:10.1016/j.talanta.2009.11.019

provide an opportunity to avoid contamination and large reagent consumption by working with closed systems. In addition, on-line systems are excellent tools for solution management, allowing the easy implementation of different steps required for selectivity and/or sensitivity enhancement. On-line methods offer higher sample throughput and better precision and accuracy compared to off-line methods. In most on-line FAAS methods, the carrier and reagent solutions are continuously fed to the flow system, mixed on-line and passed through the microcolumns prior to detection [20,21].

In the present paper, we have evaluated a new on-line system with a home-made controller having five independent channels for preconcentration and determination of Bi(III) species. Because the studies made on determination of bismuth in various matrices are insufficient in the literature, especially using on-line systems with FAAS. For this purpose, Lewatit TP-207 resin was firstly used for the on-line determination of Bi(III) ions. According to our knowledge, an on-line preconcentration system (home-made) has not been used before in the determination of Bi(III) by FAAS.

2. Experimental

2.1. Instrument

A Perkin Elmer (Norwalk, CT, USA) model AAnalyst 800 flame atomic absorption spectrometer equipped with a deuterium background correction system and an air-acetylene burner was used for the determination of bismuth. The wavelength used for bismuth was 223.1 nm. Spectral bandwidth of 0.2 nm, acetylene flow rate of 1.4 L min^{-1}, and nebulizer flow rate of 10.0 mL min^{-1} were conventional working parameters. During the signal measurements, the integration time was 0.1 s.

The flow system comprises a peristaltic pump with variable speed (Watson-Marlow Inc., Wilmington, MA, USA), a multichannel peristaltic pump (Ismatec SA, Glattbrugg, Switzerland) furnished with silicone tubes to deliver all solutions, and two three-way valves (Cole-Parmer Inc. Co., IL, USA) to select solution ways. Peristaltic pumps (PP) and valves (V) were controlled by the five-channel controller and each channel can be set for 36 different timing periods with thumble switches. This unit was constructed in our instrumentation laboratory (at low cost). The flow system was made using fittings, unions and tees made of plastic and high density polyethylene (HDPE) materials. Lewatit TP-207, a weakly acidic, macroporous-type ion exchange resin with chelating iminodiacetate groups packed into a home-made minicolumn (glass, 3.5 cm length and 0.3 cm i.d.) was used for the on-line preconcentration of the bismuth(III) ions.

2.2. Reagents and standard solutions

All the chemicals were of analytical reagent grade and provided by Merck (Darmstadt, Germany). Deionized ultra pure water was used for the preparation of the solutions. 1000 μg mL^{-1} Bi(III) was prepared by dissolving 0.2321 g of $Bi(NO_3)_3{\cdot}5H_2O$ in a 100 mL volumetric flask using 3 mol L^{-1} HNO_3 to prevent hydrolysis of the Bi(III) ions. Dilute working solutions were prepared by appropriate dilutions of the stock solution of Bi(III) with 0.1 mol L^{-1} HNO_3 just before use [12,22]. Nitric acid was also used to adjust the acidity of the solutions and used as eluent throughout the experiments.

Lewatit TP-207 resin with iminodiacetate group was used (Fluka, Buchs, Switzerland) as the solid phase extractant. In order to remove organic and inorganic contaminants, the resin was washed with distilled water, 1 mol L^{-1} HNO_3 in acetone and distilled water, respectively. The glassware used was cleaned by soaking overnight in dilute HNO_3 (1:5, v/v), and then rinsed with distilled water several times.

2.3. Preparation of the minicolumn

The minicolumn was prepared by introducing 135 mg of the chelating resin, as a slurry of the polymer beads using a syringe. The ends of the column were fitted with glass wool to retain the packing material. Before use, ethanol, acetone, 5% (w/v) nitric acid solution and deionized water were passed through the column at a flow rate of 3.0 mL min^{-1} in order to clean it. The resin bed was approximately 3.5 cm length. The packed column was washed with blank solutions to condition the Lewatit TP-207 resin. After each elution, it was automatically pre-treated with deionized water and buffer solution, respectively.

2.4. On-line preconcentration system

The performance of the on-line preconcentration method was tested with model solutions before its application to the samples. The schematic diagram of the programmable on-line system was illustrated in Fig. 1. In the preconcentration step, PP1 and V1 are active while PP2 and V2 are inactive, and the sample and/or standard solutions acidified properly with 0.1 mol L^{-1} HNO_3 were continuously passed through the minicolumn (MC) for 3.4 min at a flow rate of 7 mL min^{-1}. The bismuth was retained on the minicolumn while the effluent was sent to waste. Afterwards, the minicolumn was washed with water in order to remove matrix ions from the resin. At this period, PP1 and V2 are active while PP2 and V1 are inactive. Finally, in the elution step; the eluent (E), 3 mol L^{-1} HNO_3, was aspirated by the PP2 at a flow rate of 7.2 mL min^{-1}. During the elution, PP1 is inactive. The released metal ions are directly

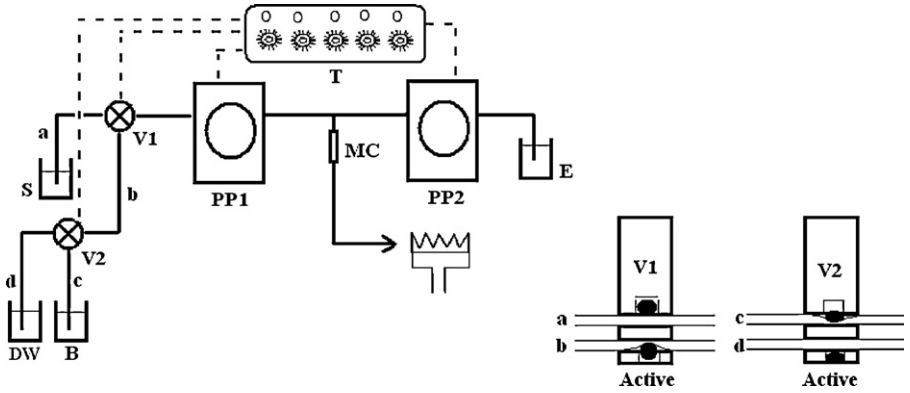

Fig. 1. Schematic diagram of on-line preconcentration system (V1: valve 1, V2: valve 2, PP: peristaltic pump, E: eluent, MC: minicolumn, T: timer, and a–d: solution ways; S: sample, B: buffer, and DW: deionized water).

transported into the nebulizer of the spectrometer. The signals were measured in the peak height mode (or maximum absorbance) using the instrument software. In the following step, the minicolumn was washed with water (PP1 and V2 are active, PP2 and V1 are inactive) to clean the resin. Afterwards, the buffer solution was pumped to the column to condition it before a new preconcentration cycle. During this period, PP1 was active while PP2, V1 and V2 were inactive. Calibration curve was linear for Bi(III) concentrations in the range of 0.1–1.0 μg mL^{-1}, with a correlation coefficient of 0.9996. Real sample solutions were similarly subjected to the on-line procencentration procedure as described above.

2.5. Application of the proposed method

The proposed method was successfully applied to the on-line determination of Bi(III) in tap water, waste water (Kayseri) and dam water samples (Seyhan Dam, Adana), which were collected in polyethylene bottles prewashed before. Tap water samples were taken from our research laboratory and analysed without pre-treatment. The other water samples were filtered through a cellulose membrane filter of 0.45 μm pore size (Millipore Co., MA, USA). 10 mL of concentrated HNO_3 (65%, w/w) and 5 mL of concentrated H_2O_2 (30%, w/w) were added to 100 mL of water samples and then evaporated near to dryness. The final volume was completed to 100 mL with 0.1 mol L^{-1} HNO_3 and the proposed procedure was applied to these sample solutions. Analyses for blank samples were carried out in the same way. Then the on-line preconcentration procedure given above was applied to the samples. The determination of Bi(III) ions in the final solutions was performed by FAAS.

The procedure was also applied for pharmaceutical cream samples. For this purpose, 10 mg of the samples were taken into 100 mL of beakers. The samples were dissolved with 5 mL of HNO_3 (65%, w/w) and evaporated near to dryness on a hot plate in hood. Then 2 mL of concentrated $HClO_4$ was added to the residue and the beakers were covered with glass watches. After the evaporation, the cooled residue was dissolved and made up to 100 mL with 0.1 mol L^{-1} HNO_3 solution. The proposed procedure given above was applied to these sample solutions. Blank analyses were carried out in the same way without the cream samples.

In order to ascertain the validation of the proposed procedure, the method was applied for the analysis of Bi(III) ions in two certified reference materials (TMDA-64 lake water and CWW TMD waste water). 100 mL portions of TMDA-64 lake water and CWW TMD waste water were previously treated with a mixture of 10 mL of HNO_3 (65%, w/w) and 5 mL of H_2O_2 (30%, w/w) and the procedures applied were similar to the preparation of water samples. Then the on-line preconcentration procedure was applied to the samples.

3. Results and discussion

The optimised chemical and hydrodynamic conditions in the flow system were determined by using a solution involving 0.5 μg mL^{-1} bismuth and the preconcentration procedure was applied to the aqueous sample solutions.

3.1. Effect of acidity on preconcentration

In order to evaluate the effect of acidity on the retention of the analyte ions, sample solutions were acidified from 0.025 to 0.5 mol L^{-1} with HNO_3, HCl and H_2SO_4, and processed according to the recommended procedure. The decrease in absorbance at acidity level lower than 0.01 mol L^{-1} HNO_3, is due to the hydrolysis of Bi(III) ions [7]. It is well known that, Bi(III) can only exist in very acidic media and it is hydrolyzed to $BiOH^{2+}$ or BiO^{+} at ≤0.1 mol L^{-1} acidic media. At these media, even insoluble compounds such as

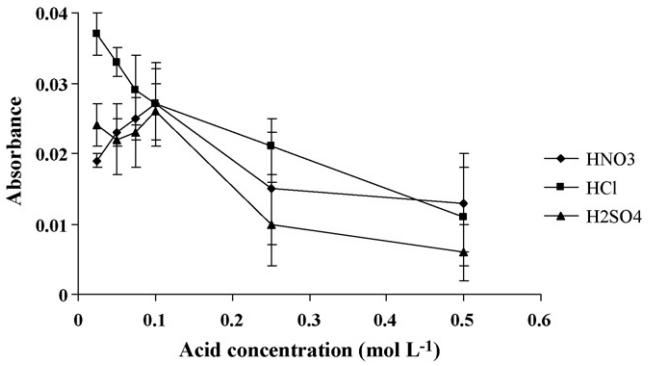

Fig. 2. Effect of acidity on the recovery of bismuth.

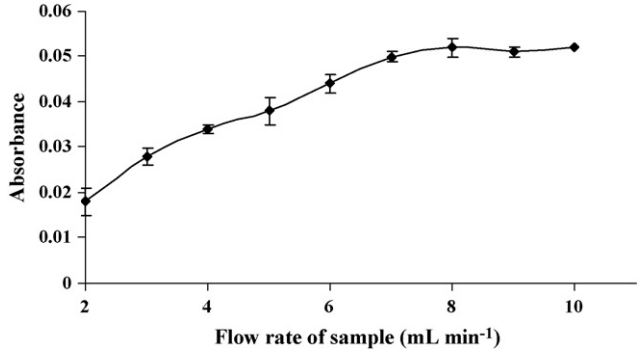

Fig. 3. Effect of sample flow rate on Bi(III) signals.

BiOCl or $BiONO_3$ could be formed [9]. These solutions were pumped through the minicolumn packed with the resin for a loading time of 3.4 min. Subsequently, the retained bismuth ions were eluted with 3.0 mol L^{-1} HNO_3 and then introduced to the nebulizer of FAAS. The corrected absorbances for bismuth as a function of the acidity are shown in Fig. 2. In the light of these results, the optimum acidity of the medium for the determination of Bi(III) was chosen 0.1 mol L^{-1} HNO_3 [7].

3.2. Flow rates of sample and elution solutions

The sample flow rate is an important parameter in on-line systems because it affects the retention of the cation on the minicolumn. At high flow rates of sample, metal ions could probably not equilibrate properly with the resin due to the increase in the velocity of the ions, which reduces the contact time between the two phases. In contrast, low flow rates decrease the sample throughput, resulting in long analysis times. For this reason, the effect of

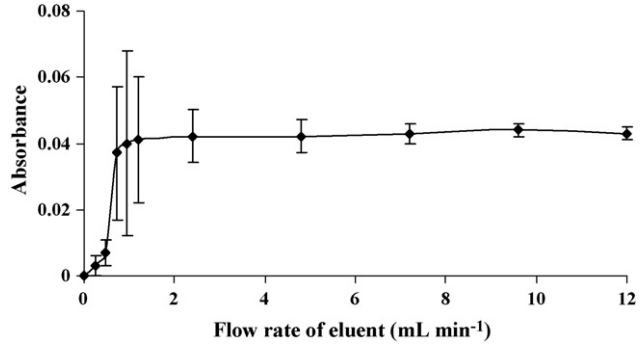

Fig. 4. Effect of eluent flow rate on Bi(III) signals.

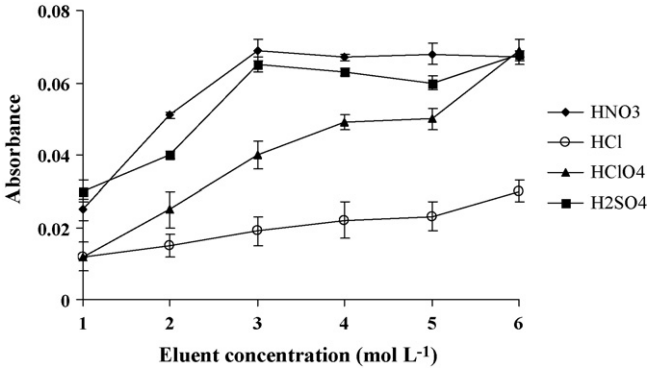

Fig. 5. Effect of eluent type and concentration on Bi(III) signals.

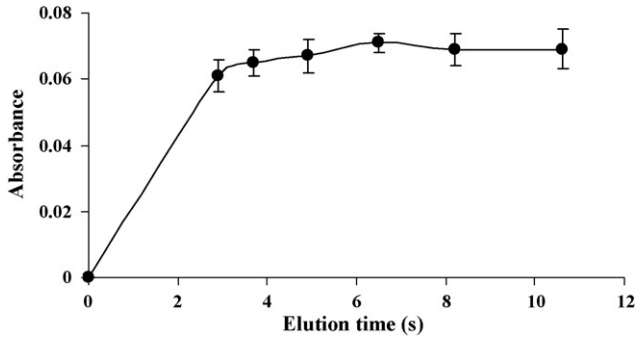

Fig. 6. Effect of elution time on Bi(III) signals.

sample flow rate on the sorption of bismuth was investigated. The results are illustrated in Fig. 3. The sample flow rate was nearly constant over 7 mL min^{-1}. Consequently, the optimum flow rate of sample was chosen to be 7 mL min^{-1} in subsequent experiments as a compromise between efficiency and stability.

The eluent flow rate is an important parameter for stripping the analytes off the column. In order to get an analytical signal as high as possible, the eluent flow rates were scanned. The scanning was carried out from 0.25 to 12 mL min^{-1}. The fluctuations of the analytical signal were too high at the eluent flow rates below the 5 mL min^{-1}, i.e., the repeatability decreased considerably resulting in broader and splitted peaks. This probably is due to an incompatibility between elution and nebulization flow rates, which causes significant dispersion when the eluent flow rate is smaller than the nebulizer flow rates. The optimum flow rate was selected to be 7.2 mL min^{-1}, corresponding to a certain rpm rate of the pump, for subsequent studies in order to match the elution and the nebulization flow rates. The results are shown in Fig. 4.

Table 1
Maximum tolerable quantities of foreign ions in the determination of 0.5 μg mL^{-1} Bi(III) using the on-line preconcentration system.

Ions	Added as	Tolerable concentration (mg L^{-1})	Recovery (%)
Na^+	$NaNO_3$	25,000	98 ± 1

Sample	Bi content (μg g^{-1})	Found (μg g^{-1})	RSD (%)
Cream 1	265	210 ± 9[a]	4.2
Cream 2	106	120 ± 4	3.0

[a] At 95% confidence level (mean ± $ts/\sqrt{N}$).

3.3. Effects of eluent type and elution time

The desorption of the retained bismuth ions from the minicolumn was tested using HCl, HNO_3, H_2SO_4, and $HClO_4$ solutions. The results obtained are shown in Fig. 5, from which it is clear that 3 mol L^{-1} HNO_3 solution is the best eluent. Increasing of HNO_3 concentration from 3 to 6 mol L^{-1} did not give any improvement on the bismuth signals. Therefore, 3 mol L^{-1} HNO_3 was chosen as eluent for stripping off Bi(III) from the column in subsequent experiments.

The elution time is important for quantitative recovery of the analyte. For that reason, the effect of the elution time was studied. When the elution time is taken short, the elution volume will be small. In this case, the analytical signals will also be low due to the insufficient elution of the retained Bi(III) ions. The influence of this parameter on the analytical signals of bismuth is shown in Fig. 6. The optimum elution time for quantitative recovery of bismuth ions was 6.5 s at the optimum speed of the peristaltic pump.

3.4. Sorption capacity of the resin

The sorption capacity of the resin for the analyte ions was determined through the recommended procedure by equilibrating 135 mg of the resin with 0.1–20 μg mL^{-1} Bi(III) in 0.1 mol L^{-1} HNO_3 medium. The resin capacity was found to be 2.6 mg Bi(III) per gram resin.

3.5. Analytical figures of merit

The characteristic data for the performance of the on-line preconcentration system under the optimum conditions were studied. Linear regression equations were obtained for calibration curve, i.e.,

$A = 0.00024 + 0.13 \times C$, where A is the absorbance and C is the Bi(III) concentration in the standard solution.

Enrichment factor was found to be 20. The detection limit as the concentration that gives a response equivalent to three times the standard deviation for the blank solutions ($n = 21$) was 2.75 $\mu g\,L^{-1}$. The precision (relative standard deviation, R.S.D.) was 3.0%, for the concentration of 0.4 $\mu g\,mL^{-1}$ Bi(III).

3.6. Effect of foreign ions

The effect of interferences on the determination of bismuth was investigated using the optimized on-line preconcentration system. Metal ions were added individually to model solutions containing 0.5 $\mu g\,mL^{-1}$ Bi(III) and then the proposed procedure was applied. The effect of each species was considered as interference when the analytical signal in the presence of the species resulted in an absorbance deviation of more than ±5%. The results are shown in Table 1. The results indicate that various substances commonly present in water and/or wastewater samples do not interfere in the analysis of bismuth(III) under the experimental conditions.

3.7. Accuracy of the method

The accuracy of the developed method was tested by measuring the bismuth content in the two certified reference materials (TMDA-64 lake water and CWW-TM-D waste water). The samples were digested using the procedure described in Section 2.5. The bismuth contents established with the present procedure agreed very well with the certified values (Table 2). The results indicate that the developed procedure can be applied to the determination of bismuth in the reference water samples being free from interference.

3.8. Application of the proposed procedure

The method was extended for the on-line determination of Bi(III) in various pharmaceutical cream samples. Preparation of the pharmaceutical cream samples to analysis was performed as described above in Section 2.5. The results are shown in Table 3.

The proposed method was applied to the analysis of various water samples, with satisfactory results for bismuth. The concentration of bismuth could not be determined due to its very low concentration. The recoveries for the additions of 0.5 $\mu g\,mL^{-1}$ Bi(III) varied from 96% to 102% (see Table 4). These results prove the validity of the proposed method. There was a good agreement between the added and the recovered amounts of the analyte.

4. Conclusions

An on-line preconcentration system using Lewatit MonoPlus TP-207 chelating resin has been successfully applied to the determination of bismuth by FAAS. Due to its high tolerance to interferences from the matrix, the proposed procedure has been demonstrated to be promising for trace bismuth analysis.

The relative standard deviation and preconcentration factor of the method were found satisfactory, i.e., 3% and 20, respectively. The elution was easily performed with 3 mol L^{-1} HNO_3. The method has a linear range from 0.1 to 1.0 $\mu g\,mL^{-1}$ Bi(III). Advantages of this method are: (a) low cost, (b) simplicity, (c) rapidity, (d) studying in acidic medium required for Bi(III) separation/preconcentration, and (e) all processes are made automatically by the system itself. The proposed method shows very good sensitivity and precision and some has good advantages over the other preconcentration methods reported in the literature. A comparison of the described method with the other preconcentration methods for bismuth is given in Table 5. As can be seen from the table, our results are comparable with the others. The developed method is probably one of the earlier works for the on-line determination of bismuth by FAAS.

α-$K_7[H_4PW_{18}O_{62}]\cdot 18H_2O$
Layer by layer assembly process

ABSTRACT

A nitrite sensor based on immobilized Dawson-type tungstophosphate α-$K_7[H_4PW_{18}O_{62}]\cdot 18H_2O$ (PW_{18}) in multilayers of charged polyelectrolyte poly(allylamine hydrochloride) (PAH) on a glassy carbon electrode is described. A nitrite sensor manufactured with 10 layers has a sensitivity of ~4 nA/μM nitrite, fast response time (<6 s), low detection limit (~0.1 μM), high selectivity towards endogenous interferences such as nitrate and molecular oxygen, a linear range from 0.1 μM to at least 20 mM nitrite and was stable for at least 2 months. In addition, such nitrite sensors can operate in a pH range from 1 to 9, and the sensitivity can be increased by increasing the number of layers at the expense of increasing the response time.

1. Introduction

Nitrite is a key species in the global nitrogen cycle. It is present in soils, waters, foods and physiological systems. Nitrite is used in meat curing [1–2] and as food preservative against poisoning by microorganisms such as clostridium botulinum [3]. Nitrites are known to react with amines forming nitrosamines, which are known to be carcinogenic [4–6]. Furthermore, when nitrite is present at high concentration in blood, they can react with the iron(III) of the hemoglobin, forming methemoglobin, which has no oxygen carrying ability; this medical condition is called methemoglobinemia or "blue baby syndrome" [7]. Therefore, nitrite with its potential toxicity has intrigued many specialists [8]. The environmental impact caused by the build-up of nitrite, due to the widespread use of fertilizers, and the problems caused by the contamination of water sources for human consumption are the driving force for research in this area [9]. Thus, the precise determination of nitrite is important for environmental reasons and for public health. Hence, many methods have been developed for nitrite determination including spectrophotometry [10], chromatography [11] and electrochemical methods [12–28]. Electrochemical detection methods are advantageous over the other methods in terms of cost and time.

Electrochemical determination of nitrite is reported in literature either by reduction or oxidation. An important point is that nitrite is electroactive at carbon electrodes. However, its reduction or oxidation requires undesirably high overvoltages [29–31]. Oxidative determination is preferable because reduction of nitrite is known to suffer from interferences such as reduction of nitrate and molecular oxygen [32]. In order to improve the sensitivity and the selectivity of the detection of nitrite, the operating potentials should be lowered and the oxidation or reduction currents should be increased. This can be achieved by modifying the surface of electrodes with suitable electrocatalysts.

Wells–Dawson heteropolytungstates belong to a class of polyoxometalates (POMs) which have been reported to show efficient electrocatalytic reduction toward nitrite, nitrate and molecular oxygen [33–35]. Some POMs, more particular α-$K_7[H_4PW_{18}O_{62}]\cdot 18H_2O$, have electrocatalytic properties toward nitrite without showing any catalytic activity toward nitrate [33,36]. In addition, our studies showed that α-$K_7[H_4PW_{18}O_{62}]\cdot 18H_2O$ has no catalytic activity towards molecular oxygen. This is important for the selective determination of nitrite because it eliminates the major interferences such as nitrate and molecular oxygen. For this reason, this complex was selected as a potential candidate for nitrite sensing. The complex was immobilized on the detector electrode using layer by layer (LBL) deposition. LBL deposition offers significant analytical advantages including good stability, reproducibility and ease of manufacturing [37–39]. Details relevant for the detection and electrocatalysis of nitrite have been reported using various types of POMs [40–43]. However, these studies did not focus on the use of POM modified electrodes for the accurate determination of nitrite.

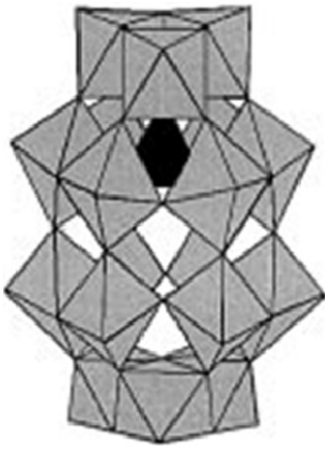

Fig. 1. Structure of the anion $[H_4PW_{18}O_{62}]^{7-}$.

The present work reports the development of an efficient and stable sensor for nitrite determination based on LBL immobilized α-$K_7[H_4PW_{18}O_{62}]\cdot 18H_2O$ (PW_{18}). The deposited films were investigated using cyclic voltammetry and amperometry. The electrochemical behavior of dissolved and immobilized PW_{18} was compared, the effect of the number of layers, scan rate, and pH were investigated. The electrocatalytic properties of the modified electrode toward nitrite reduction were demonstrated. The ability of the sensor for nitrite detection in real samples was examined by the amperometric determination of nitrite in tap water.

2. Experimental

2.1. Materials

Ultrapure milliQ water with a resistance of 18.2 MΩ cm was used for all the experiments. α-$K_7[H_4PW_{18}O_{62}]\cdot 18H_2O$ (PW_{18}) was synthesized and characterized following the procedure reported by Mbomekalle et al. [36]. The structure of the complex is shown in Fig. 1. Triton X-405, 3-aminopropyltriethoxysilane (ATS) 99%, poly(sodium 4-styrenesulfonate) (PSS) (MW 70,000), poly(allylamine hydrochloride) (PAH) (MW 15,000) were purchased from Aldrich. H_2SO_4, Li_2SO_4, LiCl, HCl, LiOH, CH_3COOLi, CH_3COOH, tris(hydroxylmethyl)aminomethane (trisH$^+$) analytical grade were purchased from Sigma–Aldrich or Acros Organic. Glassy carbon rod 3 mm in diameter was purchased from Alfa Aesar.

2.2. Methods and equipment

The electrochemical setup was an EG&G 273 potentiostat connected to a computer for data acquisition. The solutions were deaerated thoroughly for at least 30 min with pure argon and kept under a positive argon pressure during the experiments. A three compartment electrochemical cell was used. The side arms contained the saturated calomel reference electrode (SCE) and a platinum counter electrode with a surface area of approximately 1 cm^2. The reference and the counter electrodes were separated from the test solution by a fine and medium porosity ceramic, respectively. The working electrode which is also the nitrite sensor was a glassy carbon electrode (3 mm diameter, surface area ~7 mm^2). The glassy carbon rod was electrically connected to a copper wire with silver epoxy, encapsulated in epoxy resin and cured for 24 h. The surface of the glassy carbon electrode (GCE) was prepared by grinding with emery paper followed by polishing with 6, 3 and 1 μm diamond then abundantly rinsed with ultrapure water and dried.

2.3. Sensor preparation

The cleaned and well-dried GCE was first treated with pure ATS under nitrogen atmosphere for 10 min in a glove box, then removed and rinsed immediately with ultrapure water and dried under flowing nitrogen. It is observed that this treatment with ATS is important to increase the deposition rate of the POM. In other words, the electrodes prepared without ATS; by deposition of PAH as a first layer on the GCE electrode surface showed a very low deposition rate. The presence of the amine groups in ATS makes probably the electrode positively charged (see Fig. 2). The GCE/ATS was first immersed in acetate buffer solution pH 4 (1 M $CH_3COOLi + CH_3COOH$) containing 35 mg PSS/0.5 mL buffer (10^{-3} M) for 10 min. Thanks to the presence of sulfonate groups in PSS, this layer was found to be important for the deposition of a negative layer on which the PAH positively charged polyelectrolyte will deposit, and because of the presence of the aromatic rings in PSS, this may enhance the electron transfer between the immobilized PW_{18} and the carbon electrode. The GCE/ATS/PSS was rinsed with ultrapure water, dried under flowing nitrogen then immersed in a second acetate buffer solution pH 4 containing 10^{-3} M PAH (7.5 mg PAH in 0.5 mL buffer) for 10 min to provide a stable, positively charged surface to which the anion $[H_4PW_{18}O_{62}]^{7-}$ (PW_{18}) can be bound electrostatically. It was observed that addition of a small amount of Triton X-405 to the PAH solution ($\pm 10^{-5}$ M) increases the electrocatalytic activity of the film. This is perhaps due on the one hand to the presence of the aromatic ring in Triton X-405 which leads to a better electron transfer between the immobilized POM and the carbon electrode and, on the other hand, the long hydrocarbon chain of Triton X-405 may increase also the pore size of the deposited film, thus increasing the transport phenomena within the film. The GCE/ATS/PSS/PAH was immersed in 5×10^{-4} M PW_{18} in acetate buffer solution (pH 4) for 10 min. The electrode was then rinsed with ultrapure water and dried under a nitrogen stream. This procedure (POM/PAH) was repeated several times to permit the formation of multiple layers of POM on the GCE. The sensor was then stored under air at room temperature. Fig. 2 displays a schematic representation of the different layers of the PW_{18}/LBL film.

3. Results and discussion

3.1. Redox behavior of PW_{18}/LBL film

It has been reported that the complex PW_{18} is stable in the pH range of 0–4 [36]. We have observed that incorporation of this complex in LBL films increases the pH stability up to pH 12. In other words, no change in the shape of the cyclic voltammogram, current intensities or peak potentials of the PW_{18}/LBL film was observed when the modified electrode was tested at higher pH (pH > 4) and for long periods of time. This increase in the pH range stability of POMs encapsulated in LBL films has been reported elsewhere [44–45]. The encapsulation of the POM between two PAH layers prevents probably its decomposition at high pH, thus increasing its stability. Fig. 3 shows a comparison between the cyclic voltammogram of the dissolved and immobilized PW_{18} in LBL films of 2-POM layers (Fig. 3A) and 10-POM layers (Fig. 3B) in media of pH 1.2. In the domain of the explored potentials of Fig. 3A, the dissolved PW_{18} displays three merged quasireversible redox wave located respectively at $E_{pc} = -0.241$, -0.485 and -0.744 V vs. SCE. These redox waves correspond to the reduction of the tungsten centers within the POM. Immobilized in LBL film of 2-POM layers, PW_{18} displays a close similar electrochemical behavior for the two last redox waves. However, a slight decomposition in the redox process of the first wave can be observed, which disappears for LBL films with high number of layers as shown in

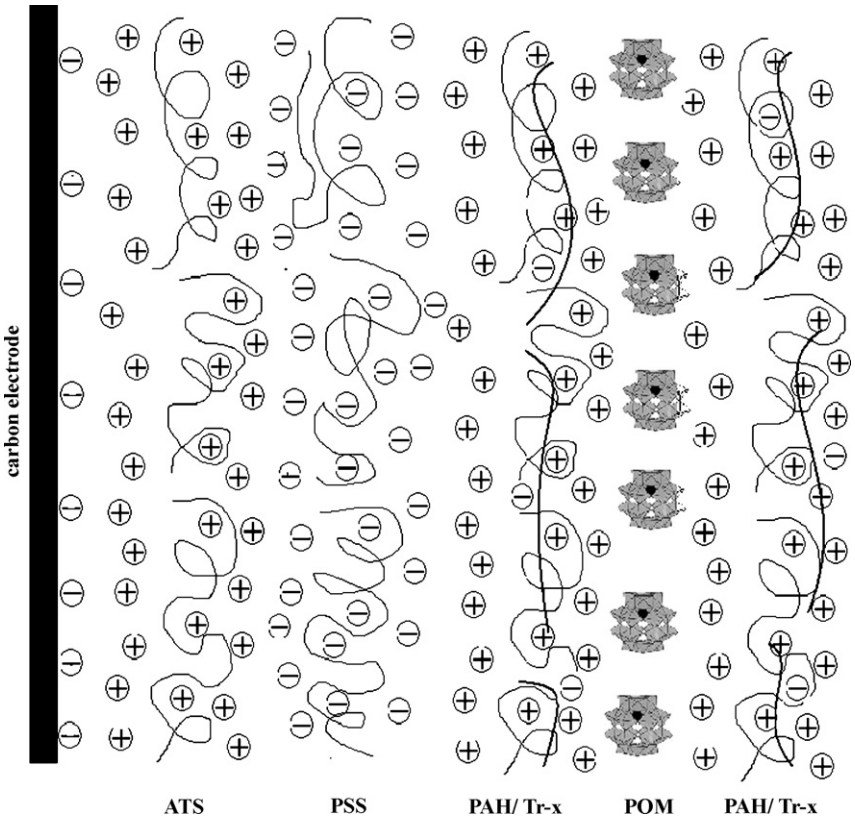

Fig. 2. Schematic cross-section of the POM/LBL film with one monolayer of PW_{18}. ATS: 3-aminotrimethoxysilane, PSS: poly(sodium 4-styrenesulfonate), PAH/Tr-x: poly(allylamine hydrochloride)/Triton X-405, POM: $[H_4PW_{18}O_{62}]^{7-}$.

Fig. 3B. It can be seen that the cathodic peak potentials of the dissolved and immobilized PW_{18} lie at the same potentials. This is related to the presence of a small amount of Triton X-405 in the film. In fact, the PW_{18}/LBL films prepared without Triton X-405 added to the PAH solution showed a shift of the cathodic peak potential to more negative values by about 8 mV. The presence of the aromatic ring in Triton X-405 probably leads to a better electron transfer between the immobilized PW_{18} and the carbon electrode, thus reducing the shift in potentials. According to Fig. 3B, immobilization of PW_{18} in LBL films of 10-POM layers, improves the reversibility of the redox process. The difference between the anodic and the cathodic peak potentials (ΔE_p) of the dissolved and immobilized PW_{18} reduces from 142 mV for dissolved to 41 mV for immobilized PW_{18}. For dissolved PW_{18}, it has been reported that the first redox wave is a two-electron transfer [36]. However, it is difficult to know the number of electrons transferred during the redox process of PW_{18} immobilized in LBL film. Controlled potential coulometry is not recommended for this kind of films because of the absence of an accurate concentration of the immobilized species. However, from the slight separation in the redox process of the first wave observed at low number of layers (Fig. 3A) and/or scan rates (2 mV/s) might indicate a two-electron process for the immobilized PW_{18}. As a matter of fact, it is observed that when PW_{18}/LBL film of 10-POM layers (Fig. 3B) was scanned at a low scan rate (e.g. 2 mV/s) a slight separation in the redox wave appears. It is believed that the merging of the redox waves observed at higher number of layers or scan rates is due to charge equilibrium within the film. In other words, when the deposited PW_{18}/LBL film is thin, the diffusion of ions through the film to insure charge neutrality is fast. However, when the film is thicker, the diffusion becomes slower. This also explains the effect of scan rate: at low scan rates, the electrochemical reduction of the immobilized PW_{18} will be slow and because the diffusion of the ions through the thicker film is slow, this will ensure adequate charge equilibrium.

The effect of the number of layers on the variation of the cyclic voltammogram on the first redox wave was investigated. As can be seen from Fig. 4A, the current response increases with number of the POM layers (curves from inside to outside: $n = 2, \ldots, 10$, respectively). In fact, the cathodic and anodic peak currents increase linearly with the number of layers (Fig. 4B). This demonstrates that equal amounts of PW_{18} are adsorbed in each layer, and implies that the thickness of the deposited film increases linearly with the number of layers.

Fig. 5A shows the variation of the cyclic voltammogram of the first redox wave of PW_{18}/LBL film of 10-POM layers with the scan rate (curves from inside to outside: $\nu = 10, \ldots, 100$ mV/s, respectively). The variation of the anodic and cathodic peak currents with scan rate is shown in Fig. 5B. It can be seen that the peak currents increase linearly with the scan rate up to 100 mV/s. This demonstrates that the redox process of the immobilized complex PW_{18} in LBL film are fast and not diffusion limited but surface-confined electron transfer processes [46,47]. Therefore, the surface coverage Γ of PW_{18} anions in the film can be estimated by Eq. (1), which is dealing with a reversible but nonideal redox process [48]:

$$\Gamma = \frac{I_p RT[4 - 2\delta\Gamma]}{n^2F^2\nu A} \cong \frac{4I_p RT}{n^2F^2\nu A} \quad (1)$$

where I_p is the peak current, δ is the interaction term, n is the number of electrons transferred per electroactive species, ν is the scan rate and A is the surface area of the electrode. Inspection of Eq. (1) and the plot of I_p vs. ν indicates that $2\delta\Gamma \ll 4$ [49]. The surface coverage of PW_{18} anions can be directly calculated from the peak current I_p because polyelectrolyte matrix is not electroactive. Based on the fact that the same amount of PW_{18} is deposited in each deposition cycle, as shown by cyclic voltammetry, the average surface con-

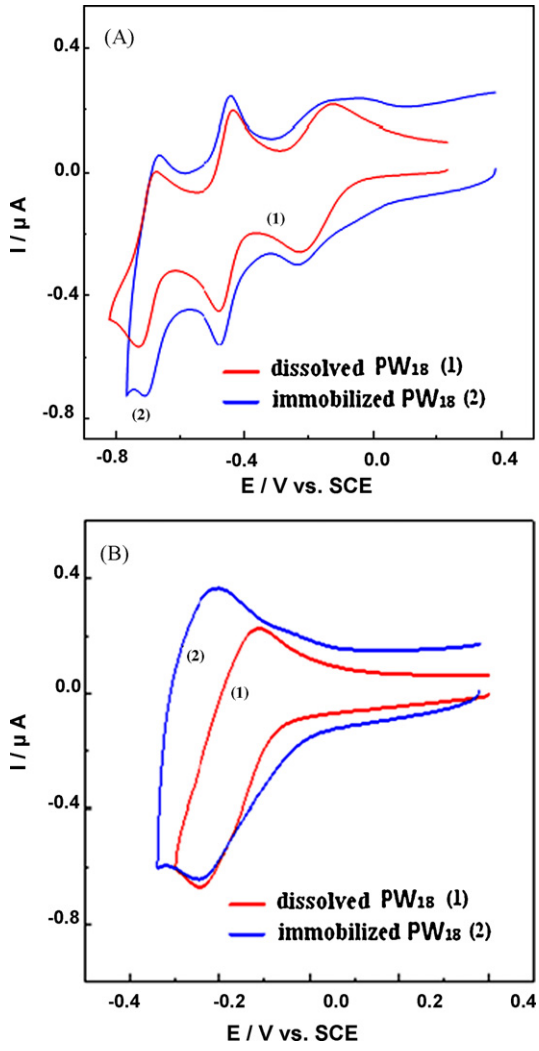

Fig. 3. Comparison between the cyclic voltammograms of dissolved (~10^{-4} M) and immobilized PW_{18}: (A) in the potential range of the three redox waves (LBL film of 2-POM layers) and (B) in the potential range of the first redox wave (LBL film of 10-POM layers). Electrolyte pH 1.2 (0.5 M $Li_2SO_4 + H_2SO_4$), scan rate 10 mV/s, reference electrode SCE.

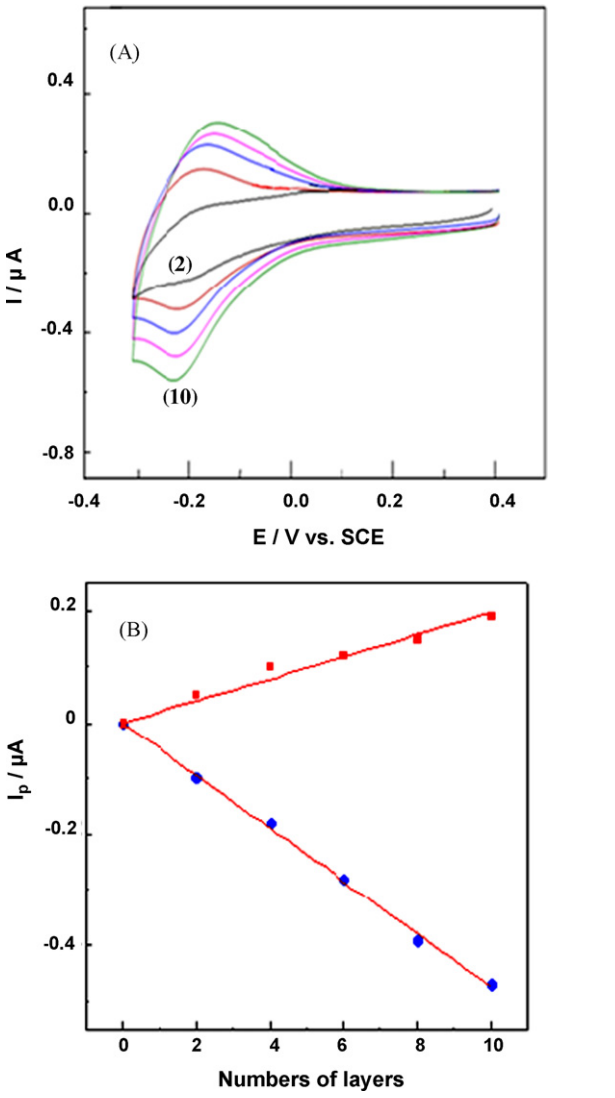

Fig. 4. (A) Variation of the cyclic voltammetry curve of PW_{18} with number of layers (2- to 10-POM layers). (B) Cathodic and anodic peak currents as a function of number of layers of PW_{18}/LBL film. Electrolyte pH 1.2 (0.5 M $Li_2SO_4 + H_2SO_4$), scan rate 10 mV/s, reference electrode SCE.

centration of PW_{18} anions per layer equals 2.95×10^{-11} mol cm^{-2} or 5.5 nm^2/PW_{18}. From structural X-ray analysis [50], the lateral dimensions of the cluster are 2.2 nm × 1.4 nm × 2.2 nm or a mean spherical diameter of 1.9 nm. Hence the projected surface area of PW_{18} is estimated to be 3.6 nm^2, which is close to the electrochemically determined surface coverage corresponding to a submonolayer.

The effect of pH on the redox behavior of immobilized PW_{18} was investigated for the LBL film of 10-POM layers. Fig. 6 illustrates the cyclic voltammograms of the immobilized PW_{18} at pH 1.2 and 4. A slight shift of the redox potentials to negative values is observed at higher pH. This is common in polyoxometallates, where the uptake of protons during reduction of the POM (PW_{18}) is to avoid charge concentration on the POM (accumulation of electrons) [51]. However, the shift in potentials due to variation of pH is surprisingly low. The cathodic peak potential shifts only by 70 mV for a pH variation of almost 3 units (or ~25 mV/pH unit). Similar behavior was reported for dissolved PW_{18} (in diffusion) and was explained by the low acidity of PW_{18} compared to other Wells–Dawson polyoxometallates [36]. Also, no significant separation in the redox wave was observed at pH 4 for the immobilized PW_{18}, while for the dissolved PW_{18}, the single two-electron wave splits into two one-electron waves [36]. This might be due to the microenvironment that the immobilized species experience inside the film [52] and especially as previously mentioned that the number of layers is also playing an important role in the merging in the redox wave. On the other hand, a decrease in the peak currents can be observed at pH 4 compared to pH 1.2, which can be explained by a slow penetration of protons to the surface of the electrode to maintain charge neutrality [53]. Finally, it is known for POMs that multiple electron uptake occurs generally through ECE, EEC and/or disproportion processes, in which the usual chemical steps are protonations [54]. The low dependence of the redox process of PW_{18}/LBL film (10-POM layers) towards the change in pH, may be explained through an EEC process as follows:

$$PW_{18}/LBL + 1e^- \Leftrightarrow PW_{18}^{\bullet -}/LBL \quad (2)$$

$$PW_{18}^{\bullet -}/LBL + 1e^- \Leftrightarrow PW_{18}^{2-}/LBL \quad (3)$$

$$PW_{18}^{2-}/LBL + 2H^+ \Leftrightarrow H_2PW_{18}/LBL \quad (4)$$

In summary, the observation of one merged redox wave for the first redox process and the apparition of the reduction process at less negative potentials are encouraging and constitute favorable conditions for electrocatalytic processes.

3.2. Electrocatalytic reduction of nitrite by PW_{18}/LBL film

It has been reported that the PW_{18} complex catalyzes only the reduction of nitrite [36] and does not show catalytic activity toward the reduction of nitrate and, our experiments showed that this complex has no catalytic properties towards molecular oxygen,

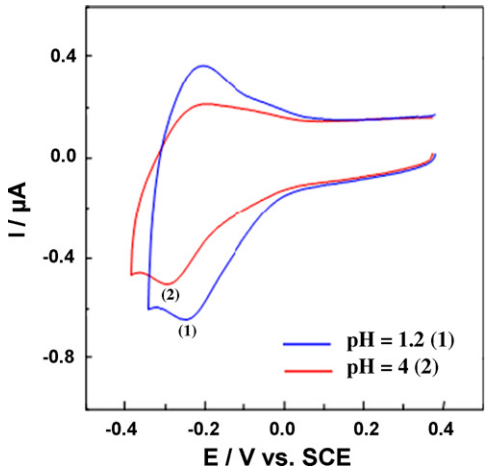

Fig. 6. Cyclic voltammograms of PW_{18}/LBL film of 10-POM layers at pH 1.2 and 4. Electrolytes: pH 1.2 (0.5 M $Li_2SO_4 + H_2SO_4$) and pH 4 (1 M $CH_3COOLi + CH_3COOH$), scan rate 10 mV/s, reference electrode SCE.

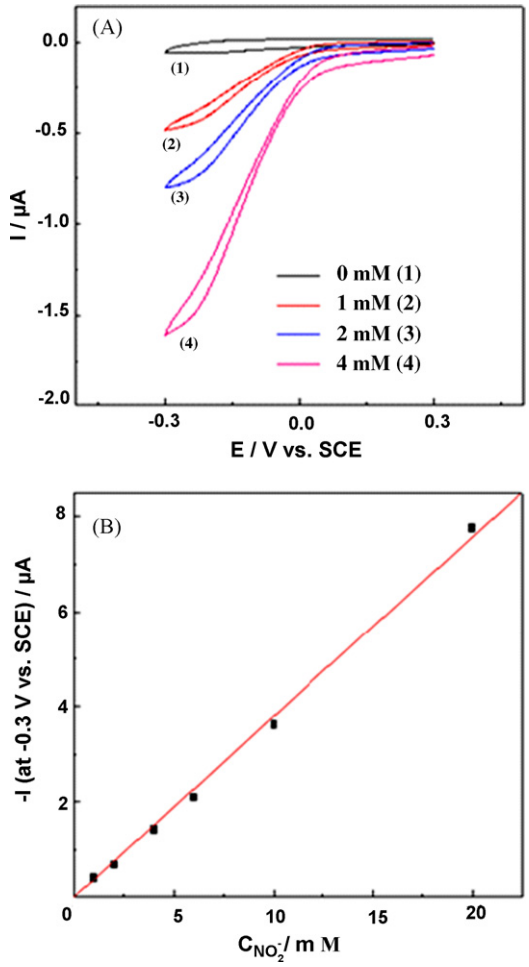

Fig. 7. (A) Cyclic voltammograms showing the catalytic activity of PW_{18}/LBL film (2-POM layers) at different nitrite concentrations. which are the two most important interferences for reduction-based nitrite sensors [32]. This is important for the selectivity of PW_{18}-based nitrite sensors. The behavior of the PW_{18}/LBL modified electrode towards the electrocatalytic reduction of nitrite was examined in detail. Fig. 7A shows the voltammetric behavior of PW_{18} immobilized in LBL film of 2-POM layers towards the reduction of nitrite at pH 1.2. At this pH, the active species could be HNO_2 and/or NO, as HNO_2 disproportionates in fairly acidic solution:

$$3HNO_2 \rightarrow HNO_3 + 2NO + H_2O \quad (5)$$

The rate of reaction (5) is known to be low. In the potential range of Fig. 7A, no direct reduction of nitrite on glassy carbon could be observed [34,55]. In addition, as can be seen from Fig. 8A, which compares the cyclic voltammetry curves of the GCE, GCE/ATS, GCE/ATS/PSS and GCE/ATS/PSS/PAH in presence of 4 mM nitrite, no catalytic activity of the LBL multilayer film without PW_{18} present towards nitrite can be observed. However, as can be seen from Fig. 7A, in presence of PW_{18} immobilized in the LBL film, the addition of nitrite (NO_2^-) leads to a large cathodic current enhancement that increases as the concentration of nitrite increases. In addition, no anodic trace was observed on potentials reversal, even for a small amount of nitrite. This implies that PW_{18} catalyzes the reduction of nitrite and the catalysis takes place during the reduction of the immobilized PW_{18}. Fig. 7B shows a linear relationship between the catalytic current taken at −0.3 V vs. SCE and the concentration of nitrite, which shows the efficiency of the PW_{18}/LBL film toward

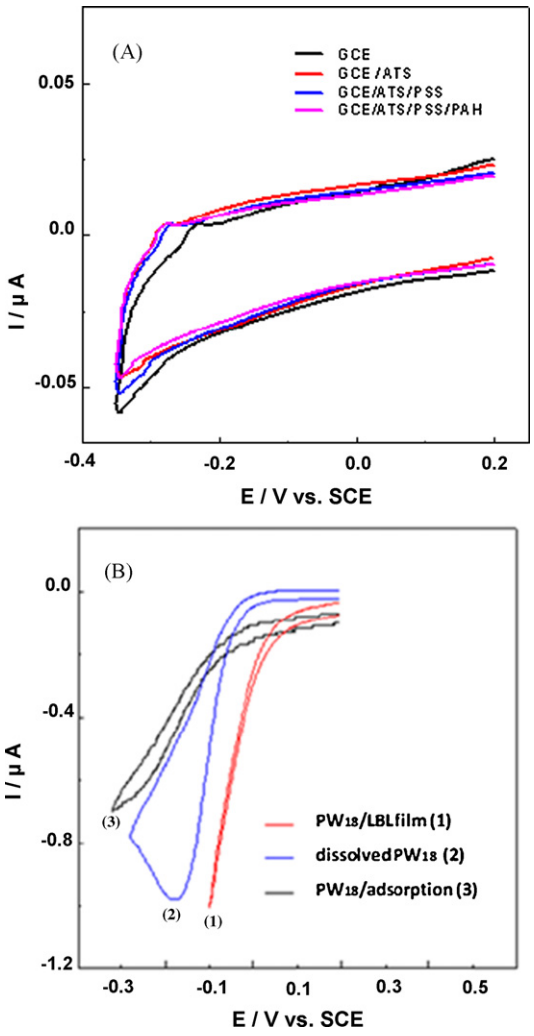

Fig. 8. Comparison between cyclic voltammograms of: (A) GCE, GCE/ATS, GCE/ATS/PSS and GCE/ATS/PSS/PAH in presence of 4 mM nitrite and (B) a PW_{18}/LBL film (2-POM layers), PW_{18} film prepared by simple adsorption and dissolved PW_{18} ($\sim 10^{-4}$ M) in the presence of 4 mM nitrite. Electrolyte pH 1.2 (0.5 M $Li_2SO_4 + H_2SO_4$), scan rate 2 mV/s, reference electrode SCE.

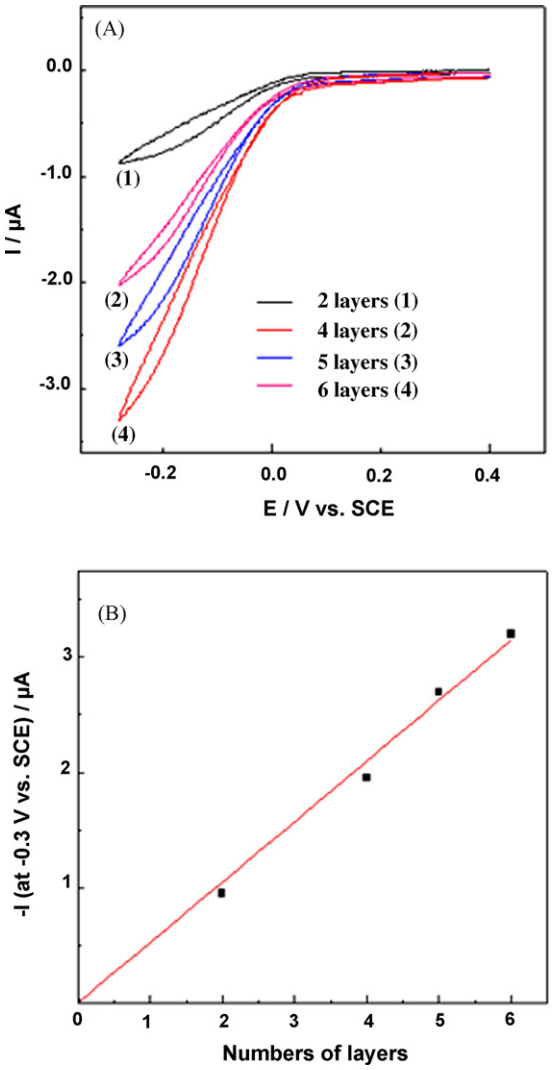

Fig. 9. (A) Variation of the catalytic current of a PW_{18}/LBL film towards 2 mM nitrite as a function of the number of POM layers. (B) Relationship between the catalytic current at −0.3 V vs. SCE and the number of layers. Electrolyte pH 1.2 (0.5 M $Li_2SO_4 + H_2SO_4$), scan rate 2 mV/s, reference electrode SCE.

the catalytic reduction of nitrite and the possibility of using the film for nitrite concentrations of at least up to 20 mM.

Fig. 8B compares the cyclic voltammograms in presence of 4 mM nitrite of PW_{18} immobilized in LBL film of 2-POM layers, PW_{18} adsorbed on the glassy carbon electrode without presence of the different polyelectrolyte layers and PW_{18} dissolved in solution. This figure shows that the catalytic reduction of nitrite is much more efficient for the PW_{18}/LBL film than the adsorbed or dissolved PW_{18}, and the reduction of nitrite starts ~100 mV earlier. The catalytic activity of the PW_{18}/LBL film for the reduction of nitrite might be related to the good three-dimensional distribution of PW_{18} in the LBL film and to the accessibility of nitrite to the immobilized complex. In addition, it is observed that the presence of a small amount of the surfactant Triton X-405 in PAH solution increases the catalytic activity and lowers the reduction potential. In fact, the electrodes prepared using the same procedure but without Triton X-405 showed less activity for the reduction of nitrite. The presence of Triton X-405 in the film probably increases the electron transfer between the immobilized POM and the electrode due to the presence of the aromatic ring and, the long hydrocarbon chain of the surfactant will also increase the pore size in the film, thus enhancing the accessibility of the immobilized PW_{18} for nitrite [56].

Fig. 9A shows the effect of the number of LBL layers on the electrocatalytic reduction of 2 mM nitrite. With increasing number of POM layers, the catalytic reduction of nitrite increases. For example, the electrocatalytic current observed with 6-POM layers is almost 3 times higher than the current observed with 2-POM layers. The relationship between the electrocatalytic current at −0.3 V vs. SCE and the number of POM layers is linear, as shown in Fig. 9B. This is understandable because equal amounts of PW_{18} are adsorbed in each layer.

Fig. 10 shows the variation of the cyclic voltammogram of PW_{18}/LBL film of 10-POM layers in presence of 2 mM nitrite as a function of pH. As the pH increases, the voltammograms shift to more negative potentials, indicating that the electrocatalytic activity decreases. The variation of the catalytic activity with pH indicates the involvement of protons in the catalyzed species and/or in its reduction products. Because the redox wave of the PW_{18}/LBL film shifts to negative potentials as the pH increases (Fig. 6), the catalytic reduction potentials displayed in Fig. 10 follow the same trend. In other words, with increasing pH, the electrocatalytic reduction of nitrite is carried out at more negative potentials, but because the shift of potential with pH is not significant (~25 mV/pH unit), it can be seen that even at higher pH the

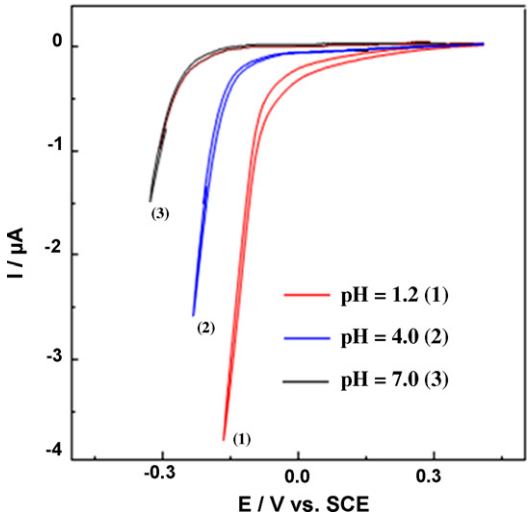

Fig. 10. Cyclic voltammograms of PW_{18}/LBL film (10-POM layers) in presence of 2 mM nitrite at three different pH. Electrolytes: pH 1.2 (0.5 M Li_2SO_4 + H_2SO_4), pH 4 (1 M CH_3COOLi + CH_3COOH), pH 7 (1 M LiCl + 0.2 M $trisH^+$), scan rate 2 mV/s, reference electrode SCE.

electrocatalysis of nitrite is carried out at relatively lower potentials, which is advantageous.

3.3. Analytical evaluation of the nitrite sensor

3.3.1. Amperometric detection of nitrite

For sensing purposes, amperometry is preferred over cyclic votammetry technique because it provides a fast evaluation of the sensor and attributes the main sensor characteristics such as sensitivity and response time. Amperometry was used to examine the characteristics of the nitrite sensor based on PW_{18}/LBL film of 10-POM layers deposited on glassy carbon. For that, the nitrite sensor and a reference SCE were immersed in 5 mL sulfate buffer solution pH 1.2. To permit a rapid diffusion of nitrite during its injection to reach the electrode and reduces, a small stirrer was added to the cell and the buffer solution was set under constant stirring during the experiments. The sensor electrode was polarization at −0.22 V and the curve current vs. time was recorded. After stabilization of the background current, successive injections of 20 µM nitrite were carried out. Fig. 11A shows the amperometric response. A current response of ~3.85 nA/µM nitrite is observed. In addition, after injection, the current reaches 95% of the final current within 6 s. As shown in Fig. 11B, the current increases linearly with increasing nitrite concentrations in the range from 20 to 220 µM. Our measurements showed that the linearity can be extended to at least 20 mM nitrite. The detection limit under these conditions was found to be around 0.1 µM (S/N = 3). However, these characteristics can be improved by increasing the number of layers. By increasing the number of layers (>10), the sensitivity and the detection limit will increase as shown previously in Fig. 9, at the expense of an increased response time.

3.3.2. Selectivity

In order to determine whether the nitrite sensor is affected by the presence of nitrate and molecular oxygen, 20 µM nitrate and 1 mL oxygen saturated solution (obtained by dissolution of pure oxygen in buffer solution for 30 min) were injected into 5 mL buffer solution at pH 1.2. Injection of 1 mL buffer solution saturated with oxygen, to 5 mL buffer solution approximately results in the normal

Electrolyte pH 1.2 (0.5 M Li_2SO_4 + H_2SO_4), polarization set at −0.22 V, reference electrode SCE.

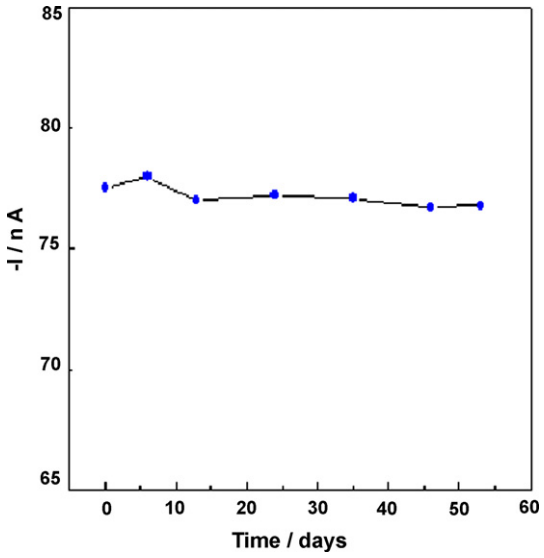

Fig. 12. Amperometric response of nitrite sensor (PW_{18}/LBL film of 10-POM layers) to injection of 20 μM nitrite over the course of 55 days. Sensor stored under air at ambient temperature. Electrolyte pH 1.2 (0.5 M $Li_2SO_4 + H_2SO_4$), polarization set at −0.22 V, reference electrode SCE.

oxygen concentration in the buffer solution. As shown in Fig. 11C, no significant increase in the amperometric response was observed. Hence, this proves that the nitrite sensor based on PW_{18}/LBL film is selective toward nitrate and molecular oxygen, the two most common interferences.

3.3.3. *Stability and reproducibility*

The stability of the nitrite sensor was investigated over a period of 55 days. The sensor was stored under air at room temperature and the current response to 20 μM nitrite injection in sulfate buffer solution pH 1.2 was checked at regular intervals. Fig. 12 shows the variation of the current to the nitrite injection. No significant change was observed within this period of time. The stability of this sensor can be attributed to the large amount of PW_{18} which is deposited on the surface of the electrode and the fact that the desorption of PW_{18} is strongly reduced by the electrostatic encapsulation inside the PAH/Triton X-405 layers (irreversible adsorption).

Table 1 illustrates the main characteristics of the nitrite sensor shown in Fig. 11.

3.3.4. *Determination of nitrite in real samples*

The nitrite sensor was tested by measuring the concentration of nitrite in drinking water. To increase the sensitivity, 20-POM layers were deposited using the LBL method. It was observed that the sensitivity of the sensor with 20-POM layers is almost double the sensitivity reported in Table 1. Under constant stirring, the nitrite sensor and a reference SCE were immersed in 2.5 mL sulfate buffer solution pH 1.2. The polarization was set at −0.22 V vs. SCE. After stabilization of the background current, injection of 500 μL of tap water was carried out, followed by successive injections of 1 μM commercial nitrite solution. The concentration of nitrite in tap water was calculated from the standard addition method (successive calibration points of 1 μM) and was found to be 0.66 ± 0.03 μM. The concentration of nitrite given by the water distribution company (Vlaamse Maatschappij voor Watervoorziening) is 0.6 μM. The accordance between the data indicates the reliability of the present sensor for nitrite determination in real samples.

Table 1
Characteristics of the PW_{18}/LBL film (10-POM layers) nitrite sensor shown in Fig. 11.

Area	∼7 mm^2
Sensitivity	3.85 ± 0.2 nA/μM nitrite
Detection limit	∼0.1 μM
Response time	<6 s
Linearity	From 0.1 μM to at least 20 mM nitrite
Response to O_2 and NO_3^-	None
Stability	At least 2 months

4. Conclusions

We have demonstrated the deposition of Dawson-type tungstophosphate α-$K_7[H_4PW_{18}O_{62}]\cdot 18H_2O$ using layer by layer assembly process. The modified electrode was characterized by cyclic voltammetry and amperometry. Compared to dissolved PW_{18}, the redox behavior of immobilized PW_{18}/LBL is more reversible. The peak currents of the deposited PW_{18}/LBL film increases linearly with the number of layers, which demonstrates that equal amounts of PW_{18} are adsorbed in each layer. The peak potential of the redox wave of the immobilized PW_{18} was found to be relatively insensitive to pH (shift of ∼25 mV/pH unit). In addition, no significant separation in the redox processes was observed at higher pH. Glassy carbon electrodes modified with PW_{18}/LBL films showed a high electrocatalytic activity towards reduction of nitrite. The activity increases linearly with nitrite concentrations and number of POM layers. Sensors based on such modified electrodes have a linear detection range from 0.1 μM to at least 20 mM nitrite, a variable sensitivity (∼4 nA/μM nitrite for 10-PW_{18}/LBL film), a low response from interferences such as nitrate and molecular oxygen, a fast response time (<6 s), can operate from pH 1 to 9, and are stable for at least 2 months, making them good candidates for nitrite determination.

SIMCA

ABSTRACT

An NMR and chemometric analytical approach to classify extra virgin olive oils according to their geographical origin was developed within the European TRACE project (FP6-2003-FOOD-2-A, contract number: 0060942). Olive oils (896 samples) of three consecutive harvesting years (2005, 2006, and 2007) coming from Mediterranean areas were analyzed by ^{1}H NMR spectroscopy. Olive oil samples from Liguria, an Italian region, were chosen as a case study and PLS-DA and SIMCA modeling analyses were used to build up statistical models both to discriminate between Ligurian and non-Ligurian olive oils and to define the Ligurian olive oil class to confirm the declared provenience.

1. Introduction

The development of accurate analytical fingerprinting methods for the authentication of olive oils and for the certification of the geographical origin is an actual issue and an important challenge also in view of the last EU Regulation 182/2009 [1] which requires mandatory labeling reporting the geographical origin of olive oils. In recent years many studies have been performed to characterize and classify olive oils using different techniques [2–6].

In our previous papers, it has been shown that high-field NMR spectroscopy together with a suitable statistical analysis allow extra virgin olive oils to be classified according to their geographical origin and cultivar [7–10]. However, up to now, the NMR methodology has been applied to compare olive oil samples coming prevalently from Italian geographical areas.

In this paper, the sampling was extended to 896 samples of three harvesting years (2005, 2006, and 2007) coming from different Mediterranean areas. The aim was to create, using ^{1}H high-field NMR data, statistical models able to trace olive oils according to the geographical origin. In particular, the Ligurian olive oils were chosen as study case and were analyzed together with olive oils coming from other Italian areas and from Spain, Greece, France and Turkey. The NMR results were processed using two different statistical pattern recognition techniques, i.e. PLS-DA and SIMCA chemometric techniques. PLS-DA and SIMCA techniques [11,12], being a discriminant technique and a class-modeling technique respectively, allow different information to be obtained [13,14]. Discriminant techniques such as PLS-DA [15,16] are focused on the differences between samples coming from different classes and operate by dividing the hyperspace of the variables in as many regions as the number of available categories, whereas class-modeling techniques such as SIMCA [17,18] are more focused on the similarities among samples of the same class than on the differences among the classes and act by defining the category space of one class at a time.

2. Materials and methods

2.1. Sampling

Olive oils (896) classified as PDO and/or extra virgin olive oil and produced in different Mediterranean areas during three consecutive harvesting years, namely, 2004/2005 (300 samples), 2005/2006 (351 samples) and 2006/2007 (245 samples), see Table 1, were collected and transported to a single laboratory (Joint Research Centre, Ispra, Italy) for subsampling and delivery to the Institute of Chemical Methodologies, CNR, Rome, Italy. Olive oils were stored at 4 °C between delivery and NMR measurements to avoid compositional changes.

Table 1
Olive oils analyzed within the TRACE project. The harvesting year, the country, the number of samples are reported. Ligurian olive oils used as case study are reported in *italic* character.

Harvesting year	Country	Number of samples
2004/2005	Italy	154
	Liguria	*62*
	Spain	38
	France	9
	Greece	23
	Turkey	14
2005/2006	Italy	172
	Liguria	*79*
	Spain	38
	Greece	10
	France	46
	Cyprus	6
2006/2007	Italy	116
	Liguria	*68*
	Spain	34
	Greece	7
	France	20

2.2. NMR measurements

Olive oil samples (20 μL) were dissolved in DMSO (20 μL) and $CDCl_3$ (700 μL) directly inside the 5 mm NMR tube. ^{1}H NMR analyses were performed on a Bruker AVANCE AQS600 instrument equipped with a 5 mm probe operating at the ^{1}H frequency of 600.13 MHz (B_0 = 14.3 T).

The ^{1}H NMR spectra were acquired at 300 K using the following experimental conditions: number of scans 1024; $\pi/2$ pulse ~8 μs; time domain (TD) 64 K data points; relaxation delay plus acquisition time 3.5 s; spectral width 18.5 ppm.^{1}H NMR spectra were obtained by the Fourier Transformation (FT) of the FID (Free Induction Decay) applying an exponential multiplication with a line-broadening factor of 0.3 Hz and a zero filling (size = 64 K) procedure. The resulting ^{1}H NMR spectra were phased manually. The error introduced in the quantitative analysis by phasing the spectra manually is <1%. Chemical shifts were reported with respect to the residual $CHCl_3$ signal set at 7.26 ppm. For ensuring a better quantitative comparability of the spectra, the baseline was corrected using a multiple point correction. In particular, the Cubic Spline Baseline Correction routine of the Bruker TOPSPIN software was used.

In order to perform the statistical analyses, the intensity, i.e. the maximum peak height, of 17 selected signals [10], see Fig. 1, was measured using an implemented semi-automatic peak-picking routine present in the Bruker TOPSPIN software [19]. The intensity of the selected signals was compared with the intensity of the resonance at 2.251 ppm, see in Fig. 1, due to α-methylene protons of all acyl chains, normalized to 1000.

To assess the repeatability of the method and to verify the applicability of the protocol, a few samples were analyzed five times. The obtained values show a very good repeatability (Relative Standard Deviation <2.5%) of the protocol for all signals.

2.3. Chemometric analysis

The intensity of 17 selected ^{1}H NMR resonances was processed using two different statistical pattern recognition techniques, i.e. PLS-DA as example of a discriminant technique and SIMCA, as example of a class-modeling approach [11].

2.3.1. Partial Least Squares-Discriminant Analysis (PLS-DA) [15,16]

Discriminant classification techniques can be viewed as aiming to find a relationship between a multivariate independent vector **X** and a qualitative vector of responses. Accordingly, if a suitably designed dummy response vector is introduced, traditional regression methods can be used also to tackle with classification problems. In particular, when dealing with a classification problem involving 2 classes, as in our case Liguria and non-Liguria, one can build a dummy binary-coded 1-dimensional response vector, so that, if a sample belongs to the class "Liguria", it will be coded as "1", while if it belongs to class "not Liguria", it will be coded as "0". Under this assumption, to compute a classification model corresponds to calculate the regression vector between the data matrix and the dummy vector of responses.

In order to compute a classification model, PLS-DA, as the name itself suggest, uses Partial Least Squares Regression [20], i.e. computes a bilinear decomposition of both X- and Y-spaces, under the assumption that a relationship between the two internal spaces exists. The result is a linear classifier that has proved to be statistically equivalent to Linear Discriminant Analysis [21], and that can be also applicable to all the cases when LDA cannot be (low number of samples to number of variables ratio and high collinearity among the variables) [16].

PLS-DA results are reported as score plots. Information about the variables most responsible for the observed classification was obtained by examining the VIP scores and the regression coefficients. The VIP score accounts for how much the single variable contributes to the bilinear model, and it is scaled in such a way that a value above 1 is considered to be significant.

Regression coefficients tell us which variables are most responsible of the separation between the categories: due to the coding used in this study, coefficients having a positive value will correspond to a variable being more concentrated in the samples from Liguria than in the others and *vice versa*.

2.3.2. Soft Independent Modeling of Class Analogies (SIMCA) [20,21]

In SIMCA, each class model is defined on the basis of a principal component model of opportune dimensionality. For instance, the model of class "Liguria" can be assumed to be described by an A principal components model, according to the equation:

$$\mathbf{X}_{Lig} = \mathbf{T}_A\mathbf{P}_A^T + \mathbf{E}$$

where $\mathbf{X}_{Lig}$ is the sub-matrix of the original data set obtained by selecting only the samples from Liguria, $\mathbf{T}_A$ and $\mathbf{P}_A$ are the matrices containing the first A scores and loading vectors, respectively, and $\mathbf{E}$ are the residuals [12]. Once the principal component model is computed, the class space is defined according to some statistically defined outlier detection criterion. In particular, the score matrix $\mathbf{T}_A$ and the residual matrix $\mathbf{E}$ are used to compute the probability distributions for the distances within the model space (T^2 statistics) and for the orthogonal distance to the model space (Q statistics), respectively. When a sample has a T^2 or a Q value exceeding a selected percentile of the corresponding distribution (usually 95%), the sample is considered to be an outlier for the category and rejected by the class model, otherwise, if the two values are lower than the thresholds, it is accepted and the sample is recognized as being part of the class.

As a consequence, SIMCA analysis provides two different figures of merit that are called sensitivity and specificity: sensitivity is the fraction of samples of the category, that we are modeling, accepted by the class model, whereas specificity is the fraction of samples from all the other categories rejected by the class model. The same figures of merit were also used as an optimality criterion to evaluate the best model complexity: indeed the principal components to be included in the SIMCA model of the class Liguria were chosen as those providing the highest value of the geometric mean between the sensitivity and the specificity, as evaluated by 10-fold

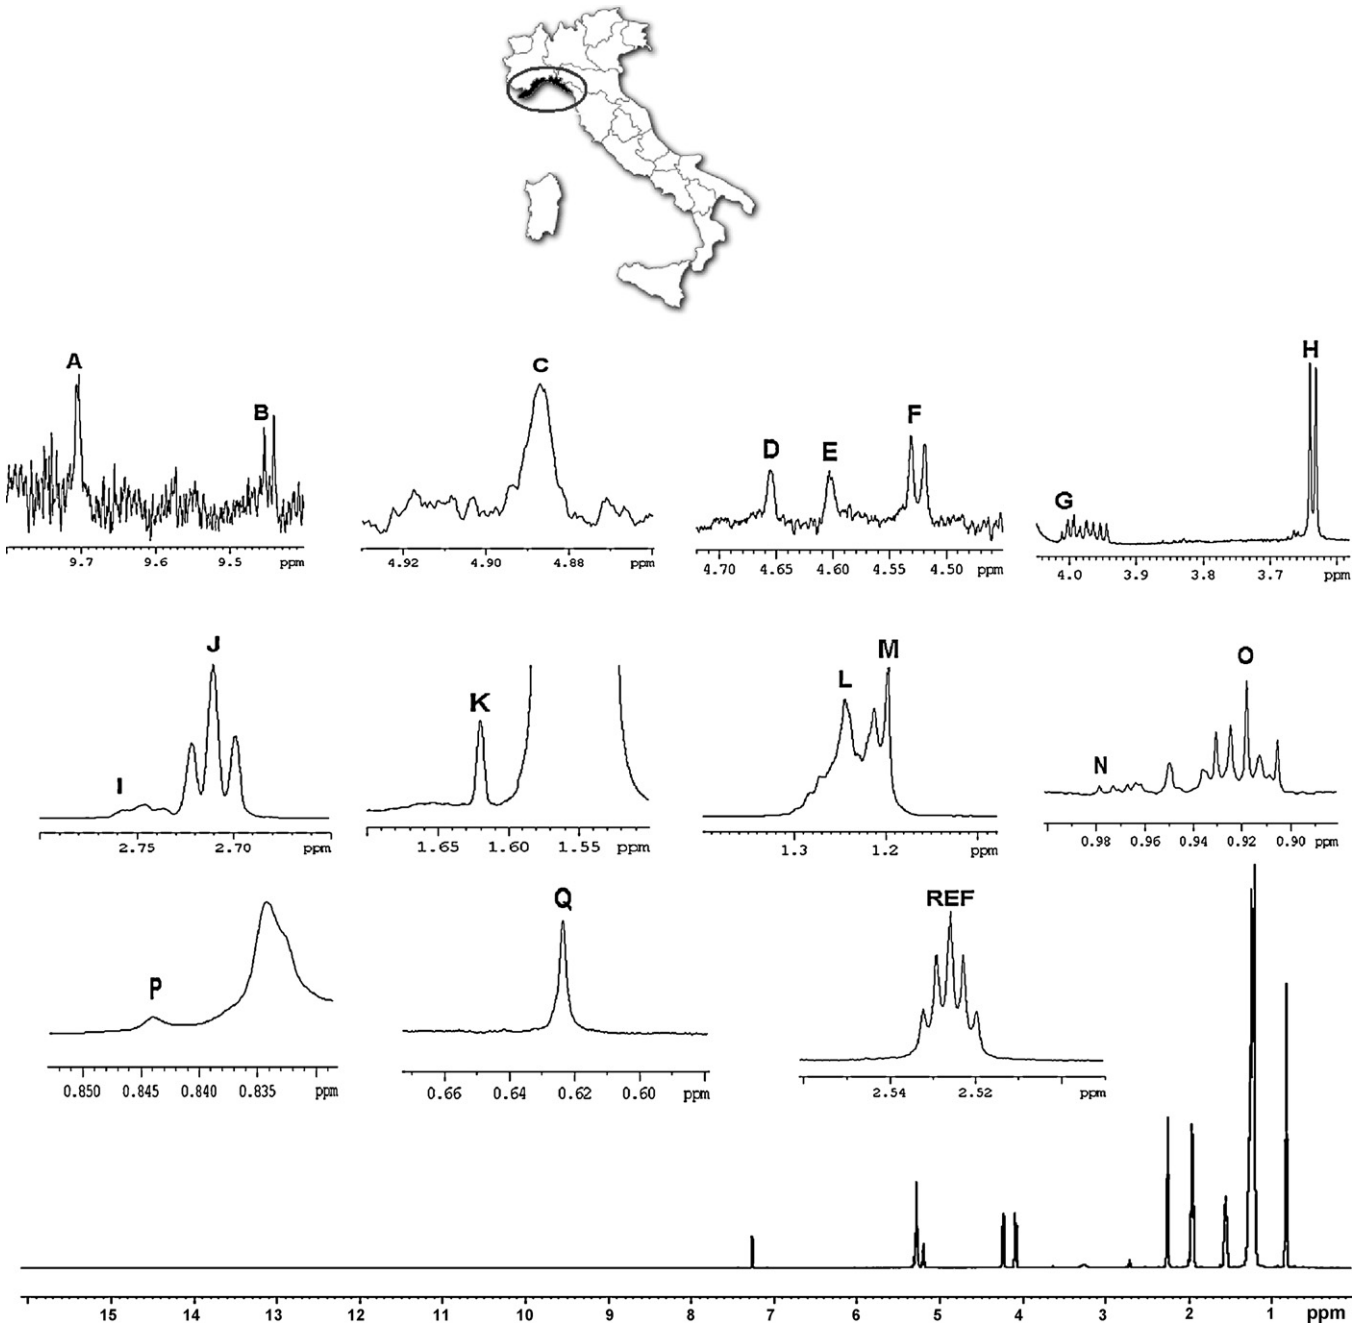

Fig. 1. 600.13 MHz ^{1}H NMR spectrum of an extra virgin olive oil. The selected NMR signals used in the statistical analysis are reported in expanded scale and labeled: A: hexanal (9.704 ppm); B: trans 2-hexenal (9.454 ppm); C: terpene 4 (4.885 ppm); D: terpene 3 (4.661 ppm); E: terpene 2 (4.609 ppm); F: terpene 1 (4.541 ppm); G: methylenic protons in α-glycerol moiety of *sn*-1,3 diglycerides (3.988 ppm); H: methylenic protons in α-glycerol moiety of *sn*-1,2 diglycerides (3.636 ppm); I: diallylic protons of linolenic fatty chains (2.746 ppm); J: diallylic protons of linoleic fatty chains (2.710 ppm); REF: reference peak due to methylenic protons bound to C2 normalized to 1000 (major peak at 2.251 ppm); K: squalene (1.620 ppm); L: methylenic protons of all unsaturated fatty chains (1.244 ppm); M: methylenic protons of palmitic and stearic fatty chains (1.197 ppm); N: wax (0.978 ppm); O: methyl of linolenic fatty chains (0.910 ppm); P: methyl of linoleic fatty chains (0.843 ppm); Q: methyl-18 of β-sitosterol (0.623 ppm). Map of Italy is also reported: Liguria region is evidenced by an ellipse.

cross-validation. Model space was built by taking into account both the distance to the model and the leverage.

3. Results and discussion

As the main objective of this work was to propose a methodology to confirm the geographical origin of olive oils, olive oils from a specific geographic area, Liguria region, see Fig. 1, were chosen as study case to develop and test the methodology. Ligurian olive oils have an important commercial value, being characterized by a mild taste in contrast to other famous Italian olive oils coming from Tuscany and Puglia, which tend to be fruity and strong. In Liguria, olive trees originate from typical cultivars such as Taggiasca and Lavagnina grown on barely accessible slopes terraced all the way down to the sea.

In order to perform this study, 896 olive oils samples, see in Table 1, were analyzed by ^{1}H NMR analysis following the protocol previously reported [10]. The intensity of 17 selected resonances sensitive to the geographical origin [10] was measured, see Fig. 1, and submitted to the chemometric analysis.

The intensities were gathered in a matrix having as many rows as the number of samples and as many columns as the number of variables. In particular, as the intensity of a relatively small number of NMR resonances was used as descriptor, the dataset contained 896 samples and 17 experimental indices.

Successively, since the goals were to discriminate between Ligurian samples and all the others and to characterize the Ligurian class, two pattern recognition methods were used, namely PLS-DA and SIMCA: while the former is a discriminant technique, the latter is an example of what are called class-modeling methods, i.e. those methods that, by focusing at one category at a time, are able to build up a model of each class separately and hence have been suggested to be more effective when in dealing with the problems of food traceability.

From the statistical viewpoint, the analysis was carried out in two stages: at first, a model including samples for all the three harvesting years was created, in order to account for as more sources of variability between the individuals as possible; then, in the following stage, three different models, one for each harvesting year, were built and validated on the samples from the two years left aside, in order to check how accurately models built on a single year could be able to recognize samples produced in different harvests and therefore to evaluate the year-to-year variability of the composition of the products.

3.1. Global model (all years)

In the first stage of our study, attention was focused on the possibility of building a model that could provide the best discrimination between the Ligurian samples and all the others. For this purpose, samples from all the available harvesting years had to be included in the set used for building the model (training set); in this way the maximum variability among the data could be represented. Samples used as training or test set were chosen randomly [2]. In order to have a balanced data set, the training set was built using 2/3 of all Ligurian samples (140) and comparable number of non-Ligurian samples (132). The test set used contains all the other samples not included in the training set: 624 samples (69 from Liguria and 555 from all the other regions). It has to be stressed that the samples included in the test set were not used at any stage of model building, so that they could be considered as really "unknown" to the models: indeed, whenever a choice had to be done to select the optimal model parameters, 10-fold cross-validation (on the training samples only) was used.

3.1.1. PLS-DA

At first modeling was performed using PLS-DA. The optimal model was selected based on the lowest non-error rate of cross-validation, as anticipated above, and it included 6 latent variables. A score plot of the projection of the training samples onto the first three PLS components is shown in Fig. 2. It evidences a good separation among the two classes. Indeed, a very good classification accuracy was obtained both in the training (89.3% for Ligurian, 87.1% for non-Ligurian) and the cross-validation (84.4% for Ligurian, 87.1% for non-Ligurian) phases. These data correspond to 15 and 18 Ligurian samples being misclassified in modeling and cross-validation, respectively. The results obtained for the model "Liguria" are shown in Table 2.

Information about the variables most responsible for the observed classification can be obtained by examining the VIP scores and the regression vector, both reported in Fig. 3. The VIP value, Fig. 3b, accounts for how much the single variable contributes to the bilinear model, and it is scaled in such a way that a value above 1 is considered to be significant: an inspection of Fig. 3b evidences that the variables that contribute the most to the projection are all the terpene peaks, the protons of *sn*-1,3 diglycerides and the diallylic protons of linolenic fatty chains.

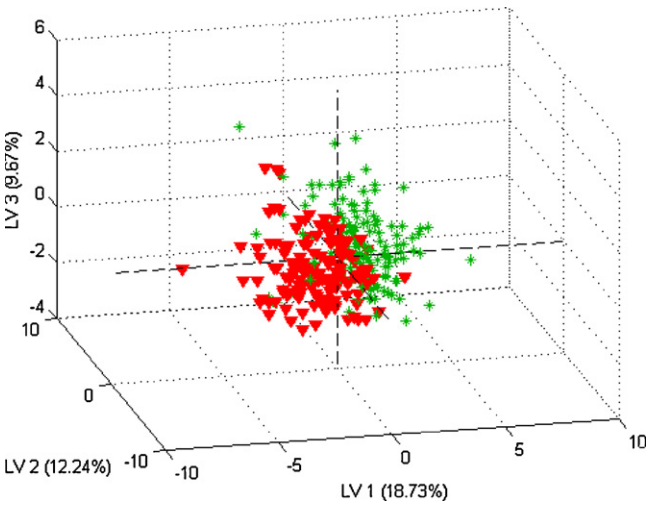

Fig. 2. A score plot of the projection of the training samples, relative to three harvesting years, onto the first three PLS component. ▼ = Ligurian olive oils, ✳ = non-Ligurian olive oils.

On the other hand, regression coefficients, Fig. 3a, tell us which variables are most responsible of the separation between the categories: due to the coding used in this study, coefficients having a positive value correspond to variables, and therefore to compounds, being more concentrated in Ligurian samples than in the others and *vice versa*. By looking at Fig. 3a, it is possible to observe that Ligurian samples have generally a higher terpene and hexanal content and a lower amount of saturated acids and β-sitosterol.

When this model was used to predict the test set samples, the resulting prediction accuracy was comparable to that evaluated in the modeling and the cross-validation phase. Indeed, 11 out of 69 (84.1% prediction accuracy) Ligurian and 79 out of 555 (85.8% prediction accuracy) non-Ligurian samples were misclassified.

3.1.2. SIMCA

The analysis on the dataset containing samples from all the three harvesting years was repeated using SIMCA. The main advantage of a class-modeling technique like SIMCA is that it is possible to build a model only for the category of interest and verify whether the samples are accepted by this category model or not. This is particularly effective in cases like the one we are studying where the discrimination is not among two well characterized classes, but between one class and all the others. A 10-fold cross-validation was used to select the optimal complexity of the model, which resulted to be 6 latent variables.

The optimal SIMCA model, reported in Fig. 4 in the form of a leverage *vs* orthogonal distance plot, resulted in a 84.3% sensitivity (118 out of 140 Ligurian samples accepted by the model) and in a 70.6% specificity (92 of the 132 samples from the other regions rejected by the model of Liguria). Similar results were obtained also in cross-validation (83.6% sensitivity and 72.0% specificity). The analysis of the modeling ability of the individual variables confirmed what already observed by PLS-DA, with terpenes and protons in glycerol moiety of *sn*-1,3 diglycerides being the indices contributing the most to the category model. All these results are shown in Table 2.

The model was also used to analyze the test set samples and, while a comparable specificity was obtained (70.6%), it showed a significantly higher sensitivity (92.8%, with 5 Ligurian samples only being refused by their own class model).

Table 2
Classification accuracy (PLS-DA), sensitivity and specificity (SIMCA) for the "Ligurian olive oil" model. All the values are given in %.

	Global model	2004/2005	2005/2006	2006/2007
PLS-DA				
Classification accuracy (modeling)	89.3%	88.7%	92.4%	86.8%
Classification accuracy (cross-validation)	84.4%	88.7%	91.1%	86.8%
Classification accuracy (test set)	84.1%	34.7%	79.2%	54.6%
SIMCA				
Sensitivity (model)	84.3%	96.8%	93.7%	94.0%
Specificity (model)	70.6%	87.0%	78.7%	78.5%
Sensitivity (cross-validation)	83.6%	82.3%	81.0%	85.1%
Specificity (cross-validation)	72.0%	89.1%	79.8%	80.8%
Sensitivity (test)	92.8%	0.0%	14.6%	41.5%
Specificity (test)	70.6%	100.0%	93.5%	90.2%

3.2. Year-to-year variability

The results obtained on the three years dataset were rather promising for the traceability of Ligurian olive oils. However, as evidenced especially by the values of the specificity in SIMCA, the built models were too prone to accept samples from other geographical regions as coming from Liguria. This result could be due to the fact that, in order to account for the various sources of variability, in particular the different year of harvesting, the class model had to be relatively large. To verify whether this assumption was correct and, anyway, to characterize in detail the year-to-year variability, in a second stage of our analysis a more thorough investigation of the year-to-year variability was carried out.

Operationally, this investigation was carried out by selecting the samples from a single year as training set and validating the obtained model on the samples from the remaining two years as external test set. As in the previous case, the analysis was done using both PLS-DA and SIMCA, the latter, due to its modeling properties, giving a more detailed result.

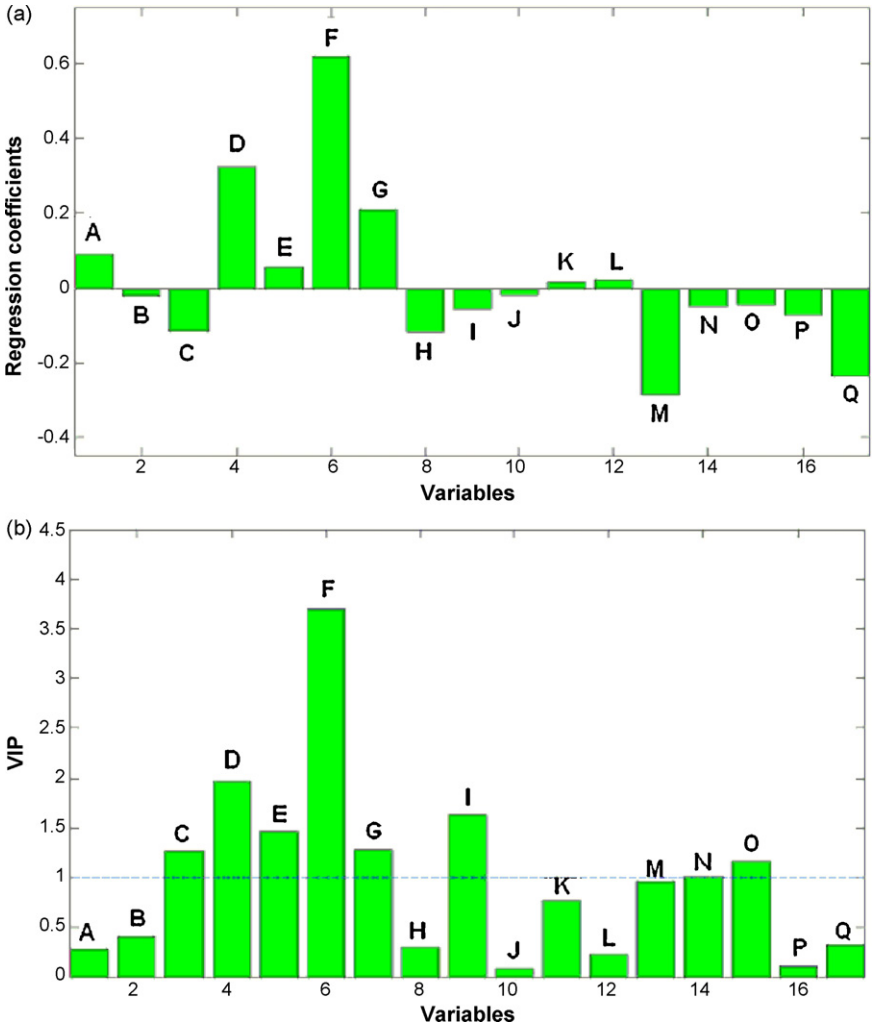

Fig. 3. The regression vector (a) and VIP scores (b) relative to three harvesting years samples. See Fig. 1 for the labeling.

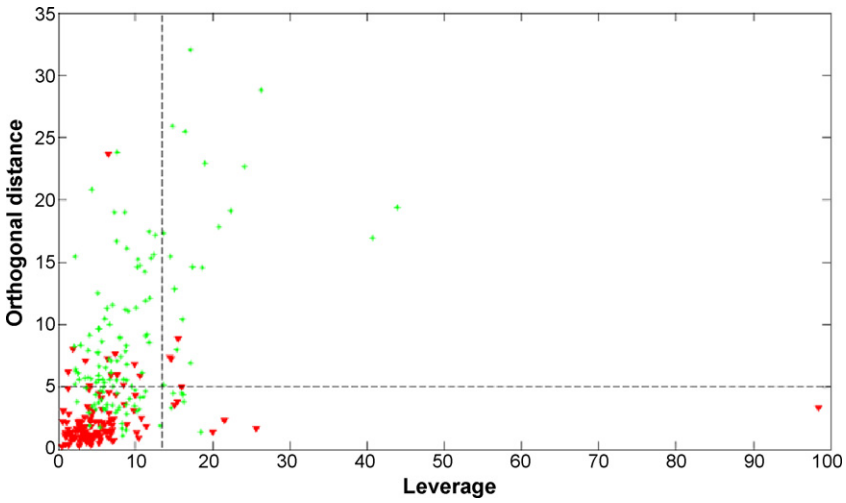

Fig. 4. SIMCA model relative to three harvesting years samples. ▼ = Ligurian olive oils, ✳ = non-Ligurian olive oils.

3.2.1. PLS-DA

PLS-DA analysis on the individual harvesting years was carried out at first by selecting as training set the data from 2004/2005 (62 Ligurian and 238 non-Ligurian) and validating the model built on the samples from the other two harvesting years (147 Ligurian and 449 non-Ligurian). As in the previous cases, 10-fold cross-validation was used to select the optimal complexity of the model, which resulted to be 4 latent variables. The classification ability of this model on the 2004/2005 samples, expressed as non-error rate, in modeling (88.7% for Liguria and 89.5% for the others) was similar to that in cross-validation (88.7% for Liguria and 89.1% for the others). However, when this model was used to predict the samples from the other harvesting years, left aside as our external validation set, the classification accuracy for the class Liguria was dramatically decreased. Indeed, non-error rates of 34.7% (Ligurian) and 98.9% (not-Ligurian) were obtained. The inspection of regression coefficients, see Fig. 5a, confirms that terpenes 1, 2 and 3 and saturated fatty chains have a significant discriminant power, terpenes being present in a higher concentration in Ligurian olive oils while saturated fatty chains in lower amount. With respect to the global model, a significant contribution of *trans*-hexenal, present in high concentration in Ligurian samples, is observable. The contribution of the variables to the model is reported as VIP scores in Fig. 5b. With respect to the global model, squalene becomes important for the model building whereas the *sn*-1,3 diglycerides do not contribute significantly to the model.

The same analysis was repeated using the 2005/2006 data (79 Ligurian and 272 non-Ligurian) as training set and leaving aside as external validation set the results of the analyses performed on the 2004/2005 and 2006/2007 samples (130 Ligurian and 415 non-Ligurian). The observed outcomes were similar to what already observed in the case of the 2004/2005 model. Indeed, the optimal model, which 10-fold cross-validation suggested to be the one including 4 latent variables, was able to provide very good classification both in modeling (92.4% Ligurian and 91.9% non-Ligurian) and in cross-validation (91.1% Ligurian and 91.2% non-Ligurian). Again, the inspection of regression coefficients, see Fig. 6a, confirms the importance of terpenes and saturated fatty chains in the olive oil discrimination. With respect to the model built on the 2004/2005 samples, some differences can be evidenced. Indeed, while in the 2004/2005 model *trans*-hexenal was important for the discrimination, in the 2005/2006 samples the *trans*-hexenal coefficient is almost zero while the hexanal coefficient is significant. On the other hand, some variables as *sn*-1,3 diglycerides, squalene, unsaturated fatty chains, wax, and linoleic fatty chains become positive and significant in the 2005/2006 model. As a consequence, when the model built on the 2005/2006 samples is used on the samples from the other two harvesting years, 79.2% and 80.0% non-error rates are obtained. In this case, the gap between the results on the training and on the validation set is smaller than for the 2004/2005 model, but is still relevant. With respect to the global model, VIP scores for 2005/2006 harvesting year, see Fig. 6b, suggest the importance of saturated fatty chains and wax in the model building whereas linolenic fatty chain does not contribute significantly to the model.

Lastly, a third model was built on the 2006/2007 samples (68 Ligurian and 177non-Ligurian) and validated on the samples from

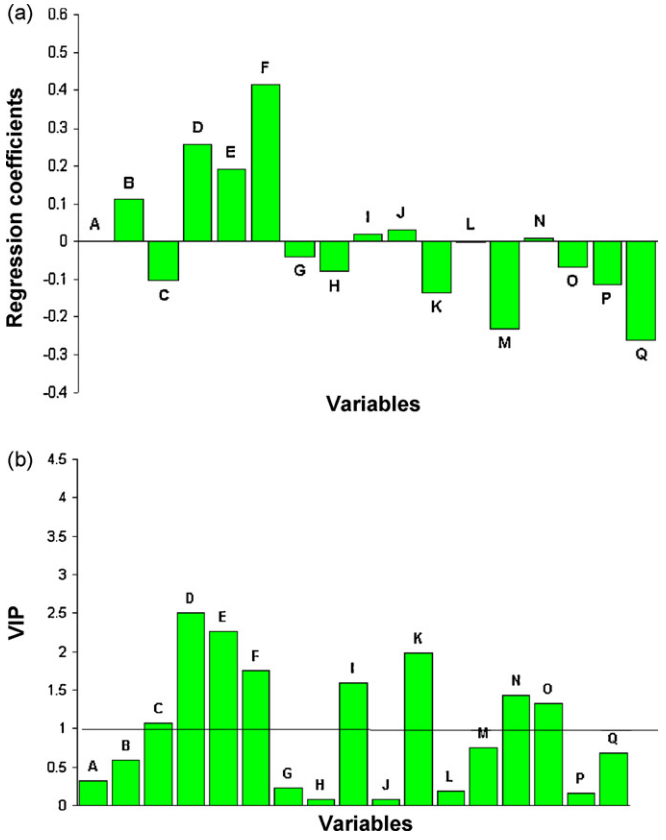

Fig. 5. The regression vector (a) and VIP scores (b) relative to the 2004/2005 harvesting year samples. See Fig. 1 for the labeling.

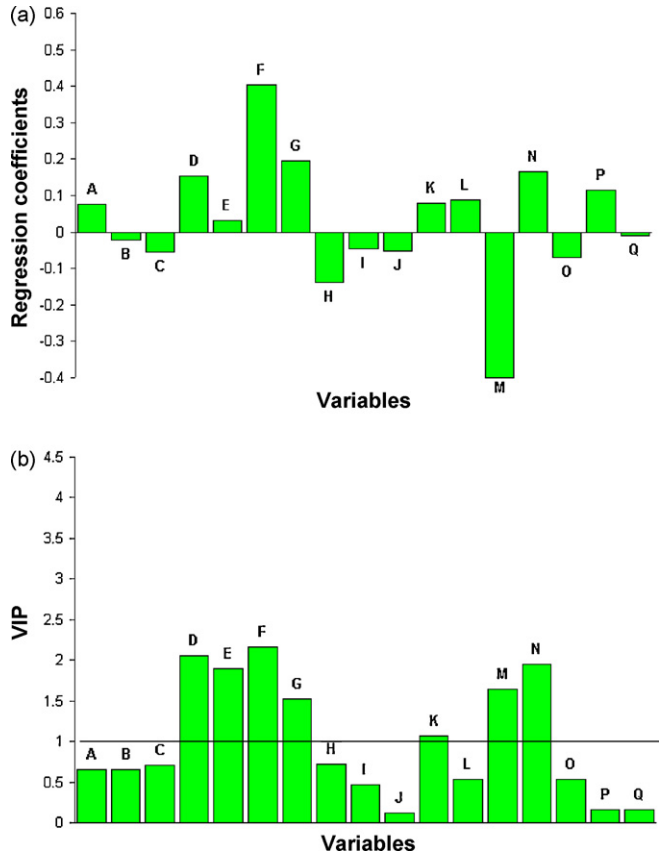

Fig. 6. The regression vector (a) and VIP scores (b) relative to the 2005/2006 harvesting year samples. See Fig. 1 for the labeling.

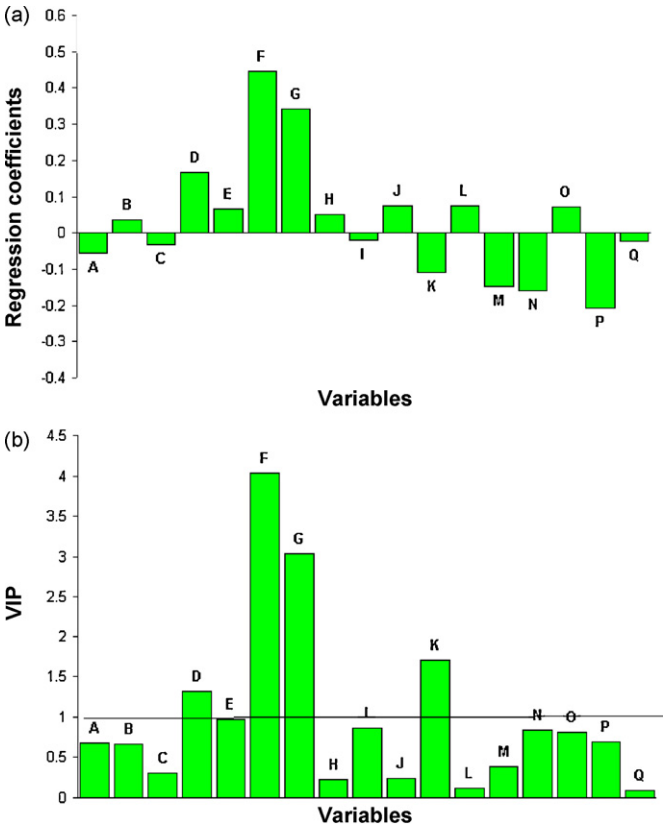

Fig. 7. The regression vector (a) and VIP scores (b) relative to the 2006/2007 harvesting year samples. See Fig. 1 for the labeling.

2004/2005 and 2005/2006 (141 samples from Liguria and 510 samples from the other regions). Three latent variables were selected on the basis of 10-fold cross-validation as the optimal complexity of the model, which provided, also in this case, a rather good and comparable non-error rate both in modeling (86.8% for Ligurian and 87.6% for the others) and cross-validation (86.8% for Ligurian and 86.4% for the others). Regression coefficients, see Fig. 7a, again confirm the importance of terpenes and saturated fatty chains in the discriminations. Ligurian samples of this harvesting year have a significantly lower amount of hexanal, squalene, saturated fatty chains, wax, and linoleic fatty chains. With respect to the global model, VIP scores, see Fig. 7b, suggest the importance of squalene in this model whereas linolenic fatty chain does not contribute significantly to the model.

When used for the prediction of the samples from the other two harvesting years, the 2006/2007 model showed a very poor classification ability in the case of the Ligurian samples (non-error rate was 54.6% for Liguria and 88.4% for the others).

All the results obtained for the model "Liguria" built in every single year are reported in Table 2.

3.2.2. SIMCA

The analysis of the year-to-year variability in the data and of the robustness of the pattern recognition models towards it was also carried out using SIMCA. As already described in the case of the global analysis, the use of SIMCA allows us to focus the attention on the category we want to trace, in particular the Ligurian samples, and build a model only of it. Accordingly, evaluation of the sensitivity and specificity of the optimized models provides a detailed information of whether the samples from other years are recognized by the category (or in other words "fall" within the category space) or not. As far as the 2004/2005 model is concerned, 9 principal components were selected on the basis of 10-fold cross-validation: this model showed a rather good sensitivity and specificity both in the modeling (96.8% sensitivity and 87.0% specificity) and in the cross-validation (82.3% sensitivity and 89.1% specificity) stages. However, this model was recognizing as outliers not only all the not-Liguria, but also all the Ligurian samples from the other two years (0% sensitivity and 100% specificity). Similar considerations, even if not as extreme as in this case, can be done for the 2005/2006 and 2006/2007 models.

The 2005/2006 model of Liguria (including 12 principal components) showed a rather good sensitivity and specificity for the samples of the same year (modeling: 93.7% sensitivity and 78.7% specificity; cross-validation: 81.0% sensitivity and 79.8% specificity) but a poor sensitivity for the Ligurian samples of the years 2004/2005 and 2006/2007 (14.6%). On the other hand, specificity with respect to non-Liguria samples of the other two harvesting years was rather high (93.5%).

Lastly, the model built on the 2006/2007 samples (9 principal components) resulted in 94.0% sensitivity and 78.5% specificity in modeling and in 85.1% sensitivity and 80.8% specificity in cross-validation, but in only 41.5% sensitivity and 90.2% specificity when it was applied to process the data of samples from 2005 and 2006. In all the examined cases, the analysis of the variables most contributing to the models confirmed the consideration already sketched when discussing the results of PLS-DA. The results obtained in modeling and in cross-validation for the model "Liguria" in every single year are reported in Table 2.

All the obtained results suggest some interesting general considerations. Olive oil as any natural "fruit juice" is a complex matrix

whose composition, quality etc depend on many different factors. Our study highlights two important aspects of Ligurian olive oils: Ligurian olive oils are always characterized by a high amount of terpenes and a low amount of saturated fatty chains. Although present in olive oils as minor components, terpenes, as volatile compounds, contribute to the sensory quality of olive oils and turned out to be important for the olive oil geographical characterization [7]. The high content of terpenes in Ligurian olive oils with respect to the other oils can be considered a "sensory marker" specific of these olive oils. On the other hand, the low amount of saturated fatty chains (probably due to the typical cultivar [8] present in this region and to the particular pedoclimatic conditions) is an important "quality marker" which makes these oils most suitable to particular diet regimes [22] among all others extra virgin olive oils. Saturated fatty acids are generally known as bad fats since they have the disadvantage of increasing the synthesis of cholesterol and promote cardiovascular problems.

The variability of some compounds in the three harvests can be due to different factors such as the different climatic conditions. The particularly hot summer in 2005 and 2006 years and/or the particularly rainy autumn in 2005 might be responsible for the observed variability.

Therefore, the NMR and chemometric approach extended to a relevant number of samples representative of the Mediterranean production has allowed not only to discriminate between Ligurian and not-Ligurian olive oils but also to define the Ligurian olive oil class which turned out to be characterized by specific sensory and quality markers. This methodology can give an important contribution in the actual debated problem of DPO characterization and confirmation.

ABSTRACT

This work reports on the performance of carbon nanotube modified screen-printed electrodes (SPE-MWCNT) for the selective determination of dopamine (DA) in the presence of ascorbic acid (AA) by adsorptive stripping voltammetry (AdSV). Several operating conditions and parameters were examined including the electrochemical pre-treatment and the previous AA interaction and DA accumulation in the presence AA at physiological conditions. Under the chosen conditions, DA peak current of differential pulse voltammograms increases linearly with DA concentration in the range of 5.0×10^{-8} to 1.0×10^{-6} mol L^{-1} with a limit of detection of 1.5×10^{-8} mol L^{-1} in connection with 600 s accumulation time. The sensitivity obtained for DA was independent from the presence or absence of AA; therefore, the proposed method can be readily applied to detect DA in real samples. The proposed methodology was successfully used for the quantification of DA in urine samples.

1. Introduction

Dopamine (DA) is one of the most important and representative catecholamine which plays an important role in the function of the central nervous, renal, hormonal and cardiovascular systems. The determination of DA is a subject of great significance in the investigation of its physiological functions and the diagnosis of nervous diseases resulting from DA abnormal metabolism, such as epilepsy, Parkinsonism and senile dementia [1]. Since DA (and the like catecholamines) is an easily oxidizable compound, electrochemical methods based on its anodic oxidation are an ideal choice for its quantitative determination [2]. The electrochemical determination of dopamine allows reaching low detention limit but it is often complicated by many coexisting compounds. Among them, ascorbic acid (AA) is of particular importance because it accompanies dopamine in biological samples. Usually, the concentration of DA is 10^{-8} to 10^{-6} mol L^{-1} while AA is as high as 10^{-4} mol L^{-1} in these samples (in the extracellular fluid of the central nervous system) [3,4]. Furthermore, DA and AA are oxidized at nearly the same potential at almost all carbon-based or metal electrodes; hence an overlapping voltammetric response for the oxidation of a mixture of DA and AA is usually obtained. Moreover, the solid electrodes very often suffer from the fouling effect due to the accumulation of oxidized products on the electrode surface which results in rather poor selectivity and sensitivity [2].

Several examples are reported in the literature regarding on the detection of DA using chemically modified electrodes including electrochemically pre-treated electrodes [5], self-assembled monolayer modified electrodes [6,7], covalent modification [8–10], polymer film [11,12], composite electrodes [13–15], among other. The different properties of each type of electrode define its own associated advantages and limitations. The detection of DA in the presence of excess of AA is still a challenging task in electroanalytical research where both sensitivity and selectivity are equally important in the development of an appropriate sensor system. Screen-printing technique is a well-established and simple process for the mass production of single use electrodes and biosensors. These electroanalytical tools combine ease of use, portability and inexpensive manufacture procedure [16] with minimum analysis volume, low reagent and sample consumption or minor generation of contaminant residuals as well as their usefulness as disposable devices. Their inherent miniaturization promotes and facilitates the possibility of rapid in situ analysis even in a small scale environment. The incorporation of nanomaterials to these screen-printed devices is of great interest for the further development of electrochemical sensors. Among these materials, carbon nanotubes present a singular structure and dimensions together with unique electronic, chemical and mechanical properties [17,18].

These remarkable features open new venues for the construction of sensors and the development of novel electrochemical bioassays [19–22]. As electrode material carbon nanotubes can facilitate electron transfer between the electroactive species and the electrode. In fact, different papers can be found in the literature where the enhancement of the rate constants for the electron transfer or electrocatalysis has been already demonstrated [23] and this was also observed when carbon nanotubes were employed in screen-printed electrodes [24]. The goal of the present paper is to investigate the voltammetric behavior of DA on screen-printed carbon nanotube electrode with the aim to propose a new methodology for its determination at low levels in the presence of ascorbic acid using a previous preconcentration step.

2. Experimental

2.1. Reagents

L-(+)-Ascorbic acid, $K_3Fe(CN)_6$ and $FeSO_4{\cdot}7H_2O$ were purchased from Panreac (Madrid, Spain) and 3-hydroxytyramine (dopamine) chloride, glucose, uric acid, 3,4 dihydroxyphenylacetic acid (dopac) and $Ru(NH_3)_6Cl_3$ were from Sigma (Madrid, Spain). All other chemicals were analytical grade and were used as received without further purification. Ultrapure water ($\rho > 18\,M\Omega\,cm$) from a Millipore-MilliQ system was used for preparing all solutions.

2.2. Apparatus and electrodes

The planar screen-printed electrode (DropSens, Oviedo, Spain) 3.4 cm × 1.0 cm × 0.05 cm (length × width × height) consists of three main parts which are a graphite counter electrode, a silver pseudo-reference electrode and a graphite working electrode, unmodified (SPE, ref. 110) or modified with multiwalled carbon nanotubes (10 nm diameter and 1–2 μm length) containing approximately 5% ratio of carboxylic groups (SPE-MWCNT, ref. 110CNT). The graphite working surface is 4 mm in diameter. Further details about them can be supplied from the following web site: www.dropsens.com.

Electrochemical measurements were performed by placing a 50 μL drop of the corresponding solution on the working area. Electrochemical measurements were conducted using a BAS 100B (BAS, West Lafayette, USA) electrochemical analyzer controlled by BAS W 2.3 software (BAS, West Lafayette, USA) through a Pentium IV PC computer or a μStat 100 potentiostat (DropSens, Oviedo, Spain) controlled by PSLite 1.6 software. A specific DropSens connector (ref. DSC) allowed the connection of the SPEs to the potentiostat. All experiments were carried out at room temperature (20–23 °C) using a new electrode for each assay.

2.3. Procedures

2.3.1. Electrode pre-treatment

The usual electrochemical pre-treatment of SPEs was carried out by applying +1.4 V for 300 s in 0.050 M phosphate buffer solution of pH 7.4.

2.3.2. Adsorptive stripping voltammetry

A 50 μL drop of 5.0×10^{-4} M AA in 0.050 M phosphate buffer (pH 7.4) was placed onto the working electrode area of a pre-treated SPE for 200 s, then rinsed with water and a volume of 50 μL of the given accumulation solution was placed for 10 min. Finally, after washing the electrode with water again, the differential pulse voltammetry (DPV) signal was recorded in fresh 0.050 M phosphate buffer (pH 7.4). The DPV parameters are the following: scan rate: 20 mV s^{-1}; pulse amplitude: 50 mV; sample width: 17 ms; pulse width: 50 ms; pulse period: 200 ms and quiet time: 2 s.

2.4. Sample preparation

Dopamine hydrochloride injection (CLORHIDRATO DOPAMINA GRIFOLS Amp. 200 mg/5 mL) was from GRIFOLS LABORATORY (Barcelona, Spain). Saline serum (Lactato de Ringer Hartmann Braun Sol. Iny) was from B. BRAUN MEDICAL, S.A. (Barcelona, Spain). Fresh urine samples from healthy donors were collected over a period of 24 h and they were acidified with HCl (to yield a final concentration of 1% of acid) and centrifuged to precipitate proteins. Then fractions of 10.0 mL of filtered urine were stored under refrigeration.

Dopamine hydrochloride injection samples were suitably diluted with 0.050 M phosphate buffer (pH 7.4) and doped with AA to obtain the desired concentration while saline serum was directly doped with AA and DA to obtain the desired concentrations. Urine samples were 10-fold diluted with 0.050 M phosphate buffer (pH 7.4) and spiked with DA and AA to obtain the desired concentrations.

3. Results and discussion

3.1. Electrode pre-treatment

Carbon electrodes are often preconditioned by electrochemical pre-treatments (EP) to enhance their electroactivity. The main effect of EP is the increase in the density of oxygenated groups on the electrode surface and the consequent improvement on the electron transfer [25,26]. In the case of SPE, the polymers present in the ink are responsible for slow charge transfer kinetics. Therefore, the activation of SPEs is often necessary for an optimum electrochemical performance *via* electrochemical pre-treatment [27].

To find an appropriate electrochemical pre-treatment for SPE and SPE-MWCNT, different electrolytes and conditions were studied using 1,4-benzoquinone in 0.050 M phosphate buffer solution of pH 7.4 as benchmark redox system. The electrochemical reduction of this marker in aqueous buffer to 1,4-hydroquinone is a well-known diffusion-controlled process involving 2 electrons and 2 protons [28].

Initially, the EP of SPE and SPE-MWCNT was carried out by applying anodic potentials ranging from +1.0 to +1.6 V in two different electrolyte solutions, 0.10 M H_2SO_4 and 0.050 M phosphate buffer solution of pH 7.4 for 60 s. The anodic-to-cathodic peak potential separation (ΔE_p), and the peak currents ratio (i_{pa}/i_{pc}) obtained from the cyclic voltammograms of 1,4-benzoquinone at untreated and pretreated SPE and SPE-MWCNT are summarized in Table 1. Regarding the untreated electrodes, the decrease in ΔE_p and the proximity of the obtained current ratio values to 1 at SPE-MWCNT, clearly demonstrate that the presence of MWCNTs at the SPE largely improved the electrochemical response of 1,4-benzoquinone. Considering pretreated electrodes, the EP mainly improves the electrochemical response of SPE. In general, as the EP applied potential increases, the reversibility of the redox couple improves at both electrodes, although in the case of SPE-MWCNT potentials as high as +1.6 V produce a negative effect on the response towards 1,4-benzoquinone. An EP is also necessary to eliminate small current contributions due to impurities present at SPE and SPE-MWCNT. Thus, a potential of +1.4 V was selected for further work.

The effect of the pre-treatment time at +1.4 V (0–300 s) in sulfuric acid and phosphate buffer solutions was also studied at SPE and SPE-MWCNT (not shown). As the pre-treatment time increased, up to 300 s, the reversibility of 1,4-benzoquinone improved. This EP time was also enough to eliminate the small contributions of fabrication impurities. A pre-treatment procedure consisting of

applying +1.4 V for 300 s in 0.050 M phosphate buffer solution of pH 7.4 was selected as the most advantageous and reproducible.

3.2. Electrochemical behavior of dopamine and ascorbic acid at SPE and SPE-MWCNT

Fig. 1 shows the cyclic voltammograms obtained for 1.0×10^{-3} M AA (A and D), 1.0×10^{-4} M DA (B and E) and a mixture of 1.0×10^{-3} M AA and 1.0×10^{-4} M DA (C and F) in 0.050 M phosphate buffer (pH 7.4) solution, on untreated SPE and SPE-MWCNT (a) and pre-treated ones (b). A decrease in the oxidation overvoltage for AA and a significant improvement in the reversibility for DA, compound that displays a quasi-reversible behavior at SPE (ΔE_p decreases 62 mV at SPE-MWCNT), was found at untreated SPE-MWCNT, demonstrating that the carbon nanotubes present at SPE-MWCNT make possible an important improvement in the voltammetric behavior of both compounds. At pre-treated SPE and SPE-MWCNT, the oxidation potential peak of AA shifts to more negative potentials at SPE and SPE-MWCNT (244 and 180 mV shifting, respectively); the ΔE_p for DA decreases (85 and 16 mV, respectively) while the anodic-to-cathodic peak currents ratio decreases from 2.5 to 2.3 at pre-treated SPE and from 3.1 to 1.7 at pre-treated SPE-MWCNT. Therefore, the EP improves the electrochemical response of AA and the reversibility of electron transfer processes for DA at both electrodes, although the most significant decrease in the oxidation overvoltages is obtained at pre-treated SPE. Nevertheless, as could be seen in panels C and F, these good features are not enough to allow the voltammetric quantification of a mixture of DA and AA, since unresolved signals were obtained either at untreated or pre-treated SPE and SPE-MWCNT. Indeed, DA oxidation signal was shifted to more positive potentials and overlapped with AA peak, probably as a consequence of crossing reactions of electrochemically generated DA oxidized forms with AA [2].

In order to evaluate the influence of adsorption processes on the electrochemical oxidation of AA and DA at pre-treated SPE and SPE-MWCNT, the effect of the scan rate on their voltammetric signals was studied from 5 to 200 mV s^{-1} (not shown). The anodic peak current, i_p, of AA (1.0×10^{-4} M) increased linearly with the square root of scan rate, $v^{1/2}$, at both electrodes (i_p (μA) = (0.26 ± 0.01) $v^{1/2}$ (mV s^{-1})$^{1/2}$, r = 0.990, n = 8 for SPE; i_p (μA) = (0.18 ± 0.01) $v^{1/2}$ (mV s^{-1})$^{1/2}$, r = 0.991, n = 7 for SPE-MWCNT), indicating that the AA electrode reaction is a diffusion-controlled process in both cases. On the other hand, the results obtained for DA (1.0×10^{-4} M) showed that, at variance with AA, the anodic (i_{pa}) and cathodic (i_{pc}) peak currents are proportional to the scan rate at SPE (i_{pa} (μA) = (0.073 ± 0.004) v (mV s^{-1}), r = 0.9997, n = 5; i_{pc} (μA) = (−0.047 ± 0.001) v (mV s^{-1}), r = −0.9997, n = 7) and at SPE-MWCNT (i_{pa} (μA) = (0.12 ± 0.01) v (mV s^{-1}), r = 0.997, n = 5; i_{pc} (μA) = (−0.073 ± 0.001) v (mV s^{-1}), r = −0.996, n = 7) suggesting that the electron transfer reaction is a surface (adsorption) controlled process [29].

For further demonstration, a preconcentration experiment was made by placing of AA (1.0×10^{-3} M) or DA (1.0×10^{-4} M) solutions on the working area of pre-treated SPE and SPE-MWCNT for 10 min and, after rising with water, recording the cyclic voltammogram in fresh buffer solution. No signal was obtained for AA, while DA peaks were clearly observed at SPE-MWCNT and weakly at SPE, pointing that DA is significantly adsorbed onto the surface of the SPE-MWCNT whereas AA was not.

3.3. Determination of DA in the presence of AA

The adsorption of DA at pre-treated SPE-MWCNT offers good possibilities for selective voltammetric detection of DA after a preconcentration in the presence of AA under physiological conditions.

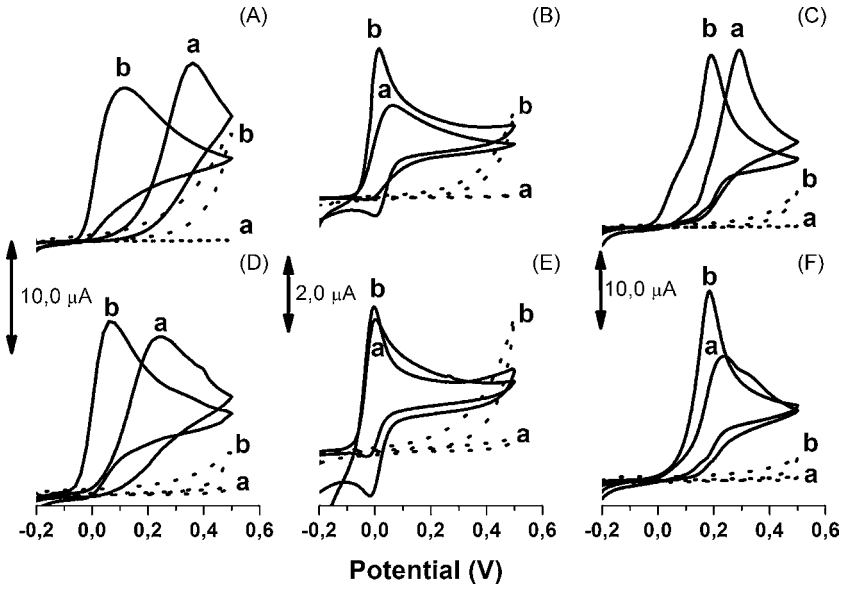

Fig. 1. Cyclic voltammograms for 1.0×10^{-3} M AA (A and D) and 1.0×10^{-4} M DA (B and E) and a mixture of both analytes in the same concentration as in individual solutions (C and F) in 0.050 M phosphate buffer (pH 7.4) solutions on SPE (A–C) and SPE-MWCNT (D–F) before (a) and after (b) the EP. The corresponding responses for the blank are also shown (dotted lines). Electrode pre-treatment: applying +1.4 V during 300 s in 0.050 M phosphate buffer (pH 7.4) solution. Scan rate: 25 mV s^{-1}.

In this sense, the selection of the experimental parameters was optimized for the development of a methodology employed differential pulse voltammetry (DPV), which allows the sensitive and selective determination of DA in the presence of a large excess of AA.

3.3.1. *Effect of AA on the voltammetric response of DA*

Fig. 2A displays differential pulse voltammograms obtained at pre-treated SPE-MWCNTs for 1.0×10^{-3} M AA, 1.0×10^{-5} M DA and a mixture of both analytes in the same concentration as in the individual solutions. The results are consistent with those obtained in the study by CV. The direct voltammetric determination of DA in the presence of AA is severely interfered due to the co-oxidation of ascorbic acid and an overlapping DPV response was obtained from a mixture of DA and AA. Furthermore, the results shown that the electrochemical process of DA is strongly influenced by the presence of AA (the oxidation peak of DA shifts to more positive potential), so different experiments were performed with the aim to acquire more insights about the influence of AA in the final DA electrochemical response. Fig. 2B displays a DPV obtained in 0.050 M phosphate buffer (pH 7.4) solution at a pre-treated SPE-MWCNT previously exposed for 5.0 min to 1.0×10^{-3} M AA and rinsed with ultrapure water (a). As expected, according to previous results, no oxidation current was obtained for AA after 5.0 min in the AA solution. Panel b shows a DPV obtained in 1.0×10^{-5} M DA solution at a pre-treated SPE-MWCNT previously exposed for 5.0 min to 1.0×10^{-3} M AA and rinsed with water, the DA oxidation peak shifts to more positive potentials (about 200 mV shifting) and the corresponding currents increases (2.0-fold) compared to DA signal obtained at an electrode previously exposed for 5.0 min to the phosphate buffer solution and rinsed with water (panel c). In this case, the oxidation peak potential and current for DA are the same as the ones obtained in the solution of DA (Fig. 2A). These results suggest that, although there is no electro-oxidation signal indicating the adsorption of AA, the interaction of AA with the electrode surface produces some modification that generates important changes in DA electrochemical process.

In order to take advantage of the improvement in DA sensitivity after AA exposure, the effect of the interaction time (from 0 to 10 min) of pre-treated SPE-MWCNT with 1.0×10^{-3} M AA on the differential pulse voltammetric peak of 1.0×10^{-5} M DA was evaluated and the corresponding results are shown in Fig. 3A. The peak current increases with the AA interaction time up to 150 s (2.0-fold) and then remains constant while the peak potential shifts to more positive potential up to 100 s (208 mV shifting). Hence, an interaction time of 200 s was selected for subsequent measurements.

The effect of AA concentration (from 5.0×10^{-6} to 1.0×10^{-3} M) on the differential pulse voltammetry peak of 1.0×10^{-5} M DA was also investigated. The experiments were carried out setting

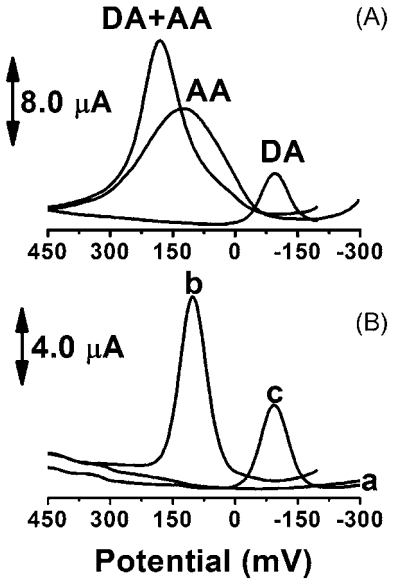

Fig. 2. DPV signals obtained in 0.050 M phosphate buffer (pH 7.4) with a pre-treated SPE-MWCNT. (A) Direct measurement of DA (1.0×10^{-5} M), AA (1.0×10^{-3} M) and a mixture of DA and AA (1.0×10^{-5} and 1.0×10^{-3} M, respectively). (B) DPV signals of blank phosphate buffer (a) and DA (1.0×10^{-5} M) (b and c) with prior exposition to 0.050 M phosphate buffer (pH 7.4) for 300 s at open circuit with (a and b) and without (c) AA (1.0×10^{-3} M). EP as in Fig. 1. DPV operational parameters: pulse amplitude: 50 mV; sample width: 17 ms; pulse width: 50 ms; pulse period: 200 ms; quiet time: 2 s; scan rate: 20 mV s^{-1}.

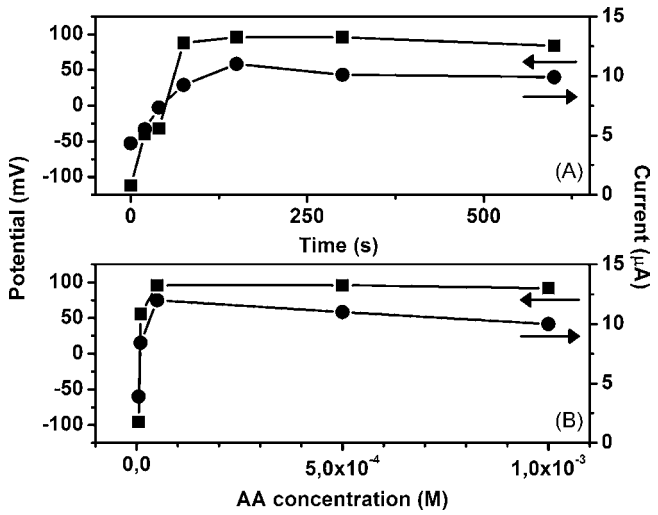

Fig. 3. Effect of AA on differential pulse voltammetry peak of DA (1.0×10^{-5} M) in 0.050 M phosphate buffer (pH 7.4). Effect of the interaction time (A): AA concentration: 1.0×10^{-3} M; effect of AA concentration (B): interaction time: 200 s. EP and DPV operational parameters as in Fig. 2.

an interaction time of 200 s. Fig. 3B shows that DA peak current increases with AA concentration up to 1.0×10^{-4} M, to remain constant thereafter. A similar trend was obtained for the peak potential which shifted to more positive values with AA concentration up to 1.0×10^{-4} M.

The results obtained suggest that no further improvement could be achieved in DA oxidation signal with larger AA concentration or longer interaction time. In view of these results and taking into account the concentration range of AA in biological samples, the selected conditions for AA interaction were 5.0×10^{-4} M AA in a 0.050 M phosphate buffer (pH 7.4) for 200 s. In this way, the DA voltammetric signal should be independent of the concentration of AA in the sample.

3.3.2. *Electrochemical characterization of the effect of AA interaction after EP*

As it was already mentioned in Section 3.1, during anodic EP several processes take place on SPE surface producing important changes, such as increase of surface active area, water oxidation to molecular oxygen (and other reactive species) [30,31] and formation of different carbon oxides [26]. When carbon nanotubes are present, EP could lead, in addition, to open their capped ends or side-walls, introducing in this way new edge plane like sites [31]. Usually, after these treatments the electrochemical performance of such electrodes is finally improved by introducing catalytic oxygenated groups and edge plane like sites within their graphene layers structure, that increase the electron transfer rate of many analytes [23,26].

Changes induced by an AA exposition on an anodized SPE-MWCNT surface could be related to its reducing properties towards carbon oxides and oxygenated species formed after EP. In order to evaluate such effect, CV of representative electrochemical benchmarks, namely hexaammineruthenium (III), hexacyanoferrate (III), iron (II), oxygen, AA and DA, were performed at untreated and pretreated SPE-MWCNT with and without AA interaction and the obtained results are summarized in Table 2.

The first tested probe was $Ru(NH_3)_6^{3+/2+}$ system, classified as an outer-sphere electrochemical process and typically unaffected by the chemical condition of the carbon electrode surface [26]. As expected, the observed electron transfer kinetics, expressed by the measured ΔE_p, was similar and relatively fast in all cases. The EP effect observed was just the increase of active surface, which was denoted by the peak current and capacitance (not shown) rise, and a slight increase in ΔE_p.

Concerning the electrochemical behavior of $Fe(CN)_6^{3-/4-}$ system, it has been reported that its electrochemistry is somehow surface dependant in several conditions [26,32]. The results obtained show that untreated SPEs display noticeable better reversibility than the treated ones, with larger ΔE_p after EP than after EP followed by AA interaction. This fact indicates that favorable electroactive sites for hexacyanoferrate were blocked after EP and part of them were recovered after AA treatment. Compton et al. have reported slower electron transfer kinetics for this electrochemical system when oxygenated species were generated in pyrolytic graphite and carbon nanotubes [32,33]. The suggested explanation was the formation of epoxy-like bridges between graphene layers in the edge plane of pyrolytic graphite which prevent the electron transfer in these sites. MWCNT employed in the SPE-MWCNT under study were functionalized with carboxylic groups by the manufacturer so these groups were present at untreated electrodes. Therefore, they did not affect the electron transfer rate as severely as EP did. It is very often assumed that EP of carbon electrodes only introduces new oxides (typically carboxylic, carbonyl and quinone groups) in their graphene planes structure but the generation of molecular oxygen and other reactive species at the edge plane like sites is usually ignored. Since most of these species were not removed from the electrode surface after EP, probably they could be adsorbed at edge plane sites and disturbing the electron transfer of redox systems such as hexacyanoferrate, especially sensitive to these sites. After AA treatment, these reactive oxygen species were reduced, liberating in this way the edge plane sites and subsequently increasing the observed hexacyanoferrate electron transfer. This rationale could also explain the slight increase on ΔE_p of hexaammineruthenium system after EP.

Next, attention was turned to $Fe^{2+/3+}$ system, whose electron transfer kinetics is well-known to be accelerated when carbonyl groups are present in the electrode surface [34]. Untreated SPE-MWCNT displayed large ΔE_p which indicated low density of carbonyl groups in MWCNT surface and poor catalytic activity of carboxylic substituents or edge plane like sites towards this system. As expected, EP largely improved the reversibility of the electrochemical system as a consequence of the introduction of new carbonyl groups. When SPE-MWCNTs were treated with AA after EP, measured ΔE_p was the same to the one obtained with SPE-MWCNT subjected only to EP. Thus, the generated carbonyl groups were not modified by AA and the same electron transfer kinetics was observed. These results reinforce the idea that AA interacts with other reactive substances or substituents distributed along MWCNT surface rather than with carboxylic, carbonyl or quinone ones.

The next electrochemical system studied was the molecular oxygen reduction which is favored when a high density of edge plane like sites is present at the electrode surface and it is also catalyzed by quinone groups [35,36]. The overpotential needed for oxygen reduction moderately decreases after EP while a larger decrease was observed after AA interaction. The peak currents were proportional to scan rate in all cases (not shown), indicating that this electrochemical process is adsorption-controlled. These results suggest again that after AA exposition, edge plane like sites are liberated, increasing the electron transfer rate and promoting the adsorption of oxygen. As a consequence of that, lower overpotentials and higher currents are obtained.

Similarly to oxygen reduction, AA oxidation is an example of inner-sphere electrochemical process [26] whose overpotential is typically decreased by the presence of edge plane like sites [37] as well as after EP [35,38]. As expected, EP of SPE-MWCNT produces a significant decrease of the overpotential and an important enhancement of the associated currents. The AA treatment only

[a] Experimental conditions: 1.0×10^{-3} M $Ru(NH_3)_6^{+3}$ and 1.0×10^{-3} M $K_3Fe(CN)_6$ in KCl 0.1 M; 1.0×10^{-3} M $FeSO_4{\cdot}7H_2O$ in $HClO_4$ 0.1 M; 1.0×10^{-3} M AA and 1.0×10^{-4} M DA in 0.050 M phosphate buffer solution (pH 7.4). Scan rate: 50 mV s^{-1}. Results shown were obtained from the average at three measurements using different electrodes. Standard deviations of measured potentials were lower than 10 mV in all cases.

supposes a slight decrease in the observed peak potential indicating that the main improvement in the electron transfer kinetics was due to oxygenated groups generated after the EP. In all cases, this electrochemical process was diffusion-controlled as peak currents were proportional to the square root of scan rate. Since adsorption did not control this electrochemical process, the positive effect of AA treatment was lighter in this case.

Finally, the effect of EP and AA exposure on DA electrochemical oxidation was also studied. This process is known to be strongly affected by surface cleanliness, presence of oxygenated groups and presence of edge plane sites, since both electrocatalysis and adsorption play a key role in DA electrochemistry [39,40]. The results obtained were qualitatively equal to those described in the precedent section where EP promotes an enhancement in electron transfer kinetics as well as an electrocatalytic effect revealed by the increase of peak currents. The further improvement in ΔE_p and sensitivity after AA treatment should be ascribed to liberation of more edge plane sites for DA adsorption.

From the results exposed all along this section it could be concluded that the improvements achieved using the AA treatment after EP are related to the reduction and elimination of reactive species located preferentially at edge plane sites which decrease the electron transfer kinetics but also especially prevent the adsorption in these sites of electroactive targets as DA in our case. The result of such treatment is a noticeable improvement in the electron transfer process and an important favoring of adsorption-controlled processes.

3.3.3. *Adsorptive behaviour of Dopamine at pre-treated SPE-MWCNT*

Taking into account the capability of the pre-treated SPE-MWCNT for the selective adsorption of DA in the presence of AA, DA was determined by adsorptive stripping voltammetry (AdSV) in presence of a large excess of AA. The experiment was carried out as follows: a 5.0×10^{-4} M AA was placed onto the pre-treated electrode during 200 s, then it was rinsed with water and the given accumulation solution was placed on the electrode for 600 s at open circuit. Finally, after washing the electrode with water again, the DPV signal was recorded in a fresh phosphate buffer solution. Fig. 4 shows the voltammograms obtained employing different accumulation solutions: blank phosphate buffer (a), 5.0×10^{-4} M AA (b), 1.0×10^{-5} M DA (c) and a mixture of 5.0×10^{-4} M AA and 1.0×10^{-5} M DA (d). An oxidation peak around 120 mV was obtained only when DA was present in the accumulation solution, demonstrating that DA is selectively adsorbed on the electrode surface. These facts are consistent with the results obtained in the previous studies. The difference in the peak oxidation current for the neurotransmitter alone or in the presence of AA is 16% (16 μA *vs* 19 μA for DA and DA + AA, respectively). The same behavior was observed for an accumulation solution containing 10-fold lower DA concentration and the same AA excess.

The analytical features of DA detection using the proposed scheme were subsequently evaluated. Fig. 5A displays differential pulse voltammograms obtained from solutions containing DA in concentration between 5×10^{-8} and 1.0×10^{-6} M in the presence of 5.0×10^{-4} M AA and the resulting calibration plot (shown as inset). A linear dependence between DA concentration and stripping peak current was observed for the concentration range studied with a regression equation of i_p (μA) = (0.16 ± 0.04) + (3.01 ± 0.08) × 10^6 C (mol L^{-1}), $r = 0.993$, $n = 8$. The limit of detection was 1.5×10^{-8} M,

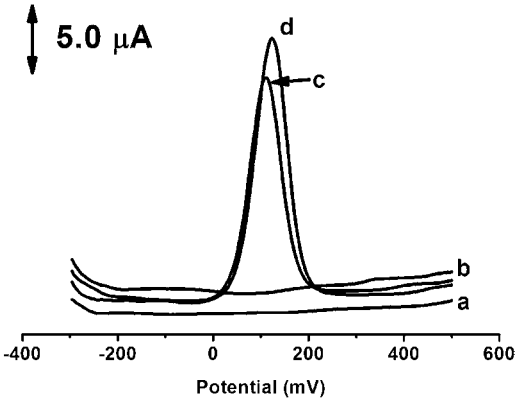

Fig. 4. AdSV obtained for different accumulation solutions: (a) blank 0.050 M phosphate buffer (pH 7.4); (b) 5.0×10^{-4} M AA; (c) 1.0×10^{-5} M DA and (d) mixture of 5.0×10^{-4} M AA and 1.0×10^{-5} M DA. Measuring procedure: (1) EP as in Fig. 2; (2) 50 μL drop of 5.0×10^{-4} M AA in 0.050 M phosphate buffer (pH 7.4) during 200 s; (3) 50 μL drop of accumulation solution during 600 s at open circuit; (4) DPV obtained in 0.050 M phosphate buffer (pH 7.4), operational parameters as in Fig. 2.

Table 3
Determination of dopamine in injections.

Sample no.	Content		Dopamine found ($\times 10^{-7}$ M)	Recovery (%)
	Dopamine ($\times 10^{-7}$ M)	Ascorbic acid ($\times 10^{-4}$ M)		
1	3.0	0	2.8	93
2	3.0	0	3.1	103
3	3.0	0	2.9	97
4	3.0	1.0	2.8	93
5	3.0	1.0	3.1	103
6	3.0	5.0	2.9	97
7	3.0	5.0	2.8	93

calculated using the $S/N = 3$ criterion, being S the sensitivity and N the standard deviation of 10 background signals. The reproducibility of the method was determined by performing 10 successive measurements of 1.0×10^{-6} M DA solutions in the presence of 5.0×10^{-4} M AA using different SPE-MWCNT. The relative standard deviation obtained was 5.6% ($n = 10$).

A closer approach to actual capabilities under physiological conditions was carried out using a synthetic serum as model matrix. Differential pulse voltammograms from samples with DA concentration between 5.0×10^{-8} and 1.0×10^{-6} M in the presence of 5.0×10^{-4} M AA in such saline serum (Na^+ 131, K^+ 5.4, Ca^{2+} 3.6, Cl^- 112, lactate 28 mEq L^{-1} with pH range 5.0–7.0) were obtained. As shown in Fig. 5B, the signal of DA was not affected by the presence of these ions and the sensitivity obtained working under these physiological conditions ($(3.2 \pm 0.2) \times 10^6$ (μA L mol^{-1})) was similar to that obtained measuring in phosphate buffer solution, indicating that the components of saline serum do not compromise the performance of the SPE and this methodology could be readily employed to DA analysis in serum samples. In addition the possible interference of coexisting 1.0×10^{-3} M glucose, 1.0×10^{-4} M uric acid or 5.0×10^{-5} M dopac was studied and variations on 1.0×10^{-6} M DA signal were similar to those observed for different SPE-MWCNT in the reproducibility study.

3.3.4. Analytical applications

The utility of the developed DA electrochemical detection scheme involving SPE-MWCNT was demonstrated in connection to the DA quantification in a pharmaceutical product (Dopamine chlorhydrate, 40 mg mL^{-1}) and in spiked samples of human urine.

Diluted samples of pharmaceutical product were determined using the proposed method in the presence or absence of different concentration of AA. Recovery results were obtained under these conditions by the standard addition method (three 2.0×10^{-7} M DA additions were made) and they are shown in Table 3. Recovery values close to 100% were obtained in all cases, demonstrating the ability of SPE-MWCNT for the selective determination of DA in real samples.

Fresh urine samples collected over a period of 24 h were treated as described in Section 2. Urine samples were 10-fold diluted with phosphate buffer (pH 7.4) and then spiked with increasing amounts of DA in the range of 1.0×10^{-7} to 2.0×10^{-6} M while keeping a constant AA concentration of 5.0×10^{-4} M. Fig. 6 shows the voltammograms obtained and the resulting calibration plot (shown as inset). Unspiked samples showed a weak DA response, insufficient for a suitable quantification. A linear dependence between DA concentration and stripping peak current was observed for spiked samples in the concentration range studied, with a regression equation of i_p (μA) = $(0.05 \pm 0.01) + (7.9 \pm 0.3) \times 10^5$ C (mol L^{-1}), $r = 0.9994$ $n = 4$. It could be noted that the sensitivity obtained in this matrix was lower than that achieved only in the presence of phosphate buffer, pointing that the proposed methodology is yet useful and applicable but the interference of urine components make mandatory the use of the standard

addition method for reliable DA quantification under these conditions.

4. Conclusion

The results presented in this work have demonstrated that the electrode pre-treatment and the presence of carbon nanotubes played a key role in the final electrochemical response of SPE-MWCNT. The proposed methodology have allowed the highly sensitive and selective DA quantification in the presence of large AA excess using low sample with little reagent consumption and simple sample treatment, showing potential application to DA determination in serum and urine. Therefore, the important advantages obtained when combining screen-printing devices with nanomaterials for one-shot electrochemical analysis, especially required for bionalytical applications, have been proved, opening the doors to the design of further bioanalytical devices.

ABSTRACT

A novel low-cost platform to assess biomolecular interactions was investigated using surface plasmon resonance and an aptamer-based assay for thrombin detection. Gold SPR surface functionalized with a carboxylated cross-linked BSA film (cBSA) and commercially available carboxymethylated dextran chip (CM5) were used as immobilization platforms for the thrombin binding aptamer. The high end commercial instrument Biacore 3000 and a custom made FIA set-up involving TI Spreeta sensor (TSPR2K23) were used to assess different concentrations of thrombin within the range 0.1–150 nM both in buffer and in a complex matrix (plasma) using the obtained aptasensors. Based on data derived from both CM5 and cBSA platforms, the cBSA aptasensor exhibited good selectivity, stability and regeneration ability, both in buffer and in complex matrices (plasma), comparable with CM5.

1. Introduction

Bioaffinity-based methods of detection usually require immobilization of one interaction partner (ligand) to the biosensor surface. Typically the ligand can be a protein or a nucleic acid. As direct physical adsorption to surfaces induces denaturation of the proteins [1], an intermediate functionalization layer for protein immobilization is needed. Thus the protein ligand will not be in direct contact with the surface hence preserving its binding activity. Currently there are several functionalization protocols and commercially available platforms for biomolecules immobilization such as carboxymethylated dextran with various carboxymethylation levels, or self-assembled monolayer of thiols, proteins, etc. [2]. The commercial platforms are usually expensive, while less expensive custom preparation protocols may require several days. Moreover, the preparation requires thorough cleaning of the surface with strong oxidizing solutions that can damage the surface or, if the case, the plastic housing.

The aim of this study was to investigate the use of the carboxylated cross-linked bovine serum albumin (cBSA) film as a functionalization platform for immobilization of biomolecules and its feasibility for surface plasmon resonance assays for thrombin quantification in complex media. The cBSA film was selected due to its carboxyl groups which allow further immobilization of biomolecules via amino-coupling chemistry and its BSA background providing good blocking ability of the gold surface. As a reference we used the CM5 sensor (Biacore AB, now GE Healthcare), a carboxymethylated 3D dextran matrix, which is a general purpose chip for immobilization of a wide range of ligands, from small organic molecules to proteins, nucleic acids and carbohydrates. The cBSA and CM5 functionalization platforms immobilized with the thrombin binding aptamer were investigated comparatively in terms of thrombin detection using the Biacore 3000. Furthermore, the cBSA platform was also implemented on a low-cost, versatile Spreeta (Texas Instruments, USA) based SPR system for aptamer immobilization and thrombin detection in buffer and in plasma.

Thrombin and its specific aptamer were selected for this study not only because this bioaffinity pair is well studied, but also because thrombin detection and quantification in complex biological samples such as serum or plasma is clinically relevant and development of an easy to use and cost-effective measurement system is of great interest. Blood coagulation conventional assays are usually indirect because they measure the clotting fibrinogen, which also depends on other factors [3].

Thrombin (coagulation factor II) is a highly specific serine protease of trypsin-like specificity that converts soluble fibrinogen into insoluble strands of fibrin. This protein which plays an important role in thrombosis and hemostasis exhibits both enzymatic and

doi:10.1016/j.talanta.2009.11.023

hormone-like properties that can be both pro- and anti-coagulant. Therefore, thrombin is a key element in various pathogenesis such as leukemia, arterial thrombosis, liver disease, etc. [4] and regulates numerous processes in inflammation and tissue repair at the vessel wall [5].

Thrombin also has hormone-like properties—it can regulate cell signaling by cleaving and activating receptors [6] and it binds with and activates blood cells (except erythrocytes), endothelial cells, fibroblasts, etc. [7].

Thrombin concentration in blood can vary significantly: under normal conditions thrombin is present in blood in its inactive form (prothrombin) and during the coagulation process can reach low micromolar concentrations. Low nanomolar levels of thrombin generated when hemostasis is initiated are also important to the entire process. Thrombin has also been detected at high picomolar range in blood of patients with coagulation abnormalities [8].

Aptamers are oligonucleic acid molecules that bind to a specific target molecule and are created by *in vitro* selection from a large random sequence pool by the SELEX (Systematic Evolution of Ligands by Exponential Enrichment) process. They are highly specific towards their molecular targets, which range from small inorganic and organic substances to proteins and even cells [4]. Although aptamers are equivalent to antibodies, they possess numerous advantages such as ease of synthesis, thermal stability and lack of immunogenicity. Also, they are designed *in vitro*, without the need for an animal host. Once selected, aptamers are readily produced with high reproducibility and purity by chemical synthesis. Moreover, an aptasensor can be used in a wide variety of sample matrixes, including non-physiological buffers and temperature conditions that would cause denaturation of typical antibodies [9].

For this study the DNA thrombin binding aptamer 15-mer 5′-GGTTGGTGTGGTTGG-3′ carrying a 20-mer poly thymine spacer was chosen because reported results indicated best performances in comparison with other available sequences. The spacer keeps the aptamer distant from the sensor surface, thus avoiding steric hindrance and allowing the proper conformation for molecular recognition [8].

The 15-mer thrombin binding aptamer was the first one selected *in vitro*, specific for a protein without nucleic acids-binding properties [10] and has a high specificity for the fibrinogen binding exosite of thrombin. This oligonucleotide is in equilibrium between a random and a folded state, equilibrium which is shifted towards the four-stranded structure by binding to thrombin. The thrombin aptamer undergoes a transition into a G-quadruplex structure upon binding thrombin [11] and restricts its activity [12]. The 15-mer thrombin binding aptamer is the most extensively investigated one although several other aptamers were also selected, including a 29-mer one specific to the heparin binding exosite of thrombin [13].

In bioaffinity assays, the aptamer immobilization to the surface is crucial. Thus, an ordered and oriented layer must be obtained to ensure the flexibility of the bioreceptor without altering the affinity for the target molecule.

Modifications induced at the biofunctionalized surface of transducers as result of specific interactions with target analytes are detected by various biosensing methods. In the present study we use surface plasmon resonance (SPR), an optical technique that enables real-time monitoring of changes in the refractive index of a thin film close to a surface (up to 150 nm distance from the surface) as a result of biomolecular interactions [14]. In the last years, SPR has matured into a powerful, well established, biosensing technique, providing real-time kinetic information on molecular binding and continuous process monitoring capabilities.

2. Experimental

2.1. Chemicals and reagents

Human α-thrombin, bovine serum albumin (BSA), streptavidin, avidin, human IgG, biotin, N-hydroxysuccinimide (NHS), 1-ethyl-3-(dimethylaminopropyl) carbodiimide (EDC) and ethanolamine were purchased from Sigma–Aldrich (Germany).

Human plasma (without fibrinogen) was provided by the National Institute of Transfusional Hematology "Prof. Dr. C.T. Nicolau" (Bucharest, Romania).

All the other reagents for buffers were purchased from Sigma, except for the Surfactant P20 which was provided by Biacore AB (Sweden).

The buffers used for the experiments are: phosphate buffer saline solution (PBS), pH 7.4 containing 137 mM NaCl, 10 mM phosphate, 2.7 mM KCl; streptavidin immobilization buffer, 10 mM acetate buffer pH 5; avidin immobilization buffer, 10 mM acetate buffer pH 4.5 containing 0.125 M NaCl; aptamer binding buffer, 300 mM NaCl, 20 mM Na_2HPO_4, 0.1 mM EDTA, pH 7.4 [8]; thrombin running buffer: 50 mM Tris–HCl, pH 7.4, 140 mM NaCl, 1 mM $MgCl_2$ [8]; streptavidin/avidin running buffer: HBS-EP buffer (10 mM HEPES pH 7.4, 150 mM NaCl, 3 mM EDTA, 0.005% Surfactant P20).

Succinic anhydride and sodium hypochlorite (NaOCl) were supplied by Acros Organics (Belgium).

The biotinylated 15-mer thrombin binding aptamer (TBA) with polyT(20) tail used in this study having the following sequence: 5′-biotin-TT TTT TTT TTT TTT TTT GGT TGG TGT GGT TGG-3′ was purchased from MWG Biotech.

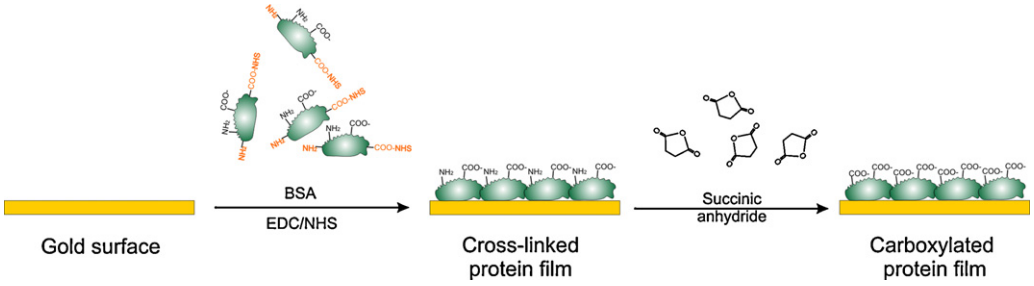
Deionized water (Millipore) was used throughout the preparations. All chemical reagents were of analytical grade and were used without further purification.

2.2. Sensor chips

CM5 (Biacore AB, now GE Healthcare).

Plain gold unmounted chips (Ssense, The Netherlands).

2.3. Equipments



2.3.1. Biacore 3000

Comparative CM5 and cBSA measurements were performed using the Biacore 3000 instrument (Biacore AB, now GE Healthcare). The SPR signal provided by the instrument is a direct measure of the angle of minimum reflected intensity. The unit of SPR response (resonance unit, RU) is an arbitrary unit chosen so that 1 RU corresponds to a shift in angle of 10^{-4} degrees, which in turn correlates with a change in refractive index of about 10^{-6} [15].

2.3.2. Custom made cost-effective SPR system

A dual channel SPR system based on the Spreeta TSPR2K23 SPR sensor (Texas Instruments, TX, USA) has been developed within International Centre of Biodynamics, Bucharest, Romania.

A two channels polydimethylsiloxane (PDMS) flow cell is mounted on the Spreeta sensor and the liquid sample is delivered over the sensor surface by the automated fluidic system comprised of syringe pumps and valves actuated by computer. The flow channels are 8 mm long by 0.8 mm wide with a height of 150 μm. Each flow channel is connected to an independent flow circuit controlled by a syringe pump, allowing simultaneous, as well as independent analyses. The flow rate range is 40–1000 μl/min with increments of 1 μl/min. Sample injection is achieved using electrically actuated injection valves, one for each flow circuit. The sample loops of the injection valves are loaded with the desired sample through a selection valve. Sample loading, injection and washing protocols are preprogrammed and the user only selects the measurement

Scheme 1. Preparation of cross-linked protein film.

flow channel, the sample volume and flow rate for both buffer and sample. Data acquisition and processing is realized with a LabView controlled interface. The signal received from the SPR sensor is processed through various software routines to subtract background and reference data in order to obtain the SPR curve. The SPR minimum is calculated online by analysis of the SPR curve. This data is converted then to refractive index units, or response units using a calibration protocol. Both SPR data (as refractive index units or response units) as well as the SPR curve for each point can be saved for further analysis.

2.4. cBSA functionalization procedure

Before functionalization, the gold sensor surface was first cleaned with 5% NaOCl, thoroughly rinsed with deionized water, ethanol and another deionized water washing steps and finally dried under nitrogen stream.

As presented in Scheme 1, sensor functionalization involves a coupled set of processes:

(a) Formation of cross-linked BSA film: 20 μl of 0.4 M EDC were mixed with 20 μl of 0.1 M NHS and 50 μl of a freshly prepared solution of 5 mg/ml BSA in PBS pH 7.4 and allowed to incubate at room temperature for 5 min. On a horizontally aligned surface, 10 μl of the mixture were spread evenly to cover the whole sensor surface. Following a 15 min reaction time at room temperature, the sensor was rinsed with 20 mM HCl and deionized water and dried under nitrogen stream. The integrity of the film was checked using atomic force microscopy (data not shown) revealing a good sensor coverage.
(b) Adding carboxylic groups to the film. Freshly prepared succinic anhydride solution: 0.2 g succinic anhydride in 500 μl DMSO were thoroughly vortexed/sonicated until fully dissolved. 50 mM Na_2HPO_4 was added to make up to a final volume of 10 ml. The pH was adjusted to 6.5 using 5 M NaOH. The BSA coated plain gold sensors were incubated overnight at room temperature in the succinic anhydride solution [16].

2.5. Aptamer immobilization

The same protocols were used for the immobilization/binding of the biotinylated aptamer on both CM5 and cBSA chips.

Either streptavidin or avidin was first immobilized on the surface. The immobilization procedure was performed at a constant flow rate of 5 μl/min and at 25 °C. The surface was activated 7 min for streptavidin and 2 min for avidin using 1:1 volumetric mixtures of 50 mM NHS and 200 mM EDC, followed by a 20 min injection of 200 μg/ml streptavidin and 50 μg/ml avidin, respectively, and 7 min blocking with 1 M ethanolamine hydrochloride pH 8.5.

Before the immobilization, the biotinylated aptamer was heated at 90 °C for 1 min to unfold the DNA strand and then cooled in ice for 10 min in order to block the DNA in its unfolded structure [8]. The thermal treatment unfolds the DNA strand, making the biotin label at the 5′-end available for the interaction with streptavidin/avidin on the surface.

The thermally treated biotinylated aptamer (1 μM) was injected for 7 min, 5 μl/min over the chip surface.

A reference channel immobilized with streptavidin/avidin and blocked with biotin and BSA was used throughout the experiments.

3. Results and discussion

3.1. Biacore 3000 measurements

Several concentrations of thrombin in the physiologically relevant range (0.1–150 nM) in both buffer and in plasma were injected over the sensors surface. All injections were performed at a constant flow rate of 5 μl/min and at constant temperature, 25 °C, with an injection time of 20 min.

The two platforms, CM5 and cBSA, were analyzed using the Biacore 3000 considering: the immobilized TBA surface coverage, the response measured for the same concentration of thrombin, the non-specific response when injecting thrombin in plasma, the baseline evolution after injection–regeneration cycles, the derived average coefficient of variation (CV) and limit of detection (LOD).

3.1.1. Quality of the cBSA film

Before avidin/streptavidin immobilization and aptamer binding, the degree of carboxylation of the cBSA film was evaluated by assessing the charge pre-concentration effect [16]. At pH values above 3.5 the carboxylic groups of the functionalization layer are negatively charged and due to electrostatic attraction the positively charged ligands (in diluted solutions 10–50 μg/ml or less) will be concentrated on the surface. As this mechanism is suited for most proteins and several other biomolecules [17] it provides, with limited reagent consumption, a direct evaluation of the reactive sites on the surface.

The pre-concentration test was performed by injecting 50 μg/ml human IgG in 10 mM acetate buffer pH 5.5. The response was high (~5700 RU) indicating that the carboxylated surface was properly formed. A higher ionic strength buffer at neutral pH (HBS) was used as running buffer so that the non-covalently bound ligand was washed off the surface after injection. A short pulse (1 min) of 1 M ethanolamine hydrochloride pH 8.5 was used leading to removal of all the remaining traces of electrostatically bound ligand.

The same test was performed for a cross-linked BSA film which was not previously treated with succinic anhydride (ncBSA). The response was significantly lower (~2000 RU).

The non-specific binding of cBSA and ncBSA was compared with a bare gold surface. The non-specific binding of human IgG directly to the gold surface is not negligible: when 50 μg/ml antibody solution was injected over the bare gold sensor a response of ~3000 RU was recorded. Yet, for the bare gold sensor surface, in contrast with the cBSA and ncBSA surfaces, regeneration with a short pulse of

Table 1
Immobilization results for the CM5 and cBSA platforms.

Platform	Protein	Protein bound (RU)	TBA bound (RU)	Protein binding capacity (RU)	TBA binding stoichiometry	TBA surface coverage (ng/mm^2)	TBA surface coverage (molecules/cm^2)
CM5	Streptavidin	3850	1400	817.7	1.71	1.12	6.01E+12
	Avidin	5060	1370	846.9	1.62	1.09	5.89E+12
cBSA	Streptavidin	2760	800	586.2	1.36	0.64	3.44E+12
	Avidin	1600	415	267.8	1.55	0.33	1.78E+12

1 M ethanolamine hydrochloride pH 8.5 had little effect on the signal, suggesting that most of the protein remained bound non-specifically.

3.1.2. Immobilized TBA surface coverage

Since the SPR response is directly proportional to the mass concentration of material at the surface, assuming a 1:1 binding stoichiometry, the analyte binding capacity of a given surface is related to the amount of ligand immobilized as follows:

analyte binding capacity (RU) = analyte MW/ligand MW × *immobilized ligand (RU)* [17]. Thus the binding stoichiometry of the aptamer to the surface for CM5 and cBSA was calculated:

binding stoichiometry = analyte bound (RU)/analyte binding capacity (RU) for 1:1 stoichiometry.

The surface coverage of immobilized aptamer molecules for Biacore was estimated considering that 1000 RU = 0.8 ng/mm^2 [18].

TBA binding stoichiometry had similar values for CM5 and cBSA for both streptavidin (1.71 and 1.36, respectively), and avidin (1.62 and 1.55, respectively), yet TBA surface coverage for CM5 in comparison to cBSA, was from double, for streptavidin, to triple, for avidin (Table 1). These results are explained due to higher surface coverage of binding sites in the 3D carboxymethylated dextran matrix in respect to the "two-dimensional" cBSA.

When several cBSA aptasensors were immobilized with streptavidin/avidin, TBA binding stoichiometry was similar (1.44 and 1.36 for streptavidin, 1.55 and 1.43 for avidin,), showing a good reproducibility in surface functionalization.

3.1.3. Response measured for the same concentration of thrombin in different matrices

For cBSA immobilized with streptavidin and 0.4 ng/mm^2 TBA surface coverage, the response for 100 nM thrombin injection in buffer was 790 RU, 60% from the response generated with the same thrombin concentration on CM5 with streptavidin and almost a three times higher TBA surface coverage 1.12 ng/mm^2. When injecting 25 nM thrombin in plasma on the same cBSA-streptavidin platform (Fig. 1A), the response was 450 RU, 70% from the response measured for the same concentration on the analogous CM5-streptavidin platform.

Again the differences are to be explained due to higher surface coverage of binding sites in the carboxymethylated dextran matrix in respect to the cBSA.

While similar to the ones indicated by [19] based on a custom made set-up, the dissociation phase for both CM5 and cBSA platforms is faster when compared to the same type of experiments reported [20] on CM5 using the Biacore X instrument. This could be explained by the difference between the flow cell volume of Biacore X (0.06 μl) and of the Biacore 3000 (0.02 μl) used in our study: although the flow rate was the same (5 μl/min), larger wall velocities are effective in the Biacore 3000 set-up.

3.1.4. Non-specific response

As the platform is intended to assess target analytes in complex matrices, thrombin spiked plasma samples 1:400 diluted with running buffer have been analyzed to check for the non-specific adsorption of proteins (protein content ~0.2 mg/ml). Thrombin in plasma determines on the reference channel a non-specific binding signal for both CM5 and cBSA aptasensors. For CM5 the non-specific response was negligible for streptavidin and around 60 RU for avidin. For cBSA the non-specific response was around 30 RU for streptavidin and 100 RU for avidin. As expected, due to the lack of carbohydrate modification and near-neutral pI [21], streptavidin platforms show lower non-specific binding as compared to avidin ones, with good correlations between CM5 and cBSA.

While the non-specific signal is not negligible (~30 RU for cBSA with streptavidin chip), it is nevertheless one order of magnitude lower than the specific signal corresponding to 25 nM of thrombin (see Fig. 1A) and correlates well with the response of the CM5 chip, considered to posses a low non-specific binding potential.

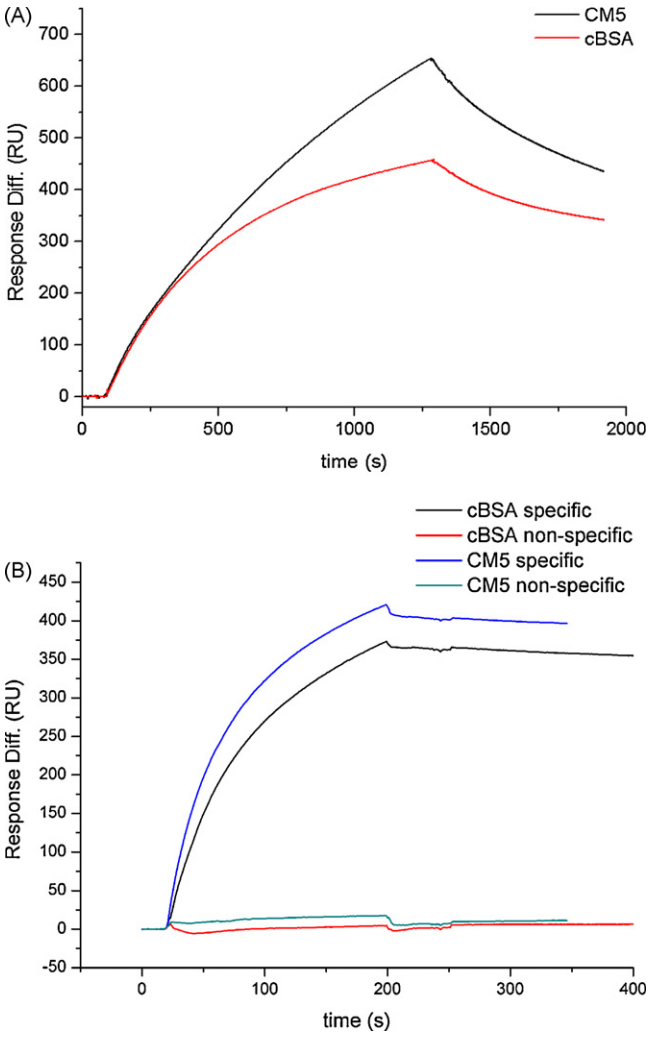


Fig. 1. (A) Injection of 25 nM thrombin in plasma on CM5 and cBSA immobilized with streptavidin. (B) Specific versus non-specific signals for cBSA and CM5 upon injection of 5 μg/ml human IgG.

Table 2
Non-specific response when injecting several proteins for cBSA and CM5 platforms.

Protein	Concentration	cBSA	CM5
		Non-specific response (RU)	
HIgG	5 μg/ml	6.5 ± 2.5	7.5 ± 2.5
BSA	1 mg/ml	20 ± 4	19 ± 4
Inactivated thrombin in diluted plasma	0.2 mg/ml	30 ± 2.5	Not tested

In order to investigate the nature of the higher non-specific binding response for the cBSA sensor, thrombin in plasma mixed with 150 nM TBA (called in the following "aptamer inactivated thrombin") was injected over the cBSA aptasensor. The specific and non-specific responses due to aptamer inactivated thrombin in plasma were the same and also similar with the non-specific response measured during regular thrombin in plasma injections, suggesting a significant effect of matrix components on the non-specific binding response.

Additional tests performed with BSA and antibody proteins (human IgG) confirmed a low non-specific binding for concentrations consistently higher than those of the target compound (Fig. 1B). A summary of the actual values related to different non-specific proteins in HBS running buffer is presented in Table 2.

3.1.5. Baseline evolution

Surface stability and efficiency of the regeneration protocol was evaluated by monitoring several injection–regeneration cycles.

For all surface types the regeneration was performed using a 1 min pulse of 50 mM NaOH, at a flow rate of 5 μl/min.

For thrombin in plasma injected on the CM5 and cBSA platforms, the baseline level after regeneration varied from one measurement cycle to another with a maximum standard deviation value of 5 RU and respectively 8 RU.

To check for the efficiency of regeneration and long term stability, we performed repeated cycles or injection–regeneration. For the CM5 aptasensor, at the end of 9 injection–regeneration cycles, the baseline decreased with 6 RU for the specific channel and with 1 RU for the reference channel for streptavidin (Fig. 2A), and with 30 RU for the specific and 10 RU for the reference channel for avidin (Fig. 2B). For the cBSA aptasensor, at the end of 9 injection–regeneration cycles, the baseline decreased with 10 RU for the specific channel and with 10 RU for the reference channel for streptavidin (Fig. 2C), and decreased with 22 RU for the specific and increased with 30 RU for the reference channel for avidin (Fig. 2D).

These results show a good efficiency of the regeneration protocol on both platforms and also a good stability of both platforms.

3.1.6. Calibration curves

Calibration curves consisting of relative response (recorded after 20 min of injection) versus concentration (for both cBSA and CM5) were fitted with a 4 parameters logistic equation (using BIAeval 4.1 software for Biacore measurements): $f(c) = R_{hi} - ((R_{hi} - R_{lo})/1 + (c/A_1)^{A_2})$, where $R_{hi} = f(c)$ when $c \to \infty$, $R_{lo} = f(c)$ when $c = 0$, A_1 is fitting constant 1 and A_2 is fitting constant 2.

In Figs. 3A and B the calibration curves for thrombin in plasma on CM5 aptasensor with avidin and streptavidin are presented, while Fig. 4A and B shows the cBSA aptasensor (with avidin and streptavidin) responses in respect to injections of thrombin in plasma.

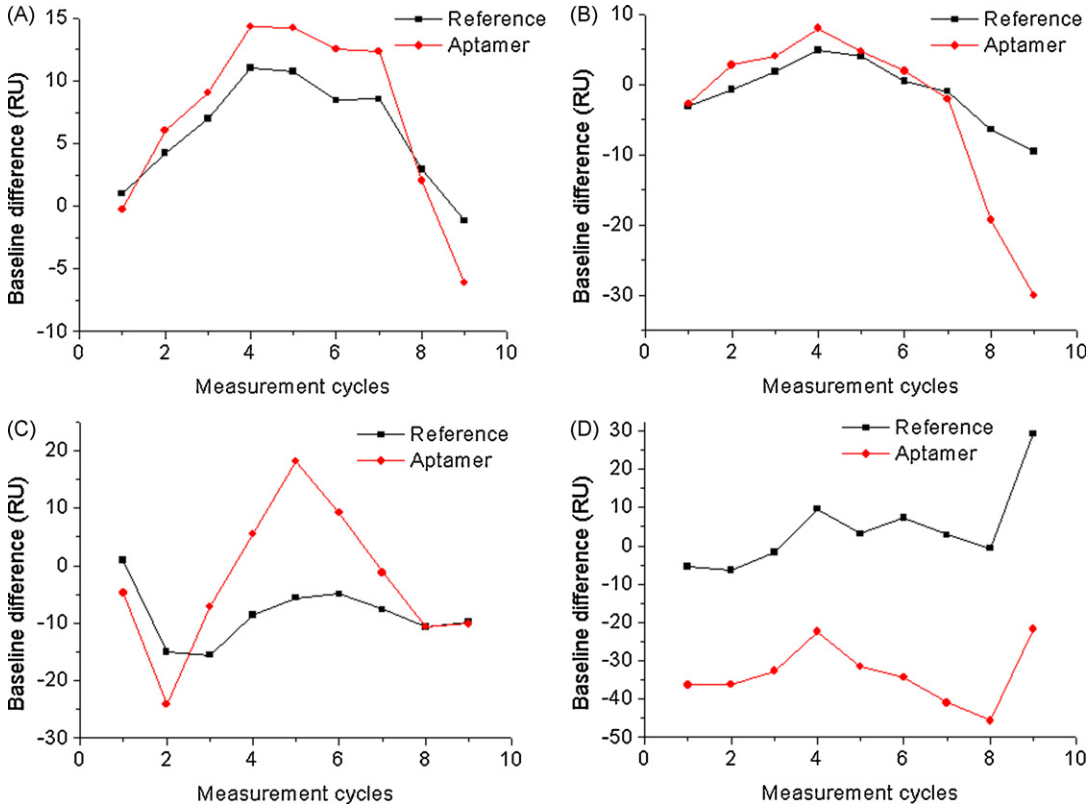

Fig. 2. Baseline variation for each injection–regeneration cycle against initial baseline at the beginning of the experiment for (A) CM5-streptavidin, (B) CM5-avidin, (C) cBSA-streptavidin, and (D) cBSA-avidin.

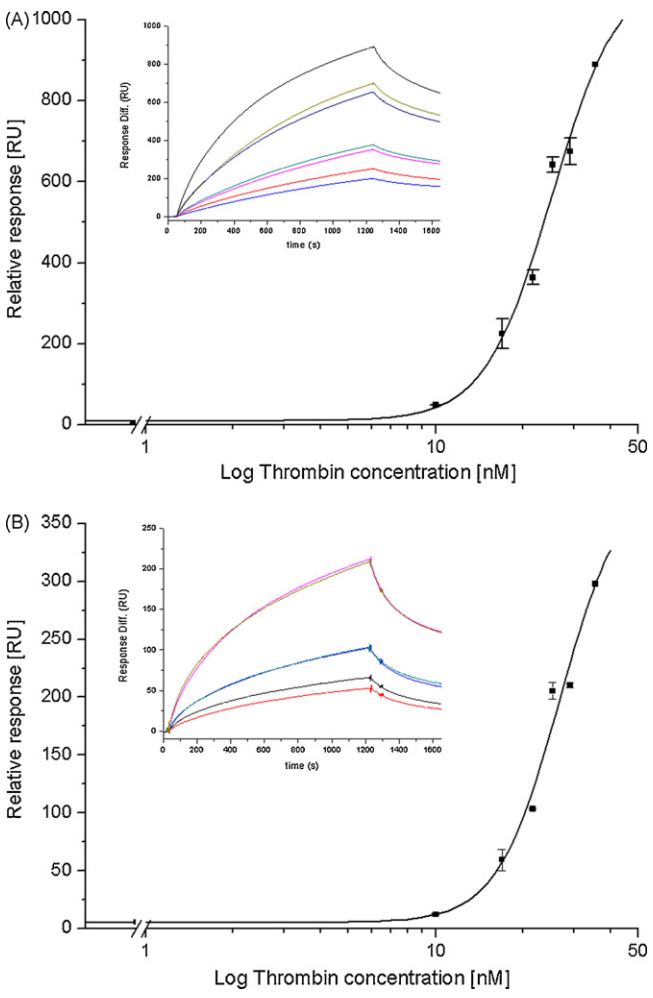

Fig. 4. (A) Calibration curve for thrombin in plasma on cBSA with streptavidin; in the inset, injection curves for different thrombin concentrations are included. (B) Calibration curve for thrombin in plasma on cBSA with avidin; in the inset, injection curves for different thrombin concentrations are included.

3.1.7. *Coefficient of variation and limit of detection*

The averaged coefficient of variation (CV) was calculated as the mean of all the coefficients of variation for all the concentrations considered. For CM5 (Biacore) the CV was 3.6% for streptavidin (data not shown) and 2.8% for avidin. For cBSA (Biacore) the CV was 5.8% for streptavidin and 5.15% for avidin.

The limit of detection (LOD) expressed as the concentration c_L is derived from the smallest measure, x_L, that can be detected with reasonable certainty for a given analytical procedure. The value of x_L is given by the equation $x_L = x_{bi} + ks_{bi}$, where x_{bi} is the mean of the blank measures, s_{bi} is the standard deviation of the blank measures, and k is a numerical factor chosen according to the confidence level desired [22].

LOD was calculated by the evaluation of the average response of the blank plus three times the standard deviation. For streptavidin, LOD for the CM5 platform (1.12 ng/mm^2 TBA surface coverage) was evaluated at 2.5 and 3 nM for cBSA (0.64 ng/mm^2 TBA surface coverage). In the case of avidin, LOD was 5 nM for CM5 (1.09 ng/mm^2 TBA surface coverage) and 5.5 nM for cBSA (0.33 ng/mm^2 TBA surface coverage), similar to the one previously reported for an aptamer-based SPR assay [19].

To increase the sensitivity of the platform, instead of binding of the aptamer directly on the gold surface of the SPR chip, an additional, intermediate layer has been considered providing: improved accessibility of the binding sites with likely better conformation of the recognition element, leading to increased binding potential and better blocking of the surface against non-specific binding.

Previous results [8] proved a 4-fold increase in the specific signal for the same concentration of target compound and aptamer for CM5 chip in comparison with bare gold. Upon optimal choice of the aptamer linker (20T) the sensitivity was further increased due to an 8-fold augmentation in the specific signal compared to bare gold.

Our present experimental data further support this improvement revealing an increased sensitivity when using streptavidin in comparison with avidin (due to the lack of carbohydrate modification and near-neutral pI of streptavidin). The surface coverage, though lower than for the 3D dextran matrix characteristic for CM5, is optimum for detection as revealed by the similar responses of cBSA-streptavidin and CM5 respectively. Notably, the surface blocking against non-specific binding is efficient (in complex matrix, the non-specific response was 6.5% of the specific response for cBSA and 1.5% for CM5).

3.2. *Custom made SPR system measurements*

Having in mind that an important goal of the study was to implement a cost-effective immobilization platform for the TBA on the Spreeta-based sensing system, avidin was chosen for immobilization on the cBSA sensor due to a better cost/performance ratio against streptavidin.

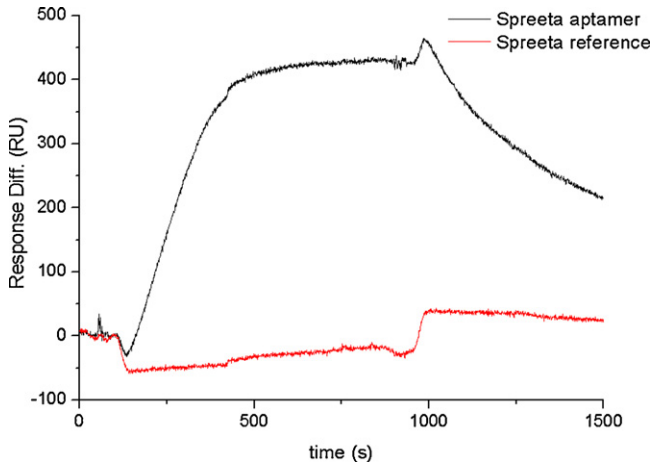

Fig. 5. 50 nM thrombin in buffer injection on cBSA aptasensor. Spreeta-based system measurement.

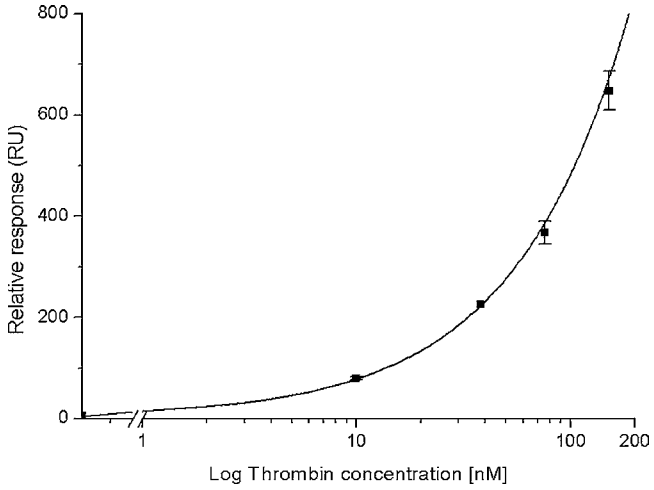

Fig. 7. Calibration curve for cBSA avidin platform measured on Spreeta sensor.

In order to maintain a similar concentration of the analyte over the surface as in the Biacore flow cell (2.4 mm × 0.5 mm × 0.02 mm), the flow rate was adjusted accordingly to our system's flow cell dimensions (0.8 mm × 8 mm × 0.15 mm).

The assay was performed using 50 μl/min flow rate and 16 min injection time (the maximum injection time for this flow rate due to sample loop volume). A typical thrombin in buffer injection on both specific and reference channel is presented in Fig. 5.

When injecting thrombin in plasma, the reference channel showed a small non-specific binding response, nevertheless, the baseline after regeneration returned to its initial value before injection (Fig. 6).

The calibration curve generated with thrombin in plasma using the same 4 parameters logistic equation is shown in Fig. 7: the signal increased with the increased concentration of the added analyte. The average coefficient of variation was 6% and a limit of detection of 10 nM was obtained for thrombin in plasma.

3.3. Further improvements

Even though the performances of the platforms are comparable to ones reported in literature [19], there are two aspects that are worth further investigating in order to improve the LOD. A recent study [23] showed that thrombin binding capacity increases as the linker length increases from 0 to 5 thymidine nucleotides and decreases as the number of thymidine residues increases to 20 (corresponding to the spacer used in our study). Furthermore, recent evidence pinpoint on the important role of cations present in solution on the G-quadruplex formation: this stabilizing conformation corresponding to aptamer–thrombin binding is not easily formed in the presence of Mg^{2+} and Ca^{2+} [24].

Thus using the optimum linker size and the optimum thrombin running buffer are possible ways to further increase the sensitivity of the assay.

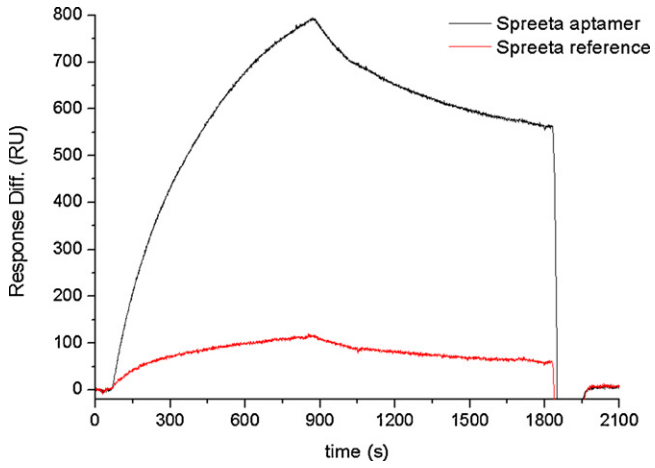

Fig. 6. 100 nM thrombin in plasma injection on a cBSA aptasensor on Spreeta-based system.

4. Conclusions

In this study a new bio-immobilization platform based on a carboxylated cross-linked BSA film was investigated and compared with the commercial available CM5 reference chip. We demonstrate that the cBSA platform is suitable for immobilization of bioaffinity compound and we tested it with streptavidin/avidin and a biotinylated aptamer. In comparison with the CM5 platform, cBSA exhibited similar sensitivity, considering the immobilized TBA surface coverage (LOD 2.5 nM for CM5-streptavidin with 1.12 ng/mm^2 and 3 nM for cBSA-streptavidin with 0.64 ng/mm^2), a similar coefficient of variation (3.6% for CM5 and 5% for cBSA) in detecting thrombin in the presence of other interfering proteins (plasma) and proved stable during numerous injection–regeneration cycles.

The low-cost cBSA aptasensor with avidin was successfully implemented on the cost-effective Spreeta-based SPR system (a LOD of 10 nM was obtained for thrombin in plasma and CV of 6%, similar to the one provided by the cBSA aptasensor measured with the Biacore) amenable for portable platforms development [25].

The cBSA platform exhibited good performance when used in complex media (plasma), the non-specific response being similar to the one obtained with the CM5 platform. This shows the potential of this immobilization platform as a low-cost analytical tool in conjunction with selected bioaffinity pairs for real samples (complex matrix) assessment.

The BSA functionalization procedure is a suitable alternative to self-assembled monolayers formation or carboxymethyldextran coatings, for most SPR chips, including the Spreeta sensor which, due to its plastic housing, can be easily altered by the organic solvents or strong oxidizing cleaning solutions (*e.g.* piranha solution).

Besides being a low-cost alternative to commercially available platforms, the cBSA film provides additional advantages: it is relatively easy to employ, the sensor surface does not require harsh washing methods and the procedure can be completed overnight, and is fully automatable. Moreover the cBSA chips can be stripped off and re-functionalized repeatedly without destroying the gold surface or other sensor components.

While current performances of the platforms are comparable to ones reported in literature, further optimizations are envisaged based on selection of appropriate linker size and thrombin running buffer as possible avenues to increase the sensitivity of the assay.

ABSTRACT

NMR spectroscopy was employed for the detection of adulteration of refined olive oil with refined hazelnut oil. Fatty acids and iodine number were determined by ^{1}H NMR, whereas ^{31}P NMR was used for the quantification of minor compounds including phenolic compounds, diacylglycerols, sterols, and free fatty acids (free acidity). Classification of the refined oils based on their fatty acids content and the concentration of their minor compounds was achieved by using the forward stepwise canonical discriminant analysis (CDA) and the classification binary trees (CBTs). Both methods provided good discrimination between the refined hazelnut and olive oils. Different admixtures of refined olive oils with refined hazelnut oils were prepared and analyzed by ^{1}H NMR and ^{31}P NMR spectroscopy. Subsequent application of CDA to the NMR data allowed the detection of the presence of refined hazelnut oils in refined olive oils at percentages higher than 5%. Application of the non-linear classification method of the binary trees offered better possibilities of measuring adulteration of the refined olive oils at a lower limit of detection than that obtained by the CDA method.

1. Introduction

Numerous attempts have been made in the past to detect virgin olive oil adulteration with seed oils and particularly with hazelnut oil [1–23]. Although no official analytical method has been adopted by the European Commission and other international institutions for the detection of hazelnut oil, several methods using chromatographic and spectroscopic techniques have been proposed to distinguish extra virgin or virgin olive oil from hazelnut oil. Several of these methodologies detect virgin olive oil adulteration with crude hazelnut oil on the basis of chemical compounds that are present in one oil but not in the other oil. For instance, filbertone, which was considered as a hazelnut oil marker [1], had been proposed to detect olive oil fraud [1–4], whereas other researchers suggested to determining chlorophylls [5], tocopherols [6], volatile compounds [7,8] and phenolic compounds [9,10]. Detection of virgin olive oil with refined hazelnut oil (RHzO) presents increasing difficulties because the filbertone marker and other minor components in hazelnut oil are removed upon refinement [3,4], and in addition the triacylglycerol profile of both oils is very similar. Chromatography has been employed to distinguish RHzO in virgin olive oil on the basis of triacylglycerol [11,12] and/or sterol [11–13] profiles. Several spectroscopic techniques in combination with multivariate statistical methods were successful in classifying edible oils and detect the presence of RHzO with little or great success [14–21]. The real problem, however, is the detection of RHzO in refined olive oil (ROO), since their minor components, and in particular their glyceridic composition, were considered to be very similar. Recent applications of FT MIR and FT-Raman and fluorescence spectroscopy [22,23] allowed detection of ROO adulteration with RHzO at concentrations >8%.

NMR spectroscopy is one of the most promising spectroscopic techniques for the analysis of complex systems, such as food matrices. It has been proven to be very successful in the analysis of olive oil and in combination with multivariate statistical methods was able to classify edible oils and detect olive oil adulteration with seed oils and olive oils of inferior quality [15,16,20,24–26]. It made possible the detection of the presence of refined hazelnut oil in virgin olive oil at concentrations 5–10% [14–16,20]. ^{1}H and ^{13}C NMR spectroscopy shows a number of advantages relative to other analytical techniques; it is fast (less than 5 min are required to record an one-dimensional ^{1}H NMR spectrum of an olive oil sample in chloroform-d); it needs no calibration with internal standards or separation of the various components prior to the analysis; it shows remarkable selectivity, inasmuch it identifies unknown compounds at a molecular level; it gives a wealth of information in a single experiment; it is quantitative with excellent repeatability and reproducibility. Disadvantages of NMR spectroscopy may be considered its low sensitivity compared with chromatographic

doi:10.1016/j.talanta.2009.11.024

and mass spectrometry techniques and the high cost of the analysis, since the NMR spectrometers are quite expensive. Nevertheless, sensitivity problems have been overcome lately by using strong magnetic fields produced by super-conductive selenoids and properly designed probes, especially cryogenic probes, whereas the screening of a large number of samples in a short period of time may compensate the high cost of the analysis. The same advantages shares the NMR spectroscopy of the phosphorus-31 nucleus, although derivatization with phosphorus reagent is needed prior to the analysis, since apart from phospholipids, compounds in olive oil do not contain phosphorus atoms in their molecules. This method is based on the replacement of the acidic hydrogens of the hydroxyl and carboxyl groups of olive oil constituents with the phosphorus reagent 2-chloro-4,4,5,5-tetramethyphospholane and the use of ^{31}P NMR spectroscopy to identify the phosphitylated compounds [27]. This facile magnetic resonance method supplements ^{1}H and ^{13}C NMR techniques, especially in cases where severe overlapped signals in ^{1}H NMR spectra or long relaxation times of the insensitive ^{13}C nuclei render the analysis a difficult task.

The aim of the present study was to assess the potential of ^{1}H and ^{31}P NMR spectroscopy to detect ROO adulteration with RHzO at low concentration. This goal will be achieved upon application to the NMR data two statistical methods, namely, forward stepwise canonical discriminant analysis (CDA) and classification binary trees (CBTs).

2. Experimental

2.1. Refined oils

A collection of 20 samples of refined olive oil were supplied by the olive oil company MINERVA (Athens, Greece). The refined oils were obtained upon refinement of lampante olive oils originated from various locations of Greece. Twenty commercial samples of RHzO were purchased from Henry Lamotte (Bremen, Germany). To detect ROO adulteration, admixtures were prepared by mixing different samples of ROO with different samples of RHzO. The percentage of RHzO in ROO of the adulterated refined olive oils (AOO) varied from 1% to 95% (1%, 2%, 3%, 4%, 5%, 7%, 10%, 12%, 15%, 17%, 20%, 25%, 30%, 50%, 60%, 70%, 80%, 90%, 95%: w/w), The ROO and RHzO samples were selected randomly for the formation of each one of the 19 admixtures. All oil samples and their admixtures were analyzed twice.

2.2. Reagents

Pinacol, triethylamine, phosphorus trichloride, protonated solvents (reagent or analytical grade), and deuterated solvents used in the present study were purchased from Sigma–Aldrich (Athens-Greece). The derivatizing phosphorous reagent 2-chloro-4,4,5,5-tetramethyldioxaphospholane used in ^{31}P NMR spectroscopy was synthesized from pinacol and phosphorus trichloride following the method described in the literature [28]. However, to increase the yield of the reaction, we utilized hexane solvent instead of benzene and pyridine instead of triethylamine suggested in the original method. This modification resulted in ~45% yield of the product against 19% obtained with the original method.

2.3. Extraction of minor polar components from refined oil

Phenolic compounds were extracted following the method developed by Montedoro et al. [29] using 35 g of olive oil and a mixture of methanol–water (80:20, v/v). The polyphenol extracts were used immediately for sample preparation and ^{31}P NMR measurements.

2.4. Sample preparation for ^{31}P NMR spectral analysis

A stock solution was prepared by dissolving 0.6 mg of chromium acetylacetonate, $Cr(acac)_3$ (0.165 μM) and 13.5 mg cyclohexanol (13.47 mM) in 10 ml of a mixture of pyridine and $CDCl_3$ solvents (1.6:1.0, volume ratio) and protected from moisture with 5A molecular sieves. Cyclohexanol was used as an internal standard for quantification purposes. 100–150 mg of each oil was placed in a 5 mm NMR tube. The required volumes of the stock solution (0.4 mL) and the reagent **1** (15 μL) were added. The reaction mixture was left to react for about 15 min at room temperature. Upon completion of the reaction, the solution was used to obtain the ^{31}P NMR spectra.

2.5. NMR experiments

All NMR experiments were conducted on a Bruker AMX500 spectrometer operating at 500.1 and 202.2 MHz for proton and phosphorus-31 nuclei, respectively, at 26 ± 1 °C.

One-dimensional ^{13}P NMR spectra were recorded by employing the inverse gated decoupling technique in order to suppress NOE effects. Typical spectral parameters for quantitative studies using reagent **1** were: 90° pulse width 12.5 μs, sweep width 55 kHz, relaxation delay 25 s, memory size 32 K. To ensure quantitative spectra, the magnitude of the relaxation delay adopted was more than five times the relaxation time (T_1 = 4.6 s) of the phosphitylated cyclohexanol; 32 transients were accumulated for each spectrum. For all FIDs, line broadening of 1 Hz was applied and drift correction was performed prior to Fourier transform. Polynomial fourth-order base-line correction was performed before integration.

One-dimensional high-resolution ^{1}H NMR spectra were acquired with the following acquisition parameters: time domain 32 K; 90° pulse width 9.3 μs; spectral width 12 ppm; relaxation delay 2 s. 16 scans and 8 dummy scans were accumulated. Baseline correction was performed carefully by applying a polynomial fourth-order function in order to achieve a quantitative evaluation of all signals of interest. The spectra were acquired without spinning the NMR tube in order to avoid artificial signals, such as spinning side bands of the first or higher order.

2.6. Statistical methods

Classification by stepwise forward CDA is used to achieve the most discriminative variables for the arrangement of samples in a space of reduced dimensionality in a way that maximizes the distances between the *a priori* formed groups and the independence of the axes of the configuration [30,31]. The *a priori* groups are ROO, RHzO, and the adulterated refined olive oils (AOO). The chemical compounds contributing most to the discrimination of preformed groups are shown by means of the *F-ratio* as a criterion for inclusion or removal of the compound in the forward stepwise CDA mode. *Wilks'* λ and the *F* approximation were used to check the significance and estimate the importance of each compound in CDA analysis. The significance of the representation of the original configuration of the samples by the newly formed discriminant axes was expressed by the last value of *Wilks'* λ. The performance of the method was measured by the percentage of total variance explained by all significant discriminant axes. In a sense, this is a measure of non-linearity and complex interrelations among variables, since CDA is a linear technique. The classificatory efficiency of CDA can be seen in the resulting classification tables which illustrate the group relations of the samples. The ability of the oil samples to be predicted by the rest is another property of CDA, although the percentage of the correctly classified oil samples is a property of the original data rather than an intrinsic feature

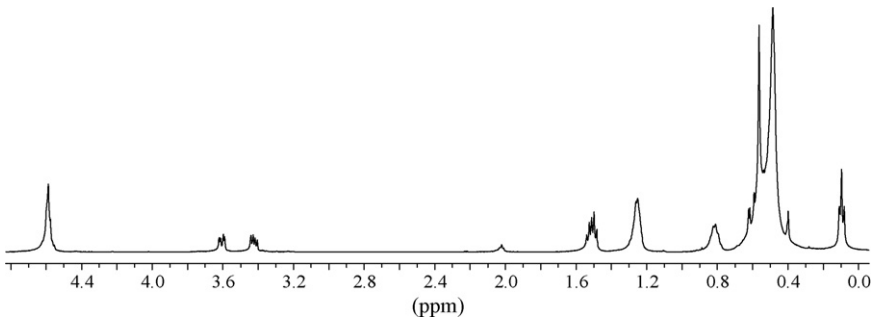

Fig. 1. 500 MHz ^{1}H NMR spectrum of a ROO sample, from which fatty acids and iodine value can be determined.

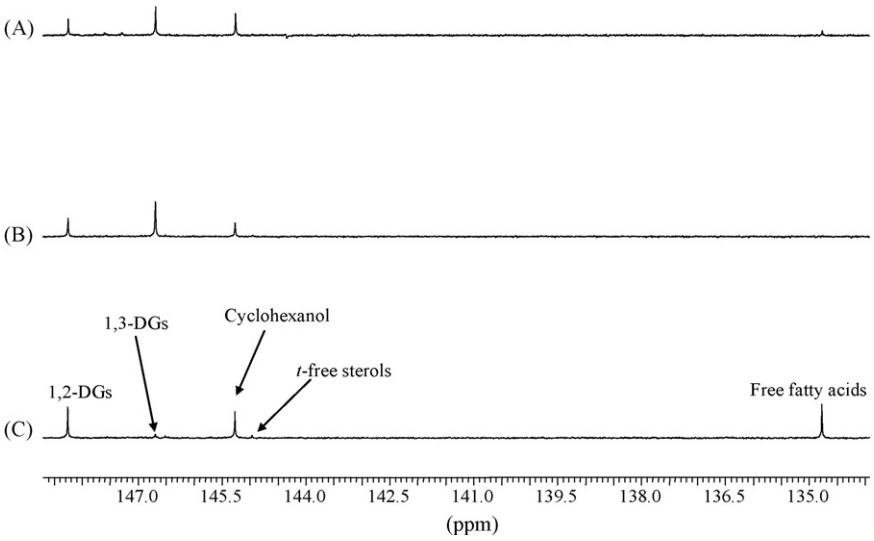

Fig. 2. 200.2 MHz ^{31}P NMR spectra of (A) RHzO, (B) ROO, and (C) virgin olive oil samples from which diacylglycerols, total free sterols and free acidity can be determined.

of the algorithm. Classification is achieved by means of the Mahalanobis distance of each oil sample from the group centroid in order to estimate the probability of misclassification for each one of the predefined groups. Oil samples, which were not engaged in the calculation of classification functions of CDA, are classified in the same way. This feature of CDA reveals its ability to classify oil samples with known compositional constitution, but unknown group affiliation [32]. In other words, CDA predicts class affiliation by using a linear combination of all compounds engaged in the construction of classification equations.

* Index compounds that are important in CDA.
# Index compounds that are important in CBT.

In contrast to CDA, CBTs is a statistical method capable to handle non-linearity and any possible interactions of compositional parameters, in order to produce a set of simple rules in the form of inequalities, which identify existing samples and with this information find the group affiliation of any new sample [33]; the latter is essential in any adulteration detection system. The construction of a CBT comprises the split of the original set of samples into two parts on the basis of a criterion involving one or two compounds in an algebraic expression. All chemical compounds involved in the construction of a CBT comprise the best diagnostic variable set for the groups already defined prior to the analysis. The groups at the beginning of a CBT construction are RHzO, ROO, and *n1*, *n2*, *n3* groups of AOO with small (1–10%), medium (12–30%) and high (50–95%) RHzO content, respectively. The original AOO group is split into three subgroups because: (a) in this way the method is capable to reveal connections of the adulterated samples with the original groups of ROO and RHzO, and (b) this is the minimum number of groups that could manifest the "intermediacy principle", that is *n3* will be closer (clustered together) to RHzO, *n1* to ROO, while *n2* samples will be between them. It should be noted that CDA does not need this split because the final arrangement is expected to depict the picture of intermediacy [26]. The tree grows according to splits that produce maximally informative and 'pure', according to an impurity function. The reduction of error in the classification is monitored by means of a loss function. Several loss functions have been proposed [33]; in this study the splitting method has been made through the information theory compatible *Gini-Simpson* index in the form of "towing" a term coined by Breiman et al. [33] on the basis of the better reduction in error they achieved.

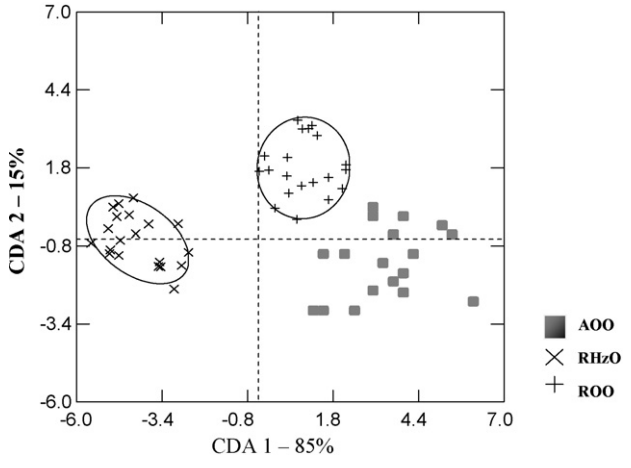

Fig. 4. CDA scattergram of refined olive oil (ROO) (+), refined hazelnut oil (RHzO) (×) samples, and adulterated ROO with RHzO. The latter admixtures denoted as AOO and shown as squares (■) were not taken into account in the construction of the scattergram. The two discriminant axes account for by all variation in the original data set (CDA 1 = 85% and CDA 2 = 15%). Ninety-five percent ellipses are drawn around the ROO and RHzO group centroids. Samples lying outside the group ellipses are correctly classified together with the AOO samples. The crosswire indicates the origin (0, 0) of the scattergram.

All statistical analyses used routines and packages in R system [34] and employed the packages "rpart" [35], and "vegan" [32]. Some algorithms and graphics were applied via SYSTAT (SYSTAT, 1999).

3. Results and discussion

3.1. Data analysis

Fig. 1 shows a typical ^{1}H NMR spectrum of a ROO sample from which the fatty acid profile and the iodine number can be calculated [16]. This spectrum shows similar characteristics with the proton spectra of RHzO samples (not shown), although it differs in certain signal intensities. Fig. 2 depicts the ^{31}P NMR spectra of the phosphitylated refined oils; diacylglycerols, free sterols, and free acidity can be determined from this spectrum [27]. The same figure shows the corresponding spectrum of a virgin olive oil sample. The

Table 2

[a] See footnote in Table 1 for the meaning of symbols.
[b] Symbols at split in CBT (see Table 4).

higher acidity of the virgin olive oil sample as compared to those of ROO and RHzO is reflected on the much stronger signal of the free fatty acids at δ 134.8. Fig. 3 compares the ^{31}P NMR spectra of the polar part of the refined oils recorded after phosphitylation of the hydroxyl groups of their minor compounds. This methodology was used for the detection and quantification of polyphenols in olive oil [36]. Also, Fig. 3 illustrates the ^{31}P NMR spectrum of a virgin olive oil sample. The most characteristic feature of the ^{31}P NMR spectra in Fig. 3 is the complete absence of phenolic compounds in RHzO. Previous studies [37,38] have shown that refining process reduces significantly or even removes completely [39,40] the content of phenolic compounds of olive oil. The mean losses of total phenols of olive oil (virgin and lampante) amount to 75–85%, respectively. This is shown clearly upon comparison of the ^{31}P NMR spectra of a virgin olive oil sample and its refined counterpart (Fig. 3). Hazelnut oil, on the other hand, contains much smaller amounts of phenolic compounds than olive oil [41], and hence the polyphenol content is expected to be practically absent after refinement. The absence of phenolic compounds in RHzO serves as a means to differentiate between RHzO and ROO (see below).

Table 1 lists the mean values of phenolic compounds, fatty acids, diacylglycerols, free sterols, iodine values, and free acidity for both refined oils. The compositional parameters for each oil, including the adulterated oils, are provided as supporting material. The mean values in Table 1 shows that there are discernible differences in fatty acid profiles, especially for linolenic acid and saturated fatty acids. However, this interesting difference alone cannot detect the adulteration of ROO with RHzO at low percentage [41]. Both refined oils are characterized by a higher content of 1,3-DGs than 1,2-DGs, contrary with what is observed for the virgin olive oil samples. This is nicely reflected in Fig. 2 on the respective signal intensities between the refined oils and virgin olive oil. Refinement accelerates the isomerisation of 1,2-DGs to 1,3-DGs, which reaches rapidly its equilibrium state and the ratio *D* (=1,2-DGs/Total DGs) assumes its equilibrium value (∼0.33) [42]. These parameters may not be suitable to discriminate between the refined oils. However, measurable differences were observed in the mean values of free sterols and iodine values (Table 1). In particular, ROO samples are characterized by higher sterols content and lower iodine values than the corresponding values of the RHzO samples. The amounts of phenolic compounds as determined by NMR are within the range of phenolic content determined by HPLC [37,38].

3.2. Chemometric approach for the detection of adulteration of refined olive oil

The entire variation of compounds in the original data set within, ROO, RHzO, and AOO groups (Table 1) was fully explained by CDA (*Wilks'* $\lambda = 0.031$, $F_{approx} = 19.46$, $df_1 = 22$, $df_2 = 92$, $P < 10^{-4}$). The eigenvalues are $\lambda_1 = 10.35$, and $\lambda_2 = 1.82$ estimating the rate of the explained variation by the two discriminant axes, i.e. 85% and 15%, respectively. The discriminant scores of the oil samples can be seen in Fig. 4. Both axes have a chemical meaning since their canonical correlations with the original important compounds is high ($r_1 = 0.96$ and $r_2 = 0.80$). The important compounds are variously weighted on the two axes as shown by the standardized coefficients of the canonical functions in Table 2. Linoleic and oleic acids are highly weighted in the negative part of CDA-1 while the iodine value in the positive part. The same compounds are highly weighted with reversed signs on CDA-2. For the linoleic and oleic acids this pattern was expected since they are the products of the same biogenetic pathway [43]. The opposite sign of the iodine coefficients are explained on the basis of the chemical treatment of the oil for the production of ROO and RHzO. The dotted lines in Fig. 4 at the origin (0, 0) of the CDA diagram leave intact only the ROO group. RHzO and the adulterated samples are located at the two ends of CDA-1 but are cut by CDA-2. This indicates that no axis alone is enough to separate adulterated oils from the groups of RHzO and ROO. However, the classification efficacy of CDA is considered to be perfect as shown by the classification matrix in Table 3 (panel a). The percentage classification for the three groups of oils was 100%. The Jackknifed classification (cross-validation) in Table 3 (panel b) indicate that classification was correct for 95% of the samples, and only 5% of the adulterated olive samples cannot be predicted by the rest. Importantly, the adulterated oils are not found in the space between the two groups which comprise the source (RHzO) and the adulteration target (ROO) as a putative intermediate product of mixing [14,16]. The violation of the "intermediacy principle" can be explained on the basis of the non-biological chemical profile of ROO.

Classification of the NMR data into the 'leaves' of the binary trees is achieved by starting from an original configuration of five groups. The first two groups are the refined hazelnut oil (RHzO group) and the refined olive oil (ROO group) and in the next three groups are the

Table 3
Classification matrix of the CDA analysis of the NMR data in Table 1.

	Predicted group affiliation			
	RHzO	ROO	AOO	% correct classifications

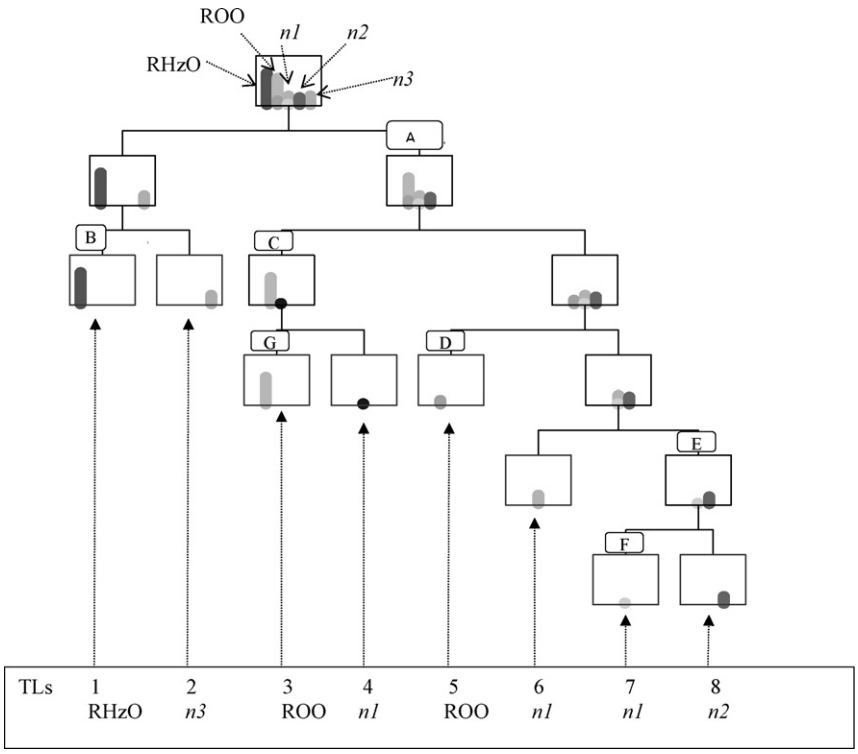

Fig. 5. CBT classification treegram (mobile) of all oil samples. The splitting criteria are those given in Table 4. The original groups are in the root node and in this order they are shown in the entire tree as circles stacked in proportion to the size of each group. The terminal leaves (TLs) at the bottom box correspond to a single group. Eight leaves – indicated by arrows – are required for a complete classification of the samples, since a specific group can form more than one TL.

adulteration levels—i.e. small (1–10%, *n1* group), medium (12–35%, *n2* group) (large 50–95%, *n3* group); ideally five site groups are produced. In the employed model the group identifier is the dependent variable, while the independent variables are the chemical compounds derived by NMR spectroscopy (Table 1). In the construction of the mobile (Fig. 5), the overall reduction in error was 100% and eight terminal leaves were found, each one corresponding to one group (Table 4). It is interesting to note that three compounds, namely *t*-hydroxytyrosol, pinoresinol, and louteolin occur twice in the splitting criteria. The growth of the tree shows that RHzO samples form the first terminal leaf (TL1) early in the process and in a second step the ROO group (TL3 & TL5) (Fig. 5). The adulterated oils spread at different terminal leaves on the basis of different compounds. On the basis of iodine value and pinoresinol (symbol A at split), oils of he *n3* group are clustered together with hazelnut oils but later they separate on the basis of 1,3-DGs and *t*-hydroxytyrosol (symbol B) (Fig. 5). The same pattern is presented with oils of the ROO group. However, here the oil samples at TL5 are separated from adulterated oil samples at another branch of the tree in accordance with the similarity of the refined hazelnut and olive oils in minor constituents. Overall the adulterated oil samples are distributed as follows: *n1* is found at TL4, TL6, and TL7; *n2* is found at TL8 while the group *n3* at TL2 as a result of the proximity to hazelnut oils. Eventually, all splitting criteria are used to separate the adulterated oils which form as many terminal leaves as their RHzO dictates. This means that *n1* is found at three terminal leaves while *n2* and *n3* at one leaf (Table 4 and Fig. 5).

With regard to the significant compounds, CDA uses a larger number of compounds (11 in Table 2) than CBT (9 compounds in seven linear combinations or splitting criteria in Table 4). The fatty acids oleic, linoleic and linolenic are of particular importance. With some exceptions, they were found to be significant in the geographical classification of Greek virgin olive oils either by CDA or CBT [31]. In this study, CDA estimates the first two acids as important while CBT the last one. It seems that the selection is justified in terms of the lipoxygenases pathway (LOX pathway) [43]. A classification method needs only one acid since both linoleic and linolenic acids are the substrates for LOX. In the same line of argumentation oleic is converted to linoleic acid in a bioreaction catalyzed by enzymes encoded by two widespread Fatty Acid Desaturases (FAD) genes. In CDA both oleic and linoleic are significant compounds (Table 2) and have very similar canonical correlations. The pure classification CBT technique does not need both acids. Instead, linoleic acid is enough for the entire classification to be described in CBT (Table 4). This is in agreement with the fact that the refinement process does not disturb the relative proportions of fatty acids.

Table 4
Significant compounds and linear combinations of two compounds expressed as improvement of CBT classification.

Symbol at split	Compounds[a]	Criterion	Fraction of predicted samples	Significance of compounds
A	IV-Pinoresinol	<83.24	0.367	0.367
B	1,3-DGs + *t*-hydroxytyrosol	<2.96	0.580	0.213
C	Louteolin-*t*-hydroxytyrosol	<0.03	0.738	0.158
D	Linoleic acid-Sterols	<0.15	0.822	0.084
E	Pinoresinol-1-acetoxypinoresinol	<0.59	0.918	0.096
F	Louteolin	<0.04	0.956	0.038
G	Apigenin	<0.19	1.000	0.044

[a] See footnote in Table 1 for the meaning of symbols.

For both methods, diacylglycerols appear to be significant compounds. 1,2-DGs is important for CDA, but with a different behavior of canonical coefficient than the ratio *D*. In CBT method 1,3-DGs are found significant. These compounds have lower variation within oil samples and vary substantially among the original groups. It is strange that *t*-DGs are not important in both methods presumably because of the similarity that exists in the lipid biosynthetic pathway that leads from diacylglycerols to triacylglycerols [44].

Phenols occur in ROO group though at reduced amounts in comparison to virgin olive oil but they are absent from RHzO as a result of chemical treatment of refinement, in spite the fact that phenols have been reported from hazel tree leaves and several species of hazel family (Angiospermae: Coryllaceae). Almost every split in the CBT tree (Fig. 5) contains one or two phenols. Exception is the split D which is the difference between linolenic acid and sterols. Amongst phenols, *t*-hydroxytyrosol, luteolin, and 1-acetoxypinoresinol are important in both CDA and CBT analyses, whereas homovanillic alcohol, apigenin and pinoresinol are important in CDA and CBT classification, respectively. Syringaresinol, *t*-tyrosol and *f*-tyrosol, *p*-coumaric acid and total phenols are not significant compounds. They have high standard deviation within groups (Table 1). Possibly, the large variation of these phenolic compounds amongst the various samples caused their exclusion from the important compound set in both classifications together with the fact that they are compounds of the same phenol biosynthetic path.

Phytosterols are also important compounds in both CDA and CBT analyses. In nature they are distributed to many species in small quantities less than 1% and usually much less. They are important nutrients for all eucaryotes; insects incapable in synthesizing them acquire the necessary amounts from endosymbiotic and in some case exobiotic bacteria from plant hosts, which supply sterols and in some cases vitamins. In CBT sterols appear in the splitting criterion that separates ROO oils from the adulterated ones in groups *n1* and *n2*.

4. Conclusions

^{1}H and ^{13}P NMR spectroscopy in conjunction with multivariate statistical analyses (CDA and CBTs) has been used with respect to its ability to discriminate between ROO and RHzO and to detect ROO fraud with RHzO. Overall, both statistical analyses showed perfect classification that is all oil samples were grouped correctly in the original group. Both analyses used different significant compounds, although in the same class and a more or less equal number of them. CBTs gave a more detailed and biologically sound hierarchical splitting while it started from more groups than CDA. This is the result of (a) non-predefined strategy, (b) its capability in treating non-linear and/or discontinuous data structures, and (c) its orientation towards hierarchical classification unlike CDA which keeps a balance between classification and ordination in a fixed number of groups [45]. RHzO was the source group of this adulteration and ROO was the group which was adulterated, and these groups cannot be altered in CDA. The reported CBTs classification is superior to other methods combining linear algorithms as principal components and simple non-linear techniques (e.g. artificial neural networks) that need a scarce knowledge of the engaged compounds and for this are unable to substantiate their biological basis.

ABSTRACT

The near-infrared (NIR)-emitting CdSeTe alloyed quantum dots (AQdots) that capped with L-cysteine were applied for ultrasensitive Cu^{2+} sensing. The sensing approach was based on the fluorescence of the AQdots selectively quenched in the presence of Cu^{2+}. Experimental results showed a low interference response towards other metal ions. The possible quenching mechanism was discussed on the basis of the binding between L-cysteine and the metal ions. In addition, biomolecules have low effect on the fluorescence due to the minimized interferences in NIR region. The response of the NIR optical sensor was linearly proportional to the concentration of Cu^{2+} ranging from 2×10^{-8} to 2×10^{-6} mol L^{-1}. Furthermore, it has been successfully applied to the detection of Cu^{2+} in vegetable samples.

1. Introduction

In recent years, contamination by large amount of heavy metals poses a serious threat to human health and the environment [1,2]. Copper is one of the heavy metals and essential element for many living organisms, it becomes toxic at high concentrations [3]. Therefore, the design and development of selective as well as sensitive method for Cu^{2+} detection in environmental and biological samples is of great importance for analytical chemists. Many methods for the detection of Cu^{2+} have been developed such as atomic absorption spectroscopy [4,5], inductively coupled plasma mass spectroscopy [6,7], X-ray fluorescence [8]. These methods offer good limits of detection (LODs) and wide working concentration ranges. However, these methods may require the use of sophisticated and relatively costly apparatus, and are unsuitable for on-line or in-field monitoring [9].

Chemical sensors can overcome these disadvantages and become increasingly important for monitoring metal ion. Some sensors have been developed for the determination of Cu^{2+}. A variety of organic fluorophore-based sensors have been proposed to selectively respond to Cu^{2+} due to their relatively high sensitivity [10–13]. However, organic fluorophore often suffer from the disadvantages like narrow excitation bands, broad emission spectra and fast photobleaching. Recently developed quantum dots (Qdots) have substantial advantages over organic dyes, including excellent fluorescence properties, high photochemical stability and excellent resistant to chemical degradation [14–16]. Therefore, the Qdots-based sensors have great potential to overcome the problems encountered with existing organic fluorophore-based sensors.

Therefore, the synthesis and application of these Qdots are of great interest in the development of novel sensitive sensors. So far only a few studies on Qdots system for Cu^{2+} detection have been reported. Chen and Rosenzweig showed the first example of thioglycerol-coated CdS Qdots sensor for Cu^{2+} [17]. Later, the optical detection of Cu^{2+} with peptide-coated CdS Qdots [18], $Cd_{10}S_{16}$ molecular cluster [19], MPA-capped CdSe [20] or CdTe [21], ZnS Qdots [22] and CdSe/CdS Qdots [23] was also proposed. However, most of the existing Qdots-based sensors were emitting at wavelengths below 550 nm. In addition, selectivity, stability and limited applicability to real sample were still among the limitations for the Qdots-based sensors proposed [24]. Therefore, the stable Qdots with near-infrared (NIR)-emission between 650 and 900 nm are of particular interest for the detection because many molecules' autofluorescence and absorbance can be reduced to the minima in this region [16,25,26]. Up to now, the sensors based on NIR-emitting Qdots for metal ions detection are very rare.

In this study, the NIR-emitting CdSeTe AQdots were prepared in aqueous solution with L-cysteine as stabilizer, and then it was demonstrated as a selective fluorescent Cu^{2+} probe with low detection limit. Moreover, the proposed sensing system has been applied for the determination of Cu^{2+} in vegetable samples and the recovery test was satisfactory.

2. Experimental

2.1. Apparatus

The fluorescence spectra of the Qdots samples were obtained with an Edinburgh FLS920P fluorescence spectrometer (Edinburgh Instruments Ltd., UK). The optical absorption spectra were measured using the Shimadzu 3600 UV–vis spectrometer (Shimadzu, Japan). The TEM images were acquired using a JEOL JEM-2100 (JEOL, Japan) transmission electron microscope operating at an acceleration voltage of 200 kV. The elemental analysis of Qdots was performed on VG PQExCell ICP-MS system.

2.2. Reagents

Selenium powder (Se, 99.5%, 200 mesh), tellurium powder (Te, 99.8%, 200 mesh) and mercaptopropionic acid (MPA, 99%) were purchased from Acros Organics (NJ, USA). L-Cysteine (98%) was purchased from Sigma–Aldrich. Cadmium chloride was purchased from Tingxin Chemical Reagent (Shanghai, China). Sodium borohydride was purchased from Tianjin Chemical Research Institute (Tianjin, China). The stock standard solutions (10 mmol L^{-1}) of Cu^{2+} were prepared by dissolving appropriate amounts of $Cu(NO_3)_2{\cdot}3H_2O$ in high purity water. Working solutions were prepared by appropriate dilutions of their stock solutions. All other reagents were of analytical grade and used without further purification. The ultrapure water with 18.2 MΩ cm^{-1} (Millipore Simplicity, USA) was used throughout the experiments.

2.3. Preparation of the AQdots

The L-cysteine-capped CdSeTe AQdots with NIR-emission were prepared through the incorporation of selenium ions into CdTe nanocrystals as reported in our previous method [27]. L-Cysteine as a sulfur amino acid was selected as capping agent for its good compatibility and the protection of Qdots-induced toxicity [28]. In the synthesis, all reactions were carried out in oxygen-free water under nitrogen. In brief, $CdCl_2$ (0.25 mmol) and L-cysteine (0.6 mmol) were dissolved in water (200 mL) and adjusted to pH 11.5 with 1 mol L^{-1} NaOH. The resulting transparent solution was deaerated by bubbling of nitrogen for 20 min and was heated to 95 °C. Under vigorous stirring, the freshly prepared 0.125 mmol of NaHTe and 0.04 mmol of NaHSe aqueous solutions were injected to the above solution. Afterward, the reaction mixture was further refluxed at 95 °C under a nitrogen atmosphere. The emission wavelength of the AQdots could be tuned by changing the refluxing time. Part of the refluxing solution was taken out at regular intervals for characterization. After 3 h, the CdSeTe AQdots with emission wavelength of 685 nm (CdSeTe685) was obtained.

2.4. Selectivity measurements

The following inorganic salts were used for the cation selectivity experiment: nickel acetate tetrahydrate, zinc acetate, barium chloride, calcium chloride, iron (III) chloride hexahydrate, iron (II) sulfate heptahydrate, sodium chloride, potassium chloride, lanthanum nitrate hexahydrate, aluminum nitrate, cobaltous sulfate, magnesium chloride, copper nitrate and lead nitrate. A 10 mmol L^{-1} salt stock solution was prepared with ultrapure water. Subsequently, the salt solutions were prepared by serial dilution with Tris–HCl solution (pH 7.4).

2.5. Procedure for spectrofluorometric detection of Cu^{2+}

Copper nitrate was used for the Cu^{2+} sensitivity studies. Various concentrations of Cu^{2+} were prepared using serial dilution of the copper nitrate stock solution to test the sensitivity limits of the AQdots. A known concentration of Cu^{2+} solution was added into the AQdots nanoparticle solution and mixed thoroughly for 10 min. The fluorescence intensity of the solution was recorded at 685 nm with the excitation wavelength of 300 nm. Both slit widths of excitation and emission were 2 nm.

2.6. Physical characterization of the fluorescence quenching

An amount of 5 μL of 1 mmol L^{-1} Cu^{2+} or Al^{3+} was added to 1 mL of 160 nmol L^{-1} CdSeTe685 AQdots solution. After incubation for 20 min, the suspended solutions of the nanoparticles were deposited onto copper grids with carbon support by slowly evaporating the solvent in air at room temperature. The high-resolution transmission electron microscopy (HR-TEM) images of Cu^{2+} and Al^{3+}-treated CdSeTe685 AQdots were acquired using a JEOL JEM-2100 (JEOL, Japan) transmission electron microscope.

2.7. Sample preparation

The vegetable samples of bean, cucumber and tomato were purchased from local market. And the accurately weighted samples were ground and then digested with 20 mL concentrated nitric acid on a gas burner until the solution became wet salt. Then, it was dissolved with 2 mol L^{-1} HNO_3 and heated until it was clear. Finally, the solution was diluted with water.

3. Results and discussion

3.1. Spectral characteristics of the AQdots

The ultrafiltration-purified L-cysteine-capped CdSeTe AQdots were well dispersed in PBS or Tris–HCl solution (10 mmol L^{-1}, pH 7.4). The absorption spectra and fluorescence spectra of the AQdots were obtained and shown in Fig. 1. The maximal fluorescence wavelength was 685 nm. It can be seen that the full width at half-maximum (FWHM) fluorescence intensity is about 60 nm and symmetric, showing that the CdSeTe AQdots were nearly of monodisperse and homogeneous. In addition, the fluorescence intensity of these AQdots was pH-dependent [29] as shown in Fig. 1B. The low fluorescence intensity in acidic medium is the result of dissociation of the nanoparticles due to protonation of the surface-binding thiolates [30]. With the increase of pH, the deprotonation of the thiol group in the L-cysteine molecule occurs. This deprotonation may strengthen the covalent bond between Cd and L-cysteine molecule, which leads to the fluorescence intensity increases with pH increasing. However, the fluorescence intensity was declined with the further increase of pH value.

3.2. Selective fluorescence quenching of the AQdots by Cu^{2+}

The experiment of selective fluorescence quenching was performed with the CdSeTe AQdots (160 nmol L^{-1}, λ_{max} = 685 nm). The purified AQdots solutions contained no free L-cysteine. The AQdots were dispersed in Tris–HCl buffer solution (10 mmol L^{-1}, pH 7.4) for its pH-dependent fluorescence intensity and then added to the same amount of metal cation solutions (1 μmol L^{-1}). The fluorescence intensity of these samples was measured and the results were shown in Fig. 2. It was found that the fluorescence intensity of AQdots has more sensitivity to Cu^{2+} than to Pb^{2+}, Fe^{2+} and no response to other cations such as K^+, Na^+, Mg^{2+}, Al^{3+}, Ca^{2+} and Zn^{2+}. In contrast, they demonstrated complete fluorescence quenching in the presence of Cu^{2+}. The quenching effect of Cu^{2+} on fluorescence emission of CdSeTe AQdots was found to be concentration dependent. Therefore, this selective response towards Cu^{2+} can be

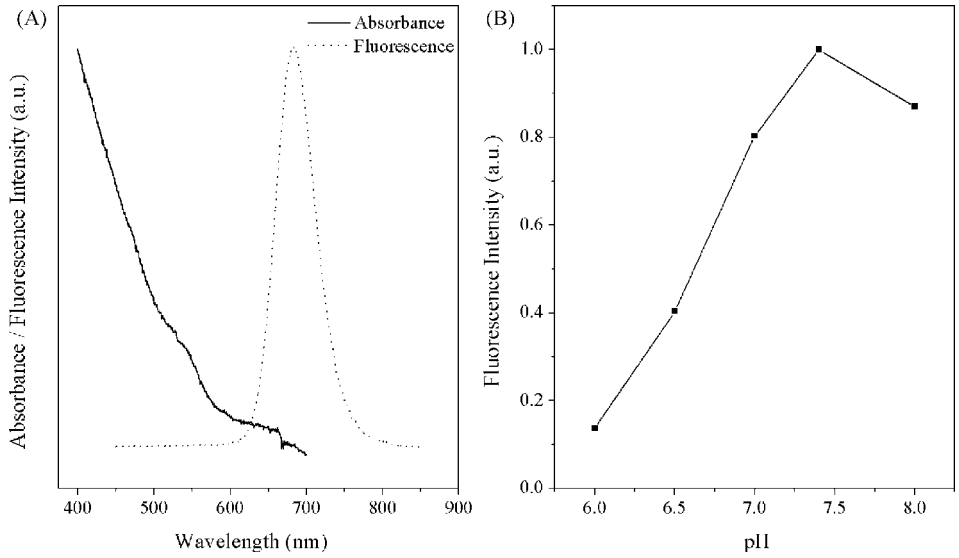

Fig. 1. (A) Absorption and fluorescence spectra of the L-cysteine-capped CdSeTe AQdots. (B) Fluorescence intensity of the CdSeTe AQdots (λ_{max} = 685 nm) in PBS buffer (10 mmol L^{-1}) at different pH values.

used for the development of a sensitive and selective sensor for Cu^{2+}.

3.3. Mechanism of the quenching effect by Cu^{2+}

L-Cysteine as a sulfur amino acid was an ideal capping agent for the CdSeTe AQdots synthesis. The cysteine capping layer was very important to improve water solubility and stability of the AQdots. Therefore, the metal–sulfide bond strength, which was characterized by their respective K_{sp} value, may be an important parameter for the fluorescence quenching effect. And the selective fluorescence quenching could be rationalized by the competitive cysteine binding between the AQdots and the metal ions present in the solution. The K_{sp} value of Cu–S (6.3×10^{-36}) is much lower than that of Cd–S (8.0×10^{-27}), Pb–S (8.0×10^{-28}), Zn–S (2.9×10^{-25}) and Fe(II)–S (6.3×10^{-18}) [31]. Therefore, we proposed that the cysteine capping layer was preferentially displaced from the surface of the CdSeTe AQdots upon the binding of Cu^{2+}. The displacement of cysteine capping consequently created imperfections on the AQdots surface, resulted in fluorescence quenching. In order to verify this hypothesis, the quenching effect of different metal ions on the fluorescence intensity of the MPA-capped CdTe Qdots (λ_{max} = 650 nm) was also investigated (Fig. 2). The MPA-capped CdTe Qdots were synthesized according to the reported methods [32]. It can be found that the quenching effect of the MPA-capped CdTe Qdots displays similar results with the L-cysteine-capped CdSeTe AQdots.

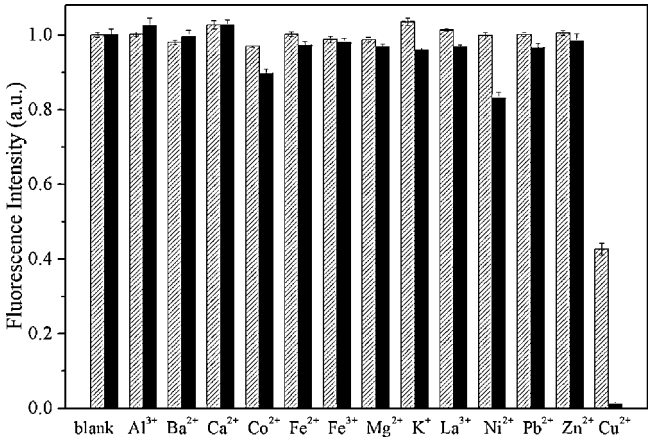

Fig. 2. The quenching effect of different ions on the fluorescence intensity of the MPA-capped CdTe Qdots (λ_{max} = 650 nm) (▨) and the L-cysteine-capped CdSeTe AQdots (λ_{max} = 685 nm) (■) in 10 mmol L^{-1} Tris–HCl buffer at pH 7.4. The excitation wavelength was 300 nm.

In addition, the fluorescence quenching experiments were conducted in the presence of free cysteine. The reduced fluorescence quenching in the presence of Cu^{2+} was observed in the CdSeTe AQdots solutions containing free cysteine. And similar reduced fluorescence quenching of the MPA-capped CdTe Qdots was observed in the presence of Cu^{2+} when the free MPA increased in the CdTe Qdots solution. This also suggested that the thiol capping agent of the Qdots was related to the fluorescence quenching effect. And the aggregation of the AQdots was also observed at high Cu^{2+} concentrations, leading to precipitation in the presence of 10 μmol L^{-1} Cu^{2+}. At high Cu^{2+} concentrations, loss of more cysteine would eventually cause the AQdots to aggregate and precipitate. The control experiment showed no aggregation of the AQdots in the same concentration of Al^{3+}. The low magnification TEM image (Fig. 3B and C) of CdSeTe confirmed the aggregation of the AQdots.

Based on the investigation, we concluded that the competitive binding of the cysteine with Cu^{2+} was the primary mechanism for the fluorescence quenching. The fluorescence intensity of CdSeTe AQdots was highly sensitive to their surface protection. Even the removal of a limited amount of surface-bound cysteine would lead to dramatic reduction in fluorescence intensity. Therefore, the lower detection limit and higher sensitivity were achieved with the lower concentration of cysteine-capped CdSeTe AQdots.

3.4. The detection of Cu^{2+}

The detection of Cu^{2+} is of particular interest due to copper importance in environment and living organisms. The CdSeTe AQdots displayed great fluorescence quenching at low concentration of Cu^{2+} compared to other metal ions. The fluorescence quenching was best described by the Stern–Volmer equation,

$$\frac{F^0}{F} = 1 + K_{SV}[Q],$$

where F and F^0 are the fluorescence intensity of the CdSeTe AQdots in the presence and absence of Cu^{2+} respectively, [Q] is the con-

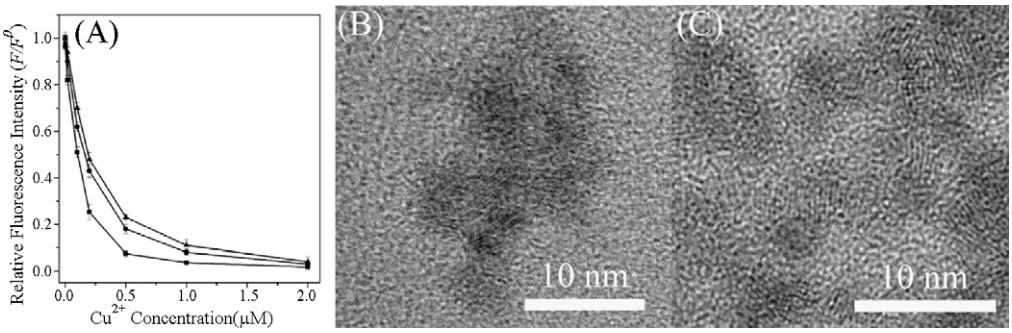

Fig. 3. (A) Fluorescence quenching by Cu^{2+} for 80 nmol L^{-1} of CdSeTe AQdots (λ_{max} = 685 nm) in the absence of free L-cysteine (■) and presence of 40 μmol L^{-1} (●) and 60 μmol L^{-1} (▲) of free L-cysteine, respectively. The excitation wavelength was 300 nm. (B) The TEM image of the CdSeTe AQdots (λ_{max} = 685 nm) in the presence of 5 μmol L^{-1} Cu^{2+}. (C) The TEM image of CdSeTe AQdots (λ_{max} = 685 nm) in the presence of 5 μmol L^{-1} Al^{3+}.

centration of the quencher (i.e., Cu^{2+}) and K_{SV} is the Stern–Volmer constant.

The influence of the concentration of L-cysteine-capped CdSeTe AQdots on fluorescence quenching by Cu^{2+} was studied. The strong fluorescence quenching was observed at low CdSeTe AQdots concentration in the presence of the same Cu^{2+} concentration as shown in Fig. 4A. Fig. 4B illustrated the high reproducibility of the CdSeTe AQdots response to Cu^{2+}. The linear relationship of the Stern–Volmer plot of F^0/F to Cu^{2+} concentration (Fig. 4C) was obtained. The linear relationship between $1/K_{SV}$ and CdSeTe AQdots concentration as shown in Fig. 4D, which suggested that the detection limit can be reduced with the decrease of AQdots concentration. Therefore, the CdSeTe AQdots concentration of 80 nmol L^{-1} was recommended. The calibration plot of F^0/F versus [Q] shows a good linear relationship (R^2 = 0.9976) for Cu^{2+} concentration in the range of 2×10^{-8} to 2×10^{-6} mol L^{-1} (Fig. 4C). The limit of detection was evaluated using $3\sigma/S$, and is found to be 7.1×10^{-9} mol L^{-1}, where σ is the standard deviation of the blank signal, and S is the slope of the linear calibration plot.

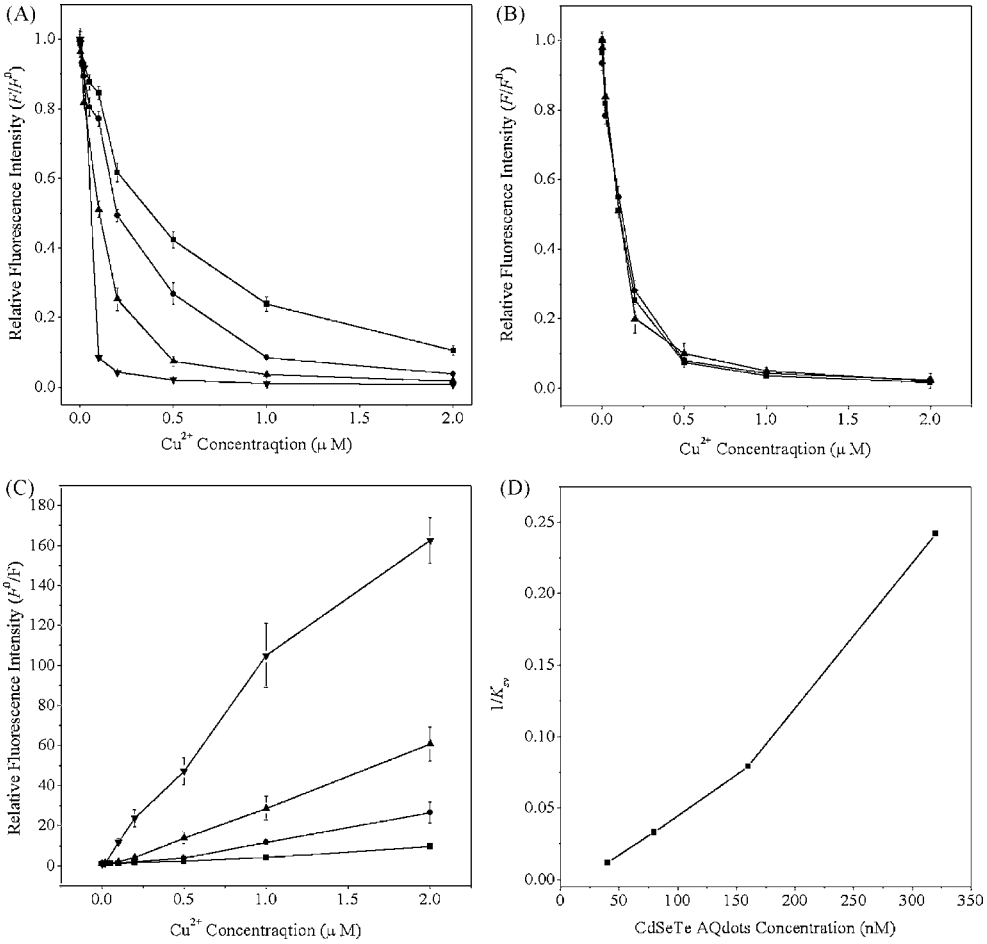

Fig. 4. (A) The quenching effect of Cu^{2+} concentration on the fluorescence intensity of 40 nmol L^{-1} (▼), 80 nmol L^{-1} (▲), 160 nmol L^{-1} (●) and 320 nmol L^{-1} (■) CdSeTe AQdots. (B) The reproducible determination of the fluorescence quenching effect of the 80 nmol L^{-1} CdSeTe AQdots. (C) Stern–Volmer plots of the different CdSeTe AQdots concentration. (D) Linear correlation of $1/K_{SV}$ values of the CdSeTe AQdots. The L-cysteine-capped CdSeTe AQdots (λ_{max} = 685 nm) was used. The excitation wavelength was 300 nm.

Table 1
Detection of Cu^{2+} in real samples.

Samples	Cu^{2+} concentration (mg/kg)				
	Proposed method	ICP-MS method	Added	Total	Recovery (%)
Bean	3.51	3.10	5	8.87	107.2
Cucumber	2.62	2.94	5	7.86	104.8
Tomato	1.96	1.65	5	7.44	109.6

3.5. Sample analysis

The proposed method has been applied to the analysis of vegetable samples including bean, cucumber and tomato. A control experiment was carried out using inductively coupled plasma-optical emission spectroscopy (ICP-OES) method. Table 1 gives the analysis results of Cu^{2+} in these vegetable samples. With standard addition method, the recoveries were found to be 104.8–109.6%. The analysis results agreed with those obtained with ICP-MS methods.

4. Conclusions

The near-infrared (NIR)-emitting L-cysteine-capped CdSeTe alloyed quantum dots (AQdots) have been demonstrated selective fluorescence quenching in the presence of Cu^{2+}. The selective quenching effect could be rationalized by the competitive cysteine capping layer binding between the CdSeTe AQdots and the metal ions present in the solution. Based on this finding, we proposed a novel NIR fluorescence sensor for sensitive Cu^{2+} detection in aqueous medium. The limit of detection (LOD) of this method is higher than that of the previous reported methods. Under the optimum conditions, the detection range of the proposed method was from 2×10^{-8} to 2×10^{-6} mol L^{-1} with the LOD of 7.1×10^{-9} mol L^{-1}. Furthermore, the practical utility of the CdSeTe AQdots sensor has been demonstrated by the determination of trace Cu^{2+} in vegetable samples, obtaining satisfactory results with the reference method. Our preliminary studies have demonstrated the potential of this method for practical applications.

ABSTRACT

In this paper a carbon ionic liquid electrode (CILE) was fabricated by using ionic liquid 1-ethyl-3-methylimidazolium ethylsulfate ([EMIM]EtOSO$_3$) as modifier and further gold nanoparticles were in situ electrodeposited on the surface of CILE. The fabricated Au/CILE was used as a new platform for the immobilization of hemoglobin (Hb) with the help of a Nafion film. Electrochemical experimental results indicated that direct electron transfer of Hb was realized on the surface of Au/CILE with a pair of well-defined quasi-reversible redox peaks appeared. The formal peak potential ($E^{0\prime}$) was obtained as −0.210 V (*vs.* SCE) in pH 7.0 phosphate buffer solution (PBS), which was the characteristic of Hb heme Fe(III)/Fe(II) redox couple. The fabricated Nafion/Hb/Au/CILE showed excellent electrocatalytic activity to the reduction of trichloroacetic acid (TCA) and the reduction peak current was in proportional to TCA concentration in the range from 0.2 to 18.0 mmol/L with the detection limit as 0.16 mmol/L (S/N = 3). The proposed electrode showed good stability and reproducibility, and it had the potential application as a new third-generation electrochemical biosensor.

1. Introduction

Direct electrochemistry between metalloproteins with electrodes has aroused great interests in the preparation of the biosensor and bioreactor [1]. But the direct electron transfer on the bare working electrode is difficult to be realized due to the deep burying of the electroactive center or the partly denaturation of the redox protein. Many methods have been proposed for the construction of protein film electrodes to achieve the direct electron transfer process between proteins and the working electrode. For this purpose various supporting films including insoluble surfactants, biopolymers, polyelectrolytes and hybrid films are used [2–4]. The presence of film on the electrode surface can provide a biocompatible microenvironment for proteins to retain their nature structure and enhance the direct electron transfer rate between the electroactive center and the underlying electrode. In recent years there are increasing interests on the direct electrochemistry of redox protein with ionic liquids (ILs) interface. ILs are green solvent with many specific physicochemical properties such as high ionic conductivity, wide electrochemical window, good stability and excellent biocompatibility [5]. Wei and Ivaska had reviewed the recent progresses of ILs in the field of electrochemical sensor [6]. ILs can be used as not only the supporting electrolyte but also the modifier for the chemically modified electrodes [7,8]. Xiong et al. studied the direct electrochemistry of hemoglobin (Hb) and its electrocatalytic activity towards hydrogen peroxide on the modified electrode with 1-butyl-3-methylimidazolium tetrafluoroborate ([BMIM]BF$_4$) as the electrolyte [9]. Maleki and co-workers fabricated a high performance carbon ionic liquid electrode (CILE) with *n*-octylpyridinium hexafluorophosphate ([OP]PF$_6$) as binder [10,11]. Our group also applied CILE to the investigation of protein electrochemistry with different nanomaterials [12–14].

Gold nanoparticle has been widely used for the immobilization of proteins, which act as the good conductive mediator to facilitate the electron transfer rate [15]. Many reports indicate that the gold nanomaterials with different appearances can be used as the immobilization matrix to realize the direct electrochemistry of redox protein. Yang et al. investigated the direct electrochemistry of Hb on a gold nanowire array [16]. Zhang et al. combined gold nanoparticle with polyvinyl alcohol and 1-octyl-3-methylimidazolium hexafluorophosphate ([OMIM]PF$_6$) for the investigation on the electrochemical behaviors of Hb [17]. Hong and Dai constructed a novel amperometric biosensor for hydrogen peroxide and nitrite by immobilizing Hb on one-dimensional gold nanoparticle [18].

In this paper a gold nanoparticle decorated CILE was fabricated by in situ electrodeposition method. CILE has been elucidated with the advantages such as high conductivity, good stability and antifouling ability with a layer of IL also presented on the surface of CILE [5]. At the same time gold nanoparticles show good conductivity

doi:10.1016/j.talanta.2009.11.026

and biocompatibility [19]. So a layer of gold nanoparticle was electrodeposited on the surface of CILE to get a novel platform for protein electrochemistry, which combined the advantages of CILE and gold nanoparticle. Then Hb was selected as the model redox protein and it was immobilized on the surface of Au/CILE with Nafion film. Nafion is a sulfonated tetrafluoroethylene based fluoropolymer–copolymer with many remarkable characteristics such as highly conductivity to cations, excellent film-forming ability, thermal and chemical stability as well as the selectively and highly permeable to water, which has been widely used in the fabrication of electrochemical biosensors [20]. The direct electrochemistry of Hb was further investigated carefully with a pair of well-defined redox peaks appeared on the cyclic voltammogram. The experimental results indicated that the direct electron transfer process was realized on the modified electrode, which proved the advantages of the prepared gold nanoparticle decorated electrode. The electrocatalytic ability of Hb on the modified electrode to the reduction of trichloroacetic acid (TCA) was further investigated.

2. Experimental

2.1. Reagents and apparatus

1-Ethyl-3-methylimidazolium ethylsulfate ([EMIM]$EtOSO_3$, Hangzhou Chemer Chemical Co. Ltd., China), bovine hemoglobin (Hb, MW 64500, Tianjin Chuanye Biochemical Co. Ltd., China), graphite powder (average particle size 30 μm, Shanghai Colloid Chemical Plant, China), chloroauric acid ($HAuCl_4$, Shanghai Chemical Plant, China) and trichloroacetic acid (TCA, Tianjin Kermel Chemical Reagent Co. Ltd., China) were used as received. 0.1 mol/L phosphate buffer solutions (PBS) were used as the supporting electrolyte. All the solutions were purged with highly purified nitrogen for 30 min and an inert nitrogen environment was maintained in the electrochemical cell during the electrodeposition and electrochemical measurements. Other chemicals used were of analytical reagent grade and the solutions were prepared with doubly distilled water.

A LK 2005 electrochemical workstation (Tianjing Lanlike Chemistry & Electron High Technology Co. Ltd., China) was employed for the electrodeposition and electrochemical measurements. Electrochemical impedance spectroscopy (EIS) was achieved on a CHI 750B electrochemical workstation (Shanghai CH Instruments, China). A traditional three-electrode system, which was consisted of a self-made Hb modified electrode as working electrode, a saturated calomel electrode (SCE) as reference electrode and a platinum wire as counter electrode, was used throughout. Scanning electron microscopy (SEM) was performed on a JSM-6700F scanning electron microscope (Japan Electron Company, Japan).

2.2. Electrode preparation

CILE was prepared according to the following procedure: 200 μL of [EMIM]$EtOSO_3$, 800 μL of liquid paraffin and 3.2 g of graphite powder were hand-mixed in an agate mortar and ground carefully. A portion of resulting homogeneous paste was packed firmly into a glass tube (Ø = 4 mm) and the electrical contact was established by a copper wire to the end of the paste in the inner hole of the tube.

Gold nanoparticle modified CILE (Au/CILE) was prepared based on a reported procedure [21]. In general gold nanoparticle was electrodeposited onto the newly prepared CILE with a solution of 5.0 mmol/L $HAuCl_4$ and 0.5 mol/L KNO_3 by controlled potential at −0.4 V for 300 s. The Au/CILE was rinsed with doubly distilled water and dried in air for further modification. Hb modified electrode was fabricated by casting 8.0 μL of 10.0 mg/mL Hb aqueous solution on the surface of Au/CILE and staying silent to allow the water evaporated gradually. Then 8.0 μL of 0.5% Nafion solution was cast on the electrode surface, which could form a stable film and fixed Hb on the surface of electrode tightly. During these procedures a small bottle was covered over the electrode so that the solvent could evaporate slowly to get a uniform film. The modified electrode was stored at 4 °C when not in use and denoted as Nafion/Hb/Au/CILE. Other modified electrodes were prepared by the similar procedure for the comparison.

3. Results and discussion

3.1. Characterization of gold nanoparticle modified carbon ionic liquid electrode

Fig. 1 showed the SEM images of different modified electrodes. On bare CPE (Fig. 1A) a layer of irregularly flasks of graphite powder was isolated. On the CILE (Fig. 1B) a more uniform surface was observed without the separated carbon layer. The results were in accordance with the previous reported results [12,13]. After electrodeposition of gold nanoparticle on the CILE surface, the interface appeared with highly regular and uniform (Fig. 1C). The average diameter of the formed gold nanoparticle was about 150 nm, indicating the successfully deposition of gold nanoparticle on the CILE. The resulted electrode was further used for the protein immobilization with an increased surface area and a three-dimensional structure.

Electrochemical behaviors of different modified electrodes in a 5.0 mmol/L $[Fe(CN)_6]^{3-/4-}$ and 0.1 mol/L KCl solution were investigated with the cyclic voltammetric results as shown in Fig. 2. A pair of quasi-reversible redox peaks was observed on the CPE (curve a), and the redox peak currents were much smaller than that of CILE (curve b). The result was attributed to the presence of the high conductive IL on the electrode surface. After the electrodeposition of gold nanoparticle on the surface of CILE (curve c), a remarkable enhance of redox peak currents occurred, indicating the high conductive metal of gold on the electrode surface. According to the Randles–Sevcik equation [22]: $I_{P,c} = (2.69 \times 10^5)n^{3/2}AD^{1/2}C^*v^{1/2}$, the effective surface area of different modified electrodes can be estimated. Where $I_{P,c}$ is the reduction peak current (A), n is the electron transfer number, A is the effective surface area (cm^2), D is the

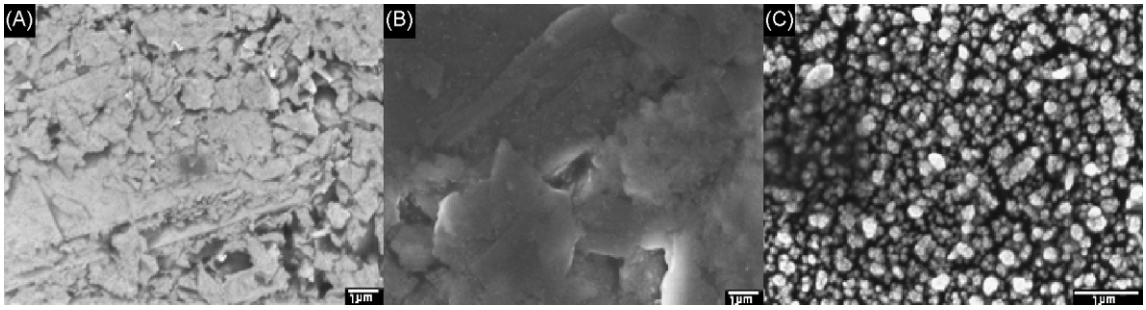

Fig. 1. SEM images of (A) CPE, (B) CILE and (C) Au/CILE.

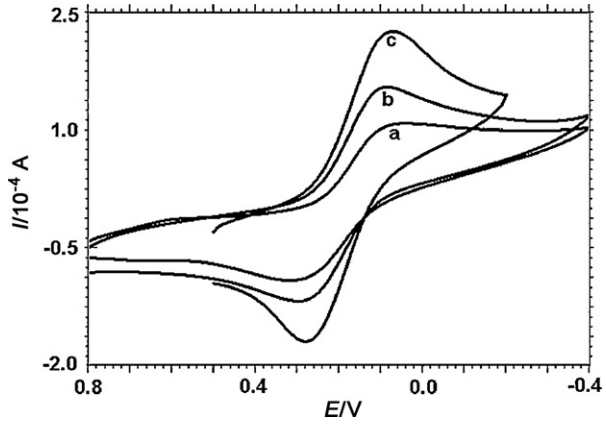

Fig. 2. Cyclic voltammograms of (a) CPE, (b) CILE and (c) Au/CILE in a 5.0 mmol/L $[Fe(CN)_6]^{3-/4-}$ and 0.1 mol/L KCl solution with the scan rate of 100 mV/s.

confusion coefficient of $K_3[Fe(CN)_6]$ in the solution (cm^2/s), C^* is the concentration of $K_3[Fe(CN)_6]$ (mol/cm^3) and v is the scan rate (V/s), Based on this method, the average effective surface area of CPE, CILE and Au/CILE were calculated as 0.109, 0.146 and 0.197 cm^2, respectively. So the effective surface area of Au/CILE was increased for 1.35 time than that of CILE, which was due to the presence of nanostructure gold particle on the electrode surface.

3.2. Electrochemical impedance spectroscopy of different electrodes

EIS is a commonly used method to probe the interface information of the impedance changes during the stepwise-assemble process of the surface modified electrode. In EIS the semicircular part at higher frequencies corresponds to the electron transfer limited process and the linear part at lower frequencies corresponds to the diffusion process. The value of electron transfer resistance (R_{et}) is estimated according to the diameter of the semicircle of the Nyquist plots at the high frequency region, which controls the electron transfer kinetics of redox probe at the electrode surface and reflects the interfacial electron transfer ability. The EIS results of different electrodes in a solution of 10.0 mmol/L $[Fe(CN)_6]^{3-/4-}$ and 0.1 mol/L KCl with the frequencies swept from 10^5 to 0.1 Hz were shown in Fig. 3. Here Z' and Z'' are the real variable and the negative value of the imaginary variable of impedance. Then the Randles circuit (inset) is further chosen to fit the impedance data obtained in the experiments. On the bare CILE a straight line appeared (curve a), which was due to the high ionic conductivity of ionic liquid present in the carbon paste electrode. On the Au/CILE, the R_{et} value was also close to zero (curve b), indicating that the high conductive gold nanoparticle present on the CILE facilitated the electron transfer. When Nafion was cast on the Au/CILE, the R_{et} value was estimated to be 480 Ω (curve c), which was due to the presence of Nafion film on the electrode surface hindered the electron transfer of $[Fe(CN)_6]^{3-/4-}$. After Hb was fixed in the Nafion film, the R_{et} value was further increased to 691 Ω (curve d), which indicated that Hb molecules were successfully immobilized on the surface of Nafion/Au/CILE and further hindered the electron transfer of electrochemical probe.

Electrochemical impedance spectroscopy for (a) bare CILE, (b) Au/CILE, (c) Nafion/Au/CILE and (d) Nafion/Hb/Au/CILE in the solution of 10.0 mmol/L $[Fe(CN)_6]^{3-/4-}$ and 0.1 mol/L KCl with the frequencies swept from 10^5 to 0.1 Hz. Inset is the Randles circuit model for the modified electrodes in the cell.

3.3. Direct electrochemistry of Hb

Fig. 4A showed the cyclic voltammograms of different electrodes in 0.1 mol/L PBS at the scan rate (v) of 100 mV/s. No redox peak appeared on CILE (curve a) and Au/CILE (curve b) but with increased background current, which also proven the existence of gold nanoparticle on the CILE surface. While on Nafion/Hb/CILE (curve c) a pair of small redox peaks appeared, indicating that the direct electron transfer rate of Hb with CILE was very slow. While on the Nafion/Hb/Au/CILE (curve d) a remarkable enhanced electrochemical response was observed with a pair of well-defined

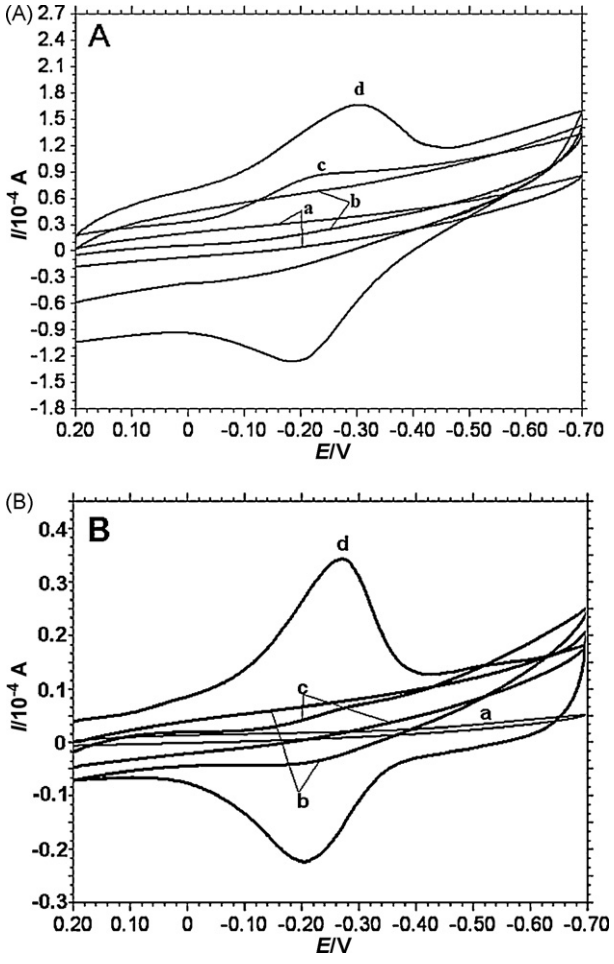

Fig. 4. (A) Cyclic voltammograms of (a) bare CILE, (b) Au/CILE, (c) Nafion/Hb/CILE and (d) Nafion/Hb/Au/CILE at the scan rate of 100 mV/s in pH 7.0 PBS. (B) Cyclic voltammograms of (a) bare CPE, (b) Au/CPE, (c) Nafion/Hb/CPE and (d) Nafion/Hb/Au/CPE at the scan rate of 100 mV/s in pH 7.0 PBS.

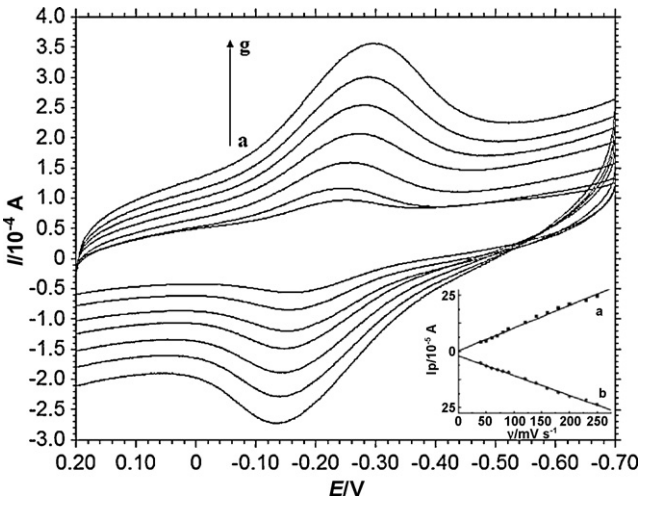

Fig. 5. Cyclic voltammograms of Nafion/Hb/Au/CILE in pH 7.0 PBS with the scan rates from a to g as 40, 60, 100, 120, 160, 200 and 250 mV/s, respectively. Inset: linear relationship of the cathodic (a) and anodic (b) peak current versus scan rate (v).

quasi-reversible redox peaks appeared. The results indicated that the presence of gold nanoparticle on the CILE surface greatly improved the direct electron transfer rate of Hb, which may be attributed to the high metal conductivity and three-dimensional structure of gold nanoparticle. The redox peak potentials were observed with the reduction potential (E_{pc}) as −0.257 V and the oxidation potential (E_{pa}) as −0.162 V. The formal peak potential [$E^{0\prime} = (E_{pc} + E_{pa})/2$] was estimated to be −0.210 V, which was the characteristic of the Hb heme Fe(III)/Fe(II) redox couple. The results showed that the Au/CILE interface was suitable for the electron transfer process between Hb and the electrode. For comparison the similar modified electrodes were prepared with carbon paste electrode (CPE) as the substrate electrode and the cyclic voltammograms were recorded at the same conditions. As shown in Fig. 4B no redox peaks appeared on the bare CPE, Au/CPE and Nafion/Hb/CPE (curve a–c) indicating no electrochemical reaction took place on the electrodes. On the Nafion/Hb/Au/CPE a pair of redox peak appeared with redox peak current much smaller than that of Nafion/Hb/Au/CILE. The results also indicated the superiority of CILE than CPE. CILE has been demonstrated to have the advantages of high conductivity, good stability and anti-fouling ability. On the surface of CILE a layer of IL was also present, which provided a specific interface for the electrodeposition of gold nanoparticle. So the electrochemical response of immobilized Hb was greatly improved with Au/CILE.

Cyclic voltammograms of Nafion/Hb/Au/CILE at different scan rates were recorded in the range from 40 to 250 mV/s with the results shown in Fig. 5. A pair of well-defined redox peaks appeared and the peak currents increased linearly with the scan rate, which indicated a typical surface-confined thin-layer electrochemical behavior [23]. Based on the following equation: $Q = nAF\Gamma^*$, the surface concentration of electroactive Hb (Γ^*) was calculated as 2.62×10^{-9} mol/cm^2, which accounted for 26.5% of the total amount of Hb cast on the electrode surface. The value was much higher than that of Hb monolayer (1.89×10^{-11} mol/cm^2) on the electrode surface [24], which indicated that several layers of Hb in the film took part in the electrode reaction. The reason can be attributed to the presence of Au nanoparticle on the surface of CILE provided a three-dimensional interface for Hb immobilization with the increased effective surface area. The redox peak potentials also exhibited linear relationship with the logarithm of the scan rate and two equations were calculated as $E_{pa}(V) = -0.034 \ln v - 0.346$ ($r = 0.980$) and $E_{pc}(V) = 0.015 \ln v - 0.114$ ($r = 0.968$). According to the Laviron's equation [23], the values of electron transfer coefficient (α) and electron transfer rate constant (k_s) were calculated as 0.573 and 0.412 s^{-1}, respectively.

3.4. Electrocatalytic reduction of trichloroacetic acid

TCA is an analogue of acetic acid in which the three hydrogen atoms of the methyl group have all been replaced by chlorine atoms. It is widely used in biochemistry for the precipitation of macromolecules, such as proteins, DNA and RNA, and cosmetic treatments, such as chemical peels and tattoo removal. It also is an environmental pollutant which can kill normal cells. For these reasons, the determination of TCA has received great attentions in recent years [25,26]. The electrocatalytic reduction of TCA on Nafion/Hb/Au/CILE was examined by cyclic voltammetry with the results as shown in Fig. 6. After the addition of TCA into the deoxygenated pH 7.0 PBS, an obvious reduction peak at −0.20 V appeared with the decrease of the corresponding oxidation peak current, which was a typical electrocatalytic reaction [13]. With the increase of TCA concentration in PBS a new reduction peak appeared at −0.42 V, which could be attributed to the formation of highly reduced form of Hb [27,28]. The catalytic peak current at −0.20 V had a good linear relationship with TCA concentration in the range from 0.2 to 18.0 mmol/L with the regression equation as $I_p(\mu A) = 0.533\,C\ (\text{mmol/L}) + 2.442$ ($r = 0.990$). The detection limit was calculated as 0.16 mmol/L based on the S/N = 3, which was lower than some previous reports [24,29]. When the TCA concentration was more than 20.0 mmol/L, the reduction peak current turned to level off, indicating a typical Michalies–Menten kinetic process. So the apparent Michalies–Menten constant (K_M^{app}) was estimated by using the electrochemical version of the Lineweaver–Burk equation [30]. By exploring the relationship of $1/I_{SS}$ versus $1/C_{TCA}$, the K_M^{app} value was calculated as 0.499 mmol/L, which was lower than some reported values [14,29]. A small K_M^{app} value suggests that the Hb on the modified electrode has higher affinity to the substrates, which can be attributed to the favorable microenvironment of Hb on the modified electrode.

3.5. Stability and repeatability of the modified electrode

The stability of the modified electrode was evaluated. After two-week storage at 4 °C, 97.3% of the initial current signal was obtained and 95.0% remained after four-week storage, indicating that the

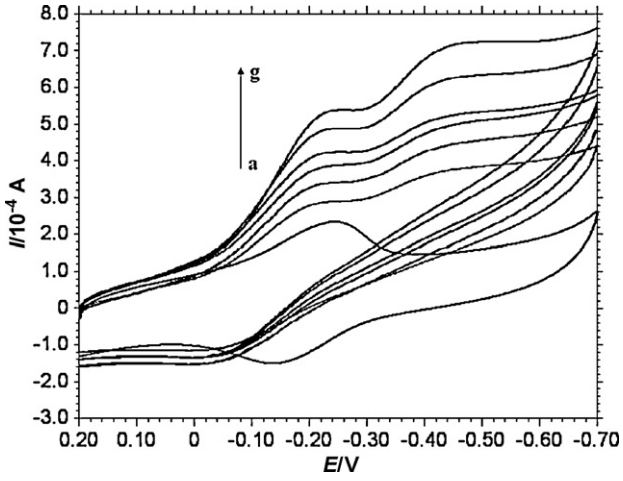

Fig. 6. Cyclic voltammograms obtained at a Nafion/Hb/Au/CILE in pH 7.0 PBS after the addition of 0, 2.0×10^{-3}, 5.0×10^{-3}, 8.0×10^{-3}, 1.0×10^{-2}, 1.4×10^{-2} and 1.8×10^{-2} mol/L TCA (a–g), respectively, at the scan rate of 100 mV/s.

prepared electrode had excellent long-term stability. To investigate the repeatability of the modified electrode, seven electrodes were made by the same procedure independently for the determination 1.0 mmol/L TCA and the relative standard deviation (RSD) value was got as 3.50%. While the RSD of 2.89% was estimated with one electrode for seven successive determinations of 1.0 mmol/L TCA, which indicated that the modified electrode had good reproducibility.

4. Conclusions

Gold nanoparticle was electrodeposited on the surface of CILE to get an effective supporting platform and Hb was immobilized on the electrode surface with Nafion film to get a Hb modified electrode. Due to the presence of gold nanoparticle direct electrochemistry of Hb was accelerated on the modified electrode and a pair of well-defined redox couples appeared with the formal peak potential ($E^{0\prime}$) as −0.210 V (*vs.* SCE). The results indicated the gold nanoparticle decorated carbon ionic liquid electrode provided an excellent interface to promote the direct electron transfer between Hb and the electrode. The Hb modified electrode showed good electrocatalytic activity to TCA with lower detection limit and wider dynamic range, which had the potential application as the third-generation electrochemical biosensor in the field of pathological research, environmental protection and quality control.

ABSTRACT

A novel and simple method for the direct and quantitative determination of L-tryptophan (Trp), L-tyrosine (Tyr) and L-cysteine (Cys) was proposed in this work. Carbon nanofibers (CNFs), made by electrospinning technique, were used to modify carbon paste electrode (CPE) without any treatment to study the electrochemical behaviors of the three amino acids using cyclic voltammetry (CV) and constant potential amperometric method. The results demonstrated that the CNFs modified carbon paste electrode (CNF-CPE) exhibited high electrocatalytic activity and good analytical performance towards the oxidation of the three amino acids. The linear ranges of Trp, Tyr and Cys were 0.1–119, 0.2–107 and 0.15–64 μM with correlation coefficients of 0.9994, 0.9985 and 0.9996, respectively. All the detection limits of the analytes were 0.1 μM (S/N = 3). In addition, the CNF-CPE displayed good reproducibility, high sensitivity and good selectivity towards the determination of the amino acids, making it suitable for the determination of Trp, Tyr and Cys in clinical and medicine.

1. Introduction

Some oxidizable amino acids such as L-tryptophane (Trp), L-tyrosine (Tyr) and L-cysteine (Cys) play important roles in many biochemical processes. Trp is an essential amino acid for human and herbivores as the precursor of hormones, neurotransmitters and other relevant biomolecules. The level of Trp in plasma is closely related with the extent of hepatic disease [1,2]. Tyr is the precursor of dopamine, thyroxin and neurotransmitters in mammalian central nervous systems [3]. The absence of Tyr could cause albinism and alkaptonuria, while a high Tyr concentration in culture medium results in increased sister chromatid exchange. Cys is another important amino acid owing to its crucial roles in biological systems, such as prospective radiation protector and cancer indicator [4]. Besides, it is widely used in the food industry as an antioxidant. Thus, simple and fast methods are needed to satisfy the great demand for the determination of Trp, Tyr and Cys in many fields such as food processing, biochemistry, pharmaceuticals and clinical analysis.

Various analytical methods have been applied to determine amino acids, such as high-performance liquid chromatography (HPLC) with fluorescence detection (FD), mass spectrum detection (MS) or ultraviolet detection (UV) [5–7], capillary electrophoresis (CE) with amperometric detection (AD) or laser induced fluorescence detection (FID) [8,9], gas chromatography (GC) with FID or MS [10,11] and ion exchange chromatography-FD [12]. In addition, spectroscopy [13,14] and electrochemical detection [15] were applied to determine amino acids. In recent years, electrochemical detection has gained considerable interest for electroactive compounds because of its simpleness, low-cost and sensitivity. Trp, Tyr and Cys are three oxidizable amino acids and have obvious electrochemical signals at various modified electrodes [16–19]. There are some reports [20–25] on the determination of these amino acids by electrochemical methods.

Carbon materials have been employed in electroanalytical investigations because of their chemical inertness, wide potential window and suitability for different types of analysis [26,27]. Because of their unique properties, carbon-based nanoscaled materials have been widely used for the preparation of modified electrodes including carbon nanotubes (CNTs) [28–30], fullerene-C_{60} [31] and carbon nanofibers (CNFs) [32–34]. As a new and interesting material member of carbon family, CNFs have attracted much attention due to their unique electronic properties and relatively high mechanical properties. Compared with CNTs, CNFs possess less order and more edge sites on the outer wall, which may lead to more facile electron transfer [28], along with better dispersion and wettability [35,36]. Because of their good electrochemical property and biocompability, CNFs have been used for designing electrochemical sensors and biosensors [32–34]. In our previous study, it had been revealed that CNFs displayed good

doi:10.1016/j.talanta.2009.11.027

catalysis towards the oxidation of dihydronicotinamide ademine dinucleotide and dopamine [37,38].

In this work, we synthesized CNFs by electrospinning and subsequent thermal treatment. Since electrospun CNFs provided with easy handling, large specific surface area and improved conductivity [37,39], an electrochemical sensor of Trp, Tyr and Cys was constructed by modifying carbon paste electrode (CPE) with the CNFs. Compared with the CNFs reported [32–34], the electrospun CNFs here were used without any treatment to ensure the property unchanged. The behaviors of Trp, Tyr and Cys were studied at CNF-CPE and the electrospun CNF showed high catalytic property towards the oxidation of the three amino acids. The results indicated that the electrospun CNFs could be a kind of good electrocatalytic nanomaterial for sensing amino acids.

2. Experimental

2.1. Apparatus

The scanning electron microscopy (SEM) experiments were made on a PHILIPSXL-30ESEM at an accelerating voltage of 20 kV. All the electrochemical measurements were performed using a CHI 832 electrochemical workstation (Shanghai, China) coupled with a conventional three-electrode cell. The three-electrode system consisted of the bare CPE or CNF-CPE working electrode, a platinum wire counter electrode and the Ag/AgCl (saturated KCl) reference electrode. The potentials in this paper are given against the Ag/AgCl. The cathodic current is assigned to be positive, and the anodic current is assigned to be negative.

2.2. Chemicals and reagents

Polyacrylonitrile (PAN), dimethylformamide (DMF), graphite powder (2 μm), L-tyrosine, L-cysteine and glutathione were purchased from Aldrich. Mineral oil, alanine, valine, leucine, isoleucine, serine, threonine, methionine, asparagines, glutamine, lysine, aspartic acid, arginine, phenylalanine, histidine, L-tryptophan, glucose, sodium citrate, oxalate and ascorbic acid (AA) were obtained from Beijing Chemical Co. (China). Dopamine hydrochloride (DA) and uric acid (UA) were purchased from Alfa Aesar. All other reagents were of analytical grade and were used without further purification. Phosphate buffer solution (PBS, 0.1 M, pH 7.0) was prepared by mixing 0.1 M Na_2HPO_4 and NaH_2PO_4. All solutions were prepared with doubly distilled water.

2.3. Synthesis of CNFs

The synthesis process of CNFs, as reported previously [37], is composed of two parts: first, PAN fibers were produced with PAN solution in DMF (8 wt.%) via an electrospinning technique; second, the CNFs were synthesized by stabilizing and carbonizing the PAN fibers. The electrospinning process was performed in the electric fields of the order of 100 kV m^{-1} obtained by applying a 30 kV voltage to a 30 cm gap between the spinneret and the collector. The stabilization and carbonization of PAN fibers were completed in a high temperature furnace by the following steps: (1) annealing in air for 3 h to oxidize PAN partially at 230 °C; (2) heating up to 300 °C at a rate of 5 °C min^{-1} and kept at this temperature in H_2 and Ar mixture (H_2/Ar = 1/3) for 2 h to stabilize the shape of the fibers; (3) heating up to 1100 °C in Ar at a rate of 5 °C min^{-1} to carbonize the fibers, staying at the highest temperature for 1 h, and then cooling down to room temperature in Ar.

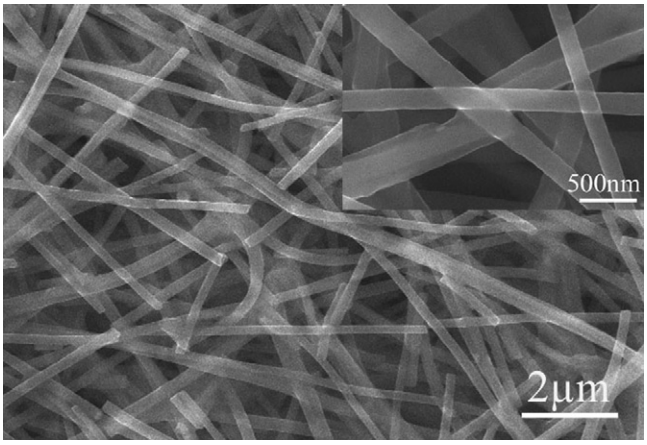

Fig. 1. SEM image of CNFs film. The inset is the SEM image of CNFs with high magnification.

2.4. Electrodes preparation and modification

The CPE was prepared via mixing graphite powder and mineral oil at the ratio of 70:30 (w/w) in a mortar followed by packing into a pipette tube (1 mm diameter; 1 cm depth) carefully. Electrical contact was established with a copper wire. And then the surface was smoothed against weighing paper and rinsed with double-distilled water. One milligram CNFs were dispersed in 1 mL water with vigorous agitation to form uniform suspension. At last, the CNF-CPE was obtained by casting 10 μL CNFs suspension, which had been proved to the optimum dosage, on the smoothed surface of the CPE followed by drying at room temperature in a desiccator.

3. Results and discussion

3.1. Characterization of CNF-CPE

The morphology of the as-prepared CNFs was investigated by SEM (Fig. 1). The inset is the SEM image of CNFs with high magnification. It can be observed that CNFs have a diameter of 200–400 nm with tens of micrometers in length. The CNFs show a uniform surface topography with cross and three-dimensional structure. This structure could significantly increase the effective electrode surface and facilitate the electron transfer.

To recognize the electrochemical properties of CNFs, cyclic voltammetries (CVs) of $K_3[Fe(CN)_6]/K_4[Fe(CN)_6]$ at CPE (curve a) and CNF-CPE (curve b) were investigated (Fig. 2). A pair of well-

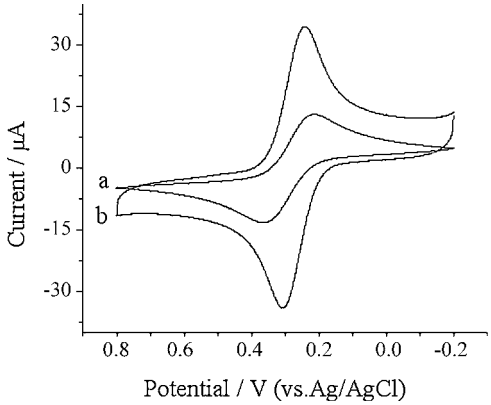

Fig. 2. CVs of 0.5 M KCl solution containing 5 mM $K_3[Fe(CN)_6]/K_4[Fe(CN)_6]$ at the CPE (a) and the CNF-CPE (b). Scan rate: 100 mV s^{-1}.

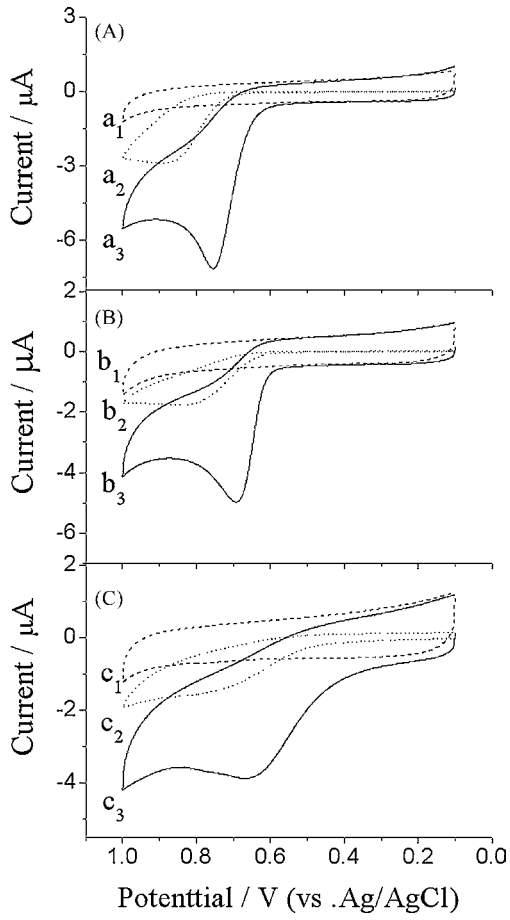

Fig. 3. CVs of CPE and CNF-CPE in the absence and presence of 1 mM Trp (A), Tyr (B) and Cys (C). The dash lines (– a_1, b_1, c_1) are CVs of CNF-CPE in PBS, the dot lines (... a_2, b_2, c_2) and the solid lines (▬ a_3, b_3, c_3) are CVs of CPE and CNF-CPE in PBS containing Trp, Tyr and Cys, respectively. Scan rate: 50 mV s^{-1}; Solution: 0.1 M PBS (pH 7.0).

defined redox peaks with peak-to-peak separation (ΔE_p) of 151 mV was observed at CPE (a), while the ΔE_p decreased to 64 mV at CNF-CPE (b). And the redox peak current at CNF-CPE was two times higher than that at CPE. Compared with that at the CPE, $[Fe(CN)_6]^{3-/4-}$ had better reversibility and much higher redox current at CNF-CPE, which indicated that CNF-CPE had the ability to accelerate electron transfer. Meanwhile, the influence of the dosage (2–16 μL) of CNFs suspension on the electrocatalytic capability was investigated in $K_3[Fe(CN)_6]/K_4[Fe(CN)_6]$ and KCl solution. The results showed the potential separation of the redox peak was affected little. The redox peak current of $[Fe(CN)_6]^{3-/4-}$ increased with the dosage of CNFs suspension increased from 2 to 10 μL. When the dosage of CNFs suspension exceeded 10 μL, the redox peak current decreased, which may be ascribed to the thick CNFs film. Furthermore, the CNFs film was easy to collapse when the dosage exceeded 14 μL, which confirmed 10 μL as the optimum dosage.

The effective surface area of CNF-CPE was estimated by CV using 5 mM $K_3[Fe(CN)_6]$ as a probe at various scan rates. The slope of the straight line ($r = 0.9990$) of I_{pc} vs.$\upsilon^{1/2}$ is 9.49×10^{-5} $As^{1/2}V^{-1/2}$. For a reversible process, $I_p = (2.69 \times 10^5)n^{2/3}$ $AD^{1/2}\upsilon^{1/2}C_0$. For 5 mM $K_3[Fe(CN)_6]$, $n = 1$, $D = 5.9 \times 10^{-5}$ cm s^{-2}, then the effective surface area of the CNF-CPE is calculated to be 1.57×10^{-2} cm^2, 4.7 times larger than that of the CPE which was estimated by the same method.

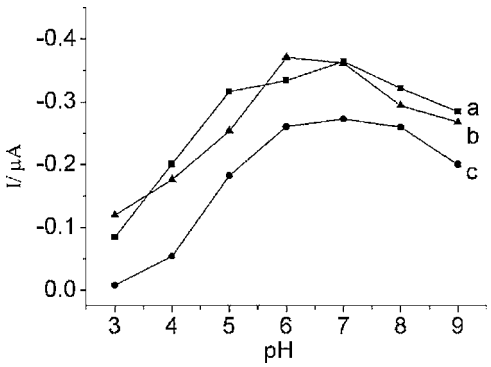

Fig. 4. Effect of pH on the oxidation current of 25 μM Trp (a), Cys (b) and Tyr (c) at CNF-CPE. The potentials were applied at 0.9, 0.8 and 0.75 V for Trp, Tyr and Cys, respectively.

3.2. Electrocatalytic oxidation of Trp, Tyr and Cys

Fig. 3 shows the CVs of CPE and CNF-CPE in 0.1 M PBS in the absence and presence of 1 mM Trp (A), Tyr (B) and Cys (C). It was found that each amino acid had only one oxidation peak in the cyclic voltammogram from 0.1 to 1.0 V at CPE or CNF-CPE, suggesting that the electrochemical processes of the amino acids were totally irreversible. The anodic peak currents responding to the oxidation of Trp, Tyr and Cys at CNF-CPE were two times higher than those obtained at CPE. Moreover, the oxidation peak potentials were 0.86, 0.8 and 0.75 V at the bare CPE, but they shifted to 0.75, 0.7 and 0.65 V at the CNF-CPE for Trp, Tyr and Cys, respectively. The results indicated that CNF-CPE could increase the peak currents and reduce the overpotentials, which proved that the CNFs film could efficiently catalyze the oxidation of these amino acids. The reasons should be attributed to the nanometer size, three-dimensional structure and more surface defects [32] of the material which bring in high surface area and large number of active sites.

3.3. Applied potentials and optimal pH for amperometric detection of Trp, Tyr and Cys

The effect of applied potentials on the amperometric responses of 25 μM Trp, Tyr and Cys at the CNF-CPE was investigated in range of 0.5–1.0 V with 0.05 V increments using constant potential amperometric method. The hydrodynamic voltammograms (not shown) showed that the response for Trp, Tyr and Cys reached peak values at 0.9, 0.8 and 0.75 V, respectively, which were chosen as the detection potentials.

The influence of the PBS pH value on the oxidation current of the three amino acids has also been studied at the optimum potentials as shown in Fig. 4. With increasing pH from 3.0 to 9.0, the oxidation current of Trp and Tyr increased from pH 3.0 to 7.0 and reached the maximum at pH 7.0, and then decreased with higher pH value. The oxidation current of Cys reached the maximum at pH 6.0 and then decreased a little at pH 7.0. Therefore, PBS at pH 7.0, which is close to the physiological level [3], was chosen for analytical experiments to obtain the maximum oxidation currents of the three amino acids.

3.4. Electrochemical determination of Trp, Tyr and Cys

The electrochemical determination of Trp, Tyr and Cys at the CNF-CPE has been studied at the optimum condition using constant potential amperometric method. Fig. 5 shows the current–time responses and the calibration curves (insets) for Trp (A), Tyr (B) and Cys (C), respectively. The results showed that the dynamic linear ranges of Trp, Tyr and Cys were 0.1–119, 0.2–107 and 0.15–64 μM with the correlation coefficients of 0.9994, 0.9985 and 0.9996,

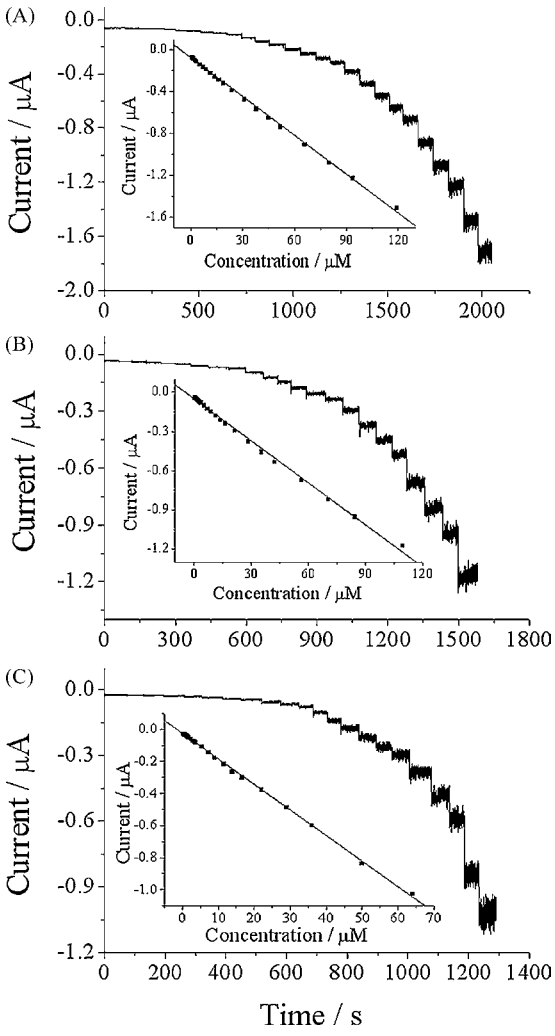

Fig. 5. Current–time responses of CNF-CPE upon successive addition of special concentration of Trp (A), Tyr (B) and Cys (C) to PBS under stirring. Insets are the calibration curves for these amino acids correspondingly. Solution: 0.1 M PBS (pH 7.0) under stirring. The potentials were applied at 0.9, 0.8 and 0.75 V for Trp, Tyr and Cys, respectively.

respectively. All the detection limits of the amino acids were 0.1 μM (S/N = 3) along with the sensitivities of 12.4 ± 0.09, 10.7 ± 0.1 and 15.9 ± 0.1 μA mM^{-1} for Trp, Tyr and Cys, respectively.

Table 1 compares the analytical performance of Trp, Tyr and Cys at the proposed CNF-CPE with that of other modified electrodes reported recently, especially those electrodes based on carbon materials. It can be seen that the detection limits of these amino acids at CNF-CPE, particularly Trp and Tyr, are among the lowest level. The linear ranges of CNF-CPE for Trp and Tyr are wider than the results reported previously and the linear range for Cys is wider than that obtained at boron-doped carbon nanotubes modified GCE [13], multi-wall carbon nanotubes (MWCNT) modified GCE [23] and screen-printed electrochemical sensor (SPES) [40]. The sensitivity of CNF-CPE is higher than that of MWCNT modified GCE [41], fluorosurfactant modified Au electrode [42], SPES [40] and SWCNT-arrayed modified Pt electrode [43]. The results above demonstrate that CNF-CPE has satisfactory analytical performance and it can be a feasible sensor for these amino acids.

3.5. Stability and reproducibility study

The stability of the modified electrode has been studied by investigating the amperometric responses of 5 μM Trp, Tyr and Cys at CNF-CPE and CPE for one hour. The results showed that the remained percentages of initial response for Trp, Tyr and Cys at CNF-CPE were 84, 86 and 70%, respectively, while those at CPE were 41, 39 and 15%, respectively, which demonstrated a good stability of the modified electrode.

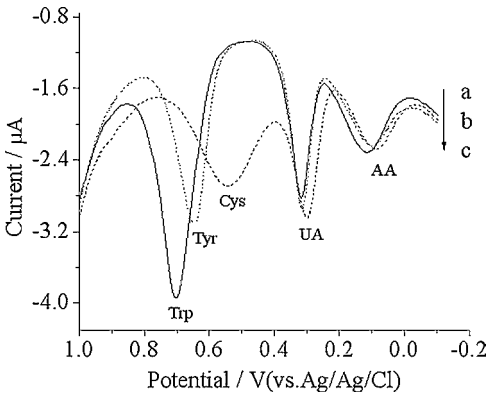

Fig. 6. DPVs of CNF-CPE in 0.1 M PBS (pH 7.0) containing 0.1 mM UA, 0.2 mM AA and 0.2 mM Trp (a), 1 mM Cys (b), 0.2 mM Tyr (c). DPV conditions: Scan rate, 6 mV s^{-1}; amplitude, 50 mV; pulse width, 100 ms; pulse period, 200 ms.

The reproducibility of CNF-CPE electrode was investigated by repetitive measurements (N = 6) of 25 μM Trp, Tyr and Cys, and the resulting relative standard deviation (RSD) was 1.0, 1.8 and 2.2%, respectively. It demonstrated that a freshly modified electrode surface could be obtained via electrochemical cleaning of the electrode, suggesting good ability of antifouling. Another extremely attractive feature of CNF-CPE is its excellent fabrication reproducibility. The result shows the response of 25 μM Tyr (a), Trp (b) and Cys (c) at seven different paralled CNF-CPEs with the RSD of 1.8, 2.2 and 1.6%, respectively. Therefore, the CNF-CPE has the advantage of good reproducibility.

3.6. Interference study

The possible interference for Trp, Tyr and Cys determination at CNF-CPE was investigated. Fourteen available amino acids (200 times content), including alanine, valine, leucine, isoleucine, serine, threonine, methionine, asparagines, glutamine, lysine, aspartic acid, arginine, phenylalanine and histidine, had no influence on the current response for 25 μM Trp, Tyr and Cys. Meanwhile, the CNFs showed an inhibiting effect on the oxidation of other electroactive species that are commonly present in biological fluids, such as glucose, sodium citrate and oxalate (200 times content). UA and AA as two kinds of important biological substances often coexist with Trp, Tyr and Cys in human fluid, food processing, pharmaceuticals and clinical analysis. Fig. 6 shows the differential pulse voltammetries (DPVs) of 0.2 mM Trp (a), 1 mM Cys (b) and 0.2 mM Tyr (c) at CNF-CPE when coexisting with 0.1 mM UA and 0.2 mM AA. The results indicated that UA and AA could be oxidized at the detached potentials of 0.3 and 0.1 V, far away from the oxidation potentials of the three amino acids at CNF-CPE. Therefore, the determination of the three amino acids had no interference from UA and AA. The interference of DA and glutathione has also been studied. The result showed that dopamine which could be oxidized at 0.1 V at CNF-CPE did not interfere with the determination of the three amino acids, while glutathione could be oxidized at 0.6 V which is close to the oxidation potential of Trp, Tyr and Cys at CNF-CPE. Thus glutathione could interfere with the detection. Furthermore, efficient simultaneous determination of these amino acids could be achieved at CNF-CPE in flow system when coupled to capillary electrophoresis (under study). The results above indicated the proposed method had good selectivity towards the determination of the amino acids.

Table 1
Comparison of the efficiency of some modified electrodes in the electrochemical determination of Trp, Tyr and Cys.

Method	Analyte	Detection limit (μM)	Linear range (μM)	Correlation coefficient	Sensitivity (μA mM^{-1})	References

4. Conclusions

The electrospun carbon nanofibers have excellent electrocatalytic activity towards Trp, Tyr and Cys. The CNF-CPE possesses many desirable properties including high sensitivity, low detection limit and satisfactory linear range which ensure trace amount determination of the three amino acids. Besides the good analytical performance, this proposed modified electrode has the advantages of good reproducibility, stability and selectivity. In addition, ease to construct, low cost and no treatment before use make it feasible to be applied in routine determination. The results indicated that the electrospun CNFs could be a kind of attractive and promising electrocatalytic nanomaterial for electrochemical sensing applications.

Essential elements
Direct analysis
Sample carbonization
Graphite powder

ABSTRACT

Availability of many biological samples in ample quantity for biomedical investigations sometimes is very restricted. Therefore, there is the need for the simple techniques allowing the analysis of small amount samples. In the present work the two-jet plasma atomic emission spectrometry techniques for the determination of Fe, P, Ca, Mg, Zn, and Cu in whole blood are proposed. The first technique is developed for direct analysis of freeze-dried blood. The sample preparation consisted in a dilution of blood powder (particle size 20 μm or less) with a spectroscopic buffer (graphite powder containing 15 wt.% NaCl). For the analysis of liquid whole blood, previous carbonization (not ashing) of blood evaporated on graphite powder was applied. Calibration samples based on graphite powder containing 15 wt.% NaCl were used. The validation of the techniques was confirmed by the use of different sample preparation procedures (wet acid digestion and dry carbonization), the analysis of IAEA A-13 reference material (freeze-dried bovine whole blood), and the comparison of the results obtained by the proposed technique with the results of the stripping voltammetry technique. Just 20–50 μL of whole blood is quite enough for all determinations. The proposed techniques were successfully applied for the simultaneous determination of Fe, P, Ca, Mg, Zn, and Cu in whole blood of living experimental rats and mice and human blood.

1. Introduction

Metals play important roles in many normal physiological and pathologic processes in all biological systems. They participate in nutrient and gas transport, thermoregulation, pH maintenance, etc. Several recent reviews cover biological role of Ca and Mg in many cell functions such as energy metabolism, synthesis and function of proteins, cytoskeleton activation [1,2]; Al, Zn, Cu, and Fe in Parkinson's disease [3]; Cu in hepatic and neuronal functions, Cu transporters and Cu chaperone proteins [4], Zn in the homeostasis of the human organism [5] and in maternal and child mental health [6]; Fe in health and pathogenesis [7]. The participation of P in many important biochemical reactions is also described [8]. The emerging research field of "metallomics" is aimed at the understanding of the molecular mechanisms of metal-dependent life processes [9]. Therefore, reliable determination of the above elements in whole blood is an important analytical task.

The majority of the techniques described in the literature such as inductively coupled plasma (ICP) atomic emission spectrometry (AES) [10], ICP mass spectrometry (ICP-MS) [11–13], and total reflection X-ray fluorescence [14,15] apply wet acid digestion of blood to decompose the organic matrix. For direct determination of single elements in whole blood, electrothermal atomization atomic absorption spectrometry has found an application [16,17]. Direct multielement analysis of blood was performed using ICP-MS [12,18,19]. Sample dilution and additional reagents (EDTA, ammonia, and Triton X-100) were used in order to prevent blood clotting and to lyse the blood cells. The multielement techniques described usually require about 1 mL of blood, which is not always convenient in experiments with living small animals.

For analysis of small amount samples, two-jet plasma (TJP)-AES presented in this work is very suitable. A TJP is a direct current (dc) plasma. Nowadays, dc plasmas have been almost universally replaced by an ICP, an excellent source of excitation for analysis of solutions. In contrast to an ICP and dc plasmas described [20,21], a TJP is high-powered source (10–15 kW), which is successfully used for direct analysis of powdered samples. It was invented in the Kyrgyzstan Institute of Physics in the mid-1970s and has been applied for direct analysis of geological and mineral samples for over 20 years [22,23]. A complete evaporation of thermo stable materials is achieved in the analytical region after the confluence of the plasma jets when the sample passes through a high-temperature region of the jet confluence. To obtain detection limits at the level of 0.01–1 $\mu g\,g^{-1}$, a 150–300-mg sample has to be introduced into the plasma.

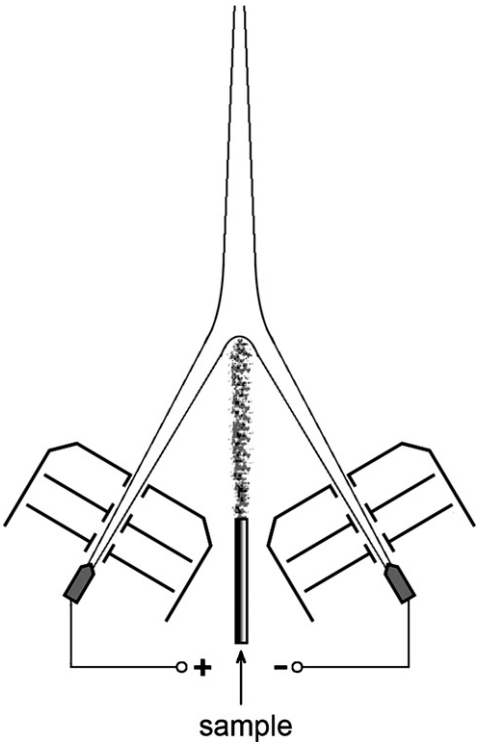

Fig. 1. Plasma burners.

In the recent papers we showed the capability of a TJP for direct multielement analysis of dry powdered biological samples including plants, bovine liver [24] and bone [25]. The use of the region before the confluence of plasma jets provided an opportunity of analysis of small samples.

The purpose of the present work was to develop the TJP-AES technique for the determination of the main essential elements (Fe, P, Ca, Mg, Zn, and Cu) in whole blood. One of the requirements to the technique was its applicability to analysis of small samples, which is important in experiments with living experimental animals (such as mice or rats).

2. Experimental

2.1. Instrumentation

2.1.1. Plasmatron

A two-jet high power plasmatron (10–15 kW) described in Ref. [26] was used. Argon plasma jets are generated in plasma burners. Every burner consists of a non-consumable tungsten electrode (anode or cathode) and three copper diaphragms (diameter ~50 mm) cooled by water. A scheme of the plasma burners is shown in Fig. 1. The experimental conditions are presented in Table 1.

2.1.2. Optical and registration system

A diffraction spectrograph with a 600 lines mm^{-1} grating covering the spectral range of 200–410 nm was used. The analytical region was focused on the slit of the spectrograph using an F–150 lens (1:1 image).

The spectra were registered using a multielement analyzer of emission spectra (MAES) produced by «VMK Optoelektronika» (Russia) [27]. The MAES system includes eight arrays, each containing 2580 photodiodes of 12.5 × 1000 μm.

The MAES is supplied with ATOM software for spectral data processing: measurement of analytical signals with background correction, construction of calibration curves, calculation of element concentrations and statistical treatment of the results. A more detailed description of the optical and registration system is given in Ref. [25].

Table 1
Working conditions of the two-jet plasma.

Parameter	Value
Current strength	80–85 A
Plasma gas	4 L min^{-1}
Carrier gas	0.7 L min^{-1}
Angle between jets	60°
Analytical region	4–5 mm lower than the point of the confluence

2.1.3. Sample introduction

A 20-mg powdered sample was placed into a Plexiglas beaker, which was inserted in a powder-introduction device where a high-frequency spark is generated between the circular and central zirconium electrodes over the surface of the powder. Blast waves from the spark agitate the powder and produce an aerosol, which is transported into plasma with a carrier gas for 6 s. A scheme of the sample introduction system was presented in Ref. [25]. The spark frequency can be varied in the range of 0.1–4 kHz. We have found that the introduction of organic biological matrices required the spark frequency not to exceed 1 kHz because the spark affected the organic matrix promoting sample melting and particle coagulation and/or partial decomposition. This resulted in both a decrease in the analytical signal and significant data scattering. For the analysis of blood, we used the frequency of 0.5 kHz.

2.2. Sample preparation and materials

For direct analysis of freeze-dried blood, a 10-mg sample ground in a Plexiglas mortar for 5 min was diluted stepwise with a spectroscopic buffer (graphite powder containing 15 wt.% NaCl) in the ratios of 1:9 and 1:99. If diluted samples were left for several hours or more, they had to be dried at 80 °C for 1 h under an IR-lamp before the analysis.

For analysis of liquid whole blood, 50 μL of blood was evaporated on 40 mg of graphite powder placed in a previously weighed quartz cup under an IR-lamp. The remainder was put into a quartz electric resistance furnace at room temperature, heated up to 400 °C and kept for 15 min at that temperature. The carbonized sample was mixed with graphite powder containing 30 wt.% NaCl in the ratio of 1:1 and ground in a Plexiglas mortar for 2–3 min. 10 mg of a diluted sample was additionally mixed with the buffer in the ratio of 1:9.

High-purity graphite powder and NaCl produced domestically were used.

2.3. Calibration samples

Calibration samples based on graphite powder containing 15 wt.% NaCl with impurity concentration range of 0.01–100 μg g^{-1} were used to construct calibration curves (lgI–lgC). These samples were prepared from Russian State reference material of graphite powder with different compositions of impurities (GSO 7751-2000, GSO 4519-89/4523-89; Ural State Technical University) by dilution of those with graphite powder containing 30 wt.% NaCl in the ratio of 1:1 in a clean room designed for manipulation with high-purity samples. The calibration samples are stable for at least a year.

3. Results and discussion

3.1. Analysis of freeze-dried blood

In contrast to quickly coagulating liquid blood, freeze-dried blood can be kept for a long time under normal conditions

Table 2
Concentration of elements in the freeze-dried blood samples ($\mu g\,g^{-1}$).

Analytical line	Human blood			Rat blood		
	Direct analysis	Carbonizing	Autoclave digestion	Direct analysis	Carbonizing	Autoclave digestion
Fe I 296.67	2300 ± 200[a]	2200 ± 160	2200 ± 200	2600 ± 200	2400 ± 170	2500 ± 200
P I 214.91	1700 ± 130	1600 ± 120	1500 ± 110	1400 ± 200	1400 ± 100	1300 ± 150
Ca II 317.93	320 ± 20	340 ± 30	300 ± 20	240 ± 30	250 ± 20	280 ± 30
Mg I 277.98	130 ± 15	150 ± 20	130 ± 10	120 ± 15	140 ± 15	150 ± 20
Zn I 213.86	28 ± 1.6	26 ± 1.4	29 ± 1.7	29 ± 2.0	32 ± 1.5	32 ± 1.4
Cu I 324.75	6.6 ± 0.5	6.2 ± 0.4	5.8 ± 0.4	3.6 ± 0.3	3.5 ± 0.3	3.3 ± 0.2

[a] 95% confidence interval, $n = 4$.

and is often used in continuous biomedical experiments. Usually 200–250 mg of dry powder is obtained from 1 mL of human whole blood.

We applied the same approach to the analysis of freeze-dried blood as in the case of the analysis of bovine liver [24]. The sample preparation procedure consisted in a 10-fold dilution of the dry powdered sample with a spectroscopic buffer (graphite powder containing 15 wt.% NaCl). Calibration samples based on graphite powder containing 15 wt.% NaCl and experimental conditions chosen for multielement analysis of graphite powder were used [28].

In order to confirm the capability of a TJP for direct analysis of freeze-dried blood, the analysis results obtained after different sample preparation procedures were compared. We used autoclave wet acid digestion in a mixture of nitric acid and hydrogen peroxide and dry carbonization of the samples. For direct analysis, 10- and 100-fold dilutions of freeze-dried blood with the spectroscopic buffer were used. A 100-fold dilution was applied for Fe and P determination because of the signal saturation. A mild carbonization procedure (400 °C, 15 min) was used instead of ashing to prevent the loss of elements. The results of the analysis of rat and human blood are presented in Table 2. The results of the direct analysis were in good agreement with the results obtained after wet acid digestion and carbonization of the samples.

For the reliable direct analysis, the particle size had to be 20 μm or less, otherwise, decreased concentrations of elements were obtained. Particles of this size were easily prepared by grinding freeze-dried blood in a Plexiglas mortar.

The proposed direct technique was additionally validated by the analysis of IAEA A-13 reference material (freeze-dried bovine whole blood). The results of the analysis are presented in Table 3.

Thereby, we have shown that TJP-AES can be used for direct determination of Fe, P, Ca, Mg, Zn, and Cu in freeze-dried blood. The relative standard deviation was in the 5–15% range. The detection limits of elements in blood powder and liquid whole blood calculated assuming that 250 mg of powder can be obtained from 1 mL of blood are given in Table 4. As evident from Tables 2 and 3, the limits are one to two orders of magnitude lower than the concentrations in the real samples. This allowed us to use less materials and a 20-fold dilution when a small amount sample was available. 5 mg of blood powder (approximately 20–25 μL liquid blood) was quite enough to obtain the result as a mean value from four replicates.

Table 3
The analysis results of IAEA A-13 freeze-dried bovine blood.

Element	Found ($\mu g\,g^{-1}$)	Target range ($\mu g\,g^{-1}$)
Fe	2300 ± 150[a]	2200–2500
P	950 ± 90	690–1120
Ca	290 ± 40	226–332
Mg	110 ± 10	81–139

Detection limits of elements in blood.

Element	Freeze-dried blood ($\mu g\,g^{-1}$)	Liquid whole blood ($mg\,L^{-1}$)
Fe I 296.67	6.0	1.5
P I 214.91	30	7.5
Ca II 317.93	4.0	1.0
Mg I 277.98	5.0	1.2
Zn I 213.86	2.0	0.50
Cu I 324.75	0.2	0.05

Table 5
Concentrations of elements in human whole blood ($mg\,L^{-1}$).

Element	Sample					
	1	2	3	4	5	6
Fe	320	610	530	520	490	520
P	260	375	480	280	350	350
Ca	82	84	81	70	110	92
Mg	34	38	46	35	35	33
Zn	5.0	9.0	5.5	5.8	7.2	6.7
Cu	1.4	1.1	1.1	0.74	0.78	1.0

3.2. Analysis of liquid whole blood

Evaporation of blood aliquots on graphite powder under an IR-lamp produced glassy and hard to grind remainder. Therefore, we had to use a carbonization procedure. The remainder was converted to fine-dispersed powder after heating at 400 °C followed by grinding. The results of the analysis of human whole blood are presented in Table 5. They generally conform to the literature data. The relative standard deviation was in the 3–10% range.

The Cu and Zn determination was also validated using an independent method. The results of the determination of Cu ($0.65 \pm 0.06\,mg\,L^{-1}$) and Zn ($11.2 \pm 1.2\,mg\,L^{-1}$) obtained by the proposed technique were in good agreement with those obtained by the direct stripping voltammetry technique (Cu $0.71 \pm 0.02\,mg\,L^{-1}$ and Zn $10.5 \pm 0.7\,mg\,L^{-1}$).

4. Conclusions

The TJP-AES techniques for the determination of Fe, P, Ca, Mg, Zn, and Cu in freeze-dried and liquid whole blood were presented. The techniques allowed the use of a simple sample preparation procedure and calibration samples based on graphite powder. We used no reagents aside from a spectroscopic buffer. The techniques required only 20–50 μL of blood, which is important in biomedical experiments with living small animals.

Phenethylamine alkaloids

ABSTRACT

Acidic potassium permanganate chemiluminescence was explored as a sensitive and selective mode of detection for phenolic phenethylamines (adrenergic amines) in consumer products containing *Citrus aurantium* extracts. Nine commercially available weight-loss products were analysed using rapid reversed-phase chromatography with a monolithic column (separation time of 4 min). The results were in good agreement with package labelling, with some notable exceptions. The products contained a wide concentration range of synephrine and total adrenergic amines, and the difference in consumer intake was even greater when the manufacturers' recommended daily consumption was considered. The quantity of the extract, often specified on the packaging as equivalent grams of dry *C. aurantium* fruit, was a poor indicator of the concentration of the active ingredients. Methionine, a thioether amino acid contained in some weight-loss products, was identified as a potential interferent for this mode of detection.

1. Introduction

The U.S. Food and Drug Administration's ban of ephedrine (Fig. 1) and related *Ephedra* protoalkaloids as ingredients in weight-loss products, due to a long association with strokes, heart attacks, and other adverse health effects, has led to a dramatic increase in the use of *Citrus aurantium* (Seville orange; Bitter orange) [1]. Extracts from the unripe fruit or peel of *C. aurantium* are rich in synephrine (oxedrine), and contain several other phenolic phenethylamines, including octopamine, tyramine, *N*-methyltyramine and hordenine (Fig. 1), that each posses adrenergic activity. There is a long history of *C. aurantium* consumption in herbal medicine, but its contemporary use may involve much higher daily intakes. Ingredients of weight-loss products can include highly concentrated extracts (up to 95% synephrine), pure individual adrenergic amines (octopamine, tyramine and/or hordenine), and herbs that contain high levels of caffeine. Concern has been expressed about the safety of these products [2].

As described in a recent review by Pellati and Benvenuti [3], many chromatographic and electrophoretic methods for the determination of synephrine (and to a lesser extent, octopamine and tyramine) have emerged, but relatively few have included quantitation of the five adrenergic amines detected in *C. aurantium* extracts. However, when examined, *N*-methyltyramine has been found at much higher concentrations than octopamine, tyramine or hordenine [4,5]. Previous chromatographic procedures have involved reversed-phase and ion-pairing separations using C_{18} columns with UV-absorbance [6–8] or fluorescence [9] detection; or separation on pentafluorophenylpropyl columns using mobile phases containing high levels of organic solvent, with UV-absorbance [4], mass spectrometric [10] or tandem mass spectrometric [5] detection.

Flow-injection analysis procedures for the determination of synephrine based on its enhancing effect on the chemiluminescent reactions of luminol with hexacyanoferrate(III) [11], and cerium(IV) with rhodamine B [12] have been reported, but these procedures are not sufficiently selective towards the target analyte in the presence of other phenolic compounds [13]. Acidic potassium permanganate can also be used for sensitive chemiluminescence detection of phenolic compounds [14,15] and has been coupled to chromatographic separations for the determination of *Papaver somniferum* (opium poppy) alkaloids in process liquors [16,17], neurotransmitter metabolites in urine [18], and synephrine in plant extracts and dietary supplements [19]. The key advantages of this mode of detection, compared to UV-absorbance and fluorescence, include the relatively high sensitivity and greater selectivity, which reduces the number of interfering compounds

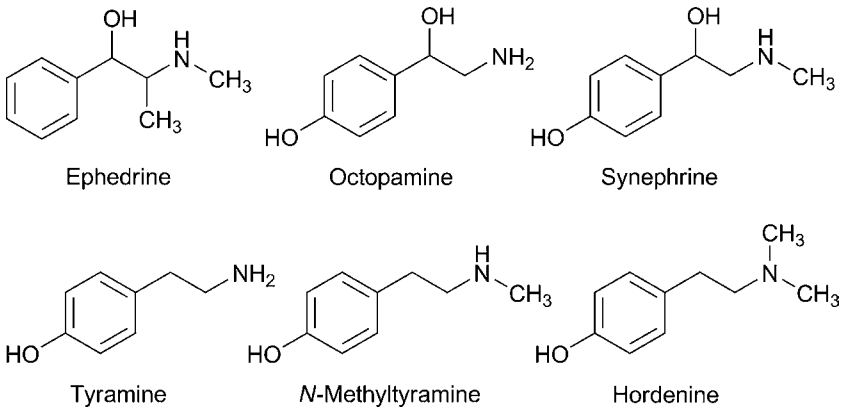

Fig. 1. Ephedrine (found in *Ephedra* species) and five phenolic phenethylamines found in *Citrus aurantium*.

that must be separated from the target analytes. However, the relationship between analyte structure and chemiluminescence intensity is yet to be fully elucidated [14]. Further investigation of potential interferences in complex sample matrices such as biological fluids and plant extracts is required to realise the full potential of chemiluminescence detection. In this study, we utilise monolithic column chromatography to explore acidic potassium permanganate chemiluminescence detection of the five bioactive phenethylamines found in weight-loss products containing *C. aurantium*.

2. Materials and methods

2.1. FIA and HPLC conditions

The flow-injection analysis (FIA) instrumentation was configured as previously described [19]. Each standard solution (70 μL) was injected into a water carrier stream that merged with the acidic potassium permanganate reagent stream at a T-fitting prior to entering a coiled transparent flow-cell, positioned against a photomultiplier tube within a light-tight housing. The solution flow rate was 3 mL/min per line. In the HPLC experiments, the column eluate (instead of the FIA carrier stream) was merged with the acidic potassium permanganate reagent stream within the chemiluminescence detector. The adrenergic amines were separated using a monolithic column (Chromolith SpeedROD RP-18e, 50 mm × 4.6 mm i.d., with 5 mm × 4.6 mm i.d. guard) under isocratic conditions (5 min: 98% deionised water adjusted to pH 2.15 with trifluoroacetic acid; 2% methanol). The column was flushed after each run, by increasing the methanol to 80% over 1 min and maintaining that concentration for 12 min, and was then re-equilibrated at the separation conditions. The flow-rate through the column was 1 mL/min and the injection volume was 10 μL.

2.2. Other instrumentation

^{1}H NMR was performed with a JEOL EX 270 MHz FT-NMR spectrometer, with samples dissolved in $CDCl_3$. Peaks were recorded as: chemical shift δ (ppm) (integral, multiplicity (s = singlet, d = doublet, m = multiplet), coupling constant J (Hz), assignment). Melting point was obtained using a heated block (SMP3, Stuart Scientific, UK). A 6210 MSDTOF mass spectrometer (Agilent Technologies, Australia) was used with the following conditions: drying gas: nitrogen (7 mL/min, 350 °C); nebuliser gas: nitrogen (16 psi); capillary voltage: 4.0 kV; vaporizer temperature: 350 °C; cone voltage: 60 V.

2.3. Reagents, standards and samples

The chemiluminescence reagent contained 1×10^{-3} M potassium permanganate (Chem-Supply, Australia) and 1% (w/v) sodium polyphosphate (Sigma–Aldrich, Australia) in deionised water and was adjusted to pH 2.5 with sulfuric acid (Merck, Australia). Synephrine, octopamine and tyramine were purchased from Sigma–Aldrich. Hordenine was synthesised using a modified Eschweiler Clark *N*-methylation reaction [20]: tyramine (1.01 g, 7.4 mmol) in methanol (50 mL) and formaldehyde (36% solution; 5.45 mL) was heated to reflux for 90 min, then cooled and stirred overnight. Sodium borohydride (1 g, 26.4 mmol) was added slowly over 30 min and stirred for a further 90 min. The solvent was removed *in vacuo*. The solid was then dissolved in water (50 mL) and extracted with chloroform (4 × 40 mL). The organic extracts were combined and dried with anhydrous sodium sulfate, filtered, and the solvent was removed. The crude product was recrystallised with 1:1 ethyl acetate:petroleum spirits to afford hordenine (615.8 mg, 51% yield; m.p. 117.3–118.1 °C, Lit. 117–118 °C [21]; MS: m/z 166.12559 $[M+H]^+$, calc. 166.12264. ^{1}H NMR (270 MHz, $CDCl_3$): δ 2.30 (6H, s, $N(CH_3)_2$), 2.55 (2H, m, $ArCH_2CH_2N$), 2.69 (2H, m, $ArCH_2CH_2N$), 6.62 (2H, d, J = 8.40, Ar), 6.99 (2H, d, J = 8.40, Ar). *N*-Methyltyramine was supplied by CSIRO Animal Health Laboratories, Australia.

The weight-loss products were supplied by or purchased from manufacturers in the USA and Australia. Tablets were ground with mortar and pestle. The powders from capsules were removed from their outer coating. A previous comparison of the effect of various solvents on the extraction of *C. aurantium* protoalkaloids from dietary supplements (using sonication or stirring with a magnetic bar) [4] revealed that water is more efficient than 0.1 M HCl, methanol or a mixture of 37% HCl and methanol (0.8:99.2, v/v). In a related study [9] it was shown that aqueous HCl (0.37% mass fraction) extracted greater quantities of the amines than methanol or acidified methanol (using sonication), but neutral aqueous solutions were not examined. In this study, samples were dissolved in a known volume of water (50–250 mL) by stirring for 45 min with a magnetic stir bar. The sample solutions were diluted with deionised water (if required) and filtered with Acrodisc PSF syringe filters (Pall Australia).

3. Results and discussion

3.1. Method development

N-Methyltyramine had not previously been detected with acidic potassium permanganate, and therefore the reaction was initially

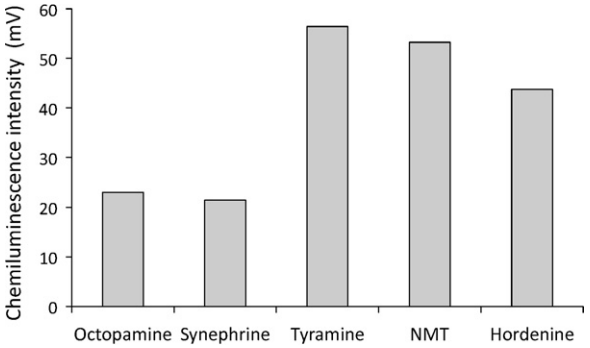

Fig. 2. Relative chemiluminescence intensity of *Citrus aurantium* protoalkaloids (1×10^{-5} M) with the acidic potassium permanganate reagent using flow-injection analysis methodology. NMT = *N*-methyltyramine.

examined in aqueous solution using FIA. The chemiluminescence intensity for this analyte was similar to that of tyramine and hordenine (Fig. 2). Phenolic compounds generally produce light with acidic potassium permanganate, but little is known of the relationship between chemical structure and emission intensity [14]. For this class of compound, it is clear that the presence of a hydroxyl group on the benzylic carbon (*i.e.* in octopamine and synephrine) and greater methyl substitution on the amine both have a detrimental effect on chemiluminescence intensity. The limit of detection (3σ) for *N*-methyltyramine was 4×10^{-9} M, which was similar to that of the other adrenergic amines (between 1×10^{-9} and 1×10^{-8} M [19]).

A HPLC solvent mixture of 98% water adjusted to pH 2.15 with trifluoroacetic acid and 2% methanol provided baseline resolution of the five adrenergic amines. Retention times for octopamine, synephrine, tyramine, *N*-methyltyramine and hordenine were 1.25, 1.56, 2.61, 3.18 and 3.66 min. Without methanol in the column eluent, greater resolution was obtained, but more time was required for both separation and re-equilibration from the elevated levels of methanol that were used to flush less polar sample components from the column. Linear calibrations were obtained using nine standard mixtures of the adrenergic amines over the range 1×10^{-5} to 1×10^{-3} M, but for the lower order of magnitude, greater accuracy was obtained by calculating the line-of-best-fit using standards from that region only. Precision was established using five replicate injections of a mid-range standard mixture (1×10^{-4} M). The relative standard deviations were 0.32%, 0.51%, 0.45%, 0.50% and 0.55% for retention time, and 2.9%, 2.4%, 3.5%, 4.1% and 4.0% for peak area, of octopamine, synephrine, tyramine, *N*-methyltyramine and hordenine, respectively.

3.2. Adrenergic amines in weight-loss products

Nine commercially available weight-loss products containing *C. aurantium* protoalkaloids were analysed. The products contained a wide range of other ingredients (including extracts from *Camellia sinesis* (green tea), *Paullinia cupana* (guarana), *Salix alba* (white willow), *Garcinia quaesita* (brindleberry), *Capsicum frutescens* (cayenne), *Zingiber officinale* (ginger), *Coleus forskohlii* and *Evodia rutaecarpa*, and pure compounds such as caffeine, tyrosine, carnitine, phenylalanine, evodiamine, theobromine, rutaecarpine, hydroxycitric acid, chromium picolinate).

Products 1 and 2 contained pure octopamine, tyramine and hordenine as ingredients. Synephrine was included as the hydrochloride salt or standardised herbal extract (95% synephrine). The measured values using the monolithic column separation with chemiluminescence detection were in reasonable agreement with the stated values (Table 1), with the exception that no tyramine was found (above the limit of detection) in product 2, which was claimed to contain 37.5 mg of tyramine per tablet. When consuming these products within the dosage range recommended by the manufacturers, daily intake of synephrine and total adrenergic amines would be 55–164 and 255–766 mg, respectively. Based on the specified values, daily intake of caffeine from these products would be 200–600 mg.

Products 3–9 contained *C. aurantium* extracts (in three cases the extract was standardised with regard to synephrine content). The quantity of the extract (per tablet/capsule) in each of these products was given in terms of equivalent dried fruit. However, this was not a good indicator of the level of active ingredients; the mass percentage of synephrine in the specified equivalent dry fruit was found to range between 0.06% and 0.46% (with an average of 0.29%), which is similar to the range reported by Avula et al. for 13 dried samples of *C. aurantium* fruits (0.04–0.41% with an average of 0.17%) [6]. For example, it was claimed that both products 8 and 9 contained an extract that was equivalent to 6000 mg of dry fruit per tablet, but the synephrine content was found to be over eight times higher in product 8 than in product 9. Unlike many of the other products, the synephrine content in these two was specified, but the content of product 9 was found to be lower than the specified value (Table 1). Lower concentrations of other adrenergic amines were detected and in agreement with several previous studies [6,8], tyramine and *N*-methyltyramine were the most prominent. Minor interferences from other ingredients prevented accurate quantification of the target analytes at below 0.5 mg per tablet/capsule. The daily intake of synephrine using products 3–9 under the manufacturers' recommended dosage would be 3–57 mg, which is lower than (but overlaps with) the range for products 1 and 2. The total adrenergic amine intake for products 3–9 was approximately 3–70 mg, which was far lower than that of the products containing individual *C. aurantium* protoalkaloids as ingredients. It should be noted that the original labelling of product 6 (which had been covered by modified directions) suggested a daily dosage of up to 6 capsules, giving a synephrine intake of over 300 mg.

3.3. Potential interferences

As described above, there are a wide range of products on the market that contain *C. aurantium* extracts and/or individual adrenergic amines, combined with many other ingredients (including other plant extracts). A close inspection of the peak shapes and retention times is warranted for new samples. We analysed four weight-loss products that did not specify *C. aurantium* extracts as ingredients (samples 10–13) and in two cases we observed a large chemiluminescence peak with a retention time similar to that for synephrine (see sample 12 in Fig. 3), but an equivalent peak was not observed in the chromatogram when UV-absorbance detection was used. To identify the compound responsible for this relatively large chemiluminescence response, the separation was coupled with mass spectrometric detection (positive ion), which showed mass peaks at *m*/*z* 150, 204, 299 and 407 for that retention time. The peak at *m*/*z* 150 was similar to a characteristic fragment peak $[M-OH]^+$ for synephrine, but the mass difference exceeded 200 ppm and the pseudo-molecular ion $[M+H]^+$ at *m*/*z* 168 for synephrine was not observed. An inspection of the specified sample ingredients indicated that *N*-acetylcarnitine ($[M+H]^+$ *m*/*z* 150) and methionine ($[M+H]^+$ *m*/*z* 204) may produce these mass peaks, which was confirmed by comparing the mass spectrum of respective standards. The peaks at *m*/*z* 299 and 407 were assigned as the $[2M+H]^+$ dimers.

Although *N*-acetylcarnitine and methionine both co-eluted with synephrine, only methionine (a thioether (R–S–R′)) was found to produce a signal with acidic potassium permanganate. Thiol compounds (R–S–H), such as cysteine, glutathione and captopril, have previously been found to produce a significant amount of

light with this reagent [22–25] (although in those studies, quinine and formaldehyde were used as enhancers rather than sodium polyphosphate). Lebedev and Tsibanova noted that the oxidation of methionine with permanganate produced light [26], but under conditions similar to those used in this study the response for methionine was far lower than that of the indolic amino acid tryptophan and the phenolic amino acid tyrosine [27], which is similar in structure to tyramine. Nevertheless, the quantity of methionine in the two weight-loss products (333 mg per tablet and 880 mg per serve (~3 g of powder)) was very high compared to the amount of synephrine in the products discussed in Section 3.2 (3.3–55.3 mg per tablet/capsule).

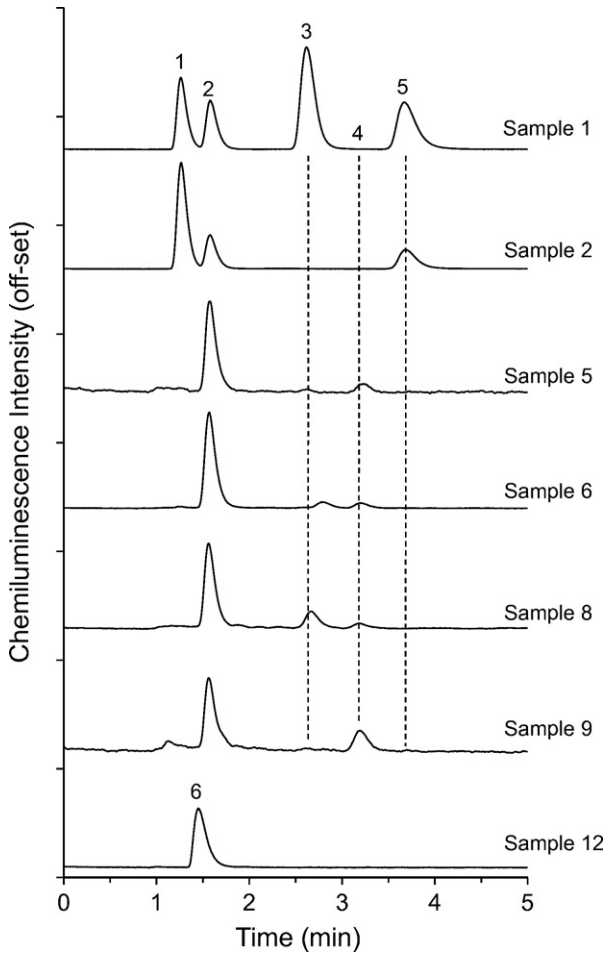

Fig. 3. Chromatograms for the determination of adrenergic amines in weight-loss products using HPLC with monolithic column (C_{18}) separation and acidic potassium permanganate chemiluminescence detection. Peaks: (1) octopamine, (2) synephrine, (3) tyramine, (4) *N*-methyltyramine, (5) hordenine, and (6) methionine. Sample 12 is discussed in Section 3.3.

4. Concluding remarks

Detection based on acidic potassium permanganate chemiluminescence offers greater selectivity for phenolic analytes than UV-absorbance, and products containing large quantities of adrenergic amines can be analysed with a rapid reversed-phase chromatographic separation coupled with chemiluminescence detection. An examination of commercially available weight-loss products showed reasonable agreement between measured quantities and package labelling (with some notable exceptions), and a very wide range of synephrine and total adrenergic amines per tablet, which was accentuated when suggested daily consumption of the products was considered.

In general, no other major peaks were observed in the same region of the chromatogram, but minor interferences from other herbal ingredients prevented accurate quantification of very low concentrations of the target analytes. Under these conditions, methionine eluted at a similar time to synephrine and when present at relatively high concentrations, produced a significant emission. Methionine is used as an ingredient in some weight-loss products, but was not included in any of the tested products that contained *C. aurantium* extracts.

To address these aspects and establish the full potential of acidic potassium permanganate for the detection of phenolic protoalkaloids in plant extracts and consumer products, we are currently exploring this mode of detection in conjunction with recent advances in the separation of *C. aurantium* samples described by Roman et al. (ion-pairing) [7] and Pellati and Benvenuti (pentafluorophenylpropyl columns) [4].

Acknowledgements

The authors thank Deakin University for funding, Dr. Steve Colgate (CSIRO) for donating the *N*-methyltyramine, and Gail Dyson (Deakin University) for assistance with the NMR characterisation of hordenine.

ABSTRACT

Peroxynitrite and hypochlorite are oxidants relevant in many pathological situations. We propose a simple spectrofluorometric assay to determine antioxidant capacity against hypochlorite and peroxynitrite based on protection against fluorescein bleaching. The assay can be performed on a microplate and requires minute amounts of material. Standard antioxidants show different reactivities for both oxidants. Antioxidant capacity of fruit bodies of edible mushrooms, tea, coffee and wine estimated as exemplary biological material point to considerable differences in the scavenging capacity of various biological material against hypochlorite, peroxynitrite and peroxyl radicals.

1. Introduction

The "Total antioxidant capacity" (TAC) assays have been widely used in various fields of research including analysis of food and beverages, analysis of plant material and analysis of body fluids, especially in pathologies. These assays quantify the resultant antioxidant activity of all molecules present in the biological material studied. Various assays of TAC rely either on inhibition of oxidation of an indicator by a chosen oxidant or on reduction of oxidized forms of appropriate indicators [1–3]. The choice of oxidants is an important issue in TAC assays. Assays based on the scavenging of the hydroxyl radical [4,5] have been criticized as this radical is very reactive, with respect not only to typical antioxidants but to virtually any organic compound. Most frequently, peroxyl radicals generated by thermolysis of an azo initiator AAPH are applied as a model oxidant due to the convenience of this system. There are, however, also other pathophysiologically relevant oxidants which are not disposed of by enzymatic means, so the total scavenging capacity of a biological material with respect to these species is of particular importance, viz. peroxynitrite and hypochlorite. Although assays for the capacity to scavenge oxyradicals have been proposed (e.g. ORAC assay, Oxygen Radical Antioxidant Capacity; TOSCA, Total Oxyradical Scavenging Capacity Assay) [2,6] a simple, cheap, high-throughput assay for the ability to scavenge hypochlorite and peroxynitrite is lacking. The most frequently and commonly applied kinetic ORAC assay, based on the calculation of the area under the curve of fluorescence and time (or lag time) of incubation is useless in case of fast reactive oxidants like hypochlorite and, especially, peroxynitrite. The commercially available OXY-Adsorbent Test which measures the antioxidant capacity of the sample against hypochlorite on the basis of the excess of oxidant after reaction is not applicable for peroxynitrite. Here, we propose a simple, competitive, end-point (instead of kinetic) assay for evaluation of the antioxidant capacity of biological fluids against hypochlorite and peroxynitrite based on the same assumption as the widely used $ORAC_{FL}$ assay—bleaching of fluorescein [7]. Both oxidants tested react rapidly with fluorescein what makes our end-point assay even simpler and much quicker.

2. Materials and methods

All reagents were from Sigma/Aldrich (Poznań, Poland). Peroxynitrite was synthesized from sodium azide and ozone according to the method of Pryor et al. [8] with small modifications [9].

Fluorescein (to obtain 2 μM final) in 100 mM phosphate buffer, pH 7.4, was mixed in the presence or absence of antioxidants (ascorbate, Trolox, uric acid, glutathione or bovine serum albumin; BSA) with 100 μM HOCl or $ONOO^-$ or 10 mM AAPH to the final volume of 100 μl on 96-well plate. Peroxynitrite and hypochlorite were added on a shaker. The immediate mixing of the sample with the oxidant added is critical for the reproducibility of the assay, especially in the case of peroxynitrite. The half-life of peroxynitrite at neutral pH is of an order of a second so it is important that, when added, the oxidant is distributed immediately in the whole reaction volume,

doi:10.1016/j.talanta.2009.11.004

in order to get reproducible results (otherwise part of the oxidant decomposes before reaching the substrate and the extent of fluorescein bleaching and its protection shows high variability). The way of addition must be reproducible between all samples compared. In our experience, the optimal procedure is to add peroxynitrite while keeping the microplate on a shaker, and use the same shaking conditions for the whole assay. After incubation at room temperature for 15 min the fluorescence of the samples containing HOCl and $ONOO^-$ was measured (excitation: 485 nm, emission: 538 nm). For comparison, we estimated the peroxyl radical scavenging capacity in our system using AAPH: samples were incubated with 10 mM AAPH at 37 °C in the dark for 1 h and fluorescence was read immediately after the end of incubation (excitation: 485 nm, emission: 538 nm). For each antioxidant the experiment was conducted in six independent repeats. The IC_{50} value was determined as the concentration of an antioxidant that provides 50% inhibition of fluorescein oxidation.

The fruiting bodies of edible mushrooms *Boletus edulis* and *Cantharellus cibarius* were collected in 2008 in Bory Tucholskie (a big forest area in the Northern part of Poland), cleaned and air-dried. Before extraction the dry fruiting bodies were cleaned carefully under running water to remove residual contamination and dried again. 1 g of dry caps of Boletus edulis and whole body of *Cantharellus cibarius* were ground into powder, then 15 ml of boiling hot water was added and all together was rubbed for the next 5 min and stirred at room temperature for 15 min. Then the mixture was centrifuged at 3000 × *g* at room temperature for 20 min. The supernatants were portioned and kept frozen at −23 °C until analysis. Individual bags of commercial teas: green PackerBest, red Dilmah Raspberry and black Lipton Imperial Earl Grey) were extracted in 50 ml of boiling water for 15 min. Similarly, 0.5 g of soluble coffee (Tchibo Family) was dissolved in 50 ml of boiling water. Cervantez De Alcardete Don Quijote semidry red wine (Spain) was used. The extracts were appropriately diluted (20–200 times) before the assay and various amounts of the diluted extracts (1–50 μl) were added to the microplate wells keeping the final volume of the reaction constant (200 μl).

Summary of the proposed procedure: Prepare 10 μM fluorescein in 100 mM phosphate buffer, pH 7.4 so to obtain final concentration of 2 μM in wells of a microplate, taking into account the volumes of additives. Measure decrease in fluorescence at the excitation/emission wavelengths of 485 nm and 538 nm, respectively, after addition of antioxidants (100 μM hypochlorite and 100 μM peroxynitrite, final). Calibrate the method using ascorbate in the concentration range from 10 to 100 μM to determine IC_{50} for ascorbate (IC_{50Asc}). Measure % inhibition of fluorescein bleaching by appropriately diluted fluids/extracts (1–50 μl in a total volume of 100 μl) and find the volume IV_{50} (corresponding to IC_{50}). Calculate the antioxidant capacity of the material analysed as equivalent concentration of ascorbic acid using the calibration curve according to the equation: AC [μM] = IC_{50Asc} [μM] × (dilution of the sample) × 100 [μl]/IV_{50} [μl].

3. Results and discussion

Fluorescein is bleached not only by hydroxyl or peroxyl radicals but also by peroxynitrite and hypochlorite. In all cases, the bleaching can be prevented by antioxidants so the degree of protection may be a measure of the antioxidant activity of a sample [10–12]. In kinetic assays, the area under curve of fluorescence intensity versus time or lag time of the oxidation are usually taken as a measure of oxidation of the probe and of its protection. In our approach the final fluorescence after completion of fast reaction with hypochlorite or peroxynitrite (or fixed time of reaction with AAPH) is used instead. Concentration of the oxidant must be chosen so to provide significant but not complete fluorescein bleaching. In our system addition of 100 μM hypochlorite and peroxynitrite to 2 μM fluorescein solution resulted in rapid drop of fluorescence (61.4 ± 7.3% fluorescein oxidation by hypochlorite, 78.7 ± 8.5% by peroxynitrite). After 1 h incubation with 10 mM AAPH the percent of fluorescein oxidized was about 51.5 ± 5.6%.

The protective action of antioxidants was expressed as per cent inhibition of the oxidation of detectors. From such plots, antioxidant or extract concentrations giving 50% protection against the fluorescein bleaching (i.e. reducing the fluorescence drop between the control and oxidant-treated samples by 50%) were read (IC_{50}).

Standard antioxidants and albumin showed different efficiency in the protection against fluorescein bleaching. In the case of HOCl, the sequence of IC_{50} values (reflecting the decreasing efficiency of protection) was: BSA (59 ± 11 nM) ≪ (glutathione (29.5 ± 0.6 μM) < urate (36.0 ± 1.9 μM) < ascorbate (67.5 ± 5.7 μM) < Trolox (72.7 ± 5.0 μM). For peroxynitrite, the sequence was: BSA (0.20 ± 0.05 μM) < urate (14.6 ± 6.8 μM) < glutathione (19.9 ± 4.9 μM) ≈ Trolox (21.6 ± 1.7 μM) < ascorbate (24.1 ± 3.3 μM). In the case of AAPH, the sequence of IC_{50} values was as follows: BSA (0.21 ± 0.06 μM < Trolox (43.1 ± 15.0 μM) ≈ urate (43.9 ± 2.1 μM) < ascorbate (69.0 ± 1.3 μM) < glutathione (105.2 ± 11.3 μM). A similar sequence of the scavenging ability of standard antioxidants against peroxyl radicals was found in the paper of Winston and co-workers [6]. Additionally, we determined the inter- and intra-day variability of this assay for ascorbate: for hypochlorite inter- and intra-day standard deviation was found to be 4.1 and 5.7 μM, respectively, while for peroxynitrite 2.1 and 3.3 μM and for AAPH 0.9 and 1.3 μM. Thus, we presented the IC_{50} values with intra-day standard deviation.

The high antioxidant activity of bovine serum albumin in the test of fluorescein bleaching is rather unusual, is not observed in other tests of antioxidant activity [13] and can be explained by the binding of fluorescein to this protein [14,15]. Binding by albumin seems to be the main factor in the protection of fluorescein against oxidants, rather than purely competitive scavenging of oxidants by the protein molecule and therefore represents a methodological artifact. Therefore, the fluorescein-based TAC assays should rather not be used for assays of albumin-containing fluids like blood plasma (though may be quite useful for deproteinized plasma). Indeed, TAC values obtained for blood plasma with $ORAC_{FL}$, based on fluorescein bleaching, are much higher than those obtained by the ORAC method based on phycoerythrin [7]. We did not find such an effect with other proteins. However, it cannot be excluded that some proteins having affinity for hydrophobic ligands could also bind the dye. Binding of fluorescein by BSA induces loss of fluorescence of the dye; in a case when such an effect is observed by addition of a sample in the absence of an oxidant, the presence of a binding protein could be expected and should be checked.

As Trolox appeared to be the weakest hypochlorite scavenger, we propose to use ascorbate as a standard and express the scavenging capacities in ascorbate equivalents.

Therefore, we used material of plant origin to test the assay for hypochlorite and peroxynitrite scavenging capacities. Results of analysis of mushroom fruiting bodies, tea, coffee and wine point to different scavenging capacities for these oxidants, generally lower for hypochlorite than for peroxynitrite, and lower than that found for the scavenging of peroxyl radicals (Table 1). Interestingly, there are considerable differences between various materials studied. Instant coffee showed an especially high ratio of the peroxynitrite to hypochlorite scavenging capacity while the fruiting body of Cantharellus showed a higher hypochlorite than peroxynitrite scavenging capacity, in contrast to Boletus.

In summary, we propose a simple and rapid spectrofluorometric test for estimation of the peroxynitrite and hypochlorite scavenging capacity of biological materials including food products, requiring very small amounts of material.

Table 1
Scavenging capacities of exemplary food products for hypochlorite, peroxynitrite and AAPH-derived peroxyl radicals (in ascorbate equivalents per liter). Mean ± SD, $n = 4$.

Material	Hypochlorite	Peroxynitrite	AAPH	Unit
Boletus edulis	47.8 ± 5.0	61.9 ± 1.1	382 ± 10	mmol/l
Cantharellus cibarius	10.5 ± 0.2	6.96 ± 1.14	251 ± 3	mmol/l
Red wine	491 ± 8	99.4 ± 6.1	573 ± 62	mmol/l
Green tea	57.6 ± 3.1	294 ± 14	728 ± 41	mmol/l
Black tea	48.1 ± 9.4	166 ± 34	367 ± 45	mmol/l
Red tea	14.0 ± 0.4	29.9 ± 3.4	695 ± 107	mmol/l
Coffee	14.9 ± 0.4	135 ± 2	219 ± 1	mmol/l

Obituary

George-Emil Baiulescu, Professor, Mentor and Friend, 1931–2009

This year, June 9, 2009, the School of Analytical Chemistry from Romania lost the most important professor, the chief of this School, Professor George-Emil Baiulescu. He was born on August 4, 1931 in a famous family from Braşov, his grandfather being the first Romanian Lord Mayor. All his life he tried to improve the quality of Analytical Chemistry from Romania.

Professor George-Emil Baiulescu obtained his B.Sc. in 1954 from the Faculty of Chemistry, University of Bucharest and between 1954 and 1958 he was researcher at the Centre of Chemical Researches (Department of Inorganic Chemistry) of the Romanian Academy of Science. He took his Ph.D. in 1960 and D.Sc. in 1970, and in 1971 he obtained the authorization for directing Ph.D. students and 36 persons obtained this title under his supervision. He worked from 1958 at the Faculty of Chemistry as assistant, lecturer, reader and professor, and in 1961, together with Professor Grigore Popa, founded the Department of Analytical Chemistry in the Faculty of Chemistry at the University of Bucharest.

His scientific activity is evidenced by more than 200 scientific papers in prestigious journals, such as Analytical Chemistry, Trends in Analytical Chemistry, Analytica Chimica Acta, Analytical Letters, Analyst, Critical Reviews in Analytical Chemistry, Mikrochimica Acta, and Talanta. For more than 30 years Professor Baiulescu was a member in the editorial board of Analytical Letters journal. His research fields were: organic reagents, separation methods, ion selective electrodes, atomic absorption and emission spectrometry, molecular emission spectrometry, chromatographic techniques, sampling, and environmental analysis. One of the most important fields in which he published a lot of papers was ion selective electrodes, for cations and pharmaceutical compounds.

He worked for more than 40 years in environmental pollution, air and water, and seven Ph.D. thesis were granted for research in this field. His environmental researches were directed to the determination of gases, such as sulfur dioxide, and the reactions of sulfur oxide in the atmosphere; of carbon monoxide and nitrogen dioxide; of cations from mineral waters, river and sea waters; and also organic polutants from different type of samples.

His conclusion about all his activity is "No analysis is better than the sample itself". Professor Baiulescu published four books in foreign publishing houses: *Stationary Phases in Gas Chromatography* with V.A. Ilie as co-author (in 1975, published by Pergamon Press, Oxford), *Applications of Ion Selective Membrane Electrodes in Organic Analysis* with V.V. Coşofreţ, in 1977 published at Ellis Horwood, translated in 1980, also in Russian, Mir, Moscow), *Education and Teaching in Analytical Chemistry* together with C. Pătroescu and R.A. Chalmers (in 1982 published at Ellis Horwood, Chichester and translated in China, 1993), and *Sampling* (1991) together with P. Dumitrescu and P. Gh. Zugrăvescu (published at Ellis Horwood, Chichester and translated in China, 1996) and one chapter in *Gold Mining: Formation and Resource Estimation, Economics and Environmental Impact,* "The Influence of Gold Mining Industry on the Pollution of Roşia Montana District", together with A.I. Stoica and R.M. Florea in Nova Publishers House, 2009. In Romanian publishing houses, Professor Baiulescu published in 1974 together with T. Năşcuţiu, *Physical Methods of Trace Analysis*, in Editura Tehnică, Bucharest and *Environmental Analytical Chemistry. Concepts*, Ars Docendi, together with A.I. Stoica and C.H. Lochmüller.

One of his most important activities was the foundation of the Romanian Society of Analytical Chemistry (SCAR) in 1990. He put

0039-9140/$ – see front matter
doi:10.1016/j.talanta.2009.10.001

all his soul and energy in organizing national and international conferences. Therefore, in 1992 at Cluj-Napoca, he organized the first Conference on Analytical Chemistry from Romania with international participation, after the Romanian Revolution in December 1989. Before December 1989, the National Council of Engineers and Technicians organized International Conferences at Mamaia (1969) and at Braşov (1971). After these Conferences, the leadership from the communist period did not allow any International Conferences. Before December 1989 only National Conferences were organized, the last one being at Brăila (1989).

Nowadays, every year the National Conferences on Analytical Chemistry and every 2 years (1994—Constanţa, 1996—Craiova, 1998—Piatra Neamţ, 2000—Braşov, 2002—Timişoara, 2004—Braşov) the International Conferences on Analytical Chemistry were organized. In 2000, at Braşov the "1st Romanian International Conference on Analytical Chemistry" in cooperation with the Division of Analytical Chemistry was organized.

The Romanian Society of Analytical Chemistry organizes conferences every last Wednesday of the month, where are presented scientific papers regarding mainly analytical research and history, but also there are invited prestigious people from different fields, like Teodor Negoiţă, the first Romanian explorer of the North Pole and Constantin Lăcătuşu, the first Romanian who climbed Mt. Everest.

He considered that the best way to learn something is to be in direct contact with specialists and for this reason he participated at a lot of conferences, with plenary and keynote lecures, and oral and poster presentations. Professor Baiulescu participated at most of the Euroanalysis Conferences, Budapest—1975, Helsinki—1981, Cracow—1984, Paris—1987, Vienna—1990, Edinburgh—1993, Bologna—1996, where he presented a keynote entitled Sampling, Basel—1998, Lisbon—2000, Dortmund—2002, Salamanca—2004 and Antwerp—2007. He was invited as plenary lecturer at Sassari, Italy (1976), Zaragoza, Spain (1983), Chiba, Japan (1991), Gdansk, Poland (1986, 1990, 1997, 1998 and 2001), Changchun, China (1994), Mansoura (1997) and Cairo (1998), Egypt. He presented a plenary lecture at the meeting of the Chemical Society, England, 1980, the theme of this lecture was to evidence the importance of method–instrument, man–instrument and method–man–instrument correlations.

One of the passions of George was to climb mountains, and his favorite mountain was Piatra Craiului, where he marked some mountain ways. All he made in his life was done with enthusiasm and energy, and he had capacity to send these to all his coworkers. George-Emil Baiulescu was a great personality, a mentor for all his Ph.D. students and not only for them.

The most important conclusion that characterizes Professor Baiulescu is "The age of each person is the age of his soul". He will be a model for me and I hope that he will be proud about all I will do in my life.

Talanta

The International Journal of Pure and Applied Analytical Chemistry

Aims & Scope

Talanta provides a forum for the publication of original research papers, preliminary communications, and critical reviews in all branches of pure and applied analytical chemistry. Papers are evaluated based on established guidelines, including the fundamental nature of the study, scientific novelty, substantial improvement or advantage over existing technology or methods, and demonstrated analytical applicability. Original research papers on fundamental studies, and novel sensor and instrumentation development, are especially encouraged. Novel or improved applications in areas such as clinical and biological chemistry, environmental analysis, geochemistry, and materials science and engineering are welcome.

Analytical performance of methods should be determined, including interference and matrix effects, and methods should be validated by comparison with a standard method, or analysis of a certified reference material. The developed method should especially comprise information on selectivity, sensitivity, detection limits, accuracy, and reliability. However, applying official validation or robustness studies to a routine method or technique does not necessarily constitute novelty. Proper statistical treatment of the data should be provided. Relevant literature should be cited, including related publications by the authors, and authors should discuss how their proposed methodology compares with previously reported methods.

Since classical spectrophotometric measurements and applications (including derivative spectrophometry), fluorimetry, solvent extraction, titrimetry, chemometrics, etc. are well established and are considered routine analytical methods, studies in such areas should demonstrate a unique and substantial advantage over presently known systems. New reagents or systems should demonstrate clear advantage, and their presentation should be comprehensive rather than generating a series of similar papers for several analytes or similar reagents. Modifications of reagents should demonstrate significant improvements. Obvious application of known chemistries or methods to established instrumental techniques are discouraged.

Application of established analytical approaches to relatively simple matrices having no major interferences, such as pharmaceutical preparations, are discouraged unless considerable improvements over other methods in the literature are demonstrated. Papers dealing with analytical data such as stability constants, pK_a values, etc. should be submitted to more specific journals, unless novel analytical methodology is demonstrated, or important analytical data are provided which could be useful in the development of analytical procedures.

Editors-in-Chief

Professor G.D. Christian, University of Washington, Department of Chemistry, 36 Bagely Hall, P.O. Box 351700, Seattle,WA 98195-1700, U.S.A.

Professor J.-M. Kauffmann, Université Libre de Bruxelles, Institut de Pharmacie, Campus de la Plaine, C.P. 205/6, Boulevard du Triomphe, B-1050 Bruxelles, Belgium

Associate Editors

Professor J.-H. Wang, Research Center for Analytical Sciences, Northeastern University, Box 332, Shenyang 110004, China

Professor J.L. Burguera, Los Andes University, IVAIQUIM, Faculty of Sciences, P.O. Box 542, 5101-A Mérida, Venezuela.

Assistant Editors

Dr R.E. Synovec, Department of Chemistry, University of Washington, Box 351700, Seattle, WA 98195-1700, U.S.A.

Professor J.-C. Vire, Université Libre de Bruxelles, Institut de Pharmacie, Campus de la Plaine, C.P. 205/6, Boulevard du Triomphe, B-1050 Bruxelles, Belgium

Calendar of forthcoming meetings

25–30 April 2010
Pattaya, Thailand
ICFIA 16
16th International Conference on Flow Injection Analysis, including Related Techniques
http://www.science.cmu.ac.th/icfia2010/

26–28 May 2010
Glasgow, UK
Biosensors 2010: The Eleventh World Congress on Biosensors. URL: http://www.biosensors-congress.elsevier.com

1–4 June 2010
Ghent, Belgium
Sixth International Symposium on Hormone and Veterinary Drug Residue Analysis
E-Mail: vdra@ugent.be
URL: www.vdra.ugent.be

May 30 – June 4, 2010
Riva del Garda, Italy
34th International Symposium on Capillary Chromatography and 7th GCxGC Symposium
Chairman: Prof. Dr. P. Sandra
E-mail: riva2010@richrom.com
URL : www.richrom.com

12–15 September 2010
Stockholm, Sweden
13th Symposium on Preparative and Industrial Chromatography and Allied Techniques
URL: www.spica2010.se/

20–23 September 2010
Antwerp, Belgium
Drug Analysis. URL: www.druganalysis.org

17–21 October 2010
Raleigh, NC
FACSS 2010
URL: http://facss.org

18–21 October 2010
Antwerp, Belgium
12th International Conference on Chemometrics in Analytical Chemistry (CAC 2010)
URL: http://www.ua.ac.be/main.aspx?c=.CAC2010&n=78007

8–10 December 2010
Nagoya, Japan
International Conference on Polymer Analysis and Characterization & 15th Symposium on Polymer Analysis in Japan.
