ABSTRACT

Optimization of a high-performance liquid chromatography separation has been developed for nine polyphenols by application of the simplex method. The nine polyphenols selected were mainly phenolic acids that can be present in wastewater and they can be removed by adsorption on activated carbon and resins. After the organic solvent (MeOH) had been chosen, a linear gradient in three stages and the furnace temperature were retained as parameters of optimization. The optimal conditions were determined by the super modified simplex and, in order to measure them a Chromatographic Response Function (CRF) was chosen. With the optimal conditions, the time of analysis was decreased from 69 to 40 min. The validation of the method was made on wastewater olive oil (WWOO) and sugar beet vinasse.

1. Introduction

Polyphenols are valuable natural compounds on account of their antioxidant properties and bactericidal effects, and they contribute to the flavour, colour, astringency and bitterness of beverages like wine, beer, fruit juice. These compounds can be divided into different fractions according to either polarity or molecular weight. The polar fraction is constituted by phenolic acids like 4-hydroxybenzoic acid and hydroxycinnamic acid. These phenolic acid compounds are present in wastewater coming from agro industrial activities related to the manufacturing of olive oil, vinasse, wine, spirits, etc. [1–3]. It is known that phenolic compounds are

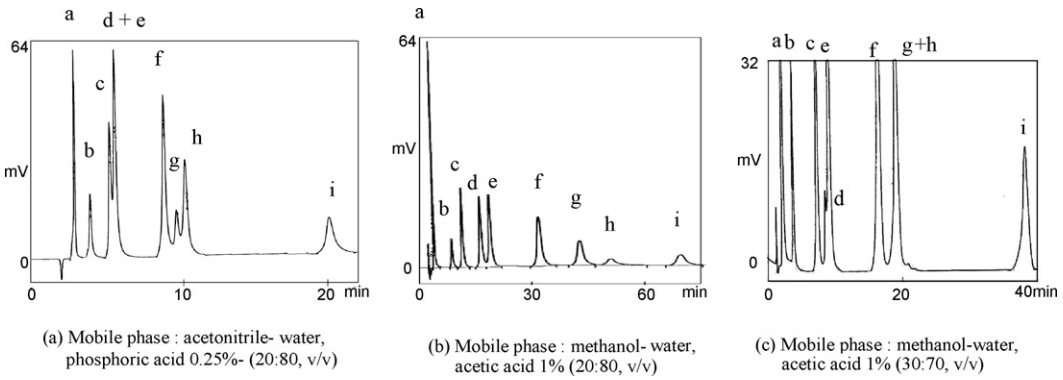
Table 1
Chemical structures of the polyphenols studied.

Benzoic acids: 4-hydroxybenzoic acid, gallic acid (3,4,5-trihydroxybenzoic acid), anisic acid (4-methoxybenzoic acid), syringic acid (4-hydroxy 3,5-methoxybenzoic acid)

Cinnamic acids: p-coumaric acid (4-hydroxycinnamic acid), caffeic acid (3,4-dihydroxycinnamic acid), ferulic acid (3-methoxy 4-hydroxycinnamic acid), synapic acid (3,5-methoxy 4-hydroxycinnaminic acid)

Catechins: (+)-catechin

major contributors to the toxicity and antibacterial activity of olive mill wastewater [4]. Consequently for a safe dispersal of the latter, a suitable treatment is recommended to remove those compounds. The most frequently used method is activated carbon adsorption [5,6]. With in the aim to optimizing such an operation, it is therefore necessary to analyse these compounds in a mixture.



They are usually identified by high pressure liquid chromatography with an ultraviolet detection. In the literature, the analytical column used is generally a C_{18} [1,7], and the detection is commonly made by UV at 280 nm [8] or with a wavelength program [9] by photodiode array detection [1,10] and/or by fluorescence detection [7]. Generally, the column is at room temperature but some analyses can be run at 40 °C. The flow of the mobile phase is around 1 mL min^{-1} and the elution condition uses a gradient condition with two mobile phases. In each case, these phases are acidified by the addition of phosphoric acid, sulfuric acid or acetic acid with an average concentration of 1% in water. In the paper of Tsao and Yang [8], pH conditions were optimized with acetic acid solution and sodium acetate with a final pH at 2.55. Several types of mobile phases were used but the organic solvent is usually methanol or acetonitrile used with or without water. Thus, the aim of the work reported in this paper was to optimize the separation of phenolic acid mixtures by HPLC to envisage the study of the co-adsorption on such an adsorbent material as activated carbon. To this purpose six common phenolic acids were selected: 4-hydroxybenzoic acid, gallic acid, p-coumaric acid, caffeic acid, ferulic acid, synapic acid and two other less usual compounds: anisic and syringic acids (Table 1). Thanks to their functional groups, the two last may be useful for interpreting the interactions between molecule and adsorbent. In addition, catechin was also chosen in order to have a molecule with a more important molar volume.

To carry out this optimization, a simplex method was used. Simplex methods are evolutionary operation techniques in which a series of experiments is set up in such a way that the reaction conditions for a given experiment are dictated by the results of the preceding experiments in the series [11,12]. To set up this method, the Chromatographic Response Function (CRF) was defined in order to quantify the improvement of the analytical system. Moreover, the parameters retained for optimization were: column temperature and three parameters for defining the linear gradient in three stages. These three parameters are: (i) the value of the initial percentage of organic solvent, (ii) the time that corresponds to the first stage or to the isocratic mode and (iii) the value of the gradient slope. Besides, the organic solvent selected was methanol and the upper percentage of methanol during the gradient was set at 30%. The aim of the optimization was to obtain a 45 min analysis time around and a resolution superior or equal to two between the different compounds. The optimized method was applied on natural residues: wastewater olive oil (WWOO) and sugar beet vinasse.

2. Experimental

2.1. Reagents and standards

The caffeic acid and syringic acid were purchased from Sigma (St. Quentin Fallavier, France), the anisic acid and 4-hydroxybenzoic

(a) Mobile phase : acetonitrile- water, phosphoric acid 0.25%- (20:80, v/v)

(b) Mobile phase : methanol- water, acetic acid 1% (20:80, v/v)

(c) Mobile phase : methanol-water, acetic acid 1% (30:70, v/v)

Fig. 1. Selection of organic solvent in isocratic mode—flow rate at 1 mL min^{-1} and column temperature = 25 °C. HPLC–UV chromatogram for a nine polyphenolic mixture standard solution (10 mg L^{-1}). Peaks: (a) gallic acid, (b) catechin, (c) 4-hydroxybenzoic acid, (d) caffeic acid, (e) syringic acid, (f) p-coumaric acid, (g) ferulic acid, (h) synapic acid and (i) anisic acid.

acid from Aldrich (St. Quentin Fallavier, France), the gallic acid synapic acid and (+)-catechin hydrate from Fluka (Buchs, Switzerland) and the p-coumaric acid and ferulic acid from Extrasynthèse (Genay, France). The solvents for liquid chromatography, i.e. methanol, acetonitrile and acetic acid, were purchased from Carlo Erba (Rueil–Malmaison, France). The individual standards were dissolved in water to obtain a stock solution of 100 mg L^{-1} for each compound. These solutions were stored in the dark in the fridge at 4 °C for 1 week to take account of their degradations especially those of the 4-hydroxybenzoic and gallic acids. The individual standard solutions injected to determine the individual retention time were prepared by dilution from the stock solutions. The standard mixture solution was prepared with 0.150 mg of each compound into 100 mL volumetric flask with water and was used for adequate dilution with water.

The vinasse sample was sugar beet vinasse obtained from the ethanol production of a sugar refinery (La Vermandoise, Toury, France) and stored in 1000 mL glass dark containers at 4 °C. WWOO was obtained from a continuous three-phases process (le Moulin à huile Jullien, Saint Saturnin les Apt, France) and stored at −20 °C in 2000 mL low density polypropylene containers. The samples were diluted with water to 50% (w/w) and 8 g were used for the liquid–liquid extraction.

2.2. Liquid–liquid extraction

Due to the natural matrices of WWOO and vinasse, a liquid–liquid extraction was used to facilitate the analyses. For extraction, previously several solvents were tried [13]: ethyl acetate, diethyl ether, trichloromethane. For determining the percent of recovery, the extraction was made with 10 mL of standard mixture adjusted to pH 4 with 10% HCl solution in weight and with the studied solvent (3 × 20 mL). The time of agitation was 15 min for each stage. The organic phase was evaporated off on a Rotavapor. The residue was dissolved in 3 mL of methanol, filtered (0.45 μm, Bioblock France) and analysed by HPLC. The aqueous phase was analysed by HPLC.

2.3. Saponification

To the aim to liberate free ferulic acid from vinasse, a saponification was realized. 100 g of vinasse were added to 400 mL of 4 M NaOH solution at 80 °C for 5 h. A sample of 15 mL was removed and the pH was adjusted at 4 by the addition of an aqueous solution of HCl (10% in weight). Finally, 8 g of this adjusted solution were used for the liquid–liquid extraction.

2.4. Apparatus

The HPLC analyses were carried out using a Varian pump (model Prostar), a TSP® membrane degazer, a Varian autosampler injector (model 400 Prostar), a CROCO-CIL thermostated oven, a Thermo Separation Products multiwave UV detector (model spectra-system UV 2000) and two Shimadzu integrators (model C-R5A). The analytical column (250 mm × 4.6 mm i.d.) used was a LichroCART 250-4 HPLC-Cartridge with a LiChrospher100 RP-18 (5 μm) equipped with a guard column from Merck (Darmstadt, Germany). For HPLC analysis, an aliquot (10 μL) was injected into the column. Wavelengths of λ = 280 nm and λ = 320 nm were used for the absorbance detector. The wavelength of 320 nm is specific to the cinnamic acids.

During the optimization, the elution conditions varied with each experiment but the nature of the mobile phase remained constant and was constituted with acid water (1% acetic acid) and methanol. The flow rate of the solvent was kept at 1 mL min^{-1}.

2.5. Simplex method

The simplex method is an evolutive method that removes the worst experiment from an initial simplex by a new one in the opposite direction. The process goes on until the optimum conditions are reached. The advantage of this kind of evaluative system is to enable the evolution of the simplex with knowledge gained from experiments, especially when data on the system to be optimized are scarce. The design of experiments, in contrast, requires previous knowledge of the system in order to obtain the optimal response within the experimental domain.

3. Results and discussion

3.1. Control variables selected and initial simplex

The literature analysis showed that a gradient was used in all cases to increase the concentration of the organic solvent (methanol or acetonitrile). Therefore, some preliminary experiments were made with each organic solvent in order to determine the elution strength. The experiments conditions, their results and corresponding chromatograms are reported in Fig. 1. This figure shows that acetonitrile is more eluent than methanol. The retention time of the last compound (anisic acid) was equal to 20.2 min with acetonitrile but the resolution needed to be improve to obtain a better separation of compounds (Fig. 1a). For the same methanol concentration, the anisic retention time was equal to 69.3 min (Fig. 1b) but all the resolutions were superior to 1.5. Increasing the methanol percentage to 30% allowed to decrease the anisic retention time to 37.8 min (Fig. 1c) but no separation was observed between the caffeic and

Table 2
Initial simplex in reduced coordinates and in real coordinates.

Experiment number	Reduced coordinate matrix				Real coordinate matrix			
	$X_{i,1}$	$X_{i,2}$	$X_{i,3}$	$X_{i,4}$	MeOH (%)	t_i (min)	Slope (% min^{-1})	T (°C)

3	0.5	0.289	0.791	0	17	19.0	0.79	25
4	0.5	0.289	0.158	0.775	17	19.0	0.71	29

syringic acids first nor between the ferulic and synapic acids. In view of these results, methanol was selected as the organic solvent and a gradient had to be implemented. To achieve this gradient, several control variables were selected: the initial value of the organic solvent (noted A), the time of the isocratic mode t_i (noted B), and the gradient slope (noted C). Besides, the gradient was stopped when the percentage of organic solvent reached 30% which permitted to have sufficient eluent strength and to decrease the time of equilibration before each following injection. In fact, 6 min were required to return to the initial conditions and 5 min of equilibration were necessary before the next injection. Finally, the last control variable selected for the optimization was the column temperature (noted D).

For these four variables, the reference values had to be defined. In the case of variable A (% MeOH), the reference value taken was 15%. The time of the isocratic mode was selected at 18 min (variable B) because, as Fig. 1b shows, a first group with five polyphenols exhibits resolutions up to 1.5. The last compound of this group is syringic acid with a retention time equal to 18.7 min. Then p-coumaric acid was eluted with a retention time equal to 31.8 min. Therefore, an interval of 13 min exists between the compounds and needs to be reduced by the action of a gradient. The reference value of the gradient slope was equal to 0.68% min^{-1} (C) and finally a 25 °C column temperature was selected. Then the first experiment (number 0 in Table 2) was made with 15% of MeOH during 18 min and then a gradient of 0.68% min^{-1} was performed up to 30% of MeOH with a column temperature at 25 °C and a flow rate at 1 mL min^{-1}. The other experiments of the initial simplex had to be built according to the type of method chosen. In our case, Czech's method [14] chosen whose matrix is represented in Table 2. If a new control variable is added, this method allows keeping the experiments already completed for building the initial simplex.

The value of the real coordinate of each parameter for each experiment was obtained by the following relation:

$$x_{i,j} = x_{0,j} + X_{i,j} \times \Delta_{xj} \quad (1)$$

where i corresponds to the simplex points from 0 to k, j corresponds to the variable from 1 to k, $x_{0,j}$ is the real coordinate for the variable j at the center of the domain studied, $X_{i,j}$ corresponds to the reduced coordinate for the variable j at the point i, and Δ_{xj} corresponds to the step size for the variable j. Moreover, the step size (Δ_{xj}) of each variable was chosen with 20% of variation related to the value at the center of each control variable. The step sizes and the values of the domain center are reported in Table 3 for each variable. For the evolution of the simplex, the modified simplex method was used [15,16]. This method is also called variable-size simplex method and allows expanding or contracting the simplex size by adjusting the step size during the progress of the improvement. The calculation of the coordinate of the new point was based on the following equation:

$$X_{r,j} = X_{g,j} + \alpha(X_{g,j} - X_{w,j}) \quad (2)$$

where $X_{r,j}$ is the reduced coordinate of the new point for the variable j, $X_{g,j}$ is the centroid of the remaining face/hyperface (i.e. the average levels for the remaining trials), $X_{w,j}$ is the rejected trial and α is a coefficient either of expansion or contraction. Therefore, this method allows not to be "too precise" in the choice of the initial step sizes that are sometimes difficult to define due to the lack of experiments in the beginning of the study.

Table 3
The control variables values at the center of the domain and their step sizes.

Control variable	Value of the domain center	Step size	Unit
$x_{0,1}$ (MeOH)	15	3	%
$x_{0,2}$ (t_i)	18	3.6	min
$x_{0,3}$ (gradient slope)	0.68	0.136	% min^{-1}
$x_{0,4}$ (temperature)	25	5	°C

3.2. Chromatographic Response Function

Moreover for measuring the quality of the separation, a response had to be chosen. We opted for the Chromatographic Response Function (CRF) [17–19]. The CRF is described with the following equation:

$$\mathrm{CRF} = \sum_{i=1}^{p-1} R_i + aP + b(t_M - t_L) \quad (3)$$

where R_i is the resolution between adjacent peak pairs, P is the number of peaks detected, t_M is the target retention time in minutes, t_L is the retention time for the last peak, and a and b are two arbitrary weighting factors. In our case, a is equal to 1 and b to 0.5. The term $(t_M - t_L)$ is negative if t_L is superior to t_M, which allows to decrease the CRF when the conditions are not favourable. Moreover under the initial conditions, the study started with a retention time for the last compound superior to the target retention time. Before starting, the optimal values of CRF had to be defined for determining the stopping point of the simplex evolution. Thus in this case, the detection of each of the nine polyphenols on the chromatogram had to be achieved with a resolution superior or equal to 2 for their quantifications and with an analysis time at most equal to 45 min. Therefore, the optimum response could be calculated with (i) $\sum_{i=1}^{p-1} R_i = (9-1) \times 2$, (ii) $P = 9$ and (iii) $0.5 \times (t_M - t_L) = 0$, so its value was 25. Besides, if the values of R_i were superior to 2 then the value 2 was attributed to R_i when inferior they kept the calculated value.

3.3. Optimization of chromatographic conditions

The parameters and results of each experiment have been reported in Table 4. This table shows the value of $\sum_{i=1}^{p-1} R_i$, maximum retention time (t_L), CRF and number of simplex with the best point (b) and the worst point (w). In the case of the initial simplex (1) experiments, the best point corresponds to experiment 4 and the worst to experiment 0. The CRF value of experiment 4 is already near the value of optimum CRF (24.49 instead of 25).

Experiment 5 is a reflection of experiment 0 with $\alpha = 1$. This point is the best of simplex 2. So to continue in this direction, an expansion coefficient was calculated using the rules of the super modified

Table 4
Relation between the Chromatographic Response Function (CRF) and the experiment number during simplex optimization (*w* corresponds to the worst point of the simplex and *b* to the best point of the simplex).

Experiment number	MeOH (%)	t_i (min)	Gradient (% min^{-1})[a]	Temperature (°C)	Time of gradient (min)	$\sum_i R_i$	t_L (min)	CRF	Number simplex

[a] MeOH ending 30%.

simplex (SMS) that consists in resolving the following polynomial equation to obtain the optimum value:

$$Y = A\alpha^2 + B\alpha + C \quad (4)$$

with the points: *W* represented by the point 0, where $\alpha = 0$ and $Y = 18.34$; *G* centroid of the simplex 1, where $\alpha = 1$ and $Y = 22.00$; *R* represented by the point 5, where $\alpha = 2$ and $Y = 25.42$.

The value of the expansion coefficient was calculated and its value is 15.75. This expansion value is too high and so it was decided to progress with the normal rule of simplex with $\alpha = 1$.

Fig. 2 shows the evolutions of CRF, sum of resolutions and t_L in function of the experiment number. In the case of CRF, the optimum CRF value was reached for experiment 5 after only six experiments. However, it was decided to continue the evolution with a view to decreasing the value of t_L. For experiment 9, the sum of resolutions decreases under 16, this is due to a resolution inferior to 2 between firstly the caffeic and syringic acids, and secondly the ferulic and synapic acids. Therefore, the conditions of experiment 8 were retained as the optimum conditions for the analysis of the nine polyphenols as they gave a maximum retention time of 41 min. Fig. 3 shows a chromatogram obtained under these conditions and points out the good separation of the polyphenols.

Moreover, the results in Table 4 permit to analyse experiments for which only one or two parameters were modified. For example, a comparison can be made between experiments 0 and 1 where only the MeOH percentage changed. Experiment 0 had a weaker eluent strength, which increased the retention times and induced a peak widening showing a resolution inferior to experiment 1. In the same way, the influence of the gradient strength can be observed by the comparison of experiments 2 and 3. Experiment 3 reveals a normal increase in CRF due to a stronger gradient (faster starting time and stronger slope).

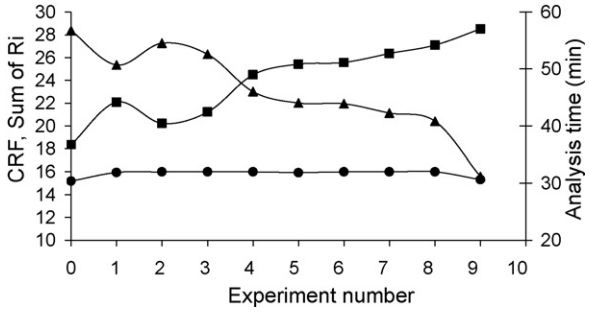

Fig. 2. Evolution of the Chromatographic Response Function (CRF) (■), retention time for the last peak (▲) and total resolution (●) as a function of the experiment number during simplex optimization.

For experiments 3 and 4, if CRF was only based on eluent strength, its value should be higher with experiment 3 (higher content in MeOH) than in experiment 4. In fact, the contrary was observed because it is assumed that the influence of temperature is greater than that of the eluent strength.

3.4. Calibration

With the view to quantify the content of phenolic compounds, the calibration graphs were expressed as chromatographic peak areas of standards corresponding to concentrations ranging from 5 to 30 mg L^{-1}. The linearity of the HPLC method was therefore checked by injecting five mixtures of standard solutions containing 5, 10, 15, 20, 30 mg L^{-1} of each polyphenol and each mixture was analysed five times. The linear range, coefficient of determination (R^2) and the limit of detection (LOD) for each compound

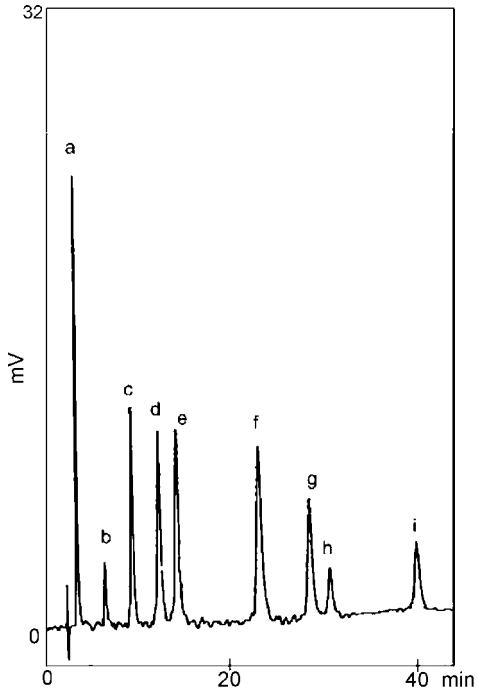

Fig. 3. Chromatogram obtained in optimal conditions: detection at 280 nm, flow rate 1 mL min^{-1}, three stages of linear gradient: started 18% of A during 19.63 min, from 19.63 to 30% in 14.9 min, and finally isocratic mode with 30% of A until the last compound was eluted (total running time of 41 min). Peaks: (a) gallic acid, (b) catechin, (c) 4-hydroxybenzoic acid, (d) caffeic acid, (e) syringic acid, (f) p-coumaric acid, (g) ferulic acid, (h) synapic acid and (i) anisic acid.

Table 5
Calibration range, correlation coefficients of the regression line, limit of detection for the polyphenols studied.

Polyphenol	Linear range (mg L^{-1})	R^2	LOD (3 S/N) (mg L^{-1})	R.S.D. (area, $n=5$)
Gallic acid	5–30	0.9998	0.1	3.00
Catechin	5–30	0.9995	1.4	2.94
4-Hydroxybenzoic acid	5–30	0.9999	0.5	2.00
Caffeic acid	5–30	0.9998	0.6	2.80
Syringic acid	5–30	0.9999	0.6	3.07
p-Coumaric acid	5–30	0.9996	0.3	2.68
Ferulic acid	5–30	0.9993	0.5	2.49
Synapic acid	5–30	0.9997	0.6	3.58
Anisic acid	5–30	0.9997	0.6	2.75

are listed in Table 5. All the R^2 were superior to 0.999. The LOD was defined as the concentration at which the signal to noise ratio (S/N) was equal or superior to three. Table 5 shows that each LOD was inferior to the minimum value of the standard concentration.

3.5. Application to natural samples

To quantify the phenolic carboxylic acids, a liquid–liquid extraction was applied and developed on a standard mixture solution of 150 ppm. To obtain the optimal recovery at pH 4, several solvents were chosen: ethyl acetate, diethyl ether, trichloromethane. With ethyl acetate, the totality of polyphenols was recovered and verified by the analysis of aqueous phase, which contains no polyphenols. Trichloromethane, a less polar solvent, induced a degradation of ferulic and synapic acids and a rate of recovery inferior to 6% for gallic, 4-hydroxybenzoic, caffeic acids and catechin. This result is consistent with the retention times of the last three polyphenols that reveal themselves as the most polar polyphenols. With diethyl ether, the rate of recovery is around 80% for gallic acid and catechin and 100% for the others. Therefore, it could be worth using trichloromethane in order to separate these polyphenols. A study at pH 10 (adjusted by NaOH) was carried out but degradation of catechin, gallic and cafeic acids were observed. Therefore, the conditions retained for the extraction are ethyl acetate at pH 4.

Fig. 4 represents the chromatogram obtained for WWOO at 280 and 320 nm. The flow rate was slightly decreased to 0.92 instead of 1 in order to compensate for the matrix effect. From the chromatogram at 280 nm, several compounds were expected to be found such as 4-hydroxybenzoic acid (tr = 11.9 min) and cinnamic acids like caffeic acid (tr = 17.1 min) or p-coumaric acid (tr = 31.0 min) and ferulic acid (tr = 36.2 min). At 320 nm, the wavelength is specific to cinnamic acids and gallic acid absorbs less. Therefore, from the comparison of the results for the two wavelengths, only caffeic, coumaric and ferulic acids were retained. Their quantifications are respectively 6 ± 2, 10 ± 2 ppm, and less than 5 ppm. These results show no p-hydroxybenzoic, syringic, gallic, sinapic acids in contradiction with the results of Zafra et al. [13]. But the concentration value depends on the process and transport conditions especially for these compounds that undergo degradation. These weak concentrations in real samples do not enable a recovery process of polyphenols with a view to valorising these compounds.

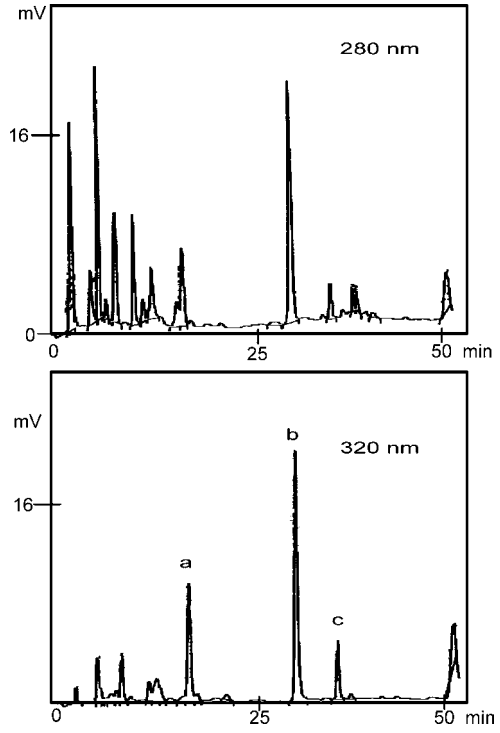

Fig. 4. Chromatogram of wastewater olive oil sample at 280 nm and at 320 nm: (a) caffeic acid, (b) p-coumaric acid, (c) ferulic acid.

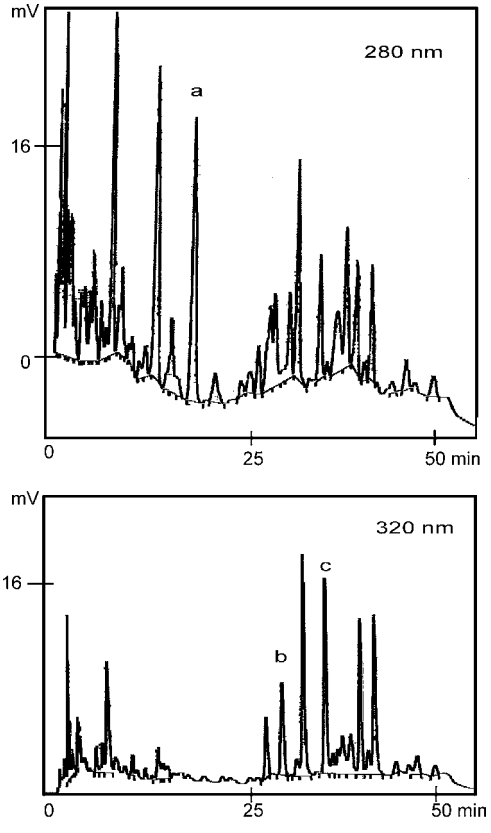

Fig. 5. Chromatogram of sugar beet vinasse at 280 nm (i) and at 320 nm (ii). (a) Syringic acid, (b) p-coumaric acid, (c) ferulic acid.

This method was also applied on sugar beet vinasse which is the last residue in the production of bioethanol. Fig. 5 represents the chromatogram at the two wavelengths obtained by adding 6 mL of MeOH into the organic residue. The latter, when compared with WWOO chromatogram, shows that more compounds are present in the organic phase. At 280 nm, the chromatogram eventually shows the presence of p-hydroxybenzoic, syringic, coumaric, ferulic and synapic acids. Only syringic acid (tr = 19.5 min) was well separated and its concentration was 56 ± 8 ppm. The chromatogram at 320 nm was used to determine 4 ± 2 ppm of coumaric acid and 12 ± 3 ppm of ferulic acid. Synapic acid was rejected because, at 320 nm, its area was inferior to the one obtained at 280 nm. p-Hydroxybenzoic was not quantified because of the bad resolution at 280 nm.

Ferulic acid could be under ferulates form as ferulate dehydrodimers [20]. Therefore a saponification was carried out with the aim to increase the quantity of free ferulic acid. This reaction lasted 5 h under the conditions described previously. It yielded a ferulic acid concentration of 71 ± 9 ppm. The result takes into account the degradation of ferulic acid during the reaction. The ratio of degradation was determined by applying the same process of saponification on a solution of ferulic acid (150 ppm).

4. Conclusion

The optimization of separation conditions was achieved using the simplex method on a mixture of nine common polyphenols. The maximum retention time targeted (45 min) was reached in only six experiments. The number of experiments obviously depends on the choice of: (i) the center of domain, (ii) the step size of factors variation and the objective.

Moreover, the method was applied on two natural samples: WWOO and vinasse in order to quantify the polyphenols selected. For WWOO, only caffeic, coumaric and ferulic were detected. For the vinasse, a saponification was carried out so as to increase the concentration of free ferulic acid. The result of saponification shows that the concentration of ferulic acid effectively increases from 12 ± 8 to 71 ± 8 ppm. The syringic acid concentration was 56 ± 8 ppm. In both cases, the quantities do not enable a recovery process to be developed with a view to valorising these compounds.

The results obtained with this method can be used to envisage the study of co-adsorption on adsorbent materials or on resin of these common polar phenolic compounds.

ABSTRACT

Micro-total analysis systems (μTAS) integrate different analytical operations like sample preparation, separation and detection into a single microfabricated device. With the outstanding advantages of low cost, satisfactory analytical efficiency and flexibility in design, highly integrated and miniaturized devices from the concept of μTAS have gained widespread applications, especially in biochemical assays. Electrochemistry is shown to be quite compatible with microanalytical systems for biochemical assays, because of its attractive merits such as simplicity, rapidity, high sensitivity, reduced power consumption, and sample/reagent economy. This review presents recent developments in the integration of electrochemistry in microdevices for biochemical assays. Ingenious microelectrode design and fabrication methods, and versatility of electrochemical techniques are involved. Practical applications of such integrated microsystem in biochemical assays are focused on in situ analysis, point-of-care testing and portable devices. Electrochemical techniques are apparently suited to microsystems, since easy microfabrication of electrochemical elements and a high degree of integration with multi-analytical functions can be achieved at low cost. Such integrated microsystems will play an increasingly important role for analysis of small volume biochemical samples. Work is in progress toward new microdevice design and applications.

1. Introduction

Since the proposal of the concept of micro-total analysis systems (μTAS) in 1989 [1], a great deal of research has been devoted to the miniaturization of biochemical analysis systems, and many types of microdevices with integration of multi-analytical functions have been developed [2]. Due to the unique advantages of microsize, low cost, ease of fabrication, flexibility in design and fast detection, miniaturized devices from this concept have continued to be a highly hot topic and gain maturity in the latest several years. These miniaturized devices have been applied in a variety of areas including immunoassays, biosensors, clinical diagnostics, environmental monitoring, biochemistry, proteomics and cell biology [3,4]. Used in biochemical assays, microdevices have been reported frequently to control the transportation, immobilization, and manipulation of biological molecules and cells, and to separate, mix, and dilute chemical reagents [5–8]. However, developing more rapid, reliable,

cheap, specific and sensitive methods for biochemical assays, is still the focus of a great deal of research, especially for applications outside the laboratory environment.

Integration of electrochemistry in μTAS is a convenient way to realize multi-analytical functions in a single miniaturized device. Electrochemical techniques have merits of simplicity, rapidity, high sensitivity and specificity, reduced power requirements, ease of microfabrication and good compatibility with biological samples [9–12]. These characteristics make electrochemistry uniquely suitable for integration in miniaturized devices. When coupled with electrochemical techniques, microanalytical devices generally employ conducting elements as electrodes in electrochemical detection [13–15], as electrodes to manipulate liquids or biological materials in electrophoresis microchips [16,17], or as base layers for electrochemical sensing and hybridization sites [18,19]. As a result, it renders microelectrodes a key component to realize the versatility of electrochemical techniques in microanalytical devices. A variety of methods including sputtering [20], evaporation [21], lift-off lithography [22,23], and thick-film techniques [24,25], have been exploited to microfabricate different conducting elements, such as planar (2D) and three-dimensional (3D) microelectrodes, which have been widely used to investigate chemical and biological processes [26,27].

This review presents the recent development of integration of electrochemical elements in μTAS for biochemical assays. After this short introduction, ingenious microelectrode design and the fabrication methods are explored in the following part. Then, the versatility of electrochemical techniques for identifying of biochemical processes is also elaborated. Finally, the potential applications such as in situ analysis, point-of-care testing and portable analyzers for complex sample matrices, are introduced. Notably, in order to overcome drawbacks of conventional analytical procedures, which commonly involve the collection of a sample at one location and then a delay while the sample is sent to the lab and processed, we expect that this review can provide significant hints for researchers to develop new microdevices with integration of electrochemistry, which are able to be used for efficient real sample analysis. Moreover, diverse design and fabrication methods of microelectrodes are now available to conduct electrochemistry conveniently in microsystems, which paves the way well to realize practical applications in complex biosamples.

2. Design and fabrication of microelectrodes

As well known, micro-electro-mechanical system (MEMS) plays a very much important role in fabricating various miniaturized analytical devices in modern analytical chemistry. For the high sensitivity derived from the precisely controlled pattern, MEMS-processed microelectrodes have been employed in electrochemical biosensors, electronic tongues or electronic noses, and detectors of capillary electrophoresis [28–32]. Attention should be firstly paid to the diverse electrode configurations and the involved microfabrication technologies, since microelectrodes serve as an indispensable component on many microanalytical devices integrated with electrochemical elements. Thin-film and thick-film electrode fabrication technologies will be introduced as follows.

2.1. Thin-film microelectrode fabrication technologies

As thin-film microelectronic fabrication technologies, sputtering and evaporation are both commonly used. A thin (typical thickness between 50 and 250 nm) metal film is deposited in vacuum onto the substrate in such cases. In order to deposit metals at designate positions, a shadow mask is always needed which projects a geometrical pattern onto the substrate. This method has a resolution of the order of a few tens of micrometres. As for more precise electrodes, lithography and lift-off process can be employed, which involves photoresist and a further development step [18,22,33,34].

Gold and platinum are often used for thin film metallization. Microelectrodes made in this fashion can be integrated conveniently both in channel and at the end channel of microfluidic chips, and various electrode configurations can be realized with minimized analyte dilution and improved sensitivity for in situ or real-time analysis of biosamples, compared with conventional end-channel detection electrodes made of solid metal wires (Pt, Au and Cu). Kurita et al. [35] developed a microfluidic device encompassing a gold film working electrode modified with lactate oxidase and ospoly(vinylpyridine) mediator containing horseradish peroxide in the microchannel, and achieved quantitative and reproducible measurements of the lactate concentration in blood samples. Compact gold microelectrode array systems, displaying high throughput, enhanced sensing performance, significantly simplified operation procedures, and reduced fabrication costs, have also been reported for in situ monitoring of dopamine release from chip-grown MN9D cells and PC12 Cells [36–38]. Akiyama et al. [39] successfully integrated Pt/Ti thin film electrodes into a Pyrex glass microchip through a newly developed vacuum hot press system, which exhibited improved chip production rate. Castano-Alvarez et al. [40] described a combination of an in-channel thin-film detector and an end-channel detector employing films and metal wires (a 300 μm diameter platinum wire or 250 μm diameter gold wire) performing amperometry on CE-microchips.

Alternatively, different from those foregoing microelectrode designs, simpler microelectrode configurations with very good stability and low mass limits of detection, have been developed by Henry and Garcia's groups [41–47]. In their work, solid metal microwires (Pt, Au and Cu) with a diameter of 25 μm were integrated on microchips as working electrodes, and aligned in the patterned electrode channel perpendicular to the separation channel. Such design allowed isolation of the detector from the separation current through the end column configuration with an electrode channel, and provided excellent chip-to-chip reproducibility of the working electrode location. In addition, an increase in electrode area in contact with solution (relative to planar electrodes) was also achieved as a result of the cylindrical shape of the electrode without an increase in electrode width. Besides single microwire electrode detectors, a microchip CE device fabricated with eight individually addressable, series gold microwire working electrodes, has also been reported recently, showing improved detection selectivity and resolution for analyses of small biological molecules, and its applicability was demonstrated by analyzing a human urine sample [48].

Thin-film fabrication methodologies are capable of constructing variable microelectrode patterns on miniaturized devices, notably. Among the diverse designs is called interdigitated array electrode (IDA). The IDA consists of quite a few electrode pairs, and in each electrode pair the "fingers" of the two microelectrodes are interdigitated in close proximity to provide enhanced sensitivity by redox-cycling. Fig. 1 shows the layout and microscopic photo of the IDA microelectrodes developed by our group [49]. The IDA microelectrodes were fabricated by spluttering thin film of Au/Ti via standard photolithography and lift-off processes. With IDA as electrochemical detectors, screening of the three liver fibrosis markers in human serum could be achieved at ng mL^{-1} concentration level. Other IDA designs for biosensors or for detection of bacteria have also been reported [29,50,51]. A point that should be mentioned is the adhesion of the metal film on the substrate. It can be strengthened either by an adhesion promoter, typically a second metal, or by a pretreatment of the substrate, e.g. by oxidization in O_2 ambient.

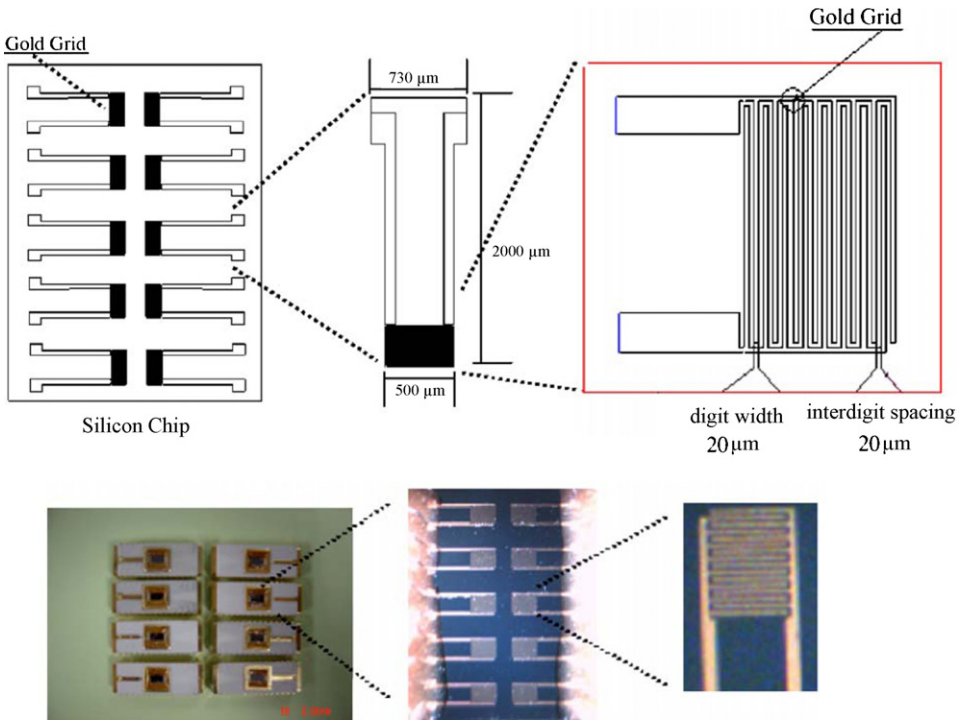

Fig. 1. Layout and photo of microelectrodes array on the silicon chips. The parameters of IDA microelectrodes array were as follows: digit width 20 μm; interdigit spacing 20 μm; number of digits 8 × 2; electrode area 3.2×10^{-3} cm^2 [49].

Apart using a lithography technique, some improved thin-film microelectrode fabrication methods are also available, such as plasma chemical vapor deposition (PCVD) and micromolding. Kadowaki et al. [52] reported that PCVD technique could deposit uniform platinum film inside a microchannel by using the precursor $Pt(C_5H_7O_2)_2$ and controlling the voltage and frequency. Thin-film gold and copper microelectrodes could also be constructed by electroless deposition and micromolding in capillary technique [53]. Such fabrication method was compatible with ordinary chemistry laboratories, and the integrated system created by this method was found to be robust for electrochemical detection of glucose, dopamine, and catechol, and was also suitable for other various applications.

2.2. Thick-film microelectrode fabrication methods

Compared with the somewhat complex fabrication technologies for thin-film microelectrodes, the fabrication methods for thick-film microelectrodes are shown to be simpler, as they obviate the need of clean room facilities and costly apparatus for vacuum deposition [54–59]. And the methods generally have a worse resolution, relative to the shadow-mask process for thin-film microelectrodes, and normally create electrodes with the thickness of some tens of micrometres. Common thick-film microelectrodes employing carbon and metal materials, can be found in the form of screen-printed electrodes (SPEs), electrodes created by airbrushing and micromolding and so on, nanoelectrode ensemble (NEE), and 3-D nano-/microelectrodes. Characteristics of these microelectrodes will be specified as below.

The development of analytical methods that respond to the growing need of performing rapid in situ analysis, shows low-cost and disposable SPEs an alternative to the conventional electrodes. Fabrication of SPEs simply uses a mesh with a geometrical pattern for the three integrated electrodes. Conducting ink made of carbon or Ag/AgCl is initially printed at designate places on a polymer support. Then, the insulating ink is printed to cover the non-working and non-conducting region of the SPEs, and give a definite shape to the working electrode. Batch production of the SPEs can be easily realized, and different configurations of the SPEs have been developed for biochemical testing [60–63].

Microelectrodes fabricated by airbrushing, another effective technique for thick-film design, have been reported lately by Walker et al. [64]. Airbrushing, a technique primarily used for commercial arts, enabled conductive inks to be patterned onto a microfluidic device through a film. The benefits of fabricating electrodes by airbrushing included a simpler process, lower cost, and less skill requirements. This technique was especially useful in circumstances where a commercial screen-printing machine was inaccessible. Additionally, outstanding work from Martin's group successfully incorporated thick-film carbon ink microelectrodes on microchips through a micromolding technique for various biological investigations [65–73]. Other thick-film designs can also be found employing carbon materials in forms of paste [74,75], glassy [76], fiber [77–80], pyrolyzed photoresist film [81], nanotubes and diamond [82].

The ordered NEE with regular pore sizes and spacing, has attracted enormous interest lately due to its excellent electrochemical characteristics, including ultra-fast electron-transfer reactions, high signal-to-noise ratios, and enhanced sensitivity. Various preparation methods for NEE microelectrodes have been proposed [83–85]. The most commonly used method involves a template synthesis process, in which metal ions, such as gold, platinum, copper and nickel, are electrochemically reduced and grown within the cylindrical and monodispersed pores of a nanoporous membrane. Among these metals, gold is mostly selected, and is used to fabricate gold nanoelectrode ensemble (GNEE) for electrochemical applications. Integrating thin GNEE films with a chip-based capillary electrophoresis system was shown feasible for in-column urea/urease reaction and electrochemical detection [86]. The direct hot-press bonding of the PC-based GNEE film onto a planar electrode provided a good electrical contact for the electrochemical detection, and the embedded GNEE electrode exhibited good detec-

tion linearity and reproducibility when detecting NH_4^+. This study proposed a new detection scheme for biosample analysis.

One more amazing design of the thick-film methods is the 3D nano-/microelectrode arrays developed by template synthesis [6,26,87]. These 3D electrodes exhibit enhanced sensitivity, faster response and lower detection limits compared with planar microelectrodes aforementioned, which render them suitable for integration with microdevices for the analysis of complex biosamples. Yun et al. [31] reported the electrochemical impedance measurement of prostate cancer cells using carbon nanotube array electrodes in a microfluidic channel. ESEM images of aligned MWCNT patterned arrays were shown in Fig. 2. The nanoarrays up to 8 mm tall were synthesized in the shape of towers, and were finally embedded into a PDMS channel as electrodes after electrodeposition of Au particles. Simple fabrication processes, including water-assisted chemical vapor deposition (CVD), a printed circuit board technique and electrodeposition, were helpful to future mass production of other cell-based biosensors. To study complex network morphologies and tissue slices containing substantial 3D neuronal structures, Rajaraman et al. [88] reported two novel non-lithographic approaches to fabricate 3D MEAs with embedded microfluidic ports for nutrient perfusion, the one concerning double-side exposure technology to create high aspect ratio structures in SU-8 was shown in Fig. 3. The ingenious fabrication method produced hollow towers, by which a coupled 3D electrical and microfluidic functionality was achieved. The 3D MEAs demonstrated the ability to pick up action potentials from a neuronal culture, and could potentially provide more information about the actual nature of the 3D networks inside the human body.

In this part, we introduced thin-film and thick-film microelectrode fabrication technologies, along with some excellent examples with unique electrode configurations. It can be envisioned that more and more electrode designs will emerge on microanalytical devices, and provide more detailed information for complex biosamples through versatile electrochemical techniques.

3. Versatility of electrochemical techniques in microsystems

Diverse microelectrode design and fabrication methods are the premise to perform the multi-functions of electrochemical techniques in microanalytical devices. The predominance of performing electrochemistry on a small scale includes high sensitivity, simple sample treatment, low-power requirement, inexpensive instrument, easy operation procedure and so forth. Electrochemistry offers significant promise for designing self-contained and totally disposable microdevices to analyze biochemical samples such as amino acids, peptides, DNA, cells and microorganisms. According to different study objectives in combining electrochemical principles in microsystems, the electrochemical detection methodology, electrical manipulation of fluids and biomaterials, and electrochemical sensing for biochemical assays were discussed in detail as below.

3.1. Electrochemical detection methodology

Electrochemical detection (ECD) methods have attracted considerable interest recently due to their compatibility in μTAS, as integration becomes one of the characteristics in modern analytical chemistry [89–93]. Laser-induced fluorescence (LIF), the most widely used detection technique in CE-microchips, is only applicable for fluorescent samples, and generally involves the use of large-scale and expensive optical systems. It always suffers a loss of sensitivity from miniaturization. In contrast, the label-free ECD method, with merits of improved sensitivity and tunable selectivity, is obviously fit for miniaturization in the microchip format.

Electrochemical techniques can be broadly divided into three categories including voltammetry, conductivity, and potentiometry [94,95]. As the most widely used detection method, voltammetry, especially the simplest technique amperometry, exhibits a remarkable performance improvement when electrode sizes are reduced into a low micrometer range. Microscale voltammetric analysis integrating voltammetric procedures with on-chip chemical reactions has been frequently reported [96–99]. When operating chemical reactions on a microscale, the surface area to volume ratio can be much higher, making mass transfer more efficient and chemical interactions much faster as the diffusion distances are shorter. For adaptation of voltammetric techniques to microfluidic chip, it should be taken into consideration that the effect of relevant experimental parameters, particularly the high voltage used for driving the electroosmotic flow, upon the background current, potential window, and size or potential of the voltammetric signal [100–104].

Conductivity detection is a universal tool monitoring conductance differences between two electrodes, and has been increasingly employed for small volume detection of charged biomolecules with tunable sensitivity [105]. Conductivity detection can be realized either by a direct contact of the electrolyte and the electrodes [106], or by a contactless fashion relying on capacitive coupling of an ac electrical field to a solution with external electrodes [107,108]. The contactless detection mode offers several distinct advantages, such as the elimination of surface fouling or bubble formation, a simplified construction and alignment of the detector, and effective isolation from high separation voltages [109,110].

Potentiometry is an ECD technique based upon the potential that arises upon a membrane between two solutions with different ionic activities. Integrated potentiometric detectors in microsystems, are generally exploited for investigation of ions [111–113]. On a microfluidic chip platform, potentiometry is applied much less compared with voltammetry and conductivity. Most probably, since microfluidic chips usually contain an inherent separation step, it is needless to discriminate one analyte from other components of the sample by ion selective electrodes [114]. Work is in progress combining potentiometry with microdevices.

There have been a lot of contributions to the advances in coupling electrochemical detection with microchips using different approaches and electrode materials, from the groups of Lunte [61,94], Henry [115–119], Martin [72,73], and Garcia [120–124]. Besides the unique designs of incorporating solid metal microwires and micromolded thick-film carbon ink microelectrodes on microchips as working electrodes, one more extraordinary design was dual-electrode amperometric detection, which is frequently employed for the selective monitoring of complex biological samples [70,74,78,81,125]. In this detection mode, the dual electrodes were serially configured, electroactive species that underwent reversible redox reactions would be detected at both electrodes, whereas electroactive species that did not have reversible redox couples could only be detected at one of the two electrodes. Additionally, the relative response at the two electrodes, along with migration time, could also be used to verify peak identity. Therefore, greater enhancement of selectivity and sensitivity could be achieved for the analysis of complex samples.

Finally, in order to make up for the shortage of single electrochemical detection method, increase throughput and provide more detailed information about the analytes, some multiple detection strategies have been combined on microchips [126,127]. Quite a few reports proposed dual detection schemes for microchips. Lapos et al. [128] presented two orthogonal detection schemes (amperometric and fluorescence detection) in a microfabricated electrophoresis chip, which allowed analysis of a wider spectrum of compounds per separation, led to higher throughput and provided a better understanding of detector alignment. Dual

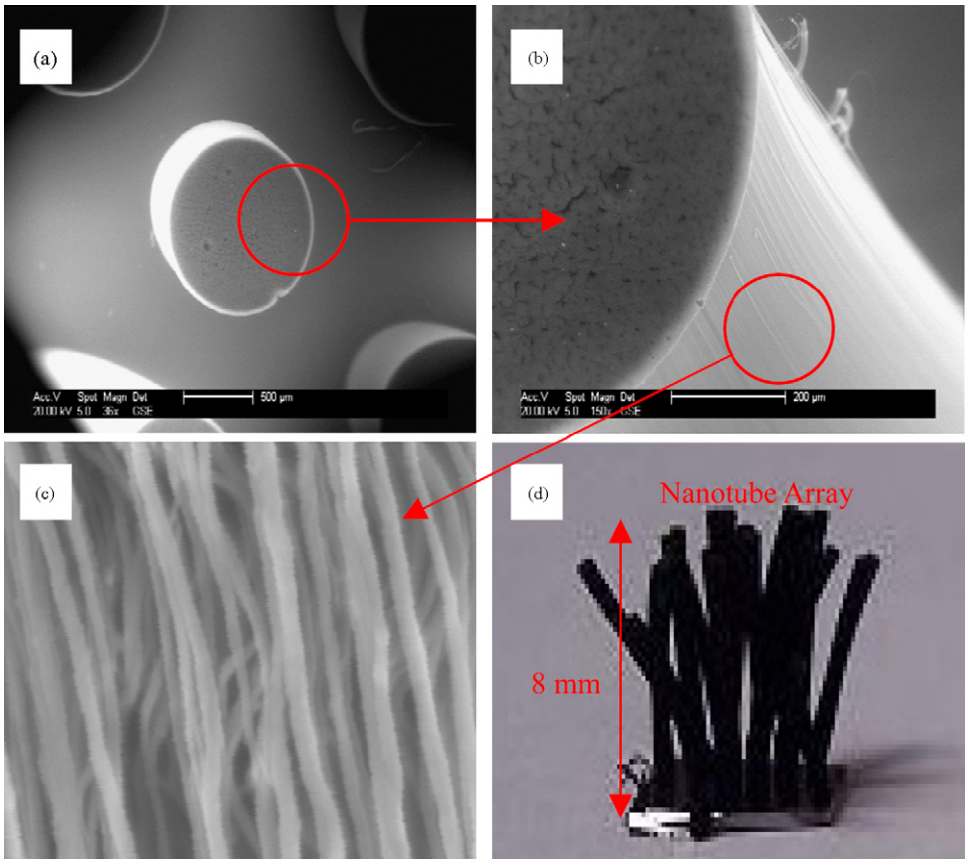

Fig. 2. ESEM images of aligned multi-wall carbon nanotube patterned arrays: (a) one bundle of nanotubes called a tower; (b) top view of a nanotube tower; (c) high resolution side view of a nanotube tower; (d) picture of an 8 mm tall MWCNT patterned array on the Si wafer [31].

fluorescence/contactless conductivity detection and simultaneous electrochemical and electrochemiluminescence detection for microchip have also been reported [129,130].

In brief summary, ECD methodology provides an arsenal of techniques, which are compatible with microfabrication, and tunable for various analytical requirements. Besides, electrochemical principles also exhibit characteristics of simplicity, rapidity, high sensitivity and specificity and so forth. These satisfactory features get ECD methods widely incorporated in μTAS.

3.2. Electrical manipulation of fluids and biomaterials

Besides electrochemical analyses, microelectrodes integrated in the miniaturized devices especially microfluidic chips, have been widely employed to conduct electrical manipulation of fluids and biochemical analytes such as DNA, proteins, cells, microorganisms, nanoparticles, and possibly single molecules in aqueous solutions [131–134]. Microelectrodes have blossomed into one of the most strongly desired elements on microdevices, and a variety of processes, including electroosmosis, dielectrophoresis (DEP) and electroporation, etc., become possible with them in a microchannel. Some significant examples for the manipulation via microelectrodes are discussed as follows.

Fluid control involving mass transport and direction through microchannels, is of crucial importance for the development of multifunctional microchips. Electroosmotic pump (EOP) based on electroosmotic flow (EOF) is the most widely used approach to drive fluids in microfluidic chips because of the simplicity of the design and fabrication methods. Using EOPs, precise flow control can be achieved by a simple current or voltage-control circuit with integrated driving microelectrodes [17,135]. To acquire a high pressure and produce enough flow in the microchannel, there have appeared quite a few designs of EOF pumps with different configurations of driving electrodes [136,137]. Borowsky et al. [138,139] presented the first demonstration of a packed bed microchannel for enhanced microchip EOF pumping, and attained the highest pressure (25 atm) on a microchip platform then. To apply the high voltage, positive and ground electrodes were directly placed in the reservoirs located upstream of the packed bed and at a sidearm channel that branched from the weir, respectively. A new high-pressure EOF pump was presented by Wang et al., utilizing silica monoliths directly bonding with the capillary wall with high charge density and high porosity [140]. While Nie et al. [141] developed a PMMA chip containing a total of nine parallel EOF pump systems, allowing the use of single, double or triple monolithic columns to produce increased flow as required. Additionally, on-chip electrochemical pumping system has also been developed for microfluidic transport, integrated with electrolysis microelectrodes, which were created by evaporation and deposition of either platinum or gold [142–144]. Those foregoing examples concerning the usage of integrated driving electrodes with appropriate designs for fluid flow control, could provide sufficient pressure and flow for determining various analytes, and could be easily combined in μTAS as a promising and indispensable fluid-driving unit.

DEP has been demonstrated to be quite effective and selective in concentrating, manipulating, and separating cells and bacteria with different sizes simultaneously [145]. All DEP microdevices involve integrating microelectrodes (Ti/Au or Cr/Au) to provide an ac electric field for DEP force generation. Cell positioning by DEP is probably the most broadly applied method among all chip-based cell separation technologies. As demonstrated in Fig. 4, Pan et al. [146] present a novel automatic positioning and sensing

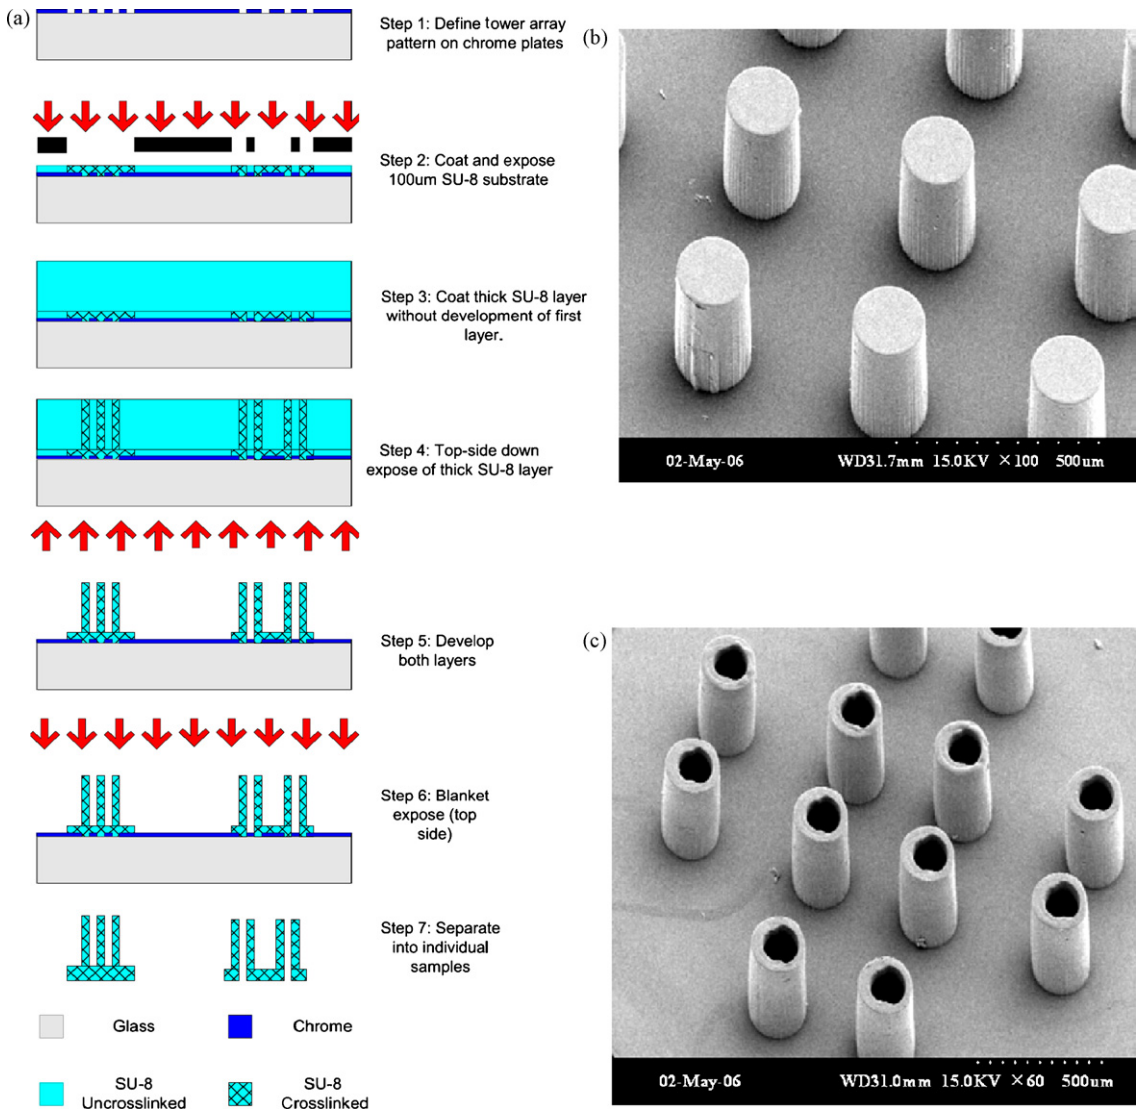

Fig. 3. Fabrication process flow for solid (a, left side) and hollow (a, right side) tower arrays, and SEM images of them (b and c) [88].

microelectrode array (APSMEA). Desired number of neurons was simultaneously positioned onto the microelectrodes automatically and scathelessly, and thus the measurement of the electrophysiological activities of neuronal populations was facilitated after functional synaptic connections formed between neurons. Alternatively, a new flow sandwich-type immunosensing method based on negative DEP was developed in microfluidic devices with 3D microelectrodes fabricated on two substrates [147]. Microparticles trapped in the caged area were used as solid supports for immunoassay. A microdevice with interdigitated electrodes was employed for dielectrophoretic separation and manipulation of viable and heat-treated cells of Listeria by using differences in dielectric properties of the cells [148]. A fixed microelectrode device was designed by Zou et al. [149] for manipulation, position and stimulation of osteoblasts using MEMS technology, on which the viability of osteoblasts under DEP was investigated. Although DEP often suffers from low survival rate of biological cells in electrical field and complicated instrumentation, with the development of microfabrication method and appearance of newly available electrode geometries, DEP manipulation in microfluidics for cell-based assay will have more applications in μTAS [150,151].

One more notable instance that has to be addressed is the usage of microelectrodes in the case of electroporation, an efficient technique for selective biochemical manipulation of contents of cells. Electroporation introduces foreign materials into cells by applying electric field impulses to create multiple transient pores in the cell membrane through a dielectric breakdown of the cell membrane. Since Lundqvist et al. first proposed single cell electroporation using carbon fiber microelectrodes in 1998 [152], significant enhancement of the electroporation system has been made by integrating diverse types of electrodes on microdevices. Huang and Rubinsky developed an electroporation microchip capable of performing controlled electroporation in single ND-1 cells [153], and they further improved the chip by employing microfluidic channels in a flow-through manner to precisely handle ND-1 cells, and achieved high effectiveness in genetic manipulation of the cells [154]. Khine et al. presented an effective polymeric electroporation chip that could selectively immobilize and locally electroporate single HeLa cells using low applied voltage [155]. The electrodes could be placed at a distance from the cell, eliminating the need to incorporate electrodes on chip and the potential of adverse products from electrode reactions. Moreover, Ag/AgCl electrodes and a patch clamp amplifier were used for accurate current traces of the electroporation process. Additionally, Ishibashi et al. [156] employed a porous membrane-based culture substrate for localized in situ electroporation of adherent Hela cells using planar electrodes. Excellent work

from Lin's group has also been reported using interdigitated Au microelectrodes on the electroporation microchips for manipulation of DNA plasmids and NIH-3 T3 cell lines [157–159]. Further miniaturization of the technique would be feasible, by using nanotip electrodes that could be inserted into a cell for exclusive electroporation of organellar structures with minimal impairment of cellular physiology.

Some other unique examples, involving the usage of microelectrodes to apply electric fields for manipulation of biomaterials within the microsystem, have also been reported. Hediger et al. [160,161] realized a compact microsystem with compact integration of measurement electrodes, micro-fluidic channels and feed-throughs for epithelial cell culture and characterization. Control of the epithelial cell layer growth and transepithelial resistance and voltage measurements of the cell monolayer were demonstrated. Mu et al. [162] described a smart microfluidic chip capable of electrically controlled adsorption/release of avidin and streptavidin with a three-electrode system. The gold working electrode was fabricated via a sputtering process, and was subsequently modified with loosely packed SAMs of thiols with terminal carboxylic or amino groups. Upon application of an external electric potential to the gold substrate, conformation of the anchored mercapto chains transformed reversibly between "bent" and "straight" states, and led to a hydrophobic or hydrophilic channel surface capable of interacting with differently charged proteins. The microchips prepared in this way also exhibited the potential of separating low-concentration avidin from the avidin/streptavidin mixture, and provided a novel alternative for preconcentrating low-abundance protein in the research of proteomics.

As seen in this section, the integrated microelectrodes on microdevices act as an important and efficient role in manipulation of biosamples, more electrode designs and new application will be explored continuously in future.

3.3. Electrochemical sensing for biochemical assays

A great variety of electrochemical biosensors fabricated on microdevices have been well documented and reviewed [19,163–165]. Electrochemical biosensing investigates a specific biological event (e.g. antibody–antigen binding) using a combination of biological receptor substances (antibody, enzyme, DNA, nucleic acid, etc.) and electrochemical methods of signal transduction. Biosensors based on amperometric, potentiometric, impedimetric and capacitive transducers can be easily found [166–168], among which amperometric biosensors are mostly employed.

With integration of easily available microelectrodes, Farrell et al. [169] performed bead-based sandwich immunoassays for mouse IgG with femtomolar detection limits. Enzymes are the most prominent labels in electrochemical immunosensor development. Microchip platforms have proven themselves as highly desirable vehicles for conducting various electrochemical immunoassay protocols. Electrochemical enzyme immunoassays, combining antigen–antibody reactions with amperometric detection of the product of the enzymatic reaction, have evolved dramatically [170]. A sensitive enzyme-linked immunosorbent assay system was constructed by encapsulating anti-IgG within the network of Al_2O_3 sol–gel in the microfluidic channels, and this design led to higher sensitivity with the detection limit of 1 pg mL^{-1} by end-column electrochemical detection [171].

A potentiometric biosensor generally consists of a permselective outer layer and a bioactive material, usually an enzyme. The enzyme-catalysed reaction generates or consumes a species, which is detected by an ion selective electrode. A new type of pH biosensor containing two platinum microelectrodes was developed for biological applications, and the microelectrode coated with an electrosynthesized polymer acted as the pH sensitive electrode

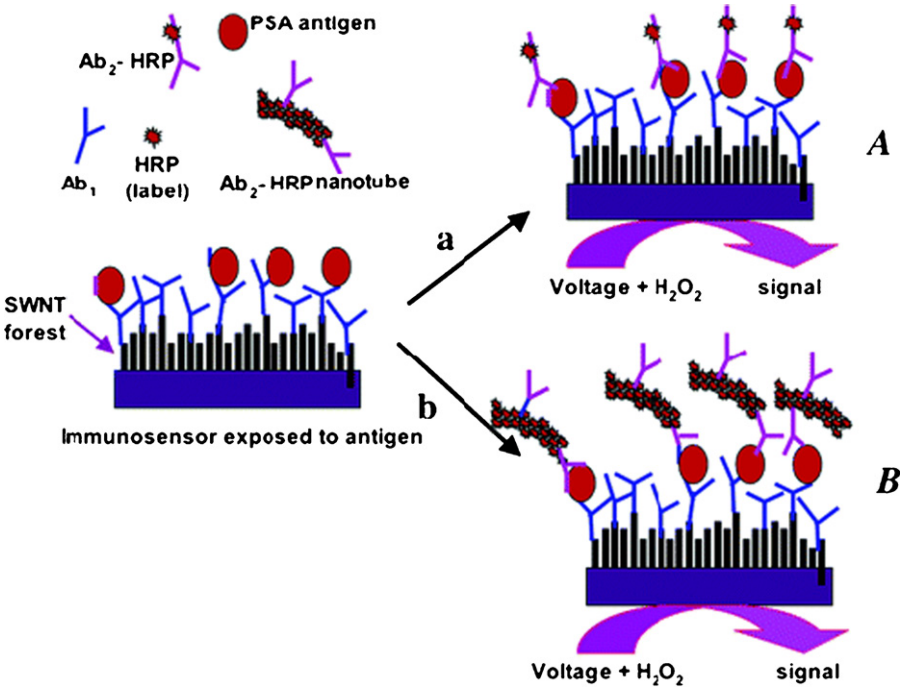

Fig. 5. A scheme for illustration of detection principles of the SWNT immunosensors [180].

[172]. Functional cellular assays were conducted on multiparametric silicon sensor chips with cellular microphysiological patterns, impedimetric electrode structures were employed to monitor cell morphological alterations [173]. A capacitive immunosensor based on ultrathin Al_2O_3 sol–gel films with embedded antibody for direct detection of hIgG antigen and the liver fibrosis markers of hyaluronan and laminin antigens, was realized on arrayed microelectrodes [174].

Recently, electrochemical nanobiosensors have attracted significant attention using nanoscale materials as electrodes or as biomolecular tracers [175], and have been applied in areas of disease diagnostics and detection of infectious organisms and biothreat agents [176,177]. With the growth of nanotechnology new opportunities are provided for biosensors construction and for developing novel electrochemical bioassays. It has been demonstrated that carbon nanotube (CNT) can enhance the electrochemical reactivity of important biomolecules, promote the electron-transfer reactions of proteins, accumulate important biomolecules and alleviate surface fouling effects [178,179]. The features of high surface area, fast heterogenous electron transfer and long-range electron transfer, render CNT extremely attractive to fabricate highly sensitive nanoscale biosensors. CNT-based electrochemical transducers offer substantial improvements in the performance of amperometric enzyme electrodes, immunosensors and nucleic-acid sensing devices. Aligned CNT "forests" lined as molecular wires allow efficient electron transfer between the underlying electrode and the redox centers of proteins. Yu et al. [180] exploited CNT amplification strategies for highly sensitive immunodetection of cancer biomarkers. Electrochemical immunosensors for detection of PSA in serum and tissue lysates, using single-wall carbon nanotube (SWNT) forest platforms, was combined with multi-label secondary antibody–nanotube bioconjugates. Detection principles of the SWNT immunosensor were illustrated in Fig. 5. Greatly amplified sensitivity was attained at high HRP/Ab_2 ratio and accurate detection of PSA was implemented in real samples. To take advantages of the striking characteristics of these unique nanomaterials in such electrochemical sensing applications, the CNT needs to be properly functionalized and immobilized. Several reviews regarding electrochemical biosensors based on nanomaterials have mentioned the important roles of nanoparticles [176,181,182]. Many kinds of nanoparticles, such as metal, oxide and semiconductor nanoparticles have been employed for constructing electrochemical biosensors. The significant functions provided by nanoparticles include immobilization of biomolecules, catalysis of electrochemical reactions, enhancement of electron transfer between electrode surfaces and proteins, labeling of biomolecules and even acting as reactant. Novel designs and fabrication methods of electrochemical biosensors are expected.

The versatility of electrochemical techniques is elaborated there above. Since electrochemistry is ideally compatible with the concept of μTAS, practical applications for real sample assays can be potentially realized by designing highly integrated microdevices.

4. Practical applications

Miniaturization, integration and intelligentization are phenomenal features of modern analytical chemistry, where MEMS plays an important role in fabricating various miniaturized analytical devices. Enormous efforts toward integration of various multifunctional components have led to remarkable developments and expansion of miniaturized instrumentation for biochemical assays of amino acids, nucleic acids, DNA, proteins, cell and tissue, and so forth [183–185]. Electrochemical techniques are highly amenable to small portable devices especially used outside the laboratory environment for clinical diagnoses, environmental monitoring, food analysis, etc. Potentially vigorous practical applications include: clinical instrumentation for point-of-care testing of tumors, genetic disorders and pathogenic bacteria and viruses; methods for glucose monitoring and the subsequent release of insulin; forensics applications including DNA analysis at crime scenes; and environmental monitoring applications such as on-site testing of pollutants or explosives [186,187]. As seen in Fig. 6, a self-contained disposable biochip device that consisted of microfluidic mixers, valves, pumps, channels, chambers, heaters, and DNA microarray sensors

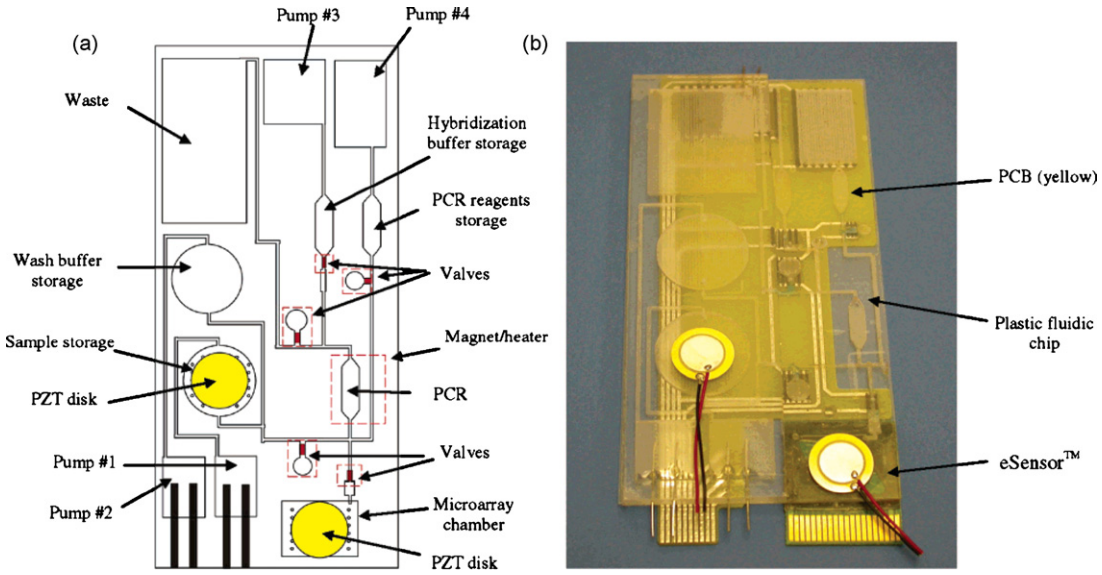

Fig. 6. (a) Schematic of the plastic fluidic chip. Pumps 1–3 are electrochemical pumps, and pump 4 is a thermopneumatic pump. (b) Photograph of the integrated device that consists of a plastic fluidic chip, a printed circuit board (PCB), and a Motorola eSensor microarray chip [188].

was developed to perform DNA analysis in *Escherichia coli*/rabbit blood samples [188]. Pathogenic bacteria detection was tested with approximately milliliters of whole blood samples, and single-nucleotide polymorphism analysis was demonstrated directly from diluted blood. What is more, both low- and high-abundance DNA detections from blood samples were also conducted using the devices. Dill et al. [167] presented the usage of individually addressable microelectrodes on the microarrays with over 1000 electrodes per square centimeter. The results of the redox enzyme amplified electrochemical detection for human α1 acid glycoprotein, ricin, M13 phage, fluorescein, etc. indicated that, this method is one of the most sensitive available, with limits of detection in the attomole range. A novel, simple and label-free multianalyte immunoassay system was described by integrating arrayed gold microelectrodes on a silicon chip for investigation of three liver fibrosis markers, hyaluronic acid, collagen type IV and lamin [189]. The measurement of real serum samples via this method was well consistent with commercial radio immunoassays, which is expected to be applied in clinical diagnosis or environment surveillance.

With the development of fabrication technologies for versatile microdevices, microanalytical processors portable for clinically or environmentally important analytes will be obtained, and accurate measurements with no requirements of experienced technicians can be imagined in the near future [144,190].

5. Conclusions

This review introduces interesting microanalytical devices integrated with electrochemical techniques for biochemical assays. We firstly introduced the microelectrode fabrication technologies and the different microelectrode design with a variety of configurations. Then, the versatility of electrochemical techniques was elaborated, including ECD, electrical manipulation of fluids and biomaterials, and electrochemical biosensing. Finally, potentially practical application of such integrated microdevices was explored. Coupling the versatility of electrochemical techniques with the rich information content of μTAS opens an array of future opportunities. Such highly integrated microdevices hold great promise for mass production of single-use μTAS. After rapid developments in microfabrication technology and their analytical applications, hand-held or portable instruments can be imagined.

Rhodamine-B
2-Chloro-4-nitrophenol
Associate

ABSTRACT

A low cost and accurate method for the detection and analytical determination of the activity of the enzyme α-L-fucosidase (AFU) was developed. The method was based upon measuring the fluorescence intensity of the complex ion associate of the ion associate of rhodamine-B and the compound 2-chloro-4-nitrophenol (RB^+ CNP^-) at 580 nm in phosphate buffer (pH 5) against the reagent blank. The influence of the different parameters, e.g. pH, incubation time, temperature, 2-chloro-4-nitrophenol concentration, foreign ions and surfactants that control the fluorescence intensity of the produced ion associate was critically investigated. The correlation between the fluorescence activity of the enzyme AFU by the developed procedures and the standard method was positive and highly significant in patients and controls ($r^2 = 0.99$, $p < 0.001$). The developed method is simple and proceeds without practical artifacts compared to the standard method.

1. Introduction

Liver cirrhosis is a pre-cancer condition that in many cases can develop into Hepatocellular carcinoma (HCC). Therefore, cirrhotic patients with cirrhosis are usually screened for HCC during their follow-up procedure [1–6]. Tumor markers represent good potential screening tools for the early diagnosis of tumors [7–10]. The primary tumor marker for HCC is a single polypeptide chain glycoprotein namely α-fetoprotein (AFP) [11,12]. The sensitivity and specificity of the AFP as a common tumor marker to detect HCC in all patient samples are insufficient [13,14]. Moreover, it is not secreted in all cases of HCC and may be normal in 40% of patients with early HCC [10,15].

The enzyme α-L-Fucosidase (AFU) can hydrolyze methyl α-L-fucoside and fucosidic linkages of fucoidan and blood-group substances [16]. The AFU enzyme compose of two-enzyme components namely: i, fucosidase which acts on 4-nitrophenyl α-L-fucoside as well as fucosidic linkages of porcine sub-maxillary mucin at optimal activity at pH 2 and ii, the fucoidanase showed highest activity around pH 5 and acts on the synthetic substrate not on the mucin [17]. The enzyme fucoidanase showed hydrolytic activity towards fucoidan, and not towards 4-nitro phenyl α-L-fucoside and blood group of livers of related species [18]. Clinical studies have demonstrated that, the activity of AFU enzyme represent an excellent test for diagnosis of HCC [19,20]. The AFU enzyme was used for the diagnosis of fucosidosis recognized in born disorder of metabolism and increases the sensitivity of detection to 95.5% in patients with HCC [21,22].

Different spectrometric methods have been reported for the determination of the activity of the enzyme AFU in serum [23–25]. These methods are limited by their long incubation time (30–60 min) for the sample and reagent blanks. Moreover, the poor affinity of the enzyme AFU towards the substrate 4-NPF as a colorimetric reagent at pH 4.8, added another disadvantage to these methods. However, the method of Jun and Hua [23] involving the synthesis of 2-chloro-4-nitrophenyl-α-L-fucopyranoside (CNPF) as a substrate has a rapid hydrolytic rate than 4-NPF method [23,24]. The activity of AFU was also determined by spectrofluorescence methods [26,27], affinity chromatography [17], column chromatography packed with Bacillus cereus [28] and disc gel electrophoresis technique [17,29]. Most of these methods are unselective, require careful experimental conditions, considerably time consuming and not compatible to detect the activity of AFU at the early stage of diseases. Thus, the present manuscript is focused on the use of the fluorescent ion associate of 2-chloro-4-nitro phenol–rhodamine-B (RB^+ CNP^-) for measuring the activity of the AFU enzyme and overcoming the difficulties caused by the previous methods [23–27]. The developed procedures will be able to control the quality of

the final marketed product in both qualitative and quantitative approaches to assure the identity of the disease. The method will be useful in medical applications to detect the different diseases at the very early stage of diseases.

2. Experimental

2.1. Apparatus

A Shimadzu RF5301 PC spectrofluorometer (290–750 nm) was used for recording the excitation; emission spectra and measuring the fluorescence intensity of the reagents and the produced complex ion associate. A two matched cuvettes (1.0 cm) and an Orion pH meter VWR scientific model (8000) were used for measuring the fluorescence intensity of the ion associate $RB^+ CN^-$ and other fluorescent species and pH measurements, respectively.

2.2. Reagents and materials and methods

Analytical reagent grade (A.R.) reagents and chemicals (99.9% purity) were used without further purification. Ascorbic acid, bilirubin, hemoglobin, glucose and uric acid, albumin, total protein, total cholesterol and triglyceride were purchased from Fluka (Fluka, AG, Buchs, Switzerland). The substrate 2-chloro-4-nitrophenyl-α-L-fucopyranoside (CNPF) and the enzyme α-L-fucosidase (AFU, EC 3.2.1.51) were laboratory reagent grade from Sigma–Aldrich, Poole, UK. The control enzyme was prepared in bovine serum base and provided in lyophilized powder. The enzyme AFU was also obtained from bovine kidney and the reagents 2-chloro-4-nitro phenol (CNP) and rhodamine-B (RB) were purchased from Sigma Co. Phosphate buffers of various pH (pH 2.5–7) were prepared from phosphoric acid and/or sodium phosphate.

2.3. Preparation of the complex ion associate $RB^+ CNP^-$

In measuring flask (100.0 mL), an accurate volume (10 mL) of the reagent 2-chloro-4-nitrophenol (5×10^{-4} mol L^{-1}) was allowed to react with 20.0 mL of rhodamine-B (5×10^{-4} mol L^{-1}). The solution was then completed to the mark with phosphate buffer of pH 5.0 and the excitation and emission spectra of the reagents 2-chloro-4-nitrophenol and rhodamine-B and the produced complex ion associate ($RB^+ CNP^-$) were then recorded.

2.4. Analytical application

An appropriate amount (450 μL) of the reagent 2-chloro-4-nitro-phenol fucopy-ranoside was immediately mixed with 50 μL of plasma/serum samples of HCC patients (26 persons) and healthy control (7 persons)) in incubator at 37 °C for 6 min. To the resultant solutions an accurate volume (300 μL) of rhodamine-B (5×10^{-4} mol L^{-1}) was added and swirled to mix the contents. Each solution was placed in an incubator at 37 °C for 5 min. The volume was completed to 3.0 mL with phosphate buffer of pH 5 and the emission intensity at 580 nm was then measured against the reagent blank. The main characteristics of the patients (male/female) and control groups are given in Table 1.

3. Result and discussion

3.1. Excitation and emission spectra

Previous studies [26] have shown that, the enzyme AFU reacts with the substrate 2-chloro-4-nitrophenol or 4-nitrophenol at pH 4–5 producing yellow colored product. This reaction has been used for measuring the activity of the enzyme AFU via the absorbance of the produced yellow colored species at pH 5.0 and 37 °C [24]. However, this, method suffered from the interference caused by the yellow color of the serum of patients and of the reagent 2-chloro-4-nitrophenol (or 4-nitro phenol). Another disadvantage was also noticed in many cases of patients of HCC that have high bilirubin [22,23]. Such methods suffered from the lake of sensitivity and accuracy due to the significant interference of the yellow color of the serum. Thus, attempts were made to overcome these disadvantages by testing the interaction of the compound 4-nitro phenol or 2-chloro-4-nitro phenol with rhodamine-B dye in aqueous medium.

In phosphate buffer (pH 5), preliminary investigations showed that, on mixing the reagent CNP with the ion pairing reagent RB and shaking, a green colored complex ion associate was developed and is most likely proceeds according to the following equation:

$$\text{2-Chloro-4-nitrophenol} + \text{Rhodamine-B} \rightleftharpoons [\text{Rhodamine-B}]^+ \text{ [2-Chloro-4-NP]-Ion associate} \quad (1)$$

After equilibrium, the excitation and emission spectra of the produced complex ion associate of rhodamine-2-chloro-4-nitrophenol or rhodamine-4-nitro phenol ($RB^+ CNP^-$) in the aqueous phase at pH 5 were recorded. The excitation and emission spectra (Fig. 1) of the complex associate $RB^+ CNP^-$ showed the characteristic excitation wavelength at 455 nm and the characteristic emission wavelength at 580 nm. The fluorescence intensity of the rhodamine-B in the emission spectrum at 580 nm decreased on adding CNP confirming the associate formation. On the other hand, rhodamine-B showed well defined emission spectrum (Fig. 2) close to the emission spectrum of the complex ion associate $RB^+ CNP^-$ (Fig. 1) while, compound 2-chloro-4-nitrophenol or 4-nitro phenol showed only excitation spectrum and no emission spectrum at 580 nm. Thus, in the subsequent work, the activity of the enzyme AFU was determined through measuring the fluorescence intensity of the ion associate $RB^+ CNP^-$ at 580 nm against a reagent blank at the optimum experimental conditions.

3.2. Analytical parameters

The influence of the hydrogen ion concentration on the fluorescence intensity of the complex ion associate $RB^+ CNP^-$ was investigated. The emission spectrum of the solution of 2-chloro-4-NP (5×10^{-5} mol L^{-1}) in the presence of rhodamine-B (5×10^{-5} mol L^{-1}) in a wide range of pH 2–8 employing dilute HCl and/or dilute sodium hydroxide was measured. The results shown in Fig. 3 revealed maximum change in the emission intensity in the pH range pH 2.5–6.0. At pH less than pH 2.5, the emission intensity of the produced complex associate $RB^+ CNP^-$ at 580 nm

Table 1

Status	Number of patients	Males/females		Age (year)	
		No.	%	Median	Range
HCC	20	15/5	75/25	51	24–75
Cirrhosis of chronic hepatitis C and B	4	2/2	50/50	48	37–69
Other neoplasms (gallbladder cancer, colon cancer and others)	2	2/0	100/0	42	28–56
Healthy adults	7	4/3	60/45	36	19–58

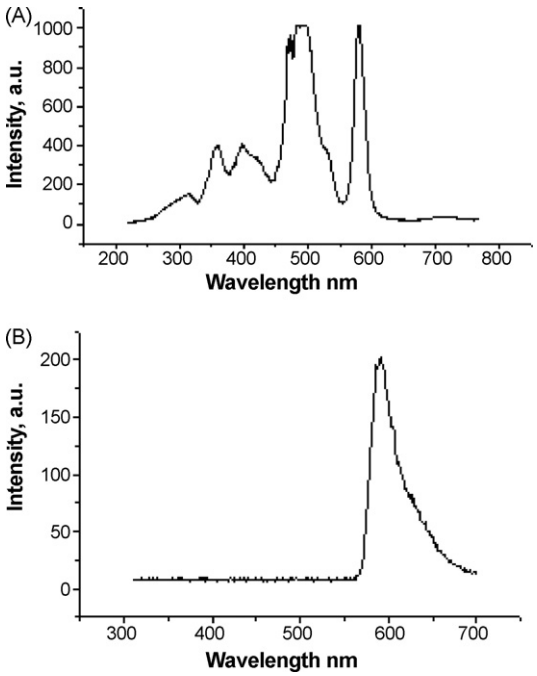

Fig. 1. The excitation (A) and emission (B) spectra of the complex ion associate 2-chloro-4-nitrophenol–rhodamine-B (2.5×10^{-5} mol L^{-1}) in phosphate buffer pH 4–5 at 37 °C.

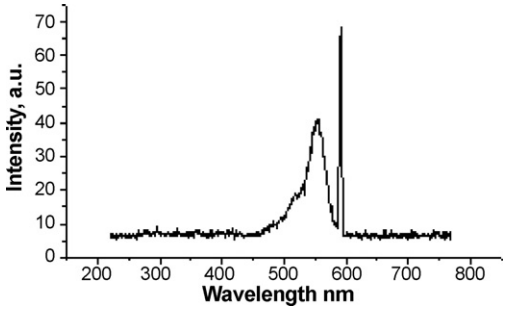

Fig. 2. The emission spectrum of rhodamine-B (5×10^{-5} mol L^{-1}) in phosphate buffer of pH 4–5 at 37 °C.

gradually decreased which is most likely attributed to the instability of the formed ion associate. At pH higher than pH 6.2, the emission intensity at 580 nm was also decreased gradually. Therefore, in the next work, phosphate buffer of pH 5 was selected for recording the enzyme AFU activity through measuring the fluorescence intensity of RB^+ CNP^- against reagent blank.

The effect of reaction time on the formation of the complex ion associate RB^+ CNP^- was critically investigated by mixing the reagent CNP (1.0 mL of 5×10^{-4} mol L^{-1}) with RB (1.0 mL of 5×10^{-4} mol L^{-1}) in phosphate buffer of pH 5 in measuring flask (10 mL). The solutions were completed to the mark with phosphate buffer of pH 5.0 and were left for various time intervals (1.0–30 min) solutions. The fluorescence intensity of the emission spectra of the solutions was then measured at 580 nm. The results revealed that, the fluorescence intensity reached maximum value at 5 min reaction time and slightly decreased at longer time higher than 30 min. Thus, a reaction time of 5–10 min was selected in the subsequent work.

The influence of temperature (15.0–70.0 °C) on the reaction of the reagent CNP and rhodamine-B was investigated in phosphate buffer of pH 5 and 5 min reaction time on a water bath. The fluorescence intensity of the emission spectra of the solutions was recorded at 580 nm versus reagent blank. The results showed that, the maximum intensity change was obtained at 35–40 °C and decreased gradually at higher temperature. This behavior may be attributed to the dissociation of the complex ion associate RB^+ CNP^-.

The influence of sodium dodecyl sulfonate (SDS), cetylpyridinium chloride (CPC) and the non-ionic surfactant Triton X100 on the fluorescence intensity of the produced associate RB^+ CNP^- at 580 nm was critically studied. In this experiment, an aliquot solution of phosphate buffer (pH 5) containing 2-chloro-4-nitrophenol (1.0 mL, 5×10^{-4} mol L^{-1}), rhodamine B (1.0 mL, 5×10^{-4} mol L^{-1}) and the required surfactant (1.0 mL, 0.1% w/v) was allowed to react for 5 min at 40 °C in an incubator. The fluorescence intensity of the produced associate at 580 nm was then measured and compared with that recorded without addition of surfactant. No significant changes on the fluorescence intensity of the associate RB^+ CNP^- were noticed with and without surfactant.

3.3. Interference study

The influence of some interfering species on the selectivity of the developed spectrofluorimetric method was investigated individually. Thus, the developed procedure was applied in the presence of various species commonly associated with the enzyme, e.g. NaCl, KCl (1×10^{-3} mol L^{-1}), albumin (0.5 g), urea (0.005 g L^{-1}), uric acid (0.008 g L^{-1}), total protein (0.001 g L^{-1}) and glucose (0.01 g L^{-1}) in phosphate buffer of pH 5.0 at 5 min contact time at 40 °C. The tolerable limit was defined as the concentration of the added species causing a deviation less than ±3.0% of the fluorescence intensity at the optimum conditions on the fluorescence intensity and emission spectrum of the ion associate RB^+ CNP^- (5×10^{-4} mol L^{-1}). The results revealed no significant change on the fluorescence intensity of RB^+ CNP^- in the presence of the

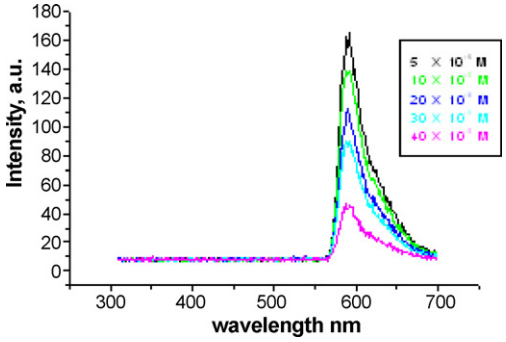

Fig. 4. Emission spectra of various concentrations (5×10^{-6}–40.0×10^{-6} mol L^{-1}) of 2-chloro-4-nitrophenol in the presence of rhodamine-B (2 mL, 5×10^{-4} mol L^{-1}) in 50-μmol L^{-1} phosphate buffer of pH 4–5 at 37 °C.

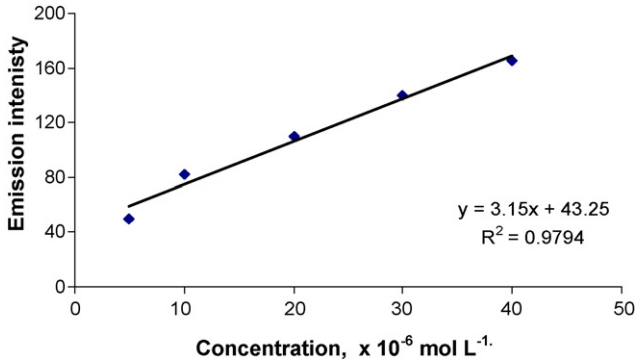

Fig. 5. Calibration plot for different concentrations of CNP in aqueous phosphate buffer of pH 4–5 versus emission intensity at 580 nm at 37 °C in the presence of rhodamine-B.

tested interfering ions indicating the selectivity of the developed method.

3.4. Dynamic range of the calibration graph and limit of detection

The validation of the proposed spectrofluorimetric procedure for measuring the AFU activity was examined via evaluation of the linear range of the plot of the fluorescence intensity measured versus various concentrations of 2-chloro-4-nitrophenol; lower limit of detection (LOD); limit of quantification (LOQ), repeatability, and specificity. The calibration plot of 2-chloro-4-nitrophenol in phosphate buffer (pH 5.0) was constructed by reacting 2-chloro-4-NP solution at various concentrations (5×10^{-6}–40.0×10^{-6} mol L^{-1}) with rhodamine-B (2.0 mL, 5.0×10^{-5} mol L^{-1}) and shaking for 5 min in an incubator at 37 °C. The emission spectra of the produced associate (RB^+ CNP^-) at various concentration of CNP are shown in Fig. 4. The plot of CNP concentration (5×10^{-6}–40.0×10^{-6} mol L^{-1}) versus the fluorescence intensity (at 580 nm) was linear (Fig. 5) with good correlation coefficient ($r^2 = 0.979$) and leveled off at concentration higher than 40.0×10^{-6} mol L^{-1} of CNP. This trend is most likely attributed to the shift of the equilibrium (equation (1)) to the left and the quantity of CNP species available to form complex ion associate with $[RB^+]_{(aq)}$ decreased which minimizes the associate formation [30] may account for the observed effect. A large excess of the reagent slightly decreased the fluorescence intensity possibly owing to the increased acidity of the aqueous phase which minimizes the associate formation [30].

The regression equation of the linear plot (Fig. 5) was: $Y = 3.15\,C$ (μM) + 43.25 with a correlation coefficient $r^2 = 0.979$, where Y = emission intensity and C represents the concentration of CNP in μM. According to IUPAC [31], the value of the LOD calculated using the formula LOD = $3S_{y/x}/b$ where $S_{y/x}$ is the standard deviation of y-residual and b is the slope of the calibration plot was found equal 1.01×10^{-7} mol L^{-1}. The value of LOQ where LOQ = $10S_{y/x}/b$ under the established conditions for lead (II) was found equal 3.4×10^{-9} mol L^{-1} and a relative standard deviation (RSD) for CNP at concentration of 5×10^{-6} was 2.5% ($n = 3$). Such limits could be improved to lower values by increasing the incubation times at the optimum experimental condition. The values of LOD and LQD confirmed the sensitivity of the proposed procedure compared to the reported methods [23–26]. This precision is suitable for the routine analysis of AFU activity for different patients. Moreover, the repeatability of AFU activity based on five replicate measurements for 5×10^{-6} mol L^{-1} of the reagent CNP calculated from the calibration curve was 97.47 ± 3.7% indicating good precision of the proposed method.

It was observed that there is no interference from other additives, e.g. interference from trace metal ions in particular Na, K which are commonly present in combination with the AFU enzyme in the serum of HCC patients. No significant difference could be detected upon comparing the emission intensity of the CNP component alone or in the presence of a high content (1:5) CNP: Na or K ions, respectively. Thus, the developed method is characterized by good specificity.

3.5. Analytical applications

The validation of the proposed spectrofluorimetric method was tested by measuring the activity of the enzyme AFU) for 33 serum samples of male and female patients (26) and healthy (7) in various ages (Table 1). The results obtained are summarized in Table 2. Good agreement between the values obtained by the developed procedure and the standard method [23]. The average value of the AFU enzyme activity obtained by the standard method [23] (29.28 ± 2.75 U/L) for the healthy samples (7) was found close to the value achieved by the developed method (31.14 ± 3.21 U/L) with an acceptable standard error (3.55–3.90). Also, good correlation between the values of the activity of serum AFU enzyme in some selected control samples measured by the standard and the developed spectrofluorometric methods ($r^2 = 0.883$, $p = 0.002$) is shown in Fig. 6. The F-and t-tests at 95% confidence levels did not exceed the theoretical ones and no significant differences between the developed and the standard [22] methods were observed confirming the accuracy of the developed procedure. In the HCC patient samples (20), the mean value of the AFU activity achieved by the standard method [23] (119.55 ± 74.80 U/L) was found also in good agreement with that obtained by the proposed method (123.5 ± 77.8 U/L) with a standard error in the range 13.99–14.08. On the other hand, an excellent correlation between the average values of the activity of the serum AFU enzyme in selected HCC patients

Table 2
Analytical results of the standard (A) and the developed spectrofluorimetric (B) methods for the healthy and patients' samples.[a]

Enzyme activity (U/L)	No	Subject	Methods		
			Standard error (SE)	Mean ± SD	Range
3.55	29.28 ± 2.75	16–41	7	Healthy	Standard method (A)
3.9	31.14 ± 3.21	15–46			Developed spectrofluorimetric method (B)
13.99	119.55 ± 74.80	54–249	20	HCC	Standard method (A)
14.08	123.5 ± 77.8	58–255			Developed spectrofluorimetric method (B)
2.81	29.95 ± 1.68	25–37.8	4	Cirrhosis of Chronic hepatitis C and B	Standard method (A)
2.61	29.25 ± 1.53	24–36.5			Developed pectrofluorimetric method (B)
2.69	29.16 ± 4.67	24–33.1	2	Other Neoplasms (gallbladder cancer, colon cancer and others)	Standard method (A)
1.85	28.33 ± 3.21	26–32			Developed spectrofluorimetric method (B)

[a] Average of three measurements ± standard deviation.

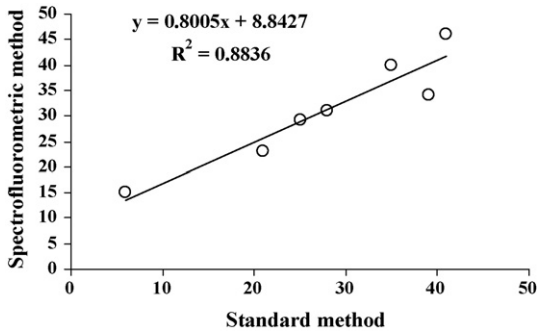

Fig. 6. Correlation between the values of the activity of serum AFU enzyme in some selected control samples as measured by the standard and the developed spectrofluorometric (pH 4–5) methods ($r^2 = 0.883$, $p = 0.002$).

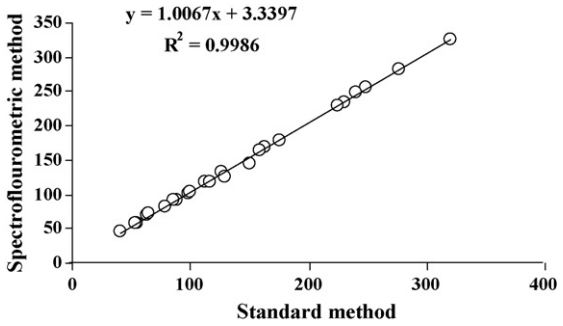

Fig. 7. Correlation between the values of the activity of serum AFU enzyme activity in some selected HCC patients measured by the standard and the developed spectrofluorometric (pH 4–5) methods ($r^2 = 0.99$, $p = 0.001$).

measured by the standard and the developed spectrofluorometric methods ($r^2 = 0.99$, $p = 0.001$) is also shown in Fig. 7 confirming the accuracy of the developed procedure. The correlation is positive and highly significant in patients and controls ($r^2 \approx 0.99$, $p < 0.001$) indicating that the proposed method has more/or less the same accuracy of measurements of AFU activity without its practical artifacts.

Moreover, for Cirrhosis of chronic hepatitis C and B samples (4), the average value obtained by the standard method [24] (29.95 ± 1.68 U/L) was found also quite close to the mean value (29.25 ± 1.53 U/L) obtained by the developed method with a standard error in the range 2.61–2.81 confirming the accuracy of the proposed procedure. In the case of neoplasm's (gallbladder cancer, colon cancer and others) samples (2) the average values obtained by the standard method and the proposed method were found equal 29.16 ± 4.67 and 28.33 ± 3.21 U/L, respectively with a standard error in the range of 1.85–2.69. The *F*-and *t*-tests at 95% confidence levels did not exceed the theoretical ones and no significant differences were observed between the developed and the standard [23] methods confirming the accuracy of the developed procedure.

4. Conclusions

The proposed method is sensitive enough, simple, reliable, fairly rapid and low cost procedure for measuring the activity of the enzyme AFU. This advantage encourages the application of the proposed method in routine quality control of measuring the activity of AFU in human serum. The method able to minimize the limitations, e.g. the interference caused by the yellow color of the serum of patients and the yellow color of 2-chloro-4-nitrophenol (or 4-nitro phenol) related to the sensitivity and selectivity for AFU activity in patients of Cirrhosis of chronic hepatitis C and B, other neoplasm's, e.g. gallbladder cancer, colon cancer and healthy adults compared to the other reported methods [21–24]. The disadvantage noticed for patients of HCC having high value of bilirubin makes the reported methods [15–18] are not compatible with the detection limit of the proposed method. This behavior is not likely attributed to the suppression effect of the interaction of CNP reagent and rhodamine-B under the optimal experimental conditions. Thus, the work is still continuing for studying the effect of various concentrations of bilirubin, memory effect, and competitive complex agents present in the investigated samples.

ABSTRACT

A new SU-8 based microchip capillary electrophoresis (MCE) device has been developed for the first time with integrated electrochemical detection. Embedded electrophoretic microchannels have been fabricated with a multilayer technology based on bonding and releasing steps of stacked SU-8 films. This technology has allowed the monolithic integration in the device of the electrochemical detection system based on platinum electrodes. The fabrication of the chips presented in this work is totally compatible with reel-to-reel techniques, which guarantee a low cost and high reliability production. The influence of relevant experimental variables, such as the separation voltage and detection potential, has been studied on the SU-8 microchip with an attractive analytical performance. Thus, the effective electrical isolation of the end-channel amperometric detector has been also demonstrated. The good performance of the SU-8 device has been proven for separation and detection of the neurotransmitters, dopamine (DA) and epinephrine (EP). High efficiency (30,000–80,000 N/m), excellent precision, good detection limit (450 nM) and resolution (0.90–1.30) has been achieved on the SU-8 microchip. These SU-8 devices have shown a better performance than commercial Topas (thermoplastic olefin polymer of amorphous structure) microchips. The low cost and versatile SU-8 microchip with integrated platinum film electrochemical detector holds great promise for high-volume production of disposable microfluidic analytical devices.

1. Introduction

Microfabricated fluidic devices have gained a great interest, especially since capillary electrophoresis (CE) microchips were proposed by Manz et al. [1,2]. These miniaturized systems are characterized by high-speed, high-throughput, small sample and reagent requirements as well as integration and compactness.

Although microfluidic devices were initially fabricated using glass substrates, in the last years, polymer materials such as poly(methylmethacrylate) (PMMA) [3,4], poly(dimethylsiloxane) (PDMS) [5], polycarbonate (PC) [6], polyester [7], poly(ethylenterephthalate) (PET) [8] and cyclic olefin copolymers (COC) [9] have been also employed owing to their mechanical and chemical properties, low cost, ease of fabrication and higher flexibility. Recently, the photoresist EPON SU-8 (hereinafter referred to as SU-8) has been used to fabricate devices for biochemical sample preparation and detection [10,11]. SU-8 is a negative tone epoxy photopatternable resist, mechanically reliable, optically transparent, chemically resistant and hydrophilic. Thus, it has been successfully employed to fabricate microfluidic systems [12–14], movable micromechanical components [15] and optical waveguides [16]. A simple process based on bonding and releasing steps of stacked SU-8 films has been developed to fabricate an electrophoretic device, which has been applied to sodium dodecyl sulfate-capillary gel electrophoresis of proteins with optical detection [17]. Electrochemical detection has not been used before in combination with SU-8 microchips.

Among the detectors used for microchip capillary electrophoresis (MCE), electrochemical detection (ED) has proven to be very effective due to characteristics such as inherent miniaturization, sensitivity, low cost, portability and compatibility with microfabrication technology. Amperometric detection, since the first reported in 1998 by Wolley et al. [18], has been the most widely employed electrochemical technique for MCE. In this detection mode, an appropriate design of the detection cell is required for ensuring electrical isolation from the high separation voltage. Various approaches have been developed with this aim including in-channel, end-channel and off-channel configurations [19].

doi:10.1016/j.talanta.2009.05.049

In- and off-channel detection modes are based on the placement of the working electrode directly within the separation channel without [20,21] or with an electric field decoupler [22,23] respectively. In these approaches, the electrodes have been normally integrated on the chip by means of films of different materials such as platinum [24,25], palladium [22,26,27], gold [21,26] and indium tin oxide (ITO) [28]. Metal layers of titanium, platinum and palladium that were the basis of thirteen electrodes (including three for detection, six for decoupling and four as high-voltage electrodes) have been integrated in a PDMS/glass microchip [5]. Apart from films, carbon fibre electrodes were also employed [29].

The end-channel configuration has been the most commonly used amperometric detection mode, where the working electrode is placed close (10–50 μm) to the outlet of the separation channel. Replaceable disk [9,30–35] or thick-film [34–37] working electrodes can be aligned off-chip using XYZ micromanipulators, guide tubes or other special cell designs. However, in this approach non-total integration of the electrochemical detector on the chip is obtained. The distance electrode–microchannel end [38] and the effect of the separation potential [39] influences the results. On the other hand, the electrodes can also be permanently integrated on-chip by means of thin-films made of platinum [18,40], gold [41–43], copper [42] or carbon [44,45] placed close to the channel exit. Inclusion of electrodes directly on the chip surface takes full advantage of the microfabrication approach. Thus, Baldwin et al. [40,46] have integrated all electrophoresis and electrochemical platinum electrodes on a glass microchip using traditional microfabrication techniques, including photolithographic patterning, wet chemical etching, direct current sputtering and thermal wafer bonding. Wilke and Büttgenbach [47] have also developed a glass microdevice with fully integrated six gold electrodes for electrophoresis and amperometric detection.

Catecholamine family of neurotransmitters: dopamine, epinephrine, norepinephrine, and catechol have been the analytes most frequently studied by MCE-ED. The reasons for this are related both to the important physiological role of these compounds in the transmission of nerve impulses and to the fact that they exhibit nearly ideal electrochemical properties for detection purposes. Thus, microchips of different materials and several electrodes have been successfully employed to separate and detect these analytes [5,18,19,22,30,32,38,46,48–55]. Detection limits cited with these devices have typically been in the nM to μM range.

In this work, a microchip electrophoresis has been fabricated for the first time on SU-8 resist with an integrated electrochemical detector based on platinum film electrodes [56]. The new microfabricated SU-8 chips have been used for separation and detection of the neurotransmitters, dopamine (DA) and epinephrine (EP). Several factors influencing the performance of the SU-8 MCE-ED have been examined. Thus, the buffer composition, separation voltage and detection potential have been evaluated.

2. Experimental

2.1. Reagents

A 125 μm thick polyimide film called Kapton from Teinser (Spain) and a 4 in. Pyrex wafers (750 μm thick) were used as substrates. Positive photoresist S1818 from Shipley was employed for lift-off and as an adhesive layer between Kapton and Pyrex. Two types of SU-8 photoresists are used for microchannel fabrication: SU-8-50 and SU-8-5 ordered from Microresist (Germany). The developer is propyleneglycol-monoether-acetate (PGMEA, Microresist). Isopropanol (IPA) from Aldrich is employed to rinse the samples.

Dopamine (DA), epinephrine (EP), tris(hydroxymethyl)aminomethane (Tris), 2-(*N*-morpholino)-ethanesulfonic acid (MES), L-histidine (His), sodium dodecyl sulfate (SDS), t-octylphenoxypolyethoxyethanol (Triton X-100), sodium hydroxide and boric acid (99.5%) were purchased from Sigma–Aldrich (St. Louis, USA). Sulphuric (95–97%) and perchloric acids (70%) were obtained from Merck (Germany).

Dopamine and epinephrine solutions were prepared daily in the running buffer. All solutions were filtered through nylon syringe filters (Cameo 30N, 0.1 μm, 30 mm) obtained from Osmonics (Minnetonka, USA).

Water was purified employing a Milli-Q plus 185 equip from Millipore (Bedford, USA). All other reagents were of analytical reagent grade.

2.2. Microchip fabrication

The electrophoretic devices have been fabricated at a wafer level using the process described in a previous work [10]. It is based on the bonding of two photopatterned SU-8 layers on two different substrates: (i) the bottom one, which is a pyrex wafer where Ti/Pt electrodes have been previously patterned, contains the SU-8 layer which defines the microfluidic channels of the chip, and (ii) the top one, which is a Kapton film bonded to a Pyrex wafer, includes the SU-8 layer which will be used as cover, closing the whole chip and leaving open the inlets and outlets. The photomasks were generated using a layout software Clewin and were printed on a plastic film photomask by a photoplotter of 64,000 dpi (J.D. Photo-Tools Ltd., UK). Both wafers are put into contact and bonded together by the use of temperature and pressure. Once both SU-8 layers are bonded, the poor adhesion between the Kapton and the SU-8 allows the releasing of the top substrate, and the chip fabrication is finished, simplifying dramatically the external connection. The following sections will describe the fabrication process in more detail.

2.2.1. Fabrication of the bottom substrate

The fabrication process starts with the electrode definition by an S1818 photolithographic step. Then, 15 nm of titanium and 150 nm of platinum are sputtered and lift-off is carried out in an acetone ultrasonic bath. After that, a photolithography of a 5 μm thick SU-8-5 layer is performed in order to improve photoresist to pyrex adhesion. In order to process this layer, is first spun at 2500 rpm and soft-baked at 95 °C for 5 min. Next, the photoresist is polymerised with an exposure of 160 mJ/cm^2 and a 5-min post-bake at 95 °C. Finally, the SU-8-5 is developed in a PGMEA developer bath for 2 min and hard baked at 170 °C for 20 min.

Once the SU-8-5 is highly polymerised to improve the adhesion, a 20 μm thick SU-8-50 layer is photopatterned to fabricate the microchannel cavities and electrode apertures. Briefly, the recipe to obtain this layer is: (i) dynamic spin coating at 5000 rpm; (ii) soft-baking at 90 °C for 8 min using ramps up and down of 7 °C/min temperature ramps to avoid microcracking; (iii) UV exposure of 140 mJ/cm^2; (iv) post-baking at 90 °C for 4 min with progressive temperature ramps; and finally (v) developing in a PGMEA bath and rinsing in IPA.

2.2.2. Fabrication of the top substrate

Firstly, a 125 μm thick Kapton film is bonded to a Pyrex wafer using the photoresist S1818 as an adhesive layer. This photoresist is spun on the Pyrex wafer at 4000 rpm for 30 s. Immediately, both substrates are put into contact under a vacuum of 0.1 Pa in a substrate bonder, pressed together at 25 kPa and heated to 100 °C for 20 min. Thus, a top Kapton–Pyrex substrate, rigid enough to perform photolithography is obtained. Finally, a 20 μm thick SU-8-50 layer is photopatterned to achieve the microchannel covers and electrode apertures using the same recipe as in the previous section.

2.2.3. Bonding

Once the SU-8-50 is photopatterned on both substrates, a bonding recipe is carried out [12]. Both wafers are brought into contact using a substrate bonder at 0.1 Pa, pressed together with 300 kPa and heated to 100 °C for 20 min, which is above the glass transition temperature of the partially polymerised SU-8. When processing parameters are correctly optimized, no changes in the different SU-8 layer dimensions can be observed due to the bonding step [10]. This causes the two polymer layers to become irreversibly bonded together. Due to the transparency of the Kapton film on Pyrex, alignment is straightforward regardless of the bottom wafer.

2.2.4. Kapton releasing

After the bonding step, the top Kapton–Pyrex wafer is detached from the SU-8 stack and bottom substrate. For that purpose, the bonded wafers are immersed in an acetone ultrasonic bath for 10 min. Subsequently, the top Pyrex wafer and the Kapton film are separated by the insertion of a razor blade. Finally, the Kapton film is easily peeled off from the SU-8 stack. Since all the layers are photopatterned before the bonding step, the Kapton releasing left the microchannel inputs/outputs and electrode apertures in contact with the outside world, radically simplifying the packaging.

Fig. 1 shows a schematic diagram of the fabrication process of the device. As a result of the fabrication process, SU-8 based two channel (50 μm wide and 20 μm deep each, Fig. 2b) electrophoresis devices on top of a pyrex wafer with integrated electrodes for electrochemical detection were obtained. SU-8 microchips are fabricated in batches, the size of the batch being 8 microchips.

2.3. Microchip design

The final design of the SU-8 microchip with integrated electrochemical detector is shown in Fig. 2. The device (38 mm × 13 mm) is formed by a 35 mm long separation channel and a 10 mm long injection channel. The injection channel is situated 5 mm from the beginning of the separation channel. The channels had 50 μm wide and 20 μm high. Holes of 2 mm diameter that act as reservoirs were situated at the end of the channels.

A commercial Topas (thermoplastic olefin polymer of amorphous structure) microchip was also used to compare with the fabricated SU-8 microchip. Topas microchips were purchased from Microfluidic-ChipShop (Jena, Germany) and these consisted of a plate (58.5 mm × 13.5 mm) of 2 mm thickness with a 54 mm long separation channel and 9 mm long injection channel. The two channels crossed each other halfway between the sample and sample waste reservoirs and 4.5 mm from the separation channel buffer reservoir. The channels were 20 μm depth with 32 μm width at the bottom and 60 μm width at the top. A cover plate of similar dimensions but 200 μm-thick is adhered for closing the channel at the top. Holes of 2 mm diameter that act as reservoirs were situated on the 2-mm-thick plate at the end of the channels.

Micropipette tips were cut for obtaining 0.5 cm long pieces with a diameter of 0.3 cm at the top. They were adhered concentrically

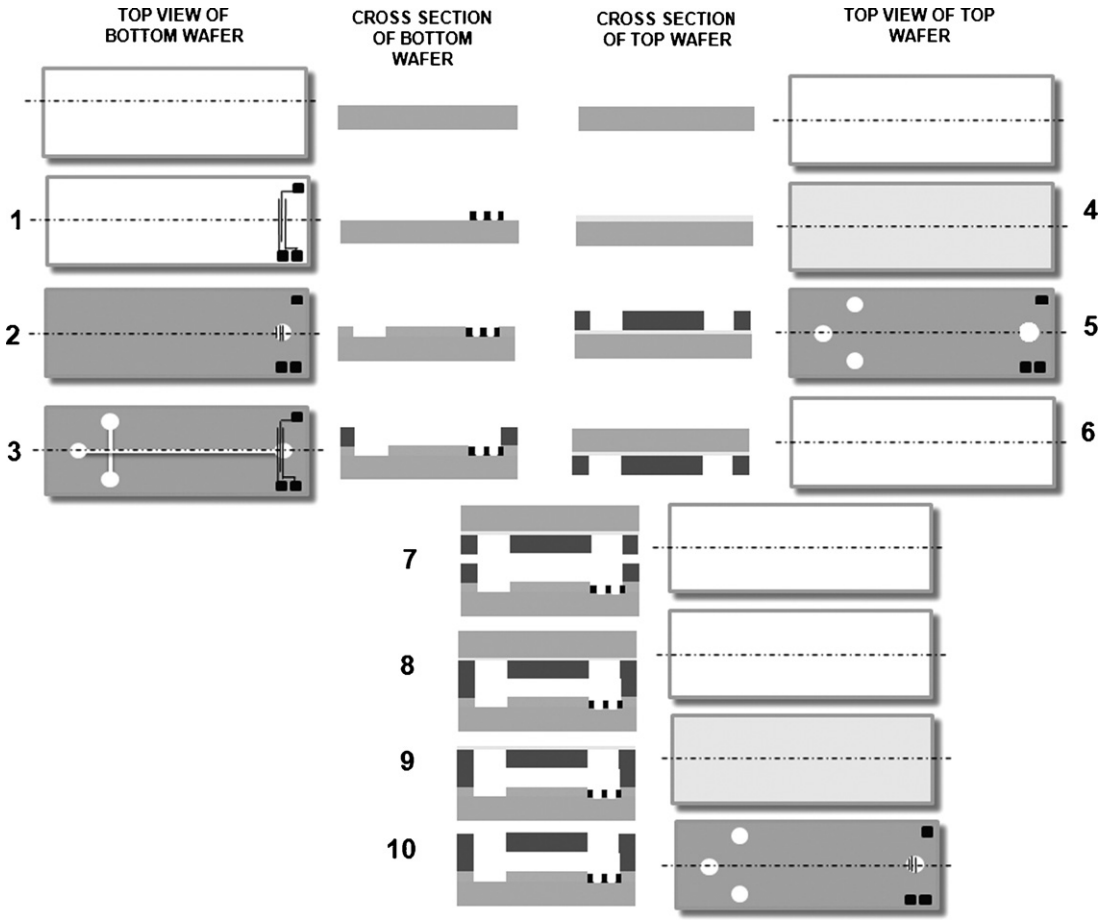

Fig. 1. A schematic diagram of the fabrication process of the device. The numbers in the figure correspond to the different steps carried out in the fabrication process: (1) fabrication of Ti/Pt electrodes by sputtering and lift-off; (2) photolithography of a 5 μm thick SU-8-5 seed layer to improve SU-8-to-glass adhesion; (3) photolithography of a 20 μm thick SU-8-50 layer to fabricate microchannel cavities; (4) bonding of a pyrex wafer and a Kapton film; (5) photolithography of a 20 μm thick SU-8-50 layer to fabricate microchannel covers; (6) turn over the top substrate to be able to align it with the bottom substrate; (7) align both substrates; (8) bonding of the two substrates; (9) pyrex wafer releasing and finally; (10) Kapton releasing.

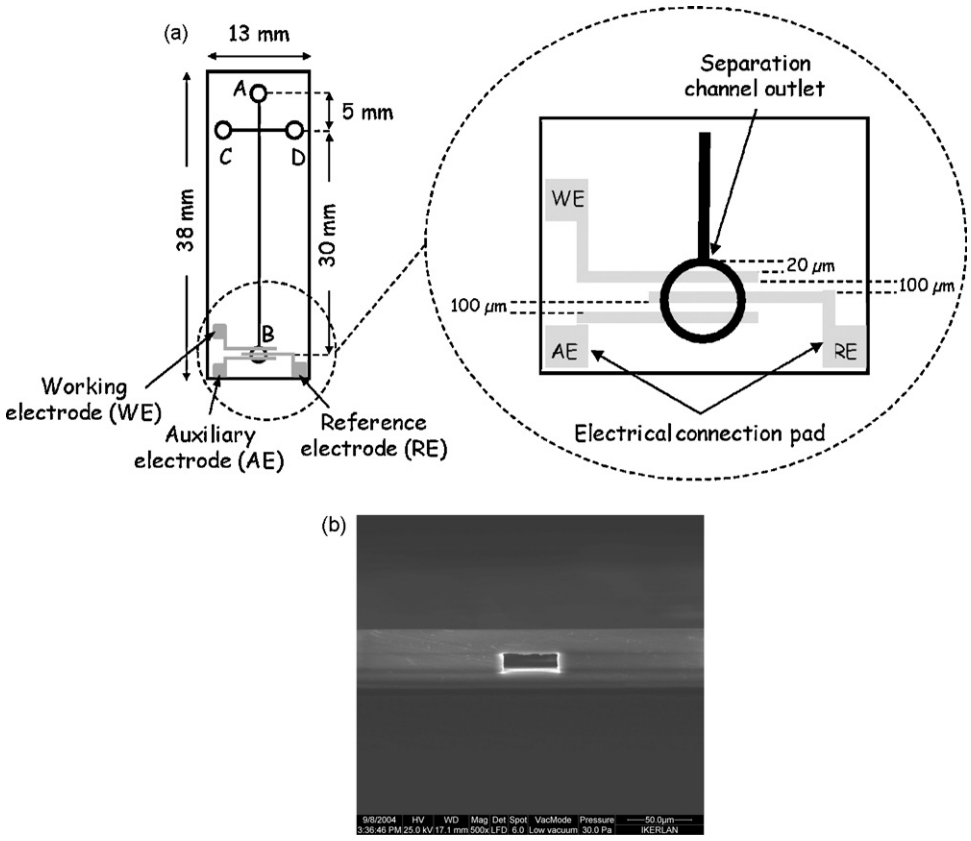

Fig. 2. (a) Scheme of the design and dimensions of the SU-8 microchip with integrated amperometric detector (running buffer (A), detection (B), sample (C) and sample waste (D) reservoirs). (b) SEM picture of the cross-sectional view of a microchannel. The dark rectangle in the center represents the microchannel cross-section.

to the chip holes (Topas and SU-8 microchips) with Araldit (Vantico AG, Basel, Switzerland) forming reservoirs of approximately 50 μL volume. A methacrylate holder (18 cm × 13 cm × 2 cm) was fabricated for accommodating the chips. Once inserted the chip on the holder, a small rectangular piece (5 cm × 1 cm × 0.8 cm) was fixed with screws with the aim of securing the chip.

2.4. Electrochemical detector

The electrochemical detector in the SU-8 microchip was integrated at the end of the separation channel as can be seen in Fig. 2a. The detector is based on three 100 μm wide Ti/Pt electrodes fabricated by sputtering and lift-off as was stated above. The working electrode was placed at a distance of 20 μm from the end of the separation channel. The other two electrodes (reference and auxiliary electrodes) were separated by a distance of 100 μm one from each other. The distance between working and reference electrodes is also 100 μm. A copper cable was fixed to platinum films with a conducting silver epoxy resin (CW2400, RS Components, UK) for electrical connection.

In the Topas microchip, the detector was situated in the waste reservoir with a three-electrode configuration as previously reported [57]. An external Ag/AgCl reference electrode and a 0.3 mm diameter platinum wire (Goodfellow, UK) auxiliary electrode were used. A 100 μm diameter gold wire (Alfa Aesar, Germany) was employed as working electrode with an end-channel configuration. The working electrode was manually aligned through a guide channel practiced on the microchip with the help of a cutter.

Amperometric detection was performed with an Autolab PGSTAT 10 (ECO Chemie, Netherlands) potentiostat interfaced to a Pentium Celeron, 333 MHz, 64MB RAM computer system and controlled by Autolab GPES software version 4.9 for Windows 98.

2.5. Electrophoresis procedure

Capillary zone electrophoresis separations were carried out in uncoated channels using two high-voltage power supplies (HVPS, MJ series) with a maximum voltage of +5000 V from Glassman High Voltage (High Bridge, NJ 08829-0317, USA). They were interfaced to a Pentium Celeron, 333 MHz, 64MB RAM computer system and monitored by a DT300 Series Board, DT Measure Foundry 4.0.6 software for Windows 98. High-voltage electrodes consisting of 0.3 mm diameter, 1 cm long platinum wires (Goodfellow, UK) were manually inserted into each of the reservoirs, except for reservoir B where the detection is located. They are connected by means of crocodile clips to the HVPS.

Prior to electrophoresis, SU-8 microchips were only rinsed with the running buffer. The microchannels were filled with the running buffer solution using a simple vacuum system. The microchip was fixed in its holder and a Faraday cage was used for housing it in order to minimize electrical interferences. The detection potential is applied for baseline stabilization, and afterwards reservoir C was filled with the sample solution and injections were performed by applying the desired voltage to the sample reservoir (C) with the detection reservoir (B) grounded. Separation was performed by applying the corresponding voltage to the running buffer reservoir (A) with the detection reservoir (B) grounded. Then the electropherogram was recorded. All experiments were performed at room temperature. Microchips are stored filled with water at room temperature and kept from the light.

Safety considerations: High-voltage power supplies should be handled with extreme care to avoid electrical shock.

3. Results and discussion

The simple procedure of microfabrication on SU-8 resist allows getting different designs of microchips (single- or dual-channel configurations). Meanwhile the geometry of glass and Topas microchannels is semicircular and trapezoidal respectively, a rectangular section is achieved in this case (see Fig. 2b). Moreover, integration of the electrodes for detection during the same process is possible. Thus, the detector design can be easily modified in order to develop end-channel or off-channel (including 1 or 2 decouplers with different dimensions) approaches. Although it is possible, the SU-8 microchips with integrated amperometric detection have been initially characterized using an only separation channel in combination with the platinum end-channel detector. Dual-channel SU-8 microchips, with a parallel channel that allows simultaneous measurements of the same or different analytes, will be checked in the future.

Several parameters such as composition of the running buffer, separation voltage and detection potential affect to the behaviour of the microchannels and detection system. Thus, the electrochemical response of the integrated platinum film electrodes on the SU-8 microchip was studied using dopamine (DA) and epinephrine (EP) as model analytes. Firstly, TB buffer (50 mM Tris–Boric acid pH = 7.0) was employed for determining the optimal detection potential of the dopamine. SU-8 presents the highest electro-osmotic mobility at pH ≥ 7 (in the order of that found for glass), suggesting equal charge densities on both surfaces [58]. Thus, the hydrodynamic voltammogram (HDV) was recorded (data not shown) between 0.0 and +0.7 V using a separation voltage of +1000 V and an injection voltage of +250 V applied during 5 s. Hydrodynamic curve reached a plateau at +0.5 V. Therefore, +0.6 V was employed as detection potential.

The effect of the separation voltage on the analytical signal (100 μM DA) was studied using an injection voltage of +250 V applied for 5 s, a detection potential of +0.6 V and TB as running buffer. When the separation voltage is varied from +250 to +1250 V, the peak current was increased from 4.4 to 9.2 nA due to the migration speed of analyte zone in the channel is enhanced and a smaller sample dispersion is produced. As expected, by enhancing the separation voltage, the migration time and the half-peak width dramatically decreased, from 166.5 to 35.7 s and from 23.7 to 4.4 s, respectively. However, the increasing interference of the high voltage (on the detection potential producing noise generation) leads to decreased efficiency, thus, a maximum theoretical plate number (N) of 21,000 m^{-1} was obtained using +500 V as separation voltage.

Electropherograms for dopamine, epinephrine and a mixture of both are shown in Fig. 3. Although the migration time of the dopamine and epinephrine was slightly different, it was not enough to separate the two analytes and only one peak was recorded for the mixture.

In order to obtain a better separation of dopamine and epinephrine, pH was lowered and a MES-His buffer was employed. 25 mM MES-His pH = 5.7 was employed as new running buffer. Since both, the analytes charge and the wall charge changes with pH, this is very important in obtaining an adequate resolution [59]. The pH of MES solution was adjusted with histidine to avoid an excessive current in the microchannel when the separation voltage was applied.

With the change of buffer composition and pH, the selection of the optimal detection potential relies newly on the construction of hydrodynamic voltammograms (HDVs). The HDVs were made using a sample mixture of DA and EP 100 μM each, a separation voltage of +750 V and an injection voltage of +250 V applied for 5 s. As is shown in Fig. 4 the curves reached a plateau at +1.1 V, thus, a detection potential of +1.2 V was employed. Compared to pH 7, the detection potential has been increased. Since protons are involved in the electrochemical reaction, the change in pH makes more difficult, in this case, the oxidation process. Therefore, a higher potential has to be employed.

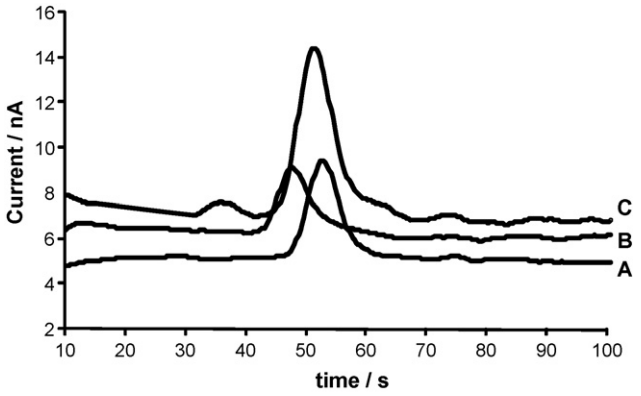

Fig. 3. Electropherograms for (A) 100 μM EP, (B) 100 μM DA and (C) a mixture of 100 μM DA-EP using an SU-8 microchip with integrated platinum film detector. *Conditions*: running buffer: 50 mM TB pH = 7.0, V_{sep} = +750 V; V_{inj} = +250 V for 5 s; E_d = +0.6 V (*vs.* Pt).

The influence of the separation voltage on a mixture of DA and EP was studied using an injection voltage of +250 V applied for 5 s, a detection potential of +1.2 V and 25 mM MES-His pH = 5.7 as running buffer. Fig. 5 displays the electropherograms for the separation of DA and EP using separation voltages between +500 and +1500 V. As expected, the migration time decreased from 161.9 and 205.1 to 51.9 and 65.7 s as well as the half-peak width from 11.7 and 16.1 to 4.0 and 5.9 s for DA and EP, respectively. A higher separation voltage supposed enhancing the peak current from 3.1 to 7.3 nA and 3.0 to 6.8 nA for DA and EP, respectively; due to smaller dispersion of the analytes in the channels. The higher theoretical plate number (39,000 ± 1000 and 30,000 ± 1000 m^{-1} for DA and EP, respectively, $n = 3$) was obtained using a voltage of +750 V. When the voltage was increased up to +750 V the plate number ($N = 5.54(t_m/w_{1/2})^2$) and the resolution ($Rs = 2(t_2 - t_1)/(w_1 + w_2)$) was gradually reduced as can be seen in Fig. 5 (inset). The influence of increasing the electric field can be also noted in a higher initial baseline slope of electropherograms (Fig. 5). However, this did not suppose an increase in the background noise level (1.5 pA), which means, the detector was effectively isolated from the high separation voltage. In this config-

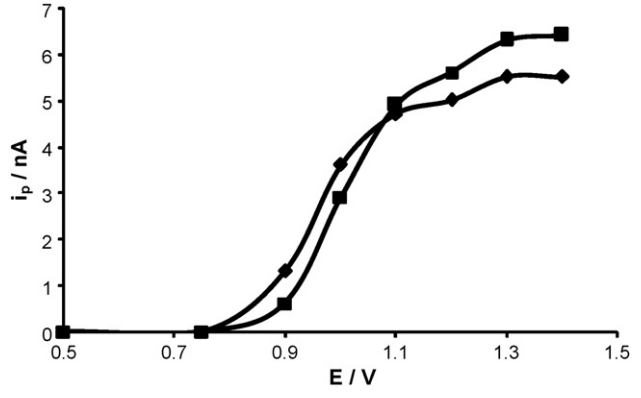

Fig. 4. Hydrodynamic voltammograms for (♦) 100 μM DA and (■) 100 μM EP on the SU-8 microchip with integrated platinum film detector. *Conditions*: running buffer: 25 mM MES-His pH = 5.7, V_{sep} = +750 V; V_{inj} = +250 V for 5 s.

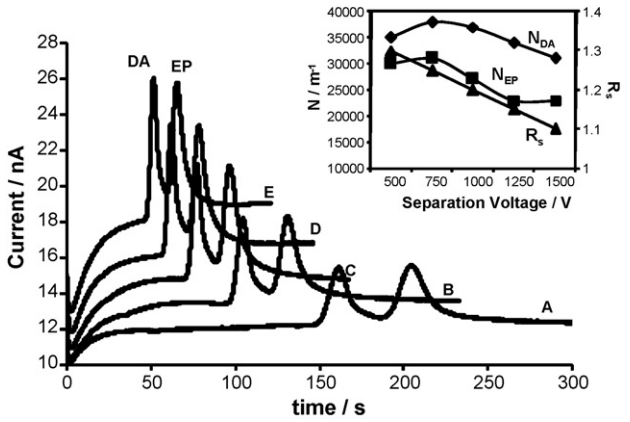

Fig. 5. Influence of the separation voltage on the detection of 100 μM DA and EP on the SU-8 microchip. *Separation voltages*: +500 (A), +750 (B), +1000 (C), +1250 (D) and +1500 V (E). Also shown (inset) the effect of separation voltage upon the resolution (▲) and the theoretical plate number for (♦) DA and (■) EP. *Conditions*: running buffer: 25 mM MES-His pH = 5.7; V_{inj} = +250 V for 5 s, E_d = +1.2 V (*vs*. Pt).

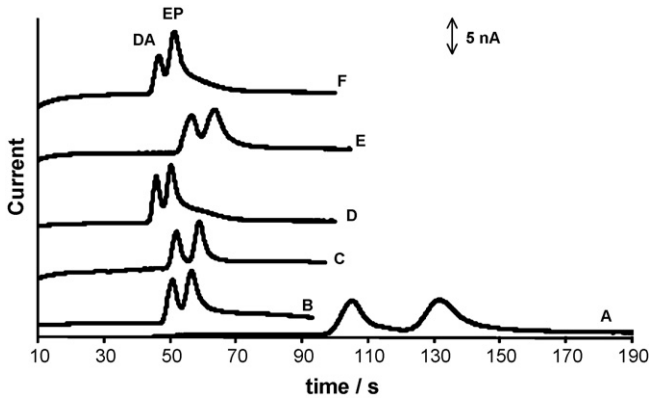

Fig. 6. Electropherograms for mixtures of 100 μM DA and EP in successive days; (A) day 1, (B) day 2, (C) day 3; with different pretreatments; (D) $HClO_4$ 0.1 M, (E) NaOH 0.1 M and (F) using 25 mM MES-His 0.1% Triton X-100 pH = 5.7 as running buffer on the SU-8 microchip. Conditions as in Fig. 5.

uration, the working electrode is outside the channel, and then, the separation voltage has a minimal influence on the baseline noise level because most of the voltage is dropped across the channel.

The precision of analytical signals on the SU-8 microchip with integrated platinum detector was evaluated from a series of repetitive injections of a sample mixture containing 100 μM DA and EP. The relative standard deviation (RSD) of peak current for ten successive signals was 1.8% ($i_{p(average)}$ = 6.4 nA) and 1.2% ($i_{p(average)}$ = 6.8 nA) for DA and EP respectively. RSD of migration time was 2.1% ($t_{m(average)}$ = 105.4 s) and 2.0% ($t_{m(average)}$ = 134.6 s) for DA and EP, respectively. No cleaning of the microchannel or the amperometric detector was necessary between measurements.

The end-channel Pt detector integrated on the SU-8 microchip displayed well-defined concentration dependence for DA and EP. Thus, a good linear relationship over a range of 0.5–200 μM with correlation coefficients (n = 8) of 0.9994 and 0.998 was obtained for DA and EP, respectively. The calibration plots showed sensitivities of 65 and 73 pA μM^{-1} for DA and EP, respectively. A detection limit of 450 nM was estimated for DA and EP considering a signal-to-noise ratio (S/N) of 3. This limit of detection (LOD) was found to be at the nM level, which is in the same order or lower than previous reports for microchips with electrochemical detection at carbon fiber [32,50,53,55], carbon-ink [48,54], CNT-modified gold [52], gold-coated platinum [30], pyrolyzed photoresist carbon [45], platinum [18] and palladium [22] films, where the LOD range was between 0.1 and 5 μM.

The reproducibility (day-to-day) of the analytical signals in the SU-8 microchip was also studied on successive days. Thus, the signals corresponding to the sample mixture containing 100 μM DA and EP in 25 mM MES-His pH = 5.7 were recorded in three successive days. Fig. 6A–C depicts electropherograms for the sample mixture of DA and EP in different days. After the first day (Fig. 6A), when the chip was emptied and newly filled a drastic change in the analytical signals was observed (Fig. 6B). Thus, the migration time decreased from 104.8 and 131.5 to 50.6 and 56.3 s for DA and EP, respectively. The peak current was slightly increased and the theoretical plate number was also enhanced from 39,000 ± 1000 and 30,000 ± 600 to 75,000 ± 2000 and 65,000 ± 1500 m^{-1} for DA and EP, respectively. However, a resolution of 1.1 ± 0.1, lower than the first day (1.55 ± 0.03), was obtained. In the third day (Fig. 6C), the migration time, the peak current and resolution (1.2 ± 0.1) was maintained and only a small increase in the plate numbers (79,000 ± 2500 and 70,000 ± 2500 m^{-1} for DA and EP, respectively) was achieved. Since microchip material is a photoresist, its structure could be modified in the successive days by chemical and light effects changing the different separation parameters. In the case of SU-8 microchips, no preconditioning with NaOH is made. This treatment is very common for other materials but epoxy groups would be open and a different surface is then presented. However, since SU-8 may change with time, studies are in progress in order to understand this behaviour and NaOH pretreatments are among those considered.

In order to get a better resolution of DA and EP, different pretreatments of SU-8 microchannels were evaluated. Firstly, the channels were washed with $HClO_4$ 0.1 M for 30 min. After this cleaning (Fig. 6D), the migration time decreased meanwhile the peak current and the plate number (92,000 ± 3000 and 72,000 ± 2000 for DA and EP respectively) were slightly increased. When the washing was made with an alkaline solution (NaOH 0.1 M, Fig. 6E), the migration time was newly increased and the peak current and the plate number (47,000 ± 4000 and 42,000 ± 4000 for DA and EP respectively) decreased drastically. Then, the channels were cleaned with other acid solution (H_2SO_4 0.1 M, data not shown), so the migration time decreased but the peak current and the plate number did not improve.

A small modification of the buffer was also made in order to enhance the analytical signals, thus, 0.1% Triton X-100 was added to MES based buffer. As is shown in Fig. 6F, the efficiency (64,000 ± 4000 and 49,000 ± 2000 N/m for DA and EP, respectively) of separation was slightly increased, however, this continued being worse than it was after perchloric acid pretreatment.

A singular fact happened when 25 mM MES-His pH = 5.7 with 0.1% SDS was employed as running buffer. In this case, the separation of DA and EP was initially improved with an increase of the resolution (data not shown), but suddenly, after various injections the resolution began to decrease until only one peak was recorded. Although the microchannels were cleaned with different solutions ($HClO_4$, NaOH and H_2SO_4), the microchip did not recover the efficiency and only one signal continued being recorded. Therefore, the SDS modified the channel surface in such a way it lost the capacity for performing separations and it was not possible to regenerate the surface again. In this study, SDS is employed in a concentration below the critical micellar concentration (8 mM). Then, the hydrophobic part of SDS can be adsorbed to the microchannel walls modifying the surface. In this way, in the first injections the channel is starting to be modified and resolution improves but modification seems to change with time and the final effect is a notable decrease of resolution.

The behaviour of the new SU-8 microchip with integrated electrochemical detection was finally compared with a commer-

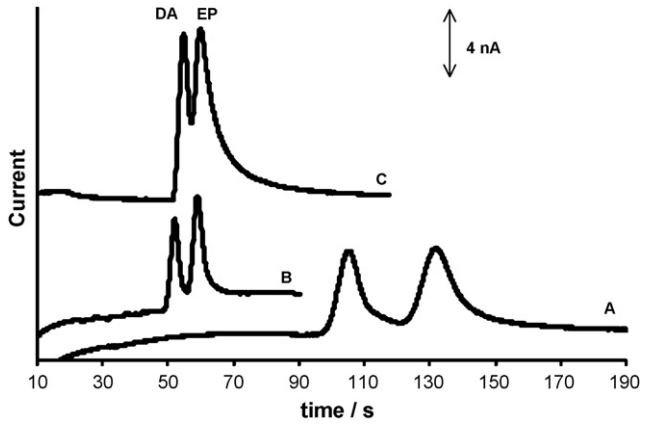

Fig. 7. Electropherograms for mixtures of 100 μM DA and EP using a SU-8 microchip with integrated platinum film detector in successive days; (A) day 1, (B) day 2; and using a Topas-microchip with an end-channel gold wire detector (C). *Conditions*: SU-8 microchip as in Fig. 5; Topas-microchip: running buffer: 25 mM MES-His pH = 5.7, V_{sep} = +2000 V; V_{inj} = +1500 V for 5 s, E_d = +1.2 V (*vs.* Ag/AgCl).

cial microchip. A Topas-microchip with an end-channel gold wire detector [57] was employed in this comparison. Fig. 7 displays the electropherograms for a mixture of DA and EP with the different microchips. The theoretical plate number (19,700 and 11,000 N/m for DA and EP respectively) and the resolution (0.5) in the Topas-microchip (Fig. 7C) were worse than SU-8 microchip, even in the three successive days (38,000 and 31,000 for DA and EP, Fig. 7A, and 73,000 and 71,000 m^{-1} for DA and EP, Fig. 7B). The SU-8 microchip with integrated amperometric detector has shown an excellent efficiency for DA and EP separation, which is in concordance with previous reports in different microchips made of glass [18,30,32,52,55], PDMS [54], PDMS/glass [22,45] or modified-PDMS [50,51,53], where the theoretical plate number range was between 10,000 and 150,000 N/m.

4. Conclusions

A new SU-8 microdevice has been fabricated for the first time with an integrated amperometric detector. After optimization of conditions, an adequate separation of DA and EP was achieved. Linearity between 0.5 and 200 μM with detection limits of 450 nM were found for both compounds. Intra-day precision results very adequate with values for RSD below 2% for ten measurements. Day-to-day precision suggests that these are single-day devices since after the first day, migration time and resolution decreases. Acid and basic solutions produce only slight changes. Treatment with SDS solution prejudices the separation of the analytes. Work is in progress in order to check new designs including multichannel configurations.

ABSTRACT

Multi-walled carbon nanotube decorated with silver nanoparticles (AgNPs-MWCNT) is used as an effective strategy for modification of the surface of pyrolytic graphite electrode (PGE). This modification procedure improved colloidal dispersion of the decorated MWCNTs in water, affording uniform and stable thin films for altering the surface properties of the working electrode. Robust electrode for sensing applications is obtained in a simple solvent evaporation process. The electrochemical behavior of sumatriptan (Sum) at the bare PGE and AgNPs-MWCNT modified PGE is investigated. The results indicate that the AgNPs-MWCNT modified PGE significantly enhanced the oxidation peak current of Sum. A remarkable enhancement in microscopic area of the electrode together with strong adsorption of Sum on the surface of the modified electrode resulted in a considerable increase in the peak current of Sum. Experimental parameters, such as scan rate, pH, accumulation conditions and amount of the modifier used on the PGE surface are optimized by monitoring the CV responses toward Sum. It is found that a maximum current response can be obtained at pH 7.4 after accumulation at open circuit for 150 s. Further experiments demonstrated that the oxidative peak currents increased linearly with Sum concentration in the range of 8.0×10^{-8}–1.0×10^{-4} mol L^{-1} with a detection limit of 4.0×10^{-8} mol L^{-1}. The modified electrode showed high sensitivity, selectivity, long-term stability and remarkable voltammetric reproducibility in response to Sum. These excellent properties make the prepared sensor suitable for the analysis in pharmaceutical and clinical preparations. The modified electrode was successfully applied for the accurate determination of trace amounts of Sum in pharmaceutical preparations.

1. Introduction

Sumatriptan (Sum), a triptan drug including a sulfonamide group, is used in human medicine for the treatment of acute migraine episodes (vascular headaches) [1,2]. Often, serotonin levels in the brain become extremely low before the onset of a migraine. Sum is administered to aid in leveling the serotonin levels in the brain. Sum is also shown to decrease the activity of the trigeminal nerve, which probably accounts for Sum's efficacy in treating cluster headaches. This type of headache is extremely painful and debilitating [3]. Large doses of Sum (200 mg day^{-1}) can cause sulfhemoglobinemia, a rare condition in which the blood changes from red to greenish-black, due to the integration of sulfur into the hemoglobin molecule. If Sum is discontinued, the condition reverses within a few weeks. Various techniques have been reported for the analytical determination of Sum in plasma and pharmaceutical formulations in the literature including: spectrophotometry [4,5], high performance thin layer chromatography (HPTLC) [5], capillary electrophoresis [6,7], high performance liquid chromatography (HPLC) with electrochemical detection [8,9], HPLC with fluorescence detection [10], HPLC with ultraviolet (UV) detection [11,12], liquid chromatography–mass spectroscopy (LC–MS) [13], liquid chromatography–electron spray ionization mass spectrometry (LC–ESI-MS) [14], liquid chromatography–mass spectrometry/mass spectrometry (LC–MS/MS) [15–18] and also, electroanalytical chemistry [19]. However, these methods suffer from some disadvantages such as high costs, long analysis times and requirement for complex and tedious sample pretreatment, and in some cases, low sensitivity and selectivity that makes them unsuitable for a routine analysis. It is essential to look for a new method with high sensitivity, simplicity and efficiency for the detection of this drug. Electrochemical techniques using modified electrodes

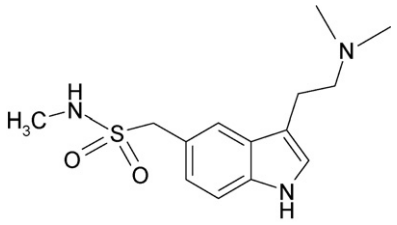
can be considered for the determination of Sum as a strong alternative to the mentioned methods.



Although Sum is an electroactive compound which can be oxidized electrochemically, only one work can be found in the literature describing the electrochemical analysis of this compound by means of differential pulse voltammetry using a glassy carbon electrode [19]. The electrochemical reaction of Sum at the bare electrode involves slow electron transfer kinetics that can be catalyzed by attaching a suitable electron transfer mediator to the surface. The electrode surface modification can facilitate charge transfer between the analyte and the electrode, thereby enhancing the sensitivity and selectivity of the analysis. To our knowledge, there are no antecedents found in the literature on using modified electrodes for determination of Sum. Modification of carbon electrodes is particularly easy and can be achieved either through physical adsorption of the modifier onto the carbon surface, or by covalent attachment of the modifier [20].

Since the discovery of multi-walled carbon nanotubes (MWCNTs) by Iijima [21], this material has attracted enormous interest because of its unique structural, mechanical and electronic properties. Some of these properties include high chemical and thermal stability, high elasticity, high tensile strength, and in some instances, metallic conductivity [22]. The modification of electrode substrates with MWCNT for use in analytical sensing is well documented to result in low detection limits, increased sensitivities, reduced overpotentials, and resistance to surface fouling.

The insolubility of CNTs in most solvents, however, limits their application in designing CNTs-based biosensing devices. The best solvents reported for effecting CNT dispersions are *N*,*N*-dimethylformamide and *N*-methylpyrrolidone [23]. Further, several strategies relied on dispersion in polyelectrolytes [24], Nafion [25,26] and surfactants [27,28] have been proposed for immobilization of CNT on electrochemical transducers. Unfortunately, the dispersions aggregate on a time scale of days.

Recent activity has focused on the development of nanoscaled particles applied in analytical chemistry for its special physicochemical characteristics [29,30]. Nanoparticle modified electrodes present unusual advantages in electroanalysis such as catalysis, enhancement of mass transport and high effective surface area [31,32]. In this region metal nanoparticles have attracted much more attention in electroanalysis because of their unusual physical and chemical properties. An interesting class of carbon nanotube derivatives results from deposition of metallic or semiconducting nanoclusters on the tubular surfaces [33–35]. Furthermore, uniform dispersion of metallic nanoparticles decorated on CNT surfaces can yield ideal nanocatalysts for application in chemically modified electrodes.

In the present work, we synthesized composite MWCNTs decorated with silver nanoparticles by a simple chemical plating method. Characterization of the morphology and nanoparticles distribution on the surface of the decorated MWCNT was performed by transmission electron microscopy (TEM). The excellent dispersibility of the resulting MWCNT decorated with silver nanoparticles in water leads to formation of a stable colloidal dispersion, which is capable to form a completely uniform and stable thin film on the surface of PGE. The prepared modified electrode was successfully applied for voltammetric determination of Sum in pharmaceutical samples. A good linear relationship was realized between the anodic peak currents and Sum concentrations in the range of 6.0×10^{-8}–1.0×10^{-4} mol L^{-1} with the detection limit of 4.0×10^{-8} mol L^{-1} and good reproducibility.

Scheme 1. Structure of sumatriptan.

2. Experimental

2.1. Chemicals and reagents

Sum, in the form of sumatriptan succinate (1:1) (>99.0% purity), was purchased from Natco India (Scheme 1). Multi-walled carbon nanotubes synthesized by catalytic chemical vapor deposition (CVD) method (purity more than 95%) with o.d. of 10–20 nm, i.d. of 5–10 nm and tube length of 0.5–200 nm was obtained from Nanostructured & Amorphous Materials (Houston, TX, USA). All other chemicals were of analytical reagent grade from Merck. All aqueous solutions were prepared with doubly distilled deionized water. Stock solutions of Sum were freshly prepared as required in appropriate buffer solution. In these experiments, a stock Britton–Robinson (BR) buffer solution was prepared which was 0.04 mol L^{-1} in each of glacial acetic acid, orthophosphoric acid and boric acid. Buffer solutions of varying pH were then prepared by the addition of 0.2 mol L^{-1} sodium hydroxide. Voltammetric experiments were carried out in the buffered solutions of Sum, deoxygenated by purging with pure nitrogen (99.999% from Roham Gas Company). Nitrogen gas was also maintained over the surface of the test solutions during the experiments. Tablets of Sum were purchased from Hakim Pharmaceutical Co. (Tehran, Iran).

2.2. Apparatus

Voltammetric experiments were performed using a Metrohm potentiostat/galvanostat model 797VA. A conventional three-electrode system was used with a basal plane pyrolytic graphite working electrode (BPPGE, unmodified or modified, $d = 3$ mm), a saturated Ag/AgCl reference electrode and a Pt wire counter electrode. A BPPGE, or an EPPGE (4.9 mm diameter, Le Carbone, Ltd., Sussex, U.K.) was used as the working electrodes. A digital pH/mV/Ion meter (CyberScan model 2500) was used for the preparation of the buffer solutions.

Electrochemical impedance spectroscopy (EIS) measurements were performed with a Potentiostat/Galvanostat/Frequency response analyzer (FRA) EG&G model 273A between 1 Hz and 1 kHz using a 5 mV rms sinusoidal modulation in 0.1 mol L^{-1} KCl solution of pH 7.0 containing 1 mmol L^{-1} of $K_4Fe(CN)_6$ and 1 mmol L^{-1} $K_3Fe(CN)_6$ (1:1) mixture, and at the $E_{1/2}$ of the $[Fe(CN)_6]^{3-/4-}$ (0.13 V vs. Ag/AgCl). All experiments were performed at 25 ± 1 °C. Solutions were deaerated by bubbling nitrogen prior to the experiments and the electrochemical cell was kept under a nitrogen atmosphere throughout the experiments.

2.3. Preparation of nanosilver decorated multi-walled carbon nanotube

The MWCNTs were purified in boiling concentrated nitric acid for 2 h, followed by rinsing with deionized water and drying at 383 K under dry N_2 atmosphere. Open-end MWCNTs with hydrophilic surface were thus obtained [36]. AgNPs-MWCNT was prepared by the reported procedure in literature [37]. In the first step, 1.0 g purified and functionalized MWCNTs was mixed with 50 mL mixture solution of 38% formaldehyde, absolute ethyl alcohol and double distilled water (volumetric ratio 3:10:10). In the second step, 50 mL

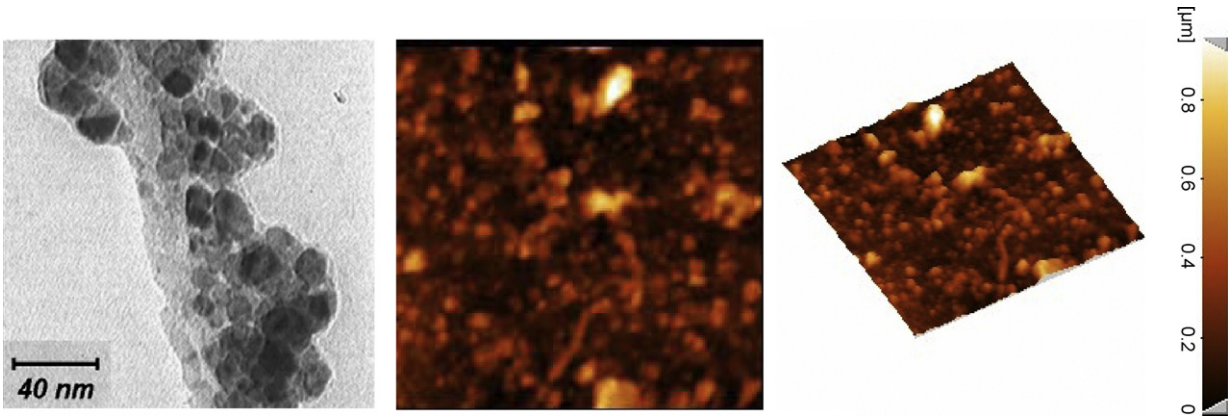


Fig. 1. Left: TEM image of MWCNTs decorated with silver nanoparticles. Right: AFM images of the surface of PGE decorated by the film of AgNPs-MWCNT.

mixture solution of 35 g L^{-1} silver nitrate ($AgNO_3$) solution and 25% ammonia solution (volumetric ratio 1:2) were dropped one by one into the mixture of MWCNT–formaldehyde–alcohol–water solution. The pH value of strongly stirred reacted solution was kept about 8–9. After completing the reaction, the product was centrifuged and washed by doubly distilled water several times then dried in vacuum oven at 60 °C.

2.4. Preparation of modified PGE

Before modification, the PGE was polished with 0.05 μm alumina slurry on a polishing cloth, rinsed thoroughly with doubly distilled water, and then sonicated in ethanol and doubly distilled water for 5 min, sequentially. The modifier suspension was prepared by dispersing 2 mg of the AgNPs-MWCNT in 2.0 ml of doubly distilled water under sonication for 30 min, giving a black dispersion that is quite stable for 4–5 months. The AgNPs-MWCNT modified PGE was prepared by casting 5 μL of the mentioned black suspension on the PG electrode surface using a micropipette and left to dry at room temperature. Before the voltammetric measurements, the modified electrode was cycled between 0 and 1 V (scan rate 100 mV s^{-1}) in 0.04 mol L^{-1} Britton–Robinson buffer solution pH 7.4 for several times until acquiring the reproducible responses. The surface morphology and the thickness of the film modifier on the surface of PGE were characterized by AFM experiments. AFM images were recorded in the contact mode in air with a MultiMode Nanoscope IV Microscope (Digital Instruments) at a scan rate of 0.50 Hz.

3. Results and discussion

3.1. Surface morphology of AgNPs-MWCNT/PG modified electrode

The surface morphology and distribution of Ag nanoparticles on the MWNT support surfaces was explored using TEM images. Fig. 1 shows the well dispersed/deposited Ag nanoparticles on the surface of MWCNTs. From the TEM images, the size of Ag nanoparticles decorated on MWCNTs was estimated to be 5–20 nm.

3.2. Electrochemical behavior of Sum at AgNPs-MWCNT/PGE

The electrochemical response of AgNPs-MWNT/PG electrode in purged N_2 Britton–Robinson buffer solution (0.04 mol L^{-1}, pH 7) is presented in Fig. 2A. A pair of redox peak was observed on the surface of AgNPs-MWCNT modified PGE at 0.26 and −0.23 V. It can be suggested that the observed redox peak is corresponding to the redox behavior of the Ag nanoparticles on the surface of the modified electrode, which proves that MWCNTs were decorated with AgNPs.

The electrochemical impedance spectroscopy (EIS) was employed to investigate the impedance changes of the electrode surface in the modified process. Fig. 2B shows the Nyquist

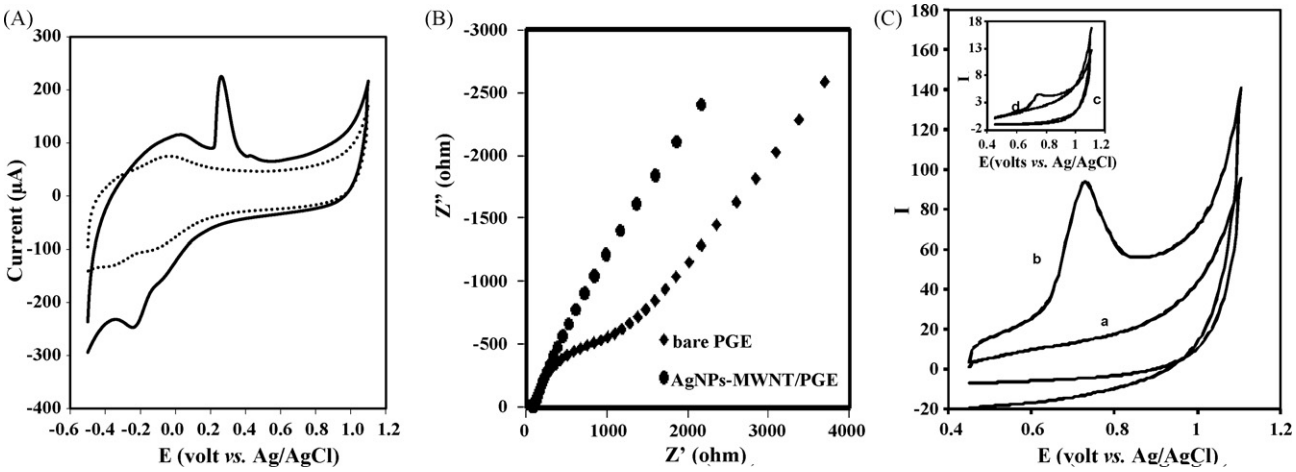

Fig. 2. (A) CVs of MWCNT/PGE (dashed) and AgNPs-MWCNT/PGE (solid) in 0.04 mol L^{-1} BR buffer solution (pH 7.4), (B) Nyquist diagram (Z″ vs. Z′) for the EIS measurements in 1 mmol L^{-1} $K_3Fe(CN)_6/K_4Fe(CN)_6$ in 0.1 mol L^{-1} KCl at the $E_{1/2}$ = 0.13 V for the bare PGE (■) and AgNPs-MWCNT/PGE (●) and (C) CVs of AgNPs-MWCNT/PGE in 0.04 mol L^{-1} BR buffer solution (pH 7.4) containing various concentrations of Sum: (a) 0.0 μmol L^{-1} and (b) 10 μmol L^{-1}; scan rate 100 mV s^{-1}. Inset shows CVs of bare PG electrode with: (c) 0.0 μmol L^{-1} and (d) 10 μmol L^{-1} Sum.

plots of $K_3Fe(CN)_6/K_4Fe(CN)_6$ at the bare PGE and the AgNPs-MWNT/PGE. High frequency zone is ascribed to the ohmic process within porous structure and the low frequency zone to the kinetic impedance of electrochemical reaction. As can be seen, a semicircle with a very large diameter is observed at the bare PGE. However, the diameter of the semicircle is significantly reduced at AgNPs-MWNT/PGE, suggesting that the surface of modified electrode exhibits lower electron transfer resistance and greatly increases the electron transfer rate.

The high electroactive surface area and excellent electronic conductivity of the decorated MWCNT make this material an attractive candidate for use as an active electrode modifier [38]. Fig. 2C shows voltammetric behavior of 10 μmol L^{-1} Sum at AgNPs-MWCNT/PGE and the bare PGE, recorded in the 0.04 mol L^{-1} BR buffer solution (pH 7.4) following 150 s accumulation at open circuit at the scan rate of 100 mV s^{-1}. Obviously, Sum's response at bare PGE is rather poor and only a weak oxidation peak is observed at 0.75 V (curve a). However, the current obtained at the AgNPs-MWCNT/PGE (curve b) is significantly larger (about 33 times) than that obtained at the bare PGE, probably reflecting the larger surface area of the modified electrode. Furthermore as shown in Fig. 2C, the ratio of faradic peak current for oxidation of Sum to background current on the AgNPs-MWCNT/PGE is much more than the bare PGE confirming that the adsorption is much stronger on the modified electrode. By considering the slight shift in the peak potential, with respect to the unmodified electrode, the observed enhancement in voltammetric response at the AgNPs-MWCNT/PGE is attributed to the increased electrode surface area and the strong adsorption of analyte on the surface of the modified electrode as a consequence of the AgNPs-MWCNT coating. Additionally, owing to the large surface area of MWCNTs, the higher background current of the modified electrode than that of the bare PGE is observed but the baseline remains flat. During these experiments, no cathodic peak is resulted for Sum during the reverse scan, suggesting a totally irreversible behavior for the electrode process.

The microscopic areas of the modified and the bare PGE were obtained by CV method and using $K_3Fe(CN)_6$ as a probe at different potential scan rates [39]. A pair of well-defined peaks was observed at about 0.2 V with peak separation of 0.077 V on the AgNPs-MWCNTs/PGE. For a reversible process, the following Randles–Sevcik formula has being used:

$$i_{pa} = 2.69 \times 10^5 n^{3/2} A C_0 D_R{}^{1/2} \nu^{1/2} \quad (1)$$

where, i_{pa} refers to the anodic peak current, n the electron transfer number, A the electroactive surface area of the electrode (cm^2), D_R the diffusion coefficient, C_0 the concentration of $K_3Fe(CN)_6$ and ν is the scan rate. From the slope of the i_{pa} vs. $\nu^{1/2}$ relation, the microscopic areas can be calculated. For 1 mmol L^{-1} $K_3Fe(CN)_6$ in the 0.1 mol L^{-1} KCl electrolyte, $n = 1$, $D_R = 7.6 \times 10^{-6}$ cm^2 s^{-1}, the electrode surface area of the AgNPs-MWCNT/PGE was 0.17 cm^2 and for bare PGE was 0.06 cm^2, indicating that the microscopic area of the AgNPs-MWCNT/PGE increased significantly and was about 2.8 times larger than the microscopic area of the bare PGE.

3.3. Optimization of the amount of the modifier

As above-mentioned, by introducing AgNPs-MWCNT on the surface of the PGE, a considerable enhancement is resulted in the electrochemical behaviors of Sum. It is obvious that the response of the modified electrode toward Sum can be affected by the amount of AgNPs-MWCNT on the electrode surface. This can be controlled by using the same volume (5 μL) of the suspensions with the different concentrations of AgNPs-MWCNT, casted on the surface of PGE. The experiments showed that, the oxidation peak current for 0.1 mmol L^{-1} Sum increased quickly by increasing the concentration of AgNPs-MWCNT suspension deposited on the surface of PGE up to 1 mg mL^{-1} (Fig. 3A). Further increase, caused a gradual decrease in the anodic peak current of Sum with increase in background current. As a result, 5 μL of 1 mg mL^{-1} AgNPs-MWCNT suspension was selected as optimum volume for preparation of the modified electrode.

3.4. Effect of accumulation potential and time

The considerable enhancement in the electro-oxidation peak current of Sum on the surface of the modified electrode is in part attributed to the strong adsorptive ability of the AgNPs-MWCNT film on PGE. It is important to fix the accumulation potential and time when adsorption studies are undertaken. Both the conditions could affect the amount of adsorption of Sum at the modified electrode. Therefore, the effect of accumulation potential and time on the peak current in the solution with 50 μmol L^{-1} of Sum was studied by CV. The oxidation peak current of 50 μmol L^{-1} Sum was compared after 150 s accumulation at different potentials. The results showed that oxidation peak current remained almost constant as accumulation potential was changed from −0.5

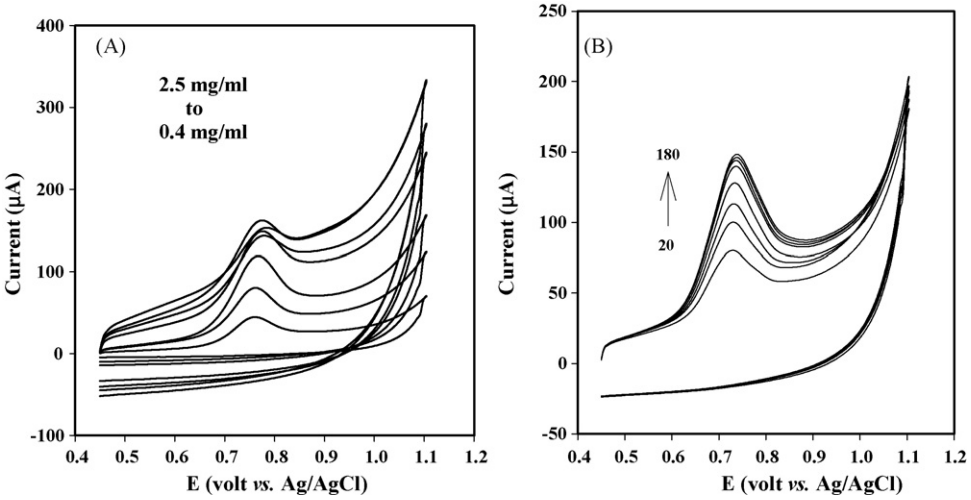

Fig. 3. (A) CVs of 50 μmol L^{-1} of Sum on the surface of the PGE decorated with 5 μL of suspension containing various amounts of AgNPs-MWCNT and (B) effect of accumulation time (min) on the CV of 50 μmol L^{-1} of Sum on the surface of the AgNPs-MWCNT/PGE. Supporting electrolyte was 0.04 mol L^{-1} BR buffer solution of pH 7.4 and sweep rate was 100 mV s^{-1}.

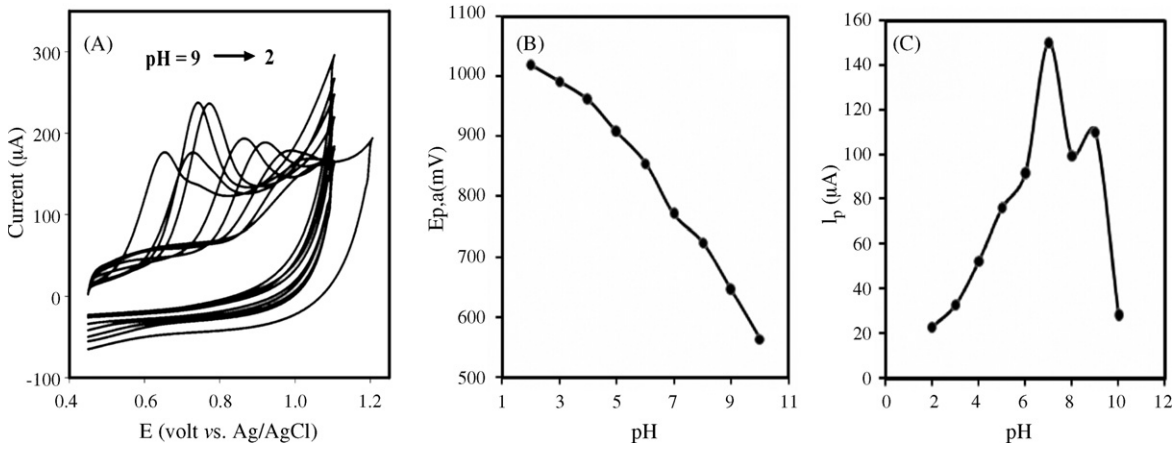

Fig. 4. (A) CVs of 50 μmol L^{-1} Sum at the AgNPs-MWCNT/PGE in various pHs (from 2 to 9: 2, 3, 4, 5.0, 5, 6.0, 7, 7.4, 8.0, 9.0) of buffer solution, dependence of (B) the oxidation peak potential (E_{pa}) and (C) the oxidation peak current (i_{pa}) with pH solution; scan rate 100 mV s^{-1}.

to 0.5 V, revealing that the accumulation potential has no influence on the oxidation peak current of Sum (Fig. 3B). Moreover, compared with an open circuit, accumulation potential had no obvious effect. Hence, the accumulation of Sum was carried out under open circuit. By increasing the accumulation time, the peak current significantly increased. The results indicated that, as the adsorptive equilibrium was reached (longer accumulation times), the amount of the adsorbed analyte (and therefore, the resulted peak currents) is increased. The oxidation peak current increased quickly within 100 s and then showed a very slow increase from 100 to 180 s. Further increasing the accumulation time would cause the peak currents to level off, so the accumulation time was set at 150 s.

3.5. Influence of pH

To optimize the experimental conditions for the determination of Sum, the effects of the composition of the buffer systems (such as phosphate, Britton–Robinson or acetate buffer) were examined. The results showed that the highest oxidation peak current for Sum can be obtained in Britton–Robinson buffer. Then, the influence of pH on the electrochemical behavior of Sum was investigated at different pH values in the range of 2.0–10.0 using 0.04 mol L^{-1} Britton–Robinson buffer as supporting electrolyte. Fig. 4A shows the CVs of 50 μmol L^{-1} Sum on the surface of the modified electrode over the discussed pH range at the potential scan rate of 100 mV s^{-1}. It was found that the peak potential shifted negatively with increasing pH (suggesting participation of H^+ in the oxidation process) and a good linear relationship was observed between the E_p and pH values (in the range of 3–9, Fig. 4B) with the following equation:

$$E_{pa}(\text{mV}) = -62.13\,\text{pH} + 1206 \quad (R^2 = 0.9870) \tag{2}$$

A value of about −62.21 mV per pH unit clearly indicates that equal numbers of electrons and protons are involved in the electro-oxidation of Sum on the surface of the modified electrode. On the other hand, the anodic peak current showed to be increased by the pH from 2 to 7.4. However, further increase in the pH of the buffer solution would make the peak height decrease slowly (Fig. 4C). Therefore, Britton–Robinson buffer with pH 7.4 was used as supporting electrolyte in all voltammetric determinations.

3.6. Effect of potential scan rate

Useful information involving electrochemical mechanism usually can be gained from the investigation of CVs in the different potential sweep rates. Therefore, the CV investigations for 50 μmol L^{-1} Sum were performed on the surface of the AgNPs-MWCNT/PGE in buffered solution of pH 7.4 at different potential sweep rates. Fig. 5A illustrates the influence of scan rate on the cyclic voltammograms of Sum in the range of 25–450 mV s^{-1}. A slope of 0.707 was revealed for the linear relation between the log(i_{pa}) and the log(ν) (Fig. 5B) indicating a mixed adsorption–diffusion

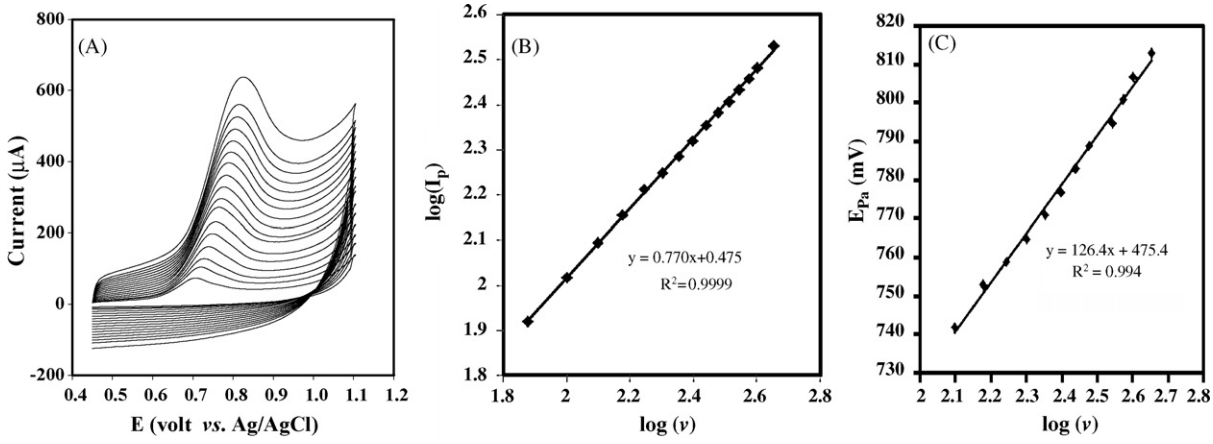

Fig. 5. (A) CVs of 50 μmol L^{-1} Sum at the AgNPs-MWCNT/PGE at different scan rates in 0.04 mol L^{-1} BR buffer solution (pH 7.4), (B) the plot of log(i_{pa}) vs. log(ν), and (C) variation of peak potential (E_{pa}) with log(ν).

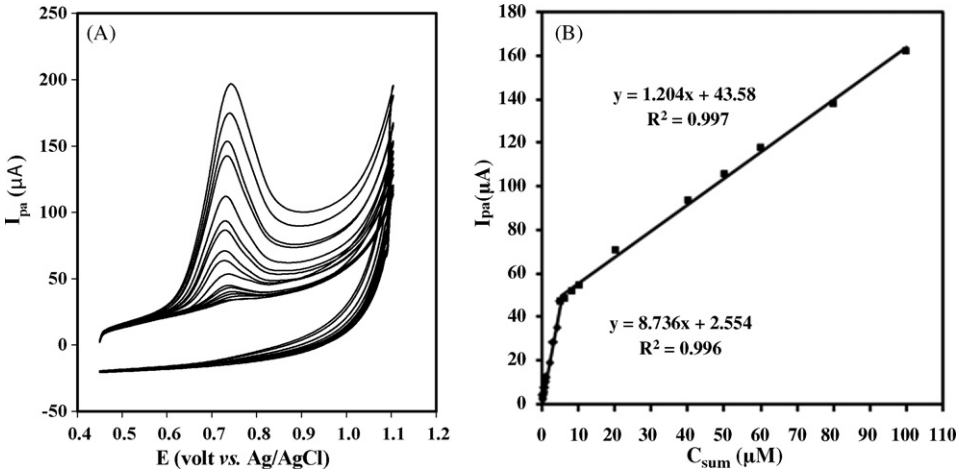

Fig. 6. (A) CVs for various concentrations of Sum in the range of (down to up), 0.08–80 μmol L^{-1} in 0.04 mol L^{-1} BR buffer solution (pH 7.4) and (B) corresponding linear calibration curve of peak current vs. Sum concentration; scan rate 100 mV s^{-1}.

controlled process on the surface of the modified electrode. The regression equation for this relationship is:

$$\log(i_{pa}) = 0.770 \log(\nu) + 0.475 \quad (R^2 = 0.9990;\ i_{pa}:\ \mu A,\ \nu:\ mV\,s^{-1}) \tag{3}$$

The relationship between the oxidation peak potential and scan rate is shown in Fig. 5C. It can be seen that the oxidation peak potential shifts positively with increasing scan rate. There is a linear relationship between E_p and the logarithm of the scan rate, Eq. (4). Such a behavior reveals the irreversible nature of the electrochemical process for Sum. Furthermore, only an oxidation peak was observed even at low scan rates, suggesting that the electrode reaction of Sum under these conditions were totally irreversible:

$$E_p = 126.4 \log \nu + 475.4 \quad (R^2 = 0.9940;\ E_p:\ mV,\ \nu:\ mV\,s^{-1}) \tag{4}$$

This behavior is in conformity with the equation for irreversible electrochemical processes [40]:

$$E_p = \left(\frac{1}{2}\right) b \log \nu + a \quad \left(b = \frac{2.303RT}{(1-\alpha)n_a F}\right) \tag{5}$$

where, α is the transfer coefficient, n_a the number of electrons involved in the rate-determining step of the electrode process, F the Faraday constant, R the gas constant and T is the absolute temperature.

The Tafel plot and its corresponding slope were used for elucidating the mechanism of the electrode process. The polarization curves (log I/E plots) for the electro-oxidation of Sum on the surface of the modified electrode were obtained at various potential sweep rates. The slopes of Tafel plots show $(1-\alpha)n_a$ values between 0.42 and 0.36 for potential sweep rates in the range of 50–250 mV s^{-1}. By considering $n_a = 1$, the value of α was calculated to be in the range of 0.58–0.64, which indicates that the activation free energy curve is not symmetrical in such an irreversible oxidation process.

3.7. Voltammetric determinations, reproducibility evaluations

The relationship between the oxidation peak current and the concentration of Sum was examined by CV on the surface of AgNPs-MWCNT/PGE, and the results are shown in Fig. 6A. Under the previous mentioned optimum conditions, the oxidation peak currents were proportional to Sum concentrations over two intervals in the range of 8.0×10^{-8}–5.0×10^{-6} and 5.0×10^{-6}–1.0×10^{-4} mol L^{-1} in 0.04 mol L^{-1} Britton–Robinson buffer solution (pH 7.4) (Fig. 6B). The linear regression equation for first region was:

$$i_{pa}(\mu A) = 8.736\, C(\mu mol\,L^{-1}) + 2.554 \quad (R^2 = 0.9960) \tag{6}$$

and for second region was:

$$i_{pa}(\mu A) = 1.204\, C(\mu mol\,L^{-1}) + 43.58 \quad (R^2 = 0.9970) \tag{7}$$

The break in the calibration curve of Sum probably reflects the formation of a sub-monolayer in the first range of calibration and the formation of a monolayer in the second range. Using the first range of this calibration plot, the detection limit ($S/N = 3$) of 40 nmol L^{-1} is obtained for Sum. This indicates that the system is quite sensitive in comparison with that reported [19]. After each determination, the modified electrode was refreshed by successive cyclic voltammetric sweeps between 0.0 and 1.0 V in a buffer solution about three cycles.

3.8. Repeatability, stability and reproducibility of the modified electrode

The repeatability of the modified electrode was investigated by repetitive recording at a fixed Sum concentration of 1×10^{-5} mol L^{-1}. The RSD for the peak currents in CVs based on six replicates was 2.9%, indicating excellent repeatability of the response of the modified electrode. Also, on using the AgNPs-MWCNT/PGE daily and storing under ambient conditions over a period of 3 weeks, the electrode retained 96.4% of its initial peak current response for a Sum concentration of 1.0×10^{-5} mol L^{-1}, which shows long-term stability of the film modifier on the surface of PGE. As well the fabrication reproducibility was evaluated by preparing five modified electrodes independently. The RSD for the peak current determinations with five prepared electrodes on 5.0×10^{-5} mol L^{-1} Sum was calculated to be 3.8% (for averages of five determinations on each electrode). The results indicate that the modified electrode has an excellent repeatability and reproducibility in both preparation procedure and voltammetric determinations with good long-term stability.

3.9. Determinations in sumatriptan succinate tablets

To assess the applicability of the proposed method, the AgNPs-MWCNT/PGE was used to determination of the content of Sum in "sumatriptan" tablets as a real pharmaceutical sample by applying CV method. Four tablets containing labeled amounts of 50 mg Sum were accurately weighted and ground to a fine powder. The amount

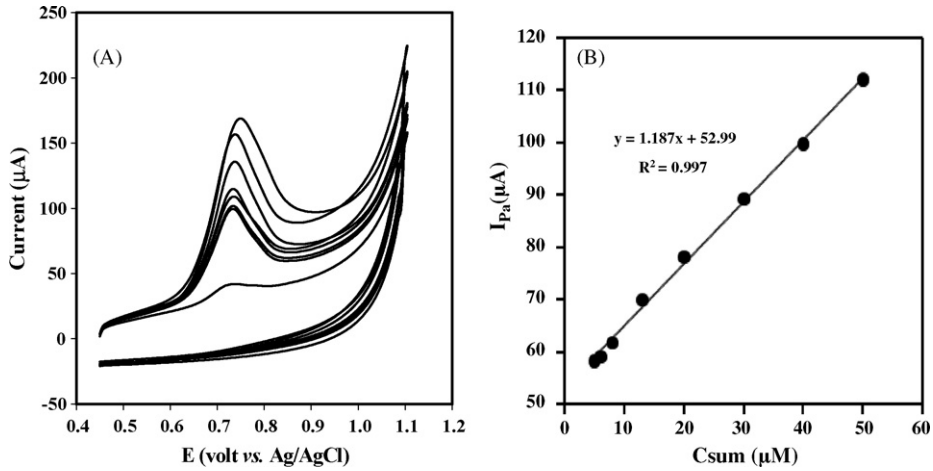

Fig. 7. (A) CVs for the addition of different amount of Sum (from down to up: 5, 6, 8, 13, 20, 30, 40, 50 μmol L^{-1}) in the real sample solution Sum diluted with 0.04 mol L^{-1} BR buffer solution (pH 7.4) at the AgNPs-MWCNT/PGE; scan rate 100 mV s^{-1} and (B) the plot of peak current vs. added concentration of Sum.

Table 1
Results of the recovery analysis of Sum spiked in tablet samples.

No	Spiked (μM)	Expected (μM)	Found[a] (μM)	Recovery (%)
1	0	5	4.93	–
2	0.5	5.5	5.30	96.44
3	1	6	6.06	101.02
4	5	10	10.15	101.50
5	10	15	15.78	105.13
6	50	55	54.89	99.80

[a] Average of four replicate measurements (rounded).

equal to 10 mg of the powdered sample was dissolved in 100 ml of 0.04 mol L^{-1} Britton–Robinson buffer solution of pH 7.4 to get a nominal concentration of 3.39×10^{-4} mol L^{-1}. Then a nominal concentration of 1×10^{-5} mol L^{-1} was achieved with further diluting with the same buffer solution. A 2.0 ml portion of the resulted solution was transferred to a 25 ml volumetric flask and spiked with the standard Sum solution in the range of 5×10^{-6}–5×10^{-5} mol L^{-1}. The CVs for various spiked solutions of Sum are shown in Fig. 7A. The linear dynamic range and the slopes of the calibration curves of the standard addition method were utilized to the evaluation of the recovery of the presented procedure. The equation for the resulting standard addition-calibration plot of peak current vs. concentration of Sum added was:

$$i_{pa}(\mu A) = 1.187C_{Sum}(\mu mol\,L^{-1}) + 52.99 \quad (R^2 = 0.9970) \qquad (8)$$

Although the accuracy was calculated on the recovery of known amounts of the standard Sum solution spiked in tablet solution. Spiked samples were prepared at five levels. The results are demonstrated in Table 1, and the recoveries were in the range from 96.44% to 105.13%. Using this standard addition method, the Sum content was obtained to be 49.30 mg with a RSD of 4.3% ($n = 4$) per tablet, which is very close to the labeled amount 50.0 mg.

4. Conclusions

In this work, it was demonstrated that modification of PGE with MWCNTs decorated with silver nanoparticles is a new and effective method for obtaining highly sensitive electrodes for electrochemical measurements. The procedure enables preparation of highly stable and reproducible uniform modifier films, which leads to a considerable enhancement in repeatability and reproducibility in the voltammetric measurements. A remarkable enhancement in microscopic area of the electrode together with effective accumulation of Sum on the surface of the modified electrode resulted in a considerable increase of the peak current of Sum. High sensitivity and improved detection limit of the AgNPs-MWCNT/PGE are promising for the determination of trace amounts of SUM in pharmaceutical and clinical preparations.

ABSTRACT

The assessment of physico-chemical properties in forest soils affected by fires was evaluated using near infrared reflectance (NIR) spectroscopy coupled with chemometric methods. In order to describe the soil properties, measurements were taken of the total organic carbon on solid phase, the total nitrogen content, the organic carbon and the specific absorbences at 254 and 280 nm of humic substances, organic carbon in humic and fulvic acids, concentrations of NH_4^+, Ca^{2+}, Mg^{2+}, K^+ and phosphorus in addition to NIR spectra. Then, a fire recurrence index was defined and calculated according to the different fires extents affecting soils. This calculation includes the occurrence of fires as well as the time elapsed since the last fire. This study shows that NIR spectroscopy could be considered as a tool for soil monitoring, particularly for the quantitative prediction of the total organic carbon, total nitrogen content, organic carbon in humic substances, concentrations of phosphorus, Mg^{2+}, Ca^{2+} and NH_4^+ and humic substances $UVSA_{254}$. Further validation in this field is necessary however, to try and make successful predictions of K^+, organic carbon in humic and fulvic acids and the humic substances $UVSA_{280}$. Moreover, NIR coupled with PLS can also be useful to predict the fire recurrence index in order to determine the spatial variability. Also this method can be used to map more or less burned areas and possibly to apply adequate rehabilitation techniques, like soil litter reconstitution with organic enrichments (industrial composts) or reforestation. Finally, the proposed recurrence index can be considered representative of the state of the soils.

1. Introduction

The Mediterranean region is seriously affected by forest fires. Each year more than 50,000 fires burn an estimated average of 600,000–800,000 ha. This area represents 1.3–1.7% of the total Mediterranean forests [1]. The studied Mediterranean ecosystem is situated in the Maures Mountains, in the south-east of France, near Sainte Maxime and Saint Tropez. Every year, forest fires cause a lot of damage in this area. Indeed, many physical, chemical, mineralogical and biological soil properties can be affected by forest fires [2]. The extent and duration of the effects of fire depend on the severity of the fire. They are controlled by several environmental factors that affect the combustion process, such as quantity, nature and moisture of live and dead fuel, air temperature and humidity, wind speed and topography of the site [2]. As a remark, it is quite impossible to obtain this data "*a posteriori*". The status of Mediterranean ecosystems may be balanced with the fire, up to a certain point depending on the frequency of the fires. A high frequency may lead to a significant degradation of the environment and to a reduction of ecological and remediation potentialities. The study of burned soils is necessary to estimate the degradation of soils and to apply adequate rehabilitation techniques like organic enrichment or reforestation. However, it would be very interesting to study the spatial variability of soils affected by fires and to map more or less affected areas taking into account fire frequencies. For such a study in a large area, it is necessary to connect observed changes with an estimation of fire frequencies. Fire-frequency, commonly used for describing or assessing fire regimes, is a rather complex concept which can be based on several descriptors, taking into account time or space, or both time and space [3]. The number of fires at a given point in a given time unit, is the simplest time-based definition for fire-frequency [4]. In such a case, fire interval can be calculated as the average time between two fires, generally many years in forest environments. However fire frequency can also be assessed with the distribution of intervals between two fires, or the average age of forest whose age distribution fits a mathematical distribution, for example negative exponential or Weibull [5]. In this work, a fire recurrence index was built, tested and calculated in order to display

doi:10.1016/j.talanta.2009.06.028

numerical values representative of the different fire conditions that affect the different soils.

Physico-chemical analyses can also be planned in order to manage the forest, such as organic carbon content, nitrogen content, nutrients and humic substances. However, these techniques are time consuming, expensive and sample destructive. Moreover, a single parameter is insufficient to give an accurate evaluation of the soil alteration. That is why several parameters need to be taken into consideration. So, reliable, inexpensive methods have to be developed for soil analyses.

Near infrared reflectance (NIR) spectroscopy is a fast, simple and non-destructive analytical method, with no chemical reagent needed and it is also cost effective. NIR spectroscopy is an alternative method replacing usual physico-chemical analysis. Moreover, the sample preparation is very easy and "*in situ*" technology application is available. Such advantages lead to an emerging awareness of near infrared spectroscopy as a tool for environmental and biological analyses. NIR spectra contain a wide variety of information due to the absorption of NIR radiation by organic matter, particularly the overtone and combination bands of C—H, N—H, S—H, O—H and O═C bonds. As a consequence of overlapping bands, it is impossible to directly interpret a spectrum by correlating the intensity or the peak areas with concentrations. That is why NIR spectroscopy should be coupled with statistical methods. Previous works [6–15] have shown the usefulness of NIR spectroscopy for soil analyses in the prediction of some physico-chemical properties, like moisture, organic carbon content, nitrogen content, cation exchange capacity and nutrients (Mg^{2+}, Ca^{2+}, K^+, NH_4^+, etc.). In addition, a recent study [16] shows the successful use of burned soils to predict maximum temperature of fires. So, NIR spectroscopy could be a valuable tool for soil characterization and management.

In this work, we have monitored the changes in various physico-chemical characteristics of forest soils affected by different fire recurrences. The measured parameters, in addition to NIR spectra, were total organic carbon, total nitrogen content, aromaticity and organic carbon in humic substances, organic carbon in humic and fulvic acid fractions, NH_4^+, Mg^{2+}, Ca^{2+} and K^+ contents.

The aim of this study was to build a numeric model for the prediction of these parameters on the basis of chemometric analyses of NIR spectra of soils samples. A prediction was made of the proposed recurrence index as well as the number of fires and the duration of time since the last fire. The main advantage was to centralize all analyses in one device which can be used "*in situ*" by low skill level operators. The evaluation of the impact of different fire events on forest soils using near-infrared spectroscopy and multivariate calibration was explored. The aim of the evaluation of fire perturbations was to select the most sustainable management practices.

2. Experimental

2.1. Sampling

The studied area is a Mediterranean ecosystem situated in the Maures Mountains, in the south-east of France (Fig. 1). The annual average rainfall is about 800–1200 mm. The monthly temperature in the area fluctuates from 12 °C in December and January to 30 °C in August; annual average temperature is 20 °C. Regarding vegetation, non-disturbed forest soils presents a tree stratum of *Quercus ilex* L., *Quercus suber* L., *Pinus pinaster Aiton* subsp. *pinaster*. Soils recently affected by fires show a total elimination of the vegetation cover

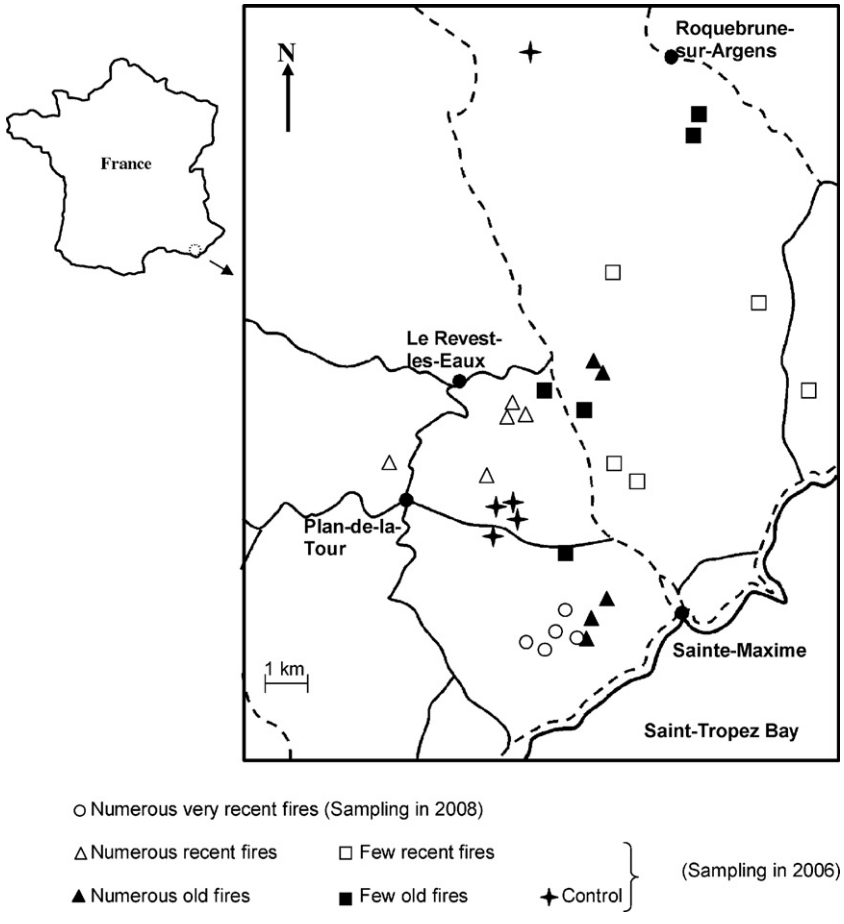

Fig. 1. Location of the sampling sites in the south-east of France.

Table 1
Number and dates of the fires affecting the different studied sites.

Condition	Number of fires	Dates of forest fire events	Fire recurrence index, RI
Control (C)	Unburned until 1950	0.13	
	Unburned until 1950	0.13	
	Unburned until 1950	0.13	
	Unburned until 1950	0.13	
	Unburned until 1950	0.13	
Few, old (FO)	2	1990/1964	0.33

	4	2007/1985/1978/1964	1.13

with a reconstitution of the vegetal cover more or less advanced, mainly occupied by herbaceous, fast growing species, *Erica arborea* L., *Cistus monspeliensis* L., *Q. suber* L. This latter species is also present in these sites due to its high capacity of regeneration after fires.

In our studied area, the fire regime in recent years is correctly known through fire history maps including all medium and larger fires since 1950. These maps were used to select the plots. However, due to the broad spatial distribution of these plots, several fire regimes could be found for the same number of fires, with different fire dates. The chosen sites involve areas unburned for 50 years and areas affected by different fire regimes. So, soil samples were collected at 30 different sampling sites (Fig. 1 and Table 1) in order to represent 6 different fire conditions (NVR: numerous very recent fires, NR: numerous and recent fires, NO: numerous and old fires, FR: few and recent fires, FO: few and old fires, C: control sites, unburned since 1950), with 5 different sites for each condition. These sites are relatively preserved from human impact and have been chosen amongst others for this reason. Moreover, they present similar aspect, exposition, slope, altitude and ecological characteristics. So, in this work the "fire factor" was the sole studied influencing factor.

First, the soils NR, NO, FR, FO and C were sampled in May 2006 for two layers (A: 0–5 cm and B: −5 to 15 cm). Then, according to the first results, a second sampling was done in May 2008, only for the A layers of NVR soils.

To take soil heterogeneity into consideration as much as possible, sampling was carried out on five positions at each site, resulting in 5 replicates per layer and per site. Then, equal volumes of the five replicates were mixed, homogenized and sieved (2 mm), to obtain one composite sample per site and per layer. The soil samples were then stored in glass bottles at −18 °C before analysis. Each sample was divided into two equal parts: one for physico-chemical analyses, and another for near infrared spectroscopy.

2.2. Fire recurrence index

To take into account the resilient dynamics of studied parameters, fitting fire-frequency to these parameters required a fire-frequency index (FRI). This had to be designed to include not only the number of fires, but also their dates and the time interval between fires.

So, a fire recurrence index was defined and calculated for all soils in order to assess the number and the date of fires according to Eq. (1).

$$\mathrm{RI} = \sqrt{\sum_{i=1}^{n} \frac{i}{S - F_i}} \quad (1)$$

where S is the sampling year, n the total number of fires, i the number of the fire from more recent to older fires (1 for the most recent, 2 for the second most recent, etc.) F_i the years of the fire i.

This equation takes into account the date of the fires by the difference between the year of sampling and the year of fires in the denominator. The more recent the fire, the greater the result of the division. Then, the number of fires appears by the number of divisions, with a multiplying factor to accentuate the fact that many fires have a bigger impact on the soils. Finally, a square root of the sum is applied to reduce the variability of the values displayed for very recent fires.

2.3. Physico-chemical analyses

Humic substances (HS), humic acids (HA) and fulvic acids (FA) amounts were obtained after alkali extraction (pH 13.0 for 20 h) and precipitation of humic-like fraction (pH 1.0) by addition of 6 mol l^{-1} HCl. Then, FA were cleaned-up with a column packed with XAD-8 resin. This method was adapted from [17].

HS, HA and FA in solution were analyzed using a high temperature combustion carbon analyzer (Shimadzu TOC analyzer 5050A, Shimadzu) in order to determine organic carbon concentrations (OC). Before analysis, all fractions were acidified to pH 2.0 with HCl to eliminate residual inorganic carbon and then N_2 bubbled during 10 min to remove dissolved CO_2.

Total organic carbon (TOC) contents of soils were quantified with the same analyzer coupled with a solid module. Organic carbon concentrations were expressed in $g\,kg^{-1}$ of dried soil.

UV absorbance spectra were recorded at room temperature for HS. Acquisition was performed using 1 cm quartz cell with an UV–vis spectrometer (UV-light, Secomam, France). Data was processed using LabPowerJ™ software package (Secomam, France). Spectra were recorded with a resolution of 1 nm between 200 and 400 nm. UV specific absorbances (UVSA) were calculated at 254 and 280 nm according to the Eq. (2) [18,19].

$$\mathrm{UVSA}_{254} = \frac{\text{Absorbance 254 nm}}{\mathrm{OC(mg/l)}} \times 100 \quad (2)$$

The $UVSA_{254}$ and $UVSA_{280}$ represent the humic substance aromaticity.

The total nitrogen content ($g\,kg^{-1}$) was obtained with a combustion method NF ISO 13878. Ammonium plus ammonia nitrogen were extracted from soils in a KCl solution [20,21]. Ammonium content in the extract was determined by continuous flow colorimetry [22,23], and expressed in $mg\,kg^{-1}$.

Phosphorus contents, expressed in $g\,100\,g^{-1}$, were determined according to the Joret Hebert method [24,25] which is a standard method (AFNOR NF X 31-161).

Exchangeable potassium, magnesium and calcium contents ($g\,kg^{-1}$) were obtained by the standard method AFNOR NF X 31-108 which uses exchangeable cation extraction by ammonium acetate [26–28].

For the physico-chemical parameters, the standard error of every method (SEM) was calculated according to Eq. (3).

$$\mathrm{SEM} = \sqrt{\frac{\sum_{i=1}^{N_1}(X_i - \overline{X_1})^2 + \sum_{j=1}^{N_2}(X_j - \overline{X}_2)^2 + \sum_{k=1}^{N_3}(X_k - \overline{X_3})^2 + \cdots}{N_1 + N_2 + N_3 + \cdots + N_t}} \quad (3)$$

where i, j, k, ... are different samples analyzed with the same method; N_1, N_2, N_3, ... are the number of replicates for each sample; X are the measured values; $\overline{X}$ is the mean of the different X; N_t is the total number of samples.

We assumed that the random error sources are the same for all measurements, because the different samples have similar composition and have been analyzed with the same analytical method.

For each analytical method, the relative error of the method (REM) was also calculated according to Eq. (4).

$$\mathrm{REM} = \frac{\mathrm{SEM}}{\bar{Y}} \times 100 \quad (4)$$

where $\bar{Y}$ is the mean of the values measured by the corresponding analytical method.

2.4. Near infrared spectroscopy

Soils were dried and ground before spectroscopic analyses. Aliquots of around 50 g of soil samples were placed in a specific round glass-sampling cup.

Fourier transformation near infrared (FT-NIR) spectra were recorded in reflectance with an integration sphere using a Nicolet Antaris spectrometer interfaced to a computer. Spectra were computed at $8\,cm^{-1}$ resolution from 4500 to 10,000 cm^{-1} using Thermo Nicolet 2.1 software. Co-addition of 64 scans symmetrical interferograms was performed for each spectrum, resulting in 1557-absorbance point's spectra.

Three spectra per sample were collected at ambient temperature (total of 165 spectra). For each sample, the subset of 3 spectra was then reduced to 1 by working out an average. Lastly, for each sample measurement, the background correction was obtained using a clean empty glass cup before each sample scan. These latter spectra were then used for PCA and PLS (55 spectra). Spectral pretreatment and multivariate calibration were performed with Unscrambler (version 9.0 from CAMO, Norway).

2.5. Principal component analysis

Principal component analysis (PCA) is a method for extraction of the systematic variations in one data set [29]. This method can be used for visualizing information in large data sets as well as for interpretation [30]. In this work, PCA was employed to verify the feasibility of classifying soils according to the fire event that affects them. This tool can show if physico-chemical and spectral results are differentiated by the different kinds of fire events. So, two different PCA were achieved with the A layer of all the studied sites: one with the spectral data and another one with physico-chemical parameters. The second one also allowed us to understand the impact of fires on the physico-chemical properties of the soils. For the PCA with spectral data, multiplicative scatter correction (MSC) of the original spectra was used [31].

2.6. Partial least square regression

Partial least square (PLS) regression is a powerful multicomponent analysis. PLS [32–34] allows a sophisticated statistical approach using the full spectral region rather than unique and isolated analytical absorption bands.

In our case, we are only looking for physico-chemical modifications, i.e. total organic carbon, total nitrogen content, ammoniacal nitrogen, humic substances, humic and fulvic acids, using the same data processing.

The evaluation of the calibration performance was estimated by computing both the standard error of calibration (SEC) after comparing the real modification with the computed one for each component and the standard error of prediction (SEP) for the estimation of the prediction performance during the step of validation of the calibration equation. Additionally, we used the relative error of prediction (REP) that shows the predictive ability of the model.

With regards to calibration and prediction of the models; after rather inconclusive tests with different parts of spectra, the whole spectra were chosen to be used for calculation.

Firstly, the physico-chemical parameters of the soils were modeled by PLS1 with all samples both A and B layers. PLS1 is a version of the PLS method in which only one Y-variable is modeled. Models were constructed using full cross validation to define the factor number (FN). A set of 44 samples was then used for the calibration to establish the model. The validation set composed of 11 samples. One soil of each kind of fire event and each layer was randomly selected to constitute this validation set in order to evaluate the ability of the multivariate calibration method for prediction. The PLS1 regression was achieved with different spectroscopic pretreatments of the spectra: no data processing, MSC, standard normal variate (SNV), normalization, first derivative and smoothing [35]. In each case, we chose the pretreatment leading to the best correlation between spectra and physico-chemical data.

Then, in the same way as for physico-chemical data, three other variables were modeled by PLS1 with the multiplicative scatter corrected spectra only for the A layer. These variables are: number of fires (NF), time elapsed since the last fire (TE) and the fire

recurrence index. MSC was chosen because it displayed the best correlation between spectra and these three variables. The calibration and validation sets were constituted of 24 and 6 samples respectively.

3. Results and discussion

3.1. Fire recurrence index

To take into account the resilient dynamics of studied parameters, fitting fire-frequency to these parameters required a fire-frequency index. This had to be designed to measure not only the number of fires but also their dates, the time in between and the last fire, and the time interval between fires. An area-based index was not required as plots were considered as points in the landscape.

So, on the basis of the sampling year S, the total number of fires (n) and the date of the fires (F_i), the fire recurrence index was designed (i) to increase with the number of fires and (ii) to decrease in a negative exponential way with the time since the last fire. It was designed to fit in with what was observed with the dynamics of most of the parameters and, more generally (iii) to give more importance to recent fires than to old fires. FRI was computed with the Eq. (1) (see Section 2).

Fig. 2 shows the graphical results of RI calculated values by the simulation of different fire conditions with a sampling date in 2008. The abscissa axis represents the date of the last fire, which is the only variable in the FRI equation. For calculation with several fires, the other dates of fire are held fixed (captions in Fig. 2). FRI values were calculated in this way from 1 to 4 fires, moving the date of the last fire and changing intervals between fires.

The FRI values show that a hierarchy between the different fire recurrences exists according to both fire number and dates of the fires. Moreover, comparing results for the 2 conditions with 4 fires, the FRI values are greater when the fires are grouped around the same time than when they are becoming less frequent. So, the index takes into account the notion of a greater impact caused by frequent fires.

Table 1 shows the calculated FRI for all sites. The controls, unburned since 1950, present a FRI of 0.13. The highest value obviously corresponds to the more impacted site and reaches 1.22. It represents 5 fires about every 15 years since 1964, the last one being in 2007. The other values consequently range from 0.13 to 1.22, reaching about 0.25, 0.60, 0.65 and 0.78 for FO, NO, FR and NR respectively. So, the FRI values of the studied sites are arranged according to a "theoretical fire impact".

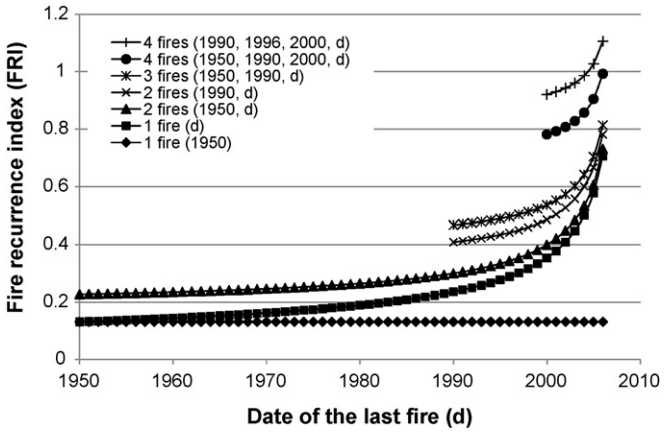

Fig. 2. FRI calculated values by the simulation of different fire conditions. Sampling date is 2008.

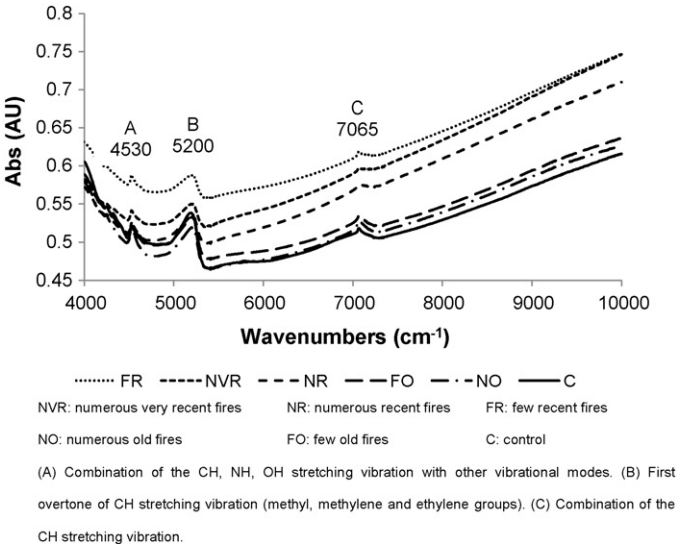

Fig. 3. Representative spectra from the soils affected by different recurrences of fires. Each presented spectra is the average of 3 raw spectra.

3.2. Spectral data

Fig. 3 shows representative spectra of the different soils affected by the different fire conditions. All spectra are very close and look like those of a previous study of Mediterranean soils [14]. According to previous works [7,11,13,14,36], all NIR spectra showed 3 large absorption bands due to harmonic and/or combination vibrations at: (i) 4530 cm^{-1}, combination of the CH, NH, OH stretching vibration with other; (ii) 5200 cm^{-1}, first overtone of CH stretching vibration (methyl, methylene and ethylene groups); (iii) 7065 cm^{-1}, combination of the CH stretching vibration.

We notice that soil spectra are arranged in order along the absorbance axis, from old to recent fires. The latter condition leads globally to a significant increase of the baseline of absorbance spectra [16], particularly in the spectral domain from 5500 to 10,000 cm^{-1}. Consequently, the spectra of soils recently burned are at the top of Fig. 3 whereas the spectra of control and formerly burned soils are at the bottom.

The interpretation of individual spectra nevertheless remains difficult. So, all additional information needs to be and will be "extracted" and highlighted by statistical treatments as principal component analysis and partial least square regression as described in the following section.

3.3. Principal component analysis of the spectral data

Fig. 4 shows the principal component analysis for NIR spectra after MSC correction of control and soils affected by the different fire conditions for the A layer. About 99% of the total spectral variance was explained after computing the first principal component on corrected spectra.

The samples are represented by bars positioned from left to right, according to the fire recurrence. The bargraph shows 2 differentiated zones. The first one gathers spectra of soils affected by recent fires, showing negative scores. The second one corresponds to spectra from controls and soils affected by old fires, showing positive scores except for 2 samples.

The examination of the first loading plot (Fig. 5) showed a similarity with sample spectra, they have the same 3 absorption bands at 4530, 5200 and 7065 cm^{-1}. However, these bands present higher intensity in the first loading plot. Spectra with positive scores (Fig. 4, control and soils affected by old fires) are correlated to the positive

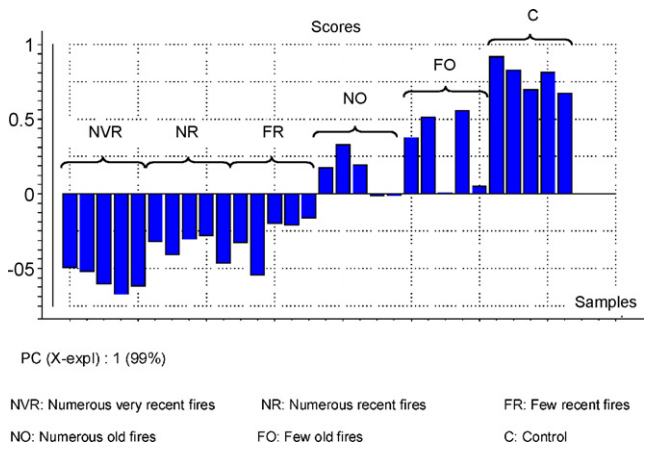

Fig. 4. Principal component analysis for multiplicative scatter corrected spectra of the layer A of soils.

part of the first loading plot, i.e. A and B bands, which are relative to the organic matter content. Spectra with negative scores (Fig. 4, soils affected by recent fires) are correlated to the negative part of the first loading plot, i.e. C band and the baseline shift, which could represent inorganic matter. So, recent fires and old fires can respectively be allocated to spectra with a large baseline deviation and spectra with intense A and B bands due to high organic matter amounts (Fig. 3).

These baseline drifts were previously shown by Zornoza et al. [14], for soils with different land-uses. We also found such drifts in industrial compost NIR spectra in a previous work [37]. Generally, baseline drifts in IR are due to light scattering because of samples granulometry (as a result of soil grinding) and/or sample composition (organic and/or inorganic).

It clearly appears that it is possible to assess the spatial heterogeneity of a burned area in this way. So, PCA can be a useful, rapid and inexpensive method for monitoring forest soils and planning adapted remediation strategies.

Soils affected by old fires are differentiated from control sites (Fig. 4). Sixteen years after the last fire, the burned soils do not return to the control state. Moreover, Fig. 4 shows that the variability between old fires is greater than the variability between recent fires. Recent fires clearly homogenize the soils. After that, the reconstruction is more or less efficient, conducting to contrasted results as shown by NO and FO fires. It suggests variability in "remediation rates" at the site level. Nevertheless, after sufficient period of time (e.g. controls), the samples seem more homogeneous. Finally, it is quite difficult to differentiate numerous fires from few fires or recent or old fires. The preponderant factor that differentiates soils appears to be the time elapsed since the last fire. The difficulty to differentiate few from numerous fires can be explained by

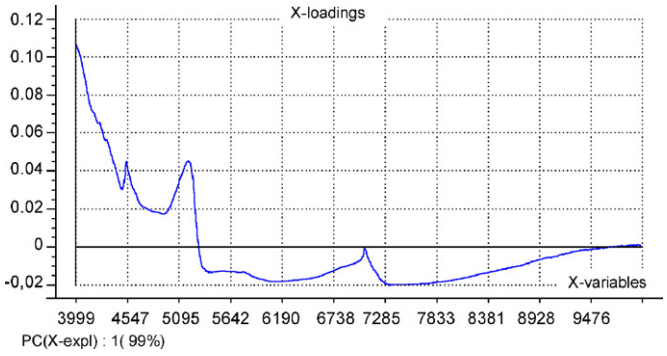

Fig. 5. First loading plot (99% of the variance).

Table 2
Variability of soil physico-chemical parameters.

Parameter	n^g	Mean	Minimum	Maximum
TOC[a]	55	30.6	14.2	81,0

$UVSA_{254}$ HS[f]	55	3.17	2.06	4.56
$UVSA_{280}$ HS[f]	55	2.73	1.68	3.93

[a] Total organic carbon ($g\,kg^{-1}$).
[b] Total nitrogen ($g\,kg^{-1}$).
[c] Phosphorus ($g\,100\,g^{-1}$).
[d] Contents ($g\,kg^{-1}$).
[e] Organic carbon in humic substances, humic acids and fulvic acids ($mg\,g^{-1}$).
[f] Specific absorbance at 254 and 280 nm of humic substances.
[g] Sample number.

the intensity of the fires that affected the soils [16,38]. The intensity of fires consists of the maximum temperature reached, and the duration of fire. These latter parameters cannot be taken in account here, but remain important for the evaluation of the fire impact. Few, intense fires could lead to a greater impact than less intense, numerous fires.

3.4. Principal component analysis of the physico-chemical parameters

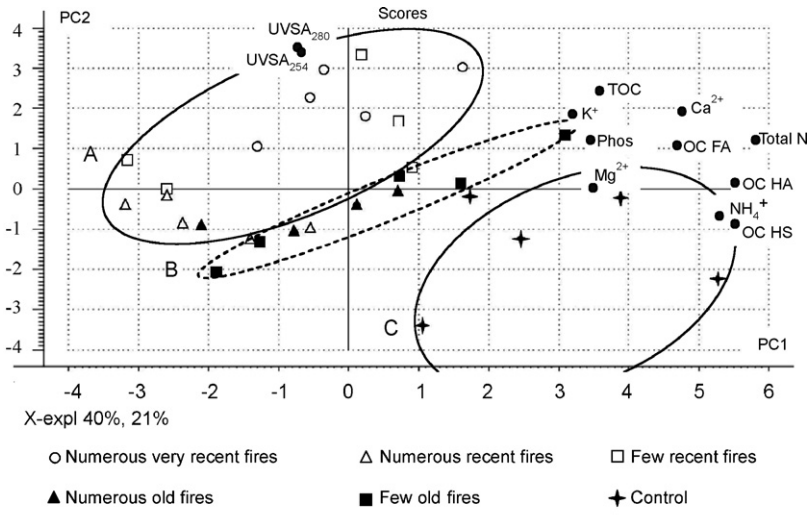

Table 2 highlighted for each considered parameter, the mean, the standard deviation and the range for all studied soils and depths. The displayed variability and range are important due to the different recurrence conditions and depths computed.

Fig. 6 shows the positions of the samples (and variables) along the two PC. Contrary to the previous spectral PCA, it is impossible to distinguish the different kinds of fire recurrences with only one axis. However, we note the separation of the A layer of recently, and very recently burned soils from formerly burned soils and from controls. This shows three different clusters respectively, A, B and C. They are distributed from the bottom right to the top left of the graph.

The position of the variables in the set of axis shows their relative contribution to the PC's construction. 61% of the total variance was explained by two components. The first PC, explaining 40% of the compositional data, is positively correlated to total nitrogen, organic carbon of humic substances and humic acids and with NH_4^+. In the same way, the second PC, explaining 21% of the compositional data, is positively correlated to the $UVSA_{254}$ and $UVSA_{280}$.

The proximity of the A cluster with the variable $UVSA_{254}$ and $UVSA_{280}$ indicates high specific absorbance values at 254 and 280 nm for soils affected by NVR, NR and FR fires included in this cluster. Moreover, the position and separation of the three clusters can be explained by the $UVSA_{254}$ and $UVSA_{280}$ representing the HS aromaticity. The soils, both very recently and recently burned show a greater HS aromaticity than the formerly burned soils. These present in their turn, a greater HS aromaticity than the controls. This trend was described in previous works, showing that in burned soils, new aromatic structures are issued from the alteration of carbohydrates [39–42], lipids and peptides [43,44].

The soils affected by NVR can be differentiated from those affected by NR by the organic carbon content, nitrogen and some nutrients. The soils affected by NVR present greater organic carbon contents, nitrogen and nutrients. After a moderate wildfire, an increase of carbon in soil is usually observed, suggesting a substantial incorporation of forest necromass [45]. Increases in soil organic

$UVSA_{254}$ and $UVSA_{280}$: HS specific absorbance at 245 and 280nm respectively;

Phos: phosphorus; Total N: total nitrogen; TOC: total organic carbon; OC HS, OC HA and OC FA: organic carbon in humic substances, humic acids and fulvic acids respectively;

(A) cluster with soils affected by very recent and recent fires; (B) cluster with soils affected by old fires; (C) cluster with control soils.

PC1 and PC2 respectively for principal component 1 and 2.

Fig. 6. Two dimensional plot of the layer A of soils using physico-chemical parameters.

matter content are also reported, due to an increased deposition of dry leaves and more or less charred plant materials in fires that affect the tree canopy [46].

Fig. 6 shows lower TOC contents for NR soils. This is probably due to an alteration of changes in soil physico-chemical properties [47,48]. Furthermore, the well known soil erodibility accentuates the loss of the soil organic matter by leaching of topsoil layers [49–51].

The FR soils are scattered, probably because of the intensity of fires once again.

For NO and FO conditions, the soils are not discriminated according to the number of fires, but are grouped in the cluster B (Fig. 6). The observed differences could again be attributed to the intensity of fires and above all, to their different reconstitution level since the last fire.

Moreover, the control soils present the greater concentrations of organic carbon contents, nitrogen and nutrients. According to previous works, the fires have a quantitative impact on the nutrients and a quantitative and qualitative impact on the organic matter [2].

4. Predictions by NIRS

4.1. Physico-chemical parameter predictions

In this part, we try to predict physico-chemical parameters with multivariate calibration models, using the NIR spectra, by partial least squares regression. The calibration set comprises of 44 samples.

The evaluation of the results was done with standard error of calibration (SEC), R^2 of calibration, standard error of prediction (SEP), R^2 of prediction, relative error of prediction (REP) and a number of factors from the PLS model (FN). The more FN are used, the greater is the noise in the model. Table 3 shows the best results obtained for physico-chemical parameters predictions with various spectral treatments.

The majority of the physico-chemical parameters are better calibrated and predicted with SNV pre-treatments. Results show that all physico-chemical parameters are very well correlated to NIR spectra, with R^2 for calibration mainly over 0.90. The exceptions are NH_4^+, HS $UVSA_{254}$ and $UVSA_{280}$ and the OC of FA which exhibit slightly lower R^2 for calibration, 0.84, 0.89, 0.77 and 0.62 respectively. Nevertheless, for all physico-chemical parameters, the observed SEC values are relatively low.

PLS models were validated by an independent prediction set of 11 samples. According to a previous work [52], $0.66 < R^2$ prediction < 0.8 indicates a rough quantitative prediction, $0.81 < R^2$ prediction < 0.9 a good prediction and R^2 prediction > 0.9 an excellent prediction. In our study, all R^2 for the prediction are greater than 0.9, except for HS $UVSA_{254}$ $UVSA_{280}$. These results allow us to expect excellent predictions. It is possible to verify this with the observation of REP values. The predictions seem very good for 5 parameters (TOC, total nitrogen, phosphorus, Mg^+ and OC in HS), with corresponding REP about 10%. The prediction of the OC in HS is particularly interesting because the REP is very close to REM (Table 3) and the usual analytical method is very time-consuming. For other parameters: Ca^{2+}, NH_4^+ and the HS $UVSA_{254}$, the predictions are not as good, with REP ranging from 15 to 20%. Concerning OC in HA and FA and the HS $UVSA_{280}$, the corresponding REP are too significant to consider an acceptable prediction. Nevertheless, the differences between REP and REM, of about 10%, are not so great for the OC in HA and FA, as the usual analytical methods present REM to be quite important. Table 3 does not show results for K^+, because, as for previous works [13,53], no correlation was found between results and NIR spectra. One explanation could be the non-direct relationship between K^+ and NIR absorption bands.

Finally, according to previous works [6,7,10,11,13–15,36,54–57], these results show the ability of NIR to predict some physico-chemical parameters of soils.

As a partial conclusion, this study shows that PLS regression models using NIR spectra are a valuable tool to assess wildfires effect on impacted soils.

Table 3
Best results obtained for predictions of physico-chemical parameters with various spectral treatments and with PLS1 regression method.

Parameter	Concentration range	REM[g] (%)	Pre-treatments	R^2 calibration	SEC[j]	R^2 prediction	SEP[k]	REP[l] (%)	FN[m]

[l] Relative error of prediction.
[m] Factor number.

4.2. Other parameter predictions

In this part, the prediction of three other variables was realized by PLS1 regression of the multiplicative scatter corrected NIR spectra for A layer of all soils. These variables are: number of fires (NF), time elapsed since the last fire (TE) and the recurrence index described above. The calibration set comprises of 24 samples. The number of samples is less than for the physico-chemical parameters because these parameters are only evaluated for A layer. As a remark, A layer was chosen because it is obviously the most impacted by wildfires.

Table 4 shows the best results obtained for calibrations and predictions. TE and RI are very well correlated to corrected NIR spectra. Their R^2 of calibration values are over 0.90 and they present low SEC. As regards NF, results are not as good, with R^2 of calibration and SEC about 0.85 and 0.37, respectively.

As for physico-chemical parameters, PLS models were also validated by an independent prediction set of 6 samples. Despite good prediction R^2, the predictions are not so good for NF and TE according to REP values over 20%. With regards to FRI, the prediction results are very good, with a R^2 of prediction about 0.98 and a REP about 10.2%. So, the soil matter evolution level does not depend on NF or TE separately, but depends on a relation between them, corresponding to the integrating parameter FRI (Table 1). The good correlation and prediction of FRI show that it is a major controlling parameter in our study. The intensity of fires could be a part of the error sources of prediction, as well as the biomass (qualitative and quantitative) presents in the studied sites. Moreover, a recent work [58] showed that the presence of ash could be an interfering factor in the estimation of the maximum temperature reached in burned soils using near-infrared spectroscopy. Another hypothesis could be the interference due to the presence of ash in the estimation of parameters studied in this work, even if it is impossible to estimate it. Nevertheless, this work shows the interest of the fire FRI. PLS regression models are successful in predicting these parameters as the fire recurrence modify NIR spectra of soils.

Table 4
Results for predictions of the number of fire (NF), the time elapsed since the last fire (TE) and the fire recurrence index (FRI) for multiplicative scatter corrected spectra of the layer A of the soils and with PLS1 regression method.

Parameter	Range	R^2 calibration	SEC[a]	R^2 prediction	SEP[b]	REP[c] (%)	FN[d]
NF	0–5	0.85	0.37	0.90	0.62	27.7	6
TE	1–56	0.93	1.21	0.98	3.52	20.1	4
FRI	0.13–1.22	0.90	0.061	0.98	0.060	10.2	5

[a] Standard error of calibration.
[b] Standard error of prediction.
[c] Relative error of prediction.
[d] Factor number.

5. Conclusions

NIR spectroscopy has a number of advantages. It is a rapid, non-destructive and green (because no chemical reagent is needed and no waste is produced) method that does not require sample pre-treatment. Despite the impossibility to directly interpret a NIR spectrum by correlating the intensity or the surface of peaks with concentrations, NIR spectroscopy coupled with chemometric methods confirms its usefulness for monitoring the forest soils affected by fires.

It clearly appears that the evaluation of the fire recurrence of unknown samples is possible with PCA and particularly the evaluation of the time elapsed since the last fire.

This study shows that NIR spectroscopy coupled with PLS is a valuable tool for soil monitoring, particularly for the prediction of the total organic carbon, total nitrogen, organic carbon and $UVSA_{254}$ of humic substances, phosphorus, Mg^+, Ca^{2+} and NH_4^+. However, further investigation should to be carried out in this field to try to make successful predictions of K^+, organic carbon in humic and fulvic acids and HS $UVSA_{280}$.

Furthermore, the proposed recurrence index can be predicted easily. NIR spectroscopy appears to be a very valuable tool to evaluate the fire effects on soils, to study the spatial variability, to map more or less burned areas and to apply adequate rehabilitation techniques, like reforestation or organic enrichment. A larger number of studied samples could lead to more robust models for a better prediction, but this study is a very promising first approach.

Acknowledgements

Financial support was provided by Region PACA, the IRISE project (http://irise.mediasfrance.org/) funded by the European Union, Forest Focus Regulation (No. 2152/2003) and the French Ministry of Agriculture and Fisheries. The authors wish to thank the IRISE staff for considerable work concerning *in situ* experiment and sampling, in particular Max Bresson for equipment support and active sampling.

ABSTRACT

This study develops a methodology based on NIR-microscopy analysis and chemometric tools for the detection of animal protein by-products in mixtures, such as compound feeds and mixtures of ingredients, using a library of animal meal by-products only. The proposed methodology is a two-step strategy which worked better than the SIMCA approach it was compared with. In the first step, animal particles are identified using one of two methods, a global or a local distance measure. In the second, *K*-nearest-neighbours (KNN) is used to discriminate between terrestrial and fish particles. The models were developed using a training set comprising 11,727 spectra of pure terrestrial meals and 5843 of fish meals. KNN using second derivative spectra and five neighbours correctly classifies 98.5% of these samples under cross-validation. The procedure was validated using two external datasets, one made up of mixtures of species (fish and bovine), and a second of commercial compound feeds. The results obtained confirm that the procedure is able to reliably detect the presence of animal meals, although further work would be needed to develop it into an accurate quantitative method.

1. Introduction

The ban on the use of animal protein by-products in compound feeds [1] is one of the measures adopted by the European Union to stop the spread of BSE and to prevent its re-occurrence. From October 2003, the European Union (EU) adopted Regulation (EC) No. 1774/2002 governing animal by-products (ABPs), which seeks to address the possible risks inherent in recycling potential infectivity due to the absence of barriers within species, and to exclude the cannibalism that may be induced by intra-species recycling [2]. This ban (avoiding cannibalism) will only be lifted if reliable analytical methods are available that ensure both the identification of species in animal by-products and the detection of animal by-products in compound feeds.

A recent review includes a revision about the methods of detection of animal proteins in feeding stuffs [3], concluded that near infrared microscopy (NIRm) is one of the methods with wider scope for this purpose, together with near infrared imaging, PCR (Polymerase Chain Reaction) and immunology. In the framework of an EU research project titled "Strategies and methods to detect and quantify mammalian tissues in feedingstuffs" (STRATFEED, G6RD-2000-CT-00414) [4], NIRm was one of the methods studied and tuned for the detection of animal proteins, obtaining promising results in this field. NIR-microscopy allows the measurement of spectra of single particles in a sample, in contrast to standard NIR technology, now also called macro-NIR, in which each spectrum collected belongs to a whole sample. Microscopic sample analysis may be necessary for the evaluation of small areas of specific interest [5].

The main advantages of NIR-microscopy, compared with the reference method according to the European Legislation, i.e. optical microscopy, or with other methods such as PCR, are that it is non-destructive, can be automated and that it does not require highly qualified and experienced analysts [6]. On the other hand, the main limitation of this technique arises from its not being a universal method, i.e. that it only allows inference for samples similar to those used in training when the application was developed, so that the construction of a spectral library that captures the variability in the application area being studied is one of the key aspects when working with this technology.

Previous works have shown the potential of this technology for the detection of animal meals, using both sedimented and raw fractions and a variety of chemometric approaches including ANN, PLS, and support vector machines [6–10]. Nevertheless, all these works have been based on the building of spectral libraries containing not only animal particles, but also vegetal particles, in order to train the model in the identification of animal and other particles presented in the compound feeds. This fact makes more difficult the building of the database for the model development, because it is necessary

doi:10.1016/j.talanta.2009.06.026

not only to collect a library of animal meals with large variability, but also to analyse many particles of many different vegetable products to cover the variability in these products, multiplying further the number of possibilities and the analysis time.

The goal of this work was to develop and optimize a methodology, based on NIR-microscopy and chemometric tools and using a library of animal meal by-products only, for the detection/quantification of animal protein by-products in mixtures such as compound feeds and mixtures of ingredients.

2. Materials and methods

2.1. Training set

The first and main step is the building of an adequate database for the development of the prediction model. This database will be based on the analysis of pure samples of animal protein by-products, i.e. collecting spectra of animal meals of each species of interest. Some of the samples were provided by Spanish rendering plants, while others were provided by European partners in the framework of different research projects. It must be highlighted that some of these samples were authenticated by PCR and some others were provided by dedicated plants, avoiding the cross-contamination of them.

The database used in this work comprises spectra of particles belonging to bovine (4657 spectra from 8 samples), ovine (2560 spectra from 4 samples), porcine (2382 spectra from 40 samples), avian (2128 spectra from 41 samples) and fish (5843 spectra from 65 samples) meals. In building the training set, it is important to include as much variability as possible. Thus it was decided to analyse as many different samples as could be obtained, taking a modest number of spectra per sample. However for some types of animal meals, especially bovine ones, their availability was limited and larger numbers of spectra per sample were collected to compensate. Since the training is based on individual spectra, and since there is considerable variability both within and between samples, the lack of balance is not important.

2.2. External validation sets

Two different sample sets were used for the validation of the models performed. The origins of these sets were totally different to the calibration samples. Validation set 1 comprised 20 experimental mixtures of fish meal adulterated with bovine meal, in inclusion percentages of 2.5–16%. Several meals were used to make these samples; none of them was represented in the training database. Validation set 2 was made up of 20 commercial compound feeds. Among them, there are five samples free of animal meals, six that only had fish meal and nine that had animal meals different from fish meals in their composition.

2.3. Analysis of the samples

The raw fraction of the sample, i.e. without sedimentation, previously milled with a 1 mm screen, was analysed. According to the methodology proposed in the SAFEED-PAP Project (FOOD-CT-2006-036221), the samples were mixed and about 100 mg was taken four times. Then, everything was put in a sieve of 250 μm and agitated for 2 min. The particles >250 μm were then taken from the sieve and placed on a spectralon plate. The particles must be disposed in a thin layer for the analysis. For the training set, between 30 and 600 particles were analysed per sample. For the validation sets, the number of particles analysed was around 200 for each sample in validation set 1 (fish meals adulterated with bovine meal) and around 600 for samples in validation set 2 (commercial compound feeds) which are much more heterogeneous.

The spectra were collected in an Auto Image Microscope connected to a Fourier Transform Near-Infrared Spectrometer (FT-NIR; PerkinElmer, Waltham, MA, USA). Using the pointer of the microscope, the light beam was focused on each particle located on the spectralon plate and the NIR spectrum (1112–2500 nm) was collected. A resolution of 4 cm^{-1}, a gain of 4, and a number of co-added scans of 10 were used. The spectra were obtained from the ratio between the raw spectra and the background consisting of the measurement of the spectralon plate. The software Autoimage v.3.2.1 from PerkinElmer was used to collect and store the spectra. The Convert Abs NM software from PerkinElmer was used to convert the tabulation of the spectra from wavenumber (cm^{-1}) to wavelength (nm) at 4 nm intervals.

2.4. Chemometric data processing

The data processing was carried out using MATLAB software version 7.0 (The Mathworks Inc., Natick, MA, USA).

The spectral range was reduced at the outset to 1500–2280 nm, in order to discard regions with high noise levels. Moreover, the main water region (1824–1976 nm) was removed, because the technological processes associated with this kind of product can cause different levels of moisture in them, and the goal of this range cutting is to avoid basing the classification on different moisture levels instead of on the main features of each animal species. Some further restrictions of the range, for example using only the region from 2040 to 2180 nm, were investigated during the development of the algorithm.

Several pre-treatment options were investigated. Smoothed $\log(1/R)$ spectra, and first and second derivatives, all computed using a Savitzky-Golay filter [11] with a window size of 15 data points and a polynomial order of 2, were tested. Each was tried without scatter correction and with scatter correction using the Standard Normal Variate (SNV) method [12], applied after the Savitzky-Golay treatment.

The aim was to develop a method for the detection of animal protein by-products in mixtures analysed by NIRm, with the ability to distinguish between terrestrial and fish meals. Two classification algorithms were investigated, SIMCA and *K*-nearest-neighbours (KNN).

The SIMCA method [11,13] constructs a principal component model for each different group of interest. As it is used here an unknown sample is compared with each group in turn by computing two distances: the Euclidean distance from the spectrum to its projection into the model for that group (distance from the model) and the Mahalanobis distance from the projected spectrum to the group mean (distance within the model), and comparing these distances with thresholds derived from the training data. If both distances are less than the threshold, the unknown is a possible member of that group. After all the comparisons have been made, the unknown sample may be identified as a possible member of none, one, or more than one of the groups. Tuning the method involves choosing a number of principal components and a pair of thresholds for each model. To calibrate the thresholds, they were expressed as percentiles of the empirical distribution of the distances for the training data. Thus a threshold of 0.95 means that the distance computed for the unknown sample must lie within the range of the smallest 95% of the corresponding distances for the training samples for the group under consideration.

The KNN method [11] classifies an unknown according to the group memberships of the *K* most similar spectra in the training database. As applied here, similarity is measured by Euclidean distance between spectra, and the classification is made by a simple majority vote of the *K* nearest spectra, with ties broken using the sums of the relevant distances. Tuning most obviously involves choosing a value for *K*, in the range 1–20 here, but also comparing

Table 1
KNN(5) classification results by cross-validation on the training set.

	Classified as terrestrial	Classified as fish
Terrestrial (n = 11,727)	11,586 (98.8%)	141 (1.2%)
Fish (n = 5843)	118 (2.0%)	5725 (98.0%)

Table 2
SIMCA classification results by cross-validation on the training set.

	Classified as terrestrial	Classified as fish	Not classified
Terrestrial (n = 11,727)	9415 (80.3%)	179 (1.5%)	2133 (18.2%)
Fish (n = 5843)	17 (0.3%)	4708 (81.8%)	1118 (19.1%)

the effect of different spectral ranges and pre-treatments, to which the method may be quite sensitive.

The overall strategy needs to work with samples that include ingredients not represented in the training database. This is not a logical problem for SIMCA, where the philosophy is the positive identification of group membership, and the option of not classifying a spectrum is available. To use KNN in this situation it was extended to a two-step procedure as follows:

Step 1 attempts to identify animal particles. This uses either a single group SIMCA, with the group defined by the whole of the database, or an extension to the KNN procedure, in which unknown spectra with at least K spectra from the database within a predetermined radius are identified as being of animal origin. Both of these approaches use distance from the training database to identify animal particles. The key difference is that SIMCA uses a global measure, depending on a model for the whole database and measuring to the centre of the model, while the alternative approach is local and more flexible, looking only at the part of the database nearest to the unknown spectrum.
Step 2 uses KNN to classify those particles identified as animal meals as either terrestrial or fish.

Given that there are four non-fish groups in the database (as described in Section 2.1), one could either treat the problem as one with five groups, combining the classifications to non-fish at the end, or combine the four non-fish groups at the outset to make it a two-group problem. Both options were investigated.

The main tuning was carried out using cross-validation on the training database, leaving out the whole of one sample (as opposed to one spectrum) at time so that other particles from the same sample did not contribute to the classification of a particle. The success of the model obtained was evaluated using the percentage of correctly classified particles (ratio of correctly classified particles to total particles). The tuning of step 1 is described in Section 3.2.

3. Results and discussion

3.1. Model development and results on the training database

The training database comprising a total of 11,727 spectra of terrestrial meals (including avian, porcine, bovine and ovine samples) and 5843 spectra of fish meals was first used to develop a detection model that allows discrimination between terrestrial and fish meal particles. Both KNN and SIMCA were investigated.

The best pre-treatment option was second derivative. Results with and without subsequent scatter correction using SNV were comparable. It seems preferable to include SNV because this will make the method more robust to minor changes in instrumentation, etc. [14], and so the results presented below all use second derivative followed by SNV. Some limited experimentation with reduced spectral ranges did not lead to better results, nor did compressing the spectra to principal components before computing the distances to the neighbours in KNN.

The selected number of neighbours for KNN with this pre-treatment was K = 5. Table 1 shows the classification results obtained by cross-validation on the training database. Overall, 98.5% of the particles were correctly classified. These results were achieved by treating the problem as one of five groups, and then combining the resulting classifications for the four terrestrial groups. The alternative strategy of combing the groups and then classifying also produces 98.5% correct classifications, but now with slightly more fish particles erroneously classified as terrestrial (134) and slightly fewer terrestrial particles classified as fish (123). This is what one would expect: KNN is affected in an obvious way by the numbers representing each group in the database. The results are not particularly sensitive to the choice of K, though K = 5 gave the best results on cross-validation.

Tuning SIMCA by cross-validation on the database resulted in the selection of a two-group model, i.e. pooling the 4 non-fish groups and making 2 principal component models only, with 10 components in each model, and thresholds of 0.99 and 0.90 for the distances to and within the model respectively. The results are given in Table 2. There are fewer total errors than for KNN, but the price is a failure to classify 18.5% of the spectra. Of these, 11.8% fail to be assigned to either group, 6.7% are judged to be possible members of both.

Similar classifications rates have been obtained by other authors. Thus, Piraux and Dardenne [7] working with raw samples and ANN to discriminate between what the authors called allowed particles (vegetal and fish) and forbidden particles (terrestrial animal meals) obtained an overall hit rate of 99.36%, while in the STRATFEED project [4], PLS was used to discriminate into several groups step by step successively (vegetal *vs* animal, terrestrial animal *vs* fish, poultry *vs* bovine and pig), resulting that 94.3% of the animal particles were correctly classified, being by classes the 95.5% of the analysed particles classified as terrestrial and the 90% as fish. De la Haba et al. [9] working with samples after sedimentation and support vector machine algorithm for the discrimination between fish and meat and bone meal obtained percentages of correctly classified samples of 95%.

3.2. The tuning of step 1

Before applying the KNN methodology to external validation sets, it needs to be extended to distinguish between particles of animal meal, similar to those in the database, and particles that are not recognised.

The SIMCA procedure for this was based on a single group principal component model using all the database samples. The number of components was chosen as 10. This is somewhat arbitrary, and is based on the (possibly irrelevant) fact that this number of components worked best for the fish/non-fish classification within the database. It would of course be possible to tune this choice using the validation samples, but then it becomes more difficult to interpret the validation results. The thresholds were both set at 0.99, a choice that if applied to the database would exclude 300 spectra, not quite 2% because some points fail on both criteria.

The KNN procedure with K = 5 was extended by applying an upper threshold to the distance from the unknown spectrum to its fifth nearest neighbour in the database. Only particles satisfying this criterion, and therefore having at least five near neighbours in the database are identified as animal. The threshold was chosen as 2 by inspecting the histogram of distances generated by the cross-validation reported in Section 3.1. Approximately 2% of these cross-validated distances are greater than 2. Some of the spectra in this tail may be outliers, the majority probably just happen to lie on the edges of the database. However these 2% (349 spectra) were

removed from the database before analysing the validation sets, to reduce the chance of false positives.

3.3. External validation

The procedure was validated using two external sample sets. The first was made up of mixtures of two species, fish and bovine. The ability to discriminate between these is essential if the use of fish meal is to be allowed in all ruminant feeds. The second set comprises 20 varied commercial compound feeds. In each case, the results for one of the three combinations studied, KNN at steps 1 and 2, are presented in detail, and then the results for the other two options, SIMCA at step 1 with KNN at step 2 or a single SIMCA, are discussed more briefly.

3.3.1. Fish meal samples adulterated with bovine meal

The validation results for KNN + KNN applied to the fish meal samples adulterated with bovine meal are shown in Table 3. This shows for each sample analysed the total number of particles analysed, the numbers and percentages of particles classified as animal or non-animal at step 1, the numbers and percentages of particles classified as fish or terrestrial in step 2, and in the last two columns the actual composition of the sample. For all the percentages quoted for the classification the divisor is the total number of particles in column 2.

The results in Table 3 show that the screening in step 1 rejects a total of 155 particles out of the 3648 analysed, 4.2%. It is not surprising that this is a little greater than the corresponding 2% for the training database: these are external samples. The percentage of

[a] As percentage of total number of particles in column 2.

particles classified as terrestrial in step 2 shows broad agreement with the true sample composition, though with some considerable variations. The potential of the method for quantification will be discussed in Section 3.4. From Table 3, it does seem to be satisfactory for the detection of bovine meal in these samples.

Replacing step 1 by a single group SIMCA has little effect on the results. The number of particles rejected at step 1 falls from 155 (4.2%) to 142 (3.9%), while the total number of terrestrial particles found by KNN in step 2 changes from 371 to 369. Thus there is nothing to choose between the use of KNN and SIMCA at step 1.

Using a two-group SIMCA for the whole exercise gives less satisfactory results. Overall 563 (15.4%) of the spectra are not classified to either group, while a further 371 (10.2%) are declared to be possible members of either the fish or terrestrial groups. The classified spectra are split 2601 (71.3% of the total) to fish, 113 (3.1% of the total) to terrestrial. The number of identified terrestrial particles in samples M1–M5 are 1, 1, 2, 1 and 0, respectively, so that the method fails to detect the contamination in sample M5.

3.3.2. Commercial compound feeds

The validation results for KNN + KNN applied to the commercial compound feeds are shown in Table 4, whose structure is the same as that of Table 3.

For samples CF1–CF5 the results are perfect. These samples have no animal meal, and none is detected. For samples CF6–CF11 the results are good. These samples contain fish meal in relatively low proportions. This is detected each time, and there are no false positives for terrestrial meal. However the proportions of fish detected are systematically low, by a factor of about 2. For samples CF12–CF20 the results are rather less impressive. These samples all contain substantial proportions of terrestrial animal meal. Particles of animal meal are always detected, but in much smaller numbers than they should be by a factor of roughly 4. Further, more than half of the identified animal particles are wrongly classified as fish.

As was observed with the other validation set, changing the first step to a single group SIMCA has little effect on the results, with all the zeros in Table 4 being maintained, and other numbers of particles changing by one or two.

Using a two-group SIMCA gives qualitatively similar results, but with a tendency to detect even fewer animal particles than KNN. For samples CF1–CF5 all the particles are correctly classified as belonging to neither group. For samples CF6–CF11 a total of 38 particles (1.1% of the total) are classified as fish, with 2 further particles possibly belonging to either of the animal meal groups. For comparison, KNN finds 44 fish particles. For samples CF12–CF20 SIMCA classifies 121 particles (2.2% of the total) as fish, 27 (0.5%) as terrestrial and 70 (1.3%) as consistent with either, compared with the 191 (3.6%) fish and 85 (1.6%) terrestrial found by KNN.

The underestimation of the quantitative prediction of animal meals was observed also in the results reported by De la Roza et al. [10] for a validation set of commercial compound feeds. Four possible reasons are:

1. A bias may be caused by the preparation of the sample previous to the analysis. A sieve is used and only particles bigger than 250 μm are analysed. Animal meals tend to be finely milled compared to some of the other ingredients present, and thus a higher proportion of these particles may pass through the sieve.
2. Because of the technological process that the compound feeds have undergone, including high pressures and temperatures, and being formed into pellets, the particles that are analysed may not be pure ingredients in most cases. If the spectra of particles correspond to a conglomerate of different ingredients, that will make difficult their identification as animal particles by a model based on pure ingredients.

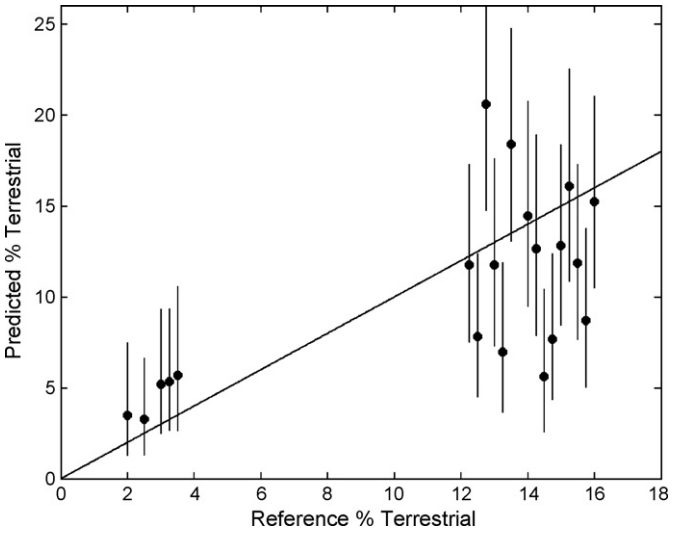

Fig. 1. Predicted *vs* reference percentages of terrestrial meal in the mixture samples M1–M20, with 95% binomial confidence intervals for sampling variability.

3. The training library, though it includes many spectra, only has a limited number of samples. Expanding the variability in the library would be expected to increase its ability to recognise animal particles.

3.4. Potential for quantification

The validation results with the mixtures of fish and bovine meals, though not those with the compound feeds, are good enough to make it worth discussing the potential of the method for quantification. Fig. 1 plots predictions *versus* reference percentages of terrestrial meal in the 20 mixtures. The predicted percentages are calculated simply as ratios of numbers of particles, whereas the reference data are percentages by weight. Since the sizes and densities of the particles vary by ingredient this might be expected to cause some discrepancies, but no attempt has been made, so far, to apply any corrections.

Also shown for each plotted point is a 95% confidence interval for the true percentage given the observed one, assuming binomial variability in the numbers of terrestrial particles that will be present in samples of the sizes analysed (approximately 200). It is clear from the plot that there are other sources of random variability affecting the results, because there is much more variability between the points in the 12–16% range than the intervals would suggest there should be. The plot also suggests that there is a downwards bias in this group of results, and probably an upwards bias in the group at 3%. The broad agreement between predicted and reference is encouraging, but further work will be necessary before the method can be regarded as anything better than semi-quantitative. Particular problems are the potential for bias in the sieving stage, biases due to particle size distributions and densities when a weight fraction is estimated by a number fraction, and the fact that the database, though it contains a large number of spectra, does not yet include all that many distinct samples.

4. Conclusions

Of the methods investigated the use of a two-stage methodology performed better than a simple SIMCA. The combination KNN + KNN was a little better than SIMCA + KNN, though the difference was not large. The method was able to detect though not quantify animal meals in compound feeds, despite having been trained only on pure animal meals. It was also able to produce

semi-quantitative results for mixtures of fish and terrestrial meals. A number of challenges remain for the development of a fully quantitative method.

Mixtures

ABSTRACT

To guarantee feed quality and safety the development and improvement of analytical methods for feed authentication and detection of contaminants is fundamental. Near infrared reflectance microscopy (NIRM) has been investigated as an alternative method to contribute to control systems for feed materials. The major task is the need to build NIRM reference spectral libraries that must represent the variability in feed ingredients. The aim of the present work was to evaluate the performance of a NIRM reference spectral library on animal feed, with external samples of animal feed ingredients and possible contaminants such as processed animal proteins, and in particular to assess its ability to identify ingredients in mixtures. Three external sample sets were used: (A) artificial mixtures, (B) synthetic mixtures and (C) synthetic binary mixtures. The prediction and repeatability results for set A, in which the spectra are from pure ingredients, were very good for both animal and vegetable ingredients and confirm that the spectral library is very good at identifying spectra from pure ingredients. For sets B and C, in which the spectra were measured on mixtures, the prediction results were very disappointing compared with the artificial samples. This means that a strategy that tries to match the spectra taken from a mixture with those of pure ingredients is unlikely to meet with much success. It is possible that an interpolation between pure ingredients for suitably chosen spectral ranges may provide a way to extend this system to mixtures, including mixtures of several ingredients.

1. Introduction

Optimal nutrition implies that animal feeds must be considered not only in terms of production efficiency but also in the light of their ability to promote health and protect against disease [1]. The health of the animal is fundamental for determining the quality, safety and wholesomeness of foods of animal origin for human consumption [2]. These new nutritional concepts require the development and dissemination of improved and more readily available analytical methods for feed authentication and detection of contaminants, to support various aspects of feed quality and safety and contribute to the improvement of existing control systems across the world.

The official analytical method to obtain qualitative and quantitative information about the ingredients in mixtures and compound feedstuffs is classical microscopy. Optical microscopy is at the moment the only official method in the European Union for detection of constituents of animal origin in feeds [3].

A number of other methods, such as polymerase chain reaction, immunoassay, and macro near infrared spectroscopy have been investigated for the analysis of ingredients in feed samples, including the detection of banned processed animal proteins [4–6]. The method studied here, near infrared reflectance microscopy (NIRM), allows the collection of hundreds or thousands of spectra from a feed sample and has been proposed as a new analytical approach for identifying ingredients in animal feeds [7,8] and detecting and quantifying undesirable substances such as meat and bone meal (MBM) in feedstuffs [9–12].

A major task in implementing this methodology is the need to build NIRM reference spectral libraries comprising thousands of spectra taken from samples from reliable sources in order to represent the natural variability in animal, vegetable and mineral feed ingredients. Once the library is built, spectra collected from animal feeds may be compared with the spectra in the library to identify the ingredients included in the feeds. As the number of possible ingredients becomes large, not only does it increase the effort involved in constructing the library and the computational effort involved in comparing an unknown with all the spectra in the library, but it becomes more difficult to discriminate between the ingredients. For example Gendrin et al. [13] reported that it becomes more difficult to find discriminating wavelengths when large numbers of ingredients are involved.

The optimization of conditions for sample presentation and spectral measurement and treatment, and the building of an NIRM

reference library have been reported previously [7,14]. An internal cross-validation of the use of the *K*-nearest neighbours algorithm [15] to classify spectra by comparison with the library showed some confusion between similar vegetal ingredients but good discrimination between ingredients of animal and vegetal origin [7].

The aim of present work was to evaluate the performance of this NIRM reference spectral library on animal feed, challenging it with external samples of animal feed ingredients and possible contaminants such as processed animal proteins, and in particular to assess its ability to identify ingredients in mixtures.

2. Materials and methods

2.1. Samples

The samples used to construct the spectral library, and the samples used for validation, were all provided by industrial sources in the north of Spain. They are samples of pure ingredients representing the natural variability encountered in the production process. The types and numbers of samples in each set are described in Sections 2.2 and 2.3.

Prior to analysis all samples were ground to a particle size of 1 mm. The ground sample was spread on a sample holder as a continuous film for spectroscopic measurement. This procedure has been described elsewhere in detail [7,14].

2.2. Spectral library

The construction of the spectral library has been described in a previous work [7]. The library includes a total of 48 456 spectra measured on 227 samples representing 30 different ingredients corresponding to the detailed list in Table 1. It includes the most common feed ingredients of different origins, the first 26 in the list, together with the most important banned ingredients, the last four in the list.

2.3. Mixtures

To assess the ability of the NIRM reference spectral library to identify ingredients in mixtures three sample sets were used. In all cases the samples, though sourced in the same way as the library samples, were external to the library.

Sample set A, which will be called "artificial mixtures" was made not by measuring spectra on mixtures, but by measuring samples of pure ingredients and constructing the artificial mixtures by combining appropriate numbers of spectra randomly selected from those measured on the pure ingredients. This set contains six samples, with the percentage ingredient contents shown in Table 1.

Sample set B, which will be called "synthetic mixtures" was produced by physically mixing pure samples in the laboratory and measuring spectra on the mixtures. This set, also shown in Table 1, contains six samples with similar percentage ingredient contents to those of sample set A.

Sample set C, which will be called "synthetic binary mixtures" was produced in the same way as sample set B. Each of the three samples in the set is a 50/50 mixture of meat and bone meal with one other ingredient. This other ingredient is barley in sample 1, maize in sample 2, and soya meal in sample 3. Spectra were measured not only on the three mixtures, but also on the four pure ingredients used to construct them. Sample set C was constructed in an attempt to understand why the system does not work well when the spectra are measured on mixtures, especially for the identification of animal by-products.

2.4. Sample analysis and treatment of the NIRM spectra

Spectra were measured using an Auto Image Microscope connected to a Perkin-Elmer Spectrum One Fourier transform near infrared (FT-NIR) spectrometer in reflectance mode (1112–2500 nm), employing a resolution of 8 cm^{-1}. Spectra were obtained from the ratio between raw spectra and the background as measurement of the spectralon plate and the spectral information was stored as $\log(1/R)$. This instrument is equipped with an InGaAs detector.

For each sample presented to the instrument, approximately 230 spectra (the number varies because of occasional bad spectra), each the average of 70 scans, were measured using fields of view of size 50 $\mu m \times 50\ \mu m$ arranged in a 13×18 grid over an area selected near the center of the sample. After referencing to a Spectralon standard and conversion to $\log(1/R)$ at 4 nm intervals, the spectra were transformed to first derivative using a Savitzky-Golay filter (The PLS Toolbox, version 3.5, Eigenvector Research, Manson, WA) with a window of 15 data points, and cut to a range of 1500–2448 nm. In the first derivative spectra of many of the ingredients there is a large peak centered on approximately 1900 nm. This peak is strongly influenced by the water band seen in the near infrared at around 1940 nm [16]. To reduce the influence of water content on the classification, the range from 1824 to 1976 nm was removed.

For mixture samples in the sets B and C 10 subsamples of each were measured as described above, to obtain information on the variability of the results. For the artificial samples in set A, 10 replicates were constructed by repeated random sampling of spectra from those measured on the pure samples, keeping the numbers of spectra from each ingredient fixed.

2.5. Data analysis

All three sets of mixture samples were analysed by comparing each spectrum in turn with all the spectra in the library, using a *K*-nearest neighbours (KNN) rule with $K = 10$ to classify the spectrum [7]. This simple algorithm finds the 10 spectra in the library that are closest to the unknown, and classifies according to the identity of these neighbours.

Each of the synthetic binary mixtures in set C was subjected to the following additional analysis. The first derivative spectra over the range 1500–2448 nm, without the removal of any peak, underwent an additional pre-treatment by SNV [17]. The combined set of spectra for the two pure ingredients and the mixture were subjected to a principal component analysis (PCA) and reduced to 20 scores. The scores for the two pure ingredients were then input to a linear discriminant analysis (LDA) and thus reduced to a single number for each spectrum, its score on the canonical variate from the LDA. Using the loadings, the canonical variate scores were calculated for the spectra from the mixture samples.

For the main computations the spectral data were exported in ASCII format from the Perkin-Elmer Spectrum v. 5.0113 software into Matlab v7.4 (The Mathworks, Inc., Natick, MA, USA), and the analyses carried out with programs specially written by one of the authors (T.F.). Coding the KNN algorithm directly is a simple task. The principal component analysis applied to sample set C employed Matlab's singular value decomposition.

To evaluate the results, the composition of each replicate was estimated using the proportions of individual spectra classified to each ingredient. Spectra classified to an ingredient not present in the mixture concerned were counted as 'other' for presentation in

Table 3
Repeatability of predictions for one artificial mixture.

Ingredient	True composition (%)	Estimated composition for each replicate (%)										SD	Coef. Var.

the tables of results. The mean and standard deviation over the 10 replicates were calculated for each ingredient and for the category 'other'.

3. Results and discussion

3.1. Sample set A, artificial mixtures

Table 2 shows the true composition and the prediction results for the six artificial mixtures. The spectra of the animal ingredient, MBM, were always correctly classified, and there were no false positives. Even the cereal ingredients were generally correctly identified, despite the fact that there is some overlap between these ingredients in the library [7]. In Table 2, the classification 'other' corresponds to ingredients not present in the sample but included in the estimated composition. These were mainly confusions with other cereals. The standard deviations over the 10 replicates ranged from 0 to 2%. Table 3 shows an example of this repeatability in detail for the sixth artificial mixture. For the minor ingredients the fact that the result is a count of spectra is evident. There are exactly two beet pulp spectra in each mixture, and the number found varies from one to three, hence the large coefficient of variation for this ingredient.

These samples are not a very stringent test of the system, being collections of spectra of pure ingredients rather than spectra measured on mixtures of ingredients. However their use confirms that the library is able to classify accurately such spectra, and enables an assessment of accuracy that is free of sampling variability. When a real mixture is measured, there is considerable uncertainty about the composition of the portion of the sample actually examined, especially for ingredients present in only small proportions in the bulk sample.

3.2. Sample set B, synthetic mixtures

The composition and prediction results for sample set B, the synthetic mixtures are displayed in Table 4. The results are very disappointing when compared with those for the artificial samples in Table 2. There are major confusions among the cereal ingredients, for example the wheat in samples 4–6 was almost undetected. The

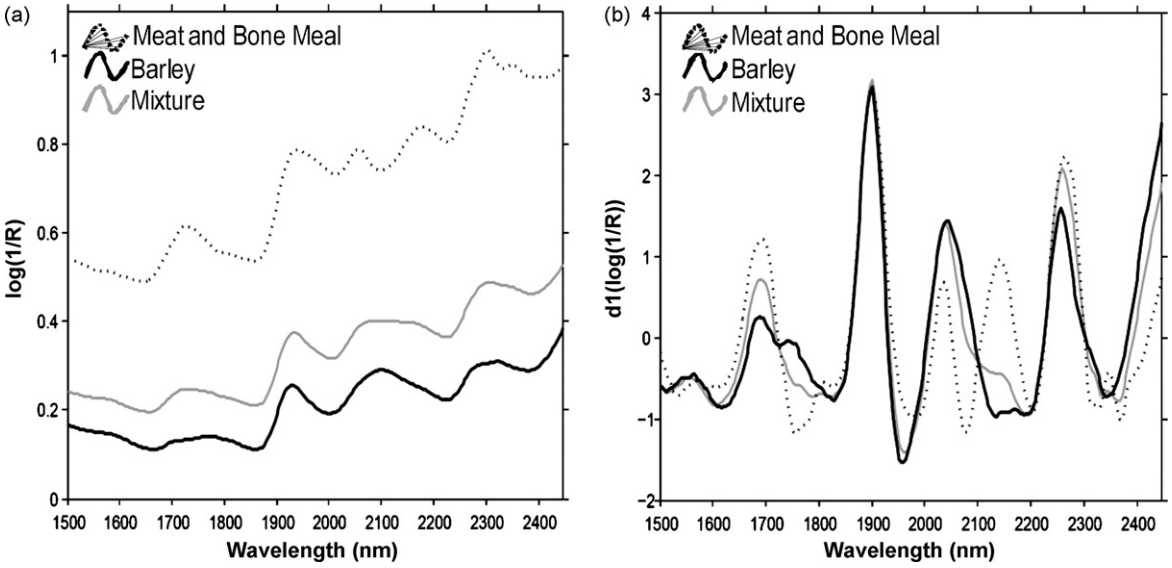

Fig. 3. Mean spectra for barley, MBM, and their mixture: (a) raw log(1/*R*) and (b) snv-treated first derivative.

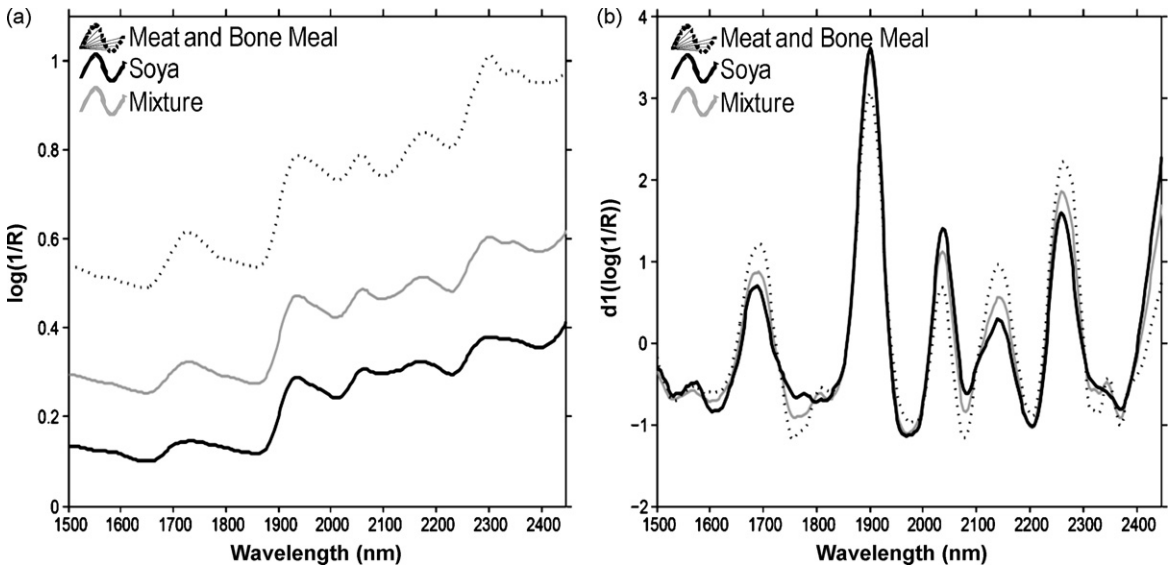

Fig. 4. Mean spectra for soya, MBM, and their mixture: (a) raw log(1/*R*) and (b) snv-treated first derivative.

main contributors to the 'other' category were oats and bran, in all the samples, and barley in sample 1. None of the four banned animal ingredients appeared in this category. Nevertheless, these confusions between cereal grains are not particularly important. In fact, the mandatory labelling for feed materials according to Article 16 (1) of Proposal for regulation of the European Parliament (2008/005 COD) says that the label shall include the name of the feed material corresponding to the respective category. Cereal grains are the category that includes oats, wheat and barley. Worse, though, is the failure to detect the MBM in any of samples 3–6, even though it is present at 5% in sample 4.

3.3. Sample set C, synthetic binary mixtures

The results for the three binary mixtures of sample set C are shown in Table 5. They are no better than those for sample set B, with the MBM being misclassified completely in sample 1, and almost completely in sample 2. Only in sample 3, a mixture of soya and MBM, does comparison with the library detect the correct two ingredients, and even in this case the estimated proportions are incorrect. The main contributors to the 'other' category are maize, soya and DDGS barley in sample 1; and soya in sample 2.

Some understanding of the spectral behaviour of the mixtures can be obtained by comparing the spectra from the mixtures with the spectra of the pure ingredients they contain. Figs. 1–4 show such a comparison for samples 1 and 3, the barley–MBM and soya–MBM mixtures. The case of sample 2, the maize–MBM mixture is very similar to that of sample 1, and will not be discussed in detail.

Figs. 1 and 2 show scores on the canonical variates for binary discrimination in the case of samples 1 and 3 respectively. The canonical variate is the direction in spectral space that best discriminates between the two ingredients. These scores are shown as relative frequency histograms for each of the three sets of spectra. The histogram for the mixture points downwards merely so that it can be distinguished from the other two where it overlaps.

The most important conclusion that can be drawn from these two figures is that in the mixture, despite the very small sample area that an individual spectrum represents, most if not all of the individual spectra are spectra of mixtures, of varying proportions. Some spectra may resemble those of the pure ingredients, and thus be correctly classified, but the majority will not, and their correct classification using the KNN rule will be a matter of chance. This explains the poor results obtained when classifying the real mixtures.

In neither case is the system quite linear, though it is much closer to being so for the soya–MBM mixture than for the barley–MBM mixture. In Fig. 1, the scores from the mixture have a distribution much closer to those of the barley than those of the MBM, despite the equal proportions in the mixture. In Fig. 2, although the separation between the two ingredients is much less, the mixture is much more symmetrically placed between them, with a slight bias in the direction of the soya, on the right of the figure. This fits with the failure to identify any MBM in sample 1 and with the too-high proportion of soya predicted for sample 3.

The source of the nonlinearity is in the spectra. Figs. 3 and 4 show the mean raw and SNV-treated first derivative spectra for the pure ingredients and the mixture in each of the two cases. In both panels of Fig. 3 it can be seen that the mean spectrum from the mixture, although between those of the two pure ingredients, is generally closer to that of the barley. This is especially true in the region around 2000–2200 nm. In Fig. 4, the mean mixture spectrum is roughly mid-way between the other two for most of the

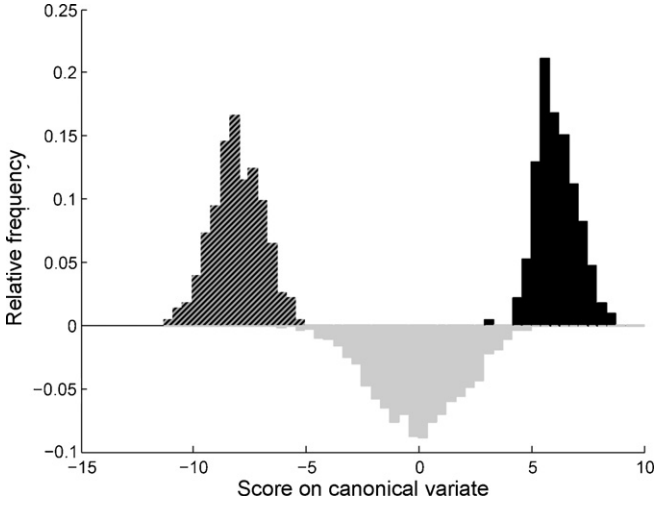

Fig. 5. Synthetic binary mixture of barley and MBM. Distributions of canonical scores of the spectra from the two pure ingredients (above the zero line, barley on the left, MBM on the right) and the spectra from the 50–50 mixture (below the line), with the spectral range restricted to 1600–1800 nm.

spectral range, especially for the derivative spectra. The positions of the mean mixture spectra explain the behaviour seen in Figs. 1 and 2, and suggest a way of making the barley–MBM system more linear. Fig. 5 is the result of carrying out the same analysis that gave rise to Fig. 1, but restricting the spectral range to 1600–1800 nm. In this region the mean mixture spectrum in Fig. 3 does resemble an average of the pure ingredient spectra, and as expected the scores for the mixture spectra have a much more symmetric and centrally situated distribution in Fig. 5.

Given the problems that arise when mixtures are measured with the methodology used here, it would be tempting to conclude that only the measurement of individual particles offers a way forward. However the sample presentation and measurement procedures used in this work offer advantages of simplicity and speed, and the results with the binary mixtures of set C are encouraging enough to suggest that further work to develop chemometric strategies to deal with the problem is a worthwhile prospect.

4. Conclusions

The artificial samples of set A confirm that the spectral library is very good at identifying spectra taken from pure ingredients. However, these excellent results were not repeated for sets B and C, in which the spectra were measured on mixtures. The explanation for this is clear from the investigation of sample set C. Even though the sample area from which the spectra are taken was small, the samples are so well mixed that few if any of the resulting spectra correspond to pure ingredients. This means that a strategy that tries to match the spectra taken from the mixture with those of pure ingredients is unlikely to meet with much success. The evidence from sample set C is that interpolation between pure ingredients is possible, and that the choice of spectral ranges is likely to be important in achieving this. Much work remains to be done to extend this system to mixtures of larger numbers of ingredients, and hence solve the general problem.

ABSTRACT

Historical or archaeological wooden objects are generally better conserved in wet environments than in other contexts. Nevertheless, anaerobic erosion bacteria can slowly degrade waterlogged wood, causing a loss of cellulose and hemicellulose and leading to the formation of water-filled cavities. During this process, lignin can also be altered. The result is a porous and fragile structure, poor in polysaccharides and mainly composed of residual lignin, which can easily collapse during drying and needs specific consolidation treatments. For this reason, the chemical characterization of archaeological lignin is of primary importance in the diagnosis and conservation of waterlogged wood artifacts. Current knowledge of the lignin degradation processes in historical and archaeological wood is extremely inadequate. In this study lignin extracted from archaeological waterlogged wood was examined using both Py-GC/MS, NMR spectroscopy and GPC analysis. The samples were collected from the Site of the Ancient Ships of San Rossore (Pisa, Italy), where since 1998 31 shipwrecks, dating from 2nd century BC to 5th century AD, have been discovered. The results, integrated by GPC analysis, highlight the depolymerization of lignin with cleavage of ether bonds, leading to an higher amount of free phenol units in the lignin from archaeological waterlogged wood, compared to sound lignin from reference wood of the same species.

1. Introduction

Wooden objects from past civilizations are very rare, because they can be easily degraded by fungi, bacteria and insects. They are therefore considered to be extremely valuable and require careful attention, conservation and study. It is particularly important to improve our understanding of the processes and the chemical changes that affect archaeological wooden artifacts during ageing and degradation, in order to develop efficient conservation treatments.

Archaeological wooden artifacts can survive better in environments where microbial and fungal activity is limited, as is the case of underwater shipwrecks. Waterlogged wood has unique features that require special consideration in terms of conservation and preservation. In aquatic environments anaerobic bacteria are primarily responsible for the depletion of wood carbohydrates, leaving a porous and unstable residual structure mainly consisting of lignin [1,2]. If these kinds of objects are allowed to dry without proper consolidation, e.g. by impregnation or bulking with polymeric materials, the wood may shrink, fragment and collapse into pieces [3]. Lignin can also degrade or become transformed to a limited extent, and very little is known about the chemical decay of lignin, although it is believed to be limited compared to the degradation undergone by cellulose and hemicellulose [4].

The type of deterioration, and how these processes impact the wood are important issues in terms of the study and appropriate preservation of waterlogged wooden objects and cultural properties. If there are variations in the composition of lignin these may influence the interactions between the wood and the impregnant/consolidant materials used to fill the cavities when the object is brought to ambient conditions and exhibited.

The optimal conservation treatment for waterlogged wood artifacts is far from being definitively assessed, and depends on many factors that vary from case to case. The choice of conservation is made even more difficult by the cost, the long period of time required and the technical problems arising when large objects such as shipwrecks need to be conserved [5]. Moreover, the long-term stability of impregnated waterlogged wood artifacts is still a matter of discussion and research, also given the recently highlighted degradation phenomena observed in world-famous

shipwrecks such as the Vasa in Stockholm, which was treated with polyethyleneglycol [6].

In this study we investigated the chemical alteration of lignin in wood samples from the archaeological site of the Ancient Ships of San Rossore (Pisa, Italy), where over the last 10 years 31 Roman shipwrecks dating between 2nd century BC to 5th century AD have been discovered [7].

Lignin is a complex three-dimensional macromolecule, made up of various different monomeric units, basically derived from coniferyl alcohol in softwoods, and from both coniferyl alcohol and sinapyl alcohol in hardwoods, bound through different bonds [8,9]. In view of the difficulties in its characterization, the adopted analytical approach integrated pyrolysis-gas chromatography/mass spectrometry (Py-GC/MS) with a set of nuclear magnetic resonance spectroscopic techniques, namely: bidimensional heteronuclear single quantum coherence (2D-HSQC,) quantitative carbon nuclear magnetic resonance (^{13}C NMR), and phosphorous nuclear magnetic resonance (^{31}P NMR).

The study was supported by Zeisel analysis to quantify lignin methoxyl groups, and gel permeation chromatography (GPC) to determine the molecular weight distribution of lignin.

The purpose was not only to gain information on lignin decay patterns in waterlogged archaeological wood, and to contribute to the complex issue concerning the study and conservation of degraded wood artifacts, but also to compare the results obtained with the adopted techniques, and to evaluate the potential of an integrated analytical approach to gain information on the chemical structure of the lignin polymer.

In terms of the specific problem of studying lignin decay processes in a highly degraded waterlogged wood, containing a very low amount of holocellulose (10–20% or less), a comparison of the analyses of sound reference wood and degraded waterlogged wood can be limited by the fact that the presence or absence of polysaccharides can influence or interfere with the analysis of lignin. For these reasons, in this study we characterized lignin extracted from archaeological wood, and compared it with lignin extracted from sound wood of the same species in the same extraction conditions. Extraction was performed in mild conditions in order to avoid further degradation. In this experimental set-up, sound reference lignin and archaeological lignin, treated in the same way in terms of the extraction, can be analyzed in the same conditions and in particular in the absence of polysaccharides.

The use of pyrolysis techniques in combination with mass spectrometry has proved to be of particular interest in the study of lignocellulosic macromolecules. In particular, Py-GC/MS provides useful information on the chemical structure of lignin [10–13]. In Py-GC/MS the macromolecules are depolymerized by heat, and the fragments produced are identified by mass spectrometry, after gas chromatographic separation. In the case of lignin, it is assumed that pyrolysis products represent, to a greater or lesser degree, the structural units that make up the macromolecule. Polymer subunits undergo thermal degradation under pyrolysis, consequently the information obtained is strictly dependent on the adopted instrumental conditions: primarily the selected pyrolysis temperature and asset of the pyrolyser; secondly, the parameters of the transfer line/interface between the pyrolyser and the GC, where secondary reactions occur. A low temperature will not produce sufficient fragmentation of the stronger bonds in the macromolecules, while on the other hand a high pyrolysis temperature will produce extensive fragmentation of the sample, yielding less informative low molecular weight fragments, and producing secondary reactions. A possible method to increase the volatility of pyrolysis products for GC/MS analysis, thus improving the analytical response, accelerating their transfer to the GC column and limiting the possibility of thermal degradation, is to perform *in situ* thermally assisted derivatization of the pyrolysis products. In the literature, the application of *in situ* derivatization methods in the pyrolysis of wood appears to be limited: results obtained with methylating [10,13,14] and silylating [15,16] reagents are described, while the majority of published applications do not use derivatization.

Py-GC/MS has been applied in the study of cellulose and lignin, to investigate decay processes in degraded wood [17–22] and also in a few cases in the specific study of historical or archaeological wood samples [23–26]. The literature data show that highlighting chemical alterations in the residual lignin structure of waterlogged wood is not straightforward. A comparison of Py-GC/MS profiles of degraded wood with those obtained from sound wood of the same species enables differences in the variations of the relative amounts (in terms of chromatographic peak areas) of minor pyrolysis products of lignin [22] to be observed. A comparison of pyrolysis profiles with those in the literature is of limited use because of the variability of pyrolysis products depending on the instrumental conditions used.

High-resolution nuclear magnetic resonance (NMR) spectroscopy has been one of the most important analytical techniques for 40 years, nevertheless until recently its impact on archaeology has been minimal for two reasons well described by Lambert et al. [27] and concerning the sensibility, sensitivity and resolution of this technique. Recent developments have dramatically changed this situation and now this technique is also used with good results in the field of cultural heritage. In particular, the possibility to determine and quantify functional groups and intermonomeric bonds in lignin by NMR has been demonstrated. In addition the high-resolution nuclear magnetic resonance of ^{13}C, developed in the field of geochemistry to characterize fungal degraded wood [28] and to evaluate lignin in organic matter [29] and sediments [30], was used to characterize archaeological wood samples from the 11th century excavation site at the Lake Paladru at Charavines, France [31]. The main result was the preservation of the most abundant intermonomeric bond in lignin structure, the so-called β-O-4. The solid state ^{13}C NMR is not sensitive enough to characterize and quantify the other important intermonomeric bonds present in lignin structure, and with this technique is not possible to observe and quantify the important functional groups such as carboxylic and alcoholic moieties. In order to avoid this problem new NMR analytical tools have been adopted, such qualitative and quantitative 2D-HSQC, quantitative ^{13}C NMR and ^{31}P NMR analysis [32,33] and especially qualitative and quantitative 2D-HSQC, which is nowadays the best tool for analyzing lignin [34,35], giving a complete picture of the chemical features of lignin.

2. Materials and methods

2.1. Reagents

The derivatization reagent for Py-GC/MS analysis was 1,1,1,3,3,3-hexamethyldisilazane (HDMS, 99.9%, Sigma–Aldrich Inc., USA). All solvents, including deuterated methyl sulfoxide-d_6 (DMSO, 99.9% Sigma–Aldrich Inc., USA) were of analytical grade and used without any further purification.

2.2. Samples

Archaeological waterlogged wood samples from bollards recovered from the excavations at the site of the Ancient Ships of Pisa (Tuscany, Italy) were made available by the Archaeological Superintendence of Tuscany (Florence), within the framework of a project for the development and evaluation of conservation treatments for waterlogged wood archaeological artifacts [36]. The wood *taxa* were: *Fagus sylvatica* (G, beech), *Ulmus* cfr. *minor* (D, elm), *Pinus pinaster* (F, pine), the same wood used to build the shipwrecks

Table 1
Value of lignin content (Klason lignin) and holocellulose content (w/w, %), previously reported by Giachi et al. [36] for the archaeological and sound wood examined in this study.

	Pine		Elm		Beech	
	Sound	Arch.	Sound	Arch.	Sound	Arch.
Klason lignin (w/w) %	25.0 ± 1.0	68.0 ± 1.0	27.0 ± 1.0	75.1 ± 0.5	24.0 ± 1.0	77.5 ± 1.0
Holocellulose (w/w) %	58.0 ± 1.0	19.3 ± 1.0	55.0 ± 1.0	6.4 ± 0.6	74.0 ± 1.0	9.2 ± 1.0

recovered at the site. The archaeological artifacts from the site are dated from a period between the 2nd century BC and the 4th century AD. Seasoned wood samples of the same species used as references were provided by IVALSA CNR (Florence). These wood samples were previously characterized [37] according to classical methods for the determination of lignin (Kalson lignin) [38], holocellulose [39], and extractives [36] and some of the results, highlighting the extensive loss of polysaccharides, are reported in Table 1.

2.3. Lignin preparation

The lignin was extracted from archaeological and reference wood using a modification of the milled wood method developed by Björkman [40] and modified by Holmbom and Stenius [41]. Wood fragments (10 g) were freeze-dried, then ground in a mortar. The wood powder was extracted in Soxhlet with ca. 250 ml of acetone–water (9:1) for 48 h and then dried at 50 °C to a constant weight. The dry wood powder was milled in a laboratory ball mill for 48 h at 75 rpm. The powder (9.5 g) was sonicated in dioxane–water (9:1) for 2 h and the dioxane–water-solution was distilled under reduced pressure until almost dry. Iced acetic acid (80 ml) was added to the powder suspension and the wood suspension was kept, under magnetic stirring, at 50 °C for 2 h. The suspension was then filtered and washed with 50 ml of iced acetic acid. Subsequently, 50 ml of distilled water was added to the filtrate and kept at a temperature of 4 °C over night in order to obtain a precipitate. The precipitate was isolated by centrifugation and washed with distilled water. The lignin was then lyophilized in order to dry it. The amount of lignin obtained was about 500 mg. Approximately 60 mg of the extracted lignin was acetylated with acetic anhydride for NMR analysis: pyridine 1:1 (v/v).

2.4. Zeisel analysis

Zeisel analyses were performed using a GC-FID as reported by Girardin and Metche [42], in order to quantify the methoxyl groups in lignin. The Zeisel method is based on the following reaction:

$$\text{L-OCH}_3 + \text{HI} \rightarrow \text{L-OH} + \text{CH}_3\text{I} \quad (140\text{–}150\,^\circ\text{C})$$

2.5. Py-HMDS/GC/MS

Py-GC/MS (pyrolysis-gas chromatography/mass spectrometry) was performed in a 5150 CDS Pyroprobe 5000 Series with a coil filament connected to a 6890 Agilent gas chromatograph (USA) coupled to a 5973 Agilent mass selective detector operating in electron impact mode (EI) at 70 eV. On the basis of a careful comparison of the literature, pyrolysis temperatures between 450 and 600 °C were tested and 500 °C was chosen. Pyrolysis was carried out for 20 μs using a platinum coil probe and quartz sample tubes. We adopted hexamethyldisilazane (HMDS) as *in situ* derivatizing agent for hydroxyl and acidic moieties. Constant amounts (40–60 μg) of lignin and hexamethyldisilazane (5 μl) solution (70% in acetone) were inserted in the centre of the pyrolysis quartz tube and placed in the pyrolysis coil filament. Chromatographic separation was performed on an HP-5MS fused silica capillary column (stationary phase 5% diphenyl–95% dimethyl-polysiloxane, 30 m × 0.25 mm i.d., Hewlett Packard, USA) with a de-activated silica pre-column (2 m × 0.32 mm i.d., J. and W. Scientific, Agilent Technologies, USA). Chromatographic conditions were as follows: an initial temperature of 31 °C, 8 min isothermal, 10 °C min^{-1} up to 240 °C, 3 min isothermal, 20 °C min^{-1} up to 300 °C, 30 min isothermal. Carrier gas: He (purity 99.995%), constant flow 1.0 ml min^{-1}. Each sample was analyzed in four replicates. Quantification was based on peak areas (total integral of identified compounds equals 100).

2.6. 2D-HSQC and ^{13}C NMR

2D-HSQC and ^{13}C NMR spectra were run in DMSO on acetylated samples, to avoid fractionation of the material before NMR analysis and to increase both solubility and chemical shift dispersion of the side chain units [43]. Thus, before NMR analyses, the extracted lignin (0.1 g) was acetylated with acetic anhydride/pyridine 1:1 (v/v) (2 ml), then 60 mg of acetylated lignin were dissolved in 0.75 ml DMSO-d_6. The inverse detected ^1H–^{13}C correlation (2D-HSQC–NMR) spectra were recorded on a Bruker (USA) 500 MHz instrument at 308 K. The spectral width was set at 5 kHz in F2 and 25 kHz in F1. A total of 128 transients in 256 time increments were collected. The polarization transfer delay was set at the assumed coupling of 140 Hz and a relaxation delay of 2 s was used. Spectra were processed using $\Pi/2$ shifted squared sinebell functions in both dimensions before Fourier transform. The assignment of predominant signals in 2D-HSQC–NMR spectra was based on the chemical shift data of lignin model compounds and milled wood lignin (MWL), as reported in the literature [32,44–46].

The 1D-^{13}C spectra were recorded at 333 K using a Varian Mercury 400 MHz instrument. Chemical shifts were referred to the solvent signal at 39.5 μg g^{-1}. To obtain quantitative ^{13}C NMR spectra, a relaxation delay of 10 s (45° pulse angle) was used between the scans [47]. A line broadening of 2–5 Hz was applied to FIDs before the Fourier transform. For each spectrum, about 16,000 scans were typically accumulated.

2.7. ^{31}P NMR

In order to characterize and quantify all the different functional groups with labile –OH, nuclear magnetic resonance analysis of phosphorus (^{31}P NMR) of lignins extracted from woods was performed, as reported in the literature [33]. Accurately weighed lignin samples (40 mg) were dissolved in a solvent mixture composed of pyridine and deuterated chloroform 1.6:1 (v/v 0.5 ml). Then 100 μl of 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane were added, together with a solutions of N-hydroxynaphthalimide as an internal standard and tris(acetylacetonate)chromium(III), [$Cr(acac)_3$], as relaxation reagent (100 μl each). The ^{31}P NMR spectra were then recorded at 333 K using a Varian Mercury 400 MHz instrument. The ^{31}P NMR data reported in this paper are averages of three experiments. The maximum standard deviation of the reported data was 2×10^{-2} mmol g^{-1}, while the maximum standard error was 1×10^{-2} mmol g^{-1}.

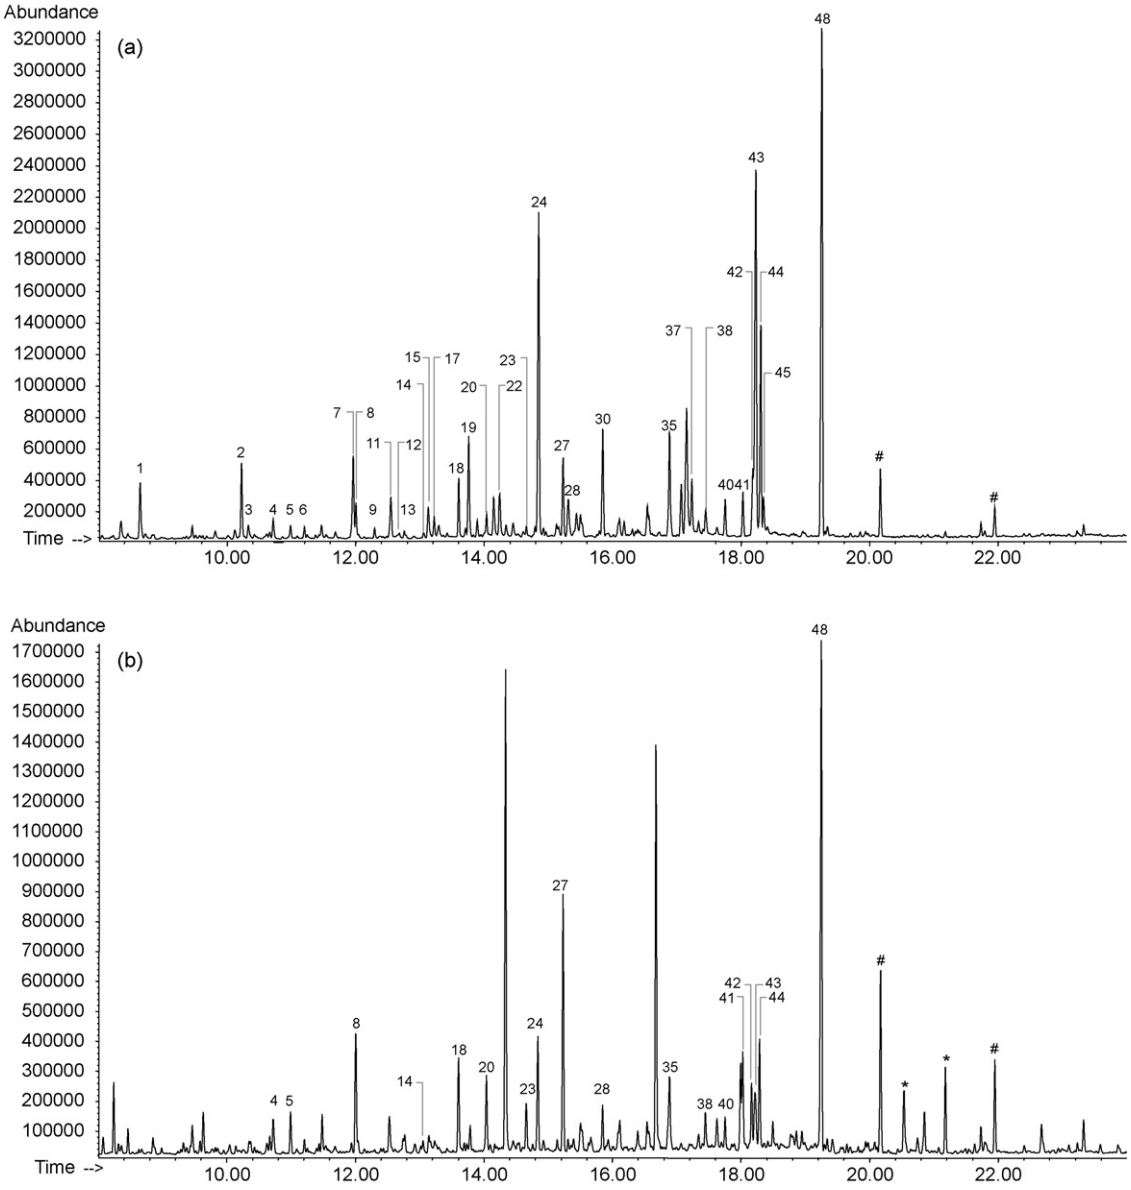

Fig. 1. Py-GC/MS profiles of lignin extracted from (a) sound pine wood (*Pinus pinaster*) and (b) archaeological pine wood from San Rossore site. (*): unidentified impurities deriving from the sediment; (#): fatty acids.

2.8. GPC

The investigation was carried out on acetylated lignin samples, following the methodology developed by Himmel et al. [48]. The analyses were performed using a Waters (USA) 600 E liquid chromatograph connected to an HP 1040 ultraviolet diode array (UV) detector set at 280 nm. The GP-column was an Agilent (USA) PL 3 μm MIXED gel E and the solvent used was tetrahydrofuran. Polystyrene (PS) standards from Polymer Laboratories (USA) were used for the calibration. The PS calibration curve was tested using acetylated dimeric, tetrameric, and hexameric lignin model compounds. The acetylated lignin samples were dissolved in THF (1 mg ml^{-1}) and analyzed at a flow rate of 0.8 ml min^{-1}.

3. Results and discussion

3.1. Py(HMDS)GC/MS

A complex mixture of phenolic products, diagnostic for the different lignin units, is formed in the pyrolysis of lignin and determined by GC/MS. Softwood lignin is characterized by guaiacyl compounds only, while the presence of both guaiacyl and syringyl compounds among pyrolysis products indicates that the lignin is of an angiosperm origin (hardwood).

In the presence of HMDS, alcoholic, phenolic and carboxylic functionalities are transformed into the corresponding trimethylsilyl-ethers and esters, although for some compounds the silylation reaction is not complete during pyrolysis, and leads to the presence of underivatized or partially derivatized compounds. The yield of the silylation is the result of many factors, including the formation rate of the pyrolysis product and its transfer rate to the GC. The partial derivatization of some peaks has the effect of increasing the complexity of the chromatograms, but this drawback is balanced by the possibility of highlighting compounds bringing polar carboxylic moieties, and of differentiating free and bound phenol groups on the basis of their degree of derivatization.

Fig. 1 shows the chromatogram obtained for reference pine lignin and archaeological pine lignin. Table 2 reports peak identification, on the basis of the mass spectral library, of the literature data, and of the interpretation of mass spectra. The most abundant

product of the pyrolysis of pine lignin, in the adopted conditions, is *E*-coniferyl alcohol. This alcohol, with a cinnamylic structure, appears in the chromatogram in two forms: the *bis*-TMS form (no. 48, MW 324) where both the alcoholic and the phenolic –OH are transformed into the corresponding silyl-ethers, and the *mono*-silylated form (no. 43, MW 252) where only the alkyl OH function is derivatized. The formation of cinnamylic alcohols as main pyrolysis product of lignin has been reported in the analysis of lignin using filament pyrolysers and in the presence of an *in situ* derivatizing agent [16]. According to the literature on the other hand, it is generally not observed when a furnace pyrolyser is used [26] and also when pyrolysis is performed in the absence of a derivatizing agent [21]. This may be explained with the fact that the trimethylsilyl group has a protective effect, during pyrolysis, towards the defunctionalisation of the primary alcohol function on the propylic side chains of lignin units. This means that, in the conditions adopted in this study, in the presence of HMDS, the pyrolysis conditions are particularly mild and pyrolysis products nearly reflect the structure of lignin monomers, avoiding the shortening and defunctionalisation of the propenyl side chain.

Other abundant pyrolysis compounds of pine lignin include guaiacol, methylguaiacol, isoeugenol, vanillin and acetovanillone.

A comparison between the pyrogram of reference pine lignin with archaeological pine lignin, shows a very good level of lignin preservation in archaeological wood, which gives the same pyrolysis products observed in non-aged lignin. The difference between the two chromatograms is not qualitative (appearance or disappearance of peaks is not observed), but it is rather in the relative

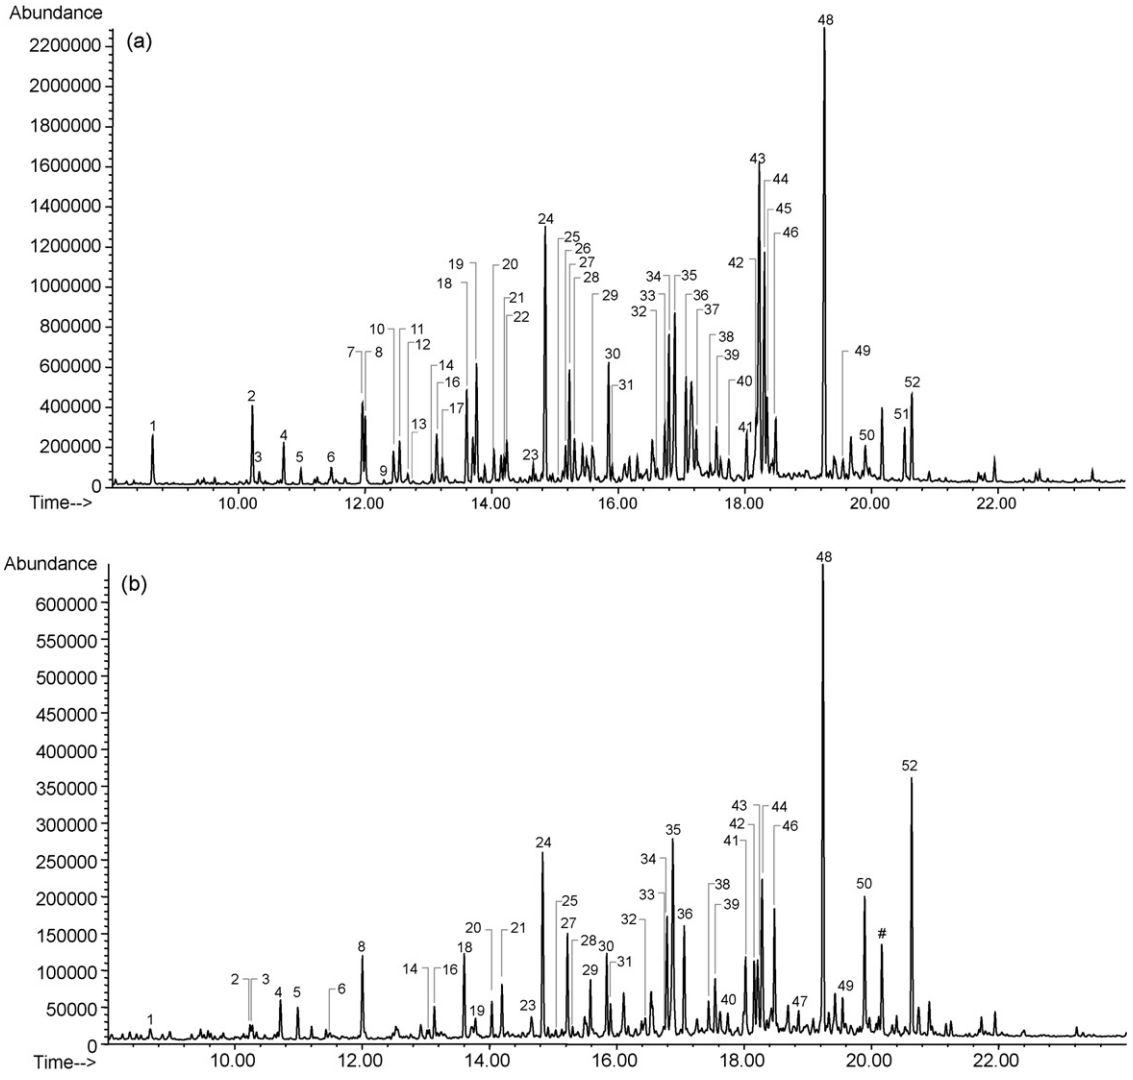

Fig. 2. Py-GC/MS profiles of lignin extracted from (a) sound beech wood (*Fagus sylvatica*) and (b) archaeological beech wood from the San Rossore site.

amounts of pyrolysis products. The evaluation of the pyrograms was therefore based on the calculation of relative peak areas, which can be considered a semi-quantitative information, even if not indicative of absolute amounts. For this reason, particular attention was given to reproducibility, and analyses were performed in four replicates of each kind of lignin. We observed that taking special care in using the same sample amount for each replicated analysis, and in positioning the sample in the centre of the tube with the aid of a capillary, permitted to enhance reproducibility, achieving a relative standard deviation for relative peak areas around 15%. The average results, in term of percentage peak areas with respect to the total area of identified peaks, are reported in Table 2.

The main difference observed in archaeological pine lignin with respect to sound lignin is in the different yield of derivatization of the phenolic function of coniferyl alcohol: in the sound pine lignin pyrogram the ratio between the *mono*-TMS form (where only the alkylic OH function is silylated) and the *bis*-TMS form (where both the alkylic and phenolic OH functions are silylated) is around 0.8, while in the archaeological lignin pyrogram the ratio between the two forms is neatly different: 0.2. Many other pyrolysis product give a higher derivatization yield in the analysis of archaeological lignin, while their underivatized form is abundant in the pyrogram of sound lignin: guaiacol, methylguaiacol, 4-ethylguaiacol, 4-vinylguaiacol, and isoeugenol.

This behavior needs to be put in relation to an increased reactivity of phenolic –OH towards HMDS in the pyrolysis of lignin extracted from archaeological wood, compared to the lignin extracted from sound wood, addressing to the fact that in aged archaeological lignin there is a higher concentration of free phenolic OH, which is more prone to react with HMDS.

This trend is also observed in the analysis of archaeological lignin from beech and elm samples, the results of which are also reported in Table 2. Chromatograms obtained in the analysis of reference and archaeological beech lignins are shown in Fig. 2. In addition to guaiacyl compounds observed in pine lignin, in beech and elm the corresponding syringyl components are present. In particular, in hardwoods, in addition to coniferyl alcohol, cinnamyl alcohol with a syringyl structure is also present: namely sinapyl alcohol. As in the case of pine, hardwood archaeological lignin from beech and elm samples produces pyrolysis products which are similar to those observed in sound lignin from the same species and analyzed in the same conditions, as can be seen from Table 2. This suggests a very good conservation state of lignin. The most interesting difference between reference and archaeological lignin from elm and beech is, as with pine, the derivatization yield of the phenolic groups, especially in terms of cinnamyl alcohols. The ratio between the amounts of *mono*-TMS-coniferyl alcohol and *bis*-TMS-coniferyl alcohol is on average 0.2 for archaeological elm lignin compared to 0.7 in refer-

Table 3
Values of methoxyl group content expressed in mmol g^{-1} for the three archaeological wood samples and three sound wood samples.

	Pine		Elm		Beech	
	Sound	Archaeological	Sound	Archaeological	Sound	Archaeological
O–CH_3 (mmol g^{-1})	3.1 ± 0.2	2.4 ± 0.2	4.1 ± 0.2	3.1 ± 0.2	3.7 ± 0.2	3.4 ± 0.2

ence elm lignin, and 0.3 in archaeological beech lignin compared to 1.3 in reference beech lignin. The corresponding values for sinapyl alcohols had the same trend: they varied from 0.7 for sound lignin to 0.1 for archaeological lignin in elm, and from 1.0 to 0.3 in beech lignin.

It is evident that in the pyrolysis-GC/MS of archaeological lignin from the San Rossore site in the presence of HMDS, phenolic groups on lignin units are silylated with a higher yield compared to the correspondent sound lignin. From the literature, this can be explained by the presence of a higher amount of the free phenol unit in archaeological lignin [16]. In fact, it is known that, due to the high stability of phenol ether bonds with respect to alkyl ether bonds, only free phenol groups on lignin units are derivatized with a high yield with thermally assisted silylation reagents, while phenol groups that are linked in a β-aryl ether bond or a β-5 bond do not react efficiently with the derivatizing agent [15]. This shows that the main difference between archaeological lignin and sound lignin is in that archaeological lignin contains a relatively greater amount of free phenol groups, not involved in intermonomeric bonds, on guaiacyl and syringyl units. A waterlogged environment would thus seem to lead to chemical pathways which themselves lead to the cleavage of phenol ether bonds, with depolymerization and a resulting increase in free phenolic groups. One important consequence is that an increased amount of free phenols creates a more polar and acidic lignin network.

These results were confirmed by the analysis of the same samples using NMR and GPC, illustrated in the following sections.

Another parameter that presents a substantial variation in archaeological elm and beech lignin compared to reference lignin is the content of *E*-sinapaldehyde-TMS, which in the pyrograms is higher in aged lignin, suggesting oxidation processes.

Py-HMDS-GC/MS has permitted also to evidence the presence of enhanced amounts of carboxyl acid functionalities on lignin units, in particular in position α respect to the aromatic ring, in some of the analyzed archaeological samples, with respect to the corresponding sound lignin. This can be seen in Table 2 which reports the amounts of vanillic and syringic acids determined in archaeological and reference lignin.

Due to the polarity of carboxylic benzyl acids and to their low amounts, their increase would not have been observed without using HMDS, which renders them volatile by transforming them into the corresponding TMS-esters.

3.2. Quantification of total methoxyl groups using the Zeisel method

A quantitative evaluation of the methoxyl content in lignin extracted from archaeological waterlogged wood and from sound wood using the Zeisel method [42] gave the values shown in Table 3. A slight demethylation was observed in archaeological lignin. Although demethylation has been shown to be a typical reaction of the enzymes present in brown rot fungi [49], underwater environments do limit the growth of fungi. Py-HMDS-GC/MS did not highlight an increase in catechols or methoxycatechols in aged lignin, compounds that are considered as products of the fungal degradation of lignin.

3.3. NMR analyses

3.3.1. 2D-HSQC

Lignin samples were analyzed by 2D-HSQC spectroscopy to identify the principal intermonomeric units in lignin and to evaluate any significant changes in the lignin structure of archaeological wood compared to lignin in the reference wood sample. The predominant intermonomeric units present in softwood and hardwood lignin (Fig. 3) include: arylglycerol-β-arylether (β-O-4), phenylcoumaran (β-5), pinoresinol (β–β), and dibenzodioxocine (5-5′-O-4). In Fig. 3 the 2D-HSQC of acetylated lignin extracted from pine used as reference is also reported. Fig. 4 reports the expansion of the intermonomeric zone of the 2D-HSQC spectrum of acetylated lignin from archaeological pine.

The results highlight that lignin from all archaeological wood samples are rich in arylglycerol β-O-4 units and at the same time cross-peaks were identified that relate to other principal intermonomeric bonds. These results confirm and reinforce the conclusion of Bardet et al. [31]: in aged waterlogged wood the

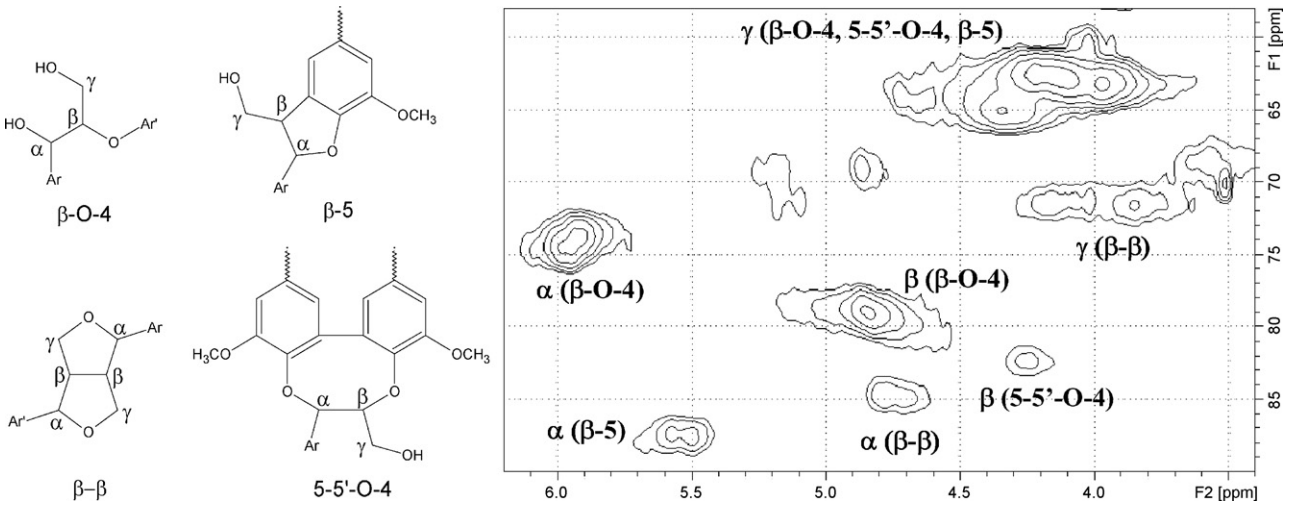

Fig. 3. 2D-HSQC of acetylated lignin sample extracted from sound pine (*Pinus pinaster*) with the interpretation of the predominant intermonomeric bonds. The symbols α, β, γ on HSQC spectra indicate the corresponding atom on the dimeric lignin structure where the H–C cross-peak is observed.

Table 4
The relative amounts of the predominant intermonomeric units are, expressed as "+" marks, where each "+" the three archaeological wood samples and three sound wood samples.

	Pine		Elm		Beech	
	Sound	Archaeological	Sound	Archaeological	Sound	Archaeological
β-O-4	+++++	++++	+++++	++++	+++++	+++
β-5	+++	++	++	+	++	traces
β–β	++	+(+)	++	+(+)	+++	+++
5-5′-O-4	++	n.d.	n.d.	n.d.	n.d.	n.d.

chemical structure of lignin is not heavily modified, and the principal intermonomeric bonds are still present. In the case of lignin extracted from archaeological pine the 5-5′-O-4 unit was not observed.

3.3.2. ^{13}C NMR

In order to better evaluate the changes in the intermonomeric units of lignin extracted from archaeological and sound wood, quantitative ^{13}C NMR analysis was performed by relating the intensity of each characteristic ^{13}C signal (80 ppm for α in β-O-4, 86 ppm for α in β-5, 84 ppm for α in β–β and 80 ppm for β in 5-5′/β-O-4) to that of the methoxyl signal (56 ppm) and multiplied by the average number of methoxyl groups per aromatic ring. The relative amounts of predominant intermonomeric units are reported in Table 4, expressed as a "+" sign, where each "+" means 0.06–0.09 referring 1 the intensity of methoxyl signal. The relative amounts were roughly estimated due to the overlap of the signals.

The results show that in all lignins extracted from archaeological wood there is was a reduction in β-O-4 intermonomeric bonds and a significant reduction in hardwood archaeological lignin (elm and beech) of β-5 intermonomeric bonds. In archaeological pine lignin it is confirmed that the 5-5′-O-4 intermonomeric bond is not detected. We were not able to detect any significant changes in the relative amounts of β–β bonds.

3.3.3. ^{31}P NMR

The lignin extracted from archaeological and sound wood was therefore also analyzed using ^{31}P NMR techniques, following procedures from the literature [33]. With this technique it is possible to distinguish and quantify *p*-hydroxycumaryl, guaiacyl, syringyl and condensed (by a C–C or C–O bond in position 5) free phenolic units, as well as carboxylic acids (Table 5).

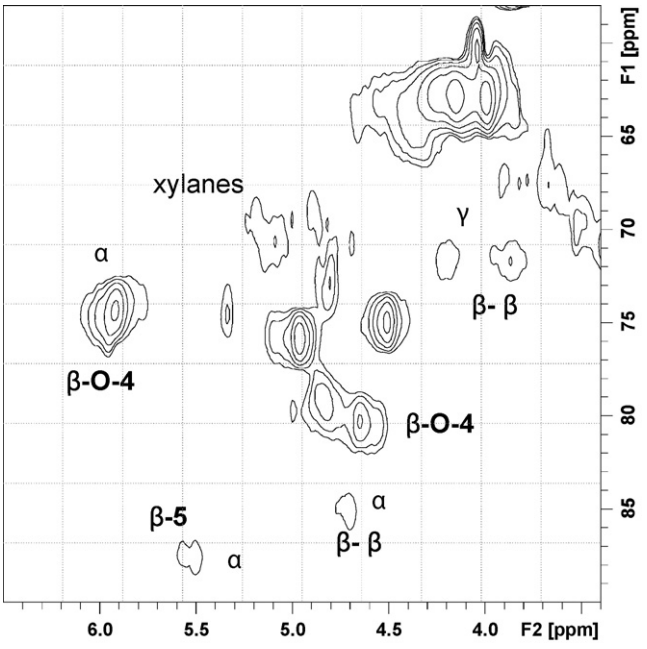

Fig. 4. 2D-HSQC of acetylated lignin sample extracted from archaeological pine.

Table 5
Content values of different free phenols (guaiacyl, syringyl, *p*-hydroxycumaryl, condensed in position 5 and total) and total acidic groups, expressed in mmol g^{-1} of lignin. The maximum standard deviation of the reported data was 2×10^{-2} mmol g^{-1}.

	Pine		Elm		Beech	
	Sound	Arch.	Sound	Arch.	Sound	Arch.
–OH guaiacyl	0.94	1.07	0.90	0.84	0.34	0.35
–OH syringyl	n.d.	n.d.	0.13	0.30	0.30	0.31
–OH *p*-hydroxy cumaryl	0.10	0.24	0.10	0.13	0.10	0.12
Condensed –OH	0.29	0.60	0.23	0.54	0.30	0.33
Total free phenols	1.33	1.91	1.36	1.81	1.04	1.11
Acidic groups	0.24	0.35	0.13	0.40	0.24	0.38

In all cases a significant increase in total free phenolic content and of acidic moieties is observed. These results are in agreement with the data from Py-HDMS-GC/MS, where an increase in free phenol and acidic compounds in three types of archaeological wood was found. The main increase in phenol content was due to condensed phenols (bringing an intermonomeric bond in position 5). The condensed phenols are represented mainly by 5-5′ and 4-O-5 units. The increase in condensed phenols and acidic units is reported in the literature by Crestini and Argyropoulos [50]. This variation can be explained by assuming that the condensed structures are the most stable to oxidation, and by assuming some condensation reactions.

3.3.4. GPC

The effects of ageing on the lignin structure of archaeological waterlogged wood were further elucidated by evaluating the changes in molecular weight distribution in the extracted acetylated lignin, in order to detect a possible increase/decrease in lignin molecular weight.

Estimating the lignin molecular weight distribution (MWD) is complicated: lignins are irregular multiple branched polymers containing various polar functionalities and are insoluble in most

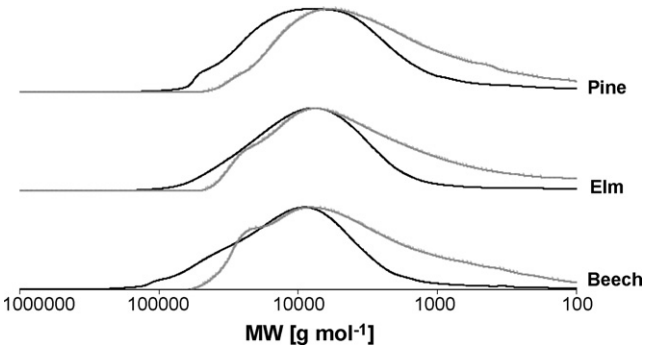

Fig. 5. Gel permeation chromatogram of acetylated lignin from beech, elm and pine. The black line refers to the sound wood samples, the grey line refers to the archaeological wood samples.

common solvents. The acetylation of lignin enhances solubility and allows the use of THF as a solvent, which decreases interactions between lignin chains thus avoiding macromolecular association. Fig. 5 reports the chromatograms obtained by GPC for lignin extracted from sound beech, elm and pine wood (black line) and the corresponding archaeological lignin (grey line). A slight decrease in lignin molecular weight for all the archaeological woods is noted compared to the sound wood. For beech and elm we only observe a loss in high fraction molecular weight, while for pine the decrease in MWD is clearer. In fact it is possible to note a shift in the chromatogram towards the region a lower molecular weight. These results generally demonstrate a partial degradation of lignin in archaeological wood.

4. Conclusions

The chemical structure of lignin in archaeological wood from San Rossore, which after a prolonged period in an aquatic environment have lost most of their original holocellulose content, is still very similar to the chemical structure of sound lignin. This confirms that in anaerobic environments, and in particular in the absence of fungi, the modifications induced in lignin are quite limited.

The use of many complementary techniques based on NMR in conjunction with the results obtained by analytical pyrolysis and GPC enables to highlight minor changes in the polymer structure of lignin. The main difference highlighted by using Py-GC/MS in the presence of HMDS as a silylating reagent of pyrolysis product is the different reactivity towards the derivatizing agent of reference lignin and archaeological lignin. The phenol groups in cinnamyl units of archaeological lignin are derivatized in a much higher yield in the three examined archaeological lignin samples compared to reference lignin. This can be explained by the fact that archaeological lignin has undergone partial depolymerization, with the cleavage of ether intermonomeric bonds and the production of a higher concentration of free phenol groups, which are free to react easily with HMDS. As alcoholic ether bonds are more easily cleaved compared to phenol ether bonds, the cinnamyl alcohols undergo fragmentation and chain shortening, producing the lower molecular weight compounds seen in the chromatogram. The phenolic ether bonds take longer to cleave, and give rise above all to *mono*-TMS cinnamyl alcohols.

The adoption of *in situ* sylilating conditions permits to enhance this specific difference in the reactivity of the two lignins (archaeological and sound), performing the same analysis in the absence of HMDS, on the other hand, does not lead to highlight significant differences between archaeological lignin and reference lignin. The main advantage of Py(HMDS)-GC/MS is that it gives meaningful information in a very short time, avoiding sample manipulation, and with only the need for a minimal amount of sample.

The data provided by Py-GC/MS are confirmed and completed by the detailed NMR investigation, which highlights many aspects of the complex chemical features of lignin including:

- The kinds of intermonomeric bonds, and how some of them are partially cleaved in pine archaeological lignin.
- The amount of methoxy groups and free phenols groups on aromatic rings, and the formation of carboxylic acid functionalities in α position that is also suggested Py-GC/MS profiles.

Moreover, although the GPC of extracted lignin does not give absolute quantitative parameters for assessing the distribution of molecular weight in lignin polymer, due to the absence of appropriate standards, it shows that the partial cleavage of intermonomeric bonds can also be highlighted using a chromatographic approach. This shows shifts, and the formation of shoulders at lower molecular weights in archaeological lignin. This is the first time that the depolymerization of lignin and the cleavage of intermonomeric bonds have been chemically shown as a result of wood degradation in ancient objects.

The most important conclusion from this investigation is that lignin from waterlogged wood samples from the site at San Rossore has been shown to have undergone the cleavage of phenol–ether bonds with the formation of free phenol groups, and oxidation with the formation of carboxyl acid groups. The presence of an increased concentration of carboxylic and free phenol functionalities in the lignin network confers enhanced polarity and cation exchange properties to archaeological wood. This needs to be taken into consideration in terms of its influence on the chemical interaction between waterlogged wood and any consolidating materials that might be used for conservation.

Acknowledgments

The authors wish to thank Dott.ssa G. Giachi (Archaeological Superintendence of Florence, Italy), Prof. I.D. Donato (University of Palermo) and IVALSA (CNR, Florence) for providing samples and for their valuable collaboration. Economic support was provided by the Archaeological Superintendence of Tuscany and by the Italian MIUR funding PRIN Cofin05.

ABSTRACT

The process of investigating paintings includes the identification of materials to solve technical and historical art questions, to aid in the deduction of the original appearance, and in the establishment of the chemical and physical conditions for adequate restoration and conservation. In particular, we have focused on the identification of several samples taken from six famous canvases painted by Pedro Atanasio Bocanegra, who created a very special collection depicting the life of San Ignacio, which is located in the church of *San Justo y Pastor* of Granada, Spain. The characterization of the inorganic and organic compounds of the textiles, preparation layers, and pictorial layers have been carried out using an XRD diffractometer, SEM observations, EDX spectrometry, FT-IR spectrometry (both in reflection and transmission mode), pyrolysis/gas chromatography/mass spectrometry and synchrotron-based μ-X-ray techniques. In this work, the advantages over conventional X-ray diffraction of using combined synchrotron-based μ-X-ray diffraction and μ-X-ray fluorescence in the identification of multi-layer paintings is demonstrated.

1. Introduction

Analytical methods are an essential requirement in the cultural heritage field, as they provide the means to understand the objects under investigation. By identifying materials (such as pigments, binders, mixtures, and processes), we can reach back through time and develop a deeper understanding of the craftsmanship and technology used. Analytical methods allow us to contribute to the blooming activity at the interface between art and science. Contributing to the development of diagnostic techniques is necessary for practical applied art conservation. The techniques concerned include: scanning electron microscopy (SEM), energy dispersive X-ray spectrometry (EDX), μ-X-ray analyses (including synchrotron radiation μ-X-ray diffraction (μXRD) and μ-X-ray fluorescence (μXRF)), Fourier transform-infrared spectrometry (FT-IR), and analytical pyrolysis in-line with gas chromatography and mass spectrometry (PY–GC/MS) [1–3]. The analytical methods used in this field of research are identical to those used at the cutting edge of modern materials science. Methods developed for advanced physics and chemistry can be applied to ancient and modern materials, as the problems encountered in the areas of advanced technology and cultural heritage are surprisingly similar. Depending on the information required, one might use a combination of non-invasive techniques; however, one should aim at the maximization of information and the minimization of the sample consumed volume [4,5]. The use of non-invasive techniques is increasing due to the improved development of instruments (e.g. able to determine the elemental and mineral composition of the micrometric multilayers of micro-samples) [6].

Analytical studies of paintings performed at the microscopic and at molecular level are the focus of this paper. Microscopic and molecular studies are carried out on paint samples derived from the painting itself. These samples are unique and in limited supply. Assuming that such samples are representative of an area

under study, valuable general information about the painting can be deduced. The information can be maximized by sequential analyses using different complimentary techniques.

Synchrotron radiation has become an increasingly important tool for research in the fields of art, archaeometry, and the conservation of objects of cultural heritage significance. Synchrotron is a source of intense, bright light of variable wavelength; the principal properties of synchrotron radiation are as follows: high flux and brilliance, ability to produce a fast data collection and the possibility to use small sample size, small beam footprint: it enables area mapping at millimeter to micron length-scale. The wavelength tunability and the energy region can be selected to suit the problem at hand [7–10]. Synchrotron techniques are particularly suited to non-destructive or to the micro-characterization of different materials including organic and inorganic materials, either amorphous or crystalline. New developments in synchrotron radiation techniques result in a significant advance to study the samples at micrometer length scale through the combination of different non-destructive techniques. The most employed till now have been synchrotron X-ray fluorescence and diffraction and, to a lesser extent, small angle scattering (on wood, bone and hair) and infrared microscopy. The synchrotron beam can be focused in sub micrometric spots, allowing the examination of very small samples. The list of artwork studied by using SR is made up of a large variety of materials [7,11].

This article is intended to illustrate the chemical description of the organic and inorganic components of the stratigraphy sequence using, in parallel, the recent applications of microanalytical methods using synchrotron radiation and the information supplied by laboratory techniques. This is exemplified by the identification of pigments and binders in six famous canvases painted by Bocanegra (XVIth century).

2. Experimental

2.1. Historical context

The first reports of Pedro Atanasio Bocanegra as a painter are from 1661 [12]. He included in his paintings many elements of his master, Alonso Cano.

According to Gomez Moreno [12], the Bocanegra paintings of the *San Justo y Pastor* of the church that represents the passages of the *S. Ignacio of Loyola life* (1491–1540) were carried out in two steps. In the first, Bocanegra painted three canvases: "*San Ignacio herido a las puertas de Pamplona*", "*La Aparición de San Pedro*" and "*San Ignacio azotado por un armenio*". In the second step, he created the other three paintings between 1670 and 1671, where these are considered the most important works of oriental Andalusia painting [13]. These canvas paintings are "*La Visión de la Storta*", "*La Aparición de la Trinidad a San Ignacio*" and "*S. Ignacio enviando a predicar a S. Fco. Javier and S. Fco. de Borja*". In these paintings, the author shows technical advances and a greater intensity of color that is reminiscent of the art of Valdes Leal [14]. The painting details are described in Fig. 1. The six paintings are a complex multi-layered composition of organic and inorganic compounds.

2.2. Sampling

The samples were collected by taking small samples close to areas that were already damaged. Twenty samples were careful extracted from different zones of the paintings using a scalpel. The obtained samples were a representative collection of white, red, and blue colors.

Sample preparation is often a tricky point for the study of micrometric fragments of paintings [15]. It may be difficult to carry out all the experiments of a unique sample; conversely, when the quantity of painting fragment is enough, different sample preparations may be followed to fit the technical requirements of each analytical technique. Three types of sample preparation were performed.

Conventional cross-section. The samples were prepared as cylinder moulds and were embedded in epoxy resin as follows: The paint piece was placed on top of the hardened block and carefully covered with resin, and then cast and left to cure for 24 h at room temperature. Next, the sample was cut to expose a face showing the cross-section of the paint layer. Finally, the surface was carefully polished on a rotating disc covered with abrasive SiC paper which spanned a grain size from 800 to 1200 mesh, and then finished with a cloth [16,17]. This method is useful for observation with an optical microscope, SEM/EDX, or FT-IR spectrometer that requires a more careful preparation in terms of surface polish.

Thin transversal cuts. Samples were embedded in a resin (Leica Historesin) to prepare thin sections with a microtome. Several thicknesses were tested, and 20–30 μm was chosen as the most appropriate thickness [18] for SR μXRF/μXRD analyses.

Raw fragments of the samples. Small fragments of the samples were ground to a powder for examination by conventional XRD and for PY–GC/MS [18,19].

Single fibres (a few micrometers in diameter) were carefully extracted from the canvas for textile identification by XRD.

2.3. Analytical techniques: instruments and methods

Observations of the cross-sections were performed by *optical microscopy* using a stereo microscope (Nikon HOPITHOT) with objectives of 20×, 50×, 100×, 200× and equipped for microphotography using a digital camera (Nikon COOLPIX 4500), which was also used to identify the stratigraphy sequences of the different paint cross-sections. The inorganic pigments have been characterized as cross-sections on a Jeol model JSM 5400 *SEM*. Analyses of elemental compositions of the different painting layers were obtained using *EDX* on a Link ISIS X-ray energy dispersive spectrometer equipped with an ultra-thin beryllium window, using an accelerating voltage of 20 keV. The cross-sections were coated with gold film before the SEM/EDX investigations. X-rays analyzed with an energy dispersive detector (EDX) result in a characterization of different chemical elements in the paint cross-section.

The crystalline phases were characterized by *X-ray diffraction* (*XRD*), using a Siemens diffractometer, model Kristalloflex D-5000 using Cu $K\alpha_1$ radiation (40 kV, 30 mA), a diffracted-beam graphite monochromator and a scintillation counter. Measurements were carried out on powders of the sample in the range of $3 < 2\theta < 65^\circ$ with steps of 0.05° and a 2 s counting time. Subsequently, the EVA data bank of standard X-ray powder diffraction patterns was used for phase identification. For textile identification by XRD, the fibres were introduced into a 0.3 mm glass capillary and these were then used to collect X-ray diffraction patterns in transmission mode on a Siemens D5000 dual diffractometer, equipped with a Ge monochromator in the incident beam and Cu $K\alpha_1$ radiation.

Fourier transformed-infrared spectrometry (*FT-IR*) is relevant for the identification of organic compounds, but the surface of the cross-section must be totally planar in order to obtain good reflections [20]. Unfortunately, when organic compounds are mixed with large amounts of inorganic matter, such as in an argillaceous earth layer or lead white, the peaks representative of the inorganic composition predominate in the FT-IR spectrum. The organic constituents are often not visualized with FT-IR, as their reflectance and relative concentrations are low [18], and the signal is reduced in a heterogeneous layer due to scattering of the infrared light within the cross-section. The Kramer–Krönig transformation is applied to the specular reflectance spectrum to transform it into an absorbance-like spectrum, which is more workable and easier to interpret. The *FT-IR spectra* were registered on a Nicolet

Fig. 1. Bocanegra paintings. (a) "San Ignacio herido en las puertas de Pamplona", (b) "Aparición de San Pedro a San Ignacio para curarle", (c) "San Ignacio azotado por un armenio a su vuelta del Monte de los Olivos, consolado por Cristo", (d) "San Ignacio envía a predicar a San Francisco Javier a las Indias y a San Francisco de Borja a Occidente", (e) "Visión de La Storta, camino de Roma, en que se aparece la Trinidad a San Ignacio", and (f) "Aparición de la Trinidad a San Ignacio".

510 spectrometer equipped with a nitrogen-cooled MCT detector and an Olympus optical microscope. The spectra were collected in reflectance mode, in the 4000–700 cm^{-1} range, with a resolution of 4 cm^{-1}. The final format of the data was in absorbance, where the background was collected through a gold film substrate. For each spectrum, at least 100 scans were accumulated. Peak positions were determined using the Nicolet Omnic software (based on a polynomial least squares method). The advantage of infrared spectroscopy is to simultaneously obtain information on both organic and mineral compounds of the painting layers.

Images of the conventional cross-section of paint samples (100×) (a) originating from Trinidad's dress in the "Visión de La Storta", (b) originating from San Ignacio's dress in the "Aparición de San Pedro a San Ignacio para curarle", (c) originating from San Ignacio's dress in the "San Ignacio azotado por un Armenio", and (d) originating from the dress in the San Ignacio Herido en las Puertas de Pamplona.

2.3.1. Synchrotron-based μ-X-ray diffraction and μ-X-ray fluorescence techniques

μ-X-ray diffraction and μ-X-ray fluorescence were performed at the ID18F beamline, at the ESRF. This beamline is a high-energy multi-technique X-ray microscope. The double-crystal monochromator, equipped with both Si[1 1 1] and Si[3 1 1] crystals, offers a wide energy range (6–70 keV) for optimal excitation conditions of a broad range of elements [21]. In this experiment, the excita-

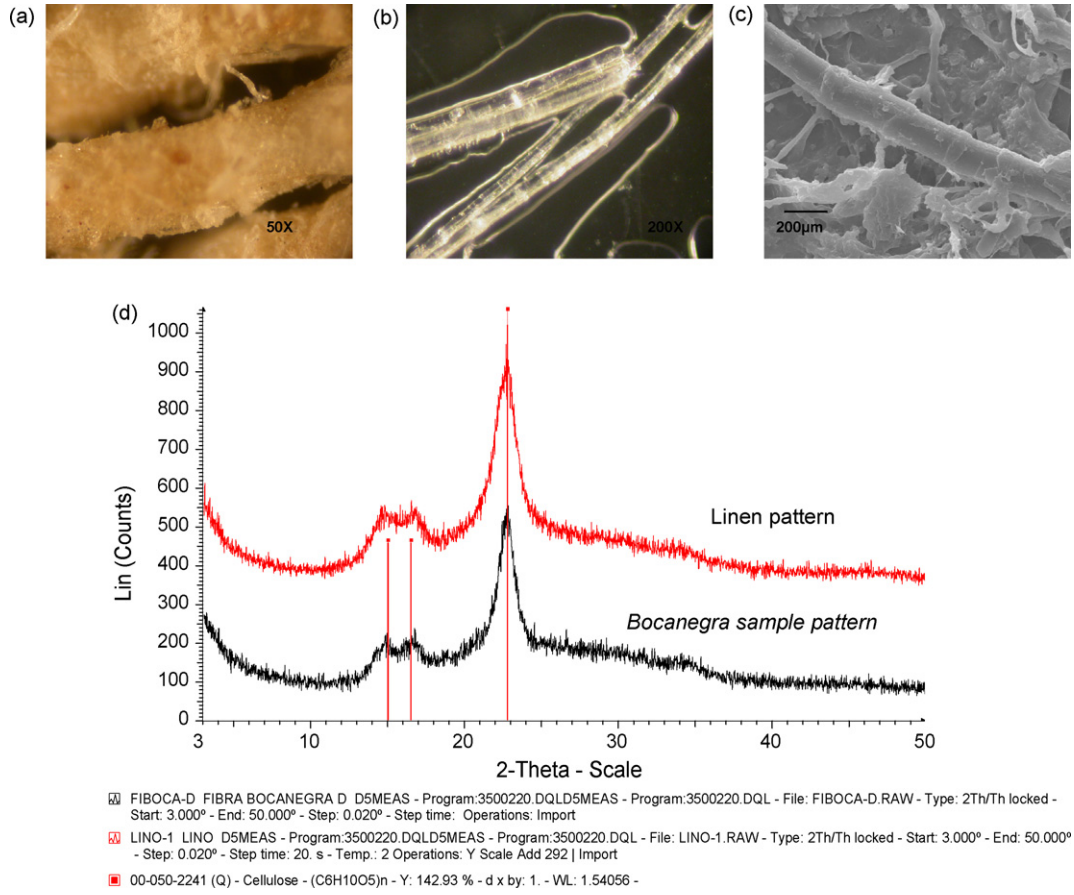

Fig. 3. Optical micrographs (a) without any clearing treatment, (b) the organic compounds were removed by water with continuous heating for 24 h, (c) SEM image of the fibres of Bocanegra paintings, and (d) X-ray diffractogram of the fibres. Linen pattern and Bocanegra fibre pattern.

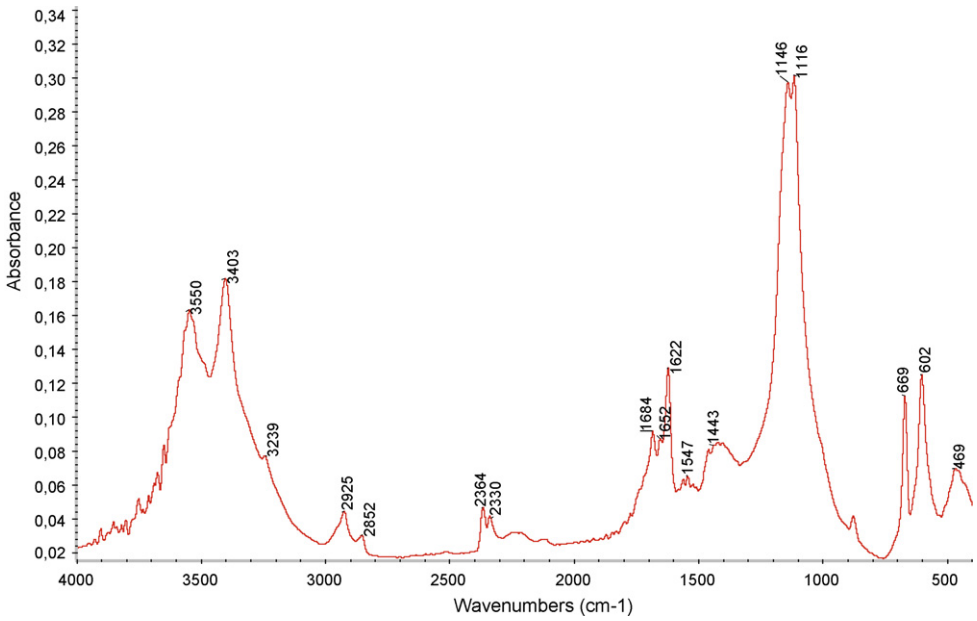

Fig. 4. FT-IR spectra corresponding to the preparation layer of the Bocanegra painting sample.

tion energy was fixed at 28 keV, corresponding to a wavelength of 0.44281 Å. The acquisition time was 20 s per pattern and the beam was focussed down to 15 μm (horizontal) × 1 μm (vertical). A two-dimensional CCD based X-ray detector (refined detector distance 134.1967 mm) was used to collect X-ray diffraction patterns in transmission mode. The X-ray fluorescence spectra were simultaneously detected with a Si(Li) detector. For these measurements, thin transversal cuts were mounted vertically, between two foils of ultralene, and the whole set was raster-scanned horizontally and vertically to obtain two-dimensional images. Thin transversal cuts were oriented horizontally such that the best resolution of the beam (1 μm, vertical) was aligned with the axis of maximum sample heterogeneity, whereas the average in the horizontal direction (15 μm) was obtained over the rather homogeneous colored layer. Three vertical line scans were acquired in each painting cross-section. X-ray fluorescence spectra were treated with PyMCA code [22] and used to identify the elemental composition of the different layers of the samples. In this program, a Levenberg–Marquardt algorithm is implemented to fit the spectra with constraints on the fitting parameters. A complete emission line series is fitted by taking into account theoretical line emission energies and theoretical energy ratios corrected by the experimental conditions (detector characteristics, detection geometry, matrix composition, excitation energy, etc.). A more detailed description of this code is given in [22]. The fitting configuration used to fit the average spectrum of a map is applied to each pixel of the 2D map to calculate the different elemental maps through a batch treatment. For each 2D X-ray diffraction pattern, the Debye–Scherrer diffraction rings were unwrapped and integrated versus the azimuthal angle to produce a 1D diffraction pattern using the ESRF package Fit2D [23]. The set of data thus generated has a format similar to fluorescence data, with a 1D diffraction pattern for each pixel.

Analytical pyrolysis was performed in the Chemical Department of Bologna University. Analytical pyrolysis, on-line with GC and mass spectrometry (PY–GC/MS), was used to generate a qualitative characterization of the organic components in a complex mixture such as the painting layers [24]. PY–GC/MS was carried out at 600 °C for 10 s at the maximum heating rate using a CDS pyroprobe-heated filament pyrolyzer (CDS, Oxford, USA) directly connected to the injection port of a Varian 3400 gas chromatograph coupled to a Saturn II ion-trap mass spectrometer (Varian Analytical Instruments, Walnut Creek, USA). A Supelco SPB-5 capillary column (30 m, 0.32 mm i.d., 0.25 μm film thickness) was used with a temperature programmed from 50° (held for 10 min) to 300 °C at 5 °C/min step intervals, with helium as the carrier gas. The temperature of the split/splitless injector and the PY–GC/MS interface were kept at 250 °C. Mass spectra were recorded at 1 scan/s under electron impact at 70 eV in the mass range of 45–650 *m/z*. Structural assignment of the pyrolytical fragments was based on matching with the NIST mass spectra library. To improve the gas chromatographic behaviour of polar pyrolytic fragments, such as carboxylic or dicarboxylic acids, 10 μl of tetramethylammonium hydroxide solution (TMAH 25% (w/w) in water) was added to the solid sample (few micrograms) before the pyrolysis. The study of the pyrogram, a gas chromatogram of the fragments of the volatile compounds of the sample, gives an indication about the organic chemical nature of the paint layer samples.

Table 1
Analyses of the preparation layer of the six samples of the six paintings.

Painting	Sample	EDX	Phase identification (XRD)	Phase identification (SR μXRD)
1	3	C, O, Mg, Al, S, Si, K, Ca, Fe		
2	6	C, O, Mg, Al, Si, S, K,Ca, Fe	Gypsum	Calcite
3	8	C, O, Mg, Al, Si, S, K, Ca, Fe	Anhydrite	Quartz
4	1	C, O, Mg, Al, Si, S, K, Ca,Fe		Goethite
5	11	C, O, Mg, Al, Si, S, K, Ca, Fe		Gypsum
6	4	C, O, Mg, Al, Si, S, K,Ca, Fe		

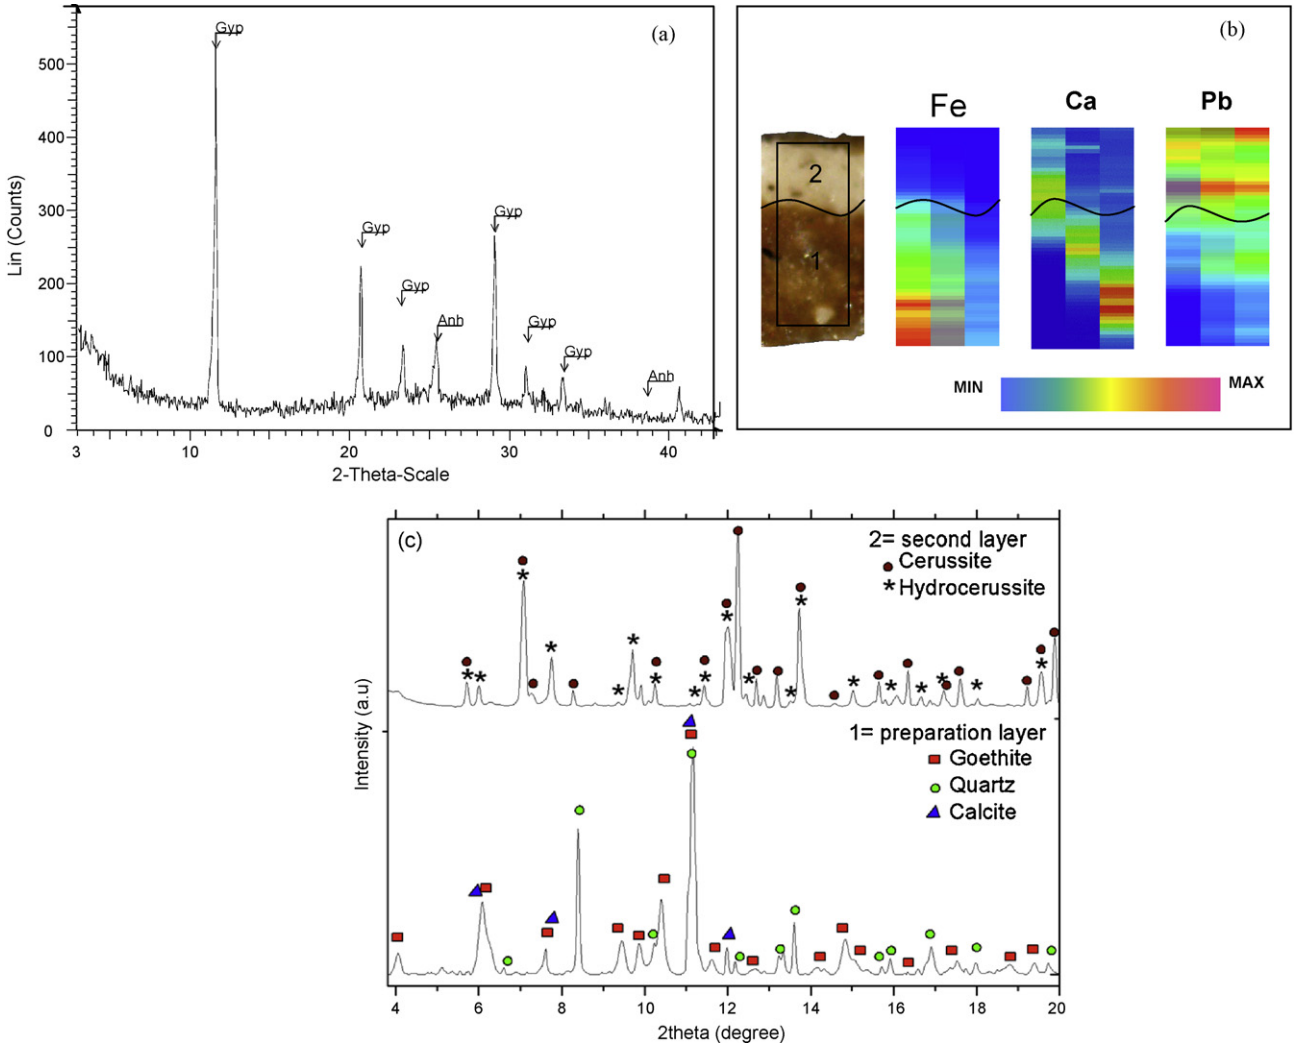

Fig. 5. (a) The XRD pattern of the powder total sample whose peaks can be attributed the presence of gypsum (Gyp), calcite (Cal) and anhydrite (Anh). (b) μXRF elemental mapping of the first layer: calcium and iron; elemental mapping of second layer: lead. (c) SR μXRD of the first layer: goethite, calcite and quartz. SR μXRD of the second layer: cerussite and hydrocerussite.

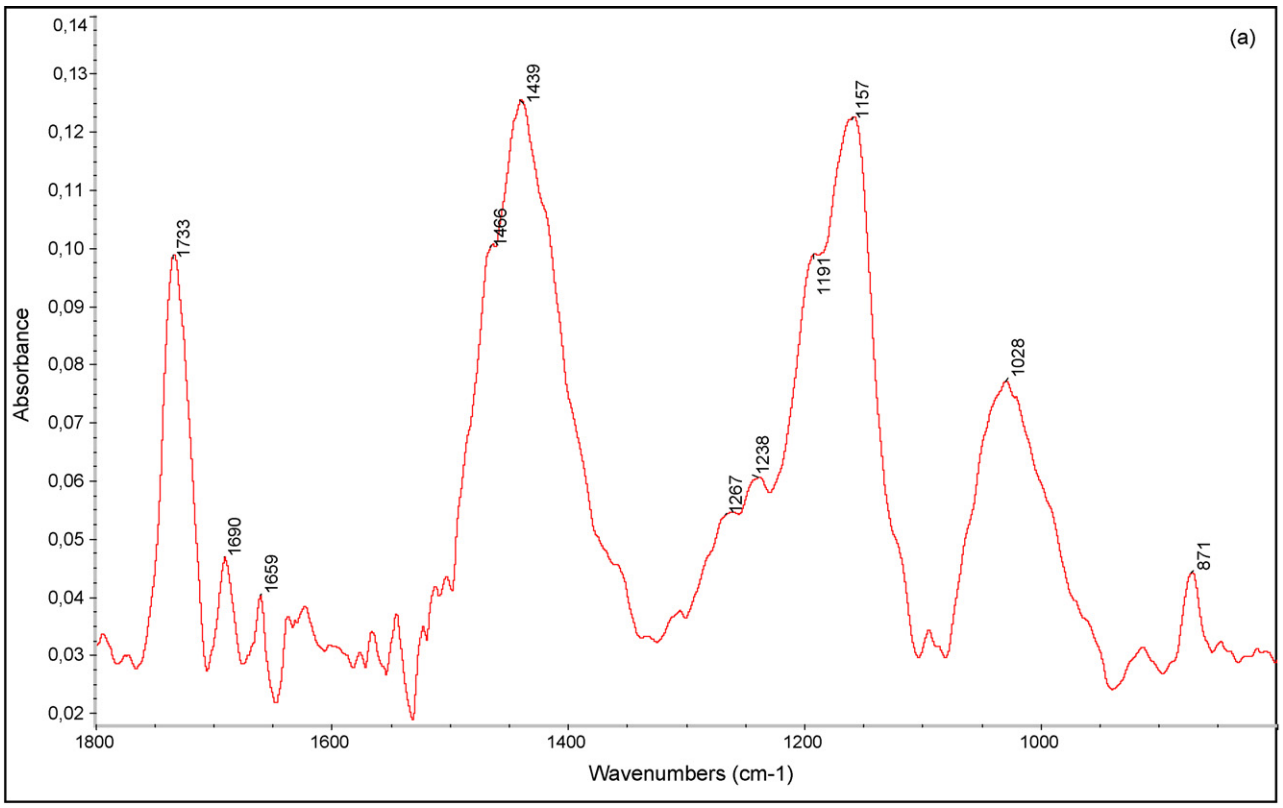
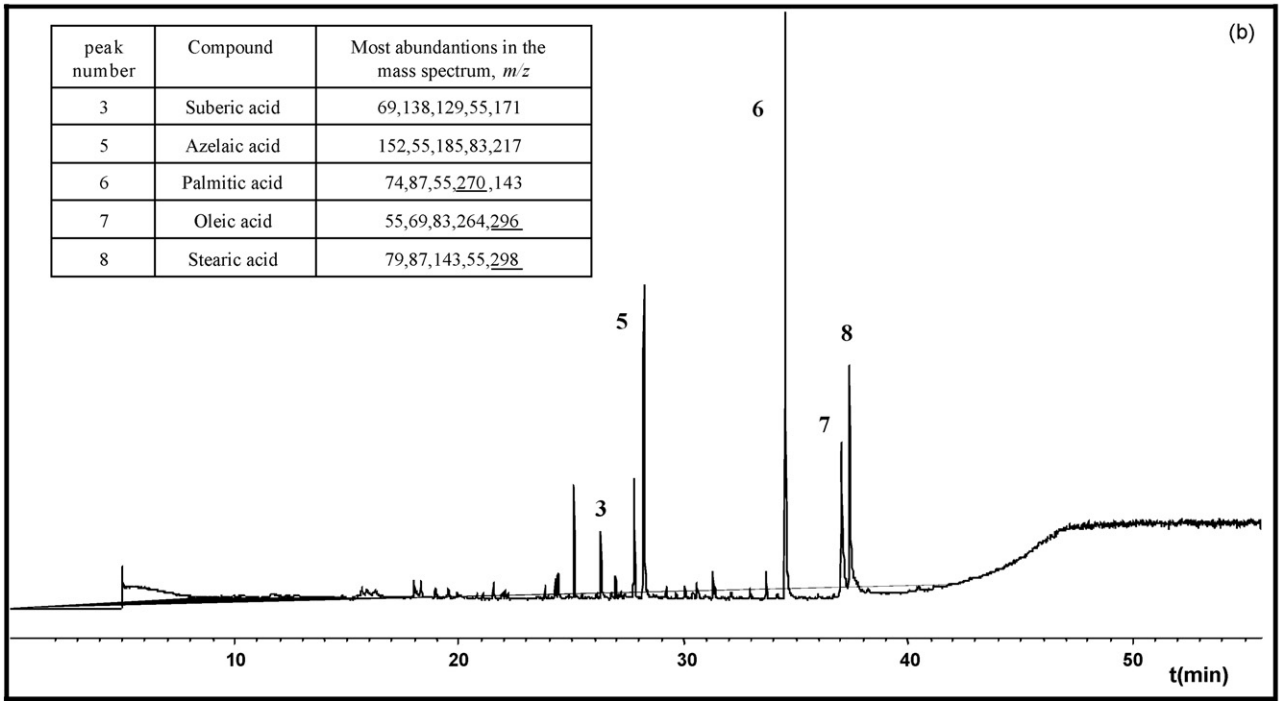
3. Results and discussion

Fig. 2 depicts the light-optical micrograph of the different samples taken from (a) "*San Ignacio azotado por un armenio*", (b) "*La Visión de la Storta*", (c) "*La Aparición de San Pedro*" and (d) "*San Ignacio Herido en las Puertas de Pamplona*" and the information gained concerns mainly the sequence and the thickness of the paint layers and the distribution of the pigments.



3.1. Textile identification



The morphological studies of fibres were realized using optical and scanning electron microscopy. SEM images of single fibres from textile fragments are shown in Fig. 3a and b. The fibre has a diameter of 16.8–16.9 μm, which, together with its morphology, is a very typical for linen (Fig. 3c) [25]. The XRD diffractograms of the fibre obtained from the painting and linen fibre used as a standard are included in Fig. 3d. The XRD pattern of the fibre sample recorded for 2θ in the range of 3–50° revealed pronounced Bragg peaks at 2θ values of around 15.2–16.6° and 22.8°, indicating the presence of a cellulose crystalline phase. The linen used in these canvases contains a greater proportion of lignified material that has survived the retting process. This factor imparts strength and color, but makes the linen more prone to deterioration. Factors that contribute to the deterioration of canvas can be summarized as follows: light, external pollution, and, to a lesser extent, the volatile acids trapped within a frame enclosure.

These results show that Bocanegra used a traditional canvas support that normally consisted of stretched linen fabric, onto which was brushed an aqueous glue, which will be discussed later. Studies of paper and linen show that the oxidation products of cellulose are carboxylic acids, which can catalyse and promote the hydrolysis of cellulose [26]. However, the fibres studied in this work have not suffered from high alteration as indicated by the presence of crystalline phases of cellulose in the XRD patterns.

Table 2
Analyses of the third white layer of the six samples of the six paintings.

Painting	Sample	EDX	Pigment identification by SR μXRD
1	3	C, O, Pb, S, Ca	Lead white (cerussite, hydrocerussite), calcium carbonate
2	6	C, O, Pb, Ca, Fe, Si	
3	8	C, O, Pb, Ca	
4	1	C, O, Pb, Ca, Si, K, Fe	
5	11	C, O, Pb, Ca	
6	4	C, O, Pb, Ca	

peak number	Compound	Most abundantions in the mass spectrum, *m/z*
3	Suberic acid	69,138,129,55,171
5	Azelaic acid	152,55,185,83,217
6	Palmitic acid	74,87,55,270,143
7	Oleic acid	55,69,83,264,296
8	Stearic acid	79,87,143,55,298

Fig. 6. (a) FT-IR spectra corresponding to: top pictorial layer, that shows the presence of bands of silicates (1028 cm^{-1}), carbonates (1439 and 1466 cm^{-1}), and drying oils (1733 and 1157 cm^{-1}). (b) Reconstructed ion chromatogram obtained from pyrolysis/methylation of Bocanegra painting sample. Numbers on top of peak refer to table (mass spectra characteristics of compounds evolved from pyrolysis methylation and structural attribution to peak numbers).

3.2. Identification of preparation layers

The preparation layer of all 20 samples is composed of gypsum, argillaceous earth, iron oxides and animal glue mixed in different proportions. Gypsum was confirmed by FT-IR spectroscopy (Fig. 4) showing, respectively, the stretching and bending absorptions of SO_4^{-2} groups at 1146–1116 cm^{-1}, the water of hydration (ν O–H at 3403 and 3547 cm^{-1}, and the δ O–H at 1684 and 1622 cm^{-1}) and animal glue was suspected by the protein bands (3239 cm^{-1}-stretching ν N–H, 1652 cm^{-1}-stretching ν C=O amide I and 1547 cm^{-1} bending δ N–H amide II). Moreover, not all elements can be detected with EDX, because the detection threshold is relatively high and the X-

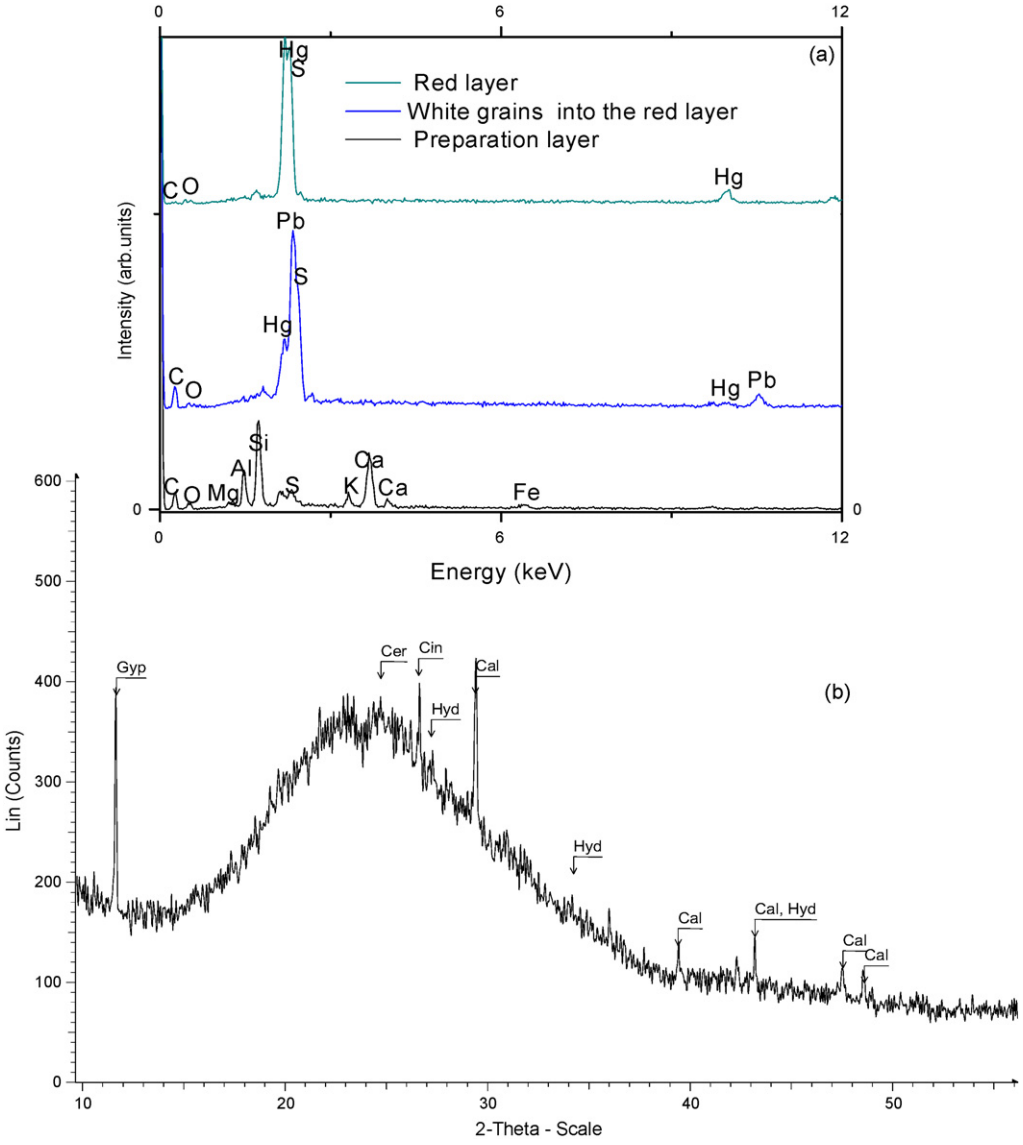


Fig. 7. (a) EDX spectra of the different three layers of the cross-section originating from red San Ignacio's dress and (b) the X-ray diffraction pattern of powder total sample obtained with under incidence angle 1° (θ), whose peaks can be attributed the presence of gypsum (Gyp), cerussite (Cer), hydrocerussite (Hyd), calcite (Cal) and cinnabar (Cin).

ray energies of several elements overlap. In general, light elements in low concentrations are hard to detect with EDX. EDX is not a suitable technique for the detection of trace elements in pigments because their concentration is often below the detection limit (the detection limit is approximately 0.1 wt% for pure materials) [27]. In Table 1, EDX analyses confirm the presence of C, O, Mg, Al, S, Si, K, Ca, and Fe. However, this technique is not sufficient to characterize the different phases.

The separation of different layers is very complicated. For this reason, the samples (including all the layers) were ground for XRD characterization. The XRD study is carried out in powder form using the conventional Bragg–Brentano method with a focusing geometry (θ–2θ coupled) that requires a very small quantity of sample. The XRD pattern of the preparation layer (Fig. 5a) confirmed the presence of calcium sulphate in two phases (mainly gypsum ($CaSO_4{\cdot}2H_2O$) and anhydrite ($CaSO_4$)).

The XRD and FT-IR techniques confirm that the preparation layers were carried out with some pieces of textile mixture with animal glue associated to the support followed by the preparation of a lean character (animal glue and gypsum) layer. In some of the preparation layers, Bocanegra employs calcite and animal glue. In addition, a superficial colored layer in which iron compounds contribute to the yellow to ochre-reddish tone variation is present. However, in these samples, the iron compounds were only detected by EDX analyses and not by conventional XRD because this instrument may not be sensitive enough to detect minor phases of the cross-section. The iron phases are present in a low proportion in the preparation layer. In addition, the powder reflections are very small in comparison with the other minerals present in the mixture. These facts are responsible for the difficult characterization of the iron compounds by conventional X-ray diffraction. Experiments on thin cross-sections with combined SR μXRF/μXRD were performed. Fluorescence and diffraction data sets were simultaneously handled with PyMCA. This set-up shows high potential by concomitantly analysing element distribution (μXRF) and structure information (μXRD) in the cross-sections.

The elemental mapping distribution of iron in the preparation layer is shown in Fig. 5b. Over the same region, the diffraction pattern is calculated (Fig. 5c) and shows the goethite phase mixture with calcite and quartz in the preparation layer. These results

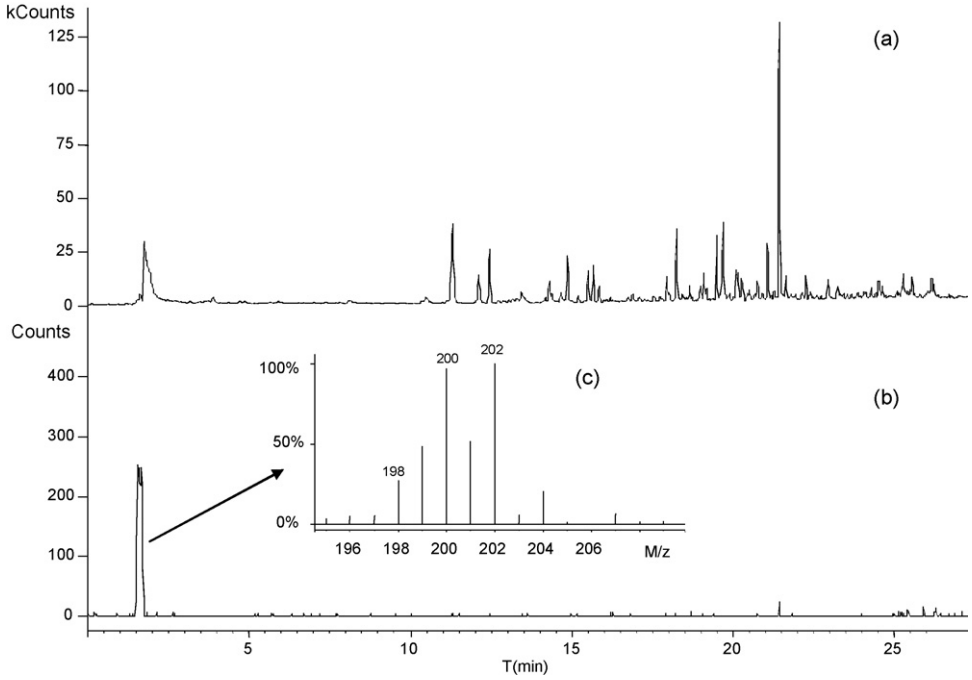

Fig. 8. (a) Reconstructed ion chromatogram, (b) single ion monitoring for m/z (198 + 200 + 202) obtained from direct pyrolysis of the Bocanegra painting sample, and (c) mass spectrum of Hg atoms.

confirm that Bocanegra used goethite in the mixture of support preparation like other famous Baroque painters such as Zurbaran and Murillo [28], and indicates that Bocanegra used a dark background due to the influence of the Tenebrism style.

3.3. Identification of pictorial layers

Above the preparation layers, different colored layers were detected in the paintings such as red, blue, ochre, and white.

3.3.1. White pigment

The EXD analyses (Table 2) show that the white layers are constituted of C, Pb and O. The μXRF map shows the elemental distribution of lead (Fig. 5b). In the white layer, mainly lead and calcium can be distinguished, with lead being the major constituent. In the lead region, μXRD confirms the presence of lead white (Fig. 5c) and shows the mineralogical phases hydrocerussite, $Pb_3(CO_3)_2(OH)_2$ and cerussite, Pb_3CO_3. The presence of the organic binding media was revealed through FT-IR spectrometry (Fig. 6a) carried out on the cross-section. The bands at 1738, 1162 and 1114 cm^{-1} could be attributed, respectively, to the C=O stretching and C–O–C stretching of the drying oils. PY–GC/MS confirms the presence of siccative oils, which gave a chromatogram (Fig. 6b) with high concentrations of palmitic, oleic, stearic and dicarboxylic acids (azelaic and suberic acids). These data show that the different pictorial layers were painted using drying oil as a ligand.

3.3.2. Red pigment

SEM/EDX and XRD give an approximation of the composition of the red pictorial layers in the different paint cross-sections. According to optical microscopy (Fig. 7a) observations, the red pigments in the pictorial layers are distributed as random aggregates of very thin particles. The EDX elemental analyses of these thin particles (Fig. 7b) identify Hg and S. The XRD diffraction pattern of the powder sample confirmed the presence of cinnabar (Fig. 7c). Pyrolysis shows the use of a siccative oil as ligand and, at the same time, the presence of Hg; in Fig. 8 the reconstructed ion chromatogram (a) and single ion monitoring for m/z (198 + 200 + 202) are reported (Fig. 8b); the mass spectrum in Fig. 8c presents the isotopic pattern of mercury that probably results from cinnabar. As reported in a previous paper [19] HgS, at high temperature and in helium atmo-

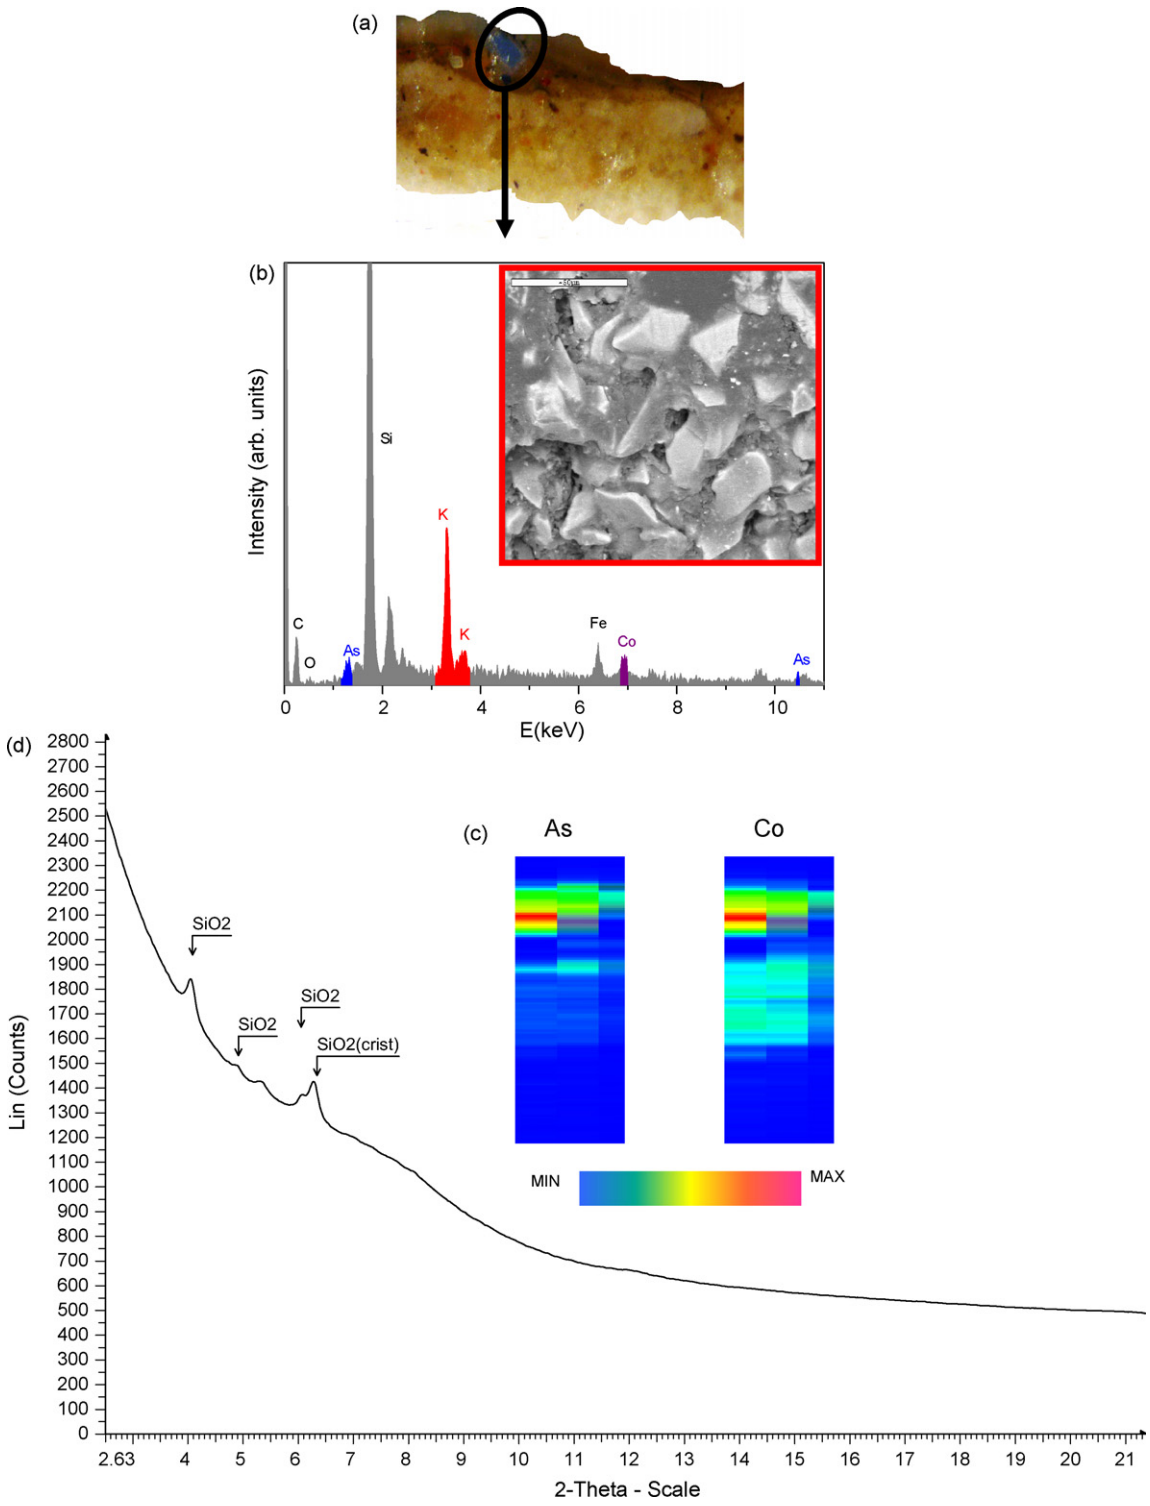

Fig. 10. (a) Paint cross-section originating from ground. The cross-section shows the blue particles in the upper layer; the color of the pigment has faded, causing yellowing of the oil medium. (b) SEM/EDX analyses show the presence of Co, As, and K in the blue particles. (c) μXRF elemental mapping of the blue particles: arsenic and cobalt. (d) SR μXRD of the amorphous phases.

sphere, is degraded into atomic mercury which is volatile and can be detected by GC–MS. The most important source of mercury is normally brilliant red, which has been used through our history as a pigment for paints. Cinnabar and vermilion are names assigned to a single chemical composition of different origin. The first is a natural compound while the second refers to the synthetic pigment. In both cases, there were no differences in structure and composition. In the Bocanegra samples, it was difficult to distinguish between cinnabar and vermilion. In Spain, the cinnabar mines in Almaden were already known from the Roman times, and the use of vermilion (artificial mercuric sulphide) was described by the Arabs in the 8th-century. In China, vermilion has been used since antiquity [29].

Using μXRF/μXRD, it was possible to distinguish between the composition of the iron phase present in the red layers of both the pictorial layer and the preparation layer. The ruby red color, similar to vermilion [30] of the pictorial layer, is constituted of hematite

in a higher proportion of goethite. The presence of only iron oxides suggests an artificial pigment. The mixture of goethite in a higher proportion together with silicates in the preparation layer suggests natural pigments with the calcite and quartz that Bocanegra used in the preparation layer. Bocanegra used different ochre pigments that contained varying amounts of octahedral iron oxides, namely hematite (αFe_2O_3) or/and goethite ($\alpha FeOOH$), mixed with quartz and calcium. When hematite is the main iron oxide, a red color is observed, whereas the ochre is yellow when the goethite dominates. These colors are due to the ion Fe^{3+} contained in both oxides, and more precisely to the charge transfer between Fe^{3+} and its ligands, O_2- or OH^- [31]. In Fig. 9a, the scheme of the stratigraphy is superimposed with the iron mapping and diffraction patterns (Fig. 9b) calculated in the same areas.

3.3.3. Blue pigments

The use of cobalt as a blue pigment in the Iberian Peninsula was reported in the 13th [32] and 14th centuries [33]. In Fig. 10a, the cross-section is shown and it is possible to observe the blue particles in the dark brown layer. In Fig. 10b, the blue particles were examined using SEM/EDX, which showed the presence of potassium, calcium, iron, cobalt, silicon and arsenic in low proportions. The thin cross-section was analyzed using μXRF/μXRD to confirm that this blue pigment was associated with a blue colored potassium glass (smalt). The scheme of the distribution is superimposed with the arsenic and cobalt mappings (Fig. 10c), and the diffraction patterns were calculated in the same areas. The XRD pattern shows an amorphous phase with a small contribution of silicon oxide that is associated with a vitreous material (glass), as shown in Fig. 10d. The presence of arsenic in the blue pigment is reported from the 16th century [34]. The uses of the benefit of the brightness of synchrotron radiation in combination with both techniques (μXRD/μXRF) confirm that this blue pigment was prepared from cobalt-rich minerals, such as cobaltite and smaltite to form cobalt oxide (Zaffer) [35]. Added as cobalt oxide during the manufacturing, with much of the arsenic being volatilized [34]. When this cobalt blue glass pigment degrades [36], it not only loses its color, but also causes yellowing of the oil so that the paintings become brownish-yellow. When smalt containing oil paint deteriorates, the alkaline component of the glass, which in the case of smalt is potassium, is lost from the pigment particles and migrates into the binding medium. There it has the potential to cause concurrent alteration and degradation of the oil, with possible processes including reactions with carboxylic acids in the oil to form potassium fatty acid soaps, or with anion sources in the environment to form species such as carbonates and sulphates [37]. Bocanegra used this blue pigment that consists of a potassium silicate glass containing cobalt oxide and a low quantity of arsenic, which is still present in the cobalt matrix.

XRD has been proven to be a valuable tool for the clear identification of copper inorganic pigments. However, with conventional XRD, it is rather difficult to acquire all of the information from these samples due to the thinness of the color layers, which are in the range of several tens of microns. Furthermore, the contributions of the small quantities of the copper pigments to the total sample are very low. Due to the small grains present in blue sample, it was difficult to identify the pigments that appeared mixed within a single layer.

To solve the difficulties involving the characterization of small quantity of pigments, experiments using μXRF/μXRD on the thin cross-sections of this sample were conducted to illustrate the potential of the combination of these techniques. Fluorescence and diffraction data sets were simultaneously handled with PyMCA. There is clear redundancy in analyzing the parallel elemental and structure information provided by XRF and XRD. The average

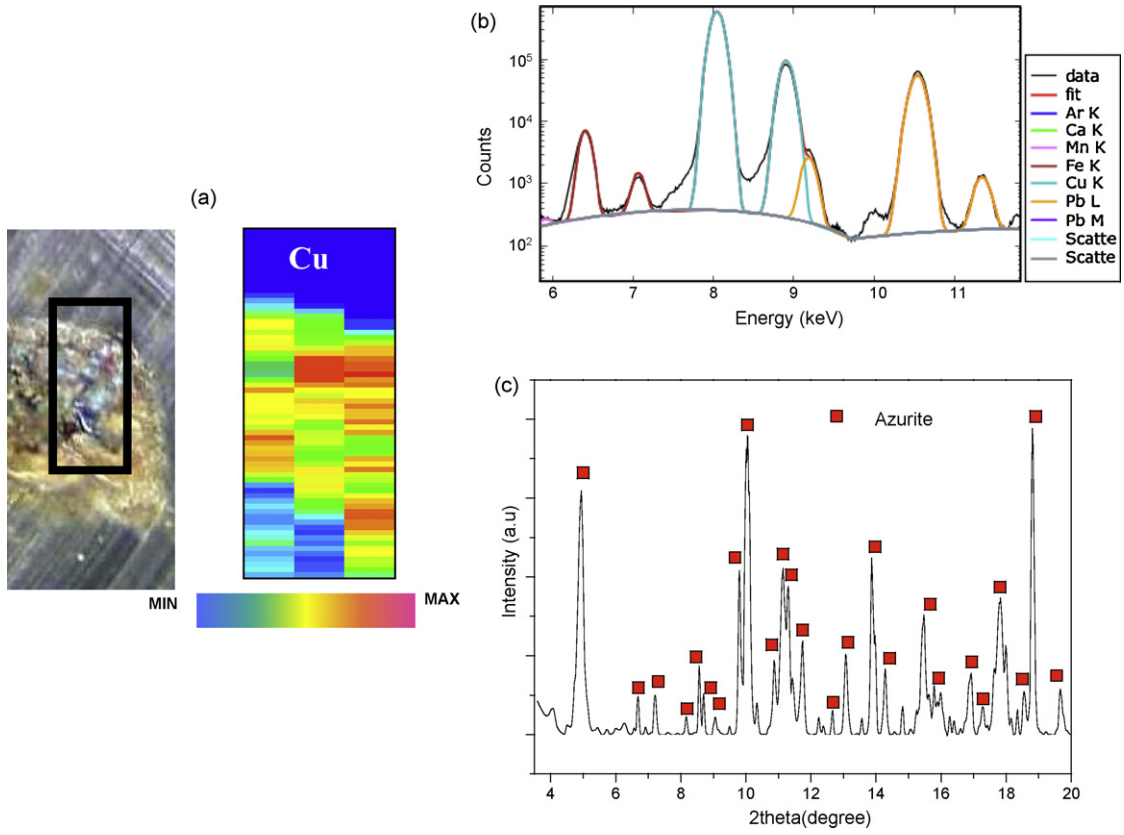

Fig. 11. (a) Thin cross-section micrographs and elemental map of Cu obtained in the pictorial layer, of sample from the dress in the San Ignacio Herido en las Puertas de Pamplona, (b) SR μXRF spectrum, and (c) SR μXRD pattern of blue grains.

diffraction patterns were calculated over the same identified areas (see Fig. 11a). In Fig. 11b, an μXRF spectrum shows the K lines for Cu, the thin cross-section is superimposed on some of the elemental mapping (Cu). The use of this technique allowed for the determination that the blue grains had an azurite pattern (Fig. 11c). Azurite is a natural blue pigment that is derived from the mineral azurite, a basic copper carbonate. Bocanegra used it in the mixture of blue and red pigments. Using μXRF/μXRD, it was possible to obtain only the contribution of azurite without any interference of the other pigments. μXRD enables a precise identification of the crystalline phase of azurite.

3.4. Organic binding medium

Analytical pyrolysis shows that all of the samples of the six paintings have, as an organic ligand, siccative oils. This gives them a high content of dicarboxylic acids, particularly azelaic acid. These acids are considered, in high concentrations, markers of this type of material. Additionally, the egg used in tempera painting has glycerides with long chain aliphatic acids, but due the scarce content of polyunsaturated acids, reactions with oxygen and the polymerisation reaction of the siccative process is practically absent, and only a low concentration of azelaic acid is observed. Chromatographic peaks indicative of proteins are absent but their presence is not excluded because the pyrolytical degradation of proteinaceous materials generally gives insignificant fragments. Only in the presence of a high concentration of protein it is possible to identify markers such as diketopiperazines, as reported in [38].

4. Conclusions

The analysis carried out in Bocanegra paintings of the San Ignacio of Loyola life using different physical–chemical techniques and analytical methodology, and evaluating the relationships between them, gave useful information about the employed materials and painting techniques in the cultural heritage field.

Scanning electron microscopy, especially in combination with energy dispersive X-ray microanalysis, has been an indispensable tool and contributed extensively to the identification of the elements that constituted the different inorganic pigments of the conventional cross-sections of the paintings studied in this work. However the phases present can not be detected, and is not a suitable technique for the detection of trace elements in pigments because their concentration is often below the detection limit. FT-IR supplied information on the organic components that the painter used in the preparation layers. The advantages of PY–GC/MS as a tool for the rapid screening of the organic composition of art objects is apparent from the results of this study; it permitted the identification of siccative oils like those used in the organic medium in these paintings. This technique is capable of providing information on the presence of inorganic compounds such as HgS.

Synchrotron-based μXRD and μXRF are particularly suited to the non-destructive study and micro-characterization of the different materials present in multi-layered paintings. This study demonstrated that synchrotron radiation micro-imaging techniques have yielded the ability to analyze pictorial layers, including grains, at the micrometer scale. μXRD is very useful for the identification of phases that are present in low proportion in multi-layer paintings with different inorganic pigments such as cerussite and hydrocerussite, and those with low powder reflection like azurite, cobalt blue, hematite, and goethite. The conventional XRD is not sensitive enough to detect these pigments in the multi-layer paintings; only cinnabar that has a high powder reflection was identified by this technique.

The non-destructive conventional technique of XRD has been applied in the study of ancient textile fibres of Bocanegra paintings. Using a glass capillary, it was possible to use only one fibre of the material. The presence of crystalline parts of the cellulose possibly means that the fibres are only partially degraded.

ABSTRACT

Scutellarin, a flavone glucuronide of 5,6,4′-trihydroxyflavone-7-O-glucoronide, is the main active component of the traditional Chinese botanic drug *Erigeron breviscapus* (*Vant.*) *Hand.-Mazz*. In this study, a method based on ultra performance liquid chromatography coupled with a time-of-flight mass spectrometer (UPLC/TOF MS) was established and validated to profile the metabolites of scutellarin in Sprague-Dawley rat urine following oral administration of single dose of scutellarin at 80.8 mg/kg. The column utilized was an Acquity BEH C18 (150 mm × 2.1 mm, 1.7 μm). The mobile phase was 0.2% formic acid and acetonitrile with gradient condition. Two standard curves of scutellarin were obtained for the concentration range of 1.065–10.65 μg/mL and 10.65–63.92 μg/mL, respectively. By automating the data processing of the software Masslynx developed by Waters Ltd., 17 metabolites of scutellarin were found and determined in rat urine, with the corresponding reactions *in vivo* such as isomerism, reduction, methylation, glucuronide conjugation, hydroxylation, hydroxylation and methylation, *etc*., most of which were discovered for the first time. For most metabolites, the time (T_p) of peak excretion was 8–12 h. Calculated as scutellarin, the cumulative urine excretion rate of the metabolites was 1.93%.

1. Introduction

Scutellarin, a flavone glucuronide of 5,6,4′-trihydroxyflavone-7-O-glucoronide (Fig. 1), is the main active component of the traditional Chinese botanic drug *Erigeron breviscapus* (*Vant.*) *Hand.-Mazz*. Recent pharmacological research showed that scutellarin favored of myocardial protection by expanding blood microvessels, improving blood microcirculation, activating K^+ channels and blocking Ca^{2+} channels [1]. It could also attenuate hydrogen peroxide (H_2O_2)-induced nitrogen monoxide (NO), cytotoxicity, intracellular accumulation of reactive oxygen species (ROS) and Ca^{2+}, lipid peroxidation, and loss of mitochondrial membrane potential (MMP) and DNA [2,3]. Furthermore, it was exciting that scutellarin could inhibit HIV-1 reverse transcriptase activity, HIV-1 particle attachment and cell fusion, all of which are essential activities for viral transmission and replication [4].

With the increasing importance of scutellarin in human health, it is important to research its absorption, distribution, metabolism, and excretion (ADME). As for the determination of scutellarin and its metabolites in biological samples, such as plasma, bile, urine and other tissues, high performance liquid chromatography coupled with ultraviolet or mass spectrometry (HPLC/UV, HPLC/MS) was often used. However, HPLC/UV methods can only be used to determine the parent drug or the metabolites with standards, limiting its usage [5–9]. HPLC/MS provides more information on molecular formulae and fragments for identification and quantification [10]. Taking scutellarin for example, using HPLC/MS/MS four metabolites could be found in human urine: scutellarin, two isomers of scutellarin, and methylated scutellarin. Isoscutellarin and the parent drug could also be found in plasma. With the aid of nuclear magnetic resonance spectroscopy (NMR), isoscutellarin could be identified as 5,7,4′-trihydroxyflavone-6-O-glucoronide [11]. Besides, HPLC/MS and HPLC/NMR could also help to find five metabolites in rat plasma and bile after oral administration of scutellarin: two compounds of scutellarin conjugated with two sulfate groups, scutellarein, 6-methyl-scutellarin, and 6-methyl scutellarein [12].

However, it has been known that the *in vivo* biochemical transformation of the drug is complicated and various reactions probably occur such as oxidation, reduction, methylation, glucuronide conjugation, sulfation, *etc*. Many metabolites, which are biomarkers of interest, will often be of low abundance, and ionization

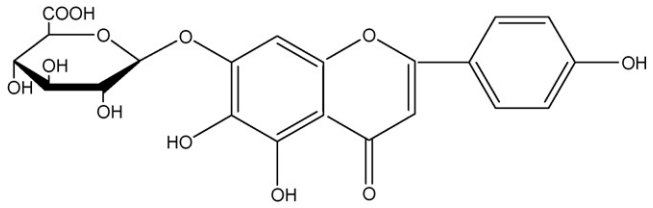

Fig. 1. Chemical structure of scutellarin.

suppression from high abundance endogenous metabolites may prevent their detection [13]. Comprehensive detection and quantitation of metabolites from a biological sample constitute the major challenges of current metabolomics research.

Compared to HPLC, ultra performance liquid chromatography (UPLC) is a recently developed technology. It can provide a higher peak capacity, greater resolution, increased sensitivity, and higher speed of analysis. For example, 11 familiar components in biodiesel, 15 flavonoids in *Epimedium*, and 11 saponins in *Panax notoginseng* could be detected in only 5 min, 12 min, and 12 min, respectively [14–16]. Since 2006, UPLC/MS has been widely used in environmental monitoring [17,18], food contamination detection [19,20], botanic and biological sample analysis [21–25], *etc*. The advantages of UPLC/MS are unique and obvious.

Therefore, the objective of this paper is to establish and validate a simple, selective, and specific UPLC/MS method in the multiple reaction monitoring (MRM) mode for the identification and quantification of scutellarin and its metabolites in urine following an oral single dose to rats, which can provide more comprehensive insights and guidance for the elucidation of side effect mechanism and safety monitoring as well as for rational formulation design in drug delivery system.

2. Experimental

2.1. Chemicals

Scutellarin was purchased from the Kunming Institute of Botany, Chinese Academy Sciences (Yunnan, China). A scutellarin standard (99.5% purity) was purchased from the National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China). Acetonitrile was of HPLC grade (Fisher, USA). HPLC grade water was obtained using a water purification system (Milli-Q Reagent Water System, MA, USA). All other chemicals were of analytical reagent grade. All mobile phases were filtered through 0.22 μm micropore filters (Jinteng Ltd., Tianjin, China) prior to use.

2.2. Instrumentation and chromatographic conditions

The UPLC/MS system "LCT Premier^{TM} XE" comprised a Waters UPLC system connected in-line with a time-of-flight mass spectrometer (TOF MS) (Waters Ltd. USA). The column utilized was an Acquity BEH C18 (100 mm × 2.1 mm, 1.7 μm) maintained at 50 °C. Mobile phases were A (0.2% formic acid) and B (acetonitrile). LC gradient condition of B was as follows: 0–5 min: 5 → 50%; 5–7 min: 50 → 95%; 7–8 min: 95 → 95%; 8–10 min: 95 → 5%; 10–15 min: 5 → 5%. The flow rate was set at 0.5 mL/min. Samples were maintained at 4 °C throughout.

2.3. Mass spectrometry

Analytes were quantified using TOF MS in negative-ion mode. Source parameters included capillary voltage of 2.2 kV, cone voltage of 35 V, source temperature of 120 °C, desolvation temperature of 350 °C, cone gas flow of 10 L/h, desolvation gas flow of 700 L/h. Product ions were monitored in W^- extended mode. In the full scan mode, the mass spectrometer was operated over a range of m/z 50–1000. Injection volumes for samples and standards were 4 μL with an auto-injector.

2.4. Animals

Six Sprague-Dawley (SD) rats (3 male and 3 female), weighing 225.4 ± 11.1 g, were purchased from Beijing Weitong Lihua Biotechnology Co., Ltd. (Beijing, China). The animals were housed and cared for under a constant temperature at (22 ± 1 °C) and humidity (50 ± 10%). Food was withheld prohibited for one day before the experiment while water was provided freely.

2.5. Drug administration and urine sample preparation

Scutellarin was dispersed in deionized water at 20.20 mg/mL by sonication for 10 min (KQB-100, Kunshan Supersonic Instrument Co., Kunshan, China) to obtain a homogeneous suspension. It has been clear that scutellarin is absorbed in the gastrointestinal (GI) tract by passive diffusion. With its low water solubility, it cannot be easily absorbed through enterocytes. Moreover, scutellarin can be hydrolyzed into scutellarein and glucuronate by gastric acid, intestinal flora, and enzymes of liver and intestine. These reasons explain the low absorption of scutellarin into blood [26] and low absolute bioavailability of scutellarin oral preparations (0.4 ± 0.19%, in Beagle dogs) [27]. Furthermore, the amount excreted into urine is often limited which complicate its determination. Therefore, the dosage of scutellarin to rats was set high at 80.8 mg/kg body weight. After administration, food was withheld for 48 h for all rats while water was provided freely. The whole urine of each rat was collected at 0–4 h, 4–8 h, 8–12 h, 12–16 h, 16–20 h, 20–24 h, 24–32 h, 32–40 h, and 40–48 h. A blank urine sample was collected before administration.

Each urine sample was centrifuged at 4500 rpm for 10 min at 4 °C (TGL 16C, Medical centrifuge Co., Beijing, China). Hundred microlitres of the upper layer was mixed with 100 μL methanol using vortex-mixing for 1 min and then centrifuged at 12,000 rpm for 15 min at 4 °C. The upper layer was transferred to another tube and mixed with 600 μL water. The mixture was centrifuged at 10,000 rpm for 10 min at 4 °C. The supernatant was injected into the UPLC system for analysis. The same sample handling process was used for the recovery and precision determinations in urine.

2.6. Identification of the metabolites

Urine samples were analysed by TOF MS. Using the MS data and Masslynx software installed on the instrument, the molecular formulae of scutellarin and its metabolites were identified. The potential biochemical transformations between the metabolites and the parent compound could also be provided by the Masslynx software.

2.7. Standard solution, calibration curves, and quality control (QC) samples

A standard stock solution (639.2 μg/mL) was prepared by dissolving 15.98 mg scutellarin in 25 mL methanol. A series of standard working solutions with concentration range of 1.065–63.92 μg/mL for scutellarin were obtained by further dilution of the standard stock solution with methanol. All solutions were stored at 4 °C. A series of 0.2 mL standard working solutions were evaporated to dryness at 40 °C under a gentle stream of nitrogen. The residues were reconstituted in 0.2 mL of blank urine to prepare the two calibration standards at the low concentration range of 1.065, 2.130, 4.260, 6.390, 8.520, and 10.65 μg/mL

and high concentration range of 10.65, 21.31, 31.96, 42.61, 53.27, and 63.92 μg/mL, respectively. Linearity was demonstrated by statistical analysis of a linear regression model: $y = ax + b$ (where x represents the concentration of scutellarin and y represents the peak area of scutellarin).

Quality control (QC) samples were prepared in the same way as calibration standards with blank plasma, and concentrations were 1.065, 10.65, and 63.92 μg/mL, respectively. The QC samples were stored at −80 °C until analysis.

2.8. Method validation

2.8.1. Recovery

Three 0.2 mL standard working solutions, with concentrations of 1.065, 10.65, and 63.92 μg/mL, were evaporated to dryness and redissolved with each in 0.2 mL of blank urine. The recoveries were calculated by comparing the peak areas of the urine samples to those of the standard working samples.

2.8.2. LOD and LOQ

The limits of quantification (LOQ) and detection (LOD) were defined as scutellarin responses which yielded a signal to noise ratio, without smoothing, of greater than 10 and 3, respectively.

2.8.3. Intra- and Inter-day precision

The intra- and inter-day precisions (%, RSD) of the method were assessed by analyses of scutellarin in QC samples of low, middle, and high concentrations (1.065, 10.65, and 63.92 μg/mL) on the same day and on three consecutive days, respectively.

2.8.4. Stability

One of the urine samples for precision determination was examined for stability at 4 °C after 0 h, 4 h, 8 h, and 12 h. The amount of scutellarin in the urine samples was determined using a freshly prepared calibration curve.

2.9. Pharmacokinetic study

The concentrations of the parent drug and the isomers of scutellarin were calculated according to the equations of linear regression of scutellarin. The concentrations of the other metabolites were calculated by the method of semi-quantification with the equations of scutellarin $y = ax + b$, x as molar concentration (μmol/mL) [28–31]. Based on the molecular weight (MW), the concentration (C, μmol/mL), and excreted urine volume (V, mL), the amounts (μg) of the metabolites (M) were calculated ($M = C \times \mathrm{MW} \times V$). Furthermore, all data on the amount of scutellarin and the metabolites were normalized to the same body weight of 250 g ($M_{250g} = M/W \times 250$, where W was the real body weight). Pharmacokinetic parameters were calculated by the method of urine excretion using DAS (ver. 2.0) pharmacokinetic software [32] provided by the Chinese Pharmacology Association.

3. Results and discussion

3.1. Identification of scutellarin and its metabolites

The main criteria for the search for metabolites were strong induction in test samples and the absence in blank control ones. The base peak intensity (BPI) chromatograms of two urine samples collected in 0–4 h and 4–8 h, respectively, are shown in Fig. 2, compared to the blank urine. The extracted ionic currents (EIC) and MS of the urine samples were studied (Fig. 3). It could be found that in BPI chromatograms, interference and ionization suppression induced by high abundance endogenous metabolites could strongly prevent the detection of these metabolites. However, with

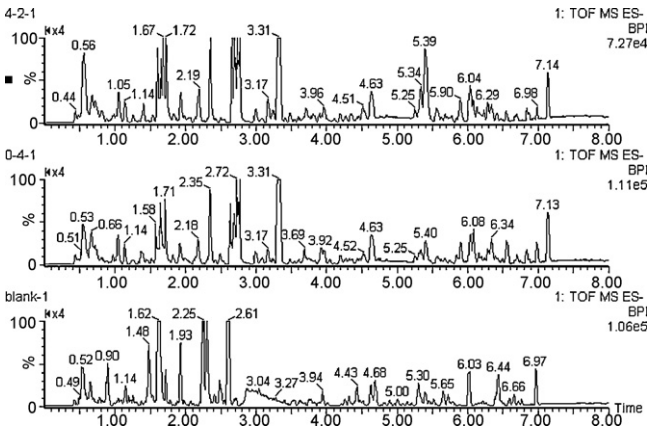

Fig. 2. The TOF MS base peak intensity (BPI) chromatograms of the metabolites of scutellarin in urine after oral single dose of scutellarin to rats.

the high selectivity of EIC, the metabolites of scutellarin showed high specificity.

By automating the data processing, Masslynx enabled rapid metabolite identification. From the information of molecular formulae of the metabolites provide by Masslynx, 17 distinct metabolites were found in rat urine, as shown in Table 1. It could also be demonstrated that some biochemical transformations occurred for scutellarin after oral administration, such as reduction, methylation, glucuronide conjugation, hydroxylation, hydroxylation + methylation, *etc*.

It was very interesting that the retention time of the scutellarin standard was 2.83 min with m/z 461.07 $(M-1)^-$. However, a compound with m/z 461.07, identical to scutellarin, was found with a retention time of 3.95 min, implicating that it was not scutellarin. It had been reported that scutellarein, with m/z of 287 $(M+1)^+$ could easily be found in rat plasma after oral administration and there are two possible pathways of metabolism. In the first pathway, scutellarin is absorbed into the blood and metabolized to scutellarein by a glucuronate enzyme. In the second pathway, scutellarin is first biotransformed into scutellarein in the gastrointestinal (GI) tract and scutellarein is then absorbed into the blood [12]. Therefore, it could easily be concluded that scutellarin is metabolized into scutellarein in the GI tract, liver or blood and scutellarein is reconjugated with glucuronate and then excreted into the urine. From the chemical structure of scutellarein, each of 5, 6, 7, and 4′ positions is a possible site for conjugation with glucuronate. The compound scutellarein conjugated with glucuronate at position 6 was identified in human plasma and named isoscutellarin [11]. Therefore, the metabolite with m/z 461.07 eluting at 3.95 min in this study could also be named isoscutellarin which is scutellarein conjugated with glucuronate at positions 5, 6, or 4′.

As for the compound with m/z 477.09, there were two main peaks in the chromatogram with retention time of 5.63 min and 5.72 min, respectively, indicating that they are isomers with molecular formula $C_{21}H_{18}O_{13}$. Each one is scutellarin with a hydroxyl group at a different site.

The glucuronide conjugate of scutellarin was also found as $C_{27}H_{26}O_{18}$ with m/z 637.10. A similar compound had been reported in mouse blood, liver, and intestine [33].

The compound $C_{21}H_{18}O_{11}$ with m/z 445.05, lacking a molecular O compared with the parent scutellarin, might be baicalin (5,6-bihydroxyflavone-7-O-glucuronide) or its isomer.

The molecular formulae of 17 metabolites are shown in Table 1. The potential biochemical transformations that occurred *in vivo* are also provided, such as reduction, hydrolysis, hydroxylation, hydroxylation and methylation, reduction and hydroxylation, decarboxylation and glucuronidation, *etc*. For three metabolites,

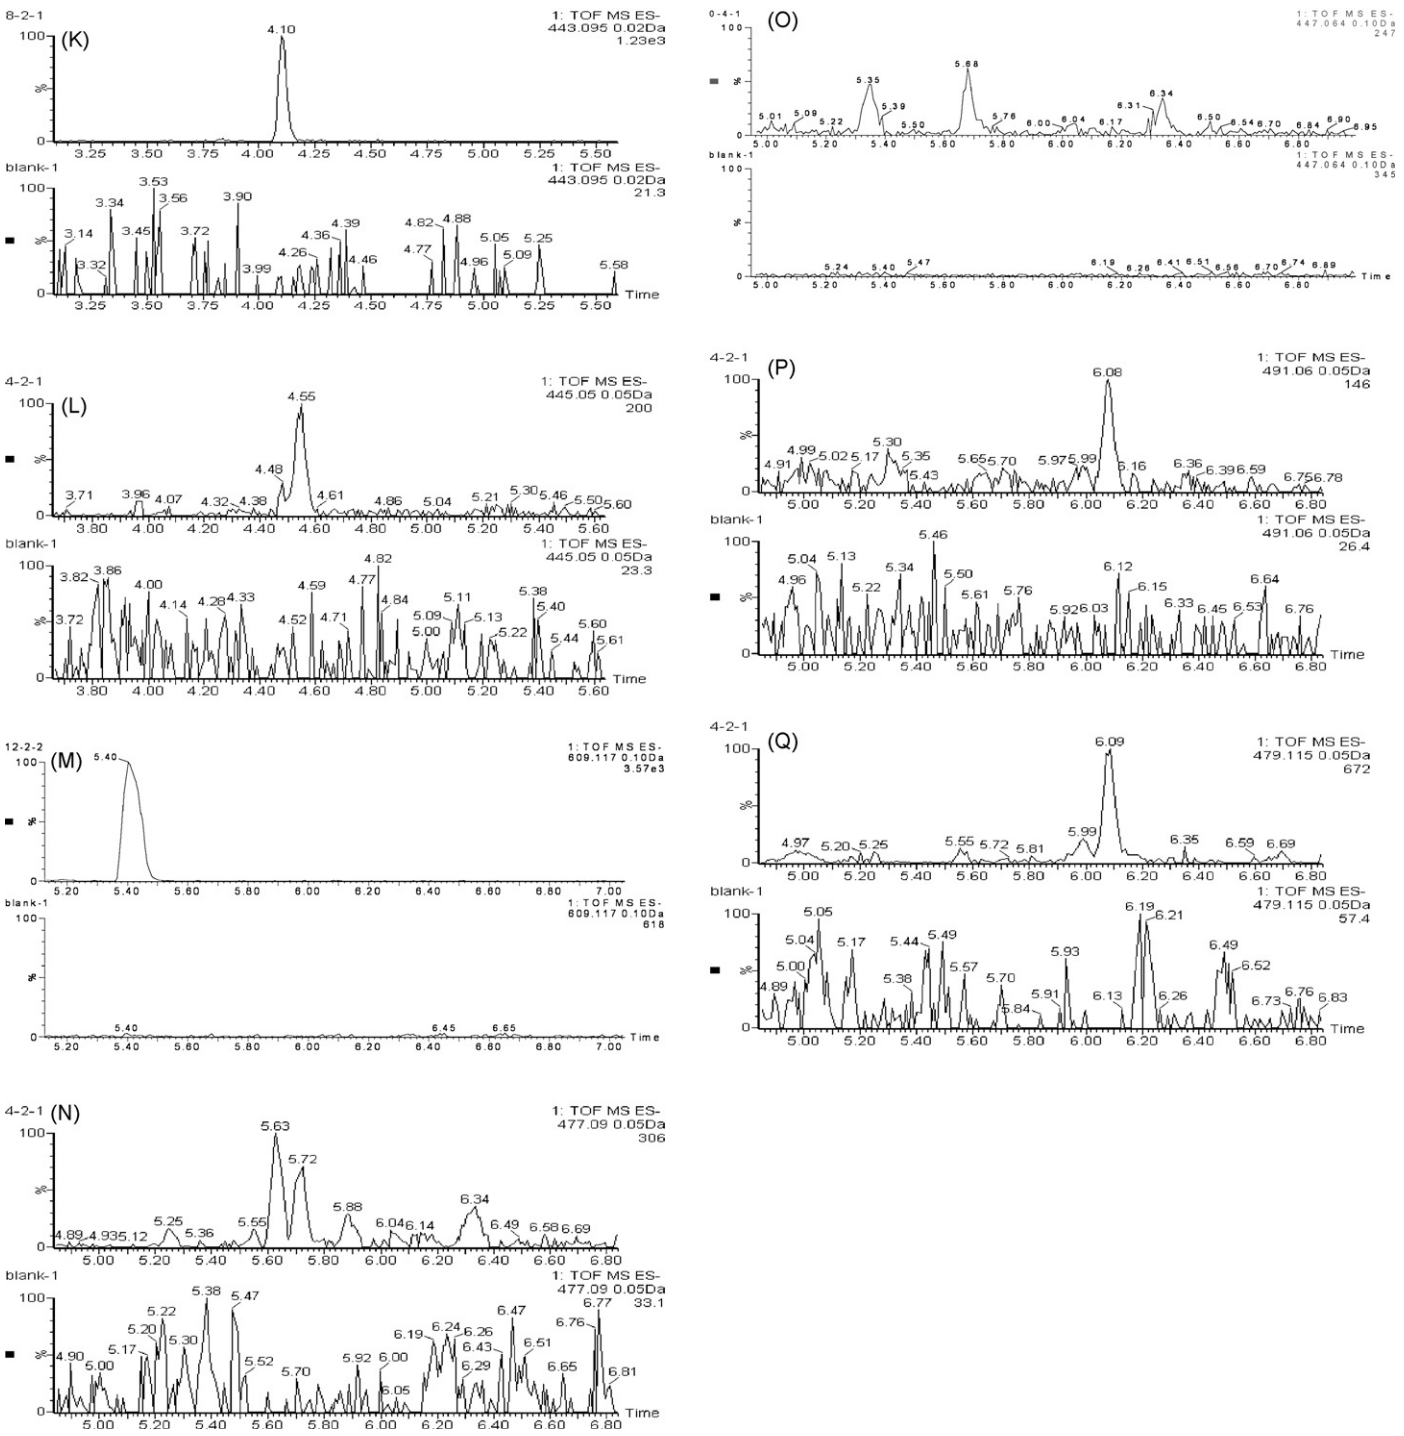

Fig. 3. (*Continued*).

the transformations are still unknown and need to be studied further.

For TOF MS, the most outstanding advantage is that it can provide accurate molecular formulae for the compounds, although its disadvantage is also obvious in that it cannot produce fragments as MS/MS or MS(n) just like Ion Trap MS, which is very helpful for structural identification. However, for metabolite studies, so many unknown compounds may be produced and most are even new and without reference standards. Therefore, using TOF MS to identify the molecular formulae of the metabolites is very important. Based on the known molecular formulae, further study will be much easier.

3.2. Metabolism profile in urine

Only a few metabolites of scutellarin were reported after administration to humans [11], Wistar rats [12], and Kunming mice [33]. From the present study, 17 metabolites could easily be found and determined, most of which were discovered for the first time. According to the biochemical transformations of

Table 1
Metabolites of scutellarin in rat urine after oral single dose of scutellarin.

Peak number	Rt (min)	Reaction	Molecular formula	$[M-H]^-$	Chemical structure
1	0.63	Unknown	$C_{21}H_{18}O_{15}$	509.06	Unknown
2	1.01	Methylation	$C_{22}H_{20}O_{12}$	475.10	M + CH_3
3	1.62	Hydrolysis + sulfate	$C_{15}H_8O_8S$	346.98	Aglycone – H_2O + SO_3
4	2.19	Unknown	$C_{22}H_{20}O_{14}S$	539.17	Unknown
5	2.69	Unknown	$C_{20}H_{19}O_{11}N$	448.11	Unknown
6	3.27	Glucuronide conjugation	$C_{27}H_{26}O_{18}$	637.10	M + glucuronate – H_2O
7	3.47	Reduction	$C_{21}H_{20}O_{12}$	463.08	M – 2H
8	3.49	Reduction + acetylation	$C_{23}H_{22}O_{13}$	505.13	M – 2H + $COCH_3$
9	3.96	Isoscutellarin	$C_{21}H_{18}O_{12}$	461.07	Iso-M
10	4.11	Hydrolysis	$C_{21}H_{16}O_{11}$	443.09	M – H_2O
11	4.55	Loss of O	$C_{21}H_{18}O_{11}$	445.05	M – OH (baicalin or its isomer)
12	5.39	Decarboxylation + Glucuronidation	$C_{26}H_{26}O_{17}$	609.12	M + glucuronate – COOH
13	5.63	Hydroxylation	$C_{21}H_{18}O_{13}$	477.09	M + OH
14	5.72				
15	5.68	Demethylation	$C_{20}H_{16}O_{12}$	447.06	M – CH_3
16	6.08	Hydroxylation + methylation	$C_{22}H_{20}O_{13}$	491.06	M + OH + CH_3
17	6.09	Reduction + hydroxylation	$C_{21}H_{20}O_{13}$	479.11	M – 2H + OH

the metabolites provided by Masslynx, the potential metabolism profile of scutellarin in SD rat urine following oral administration could be described as shown in Fig. 4.

For the compounds $C_{22}H_{20}O_{13}$ and $C_{21}H_{20}O_{13}$, there might be two pathways. For $C_{22}H_{20}O_{13}$, the first pathway is methylation of scutellarin to $C_{22}H_{20}O_{12}$, which is then hydroxylated to be $C_{22}H_{20}O_{13}$. In the second one scutellarin is first hydroxylated to $C_{21}H_{18}O_{13}$ and then methylated to $C_{22}H_{20}O_{13}$. For $C_{21}H_{20}O_{13}$, the first pathway is hydroxylation of scutellarin to $C_{21}H_{18}O_{13}$, followed by reduction to $C_{21}H_{20}O_{13}$. In the other pathway scutellarin is reduced to $C_{21}H_{20}O_{12}$ and then hydroxylated to $C_{21}H_{20}O_{13}$.

For the compound $C_{21}H_{18}O_{13}$, two isomers exist which are products of hydroxylated scutellarin. For the compound $C_{23}H_{22}O_{13}$, the metabolism mechanism might be that scutellarin is reduced to $C_{21}H_{20}O_{12}$ and then acetylated to $C_{23}H_{22}O_{13}$.

There are also two metabolites of scutellarin with glucuronation occurring at two different sites. One is $C_{27}H_{26}O_{18}$, where scutellarin is glucuronated and a molecular H_2O was lost. The other one is $C_{26}H_{26}O_{17}$, where scutellarin is glucuronated and decarboxylated.

3.3. Method validation

Two regression equations of the standard curves for scutellarin were obtained: $y = 2220.5x + 2.2247$ (correlation coefficient $r = 0.9944$) for the concentration range of 0.0023–0.023 μmol/mL (1.065–10.65 μg/mL) and $y = 1830.6x + 5.2046$ ($r = 0.9981$) for

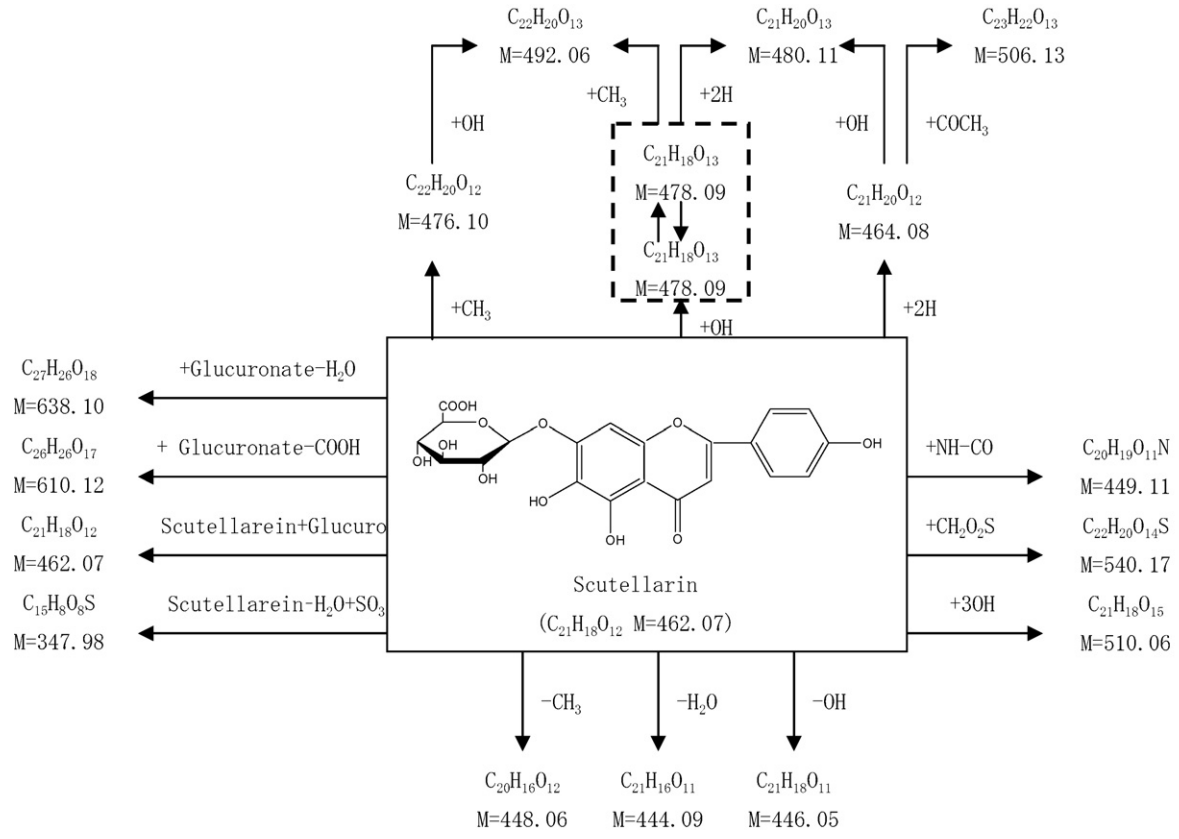

Fig. 4. Metabolism profile of scutellarin in urine after oral single dose of scutellarin to rats (80.8 mg/kg, $n = 6$).

Table 2
Recoveries and precisions of QC levels of scutellarin ($n = 3$).

Spiked concentration (μg/mL)	Recovery (%)	Intra-day precision (RSD%)	Inter-day precision (RSD%)
1.065	96.51 ± 2.11	11.16	13.22
10.65	99.33 ± 1.27	5.43	7.39
63.92	99.24 ± 0.88	3.18	4.91

0.023–0.138 μmol/mL (10.65–63.92 μg/mL). They showed good linear relationships between y and x. LOQ for scutellarin was 1.065 μg/mL, which actually was the lowest concentration of the standard curves. And the LOD was 0.365 μg/mL.

The recoveries, intra-day precisions, inter-day precisions of low, middle, and high QC levels of scutellarin (1.065, 10.65, and 63.92 μg/mL) are shown in Table 2. Using the content of scutellarin as index, the determined urine sample was stable at 4 °C for at least 8 h with RSD of 6.22%.

3.4. Urine pharmacokinetics

For the metabolites, it is best if their chemical structures can be confirmed by comparison with synthesized reference compounds [34]. However, the reference standards were hard to get and some compounds are even new. Considering that most metabolites have the same or a similar parent nucleus, using the parent drug to semi-quantitate is a useful tool. The excreted amount time profiles of the main metabolites of scutellarin are shown in Fig. 5. For most metabolites, the time (T_p) of peak excretion was 8–12 h. Only for the compounds with MW of 347.98, 540.17, and 448.06, T_p was 4–8 h. The main pharmacokinetic parameters of the metabolites are shown in Table 3. It is clear that the compounds with MW of 449.11, 638.10, 540.17, 610.02, 347.98, and 506.13 are the main metabolites. Calculated as scutellarin, the cumulative amount of metabolites excreted into urine was 389.26 μg and the cumulative urine excretion rate was 1.93% compared with the oral dosage of 20.2 mg per rat with a body weight of 250 g (i.e. 80.8 mg/kg).

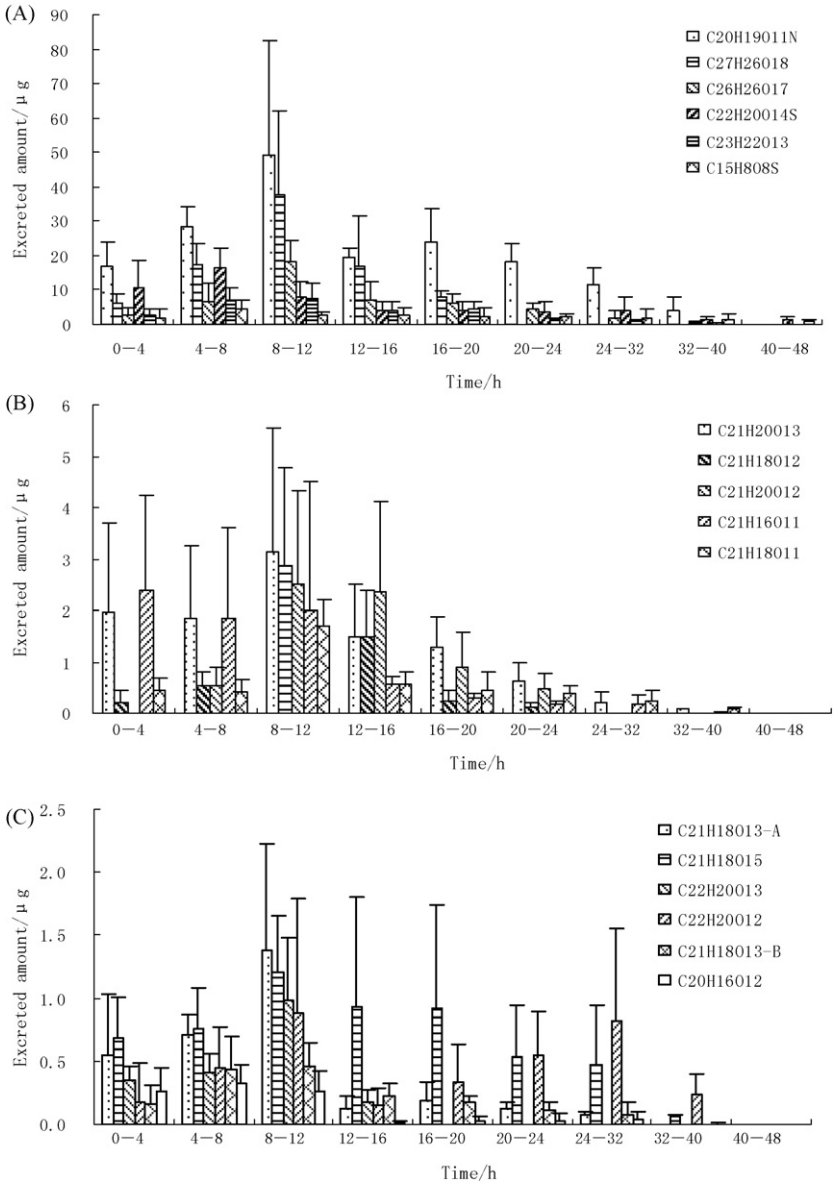

Fig. 5. Excreted amount of the metabolites of scutellarin in urine after oral single dose of scutellarin to rats (80.8 mg/kg, $n = 6$). (A) Compounds of $C_{20}H_{19}O_{11}N$, $C_{27}H_{26}O_{18}$, $C_{26}H_{26}O_{17}$, $C_{22}H_{20}O_{14}S$, $C_{23}H_{22}O_{13}$, and $C_{15}H_8O_8S$, (B) Compounds of $C_{21}H_{20}O_{13}$, $C_{21}H_{18}O_{12}$, $C_{21}H_{20}O_{12}$, $C_{21}H_{16}O_{11}$, and $C_{21}H_{18}O_{11}$, (C) Compounds of $C_{21}H_{18}O_{13}$-A ($t_r = 5.63$ min in UPLC), $C_{21}H_{18}O_{15}$, $C_{22}H_{20}O_{13}$, $C_{22}H_{20}O_{12}$, $C_{21}H_{18}O_{13}$-B ($t_r = 5.72$ min in UPLC), and $C_{20}H_{16}O_{12}$.

4. Conclusion

The metabolism profile of scutellarin in urine was studied following oral administration of a single dose of scutellarin to SD rats. Using UPLC/TOF MS, 17 metabolites of scutellarin were found and determined in rat urine, including isoscutellarin, methylated scutellarin, reduced scutellarin, scutellarin conjugated with glucuronate, *etc*., most of which were discovered for the first time. The main advantages of UPLC/MS were that the separation time was much shorter and the resolving power was significantly improved. Therefore, the method could be used to assay trace metabolites and to identify the reactions generating these metabolites especially with the aid of software such as Masslynx. This could provide more comprehensive insights and guidance for elucidation of side effect mechanism and safety monitoring as well as for rational formulation design in drug delivery system.

Excited-state intramolecular proton transfer

ABSTRACT

A ratiometric fluorescent probe **1** for fluoride ion was developed based on modulation of the excited-state intramolecular proton transfer (ESIPT) process of 2-(2′-hydroxyphenyl)benzimidazole (HPBI) through the hydroxyl group protection/deprotection reaction. The probe **1** was readily prepared by the reaction of HPBI with *tert*-butyldimethylsilyl chloride (TBS-Cl) and shows only fluorescence emission maximum at 360 nm. Upon treatment with fluoride in aqueous DMF solution, the TBS protective group of probe **1** was removed readily and ESIPT of the probe was switched on, which resulted in a decrease of the emission band at 360 nm and an increase of a new fluorescence peak around 454 nm. The fluorescent intensity ratio at 454 and 360 nm (I_{454}/I_{360}) increases linearly with fluoride ion concentration in the range 0.3–8.0 μmol L^{-1} and the detection limit is 0.19 μmol L^{-1}. The proposed probe shows excellent selectivity toward fluoride ion over other common anions. The method has been successfully applied to the fluoride determination in toothpaste and tap water samples.

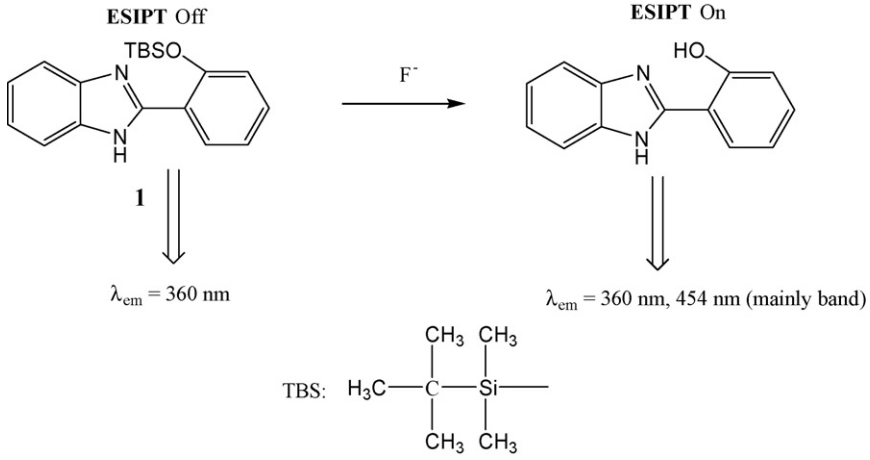
1. Introduction

The development of fluorescent sensors and probes for anions has received considerable attention due to their important roles in chemical and biological process [1–3]. Fluoride ion is of particular interest because of its role in preventing from dental cares and in treatment of osteoporosis [4]. However, a high intake of fluoride ion can lead to fluorosis [5], which corresponds to a fluoride 'disease'. Therefore, the design of reliable sensing method for fluoride ion is needed for environment and human health care. Unfortunately, most fluoride probes developed so far are operative at only the detection signal [6–11], factors such as instrumental efficiency, environmental conditions, and the probe concentration can interfere with the signal output.



Ratiometric fluorescent probes allow the measurement of emission intensities at two different wavelengths, which can overcome the drawbacks of intensity-based measurements due to a built-in correction for environmental effects (i.e. cancelling artifacts due to probe concentration variations) and increase the selectivity, sensitivity and dynamic ranges of the method [12–14]. However, up to now, only a few ratiometric fluorescent probes for fluoride ion [15–17] have been reported and they suffered some drawbacks such as low sensitivity [17] or non-aqueous solvent media requirement [16]. Therefore, there is a strong desire to develop new ratiometric fluorescent probes for fluoride with new mechanism.

It is well-known that 2-(2′-hydroxyphenyl)benzimidazole (HPBI) can undergo an excited-state intramolecular proton transfer (ESIPT) from the acidic (hydroxyl proton) to the basic site (aromatic nitrogen) when photoexcitation changes their charge density distribution [18–21]. In the ground state, the most stable form of HPBI is usually the enol form (**E**). However, in the first excited singlet state, in which the hydroxyl group is much more acidic and the nitrogen much more basic than in the ground state, the most stable structure is usually the keto tautomer (**K**). As a result, excitation of the enol form of HPBI tends to be followed by transformation to the keto form in the excited state via ESIPT reaction. This photo-induced tautomerization process is usually ultrafast because the transferring proton is already next to the proton acceptor at the moment of excitation. Accordingly, HPBI can emit two emission bands upon photoexcitation. The emission near 360 nm is the E* form, and the emission near 454 nm is the K* form. As the regulation of ESIPT can effectively shift the emission wavelength, we envisioned that this signal transduction mechanism could be employed to probe design.

Herein, a ratiometric fluorescent probe **1** for fluoride ion was developed. The probe **1** was prepared by the reaction of HPBI with *tert*-butyldimethylsilyl chloride (TBS-Cl). Once its hydroxyl group was protected by TBS group, the ESIPT process of HPBI was switched off and probe **1** shows only fluorescence emission maximum at 360 nm (the E* form). Because of the high affinity of fluoride for silicon, silyl ethers are easily cleaved by fluoride. Upon introducing fluoride in DMF/water (80:20, v/v), the TBS group of probe **1** was

Scheme 1. Design concept of ratiometric fluorescent probe **1** for fluoride.

removed readily through a fluoride-induced Si–O bond cleavage and the ESIPT process of the probe was switched on. Accordingly, it was observed that the fluorescence emission at 360 nm shows "turn-off", while the fluorescence emission at 454 nm shows "turn-on" (Scheme 1). The fluorescent intensity ratio of I_{454}/I_{360} (where I_{454} and I_{360} represents the fluorescence emission signal at 454 and 360 nm, respectively) increases linearly with fluoride concentration in the range 0.3–8.0 μmol L^{-1} and the detection limit is 0.19 μmol L^{-1}. The proposed probe shows excellent selectivity toward fluoride over other common anions, and the proposed probe has been successfully applied to the fluoride determination in toothpaste and tap water samples.

2. Experimental

2.1. Apparatus

The fluorescence spectra and relative fluorescence intensity were measured with a Sanco CRT-970 spectrofluorimeter (Shanghai, China) with a 10 mm quartz cuvette. The excitation and emission wavelength bandpasses were both set at 10 nm. The absorption spectra were measured with a Shimadzu UV-1700 spectrophometer (Tokyo, Japan). The pH was measured with a Model pHs-3B meter (Shanghai, China). Infrared spectra were taken in KBr pellets on a Bruker Tensor 27 FTIR spectrometer. Mass spectra were obtained with AXIMA-CFR plus MALDI-TOF Mass Spectrophotometer. ^{1}H NMR spectra were recorded on an INOVA-400 spectrometer (Varian Unity), using tetramethylsilane (TMS) as internal standard.

2.2. Reagents

A stock solution of 0.01 mol L^{-1} fluoride was prepared by dissolving 42.0 mg of sodium fluoride in 100 mL water. Standard test solutions were prepared by appropriate dilution of the stock solution. The solution of **1** (0.5 mmol L^{-1}) was prepared by dissolving 16.2 mg of the probe in 100 mL ethyl acetate, and this solution was stored in the refrigerator at 4 °C. A 0.2 mol L^{-1} Na_2HPO_4–NaH_2PO_4 buffer solution (pH 7.0) was employed. The sources of reagents were as follows: sodium fluoride was obtained from Beijing Chemical Reagent factory; *tert*-butyldimethylsilyl chloride was obtained from Shanghai Heqi Chemical Reagent Co.; 2-phenylbenzimidazole (PBI) was obtained from Alfa Aesar; o-phenylenediamine and salicylaldehyde were obtained from Xi'an Chemical Reagent Co.

All the reagents were of analytical-reagent grade, and doubly distilled water was used throughout.

2.3. Synthesis of probe *1*

HPBI was synthesized according to the method reported by Tavman for the synthesis of 2-(5-methyl-1H-benzimidazol-2-yl)-4-bromo/nitro-phenols [22]. The probe **1** was prepared by a modification of published method [11,24] using a simple one-step reaction of HPBI with *tert*-butyldimethylsilyl chloride (TBS-Cl) by using imidazole as catalyst and THF as solvent. Briefly, HPBI (0.30 g, 1.43 mmol) was combined with imidazole (0.2769 g, 4.07 mmol) in 7 mL anhydrous THF and stirred. To the above solution TBS-Cl was added (0.3441 g, 2.28 mmol). The reaction mixture was stirred at room temperature overnight. Then, the reaction mixture was poured into saturated brine (~50 mL) and extracted with ethyl acetate. The combined organic extracts were washed with saturated brine, dried over anhydrous Na_2SO_4 and the solvent evaporated to dryness, giving 0.34 g of orange solid. This solid was subjected to silica gel (200–300 mesh) chromatography eluted with acetone/petroleum ether (1:4, v/v) to afford the desired product (0.25 g, 55% yield) as off-white solid. TLC R_f 0.46 (1:4, acetone/petroleum ether). IR (KBr, cm^{-1}), 2929, 2857, 1602, 1489, 1471, 1457, 1389, 1256, 1159, 1109, 917, 838, 826, 782, 759 (Fig. S1). MS (MALDI-TOF): calculated for MH^+, 325.50; found 325.47 (Fig. S2). ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.02 (d, 1H, J = 7.6 Hz), 7.72 (d, 1H, J = 7.6 Hz), 7.54 (d, 1H, J = 7.2 Hz), 7.44 (m, 2H), 7.25–7.13 (m, 2H), 6.82–6.95 (m, 1H), 1.07 (s, 9H), 0.28 (s, 6H).

2.4. General procedure

The fluorogenic reaction was performed in a 10-mL volumetric tube. Typically, to a test tube containing 4.0 mL of DMF and 24 μL of 0.5 mmol L^{-1} of **1**, different concentrations of fluoride was added and the reaction mixture was diluted to 5.0 mL with water. The reaction solution was kept at room temperature (25 °C) for 40 min, then 1.0 mL of 0.2 mol L^{-1} Na_2HPO_4–NaH_2PO_4 buffer solution (pH 7.0) was added and the solution was diluted to 10 mL with water. The fluorescence ratio of I_{454}/I_{360} was measured with the excitation and emission wavelengths at 310 and 454/360 nm, respectively.

3. Results and discussion

3.1. Design of probe *1*

It was reported that HPBI displays dual fluorescence emission due to ESIPT [19–21]. To identify the above results, the absorption and fluorescence spectra of HPBI were measured and compared with that of PBI (the structure is shown Fig. 1). As can be seen from

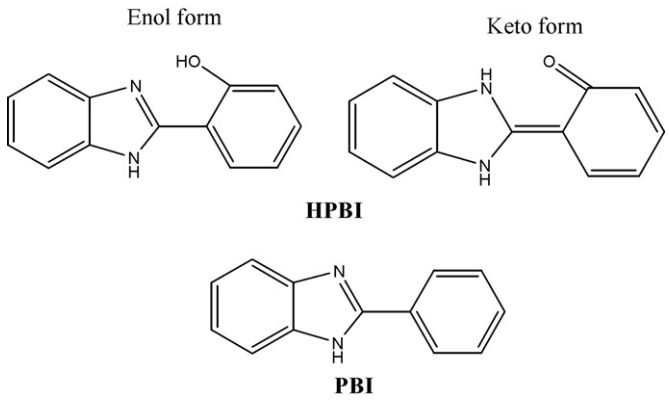

Fig. 1. Chemical structures of PBI, enol and keto form of HPBI.

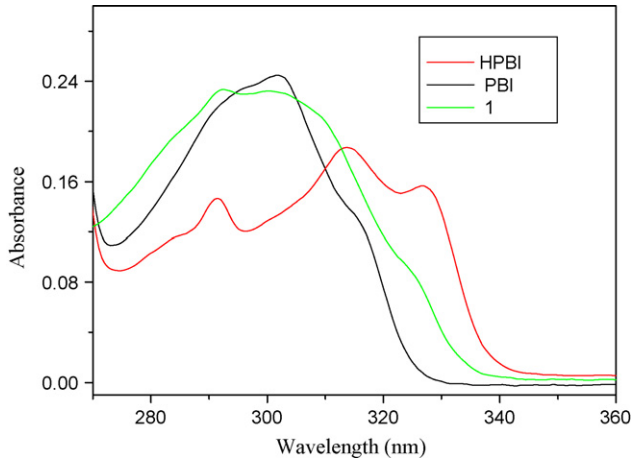

Fig. 2. Absorption spectra of 10 μmol L^{-1} HPBI, PBI and **1** in 20% (v/v) methanol–water solution buffered at pH 7.0.

Fig. 2, the absorption spectrum of HPBI shows absorption at 291, 315 and 324 nm, while for PBI, only a broad absorption band centered at 308 nm is observed. Furthermore, the fluorescence spectra of HPBI and PBI were recorded under identical conditions (Fig. 3). It can be observed that HPBI shows two emission bands centered at 360 and 454 nm, respectively. As for PBI, ESIPT cannot occur because of lacking hydroxyl group on its structure, thus only a single fluorescence emission band at 360 nm being observed. The above results

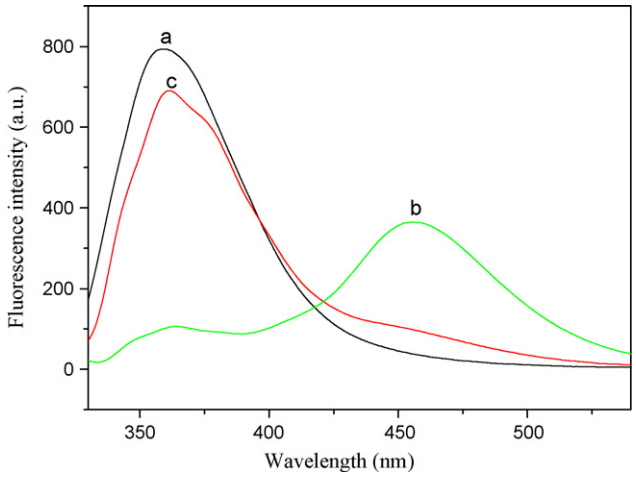

Fig. 3. Fluorescent spectra of 1.0 μmol L^{-1} PBI (a), HPBI (b) and **1** (c) in 40% (v/v) DMF–water solution buffered at pH 7.0 (λ_{ex} = 310 nm).

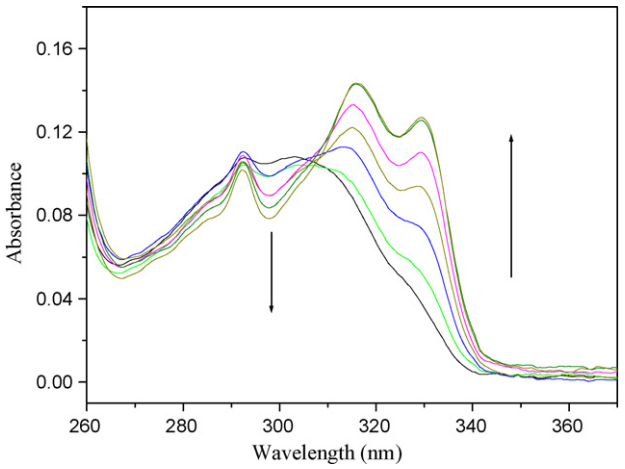

Fig. 4. Absorption spectra of **1** (5.0 μmol L^{-1}) after incubation with increasing concentrations of fluoride ion [0, 2, 4, 6, 8, 10 and 20 μmol L^{-1}, respectively] in DMF–water solution buffered at pH 7.0. Other reaction conditions are the same as those described in Section 2.4.

indicate that hydroxyl group on HPBI plays a key role for its emission characteristics. Encouraged by these results, we anticipated that ESIPT process of HPBI would be switched off if the hydroxyl group of HPBI was modified, and its spectral characteristics should behave like that of PBI. As expected, when the hydroxyl radical of HPBI was protected by TBS group (yielding the probe **1**), its absorption and fluorescence spectra are very similar to that of PBI at the same conditions (shown in Figs. 2 and 3). In the presence of hydroxyl group, ESIPT can take place and the K* emission at 454 nm is the major emission band. However, when the hydroxyl group is in a state of protection, only the E* emission at 360 nm can be recorded. Therefore, modulation of the features of the functional hydroxyl group of HPBI can manipulate ESIPT to afford a large wavelength shift in the spectra of the probe with and without the addition of analyte.

On the other hand, it is well known that *tert*-butyldimethylsilyl ether has been extensively utilized as protecting group in organic synthesis for hydroxy functionality [23–28]. The resulting silyl ethers can be easily converted to their parent compounds by fluoride ion [27]. Such mechanism has been exploited in the design of fluoride-sensing systems [8,10,11,29,30] but no ratiometric fluorescent probes for fluoride were reported. Based on these considerations, probe **1** was designed as a ratiometric fluorescent probe for fluoride based on modulation of ESIPT process via protection/deprotection of the functional hydroxyl group.

3.2. Spectral characteristics

Fig. 4 depicts the spectrophotometric changes of probe **1** upon mixing with fluoride ion in aqueous DMF solution. With an increasing amount of fluoride ion, the absorption band at 293 nm decreased, while the new band at 315 and 324 nm increased gradually. The final spectrum is in agreement with the characteristic absorption of HPBI, indicating that HPBI is formed in the present deprotection reaction. Furthermore, the probe **1** was mixed with different concentrations of fluoride, and the changes of fluorescence spectra are shown in Fig. 5. In the absence of fluoride, probe **1** exhibited one typical fluorescence peak at 360 nm. However, upon addition of an increasing concentration of fluoride, the emission band of probe **1** at 360 nm gradually decreased with the concomitant growth of a new emission band at 454 nm due to the restoration of ESIPT process.

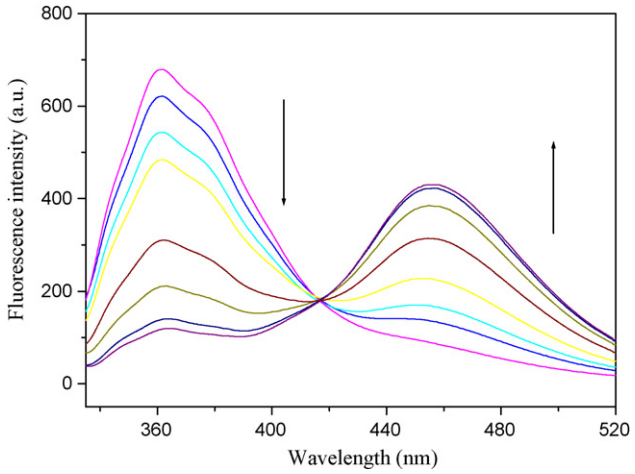

Fig. 5. Fluorescent emission spectra (λ_{ex} = 310 nm) of **1** (1.2 μmol L^{-1}) after incubation with increasing concentrations of fluoride ion [0, 0.3, 0.5, 1, 2, 4, 6 and 8 μmol L^{-1}, respectively] in DMF–water solution buffered at pH 7.0. Other conditions are the same as those described in Section 2.4.

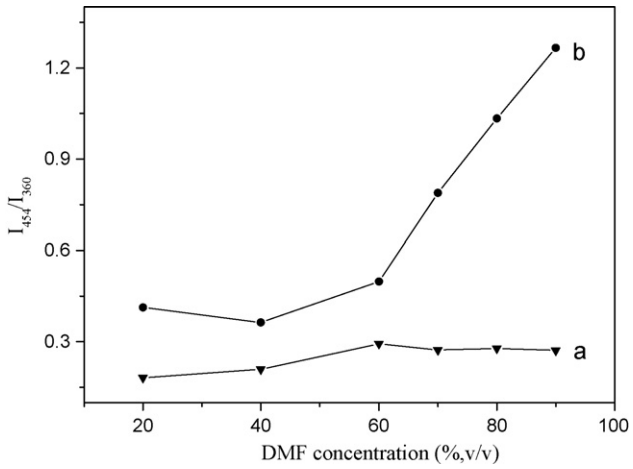

Fig. 6. Effect of DMF concentration on I_{454}/I_{360} of **1** (1.2 μmol L^{-1}) in the absence (a) and presence (b) of fluoride ion (2.0 μmol L^{-1}) in DMF–water solution buffered at pH 7.0. Other conditions are the same as those described in Section 2.4.

3.3. Effect of the reaction media and detection pH

It was reported that the removal of silyl protecting group by fluoride ion was favorable in aprotic medium [27]. However, non-aqueous reaction media was unfavorable for real sample assays. In the present study, we tuned the reaction conditions to the water/organic cosolvent mixtures and different organic solvents were tested under identical conditions. It can be seen from Table 1 that organic solvent has great effects on the deprotection reaction. When the deprotection reaction was performed in DMF–water solution, a high I_{454}/I_{360} was obtained, indicating that the cleavage of silyl ether by fluoride ion was more efficient in DMF–water solution.

Further, the effect of DMF concentration on I_{454}/I_{360} value of the reaction system was studied, and the results are shown in Fig. 6. It can be seen that I_{454}/I_{360} value remains almost unchanged when DMF concentration is in the range 0–60%, and increases dramatically when the concentration of DMF is above 60%. To facilitate the real sample analysis, 80% DMF–water solution was selected as the reaction media in the following experiment.

The detection pH of the reaction solution was investigated in the range 4.0–12.0, and it was found that probe **1** was unstable in high or low pH media and would cause a high background signal (Fig. S3). On other hand, the fluorescence ratio signal of HPBI remained stable in the pH range 4.0–10.0 (Fig. S4). Therefore, pH 7.0 phosphate buffer solution was selected as the detection media in the following study.

Table 1
Effect of solvent on the deprotection of **1** by fluoride ion.

Solvent[a]	I_{454}/I_{360}[b]	I_{454}/I_{360}[c]
Methanol	0.09	0.11
Ethanol	0.07	0.11
Acetone	0.25	0.38
DMF	0.13	0.92
Acetonitrile	0.09	0.22
THF	0.08	0.16

[a] Solvent concentration: solvent/water, 4:1 (v/v). Probe **1**: 1.2 μmol L^{-1}. Other conditions are the same as those described in Section 2.4.

[b] The emission ratio of probe **1** in the absence of fluoride.

[c] The emission ratio of probe **1** in the presence of fluoride (2.0 μmol L^{-1}).

3.4. Effect of reaction time

The effect of the reaction time on I_{454}/I_{360} of the system was studied and the results are shown in Fig. 7. It can be seen that I_{454}/I_{360} increased gradually with increasing the reaction time, and the complete cleavage of TBS group from the probe required several hours under the selected reaction conditions. Though the sensitivity of the present method could be increased with increasing the incubation time, a 40-min reaction time was selected as a compromise of sensitivity and analytical frequency.

3.5. Effect of probe concentration and reaction temperature

The effect of probe concentration on I_{454}/I_{360} of the system was studied and the results are shown in Fig. S5. It can be observed that I_{454}/I_{360} decreased with increasing the concentration of probe **1**. As a compromise of high sensitivity and wide linear range, the concentration of probe **1** was selected at 1.2 μmol L^{-1}.

The effect of reaction temperature on the fluoride-induced cleavage of TBS group from probe **1** was investigated in the range 20–60 °C (Fig. S6). The results showed that both background and fluorescence ratio signal increased with increasing temperature, but the signal-to-noise ratio (S/N) remained stable in the range

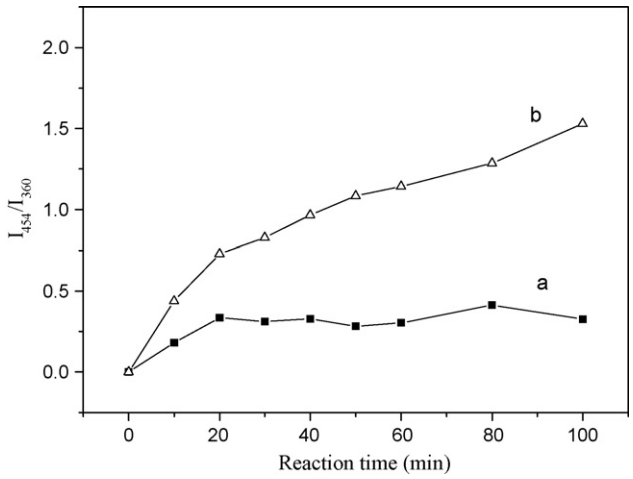

Fig. 7. Reaction-time profile of **1** (1.2 μmol L^{-1}) in the absence (a) and presence (b) of fluoride ion (2.0 μmol L^{-1}). The I_{454}/I_{360} changes were continuously monitored at time intervals. Other conditions are the same as those described in Section 2.4.

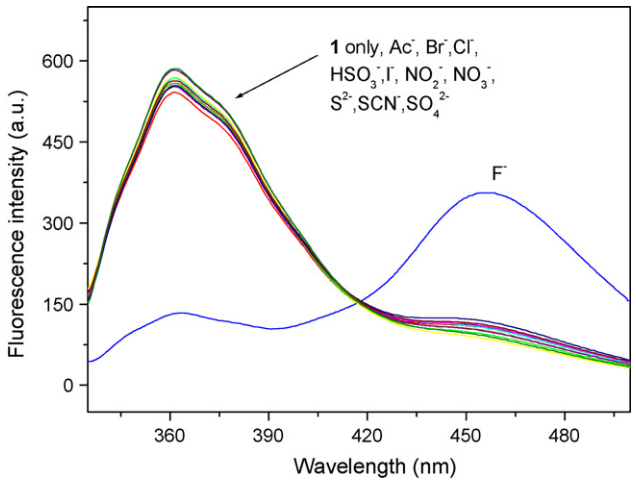

Fig. 8. Fluorescent emission changes (λ_{ex} = 310 nm) of **1** (1.2 μmol L^{-1}) upon addition of various anions (4.0 μmol L^{-1}) in DMF–water solution buffered at pH 7.0. Other conditions are the same as those described in Section 2.4.

20–50 °C, and thereafter decreased. Therefore, the reaction temperature was selected at 25 °C (room temperature) in the subsequent experiments.

3.6. Selectivity study

Changes in the fluorescence spectra of probe **1** caused by other anions, such as Cl^-, Br^-, I^-, NO_3^-, NO_2^-, S^{2-}, HSO_3^-, SO_4^{2-}, SCN^-, Ac^- were also investigated. After the addition 1.0 equiv. of each of these anions for 40 min, the fluorescence spectra of solution **1** were measured and shown in Fig. 8. It can be observed that only fluoride gave dramatic changes in fluorescence spectra, while other anions did not cause obvious changes under identical conditions. This result implies that the selectivity of **1** to fluoride over other anions is remarkably high.

To further investigate the effective applications of the probe, the effect of coexisting ions on fluoride determination were also studied by analyzing a standard solution of fluoride ion (2.0 μmol L^{-1}) to which increasing amounts of interfering species were added, using an error <5% as the criterion. The results are shown in Table 2. It can be seen that most of ions have little interference with the determination of fluoride. The high selectivity of the present probe toward fluoride over other anions can be explained by the specificity with which fluoride reacts with silicon atom. Moreover, though some heavy ions such as I^- can lead to the fluorescence quenching of the present system, the ratiometric response of probe **1** remains unchanged under these conditions, which is valuable for measuring fluoride ion in complex solutions.

3.7. Analytical characteristics of *1* for fluoride ion

Under the selected experimental conditions, I_{454}/I_{360} was plotted as a function of the fluoride concentration, and a typical calibration graph was obtained. The I_{454}/I_{360} value is linear with fluoride concentration (C) in the range 0.3–8.0 μmol L^{-1} with a correlation coefficient of r = 0.9974 (n = 7). The linear regression equation was determined to be $I_{454}/I_{360} = 0.451 \times 10^6 C$ [mol L^{-1}] + 0.095 (n = 7, r = 0.9974). According to IUPAC, the detection limit was determined from three times the standard deviation of the blank signal (3σ) as 0.19 μmol L^{-1}. The relative standard deviation (n = 7) was 4.1% for 2.0 μmol L^{-1} of fluoride ion.

Table 2
Tolerance limits of some foreign ions on the determination of fluoride ion.

Foreign ions	Molar ratio to fluoride ion[a]
Br^-, I^-, SO_4^{2-}, NO_3^-, SCN^-, Cl^-, Ba^{2+}, HSO_3^-, S^{2-}, NO_2^-, Mn^{2+}, Co^{2+}	100
Ac^-	50
Ni^{2+}, Hg^{2+}	10
Mg^{2+}, Pb^{2+}	1

[a] Fluoride concentration: 2.0 μmol L^{-1}.

Table 3
Results of determination fluoride ion in toothpaste and tap water[a].

Sample	Proposed method	ISE method
Toothpaste 1	1.19 ± 0.035 mg g^{-1}	1.16 ± 0.040 mg g^{-1}
Toothpaste 2	1.68 ± 0.025 mg g^{-1}	1.59 ± 0.052 mg g^{-1}
Tap water 1	11.06 ± 0.16 μmol mL^{-1}	11.41 ± 0.29 μmol mL^{-1}
Tap water 2	12.89 ± 0.21 μmol mL^{-1}	12.71 ± 0.19 μmol mL^{-1}

[a] Average of three measurements (±S.D.).

3.8. Sample analysis

To investigate the feasibility of probe **1** for analysis fluoride in real samples, fluoride content in toothpaste was examined. An accurately weighed amount of the commercial toothpaste sample (~1.0 g) was dispersed in 30.0 mL of double-distilled water, and stirred for 3 h at 70 °C in a polypropylene vessel with a magnetic stirrer [29]. The resulting solution was cooled to room temperature and then filtered to eliminate solids in suspension. The insoluble part was washed several times with water, and the resulting solution was diluted to 100 mL with water. This solution was diluted appropriately with water and was analyzed by the proposed method and fluoride ISE standard method [31], respectively. Moreover, the proposed probe was applied to the determination of fluoride in tap water samples by appropriate dilution with water. The results are listed in Table 3. It can be seen that the fluoride content determined using the proposed method is close to the values determined by the fluoride ISE standard method.

4. Conclusions

In summary, we have developed a ratiometric fluorescent probe for fluoride ion which operates by modulation of the ESIPT of the probe through protection/deprotection of the functional hydroxyl group. The probe **1** features a ratiometric fluorescent response to fluoride with a marked emission wavelength shift and displays high selectivity for fluoride over other anions. The method is proved to be simple, sensitive and can be broadly applicable to detection of fluoride ion in an aqueous environment. Moreover, the successful fabrication of the proposed probe provides a suitable platform to design ratiometric fluorescent probes by controlling its ESIPT process through molecular recognition reaction.

ABSTRACT

The preparation and characterization of an immunoaffinity chromatography (IAC) column for the specific extraction and enrichment of trace contraceptive drug levonorgestrel (LNG) from water samples were described. The IAC column was constructed by covalently coupling specific polyclonal antibody against LNG to CNBr-activated Sepharose 4B and packed into a common solid phase extraction (SPE) cartridge. The extraction conditions including loading, washing and eluting solutions, as well as the effect of flow rate on the extraction were carefully optimized. Pure water, 5% of methanol and 50% of methanol were respectively selected as loading, washing and eluting solutions, while the flow rates in the loading, washing and eluting steps were selected to be 1.0, 2.0 and 0.5 mL min^{-1}, respectively. Under optimal conditions, the IAC column was characterized in terms of maximum capacity, extraction recovery and stability. It was found that, for IAC column packed with 0.2 g of solid support immobilized with antibody, the maximum capacity for LNG was about 260 ng. The extraction recoveries of the column for LNG at three different spiked concentrations were within 95.3–106.9%. After more than 35 times repeated usage, there was not significant loss of specific recognition. Using high performance liquid chromatography (HPLC) as an analytical tool, trace amount of LNG in the range of ng L^{-1} was found in river water and wastewater samples after 600-fold enrichment, demonstrated the feasibility of the prepared IAC column for LNG extraction.

1. Introduction

Levonorgestrel (LNG, Fig. 1) is a synthetic progestin used as a progestin-only emergency contraceptive, and when administered at lower doses either alone or in combination with an estrogen, as an oral contraceptive [1]. LNG was considered to be safe with highly effective contraceptive for humans and has been widely used in the world. However, it has been reported that LNG has deleterious reproductive effects including the turbulence of catamenia, increasing rate of galactophore cancer, etc. [2,3]. LNG and other steroids were normally excreted from the human body, entering the receiving water through sewage effluent. Long time existence of such drugs at trace concentration in aquatic system may disrupt endocrines of aquatic animals. LNG and other steroids are stable in environment, so they may be cumulated in human bodies through food-chain and cause a potentially adverse effect on humans. On the other hand, as the content of steroids in real wastewater samples was extremely low (in the range of ng L^{-1}) [4,5] and the interference from other compounds on the determination of LNG was unavoidable. With the increasing concern of the adverse effect of LNG and other steroids on aquatic animals and human being, effective and specific extraction of LNG or other steroids from water samples prior to analysis is urgently demanded.

Natural and synthetic steroids in water matrix are usually determined by instrumental analysis such as gas chromatography –mass spectrometry (GC–MS) [6], GC–MS/MS [7], liquid chromatography–diode array detector (LC–DAD) [4], LC–DAD–MS [5,8], LC–MS/MS [9] and LC–MS/MS with electrospray ionization (ESI) [10] or with atmospheric pressure chemical ionization (APCI) [11]. In most cases, these chromatographic methods could detect trace levels of target analytes when an extensive pre-treatment step such as solid phase extraction (SPE) was coupled with. However, current SPE is based on physicochemical retention on functionalized surface which captures not only the target analyte but also other matrix components [12,13]. The drawbacks of routine SPE techniques are their low selectivity toward the particular target analyte. New efficient cleanup techniques employing the sorbents with the high selectivity for analyte are indispensable.

Immunoaffinity chromatography (IAC) is a separation method that takes advantage of the specific and reversible interaction

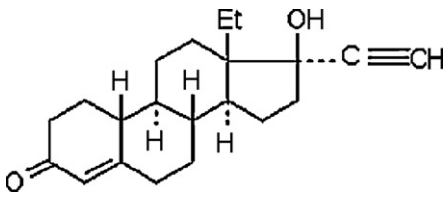

Fig. 1. Molecular structure of LNG.

between antibody and antigen [14,15]. Antibodies produced against a target analyte (antigen) are immobilized on a solid support. The immobilized antibodies will specifically retain the antigen from a solution passed through the support. Bound antigen can then be eluted and the support regenerated for reuse. IAC offers unique and powerful techniques, which enables selective extraction and enrichment of individual compounds or classes of compounds in one step. Additionally, IAC uses little or no organic solvents and columns may be reused and easily automated. IAC techniques have been widely used in clinical, biological, food and environmental areas for the extraction and enrichment of enzymes, peptides, hormones, receptors, viruses, drugs, mycotoxins, pesticides, organic contaminants in different matrices prior to analysis by on-line and off-line HPLC, gas chromatography (GC), capillary electrophoresis, or enzyme-linked immunosorbent assay (ELISA) [16–26].

In our previous study, we properly modified the LNG molecule and produced polyclonal antibody (pAb) against LNG. Then, coupled with SPE, we successfully developed a sensitive and specific ELISA for the detection of LNG in wastewater samples [27]. To overcome the non-specific absorption of SPE column, taking advantage of the specific binding of the antibody against target analyte (LNG), the aim of this work is to develop and characterize an IAC column for the effective extraction and enrichment of trace LNG from water samples prior to the analysis by HPLC. The purified pAb was covalently coupled to CNBr-activated Sepharose 4B particles and packed into a SPE column. The extraction conditions of the IAC column for LNG from water samples were optimized and the IAC column was characterized in terms of maximum capacity, extraction recovery and stability. Then IAC column was applied for the extraction and enrichment of trace LNG in real water samples. To our knowledge, it is the first report for the extraction of LNG in water samples with IAC column.

2. Experimental

2.1. Chemicals, buffers and solutions

Levonorgestrel (LNG), casein, bovine serum albumin (BSA), chicken egg ovalbumin (OVA), goat anti-rabbit IgG labeled with peroxidase (GaRIgG-POD) were purchased from Sigma (St. Louis, MO, USA). Dimethyl formamide (DMF), dimethyl sulfoxide (DMSO) and 3,3,5,5-tetramethylbenzidine (TMB) were purchased from Ameresco (Solon, Ohio, USA). CNBr-activated Sepharose 4B was purchased from Pharmacia Biotech (Uppsala, Sweden). Acetonitrile and methanol (HPLC grade) were obtained from Fluka (Buchs, Switzerland). The other reagents are all analytical grade.

Buffers and solutions: (1) coating buffer: 0.05 mol L^{-1} carbonate buffer, pH 9.8; (2) assay buffer: 0.01 mol L^{-1} phosphate-buffered saline (PBS), pH 7.4; (3) washing buffer (PBST): PBS with 0.1% (v/v) of Tween-20; (4) blocking buffer: 1% of casein in PBS; (5) acetate buffer: 100 mmol L^{-1} sodium acetate acid buffer, pH 5.7; (6) substrate solution (TMB + H_2O_2): 200 μL of 10 mg mL^{-1} TMB dissolved in DMF, 20 μL of 5% H_2O_2 and 1 mL of acetate buffer were added to 20 ml of pure water; (7) stop solution: sulfuric acid (5%); (8) LNG standard solution: the stock solution was prepared by dissolving LNG with methanol to a concentration of 1 mg mL^{-1} and stored at 4 °C. LNG standard solutions at concentrations of 0, 0.1, 0.3, 1, 3, 10, 30, 100 ng mL^{-1} was prepared by diluting the stock solution with pure water.

2.2. Instruments

Microtiter plate reader (Sunrise Remote/Touch Screen) and plate washer (M12/2R, Tecan) were bought from Tecan. Com. (Columbus plus, Austria). Ultraviolet visible spectrophotometer (UV-2300) was purchased from Techcom Com (Shanghai, China). Microtiter plate shaker (KJ-201C, Oscillator) was from Kangjian Medical Apparatus Co., Ltd. (Jiangsu China). Microtiter plates were from Haimen Plastic Co., Ltd. (Jiangsu, China). Deionized-RO water machine (DZG-303A) was purchased from AK Company (a conjunctive company between Chengdu and Taiwan, Chengdu, China).

2.3. Production and purification of polyclonal antibodies

The polyclonal antibody against LNG was produced according to the procedure described in our previous study [27]. The carbonyl group at position 3 on LNG molecule was reduced to hydroxyl group, which was then linked to ethyl bromoacetate. After hydrolysis, the LNG derivative with carboxylic group at the end of a spacer arm was obtained and covalently coupled to carrier protein. The LNG-BSA conjugate was used as immunogen for antibody production. The obtained antiserum was purified using a saturated ammonium sulfate method. The purification processes were as follows. To 2 mL of antiserum diluted with the same volume of saline, 4 mL of saturated $(NH_4)_2SO_4$ solution (pH adjusted to 7.4) was added dropwise under gently magnetic stirring at 4 °C. The obtained turbid solution was transferred to a centrifuge tube and allowed to stand for more than 1 h or overnight. Then the solution was centrifuged at 13,000 rpm for 10 min at 4 °C. The supernatant was discarded and the precipitates were dissolved in 2 mL of saline. To this solution, 1 mL of saturated $(NH_4)_2SO_4$ solution was added under magnetic stirring and allowed to stand for 1 h. Then the solution was centrifuged at 13,000 rpm for 10 min at 4 °C and the supernatant was discarded. The precipitates were dissolved in 1 mL of saline and dialyzed against 0.01 mol L^{-1} PBS. The immunoglobulin (IgG) concentration in the obtained solution was measured with a 1 cm cell using a UV 2300 spectrophotometer and calculated based on the UV absorption difference between 280 and 260 nm. The formula used for the calculation was: $C_{protein}$ (mg mL^{-1}) = $1.45A_{280\,nm} - 0.74A_{260\,nm}$ [28].

2.4. Preparation of IAC column

The IAC column was prepared by covalently coupling polyclonal antibodies against LNG to CNBr-activated Sepharose 4B and packed into a common SPE cartridge.

The covalent immobilization of Ab on solid support was performed according to the manufacturer's instructions and related literature [28,29]. Briefly, 0.2 g freeze–dried powder of CNBr-activated Sepharose 4B was weighed into a clean beaker with 20 mL of 1 mmol L^{-1} HCl to remove the protecting suspended groups. The suspension was transferred to a sintered glass filter and the gel was washed with 200 mL of 1 mmol L^{-1} HCl in three to four fractions. The outlet of the filter was sealed, then 1.5 mL coupling buffer (0.1 mol L^{-1} $NaHCO_3$ containing 0.5 mol L^{-1} NaCl, pH 8.3) was added to the gel. The obtained gel solution was pipetted into a conical flask containing 1.0 mL (~9.0 mg) purified antibody and the reaction proceeded in the incubator shaker at room temperature for 3 h.

The resultant immunosorbent was transferred to a common SPE cartridge with frits placed on both top and bottom. The effluent was collected and measured with UV spectrophotometer. The column was washed with the coupling buffer until the UV absorbance of

Table 1
The extraction recovery of the IAC column for LNG.

Spiked concentration (ng mL^{-1})	Volume added (mL)	LNG measured (ng)	Recovery (%)	RSD (%) (n = 3)
0.01	500	4.76	95.3	7.3
0.1	100	10.69	106.9	2.1
1.0	100	103.1	103.1	9.2

the effluent at 280 nm was zero. The excess active groups on the immunosorbent were capped with the blocking buffer (0.1 mol L^{-1} Tris–HCl buffer, pH 8.0). To ensure complete blocking, the outlet of the column was sealed and the gel was immersed in two column volumes of the blocking buffer and allowed to stand for 2 h. Then the column was washed extensively with of 0.1 mol L^{-1} acetate buffer containing 0.5 mol L^{-1} NaCl (pH 4.0), and 0.1 mol L^{-1} Tris–HCl buffer containing 0.5 mol L^{-1} NaCl (pH 8.0). Finally, the column was washed with 0.01 mol L^{-1} PBS (pH 7.4) and stored in 0.01 mol L^{-1} PBS containing 0.02% NaN_3 at 4 °C until use. For comparison, a blank column without antibody immobilization was prepared as the same way described above.

2.5. Optimization of extraction conditions for IAC column

To obtain high extraction efficiency, the extraction conditions such as loading, washing and eluting solutions, as well as the effect of flow rate on the extraction should be carefully optimized. In this study, to find the optimal extraction conditions, three loading solutions (10% acetone, pure water, 0.01 mol L^{-1} PBS) at flow rate of 0.5, 1.0, 2.0 and 4.0 mL min^{-1}, two washing solutions (pure water, 5% methanol) at flow rate of 1.0, 1.5 and 2.0 mL min^{-1} and four eluting solutions containing 20%, 30%, 40% and 50% of methanol/water (v/v, %) at flow rate of 0.5, 1.0 and 2.0 mL min^{-1} were examined. 1 mL of LNG standard solution prepared in either 10% acetone, pure water or 0.01 mol L^{-1} PBS at the concentration of 100 ng mL^{-1} (total LNG: 100 ng) was loaded onto the IAC column. Then 3 mL of washing solution (pure water or 5% methanol) was applied to the column to remove the unspecific binding. Finally, 2 mL of eluting solution was loaded onto the column to elute the target analyte specifically bound on the column. All fractions in the loading, washing and eluting steps are collected (0.5 mL/tube) and evaporated to dryness by low-pressured rotation evaporator at 45 °C. The residues were dissolved in 0.5 mL pure water and detected by ELISA.

2.6. Maximum capacity of IAC column

The LNG-binding capacity (e.g. the maximum amount of LNG to be retained by immobilized antibodies in IAC column) was determined by continuously loading LNG standard solution onto the IAC column so that excess amount of LNG would saturate all accessible sites of the IAC. Under optimal extraction conditions, 9 mL of LNG standard solution at concentration of 50 ng mL^{-1} (total LNG: 450 ng) was loaded on the column. All fractions in the loading, washing and eluting steps were collected and evaporated to dryness by low-pressured rotation evaporator at 45 °C. The residues were dissolved in 0.5 mL pure water and detected by ELISA.

2.7. Procedures of ELISA

During the processes of optimizing extraction conditions and testing maximum capacity of IAC column, many fractions from the column should be collected and detected. As high throughput and low testing cost, the previously developed ELISA was employed for the detection of LNG in the fractions. The ELISA procedures were as follows. 200 μL/well of coating antigen dissolved in carbonate buffer, pH 9.8 was added to a microtiter plate (96 wells). The plate was incubated overnight at 4 °C and then washed with PBST using an automatic plate washer. Some binding sites not occupied by the coating antigen were blocked by the blocking buffer (280 μL/well) for 1 h at room temperature. After the plate was washed as before, standard solutions or samples (100 μL/well) and diluted antiserum (100 μL/well) were added and incubated for 1 h at room temperature. After washing plate, GaRIgG-POD was added (200 μL/well) and the plate was incubated for 1 h at room temperature. Washing plate again, the substrate solution (200 μL/well) was added and then the plate was shaken for about 15 min for the color development. Sulfuric acid (5%, 80 μL/well) was added to stop the enzyme reaction and the absorbance was measured at 450 nm with ELISA reader. The calibration curve in the form of absorbance ~log C was plotted automatically by the corresponding software embedded in ELISA reader. The concentrations of LNG in samples could be calculated from the standard curve run in the same plate.

2.8. Extraction recovery of IAC column

Under optimal extraction conditions, the recovery of the IAC column was measured by loading three different concentrations of LNG standard solution: 0.01, 0.1 and 1 ng mL^{-1}. Each concentration was loaded onto the column with the volume of 500, 100 and 100 mL (total LNG: 5.0, 10 and 100 ng, respectively, Table 1). The eluting solution in the eluting step was collected and evaporated to dryness by low-pressured rotation evaporator at 45 °C. The residues were dissolved in 0.5 mL mobile phase and analyzed by HPLC. The same recovery testing was performed three times

2.9. Extraction of LNG from real water samples by IAC column

Three types of water samples were collected and extracted by IAC column. Tap water, river water and wastewater (one influent and one effluent) were respectively collected from this lab, Funan River (Chengdu, China) and Wastewater Treatment Plant (Chengdu, China). River and wastewater samples were filtrated with a 0.45 μm nylon membrane filter, then the pH value of the samples was adjusted to 7.0 using 0.1 mol L^{-1} of NaOH.

300 mL of above water samples without LNG spiking was loaded to the IAC column. After loading, the column was washed with 3.0 mL methanol/water (5/95), then the LNG retained on the column was eluted with 2.0 mL of 50% of methanol/water (v/v, %). The eluting solution from eluting step was collected and evaporated to dryness by low-pressured rotation evaporator at 45 °C. The residues were dissolved in 0.5 mL of mobile phase to obtain 600-fold enrichment and analyzed by HPLC.

2.10. HPLC method

HPLC was considered a more accurate analytical method for the detection of small organic compounds, so in this study, the LNG concentration in eluting solutions in Sections 2.8 and 2.9 were measured by HPLC. A HPLC system from Alltech Associates, Inc. (Deerfield, IL, USA) with a C18 column (250 mm × 4.6 mm, 5.0 μm particle size) and the HPLC work station software used for the instrument control and data analysis was employed for detection of LNG. 20 μL sample loop was used and the detection was realized with a UV–vis 201 detector integrated into the HPLC. The mobile phase was acetonitrile/water (54:46, v/v) and the flow rate was at

1.0 mL min^{-1}. The UV detection wave length was set at 242 nm and the standard curve for LNG was constructed in the concentrations of 0, 5, 10, 50, 100, 500, 1000 ng mL^{-1}. The linear equation was found to be $y = 71.86x + 141.64$ ($R^2 = 0.999$, $n = 7$) with the detection limit of 2.5 ng mL^{-1}.

3. Results and discussions

3.1. Antibody property and purification

The property of antibody is the key parameter for the preparation of the IAC column. A high specific antibody was utilized, whose property was described in reference [28]. There are many methods for antibody purification. In this study, the saturated $(NH_4)_2SO_4$ precipitate method was employed for antibody purification due to its simplicity and avoiding loss of antibody activity. By measuring absorbance at 280 and 260 nm, the concentration of purified antibody was calculated to be 9.0 mg mL^{-1}.

3.2. Preparation of IAC column

The solid support is also a critical parameter for the preparation of IAC column. Generally, an immunoaffinity support should be mechanically and chemically stable, porous, inert, easily activated to allow antibody attachment, and possess good flow properties. Commonly used support materials include silica, agarose, cellulose, and synthetic polymers. In this study, CNBr-activated Sepharose 4B was used as a solid support because the activated functional ligands on the surface make the particles to be easy for antibody immobilization. In addition, Sepharose 4B with the properties of good chemical stability, low back pressure resistance and poor non-specific interactions is also considered to be ideal particles used in off-line applications.

The IAC column was constructed by packing the antibody immobilized Sepharose 4B into a common SPE cartridge. The effluent was collected and measured with UV spectrophotometer. The antibody bound on the column was calculated by subtracting the antibody in the effluent from initial antibody. The coupling efficiency of LNG antibody on solid support was estimated according to the ratio of Ab coupled to solid support/initial Ab. In this study, three IAC columns were prepared and the coupling efficiencies were found to be 90.0%, 91.4% and to 91.9%, e.g. about 8.1 mg of antibody was covalently coupled to 0.2 g Sepharose 4B gel packed into one IAC column.

3.3. Optimization of extraction conditions for IAC

The extraction conditions should be optimized so that in the loading step, all target analyte can be specifically bound on the column, while in the washing step, the possibly non-specifical adsorption should be removed completely, and moreover, in the eluting step, all the bound analyte should be eluted and the Ab activity should be remained as much as possible. In this study, when total 100 ng of LNG was loaded onto the IAC column, three loading solutions (10% acetone, pure water, 0.01 mol L^{-1} PBS), two washing solutions (pure water, 5% methanol) and four eluting solutions (20%, 30%, 40% and 50% of methanol/pure water, v/v) were examined. It was found that when 10% acetone was used as loading solution at flow rate of 1.0 mL min^{-1}, only about 80% of LNG was bound on the column; while when pure water or 0.01 mol L^{-1} PBS was used as loading solution at 1.0 mL min^{-1}, almost all analyte was specifically bound on the column. As the IAC column was expected to be used for the extraction of LNG from water sample, therefore, pure water was selected as loading solution. At pure water as a loading solution, it was found that, at flow rate of 0.5, 1.0, 2.0 and 4.0 mL min^{-1}, 98.5%, 97.5%, 88.2% and 80.4% of analyte was specifically bound on the column, respectively. As the amount of analyte bound on the column at 0.5 and 1.0 mL min^{-1} was very close and near 100%, to reduce the loading time, the rate of 1.0 mL min^{-1} was selected for loading sample. In washing step, it was observed that either with pure water or 5% methanol to wash the column, there was no LNG in the effluent fractions, e.g. no LNG was removed from the column, but 5% methanol had the higher capability to remove non-specific binding, so 5% methanol was chosen as washing solution. At 5% methanol as a washing solution, it was found that, at flow rate of 1.0, 1.5 and 2.0 mL min^{-1}, there was no LNG removed from the column. To reduce washing time, 2.0 mL min^{-1} was chosen for washing sample. In most off-line IAC procedures, eluting the analyte bound on the column was achieved with a high percentage of an organic solvent mixed with water [26,27]. As shown in Fig. 2, with the increase of methanol concentration from 20% to 50%, the LNG content found in eluting solution at flow rate of 0.5 mL min^{-1} were increased too, from 39 to 90 ng. High concentration of methanol in eluting solution might enhance the extraction efficiency, but also would be more harmful to the antibody, decreasing the stability of the column. Therefore, 50% of methanol/water (v/v) was used as eluting solution. It was also found that, when

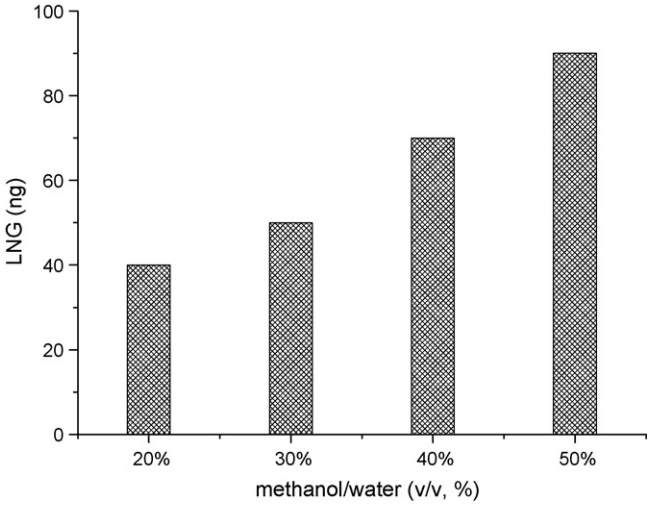

Fig. 2. LNG content found in the fractions of eluting step when 20%, 30%, 40% and 50% of methanol/water (v/v, %) were used as eluting solutions. 100 ng of LNG was loaded onto the IAC column.

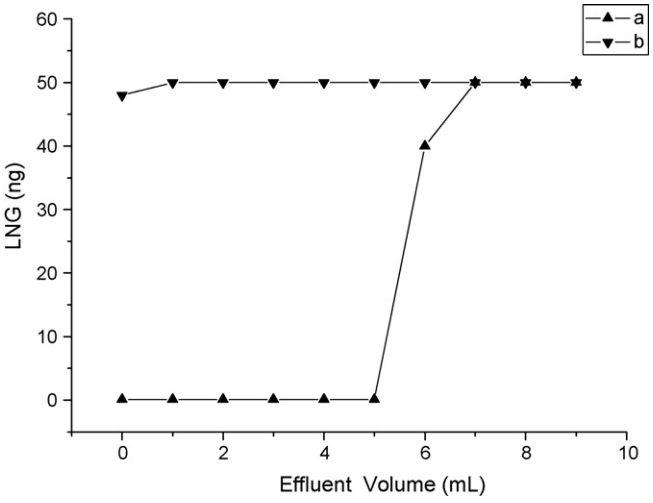

Fig. 3. Elution profiles for the continuous loading 9 mL of LNG standard solution at concentration of 50 ng mL^{-1} onto IAC column (a) and blank column (b).

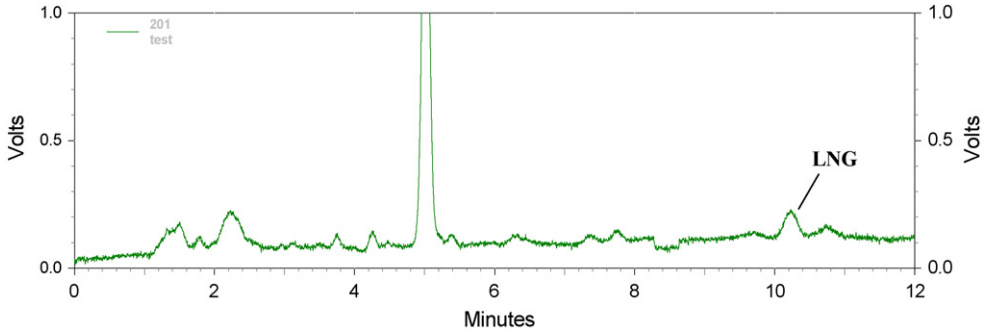

Fig. 4. HPLC chromatogram of LNG after a 600-fold enrichment by IAC column from river water sample. The LNG peak represents the concentration of 0.0075 ng mL^{-1} × 600 = 4.5 ng mL^{-1}.

2 mL 50% of methanol/water (v/v) was used as eluting solution at flow rate of 0.5, 1.0, 2.0 mL min^{-1}, 92.5%, 81.3% and 70.6% of analyte bound on the column was respective removed, therefore, so 0.5 mL min^{-1} was chosen for eluting sample.

3.4. Maximum capacity of IAC column

Under optimal extraction conditions, e.g. pure water, 5% of methanol and 50% of methanol were respectively selected as loading, washing and eluting solutions; the flow rates in the loading, washing and eluting steps were selected to be 1 mL min^{-1}, 2.0 mL min^{-1} and 0.5 mL min^{-1}, respectively, the IAC column was characterized in terms of maximum capacity, extraction recovery and reusability.

The maximum LNG-binding capacity of the IAC was measured by breakthrough volume test. 9 mL of LNG standard solution at concentration of 50 ng mL^{-1} was loaded on the column. The results of continuous samples loading on the IAC and blank columns were illustrated in Fig. 3. It was seen that the all LNG loaded on blank column went through the column immediately without any specific binding; while for IAC column, after loading 5 mL, there was still no LNG found in the effluents, showing its ability to recognize and retain the LNG. During loading 6 mL of LNG standard, 40 ng of LNG was observed in the effluent. Therefore, the maximum LNG-binding capacity of the IAC column packed with 0.2 g CNBr-activated Sepharose 4B was estimated to be: 5 × 50 + 10 = 260 ng. In another word, the maximum capacity of CNBr-activated Sepharose 4B was about 1.5 μg LNG/g of the solid support.

3.5. Extraction recovery of IAC column

500 mL of LNG standard solutions at concentrations of 0.01 ng mL^{-1}, 100 mL at 0.1 ng mL^{-1} and 100 mL at 1 ng mL^{-1} were respectively loaded on IAC column. The LNG content in the fraction of eluting step was detected and compared with that of total loading. As shown in Table 1, the LNG recoveries from the IAC column were found to be 95.3%, 106.9% and 103.1% with the relative standard deviation of 7.3%, 2.1% and 9.2%, respectively, indicating high extraction efficiency of the column.

3.6. Stability of IAC column

The antibodies against small molecular compounds are normally difficult to obtain and are very expensive. Therefore, the prepared IAC columns are expected to be used for many times. Actually most antibodies are tolerant to some extent of organic solvent without significant loss of activity and the IAC column can be easily regenerated with PBS solution.

The IAC column with the maximum capacity of 260 ng LNG was tested for its stability. It was observed that within 20 repeated usages, there was no any decrease of maximum capacity. After 35 times usage, about 80% of the maximum capacity was still remained, indicating high stability of the IAC column.

The regeneration and storage of the IAC column should be mentioned. After each extraction, the IAC column should be washed alternatively with no less than three column volumes of 0.1 mol L^{-1} pH 4.5 acetate buffer containing 0.5 mol L^{-1} NaCl and 0.1 mol L^{-1} Tris–HCl buffer, pH 8.5, containing 0.5 mol L^{-1} NaCl for three cycles. Finally, the column was washed with 0.01 mol L^{-1} PBS. For short-term (2–3 days) storage, the IAC column was simply kept in 0.01 molL^{-1} PBS at 4 °C; while for relatively long-term storage (over a week), it was kept in 0.01 mol L^{-1} PBS containing 0.02% NaN_3 at 4 °C. The IAC column was stable for at least 3 months without significant loss of binding activity.

3.7. Extraction of LNG from real water samples by IAC column

After filtrating and pH adjustment, 300 mL of collected water samples without LNG spiking was extracted with IAC column. The residues dissolved in 0.5 mL mobile phase with 600-fold enrichment were detected by HPLC. It was found that there was no detectable LNG in tap water, however, very small amount of LNG was found in other water samples. The trace concentrations of LNG found in original Funan river water, influent and effluent were 0.0075, 0.0743 and 0.0081 ng mL^{-1}, respectively. A HPLC chromatogram of LNG in Funan river water sample after 600-fold enrichment was illustrated in Fig. 4. Obviously, a small absorption peak of LNG with the retention time at 10.2 min was appeared, demonstrating the capability of the IAC to enrich the trace analyte and to clean the sample. It was also noticed that the LNG concentration in effluent was about 9-fold lower than that in influent, demonstrating that most of LNG was eliminated during the processes at wastewater treatment.

4. Conclusions

By covalently coupling the highly specific anti-LNG antibody on CNBr-activated Sepharose 4B and packing the immunosorbents into a SPE cartridge, the IAC column for selective extraction and enrichment of trace contraceptive drug LNG was firstly prepared and applied to real water samples prior to analysis by HPLC. The extraction conditions in the processes of loading, washing and eluting were optimized and the IAC column was characterized in terms of maximum capacity, extraction recovery and reusability. The recoveries values of LNG at three different spiked concentrations were within 95.3–106.9%, and after 35 times usage, about 80% of the maximum capacity was still remained. Trace amount of LNG in the range of ng L^{-1} was found in river water and wastewater samples after 600-fold enrichment, demonstrating the feasibility of the prepared IAC column for LNG extraction.

Pyrolysis residues

ABSTRACT

A method for the determination of 15 aromatic hydrocarbons in eluates from solid residues produced during the co-pyrolysis of plastics and pine biomass was developed. In a first step, several sampling techniques (headspace solid phase microextraction (HS-SPME), static headspace sampling (HS), and dispersive liquid–liquid microextraction (DLLME) were compared in order to evaluate their sensitivity towards these analytes. HS-SPME and HS sampling had the better performance, but DLLME was itself as a technique able to extract volatiles with a significant enrichment factor.

HS sampling coupled with GC–MS was chosen for method validation for the analytes tested. Calibration curves were constructed for each analyte with correlation coefficients higher than 0.999. The limits of detection were in the range of 0.66–37.85 ng/L. The precision of the HS method was evaluated and good repeatability was achieved with relative standard deviations of 4.8–13.2%. The recoveries of the analytes were evaluated by analysing fortified real eluate samples and were in the range of 60.6–113.9%.

The validated method was applied in real eluate samples. Benzene, toluene, ethylbenzene and xylenes (BTEX) were the compounds in higher concentrations.

The DLLME technique coupled with GC–MS was used to investigate the presence of less volatile contaminants in eluate samples. This analysis revealed the presence of significant amounts of alkyl phenols and other aromatic compounds with appreciable water solubility.

1. Introduction

The evaluation of the toxicity of industrial residues is a fundamental task to define the disposal methods more adequate to each particular waste. To assess the environmental impact of the landfill disposal of solid residues, leaching tests are made in order to define the mobility of organic and inorganic contaminants present in their matrices. The eluates are complex mixtures that can contain volatile and/or water soluble organic compounds whose toxicity and mobility might be environmentally relevant [1–11].

One of the industrial processes that produce wastes with an important organic content is pyrolysis. In this process, the wastes are subjected to thermal degradation in the absence of oxygen, producing a hydrocarbon mixture (vapour and liquid fractions) and a carbonaceous residue (the solid fraction). The vapour and liquid fractions have an economical value since they can be used as fuel or as feedstock in chemistry industries. The solid fraction is not normally reused and is, therefore, disposed off in landfills. However, this carbonaceous residue is saturated with the components of the liquid fraction. Therefore, it must be treated in order to reduce its organic load before it can be disposed off.

In a previous work [12] it was studied the qualitative profile of volatile organic compounds present in eluates from solid residues produced in the co-pyrolysis of plastics and biomass using static headspace sampling (HS) and gas chromatography coupled with mass spectrometry (GC–MS). Benzene, toluene, ethylbenzene and xylenes (BTEX) were detected at high levels and several other aromatic compounds as well as phenol derivatives, among others, were also detected. Although BTEX are the only volatile organic compounds whose determination in eluates from industrial wastes is required by the European legislation [13] for establishing a classification for this kind of wastes (hazardous, non-hazardous or inert), the presence of a relatively high number of other organic compounds can greatly increase the toxicity of the eluates [5,11,12].

In this work an analytical method, using HS-GC–MS, for the quantitative determination of 15 volatile aromatic compounds in eluates from solid residues produced during the co-pyrolysis of plastics and biomass, was validated. These 15 aromatic compounds are the main volatile contaminants in this kind of eluates produced from the non-treated pyrolysis residues [12].

The more common sampling methods for volatile organic compounds (VOCs) in aqueous samples are HS sampling with

doi:10.1016/j.talanta.2009.06.037

a gastight syringe or solid phase microextraction (SPME) [1,6,14–17].

A comparative study of static headspace (HS), headspace solid-phase microextraction (HS-SPME) and dispersive liquid–liquid microextraction (DLLME) as sampling techniques for the 15 volatile aromatic compounds was made in order to evaluate the sensitivity of each of these techniques towards this group of aromatic hydrocarbons. Other organic contaminants present in these eluates were studied using the DLLME technique and a tentative identification of the less volatile organic contaminants was made.

Recently, the DLLME technique has been used in the determination of a great variety of analytes, such as: polycyclic aromatic hydrocarbons (PAHs) [18], chlorophenols [19], triazine herbicides [20], PCBs [21], phthalate esters [22], chlorobenzenes [23], volatile phenols [24] and even BTEX [18], among others. The advantages of this technique are its simplicity and low volume consumption making it an attractive choice to perform screening of organic compounds in environmental liquid samples.

2. Experimental

2.1. Pyrolysis and leaching

A mixture of pine biomass and plastics (mixture of polypropylene, polyethylene, and polystyrene) was submitted to pyrolysis, and part of the solid residue produced was subjected to extraction with dichloromethane (DCM) as already described elsewhere [12,25–27]. The extracted residue (residue A) and the raw residue (residue B) were submitted to the leaching test ISO/TS 21268-2 [28]. The leachant solution used was a calcium chloride solution with a concentration of 0.001 mol/L (according to the standard). Two types of eluates were obtained: eluates from residue A (eluate 1) and eluates from residue B (eluate 2). The eluates were maintained at a temperature of 4 ± 1 °C until analysis.

2.2. Sampling and extraction procedures

The static HS was performed using the following optimized experimental conditions: equilibration time, 30 min; extraction temperature, 60 °C; vial volume, 50 ml; sample solution volume, 25 ml; injection volume, 0.5 ml.

The HS-SPME was performed using two types of fibers, namely, the PDMS (Polydimethylsiloxane) 100 μm fiber and the Car–PDMS (Carboxen–Polydimethylsiloxane) 85 μm fiber. The experimental conditions for the HS-SPME experiments were: vial volume, 50 ml; sample volume, 25 ml; equilibration time, 30 min; extraction temperature, room temperature; extraction time, 5 min; desorption time, 3 min; desorption temperature: PDMS, 200 °C and Car–PDMS, 250 °C.

The experimental conditions for the DLLME technique were: sample volume, 5 ml; extraction solvent volume, 50 μL of carbon tetrachloride (CCl_4); disperser solvent volume, 0.5 ml of acetone; centrifugation, 5 min at 4000 rpm; injection volume, 1 μL.

2.3. GC–MS analysis

The chromatographic analysis conditions for the static HS experiments were performed using a Focus gas chromatograph equipped with a split–splitless injector, a TR-V1 capillary column (30 m × 0.25 mm I.D. × 1.4 μm film) and a Polaris Q mass spectrometer detector. The carrier gas was helium at 1.5 ml/min; samples were injected at 60 °C in the splitless mode with a splitless time of 1 min and a split flow of 50 ml/min; the interface and ion source were kept at 220 °C; the oven temperature program was as follows: 32 °C (hold 5 min), up to 100 °C (5 °C/min), up to 250 °C (10 °C/min) and finally up to 280 °C (50 °C/min, hold 1 min). The MS system was operated in the full scan mode with a mass range from m/z 50 to 200.

For the HS-SPME experiments the equipment and GC–MS conditions were the same except for the injection temperature (250 °C for the Car–PDMS fiber and 200 °C for the PDMS fiber).

The GC–MS analysis of the DLLME extracts was performed in the same equipment but with a DB5 column (30 m × 0.32 mm × 1 μm); the injector was kept at 220 °C; the carrier gas flow was 1 ml/min and the injection volume was 1 μL. The oven temperature program was 35 °C (hold 3 min) and heating ramp up to 300 °C (5 °C/min). The MS detector was operating with the full scan mode covering a mass range from m/z 50 to 650. All the other chromatographic parameters were the same as in the previous experiments.

2.4. Reagents and chemicals

Pure dichloromethane (99.9% purity, supplied by Fischer Scientific), methanol (99.8% grade, supplied by Fluka), acetone (99.8% purity, supplied by Labscan) and carbon tetrachloride (99.8% purity, supplied by Pronalab) were used.

The aromatic standards were purchased from: Panreac (benzene and toluene, 99.5%), Fluka (ethylbenzene, >99%), Acros Organics (*m*/*p*/*o*-xylenes, 99%), Aldrich (cumene, 98%; propylbenzene, 98%; 4-ethyltoluene, 90%; *tert*-butylbenzene, 99%; 1,2,4-trimethylbenzene, 98%; 1-methylpropylbenzene, 99%; butylbenzene, 99%; 1,4-diethylbenzene, 96% and 1,2,4,5-tetramethylbenzene, 98%).

A stock standard solution with a concentration of 1 mg/L of each 15 analytes in methanol was prepared. A standard solution of 500 ng/L was prepared by dilution of the stock standard solution in the leachant solution ($CaCl_2$ 0.001 mol/L) and used to evaluate the limits of detection of the three techniques tested. The HS method was selected for complete validation. For this method, calibration curves were constructed for each analyte using standard solutions with concentrations in the range of 100–2000 ng/L.

3. Results and discussion

3.1. Determination of the 15 aromatic volatiles using different extraction techniques

In the first part of this work, the efficiency of different techniques (static HS, HS-SPME and DLLME) for sampling volatile aromatic compounds was tested using a standard aqueous solution of benzene, toluene, ethylbenzene, xylenes, cumene, propylbenzene, 4-ethyltoluene, *tert*-butylbenzene, 1,2,4-trimethylbenzene, 1-methylpropylbenzene, butylbenzene, 1,4-diethylbenzene and 1,2,4,5-tetramethylbenzene, with a concentration of 500 ng/L and making the analytical separation by GC–MS.

The limits of detection for each analyte were estimated using the signal-to-noise ratio of 3 ($LOD_{S/N}$) from the corresponding chromatographic peaks (Table 1). Although it is known that the limits of detection evaluated from the signal-to-noise ratio are in general overestimated, this measure can be used as a basis for comparison of different techniques before making a more detailed study of each one [29]. Most of the analytes tested (except benzene and toluene) were detected in the pg/L range using static HS or HS-SPME (with PDMS or Carboxen). The lowest $LOD_{S/N}$, in the range of 10–290 pg/L, was obtained using HS-SPME with a 100 μm PDMS fiber. Benzene and toluene had higher $LOD_{S/N}$ than the other analytes (16.5 and 1.3 ng/L, respectively, with PDMS fiber) reflecting their higher volatility and therefore their smaller partition into the SPME fiber. Using HS-SPME with the Carboxen–PDMS fiber or using static HS we were able to obtain lower $LOD_{S/N}$ for benzene and toluene (0.72–6.76 ng/L).

Table 1
Comparison of the limits of detection ($LOD_{S/N}$), in ng/L, of the three techniques proposed for the determination of 15 volatile aromatic compounds.

Analyte	PDMS 100 μm	Carboxen–PDMS 85 μm	HS-GC–MS	DLLME–GC–MS
Benzene	16.5	6.76	3.57	n.d.
Toluene	1.30	0.83	0.72	8.82
Ethylbenzene	0.29	0.32	0.32	24.6
m/*p*-Xylene	0.13	0.11	0.15	10.4
o-Xylene	0.23	0.27	0.27	19.6
Cumene	0.06	0.13	0.13	8.25
Propylbenzene	0.04	0.08	0.12	16.0
4-ethyltoluene	0.03	0.08	0.12	14.0
Tert-butylbenzene	0.02	0.09	0.10	6.45[a]
1,2,4-Trimethylbenzene	0.03	0.09	0.13	
1-Methylpropylbenzene	0.02	0.06	0.10	14.2
Butylbenzene/1,4-diethylbenzene	0.01	0.05	0.08	6.47
1,2,4,5-Tetramethylbenzene	0.02	0.07	0.11	1.02

n.d., not detected.
[a] co-elution.

With the DLLME technique, higher $LOD_{S/N}$ were obtained as it would be expected since it is not a technique specific for volatiles. However, the sensitivity of this technique with volatiles, in the range of ng/L, is remarkable and can be improved with an optimization study.

In conclusion, all of the techniques tested seemed to be adequate for the detection and quantification of these 15 aromatic hydrocarbons in the eluates from industrial residues at levels that are considerably lower than the limits proposed in legislation for the hydrocarbons of the BTEX group (100 μg/L) [13].

The static HS was chosen for method validation because it is a solvent-free technique and considerably less expensive than SPME. Moreover, the HS-SPME showed some fiber memory effects that require frequent conditioning of the SPME fiber.

3.2. Validation of the HS-GC–MS method for the determination of volatile aromatic compounds in eluates

The chromatographic conditions were optimized in order to obtain baseline separation for most analytes. The exceptions are the pairs butylbenzene/1,4-diethylbenzene and *m*/*p*-xylene that completely co-elute in all conditions tested and were, therefore, quantified together. The calibration curves were constructed in the range of 100–2000 ng/L, with five concentration levels. The calibration standard solutions were prepared by spiking the leachant solution with appropriated amounts of the methanolic standard solution (1 mg/L) of the 15 volatile aromatics. Duplicates were made at each concentration level. Table 2 shows the calibration equations and the correlation coefficients for each analyte. All analytes presented correlation coefficients above 0.999. The limits of detection (LOD) and of quantification (LOQ) for each aromatic hydrocarbon (Table 2) were calculated according to the criteria $33 \times (S_{y/x}/m)$ and $10 \times (S_{y/x}/m)$, respectively, where $S_{y/x}$ is the standard error of the calibration curve and m is the slope for each calibration curve. The LOQs were in the range of 2.2–126.2 ng/L, which are far bellow the maximum admissible values for leachates of industrial wastes (100 μg/L for the compounds of the BTEX group) [13], and even bellow the maximum admissible values for some of these analytes in drinking water (1 μg/L for benzene) [30]. The LODs evaluated from the calibration curves are in the range of 0.66–37.85 ng/L.

The repeatability of this proposed HS-GC–MS method was evaluated by analysing five replicates of the leachant solution spiked with the analyte mixture at two different concentration levels (Table 3). The relative standard deviations (R.S.D.) were between 4.8% and 13.2%. The accuracy of the method was evaluated using the recoveries of real eluate samples spiked with the methanolic standard solution at a concentration of 500 ng/L (Table 3). The average recovery for all analytes was 100.8% for both leachates tested, and varied in a range from 96.4% to 113.9%. Benzene was an exception with recoveries of 60.6% and 66.9%, due to the poor chromatographic focusing of the corresponding peak.

3.2.1. Analysis of eluates

The validated HS-GC–MS method was used to determine the concentrations of the 15 volatile aromatic compounds in both eluates (Table 4). Duplicate analyses were performed for each determination. When the concentration of the analytes exceeded the linearity range, the samples were diluted to an appropriate concentration using the leachant solution.

None of the 15 volatile compounds were detected in eluate 1 obtained from residue A that was previously extracted with dichloromethane which means that this extraction step was effi-

Table 2
Analytical performance of the HS-GC–MS method for the determination of 15 volatile aromatic compounds in eluates.

Analyte	Linearity range (ng/L)	Regression equation	Correlation coefficient, R^2	LOD (ng/L)	LOQ (ng/L)
Benzene	250–2000	$Y = 13{,}628x + 143{,}130$	>0.9999	12.86	42.88

cient in removing the majority of the volatile organic fraction from the pyrolysis residue.

Eluate 2 showed a high contamination with toluene, ethylbenzene, *o*-xylene and cumene (Fig. 1), in concentrations from 9 to 511 μg/L, as shown in Table 4, with predominance of toluene. This is consistent with the fact that toluene and ethylbenzene are also the compounds detected in higher amounts, in the liquid fractions obtained in the pyrolysis process [25,26]. Other volatile benzene derivatives appear in eluate 2 in concentrations from 0.08 to 1.59 μg/L. Although these concentrations can be considered low when considered individually their sum gives a value of 3.96 μg/L. Besides the benzene derivatives studied, several other minor peaks corresponding to phenolics, polycyclic aromatic hydrocarbons (PAHs) and other aromatics were also detected [12]. These less volatile contaminants tend to remain in the water phase because they are heavier or more polar than the compounds monitored in the HS-GC–MS method.

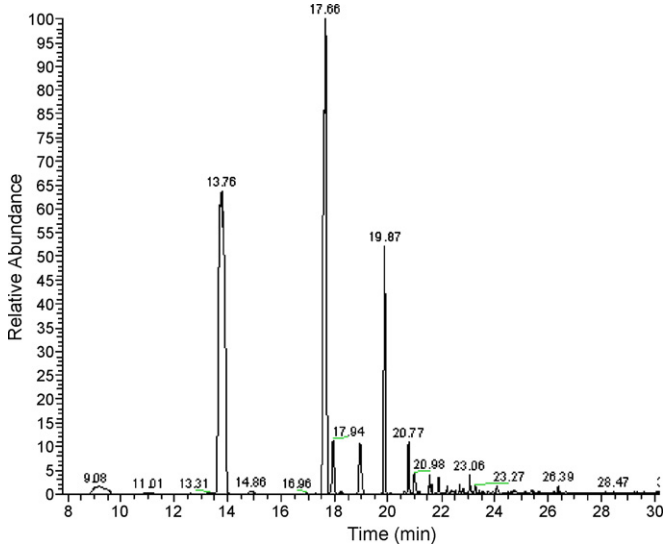

Fig. 1. HS-GC–MS chromatogram of eluate 2. Major peaks: RT = 9.08, benzene; RT = 13.76, toluene; RT = 17.66, ethylbenzene; RT = 17.94, *m*/*p*-xylenes, RT = 18.96, *o*-xylene; RT = 19.87, cumene; RT = 20.77, propylbenzene, RT = 20.98, 4-ethyltoluene.

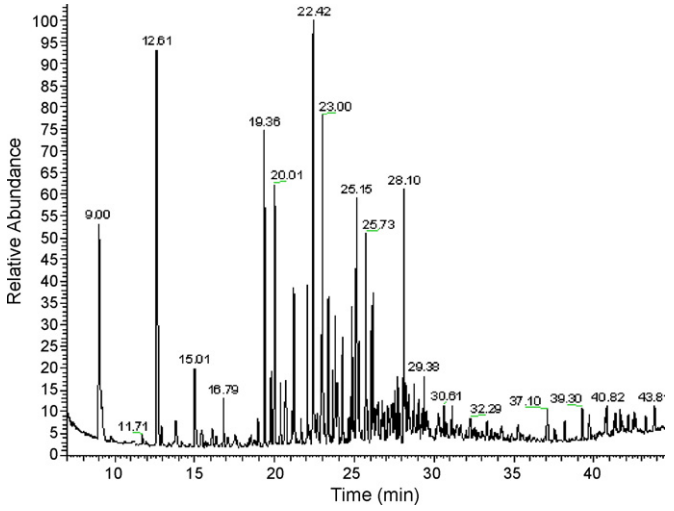

Fig. 2. DLLME–GC–MS chromatogram of eluate 2.

3.3. DLLME–GC–MS analysis

The identification of less volatile compounds present in the eluates was performed using DLLME and GC–MS (Table 5). The DLLME extract from eluate 1 showed no detectable chromatographic peaks indicating that the dichloromethane extraction was also effective in removing non-volatile contaminants from the pyrolysis residues as previously observed for the volatile ones. The DLLME extract from eluate 2 showed a strong contamination with alkyl phenols that were tentatively identified by GC–MS. These phenolic compounds result from the pine biomass pyrolysis [31]. The identity of 15 alkyl phenol contaminants was confirmed by co-injection of authentic standards. Fig. 2 shows the DLLME chromatogram of eluate 2.

4. Conclusions

The HS-GC–MS method developed allowed the determination of the 15 selected volatile aromatic hydrocarbons at levels adequate to the monitorization of these analytes in water samples (either surface and groundwaters for human consumption or leachates from industrial residues).

In the case of more contaminated water samples, this method has the advantage of being specific for volatile compounds, therefore eliminating polar or heavier matrix interferences. It is also a robust method when compared with HS-SPME because is not affected by fiber performance that can be highly variable in the case of complex samples with large organic loads.

The DLLME method used is a fast and simple procedure to screen the presence of organic compounds in water samples. The only drawback of the DLLME method is the use of a chlorinated solvent but since the solvent consumption is in the microliter range it produces very small amounts of residues.

Eluates from untreated pyrolysis residues are heavily contaminated with aromatic volatiles. BTEX concentration measured in eluate 2 is 843 μg/L when the corresponding limit value is of 600 μg/L [13] and heavier alkyl benzenes are present at a concentration of 13 μg/L. Eluates from residues extracted with dichloromethane showed a BTEX concentration of less than 0.09 μg/L, far bellow the legislation limit value [13] and concentrations of heavier alkyl benzenes lower than 0.13 μg/L. Comparison of the chromatographic profile of extracts obtained from leachates of treated and untreated pyrolysis residues shows that phenolic compounds are also removed by the extraction with dichloromethane. The decontamination of the residues with dichloromethane is, therefore, an efficient method to reduce their organic content.

The toxicity of the eluates depends on the total amount of organic contaminants as well as on the specific toxicity of each contaminant. Both the extracts analysed with HS-GC–MS or with DLLME–GC–MS revealed the presence of a large number of minor aromatic contaminants that can influence the toxicity of the eluate due to their individual toxicity properties, to the occurrence of synergistic effects or simply because of their overall concentration.

ABSTRACT

In this work, ultrasound-assisted emulsification with a probe system is proposed as a rapid and simple sample treatment for atomic spectrometric determinations (Electrothermal Atomic Absorption Spectrometry, Inductively Coupled Plasma Optical Emission Spectrometry, Flame Atomic Absorption Spectrometry and Cold Vapour Atomic Absorption Spectrometry) of trace elements (As, Cd, Cr, Cu, Hg, Mg, Mn, Ni, Sr and Zn) in cosmetic samples such as shampoos, gel (hair gel), crèmes (body milk, hair conditioner) and oil (body oil). The type of dispersion medium, the sample mass-to-dispersion medium volume ratio, as well as the parameters related to the ultrasound-assisted emulsification (sonication amplitude and treatment time) were exhaustively studied. Only 1 min of ultrasonic shaking and a dispersion medium containing 0.5% (w/v) of SDS + 3% (v/v) of HNO_3 or HCl allows obtaining a stable emulsion at least for 3 months. Thermal programs, nebulization of emulsions, speed of pumps and concentration of reagents used in cold vapour generation were optimized. Calibration using aqueous standards was feasible in all cases. Calibration by the standard addition method and recovery studies was also applied for validation. Microwave-assisted digestion and Inductively Coupled Plasma Mass Spectrometry were used for comparison purposes. Relative standard deviations from analysis of five independent emulsions were less than 9% in all cases.

1. Introduction

At present, cosmetics represent an important industry worldwide, but especially in Europe. These products are subjected to restrictive regulations, such as the European Directive 76/768/EEC [1], in order to ensure their safety and usefulness [2,3]. Legislations include information requirements about: (i) substances banned (these must not be found in the finished product); (ii) substances restricted; (iii) substances subjected to positive listing (used in controlled concentration). Among these, some metals and metalloids are included, namely, Cd, Pb and Sb (prohibited all their compounds); Co, Cr and Ni (most of their compounds are prohibited); Se (only as disulphur, up to 1% w/w) or Zn (up to 1% w/w) [1]. Therefore, sensitive and selective determinations of different metals in cosmetics are necessary for the control of these products.

Matrix of cosmetics is not simple; it usually contains a high number of ingredients and often requires time-consuming and tedious sample treatments [4]. Official analytical methods have been recommended in different legislations. Most of these methods use digestion or calcination as sample treatment and atomic spectrometry as determination technique [5,6].

It is advisable to improve cosmetic quality control using different recent developments of sample treatment but the number of papers focusing on this subject is scarce. Sample treatments, which involve the use of concentrate acids (i.e. HNO_3, $HClO_4$, H_2SO_4 or HF) and high temperatures and pressures, similar to those recommended by the official methods, are applied [7–14]. Sometimes, even with these strong treatments, complete solubilization of a sample is not feasible. Substances such as metallic oxides and pigments form a residue that must be removed by means of filtration or centrifugation, or submitted to a fusion treatment [10,12,15].

Sample emulsification procedures have been proposed as an interesting strategy for sample solubilization when liposoluble matrices are analyzed by Atomic Spectrometry [16–23]. This allows a direct and rapid analysis of samples, avoiding the use of strong acids and large volumes of organic solvents. The use of emulsification as sample treatment for metal determination in cosmetics can minimize the above problems. Nevertheless, this strategy has been scarcely used. Vondruska [24] determined Cd by Electrothermal Atomic Absorption Spectrometry (ETAAS) in cosmetic oil forming a water emulsion. Salvador et al. [12] determined Zn and Fe by Flame Atomic Absorption Spectrometry (FAAS) in sunscreen, forming a sample emulsion by shaking with a non-ionic tensioactive and isobutyl ketone.

In general, mechanical or manual agitation is used for emulsion formation, and in addition, agitation is required to maintain its stability during analysis [23]. The use of ultrasound for shaking allows obtaining a stable and homogeneous emulsion more quickly in comparison with mechanical processes [25]. Ultrasound-assisted emulsification is considered an interesting approach for accelerating the formation of emulsions in analytical chemistry, as well as for the determination of organic compounds and metals [26]. Two processes occurs in ultrasonic emulsification: (a) interfacial instability of the oil–water interface and (b) transient cavitation bubbles that generate micro streaming, high-pressure shock wave and high local temperature during their collapse. These phenomena accelerate the mass-transfer process between two immiscible phases by generating smaller droplet size of the dispersed phase [27,28]. However, some drawbacks related to the possible surfactant degradation can appear during ultrasonic emulsification [29]. Then, detailed studies of the process must be performed when this approach is followed.

In this work, we propose a simple and fast methodology based on ultrasound-assisted emulsification with a probe as a minimalist sample treatment for the determination of metals and metalloids in different cosmetics. This sample preparation was assessed in combination with different analytical techniques: Electrothermal Atomic Absorption Spectrometry, Inductively Coupled Plasma Optical Emission Spectrometry (ICP-OES), Flame Atomic Absorption Spectrometry and Cold Vapour Atomic Absorption Spectrometry (CV-AAS). Different variables related to ultrasonic emulsification were studied: surfactants, sonication time, sonication amplitude, sample mass and dispersive phase volume. Microwave-assisted digestion and ICP-MS (Inductively Coupled Plasma Mass Spectrometry) were used as a comparative methodology.

2. Experimental

2.1. Instrumentation

A Unicam atomic absorption spectrometer Model Solaar 939 (Cambridge, UK) equipped with a Unicam GF-90 graphite furnace and a Unicam FS-90 autosampler was used for Cd, Cr and Ni determination. A multielement hollow cathode lamp of Cr/Ni/Cu/Mn (Thermo Scientific, Cambridge, UK) and a hollow cathode lamp of Cd (Unicam) were used as radiation sources. Pyrolytically coated graphite tubes with platform were employed for Cd and without platform for Cr and Ni.

ICP-OES measurements were performed using an Optima 4300 DV inductively coupled plasma optical emission spectrometer (PerkinElmer, Überlingen, Germany) equipped with an AS-90 autosampler, a concentric glass nebulizer (Meinhard Type K), a cyclonic spray chamber and nickel interface sampler and skimmer cones. Axial and radial viewings were used. ICP-OES measurement conditions for As, Cd, Cr, Cu, Mg, Mn, Ni, Sr and Zn were optimized to achieve maximum signal-to-noise ratio.

A Unicam atomic absorption spectrophotometer Model Solaar 969 (Cambridge, UK) equipped with 10 cm burner head was used for Mg and Zn determination. Hollow cathode lamps Thermo Electron (Cambridge, UK) and Heraeus (Cambridge, UK) were used as radiation sources for Mg and Zn, respectively.

A PerkinElmer (Überlingen, Germany) Model 4110 ZL atomic absorption spectrometer equipped with a quartz cell atomizer and a flow injection system FIAS-400 (PerkinElmer) was used for Hg determination. The hollow cathode lamp PerkinElmer Lumina was employed as radiation source for Hg. The quartz cell was maintained at room temperature during operation.

ICP-MS measurements were performed using a Thermo Elemental X7 Series ICP-MS equipped with an ASX-520 autosampler (CETAC, Omaha, USA), a glass expansion concentric nebulizer, a spray chamber of quartz impact bead with a Peltier system, a quartz vessel torch and nickel interface cones. The isotopes ^{111}Cd, ^{65}Cu, ^{24}Mg, ^{55}Mn, ^{60}Ni, ^{88}Sr and ^{66}Zn were measured using standard mode with guard electrode (plasma screen) and isotopes ^{75}As and ^{52}Cr were measured using cell collision technology (CCT).

The operating conditions for ETAAS, ICP-OES, FAAS, CV-AAS and ICP-MS are summarised in Table 1. Thermal programs for Cd, Cr

and Ni were carefully optimized with the emulsified samples. Optimum conditions for emulsion nebulization in FAAS and ICP-OES were used. Speed of pumps in the flow injection system and concentrations of $NaBH_4$ and HCl were also appropriately optimized.

A 100 W 20 KHz Sonic and Materials (Danbury, CT, USA) high intensity ultrasonic processor, model VC 50-1, equipped with titanium microtip of 3 and 6 mm of diameter was used for ultrasound-assisted emulsification. A Multiwave 3000 Oven system (Anton Paar, Graz, Austria) equipped with a sample rotor of 8 vessels was used for microwave-assisted digestion of samples. A UVIKON XS UV/VIS spectrophotometer (Domont, France) equipped with quartz cells was used to acquire the spectrum of the emulsions. A Cannon-Fenske Serie 150 viscosimeter (Afora, Barcelona, Spain) was used for viscosity measurements.

2.2. Reagents and samples

High-purity deionised water was obtained from a PETLAB ultrapure water production system (Peter Taboada, Vigo, Spain). Multielement standard stock solution of 10 mg L^{-1} for Cd, Cr, Cu, Mg, Mn, Ni and Sr and 100 mg L^{-1} for As and Zn (ICP Multi Element Standard Certipur® VI Merck, Darmstadt, Germany) were used for calibration purposes in ICP-OES and ICP-MS. Internal standardization was carried out with ^{89}Y (0.5 μg L^{-1}) and ^{115}In (5 μg L^{-1}) prepared from a single element standard stock solution of 1000 mg L^{-1} (Merck). Single element standard stock solutions containing 1000 mg L^{-1} were prepared dissolving the pure metal or the appropriate salts: magnesium chips (Aldrich, Steinheim, Germany), nickel metal (Aldrich), zinc fine powder (Prolabo, Fontenay-sous-Bois, France), cadmium nitrate (Panreac, Barcelona, Spain), potasium chromate (Prolabo), mercury chloride (Prolabo).

Surfactants used for preparing ultrasound-assisted emulsifications were: sodium dodecyl sulphate (SDS, Fluka, Steinheim, Germany), hexadecyl trimethylammonium bromide (CTAB, Sigma–Aldrich, Milwaukee, USA), Tween 80 (Sigma–Aldrich) and triton X-100 (Merck). Concentrated HNO_3 (Suprapur, Merck), H_2O_2 33% (w/v) (Panreac) and HF 40% (v/v) (Merck) were used for microwave-assisted digestion procedures. Palladium nitrate (Fluka) was used as chemical modifier for Cd determination by ETAAS. Concentrated HCl of analytical grade quality (Prolabo), NaOH (Prolabo), $NaBH_4$ (Merck) and the Antifoam A (Fluka) were used for CV-AAS measurements.

Four hairs care products (conditioner, antidandruff shampoo, intensive antidandruff shampoo and hair gel) and two bath/shower preparations (body milk and body oil) were analyzed. In general, these products are emulsions and hence, a re-emulsification is necessary prior to analysis. These samples content a large number of components, such as tensioactives, fragrance agents, stabilizer agents, antimicrobial preservatives and water. Moreover, shampoos, hair gel and body milk contained a SiO_2-based compound (i.e. dimethicone). Elements like Zn (present in the anti-dandruff shampoo as pyrithione or carbonate) and Mg (present in the antidandruff shampoo as sulphate or carbonate) are active principles in shampoos. Levels of these elements were not mentioned in the commercial labels.

Glassware and plasticware used throughout the work were washed with 10% (v/v) nitric acid followed by repeated rinsing with ultrapure water.

2.3. Procedures for ultrasound-assisted emulsification

Different emulsification procedures were proposed in order to adapt this approach to some monoelemental and multielemental atomic spectrometry techniques: ETAAS, ICP-OES, FAAS and CV-AAS.

For the determinations by ETAAS (Cd, Cr and Ni): a portion of 15 mg of cosmetic sample was weighed into an autosampler cup and 1 mL of acid solution with surfactant (0.5% w/v SDS and 3%, v/v HNO_3 solution) was added as dispersing medium. Then, the mixture was sonicated for 1 min at 20% amplitude by means of the 3 mm probe.

For the determinations by ICP-OES (As, Cd, Cr, Cu, Mg, Mn, Ni, Sr and Zn) and FAAS (Mg and Zn): a portion of cosmetic sampled in the range 0.05–0.2 g was weighed into a 50 mL polyethylene tube, and then 15 mL of dispersing solution was added. This mixture was sonicated for 1 min at 20% amplitude by means of the 6 mm probe.

For the determination of Hg by CV-AAS, the emulsification procedure was similar to that employed in ICP-OES and FAAS, but HCl was used instead of HNO_3 in the composition of the dispersion medium. Also, addition of 200 μL of antifoam after sonication was needed in order to avoid foam formation in the gas–liquid separator.

Blanks were treated in the same way. In all cases the emulsion obtained was directly introduced in the analytical instrument.

2.4. Procedure for microwave-assisted digestion

Different digestion procedures were studied for the cosmetic samples containing a SiO_2-based compound, such as shampoos, hair gel and body milk. When digestions were carried out using only HNO_3 (4 mL of concentrated nitric acid), it was necessary to filtrate in order to remove the silicate residues [8,11]. The addition of HF was also tried for the digestion of these samples (a mixture of 3 mL of HNO_3 and 0.5 mL of HF was used and then, the resulting solution was heated in a sand bath nearly to dryness). The mixture of H_2O_2 and HNO_3 was also tried (4 mL of HNO_3 and 2 mL of H_2O_2). No significant differences were observed when the different procedures were statistically compared.

Microwave-assisted digestion of the cosmetics was carried out for comparison purposes. The selected procedure was as follows: about 0.2 g of sample was weighed into the PFA vessel, and then, 4 mL of concentrated HNO_3 and 2 mL of ultrapure water were added. The digestion vessels were closed and heated in a microwave oven using a preselected program: first stage of 5 min at 900 W, second stage of 2 min at 0 W and a third stage of 20 min at 900 W. After cooling, digests were quantitatively transferred into a 50-mL volumetric flask and made up to volume with ultrapure water. Blanks were treated in the same way. A dilution 1:5 was made for As, Cu, Sr and Zn measurements by ICP-MS in order to avoid matrix effects. Determinations by ICP-MS were based on a calibration graph obtained from standard aqueous solutions. Recovery studies were carried out for validation purposes.

3. Results and discussion

The type of surfactant and its concentration, the acid and its concentration, the quantity of sample in relation to the volume of dispersion medium, as well as the parameters related to the ultrasound-assisted emulsification (amplitude and sonication time) were exhaustively investigated. Preliminary experiments were carried out in order to visually check the stability of emulsions and then to establish suitable conditions in which stable emulsions were formed. In this work, an oil-in-water emulsion (o/w) is formed because the aqueous medium forms the continuous phase.

3.1. Study of the dispersion medium

Different surfactants were considered in this work: Triton X-100 (non-ionic), Tween 80 (non-ionic), SDS (anionic) and CTAB (cationic). These surfactants were selected due to their high solubility in water. All them have a HLB (hydrophilic lipophilic balance) higher than 10 (dimensionless scale) and can form (o/w) emulsions.

In general, surfactants with high HLB, as SDS (40), display high solubility in water and generally act as good solubilizing agents, detergents and stabilizers for (o/w) emulsions. The lower HLB of the others surfactants studied (15 for Tween 80, 13.5 for Triton X-100, and 10 for CTAB) can predict their lowest performance in (o/w) emulsification. These surfactants have been successfully used by other workers for samples such as gasoline, crude oil or edible oil [16,22,30,31].

Surfactants play a basic role in the formation and stability of emulsions (electrostatic and/or steric repulsion between emulsion droplets mainly depend on the surfactant), but an increasing viscosity can occur. On the other hand, the cavitation pressure threshold in a liquid increases on increasing viscosity. Less viscous emulsions allow achieving cavitation more easily [32]. In order to prevent potential problems in the emulsification procedure and, especially, during the sample introduction step in the different analytical instruments, viscosity of emulsions was tested. Emulsions with different surfactant concentration were prepared: CTAB (between 0.1% and 1% w/v), Tween 80 (between 0.005% and 0.5% w/v), SDS (between 0.05% and 1% w/v) and Triton X-100 (between 0.001% and 0.5% w/v). Small quantities of surfactant were tried in order to obtain suitable blanks for trace metal determinations. The blanks obtained with the different surfactants were suitable in all cases. When ultrasound energy is used, less surfactant could be necessary, and it would represent an important advantage of ultrasound-assisted emulsification procedures.

The minimum concentration of surfactant that forms a visually stable emulsion was established and then, kinematic viscosity of stable emulsions was measured. Table 2 shows the results obtained. As can be seen, emulsions formed with CTAB showed high viscosity, which was troublesome in some measurements, so this surfactant was rejected. Emulsions formed with Triton X-100 showed low stability and the breakup of the emulsion occurred at 30 min for concentrations up to 0.01% (w/v). The emulsions formed with Tween 80 showed good stability but their turbidity increased with time. SDS showed very good stability and no turbidity for concentrations up to 0.05% (w/v).

Stability and turbidity studies were made by ETAAS (Ni was determined in hair conditioner emulsions prepared with different surfactants) (Fig. 1) and by spectrophotometry (absorption spectra of the formed emulsions were obtained). The results were in good agreement with those obtained visually. SDS was selected for preparing emulsions on the basis of its good stability and lack of turbidity. A SDS concentration of 0.05% (w/v) was necessary to reach stable emulsions. Then, a concentration in the range 0.1–0.5% (w/v) of SDS was used for this purpose. Stability studies were also carried out for the rest of elements.

Nitric acid is usually added to the dispersion medium because it helps improving the stability of the analyte in emulsions of samples such as biodiesel [23]. HNO_3 can also convert organic species, metallic solid particles and oxide species of the analytes into their inorganic forms. In addition, it has been demonstrated that the use of emulsions (gasoline and kerosene) acidified with HNO_3 enables direct correlation between the signal of the analyte in the samples and the signal of it in aqueous inorganic standards [33]. When

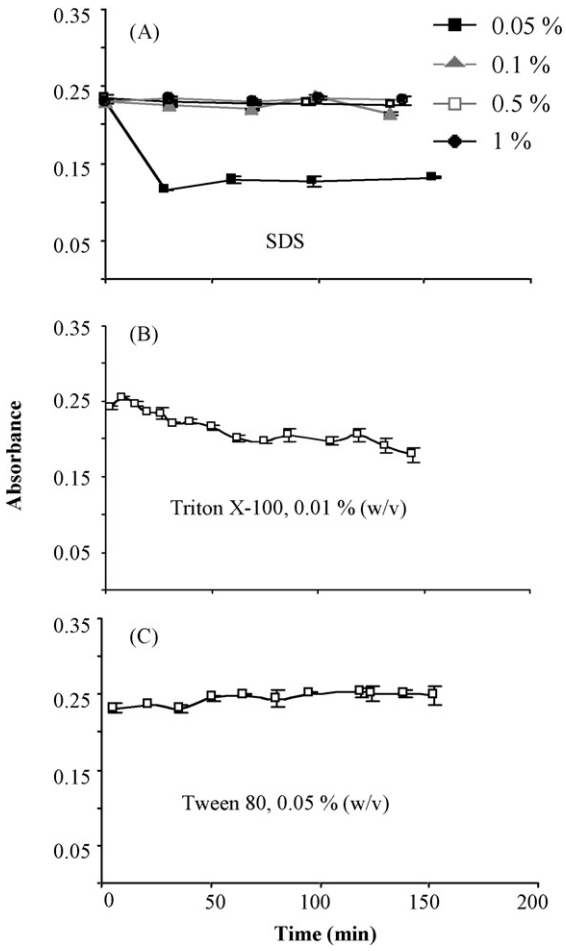

Fig. 1. Variation of absorbance *vs.* time for 20 μg L^{-1} of Ni in emulsions of hair conditioner (0.015 g of sample in 1 mL of dispersion medium) prepared with different surfactants (A) ■, SDS 0.05%; ▲, 0.1%; □, 0.5%; ♦, 1% (w/v); (B) Triton X-100, 0.01% (w/v) and (C) Tween 80, 0.05% (w/v).

only SDS was added to the water phase in our experiments, persistent foam and slight turbidity were observed in the formed emulsion. Therefore, acid concentration was studied in the range 0.5–4% (v/v). Foam formation was observed for acid concentrations lower than 1% (v/v), a nitric acid concentration of 3% (v/v) being selected. The use of hydrochloric acid was also considered in the application of the CV-AAS technique, although no differences were observed.

3.2. Oil/water ratio

The use of a maximum amount of sample in the emulsion is desirable in order to increase the analytical sensitivity, but it also increases the viscosity, thereby reducing the cavitation and the nebulization efficiency. Then, the sample mass was varied between

Table 2
Kinematic viscosity of emulsions.

Surfactant	Visually non-stable emulsions (up to % w/v)	Assayed range		Concentration (% w/v)	K. viscosity[a] (cSk)
		Concentration (% w/v)	K. viscosity (cSk)		
SDS	0.05	0.1–1	0.989–1.082	0.50	1.007
Tween 80	0.01	0.02–0.5	1.120–1.176	0.05	1.160
Triton X100	0.005	0.01–0.5	1.138–1.176	0.01	1.145
CTAB	0.5	1	43.5	–	–

[a] K. Viscosity is kinematic viscosity. The kinematic viscosity for deionized water is 0.999 cSk.

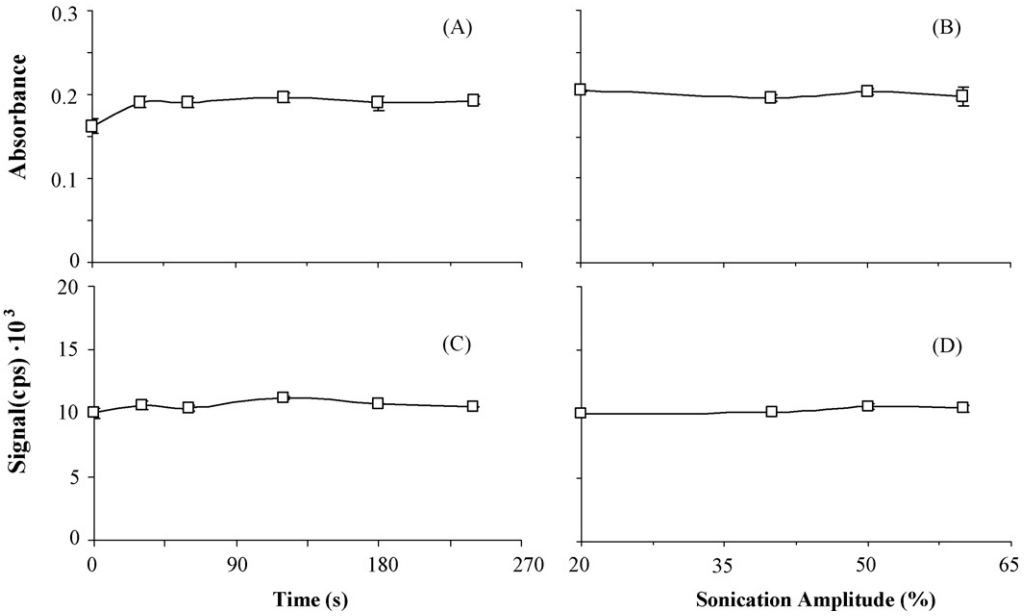

Fig. 2. Optimization of the sonication time (min) and amplitude (%) in emulsions formed with hair conditioner. (A) Absorbance of Ni obtained by ETAAS *vs.* ultrasound time; (B) absorbance of Ni *vs.* sonication amplitude; (C) emission signal of Mg by ICP-OES *vs.* sonication time and (D) emission signal of Mg *vs.* ultrasound amplitude. Experimental conditions for (A) and (B) were: 0.015 g of sample in 1 mL of dispersion medium (0.5% w/v of SDS and 3% v/v nitric acid). Experimental conditions for (C) and (D) were: 0.2 g of sample in 15 mL of dispersion medium.

0.05 and 0.2 g for 15 mL of dispersion medium and the viscosity was measured. Viscosities were found in the range 1.008–1.119 cSk. Larger sample masses caused an important increase in viscosity and besides persistent foams. Then, under these conditions, a (o/w) ratio of about 0.015 g mL^{-1} was established for the different analytical techniques including ETAAS, where 1 mL of dispersion medium was used.

3.3. Sonication parameters

Besides the surfactant concentration and the (o/w) ratio, main parameters influencing the emulsification process included power or amplitude and sonication time. In general, it is considered that an increase in the irradiation time and power causes a decrease in droplet size and an increase in the stability of the emulsion [34]. Then, sonication time and sonication amplitude were optimized for the emulsions formed with 1 or 15 mL of dispersion medium. Different techniques and samples were used for this purpose. In all cases, the results showed that 1 min is enough to form a stable and homogeneous emulsion (Fig. 2). Higher sonication amplitude had no effect on the emulsion formation so it was maintained at 20% level.

In comparison with the probe system, when an ultrasound bath was used in this work, a time of 15 min was necessary in order to obtain a transparent emulsion. When mechanical stirring was used, a turbid emulsion was obtained after 30 min. Similar times have been required by other authors with ultrasonic baths [22,35–38] and with mechanical stirring [30].

Sonication probe systems bring about some benefits for ultrasound-assisted emulsification, such as faster formation of stable emulsions and lower surfactant concentration, since cavitation is easily reached with these systems.

3.4. Studies of stability

Emulsions of the different cosmetic samples, prepared as pointed out above, were visually stable at least for 3 months. For longer times, phase separation takes place.

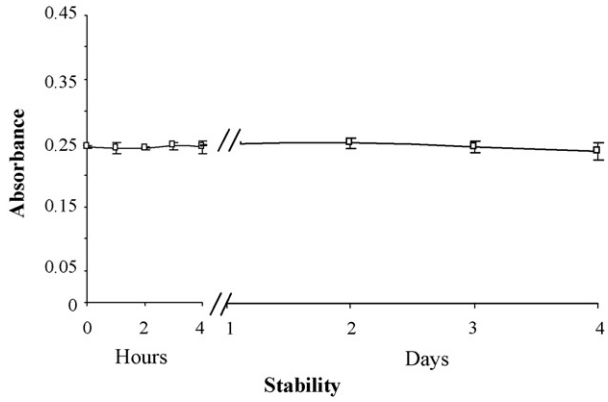

Fig. 3. Stability study of an emulsion prepared with the antidandruff shampoo (0.2 g of sample in 15 mL of dispersion medium). Zn absorbance measured by FAAS during four consecutive days.

The stability of emulsions was investigated for a period of several days. As can be seen in Fig. 3, the analytical signal of Zn in the antidandruff shampoo emulsion indicates a very good stability. Then, no immediate determinations need to be carried out.

3.5. Calibration studies

Chemical interferences caused by matrix components when emulsions are directly introduced into the analytical instruments, makes it necessary the development of different strategies for calibration. Aqueous standards have been adequate in the determination of several metals in oil-water emulsions [19,39]. de Souza et al. [18] used aqueous standards containing surfactant. Standard additions have been used with inorganic standards [38] and metal-organic standards [22]. Emulsions prepared with a single organic solvent using aqueous or organometallic stock solutions have also been used [40]. Different emulsions prepared by using purified samples and adding the metal as inorganic or as organic form have also been employed by several authors for calibration purposes [16,17,20,22,23,35].

In our work, potential matrix effects were studied by comparison of slopes obtained for aqueous standards and standard addition calibration methods. Calibration curves were built from three measurement replicates and, in all cases, regression coefficients were higher than 0.995. The slopes obtained and the linear ranges used are shown in Table 3. The comparison of slopes is presented in terms of percentage of change in slope (aqueous standard/standard addition). In all cases these percentages of change were less than 5%. These results indicate that there are not significant matrix effects and hence, calibration with aqueous standard can be carried out in all cases.

3.6. Validation of the proposed methodology

Validation of the ultrasound-assisted emulsification procedure in order to demonstrate its applicability to cosmetic samples was performed. This included detection and quantification limits, linearity, precision and accuracy.

Instrumental limits of detection (LOD) and quantification (LOQ) were determined following the 3σ and 10σ criteria, respectively. Procedural LOD and LOQ values in cosmetic samples were determined considering the instrumental LOD and LOQ values and the sample treatment (0.015 g of sample in 1 mL of solution for ETAAS and 0.2 g of sample in 15 mL of solution for ICP-OES, FAAS and CV-AAS). These limits are shown in Table 4.

Precision of the method, expressed as relative standard deviation (RSD), was evaluated in terms of repeatability. RSDs from five independent emulsions are shown in Table 4. Emulsions of cosmetic samples provided good precision. In all cases, repeatability from three replicates of the same emulsion was lower than 3% for all elements.

Accuracy was tested by means of recovery studies because certified reference materials for determining trace elements in cosmetics were not available. These studies were carried out in triplicate upon addition of known amounts of the element under study prior to sonication. As can be seen in Table 4, quantitative results were obtained in all cases.

Although mercury is used in cosmetics as a preservative in the form of phenylmercury salts and thiomersal, in this work, only inorganic mercury was determined. When ultrasound irradiation is performed in aqueous media, a series of radicals that are formed at the gas-phase interface of the cavitation bubble and to a lesser extent in the bulk solution, can reduce Hg(II) to Hg(0). However, when the medium contains HCl, this reaction does not take place [41]. Then, nitric acid was replaced by hydrochloric acid in the dispersion medium. Recovery studies confirm the maintenance of Hg(II) in the emulsion and further generation of Hg(0) from Hg(II) upon reduction with $NaBH_4$.

3.7. Analytical results for analyzed samples

Hair care products and bath/shower preparations were analyzed following the established procedure of ultrasound-assisted emulsification and different atomic spectrometric techniques (ETAAS, ICP-OES, FAAS and CV-AAS). External calibration with aqueous standards was used throughout. As a comparative methodology, samples were analyzed following microwave-assisted digestion and ICP-MS. Analytical results from three sample preparations for both ultrasound-assisted emulsification and microwave-assisted digestion procedures and three replicates of each one are shown in Table 5. After application of a t-test, no significant differences were generally observed between the results obtained by ultrasound-assisted emulsification and those obtained following microwave-assisted digestion.

In general, elements considered toxic such as Cd or Hg display concentrations below the LODs in the cosmetics under study.

[a] Concentrations are expressed in $\mu g\,g^{-1}$.

[b] t_{exp} values are shown between parenthesis. t_{crit} is 2.776 ($N = 3$, $p < 0.05$).

LODs for ICP-MS were: 0.01 $\mu g\,g^{-1}$ for As, 2.0 $ng\,g^{-1}$ for Cd, 0.04 $\mu g\,g^{-1}$ for Cr, 0.01 $\mu g\,g^{-1}$ for Cu, 5.0 $ng\,g^{-1}$ for Mg, 1.8 $ng\,g^{-1}$ for Mn, 9.3 $ng\,g^{-1}$ for Ni, 10. $ng\,g^{-1}$ for Sr and 0.04 $\mu g\,g^{-1}$ for Zn.

Only shampoos have a detectable content of As (87 $ng\,g^{-1}$ in antidandruff and 271 $ng\,g^{-1}$ in intensive antidandruff shampoos). Cr was detected at low levels (between 38 and 429 $ng\,g^{-1}$). In the case of Ni, for which most of their compounds are prohibited, levels found were between the LOD and 14 $\mu g\,g^{-1}$. Cu concentration ranged between the LOD and 313 $ng\,g^{-1}$. Mg displays a large variability depending of the cosmetic sample. The antidandruff shampoo, where Mg is one of the active principles, contains around 480 $\mu g\,g^{-1}$. Mn concentration was between LOD and 241 $ng\,g^{-1}$. Sr concentration ranged between undetectable concentrations and 412 $ng\,g^{-1}$, with the maximum level in the intensive antidandruff shampoo. For Zn, only detectable concentrations were observed in the shampoos, with the maximum content in the antidandruff shampoo (about 13 $mg\,g^{-1}$), in which is used as an active principle.

Overall, element concentrations are below the sensitizing limit proposed for consumer products and therefore, in agreement with the European legal regulations [1].

4. Conclusions

The developed procedure based on ultrasound-assisted emulsification with a probe ultrasonic processor provides an accurate and precise methodology for preparation of cosmetic samples prior to elemental analysis by ETAAS, ICP-OES, FAAS and CV-AAS. It can

be considered as an advantageous alternative in respect to digestion procedures due to its simplicity (minimal operations involved), rapidity and low consumption of reagents. These characteristics make this sample preparation suitable for routine analysis in the cosmetic industry.

An emulsion with very high stability is obtained. High intensity sonication for emulsion preparation facilitates the use of a surfactant (SDS) at low concentration. Addition of acid to the dispersion medium is necessary in order to remove foaming when cosmetics containing detergents such as shampoos are analyzed. A significant reduction in treatment time used for emulsion formation is achieved with probe sonication as compared to bath sonication.

Oil/water emulsions have similar viscosities in comparison with aqueous solutions and hence, no problems were found with nebulization systems in FAAS and ICP-OES instruments, with the flow injection system used in CV generation or with the autosampler used in ETAAS determinations. Also, matrix effects were not present when emulsions are used. Conventional calibration with aqueous standards can be made in all cases.

ABSTRACT

An HPLC method for the separation of seven cephalosporins [Cefepime (CEP), ceftazidime (CTA), ceftizaxime (CTI), ceftriaxone (CTR), cefotaxime (COT), cefixime (CIX) and cefoperazone (COP)] in human plasma and amniotic fluid has been developed. Optimization of the chromatographic method was performed in three steps: a series of initial experiments followed by two sets of experiments based on different experimental designs. The initial experiments were performed to decide the basic analytical requirements of the method. Then screening experiment fractional factorial design was used in order to decrease the number of parameters by eliminating parameters which having insignificant effect on responses. The parameters having significant effect were further optimized through a full factorial design. Having studied two responses (retention times and resolutions), a desirability function that assess the responses together, was used to find experimental conditions where the system generated desirable results. The desirable results were obtained with XTerra C18 (250 mm × 4.6 mm, 5 μm i.d.) column, 40 mM phosphate buffer, pH 3.2, 18% MeOH, 0.85 mL min^{-1} flow rate and 32 °C column temperature. Gradient elution with MeOH was applied. A simple and efficient solid-phase extraction was applied for the preparation of plasma and amniotic fluid samples. The validation parameters of the method were evaluated in accordance with ICH guideline. The method validated was applied to the analysis of CEP and COP in maternal venous, fetal venous and fetal arterial plasma, and to the analysis of CIX in maternal venous plasma and amniotic fluid.

1. Introduction

Cephalosporins are structurally and pharmacologically related to the penicillins. Like the penicillins, cephalosporins have a beta-lactam ring structure that interferes with the synthesis of the bacterial cell wall. They are used for the treatment of infections caused by Gram (+) and Gram (−) bacteria. They are among the safest and the most effective broad-spectrum bactericidal antimicrobial agents and therefore, they are the most frequently prescribed class of antibiotics [1,2].

It is well accepted that changes in body compartments and alterations in cardiac output and renal function occur during pregnancy along with subsequent subtherapeutic maternal serum levels for several antibiotics. For many drugs, absorption is decreased and elimination increased, thus tending to reduce plasma concentrations [3]. Therefore, the concentration of drugs in pregnancy must be determined in order to be monitored if therapeutic dosage is to be achieved or over-dosage prevented. Moreover, the determination of drugs in amniotic fluid is an important piece of information as an indicator of placental penetration [4].

The analysis of cephalosporins in biological materials from human origin [5–12] and in food-producing animals [10,13] foods [10,14], waters [11,15] and pharmaceuticals [16–18] was performed with liquid chromatographic [5–11,13–15], capillary electrophoretic [10,18], spectroscopic [10,14,16–18] and electrochemical methods [7,10,12]. None of them, however, was analyzed the seven cephalosporins simultaneously. In addition, to the authors knowledge, no other article has previously been written regarding the analysis of CEP, CTA, CTI, COT, CIX and COP in amniotic fluid by HPLC.

The method of changing one variable at a time to investigate the outcome of an experiment most likely dates back to the beginnings of systematic scientific research. The idea was fairly simple. In order to simplify control and interpretation of the results, only one of the factors was chosen for variation while the rest keep at constant values. However, the influence of several factors also needed to be investigated during optimization. Thus the conventional step-by-step optimization procedure was too tedious due to the number of

doi:10.1016/j.talanta.2009.06.034

variables involved, and did not take into account possible interactions between factors. With this in mind, the experimental design selects the best location of experimental points in the predictor space and collects these points in a design matrix [19,20].

In this study, chemometric approaches were employed to systematically optimize the relevant operating parameters. The optimization of the method was performed in three steps i) initial experiments to decide basic requirements of the method ii) screening to select important parameter(s) and iii) response surfacing to find the optimum point. During the optimization steps, resolution and retention time responses were screened in order to maximize the resolutions and minimize the analysis time of the developed method.

In the study, fourteen responses (retention time of the seven cephalosporins and seven resolutions between the adjacent peaks) were screened. To evaluate all these responses at the same time, a multicriteria decision-making approach (the desirability function) was used to find the best compromise between the responses [21–23].

Sample preparation from plasma and amniotic fluid was performed with the solid-phase extraction (SPE) method in order to make use of its benefits, i.e. it consumes less solvent, provides more complete extraction of the analyte, and especially, provokes more efficient separation of interfering substances from analytes [24,25].

In this paper, an HPLC method with UV detection was presented for seven cephalosporins given in Fig. 1. The cephalosporins selected in the present study were those that were currently on the market in Turkey for the treatment of humans. The cephalosporins were determined from two matrices (plasma and amniotic fluid). Specifically, the aim was to develop a general method that allowed the determination of each agent without the need for the development of separate and distinct methods. Validation studies were performed with respect to system suitability, stability, linearity, LOD, LOQ, precision, accuracy, selectivity and robustness. Finally, the method was applied to the analysis of CEP and COP in maternal venous and fetal arterial and venous plasma obtained during delivery and CIX in maternal venous plasma and amniotic fluid, obtained from pregnant women between the 16th and 20th gestational weeks during amniocentesis.

2. Experimental

2.1. Reagents

Cefixime (CIX), Cefepime (CEP), Ceftazidime (CTA), Ceftizoxime (CTI), Ceftriaxone (CTR), Cefotaxime (COT) and Cefoperazon (COP) were kindly supplied from Eczacıbaşı Drug Inc. (Turkey).

All reagents were of analytical grade. Acetonitrile, methanol (MeOH) and potassium dihydrogenphosphate were purchased from Merck (Darmstadt, Germany). Milli-Q water was used for the preparation of buffer and other aqueous solutions.

The SPE cartridges used in the study were Strata X (30 mg/1 mL; Phenomenex; California, USA), Oasis HLB (60 mg/3 mL; Waters, Massachusetts, USA), Chromapack C_{18} and C_8 (100 mg/1 mL; Macherey-Nagel, Düren, Germany) and Isolute ENV$^+$ (200 mg/3 mL; Biotage, Uppsala, Sweden).

2.2. Instrumentation

Chromatographic separation of the cephalosporins was performed on a XTerra C_{18} column (250 × 4.6 mm, 5 μm i.d.; Massachusetts, USA) protected with a Phenomenex C_{18} guard column (4 × 3.0 mm i.d.; California, USA).

The HPLC equipment comprised of a solvent delivery system (Shimadzu 10 AT_{VP}, Tokyo, Japan), an auto sampler (Shimadzu SIL 10 AD_{VP} Tokyo, Japan), a column oven (Shimadzu CTO 10 AS_{VP}, Tokyo, Japan) and a photodiode array detector (Shimadzu M 10$_{VP}$, Tokyo, Japan). A ChromQuest software (Shimadzu Technologies) was used for data acquisition and evaluation.

A Mettler Toledo MA 235 pH meter connected with a Mettler Toledo Inlab 413 pH electrode were used to measure the pH of the aqueous mobile phase.

Microsoft Excel 2007 (California, USA) and SPSS 16 (Illinois, USA) was used to calculate matrices and *p* values of the regression coefficients.

2.3. Standards and stock solutions

A stock solution of the CIX (1000 μg mL^{-1}) was prepared in MeOH while the other stock solutions of the cephalosporins (1000 μg mL^{-1}) were in water. All of the stock solutions were stored at +4 °C. Working solutions, containing all cephalosporins, used to spike plasma, amniotic fluid and water were prepared at 10.00, 1.00 and 0.10 μg mL^{-1} concentrations from stock solutions by diluting with water.

2.4. Buffer solutions

An aliquot of 2.7 mL concentrated phosphoric acid for 40 mM phosphate buffer (pH 3.2) and 3.3 mL concentrated phosphoric acid for 50 mM phosphate buffer (pH 2) were transferred into two separate 500 mL volumetric flasks and then diluted to the mark with distilled water and the desired pH was adjusted by the addition of 5 M NaOH.

2.5. Sample collection

Maternal venous, fetal venous and fetal arterial blood were taken during delivery (cesarean section). Single dose antibiotic administration (COP and CEP) was started one hour before delivery intravenously and completed in 30 min. Blood samples were taken from the maternal left hand venous and the umbilical cord of the placenta, discarding material, to obtain fetal veneous and arterial blood samples during delivery. Blood samples were centrifugated at 4500 rpm for 10 min to obtain plasma.

Amniotic fluid was taken from pregnant women between the 16th and 20th gestational weeks to investigate the karyotype of the fetus. To prevent development of an infection, a single dose of antibiotic (CIX) was given orally. After two hours, amniotic fluid and maternal venous blood were taken and venous plasma was obtained from blood by centrifugation at 4500 rpm for 10 min.

Plasma and amniotic fluid samples were stored at −20 °C protected from light until analysis.

The Local Ethical Committee of the Faculty of Medicine at the Hacettepe University, approved this study (LUT 05/112) and the informed written consent was obtained from all patients accepted to the study.

2.6. Sample preparation

An aliquot of 0.5 mL plasma (excepting COP administrated maternal plasma samples; 0.25 mL plasma) or amniotic fluid was transferred into 1.5 mL of an eppendorf tube. Subsequently, 50 μL stock solution of the internal standard (CTI) (100 μg mL^{-1}) was added. After gently mixing, the sample was prepared as explained in the section entitled SPE.

2.7. SPE

A polymeric sorbent (Strata X) was activated with 2 mL of MeOH, 1 mL of water and 1 mL of 50 mM phosphate buffer (pH 2). Samples were diluted to 1.5 mL with 50 mM phosphate buffer (pH 2) and then the samples were loaded without any delay. After pass-

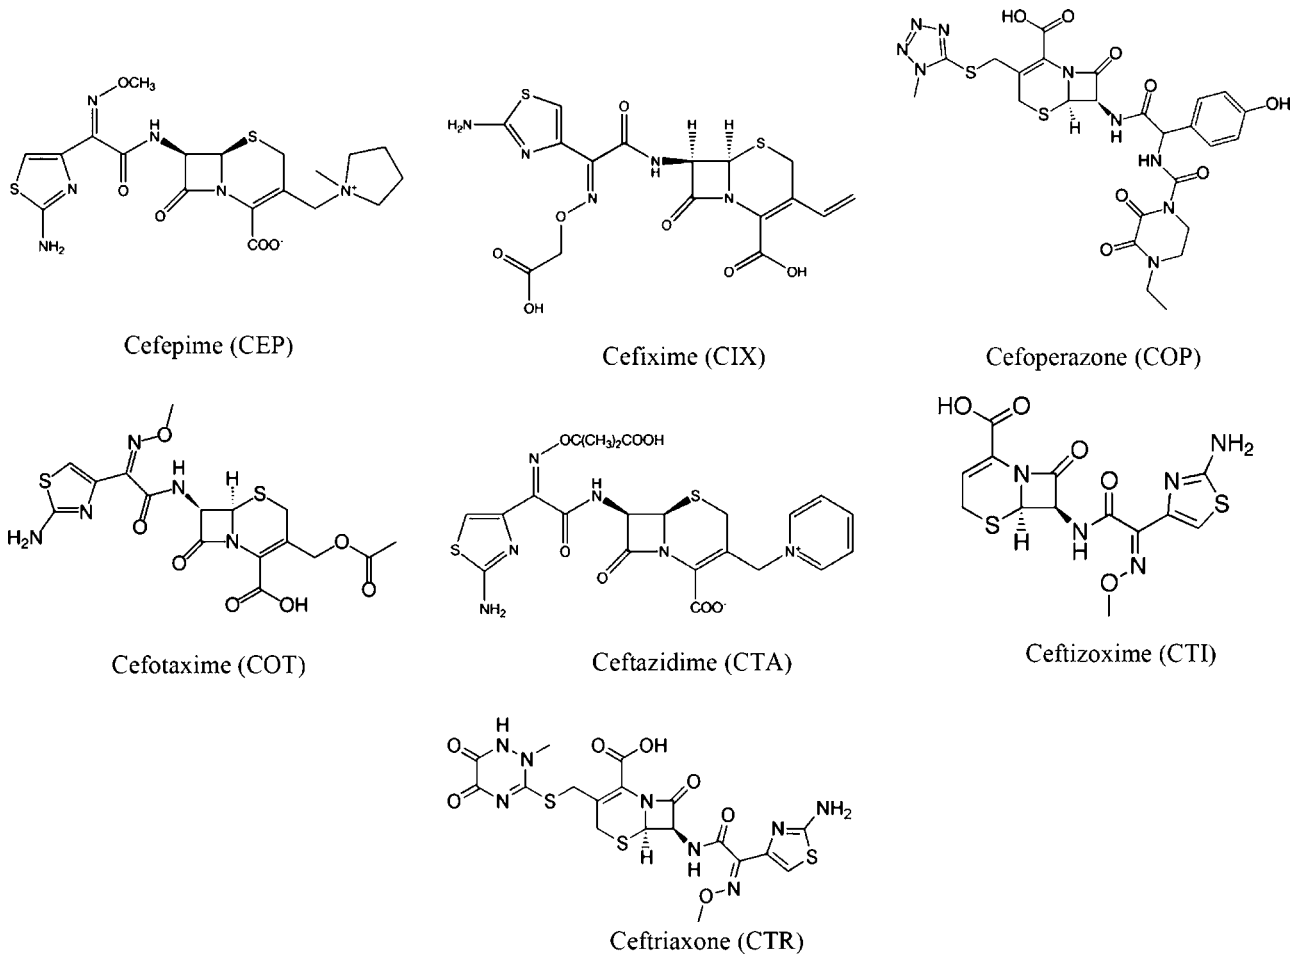

Fig. 1. Chemical structure of the cephalosporins.

ing all the sample through the cartridge, the cartridge was washed with 2 mL of 50 mM phosphate buffer (pH 2) and dried with passing air for two minutes. Elution was done with 2 mL of MeOH and the eluate was evaporated to the dryness at 45 °C under a stream of nitrogen. The residue was reconstituted with 200 μL of MeOH:water (20:80, v/v) mixture and then injected into the HPLC system.

2.8. Chromatographic conditions

The mobile phase was a mixture of 40 mM phosphate buffer (pH 3.2) and MeOH. The mixing of the mobile phase was done during the analysis with the help of a quaternary gradient pump. Gradient elution was applied with the mobile phase as follows: from 0 to 5 min the mobile phase contained 18% MeOH; from 5 to 15 min the percentage of MeOH linearly increased to 45%; from 15 to 16 min the MeOH percentage increased to 55% and maintained at this percentage until 21 min; finally the percentage of MeOH decreased to 18% from 21 to 22 min. The flow rate was 0.85 mL min^{-1}, the injection volume was 20 μL and the column temperature was 32 °C.

2.9. Validation

Validation parameters (system suitability, stability, linearity, sensitivity, accuracy, precision, selectivity, and robustness) of the proposed method were evaluated according to ICH guideline [26].

3. Results and discussion

3.1. Optimization of separation

Optimization of the chromatographic method was performed in three steps: a series of initial experiments followed by two sets of experiments based on different experimental designs. The experimental designs were carried out to obtain maximum resolution in short analysis time.

3.1.1. Initial experiments

The initial experiments were performed to decide the basic analytical requirements of the method, such as the type of column (C_{18} and C_8), buffer, pH range, organic modifier in the mobile phase, ion-pairing reagent, flow rate, and column temperature. A standard solution containing 10 μg mL^{-1} of each of cephalosporins was used during the initial experiments.

The performance of three analytical columns (Zorbax Eclipse XDB-C_8 150 mm × 4.6 mm, 5 μm i.d.; Zorbax Eclipse XDB-C_{18} 150 mm × 4.6 mm, 5 μm i.d. and XTerra C_{18} 250 mm × 4.6 mm, 5 μm i.d.) was checked by running different mobile phases. The better peak asymmetries and resolutions were obtained with XTerra C_{18}. Therefore this was selected as the analytical column.

Phosphate and citrate buffer were tested on the separation of cephalosporins. The better resolutions and peak shapes were obtained with phosphate buffer. Therefore the phosphate buffer was selected as the buffer in the mobile phase. To investigate

the effect of buffer concentration (ionic strength) within a range, 20–40 mM was selected.

The pH range of the buffer and the column temperature were determined according to column user's instruction in order to get long column life. According to the column user's instruction, the best column life was achieved with the operation at ≤40 °C and pH 2.5–6.0. Therefore these recommendations were accepted for the further optimization procedure of screening.

The effects of an organic modifier in the mobile phase were investigated by using different percentages of MeOH, acetonitrile or MeOH–acetonitrile mixture. Better resolutions and peak asymmetries were obtained with MeOH resulting in MeOH being selected as the organic modifier in the mobile phase.

The effects of different ion-pairing reagents (tetramethylammonium bromide, triethylamine and tetramethylammonium hydroxide) on separation were investigated. Contrary to expectations, it was noted that the peak shapes of cephalosporins were not effected significantly by the ion-pairing reagents. Moreover the baseline noise increased during the gradient elution done with MeOH. Therefore an ion-pairing reagent was not used.

Finally, 0.7–1.0 mL min^{-1} flow rate range was selected to investigate flow rate effects on the retention times and resolutions of cephalosporins.

3.1.2. Screening based on a fractional factorial design

If the number of variables is high, a complete response surface would be a complicated multidimensional structure requiring much more experimental research in order to be fully determined [20]. Thus a screening phase was applied to select significant parameters on separation.

A two level fractional factorial design consisting 11 experiments ($2^{5-2}+n$) (Table 1), was applied, where $n=3$ was the number of replicates of the central point in order to test the model linearity and to obtain an estimate of experimental variance. This fractional factorial design permitted evaluation of whether parameters have a significant influence on the selected response or not. The experiments were performed in a random order to prevent systemic errors. The parameters considered in the fractional factorial design were the MeOH percentage, the pH and concentration of the phosphate buffer, the temperature of the column, and the flow rate. The experimental ranges of the variables were selected on the basis of initial experiments (Table 2). The defined responses of the variables were the resolution between adjacent peaks and retention times.

Evaluation of the parameters was done according to their regression coefficient, but the evaluation of each parameters individually was very difficult because the number of responses (retention times and resolutions) was relatively high and they had two different scales. In order to overcome these difficulties, all of these results were evaluated at the same time with a total desirability function. This function was based on the transformation of the measured properties to a dimensionless desirability scale for each criterion, so that values of several properties, obtained from different scales of measurements, may be combined [21–23,27]. The scale of the desirability function ranges between $d=0$ for a completely undesired response to $d=1$ for a fully desired response, above which further improvements would have no importance. In the second step the overall quality D was calculated combining the desirability values obtained for the different criteria by means of the geometric mean:

$$D = (d_1^{w_1} \times d_2^{w_2} \ldots d_n^{w_n})^{1/(w_1+w_2 \ldots w_n)}$$

where d_i was the individual desirability function of each response obtained from the transformation of the individual response of each experiment, w_i was the weight of the response and n the number of responses.

The retention times and resolutions acquired from experiments were transformed to a desirability scale to get maximum resolution and minimum retention time (Table 1). The scale of the desirability function ranged between $d=0.1$ and 1 in this study. The total desirability function for many experiments was calculated as zero and this caused the occurrence of invalid models, when the range between $d=0$ and 1 was applied. Therefore the scale of the desirability function ranging between $d=0.1$ and 1 was used. The weight for retention times of cephalosporins was the same ($w=1$) while the weight for resolutions was different. The weight of the resolutions between some cephalosporins was given the value of 1 because the resolutions between them were bigger than 2 in all experimental conditions. For the others, the weight for resolution was two (Table 1). According to these values the desirability of retention times (D_{tr}), desirability of resolutions (D_{Rs}), and desirability of resolutions + retention times (D_{All}) were calculated (Table 1).

The regression coefficients calculated from the total desirability function is shown in Fig. 2. As can be seen in Fig. 2, phosphate buffer concentration for D_{Rs}, and pH, flow rate and temperature for D_{All} had a negative effect while the others had a positive effect on D_{tR}. Nevertheless pH, MeOH% and phosphate buffer concentration had significant effect on three total desirability functions, pH and MeOH% were selected for further optimization. Phosphate buffer concentration was not selected for examination because of its positive effect on three total desirability functions. It was, therefore, fixed to its maximum value (40 mM). The flow rate

Table 2
Selected variables and their levels in the fractional factorial design.

and temperature were fixed to their central levels, which were 0.85 mL min^{-1} and 32 °C, respectively, to minimize analysis time and maximize resolution.

3.1.3. Response surfacing based on 3^k full factorial design

Response surface mapping was an effective way to find the optimum condition. In this case, the 3^k full factorial design was employed to draw response surface graphs to determine the optimal conditions and to investigate parabolic interactions between parameters (pH and MeOH%). This design permitted the response surface to be modeled by fitting a second-order polynomial with the number of experiments equal to $3^k + n$, where k is the number of variables and n the number of center runs. In this study, $k = 2$ and n was set to 3, which composed a total of 12 experiments to be executed (Table 3). The design fitted with a full quadratic model is given below:

$$y = b_0 + b_1x_1 + b_2x_2 + b_{12}x_1x_2 + b_{11}x_1^2 + b_{22}x_2^2$$

where y represents the experimental response, x the independently evaluated factors (in coded variables), b_0 the intercept and b_n the parametric coefficients of the model obtained by multiple regression. Experiments were performed according to the design listed in Table 3 and responses measured are given in the same table.

The regression coefficients calculated from full factorial design are given in the equations below. For the models fitted, ANOVA tests were applied to calculate F-values, and significant probabilities of the models. The ANOVA tests showed that the models appeared to be adequate, with no significant lack of fit ($p < 0.05$), and with a satisfactory coefficient of correlation (r). Thus the models could be used to navigate the design space.

$$D_{Rs} = 0.474 + 0.245x_1 + 0.118x_2 - 0.003x_1x_2 + 0.049x_1^2 - 0.031x_2^2 \quad (r = 0.9791)$$

$$D_{tR} = 0.932 - 0.103x_1 - 0.262x_2 - 0.088x_1x_2 + 0.049x_1^2 - 0.296x_2^2 \quad (r = 0.9712)$$

$$D_{All} = 0.722 + 0.062x_1 - 0.100x_2 - 0.108x_1x_2 + 0.030x_1^2 - 0.205x_2^2 \quad (r = 0.9488)$$

The response surface graphs were drawn as a function of pH and MeOH (Fig. 3). These response surface graphs allowed the determination of an optimal zone, where a good-quality separation could be established.

Optimum conditions were chosen by total desirability as near as 1.00. The highest desirability (around 0.85) was achieved at pH 3.2 and 20% MeOH. However, at 20% MeOH there was an interference with CEP. Therefore, MeOH% was decreased to 18% to eliminate interference. The final optimum conditions for chromatographic separation were 40 mM phosphate buffer, pH 3.2, 18% MeOH, 0.85 mL min^{-1} flow rate and 32 °C column temperature. At these conditions, the seventh cephalosporin, COP, was not eluted in 50 min. Therefore, different gradient elutions were tried in order to obtain short analysis time. The short analysis time obtained with as explained in the section entitled chromatographic conditions. At these conditions, the separation of seven cephalosporins was completed within 25 min (Fig. 4).

Table 3
Experimental conditions according to the full factorial design and total desirability function calculated from the responses.

Exp. No.	Run Order	MeOH	pH	D_{tR}	D_{Rs}	D_{All}
1	2	−1	−1	0.17	1.00	0.53
2	4	0	−1	0.26	0.82	0.54

D_{Rs}: Desirability of resolutions, D_{tR}: Desirability of retention times, and D_{All}: Desirability of resolutions and retention times.

3.2. Optimization of SPE

Sample preparation from plasma and amniotic fluid was performed with SPE method to utilize the benefits mentioned earlier.

In the previously published literature, a lot of sorbents and different conditions, washing and elution steps in SPE were used to gain high recovery from food, biological tissues and waters [8,10,24,25,28]. In this study, the optimization of SPE was performed in three steps. The experiments in the first step, endeavored to discover the most suitable sorbent(s). For this purpose, six different commercial SPE cartridges (M&N, Strata X, ENV+, Oasis HLB, Oasis MAX, Chromabond C_{18} and Chromabond C_8) were tried in order to get high recovery without interference. In the initial experiments, the sorbents were conditioned with 2 mL of MeOH and 2 mL of water, respectively. Then the 0.5 mL sample was diluted with 1 mL water and loaded to sorbents. Washing of the sorbents was carried out with 2 mL of water and then eluted with 2 mL of MeOH. The eluate was evaporated to the dryness at 45 °C under a stream of nitrogen. The residue was reconstituted with 200 μL of MeOH:water (20:80, v/v) mixture and then injected into the HPLC system. To decide which sorbent was useful for sample preparation, the endogen peak numbers which may cause interference and absolute recovery were evaluated. Although the least endogen peaks were obtained with ENV+, the other sorbents were also evaluated for absolute recovery (Table 4). The highest recovery was obtained with Oasis HLB (62%). However, it was not high enough. Therefore Oasis HLB and Strata X, which have higher recovery than others, were selected to improve recoveries of cephalosporins. Secondly the effect of buffer solution on the recoveries was investigated. During the optimization of chromatographic conditions, it was realized that at low pH, the retention times of cephalosporins on the C_{18} column increased. Therefore, pH 3 phosphate buffer was tried in order to increase recoveries. When the conditioning and washing steps of the sorbents and dilution of the samples were completed with the phosphate buffer, the mean recovery of the cephalosporins was increased. The highest mean recovery

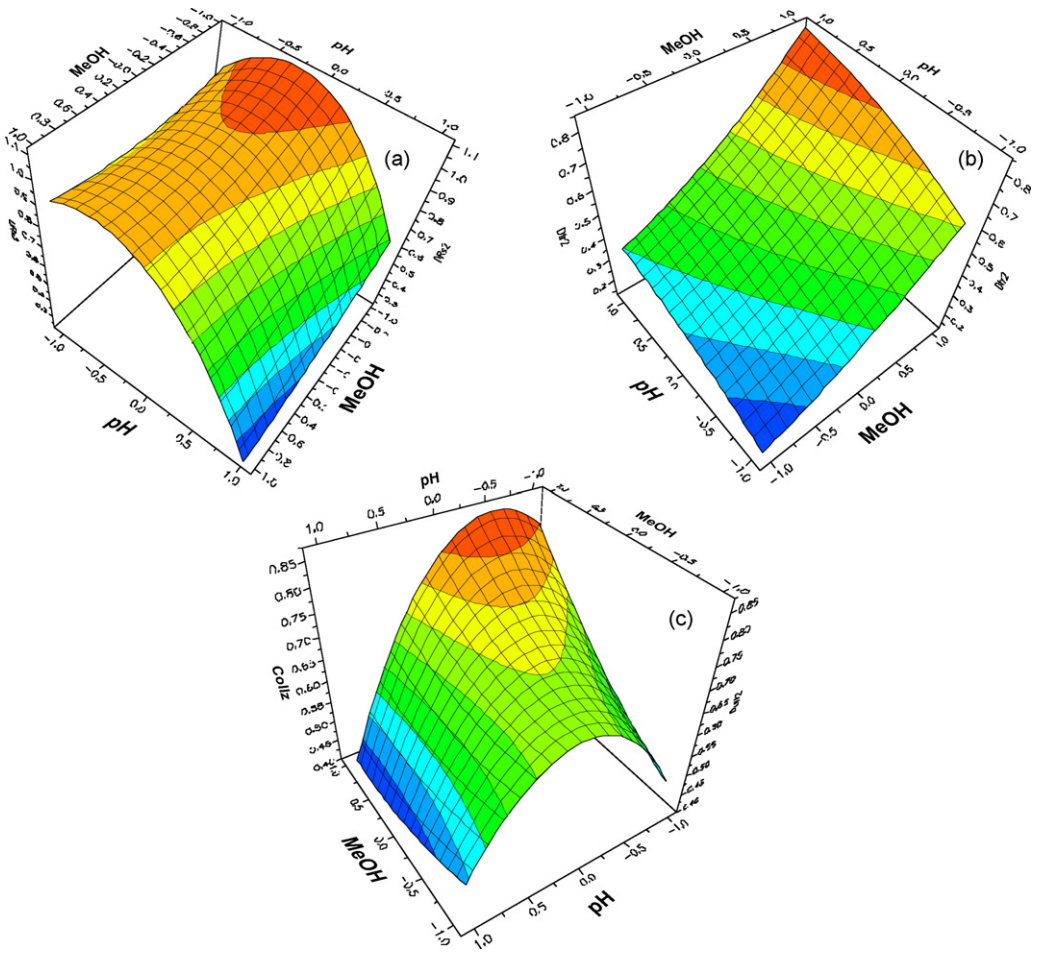

Fig. 3. Response surface graph functions of MeOH% and pH, a) D_{Rs}, b) D_{tR} and c) D_{All}.

was obtained with Strata X but the recovery was still not high enough for CIX and CTR. In the last step the effect of pH was investigated, Strata X was selected to improve recovery of CIX and CTR by changing pH of the buffer (pH 2 and 3). High mean recovery was obtained with 50 mM phosphate buffer solution at pH 2. Thus this buffer was selected for sample preparation in SPE.

Cephalosporins were less stable in solutions, in comparison to other drugs. The stability of the cephalosporins in solutions depends on temperature, pH, etc. [8,10,28]. Therefore samples were diluted with phosphate buffer just before sample loading to prevent degradation.

3.3. Validation

The validation studies were applied for CIX, COP and CEP, for which placental passage rates were unknown. CTI was selected as an IS in order to compensate for errors from extraction process. CIX and CTI were monitored at 285 nm while COP and CEP at 260 nm. The assay was validated with respect to system suitability, stability, LOD, LOQ, linearity, precision, accuracy, selectivity and robustness.

3.3.1. System suitability

The system suitability was assessed by ten replicate analyses of the CEP, CIX, COP and IS at a concentration of 10.0 μg mL^{-1}.

Table 4
The absolute recoveries of cephalosporins obtained from different sorbents and conditions.

Cephalosporins	Steps									
	First						Second		Third

Theoretical plate numbers	8304	10488	10630	40903
Peak asymmetry (%10)	1.1	1.0	1.1	1.2

[a] The values given in blankets were RSD % of retention times ($n = 10$).
[b] Dead retention time was found with the injection of urasil at the same conditions: $t_0 = 1.5$ min.
[c] Values are resolution between adjacent peaks.

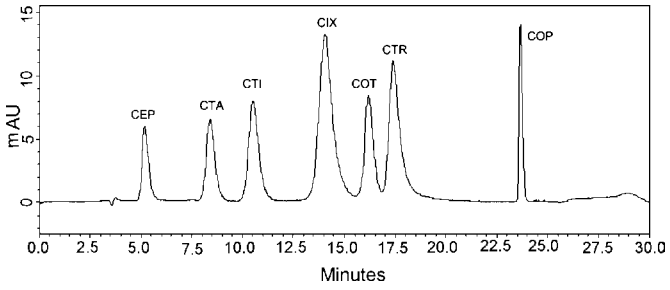

Fig. 4. Chromatogram of cephalosporins (gradient elution with MeOH) (40 mM phosphate buffer, pH 3.2, 18% MeOH, 0.85 mL min^{-1} flow rate and 32 °C column temperature).

Their retention times, capacity factors, resolutions, theoretical plate numbers and peak asymmetries were within acceptable criterion (Table 5).

3.3.2. Stability

The stabilities of CEP, CIX and COP (at 10.00 μg mL^{-1}) were evaluated according to a freeze–thaw cycle, short term (+4 °C in refrigerator), long term (−20 °C in deepfreeze) and autosampler stability.

A sample spiked and a freshly prepared one were compared to determine whether the analyte concentration had changed by more than 10% [29].

In the freeze–thaw cycle test, plasma and amniotic fluid samples spiked with CEP, CIX and COP were stored at −20 °C. Samples were taken out of the deepfreeze and equilibrated to room temperature and analyzed in duplicate. This process was repeated three times and results were compared with the control sample which was freshly prepared (without freezing). According to results the changing of the analyte concentration (from 90.6 to 100.3%) was within the limits. Therefore they were stable at least three freeze–thaw cycles in plasma and amniotic fluid.

The short term (+4 °C in refrigerator) stabilities of CEP, CIX and COP were evaluated in plasma and amniotic fluid. Plasma and amniotic fluid samples spiked with CEP, CIX and COP were refrigerated. The samples were periodically taken out of the refrigerator (2, 6, 12, and 24 h) and equilibrated to room temperature and analyzed in duplicate. The results were compared with a freshly prepared one to determine refrigerator stability. The analyte concentration of CEP in plasma and amniotic fluid decreased 25% at the end of 24 h, while CIX and COP was decreased in the range of 14–18%. This results showed the necessity to perform the analysis of CEP from plasma within 2 h and from amniotic fluid within 6 h, CIX from plasma within 12 h and from amniotic fluid within 6 h and COP from plasma and amniotic fluid within 12 h.

Long-term (−20 °C in deep freeze) stability studies of the CEP, CIX and COP were assessed after storage of spiked plasma and amniotic fluid samples in the deepfreeze at −20 °C for 2 months. CEP, CIX and COP were found stable at least 2 months in both biological materials.

Autosampler stabilities of CEP, CIX and COP in the reconstituted plasma and amniotic fluid extracts were evaluated for 24 h. Eluates were analyzed at 0, 6, 12, and 24 h and CEP, CIX and COP were found stable at least 24 h in autosampler.

3.3.3. The limit of detection (LOD) and quantitation (LOQ)

The LOD and LOQ of CEP, CIX and COP were estimated on the basis of the results for three replicates of plasma and amniotic fluid spiked at different levels, considering a signal-to-noise ratio of 3 and 10, respectively. The LOD values of CEP, CIX and COP were found to be 25, 10 and 15 ng mL^{-1}, respectively. Those for LOQ were 80, 35 and 50 ng mL^{-1}, respectively.

3.3.4. Linearity

The calibration curve consisted of eight concentration levels of spiked standards samples (LOQ, 0.5, 1, 5, 10, 20, 30, and 50 μg mL^{-1}) to distilled water, plasma and amniotic fluid. Each level was pre-

Table 6
Data for the calibration graph of CEP, CIX and COP spiked in water, plasma and amniotic fluid.

	Slope	Intercept	r	p[a]
Water				
CEP	2.8582 (2.6481–3.0676)	0.2464 (−0.2413–0.7341)	0.9986	0.2334

Relative	98.8 ± 1.3 (3.6%)	98.1 ± 1.5 (4.0%)	99.1 ± 2.3 (5.8%)
Amniotic fluid			
Absolute	96.4 ± 0.9 (2.2%)	98.3 ± 1.4 (3.5%)	95.5 ± 1.3 (3.6%)
Relative	98.5 ± 0.9 (2.4%)	99.2 ± 1.0 (2.9%)	99.8 ± 2.1 (5.8%)

[a] and [b] The intra- and inter-day data showed are the minimum and maximum RSD % and Bias % values, respectively. The corresponding samples were prepared at 0.50, 5.00 and 30.00 μg mL^{-1}.
[c] Numbers in brackets were RSD.

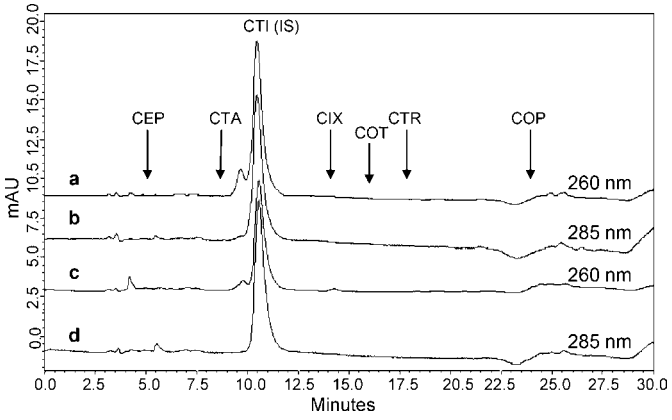

Fig. 5. Chromatogram of blank plasma (a and b), and blank amniotic fluid (c and d) spiked with 10.00 μg mL^{-1} IS (CTI) (40 mM phosphate buffer, pH 3.2, 18% MeOH, 0.85 mL min^{-1} flow rate and 32 °C column temperature, gradient elution with MeOH).

pared in duplicate. The results were calculated as a ratio of the peak area of the respective cephalosporin and the IS vs. cephalosporin/IS concentration ratio. The linear calibration curve between the ratio of the peak area and the concentration of the target cephalosporin was established by linear regression. The calibration curves for all compounds present determination coefficients were higher than 0.992, as can be seen in Table 6.

3.3.5. Precision

The assay was investigated with respect to injection repeatability and intermediate precision. The injection repeatability of the system was evaluated by ten consecutive injections. The RSD values of retention times were <1% (Table 5). This result indicates that the system had a good injection repeatability.

To assess intra-day precision, six spiked samples at three concentration levels (0.50, 5.00 and 30.00 μg mL^{-1}) were prepared and analyzed twice. For inter-day precision, three different daily renewals of the intra-day precision were carried out. The RSD values of intra- and inter-day studies varied from 0.8 to 9.80% showed that the intermediate precision of the method was satisfactory (Table 7).

3.3.6. Accuracy

The accuracy of a method is expressed as the closeness of agreement between the found value and reference value. It is determined by calculating the percentage relative error between the measured mean concentrations and added concentrations (Bias %). Intra-day and inter-day accuracies (Bias %) were <6.0 which shows good accuracy (Table 7).

The accuracy of the proposed method was also tested by recovery experiments. Recovery experiments were performed at six concentrations (0.5, 1, 5, 10, 20, and 50 μg mL^{-1}) by duplicate analysis. Spiked plasma, amniotic fluid and water samples were treated as described in the procedure for sample preparation. The recovery of CEP, CIX and COP were evaluated as relative and absolute recovery. The relative recoveries of the analytes were measured by comparison of the peak area ratios obtained from extraction of spiked plasma and amniotic fluid samples with those obtained from extraction of equivalent amounts of analyte in spiked water. Absolute recoveries were determined by comparison of the peak area ratios of analytes obtained from spiked plasma and amniotic fluids samples with those obtained from equivalent standard solutions spiked after the extraction procedure that were considered to be showing 100% recovery. High relative and absolute recovery for CEP, CIX and COP were obtained from both matrices (Table 7).

The recovery values were higher than 94% and in all cases comparable results were obtained among absolute and relative recovery (Table 7). The slopes of the calibration curves obtained from different spiked samples were close (Table 6). All of these results indicate that water spiked standards can be used as the calibration curve.

3.3.7. Selectivity

The selectivity of an analytical method allows to quantification of the cephalosporins in the presence of components that may be expected to be present as impurities, degradedness or matrix components. The selectivity of the method was evaluated by analyzing blank amniotic fluid and plasma obtained from different pregnant women. In the evaluation of the selectivity, cephalosporins were

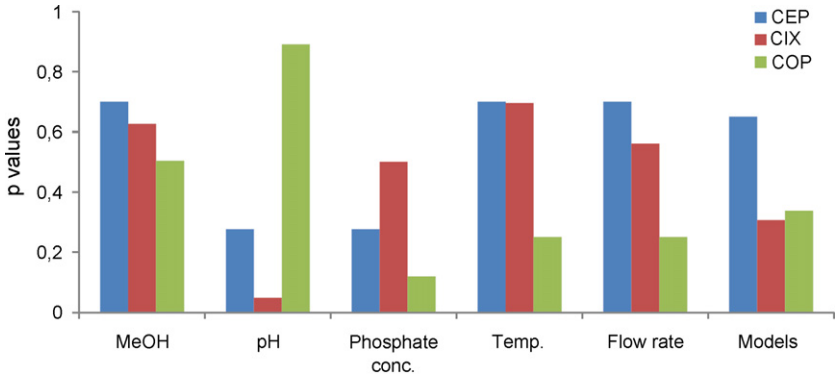

Fig. 6. *p* values calculated from robustness studies of CEP, CIX and COP.

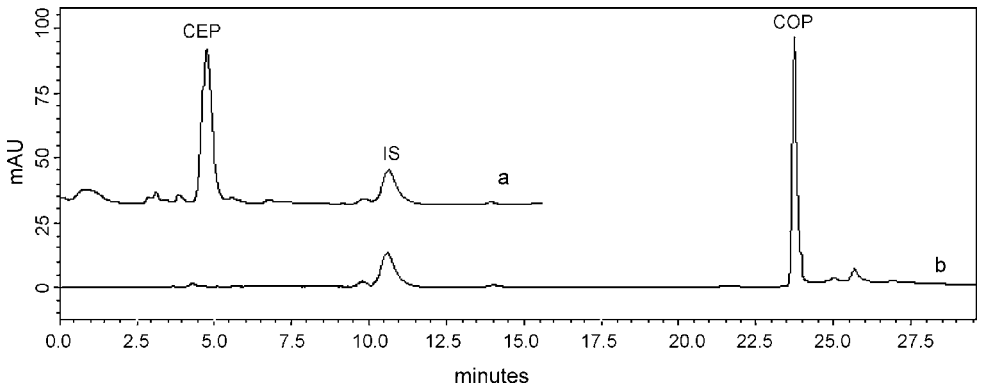

Fig. 7. Chromatogram of a) plasma obtained from pregnant woman administrated CEP and b) plasma obtained from pregnant woman administrated COP (40 mM phosphate buffer, pH 3.2, 18% MeOH, 0.85 mL min^{-1} flow rate and 32 °C column temperature, gradient elution with MeOH) (IS: 10 μg mL^{-1}).

well resolved from baseline and separated from each other and there was no matrix effect from plasma or amniotic fluid (Fig. 5) at the same time of cephalosporins. The peak purity index of CEP, CIX and COP belonging to their analysis in plasma, amniotic fluid and water were found to be higher than 0.9951. In addition, the slopes of the CEP, CIX and COP obtained from different matrix were not different from each other and confidence intervals were overlapping. All of these results showed that the method presented in this study was specific.

3.3.8. Robustness

In robustness testing of an analytical method, the aim is to explore how sensitive the responses are to small changes in the factor settings. The robustness of the method was tested using experimental design in order to study the simultaneous variation of the factors. An eleven-run fractional factorial design, three experiments within the optimized conditions, were chosen to evaluate whether a change in factor value produced a statistically significant variation in the observed responses. In the study the ranges examined were small deviations from the method settings with regard to MeOH % (16–20), buffer pH (3.0–3.4), phosphate buffer concentration (38–42 mM), column temperature (30–34 °C) and flow rate (0.8–0.9 mL min^{-1}). To evaluate the robustness of the method, ANOVA test was applied and p values of regression coefficient and regression equation were calculated. The p values were ≥0.05 which indicates that small changes didn't significantly effects on the peak area ratio (Fig. 6). Thus, the method could be considered robust.

3.3.9. Analysis of COP, CEP and CIX

The method was applied to the analysis of plasma and amniotic fluid samples obtained from pregnant women. CEP (n = 6) or COP (n = 6) was administered intravenously during delivery (Fig. 7) while CIX (n = 6) were administrated orally before amniocenteses (Fig. 8) to prevent any infection. The results of the analysis are given in Tables 8 and 9. All concentrations were higher than the lower determination and quantitation levels of the CEP, CIX and COP.

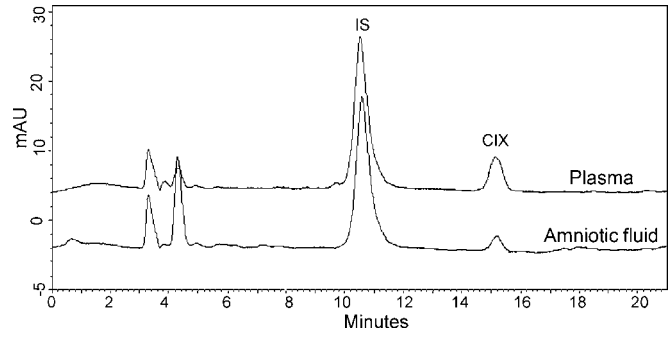

Fig. 8. Chromatogram of plasma and amniotic fluid obtained from pregnant woman administrated CIX (40 mM phosphate buffer, pH 3.2, 18% MeOH, 0.85 mL min^{-1} flow rate and 32 °C column temperature, gradient elution with MeOH) (IS: 10 μg mL^{-1}).

5	1.3	0.8
6	3.7	0.5

4. Conclusion

An HPLC method was developed to separate seven cephalosporins in human plasma and amniotic fluid and applied to quantify CEP and COP in plasma and CIX in plasma and amniotic fluid. Experimental designs have been utilized during the development of the method to minimize retention times and maximize resolutions. A total desirability function has been used to evaluate more than one response at a time (retention times and resolutions) and the optimum conditions were found by plotting response surface graphs. An efficient SPE method was developed for extraction and the clean-up process. Detailed validation studies were performed to evaluate the validity of the methods according to ICH guideline and the method was found to be sensitive, linear,

accurate, precise, specific and robust. Finally, the method was applied to the analysis of CEP and COP in maternal and fetal plasma and CIX in maternal plasma and amniotic fluid obtained from pregnant women.

Tungsten trap
Hydride generation atomic absorption spectrometry (HGAAS)

ABSTRACT

The determination of bismuth requires sufficiently sensitive procedures for detection at the $\mu g\,L^{-1}$ level or lower. W-coil was used for on-line trapping of volatile bismuth species using HGAAS (hydride generation atomic absorption spectrometry); atom trapping using a W-coil consists of three steps. Initially BiH_3 gas is formed by hydride generation procedure. The analyte species in vapor form are transported through the W-coil trap held at 289 °C where trapping takes place. Following the preconcentration step, the W-coil is heated to 1348 °C; analyte species are released and transported to flame-heated quartz atom cell where the atomic signal is formed. In our study, interferences have been investigated in detail during Bi determination by hydride generation, both with and without trap in the same HGAAS system. Interferent/analyte (mass/mass) ratio was kept at 1, 10 and 100. Experiments were designed for carrier solutions having 1.0 M HNO_3. Interferents such as Fe, Mn, Zn, Ni, Cu, As, Se, Cd, Pb, Au, Na, Mg, Ca, chloride, sulfate and phosphate were examined. The calibration plot for an 8.0 mL sampling volume was linear between 0.10 $\mu g\,L^{-1}$ and 10.0 $\mu g\,L^{-1}$ of Bi. The detection limit (3 s/m) was 25 $ng\,L^{-1}$. The enhancement factor for the characteristic concentration (C_o) was found to be 21 when compared with the regular system without trap, by using peak height values. The validation of the procedure was performed by the analysis of the certified water reference material and the result was found to be in good agreement with the certified values at the 95% confidence level.

1. Introduction

It is known that bismuth (Bi) has been used for different medical purposes. For instance, some of its compounds have been added to pharmaceutical samples for the treatment of gastritis and peptic ulcer [1]. It was also reported that though Bi is not essential element for human being, nearly 5–20 μg of this element is taken with food in general population [2]. Indeed, due to its potential for inducing metallothionein expression, this element has some effect on reducing tissue toxicity after cisplatin cancer therapy [3].

For the determination of Bi in different matrices, many analytical techniques have been applied. For example, atomic absorption spectrometry (AAS), electro thermal atomic absorption spectrometry (ETAAS), inductively coupled plasma optical emission spectrometry (ICP-OES) and inductively coupled plasma mass spectrometry (ICP-MS) in different matrices [4–6]. Even though AAS has been presented in many analytical laboratories, sensitivity of this technique is not enough for the trace level. Thus, ETAAS has been largely used for trace levels. However, elimination of matrix causing interferences to improve the lifetime of graphite tubes is the requirement [4]. Although ICP-MS has very low detection limits, this instrument is not commonly used for Bi determination due to its high cost. Hydride generation atomic absorption spectrometry (HGAAS) is undoubtedly one of the most sensitive and convenient analytical techniques for the determination of bismuth because of its appropriate sensitivity. Therefore, this technique is ideally suited for the trace and ultratrace analysis of Bi. In addition, in the literature, the detection limits for Bi have varied from one technique to other. For instance, the detection limit was found as 0.02 $ng\,mL^{-1}$ determination of Bi in tap water and biological samples such as urine and hair by ETAAS after preconcentration by the

doi:10.1016/j.talanta.2009.06.084

cloud point extraction technique [7]. By using ICPOES system with a continuous-flow hydride generation technique (HG-ICP) detection limit was found to be 0.7 ng mL^{-1} [8]. Although it is expected that ICP-MS has very low detection limit, this value was found to be 9.7 ng mL^{-1} for Bi in serum and urine by direct injection nebulization inductively coupled plasma mass spectrometry [9].

In order to improve sensitivity in Bi determination, different sorts of traps have been applied. W-coil was used for on-line trapping of volatile bismuth species using HGAAS; a limit of detection of 2.7 ng L^{-1} was obtained [10]. Quartz was also used as an atom trap with a detection limit of 3.9 ng L^{-1} [11].

In the analytical chemistry, elimination of any possible interferences during measurement step is very crucial in order to obtain accurate results. Although Dedina and Tsalev have explained the basic mechanism of interferences, number of studies in this field is not high [12]. Recently, interference effects of some elements were studied for hydride generation system [13,14]. According to Dedina and Tsalev, interferences can be categorized not only as spectral and non-spectral interferences but also as liquid phase and gas phase interferences occurring during either in transportation or in the atomizer. It is expected that most of the liquid phase interferences can be eliminated using W-coil trap HGAAS system due to elimination of these type interferences prior to atom cell. In the literature, there have been so many studies related with the effects of different kinds of interferences on Bi determination using hydride generation technique.

The objective of the present study was not only to find and develop a sensitive method but also decide whether the tungsten trap has any advantages for the elimination of different interferences on Bi signal or not. Interferences have been investigated in detail during Bi determination by hydride generation in both with and without W-coil trap in the same HGAAS system.

2. Experimental

2.1. Instrumentation

An ATI Unicam 929 atomic absorption spectrometer equipped with a deuterium background correction system was used. A Philips data coded hollow cathode lamp was operated at 12.0 mA; the analytical line at 223.1 nm was used in the measurements with 0.5 nm as the spectral bandwidth. Quartz T-tube atomizer (QTA) heated by a stoichiometric air/acetylene flame was used as atomizer. QTA consisted of a horizontal arm with dimensions of 140 mm in length, 15 mm in od and 12.8 mm in id; inlet arm was 90 mm in length, 7 mm in od and 4.5 mm in id. Another smaller quartz tube was inserted and fixed in the inlet arm with dimensions of 4.0 mm in od and 2.0 mm in id; it extended between the open end of the inlet arm and a point that was 5.0 mm away from the W-coil; analyte vapor was transported through this inner tube. Hydride generation for both conventional and trap systems was carried out in continuous-flow (CF) mode using a Gilson Minipuls 3 (Villers le Bell, France) 4-channel peristaltic pump. Tygon peristaltic pump tubing of 0.8 mm id (Ismatec, Germany) was used for pumping the analyte and reductant solutions that are mixed in a 3-way PTFE connector (Cole Parmer Instrument Co., USA). For the separation of Bi hydride from the liquid phase, a laboratory-made cylindrical gas–liquid separator (GLS) was employed. Tygon tubing of length of 4.0 cm and 6.0 mm id (Masterflex, Cole Parmer Instrument Co.) was used between the GLS and the inlet arm of the silica T-tube atomizer. The composition of the gas mixture was the same for both conventional HGAAS and collection stage on W-coil trap. A mixture of H_2 and Ar was used in both conventional HGAAS and W-coil trap studies. The flow rates of these gases were measured by two separate flow meters (Cole Parmer Instrument Co., USA). The W-coil used for trapping was obtained from a 15 V, 150 W projector bulb (Halogen Photo optic Lamp Xenophot, Osram, Germany) and placed in the inlet arm of a silica T-tube, 5.0 cm away from the connection point to the horizontal arm. The experimental set-up for hydride generation and trap was reported previously [15] except for the fact that the way W-coil was inserted into the inlet arm. In this study, a laboratory-made quartz female joint was attached to the inlet arm. The W-coil with its socket base was fixed inside the male portion of the glass joint; in order to assure immobilization of the set-up, ordinary silicone type glue was used. This configuration allows a very rapid and convenient change of W-coil trap when needed. The W-coil was positioned so that its longer axis was perpendicular to the gas flow that is reaching to it through the smaller quartz tube in the inlet arm. The coil temperature was manually controlled by a variable potential power supply (Variac) and a 750 W transformer connected to mains electricity (220 V ac) through a power switch. The input voltage of the variable potential power supply was 220 V. The temperature measurements were carried out with a Ni–Cr thermocouple.

2.2. Reagents

All reagents used throughout the study were at least analytical reagent grade. The standard solutions of Bi were prepared by making necessary dilutions from 1000 mg L^{-1} Bi (Aldrich) of stock standard solution. In order to obtain the optimum acidification of reagents, appropriate amount of analytical grade 65% (w/w) HNO_3 (Merck) was used. Reductant solutions were prepared daily from the powder sodium tetrahydroborate (III) (Merck, min. Purity 98%). For the stabilization of the $NaBH_4$ solution, NaOH (Carlo Erba, Milano, Italy) was used. Dilutions were made using 18 MΩ cm deionised water obtained from a Milli-Q water purification system (Millipore, Bedford, MA, USA).

2.3. Procedure

The experiments were carried out in continuous-flow (CF) mode in both the conventional HGAAS and the W-coil trap-HGAAS studies. The HNO_3 and $NaBH_4$ concentrations were optimized in conventional HGAAS studies by using a 20.0 ng mL^{-1} of Bi solution containing 1.0 mol L^{-1} HNO_3. Blank was 1.0 mol L^{-1} HNO_3 solution. The reductant and analyte solutions were pumped at the flow rates of 8.0 mL min^{-1} which were optimised by both reductant and analyte solutions. The optimizations were made in several cycles until the results obtained did not differ from the last optimized value. During any optimization as the value of the parameter in question was varied, all the other parameters were in their optimized values. The generated Bi hydride was separated from the liquid phase by the GLS and was transferred to QTA through a Tygon tubing using a carrier gas mixture composed of H_2 and Ar at flow rates of 37.5 mL min^{-1} and 75 mL min^{-1}, respectively.

In trap experiments, initially the carrier gas mixture was sent through the system. Then, the trap was brought to its optimum collection temperature and the pumps were activated to start the flow of carrier and reductant solutions. The transferred bismuth hydride was trapped on the W-coil atom trap placed in the inlet arm of quartz T-tube explained in Section 2.1. At the end of the collection period, the power to heat the trap was discontinued and the pumps were deactivated. Under optimum gas flow, the trap temperature was brought to the optimum value for revolatilization and the residence time of the 0.1 ng L^{-1} for Bi on the light path is very short and transient signal is obtained in less than 1.0 s shown in Fig. 1.

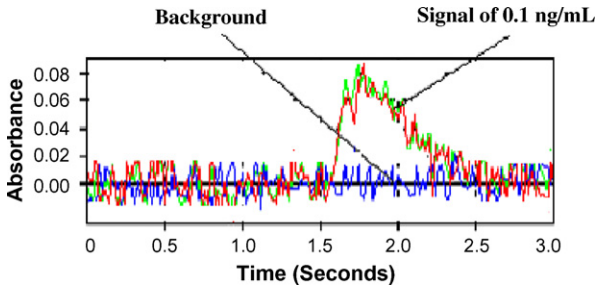

Fig. 1. The analytical signal obtained by the W-trap HGAAS method for 0.1 ng mL^{-1} Bi.

3. Results

3.1. W-coil system

For the Bi determination, resistively heated W-coil was used as a trap medium in this study. Each coil can be used for at least 100 firings under optimum parameters. H_2 flow in the system directly affects the firing amount. If W-coil trap is not changed, sensitivity of system is around 25% decreased because of oxidation of W-coil. If the flow rate of the H_2 is lower than 37.5 mL min^{-1} in collection and revolatilization step, the lifetime of W-coil becomes shorter. The presence of H_2 gas is necessary for both affecting a more efficient revolatilization and protecting the W-coil against oxidation. The coil should be heated as fast as possible at the revolatilization stage to obtain relatively sharp signals. For this purpose, a power switch was connected in front of the variable potential power supply and then the switch was turned on to assure the highest heating rate. Although the chemical nature of the revolatilized analyte species is not known, heating of quartz T-tube atomizer was necessary.

3.2. Optimization of system

The optimization of the experimental parameters was carried out using both CF-HGAAS and W-coil trap HGAAS. In the optimization studies, one parameter was varied while the others were kept constant. Optimization cycles were repeated until stable and repeatable signal was obtained. Optimizations of reaction and stripping coil lengths, concentrations of carrier and reductant solutions were common in both CF-HGAAS and W-coil trap HGAAS systems. The optimum HNO_3 and $NaBH_4$ concentrations were determined in no-trap studies in CF mode by using 20.0 ng mL^{-1} Bi as a standard solution.

3.2.1. Optimization of lengths of reaction and stripping coils

Reaction coil consists of the tubing between the merging point of sample and reductant solutions and the point where Ar and H_2 are introduced as the purge gases; as the continuation of the flow system, stripping coil is the tubing between the Ar/H_2 introduction point and the GLS. In the optimization study, length of reaction coil was varied between 5 cm and 30 cm while length of stripping coil was changed between 2 cm and 30 cm. The optimum lengths for reaction coil and stripping coils were found to be 10 cm and 4 cm, respectively. The analyte signal decreased with the values both lower and higher than the optimum values.

3.2.2. Optimization of concentration of reductant solution

For the production of Bi hydride species, $NaBH_4$ was used as a reductant solution. The effect of $NaBH_4$ concentration on BiH_3 production was investigated by using continuous flow. In order to find the optimum $NaBH_4$ concentration in the reductant solution, concentration was varied between 0.1% and 1.2% (w/v); 0.5% (w/v) $NaBH_4$ was found as the optimum reductant solution using the changes in the peak height of the analytical signal with respect to reductant concentration for no-trap studies. In this optimization, it was observed that the signal increased up to a concentration of 0.5% (w/v) and decreased for higher values. The decrease can be explained by the dilution effect, since more H_2 was generated at higher concentrations of reductant.

In addition, NaOH was used for the stabilization of $NaBH_4$. Concentration of NaOH was varied between 0.1% and 0.5% (w/v). Concentration of NaOH was optimized in no-trap studies and then checked also in W-trap HGAAS system. It was found that concentration of NaOH has a significant effect on the analytical signal of bismuth. The highest signal for bismuth was obtained using the reductant solution containing 0.2% (w/v) of NaOH while the other parameters were kept at their optimum found values.

3.2.3. Optimization of concentration of carrier solution

In this study, HNO_3 was used as carrier solution. In order to find the optimum HNO_3 concentration, HNO_3 concentration in the analyte solution was varied between 0.5 mol L^{-1} and 3.0 mol L^{-1}. The optimum value for HNO_3 was found as 1.0 mol L^{-1}, somewhat in the middle of the plateau. Higher and lower values resulted in a gradual decrease in the peak height of the analytical signal. When the concentration of HNO_3 in either solution exceeds 1.0 mol L^{-1}, decreases in signals were investigated. The effect of sample acidity was also checked in W-coil trap HGAAS system and found to be as same as in no-trap system.

3.2.4. Optimization of flow rates and composition of gases in the collection and revolatilization stages

In the hydride generation system, different carrier gases introduced before the stripping coil are used to separate the volatile species from the liquid phase and furthermore transport these species from GLS to externally heated quartz T-tube atomizer. In this study, a mixture of Ar and H_2 was applied not only in the collection but also in the revolatilization steps. In general, the flow rate of H_2 was kept constant at an optimized value where the oxidation of the W-coil trap was minimized or eliminated. Here, H_2 was used not only to prevent oxidation of the W-coil by creating a reducing environment around the W-coil but also to improve the revolatilization efficiency of Bi species from the W-coil trap. If flow rate of H_2 higher than optimized value, excess H_2 causes temparature decrease around the coil that affects sensitivity.

In the optimum collection and revolatilization steps, Ar flow rates were determined in CF mode in both without and with trap studies. Ar and H_2 flow rate were kept constant at 75 mL min^{-1} and 37.5 mL min^{-1} for both steps; and found that lower H_2 flow rates caused oxidation of the W-coil, which resulted in relatively higher background absorption.

The flow rate of Ar was varied between 50 mL min^{-1} and 400 mL min^{-1} during the optimization. The optimum value was found to be 75 mL min^{-1}; signal decreased for lower and higher values. Also the flow rate of H_2 was varied between 10 mL min^{-1} and 150 mL min^{-1} during the optimization. The optimum value was found to be 37.5 mL min^{-1}; signal decreased for lower and higher values.

3.2.5. Optimization of flow rates of carrier and reductant solution

The efficiency of the production of Bi hydride species is directly related with the flow rates of carrier and reductant solutions. In this study, the flow rate of HNO_3 that was used as the carrier solution was varied between 1.0 mL min^{-1} and 10.0 mL min^{-1} and the optimum value was found to be 8.0 mL min^{-1}. The signal increased as the flow rate was increased until the value of 8.0 mL min^{-1} is reached and stayed constant afterwards. The flow rate of $NaBH_4$ solution was varied between 1.0 mL min^{-1} and 10.0 mL min^{-1}; the optimum result was found as 8.0 mL min^{-1}. For the higher and

lower flow rates of $NaBH_4$, the peak height of Bi signal sharply decreased.

Optimization of concentrations and flow rates for HNO_3 and reductant solutions were carried out by keeping all parameters constant while only the test parameter was varied.

In this study, also the suction rate of the waste rate optimization was carried. The suction rate of the waste affected the Bi signal. If the suction rate of the waste was increased, Bi signal was decreased. In this study, suction rate of the waste was selected as 6 mL min^{-1}. As an example, if suction rate of the waste is selected 15 mL min^{-1} instead of 6 mL min^{-1}, signal intensity is decreased around 28%. Therefore, the waste rate must be minumum. If the suction rate is very low, waste could have gone to the atomizer. To the best of our knowledge, waste rate optimization is the first study in the literature.

3.2.6. Optimization of collection and revolatilization trap temperatures

In order to obtain a high trapping efficiency, W-coil atom trap temperature should be carefully optimized. In this study, collection trap temperature was varied from 100 °C to 540 °C. The trapping efficiency of W-coil increases sharply as the temperature increases up to approximately 289 °C. Increasing the trapping temperature resulted in a decrease in the analytical signal due to the partial release of the trapped Bi species and lowered trapping efficiency. Hence, 289 °C was found as the optimum trap temperature for efficient preconcentration of Bi species on W-coil trap. Revolatilization trap temperature was varied from 750 °C to 1500 °C while the collection temperature was kept constant at its optimized value. The optimum temperature for revolatilization was 1348 °C at which the highest signal was obtained. There is no need for waiting to cool the W-coil atom trap after revolatilization step or heat for the activation of W-coil before each collection cycle because the trap cools down very rapidly in only few seconds due to the continued gas flow. In order to protect the W-coil trap, hydrogen flow should be on throughout the experiment.

3.3. Analytical figures of merit

3.3.1. Calibration plots and linearity

Calibration plots with and without using W-coil trap were constructed. The linear portion of calibration without trap included Bi concentrations of 2.0–100 ng mL^{-1} using peak height values. In this linear range, linearity equation was found as $y = 0.0105x + 0.0263$ and correlation coefficient (R^2) was found as 0.9977; y is absorbance value for CF mode and x is concentration in ng mL^{-1}. In the W-coil trap studies, linear range included Bi concentrations of 0.1–10.0 ng mL^{-1}; best line equation was found to be $y = 0.2603x + 0.0376$ and correlation coefficient (R^2) was found as 0.9997; y is absorbance for peak height measurement and x is concentration in ng mL^{-1}. When the slope of calibration curve in trap studies is divided to that of the without trap studies, preconcentration factor was found to be 24.8.

3.3.2. LOD, LOQ and C_o

Three and ten times the standard deviation of blank values were used in the LOD and LOQ calculations, respectively. In W-coil trap studies, 1.0 min collection period was applied for the LOD and LOQ calculations. LOD values in W-coil trap and no-trap study are 25 ng L^{-1} and 470 ng L^{-1}, respectively. The enhancement factor in the limit of detection found to be 19 when compared to conventional CF-HGAAS. In calculations of characteristic concentration, C_o, for W-coil trap and no-trap studies, 15.9 ng L^{-1} of Bi and 336 ng L^{-1} Bi were used, respectively. Peak height values were used in all calculations. Analytical figures of merit mentioned above are shown in Table 1. Using C_o values, an enhancement factor of 21 is found for the present conditions.

Table 1
Analytical figure of merit and enhancement factors for Bi calculated by using peak height of analytical signal without trap and with trap medium.

	With trap	Without trap
LOD (ng L^{-1})	25	470
C_o (ng L^{-1})	15.9	336
% RSD	5.2	9.21

The accuracy of the method was tested using the certified reference material (CRM) Trace metals in Drrinking Water (Cat. No. CRM-TMDW Lot # 818921) supplied by High Puritiy Standarts (Charleston, SC, USA) and containing 10 ng mL^{-1} Bi. Analysis of CRM was carried out by diluting 1.0 mL of the CRM to 100 mL with 1.0 mol L^{-1} HCl, resulting in a solution of 0.100 ng mL^{-1} Bi. The result ($n = 3$ for each analysis) was 10.2 ± 1.3 ng mL^{-1} Bi and the result is in good agreement with the certified value.

3.4. Interference studies

Two classes of interferences are observed in AAS that is spectral and non-spectral. Spectral interferences are owing to radiation absorbed by species rather than free atoms of the analyte. Non-spectral interferences are due to influence of sample constituents on the analyte signal. Owing to the separation of analyte from the matrix, spectral interferences in hydride generation AAS are much less serious than for liquid sampling AAS. Line interferences do not occur at all; nonselective background absorption can be observed when a significant amount of species transported to the atomizer from a hydride generator. This may typically happen in the presence of an excess of other hydride forming elements in sample matrix or in the case of hydride generation from non-aqueous media [12].

Recently, interference effects of some elements were studied for hydride generation system. In our study, interferences have been investigated in detail during Bi determination by hydride generation, both with and without trap in the same HGAAS system. It is known that since W-coil trap system is capable of having better sensitivity and diluted interferents are less effective. Interferent/analyte (mass/mass) ratio was kept at 1, 10 and 100. Experiments were designed for carrier solutions having 1.0 M HNO_3. Interferents such as Fe, Mn, Zn, Ni, Cu, As, Se, Cd, Pb, Au, Na, Mg, Ca, chloride, sulfate and phosphate were examined in this study.

In the preliminary of the intereference studies, a concentration level was used to be the same for both systems that are with and without trap, thus 20 ng mL^{-1} was chosen for analyte concentrations. And also in trap studies, collection time was selected as 6 s to reach same absorbance value with no-trap studies. Interferant/analyte (mass/mass) ratio was kept as 1, 10 and 100, respectively. Experiments were designed for carrier solutions having 1.0 M HNO_3. In this circumstance, Mn and Cu which are called as transition elements, As, Cd and Pb which are called as hydride forming elements and Au show severe interferences in both cases. Besides this study, Bi concentration was changed as 0.4 ng mL^{-1} and collection time was selected as 300 s in order to keep total amount of Bi constant with 20 ng mL^{-1} Bi where collection time was selected as 6 s in trap studies. When this solution was used, interference effects of Mn, Cu, As, Cd, Pb and Au were obviously decreased by using W-coil trap study as shown in Figs. 3, 5 and 7, respectively. This shows that if the analyte solution is diluted, interference effects of these elements on Bi signal are decreased.

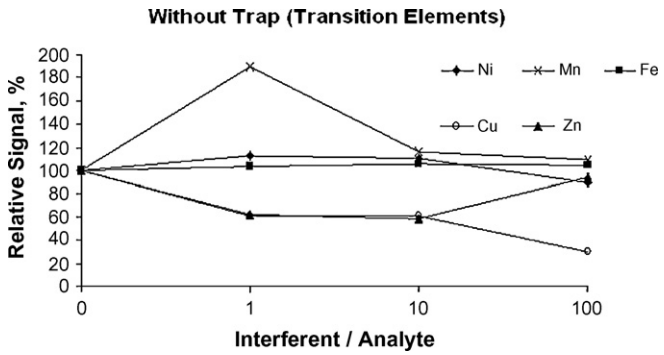

Fig. 2. Relative signal of Bi in different transition metals medium by without trap studies.

4. Discussion

Optimization of the systems was carried out by keeping all parameters constant while only the test parameter was varied. The analyte signal decreased with the values both lower and higher than the optimum values.

The analytical signal obtained by W-coil trap HGAAS under optimum conditions was very sharp. The residence time of the 0.1 ng mL^{-1} for Bi on the light path is very short and transient signal is obtained 0.1 ng mL^{-1} for Bi in less than 1.0 s shown in Fig. 1. The shape and base width of the analytical signal depend on the heating rate of the coil and also the carrier gas flow rates. If higher collection temperatures were used, the quartz around W-coil trap reaches to temperatures at which volatile Bi species are partially trapped on this surface. At the releasing stage, these trapped species revolatilized gradually as quartz surrounding the W-coil trap is being heated relatively slow compared to the W-coil trap. Under these conditions, a tailing is observed in the analytical signal. In addition, since there is a temperature gradient between the trap and the atomizer due to the heating effect of flame, some of the volatile Bi species are trapped on the inner surface of quartz inlet arm between trap and the atomizer. Regardless of the collection temperature, if a higher releasing temperature, which is sufficient for revolatilization of Bi species trapped on quartz surface, the analytical signal tails due to gradually revolatilization of Bi species from quartz surface between trap and the atomizer. Deviations from the optimized collection and release cycles may cause degraded repeatability due to undesired trapping and releasing effects. Under optimum conditions, where optimum collection and revolatilization temperatures were not exceeded, only a single sharp peak created by volatile Bi trapped on W-coil trap is achieved. The precision of the measurements based on the peak height of the analytical signal has an RSD of 5.2%, which is obtained by replicate measurements of reagent blanks for a collection volume of 8.0 mL corresponding to 1.0 min collection.

Effects of some transition elements on Bi determination using both without trap and W-coil trap studies can be seen in Figs. 2 and 3, respectively. As seen, Mn and Cu show severe interference in without trap experiment. It is well known that Cu is an interferent in HGAAS determination of Bi. During the determination of Bi in geological reference samples, the Cu/Bi mass ratio was only 3 and no interference was observed. Elsewhere, a signal reduction of 77% and 100% signal reductions was reported for Cu/Bi mass ratio values of 20 and 200, respectively [10]. Trap system has lower interference effect in cases Fe and Zn. In these interference studies, the concentration of the Bi analyte was selected as 20.0 ng mL^{-1} in without trap experiments and in with trap experiment Bi concentration was selected as 0.4 ng mL^{-1}, collection time was 300 s. When 0.4 ng mL^{-1} was used, interference effects of Mn, Fe, Cu, Zn and Ni were obviously decreased using W-trap studies as seen in

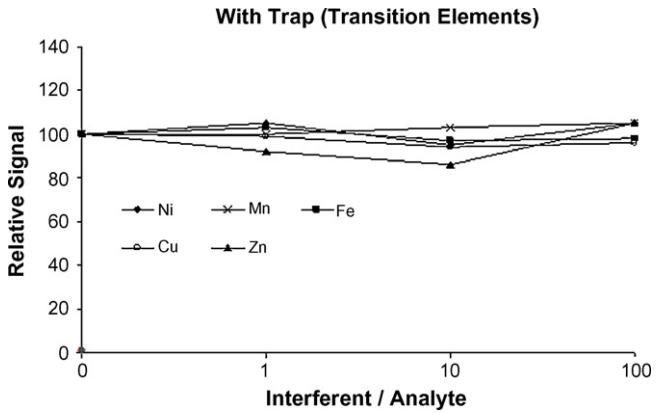

Fig. 3. Relative signal of Bi in different transition metals medium by trap studies (Bi concentration: 0.4 ng mL^{-1} and collection time: 300 s).

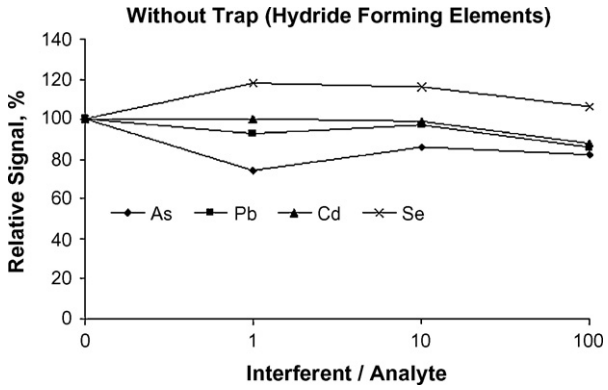

Fig. 4. Relative signal of Bi in hydride forming elements medium by without trap studies.

Fig. 3. This shows that if the analyte solution is diluted, interference effect of the elements on Bi signal is decreased.

Effects of some hydride forming elements on Bi determination using both without trap and W-coil trap studies shown in Figs. 4 and 5, respectively. Hydride forming elements may be in gas phase interferents and liquid phase interferents. In the liquid phase interferences, due to compound and matrix interferences, signal may be decreased. If these types of interferences occurred, using trap, these effects could not be eliminated because interfering effects of liquid phase interferents are finished before the trap medium. So, trap is not a way to minimize effects of liquid phase interferents. On the other hand, when 0.4 ng mL^{-1} Bi concentration

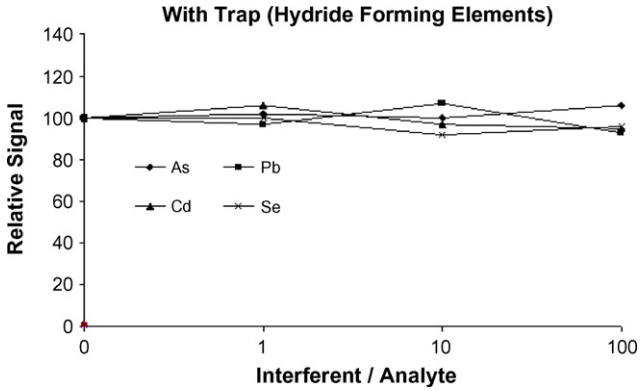

Fig. 5. Relative signal of Bi in hydride forming elements medium by trap studies (Bi concentration: 0.4 ng mL^{-1} and collection time: 300 s).

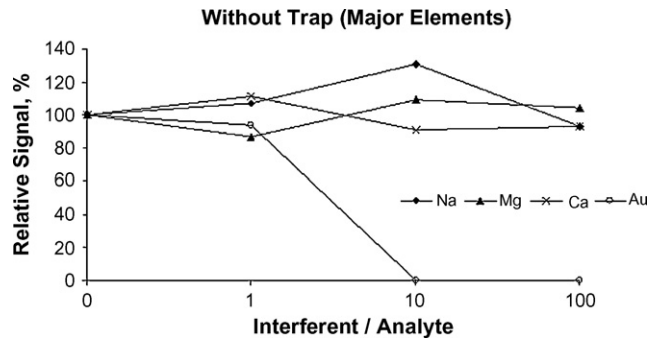

Fig. 6. Relative signal of Bi in major elements medium by without trap studies.

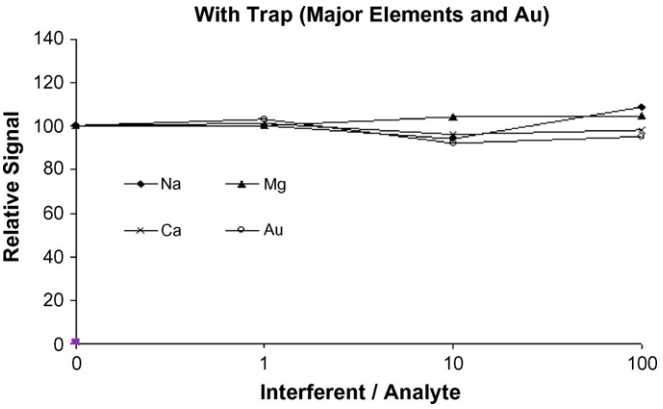

Fig. 7. Relative signal of Bi in major elements medium by trap studies (Bi concentration: 0.4 ng mL^{-1} and collection time: 300 s).

was used, interference effect of As was reduced owing to dilution effect as shown in Fig. 5.

Figs. 6 and 7 show the effect of major elements on Bi determination using both without trap and W-coil trap studies. It can be seen from Fig. 6, Au shows very high interferent effect on Bi signal especially interferent/analyte concentration is 10 and 100 in without trap study. On the other hand, when the Bi concentration was changed from 20 ng mL^{-1} to 0.4 ng mL^{-1} in trap study, interference effect of the Au on Bi signal was reduced using W-coil trap due to dilution effect as shown in Fig. 7.

And also, the interference effect of the some anions on the Bi signal in both without trap and W-coil trap were studied. By using W-coil trap, intereference effect of the PO_4^{3-}, SO_4^{2-} and Cl^- was reduced. Therefore interference effect of these anions is in gas phase.

Besides, for the decreasing of the interference effect of the some elements on the Bi signal, analyte concentration was diluted but total amount of the analyte was not changed. By doing this, interference effect of the elements on the Bi signal was decreased very well. This shows that trap has two advantages regarding interferences: dilution + trap itself.

5. Conclusion

A simple flame AAS instrument, a peristaltic pump and a simple flow system are needed to obtain sensitivity at ng L^{-1} Bi concentration level. All experimental parameters that influence the collection/volatilization efficiency were optimized in order to have the best sensitivity in W-coil trap HGAAS system.

Interferences have been investigated in detail during Bi determination by hydride generation in both with and without W-coil trap in the same HGAAS system. Experiments were designed for carrier solutions having 1.0 M HNO_3. Interferents such as Fe(III), Mn(II), Zn(II), Ni(II), Cu(II), As(III), Se(IV), Cd(II), Pb(II), Au(III), Na(I), Mg(II), Ca(II), chloride, sulfate and phosphate were examined in this study. In the case of W-coil trap, interference effects from chloride, sulfate and phosphate ions are significantly reduced as compared with the no-trap system. Cd, Pb and Mg have effects within ±10% in without trap study. On the other hand, when W-coil trap is used, the interference effect of these analyte is decreased. Mn, Zn, Se, As, Na and Cu show severe interference effect on Bi signal in without trap study. Trap system has lower interference effect in cases of these elements. Another important point is that in no-trap study, Au shows severe interference effect on Bi signal especially interferent/analyte concentration is 10 and 100. When the W-coil trap is used, the interference effect of Au was decreased severely. In this study, also optimization of waste suction rate was carried. The calibration plot for an 8.0 mL sampling volume was linear between 0.10 μg L^{-1} and 10.0 μg L^{-1} Bi. The detection limit (3 s) was 25 ng L^{-1}. The enhancement factor for the characteristic concentration (C_o) was found to be 21 when compared with the regular sytem without trap, by using peak height values.

ABSTRACT

In this work, a novel method is described for the determination of bromhexine in biological fluids using molecularly imprinted solid-phase extraction as the sample cleanup technique combined with high performance liquid chromatography (HPLC). The water-compatible molecularly imprinted polymers (MIPs) were prepared using methacrylic acid as functional monomer, ethylene glycol dimethacrylate as cross-linker, chloroform as porogen and bromhexine as the template molecule. The novel imprinted polymer was used as a solid-phase extraction sorbent for the extraction of bromhexine from human serum and urine. Various parameters affecting the extraction efficiency of the polymer have been evaluated. The optimal conditions for molecularly imprinted solid-phase extraction (MISPE) consisted of conditioning 1 mL methanol and 1 mL of deionized water at neutral pH, loading of 5 mL of the water sample (25 $\mu g\,L^{-1}$) at pH 6.0, washing using 2 mL acetonitrile/acetone (1/4, v/v) and elution with 3× 1 mL methanol/acetic acid (10/1, v/v). The MIP selectivity was evaluated by checking several substances with similar molecular structures to that of bromhexine. Results from the HPLC analyses showed that the calibration curve of bromhexine using MIP from human serum and urine is linear in the ranges of 0.5–100 and 1.5–100 $\mu g\,L^{-1}$ with good precisions (3.3% and 2.8% for 5.0 $\mu g\,L^{-1}$), respectively. The recoveries for serum and urine samples were higher than 92%.

1. Introduction

Bromhexine (Fig. 1), N-cyclohexyl-N-methyl-(2-amino-3,5-dibromobenzyl)-amine, was proved to be antitussive and mucolytic because of promotion of bronchial secretion and splitting of polysaccharide fiber. Bromhexine, is a mucolytic agent used in the treatment of respiratory disorders associated with viscid or excessive mucus [1]. It undergoes oxidation and conjugation hepatic biotransformation, and the drug and its metabolites are excreted in urine and feces [2]. The drug has been quantified using different methods such as UV–vis spectrophotometry [3–5], voltammetry [6], thin layer chromatography (TLC) [7], high performance liquid chromatography (HPLC) [8,9], inductively coupled plasma mass spectrometry [10], capillary zone elecrophoresis [11], capillary isotachophoresis [12], electrokinetic chromatography [13], gas liquid chromatography [14], chemiluminecence [15] and flow injection analysis with ion-selective electrode [16]. Most of them are, however, difficult and/or time-consuming, requiring a derivatisation step or a specific solvent extraction. HPLC technique has been extensively applied to the determination of bromhexine in pharmaceutical or biological samples but it combined with a liquid–liquid extraction (LLE) step [17–19] that hindered the degree of automation. However, none of the available methods was ideal, and an improved method for selective extraction and determination of bromhexine was necessary.

Sample preparation is essential for the analysis of compounds in real samples. Due to unsatisfactory selectivity, the traditional sorbents usually cannot separate analytes efficiently in complex biological or environmental samples. Solid-phase extraction (SPE) is the most popular of cleanup techniques due to factors such as convenience, cost, time saving and simplicity. Compared to LLE, SPE can reduce the time required, especially for automated methods, can handle small samples, and consumes small amount of solvent [20]. As a result, SPE is the most accepted sample pretreatment method today [21]. A relatively new development in the area of SPE is the use of molecularly imprinted polymers (MIPs) for the sample clean up [22–25]. MIPs are synthetic polymers possessing specific cavities designed for a target molecule. MIPs are synthesized by polymerization of different components. In the most common preparation process, monomers form a complex with a template

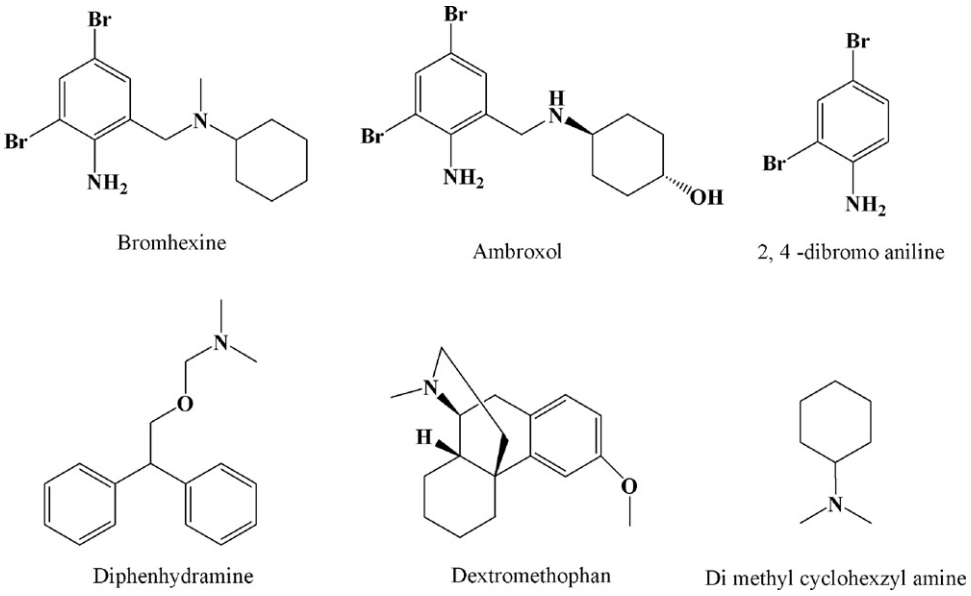

Fig. 1. Chemical structure of investigated organic compounds and drugs.

through covalent or non-covalent interactions and are then joined by using a cross-linking agent. After removing of the template by chemical reaction or extraction, binding sites are exposed which are complementary to the template in size, shape, and position of the functional groups, and consequently allow its selective uptake. MIPs are often referred to as 'artificial antibodies'. Unlike antibodies, MIPs are stable to extremes of pH, organic solvents and temperature which allows for more flexibility in the analytical methods [22,26]. The use of MIPs for SPE can involve various modes, including conventional SPE where the MIP is packed into columns or cartridges [27,28] and batch mode SPE where the MIP is incubated with the sample [29]. Another major advantage of MIP-based SPE, related to the high selectivity of the sorbent, is the achievement of an efficient sample clean up.

Recently, we applied MIPs as new sensing material in potentiometric detection of hydroxyzine [30], cetirizine [31] and SPE of verapamil [32]. In this article we present a novel method for the performance evaluation of bromhexine based MIPs as selective SPE sorbents for efficient sample clean up and followed determination of bromhexine from complex matrices by high performance liquid chromatography. This scheme as molecularly imprinted solid-phase extraction (MISPE) allows the sensitive, simple and inexpensive extraction and determination of the analyte in human serum and urine samples.

2. Experimental

2.1. Chemicals and reagents

Methacrylic acid (MAA) from Merck (Darmstadt, Germany) was distilled in vacuum prior to use in order to remove the stabilizers. Ethylene glycol dimethacrylate (EGDMA), 2,2′-azobis isobutyronitrile (AIBN), 2,4-dibromo-aniline and dimethyl-cyclohexyl-amine from Sigma–Aldrich (Steinheim, Germany) were of reagent grade and were used without any further purification. All solvents used in chromatography analyses were HPLC grade and supplied by Merck. Bromhexine HCl, ambroxol HCl, dextromethorphan HBr and diphenhydramine HCl were obtained from the ministry of health and medical education (Tehran, Iran). Bromhexine USP reference standard was used for preparing stock and standard solutions. The bromhexine stock solutions (1000 $\mu g\,L^{-1}$) were prepared monthly and stored at 4 °C. Intermediate standard solution of 10 $\mu g\,L^{-1}$ was prepared weekly by dilution of stock solutions with water. Working standard solutions of different concentrations were prepared daily by diluting the intermediate standard solution with mobile phase solution.

2.2. Apparatus

The HPLC system consisted of a Waters 515 pump, a 486 Waters UV/vis detector, a model 7725i Rehodyne injector with a 25 μL sample loop and a micro-Bondapak C18 column of 4.6 mm × 150 mm HPLC column. HPLC data were acquired and processed using a PC and Millennium 2010 Chromatogram Manager software (Version 2.1 Waters). pH of solutions were adjusted using a model 630 digital Metrohm pH meter equipped with a combined glass-calomel electrode. FT-IR spectra (4000–400 cm^{-1}) in KBr were recorded on a Bruker VERTEX 70 spectrometer.

2.3. Procedures

2.3.1. MIP and NIP preparation with bulk polymerization

For the preparation of the bromhexine imprinted polymer, the template (94 mg, 0.25 mmol) was dissolved in chloroform in a 25-mL thickwalled glass tube. The functional monomer (MAA) (0.129 mL, 1.5 mmol), the cross-linking monomer (EGDMA) (2.6 mL, 14 mmol), and the initiator (AIBN) (24 mg, 0.164 mmol) were then added to the above solution. The mixture was uniformly dispersed by sonication for 40 min to remove oxygen. Then the solution was placed in a water bath at 60 °C. The reaction was allowed to proceed for 16 h. The hard polymers, P(MAA-co-EGDMA), that were obtained were crushed. After the polymerization procedure and drying, the polymer particles were washed with methanol and acetic acid (10:1, v/v, of 98% methanol and pure acetic acid) for three times and with distillated water for two times. The complete removal of template was followed by HPLC-UV, after three times washing spectra of bromhexine were not seen. In order to verify that retention of template was due to molecular recognition and not to non-specific binding, a control, non-imprinted polymer (NIP) was prepared as the same procedure, including washing, but with the omission of the target molecule, bromhexine. The size of the particles used after crushing and sieved was between 30 and 45 μm.

2.3.2. MISPE conditions

MIP and NIP columns were prepared by packing 150 mg of the polymer into 2 mL empty cartridge. The cartridge was conditioned sequentially with 1 mL of methanol and 1 mL of deionized water. Extraction experiments involved loading the column with 5 mL of water solution containing 25 $\mu g\,L^{-1}$ bromhexine (pH 6.0, 20 $mmol\,L^{-1}$ citrate buffer) at a flow rate of 1 $mL\,min^{-1}$. After loading, column was washed with 2 mL of acetonitrile/acetone (1/4, v/v) and a full vacuum was applied through the cartridge for 2 min to remove residual solvent. Finally, the elution was performed by passing 3× 1 mL of methanol–acetic acid (10:1, v/v). All fractions were evaporated to dryness at 20 °C under a stream of nitrogen and finally recovered in 1 mL of mobile phase. Then, 20 μL of each sample was injected onto the analytical column of HPLC.

2.3.3. Chromatographic conditions

The HPLC was carried out at room temperature. A degassed mixture of acetonitrile:phosphate buffer (0.01 $mol\,L^{-1}$, pH 3.0) (30:70) at a flow rate of 1.0 $mL\,min^{-1}$ was selected as a mobile phase [6]. All of the analyses were carried out at an operation wavelength of 245 nm and the results were recorded by Millennium chromatography software.

2.3.4. Rebinding experiments

Batch adsorption experiments were used to evaluate the binding affinity of the imprinted polymer as reported before [33,34]. The general procedure for extraction of bromhexine by the MIP was as follows: the polymer beads were suspended in aqueous solutions and the pH was adjusted at 6. Then 25 mg of polymer particles were added in 5-mL flask containing bromhexine solutions of various concentrations (5–100 $\mu g\,L^{-1}$). The mixtures were thermo-stated at 25 °C for 1 h under continuous stirring at 200 rpm and then were filtrated on a paper filter (flow rate = 100 $mL\,min^{-1}$ by applied vacuum). The free concentration of bromhexine after the adsorption was recorded by HPLC-UV at 245 nm. Three replicate extractions and measurements were performed for each aqueous solution. The adsorbed bromhexine was desorbed from the MIP by treatment with 2 mL of methanol and acetic acid (10:1, v/v, of 98% methanol and pure acetic acid). The amount of bound analyte to the polymer was calculated by subtracting the nonbounded amount, from the initial bromhexine concentration in the mixture. The binding experiments were carried out by triplicate. In order to know that the bromhexine is retained by specific interactions and not the non-specific ones, the same procedure was followed for NIP particles.

2.3.5. Extraction procedure for human serum and urine samples

Drug free human serum was obtained from the Iranian blood transfusion service (Tehran, Iran) and stored at −20 °C until use after gentle thawing. Urine was also collected from healthy volunteers (males, around 30-year old). Stock standard solutions of bromhexine were prepared in water. Standard solutions were prepared by adding appropriate volumes of bromhexine solution to a 10 mL volumetric flask and the solution was diluted to the mark with biological fluids and vortexed for 3 min. 2 mL of the serum and urine samples spiked by bromhexine were diluted with 2 mL buffer pH 6.0 and were centrifuged for 20 min at 8000 rpm and then filtered through a cellulose acetate filter (0.20 μm pore size, Advantec MFS Inc. CA, USA). The filtrate were collected in glass containers and stored at −20 °C until analysis was performed. 2 mL of the filtered supernatant was collected to be directly percolated through the MIP or the NIP.

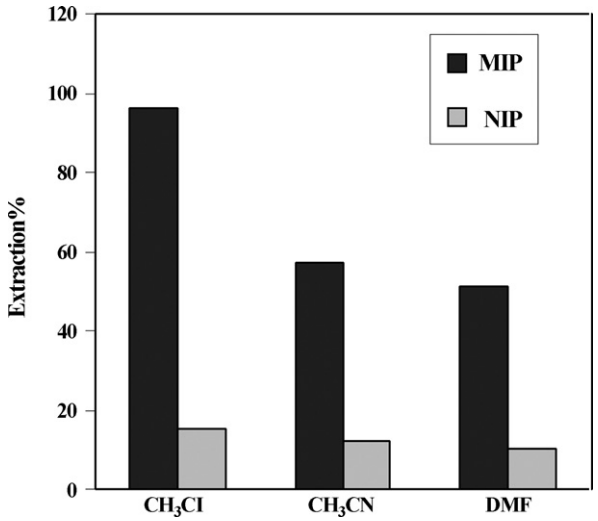

Fig. 2. Recoveries obtained using the MIP and NIP polymers synthesized in different organic solvents. Batch experiments with 25 mg or polymer particles; sample volume, 5 mL; pH, 6.0; bromhexine concentrations, 25 $\mu g\,L^{-1}$.

3. Results and discussion

3.1. Characterization

In the IR spectra, as a result of the hydrogen binding with the –COOH group of MAA, the O–H stretching and the bending vibrations at 3473 and 1394 cm^{-1} in the leached MIP materials were shifted to 3457 and 1388 cm^{-1} in the corresponding unleached MIP, respectively. Furthermore, there were two other distinct differences between the IR spectra of the leached and unleached MIPs. In the leached polymer, there were one broad band around 2704 cm^{-1} and one sharp band around 2956 cm^{-1}. The first was shifted to 2636 cm^{-1} and another appeared around 2987 cm^{-1}. Other absorption peaks match both those of MIP, as well as NIP: 1731 cm^{-1} (stretching vibration of C=O bonds on carbonyl groups); 1636 cm^{-1} (stretching vibration of residual vinylic C=C bonds) and vibrations at 1259, 1157, 954, 875, 817 and 757 cm^{-1}.

3.2. Optimal MIP formulation and progenic solvent

There are several variables, such as amount of monomer or nature of cross-linker and solvent that affects the final characteristics of the obtained materials in terms of capacity, affinity and selectivity for the target analyte. Thus, by achieving an optimum combination of cross-linker and functional monomer non-specific binding should be able to be minimized. Primary experiments revealed that the imprinted polymers prepared in chloroform show better molecular recognition ability than acetonitrile (AN) and dimethyl formamide (DMF) in aqueous environment (Fig. 2). Thus, in chloroform, different formulations for the obtainment of MIPs with improved molecular recognition capabilities have been used. Generally, proper molar ratios of functional monomer to template are very important to enhance specific affinity of polymers and number of MIPs recognition sites. High ratios of functional monomer to template result in high non-specific affinity, while low ratios produce fewer complexation due to insufficient functional groups [35]. Four molar ratios of the monomer MAA to the template of 2:1, 4:1, 6:1 and 8:1 were used in the experiments. The optimum ratio of functional monomer to template for the specific rebinding of bromhexine was 6:1 (Table 1), which had the best specific affinity and the highest recovery of 96%, while that of the corresponding NIPs was low at 15%. The specific adsorption recovery of bromhexine at 6:1 was 81%, while those at 2:1, 4:1 and 8:1

Table 1
Compositions and comparisons of the extraction of polymers.

MIP	MAA (mmol)	Bromhexine (mmol)	EGDMA (mmol)	AIBN (mmol)	Extraction (%) (mean ± SD)[a]
MIP1	2.0	1.0	64	0.347	41 (±1.9)
MIP2	4.0	1.0	64	0.347	51 (±2.2)
MIP3	6.0	1.0	64	0.347	96 (±4.1)
MIP4	8.0	1.0	64	0.347	41 (±2.0)
NIP1	2.0	0	64	0.347	26 (±1.7)
NIP2	4.0	0	64	0.347	32 (±2.1)
NIP3	6.0	0	64	0.347	15 (±1.1)
NIP4	8.0	0	64	0.347	24 (±1.8)

[a] Average of three determinations.

were 15%, 19% and 17%, respectively. Therefore, a typical 1:6:64 template:monomer:cross-linker molar ratio was used for further studies.

3.3. Effect of pH, choice of loading, washing and eluent solution

It has been demonstrated that efficient imprint rebinding is possible in aqueous buffer solutions, showing high binding affinity and selectivity as a result of hydrophobic interactions. The effect of pH on the rebinding efficiency of bromhexine was investigated by varying the solution pH from 2.0 to 9.0 Several batch experiments were performed by equilibrating 25 mg of the imprinted and non-imprinted particles with 5 mL of solutions containing 25 $\mu g\,L^{-1}$ of bromhexine under the desired range of pH. It was observed that bromhexine underwent complete rebinding/elution at pH 6.0. The lower responses observed at lower and higher pHs may be attributed to the protonation of the amine group of bromhexine and deprotonation of carboxyl groups of the polymer, respectively.

Generally, the polymers have binding ability with both specific and non-specific interactions. The specific interactions may originate mainly from the imprinting procedure, which creates selective recognition sites for the template. The non-specific interactions were assessed by measuring the binding of the non-imprinted polymer. At first, cartridges were conditioned with 1 mL of methanol followed by 1 mL of deionized water at neutral pH. Water samples were then loaded onto the cartridges at a flow rate of 1 mL min^{-1} and the wash procedure was assessed for obtaining maximum recovery of the analytes using a variety mixtures including: acetonitrile, acetone, tetrahydrofuran, dimethyl formamide, acetonitrile–acetone, dichloromethane–acetone, acetonitrile–methanol and dichloromethane–methanol. In order to investigate the usefulness of the washing step, 5 mL of 25 $\mu g\,L^{-1}$ bromhexine aqueous solution was loaded on the MIP and NIP cartridges separately, followed by the desorption with the washing solvent. The results were showed that washing with 2 mL of acetone, tetrahydrofuran and dichloromethane had no obviously effect on the retention of bromhexine on both MIP and NIP cartridges. In contrast, polar organic solvents, such as methanol, dimethyl formamide and acetonitrile had noticeably effect on the retention of bromhexine on both MIP and NIP cartridges. With the mixture of acetonitrile/acetone (1/4, v/v), the recovery of bromhexine in NIP cartridge was decreased to 8%, while the recovery of bromhexine by the MIP cartridges was not reduced (94.0%). For the recovery of strongly bound bromhexine, the polymer were eluted with 3× 1 mL of methanol/acetic acid (10/1, v/v). As a result, recovery after the whole SPE process avoids contaminating HPLC column. Meanwhile, increasing of the sample volume up to 100 mL, just had a light effect on the extraction of bromhexine.

The reproducibility and repeatability of the method were evaluated from run-to-run MISPE experiments (5 $\mu g\,L^{-1}$ standard solution, $n = 5$) and day-to-day experiments (five successive days) and RSDs of 5.8% and 2.5% for the extraction amounts of bromhexine were obtained, respectively.

3.4. Adsorption capacity

The capacity of the sorbent is an important factor that determines how much sorbent is required to remove a specific amount of drug from the solution quantitatively. In the measurement of the adsorption capacity of MIP and NIP absorbents, the absorbents (10 mg) were added into 5 mL bromhexine solutions at concentrations of 1.0–500 mg L^{-1}, and the suspensions were mechanically shaken for 1 h at room temperature, followed by centrifugally removing of the absorbents. The remained bromhexine in the supernatant was measured by HPLC, and the isothermal adsorptions are plotted in Fig. 3. According to these results, the maximum amount of bromhexine that can be absorbed by MIP was found to be 90 mg g^{-1} (240 $\mu mol\,g^{-1}$) at pH 6.0. Such behavior is coherent with previous data with MIP capacities ranged from 40 to 200 μmol per gram [36,37]. For higher bromhexine amounts, a slight increase of retained bromhexine was observed on MIP capacity curve.

3.5. Study of MIP selectivity

Dextromethorphan and diphenhydramine as antitussive (cough suppressant) drugs, ambroxol as an active metabolite of bromhexine, 2,4-dibromo-aniline and dimethyl-cyclohexyl-amine as structural analogues of bromhexine were selected to investigate the selectivity of the MIP. Their molecular structures are shown in Fig. 1. Solutions of all compounds were prepared individually with the concentration of 50 $\mu g\,L^{-1}$. Extraction solvent was methanol/acetic acid (10/1, v/v). The extraction yields of the selected compounds with the MIP and NIP are shown in Fig. 4. Obviously, the extraction yields of analogues with the MIP were much higher than that of the NIP. It was indicated that the bromhexine based-MIP possessed better affinity to the structural analogues of template molecule.

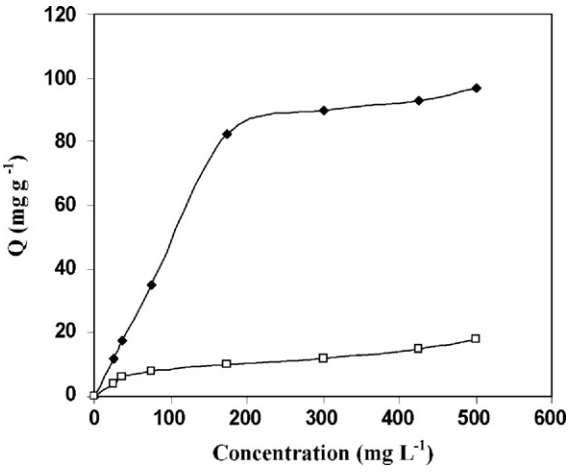

Fig. 3. Curve of capacity obtained after the loading of 5 mL aqueous solution spiked with increasing amounts of bromhexine onto the MIP particles.

Table 2
Assay of bromhexine in human serum and urine by means of the described MISPE procedure.

Sample	Spiked value (ng/mL)	Proposed SPE-HPLC procedure (recovery% ± SD)[a]	
		MIP	NIP
Human serum	5.0	93 ± 3.3	23 ± 2.0
	10	96 ± 3.1	20 ± 2.1
	25	92 ± 2.8	22 ± 2.5
Human urine	5.0	97 ± 2.8	19 ± 2.0
	10	95 ± 3.0	18 ± 1.8
	25	93 ± 2.7	18 ± 1.9

[a] Average of three determinations.

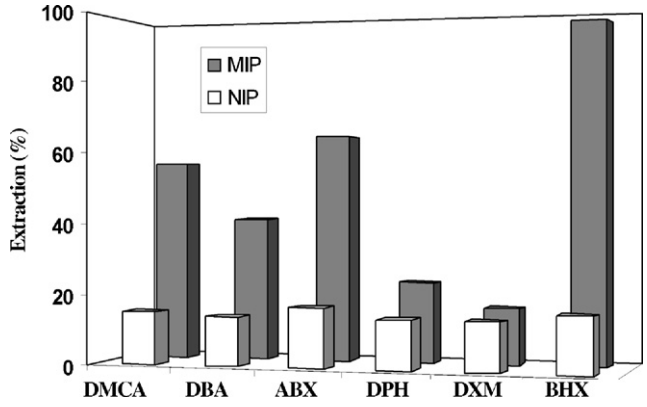

Fig. 4. Extractions of bromhexine (BHX), dextromethorphan (DXM), diphenhydramine (DPH), ambroxol (ABX), 2,4-dibromo-aniline (DBA) and dimethyl-cyclohexyl-amine (DMCA) with MIP and NIP at 50 μg L^{-1} level. Batch experiments at 25 °C and 200 rpm; sample volume, 5 mL; pH, 6.0.

This affinity is mainly caused by the hydrogen bonding interaction between amino groups possessed by all analogues and carboxylic groups in the MIP. However, for the MIPs, the extractions of dextromethorphan, diphenhydramine, ambroxol, 2,4-dibromo-aniline, dimethyl-cyclohexyl-amine and bromhexine according to adsorption experiments (without using washing step) were 16, 23, 65, 41, 57, and 97 percent, respectively. A possible reason for the difference was that the extractions of analogues were relative to their structural similarity with the template molecule of MIP. Ambroxol, having identical structural analogues, could be extracted 65%. For the NIPs, the extractions of less than 18% were obtained for all compounds because of the non-specific adsorption.

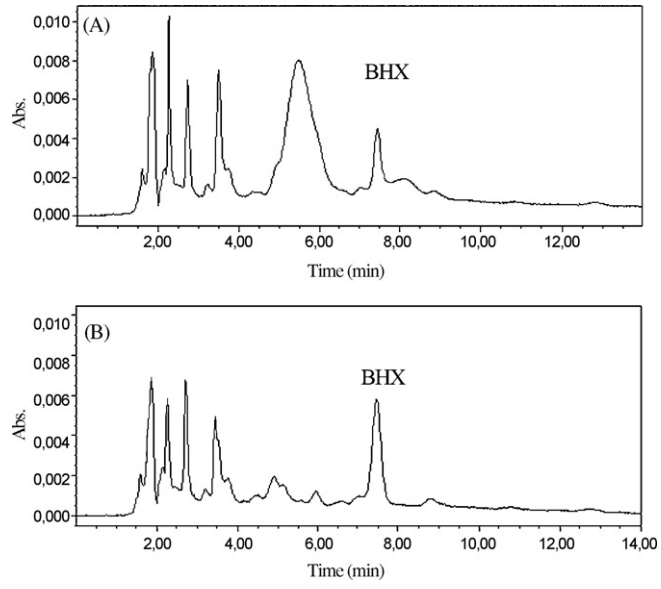

Fig. 5. HPLC chromatograms obtained after percolation of 2 mL human serum spiked with 10.0 μg L^{-1} of bromhexine with a cleanup step comprising the (A) NIP and (B) MIP monitored at 245 nm; conditions: column ACE 5 μm, C18 4.6 mm × 250 mm at +40 °C, eluent acetonitrile:phosphate buffer (0.01 mol L^{-1}, pH 3.0) 30:70 at flow rate of 1.0 mL min^{-1}.

3.6. Bromhexine assay in human serum and urine samples

To demonstrate the potential of MIP for the selective clean up of analyte, the MIP was applied to the purification of spiked bromhexine in human serum and urine. Aqueous media was employed for the loading solution and the wash procedure was assessed for obtaining maximum recovery of the analytes using acetonitrile–acetone (1:3). It was seen that acetonitrile–acetone

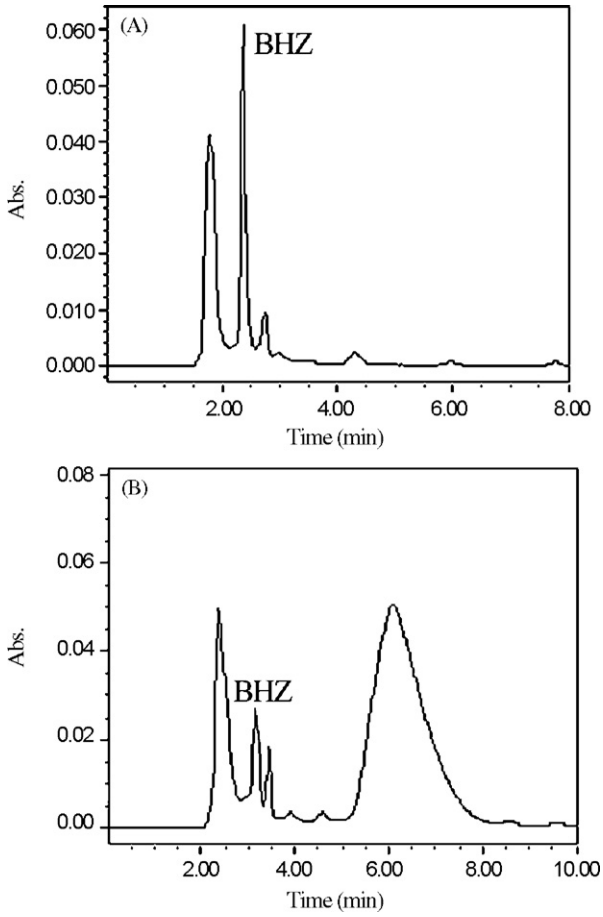

Fig. 6. HPLC chromatograms obtained after clean up a 50.0 μg L^{-1} solution of bromhexine (BHX) in urine samples with the (A) MIP and (B) NIP monitored at 245 nm; conditions: column ACE 5 μm, C18 4.6 mm × 250 mm at +40 °C, eluent acetonitrile:phosphate buffer (0.01 mol L^{-1}, pH 3.0) 25:75 at flow rate of 1.1 mL min^{-1}.

(1:3) mixture can elute interferences and avoid contaminating HPLC column. The chromatograms obtained for serum and urine samples were compared in Figs. 5 and 6. This efficient method allowed cleaner extracts to be obtained and interfering peaks arising from the complex biological matrices to be suppressed. Results from the HPLC analyses showed that the calibration curve of bromhexine for serum and urine samples are linear in the ranges 0.5–100 $\mu g\,L^{-1}$ and 1.5–100 $\mu g\,L^{-1}$ with good precision (3.3% for and 2.8% for 5.0 $\mu g\,L^{-1}$) and recoveries (between 92–96% and 93–97%), respectively (Table 2). Typical chromatograms presented in Figs. 5 and 6 reveal that the MIP can be used for clean up and when MIP sorbent was used, a board peak in chromatogram was omitted. The limit of detection (LOD) and limit of quantification (LOQ) for bromhexine in serum samples were 0.1 and 0.4 $\mu g\,L^{-1}$ respectively. These limits for bromhexine in urine samples were 0.3 and 1.0 $\mu g\,L^{-1}$ respectively.

4. Conclusions

In this paper for the first time, a novel bromhexine MIP was prepared by bulk polymerization. The bromhexine MIP showed higher molecular recognition than NIP on chromatographic evaluation. A SPE-HPLC method based on MIP has been developed for the extraction of bromhexine from aqueous solutions. Furthermore, the MIP particles as new sorbents in SPE were successfully investigated for the clean up of human serum and urine samples with an optimized procedure. This efficient method allowed cleaner extracts to be obtained and interfering peaks arising from the complicated biologic samples to be suppressed. The method was applied to the trace bromhexine determination at three levels, and the recoveries for the spiked human serum and urine samples were higher than 92% in the 5–25 $\mu g\,L^{-1}$. It could be concluded that the technique has great potential in developing selective extraction method for other compounds.

ABSTRACT

An atmospheric pressure dielectric barrier discharge (DBD) atomizer was investigated for bismuth (Bi) determination with hydride generation (HG) atomic fluorescence spectrometry (AFS). The characteristics of the atomizer and the effects of experimental parameters, including observation height, discharge power, flow rate of discharge gas and AFS carrier gas were optimized. The linear range of present method for Bi determination is 0.5–300.0 $\mu g\,L^{-1}$ with a detection limit of 0.07 $\mu g\,L^{-1}$ (3σ). The method was validated by the analysis of reference materials (GBW08517 and GSB-14) and the results agreed well with the reference values. The established method was applied to the determination of Bi in ore, soil and ash samples.

1. Introduction

Although bismuth (Bi) is a relatively rare element in earth, large quantities of bismuth are produced annually in different areas, such as semiconductors, cosmetic products (e.g. pigments in eye shadow, lipsticks and hair dyes), medicines (such as for treatment of syphilis, peptic ulcers and dermatological disorders), alloys, by-product of copper and tin refining, metallurgical additives, and preparation and recycling of uranium in nuclear fuels [1]. There are many methods available for the determination of Bi at trace level, such as molecular spectrometry [2], inductively coupled plasma mass spectrometry (ICP-MS) [3], X-ray fluorescence spectrometry [4], nuclear techniques [5] and electrochemical techniques [6]. Especially, hydride generation (HG) coupled to atomic fluorescence spectrometry (AFS) [7,8] offers a useful tool for ultra-trace determination of hydride-generable elements including Bi [9,10]. Both excellent sensitivity and low cost make this method grow tremendously in recent years [11–14]. Normally, AFS was equipped with hydrogen–air and hydrogen–oxygen–argon combustion flame quartz furnace atomizer. For the sake of the high temperature and unenclosed nature of flame quartz furnace atomizer, it is difficult to make AFS become a miniaturized instrument for on-site, real time monitoring.

Recently, numerous studies have focused on the development of miniaturized instruments for the determination of trace elements [15,16]. Small atomization/ionization sources, based on inductively coupled plasma (ICP) [17,18], microwave-induced plasma (MIP) [19], laser-induced plasma [20], glow discharge (GD) [21], and the dielectric barrier discharge (DBD) [22], have been developed for this purpose. The advantages of small size, simplicity, low gas temperature, atmospheric operation and excellent dissociation capability made DBD plasma become an attractive technique when it is coupled with atomic absorption spectrometry (AAS) [23], atomic fluorescence spectrometry (AFS) [24], optical emission spectrometry (OES) [25], and mass spectrometry (MS) [26]. DBD is a suitable technique to develop an effective low-temperature atomizer for miniaturized AFS, since the DBD atomizer do not need a H_2 flame to atomize the hydride [24]. In previous studies, DBD used as atomizer coupled with AFS showed features of low operation temperature (between 44 and 70 °C, depending on the operation conditions), low power consumption and operation at atmospheric pressure, small size, simplicity of fabrication, and prevention of the contamination from the electrodes. This not only facilitates the treatment of the residue poisonous hydride, but also greatly reduces the gas consumption. However, previous work based on DBD microatomizer/microplasma [23–25,27] is focused on the determination of mercury and arsenic. It is still unknown that this new atomizer is capable of dissociating other hydride-forming elements, such as Bi. Therefore, it is still needed to further expand the applicable scope of the new atomization method.

In this work, a microplasma DBD atomizer combined with HG-AFS for the determination of Bi in solid environment samples has been proposed. After validation by the analysis of reference materials, the method has been applied to the quantitative analysis of Bi in ore, soil and ash samples. The results presented in this paper

show that the method is highly sensitive for the detection of Bi in real samples.

2. Experimental

2.1. Instrumentation

The AFS-3000 HG-AFS (KCHG Co. Ltd., China) fitted with a programmable intermittent reactor was employed in this study. The experimental set-up includes a sample introduction unit, a DBD chamber, a high-performance hollow cathode lamp (HCLs, Beijin Haiguang Co. Ltd., China) and a photomultiplier tube (Fig. 1). DBD power supplies were purchased from Coronalab (Coronalab Co. Ltd., China).

The gaseous hydrides were produced by mixing acidified samples and KBH_4 in 0.5% NaOH through a two-channel peristaltic pump into a Y conjunction. The hydrides were separated by a gas–liquid separator (GLS) and transported to DBD atomizer by Ar gas. The plasma atomization cell was positioned between the Bi hollow cathode lamp (HCL) and the detector (Photomultiplier Tube, PMT). The radiation from the Bi HCL was focused with a lens onto outlet of the atomization cell. The gaseous hydrides were decomposed by the plasma and the formed atoms were excited by radiation beam of Bi HCL at the outlet of DBD chamber. The fluorescence was collected at an angle of 90 °C with respect to the excitation beam. The operation conditions of the AFS were listed in Table 1 and the working program of the intermittent reactor was given in Table 2.

For the comparison of analytical results, a Thermo X II ICP-MS (Thermo Fisher Scientific, Bremen, Germany) was used for the determination of Bi in certified reference materials (CRMs) and real samples. A standard glass concentric nebulizer and a standard glass conical impact bead spray chamber were employed with a sample introduction rate of about 0.5 mL min^{-1}. The radio frequency power was set to 1200 W, and the coolant gas flow, nebulizer gas flow and auxiliary gas flow were set to 14, 0.84 and 0.7 L min^{-1} respectively.

Table 1
The parameters of AFS and DBD atomizer.

Parameters	Setting value
Lamp primary current	60 mA
Lamp boost current	30 mA
Negative high voltage of PMT	300 V
Flow rate of carrier gas	0.6 L min^{-1}
Discharge power	18.6 W
Flow rate of shield gas	5.3 L min^{-1}
KBH_4 concentration (m/v)	2%

Table 2
Program of the intermittent flow reactor.

	Step	Pump rate (rpm)	Time (*s*)	Function
1	Sample KBH_4 solution	120 100	10	Sample tube in sample solution
2	Sample KBH_4 solution	0 0	6	Sample tube in 5%HCl solution
3	5%HCl solution KBH_4 solution	120 120	16	Readout
4	5%HCl solution KBH_4 solution	0 0	6	Return to step 1

2.2. Reagents and samples

Bi standard solutions were prepared just before use by the dilution of the Bi stock solution (National Research Center for Certified Reference Material, China). The KBH_4 solution was prepared by dissolving KBH_4 (Beijing Chemicals Co., China) in a 0.5% (m/v) NaOH (Beijing Chemicals Co., China). Argon (99.99%) (Praxair Inc., Beijing, China) was used as the carried gas and shield gas. All the reagents in the present work were of analytical grade. Water was purified with a water purification system (Membrapure, Astacus, Germany).

2.3. Samples and sample pretreatment

To validate the accuracy of the developed method, the certified reference materials were obtained from the National Research Center for Certified Reference Material of China: Lamiaria Japonica Aresch GBW08517 (certified value 3.3 ± 0.4 mg kg^{-1}), and Laver GSB-14 (certified value 3.1 ± 0.4 mg kg^{-1}). Soil, ore and coal ash samples were also used for the validation of the method. Samples were decomposed using microwave-assisted digestion. Briefly, 0.5 g of the sample was added to Teflon vessels containing 9 mL HNO_3, 3 mL HCl and 1 mL HF. The Teflon vessels were closed tightly and put into the microwave oven for digestion. The heating program was 120 °C for 8 min and 180 °C for 8 min. After cooling to ambient temperature, the digests were then quantitatively transferred into Teflon crucibles and heated to almost dry on the electric hot plate at 160 °C. The residues were diluted with pure water and adjusted to the final composition containing 5% (v/v) HCl.

3. Results and discussion

The operation parameters of DBD–HG–AFS were optimized with respect to the DBD shield flow rate, observation height, discharge power, and flow rate of carrier gas. For the optimization studies, the peak area read mode was used and three replicate injections were made for each experimental condition.

3.1. Optimization of shield gas flow rate and observation height

The two key factors, which have effect on the fluorescence signal synchronously, were the shield gas flow rate and observation height of the DBD–HG–AFS. Intermittent flow injection was used in the optimization with standard solutions of 100 μg L^{-1} Bi. A single Ar stream was used as discharge shield gas owing to the lower fluorescence quenching and lower cost [8]. Fig. 2 shows the effects of observation height (4.5–10.5 mm) on the fluorescence signal intensity at different flow rate of shield gas (160–480 L h^{-1}). The maximum signal intensity was obtained with the shield gas flow rate of 320 L h^{-1} and the observation height of 7.5 mm. The lower flow rates than 320 L h^{-1} may cause the decrease of free atom population caused by oxygen contamination, while higher flow rates can lead to the dilution of the bismuth atoms in the Ar/H_2 flame.

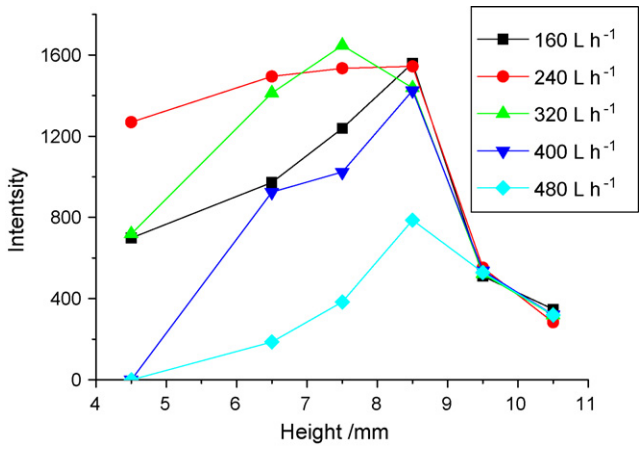

Fig. 2. The effect of observation height and flow rate of shield gas on the fluorescence signal intensities.

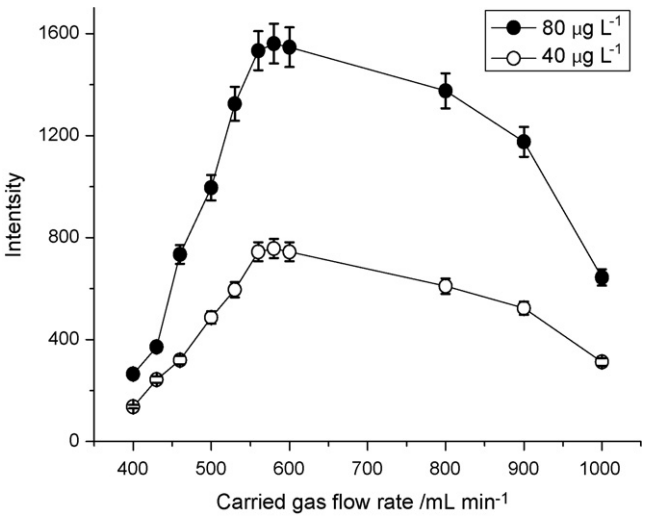

Fig. 3. Effect of the flow rate of carried gas on the fluorescence signal intensity.

[9] The signal intensity was sensitive to observation height, and the optimum observation height was found to be 7.5 mm probably due to the fine alignment of fluorescence light path.

3.2. Optimization of carried gas flow rate

The effect of carried gas flow rate (40–1000 mL min^{-1}) was optimized with standard solutions of 40 and 80 μg L^{-1} (Fig. 3). It was shown that increasing carried gas flow rate from 400 to 600 mL min^{-1} lead to the increase of signal intensity. After that, the signal decreased gradually. The maximum signal was obtained at 600 mL min^{-1} for both concentrations.

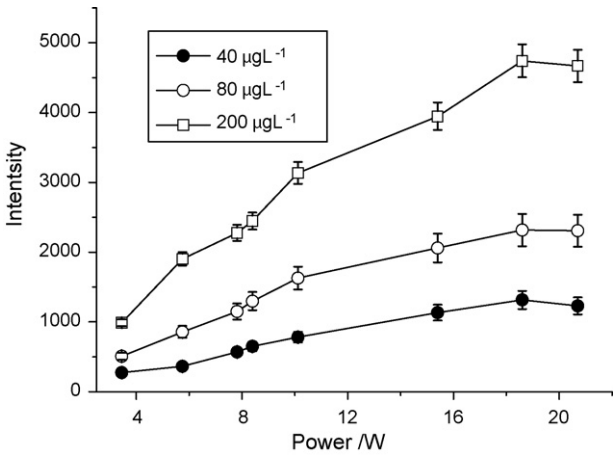

Fig. 4. Investigation of discharge power on the fluorescence signal.

3.3. Optimization of discharge power

A higher discharge power gives stronger signal intensity of Bi. The effects of discharge power (2–22 W) on the fluorescence signal of 40, 80 and 200 μg L^{-1} of Bi were shown in Fig. 4. The maximum fluorescence signal was observed at the power of 19 W. The plasma became unstable with observable flicker when the power is above 22 W.

3.4. Analytical performance

Using the peak area as quantitative parameter, the calibration curve of Bi concentration was linear over the range of 0.5–300 μg L^{-1}. The relative standard deviation for 10 and 50 μg L^{-1} Bi standard solution were 2.0% and 2.2% ($n = 11$) respectively. The limit of detection was 0.07 μg L^{-1}, calculated by the concentration of analyte producing a signal equal to three times the standard deviation of the blank (3σ).

3.5. Validation and sample analysis

To demonstrate the analytical accuracy of the present procedure, the use of HG–DBD–AFS for Bi determination was validated by the analysis of reference materials (Lamiaria Japonica Aresch GBW08517, and Laver GSB-14). The results were shown in Table 3 and the determined results are in agreement with the certified values, indicating the effectiveness of the established method.

The method was applied for the determination of Bi in soil, ore and coal ash samples. The results were given in Table 3. For comparison, results obtained by using ICP-MS were also given in Table 3. The results showed good agreement with the values of ICP-MS. The samples were also spiked with a standard Bi solution and recovery factors were found to be from 95.2 to 106.

Table 3
Analytical results of Bi in CRMs and real samples*.

Sample	Certified (mg kg^{-1})	ICP-MS (mg kg^{-1})	HG-AFS (mg kg^{-1})	Recovery (%)
GBW08517 (Lamiaria Japonica Aresch)	3.3 ± 0.4	2.97 ± 0.01	2.93 ± 0.06	106.3
GSB-14 (Laver)	3.1 ± 0.4	2.85 ± 0.02	2.85 ± 0.07	105.4
Ore	–	0.493 ± 0.007	0.490 ± 0.008	98.6
Soil	–	0.221 ± 0.004	0.21 6 ± 0.002	95.2
Coal ash	–	0.728 ± 0.003	0.71 5 ± 0.012	96.7

ABSTRACT

A new rapid separation method that allows separation and preconcentration of actinides in urine samples was developed for the measurement of longer lived actinides by inductively coupled plasma mass spectrometry (ICP-MS) and short-lived actinides by alpha spectrometry; a hybrid approach. This method uses stacked extraction chromatography cartridges and vacuum box technology to facilitate rapid separations. Preconcentration, if required, is performed using a streamlined calcium phosphate precipitation. Similar technology has been applied to separate actinides prior to measurement by alpha spectrometry, but this new method has been developed with elution reagents now compatible with ICP-MS as well. Purified solutions are split between ICP-MS and alpha spectrometry so that long- and short-lived actinide isotopes can be measured successfully. The method allows for simultaneous extraction of 24 samples (including QC samples) in less than 3 h. Simultaneous sample preparation can offer significant time savings over sequential sample preparation. For example, sequential sample preparation of 24 samples taking just 15 min each requires 6 h to complete. The simplicity and speed of this new method makes it attractive for radiological emergency response. If preconcentration is applied, the method is applicable to larger sample aliquots for occupational exposures as well. The chemical recoveries are typically greater than 90%, in contrast to other reported methods using flow injection separation techniques for urine samples where plutonium yields were 70–80%. This method allows measurement of both long-lived and short-lived actinide isotopes. ^{239}Pu, ^{242}Pu, ^{237}Np, ^{243}Am, ^{234}U, ^{235}U and ^{238}U were measured by ICP-MS, while ^{236}Pu, ^{238}Pu, ^{239}Pu, ^{241}Am, ^{243}Am and ^{244}Cm were measured by alpha spectrometry. The method can also be adapted so that the separation of uranium isotopes for assay is not required, if uranium assay by direct dilution of the urine sample is preferred instead. Multiple vacuum box locations may be set-up to supply several ICP-MS units with purified sample fractions such that a high sample throughput may be achieved, while still allowing for rapid measurement of short-lived actinides by alpha spectrometry.

1. Introduction

The use of nuclear power and the risks associated with nuclear proliferation have led to growing public concern about potential contamination of radioactive materials on the environment and on the health of individuals. Actinides are considered extremely hazardous radionuclides due to their chemical toxicity and high dose contribution for many of the isotopes. Even small quantities of actinides can cause can cause serious health hazards. The measurement of actinides in urine is not only important for occupational health monitoring but also in response to a radiological emergency event, such as the nuclear accident at Chernobyl or detonation of a radiological dispersal device (RDD) by terrorists. There is an increasing need to develop faster analytical methods with high sample throughput for emergency response, including emergency urine samples [1]. Rapid methods using extraction chromatography and alpha spectrometry have been reported by this laboratory for both emergency water and urine samples [2–4]. Inductively coupled plasma mass spectrometry (ICP-MS) is a versatile technique for elemental and isotopic analysis. The measurement time for sequential assay by ICP-MS is typically shorter than alpha spectrometry, although the alpha spectrometry measurements may be performed simultaneously with large numbers of detectors. ICP-MS is particularly effective for longer lived actinide isotopes, where alpha spectrometry works very well for short-lived actinide isotopes. Alpha spectrometry cannot differentiate well between alpha isotopes with overlapping alpha energies. Although alpha spectrometry can measure total ^{239}Pu + ^{240}Pu, for example, it cannot differentiate between ^{239}Pu and ^{240}Pu isotopes. In contrast, ^{239}Pu and ^{240}Pu are easily differentiated by ICP-MS. Actinide determination by ICP-MS, however, can be hampered by isobaric, polyatomic interferences and signal suppression [5]. Both mea-

doi:10.1016/j.talanta.2009.06.041

surement techniques may require separation of interferences to determine actinide isotopes accurately, depending on the sample matrix and the detection limit required. A variety of online and offline separation techniques have been reported in recent reviews for ICP-MS applications, covering a wide range of matrices (soil, sediment, water, biological and urine samples) [6]. This paper will focus more specifically on recent developments and progress with regard to assay of actinides in urine samples, but progress in rapid actinide separation techniques for urine have application to environmental and biological matrices as well.

A large number of flow injection techniques coupled with ICP-MS instrumentation have been reported for urine. Hang et al. using TRU Resin to separate actinides, but this work lacked the selectivity needed to measure actinides at ultra trace levels in urine, due to overlapping of actinide peaks [7]. Pappas et al. reported a rapid method for emergency response for Pu in 1 ml urine samples without digestion or coprecipitation before chemical separation. TEVA resin was used along with a desolvating introduction system to minimize the impact of $^{238}U^{1}H^{+}$ and other interferences at $m/z = 239$. The plutonium was eluted from TEVA Resin with 1 ml 1.4 M HF, after rinsing TEVA Resin with 0.8 M HNO_3. The reduction in uranium interference was significant, and the accuracy of Pu-239 in spiked urine samples was very good, but Pu-242 yield results were not reported. [8]. Epov et al. reported an automated preconcentration system using TRU Resin, but indicated that the separation of uranium from plutonium was not complete. In addition, the Pu yields using TRU Resin were variable and at times less than 50%, without yield correction using ^{175}Lu tracer. After correction using ^{175}Lu tracer, which was also retained on TRU Resin, the Pu recoveries were typically greater than 90%. Urine sample matrix effects were reduced with sample digestion, but this increased sample analysis time from 1 to 4 h for 5 samples [9]. Lariviere et al. reported an automated flow injection system using TEVA Resin with chemical yields averaging 83% for 10 ml urine sample aliquots, but when a co-precipitation step was added for larger sample aliquots, the chemical yield for Pu dropped to approximately 70% [5]. This system was very rapid and effective, but this work was limited to plutonium separation only. Zoriy, who used a similar calcium phosphate protocol for occupational health samples, also reported chemical yields of about 70% for plutonium in urine using TEVA Resin [10].

Varga et al. used alpha spectrometry to determine the relatively short-lived isotopes ^{241}Am and ^{238}Pu and inductively coupled plasma sector field mass spectrometry (ICP-SFMS) for ^{239}Pu, ^{240}Pu and ^{241}Am in small soil samples [11]. UTEVA and TRU Resins were used to separate Am and Pu fractions. The Pu strip solution (0.1 M ammonium bioxalate) and the Am strip solution (9 M HCl + 4 M HCl) from TRU Resin were evaporated to dryness multiple times and wet-ashed with concentrated HNO_3 and H_2O_2 to prior to analysis by ICP-SFMS and alpha spectrometry, increasing the sample preparation time.

Ayranov et al. reported a method which employed TOPO (tri-n-octylphosphine oxide) in cyclohexane liquid–liquid extraction combined with subsequent TRU Resin and TEVA Resin separations [12]. The initial separation using TOPO extraction was reported to be somewhat time-consuming, but more effective for removal of U and Th interferences than using the TRU Resin/TEVA Resin alone. The chemical yields for Pu and Am using this method were good. The Pu recoveries were greater than 90% by high resolution inductively coupled mass spectrometry (HR-ICP-MS), but 79.7% by alpha spectrometry. The Am recoveries were 87% by HR-ICP-MS, but 79% by alpha spectrometry. Pu was stripped from TEVA Resin using 0.02 M HNO_3–0.02 M HF, referencing a 1997 paper from this SRS laboratory [13].

TEVA Resin has been used in the Savannah River Site (SRS) Environmental Bioassay Laboratory for many years, with excellent recovery of Pu. The key to achieving quantitative elution for trace level Pu from TEVA Resin is the use of a reductant during the elution step to reduce Pu(IV) to unretained Pu(III) [1,14]. Our experience has been that TEVA Resin eluant strip solutions such as 0.02 M HNO_3–0.02 M HF work well for higher level Pu samples (nuclear process level samples), but not very well for low level Pu (environmental and bioassay samples). Low level Pu is not stripped effectively from TEVA Resin without the presence of a reductant in the eluant solution. With a reductant present, the stripping of Pu from TEVA Resin is quantitative.

Recently, the SRS lab participated in the NIST NRIP emergency response exercise and reported actinide results for emergency urine samples in 3–4 h. This rapid method employed calcium phosphate precipitation, stacked TEVA Resin and TRU Resin cartridges and alpha spectrometry with very rapid flow rates [3]. This work has shown that alpha spectrometry methods, using vacuum boxes and stacked cartridge technology, can be performed very rapidly. The goal of this work was to adapt this rapid separation technology for ICP-MS measurements of actinides in urine samples.

A new method has been developed in the Savannah River Site (SRS) Environmental Bioassay Laboratory to allow a flexible, hybrid approach for urine samples: the separation of longer lived actinide isotopes for measurement by ICP-MS and short-lived actinide isotopes by alpha spectrometry.

The rapid separation method uses stacked TEVA and TRU Resin cartridges, followed by DGA Resin to allow additional purification of Am/Cm isotopes and the use of a more desirable eluant for ICP-MS applications. If uranium separation is not required for measurement (direct dilution for U isotopes is used instead), TRU Resin is not required, and a stacked TEVA Resin plus DGA Resin column may be used. ^{239}Pu, ^{242}Pu, ^{237}Np, ^{243}Am, ^{234}U, ^{235}U and ^{238}U were measured by ICP-MS, while ^{236}Pu, ^{238}Pu, ^{239}Pu, ^{241}Am, ^{243}Am, and ^{244}Cm were measured by alpha spectrometry. The same column chemistry may be used with small or large urine aliquots. Direct urine aliquots (20 ml or less) may be analyzed with acidification, while large volume sample aliquots may be analyzed when a calcium phosphate preconcentration step is applied. The calcium phosphate precipitation has been streamlined such that it only adds about an hour to the sample preparation time. The goal of this work was to provide a rapid separation chemistry compatible with both alpha spectrometry and ICP-MS to offer maximum flexibility so that both short-lived and long-lived actinide isotopes can be measured using a complementary, hybrid approach.

2. Experimental

2.1. Reagents

The resins employed in this work are TEVA Resin® (Aliquat™336), TRU-Resin® (tri-n-butylphosphate (TBP) and N,N-diisobutylcarbamoylmethylphosphine oxide (CMPO)), and DGA Resin® (N,N,N′,N′ tetraoctyldiglycolamide), available from Eichrom Technologies, Inc., (Lisle, IL, USA). Nitric, hydrochloric and hydrofluoric acids were prepared from reagent-grade acids (Fisher Scientific, Inc., Pittsburgh, PA, USA). All water was obtained from a Milli-Q2™ water purification system. All other materials were ACS reagent grade and were used as received. Radiochemical isotopes ^{239}Pu, ^{242}Pu, ^{237}Np, ^{243}Am, ^{234}U, ^{235}U, ^{238}U ^{236}Pu, ^{238}Pu, ^{241}Am and ^{244}Cm were obtained from Analytics, Inc. (Atlanta, GA, USA) and diluted to the appropriate levels. The synthetic urine composition is shown in Table 1.

2.2. Procedures

2.2.1. Column preparation

TEVA, TRU, and DGA-Resin columns were obtained as cartridges containing 2 ml of each resin from Eichrom Technologies, Inc. (Lisle,

Table 1

IL, USA). Small particle size (50–100 μm) resin was employed, along with a vacuum extraction system (Eichrom Technologies). Flow rates of 1–2 ml min^{-1} were typically used for this work.

2.2.2. Sample preparation

Two different approaches were used. A small volume urine aliquot (5 ml) was acidified to ~3 M HNO_3 and processed through the column chemistry. For large urine aliquots (100 ml), calcium phosphate co-precipitation was applied.

2.2.3. Sample preparation-No Co-precipitation

A 5 ml urine sample was aliquoted into a 50 ml plastic tube. Tracers were added and 1.5 ml 15.7 M HNO_3 was added to adjust the acidity of each sample to ~3 M HNO_3. The samples were swirled to mix each solution. Valence adjustment of the samples was performed by adding 0.25 ml 1.5 M sulfamic acid and 0.5 ml 1.5 M ascorbic acid with a 3-min wait step to reduce plutonium to Pu^{3+}. When ^{237}Np separation was desired, 0.05 ml 5 mg/ml Fe as ferric nitrate was also added to facilitate ^{237}Np reduction to Np^{4+}. The ferric ions are reduced to ferrous ions by the ascorbic acid, which reduces Np effectively to Np^{4+}. After the reduction step, 1 ml 3.5 M sodium nitrite was added to oxidize plutonium to Pu^{4+}. This column load solution was now ready for column separation as described below.

2.2.4. Sample co-precipitation

After the 100 ml urine sample aliquots were dispensed, 1 ml 1.25 M calcium nitrate (50 mg Ca) and 3 ml 3.2 M ammonium hydrogen phosphate were added to each sample. For samples, the sample dispensing and the above reagent additions were performed in 225 ml (urine) centrifuge tubes to save time. The pH was adjusted to ~pH 9.5 with concentrated ammonium hydroxide using a dark pink phenolphthalein endpoint. For darker urine samples, pH paper or a pH meter may be used. The samples were centrifuged at 3500 rpm for ~7 min. After discarding the supernatant, the precipitate was rinsed once with ~15–20 ml of water and centrifuged again at 3500 rpm for ~5 min. The precipitate was dissolved in 8 ml 6 M HNO_3 and 8 ml 2 M $Al(NO_3)_3$ directly in the centrifuge tubes. The final load solution contained 16 ml 3 M HNO_3 and 1 M $Al(NO_3)_3$. The aluminum nitrate was previously scrubbed to remove trace uranium by passing approximately 250 ml 2 M aluminum nitrate through a large column (Environmental Express, Mount Pleasant, SC, USA) containing ~7 ml of UTEVA Resin® (Eichrom Technologies) at ~10 ml/min. The column was prepared from a water slurry of the UTEVA resin. For the 100 ml samples, valence adjustment was performed by adding 0.5 ml 1.5 M sulfamic acid and 1.25 ml 1.5 M ascorbic acid with a 3-min wait step to reduce plutonium to Pu^{3+}. When ^{237}Np separation was desired, 0.4 ml of 5 mg/ml Fe as ferric nitrate was also added to facilitate ^{237}Np reduction to Np^{4+}. To oxidize plutonium to Pu^{4+}, 2 ml 3.5 M sodium nitrite was added to each sample solution. This column load solution was now ready for column separation.

2.2.5. Column separation

The following column separation was performed on small volume or large volume urine sample aliquots (Fig. 1). TEVA and TRU Resin cartridges were stacked on the vacuum box from top to bottom, in that order. Fifty-milliliter centrifuge tubes were used to collect rinse or final purified fractions.

After the valence adjustment, the sample solution was loaded onto the stacked column at approximately ~1 drop/s. After the sample was loaded, a tube rinse of ~ 5 ml 3 M HNO_3 was transferred to the stacked column and allowed to pass through the resin at ~1–2 drop/s. Years of experience in this laboratory has shown there are no channeling or performance issues with small particle resin cartridges going dry. A rinse of 5 ml 3 M HNO_3 was added directly to the stacked column at ~2 drop/s. The TRU Resin cartridges were removed and the TEVA cartridges were kept on the vacuum box. The TEVA cartridge was rinsed with 10 ml 3 M HNO_3 at ~2 drop/s to remove sample matrix components. To elute thorium from TEVA Resin, 15 ml 9 M hydrochloric acid was added at ~1–2 drop/s and discarded. An additional 10 ml 3 M HNO_3 rinse was added after the 9 M HCl rinse to minimize extractant bleedoff during the plutonium elution step and to reduce ICP-MS signal suppression, which may occur with a change in solution viscosity.

The plutonium was stripped from TEVA Resin with 14 ml 0.25 M hydrochloric acid–0.005 M hydrofluoric acid–0.0001 M titanium(III) chloride. The volume was adjusted after elution to exactly 15 ml with the same solution. Typically in this laboratory, when a tracer is used, no volume adjustment is made and 15 ml would be added directly to the column. Since no tracer was used to perform chemical yield adjustment for the ICP-MS measurements, the eluant volume was added in this way with a final volume adjustment to 15 ml after elution. The purified solutions were analyzed by alpha spectrometry and ICP-MS. Five milliliters of each plutonium/neptunium eluant solution was transferred to a separate 50 ml tube and 50 μg of cerium as cerium nitrate were added to the tubes, along with 1 ml concentrated hydrofluoric acid (49%). A 0.5 ml volume of 30 wt% hydrogen peroxide was added after the plutonium was eluted to oxidize any residual uranium to U^{6+} as a precaution. After waiting 15 min, the solutions were filtered onto 0.1 μm 25 mm polypropylene filters (Resolve® filter-Eichrom Technologies) and counted by alpha spectrometry. The remaining solution was transferred to the ICP-MS for Pu and Np measurement.

The TRU cartridges were placed on a separate vacuum box and processed at the same time as the TEVA Resin cartridges to save time. DGA Resin cartridges were placed below each TRU Resin cartridge. Americium/curium was eluted from TRU Resin onto DGA Resin with 15 ml 4 M HCl at ~1–2 drop/s. The TRU Resin cartridges were removed and the DGA Resin was rinsed with 3 ml 1 M HNO_3, then 5 ml of 0.1 M HNO_3 at ~1 drop/s to remove any residual uranium. Am and Cm were eluted using 9.5 ml of 0.25 M HCl at ~1 drop/s. The volume was adjusted after elution to exactly 10 ml with the same solution for reasons described previously. Two milliliters of each solution was transferred to a separate 50 ml tube containing ~10 ml of 0.25 M HCL and 50 μg of cerium as cerium nitrate were added to the tubes, along with 1 ml of concentrated hydrofluoric acid (49%), and filtered after about 15 min to prepare alpha spectrometry mounts. The remaining solution was transferred to the ICP-MS for Am measurement.

Uranium was stripped from TRU Resin using 14 ml 0.01 M ammonium bioxalate at ~1–2 drop/s. The volume was adjusted after elution to exactly 15 ml with the same solution. If uranium sep-

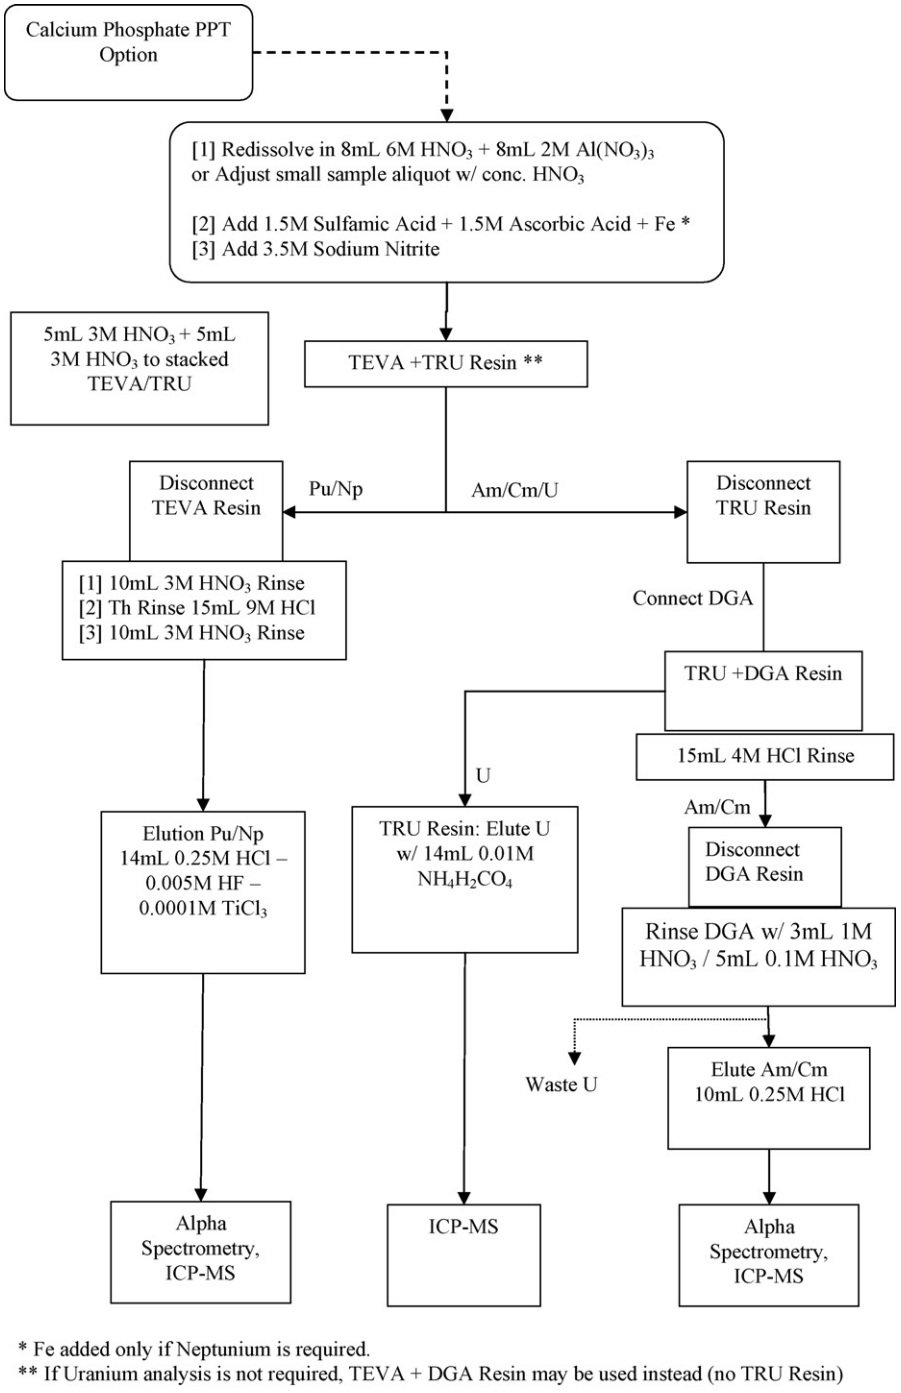

Fig. 1. Flow chart of rapid column extraction method for urine.

aration and measurement is not required, TRU Resin is not needed, and TEVA and DGA Resins can be stacked in tandem without TRU Resin. An increased rinse volume of DGA Resin (15 ml 0.1 M HNO_3 vs 5 ml HNO_3) can be used to remove uranium if TRU Resin is not in place to collect U. It would be possible to strip Am/Cm directly from TRU Resin without DGA Resin but this would require a strong acid such as 4 M HCl, which would typically have to be diluted or evaporated and wet-ashed prior to analysis using ICP-MS. DGA allows Am/Cm elution with 0.25 M HCl, which is more compatible with ICP-MS, and can provide additional uranium removal if needed.

Actinide filters were counted by alpha spectrometry for approximately 16 h, but shorter count times (<1 h) can also be performed for emergency response samples using higher level tracers [2], depending on the detection limit needed.

2.3. Apparatus

Plutonium, americium, and uranium measurements were performed by alpha-particle pulse-height measurements using Passivated Implanted Planar Silicon (PIPS) detectors. Polycarbonate vacuum boxes with 24 positions and a rack to hold 50 ml plastic tubes were used. Two boxes were connected to a single vacuum source by using a T-connector and individual valves on the tubing to each box.

An Agilent Quadrupole ICP-MS was used to perform the ICP-MS measurements. The instrument operating conditions are shown in Table 2.

The ICP-MS methodology is described in "Standard Practice for Alternate Actinide Calibration for Inductively Coupled Plasma-Mass

Spectrometry" [15]. The calibration is mass bias adjusted using thorium-232 (^{232}Th) and uranium-238 (^{238}U) standards. At each standard concentration, the slope of the line defined by ^{232}Th and ^{238}U is used to derive linear calibration curves for each mass of interest (232–244 amu) using interference equations. The mass bias corrected calibration curves, although generated from interference equations, are specific to the instrument operating parameters and tuning in effect at the time of data acquisition. One of the benefits of this standard practice is the ability to calibrate for the analysis of highly radioactive actinides using calibration standards at much lower specific activities.

3. Results and discussion

The rapid separation of actinides was performed on ten 100 ml urine samples. Samples 1–5 were blank human urine, while samples 6–10 were synthetic urine samples. Known amounts of actinide isotopes were added to each sample. Calcium phosphate precipitation, as described above, was applied to all 10 samples. Samples were analyzed for short-lived isotopes by alpha spectrometry and longer lived actinide isotopes were analyzed by ICP-MS. ^{239}Pu and ^{243}Am isotopes were measured by both ICP-MS and alpha spectrometry techniques. The results for the determination of Am–Cm isotopes by alpha spectrometry are shown in Table 3. The average tracer recovery for ^{243}Am was 105% (±2.5% RSD), with an average measured value for ^{243}Am of 72.0 mBq (−2.65% bias) and an average measured value for ^{244}Cm of 65.4 mBq (+2.14% bias). The ^{241}Am and ^{244}Cm results were corrected for the ^{243}Am tracer recoveries in each sample. The Am/Cm recoveries were excellent, with high chemical yield and very little bias for ^{241}Am and ^{244}Cm.

The results for the Pu isotopes by alpha spectrometry are shown in Table 4. The average tracer recovery for ^{236}Pu was 99.0% (±10% RSD). The average result for ^{238}Pu was 73.7 mBq (1.12% bias) and the average result for ^{239}Pu was 854 mBq (2.58% bias). The MDA using alpha spectrometry, which is dependent on sample volume used and count time, can be adjusted as needed for emergency or routine samples [3].

The Pu and Np isotope results by ICP-MS are shown in Table 5. The average ^{239}Pu result at the ICP-MS was 0.0252 ng/ml (4.02% bias) and the average ^{242}Pu result was 0.1366 ng/ml (−0.01% bias). The Pu results by ICP-MS were not corrected for tracer, but instead were corrected for a negative bias at the ICP-MS observed on a Pu standard in the same matrix that did not undergo column separation. This bias was only seen on this particular analysis run and does not seem to be caused by the eluant matrix, which has been used previously with no negative bias. Tracer correction using ^{242}Pu would have also corrected for the bias observed for this analysis run. The average result for ^{237}Np was 0.1829 ng/ml (0.24% bias), indicating excellent recovery of ^{237}Np as well. Six additional 100 ml urine samples were analyzed for Pu isotopes by ICP to verify that the Pu eluant matrix does not cause a significant negative bias at the ICP-MS. Table 6 shows the Pu results by ICP-MS from this test. The average ^{239}Pu result was 0.0447 ng/ml (−7.71% bias) and the average ^{242}Pu result was 0.1278 ng/ml (−6.42%), indicating the Pu eluant matrix does not cause any significant bias at the ICP-MS and confirming that the method provides a high chemical yield for plutonium. Tracer correction using ^{242}Pu could have been applied, if desired, and an even smaller negative bias would have resulted.

No correction made for direct Pu standard vs. calibration. Concentration (ng/ml) in final solution at ICP-MS.

Fig. 2 shows the ^{209}Bi internal standard measurements for the same set of six urine samples analyzed for Pu isotopes by ICP-MS. There is a slight reduction in ^{209}Bi internal standard signal for the urine samples in the Pu sample eluant matrix (avg. = 1.24E6 cps) compared to the 1% nitric acid blanks (avg. = 134E6 cps) analyzed along with the samples. This is only a 7.5% reduction in internal standard signal, well within the normal range of instrument drift, demonstrating minimal potential impact on signal reduction using the Pu eluant matrix (0.25 M HCL–0.005 M HF–0.0001 M $TiCl_3$) without dilution. The decontamination factor (DF) from uranium is very good using TEVA Resin, with sufficient rinsing with 3 M HNO_3 to remove U. The amount of U-238 found in most of the Pu fractions was not detectable by ICP-MS. The DF for uranium was estimated at >1000, which is typical for a single column extraction chromatography separation.

Table 7 shows Am-243 isotope results by ICP-MS. The Am-241 and Cm-244 levels were too low to determine, but the Am-243 measurements were very good. The average ^{243}Am result at the ICP-MS was 0.0244 ng/ml (−2.44% bias). No chemical yield correction was applied. This test demonstrates that Am can be measured by ICP-MS using this method, including ^{241}Am if the ICP-MS used had sufficient sensitivity. The decontamination factor from uranium is excellent because the Am and Cm is moved from TRU Resin to DGA Resin, with a additional rinsing prior to elution of Am and Cm. The average amount of U-238 found in the Am fraction was 0.0013% (DF = ~75,000). The Am/Cm eluant strip solution for DGA, 0.25 M HCl, was analyzed directly by ICP-MS without evaporation or wet-ashing. As noted earlier, if U measurement is not required, a stacked column using TEVA Resin + DGA Resin may be used instead. The only change in protocol is increased rinsing of DGA with 0.1 M HNO_3 to ensure adequate uranium removal from DGA.

The results for ^{238}U by ICP-MS are shown in Table 8. The first five results from human urine sample show an average result for ^{238}U of 3.556 ng/ml at the ICP-MS (6.79% bias), while the synthetic urine sample showed a significant positive bias. It was found that the synthetic urine had ^{238}U content in the blank solution of

[a] U-238 corrected for U-238 content in blank synthetic urine.

1.79 ng ^{238}U/ml. After the sample results were corrected for this uranium content in the unspiked synthetic urine the result was reduced from 5.54 to 3.74, only a 12.5% positive bias.

Table 9 shows uranium isotope results from the analysis of an emergency urine sample received from the National Institute of Standards and Technology (NIST). Five ml replicate sample aliquots were analyzed without calcium phosphate preconcentration. The average result for ^{234}U was 0.0036 ng/ml (13.28% bias). This result is very good, considering the shorter half life of ^{234}U and the low level of ^{234}U present. The average result for ^{235}U was 0.4296 ng/ml (−0.44%) and the average ^{238}U measured value was 60.99 (2.71% bias). The other shorter lived actinide isotopes (^{238}Pu, ^{241}Am) in the NIST emergency exercise samples were too low to measure by ICP-MS with the 5 ml aliquots analyzed. This illustrates the value of rapid calcium phosphate precipitation preconcentration step to improve detection limits. Other shorter lived actinide isotopes

(^{238}Pu, ^{241}Am) present in the NRIP urine samples were too low to determine using ICP-MS using a 5 ml sample aliquot.

Table 10 shows method LLD and LLQ values for the different isotopes by ICP-MS using a 100 ml sample aliquot. The LLD and LLQ results were calculated using the equations as prescribed by Taylor [17]. These method LLD and LLQ results include a preconcentration factor of 6.67 for all the isotopes except the ^{243}Am results, which include a preconcentration factor of 10. The LLD and LLQ results can be lowered by increasing the sample aliquots as needed. Table 11 shows method LLD and LLQ values for the uranium isotopes by ICP-MS using a 5 ml direct sample aliquot. These method LLD and LLQ results include a dilution factor of 1/3 when a 5 ml aliquot is taken, increasing the LLD and LLQ. The LLD and LLQ results can be lowered by increasing the sample aliquots as needed. The ^{238}U LLD and LLQ values are likely higher due to slight ^{238}U contamination, which may have added variability to the ^{238}U measurements.

The MDA (Minimum Detectable Activity) for the actinide isotopes by alpha spectrometry were calculated according to equations prescribed by Currie [16]:

$$\mathrm{MDA} = \frac{3 + 4.65\sqrt{B}}{\mathrm{CT} \times R \times V \times \mathrm{EFF} \times 0.060}$$

where B = total background counts, =BKG (rate) × BKG count time; CT = sample count time (min); R = chemical recovery; V = sample volume (l); EFF = detector efficiency; 0.060 = conversion from dpm to mBq

In low-level counting, where a zero background count is quite common, the constant 3 is used to prevent an excessively high false positive rate.

The MDA for the alpha spectrometry results can be adjusted as needed, depending on the sample aliquot and count time. Pappas has established the ^{239}Pu action level as 4.8 mBq l^{-1} based on a single dose exposure of 500 mSv [5]. For a 100 ml sample aliquot,

the MDA for a 2 h count time is 16.3 mBq l^{-1}. For a 400 ml sample aliquot and 2 h count time the MDA is 4.07 mBq l^{-1}. For a 100 ml sample aliquot, the MDA for a 22 h count time is 1.5 mBq l^{-1}. For a 400 ml sample aliquot and 22 h count time the MDA is 0.37 mBq l^{-1}. Depending on the MDA required, the sample aliquot and count time may be adjusted accordingly.

The rapid column separation is compatible with ICP-MS or alpha spectrometry and can be used with or without calcium phosphate preconcentration. The chemical yields were very good and the accuracy and precision of the measurements on the actinide isotopes spiked into the urine samples standards were excellent. The trace level titanium chloride (0.0001 M) used in the plutonium stripping solution effectively reduces Pu to Pu^{3+} for effective elution of Pu from TEVA Resin without adversely affecting the ICP-MS assay. The 0.25 M HCl and 0.01 M ammonium bioxalate eluting reagents are also very compatible with ICP-MS.

The vacuum box column separation system is a low budget alternative to flow injection separation techniques. This stacked cartridge approach provides rapid flow rates and effective removal of spectral and other sample matrix interferences for a large number of samples prepared simultaneously. The separation method is flexible and can be adapted to fit specific analytical needs. For example, if uranium separation is not required, TRU Resin is not required in the separation method. Direct urine aliquots up to ~20 ml may be analyzed with acidification, while calcium phosphate coprecipitation may be applied to very large urine aliquots as needed. Multiple vacuum box locations can be used to prepare a large number of samples in an emergency that can be analyzed by alpha spectrometry and/or ICP-MS. Tracer corrections were not applied to the ICP-MS results to highlight the high chemical yields and minimal sample matrix impacts observed, but tracer corrections may be easily applied as needed.

4. Conclusions

A new rapid separation method that allows separation and preconcentration of actinides in emergency or routine urine samples was developed for the determination of longer lived actinides by inductively coupled plasma mass spectrometry (ICP-MS) and short-lived actinides by alpha spectrometry, a hybrid approach. This method uses stacked extraction chromatography cartridges and vacuum box technology to facilitate rapid separations. The method can be used with small acidified urine aliquots or using a streamlined calcium phosphate co-precipitation to preconcentrate actinides in larger sample aliquots. Similar technology has been applied to separate actinides prior to measurement by alpha spectrometry, but this new method has been developed with elution reagents now compatible with ICP-MS as well. The ASTM standard practice for alternate actinide ICP-MS calibration is a good analytical fit with the separation methods described. A single mass bias corrected calibration based on ^{232}Th and ^{238}U enables rapid ICP-MS determination of a suite of actinide isotopes. Purified solutions are split between ICP-MS and alpha spectrometry so that long and short-lived actinide isotopes can be measured successfully. The method is rapid, flexible, offers high chemical recoveries, excellent removal of interferences and can be used to provide high sample throughput in a radiological emergency.

Acknowledgments

This work was performed under the auspices of the Department of Energy, DOE Contract No. DE-AC09-96SR18500. The authors wish to acknowledge Rebecca Chavous for her assistance with this work.

Pharmaceutical analysis

ABSTRACT

Studies were carried out, for the first time, to investigate the charge–transfer reactions of ganciclovir as n-electron donor with the σ-acceptor iodine and various π-acceptors: 7,7,8,8-tetracyanoquinodimethane; tetracyanoethylene; 2,3-dichloro-5,6-dicyano-1,4-benzoquinone; *p*-chloranilic acid; 2,3,5,6-tetrabromo-1,4-benzoquinone; 2,3,5,6-tetrachloro-1,4-benzoquinone and 2,4,7-trinitro-9-fluorenone. The formation of the colored charge–transfer complexes was utilized in the development of simple, rapid and accurate spectrophotometric methods for the analysis of ganciclovir in pure form as well as in its pharmaceutical formulation (capsules). Different variables affecting the reactions were studied and optimized. Under the optimum reaction conditions, linear relationships with good correlation coefficients (0.9993–0.9998) were found between the absorbance and the concentration of ganciclovir in the range of 2.0–240 μg mL^{-1}. For more accurate analysis, Ringbom optimum concentration range was found to be between 5.0 and 225 μg mL^{-1}. The limits of detection ranged from 0.36 to 2.45 μg mL^{-1} and the limits of quantification ranged from 1.20 to 8.17 μg mL^{-1}. A Job's plot of the absorbance versus the molar ratio of ganciclovir to each of acceptors under consideration indicated (1:1) ratio. The proposed methods were applied successfully for simultaneous determination of ganciclovir in capsules with good accuracy and precision and without interferences from common additives. The recovery percentages ranged from 99.45 ± 0.73% to 100.35 ± 1.40%. The results were compared favourably with the reported method.

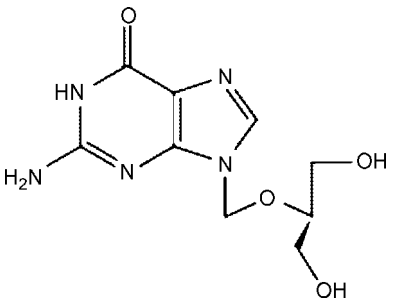
1. Introduction

Ganciclovir (GCV), (2-amino-9-{[(1,3-dihydroxypropan-2-yl)-oxy]methyl}-6,9-dihydro-3*H*-purin-6-one) is an antiviral medication used to treat or prevent cytomegalovirus (CMV) infections, a virus that affects the eyes of immunosuppressed patients. Ganciclovir (GCV), is nucleoside analogue with antiviral activity for prophylaxis and treatment against herpes simplex virus or CMV [1]. The structures of this antiviral drug (GCV) is shown in Scheme 1.



The quantitation of GCV in biological samples poses an important challenge because this drug is structurally similar to endogenous substances. Hence, this complicates analysis and requires using a highly selective analytical method. Some analytical methods have been reported for determination of GCV including voltammetry [2], chemiluminescence [3], capillary electrophoresis [4], high-performance liquid chromatography (HPLC) [5–17]. Visible spectrophotometry, because of simplicity and cost effectiveness, sensitivity and selectivity, fair accuracy, precision and available in most quality control laboratories, has remained competitive in an area of chromatographic techniques for pharmaceutical analysis. Furthermore, they do not need costly instrumentation required for published HPLC methods.

The molecular interactions between electron donors and acceptors are generally associated with the formation of intensely colored charge–transfer complexes, which absorb radiation in the visible region [18]. A variety of electron donating compounds have been reported to yield charge-transfer complexes with various acceptors. The rapid formation of these complexes leads to their utility in the development of simple and convenient spectrophotometric methods for these compounds [19–39].

Ganciclovir is a good n-electron donor and will form charge–transfer complexes with σ-acceptor like iodine and π-acceptors such as 7,7,8,8-tetracyanoquinodimethane (TCNQ); tetracyanoethylene (TCNE); 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ); *p*-chloranilic acid (*p*CA); 2,3,5,6-tetrabromo-1,4-benzoquinone (BL), 2,3,5,6-tetrachloro-1,4-benzoquinone (CL) and 2,4,7-trinitro-9-fluorenone (TNF) are known to yield charge–transfer complexes and radical anions. The charge– transfer reaction has not yet been reported for GCV; therefore the aim of the present study was directed to investigate simple, direct, sensitive and precise spectrophotometric methods for simultaneous determination of GCV via complexation with σ- and π-acceptors in pure form and its dosage forms (capsules).

Scheme 1. Structural formula of ganciclovir.

2. Experimental

2.1. Apparatus

All absorption spectra were made using Kontron 930 (UV–visible) spectrophotometer (German) with a scanning speed of 200 nm min^{-1} and a bandwidth of 2.0 nm, equipped with 10 mm matched quartz cells.

2.2. Materials and reagents

Pure grade ganciclovir (GCV) and its pharmaceutical formulations were obtained from Roche Pharm. Inc. (New Zealand) and were used as working standard.

7,7,8,8-tetracyanoquinodimethane (TCNQ), Aldrich Chem. Co., Milwaukee, USA, and tetracyanoethylene (TCNE), Nacalai Tesque, Kyoto, Japan, 1.0 mg mL^{-1} were prepared in acetonitrile, the solutions were stable for at least one week at 4 °C. Chloranilic acid (*p*CA) and chloranil (CL), Fluka, Switzerland, 2.0 mg mL^{-1} in acetonitrile, were prepared fresh daily.

2,3-Dichloro-5,6-dicyano-p-benzoquinone (DDQ), Merck-Schuchardt, Munich, Germany and p-bromanil (BL), Hopkin and William, Essex, England, 2.0 and 5.0 mg mL^{-1} in methanol, the solutions were prepared fresh daily.

Iodine resublimed, Riedel De-Haen, Germany and 2,4,7-trinitro-9-fluorenon (TNF), Fluka, Switzerland, 5.0 and 2.0 mg mL^{-1} in 1,2-dichloroethane were prepared, the solutions were stable for at least one week at 4 °C. All reagents and solvents used were of analytical-reagent grade. In the same manner, stock solution of 2×10^{-3} M of acceptor was also prepared.

2.3. Pharmaceutical formulations

The commercial capsules used in the present investigation were Cymevene capsules (Roche Pharm. Inc., New Zealand), labeled to contain 250 mg GCV per capsule.

2.4. Preparation of stock standard solution

Standard stock solution of GCV (1.0 mg mL^{-1}) was prepared by accurately weighting and dissolving 100 mg of GCV in 2.0 mL methanol in a 100 mL calibrated flask and completed to volume with the same solvent (for DDQ and BL), with 1,2-dichloroethane (for iodine and TNF), and with acetonitrile (for the other acceptors, TCNQ, TCNE, *p*CA an CL). These stock solutions were diluted with the respective solvents to obtain suitable concentrations that lie in the linear range of each particular assay method, in the same manner, stock solution of 2×10^{-3} M of drug was also prepared. The solutions were stable for at least one week at 4 °C.

2.5. General analytical procedure

Into 10-mL calibrated flasks were placed 0.1–2.4 mL aliquot volumes of 1000 μg mL^{-1} of GCV in methanol for DDQ and BL, in 1,2-dichloroethane for iodine and TNF and in acetonitrile for TCNE, *p*CA and CL and placed 0.1–2.5 mL aliquot volumes of 200 μg mL^{-1} of GCV in acetonitrile for TCNQ. One milliliter of the acceptor reagent solutions was added. The reaction mixture was allowed to stand for 5.0, 10 and 15 min at (60 ± 2 °C) in case of (TCNE and DDQ), (TCNQ, *p*CA and CL) and (BL and TNF), respectively. The reaction in case of iodine was achieved instantaneously. The volume was made up 10 mL with methanol (for DDQ and BL), 1,2-dichloroethane (for iodine and TNF) and with acetonitrile (for the other acceptors, TCNQ, TCNE, *p*CA an CL). The absorbance of the resulting solutions was measured at the wavelengths of maximum absorption 365, 840, 415, 465, 530, 460, 550, and 413 nm for iodine, TCNQ, TCNE, DDQ, *p*CA, BL, CL, and TNF, respectively against reagent blank prepared in the same manner.

2.6. Procedure for capsules

Ten capsules of the drug were weighed and a quantity of the content capsules equivalent to 100 mg was transferred into a 50-mL calibrated flask, dissolved in 2.0 mL methanol, swirled and sonicated for 5 min, completed to volume with the corresponding solvent (as in stock solutions), shaken well for 10 min, and filtered. The first portion of the filtrate was rejected, and a measured volume of the filtrate was diluted quantitatively with a suitable solvent to yield suitable concentrations lie in the linear range of each particular assay method; then the procedure was followed as above.

2.7. Determination of molar ratio of reactants in complex

Job's method of continuous variation [40] was employed, a 2.0×10^{-3} M standard solution of drug and reagents were used. A series of solutions was prepared in which the total volume of GCV and reagent was constant (2.0 mL). The drug and reagents were mixed in various complementary proportions (0:10, 1:9, . . ., 9:1, 10:0, inclusive) and then diluted in a 10-mL calibrated flask with

Table 1
Optimum reaction conditions for the charge–transfer reaction of GCV with various acceptors.

Acceptor	Reagent concentration (mg mL^{-1})	Solvent	Time (min)	Temp, °C	λ_{max}, nm
Iodine (1.7)[a]	5.0	1,2-Dichloroethane	At once	25 ± 2	365
TCNQ (1.7)	1.0	Acetonitrile	10	60 ± 2	840
TCNE (2.2)	1.0	Acetonitrile	5	60 ± 2	415
DDQ (1.9)	2.0	Methanol	5	60 ± 2	465
pCA	2.0	Acetonitrile	10	60 ± 2	530
Bromanil (1.37)	5.0	Methanol	15	60 ± 2	460
Chloranil (1.37)	2.0	Acetonitrile	10	60 ± 2	550
TNF (1.1)	2.0	1,2-Dichloroethane	15	60 ± 2	413

[a] Figures in parenthesis are the electron affinities of the acceptors; from Ref. [18].

the optimum solvent. The reactions were allowed to proceed for the optimum reaction time (Table 1) and the absorbance of the resulting solutions was measured at the corresponding wavelengths of maximum absorbance (λ_{max}) against a reagent blank under the same conditions.

2.8. Association constant

Serial volumes of 1.0–5.0 mL of 2.0×10^{-3} M GCV solution (in 1.0 mL steps) in the optimum solvent were transferred in 10-mL calibrated flasks. To each flask, 1.0 mL of acceptor solution (2.0×10^{-3} M) was added and continued as directed under general procedure.

3. Results and discussion

3.1. Spectral characteristics of the reaction

3.1.1. Reaction with σ-acceptor (iodine)

The color of iodine in 1,2-dichloroethane is violet showing absorption maximum (λ_{max}) at 520 nm. This color was immediately changed into lemon yellow, and the absorption spectrum of GCV-iodine reaction product showed absorption peaks at 290 and 365 nm (Fig. 1). This change in color, and the appearance of these two peaks were attributed to the formation of charge–transfer complex between the GCV and iodine, having an ionized structure $DI^+ \ldots I_3^-$, taking into account that the absorption spectrum of I_3^- in 1,2-dichloroethane showed the two absorption maxima at 290 and 365 nm. This complex should originate from an early intermediated outer complex $D \ldots I_2$, according to the following scheme:

$$D + I_2 \rightleftharpoons \underset{\text{Outer complex}}{D\text{-}I^+ I^-} \rightleftharpoons \underset{\text{inner complex}}{[D\text{-}I^+]} + I^- \rightleftharpoons \underset{\text{tri-iodide ion pair}}{I_3^-}$$

Further confirmation for the charge–transfer nature of the reaction, GCV was extracted from the complex by shaking with aqueous mineral acids. The color of iodine in 1,2-dichloroethane layer was restored to violet, confirming the charge–transfer nature of the reaction. Measurements were carried out at 365 nm due to the interference from the native UV absorption of GCV at 290 nm.

3.1.2. Reaction with π-acceptors

The interaction of GCV with selective polyhaloquinone and polycyanoquinone π-acceptors in non-polar solvents such as dichloroethane was found to produce colored charge–transfer complexes with low molar absorptivity values [41]. In polar solvents such as methanol or acetonitrile, complete electron transfer from the GCV (D), as an electron donor, to the acceptor moiety (A) takes place with the formation of intensely colored radical ions with high molar absorptivity values, according to the following scheme:

$$D^{\bullet} + A \rightleftharpoons \underset{\text{DA complex}}{\left[D^{\bullet\bullet} \rightarrow A\right]} \overset{\text{Polar solvent}}{\rightleftharpoons} D^{\bullet+} + \underset{\text{radical anion}}{A^{\bullet-}}$$

The dissociation of the (D–A) complex was promoted by the high ionizing power of the polar solvent and the resulting peaks in the absorption spectra of GCV-acceptor reaction mixtures were similar to the maxima of the radical anions of the acceptors obtained by the iodide reduction method [41].

The interaction of GCV with π-acceptors at optimum temperature gave colored chromogens showing different absorption maxima at 840, 415, 465, 530, 460, 550, and 413 nm for TCNQ, TCNE, DDQ, *p*CA, BL, CL and TNF, respectively (Figs. 2–5).

The resulting maxima of the investigated drug with DDQ, TNF, *p*CA, BL and CL are similar to that of the radical anion of these acceptors obtained by the reduction method and coincide with the values reported in previous work [42,43].

The predominent chromogen with TCNQ in acetonitrile is the bluish-green colored radical anion, which exhibits strong absorption maxima at 840, 825, 762, and 742 nm. These bands may be attributed to the formation of the radical anion $TCNQ^{\bullet-}$, which was probably formed by the dissociation of an original donor–acceptor

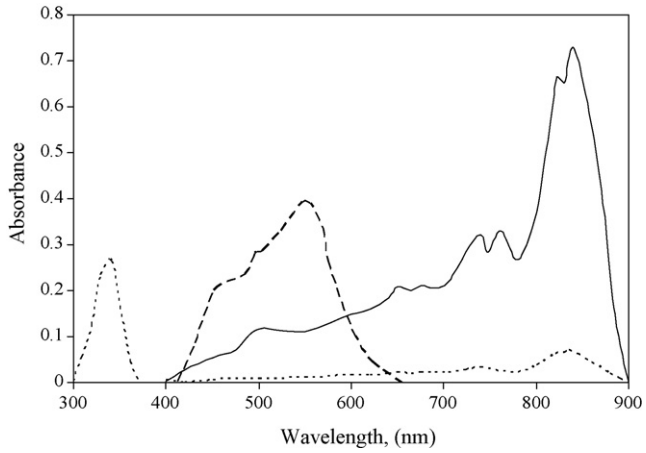

Fig. 2. Absorption spectra of TCNQ and CL (. . .) and the reaction product of 25 and 50 μg mL^{-1} GCV with TCNQ (—) and CL (- - - -), respectively in acetonitrile.

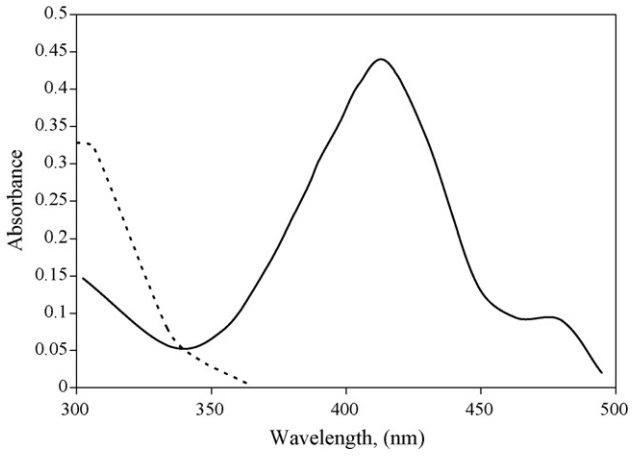

Fig. 3. Absorption spectra of TCNE (. . .) and the reaction product of 100 μg mL^{-1} GCV with TCNE (—) in acetonitrile.

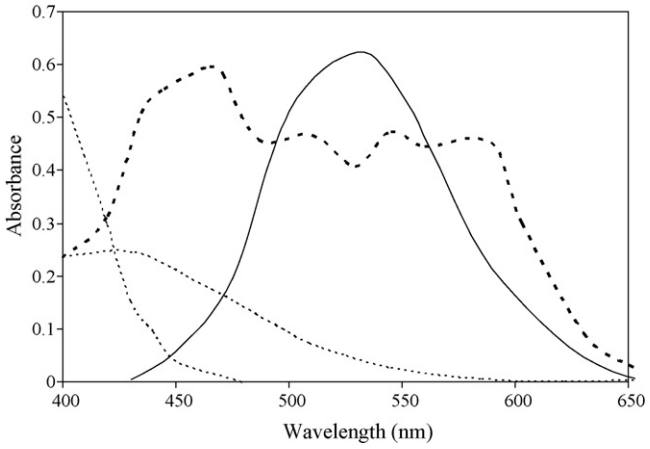

Fig. 4. Absorption spectra of DDQ and *p*CA (. . .) and the reaction product of 100 and 75 μg mL^{-1} GCV with DDQ (—) in methanol and *p*CA (- - - -) in acetonitrile, respectively.

(D–A) complex with GCV. The dissociation of the complex was promoted by the high ionizing power of acetonitrile. Further support of this assignment was provided by the absorption maxima with those of TCNQ radical anion produced by the iodide reduction method [43] (Fig. 2).

For GCV and TCNE, the characteristically shaped absorption band of TCNE radical anion with reported maximum in acetonitrile at 432 nm was not formed. Instead a doublet at 394 and 415 nm in acetonitrile was formed which corresponds to the 1,1,2,3,30-pentacyanopropenide (PCNP) anion. From the quantitative point of view, PCNP anion is preferable to TCNE anion on grounds of its higher molar absorptivity [41] (Fig. 3).

Chloranilic acid (*p*CA) exists in three ionic forms, the neutral yellow–orange H_2A at very low pH, the dark purple HA^- which is stable at pH 3 and a colorless A^{2-}, which is stable at high pH; these transformations are illustrated in the following scheme:

$$H_2A \rightleftharpoons H^+ + HA^- (\text{violet})$$

$$HA^- \rightleftharpoons H^+ + A^{2-} (\text{colorless})$$

Since the interaction of GCV with *p*CA in acetonitrile gave a violet product, it might be concluded that HA^- was the form of pCA involved in the reaction described herein (Fig. 4).

The relative sensitivity of the eight acceptors employed in the present analytical work may be attributed to their difference in electron affinities (Table 1), as well as the conditions employed in the reaction (reagent concentration, reaction time, and solvent).

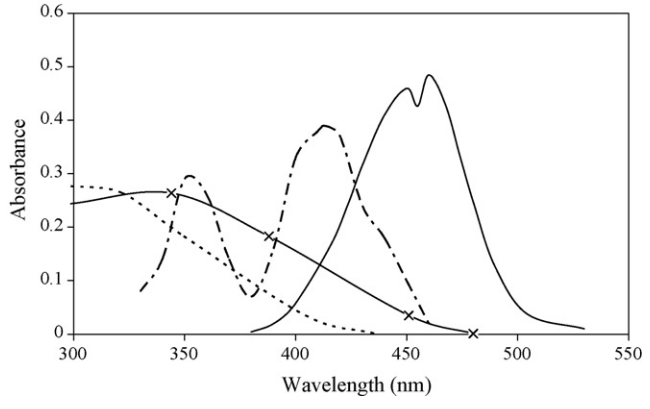

Fig. 5. Absorption spectra of BL (. . .) and TNF (-×-×-) and the reaction product of 100 μg mL^{-1} GCV with BL (—) in methanol and TNF (- - - -) in 1,2-dichloroerthane.

The weak and small molar absorptivity values in cases of TCNE, BL, CL and TNF may be explained on the basis of insufficient ionization of these relatively weak π-acceptors that possess lower electron affinities, than TCNQ, *p*CA and DDQ, exhibiting higher molar absorptivities.

3.2. Optimization of reaction conditions

3.2.1. Effect of reagent concentration

The results for variation of reagent concentration, indicated that 1.0 mL of either 5.0 mg mL^{-1} iodine and BL, 1.0 mg mL^{-1} TCNQ and TCNE and 2.0 mg mL^{-1} DDQ, pCA, CL and TNF are suitable. The higher concentrations of the reagents may, on the other hand, be useful for rapidly reaching equilibrium and complete color development, the results are given in Table 1. This minimizes the time required to attain the maximum absorbance at the corresponding wavelength of the charge–transfer complex.

3.2.2. Effect of solvent

Although charge–transfer complexes are probably formed in many solvents, the high cut-off points of some solvents obscured the scanning of the shorter wavelengths and therefore clear-cut spectroscopic evidence for charge–transfer formation could not be ascertained. Also the low solubility of the GCV in some other solvents restricted their use.

1,2-Dichloroethane was found to be an ideal solvent in case of iodine and TNF (Table 1), because it is favourable for the formation of tri-iodide ion pair (inner complex). With iodine, GCV showed a major charge–transfer band at 365 nm. Methylene chloride, chloroform and carbon tetrachloride produced lower absorption readings. Polar solvents were found to be unsuitable as their blanks with iodine and TNF gave higher readings.

The formation of TCNQ radical was possible in methanol; however, the response between absorbance and concentration was not linear. Furthermore, the molar absorptivity of the obtained chromogen was relatively low compared with that in acetonitrile. The latter was considered as an ideal solvent because it offered excellent solvating power for TCNQ reagent and gave high absorbance.

For TCNE, *p*CA, CL complex formation, acetonitrile afforded maximum sensitivity when compared with all other solvents (benzene, chloroform, ethylene chloride and methanol). This is because it possesses the highest dielectric constant of all solvents examined [44], a property which is known to promote the dissociation of the original charge–transfer complexes to the radical ions. Methylene chloride is a possible candidate, although it suffers from low boiling point which could result in fluctuations of concentration during handling and manipulation. Benzene and chloroform were unsuitable owing to the limited solubility of the reagents [45,46]. The results obtained with *p*CA, as a representative example, are given in Table 2.

Table 2
Effect of solvents on the position and intensity of absorption of the reaction of GCV (100 μg mL^{-1}) with *p*CA (2.0 mg mL^{-1}).

Solvent	Dielectric constant [a]	λ_{max} (nm)	Absorbance
Acetonitrile	37.5	530	0.632
Methanol	32.7	527	0.531
Ethanol	24.6	525	0.450
Acetone	20.7	525	0.432
Propan-1-ol	20.3	525	0.416
Butan-1-ol	17.5	525	0.347
Diethylether	4.3	530	0.321
Benzene	2.3	535	0.345
Carbon tetrachloride	2.2	520	0.322
Toluene	2.4	535	0.307
1,4-Dioxane	2.2	520	0.281

Full-size table.

[a] Ref. [50].

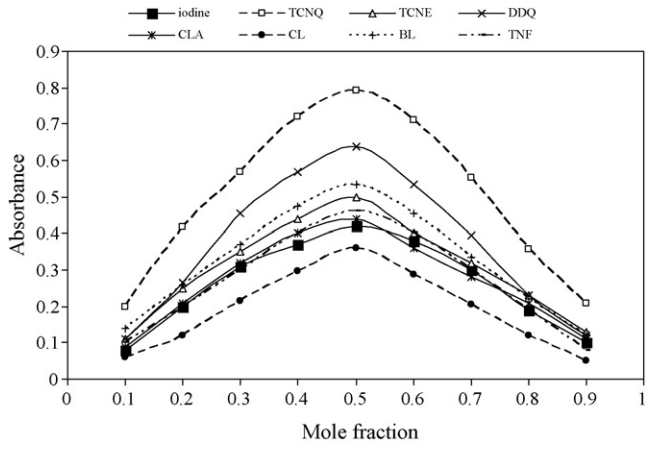

Fig. 6. Continuous variation graph for the reaction of GCV with iodine, TCNQ, DDQ, TCNE, *p*CA, CL, BL and TNF.

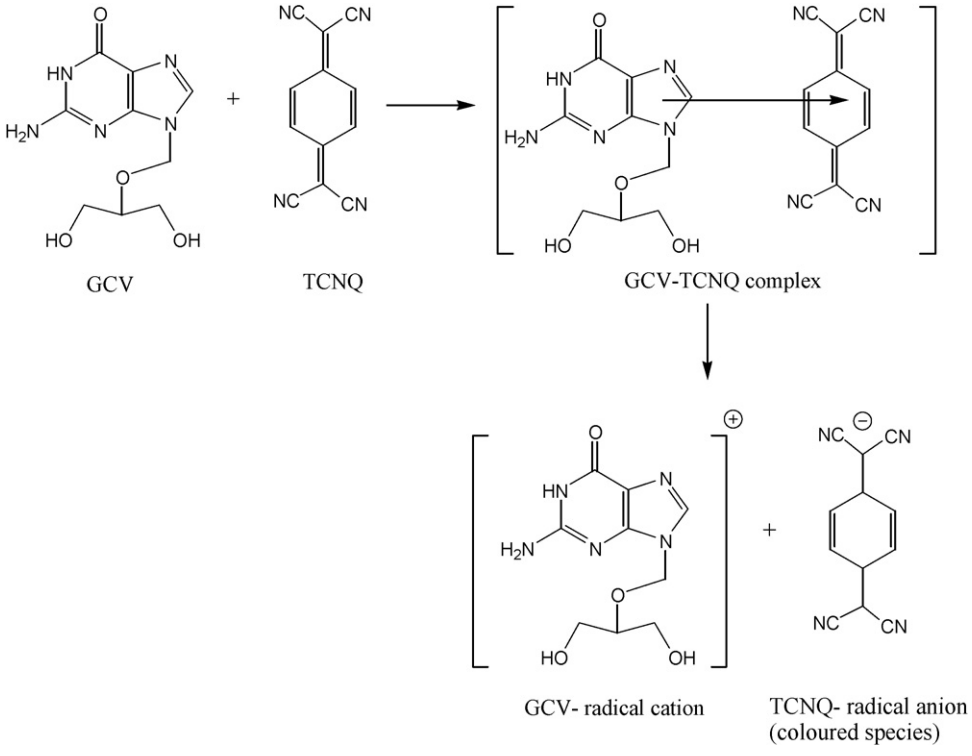
On the other hand, methanol affords maximum sensitivity and full color development with DDQ and BL. In addition, it is a good solvent for the reagent. Of the other solvents examined, acetonitrile, dichloromethane and 1,2-dichloroethane are possible substitutes.

3.2.3. Effect of reaction time

Complete color development, was attained instantaneously using iodine, whereas for TCNQ, TCNE, DDQ, *p*CA, CL, BL and TNF, complete color development was attained after 60, 40, 50, 50, 60, 90 and 75 min, respectively. To consume the time required for complete color development heating in a water bath at $60 \pm 2\,^{\circ}C$ for 5.0, 10 and 15 min in case of (TCNE and DDQ), (TCNQ, *p*CA and CL) and (BL and TNF), respectively. The color remained stable for 2.0, 1.5, 2.0, 3.0, 2.5, 2.0 and 1.0 h using TCNQ, TCNE, DDQ, *p*CA, CL, BL and TNF, respectively, except in case of iodine whereas the color decreased dramatically resulting in high imprecision of the readings.

3.3. Molar ratio of the reaction

Job's continuous variation graph [40] for the reaction between GCV and different reagents (Fig. 6) shows that the interaction occurs on an equimolar basis via the formation of a charge–transfer complex (1:1). The colored reaction product can be represented, taking TCNQ as an example, by Scheme 2. A more detailed examination was made for GCV complexes with the studied acceptors. The absorbance of the complex was used to calculate the association constant using the Benesi–Hildebrand equation [47].



$$\frac{[A_0]}{A^{AD}} = \frac{1}{\varepsilon_\lambda^{AD}} + \frac{1}{K_c^{AD}\varepsilon_\lambda^{AD}} \times \frac{1}{[D_0]}$$

where $[A_0]$ and $[D_0]$ are the total concentrations of the interacting species, A_λ^{AD} and ε_λ^{AD} are the absorbance and molar absorptivity of the complex at their λ_{max}, and K_c^{AD} is the association constant of the complex. On plotting the values of $[A_0]/A_\lambda^{AD}$ versus $1/[D_0]$, a line was obtained with slope equals $(\varepsilon_\lambda^{AD} \cdot K_c^{AD})^{-1}$ and intercept of this line with the ordinate is $(\varepsilon_\lambda^{AD})^{-1}$. The calculated association constants are recorded in Table 3, whereas the molar absorptivities were comparable with those obtained from regression line equation of Beer's law. The low values obtained for the association constants are common in these complexes due to the dissociation of the original donor–acceptor complex to the radical anion.

3.4. Development and validation of the analytical methods

3.4.1. Calibration curves, linearity and sensitivity

Under the specified optimum reaction conditions, the calibration curves for GCV with the different analytical reagents employed in the present work were constructed. The regression equations for the results were derived using the least-squares method. In all cases, Beer's law plots ($n = 6$) were linear with very small intercepts and good correlation coefficients in the general concentration range of 2.0–240 $\mu g\,mL^{-1}$ (Table 3). For comparison, the HPLC reported

Scheme 2. Suggested structure of GCV-TCNQ charge–transfer complex.

Table 3
Quantitative parameters for the charge–transfer reaction of GCV with various acceptors.

Parameters	Iodine	TCNQ	TCNE	DDQ	*p*CA	CL	BL	TNF
Beer's law limits ($\mu g\,mL^{-1}$)	10–160	2.0–50	20–200	10–240	20-180	20–240	20-160	15-150

Sandell's sensitivity ($\mu g\,cm^{-2}$)	0.243	0.040	0.439	0.203	0.365	0.587	0.386	0.464
Association constant log *K*	3.70	3.90	3.85	4.05	3.80	3.75	3.85	3.65
Regression equation[a]								
Slope (*b*)	0.0038	0.0166	0.0022	0.0041	0.0028	0.0011	0.0023	0.002
Intercept (*a*)	0.0096	0.0567	0.005	0.0264	−0.0037	0.0017	0.016	0.0126
Correlation coefficient (*r*)	0.9994	0.9996	0.9994	0.9998	0.9994	0.9996	0.9993	0.9993
Detection limits LOD ($\mu g\,mL^{-1}$)	1.10	0.36	1.90	1.25	1.65	2.45	1.80	1.45
Quantification limits LOQ ($\mu g\,mL^{-1}$)	3.67	1.20	6.33	4.17	5.50	8.17	6.0	4.83
RSD%	0.98	0.85	1.15	1.34	1.12	1.41	1.20	1.10
RE%	1.03	0.894	1.21	1.41	1.18	1.48	1.26	1.15

LOD, limit of detection; LOQ, limit of quantification; ε, molar absorptivity coefficient.
[a] $A = a + bC$, where A is the absorbance, a is the intercept, b is the slope and C is the concentration of drug in $\mu g\,mL^{-1}$.

Table 4
Statistical analysis of the results obtained for assay of authentic GCV drug using the proposed methods compared with the reported HPLC method [9].

Parameter	Reported	Iodine	TCNQ	TCNE	DDQ	pCA	BL	CL	TNF
Mean recovery, %[a]	100.43	99.45	100.20	99.85	100.05	100.35	99.80	99.76	99.90
±Standard deviation	0.78	0.73	1.15	0.84	1.07	1.40	1.34	0.97	1.08
Number of experiments	6	6	6	6	6	6	6	6	6
Variance	0.61	0.50	1.32	0.71	1.14	1.96	1.80	0.94	1.17
t-test[b]		1.26	0.37	1.13	0.64	0.39	0.91	1.20	0.89
F-ratio[b]		1.22	2.16	1.16	1.87	3.21	2.95	1.54	1.92

[a] Average values of six determinations were used for the reported and the proposed methods, respectively.
[b] Theoretical values for *t* and *F* at 95% confidence limit are 2.57 and 5.05, respectively.

method [9] was applied. Statistical analysis of the results obtained (Table 4), indicated that the proposed procedures were accurate and precise.

The limits of detection (LOD) and limits of quantitation (LOQ) were determined [48] using the formula:

$$\text{LOD or LOQ} = \kappa \text{S.D.}\frac{a}{b},$$

where $\kappa = 3$ for LOD and 10 for LOQ, S.D.*a* is the standard deviation of the intercept, and *b* is the slope. Based on the basis of six replicate measurements, the limits of detection were 0.36–2.45 $\mu g\,mL^{-1}$ and the limits of quantification were 1.2–8.17 $\mu g\,mL^{-1}$. Both LOD and LOQ values confirmed the sensitivity of the proposed methods.

3.4.2. Precision

The precisions of the assays (within-assay and between-assays) were determined at the GCV concentrations cited in Table 5. The within-assay precision was assessed by analyzing six replicates of each sample as a batch in a single assay run, and the between-assays precision was assessed by analyzing the same sample, as triplicate, in two separate assay runs. The relative standard deviations (R.S.D.) were less than 2% (Table 5). This level of precision of the proposed methods was adequate for the quality control analysis of GCV.

Table 5
Precision of the proposed methods for analysis of GCV ($n = 6$).

Method ($\mu g\,mL^{-1}$)	GCV	Within-assays		Between-assays	
		Mean ($\mu g\,mL^{-1} \pm$ S.D.)	R.S.D.	Mean ($\mu g\,mL^{-1} \pm$ S.D.)	R.S.D.
Iodine	100	98.75 ± 1.24	1.26	99.30 ± 0.63	0.63
TCNQ	25	24.78 ± 0.26	1.05	25.10 ± 0.19	0.76
TCNE	100	100.73 ± 0.43	0.43	99.35 ± 0.26	0.26
DDQ	100	99.51 ± 0.23	0.23	99.50 ± 0.56	0.56
*p*CA	90	88.90 ± 0.31	0.35	90.05 ± 0.72	0.80
BL	80	80.17 ± 0.57	0.71	89.90 ± 1.15	1.28
CL	100	100.50 ± 0.64	0.64	99.25 ± 1.10	1.11
TNF	150	148.48 ± 1.70	1.14	151.10 ± 1.25	0.83

S.D.; Standard deviations. R.S.D.; Relative standard deviations.

3.4.3. Specificity and interference

The proposed spectrophotometric methods have the advantages that the measurements in all of these methods are performed in the visible region, away from the UV-absorbing interfering substances that might be co-extracted from GCV containing dosage forms. Regarding the interference of the excipients and additives usually presented in pharmaceutical formulation (croscarmellose sodium, magnesium stearate, povidone, gelatin, titanium dioxide and yellow iron oxide), the energy of the charge–transfer (ECT) depends on the ionization potential (IP) of the donor and the electron affinity of the acceptor (EA), hence the λ_{max} values of the other π-donors mostly differ from that of the investigated compounds if they are able to form CT complexes. Preliminary experiments showed that all additives and excipients did not form CT complexes with the studied acceptors indicating the high selectivity of the proposed methods and applicability to use for routine determination in pure and in dosage forms.

3.4.4. Ruggedness and robustness

The ruggedness of the proposed methods was assessed by applying the procedures using two different instruments in two different laboratories at different elapsed time. Results obtained from lab-to-lab and day-to-day variations were found to be reproducible as R.S.D did not exceed 2%. Robustness of the procedures was assessed by evaluating the influence of small variation of experimental variables: concentrations of acceptor reagent, and reaction time, on the analytical performance of the method. In these experiments, one experimental parameter was changed while the other parameters were kept unchanged, and the recovery percentage was calculated each time. The small variations in any of the variables did not significantly affect the results; recovery percentages were 98.48–101.50 ± 0.78–1.84%. This provided an indication for the reliability of the proposed methods during routine work.

Table 6
Determination of GCV in Cymevene® capsules (250 mg GCV/capsule) by the proposed and reported HPLC method [9].

Parameter	Reported	Iodine	TCNQ	TCNE	DDQ	*p*CA	BL	CL	TNF
Mean recovery, %[a]	99.47	100.41	100.07	99.59	99.92	100.18	99.54	100.32	99.85
±Standard deviation	0.66	0.86	0.94	1.10	0.69	0.88	1.20	0.78	1.09
Number of experiments	6	6	6	6	6	6	6	6	6
Variance	0.44	0.74	0.88	1.21	0.48	0.77	1.44	0.61	1.19
t-test[b]		1.93	1.17	0.21	1.05	1.44	0.11	1.86	0.67
F-ratio[b]		1.68	2.0	2.75	1.09	1.75	3.27	1.39	2.70

Full-size table.

[a] Average values of six determinations were used for the reported and the proposed methods, respectively.

[b] Theoretical values for *t* and *F* at 95% confidence limit are 2.57 and 5.05, respectively.

3.5. Application of the method to the analysis of capsules

The obtained satisfactory validation results made the proposed procedures suitable for the routine quality control analysis of GCV and its pharmaceutical formulations (Cymevene® capsules). The results obtained by the proposed methods were statistically compared with those obtained by the reported method [9]. The obtained mean values of the labeled amounts ranged from 99.54 ± 1.20% to 100.41 ± 0.86% (Table 6). In the *t*- and F-tests, no significant differences were found between the calculated and theoretical values of both the proposed and the reported methods at 95% confidence level [49]. This indicated similar precision and accuracy in the analysis of GCV in its formulations. It is evident from these results that all the proposed methods are applicable to the analysis of GCV in its capsules with comparable analytical performance. However, the critical recommendations of some of these methods might be based on the experimental conditions (e.g. reaction time), and the ultimate sensitivity that determines the amount of specimen required for analysis. For example, the methods involving TCNE and DDQ are recommended whenever rapid analysis is required; this is because they have very short reaction time. The method involving TCNQ is recommended, as high sensitivity is required on the expense of the analysis time.

3.6. Conclusions

The charge–transfer complexation reaction of GCV as electron donor and some electron acceptors has been investigated. The obtained colored complexes were utilized in the development of eight simple, accurate and sensitive with good precision and accuracy spectrophotometric methods for the analysis of GCV in pure form as well as in dosage forms. With these methods, one can do the analysis at low cost without losing accuracy. The proposed methods can be used as alternative methods to the reported ones for the routine determination of Cymevene® capsules. This encourages their successful use in routine analysis of these drugs in quality control laboratories and they involve very simple procedures.

ABSTRACT

A separation/preconcentration of aluminum (III) (Al^{3+}) has been developed to overcome the problem of high matrix species, which may interfere with the determination of trace quantity of Al^{3+} in natural water samples. The separation of Al^{3+} in water samples was carried out from interfering cations by complexing them with 2-methyle 8-hyroxyquinoline (quinaldine) on activated silica. Whereas the separated trace amounts of Al^{3+} was preconcentrated by cloud point extraction (CPE), as prior step to its determination by spectrofluorimetry (SPF) and flame atomic absorption spectrometry (FAAS). The Al^{3+} react with 8-hydroxyquinoline (oxine) and then entrapped in non-ionic surfactant Triton X-114. The main factors affecting CPE efficiency, such as pH of sample solution, concentration of oxine and Triton X-114, equilibration temperature and time period for shaking were investigated in detail. The validity of separation/preconcentration of Al^{3+} was checked by certified reference material of water (SRM-1643e). After optimization of the complexation and extraction conditions, a preconcentration factor of 20 was obtained for Al^{3+} in 10 mL of natural water samples. The relative standard deviation for 6 replicates containing 100 $\mu g\,L^{-1}$ of Al^{3+} was 5.41 and 4.53% for SPF and FAAS, respectively. The proposed method has been applied for determination of trace amount of Al^{3+} in natural water samples with satisfactory results.

1. Introduction

Aluminum (Al^{3+}) is a non-essential, toxic metal to which humans are frequently exposed. Normally it is very insoluble and in most neutral natural waters its concentration is very low. In recent years, however, a large amount of Al^{3+} has been released into the environment through water acidification, waste discharge, and soils extract from acidic rain. The maximum permissible content of Al^{3+} in drinking water is only 200 $\mu g\,L^{-1}$ [1]. Nowadays, much interest has been raised by the toxicity and biological effect of Al^{3+} [2]. Some studies suggested that Al^{3+} may be accumulated in the brain via different routes (drinking waters, food, and medicines) and interfere with the normal activities of nervous system [3,4]. This metal ion has been considered as a possible cause of renal osteodystrophy, Parkinson and Alzheimer disease [4]. The determination of very low levels of Al^{3+} has become increasingly very important in environmental and clinical chemistry since its negative role in the human life [5]. Therefore, there is a strong need for Al^{3+} monitoring in natural water resources [6].

There are a variety of analytical techniques such as, atomic absorption spectrometry [7], inductively coupled plasma-atomic emission spectrometry (ICP-AES) and spectrofluorimetry are used for the determination of Al^{3+} in environmental samples [8,9]. However, all of the techniques are required enrichment methods for the determination of trace amounts of Al^{3+} [10].

Due to presence of interfering cations such as iron (Fe^{3+}), chromium (Cr^{3+}), copper (Cu^{2+}), lead (Pb^{2+}) and zinc (Zn^{2+}) in environmental samples or the presence of Al^{3+} below the detection limit, becomes difficult for accurate determination of Al^{3+} by spectroscopic techniques [11]. So, the separation and preconcentration steps for Al^{3+} contents are still necessary to applying simple and less expensive techniques such as spectrofluorometry (SPF) and flame atomic absorption spectrometry (FAAS) [12,13]. The widely used techniques for the separation and preconcentration of Al include liquid–liquid extraction [14], ion exchange [15], solid-phase extraction (SPE) [16] and cloud point extraction (CPE) [17]. Separation and preconcentration based on SPE and CPE are important alternatives and have a lot of practical applications in the field of surface chemistry [16,18]. The SPE and CPE are offered the most frequently used extraction methodologies, which are simple, cheap, most

doi:10.1016/j.talanta.2009.06.055

efficient and less toxic than other extraction methods [19]. Recently, the SPE technique has become increasingly popular, by using a suitable complexing reagent which initiates the separation or elimination of interference [20]. The CPE is based on the preconcentration of metal ions after the formation of sparingly water-soluble complexes in the surfactant-rich phase prior to the determination by different spectrophotometric techniques [21,22]. The CPE coupled with spectrophotometry for the determination of Al^{3+} has also been reported [23]. In addition, the cloud point strategies can enlarge the FAAS applications, because depending on preconcentration factors obtained, its sensitivity can significantly be increases, thus making the method more advantageous when compared with those bases on direct determination using electrothermal atomic absorption spectrometry and ICP-AES techniques [24].

The complexing reagent 8-hydroxyquinoline (oxine) has been acknowledged as one of the most sensitive organic ligands used for the determination of Al^{3+} [25,26]. It forms a highly fluorescent complex, without showing any intrinsic fluorescence itself. In the extraction of Al^{3+} by complexing with oxine, the interference of Fe^{3+}, Cu^{2+}, Cr^{3+}, Zn^{2+} and other metals ions, which are made complex with oxine, can be eliminated partly by using a masking agent, but it is inconvenient in operation and not very sensitive because of the use of organic reagent [16].

The aim of present work was to develop and establish a separation/preconcentration of trace quantity of Al^{3+} in surface water (river, canal and lake) samples. For separation of Al^{3+} from other interfering cations, 2-methyl 8-hydroxyquinoline (quinaldine) was used which is selective for complexation with different metal ions adsorbed on activated silica, while for enrichment of separated Al^{3+}, a CPE was used to react with oxine and resulted complex entrapped by Triton X-114 prior to its determination by SPF technique, and for comparative purpose FAAS with nitrous oxide-acetylene flame. Several experimental variables affecting the method sensitivity and stability were investigated in detail. The proposed method has been applied for determination of trace amount of Al^{3+} in surface water samples of different origin with acceptable results.

2. Experimental

2.1. Instrumentation

A centrifuge of WIROWKA Laboratoryjna type WE-1, nr-6933 (speed range 0–6000 rpm, timer 0–60 min, 220/50 Hz, Mechanika Phecyzyjna, Poland) used for centrifugation. The pH was measured by pH meter (720-pH meter, Metrohm) and global positioning system (iFinder GPS, Lowrance, Mexico) was used for sampling locations [27]. Fluorescence measurement of Al–oxine was made on a Shimadzu RF-510 (Kyoto, Japan) spectrofluorophotometer equipped with a 150 W Xenon lamp and using 1.00 cm quartz cells. Instrument excitation and emission slits were adjusted to 10 nm. The concentration of Al^{3+} in extracts was also determined by a double beam PerkinElmer model A Analyst 700 atomic absorption spectrometer (Norwalk, CT, USA) equipped with deuterium background correction. An aluminum hollow-cathode lamp was used as radiation source at wave length (nm) 309.3, slit width (nm) 1.3, and lamp current (10 mA). The Al^{3+} was measured under optimized operating conditions by FAAS with fuel (acetylene 0.45 kg cm^{-1}) and oxidant (nitrous oxide as oxidant = 1.6 kg cm^{-2}) at burner height (12.5 mm).

2.2. Reagents

Ultrapure water obtained form ELGA labwater system (Bucks, UK), was used throughout the work. The non-ionic surfactant Triton X-114 was obtained from Sigma (St. Louis, MO, USA) and was used without further purification. Stock standard solution of Al^{3+} at a concentration of 1000 μg L^{-1} was obtained from the Fluka Kamica (Bush, Switzerland). Working standard solutions were obtained by appropriate dilution of the stock standard solutions before analysis. Concentrated nitric acid, hydrochloric acid were analytical reagent grade from Merck (Darmstadt, Germany) and were checked for possible trace Al^{3+} contamination by preparing blanks for each procedure. The 8-hydroxy quinoline and 2-methyl 8-hydroxyquinoline were obtained from (Merck), both reagents were prepared by dissolving appropriate amount of these reagents in 10 mL ethanol (Merck) and diluting to 100 mL with 0.01 M acetic aid and were kept in refrigerator (4 °C) for one week. The 0.01 mol L^{-1} acetate buffer was used to control the pH of the solutions. The pH of the samples was adjusted to the desired pH (3–8) by the addition of 0.1 mol L^{-1} HCl or NaOH solution in acetate buffer. For the accuracy of methodology, certified reference material of water SRM-1643e (National Institute of Standards and Technology (NIST), Giathersburg, MD, USA) was used.

For analysis of trace quantity of Al^{3+}, contamination is a serious problem. Hence, the utmost care was taken in preparing standards and samples, and the working area around the instruments was kept as clean as possible, especially for the determination of Al^{3+} by SPF technique. The glass and plastic wares were soaked in 10% nitric acid overnight and rinsed many times with deionized water prior to use to avoid contamination.

2.3. Sampling

The surface water samples of different origin (river, canal and lake) were collected on alternate month in 2008 from 210 sampling sites of Jamshoro, Sindh (southern part of Pakistan) with the help of Global positioning system (GPS). The understudy district positioned between 25°19′–26°42′N and 67°12′–68°02′E. The sampling network was designed to cover a wide range of determinates of whole district. From each sampling site, a fresh surface water samples from canal (CS), river (RS), and lake (LS) were collected from main stream of five to six different sampling points at a depth of 20–30 cm. The collection of surface water samples was performed by using Van Dorn plastic bottles (1.5 L capacity) and was kept in well stoppered polyethylene plastic bottles previously soaked in 10% nitric acid for 24 h and rinsed with ultra pure water. All water samples were filtered through a 0.45 μm pore size membrane filter to remove suspended particulate matter and were stored at 4 °C.

2.4. Solid-phase extraction

For separation of Al^{3+} from different interfering cationic species present in matrices of water samples, a glass column with an inner diameter of 20 mm and a length of 25 cm was filled up to a height of about 20 cm with activated silica gel at 100 °C. Prior to use, the column was preconditioned with buffer solution (acetate buffer pH 6.2), and passed 10 mL of 0.1 mol L^{-1} quinaldine solution prepared in ethyl alcohol-acetic acid at pH 6.2. A 25 mL of replicate six sample of SRM and real water samples were passed through this column to separate Al^{3+} from other interfering cations at the flow rate of 0.5–5.0 mL min^{-1}. The treated SRM and real water samples were then divided into two sub-samples of 10 mL each. After several separation experiments (n = 20), the column was rinsed with 10% ethanol in 0.1 mol L^{-1} HNO_3 and deionized water then used for further experiments.

2.5. Cloud point extraction

For Al^{3+} preconcentration, aliquots of 10 mL of standard solutions containing Al^{3+} (in the range of 10–200 μg L^{-1}), replicate six samples of SRM, surface water samples, treated with quinaldine to

remove interfering species were simultaneously preconcentrated by CPE. The same sub-samples of SRM and water without removing interfering cations were taken in graduated centrifuge tubes and subjected to preconcentration for comparison purposes.

In 10 mL of each standard SRM, and real samples, added 0.2–0.8 mL of oxine solution (6.90×10^{-3} mol L^{-1}), 2 mL of Triton X-114 (0.05–0.2%, v/v) and 2 mL of different buffers to adjust a pH range of 4–8. The tubes were placed in an ultrasonic bath at 30–70 °C for 10–30 min. After different time intervals, the separation of the two phases was achieved and then centrifuged for 5 min at 3500 rpm ($1852 \times g$). The contents of tubes were cooled in an ice-bath, the surfactant-rich phase became viscous and the supernatant aqueous phase was decanted.

To decrease the viscosity of one of the duplicate extracts, added 0.5 mL of ethanol–water mixture (1:1) and fluorescence intensity of obtained Al^{3+} chelate in the micellar phase was measured by SPF at $\lambda_{excitation}$ 375 ± 3 nm and $\lambda_{emission}$ at 510 ± 3 nm against a corresponding reagent blank. While simultaneously, the viscosity of surfactant-rich phase of other sub-sample was decreased by adding acidic-ethyl alcohol (0.1 mol L^{-1} HNO_3) and introduced into flame by conventional aspiration. A blank submitted to the same procedure was measured parallel to the calibration solutions of standards, SRM and real samples.

3. Results and discussion

To overcome the problem of high matrices concentration, which is thought to interfere with the determination of low levels of Al^{3+} in environmental samples. The Al^{3+} was separated from interfering species in real water sample by adsorbing on quinaldine modified silica, then separated Al^{3+} was react with oxine in a micellar medium and form a hydrophobic complex (Al–oxine), which is subsequently trapped in the non-ionic surfactant and separated from the aqueous phase. The oxine is strong chelators for Al^{3+} and gives rise to fluorescent complex [20,5]. To check the accuracy of the SPE and CPE, the results obtained by spectrofluorimetry were compared with those obtained by FAAS.

3.1. Optimization of SPE

As reported earlier that Al^{3+} was not reacted with quinaldine due to stearic hindrance of the methyl group at the 2-position of aromatic ring [28]. The quinaldine adsorbed on activated silica used as absorbent for SPE of interfering species (Fe^{3+}, Cr^{3+}, Cu^{2+}, Pb^{2+} and Zn^{2+}), which can quantitatively eliminate the interfering cations at pH 5.5 with high adsorption capacity. The separation of Al^{3+} from interfering ions is necessary for determination of its trace quantity, particularly to measure the fluorescence intensity of Al–oxine complex using SPF technique.

3.1.1. Effect of pH on sorption

The influence of pH on the retention of interfering elements was determined. The pH ranges of (4–8) of standards solution of interfering ions, SRM and real water samples were adjusted by buffer solution with either 0.1 mol L^{-1} nitric acid or sodium hydroxide. These solutions were then passed through the column at 0.5–5.0 mL min^{-1}. It was found that the maximum retention of interfering ions were achieved at pH 5.0–6.0 and begins to decrease when the solution is over pH 6.5. Therefore, the pH 5.5 was used for separation of Al^{3+} ions from interfering cations.

3.1.2. Effect of flow rate on sorption

The retention of interfering ions on the quinaldine modified silica was studied at different flow rates. The separation of Al was >95% at optimum flow rate of the sample solution up to 2 mL min^{-1}. However, at a flow rate above 5 mL min^{-1}, there was a decrease in the sorption percentage of interfering ions, because ligand formation between interfering ions and quinaldine is slow at room temperature. The retention of interfering ions was confirmed by FAAS (not reported) and for further work a 1.0 mL min^{-1} flow rate was selected. The SPE is a highly selective and sensitive method for simple and quick elimination of interfering of matrixes elements, to determined fluorescence intensity of Al–oxine chelate.

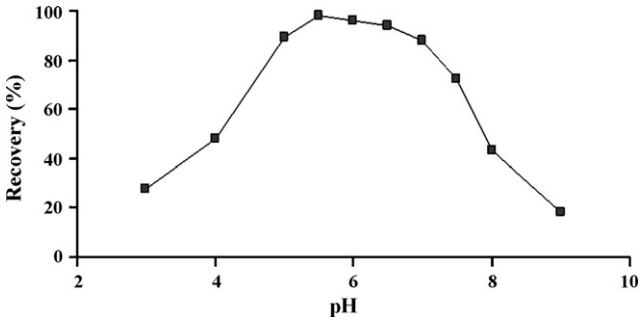

Fig. 1. Effect of pH on the spectrofluorimetric responses: 100 μg L^{-1} Al, 6.85×10^{-5} mol L^{-1} 8-HQ, 0.1% (w/v) Triton X-114, temp. 40 °C, stirring time 20 min.

3.2. Optimization of CPE

3.2.1. pH effects

The pH plays a distinctive role on metal-chelate formation and subsequent extraction, this factor is proved to be a main parameter for CPE method. The replicate six standard, SRM and real sample solution of Al^{3+} (100 μg L^{-1}) were adjusted to the pH range of (pH 3–8), each desired pH value was obtained by the addition of 0.1 mol L^{-1} HNO_3 and/or 0.1 mol L^{-1} NaOH solution in the presence of acetate buffer solution. Fig. 1 shows the effect of pH on the extraction recovery of Al-oxinate which were calculated on the basis of certified value of Al in SRM and in the surfactant-rich solution after CPE using SPF. As can be seen that quantitative extraction (>96%) was obtained for Al^{3+} in the pH range of 5–7 and starts to decrease after pH 7.0. Hence, a pH of 6.5 was chosen for optimum CPE of Al^{3+}. Based on the obtained results, there may be no need for adjusting the pH in the case of understudy water samples, because their pH values fall near to the required range (6.8–7.5), while it was also observed that after pH 7, abrupt decline in % recovery.

3.2.2. Effect of oxine concentration

The % recovery of Al^{3+} as a function of the concentration of the chelating agent, oxine is shown in Fig. 2, where 10 mL of standard, SRM and real sample solution containing Al^{3+} in the presence of 0.1% (w/v) Triton X-114 and added appropriate buffer solution to kept pH 6.5 and concentrations of oxine solutions in the range of $(1.37–10.9) \times 10^{-5}$ (0.1–0.8 mL from 1.37×10^{-3} mol L^{-1}

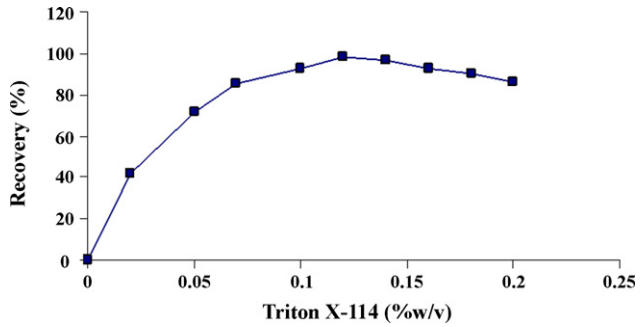

Fig. 2. Effect of oxine concentration on the %recovery: 100 μg L^{-1} Al, 0.1% (w/v) Triton X-114, pH 6.5, temp. 40 °C, stirring time 20 min.

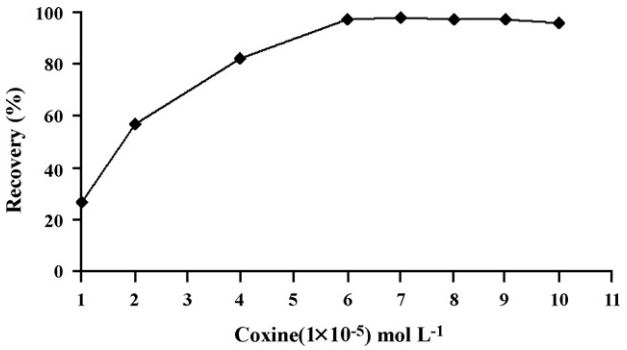

Fig. 3. Effect of Triton X-114 on the %recovery: 100 μg L^{-1} Al, 6.85 × 10^{-5} mol L^{-1} 8-HQ, pH 6.5, temp. 40 °C, stirring time 20 min.

oxine solution) were subjected to cloud point preconcentration. The extraction efficiency of Al^{3+} increases up to 6.85 × 10^{-5} mol L^{-1} of oxine, then reaching a plateau, indicated that this amount of oxine is sufficient for total complexation and the extraction. The concentrations above this value have no significant effect on the efficiency of CPE. The stoichiometry of the Al–oxine ternary complex, as reported in literature is 1:3 ratios [29].

3.2.3. Effect of Triton X-114 concentration

In present work Triton X-114 was chosen because of its higher extraction efficiency and lower cloud point temperature as compared with other reported surfactants [30]. The low cloud point temperature avoids back extraction during centrifugation. Fig. 3 shows the variation in extraction efficiency of Al–oxine complex within the concentration range of 0.05–0.2% (w/v) of Triton X-114, while other factors were at optimum levels. The 60–70% recovery was observed at 0.05% of Triton X-114, while the extraction efficiency reaches a maximum in the concentration range of 0.1–0.15%. A concentration of 0.1% (w/v) of Triton X-114 was chosen as the optimum surfactant concentration in order to achieve the highest possible extraction recovery of Al^{3+} from standards, SRM and real samples. Whereas at lower than 0.1% of Triton X-114, the extraction efficiency of complexes is low probably because of the inadequacy of the assemblies to entrap the hydrophobic complex quantitatively, on the contrary at higher concentrations, the signals decrease because of the increment in the volumes and the viscosity of the surfactant phase (ethanol–water for SPF and ethanol–nitric acid for FAAS) to reducing the viscosity of the surfactant.

3.2.4. Effect of temperature and time

A sufficiently long reaction time was allowed for the Al–oxine complex formation to precede up to 300 min at room temperature. The effects of equilibration temperature and time on the analytical signal were studied in the range of 30–60 °C in ultrasonic bath for 10–60 min, respectively. In the present study low temperature was required for optimum extraction efficiency of Al^{3+}. It was observed that the optimum % recovery of Al^{3+} was achieved at equilibration temperature of >50 °C and a time of 20 min. At higher temperature the fluorescent intensity of Al–oxine complex was lowered, may effects the viscosity of medium and the number of collisions of molecules of the fluorophore with solvent molecules. So, 40 °C was chosen for further experiments. We preferred to stop the reaction at 60 min, as a longer reaction time did not increase fluorescence intensity and % recovery of Al^{3+}.

3.3. Interferences

The interferences studied were those relating to the preconcentration step, i.e. cations may react with oxine or species that may react with Al^{3+} and decrease the extraction efficiency and also interference in determination of fluorescence intensity using SPF. The interference from these ions can be eliminated by SPE using quinaldine that form chelate with these ions except Al^{3+}. To perform this study, 10 mL solution containing 100 μg L^{-1} of Al^{3+} and interfering ions in different interferent to analyte ratios were subjected to the complete procedure. The determination of Al^{3+} in the presence of Zn (50 μg L^{-1}) produce positive error and broad band in emission spectrum was observed, while Fe^{3+}, Cr^{3+}, Pb^{2+} and Cu^{2+} (1000, 20, 20 and 100 μg L^{-1}), respectively, can interfere with the determination of Al^{3+}, to produce negative effects (Table 1). Our results are not consistent with other study to determine simultaneously Al^{3+} and Zn^{2+} using oxine as chelating reagent [17].

3.4. Validity and applicability

The calibration graph using the preconcentration system for Al^{3+} was linear with a correlation coefficient of 0.9997 at 10–200 μg L^{-1}. The surfactant-rich phase was diluted with 0.5 mL of water–ethanol and the fluorescence intensity of the chelate was measured. In all cases, linear relationships between the fluorescence measured and the concentration of the Al in the standards, SRM and real water were attained. Simultaneous same sub samples diluted with acidic alcohol were subjecting to FAAS for comparison purposes.

The reproducibility was calculated as % relative standard deviation for 6 replicates containing 100 μg L^{-1} of Al^{3+}, obtained 5.41 and 4.53% for SPF and FAAS, respectively. The limit of detection (LOD) calculated (0.5 μg L^{-1}) as three times the standard deviation of the blank signals.

The obtained LOD was sufficiently low as compared to reported work [5] and to be valuable for detecting Al^{3+} in different types of surface water samples. Quantitatively accurate results were obtained by adopting matrix-matched calibration of certified standards and certified reference material of water, thus avoiding the use of more time-consuming and laborious standard additions into each sample.

The Student's *t*-test showed that the results obtained by SPF and FAAS were not significantly different at 95% confidence level (Table 1). After optimization, the preconcentration factor (CF) of 20 was achieved. The CF obtained in this work was comparable with those obtained in other CPE methods used for extraction and preconcentration of Al^{3+} [20]. It is obvious that this CF and LOD can be improved by using larger volume of initial solution or small-volume cells and diluting the surfactant-rich phase by small amounts of ethanol. The method was successfully applied to the determination of Al^{3+} in different natural water samples.

The obtained results showed variations among the concentration of Al^{3+} in surface water samples of three origins (Table 2). The concentration of Al^{3+} in RS, CS and LS water samples was

Table 1
Validation of CPE of Al^{3+} in certified sample of water SRM 1643e using spectrofluorimetry (SPF) and flame atomic absorption spectrometry (FAAS) (μg L^{-1}).

Element (Al^{3+})	Certified value of SRM 1643e (water)	SPF $\bar{x} \mp ts/\sqrt{n}$	FAAS $\bar{x} \mp ts/\sqrt{n}$	Paired *t* test[a] $t_{Experiment}$
CPE	141.8 ± 8.6	139 ± 7.5 (98.0%)	140 ± 6.4 (98.7%)	0.78
Without CPE		137 (96.6%)	138 (97.3%)	

Value in parenthesis = % recovery.

[a] $t_{certical}$ = 2.28 at 95% confidence limit (*n* = 6) (5.41) (4.53).

Table 2
Ranges of pH and Al^{3+} concentration in the surface and ground water samples of district Jamshoro, Sindh, and Pakistan.

Parameter	Unit	WHO values	Canal water			River water			Lake water		
			$n = 120$			$n = 30$			$n = 30$		
			Min	Max	Mean	Min	Max	Mean	Min	Max	Mean
pH	–	6.5–8.5	7.1	7.6	7.27	7.0	7.5	7.2	7.10	8.20	7.4
Al^{3+}	$\mu g\,L^{-1}$	200	90	150	80	10	150	90	750	1340	1000

observed in the ranges of 10.0–150, 90–150 and 750–1340 $\mu g\,L^{-1}$, respectively. The concentration of Al^{3+} in three studied origins was obtained in increasing order: RS < CS < LS. It was observed that concentration of Al^{3+} in RS and CS water samples are within WHO permissible level for drinking water [1], while in LS water samples high content of Al^{3+} was found. This can be attributed to reduction in precipitation, surface wastage runoff with rain water into understudy Lake and increasing rate of evaporation during summer [31]. All this provides evidence that anthropogenic and geological environment play a key role in the distribution of Al^{3+} in understudy water bodies. Number of epidemiological studies showed an association between Al in drinking water and Alzheimer's disease, an important form of senile dementia in man [29,32].

4. Conclusions

The separation and preconcentration methodologies for the determination of trace quantities of Al^{3+} in water samples, offers a simple, sensitive, inexpensive and non-polluting alternative to other separation/preconcentration techniques using toxic organic solvents. To the best of our knowledge, modified silica with 2-methyl 8-hydroxyquinoline as a solid-phase extractor is first time used by us to separate interference elements from environmental sample matrixes, to determine the fluorescence intensity of Al–oxine complex. The Al^{3+} is not reacting with quinaldine due to stearic hindrance effect of methyl group. The proposed CPE method gives low LOD, good RSD, less time-consuming, achievement of high enrichment factors and solvent-free extraction of trace quantity of Al^{3+} in natural water matrixes. The surfactant-rich phase can be easily diluted with ethyl alcohol–water and ethyl alcohol–0.1 mol L^{-1} HNO_3 systems prior to its determination by SPF and FAAS. Due to versatility, it can be applied to the monitoring of trace quantity of Al^{3+} in various samples of environmental, toxicological and clinical analysis.

ABSTRACT

A simple yet sensitive method is developed for the determination of sericin using voltammetry based on the interaction between sericin and carmine for the first time. In the absence of sericin, carmine has a pair of well-defined redox peaks in a pH 1.81 Britton–Robinson buffer solution. Although no new redox peaks appear upon the addition of sericin into a carmine solution, the peak currents of the old peaks reduce while the peak potentials shift positively. This observation is attributed to the decrease in the diffusion coefficient and electrode reaction rate constant of carmine in the presence of sericin. A binding mechanism is proposed and discussed, and the binding constant and binding ratio are calculated as 2.32×10^6 L mol^{-1} and 1:1, respectively. Furthermore, the decrease in the peak currents is found proportional to the sericin concentration in the range of 32.0–800.0 μg mL^{-1} with a detection limit of 13.52 μg mL^{-1}. The method is further applied to the determination of sericin in degumming wastewater with satisfied average recoveries from 96.7 to 103.3%. The results are in good agreement with those obtained by the conventional Coomassie brilliant blue G-250 spectrophotometric method.

1. Introduction

Sericin (SE) is a family of water-soluble globular proteins found in silkworms. It constitutes 20–30% of cocoons and executes the function of gluing the silk fibers together and imparting strength to them [1–3]. SE has exhibited excellent moisture absorption and release properties [1,4]. It also has many desired biological properties, e.g. antibacterial activity [5], UV resistance [6], tyrosinase activity inhibition and antioxidation [7], which make SE extensively applicable in many fields, including food, cosmetics, pharmaceutical products, textile and biomaterials [8,9].

Although SE is considered a valuable natural protein source [10] widely used in above mentioned applications, so far, little work has been performed for its quantitative determination. SE is generally either extracted directly from cocoons or recovered from degumming wastewaters [11]. Therefore, a practical analytical method with simple procedures for monitoring SE is highly desired.

Several methods based on dye-binding for protein determination, such as spectrophotometry [12,13], fluorimetry [14,15], light scattering technique [16–18] and electrochemical methods, have been reported in the past [19–22]. Compared with spectroscopic methods, electro-analysis is especially suitable for studying binding reactions between dyes and proteins because the required amount of samples on the electrode/solution interface is minimal. The electro-analysis is also simple and practical yet with good selectivity, high sensitivity, low cost, rapid response and wide dynamic ranges. Thus, the electrochemical methods have attracted more and more attention in recent years.

Carmine (CA) is a monoazo dye which has been well-known to food and textile industries for a long time. Recently, it is also more and more widely applied in the electrochemistry. For example, a modified glass carbon electrode (GCE) prepared by the electro-polymerizing CA has shown great electro-catalytic properties [23–25]. However, to the best of our knowledge, there is still no report on its binding protein. In the current paper, electrochemical studies in the interactions between CA and SE at a carbon paste electrode are reported for the first time. In the presence of SE, the peak currents of CA are found to decrease with the positively moving potential. The concentration of SE is revealed linear with the decrease of the oxidative peak currents of CA. Hence, a sensitive method based on these observations can be developed for the determination of SE.

2. Experimental

2.1. Reagents

Standard SE (purity > 99%) was purchased from Zhejiang Silk Institute, China. Fresh silkworms were obtained from Hangzhou Jin Li Silk Limited Company, China. An SE standard solution (1.00 g L^{-1})

doi:10.1016/j.talanta.2009.06.045

was prepared by dissolving SE in twice-distilled water and stored at 4 °C before use. CA (analytical pure) was purchased from Beijing Hongxing Chemical Plant, and its solution (9.91×10^{-4} mol L^{-1}) was prepared and used as a stock solution. Working solutions were thus prepared by diluting the stock solution to certain concentrations prior to use.

Graphite powders (spectral pure) were purchased from Tianjing Fendeng Reagent Corporation, China, while di-methyl silicone oil (chromatographic pure) was from Chengdu Kelong Reagent Corporation, China. All other chemicals were of analytical-reagent grade or better. Twice-distilled water was used throughout the experiments.

2.2. Apparatus

All voltammetric experiments were performed by a CHI 660A electrochemical workstation (Shanghai Chenghua, China) with a three-electrode configuration: a homemade carbon paste working electrode (CPE), a saturated calomel reference electrode (SCE) and a platinum wire auxiliary electrode. UV–Vis absorption spectra were recorded on a model UV-2450 PC UV–Vis spectrophotometer (Shimadzu, Japan). pH values of all solutions were measured with a RHSJ-4A pH meter (Shanghai Ridao, China), which was first calibrated with three common standard pH buffer solutions at 25 °C. These standard pH buffer solutions were potassium hydrogen phthalate (pH 4.01), potassium phosphate monobasic–sodium phosphate dibasic (pH 6.86) and sodium tetraborate (pH 9.18).

2.3. General procedure

To a 10 mL volumetric flask, a CA solution (2.0 mL, 9.91×10^{-4} mol L^{-1}), a Britton–Robinson buffer (2.0 mL, 0.04 mol L^{-1}, pH 1.81), and appropriate amounts of the standard SE solution or a degumming wastewater sample were added consecutively. The mixture was further diluted to 10 mL with twice-distilled water and then mixed homogeneously at room temperature. After 40 min, it was transferred into a voltammetric cell. The oxidative peak current (i_{pa}) was recorded in the potential range of 0.40–1.00 V (*vs.* SCE) by square wave voltammetry with the following parameter settings: frequency 20 Hz, pulse amplitude 80 mV, and scan increment 4.0 mV.

Under the same conditions, the mixture without the addition of SE was used as the blank solution and the voltammetric peak current ($i_{pa,0}$) was also recorded. The differences between these two peak currents ($\Delta i = i_{pa,0} - i_{pa}$) were calculated and used to indicate the changes in the electrochemical responses in the reaction systems.

The degumming wastewater samples were prepared as follows: The cocoon silk of silkworms was first degummed with 5.0 g L^{-1} Na_2CO_3 solution at 90 °C. The degumming wastewater was then collected, and its pH was adjusted to neutral with 0.1 mol L^{-1} HCl before it was used in analysis.

The spent CPE was renewed after each measurement. The preparation and renewal of the CPE were similar to reference reported [26] except that the ratio of the graphite powder and di-methyl silicone oil in the CPE was 7:3 (m/m). All the potentials reported in this work were referred to the SCE, and all the experiments were carried out at room temperature (25 ± 2 °C) unless described otherwise.

3. Results and discussion

3.1. Spectra and voltammetry characteristics

Fig. 1 showed the UV–Vis absorption spectra of CA in both the absence (CA system) and presence of SE (CA–SE system). With the

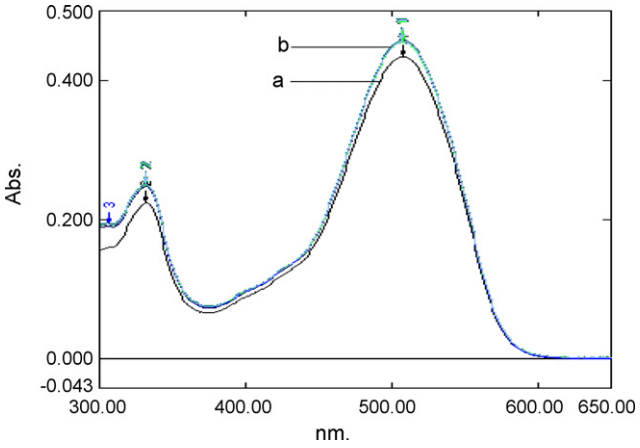

Fig. 1. UV–Vis absorption spectra of CA in the absence (a) and presence of SE (b) in the pH 1.81 Britton–Robinson buffer solution. C_{CA}: 2.00×10^{-5} mol L^{-1}; C_{SE}: 80.0 μg mL^{-1}; Reaction time: 20 min.

pH 1.81 Britton–Robinson buffer solution and in the scanning range of 300–650 nm, CA showed a maximum absorption peak at 508 nm (curve a). When SE was mixed with CA, the absorbance of CA at 508 nm increased without any shift in the maximum absorption wavelength (curve b), which suggested a binding reaction between CA and SE took place and a new complex was formed.

Cyclic voltammograms of the CA and CA–SE systems were recorded under certain conditions, and the results were shown in Fig. 2. In the potential range of 0.30–1.20 V and with the potential scan rate of 0.10 V s^{-1}, a pair of well-defined oxidative and reductive peaks at 0.71 and 0.60 V (both *vs.* SCE) with peak currents 20.79 and 18.57 μA, respectively, was observed in the CA system (curve a); but no voltammetric response was recorded in the SE system (curve b). For the CA–SE system (curve c), no new redox peaks appeared in the same scan potential range. However, the peak currents of the old oxidative and reductive peaks decreased to 12.70 and 12.20 μA, and their peak potentials shifted positively to 0.77 and 0.64 V, respectively. These results suggested that there were interactions existing between CA and SE.

On the other hand, like other proteins, the dissociation of SE in an aqueous solution can be expressed as follows [27]:

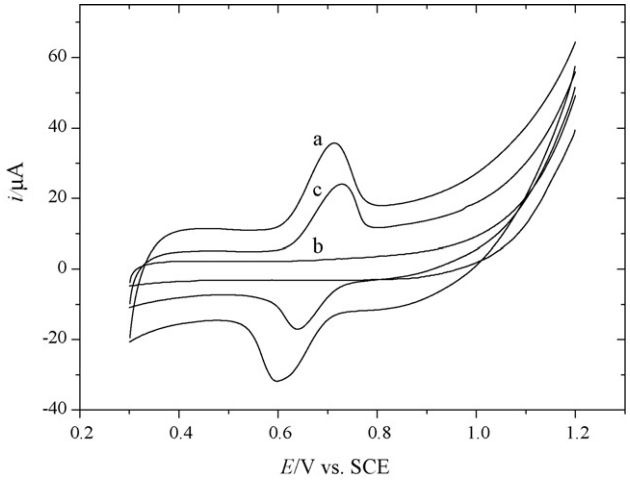

Fig. 2. Cyclic voltammograms of CA (a), SE (b) and CA – SE (c) in the pH 1.81 Britton–Robinson buffer solution. C_{CA}: 1.98×10^{-4} mol L^{-1}; C_{SE}: 200.0 μg mL^{-1}; Scan rate: 0.10 V s^{-1}.

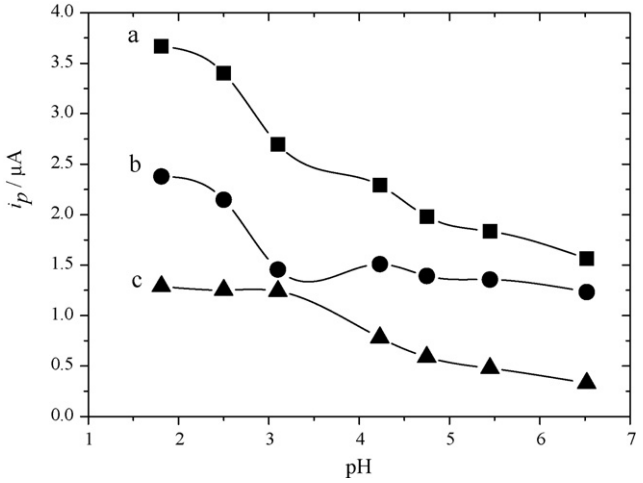

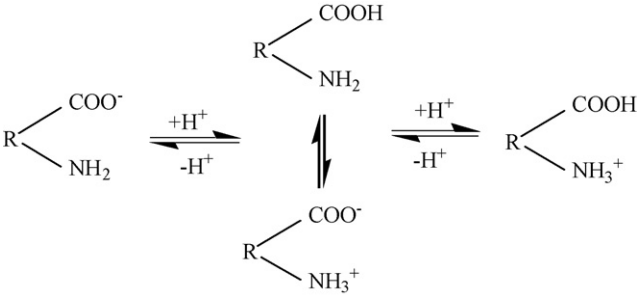

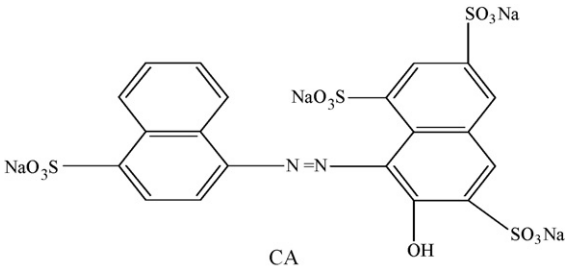

Fig. 3. Influence of pH over oxidative peak currents of the CA in the absence (a) and presence of SE (b). C_{CA}: 1.98×10^{-5} mol L^{-1}; C_{SE}: 200.0 μg mL^{-1}; Curve (c): the plot of Δi *vs.* pH.

Moreover, the isoelectric point (pI) of SE is in the range of 3.8–4.5. Thus, in the pH 1.81 Britton–Robinson buffer solutions, SE was positively charged, while CA was negatively charged because of the deprontonated of sulfonic groups. According to Refs. [21,22], the binding of proteins with small molecules can result from either ionic, van der Waals and hydrogen bonding, electrostatic binding, or hydrophobic interactions. Therefore, it was possible that the electrostatic attraction played a key role in the interactions of CA with SE here.

3.2. Analytical application

3.2.1. Optimization of reaction conditions and SWV parameters

The oxidative peak of CA was used as the study signal because it was much more sensitive than the reductive one. Different supporting electrolytes, such as H_2SO_4, HAc–NaAc and Britton–Robinson buffers, were investigated, and the response in the Britton–Robinson buffer was the strongest. The influence of pH over the peak currents of CA in both the absence and presence of SE was studied in the pH range of 1.81–6.52, and the results were shown in Fig. 3. As shown, the difference of the peak currents reached a maximum at pH 1.81. So the pH 1.81 Britton–Robinson buffer was selected as the supporting electrolyte in all measurements. In addition, in the final 10 mL solution, the 0.04 mol L^{-1} Britton–Robinson buffer (pH 1.81) performed well with the volume of 1.5–3.5 mL, thus the 2.0 mL volume of the buffer solution was chosen for the reactions.

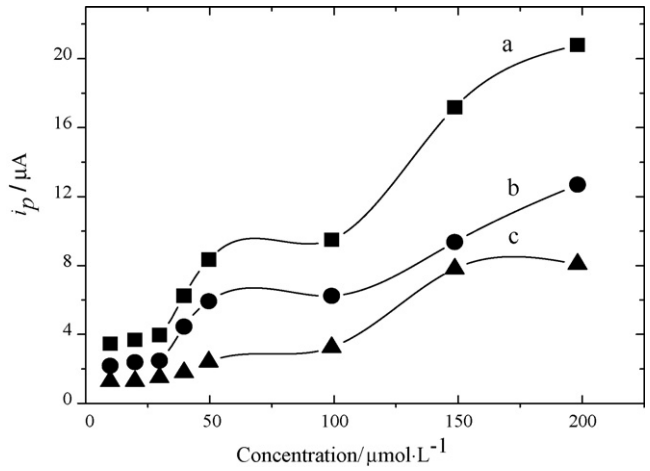

Fig. 4. Effects of CA concentrations on oxidative peak currents of the CA (a), CA – SE systems (b), and Δi (c) in the pH 1.81 Britton–Robinson buffer solution. C_{SE}: 200.0 μg mL^{-1}.

Different addition orders of CA, SE and Britton–Robinson buffer solutions were also studied. The best addition sequence was found to be CA, the Britton–Robinson buffer and then SE in terms of stability and intensity of the voltammetric response, which suggested that mixing CA with the Britton–Robinson buffer solution as the first step provided a proper acidic condition for the dissociation of CA and SE and the combination of CA with SE by the electrostatic binding mode.

The temperature influence over the reaction systems was investigated at 15 °C, room temperature (25 ± 2 °C), and 40, 60 and 90 °C. No obvious differences were observed among these temperatures. So room temperature was used throughout the experiments because of its simplicity. After CA and SE were mixed, the difference in the peak currents reached a maximum when the reaction underwent for 40 min at room temperature, and then the difference remained almost a constant for at least 2 h. Therefore, the reaction time of 40 min was used in later measurements.

The influence of the CA concentration was studied subsequently. As illustrated in Fig. 4, curve a was the plot of $i_{pa,0}$ *vs.* the CA concentration; curve b represented the change of i_{pa} at various concentrations of CA in the presence of 200.0 μg mL^{-1} SE, and curve c was the differences between curves a and b, which revealed the correlation between Δi and the concentration of CA. With the increase of the CA concentration from 9.91×10^{-6} to 9.91×10^{-5} mol L^{-1}, the Δi raised gradually; when the final CA concentration was in the range of 1.49×10^{-4} to 1.98×10^{-4} mol L^{-1}, the Δi reached a maximum and remained basically unchanged thereafter. Therefore, 1.49×10^{-4} mol L^{-1} CA was used in later assays.

Square wave voltammetry (SWV) was proposed because it was much more sensitive than cyclic voltammetry. The SWV parameters were optimized for the CA–SE system (1.49×10^{-4} mol L^{-1} CA + 200.0 μg mL^{-1} SE) in the pH 1.81 Britton–Robinson buffer. At scan increment of 4 mV and pulse amplitude of 25 mV, the oxidative peak currents increased with the rise of the frequency and reached the maximum at 20 Hz; when the frequency was above 20 Hz, the peak currents started to decrease gradually. The optimum pulse amplitude was examined at the 20 Hz frequency and 4 mV scan increment. Although the peak currents increased with the increase of the pulse amplitude from 15 to 100 mV, a much better-defined

[a] Standard deviation.
[b] The value of calculated *t*-test.

and sharper peak was obtained at 80 mV. Thus, the pulse amplitude of 80 mV was chosen for the assays.

3.2.2. Calibration curve and detection limit

Under the above selected optimum conditions, the peak current difference Δi was linear with the SE concentration in the range between 32.0 and 800.0 $\mu g\,mL^{-1}$ with a linear regression equation as follows: $\Delta i = 16.77 + 0.05C_{SE}$ ($\mu g\,mL^{-1}$) ($R = 0.999$ and $n = 5$). The detection limit was 13.52 $\mu g\,mL^{-1}$ ($3\sigma/s$, where σ is the standard deviation of the intercept, and s is the slope of the calibration curve). The reproducibility of the proposed method was tested with a 200.0 $\mu g\,mL^{-1}$ SE solution. The relative standard deviation of Δi was calculated at 3.22% for seven parallel measurements. Therefore, the method was sensitive and reproducible.

3.2.3. Effect of coexisting species

The effect of coexisting substances, such as metal ions and amino acids, over the measurement in the 200.0 $\mu g\,mL^{-1}$ SE solution was studied. The tolerance limit of the interference was determined when the maximum concentration gave a relative error <±5%. No interference was found with 800-fold Na^{2+}, Cl^-, 200-fold Zn^{2+}, Mn^{2+}, 50-fold Cu^{2+}, 30-fold Al^{3+}, 35-fold tyrosine monomer, 40-fold tryptophan monomer, and 100-fold other 16 kinds of amino acid monomers, such as glycine, alanine, valine, leucine, isoleucine, phenylalanine, serine, threonine, cystine, aspartic acid, glutamic acid, methionine, arginine, lysine, histidine and proline. Thus, the proposed method was effective for the determination of SE.

3.2.4. Sample determination

The proposed method was further applied to monitor SE in the degumming wastewater. The obtained results were compared with those measured using the Coomassie brilliant blue G-250 spectrophotometric method. Student's *t*-test was also used to evaluate the two methods. As shown in Table 1, the average recovery of SE for the two methods was from 96.7 to 103.3% and 98.9 to 104.2%, respectively. Additionally, all calculated values of t for the three samples were less than 2.23 (the critical value of t_{10}, $P = 95\%$), indicating the difference between the two methods was insignificant at a 95% confidence level. Therefore, the two methods used for the determination of SE in degumming wastewater were in good agreement and comparable.

3.3. Evaluation of electrochemical parameters of two systems

The electrochemical parameters of CA in both the absence and presence of SE were calculated and compared. Firstly, with potential-controlled coulometry, the numbers of electron transfer in the CA and CA–SE systems were estimated at 2.02 and 1.95, respectively. Such results indicated that ~2 electrons were transferred in the electrode reaction for each of these two systems. Secondly, the effect of the scan rate was studied. As shown in Fig. 5, their redox peak currents were both linear with the square root of the scan rate in the range of 0.10–0.45 $V\,s^{-1}$, suggesting that their electrode processes were both diffusion-controlled. Also, the diffusion coefficient can be estimated with

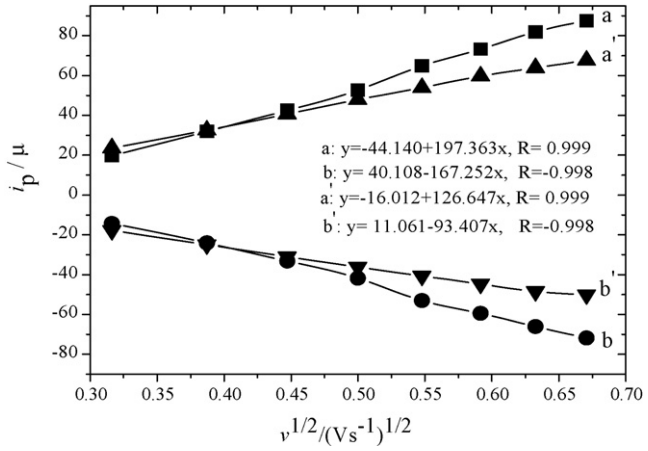

Fig. 5. Plots of i_p vs. $v^{1/2}$ of 1.49×10^{-4} mol L^{-1} CA in the pH 1.81 Britton–Robinson buffer solution in the absence (a and b) and presence of 200.0 $\mu g\,mL^{-1}$ SE (a′ and b′).

Table 2
Rate constant k_s and diffusion coefficient D of the CA and CA–SE systems.

System	k_s (s^{-1})	D ($cm^2\,s^{-1}$)	
		Oxidative process	Reductive process
CA	0.45	4.32×10^{-4}	6.01×10^{-4}
CA–SE	0.35	1.45×10^{-4}	2.67×10^{-4}

the Randles–Sevick equation [28]: $i_p = 2.69 \times 10^5 n^{3/2} S C^0 v^{1/2} D^{1/2}$. Assuming $S = 0.071\ cm^2$, based on the slope of i_p *vs.* $v^{1/2}$, the diffusion coefficients D were calculated and disclosed in Table 2.

The plots of peak potentials E_p *vs.* ln v for the CA and CA–SE systems were shown in Fig. 6. All of them revealed well-defined straight line fittings. Based on the Laviron's theory [29], the electron transfer coefficients α were determined by examining the potential

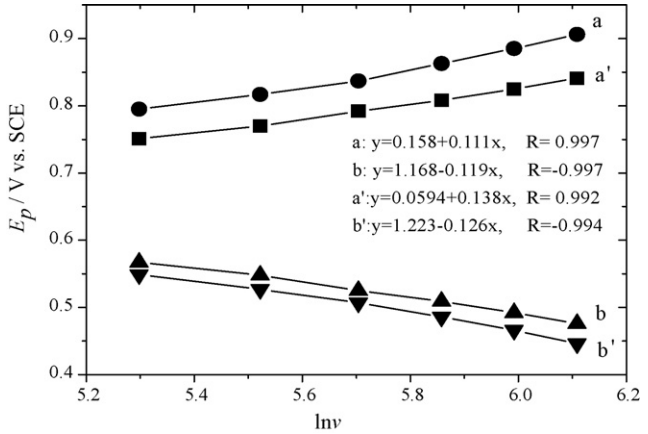

Fig. 6. Plots of E_p vs. ln v for the CA (a and b) and CA–SE systems (a′ and b′). Other conditions the same as Fig. 5.

variations with the logarithm of the scan rate. From the slopes of them, α was calculated at 0.48 and 0.52 for the CA and CA–SE systems, respectively. Moreover, the electrode reaction rate constant k_s could also be determined according to the following equation:

$$\log k_s = \alpha \log(1-\alpha) + (1-\alpha)\log\alpha - \log\left(\frac{RT}{nF\nu}\right) - \frac{\alpha(1-\alpha)nF\Delta E_p}{2.3RT}$$

where ΔE_p is the peak-to-peak potential separation of the oxidative and reductive peak potentials, and other symbols have normal meanings. The calculated values of k_s for CA in both the absence and presence of SE were also listed in Table 2.

Finally, the correlation between the formal potential $E^{0\prime}$ and the solution pH value (from pH 1.81 to 6.52) was studied by cyclic voltammetry. The formal potential $E^{0\prime}$ ($E^{0\prime} = (E_{pa} + E_{pc})/2$) of them both shifted negatively with the increasing pH. The linear regression equations could be expressed as follows: $(E^{0\prime}{}_{\text{CA system}}\ (\text{V}) = 0.753 - 0.033\,\text{pH}$ ($R = 0.999$, $n = 7$) and $(E^{0\prime}{}_{\text{CA–SE system}}\ (\text{V}) = 0.751 - 0.023\,\text{pH}$ ($R = 0.992$, $n = 7$), which indicated one proton was involved in the electrode reaction for each of these two electrochemical systems.

It was clear that the two systems were both two-electron and one-proton electrode processes. However, the diffusion coefficients and rate constants of the electrode reactions of CA in the absence and presence of SE showed significant differences. Compared with the CA system, the diffusion coefficient and rate constant of the electrode reaction of CA–SE system both decreased, which leaded to the peak current of CA reducing and the peak potential moving positively.

3.4. Measurement of stoichiometry of CA–SE complex

It is assumed that CA and SE produce a single complex of SE–*m*CA. Since the new complex SE–*m*CA was formed between electro-inactive SE and electro-active CA, the apparent binding constant β and the binding ratio m of SE with CA could be measured on the basis of peak current differences of CA in the absence and presence of SE when CA was in excess [30]. The equilibrium forming SE–*m*CA was listed below:

$$\text{SE} + m\text{CA} \leftrightarrow \text{SE} - m\text{CA}$$

The equilibrium constant was expressed as follows:

$$\beta = \frac{[\text{SE–CA}]}{[\text{SE}][\text{CA}]^m}$$

And the following equations were then derived:

$$\Delta i = k[\text{SE}–m\text{CA}], \quad [\text{SE}] + [\text{SE}–m\text{CA}] = C_{\text{SE}}, \quad \Delta i_{\max} = kC_{\text{SE}}$$

Therefore, $\Delta i_{\max} - \Delta i = k(C_{\text{SE}} - [\text{SE}–m\text{CA}]) = k[\text{SE}]$; where $\Delta i = i_{pa,0} - i_{pa}$, $i_{pa,0}$ and i_{pa} were oxidative peak currents of the CA and CA–SE systems, respectively; $\Delta i_{\max}$ was the oxidative peak current when the concentration of CA was extremely higher than that of SE. C_{SE}, [SE–*m*CA], and [SE] were corresponding to the total, SE bound, and free concentration of SE in the solution, respectively. The above equations could lead to the following equation: $(1/\Delta i) = (1/\Delta i_{\max}) + (1/\beta\Delta i_{\max}[\text{CA}]^m)$. By keeping the SE concentration at 200.0 μg mL^{-1} and varying the concentration of CA, a linear correlation of $1/\Delta i$ with $1/[\text{CA}]^m$ was obtained as follows: $(1/\Delta i) = 0.452 + (1.945 \times 10^{-7}/[\text{CA}])$ ($R = 0.994$, $n = 5$). From the intercept and slope, the binding constant $\beta = 2.32 \times 10^6$ L mol^{-1} and the binding ratio $m = 1$ were calculated.

4. Conclusion

In this paper, detailed studies were carried out on the interaction of CA with SE by the electrochemical methods. The studies showed that a 1:1 complex was formed between CA and SE, and the main binding mode was through the electrostatic attraction. The diffusion coefficient (D) and electrode reaction rate constant (k_s) of CA–SE system were both less than those of free CA, which resulted in a decrease in the voltammetric peak current of CA with the peak potential shifting positively. The binding of SE with CA was applied to the quantitative detection of SE. The results confirmed the proposed method as being a suitable alternative for the analysis of SE in degumming wastewater. Moreover, this method had great potential as a sensitive and simple detection technique with the advantages of wide linear range, low detection limit and good selectivity.

ABSTRACT

The present article reports on the application of modified multiwalled carbon nanotubes (MMWCNTs) as a new, easily prepared and stable solid sorbent for the preconcentration of trace rhodium ion in aqueous solution. Rhodium ions were complexed with 1-(2-pyridylazo)-2-naphthol (PAN) in the pH range of 3.2–4.7 and then the formed Rh-PAN complex was adsorbed on the oxidized MWCNTs. The adsorbed complex was eluted from MWCNTs sorbent with 5.0 mL of N,N-dimethylformamide (DMF). The rhodium in eluted solution was determined by flame atomic absorption spectrometry (FAAS). Linear range for the determination of rhodium was maintained between 0.16 ng mL^{-1} and 25.0 μg mL^{-1} in initial solution. Relative standard deviation for the 10 replicated determination of 4.0 μg mL^{-1} of rhodium was ±0.97%. Detection limit was 0.010 ng mL^{-1} in initial solution ($3S_{bl}$, $n = 10$) and preconcentration factor was 120. Sensitivity for 1% absorbance of rhodium (III) was 0.112 μg mL^{-1}. The sorption capacity of oxidized MWCNTs for Rh (III) was 6.6 mg g^{-1}. The effects of the experimental parameters, including the sample pH, flow rates of sample and eluent solution, eluent type, breakthrough volume and interference ions were studied for the preconcentration of Rh^{3+}. The proposed method was successfully applied to the extraction and determination of rhodium in different samples.

1. Introduction

Carbon nanotubes (CNTs) are an allotrope of carbon. A carbon nanotube is a one atom thick sheet of graphite rolled up into a seamless cylinder with diameter of the order of a nanometer. It caused in an essentially one-dimensional nanostructure where the length-to-diameter ratio exceeds 1000. Such cylindrical carbon molecules have novel properties that make them potentially useful in a wide variety of applications in nanotechnology, electronics, optics and other fields of materials science. They exhibit extraordinary strength and unique electrical properties, and are efficient conductors of heat [1]. Carbon nanotubes name is derived from their size, since the diameter of a nanotube is on the order of a few nanometers, while they can be up to several millimeters in length. There are two main types of carbon nanotubes: single walled carbon nanotubes (SWCNTs) and multiwalled carbon nanotubes (MWNTs) depending on the carbon atom layers in the wall of the nanotubes [2]. Since carbon nanotubes were first prepared in 1991 [3], they have become attractive materials for their novel structure characteristics [4]. CNTs have high surface area, mechanical strength, thermal and chemical stability. Due to their unique characteristic and strong adsorption ability [5], they have been successfully used to remove many kinds of pollutants such as dioxin from air [6], lead [7], cadmium [8], zinc [9], fluoride [10], 1,2-dichlorobenzene [11] and trihalomethanes [12] from different matrices.

Rhodium is present at about 0.001 μg mL^{-1} in the crust of the earth. Rhodium metal is known for its stability in corrosive environments, physical beauty and unique physical and chemical properties. The determination of rhodium has been studied by different techniques such as atomic absorption spectrometry [13], spectrophotometric methods [14], ICP-OES and ICP-MS [15] in catalysts, geological, environmental and alloy samples. The direct determination of rhodium ions in complex matrices is limited due to their usually low concentrations and matrix interferences. In trace analysis, therefore, a preconcentration and separation are necessary to improve sensitivity and selectivity of determination. Ideally, an analytical separation method should be rapid, simple, and inexpensive, give quantitative recovery of analytes without loss or degradation; should yield a solution of analyte that is sufficiently concentrated to permit the final measurement to be made without the need for concentration, and generate little or no laboratory waste that has to be disposed [16].

Several procedures have been proposed and applied for the separation and determination of rhodium by atomic spectrometry based on the nature of samples, the content of analytes and the measurement techniques [17,18].

For many decades the most common method for performing analytical separation on complex environmental was liquid extraction. Unfortunately, liquid–liquid extractions frequently fail to meet several of the ideal criteria listed in the previous paragraph. The use of solid phase extraction is an attractive way to avoid many difficulties associated with liquid extraction. Various sorbents such as thiol cotton [19], silanized glass beads [20], silica gel [21], Amberlite XAD-4resin [22], cellulose [23], green tea leaves [24] and polythioether foams [25] were used in solid phase extraction. To the best of our knowledge, however, there were no references to the application of MWCNTs for the preconcentration of trace amounts of Rh^{3+}. The goal of this work is the application of MWCNTs as a new sorbent for the preconcentration of trace amounts of Rh^{3+}.

2. Experimental

2.1. Apparatus

A Varian Model SpectrAA 220 atomic absorption spectrometer was used for the measuring of Rh^{3+} in an air–acetylene flame. The operating conditions were as follows: wavelength, 343.5 nm; lamp current, 5.0 mA and slit width, 0.5 nm. The acetylene flow and the air flow were 1.5 and 3.5 L min^{-1}, respectively. The pH measurement was carried out using a Metrohm pH meter (model 713) with a combined pH glass electrode calibrated against two standard buffer solutions at pH 4.0 and 7.0. A funnel-tipped glass tube (80 mm × 10 mm) was used as a column for preconcentration. All glassware and columns were washed with a mixture of concentrated hydrochloric acid and concentrated nitric acid (1:1) before application.

2.2. Reagents and materials

High purity reagents from Sigma (St. Louis, MO, USA) and Merck (Darmstadt, Germany) were used for the preparation of all standard and sample solutions. Stock solutions were prepared daily from Rh^{3+} standard solution 1000.0 mg L^{-1} (Merck, Germany) by serial dilution water. A 0.025% solution of 1-(2-pyridylazo)-2-naphtol (Merck, Germany) was prepared by dissolving an appropriate amount in ethanol. Platinum–iridium alloy purchased from Fine Wire Company (CA, USA). Buffer solutions were prepared from 0.5 mol L^{-1} acetic acid and 0.5 mol L^{-1} sodium acetate for pH 3–6, from 0.1 mol L^{-1} potassium dihydrogen phosphate and 0.1 mol L^{-1} disodium hydrogen phosphate for pH 6–8 and from 0.5 mol L^{-1} ammonia and 0.5 mol L^{-1} ammonium acetate for pH 8–10. MWCNTs with an average outer diameter of 3–20 nm, length of 1–10 μm, number of walls 3–15 and surface area of 350 m^2 g^{-1} were obtained from Plasma Chem. GmbH (Berlin, Germany).

2.3. Preparation of oxidized MWCNTs

Raw MWCNTs were heated at 300 °C for 40 min to remove amorphous carbon. Prior to use, MWCNTs were oxidized with concentrated HNO_3 according to the literature, in order to create binding sites onto the surface of MWCNTs [26]. The treatment was carried out by dispersing 25 mL of concentrated HNO_3 to 1.0 g of MWCNTs, and then refluxing for 6 h at 100 °C. Afterward, the oxidized MWCNTs were washed with distilled water until removing any excess of nitric acid (neutral pH of solution) [27].

2.4. Preparation of column

20 mg of oxidized MWCNTs was slurred in water, and then poured into a funnel-tipped glass tube plugged with a small piece of glass wool at the ends. A glass column packed with 0.02 g of oxidized MWCNTs sorbent (height of packing being about 10 mm) was used as the operational column. The column could be used repeatedly for 50 times after washing with distilled water.

2.5. General procedure

Initially, distilled water was passed through the column for column conditioning. An aliquot of rhodium solution and 5.0 mL of 0.025% PAN reagent was placed in a 100 mL beaker and the mixture was diluted to 30 mL with distilled water. The pH was adjusted to 3.7 with acetate buffer and the solution was heated for 60 min at 90 °C to form Rh-PAN complex [28]. Then, the obtained Rh-PAN complex was passed through the column at a flow rate of 2 mL min^{-1}. Finally, the adsorbed Rh-PAN complex was eluted from sorbent with 5.0 mL of DMF. The eluted solution was aspirated directly into the flame of atomic absorption spectrometry and compared with a blank that was prepared in the same manner without the addition of Rh^{3+}.

3. Results and discussion

Preliminary experiments showed that although, oxidized MWCNTs have a low tendency for the retention of adsorption Rh^{3+} (less than 50%), they are not selective for the separation of rhodium ions. Therefore, the oxidized MWCNTs do not judge a suitable sorbent for the separation of rhodium ions. A recent work [29] indicates that MWCNTs can be adsorbed on organic materials. So, we decided to form complex between Rh^{3+} and PAN ligands. Then, the formed Rh-PAN complex was adsorbed onto oxidized MWCNTs. The results showed that the recovery of rhodium ions by using oxidized MWCNTs is higher than 97%. Moreover, oxidized MWCNTs are selective for the separation of Rh-PAN complex. In order to obtain highly sensitive, accurate, and reproducible results, analytical parameters including pH, type and volume of eluent solution, breakthrough volume and flow rates of sample and eluent were optimized for the preconcentration of Rh^{3+}.

3.1. Effect of the sample pH

As pH is one of the important analytical factors in the solid phase extraction of metal ions [30], the influences of pH of the aqueous

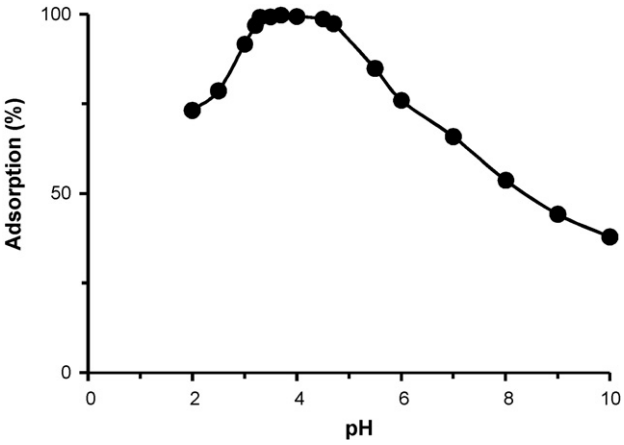

Fig. 1. The effect of sample solution pH on the percent sorption of Rh^{3+}. Conditions: Rh, 20.0 μg; sample flow rate, 2 mL min^{-1}; eluent solution, 5.0 mL DMF with a flow rate 1 mL min^{-1}. Instrumental settings: wavelength, 343.5 nm; lamp current, 5.0 mA; slit width, 0.5 nm; acetylene flow, 1.5 L min^{-1}; air (as oxidant) flow, 3.5 L min^{-1}.

Table 1
Obtained recoveries in choosing the eluent type.

Ni^{2+}	0.2

Conditions and instrumental settings were same as Fig. 1.

solution on the recovery of rhodium ions on oxidized MWCNTs were investigated. The percent sorption of rhodium ion on the sorbent surface as a function of sample pH is shown in Fig. 1. As can be seen, the sorption percent of Rh(III) depends on the pH of the sample solution. The optimum pH range was around 3.2–4.7. In subsequent studies, the pH was maintained at approximately 3.7 with acetate buffer.

3.2. Sorption capacity

In order to evaluate the sorption capacity of oxidized MWCNTs for rhodium ion, a batch method was used. Accordingly, 40 mL of solution containing 0.6 mg of rhodium and 32 mg of PAN reagent at pH 3.7 was prepared. This solution was heated for 60 min at 90 °C, and then was added to it 20 mg oxidized MWCNTs. After shaking for 30 min, the mixture was filtered. The maximum capacity of the sorbent was 6.6 mg of Rh^{3+} per gram of sorbent. The oxidized MWCNTs sorbent were subjected to several loadings with the sample solution and subsequent elution. It was found that the adsorption properties of the adsorbent remained constant after 50 cycles of sorption and desorption.

[a] Mean ± standard deviation (n = 4).

3.3. Effect of flow rate of sample

Flow rate of the sample solution is a measure of the contact time between the sample solution and the sorbent. The results showed that the flow rate variation in the range of 0.2–2.5 mL min^{-1} did not have a significant effect on the sorption of the rhodium. It was found that the adsorption of Rh-PAN complex on oxidized MWCNTs is relatively rapid. In order to achieve good precision, a flow rate of 2 mL min^{-1} was therefore chosen for further studies.

3.4. Effect of eluent flow rate

The effect of eluent flow rate on desorption of Rh-PAN complex from the sorbent surface was studied in the range of 0.2–2.5 mL min^{-1}. Flow rate of 1 mL min^{-1} was chosen in subsequent work.

3.5. Selection of eluent

Desorption of the adsorbed material on the solid phases is an important step for the solid phase extraction studies [30]. A series of solvents such as, DMF, dimethyl sulfoxide (DMSO), tetrahydrofuran (THF), 1-butanol, 1-propanol, ethanol and acetone, were used in order to find the best eluent. The results showed that the best recovery was achieved when DMF was used as eluent. It was found that 5.0 mL of this solvent was sufficient to elute the complex from oxidized MWCNTs. The results are shown in Table 1.

Table 3
Analysis of rhodium ion in synthetic samples.

3.6. Breakthrough volume

When solutions containing 20.0 μg of rhodium in 350, 400, 450, 500, 550 and 600 mL of water were passed through the columns, the Rh(III) was quantitatively retained in all cases. We concluded that the breakthrough volume of the method under optimum conditions should be greater than 600 mL. Consequently, by considering the final elution volume of 5.0 mL of DMF, and a breakthrough volume of 600 mL, a preconcentration factor of 120 was easily achievable.

3.7. Interferences

The interferences of coexisting ions in binary mixtures of Rh (III) with foreign ions were studied on the percent recovery of rhodium ($4.0\,\mu g\,mL^{-1}$). After introducing the binary solution into a column, the adsorbed rhodium ion was eluted by DMF solvent. The content of rhodium ions in effluents was determined using FAAS, and the recoveries were calculated. The results, summarized in Table 2, clearly indicate that most of the tested ions do not interfere with the determination of rhodium. The tolerance limit was set as the amount of foreign ions required to cause a ±4% error.

3.8. Analytical figure of merit

Analytical figure of merit was evaluated for the determination of rhodium according to the recommended procedure. Under optimum conditions, the calibration curve was linear from $0.16\,ng\,mL^{-1}$ to $25.0\,\mu g\,mL^{-1}$ in initial solution or 0.02 to $25.0\,\mu g\,mL^{-1}$ in final solution with a correlation coefficient (R^2) of 0.999 and the equation of the calibration curve was $A = 0.034C + 0.006$, where A is the absorbance value of the eluent and C is the concentration of Rh (III) ($\mu g\,mL^{-1}$) after preconcentration in the eluent. The recommended procedure was repeated 10 times to find the relative standard deviation in the determination of $4.0\,\mu g\,mL^{-1}$ of Rh (III) ion, whose RSD was found to be ±0.97% in final solution. The obtained limit of detection $0.010\,ng\,mL^{-1}$ was based on three times the standard deviation of the blank solution measurements ($n = 10$) in original solution. The sensitivity for 1% absorbance was $0.112\,\mu g\,mL^{-1}$.

3.9. Determination of rhodium in synthetic samples

Since no standard samples were available for testing the validity of the developed method for analysis of real samples, the method was applied to synthetic mixtures. Accordingly, various synthetic mixtures simulating different cations were prepared. Aliquots of the synthetic mixture were taken; pH was adjusted to ~3.7 with acetate buffer of pH 3.7 and then the general procedure applied. The results are given in Table 3.

3.10. Analysis of water samples

In order to test the applicability and reliability of the proposed method, tap water, well water, river water, sea water and waste water samples were analyzed. For this purpose, 100.0 mL of each sample was preconcentrated in accordance to the proposed method. The results are shown in Table 4. In all cases the spiked recoveries confirmed the reliability of the proposed method. Also, we applied standard addition method for the determination of rhodium ion in spiked real samples mentioned in Table 4. The results showed that good recoveries of 96.06–104.63% were achieved for analyzed samples.

3.11. Analysis of a platinum–iridium alloy

In order to test the applicability of the proposed method for the analysis of real samples, one platinum–iridium alloy was analyzed. To 5.0 mg of the alloy with known composition, 7 mL of aqua regia was added and the solution was evaporated. Five milliliters of concentrated hydrochloric acid was added to it and the solution was warmed, transferred to a 100 mL volumetric flask, and made up to the mark with distilled water. An aliquot of this solution was taken and rhodium was determined by the general procedure. Four determinations were made, and the result is given in Table 5.

4. Conclusion

The present study demonstrates the use of oxidized MWCNTs as a new sorbent in the preconcentration of rhodium ion in different matrices. The preparation of oxidized MWCNTs is simple and of low cost. These sorbents are simple and of low cost, which can be used several times without a marked loss in sorption capacity. The developed method is simple, rapid, precise, accurate and reliable offering a higher preconcentration factor and lower detection limit for rhodium ion than the other sorbents. Table 6 compares the proposed method with those reported previously for the determination of rhodium after preconcentration procedure. It shows that the proposed method has a low detection limit compared with previous studies [31–37] and it allows the determination of $ng\,mL^{-1}$ levels of rhodium. The method is economical due to the possibility of multiple uses of the sorbent.

ABSTRACT

A novel cloud point phase separation of cationic surfactant, Aliquat-336 and capabilities of its reactive solubilizing sites for selective extraction of chromium species at ultra trace levels was examined in natural water. The phase separation behavior of Aliquat-336 is studied with various additives. The nonionic surfactant, Triton X-114 was found to induce the cloud point phase separation of Aliquat-336. The separation of anionic Cr(VI) was enabled by the formation of ion associate with quaternary ammonium head group of Aliquat-336 at pH 2, and the recovery of Cr(VI) and Cr(III) were 101.4 ± 1.4% and 2.2 ± 0.4%, respectively at 0.5–1 ng mL^{-1}, Total Cr was pre-concentrated as Cr-APDC species using the hydrophobic tail group at pH 6.5. The Cr(III) concentration was obtained by subtracting Cr(VI) from total Cr. The recovery of total Cr was 99.5 ± 1.2%. Parameters affecting extraction were assessed. The procedure was applied to NIST 1643c and NIST 1643d waters, and the sum of individual species obtained was compared with the certified chromium values. The method was also applied to various natural waters with limits of detection and pre-concentration factor of 0.010 and 0.025 ng mL^{-1}; 10 and 10, respectively, for Cr(VI) and Cr(III)-APDC using ICP-MS operated in DRC mode.

1. Introduction

Since its introduction in the early 1980s nonionic surfactant based phase separation (cloud point extraction, CPE) has proved to be the most efficient and environmental friendly procedure for the separation and pre-concentration of a various metal-chelates and organic compounds [1–4]. Phase separation is easily achieved by altering the solution properties such as temperature or additives. Furthermore, a common concept of hydrophobic interaction of nonionic micelles is used to account for the success of all these CPE procedures. However, nonionic surfactants have some major drawbacks such as lower extraction efficiencies and instability of the thermally labile water soluble organic and inorganic species [5,6]. One of the main reasons for these drawbacks is due to the lack of electrostatic interacting sites in the extracting nonionic micelles. Hence, there is a continuous quest to overcome these limitations.

Ionic surfactant based phase separation (coacervate extraction, CE) is being used for the extraction of partially water soluble organic compounds through their interaction with charged hydrophilic head groups, which partially alleviate the above problem [7–11]. In these cases, the phase separation is induced by the addition of dehydrating agents such as high electrolytes and acids. Unfortunately, these agents partially neutralize the useful reactive charge of the hydrophilic head groups [7,11], which diminish the extraction efficiencies and elevates the procedural blank in case of inorganic ionic species. These difficulties are further exacerbated due to the troublesome surfactant-rich phase separation process [6,12]. There is a dearth of information about the phase separation of number of ionic surfactants. Thus, CE is exploited scarcely, for the extraction of hydrophilic inorganic ionic species, despite having reactive charged head groups.

For clear phase separation, balancing the hydrophobic to hydrophilic interaction is very important in micelle solutions [13]. The phase separations of all the reported CPE and CE procedures have used the same concept of reducing the hydrophilic character of micelles by the addition of dehydrating agents. On the other hand, the concept of increasing the hydrophobic character of micelles has not received much attention. The success of this new concept in ionic surfactants is more useful to develop efficient procedures for the extraction of hydrophilic ionic species along with organic compounds. Fewer research groups are involved in this topic and have studied only changes in the physical properties of ionic surfactants by addition of hydrophobic counter ions [14]. Until now, no analytical procedure has been reported by using this concept

doi:10.1016/j.talanta.2009.06.051

of hydrophobic species induced phase separation of ionic surfactant. Therefore, we have put efforts in this direction and studied the phase separation behavior of cationic surfactant with various additives. Cationic cloud point phase separation has been achieved for the first time using the novel concept of increasing the hydrophobic character of micelles with nonionic surfactant. This process provides the uncompromised cationic active sites in the cationic surfactant based CPE, which overcomes the limitations related to high salts in CE and drawbacks in nonionic surfactant based CPE processes. It is envisioned that the micelle aggregates formed must have significantly high hydrophobic interacting sites along with unaltered active cationic head group sites, which react more selectively with anionic and organic species, avoiding the requirement to add other chelating agents for extraction of hydrophilic anionic species.

For demonstrating the analytical applicability of this novel concept, we have selected the chromium speciation in natural waters, as these species show opposite toxicity and reactivity [15]. Furthermore, Cr(VI) is classified as a Class A carcinogen that dissolves more in water and spreads easily to all natural water bodies [16]. Hence, there is a demand to develop a simple extraction procedure for the ultra trace speciation analysis of chromium in natural water. The nonionic surfactant based CPE has been applied for the speciation analysis of chromium in water only by using chelating agents [17,18].

Determination of chromium species at ultra trace levels in organic and chloride rich matrices is still a difficult task even after using more versatile quadrupole ICP-MS [19]. A major concern in ICP-MS analysis is caused by severe spectral interferences on major isotopes, which hamper the accuracy of the results. For alleviating these interferences dynamic reaction cell (DRC) facility of ICP-MS with ammonia as the reaction gas has been used effectively [20].

This paper describes, a novel nonionic surfactant induced cationic cloud point extraction procedure and explores its capabilities to ultra trace speciation analysis of chromium from natural water using ICP-DRC-MS. Aqueous solution of cationic surfactant (Alquat-336) separates into two phases, same as in CPE, in presence of Triton X-114. Surfactant-rich phase settle at the bottom of solution, which entraps selectively the highly water soluble anionic hydrophilic ($HCrO_4^-$) and hydrophobic (Cr-APDC) species from bulk aqueous phase, which confirm our assumption. To confirm the accuracy of our assumption, the developed procedure is verified by analyzing two certified reference materials such as NIST 1643c and 1643d Trace Elements in Water and also been applied to real natural water samples collected locally.

2. Experimental

2.1. Instrumentation

An ELAN 6100 DRC II ICP-MS (Perkin-Elmer SCIEX, Concord, Ontario, Canada) was used. Using ammonia as a reaction gas, the DRC conditions were optimized for obtaining the best signal to noise ratio at two isotopes of chromium [19]. The optimized operating conditions are given in Table 1.

Table 1
Optimized operating conditions of ICP-DRC-MS.

ICP-MS instrument	PE-SCIEX ELAN 6100 DRC II

Rejection parameter, *a*	0.0

2.2. Reagents standards and samples

Ultrapure water (18.2 MΩ cm) was obtained from a Millipore (Bedford, MA, USA) system. $K_2Cr_2O_7$ from Merck (Darmstadt, Germany) and Cr(III), nonionic (Triton X-114) and cationic (Aliquat-336) surfactants and ammonium pyrrolidinedithiocarbamate (APDC) were procured from Aldrich (Steinheim, Germany). Methanol and hydrochloric acid (Suprapur, Merck, Darmstadt, Germany) were used for dissolving the surfactant-rich phase. The pH of water samples was adjusted by using HCl and acetate buffer solutions. Rhodium internal standard was purchased from SPEX, USA. The interferences studies were performed by using varying amounts of single elemental stock standard solutions of 1 mg mL^{-1} Ca, Mg, Cd, Cu, Sn, F and Pb (Fisher, Fair Lawn, NJ, USA), Ni, Pd, Pt, NaCl, KCl, $NaNO_3$, NaH_2PO_4 and Na_2SO_4 (Merck, Darmstadt, Germany) and humic acid (Sigma–Aldrich, Steinheim, Germany). Certified reference materials 1643c and 1643d trace elements in waters were obtained from NIST. Natural water samples such as tap, lake, under ground and municipal drinking water were collected locally, and filtered through a 0.45 μm membrane filter and used immediately.

2.3. Procedures

2.3.1. Determination of the phase separation behavior and CPT of Aliquat-336

The phase separation behavior of Aliquat-336 was studied after adding various amounts of additives such as Triton X-114, HCl and NaCl. The phase separation behavior was observed as a function of Aliquat-336 and additive concentrations at room temperature (RT), which is 25 °C, after 24 h. The cloud point temperature (CPT) of various solutions, obtained by varying the HCl and Aliquat-336 concentrations in presence of 1% (m/v) Triton X-114, was measured as the temperature at which the turbidity appeared in the solution.

2.3.2. CPE procedure

2.3.2.1. Extraction of hydrophilic Cr(VI). An aliquot of 15 mL water sample was taken in a tube and maintained the pH 2 using HCl. To this solution, 0.3 mL of 10% (m/v) Aliquat-336 and 1.5 mL of 10% (m/v) Triton X-114 were added. The solution was left to stand for 2 h at RT, which lead to phase separation. The head group of the cationic surfactant behaves like a chelating agent and react with anionic species of Cr(VI) and pre-concentrated into surfactant-rich phase, which avoids the addition of external chelating agent. The surfactant-rich phase formed was easily separated by removing the bulk aqueous phase by using micropipette and used for determination of Cr(VI).

2.3.2.2. Extraction of hydrophobic Cr-APDC. For the determination of total Cr, fresh aliquot of water sample was taken into a tube and maintained the pH 6.5 using acetate buffer. To this solution,

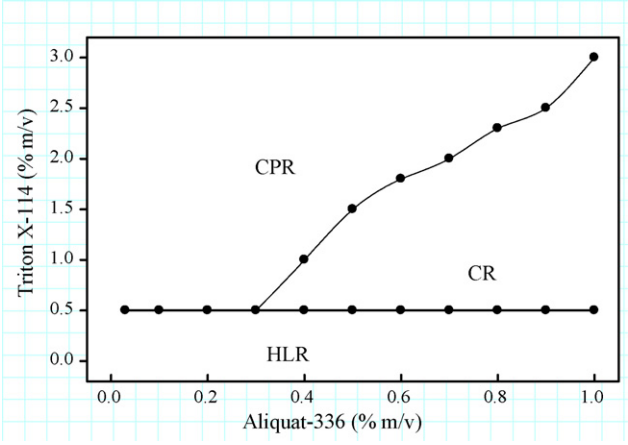

Fig. 1. Phase behavior of Aliquat-336 with Triton X-114 in presence of 1% (v/v) HCl at room temperature.

0.45 mL of 10% (m/v) APDC was added and mixed well for 2 min. Mixture of Aliquat-336 and Triton X-114 was added and the above procedure was followed. The APDC reacts with both chromium [Cr(III) and Cr(VI)] species, and the Cr-APDC hydrophobic species pre-concentrated into the surfactant-rich phase was used for the determination of total Cr [17,18]. The viscosity of 0.4 mL surfactant-rich phase was reduced by dissolving in 1.5 mL of 0.2% HCl, and analyzed for Cr(VI) and total Cr. Procedural blanks were also prepared in the similar manner.

3. Results and discussion

3.1. Effect of additives on the phase separation behavior and CPT of Aliquat-336

The phase separation behavior of ionic surfactant can be varied by the addition of certain dehydrating additives [9]. Therefore, the phase separation behavior of Aliquat-336 was studied with various additives, such as Triton X-114, HCl and NaCl, at room temperature. Fig. 1 shows the phase behavior of Aliquat-336 with Triton X-114 taken in 1% (v/v) HCl when their concentrations were varied independently in the range 0.03–1% (m/v) and 0.1–3% (m/v) respectively. As shown in Fig. 1, three different regions were observed with a clear phase boundary. They were formed by nonionic surfactant induced cloud point region (CPR) and cationic surfactant dominated coacervate region (CR) and a homogeneous liquid region (HLR). The breadth of each region depends up on the concentrations of Aliquat-336 and Triton X-114. Clear HLR was observed at all studied concentrations of Aliquat-336, when Triton X-114 concentration was below 0.5%. Above 0.5%, there was a clear phase boundary between CPR and CR when concentration of Aliquat-336 was more than 0.3%. Both CPR and CR regions contain mixed micelles nonionic being predominant in CPR and vice versa. At higher concentrations of HCl (>10%) and NaCl (>4%) coacervate region was found to be predominant.

Cloud point temperature of surfactants depends on the balance between hydrophilic and hydrophobic interactions of the system, which changes with additives [13]. Hence, the variation of CPT of Aliquat-336 was studied by varying the Aliquat-336 concentration in the range of 0–0.4% (m/v) with HCl in the range of 1–30% (v/v) at 1% Triton X-114. The results showed that at 0% Aliquat-336, the CPT was increased with HCl concentration. However, when Aliquat-336 was added the CPT was constant up to a concentration of 0.005% and then decreased to <10 °C beyond 0.2% Aliquat-336 at all studied concentrations of HCl.

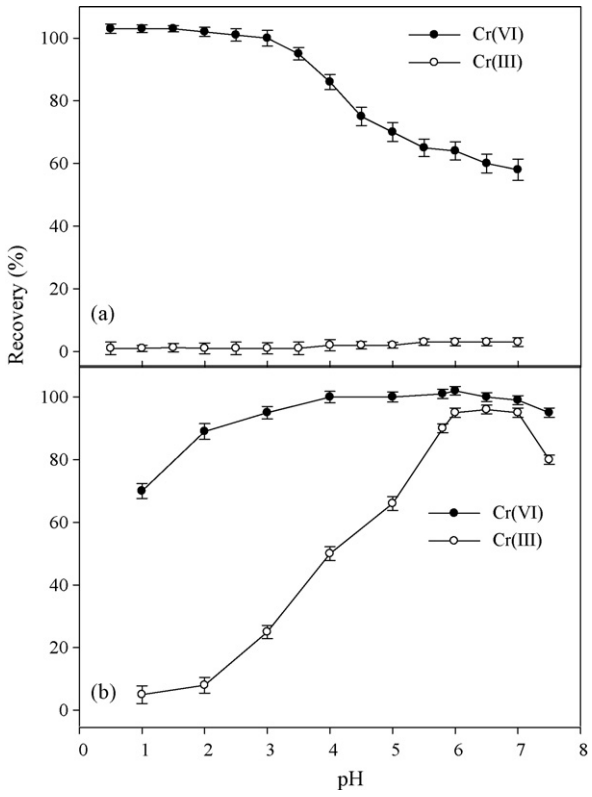

Fig. 2. Effect of pH on the analytical recovery of Cr(III) and Cr(VI) using room temperature cloud point extraction in presence of 0.2% (m/v) Aliquat-336 and 1% (m/v) Triton X-114. (a) Without APDC; (b) with 0.3% (m/v) APDC. The error bars indicate the relative standard deviation (%) at each measurements ($n = 4$).

3.2. Optimization of cationic cloud point extraction parameters

The parameters affecting the extraction of hydrophilic anionic species of Cr(VI) such as $HCrO_4^-$ and hydrophobic Cr-APDC species by the reactive solubilizing sites of Aliquat-336 were studied individually using 0.5 ng mL^{-1} each Cr(VI) and Cr(III) spiked tap water.

Chromium exists in various forms and the relative concentration of each species depends up on the total chromium concentration and pH of the aqueous solution. Hence, the effect of pH on the recovery of Cr(III) and Cr(VI) was studied in the pH range 1–7.5, in presence of 0.2% (m/v) Aliquat-336 and 1% (m/v) Triton X-114, with and without APDC, and the results are shown in Fig. 2(a) and (b). The results indicate that without APDC in Fig. 2(a), 100–103% recovery of Cr(VI) was achieved in the pH range 0.5–3, and then decreased to 60% by further increase in the pH of the solution to 7.5. Whereas, only 2–3% recovery of Cr(III) was observed at the whole studied pH range. Thus, pH 2 was used for selective separation and pre-concentration of Cr(VI) in presence of Cr(III), without using any external chelating agent. In presence of APDC in Fig. 2(b), 100–102% and 94–96% recoveries of Cr(VI) and Cr(III) were achieved in the pH range 5.5–7. Therefore, a pH 6.5 was selected for simultaneous extraction of Cr(III) and Cr(VI), which gives the total chromium concentration. As the reactivity of Cr(VI) with APDC is very fast, the optimization studies were carried out using Cr(III) standard alone.

In order to develop a successful nonionic surfactant induced cationic CPE procedure, optimization of concentrations of cationic and nonionic surfactant required is a must. Fig. 3(a) shows the effect of Aliquat-336 concentration on percentage recovery of Cr(VI) as $HCrO_4^-$ and Cr(III)-APDC, by keeping the Triton X-114 concentration at 1% m/v. The results showed that without Aliquat-336, at RT, no phase separation was observed because the CPT of the solution was 31 °C. Clear phase separation was observed at 0.01% Aliquat-

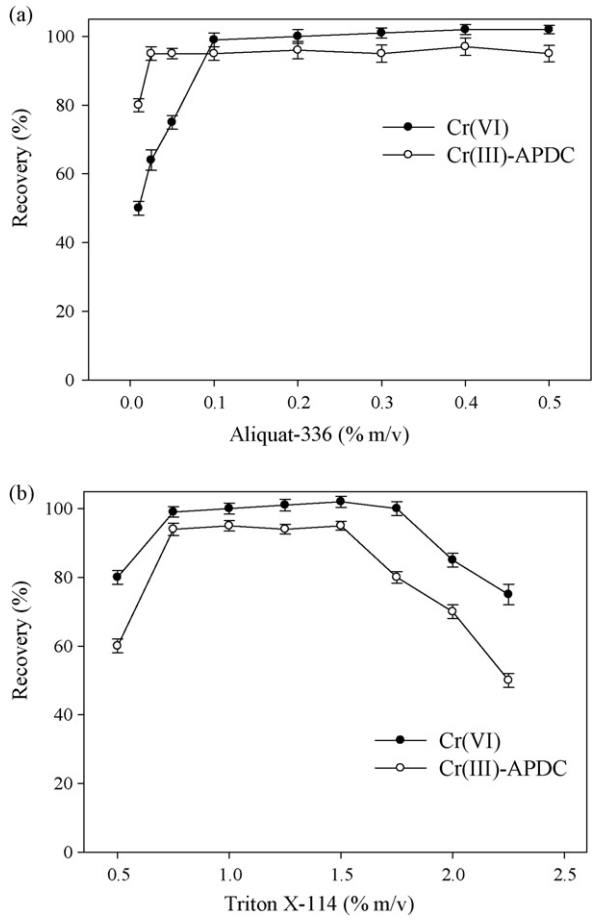

Fig. 3. Effect of Aliquat-336 (a) and Triton X-114 (b) concentration on the recovery (%) of Cr(VI) and Cr(III)-APDC using room temperature cloud point extraction in presence of (a) pH 2 for Cr(VI) and pH 6.6 for Cr(III), 0.3% (m/v) APDC and 1% (m/v) Triton X-114; (b) pH 2 for Cr(VI) and pH 6.6 for Cr(III), 0.3% (m/v) APDC and 0.2% (m/v) Aliquat-336. The error bars indicate the relative standard deviation (%) at each measurements ($n = 4$).

336 addition at RT. This is mainly because of the increase in the hydrophobic nature of the formed mixed micelles that reduces the CPT to 10 °C. Under this condition, the recovery of Cr(VI) and Cr(III)-APDC species were 50 and 80%, respectively. These recoveries were increased gradually to 65 and 95%, respectively by the addition of 0.025% Aliquat-336. Further increase in the concentration of Aliquat-336 to 0.1%, increase the recovery of Cr(VI) and reached a plateau, without any adverse effect in the recovery of Cr(III)-APDC. The low recoveries of Cr(VI) and Cr(III)-APDC at 0.01% Aliquat-336 may be due to non-availability of sufficient hydrophilic and hydrophobic solubilizing sites. Therefore, a concentration of 0.2% Aliquat-336 was selected for quantitative extraction of both the species. Fig. 3(b) shows the effect of Triton X-114 on the percentage recovery of Cr(VI) as $HCrO_4^-$ and Cr(III)-APDC species in the range 0–2.25%, by keeping the Aliquat-336 concentration at 0.2% at RT. The results showed that no phase separation was observed in the range of 0–0.5% Triton X-114. The recoveries increased with increase in the Triton X-114 concentration up to 0.75%, and then reached a plateau up to 1.5%. Further increase caused reduction of the recoveries of both the species. Therefore, a concentration of 1% Triton X-114 was selected. The concentration of APDC required was also studied in the range of 0.1–0.6% (m/v) and 0.3% was found to be optimum for the extraction of both Cr(VI) and Cr(III) species.

The optimization of incubation temperature is necessary, especially, for complete complexation and extraction of water soluble $HCrO_4^-$ and hydrophobic Cr-APDC species into various solubilizing micelles aggregates. For the formation of cloud point phase separation, the selected incubation temperature must be higher than the cloud point temperature of the clouding solution. The clouding temperature of the solution under optimized conditions was 5 °C. Therefore, the effect of incubation temperature was studied in the range 20–90 °C for efficient extraction using incubation time of 120 min. The results showed that the recoveries of Cr(VI) and Cr(III)-APDC were 102 and 96%, respectively at 25 °C. These recoveries were constant up to 40 °C for both the species, and further increase in the incubation temperature to 90 °C, caused decrease in the recovery of Cr(VI) without any adverse effect in the recovery of Cr-APDC. The constant recovery of Cr(III)-APDC over the studied temperature range indicates that the interaction of hydrophobic species (Cr-APDC) with the hydrophobic solubilizing sites of the micelles aggregates is efficient. The reduction in the recovery of Cr(VI) at higher temperatures (>40 °C) may be due to change in the hydrated sphere and ionic environment of extracted species and hydrophilic solubilizing sites compared to the species extracted at room temperature. Therefore, room temperature incubation temperature was selected for both the species.

Sufficient incubation time is required for completing the formation of extractable ion associated and chelating species and their effective interaction and quantitative transfer into the solubilizing sites. Therefore, the effect of incubation time was investigated over a time period from 30 to 240 min at RT. The experiments showed that the phase separation was achieved with in 30 min with 60 and 70% recoveries, respectively for Cr(VI) and Cr-APDC, which were increased to 100 and 97% at 100 min time. Further increase in the incubation time up to 240 min did not change the recoveries. Therefore, 120 min incubation time was selected.

At the optimum conditions the pre-concentration factors, i.e., the ratio of the analyte concentration in the final surfactant-rich phase to that of the initial aqueous phase was evaluated. The final dilution of surfactant-rich phase was performed by compromising the pre-concentration factor in order to make solution suitable to pass through conventional pneumatic nebulizer. Therefore, the 0.4 mL surfactant-rich phase was diluted to 1.5 mL using 0.2% (v/v) HCl. A pre-concentration factor of 10 was achieved for both the species. The dissolved surfactant-rich phase was homogeneous and

provided stable signal for Cr(VI) and Cr(III)-APDC extracted species for more than 2 weeks.

3.3. Analytical recovery

The recovery studies of Cr(VI), Cr(III) and total Cr were performed separately after spiking tap water samples with Cr(III) and Cr(VI) species individually in the range of 0.5–1 ng mL^{-1} and at different ratios. The recoveries obtained are given in Table 2. Cr(III) values were obtained by subtracting the Cr(VI) values from total chromium. As shown in Table 2, the recoveries were in between 95 and 102% for all types of waters studied. Therefore, this procedure was used for determination of individual chromium species in natural water samples. The relative standard deviations were in between 0.8 and 2%.

3.4. Interferences

In order to evaluate the performance of this procedure, the highest tolerability of various common interfering ions were studied. Interferences may occur mainly due to competition of other existing anionic species in the water samples that may form ion associated complexes with the cationic hydrophilic solubilizing sites and also from the natural organic matter in the form of humic acid, which forms strong complexes with the hydrophobic solubilizing sites of the aggregates. Therefore, the tolerable limits of various foreign ions were studied in tap water, spiked with 1 ng mL^{-1} each of Cr(VI) and Cr(III) independently, by keeping the relative error between ±5%. It was found that 2 and 1 g L^{-1} of Na^+ and K^+; 500 mg L^{-1} of Mg^{2+}; 50 mg L^{-1} of Ca^{2+}; 100 mg L^{-1} of Ni^{2+}; 50 mg L^{-1} of Cu^{2+}; Cd^{2+} and Pb^{2+}; 1 mg L^{-1} of Pd^{2+}; 0.2 mg L^{-1} of Pt^{4+} and Sn^{4+} cations and 3 g L^{-1} of Cl^-; 0.5 g L^{-1} of SO_4^{2-}; 3 g L^{-1} of NO_3^-; 1 mg L^{-1} of F^- and PO_4^{2-} anions showed no interference. In addition to the above, no interference was observed from humic acid up to 6 mg L^{-1}. These results demonstrated the selectivity of the procedure, and which can be applied to the analysis of real water samples.

3.5. Analytical figures of merit

Under the optimized experimental conditions, the calibration curves were obtained by pre-concentrating the tap water samples successively spiked with five standards of Cr(VI) and Cr(III) with APDC in the range of 0.2–10 and 0.3–5 ng mL^{-1}, respectively. The correlation coefficient was 0.9998 and 0.9956 for Cr(VI) and Cr(III) with APDC, respectively. Quantifications have been performed by using aqueous standards prepared in 0.2% HCl. The relative standard deviation (% RSD) of Cr(VI) and Cr(III)-APDC were in between 0.6 and 3% at 1 ng mL^{-1}. The limits of detection calculated based on three times the standard deviations of the ten measurements of procedural blanks of Cr(VI) and Cr(III)-APDC were 0.010 and 0.025 ng mL^{-1}, respectively. A comparison of the proposed cationic CPE procedure with the previously reported CPE procedures for the speciation analysis of chromium is given in Table 3, which indicates that the present procedure shows the comparable or better LOD with the reported procedure. The other advantages are i) The analytical capabilities of the both (hydrophilic and hydrophobic) solubilizing sites of the Aliquat-336/Triton X-114 mixed micelles have been proved by selective extraction of Cr(VI) and Cr-APDC species separately. ii) The cationic head group of the mixed micelle act as an internal chelating as well as extracting agent for the extraction of $HCrO_4^-$ species and avoids the addition of external chelating agents. iii) Temperature independent extraction of Cr-APDC species shows the high reactivity of the hydrophobic solubilizing sites of mixed micelles. iv) The room temperature phase separation and stability of the extracted chromium species in surfactant-rich phase are useful to handle the samples at sampling sites and transporting

the small volume of surfactant-rich phase containing Cr species to environmental laboratories.

3.6. Validation of the method and analysis of real samples

The accuracy of the proposed procedure was verified by analyzing certified reference materials such as NIST 1643c and 1643d water. This procedure was also applied to the determination of Cr(VI) and Cr(III) species in real samples analyzed directly without any sample pretreatment. The results are given in Table 4. The results showed that there is good agreement between the measured chromium and the certified values indicating the accuracy of the procedure. Both the isotopes of the chromium showed the same results indicating the interference free measurements. The values of Cr(VI) in tap, lake, under ground and municipal water samples were 85, 55, 189 and 65 pg mL^{-1}, respectively. The precision of the results were between 0.2–0.6 and 0.5–1.1% for total chromium and Cr(VI), respectively.

4. Conclusions

We have presented a new concept of increasing the hydrophobic nature of cationic micelles with nonionic surfactant for inducing the cloud point phase separation. Its analytical applicability has been demonstrated by extraction of both hydrophilic anionic and hydrophobic species of chromium. The limits of detection of Cr achieved are comparable or superior to reported procedures. Additionally, the room temperature phase separation and stability of the extracted species in surfactant-rich phase are useful to handle the collected samples at sampling sites and transporting the small volume SRP to environmental laboratories. Therefore, these features make the procedure more attractive to handle the thermally labile analytes easily.

ELISA

ABSTRACT

For the first time, an enzyme-linked immunosorbent assay (ELISA) has been developed and validated for the determination of fluvastatin (FLV) in plasma samples at picogram level. The assay employed a polyclonal antibody that specifically recognizes FLV with high affinity, and FLV conjugate of bovine serum albumin (FLV–BSA) immobilized onto microplate wells as a solid-phase. The assay involved a competitive binding reaction between FLV, in plasma sample, and the immobilized FLV–BSA for the binding sites on a limited amount of the anti-FLV antibody. The bound anti-FLV antibody was quantified with horseradish peroxidase-labeled second anti-rabbit IgG antibody (HRP-IgG) and 3,3′,5,5′-tetramethylbenzidine (TMB) as a substrate for the peroxidase enzyme. The concentration of FLV in the sample was quantified by its ability to inhibit the binding of the anti-FLV antibody to the immobilized FLV–BSA and subsequently the color intensity in the assay wells. The conditions for the proposed ELISA were investigated and the optimum conditions were employed in the determination of FLV in plasma samples. The assay limit of detection was 10 pg mL^{-1} and the effective working range at relative standard deviations (RSD) of ≤5% was 20–1000 pg mL^{-1}. Analytical recovery of FLV from spiked plasma was 97.1–102.7 ± 2.85–6.25%. The precision of the assay was satisfactory; RSD was 2.46–5.37 and 3.19–6.64% for the intra- and inter-assay precision, respectively. The analytical procedure is convenient, and one can analyze ~200 samples per working day, facilitating the processing of large-number batch of samples. The proposed ELISA has a great value in routine analysis of FLV for its therapeutic monitoring and pharmacokinetic studies.

1. Introduction

Atherosclerosis of the coronary and peripheral vasculature is the principal cardiovascular disease that causes morbidity and mortality worldwide [1]. Elevated plasma levels of the total cholesterol (hypercholesterolemia) are predictive for the premature coronary heart disease [2]. Lowering the cholesterol levels can arrest or reverse atherosclerosis in all vascular beds and can significantly decrease the morbidity and mortality associated with the atherosclerosis [3]. The most efficient and frequently prescribed drugs for the treatment of hypercholesterolaemia are the 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors [4]. These agents specifically inhibit HMG-CoA reductase, the enzyme that catalyzes the conversion of HMG-CoA to mevolanate, which is the early rate-limiting step in the biosynthesis of cholesterol in the body [5].

Fluvastatin [*R**,*S**-(*E*)]-(±)-7-[3-(4-fluorophenyl)-1-(1-methylethyl)-1H-indol-2-yl]-3,5-dihydroxy-6-heptenoic acid, is a totally synthetic highly potent HMG-CoA reductase inhibitor. As well, FLV reduces the level of low-density lipoprotein (LDL) in plasma, and it is well tolerated by the patients [6]. FLV has a short elimination half-life, and is highly bound to plasma proteins. Furthermore, the bioavailability and pharmacodynamics of FLV are not affected by food. Because of the hydrophilicity of FLV, it does not cross the blood–brain barrier, thus it has no central nervous system side effects (e.g. insomnia) [7]. These qualities made FLV one of the most prescribed drugs for the treatment of hypercholesterolemia.

Because of the therapeutic importance and clinical success of FLV, several methods have been developed for its quantitative determination in plasma samples. These methods include HPLC [8–13], gas chromatography [14], and capillary electrophoresis [15]. These methods involved tedious steps for the pre-treatment of the samples, pre-derivatization with critical derivatizing reagents, and use of expensive detectors (e.g. tandem mass spectrometry) that are not available in most laboratories [13]. For these reasons, the development of new alternative analytical technology for determination of FLV in plasma with adequate sensitivity, improved simplicity, and lower cost was seriously needed.

Immunoassays have been widely used in pharmaceutical and clinical analysis because of their inherent specificity, applicability for a wide range of analytes, high-throughput, and low cost [16]. ELISA is the most versatile format of the immunoassays. ELISA is

doi:10.1016/j.talanta.2009.06.052

remarkably quick, easily performed, and also offers great sensitivity when appropriate enzyme labels are used. As well, ELISA, as it uses analyte-specific antibodies, does not require pre-treatment for the samples and it is well suited for the screening of large-number of samples.

The present study describes, for the first time, the development and validation of a highly sensitive ELISA for determination of FLV at concentrations as low as 20 pg mL^{-1} in plasma samples.

2. Experimental

2.1. Instruments

FLX808 microplate reader (Bio-Tek Instruments Inc., USA). FLX50 microplate washer (Bio-Tek Instruments Inc., USA). EM-36N microtube shaker (Taitec, Japan). Biofuge Pico centrifuge (Heraeus Instruments, Germany). Incubator (Mini/18, Genlab Ltd., UK). Water purification system (Milli-Q Labo, Millipore Ltd., Bedford, USA).

2.2. Materials

Fluvastatin was obtained from Biocon India Ltd., India. HRP-IgG, BSA, 2,4,6-trinitrobenzene sulfonic acid, 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC), and tween-20 were purchased from Sigma Chemical Co. (St. Louis. MO, USA). TMB peroxidase substrate was obtained from Kirkegaard-Perry Laboratories (Gaithersburg, MD, USA). ELISA high-binding microwell plates were a product of Corning/Costar, Inc. (Cambridge, MA, USA). Centricon-30 filter (Amicon, Inc., Beverly, MA, USA). BCA reagent for protein assay was obtained from Pierce Biotechnology Inc. (Rockford, IL, USA). All water was purified by filtration through a water purification system.

2.3. Procedures

2.3.1. Preparation of anti-FLV antibody and FLV–BSA conjugate

Anti-FLV polyclonal antibody was induced by immunization of an eight weeks old female New Zealand white rabbits with FLV conjugated with keyhole limpt hemocyanin protein (FLV-KLH). The procedures for preparation of FLV-KLH, immunization, purification, and characterization of the antibody have been submitted for publication elsewhere. The coating conjugate (FLV–BSA) was prepared by linking FLV (via its carboxylic group) with BSA protein (via its amino group) by EDC reagent (Fig. 1). EDC (150 mg) was added to FLV solution (10 mL, 5 mg mL^{-1}) in 1.25×10^{-2} mol L^{-1} phosphate buffer (PB) of pH 5, and the pH was maintained at pH 5–5.5 using 0.01 mol L^{-1} HCl for 5 min. Five mL of BSA solution (5 mg mL^{-1}, in 5×10^{-2} mol L^{-1} PB of pH 7.2) was added, and the pH of the reaction mixture was rapidly adjusted to 6.4 and maintained constant for 90 min. The reaction was left to proceed overnight in dark at 4 °C. The uncojugated FLV residues were removed from the FLV–BSA conjugate by buffer exchange using a Centricon-30 filter. Protein content of the conjugate was determined by BCA reagent kit and the extent of substitution of free amino groups on the BSA was determined by estimation of free amino groups on equal amounts of unreacted BSA and on BSA subjected to the conjugation by the procedure described by Habeeb [17]. The extent of conjugation = $(A_{FLV-BSA}/A_{BSA}) \times 100$; where $A_{FLV-BSA}$ and A_{BSA} were the absorbances obtained from the reaction of 2,4,6-trinitrobenzene sulfonic acid with FLV–BSA and BSA, respectively. The extent of conjugation was found to be 24.8% of the total amino group residues.

2.3.2. Determination of the optimum concentrations of antibody and coating conjugate

The optimum FLV–BSA concentration required for coating onto the microwell plates and the best working concentration of the anti-FLV antibody were determined by checkerboard titration employing the procedures described by Darwish et al. [18]. Different concentrations (0.1–5 μg mL^{-1}) of FLV–BSA in 50 μL of PBS were coated onto the microwell plates in triplicate rows by incubation for 2 h at 37 °C with gentle agitation by microtube shaker. After incubation, the plates were washed with PBS containing 0.05% Tween-20 (PBS-T) using microplate washer. The wells were blocked with 200 μL of 3% BSA in PBS by incubation at 37 °C for 1 h. Fifty microliters of different concentrations (0.5–4 μg mL^{-1}) of anti-FLV antibody solution (in PBS) was added in columns across the microwell plates. After incubation for 1.5 h at 37 °C, the plates were washed with PBS-T, and 50 μL of HRP-IgG (1/5000 in PBS) was added to each well. After similar incubation and washing step, 50 μL of TMB substrate solution was added and the reaction was allowed to proceed for 10 min at 37 °C for color development. The absorbance of each well was measured at 630 nm by the microplate reader. Concentrations of FLV–BSA conjugate and anti-FLV antibody that yielded absorbance units of 1–1.5 were considered as reference binding conditions for further testing.

2.3.3. ELISA procedures and data analysis

Plasma samples were centrifuged at 3500 rpm at 4 °C for 10 min and the supernatants were collected, and spiked with FLV. Aliquots (50 μL) of the spiked samples were diluted five-fold with PBS. The diluted samples were mixed with equal volumes of anti-FLV antibody (4 μg mL^{-1}). Aliquot (50 μL) of the mixture was added to each well of the microwell plate that had been previously coated with FLV–BSA (1 μg mL^{-1}) and blocked with BSA (3%, w/v). After incubation for 1.5 h at 37 °C, the plates were washed with PBS-T, and 50 μL of HRP-IgG (1/5000 in PBS) was added to each well. After incubation

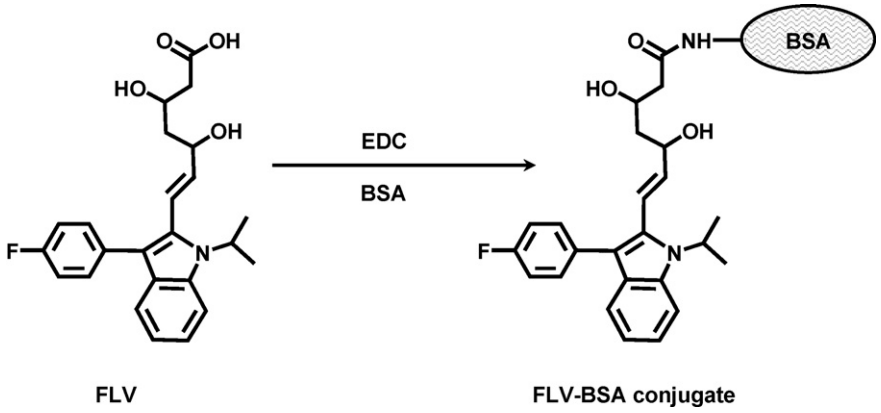

Fig. 1. Preparation of FLV–BSA conjugate.

for 1.5 h, the plates were washed with PBS-T and the amount of the bound HRP-IgG was quantified using TMB as described above. The data were acquisitioned by KC Junior software (Bio-Tek Instruments Inc., USA), and transformed to a four-parameter curve fitting using Slide Write software, version 5.011 (Advanced Graphics Software, Inc., USA). Values for IC_{50} were those that gave the best fit to the following equation: $A = A_0 - \{(A_0 - A_1)[FLV]/(IC_{50} + [FLV])\}$

Where A is the signal at a definite known concentration of FLV, A_0 is the signal in the absence of FLV, A_1 is the signal at the saturating concentration of FLV, and IC_{50} is the FLV concentration that produces a 50% inhibition of the signal. The concentrations of FLV in the samples were then obtained by interpolation on the standard curve.

3. Results and discussion

This study describes the development of a highly sensitive ELISA for determination of FLV in plasma samples; Fig. 2 describes the features of this ELISA. In this assay, microwell plates were coated with FLV–BSA conjugate. A polyclonal antibody that recognizes FLV with high affinity and specificity was mixed with FLV sample, and the mixture was incubated with FLV–BSA immobilized onto the microwells. During this incubation, FLV competed with FLV–BSA for binding to the available limited binding sites on the anti-FLV antibody. After removal of the unbound reagents, the amount of anti-FLV antibody bound to the microwells was determined using HRP-IgG and TMB as a chromogenic substrate. The concentration of FLV in the sample was quantified by its ability to inhibit the binding of anti-FLV antibody to the immobilized FLV–BSA, and the color development was inversely proportional to the concentration of FLV in the original sample solution.

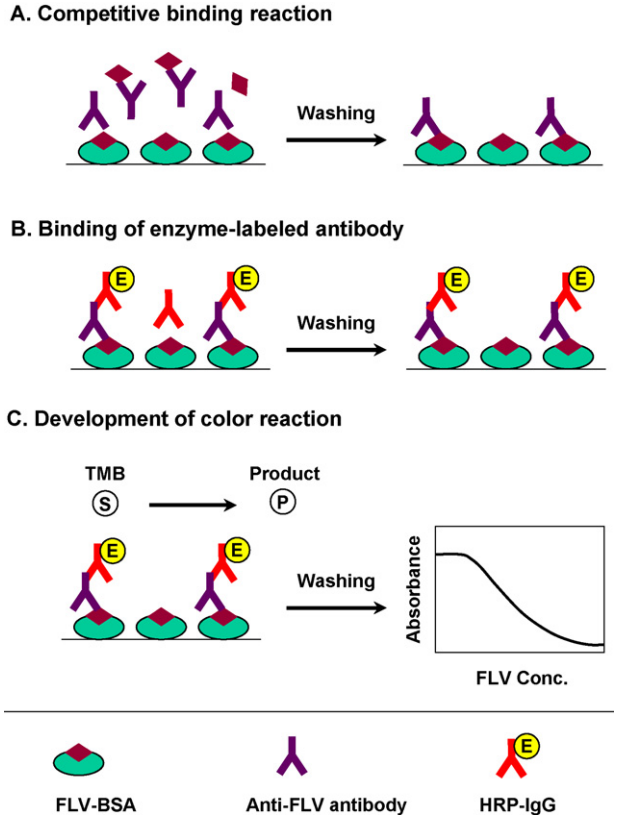

Fig. 2. Schematic diagram of the competitive ELISA for FLV. (A) Sample containing FLV is premixed with anti-FLV antibody. The mixture solution containing the FLV and its specific antibody is dispensed into microwell plates that have been coated with FLV–BSA conjugate. The soluble FLV competes with the immobilized FLV–BSA conjugates for the anti-FLV antibody binding sites. (B) After a wash step to remove any antibody bound to the soluble FLV, HRP-IgG is added. A second wash step removes unbound secondary antibody. (C) The signal is generated by the addition of TMB as a colorimetric substrate, and the measured color intensity are correlated with the FLV concentrations for generating the calibration curve for determination of FLV.

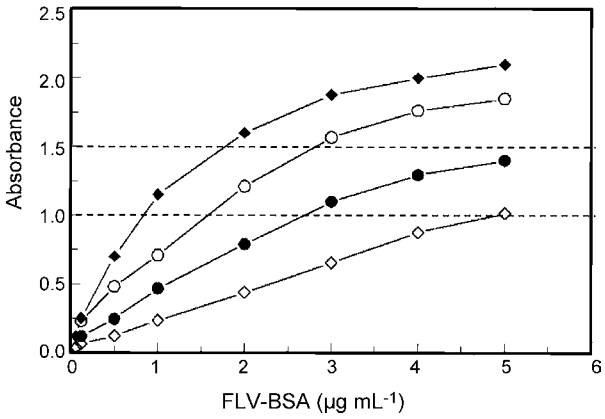

Fig. 3. Checkerboard titrations for FLV–BSA versus anti-FLV antibody. Varying concentrations (0.01–4 μg mL^{-1}) of FLV–BSA conjugate were coated onto the microwell plates. Varying concentrations of anti-FLV antibody were allowed to bind to the immobilized FLV–BSA. These concentrations were 0.5 (◊), 1 (●), 2 (○), and 4 (♦) μg mL^{-1}. Signals were generated as described in the Section 2. Absorbance values were plotted as a function of FLV–BSA concentrations.

3.1. Optimization of assay variables

3.1.1. Choice of conjugate and antibody concentrations

To determine the optimum concentration of FLV–BSA required for immobilization onto the microwell plates and the concentration of anti-FLV antibody for an effective competitive binding reaction, checkerboard titration of FLV–BSA versus anti-FLV antibody was carried out. The conjugate and antibody concentrations that gave absorbance units of 1–1.5 (in the direct ELISA), and lowest IC_{50} (in the competitive ELISA) were considered as reference optimum binding conditions. These conditions were attained at varying concentrations of FLV–BSA conjugate and anti-FLV antibody (Fig. 3). In order to select the most appropriate concentrations that give the most sensitive assay, competitive ELISA was carried out using FLV as a competitor. The most sensitive assay (lowest IC_{50}) was achieved when the concentrations of FLV–BSA conjugate and anti-FLV antibody were 1 and 4 μg mL^{-1}, respectively (Table 1). Therefore, these concentrations were used in all the further investigations.

3.1.2. Binding of FLV–BSA to microplate wells

Optimum binding of the FLV–BSA conjugate to the microwells was attained when the incubation time was 2 h at 37 °C, and more than 6 h at room temperature (25 ± 5 °C) (Fig. 4). For more convenience in the screening of clinical specimens, it was important to check the lifespan of the FLV–BSA after its immobilization onto the microwell plates. Plates were coated with the FLV–BSA and stored at 4 and −20 °C for varying periods of time, and then the plates were analyzed for the amount of immunoreactive conjugate remained on

Table 1
IC_{50} values that have been obtained at varying concentrations of coating FLV–BSA conjugate and anti-FLV antibody.

FLV–BSA (μg mL^{-1})	Anti-FLV antibody (μg mL^{-1})	IC_{50}[a] (pg mL^{-1})
1	4	100
2	2	400
3	1	1000
4	1	2000
5	0.5	5000

[a] Values are mean of 3 determinations.

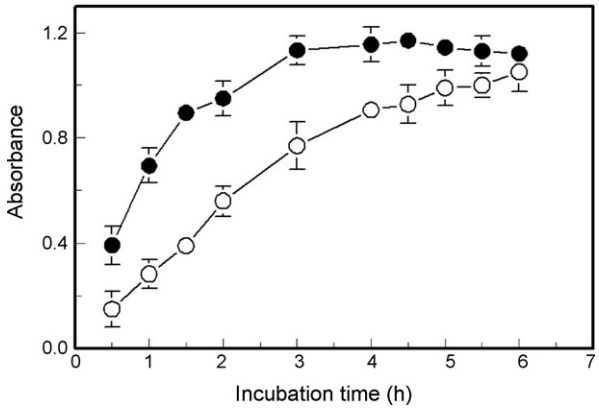

Fig. 4. Effect of temperature and incubation time on the immobilization of FLV–BSA onto the microwells. Incubations were carried out at 37 °C (●), and room temperature (25 ± 5° C) (○).

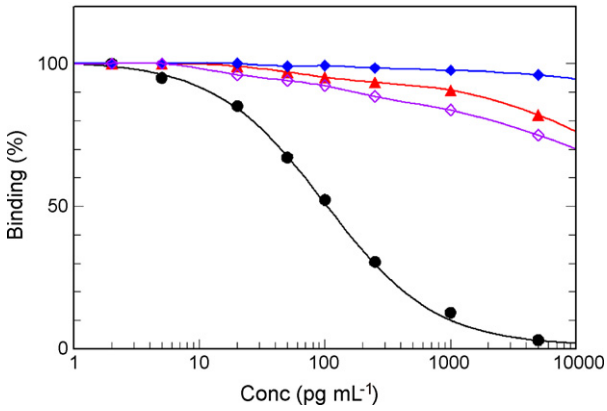

Fig. 6. Competitive binding assay for FLV (●), atorvastatin (◊), pitavastatin (▲), and rosuvastatin (♦).

the microwells. The results indicated that the plates could be stored for at least 4 and 6 weeks at 4 and −20 °C, respectively. This gives an advantage that the use of pre-coated and blocked plates could reduce 3 h from the total assay time.

3.2. Validation of the assay

3.2.1. Calibration curve and detection limit

The calibration curve for determination of FLV by the proposed ELISA is shown in Fig. 5. This curve was generated using FLV concentrations in the range of 2–5000 pg mL^{-1}, prepared in PBS. The data showed good correlation coefficient (r = 0.9985) on the four-parameter curve fit. The limit of detection of the proposed ELISA, defined as the lowest FLV concentration significantly different from zero concentration at 95% confidence limit (mean of zero ± 4.65 SD) was determined [19]. Based on the basis of 8 replicate measurements, the limit of detection was found to be 10 pg mL^{-1}. This high sensitivity enables the determination of low concentrations of FLV in plasma without any sample pre-concentration procedure as the reported FLV plasma level were 53–370 and 200–440 ng mL^{-1} after 20 and 40 mg-daily dosing, respectively [20]. It is worth noting that none of the previously reported HPLC [8–13], gas chromatography [14], and capillary electrophoretic [15] methods could achieve the high sensitivity of the proposed ELISA (pg level) as all the reported limits of detection of these methods were in ng levels. As well, the selective determination of FLV by most of the reported methods was not possible without prior selective liquid–liquid or solid-phase extraction for the drug followed by its careful separation from endogenital sample component. However, the proposed ELISA as it relied on a selective antibody, was able to selectively determine FLV without such extraction and separation procedures.

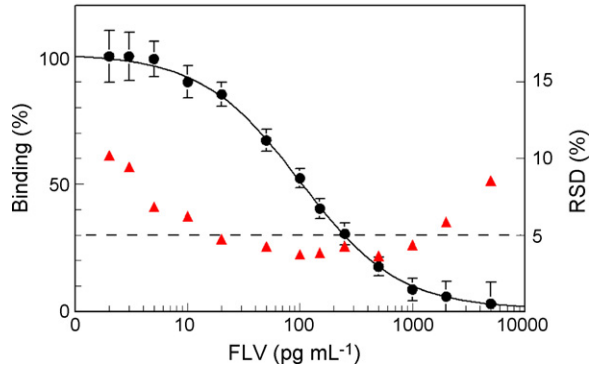

Fig. 5. Calibration curve (●) and precision profile (▲) of the proposed ELISA for FLV. Varying concentrations of standard FLV were mixed with anti-FLV antibody (2 μg mL^{-1}). The reaction mixtures were further manipulated as described in the Section 2. The values plotted are mean ± SD of three determinations.

3.2.2. Precision profile

The assay precision profile obtained from the results of calibration standard samples, assayed in triplicate, is shown in Fig. 6. From this profile, the working range of the assay at RSD values of less than 5% was derived. This range was found to be 20–1000 pg mL^{-1}. The RSD at the detection limit of the assay (10 pg mL^{-1}) was found to be 6.21%. The intra- and inter-assay precisions were tested at three varying levels of FLV. The intra-assay precision was assessed by analyzing eight replicates of each sample in a single run and the inter-assay precision was assessed by analyzing the same samples, as duplicates, in four separate runs. According to the recommendations of immunoassay validation [21], the assay gave satisfactory results; the RSD was 2.46–5.37 and 3.19–6.64% for the intra- and inter-assay precision, respectively (Table 2).

In general, the precision in competitive immunoassays depends mainly upon the uniformity in the quantity of the coated reagent from well to well in a microwell plate. Any interference in this uniformity could arise from the experimental protocol and other manipulations; change in the temperature of incubation and dispensing the reagents. The good precision observed in the proposed ELISA was attributed to the facts that all the incubation steps of the assay were carried out at the same temperature.

3.2.3. Assay specificity

Although, the assay utilized an antibody specific to FLV, it was necessary to investigate this specificity under the specified experimental assay conditions. The specificity of the present method was determined by carrying out the competitive assay using various HMG-Co A reductase inhibitors (atorvastatin, pravastatin, lovastatin, simvastatin, rosuvastatin, and pitavastatin), and various drugs that are administered in combined therapy with FLV (ezetimibe [22], gemfibrozil [23], aspirin [24], gemcitabine [25], cholestyramine [26] and estradiol [27]) as competitors at concen-

Table 2
Precision of the proposed ELISA for determination of FLV.

FLV (pg mL^{-1})	Intra-assay		Inter-assay	
	Mean ± SD[a] (pg mL^{-1})	RSD (%)	Mean ± SD (pg mL^{-1})	RSD (%)
20	20.5 ± 1.1	5.37	21.1 ± 1.4	6.64
100	101.5 ± 2.5	2.46	100.4 ± 3.2	3.19
500	489.4 ± 15.8	3.23	98.56 ± 20.5	4.16

[a] Values are mean of 8 determinations ± SD.

Table 3
Analytical recovery of FLV spiked into three different batches of plasma samples.

Spiked FLV (pg mL^{-1})	Recovery[a] (% ± RSD)		
	Batch A	Batch B	Batch C
25	102.0 ± 4.25	97.1 ± 5.12	100.2 ± 6.25
50	100.4 ± 4.21	99.6 ± 5.45	101.2 ± 5.12
100	100.5 ± 2.85	102.1 ± 3.48	97.8 ± 3.55
200	99.1 ± 4.12	100.5 ± 5.02	98.2 ± 3.24
400	102.7 ± 4.05	98.5 ± 3.52	100.1 ± 4.58

[a] Values are mean of three determinations.

trations considerably higher than that may be present in patient plasma. The cross reactivity was calculated using the formula: IC_{50} (competitor)/IC_{50} (FLV) × 100. It was found that the values of IC_{50} for all the competitors used were higher than the maximum FLV concentration used in the assay (5000 pg mL^{-1}). The data that have been generated for atorvastatin, pitavastatin, and rosuvastain are given in Fig. 6. The other competitors gave binding profile very similar to that of rosuvastatin. These data proved that none of these competitors showed any cross reactivity with FLV in the assay indicating the high specificity of the proposed ELISA for determination of FLV.

3.2.4. Accuracy and application of the proposed ELISA

The accuracy of the proposed ELISA and its applicability was assessed by the recovery study. Samples were prepared by spiking varying concentrations (25–400 pg mL^{-1}) of FLV into three different batches of drug-free plasma. The spiked samples were analyzed for their contents of FLV, as described in the Section 2. The analytical recovery was calculated as the ratio of the found FLV concentration to that of the spiked concentration, and the ratio was expressed as percentage. The analytical recovery values were 97.1–102.7% with RSD 2.85–6.25% (Table 3). These recovery values, according to the guidelines for immunoassay validation [21], indicated the accuracy of the proposed method for determination of FLV in plasma samples, and absence of endogenous interfering substances in the plasma samples.

4. Conclusions

The present study described, for the first time, the development and validation of a highly sensitive ELISA for the determination of FLV in plasma at picogram level. The entire protocol of the present assay is very easy to perform in a 96-well plate and permits an operator to analyze a batch of 200 samples, in triplicate, per day when the plates have been previously coated with FLV–BSA and blocked with BSA. This facilitates the processing of large-number of samples. Since the assay produces a colored read-out, only a colorimetric plate reader is required. Unlike HPLC, the marked specificity of the proposed ELISA eliminates the need for pre-treatment of plasma samples by affinity chromatography or other sophisticated equipment. For these reasons, the proposed ELISA is expected to contribute to the therapeutic monitoring and pharmacokinetic studies of FLV.

Lead(II)
Adsorptive stripping voltammetry
Sodium dodecyl sulfate

ABSTRACT

A simple and sensitive electroanalytical method is developed for the determination of lead by adsorptive stripping voltammetry (AdSV) in the presence of morin-5′-sulfonic acid (MSA) and sodium dodecyl sulfate (SDS). The Pb-MSA complex accumulates on the surface of a hanging mercury drop electrode (HMDE) and peak current is measured by square wave voltammetry (SWV). The complex is reduced at −0.48 V and peak current increases when low concentrations of SDS are added to the sample solution. The experimental variables pH, MSA concentration (C_{MSA}); accumulation time (t_{acc}); accumulation potential (E_{acc}), and SDS concentration (C_{SDS}), as well as potential interferences, are investigated. Under the optimized conditions (pH 3.2; C_{MSA}: 0.5 μmol L^{-1}; t_{acc}: 60 s; E_{acc}: −0.35 V, and C_{SDS}: 20 μmol L^{-1}), peak current is proportional to the concentration of Pb(II) over the 0.1–32.0 μg L^{-1} range, with a detection limit of 0.04 μg L^{-1}. The relative standard deviation for a solution containing 5.0 μg L^{-1} of Pb(II) solution was 1.5% for seven successive assays. The method was validated by determining Pb(II) in synthetic sea water (ASTM D665) spiked with ICP multi-element standard solution and in certified reference water (GBW08607). Finally, the method was successfully applied to the determination of Pb(II) in tap water and sea water after UV digestion.

1. Introduction

Lead is a ubiquitous environmental pollutant with no known biological functions that has strong chemical toxicity at low concentrations. It can occur as a result of industrialization in the production of pigments, anticorrosion coatings, lead smelters, alloys, and batteries, causing significant disturbances in air, dust, soil, water, sediments, food, etc. The World Health Organization (WHO) and the U.S. Environmental Protection Agency (EPA) have set maximum levels of 50 and 10 μg L^{-1} of Pb in seawater and drinking water, respectively [1,2].

Anodic stripping voltammetry (ASV) has long been recognized as a powerful technique for trace metals owing to its sensitivity, relatively inexpensive instrumentation, and ability for multi-element determination. The mercury film electrode (MFE) and the hanging mercury drop electrode (HMDE) have been traditionally used for ASV because of the advantageous analytical properties of mercury in the negative potential range, however in the last years a large number of electrodes have been used. de Carvalho et al. [3] made a comparative study of the determination of Pb and other metal ions in highly saline samples using mercury film electrode (MFE) and bismuth film electrode (BiFE), achieving limits of detection (LODs) of 0.060 and 0.10 μg L^{-1}, respectively. The following have also been used: thin mercury film electrode (TMFE) [4]; bismuth-modified carbon nanotube electrode [5] (LOD: 1.3 μg L^{-1}); mercury film deposited on a wax-impregnated carbon paste electrode [6] (LOD: 1.12 ng L^{-1}); bismuth powder-modified carbon paste electrode [7] (LOD: 0.9 μg L^{-1}); bismuth-modified zeolite-doped carbon paste electrode [8] (LOD: 0.10 μg L^{-1}); disposable pencil-lead graphite as substrate for BiFE [9] (LOD: 0.4 μg L^{-1}); multiwall carbon nanotubes dispersed in Nafion solution in combination with bismuth [10] (LOD: 25 ng L^{-1}); titanium carbide [11] (LOD: 0.4 μg L^{-1}); silver ring [12] (LOD: 41 ng L^{-1}) and lately screen-printed electrodes [13] (LOD: 1.8 μg L^{-1}).

Because of the sensitivity enhancement obtained with adsorption stripping voltammetry, several complexing agents have been studied for the adsorptive collection of complexes with Pb on HMDE, among them 2-acetylpyridine salicyloylhydrazone [14] (LOD: 35 ng L^{-1}); calcein blue [15] (LOD: 8 ng L^{-1}); o-cresolphthaleine [16] (LOD: 40 ng L^{-1}); 8-hydroxyquinole [17,18] (LODs: 0.931 μg L^{-1} and 4 ng L^{-1}, respectively); xylenol orange [19,20] (LODs: 6 ng L^{-1} and 0.98 μg L^{-1}, respectively); morin [21] (LOD: 0.08 μg L^{-1}). Catechol, 4-methylcatechol, 4-t-butylcatechol, and resorcinol [22] have also been used as complexing agent to determine Pb and other metal ions.

One possible way of enhancing the adsorptive process and the sensitivity of the method is the use of surfactants, whose beneficial effects are unpredictable, as they tend to interfere by

doi:10.1016/j.talanta.2009.06.046

competitive adsorption. However, addition of the anionic surfactant sodium dodecylbenzene sulfonate (SDBS) has been found to greatly improve the adsorption of palladium-dimethylglyoxime complex [23], and the cationic surfactant cetyltrimethylammonium bromide (CTAB) has increased at least 40-fold the sensitivity of the determination of progesterone and cobalt in the presence of nioxime with a mercury electrode [24,25]. The effect of surfactants has been studied in the determination of organic compounds such as pharmaceuticals, hormones, biomolecules, proteins, pesticides, etc. [26–32]. The presence of surfactants can shift the complexation pH to a more acidic region, and it has been reported that they increase molar absorptivities [33], fluorescence properties [34], the solubility of ligands and complexes in organic solvents [35], they can change the kinetics of the electron-transfer reaction and affect the reversibility of the systems, etc. [36,37]. Cationic or anionic surfactants can be adsorbed easily onto the mercury electrode by hydrophobic and electrostatic attraction. Neutral metal complexes in the solution can be attracted by the positively charged surfactant to form stable compounds and be transported consequently to the electrode surface in the accumulation step.

The interaction of the flavonoids morin and quercetin with anionic (SDS) and cationic (CTAB) surfactants has been studied by Liu and Guo using electronic absorption, fluorescence emission spectra, ATR-FTIR spectra, cyclic voltammetry, and ab initio quantum calculations [38,39]. They reported that when the concentration of morin is about 4×10^{-5} mol L^{-1} it exists mainly as a monomer, but when the concentration is about 1×10^{-4} mol L^{-1} morin undergoes H-aggregation forming a dimer. In the presence of CTAB, depending on concentration it forms premicelles, spherical micelles, and rodlike micelles in the aqueous solution. These micelles shift the wavelength and intensity of the absorption maximum.

We now report the effect of SDS on the sensitivity of the determination of lead in the presence of morin-5′-sulfonic acid. The sulfonic group, which does not participate directly in the metal–ligand bond, can be adequate for this study because it contributes a negative charge which strengthens the bond with the surfactant and then with the electrode. The procedure is based on the reduction of the complex after accumulation on the surface of a hanging mercury drop electrode (HMDE). SDS was added to synthetic and real samples. Morin-5′-sulfonic acid is also adequate for the determination of cadmium, but the optimum conditions are different from those for lead.

2. Experimental

2.1. Reagents

Water used for washing and for preparing solutions was 18.2 MΩ cm deionized water from a Millipore system. All the chemicals (nitric acid, hydrochloric acid, peroxide, boric acid, acetic acid, etc.) were analytical grade from Merck (Darmstadt, Germany). Standard stock solutions with 1.0 or 0.1 mg L^{-1} of Pb(II) and Cd(II) were prepared from standard Pb(II) and Cd(II) 1000 mg L^{-1} solutions (Merck). Morin-5′-sulfonic acid (MSA) was synthesized as reported by Kopacz [40] and was prepared in water or methanol for lead and cadmium analysis, respectively. Sodium dodecyl sulfate (SDS, Sigma) and cetylpyridinium bromide (CPB, Aldrich) were prepared by dissolving the reagent in water. Synthetic sea water (ASTM D665, Aldrich) contaminated with ICP multi-element standard solution IV (23 elements in dilute nitric acid. Merck); and certified reference natural water (GBW08607) containing K^+ 2.2; Na^+ 23, Ca^{2+} and Mg^{2+} 11 mg L^{-1} in 0.5 mol L^{-1} HNO_3 with certified values of Cd 0.100; Cr 0.500; Cu 1.00; Ni 0.500; Pb 1.00 and Zn 5.00 μg g^{-1} were used for validation measurements. Britton-Robinson buffer [41] was prepared by mixing equal volumes of 0.4 mol L^{-1} orthophosphoric acid, acetic acid, and boric acid, adjusting to the required pH with 0.2 mol L^{-1} NaOH solution, and diluting 10 times with water.

2.2. Instrumentation

Square wave adsorptive stripping voltammetry (SWAdSV) was carried out on an MDE 150 polarographic stand (Radiometer Analytical, Lyon, France). The MDE 150 was controlled with TraceMaster 5 PC software. The three-electrode classical cell consisted of an HMDE, an auxiliary platinum electrode, and an Ag/AgCl/KCl 3 mol L^{-1} reference electrode, a mechanical mini stirrer, and a capillary to supply an inert gas. The solutions were de-aerated using high-purity argon. An Orion 430 pH meter was used for pH measurements. UV-irradiation of water samples was carried out in quartz tubes in a 705 UV-digester with a high-pressure mercury lamp (Metrohm).

2.3. Sample preparation

Nine seawater samples from the sea surface were collected in early spring (September 20, 2008) from three points of the Quintero beach, which is close to several industries and belongs to a highly populated and tourist area (South Pacific coast, Chile). The samples were collected in high-density polyethylene bottles which had been acid-washed and rinsed with Milli-Q water. Prior to filling with sample, the bottles were conditioned three times with the same water. The collected seawater samples were filtered through a polycarbonate 0.45 μm membrane filter, acidified with HNO_3 to pH close to 2, and stored frozen until analysis. Domestic tap water samples were collected in our laboratory. Before the analysis all the samples were digested for 90 min at 90 °C in the presence of H_2O_2 (10.0-mL of sample with 100 μL of 30% H_2O_2) to decompose organic substances. To make sure of the reliability of the method the samples were analyzed by ICP-AES.

2.4. Voltamperometric procedure

Voltammetric measurements were made using the following procedure: 10.0-mL of deionized water, 100-μL of Britton-Robinson buffer (0.04 mol L^{-1}), 100–400 μL of morin-5′-sulfonic acid solution (0.04 mmol L^{-1}), and aliquots of Pb(II) or Cd(II) solution (0.1 or 1.0 mg L^{-1}) were pipetted into the voltammetric cell. The measurements were made in the presence and absence of surfactants. The solution was purged with argon (saturated with water vapor) for 5 min. Then, after eliminating five drops, a new mercury drop was extruded to initiate the preconcentration step for a given t_{acc} and E_{acc} at a stirring speed of 400 rpm. After an equilibration time of 10 s, the adsorptive voltammogram was recorded, while the potential was scanned from −0.35 to −1.20 V using square wave modulation with 0.01 V step amplitude, 0.05 V pulse amplitude, and a frequency of 25 Hz. The calibration curves were drawn and linear regression and detection limits were calculated. All data were obtained at room temperature (≈25 °C).

For the voltammetric analysis of real samples, a 10.0-mL aliquot of UV-digested seawater (or tap water) was pipetted in the cell, 100 μL of Britton Robinson pH 3.2 buffer, and aliquots of ligand solution were added, and the determination was carried out using the standard addition method. Each voltammogram was repeated three times.

3. Results and discussion

Morin-5′-sulfonic acid ($pK_1 = 4.7$; $pK_2 = 7.8$; $pK_3 = 9.8$; $pK_4 = 10.7$) has good aqueous solubility and forms complexes

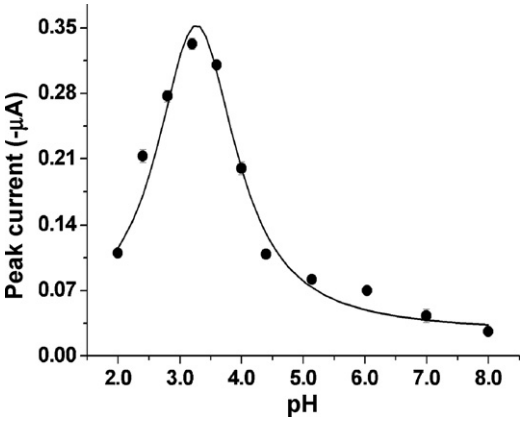

Fig. 1. Influence of pH on the peak current of the Pb-MSA complex. Conditions: Pb(II), 4.9 μg L^{-1}; C_{MSA}: 0.5 μmol L^{-1}; t_{acc}: 60 s; E_{acc}: −0.35 V; step amplitude: 10 mV, pulse amplitude: 50 mV, and frequency: 25 Hz.

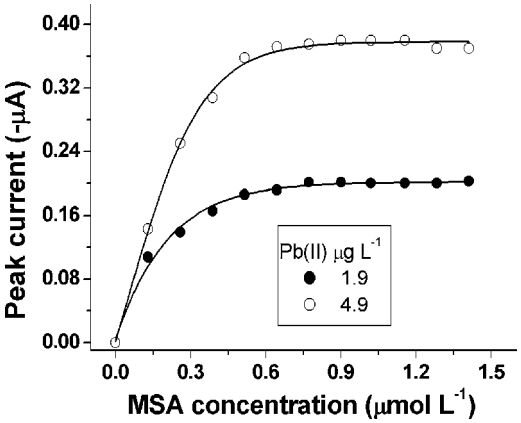

Fig. 2. Influence of C_{MSA} concentration on the peak current of the Pb-MSA complex. Conditions: Pb(II), 1.9 and 4.9 μg L^{-1}; pH 3.2; t_{acc}: 60 s; E_{acc}: −0.35 V. Other conditions as in Fig. 1.

with lead (PbH_4L) and cadmium ($Cd(H_3L)_2$) that are poorly soluble in water (10^{-4} to 10^{-5} mol dm^{-3}, 20 °C). In the complexes the metal is chelated by three C–OH and four C=O, and the sulfonic group contributes a negative charge [40,42].

Preliminary experiments were carried out to determine the effect of SDS and CPB on the absorbance and electrochemical reactions of free morin-5′-sulfonic acid at pH 4.0 and 6.0. The results showed the same trends found by Liu and Wou [38,39] with morin and quercetin. SDS and CPB shift the absorption peaks (λ, ε) and electrochemical oxidation (E_{peak}, i_{peak}, glassy carbon electrode) of morin-5′-sulfonic acid. In order to find the optimum conditions with the highest sensitivity for the determination of Pb(II) with HMDE, the influence of various parameters such as pH, C_{MSA}, t_{acc}, E_{acc}, and C_{SDS} on peak current was studied.

3.1. Effect of operational parameters

3.1.1. Effect of pH variation

The effect of the solution's pH on peak current of the Pb-MSA complex was studied in the 2.0–8.0 range. In order to keep the composition of the buffer constant when studying the effect of pH, Britton Robinson (BR) buffers were used (Fig. 1). C_{Pb} and C_{MSA} were 4.9 μg L^{-1} and 0.5 μmol L^{-1}, respectively (E_{acc}: −0.35 V, t_{acc}: 60 s). It is clear that the peak current of the Pb-MSA complex is maximum at pH 3.2 and decreases rapidly at pH values between 4.0 and 8.0. At pH 8.0 the signal is very broad. On the other hand, peak potential was −0.47 V at pH 2.0 and −0.56 V at pH 6.0. The charge of the Pb-MSA complex at higher pH values changes and it is probably not adsorbed onto the electrode (pK_1 MSA 4.7). A pH value of 3.2 was chosen for the whole study. A study as a function of buffer concentration was carried out adding aliquots of 0.04 mol L^{-1} of BR buffer, getting the highest peak current of the Pb-MSA complex when 100 μL was added.

3.1.2. Effect of morin-5′-sulfonic acid concentration (C_{MSA})

MSA concentration had a considerable effect on the method's linear range and sensitivity. The effect of C_{MSA} was studied for Pb(II) at the levels of 1.9 and 4.9 μg L^{-1}, while other standard measuring conditions remained constant (pH: 3.2; t_{acc}: 60 s, E_{acc}: −0.35 V). C_{MSA} was changed from 0.0 to 1.4 μmol L^{-1}. The results show that peak current increases with increasing MSA concentration up to 0.5 μmol L^{-1} (Fig. 2). At higher C_{MSA} the peak current tended to level off. Therefore, an optimum C_{MSA} of 0.5 μmol L^{-1} was chosen for further optimization study with synthetic solutions. However, when the spiked or real water samples contained several metal ions a ligand concentration of 1.2–1.5 μmol L^{-1} was added to ensure complete complex formation.

3.1.3. Effect of accumulation time (t_{acc})

Accumulation time is one of the important parameters that have a pronounced effect on sensitivity in stripping procedures. Accumulation time was examined in the 0–300 s range, while other standard measuring conditions remained constant (Pb(II), 4.9 μg L^{-1}; C_{MSA}, 0.5 μmol L^{-1}; pH: 3.2; E_{acc}: −0.35 V). Peak current increases with increasing accumulation prior to the potential scan, indicating that the Pb-MSA complex is readily adsorbed on the HMDE. Peak current increased linearly with increasing accumulation time up to 300 s and no saturation of the electrode surface was observed. However, for longer accumulation times (above 180 s) a small shoulder at −0.62 V is seen in the adsorptive voltammograms. On that basis, and considering the speed of the measurement, a t_{acc} of 60 s was used for further studies.

3.1.4. Effect of accumulation potential (E_{acc}) in the absence and presence of sodium dodecyl sulfate (C_{SDS})

The effect of E_{acc} was studied for Pb(II) at the levels of 1.9 and 4.9 μg L^{-1}, while other standard measuring conditions remained constant (pH: 3.2; C_{MSA}: 0.5 μmol L^{-1}; t_{acc}: 60 s). E_{acc} varied from 0.00 to −0.40 V. Fig. 3 shows the results obtained with Pb(II) 1.9 μg L^{-1}. These measurements were carried out in the absence

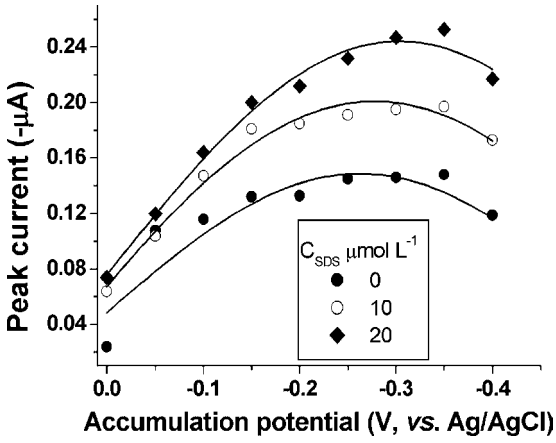

Fig. 3. Influence of E_{acc} on the peak current of the Pb-MSA complex in the absence and presence of SDS. Conditions: Pb(II), 1.9 μg L^{-1}; C_{SDS}: 10 and 20 μmol L^{-1}; pH 3.2; C_{MSA}: 0.50 μmol L^{-1}; t_{acc}: 60 s. Other conditions as in Fig. 1.

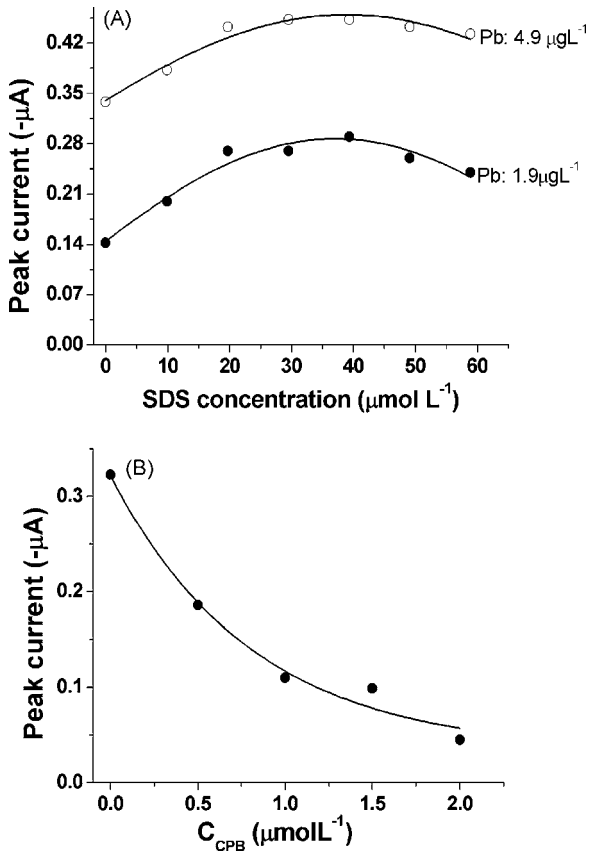

Fig. 4. Influence of C_{SDS} and C_{CPB} on the peak current of the Pb-MSA complex. Conditions: (a) Pb(II), 1.9 μg L^{-1}, (b) Pb(II), 4.9 μg L^{-1}. pH 3.2; C_{MSA}: 0.50 μmol L^{-1}; E_{acc}: −0.35 V; t_{acc}: 60 s. Other conditions as in Fig. 1.

and in the presence of SDS 10 and 20 μmol L^{-1}. As shown in Fig. 3, in the presence or absence of SDS, peak current increased with changing potential from 0.00 to −0.35 V. However, it decreased slightly when the potential was changed to −0.40 V. An accumulation potential of −0.35 V gives the best sensitivity and was chosen for the study. More negative potential values cause electrolysis of Pb(II). In the presence of small amounts of a surfactant such as SDS the peak current of the Pb-MSA complex increases, the possible mechanism of this enhancement effect involves the formation of negatively charged micelles of SDS with the lead complex and the positive charge of mercury electrode to potentials about −0.40 V.

3.1.5. *Effect of sodium dodecyl sulfate (SDS) and cetylpyridinium bromide (CPB) concentration*

The influence of C_{SDS} was studied for Pb(II) at the levels of 1.9 and 4.9 μg L^{-1}, while other standard measuring conditions remained constant (pH: 3.2; C_{MSA}: 0.5 μmol L^{-1}, t_{acc}: 60 s, E_{acc}: −0.35 V). The SDS concentration range examined was 0–60 μmol L^{-1}. The influence of C_{SDS} on the peak current of the Pb-MSA complex is presented in Fig. 4a, which shows that the peak current suddenly increases as SDS concentration increases from 0 to 10 μmol L^{-1} and then reaches a maximum at 20 μmol L^{-1}. At SDS concentrations of 50–60 μmol L^{-1} peak current decreased slowly. At pH 3.2 the Pb-MSA complex is positively charged ($[Pb(H_4L)^+]$) [40]. SDS and the negatively charged Pb complex-SDS micelles may be adsorbed on the surface of the mercury electrode by electrostatic attraction. SDS concentration had no influence on peak potential. The effect of the presence of CPB was examined in the 0.0–2.0 μmol L^{-1} range. The results are shown in Fig. 4b, where it is seen that, in contrast with the effect of SDS, in the presence of small amounts of cationic surfactant the peak current of the Pb-MSA complex decreases rapidly as C_{CPB} increases. At a C_{CPB} of 2.0 μmol L^{-1} peak current is only 14% of the initial value when C_{CPB} is 0.

3.2. *Effect of instrumental variables (frequency, step potential, and amplitude)*

A linear increase of the peak current of the complex was seen when the size of the mercury drop varied from 0.25 to 1.25 mm^2, and 0.75 mm^2 was adopted as optimum, with larger sizes not convenient because mercury drops fall more frequently. The peak current of the Pb-MSA complex increased when the frequency increased from 25 to 50 Hz. However, at frequencies of 50 Hz there was a deterioration of the peak shape and the backgroundand and 25 Hz was adopted as optimum. Peak current increased linearly with step potential variations from 1 to 10 mV and pulse amplitude from 5 to 50 mV. 10 and 50 mV were adopted as optimum for step potential and pulse amplitude, respectively.

3.3. *Analytical parameters*

The calibration graph for the determination of lead was obtained under the optimized conditions. pH 3.2 (100 μL of 0.04 mol L^{-1} BR buffer); C_{MSA}: 0.5 μmol L^{-1}; t_{ads}: 60 s; E_{ads}: −350 V. If C_{MSA} is 0.50 μmol L^{-1}, adsorptive curves of Pb(II) at concentrations from 0.1 to 10.0 μg L^{-1} produce a linear calibration plot (r = 0.9996), but if C_{MSA} is 1.50 μmol L^{-1} the plot is linear until 32.0 μmol L^{-1}. The precision expressed as the relative standard deviation (R.S.D.) was 1.5% for seven successive measurements of the same sample containing 5.0 μg L^{-1} of Pb(II). The limit of detection (LOD) was calculated according to the IUPAC upper limit approach (ULA) [43] and was 0.062 μg L^{-1} in the absence and 0.043 μg L^{-1} in the presence of 20 μmol L^{-1} of SDS.

In the voltammetric determination of Pb(II) the main interference may be caused by the presence of Cd(II) because of its reduction potential close to that of Pb. Fig. 5 shows adsorptive voltammograms of Pb(II) and Cd(II) in the presence of MSA, with cadmium concentrations twice those of lead, and yet the currents are smaller. The method is not sensitive for the determination of lead and cadmium simultaneously. Higher peak currents for Cd-MSA were obtained at pH 4.0 and the optimum C_{MSA} was 2.5 μmol L^{-1}. For cadmium similar peak currents were obtained applying adsorptive potentials between 0.00 and −0.50 V (t_{acc}: 60 s).

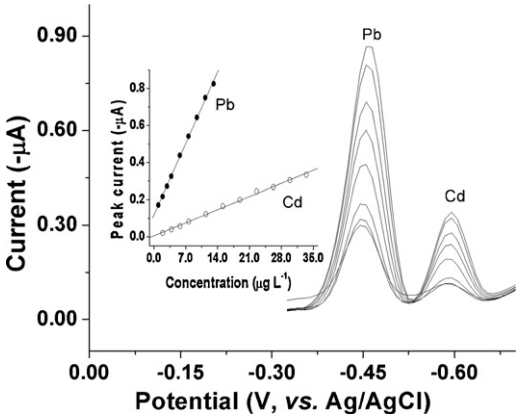

Fig. 5. Adsorptive voltammograms (top) and corresponding calibration plot (bottom) of Pb(II) and Cd(II) standard solutions. Conditions: pH 3.2; C_{MSA}: 1.50 μmol L^{-1}; E_{acc}: −0.35 V; t_{acc}: 60 s. Other conditions as in Fig. 1.

Table 1
Determination of lead in water samples[a,b].

Sample	Pb(II) found ($\mu g\,L^{-1}$)	S.D.
Tap water	4.9	0.5
Sea water[c]	1.4	0.1
Sea water[d]	6.9	0.2
Sea water[e]	1.3	0.0

[a] All the samples were analyzed by ICP-AES and the level of Pb was low 10 $\mu g\,L^{-1}$.
[b] Three replicate analyses were performed for each sample.
[c] Borders of the beach.
[d] Near the dock.
[e] 12 m towards the interior of the sea.

3.4. Interference studies and validation of the method

An aliquot of synthetic sea water (ASTM D665) was contaminated with an ICP multi-element standard solution containing metal ions such as Ag, Al, Cd, Co, Cr, Cu, Fe, Ga, Ni, Zn, Pb and others in equal concentration (5.0 $\mu g\,L^{-1}$), and aliquots of MSA were added until the Pb-MSA current peak reached a maximum before the analysis of Pb was carried out using the standard addition method. The results obtained for Pb(II) were $5.1 \pm 0.3\ \mu g\,L^{-1}$ (pH 3.2; C_{MSA}: 1.50 $\mu mol\,L^{-1}$, t_{acc}: 60 s; E_{acc}: −0.35 V). The usefulness of the present method was also evaluated by determining Pb(II) in certified reference water (20 μL. GBW08607) containing Cd 0.100; Cr 0.500; Cu 1.00; Ni 0.500; Pb 1.00, and Zn 5.00 $\mu g\,g^{-1}$. Three replicate analyses were performed for each sample. The value obtained was $1.08 \pm 0.10\ \mu g\,g^{-1}$. These measurements were made in the presence and absence of SDS (20 $\mu mol\,L^{-1}$), giving higher values and slopes in the presence of the anionic surfactant.

3.5. Analysis of real samples

The proposed method was applied to the detection of lead in sea water and domestic tap water previously digested with UV radiation in the presence of H_2O_2 solution. The samples were obtained from three points of the Quintero beach: the edge of the beach, near the dock, and 12 m away from the edge. These analyses (10-mL samples) were carried out in the presence of SDS 20 $\mu mol\,L^{-1}$ (pH 3.2; C_{MSA}: 1.20 $\mu mol\,L^{-1}$; t_{acc}: 60 s; E_{acc}: −0.35 V). To check the reliability of the method the samples were analyzed by ICP-AES, however the results obtained with this technique were below 10 $\mu g\,L^{-1}$, which is the detection limit of this procedure. Table 1 shows the results. The highest value was $6.9 \pm 0.2\ \mu g\,L^{-1}$ of Pb (sea water). The Pacific ocean where the samples were collected is close to several industries and belongs to a highly populated and tourist area, however the levels are below the limit proposed by the EPA [1].

4. Conclusions

This work reports the trace determination of Pb(II) in the presence of morin-5′-sulfonic acid and the effect of SDS on the peak current of the corresponding Pb-MSA complex. The presence of SDS always increases the peak current of the complex and the slope of the i_{peak} vs. Pb concentration plot, but the exact i_{peak} ratio in the presence and absence of SDS is dependent on the analyte's concentration.

KYSE30 cancer cells

ABSTRACT

This paper presents a novel microchip with nanoporous anodic alumina membrane for the study of anti-cancer drug effect of retinoic acid (RA) on human esophageal squamous epithelial KYSE30 cancer cells *in vitro* with impedance spectroscopy. The impedance experiments with 0.01 M retinoic acid (RA) were explored for the study of anti-cancer drug effects on KYSE30 cancer cells. The impedance was monitored in the time domain at 0.1 Hz. After addition of 0.01 M RA to the cell chip, the impedance magnitude decreased with time from the value with confluent cell layer and returned to the initial base line after around 12 h. The fluorescence experiments testified that this impedance decrease was due to the cell morphology change induced by RA.

1. Introduction

In drug-curable cancers, apoptosis is a prominent mechanism associated with the induction of cancer remission [1]. Thus, a drug that activates apoptosis might achieve significant efficacy in treatment of cancer. Since apoptosis was formerly defined on morphological grounds, identification of apoptotic cells should be morphology-based [2]. The majority of existing techniques to monitor apoptosis *in vitro* is based on fluorescence probes designed to specifically label relevant molecules in apoptotic cells which can then be detected either by fluorescence microscopy or by flow cytometry [3,4]. However, there are several limitations for the conventional techniques, which are labor-intensive, time-consuming, invasive and not in real time. Electric cell-substrate impedance sensing (ECIS) has been used to monitor the morphology, viability, and environmental change for the adherent cells [5–8]. Recently, it has increased interest in using ECIS for *in vitro* cell apoptosis monitoring [9]. Arndt et al. [10] used endothelial cells as the sensory elements to study the cycloheximide induced apoptosis. Aspirin-treated human colon cancer HT-29 cell shape was also monitored during apoptosis [11]. However, this method has some restrictions. As the size of electrodes decreases, the electrode impedance caused by the electrode polarization is increased at the low frequency range. If the impedance related with adherent cells is much smaller than this high electrode impedance, it is hard to extract the portion of adherent cells from total measured impedance spectrum. It is necessary to develop a new morphology-sensitive electrochemical system with high sensitivity in low frequency range.

Generally, the measured signals of impedance spectroscopy provide the interfacial dielectric information of liquid/surface layer based on the charge transfer rate and surface electrochemical reaction. Due to the nanoscale dimension, the nanostructured substrates have enhanced charge transfer rate and increased surface reaction/affinity area compared with flat substrates. With the capabilities of integrating electrochemical impedance spectroscopy with nanometrology, nanostructured substrates have been widely used for biosensing. High aspect ratio nano-ordered materials are particularly intriguing for the dramatic increasing of surface area, surface chemical reaction rate and intensification of the electron transfer (i.e. biosensor output signal) through the solid–liquid interface. Nanoporous anodic alumina membrane is of particular interest due to its excellent biocompatibility as well as the established fabrication process [12–14]. Precise control of pore diameter and length can also be achieved [15,16]. Due to these fairly well-defined nanopores, nanoporous alumina membrane has found wide applications in areas such as DNA biological and chemical separations [17], micro-flow regulation [18,19], and lipid membrane-based biosensors [20]. However, the usage of nanoporous alumina membrane for cell-based sensing with impedance spectroscopy has not been explored. The biocompatibility for cell culture and non-conductive frame with pores make nanoporous alumina membrane a suitable electrochemical platform for cell study.

Fig. 1 shows the sensing mechanism of this cell chip. After seeding, cells adhere closely to the nanoporous alumina membrane.

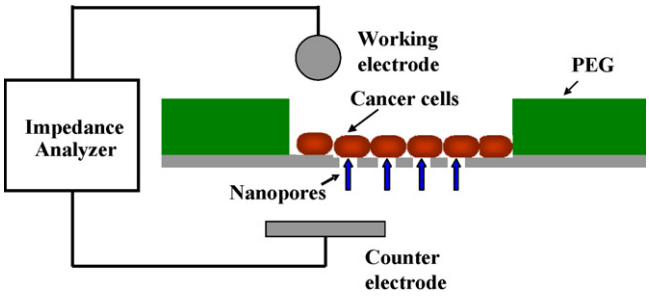

Fig. 1. Schematic diagram for impedance sensing using nanoporous membrane with PEG hydrogel microwell.

When the nanopores are covered by the adherent cells, the electrolyte current is blocked which can be monitored by the impedance spectrum. When the electric fields are applied in the cell culture medium through the nanopores on the insulated membrane, ionic current are generated through the nanoholes but no electric double layers are generated. The non-conductive alumina membrane avoids the electrode polarization effects during the impedance monitoring compared with the traditional metal-based electrode impedance sensor.

In this work, a novel nanostructured cell chip with impedance spectroscopy has been developed. The impedance experiments testified that the new morphology-sensitive electrochemical micro-system with nanoporous membranes could detect the impedance change induced by a limited number of cancer cells covering on the nanopore membranes in the low frequency domain. The effect of anti-cancer drug retinoic acid (RA) on cell adherence and morphology change was also monitored by impedance spectroscopy.

2. Materials and methods

2.1. Nanoporous alumina membrane fabrication

In this experiment, nanoporous alumina membrane was made from pure aluminum foil (99.9% purity, Alfa Aesar) by the standard two-step anodization process. The first anodization process was taken in 0.25 M oxalic acid and the aluminum was used as anode while copper (Cu) sheet was used as cathode. The oxidation layer was characterized by numerous defects, originally caused by defects in the aluminum surface. Owing to the decreasing current with the increase of the thickness of the barrier layer, the formation of pores was initiated at defect positions. Then, alumina and hydroxide at the pore walls were preferentially dissolved by the acidic electrolyte which consists of 4 wt% chromic acid and 8 wt% phosphoric acid in the etching step. The second anodization step was then repeated in 0.25 M oxalic acid. Finally, the amorphous barrier layer of alumina was etched away using a solution of 8 wt% phosphoric acid and 0.1 M $CuCl_2$.

2.2. Functionalizaiton of nanoporous alumina membrane

With the goal of improving hydrogel adhesion on nanoporous alumina membrane, the substrate was silanized with 3-(trimethoxysilyl)propyl methacrylate (TPM) (Aldrich). Briefly, the chip with alumina membranes was boiled in 30% hydrogen peroxide for 30 min to clean the surface. This step introduced OH groups on the surface which facilitated subsequent modification by silane. After treating with hydrogen peroxide, washing in boiling deionized water was followed for 15 min. The chip was then air-dried. For the silanization, the chip was immersed into a 5% (v/v) solution of 3-(trimethoxysilyl)propyl methacrylate (TPM) in anhydrous toluene at 50 °C for 2 h. Then the membranes were washed by toluene, followed by methanol and deionized water. The membranes were further air-dried and stored in nitrogen.

2.3. Fabrication of PEG hydrogel microwell on nanoporous alumina membrane

Poly(ethylene glycol) (PEG) hydrogel micropatterns were generated from the precursor solution of PEG-DA (MW 700, Aldrich) with 1% (w/v) photoinitiator DMPA using photolithography method. The precursor solution was first injected into a pre-fabricated SU-8 chamber with the height of 20 μm on the silane-treated nanoporous alumina surface. A glass slide was then used to cover the chamber and a photomask with the desired pattern was put into proximity of the gel precursor. Photoreactions were performed by exposure to 365 nm UV light (30 mW/cm^2) for 90 s using a UV spot curing system (EXFO, S1000 Omnicure, Canada). The UV exposed PEG region was solidified and the desired micropatterns were achieved by washing away the unreacted precursor solution with DI water.

2.4. Cell culture

The chamber, fabricated of Teflon, consists of two compartments A and B separated by the desired nanoporous alumina membrane. The upper chamber is open for cell culture purpose. Human esophageal squamous epithelial cancer cell line KYSE30 was obtained from American Type of Culture Collection (ATCC). The cells were maintained routinely in Dulbecco's modified eagle medium (DMEM) with 4500 mg/L glucose (Invitrogen) as basic medium supplemented with 5% fetal bovine serum (FBS, Invitrogen) together with penicillin and streptomycin (Invitrogen). They were cultured on a 35 mm diameter tissue culture dish (Nunc GmbH & Co. KG, Germany) in a humidified incubator at 37 °C with 5% CO_2/95% air. The culture medium was exchanged three times a week and routine subculturing of confluent cell layers was performed using standard trypsinization (0.05% (w/v)/1.5 mM EDTA) techniques. The cells were then seeded on the hydrogel patterned nanoporous alumina membrane treated with fibronectin and cultured for 1 day. Phalloidin-TRITC (Sigma–Aldrich) was used to stain actin filaments of the cells. The sample was finally viewed using a fluorescence microscope (Nikon, ECLIPSE 80i).

2.5. Impedance measurement

An Ag/AgCl counter electrode was placed in the lower chamber and a Pt wire was immersed into upper chamber as the working electrode. Impedance data was obtained from an electrochemical analyzer VersaSTAT3 (METEK) with the software V3-Studio (Princeton Applied Research). The impedance measurements were performed in the cell culture medium. To validate the applicability of this device, impedance spectrum with addition of retinoic acid (RA) (Sigma–Aldrich Co., USA) was monitored.

3. Results

3.1. Patterning of cells in the hydrogen microwell on nanoporous alumina membrane

Protein/cell repelling hydrogel layer with 500 μm microwell was fabricated on the functionalized nanoporous alumina membrane with the nanopore size of 75 nm (Fig. 2a). The microwell was surrounded by PEG hydrogel layer and the height of microwell was approximately 15 μm (Fig. 2b). Based on the SEM images (Fig. 2c), the fabrication process did not change the pore structure of the membrane and the "open" pores are observed.

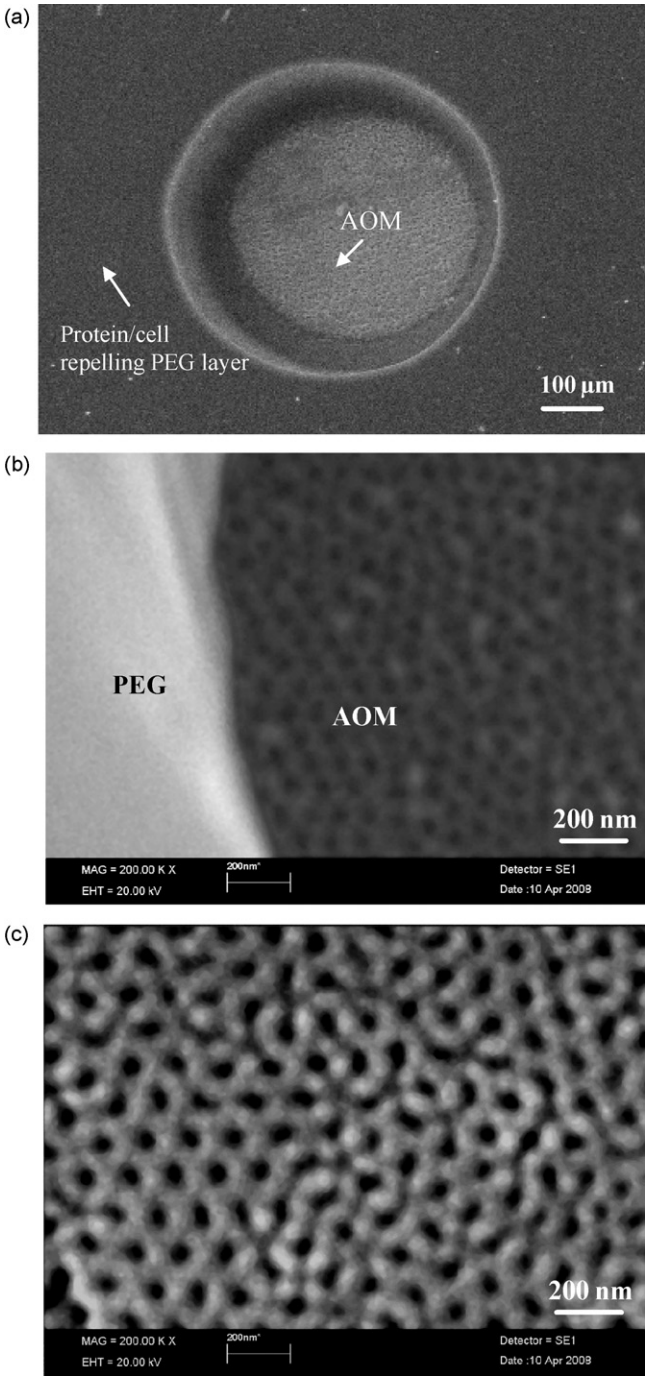

Fig. 2. Scanning electron microscopy image of (a) PEG layer with a microwell on the modified nanoporous membrane; (b) boundary of PEG/alumina membrane microwell; (c) open nanopores were observed on the nanoporous membrane within the fabricated microwell.

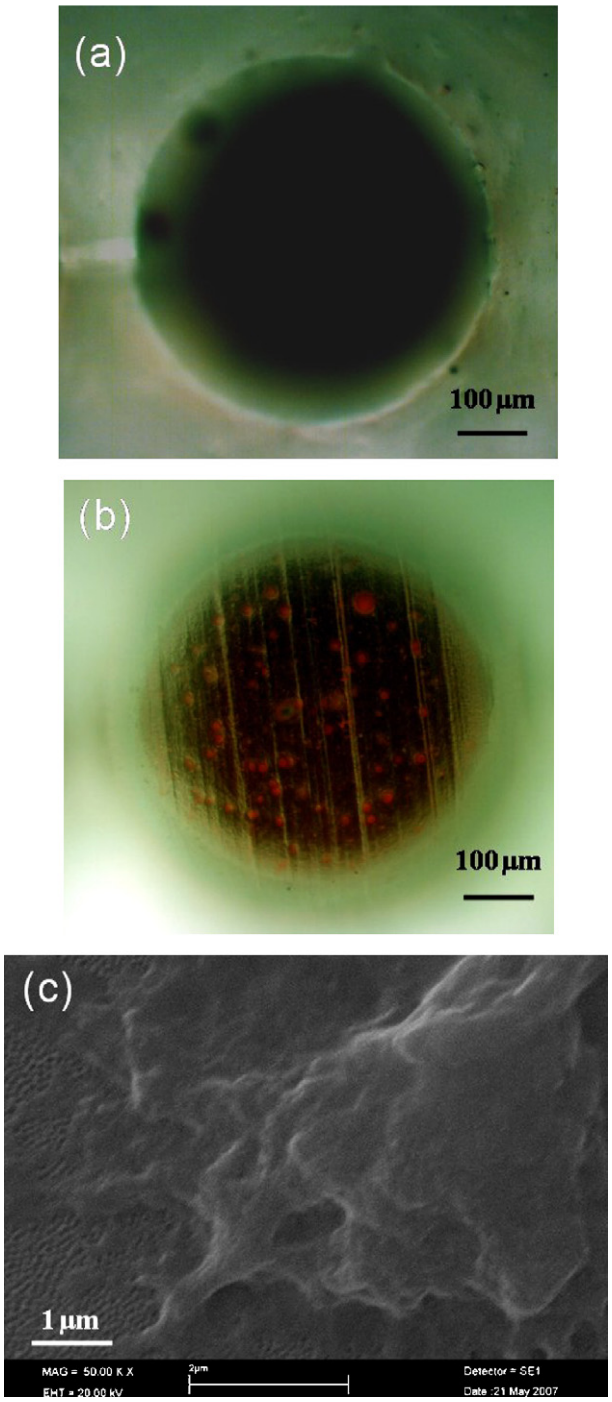

Fig. 3. Fluorescence images (a) before and (b) after cancer cells seeding; (c) SEM image of an adherent KYSE30 cancer cell on the surface of nanoporous alumina membrane.

The PEG hydrogel micropattern on the silane modified nanoporous alumina surface created controlled spatial distribution of hydrophobic and hydrophilic regions, which interacted differently with cells. The PEG patterned substrates were incubated with KYSE30 cancer cells for 1 day. After incubation, the chip with adhered cells was removed from cell culture media followed by briefly washing. The patterned cells were then stained and observed using fluorescence microscopy. The microwell surfaces were examined using fluorescent microscopy before and after the cells seeding (Fig. 3a and b). The results showed that fluorescence labeled cells were captured within the microwell after the experiments. The difference of cell adhesion between PEG and modified nanoporous alumina membrane surface enabled the spatial control of cells. The modified nanoporous alumina membrane was more capable of cell adhesion than PEG surface. Fig. 3c shows a SEM image of a KYSE30 cell on the nanoporous alumina membrane. It can be noted that part of the membrane was blocked by the adherent cell.

3.2. Impedance characterization without cells

The impedance spectrum of PEG coated nanoporous membrane with the microwell, immersed in culture medium DMEM is

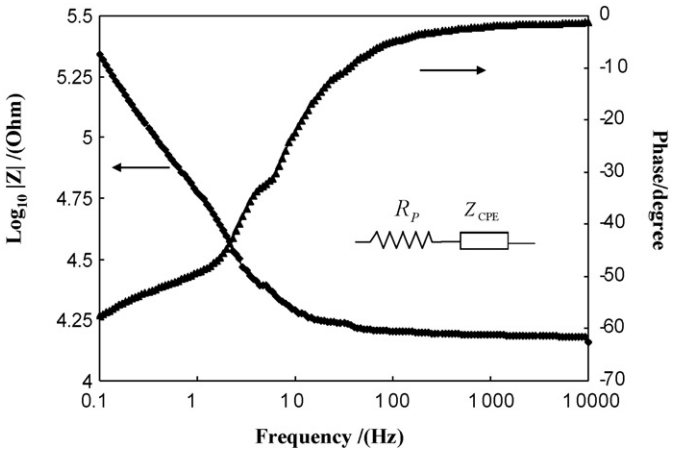

Fig. 4. Impedance spectrum of device without cells in the cell culture medium. Inset is the equivalent circuit.

shown in Fig. 4. The effective sensing area of nanoporous alumina membrane is around 0.002 cm^2 with the diameter of 250 μm. The impedance module $|Z|$ showed a plateau region from 10^4 to 10^1 Hz and increased linearly from 10^1 to 10^{-1} Hz. The linear increase of $|Z|$ indicated the generation of surface/electrolyte double layer. Compared with reported literature data of gold microelectrodes for cell impedance sensing with larger area [21], where the electrode polarization started around 10^5 Hz, this fluidic-pore system with non-conductive membrane layer could obviously decrease the electrode polarization effects. Impedance spectra for bare nanoporous membrane and PEG modified membranes with the same area in culture medium DMEM were measured to determine whether surface modification process influenced the charge transport properties of the membranes. No obvious difference of the impedance spectra could be observed between the bare and modified membranes. This can be explained by the following reasons: (1) the hydrophilic PEG molecules do not cause much change for the water permeability of the membranes; (2) most ions in the DMEM cell culture medium such as Na^+, K^+, Ca^{2+} have stokes radius less than 1 nm, which are much smaller than the nanopore size of 75 nm. The slight decrease of effective nanopore size by PEG molecule adsorption will not have much effect on the ion transport property of the membranes.

The impedance spectrum of this system without cells can be represented by an equivalent circuit with two parameters R_P and Z_{CPE} shown in Fig. 4. R_P is the resistance related to the electrical current flow through the nanopores of nonconductive alumina layer; Z_{CPE} is the constant phase element (CPE) which represents the interfacial double layer effects of the pore surfaces. Here, the constant phase element Z_{CPE} is represented by [8,22]:

$$Z_{CPE} = \frac{1}{(j\omega A)^{\alpha}} \quad (1)$$

where A is analogous to capacitance, ω is the frequency expressed in rad/s, and $0 \le \alpha \le 1$. When $\alpha = 1$, Z_{CPE} becomes a capacitance, and when $\alpha = 0$, Z_{CPE} becomes a resistance. The impedance spectrum with nanoporous membrane was interpreted using this equivalent circuit model, where $R_P = 574.1 \pm 7.5\ \Omega$, $A = 12.4 \pm 0.8\ \mu F$, and $\alpha = 0.868 \pm 0.009$.

3.3. Impedance spectrum of cancer cell grown on nanoporous membrane

Measured impedance spectra with different days of cell cultivation were shown in Fig. 5. When KYSE30 cancer cells were cultured on the nanoporous alumina membrane, the impedance spectra were measured in the low frequency of 10^{-1} Hz to 1 kHz

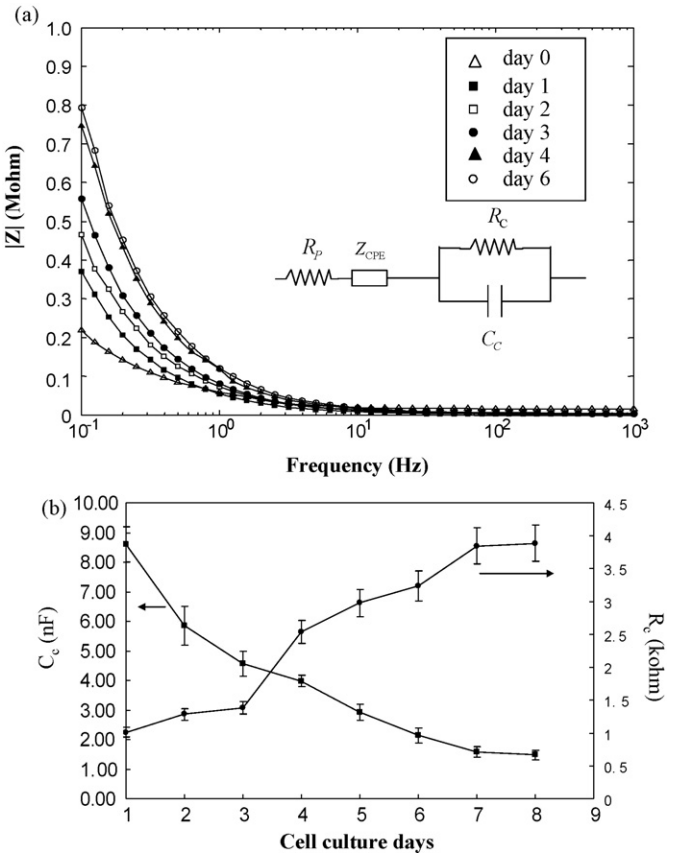

Fig. 5. (a) Measured impedance magnitude of cell growth for different cultivation days; (b) circuit model parameters R_C and C_C variation versus cell cultivation days.

from day 0 to day 6. The impedance magnitude increased with days and became stable after 6 days, as can be seen from Fig. 5a. The average impedance amplitude of day 0 was $218.8 \pm 8.4\ k\Omega$ at 0.1 Hz. When cancer cells achieved confluence on the nanoporous membrane after 6 days of cultivation, the average impedance amplitude was increased to $793.5 \pm 14.3\ k\Omega$ at 0.1 Hz. No big difference of impedance amplitude could be observed when the frequency was above 10 Hz.

To correlate the variation of impedance to KYSE30 cells behavior, the impedance spectra were fitted with the equivalent circuit

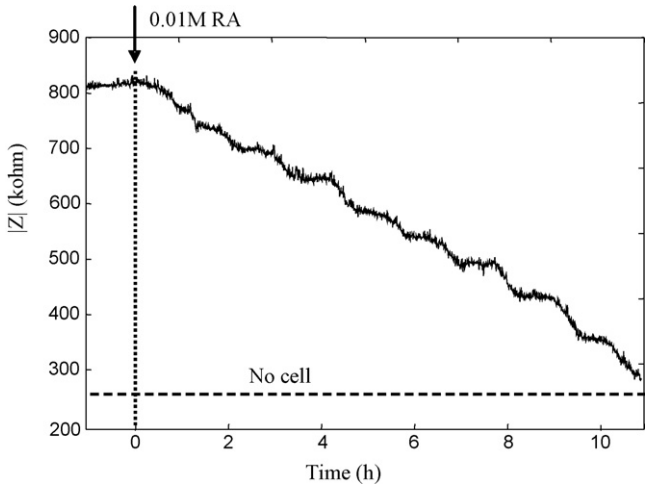

Fig. 6. Impedance amplitude change with time under the effect of retinoic acid (0.01 M) at 0.1 Hz.

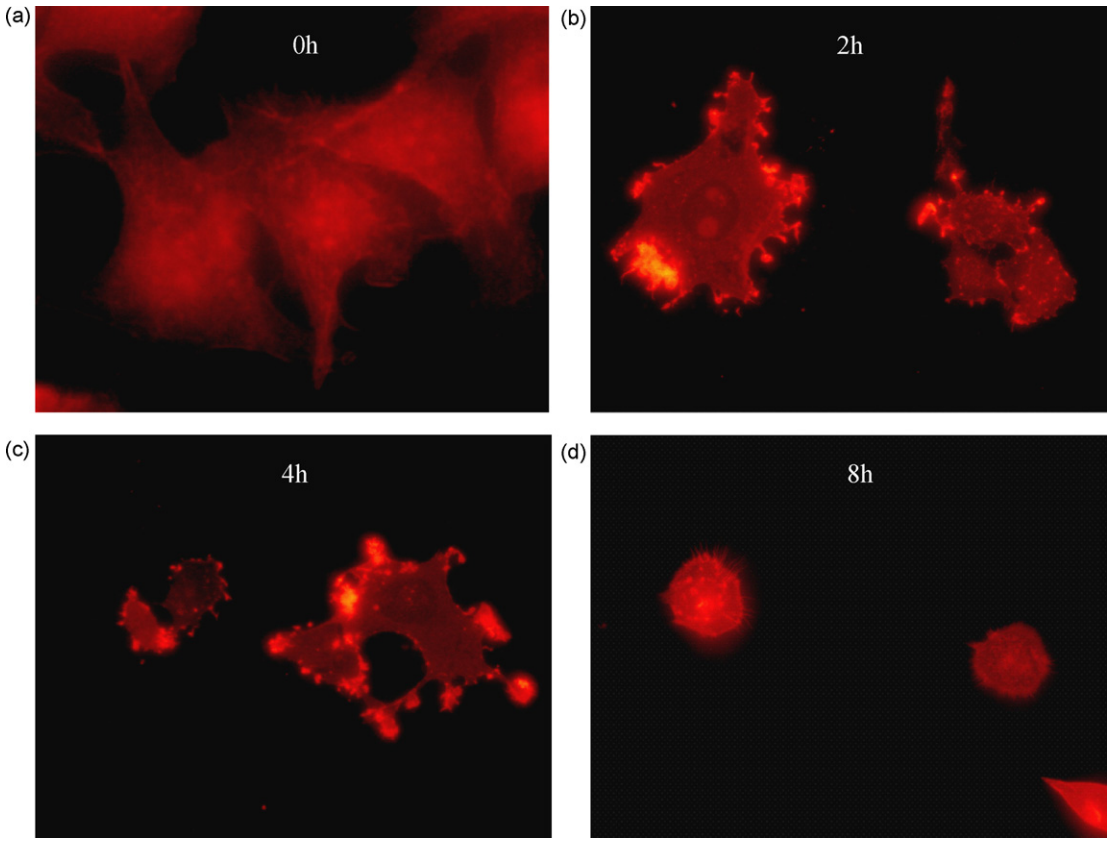

Fig. 7. Fluorescence images of KYSE30 cancer cells cultured on the nanoporous membranes for the treatment of retinoic acid (0.01 M). (a) $t = 0$ h; (b) $t = 2$ h; (c) $t = 4$ h; (d) $t = 8$ h.

shown in the inset of Fig. 5a. Here R_C and C_C are resistance and capacitance related to the cell layer covered on the pores. R_P and Z_{CPE} are the electrolyte resistance and constant phase element, respectively. Values of $R_P = 485.3 \pm 11.6\ \Omega$, $A = 4.48 \pm 0.11\ \mu$F, and $\alpha = 0.802 \pm 0.006$ remain constant in the equivalent circuit while values of R_C and C_C components vary as a function of cultivation days as shown in Fig. 5b. The average values and error bar were indicated in the diagram. As shown in Fig. 5b, the cell layer resistance R_C changes from 1.01 to 3.88 kΩ and the capacitance C_C decreases from 8.59 to 1.49 nF. The change of R_C and C_C may be related to the increase of blocked nanopore area by cell spreading or cell proliferation and the gap decrease between cells and the nanopores during the cell culture process.

3.4. Retinoic acid impedance monitoring

Retinoic acid (RA) is an immunomodulator and both a preventive and chemotherapeutic anti-cancer agent, and its derivatives have been already used to treat many cancer and tumor types [23,24]. The anti-cancer effects of retinoic acid are in part due to their ability to inhibit proliferation of cancer cells. RA inhibits cancer cell-substrate adhesion and motility and also induces morphological and functional terminal differentiation of a cell line.

In this experiment, the cell chip was initially inoculated with a cell density of 3.2×10^5/ml. After 6 days culture, the impedance amplitude was stable around a constant value of 800 kΩ. Then, retinoic acid (RA) with 0.01 M concentration was added for the anti-cancer drug experiment. The impedance was monitored at 0.1 Hz. After addition of 0.01 M RA to the cell chip, the impedance magnitude decreased with time and returned to the initial base line without cells after 12 h (Fig. 6).

The cellular morphology changes due to the RA addition were also studied. To visualize stress fibers of the cytoskeletal structure, the cells were fixed and labeled. Then the stained cells were visualized using fluorescence microscope. Before the experiments, the cells were cultured 1 day for the good attachment and spreading on the membranes. Fig. 7 shows the change of cell morphology after exposure to 0.01 M RA. In the absence of RA, typical cell spreading and cytoskeletal organization were observed shown in Fig. 7a, where $t = 0$ h. RA treatment reduced the abundance of large fibers and started to shrink from the edges after 2 h (Fig. 7b). After 4 h, an obvious morphology change could be observed in Fig. 7c with a much smaller covering area compared with initial morphology. The KYSE30 cells on the nanoporous membrane rounded up completely after 8 h (Fig. 7d). This experiment testified that the impedance amplitude decrease was really due to the cell morphology change after the treatment of RA.

4. Conclusion

In this work, a novel poly(ethylene glycol) (PEG) hydrogel-based microchip with patterned nanoporous alumina membrane was presented for nanopore based impedance sensing in the low frequency domain. The PEG hydrogel layer with the microwell was fabricated on the silane modified nanoporous alumina surface with controlled spatial distribution of hydrophobic and hydrophilic regions. The KYSE30 cancer cells were patterned within the microwell. Impedance experiments with single microwell were explored. This new morphology-sensitive electrochemical micro-system was testified by detecting the impedance change for both cell growth and drug induced change in the low frequency domain.

ABSTRACT

A new matrix additive, poly (*N*,*N*-dimethylacrylamide)-functionalized gold nanoparticle (GNP-PDMA), was prepared by "grafting-to" approach, and then incorporated into quasi-interpenetrating network (quasi-IPN) composed of linear polyacrylamide (LPA, 3.3 MDa) and PDMA to form novel polymer/metal composite sieving matrix (quasi-IPN/GNP-PDMA) for DNA sequencing by capillary electrophoresis. Without complete optimization, quasi-IPN/GNP-PDMA yielded a readlength of 801 bases at 98% accuracy in about 64 min by using the ABI 310 Genetic Analyzer at 50 °C and 150 V/cm. Compared with previous quasi-IPN/GNPs, quasi-IPN/GNP-PDMA can further improve DNA sequencing performances. This is because the presence of GNP-PDMA can improve the compatibility of GNPs with the whole sequencing system, enhance the entanglement degree of networks, and increase the GNP concentration in system, which consequently lead to higher restriction and stability, higher apparent molecular weight (MW), and smaller pore size of the total sieving networks. Furthermore, the composite matrix was also compared with quasi-IPN containing higher-MW LPA and commercial POP-6. The results indicate that the composite matrix is a promising one for DNA sequencing to achieve full automation due to the separation provided with high resolution, speediness, excellent reproducibility, and easy loading in the presence of GNP-PDMA.

1. Introduction

The separation medium has played an important role in high-performance capillary electrophoresis (CE) for DNA separations. Although a lot of polymers have been developed and tested as sieving matrices for CE, searching for an ideal matrix simultaneously possessing low viscosity, high-sieving ability and self-coating ability is still an important issue for high-throughput DNA analysis [1]. Recently, a noncross-linking quasi-interpenetrating network (quasi-IPN) consisting of linear polyacrylamide (LPA) with very high molecular weight (MW, up to 9.9 MDa) and poly (*N*,*N*-dimethylacrylamide) (PDMA) was prepared as a high-performance single-stranded DNA (ssDNA) sequencing medium, which combined the high sieving ability of high-MW LPA and the dynamic coating ability of PDMA [2]. However, the viscosity of the matrix containing LPA (9.9 MDa) is high and the preparation of long-chain LPA is not so easy. Inspired by previous papers [1,3–6] in which various nanoparticle additives were incorporated into polymer solutions to increase double-stranded DNA (dsDNA) separation performances, gold nanoparticles (GNPs) were selected as an additive and added into quasi-IPN consisting of LPA with low MW (3.3 MDa) and PDMA to form polymer/metal composite matrix (quasi-IPN/GNPs) in order to compensate for the loss of the ssDNA sequencing properties using low-MW LPA [7,8]. The interactions between GNPs and polymer chains and the formation of physical cross-linking points may help to stabilize the sieving network, so that the performances of quasi-IPN/GNPs were better than those of quasi-IPN without GNPs.

At high concentration of salt in buffer solution, however, GNPs tended to aggregate especially when GNP concentration in matrices increased [7,8] and the compatibility of GNPs with the sequencing system was not so good. To overcome this kind of difficulty, it is necessary to design the coating of GNPs to make them more compatible with the polymer matrix, and it is speculated that GNPs whose polymer coat is chemically the same as the matrix would be more thermodynamically favorable to their incorporation [9]. "Grafting-to" approach has mainly been developed for the synthesis of metal (or metal oxide)/polymer hybrid structures, in which preformed end-functionalized polymers with controllable MW were directly immobilized to the surface of substrates by coupling reactions, chemical bonding, electrostatic interactions, or spin coating. In the case of GNPs, dithioester groups on polymers prepared by reversible addition-fragmentation chain transfer (RAFT) polymerization (an exceptionally versatile controlled/"living" free

doi:10.1016/j.talanta.2009.06.048

radical polymerization technique) can be chemically modified to thiol groups (–SH) for the direct grafting of the polymers onto GNPs through Au–S interactions [10]. Clearly, polymer-protected GNPs possess the functionality and dispersibility derived from the polymer shell. And the modified nanoparticles can be stored for long periods in the dry state and are easily redispersed in aqueous solutions where they give stable solutions, even at high concentration. So we consider polymer-functionalized GNPs may be the potential additive for the separation and sequencing analysis of DNA by CE.

In this work, in order to improve the compatibility of GNPs with the whole sequencing system and further improve the ssDNA sequencing properties using quasi-IPN/GNPs, a novel matrix additive, PDMA-functionalized gold nanoparticle (GNP-PDMA) was prepared by "grafting-to" approach, and then incorporated into quasi-IPN containing LPA (3.3 MDa) and PDMA to form polymer/metal composite sieving matrix (quasi-IPN/GNP-PDMA). PDMA was selected to functionalize GNPs because PDMA is one of components of quasi-IPN and is soluble in water and compatible with biological components and quasi-IPN, furthermore, PDMA could reduce electroosmotic flow (EOF) and the adsorption of DNA on the capillary wall for its dynamic coating ability. The CE results demonstrated that DNA sequencing performances were enhanced by the addition of GNP-PDMA. The effect of GNP-PDMA concentration in matrices on ssDNA sequencing performances was studied in detail in the bare fused-silica capillaries and this novel composite matrix was compared with quasi-IPN/GNPs, quasi-IPN containing higher-MW LPA, and commercial POP-6.

2. Materials and methods

2.1. Materials

$HAuCl_4{\cdot}4H_2O$, trisodium citrate dihydrate, $NaBH_4$, dioxane, tetrahydrofuran (THF), diethyl ether, and other reagents were obtained from Sinopharm Chemical Reagents (Shanghai, China). 2, 2′-Azobis(isobutyronitrile) (AIBN) was purified by recrystallization from ethanol. RAFT chain transfer agent, 2-cyanoprop-2-yl dithiobenzoate (CPDB) was synthesized according to the procedure [11]. *N*,*N*-dimethylacrylamide (DMA) was purchased from Aldrich Chemical Company (Milwaukee, WI, USA) and distilled under reduced pressure before use. The details of other reagents used for the preparation of quasi-IPN and 1× TTE buffer (50 mM Tris/50 mM TAPS/2 mM EDTA in water) or 1× TTE/7 M urea buffer can be seen in the previous works [7,8]. BigDye Terminator kit V3.1 sequencing standard (hsp69) sample and formamide (Hi-Di™) were purchased from Applied Biosystems (Foster City, CA, USA). Prior to sequencing, 100 μL formamide was added to the vial containing the lyophilized sequencing standard DNA. The sample was mixed thoroughly on a vortex mixer and centrifuged at 3000 rpm for 60 s, then denatured by heating for 2 min at 95 °C and quickly chilled on ice until ready to load on the instrument.

2.2. Preparation and characterization of quasi-IPN/GNP-PDMA

Here the synthesis of PDMA with terminal dithioester groups (PDMA-SC(S)Ph) through RAFT polymerization [12,13] is described in brief, as shown in Fig. 1A. In a typical run, DMA monomer (2.0 mL), CPDB chain transfer agent (10.2 mg), and AIBN initiator (1.6 mg) were dissolved in dioxane solvent (4 mL) in a round-bottom tube equipped with a magnetic bar. The mixture was degassed by three freeze-pump-thaw cycles, flame sealed under vacuum, and polymerized in a thermostated oil bath at 80 °C for 24 h. Then the tube was cooled to room temperature rapidly. After the tube was broken, THF was added. The polymer was precipitated by pouring the polymer solution into excess of anhydrous diethyl ether (15 times volume), and the light pink polymerization product was washed with diethyl ether several times to remove residual DMA monomer. The precipitation-washing operation was repeated for three times at least, and the polymer product was finally dried under vacuum.

Au colloids (citrate-capped GNPs) were prepared according to the citrate reduction protocol [14] with slight modifications. In a typical synthesis, 100 mL of 1 mM $HAuCl_4$ solution was added in a 250-mL round-bound flask equipped with a condenser and heated to boil with vigorous stirring. 10 mL of 38.8 mM trisodium citrate solution were rapidly added into this $HAuCl_4$ solution, and the solution changed color from pale-yellow to blue and then to wine-red, indicating the formation of the GNPs. Boiling continued for an additional 10–15 min, then the heating source was removed. The colloids were stirred for another 15 min and cooled to room temperature.

GNP-PDMA was synthesized using the "grafting-to" technique (Fig. 1A), similar to Refs. [15–17]. PDMA with thiol end groups (PDMA-SH) was prepared by reduction of PDMA-SC(S)Ph with $NaBH_4$ in N_2 atmosphere. Into a round-bottom flask equipped with a magnetic stirring bar, PDMA-SC(S)Ph was dissolved in deionized water and 1.0 M $NaBH_4$ aqueous solution was added under vigorous stirring, with a molar ratio of 1/25 for PDMA/$NaBH_4$. The reaction mixture was stirred at room temperature for more than 3 days to ensure that the dithioester terminal groups were completely reduced to yield PDMA-SH. Then a calculated amount of citrate-capped GNPs (at a thiol/gold molar ratio of 1:10) was added dropwise under vigorous stirring. After 3 days of equilibrium at room temperature, the reaction solution was centrifuged at

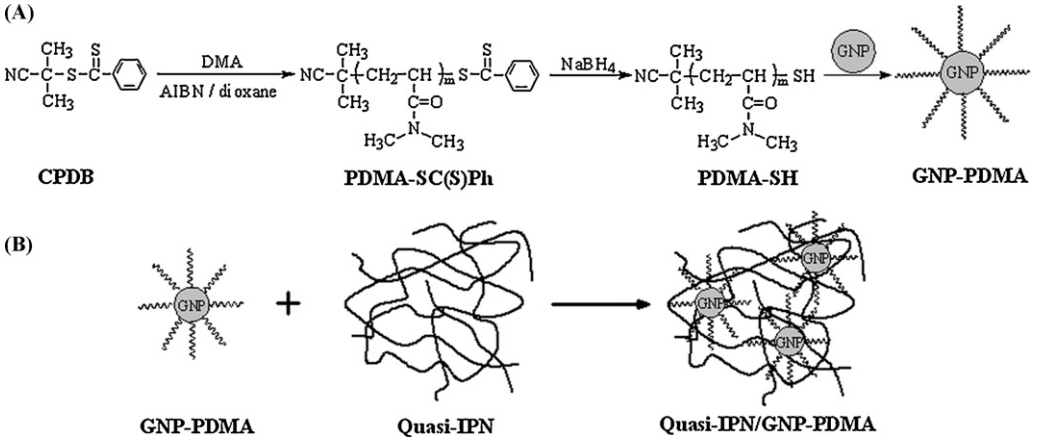

Fig. 1. The schematic representation of reaction routes for (A) GNP-PDMA and (B) quasi-IPN/GNP-PDMA.

12,000 rpm for 1 h at room temperature and the supernatant was removed. This process removed the free polymer chains that were not conjugated to GNPs. The resulting precipitate was redispersed in deionized water followed by centrifugation to wash away residue polymers and this washing procedure was repeated three times to ensure that only covalently bound polymers remained in the colloidal solutions of the stabilized nanoparticles. Finally, pure purple GNP-PDMA was obtained free of polymer contamination.

The synthetic procedures of quasi-IPN have been reported elsewhere [7,8]. Various quasi-IPN/GNP-PDMA composite sieving matrix solutions were prepared by mixing quasi-IPN and GNP-PDMA with 1× TTE/7 M urea buffer to the desired concentrations: the same 2.5% (m/v) of quasi-IPN but different amounts of GNP-PDMA, i.e., quasi-IPN/GNP-PDMA-1, -2, and -3 with the neat GNP concentrations of 0.002, 0.080 and 0.400 mg/mL, respectively. For the sake of comparison, quasi-IPN/GNPs solution (0.002 mg/mL GNPs) was also prepared.

The molecular weight distribution of PDMA-SC(S)Ph ($\overline{M}_w/\overline{M}_n$ = 1.07) was characterized using gel permeation chromatography (GPC) (Waters 1515 using narrow polydispersity polystyrene as calibration standard and *N*,*N*-dimethylformamide as eluent at a flow rate of 1.0 mL/min and 30 °C, USA). The size and shape of GNPs and GNP-PDMA were determined by a Hitachi H-800 Transmission Electron Microscope (Hitachi High-Technologies, Japan). The surface plasmon resonance band of GNPs and GNP-PDMA in water were recorded by a UV-2401PC UV–vis Spectrophotometer (Shimadzu Corp., Japan). ^{1}H NMR and FTIR spectra were recorded by an AVANCE 300 ^{1}H NMR Spectrometer (BRUKER BIOSPIN AG, Switzerland) and a Bruker EQUINOX55 Fourier Transform Infrared Spectrometer (Bruker, Germany), respectively. Thermogravimetric analysis (TGA) data were obtained by a Shimadzu DTG-60H Thermal Analyzer (heating rate of 10 °C/min, nitrogen flow of 30 mL/min, Shimadzu, Japan). Intrinsic viscosities [η] of the samples were measured using an Ubbelohde viscometer in 1× TTE/7 M urea buffer at 30 °C.

2.3. DNA sequencing by CE and data processing

Sequencing (base C, T, A, and G) of standard DNA sample was carried out on an ABI 310 PRISM™ Genetic Analyzer (PerkinElmer, Applied Biosystems Division, USA) with four-color laser-induced fluorescence (LIF) detection. Sequencing conditions: effective/total length of bare fused-silica capillaries (Polymicro Technologies, Phoenix, AZ, USA), 50/61 cm; id/od, 75/365 μm; sequencing electric field strength, 150 V/cm; DNA electrokinetic injection, 41 V/cm for 30 s; anode buffer, 1× TTE; cathode buffer, 1× TTE/7 M urea; sequencing temperature, 50 °C. The four-color raw data were collected and analyzed by ABI PRISM 310 Data Collection Software and ABI PRISM DNA Sequencing Analysis Software, respectively. The raw LIF data were also transformed through the ABI-Browser software and Origin 7.5 software (Microcal, Northampton, MA, USA) was used to extract data from transformed data, which were fitted into Gaussian peaks by using PeakFit™ 4.06 software (SPSS Inc., Chicago, USA). All the peak fittings had $r^2 > 0.99$. In order to quantify the separation performance of a matrix and compare it with other matrices, the resolutions (R) of selected nine pairs of DNA fragments with

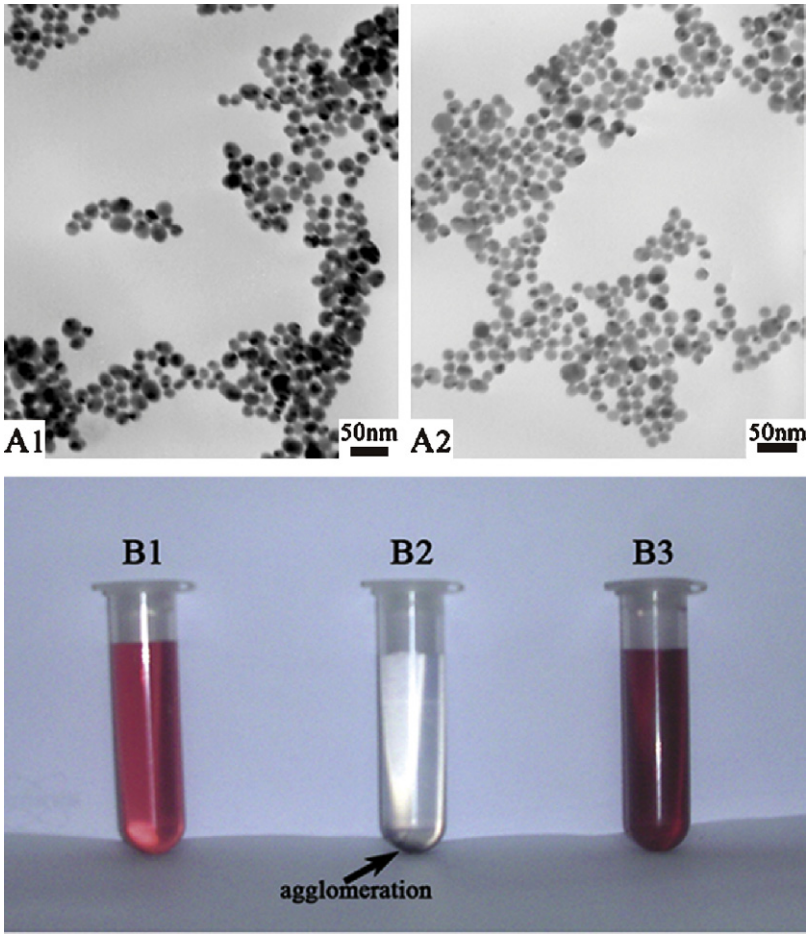

Fig. 2. TEM images of (A1) GNPs (~18 nm) and (A2) GNP-PDMA; photographs of (B1) fresh GNP solution, (B2) GNP solution after two months, and (B3) GNP-PDMA solution after ten months.

base length of 79/80, 98/99, 192/193, 344/345, 412/413, 514/515, 635/638, 828/830, and 924/927 were calculated according to the following equation [18], respectively:

$$R = 2 \times \frac{t_2 - t_1}{[1.699 \times (w_2 + w_1)]} \quad (1)$$

where t and w are migration time and full peak width at half height of selected peaks, respectively, which can be obtained from sequencing electropherogram using PeakFit. There are two parameters (separation selectivity S and separation efficiency N) affecting resolution. R, S, and N have the following relationship:

$$R = \frac{(SN^{1/2})}{4} \quad (2)$$

The selectivity and separation efficiency can be calculated by the following two equations:

$$S = 2 \times \frac{(t_2 - t_1)}{(t_2 + t_1)} \quad (3)$$

$$N = 5.54 \times \left(\frac{t}{w}\right)^2 \quad (4)$$

3. Results and discussion

3.1. Preparation and characterization of quasi-IPN/GNP-PDMA

Approximately spherical GNPs with mean diameter of about 18 nm, prepared through citrate reduction, are observed according to the TEM image (Fig. 2A1). The photograph of red fresh GNP solution is shown in Fig. 2B1. The surface of GNPs was negatively charged with citrate. After mixing of GNPs with PDMA-SH, the polymer can directly covalently bind onto GNP surface through Au–S interactions. The bond strength between Au and S is stronger than that between Au and citrate, so citrates could be exchanged with thiol [10]. After the exchange, GNP-PDMA was easily obtained and the TEM image can be seen in Fig. 2A2. As shown in Fig. 2B2, GNP agglomeration in buffer solution with high salt concentration appeared in the bottom of the tube and the system changed from red to colorless less than two months, whereas GNP-PDMA easily dispersed and no precipitation was observed even after ten months (Fig. 2B3). These phenomena prove that GNP-PDMA synthesized by "grafting-to" method enhanced the dispersivity and stability of GNPs.

UV–vis spectra (Fig. 3) of the citrate-capped GNPs and GNP-PDMA in water reveal that the characteristic maximum absorbance wavelengths were 521 and 526 nm for GNPs and GNP-PDMA, respectively, which indicates the formation of GNPs and shows a slight red-shift after GNPs grafted by PDMA. The position of the surface plasmon resonance band is sensitive to particle size and shape as well as to the optical and electronic properties of the particle surroundings, such as the stabilizing ligand shell, which can further change the optical properties of the GNPs. Thus, the wine-red color of the citrate-coated GNPs solution was changed to purple color and band displays a red-shift after GNPs were modified with PDMA.

PDMA-SC(S)Ph and GNP-PDMA were characterized by ^{1}H NMR using D_2O as the solvent, and the characteristic peaks of PDMA are clearly found: the chemical shifts of methylene and methylidyne protons appear at ~1.6 and ~2.6 ppm, respectively, and the characteristic signals of methyl protons appear at 2.8–3.2 ppm, as shown in Fig. 4. Furthermore, the three weak peaks (7.4–8.0 ppm) represent the aromatic protons of the phenyl groups on PDMA-SC(S)Ph (Fig. 4A) revealing the presence of dithioester end groups, whereas, they disappear after the formation of GNP-PDMA (Fig. 4B), which indicate the complete transformation of dithioester end groups into thiol groups with the addition of $NaBH_4$.

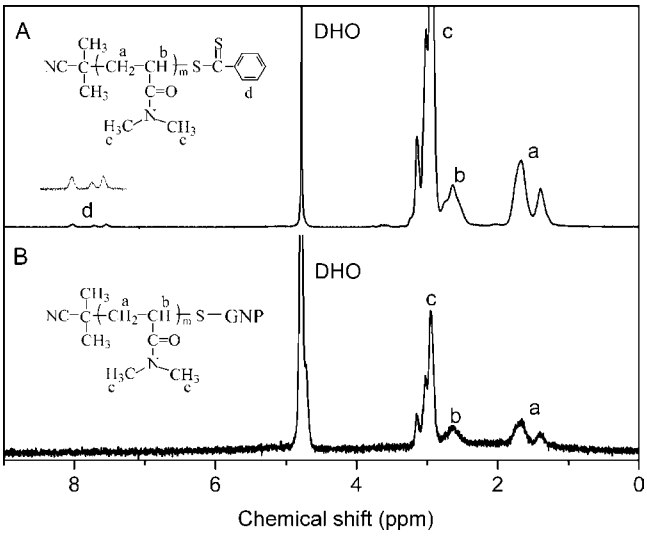

Fig. 4. ^{1}H NMR spectra of (A) PDMA-SC(S)Ph and (B) GNP-PDMA using D_2O as the solvent.

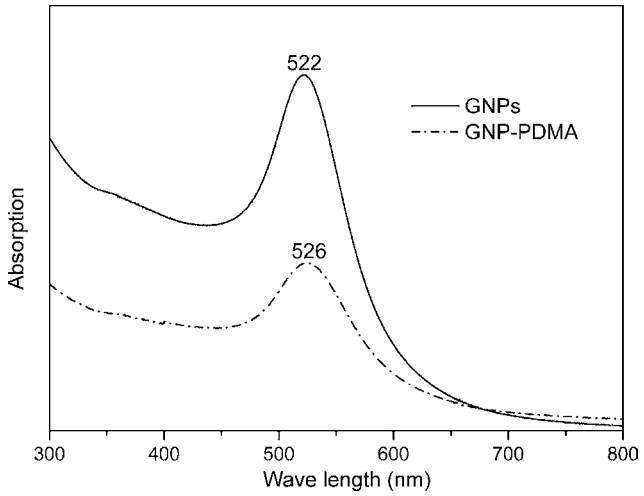

Fig. 3. UV–vis spectra of (A) GNPs and (B) GNP-PDMA in water.

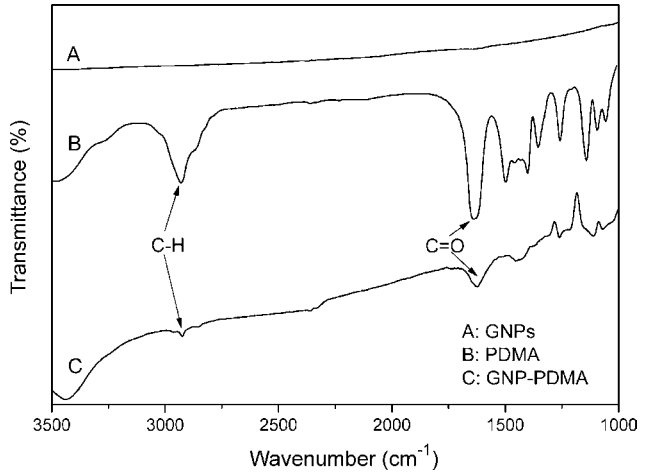

Fig. 5. FTIR spectra of (A) GNPs, (B) PDMA, and (C) GNP-PDMA.

Fig. 5 shows FTIR spectra of GNPs, PDMA, and GNP-PDMA. The characteristic absorption peaks in Fig. 5B, such as C=O (acylamide carbonyl) at 1630 cm^{-1} and C–H at 2926 cm^{-1} demonstrates the successful preparation of PDMA. Different from Fig. 5A (GNPs), Fig. 5C (GNP-PDMA) also reveals these peaks similar to Fig. 5B, which indicates that PDMA chains have been bound successfully to the surface of GNPs.

Because the grafted polymer and metal display distinct thermal stabilities, TGA results can give content of the PDMA grafted on GNPs. GNP sample is steady without significant weight loss below 600 °C, whereas the GNP-PDMA sample displays weight loss of ~20% from TGA data (Fig. 6), and this weight loss results from the thermal degradation of polymer layer on the surface of GNPs. The major decomposition temperature of PDMA grafted on GNPs is higher than that of pure PDMA, indicating that PDMA were covalently linked to GNPs, which is consistent with the previous work [19].

LPA (3.3 MDa) was produced through inverse emulsion polymerization [7,8]. Quasi-IPN was formed by solution polymerization of DMA in LPA aqueous solution [7,8], which is a noncross-linking network with a higher sieving ability [2,20,21] different from traditional cross-linking IPN network. Estimated from the integral peak area ratio in ^{1}H NMR spectra, the molar ratio of acrylamide unit to DMA unit for polymer versions in the resultant quasi-IPN is about 30/1.

The intrinsic viscosities ([η]) of quasi-IPN and composite matrices in 1× TTE/7 M urea buffer were measured in order to study the effect of addition of GNP-PDMA on matrix solution properties. Compared with that of quasi-IPN (0.799 mL/mg), intrinsic viscosities of all quasi-IPN/GNP-PDMA matrices (0.850, 0.877, and 0.888 mL/mg for quasi-IPN/GNP-PDMA-1, -2, and -3, respectively) increased. The overlap concentration ($c^* \approx 1/[\eta]$), is the concentration of polymer in solution at which polymer chains interact with each other in solution, and the c^* values are 1.252, 1.176, 1.140, and 1.126 mg/mL for quasi-IPN, quasi-IPN/GNP-PDMA-1, -2, and -3, respectively. The ratio of polymer concentration to polymer overlap concentration (c/c^*), i.e., the extent of polymer–polymer entanglements, controls the lifetime of the virtual polymer "tube" that the DNA migrates through under the electric field [22]. Consequently, c^* decreased and c/c^* increased after addition of GNP-PDMA, which suggests the enhancement of entanglement extent and the increase in apparent MW and stability of the total sieving networks in the presence of GNP-PDMA. Moreover, the extent of inter-chain entanglements (c/c^*) will be enhanced with the increase in GNP-PDMA concentration.

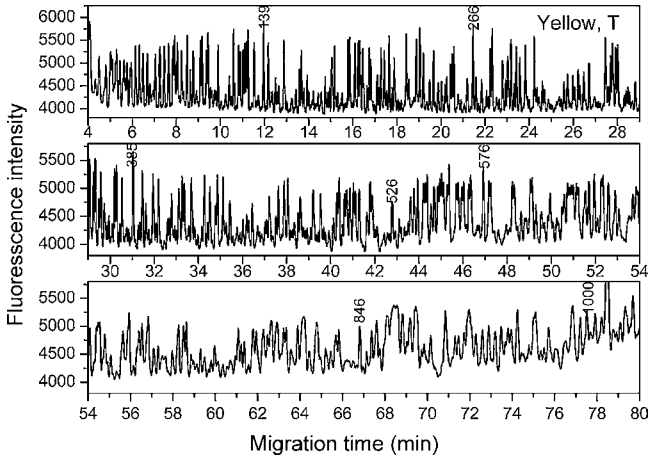

Fig. 7. A part (e.g. yellow-track, base T) of four-color electropherograms of Bigdye Terminator V 3.1 sequencing standard DNA sample by CE using quasi-IPN/GNP-PDMA-2 as sequencing matrix. Sequencing conditions: effective/total length of bare fused-silica capillaries, 50/61 cm; id/od, 75/365 μm; sequencing electric field strength, 150 V/cm; DNA electrokinetic injection, 41 V/cm for 30 s; anode buffer, 1× TTE; cathode buffer, 1× TTE/7 M urea; sequencing temperature, 50 °C; solution concentration, 2.5% (m/v) quasi-IPN + 0.080 mg/mL neat GNP for quasi-IPN/GNP-PDMA-2.

3.2. Effect of GNP-PDMA on DNA sequencing by CE

Fig. 7 shows a part (e.g. yellow-track, base T) of four-color electropherograms of DNA sample using quasi-IPN/GNP-PDMA-2 as sequencing matrix at 50 °C. Resolution comparison of DNA sequencing using quasi-IPN, quasi-IPN/GNPs, quasi-IPN/GNP-PDMA-1, -2, and -3 at 50 °C are shown in Fig. 8, to reveal the relationship between the resolutions and GNPs as well as the GNP-PDMA concentration in the matrices. Obviously, additives (whether GNPs or GNP-PDMA) can improve the sequencing abilities of quasi-IPN. In order to further examine the reasons for better separation performances using quasi-IPN/GNPs or quasi-IPN/GNP-PDMA matrices, two parameters (selectivity and separation efficiency of nine pairs of DNA fragments) affecting the resolution were calculated and plotted against the base number (figures not shown). Selectivity is defined as the mobility difference between two peaks divided by the average mobility. It is observed there was no significant change in selectivity with increasing the concentration of GNPs or GNP-PDMA. On

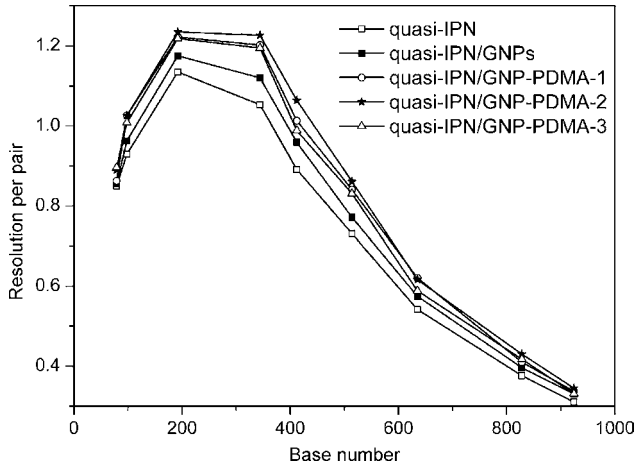

Fig. 8. Resolution vs. base number in sequencing of standard DNA sample by CE using quasi-IPN, quasi-IPN/GNPs, quasi-IPN/GNP-PDMA-1, -2, and -3. Solution concentration: 2.5% (m/v) quasi-IPN + 0, 0.002, 0.002, 0.080 and 0.400 mg/mL neat GNP for quasi-IPN, quasi-IPN/GNPs, quasi-IPN/GNP-PDMA-1, -2, and -3, respectively. Other sequencing conditions and DNA sample are as in Fig. 7.

the other hand, the separation efficiency (theory plate numbers per meter) implies the peak broadening effect since the peak width is involved. At a solution concentration above c^*, the linear polymer chains entangled one another to form a transient network with a certain mesh size (pore size). If the DNA fragment has a size larger than the mesh size, it will adjust itself to migrate through like a snake, as described by the reptation model [23,24]. At the same time, the network would also make an "adjustment" to enlarge the mesh size by changing the positions of the entanglements by a slide of the chains, resulting in a lower sieving ability [25]. However, it is clearly showed that the addition of GNPs or GNP-PDMA into the quasi-IPN networks could improve separation efficiency, which was mainly originated from more stable networks due to the interactions of GNPs or GNP-PDMA with polymer chains, slower polymer chain disentanglement (longer pore lifetime) and more extended chains of the networks [26]. Moreover, it is also noted that high efficiency was partially due to minimized DNA adsorption on the capillary wall in the presence of GNPs or GNP-PDMA that were adsorbed on the wall [27]. Depending on the selectivity and separation efficiency, the resolutions using quasi-IPN/GNPs or quasi-IPN/GNP-PDMA are better than those using quasi-IPN (Fig. 8).

We can find from Fig. 8 that the resolutions of quasi-IPN/GNPs were higher than those of quasi-IPN without GNPs, but the resolutions would decrease with further increase of GNP concentration (data not shown), as described in previous works [7,8]. This is because local aggregation of GNPs in polymer network might occur as the GNP concentration increased. This incompatibility could then result in non-homogeneous polymer–DNA interactions and decrease the efficiency in sequencing, so the GNP concentration in the sequencing system is very limited and the effect of GNPs on sequencing performance is also restricted. But when GNP-PDMA with the same neat GNP concentration (0.002 mg/mL) as GNPs were added in quasi-IPN, the resolutions increased markedly, that is, quasi-IPN/GNP-PDMA-1 showed higher resolutions than not only quasi-IPN but also quasi-IPN/GNPs. In previous works [7,8], the addition of GNPs in matrix could improve ssDNA sequencing performances due to the interactions between GNPs and quasi-IPN polymer chains and the formation of physical cross-linking points. In this work, besides the reasons mentioned above, functionalized GNPs with PDMA chains on the surface possess higher compatibility with quasi-IPN system and higher solubility in water; on the other hand, PDMA chains on the GNPs result in easier and more entanglement between GNP-PDMA themselves or between GNP-PDMA and quasi-IPN system (Fig. 1B). All these factors cause the network with GNP-PDMA more restricted and stable, polymer chain disentanglement slower, and the apparent MW higher, and thus lead to the increase in separation efficiency and resolution for long DNA fragments. In addition, the addition of GNP-PDMA enhances the separation of small DNA molecules due to the network exhibiting smaller pore size than quasi-IPN. Anyway, the improved sequencing of both long and small DNA fragments can be obtained by the addition of GNP-PDMA due to more restricted, stable and smaller nanopore structure.

Furthermore, it should be noted that, different from that of quasi-IPN/GNPs, the resolutions of quasi-IPN/GNP-PDMA continue increase with an increase in GNP concentration up to 0.080 mg/mL (i.e., quasi-IPN/GNP-PDMA-2). It is expected that the matrix network will become more stable because more entanglement points will form as the amount of GNP-PDMA increases. However, the resolutions will not always improve with increased GNP-PDMA concentration, and further increase in concentration even results in decreased resolutions (i.e., quasi-IPN/GNP-PDMA-3). Too high concentration of GNP-PDMA in the solution probably leads to too small pores and too many entanglement points, and local non-homogeneous matrix causes the decrease in sequencing efficiency, which is similar to the GNP system studied previously [7,8].

The presence of GNP-PDMA has little effect on migration time of DNA fragments, for instance, quasi-IPN and quasi-IPN/GNP-PDMA-2 both resulted in 1000 bases being detected in about 78 min. On the one hand, some GNP-PDMA adsorbed on the capillary wall surface, leading to the decrease in EOF and thus the increase in observed DNA mobility; on the other hand, the network with smaller pore size will make DNA molecules migration slower. These two contrary factors affect DNA movement together and result in neglectable change in migration time. However, the readlength at 98% accuracy of quasi-IPN increased from 715 to 801 bases after the addition of GNP-PDMA.

3.3. Comparison with other matrices

Generally, the higher LPA MW, the better the DNA sequencing performance. That is, higher LPA MW helps to obtain higher resolution and longer readlength, but high MW will cause drawbacks such as difficult preparation and high viscosity of LPA. Quasi-IPN containing LPA with higher MW of 6.5 MDa (quasi-IPN-H) were also prepared and used for further comparison. It is shown from Fig. 9 that when both quasi-IPN concentrations are 2.5% (m/v), the resolutions of quasi-IPN/GNP-PDMA-2 with lower LPA MW of 3.3 MDa are even slightly higher than those of quasi-IPN-H without GNP-PDMA, further indicating that the addition of GNP-PDMA in quasi-IPN would form more robust sieving matrix network, increase apparent MW of quasi-IPN, consequently, improve sieving properties based on separation mechanisms. And the readlength at 98% accuracy of quasi-IPN/GNP-PDMA-2 is also slight higher than that of quasi-IPN-H (801 bases vs. 785 bases). So the use of LPA with lower MW (which is easily prepared and not so viscous) in the presence of GNP-PDMA will be more practical and feasible.

Performance Optimized Polymer (POP-6) obtained from Applied Biosystems is a commercial product used widely for ABI 310 Genetic Analyzer, so it was also selected and compared with our matrix. For a proper comparison, sequencing by using POP-6 was conducted under its individual conditions, which were suggested by the suppliers to optimize sequencing performances, for example, sequencing electric field strength was 200 V/cm for POP-6 (while 150 V/cm for our sequencing matrices). As can be seen in Fig. 9, quasi-IPN/GNP-PDMA-2 shows better resolutions than POP-6 with the exception of small DNA fragments (smaller than about 250 bases) owing to higher solution concentration of POP-6 helpful to separate small ones. And the composite matrix pos-

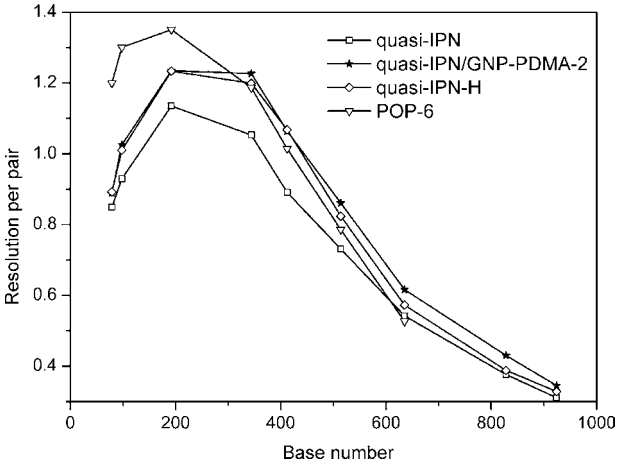

Fig. 9. Resolution vs. base number in sequencing of standard DNA sample by CE using quasi-IPN (2.5%, m/v), quasi-IPN/GNP-PDMA-2 (2.5%, m/v + 0.080 mg/mL), quasi-IPN-H (2.5%, m/v) and commercial POP-6. Sequencing electric field strength, 150 V/cm for our sequencing matrices and 200 V/cm for POP-6. Other sequencing conditions and DNA sample are as in Fig. 7.

sesses longer readlength (801 bases vs. 638 bases at 98% accuracy) and much shorter migration time (50.4 min vs. 107.0 min for base 620, respectively) than POP-6. All the above results demonstrate that quasi-IPN/GNP-PDMA composite matrix is potential for DNA sequencing. It should be noted that separation performance of small DNA fragments strongly depends on the overall concentration of sieving matrix [28,29], and small DNA molecules interact preferentially with these low-MW polymer fibers [30,31]. The concentration of the composite sieving matrix can be increased by addition of very-low-MW (such as ~50 kDa) LPA. As a result, in order to obtain higher-performance separation of both short and long DNA fragments, the mixed quasi-IPN/GNP-PDMA composite matrix containing both very-low-MW and high-MW LPA can be selected for use as a compromise to balance the requirements according to Salas-Solano et al. [32]. On the other hand, for the analysis of some very small templates or exons, the quasi-IPN/GNP-PDMA composite (containing only low-MW LPA) with high solution concentration (such as LPA concentration) and high GNP-PDMA concentration can be used as sieving matrix directly. Moreover, the matrix viscosity is not high because of low-MW LPA.

3.4. Reproducibility

The relative standard deviation (RSD) of the migration time and resolution using quasi-IPN/GNP-PDMA matrices in the same bare fused-silica capillary for the first ten runs shows high reproducibility and are all less than 2.3%.

4. Conclusions

Novel polymer/metal composite sieving matrix for DNA sequencing by CE was formed by incorporating GNP-PDMA additive into quasi-IPN. Without complete optimization (such as base calling software), quasi-IPN/GNP-PDMA-2 yielded a readlength of 801 bases at 98% accuracy in about 64 min by using the ABI 310 Genetic Analyzer at 50 °C and 150 V/cm, showing the composite matrix combines optimal sieving ability with dynamic coating ability and with moderate viscosity. Quasi-IPN/GNP-PDMA can further improve ssDNA sequencing performances because the presence of GNP-PDMA can lead to higher restriction and stability, higher apparent molecular weight, and smaller pore size of the total sieving networks. Furthermore, the comparison studies between the composite matrix with other matrices indicate that it is a promising one for DNA sequencing to achieve full automation (especially for microfluidic systems) due to the separation provided with high resolution, speediness, excellent reproducibility, and easy loading owing to the addition of GNP-PDMA. The raw materials used to prepare the composite matrix are commercial and cheap and the preparation process is easily carried out, so the cost of this matrix is low and it is applicable to high throughput DNA sequencing. Moreover, considering excellent performances of the composite matrix for DNA sequencing, it is expected that quasi-IPN/GNP-PDMA matrix with lower concentration may also be used for other models of ABI Genetic Analyzer, such as fragment analysis, microsatellite and single nucleotide polymorphism (SNP) genotyping analysis.

Other parameters will be optimized in the future to further improve the DNA sequencing performances, and one of our interests is to use functionalized nanoparticles to separate other biomacromolecules by CE.

Glucose

ABSTRACT

Amino-functionalized luminescent silica nanoparticles (LSNPs) doped with the europium(III) mixed complex, $Eu(TTA)_3phen$ with 2-thenoyltrifluoroacetone (TTA) and 1,10-phenanthroline(phen) were synthesized successfully using an revised Stöber method. Scanning electron microscopy (SEM), transmission electron microscopy (TEM), Fourier-transform infrared (FTIR), and fluorescence spectroscopy were performed for characterizing the synthesized nanoparticles. In the presence of glucose, the fluorescence intensity of the amino-functionalized LSNPs was enhanced due to the enhanced fluorescence resonance energy transfer. Based on fluorescence-enhancing effect, a simple and sensitive method for the determination of glucose was proposed. Under the optimized experimental conditions, the enhanced fluorescence intensity ratio ($\Delta F/F_0$) was linear with the concentration of glucose (c) in the range of 0.0–180 $\mu g\,ml^{-1}$ with a detection limit of 0.8 $\mu g\,ml^{-1}$ (S/N = 3). The R.S.D. values were 0.33% and 0.37% at the levels of 22.5 and 100 $\mu g\,ml^{-1}$, respectively. The proposed method was applied to the determination of glucose in synthetic samples with satisfactory results. The proposed method was also performed to the analysis of blood glucose in human serum samples and the results were in good agreement with clinical data provided by the hospital, which indicates that the method presented here is not only simple, sensitive, but also reliable and suitable for practical applications.

1. Introduction

In recent years, the development of glucose sensors has been received considerable attention, due to the demands of glucose controlling in various food processing, fermentation and biotechnological processes, as well as the continuous glucose self-monitoring for substantially reducing morbidity and mortality among diabetes patients [1–4]. To date, many different approaches to develop glucose sensors have been pursued including different electrochemical methods [1,5–9], Fourier-transform infrared spectroscopy [10], UV–vis spectroscopy [11], localized surface plasmon resonance [12,13], capillary enzyme bioreactor [14] as well as fluorometry [15–21]. Among these approaches, fluorescence-based systems are actively explored and receiving increasing attention encouraged by special advantages of fluoremetry for biological analysis [2,15–21]. For example, the technique is extremely sensitive; fluorescence measurements cause little or no damage to the host systems; measurements can be made by different parameters such as fluorescence intensity, fluorescence decay time, etc.; the structure and distribution of biomolecules can also be probed by the phenomenon of fluorescence (or Förster) resonance energy transfer (FRET).

Among these fluorescence-based glucose sensors, traditional organic fluorophores (*e.g.* organic dyes) are widely used as recognition elements. Recently, fluorescent quantum dots (QDs) have also attracted much attention [17–20]. Interests in fluorescent QDs derive from their broad adsorption, narrow emission, intense brightness, and good photostability relative to conventional organic dyes. However, they do have some drawbacks [22]. QDs are difficult to make; the surface-modification chemistry is still under investigation; the "blinking" behavior (luminescence emission switches "on" and "off" by sudden stochastic jumps under continuous excitation) is a limiting factor for in vivo applications. Compared with the above-mentioned fluorophores, fluorophore-doped silica nanoparticles (NPs) possess several distinguished properties [22–32]. Silica NPs are easy to separate via centrifugation during particles preparation, surface modification, and other solution treatment processes because of the high density of silica; silica NPs are more hydrophilic and biocompatible; silica NPs surface can be modified easily with many biomolecules for added biochemical functionality and extended application. Silica NPs also have intense brightness and anti-photobleaching.

doi:10.1016/j.talanta.2009.06.050

Generally, the dye-doped silica nanoparticles can be synthesized easily via the reverse microemulsion (water-in-oil microemulsion) system, which is a robust and efficient method for the preparation of monodisperse spherical nanoparticles in the nanometer range [23–32]. In our previous research work, we have developed dye-doped silica NPs for pH sensing [33,34] and aminated silica NPs for the determination of γ-globulin [35] and hydrogen peroxide [36]. In the present study, amino-functionalized luminescence silica nanoparticles (aminated LSNPs) doped with the fluorescent europium(III) mixed complex, $Eu(TTA)_3phen$ (TTA: 2-thenoyltrifluoroacetone, phen: 1,10-phenanthroline), in place of conventional fluorescent dyes, were synthesized successfully by using an revised Stöber method. The reason to choose rare earth complex rather than conventional dyes is based on its particular luminescence advantages [37,38]. Rare earth complexes exhibit strong, spiculate, and narrow spectrum; the fluorescence lifetime of rare earth complexes spans six magnitudes from nanosecond to millisecond; rare earth complexes present a multifluorescence characteristic due to special electronic structure of rare earth ions. The aminated LSNPs was demonstrated as an indicator for nonenzyme fluorescence determination of glucose in this paper.

2. Experimental

2.1. Apparatus

Fluorescence spectra were recorded on an F-4500 fluorescence spectrophotometer (Hitachi, Japan). Morphological and size measurement of the silica nanoparticles were performed by an S-4800 field emission scanning electron microscopy (SEM, Hitachi, Japan). The transmission electron microscopy (TEM) image of the LSNPs was acquired on an H-600 transmission electron microscope (Hitachi, Japan). Infrared spectra of the NPs was measured on a Fourier-transform infrared (FT-IR) 8400S spectrophotometer (Shimadzu, Japan). The desired pH buffer solutions were adjusted with a model pHS-3C pH meter (Zhejiang, China).

2.2. Reagents

Europium oxide (Eu_2O_3, purity ≥99.9%) was purchased from Shanghai No. 3 Chemical Reagent Co. (Shanghai, China). 1,10-Phenanthroline (Phen) and polyethylene glycol (PEG, with molecular weight of 2000 Da) were provided by Sinopharm Chemical Reagent Co. (Shanghai, China). 2-Thenoyltrifluoroacetone (TTA) was obtained from Sigma Co. (USA). Tetraethylorthosilicate (TEOS) and (3-aminopropyl)triethoxysilane (APTS) were purchased from Fluka (USA). Glucose was obtained from Shanghai Sangon Co. (shanghai, China). All other reagents were of analytical grade and used as received. Prior to use, 10 mg ml^{-1} of glucose stock solution was kept in fridge at 4 °C to equilibrium the isomers of glucose for 24 h. Triplex distilled water was used throughout the experiments.

Five serum samples were obtained by centrifuging (2000 rpm, 5 min) the fresh blood samples which were taken from three healthy adults and two diabetes patients (provided by Yijishan Hospital, Wuhu, China).

2.3. Analytical procedure for the determination of glucose

Ten milligrams of the as-prepared amino-functionalized LSNPs were dispersed in 10 ml of anhydrous ethanol and 1 mg ml^{-1} colloid solution was obtained. To a 2-ml test-tube, 100 μl of the LSNPs colloid solution and a known concentration of glucose were added, then diluted to the mark with phosphate buffer solution (PBS) and shaken thoroughly in order to mix well. After 20 min, the fluorescence intensity was measured at 618 nm with excitation at 350 nm in a 1-cm quartz cell. The difference of fluorescence intensity is represents as $\Delta F = F - F_0$. Here F_0 and F are the fluorescence intensity of the system without and with glucose, respectively.

For the measurement of human serum samples, 200 μl human serum was added to the test-tube instead of glucose standard solution, other procedures are same as above mentioned.

3. Results and discussion

3.1. Synthesis of the luminescent silica nanoparticles aminated LSNPs

$Eu(TTA)_3phen$ with quite strong red fluorescence were prepared by our previous reported procedure [38]. Briefly, in a 500 ml three-necked round-bottomed flask, 100 ml of water, 200 μl of 0.5 mol l^{-1} of $EuCl_3$ and 100 μl of polyethylene glycol were added into the flask, respectively. Under vigorous stirring, 10 ml of 0.03 mol l^{-1} of TTA aqueous solution was added, then 10 ml of 0.01 mol l^{-1} of 1,10-phenanthroline ethanol solution was added slowly. All the mentioned procedures were carried out in the nitrogen atmosphere. After that, the mixture was kept for 24 h without stirring. Then it was centrifuged and washed with water and ethanol several times to remove any uncoordinated molecules and the straw yellow powder of the metal-organic luminescent coordination compound, $Eu(TTA)_3phen$ was obtained after drying for about 8 h at 60 °C. The preparation of luminescent silica nanoparticles (LSNPs) doped by $Eu(TTA)_3phen$ was described as following: 10 mg of the $Eu(TTA)_3phen$ powder was dissolved in 1 ml of acetone. Then 0.5 ml of the acetone solution was added to a 100 ml mono-necked round-bottomed flask containing 30 ml of ethanol and 18 ml of water under vigorous stirring. Subsequently, 2 ml of ammonium hydroxide (NH_4OH) and 1 ml of TEOS were introduced into the reaction and kept stirring for 6 h. The LSNPs were obtained by centrifuging and washing with water and ethanol. The LSNPs were then dispersed into the mixed solution of anhydrous ethanol (8.0 ml) and triplex water (0.6 ml). Thereafter, 600 μl of NH_4OH and 200 μl of APTS were added and the mixture was stirred overnight. The amino-functionalized LSNPs (aminated-LSNPs) were obtained by centrifuging and washing with water and ethanol for at least three cycles. Ultrasonication was performed while washing the nanoparticles in order to remove any physically adsorbed moleculars from the surface of nanoparticles.

3.2. Characterization of the aminated LSNPs

Fig. 1a shows the scan electron microscopy (SEM) image of the as-prepared aminated-LSNPs. 10 μl of the NPs colloid solution was dropped on a small copper grid. The copper grid was adhered by conductive adhesive on a silicon tray after the colloid solution dried. SEM image was performed on an S-4800 field emission scanning electron microscopy operating at an accelerating voltage of 5 kV. The sample was observed without any metal coating. It can be clearly seen that the as-prepared NPs presented monodisperse nanospheres ($d = 75 \pm 15$ nm). Fig. 1b shows the transmission electron microscopy image of the aminated LSNPs. The sample was prepared similar to the SEM, one drop of the aminated LSNPs colloid solution was dropped on a small copper grid. The size and structure of the LSNPs were observed by using a Hitachi H-600 transmission electron microscope with a tungsten filament at an accelerating voltage of 100 kV. From the SEM and TEM images, we can see that the prepared aminated nanoparticles are monodispersed and uniform in size.

The Fourier-transform infrared (FTIR) spectrum of the aminated LSNPs was shown in Fig. 2. The wave number was set in the range from 400 to 4000 cm^{-1}. As shown in Fig. 2, the most

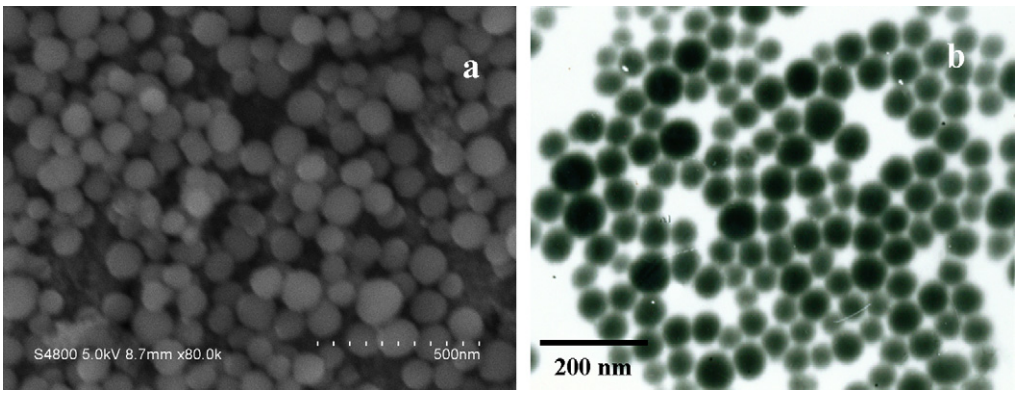

Fig. 1. (a) SEM image with magnitude ×80,000 of the LSNPs and (b) TEM image of the amino-functionalized LSNPs.

notable moiety is the absorption peak at 3448 cm^{-1}, which is assigned to amino groups attached to the surface of LSNPs [35]. This demonstrates that the LSNPs were successfully functionalized by amino groups on its surface. There is a superstrong absorption peak located at 1091 cm^{-1}, which is assigned to the asymmetric stretching vibrations of the Si–O–Si from the silica shells [29,39]. Meanwhile, the C=O group of the ligand TTA exhibits an asymmetry stretching vibration peak at 1637 cm^{-1}, which conforms the rare earth complex was doped in the silica matrix [38]. All of the results indicate that rare earth complexes are doped into the silica nanoparticles and the LSNPs are functionalized by amino groups successfully.

3.3. Fluorescence spectra of the aminated LSNPs in the presence of glucose

As shown in Fig. 3 (curve a), the as-prepared aminated LSNPs show a strong fluorescence peak located at 618 nm under the excitation at λ_{ex} = 350 nm. The red emission at 618 nm is attributed to the transition of $^5D_0 \rightarrow {}^7F_2$ of Eu^{3+} ion [38]. In the presence of different concentration of glucose, the location of fluorescence emission changed little, but the fluorescence intensities were increased with the increasing of glucose concentration as shown in Fig. 3(from curve b to curve j). Based on the enhancement effect of aminated LSNPs in the presence of glucose, a method for determining glucose was proposed.

As we know, in the preparation of europium ion–organic coordination compounds, coordinated water moleculars are often present in their structure as an additional ligand at the ninth coordination site due to the strong coordination ability between water moleculars and europium [38,40,41]. From the experimental findings, we assume the C=O groups from glucoses penetrate into the SiO_2 network and coordinate with europium instead of water molecular. Because water moleculars act as quenchers in the europium compound [41], the fluorescence intensity will be increased after the water molecular are replaced by glucose. Furthermore, the coordination of C=O groups with europium ion cause the structural arrangement of the europium complex, which is favorable to transfer energy from ligands to the europium, resulting in the enhanced energy transfer. In addition, the abundant amino groups on the surface of nanospheres are more favorable for glucose to approach the nanospheres.

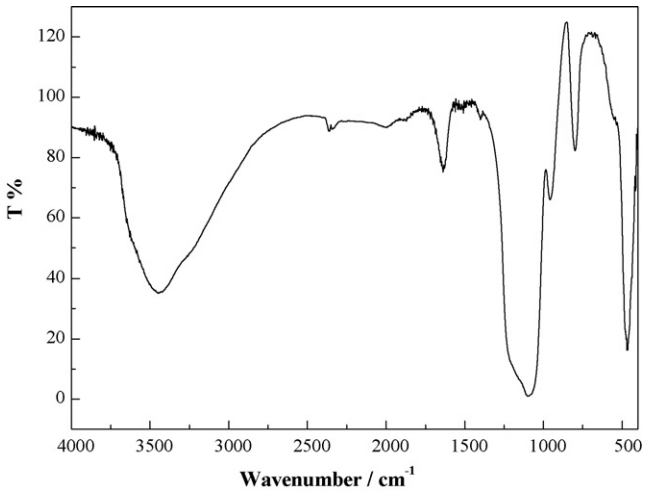

Fig. 2. FTIR spectrum of the amino-functionalized LSNPs.

3.4. Analytical application of aminated LSNPs in glucose sensor

3.4.1. Optimum of experimental conditions

In order to further enhance the performance of the analytical system for glucose sensor, the experimental conditions including pH and duration of the reaction between NPs and glucose were investigated.

The effect of pH on the fluorescence intensity of this system in presence or absence of 35 μg ml^{-1} of glucose was investigated from pH 4.5 to 8.5. The results showed that the maximum differ-

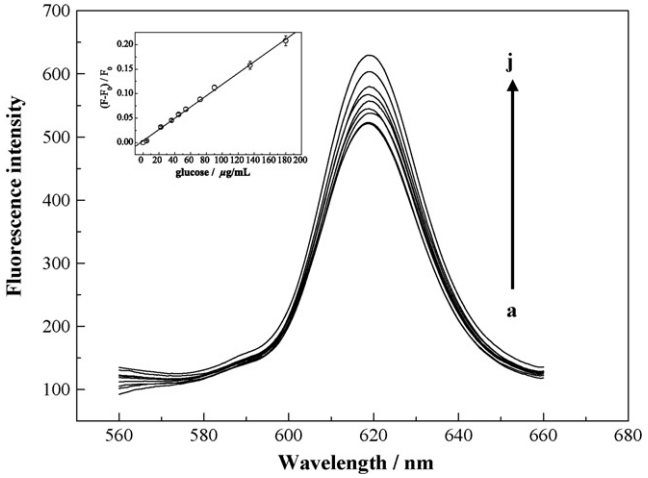

Fig. 3. The fluorescence emission spectra of the amino-functionalized LSNPs with variable concentrations of glucose from bottom to up: 0.0, 4.5, 22.5, 40, 50, 60, 80, 100, 140, 180 μg ml^{-1}, respectively. NPs: 50 μg ml^{-1}, 0.1 M phosphate buffer solution, pH 6.5. Inset: The linear plot of $\Delta F/F_0$ against glucose concentration in the range of 0.0–180 μg ml^{-1}.

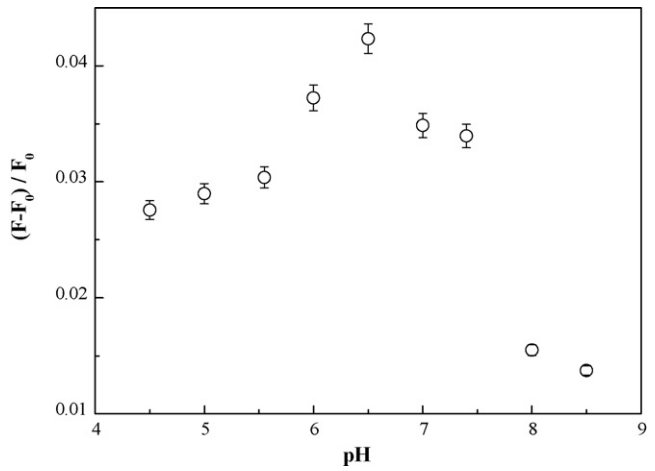

Fig. 4. Effect of pH on the fluorescence intensity in this system in the presence or absence 35 μg ml^{-1} glucose. NPs: 50 μg ml^{-1}, 0.1 M phosphate buffer solution, pH 6.5.

ence of the fluorescence intensity ($\Delta F/F_0$) was obtained at pH 6.5 (as shown in Fig. 4). In all experiments, a pH of 6.5 was, therefore, chosen to run the assay. Different buffers, such as Tris–HCl, Na_2HPO_4–NaH_2PO_4, Briton–Robison, were studied and the results showed a similar changing trend with slightly different effect on the fluorescence intensity. Finally, 0.1 M Na_2HPO_4–NaH_2PO_4 buffer with pH 6.5 was chosen.

The reaction time of the aminated LSNPs and glucose was also investigated. As shown in Fig. 5, in the presence of 100 μg ml^{-1} glucose, the maximum fluorescence intensity of the reaction system was obtained in 20 min and the fluorescence intensity showed little change in an hour at room temperature. In the subsequent studies, duration of 20 min was recommended for the determination of glucose.

3.4.2. Linearity, detection limit, and reproducibility

Under optimized experimental conditions, the changes in fluorescence spectra of aminated LSNPs in the presence of different concentrations of glucose in the range of 0.0–180 μg ml was monitored, as shown in Fig. 3. The plot of $\Delta F/F_0$ against glucose concentration showed linear relationship in the range of 0.0–180 μg ml (shown in inset of Fig. 3). The linear fit was described as $\Delta F/F_0 = 0.0035 + 0.0012c$ (c: μg ml) with a correlation coefficient r^2 of 0.998 ($n = 10$). The detection limit was calculated to be 0.8 μg ml from the statistical analysis (S/N = 3). The precision of the method was evaluated at two glucose concentrations (22.5, 100 μg ml), and the relative standard deviations, R.S.D. ($n = 7$ for each level) were 0.33% and 0.37%, respectively. These results demonstrate that the proposed method is sensitive and reproducible and may be applied to the determination of glucose in real samples.

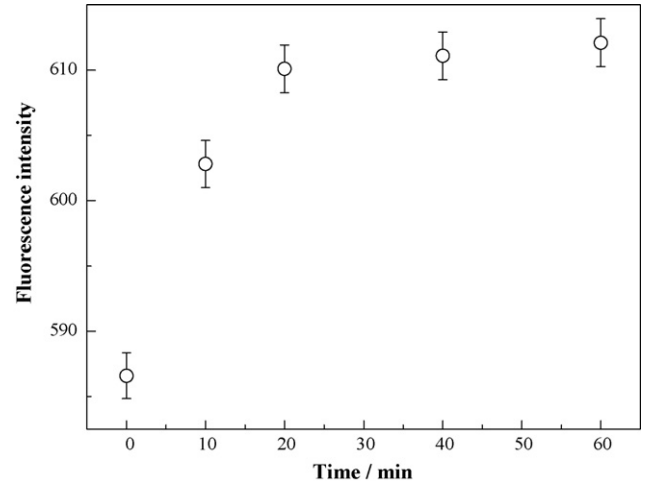

Fig. 5. The fluorescence intensity as a function of the time of reaction between the NPs and glucose in this system. NPs: 50 μg ml^{-1}, glucose: 100 μg ml^{-1}, 0.1 M phosphate buffer solution, pH 6.5.

[a] Glucose: 20 μg ml^{-1}; the amino-functionalized LSNPs: 50 μg ml^{-1}; buffer solution used: 0.1 mol l^{-1} PBS; pH 6.5.

3.4.3. Interference of co-existing foreign substances

To investigate the selectivity of the system for determining glucose, the influence of common foreign substances including sugars, common species present in biological systems was studied (see Table 1). A relative error of ±5% in the change of fluorescence intensity with and without co-existing substance is considered tolerable. It can be seen that the relative errors of the common interferences were within ±5% and exhibited little influence on the determination of glucose, so no special treatment was taken before using in real sample analysis. Among the electrochemical methods for the determination of glucose, ascorbic acid and uric acid present in biological fluids are the most important interferences due to their electrochemical oxidation on electrodes especially nonenzymatic sensors [42]. In this system, ascorbic acid and uric acid show little interference on the determination of glucose, which suggests that the proposed method is suitable for the direct determination of glucose in biological fluids.

3.5. Sample analysis

3.5.1. Determination of glucose in synthetic samples

The concentration of glucose in synthetic samples was determined with the proposed method. The synthetic samples were prepared by mixing some ions, organic substances, and biomolecules with a known concentration of glucose. The determination was performed by the procedure described above and the determination for each sample was reproduced five times. As shown in Table 2, the recovery for each determination is located in the range of 96–104%. The results show that the proposed method is reliable for the determination of glucose in synthetic samples and suitable for application.

Table 2
Results of the determination of glucose in synthetic samples.

Sample no.	Glucose added ($\mu g\,ml^{-1}$)	Co-existing substances ($\mu g\,ml^{-1}$)	Found average ($\mu g\,ml^{-1}$, $n=5$)	Recovery (%)	R.S.D. (%)
1	60	Fructose 100, Al^{3+} 200, L-cystein 100, Cl^- 300, ascorbic acid 50	61.6	99–104	2.9
2	140	Sucrose 300, K^+ 500, HAS 100, NO_3^- 500, DL-glutamine 250	138.5	96–103	3.8

Table 3
Analysis results of the direct determination of glucose in human serum samples.

Sample no.	Data provide by hospital (mM)	This method (mM) ($n=7$)	R.S.D (%)
1	4.78	4.90	−1.77
2	5.79	6.40	7.13
3	6.31	6.37	1.90
4	9.83	9.87	3.6
5	11.78	11.90	−1.77

3.5.2. Determination of glucose in real human serum samples

To further evaluate the applicability of the proposed glucose sensor in biological samples, a comparative study with clinically used glucose analyzer (Hitachi 7170, Japan) in measuring blood glucose of human serum samples was performed. Serum samples were obtained by centrifuging (2000 rpm, 5 min) the fresh blood samples which taken from three healthy adults and two diabetes patients (provided by Yijishan Hospital, Wuhu, China). The serum glucose concentration was determined with the above-mentioned procedures. The detected glucose content in serum samples was derived from the standard curve and the regression equation. The final concentration was converted into molar concentration in mM. The measurement results and the clinical data provided by hospital were summarized in Table 3. As shown in Table 3, the results obtained by proposed method show reasonable agreements with the data provided by the hospital. The results indicate that the proposed method has the potential for practical applications in the determination of blood glucose in real human serum.

4. Conclusions

In summary, amino-functionalized LSNPs doped with the europium complex $Eu(TTA)_3phen$ were synthesized successfully using an revised Stöber method. SEM, TEM, FTIR, and fluorescence were performed for characterization. Due to the enhanced effect of glucose on the fluorescence intensity of amino-functionalized LSNPs, a simple and sensitive fluorescence sensor for glucose was proposed. The results of sample analysis show that the reproducibility and the reliability of the proposed method are satisfactory, indicating that the proposed method has potential applications in the determination of glucose.

Preconcentration and speciation of mercury
Environmental matrices
Inductively coupled plasma mass spectrometry
High-performance liquid chromatography

ABSTRACT

This paper describes a preconcentration method for Hg^{2+} and $MeHg^{+}$ in water samples using sodium diethyldithiocarbamate immobilized in polyurethane foam (PU-NaDDC) and an extraction method for several mercury species in sediment samples, including $MeHg^{+}$, $EtHg^{+}$ and $PhHg^{+}$, which is simple, rapid, and uses a single organic solvent. Separation and measurement were done by high-performance liquid chromatography on-line with inductively coupled plasma mass spectrometry (HPLC/ICP-MS). Initially, the test of recovery was applied using procedures compatible with HPLC. Under the optimum extraction conditions, recoveries of 96.7, 96.3 and 97.3% were obtained for $MeHg^{+}$, $EtHg^{+}$, and $PhHg^{+}$, respectively, from $n = 4$ spiked sediment samples. This study also demonstrates that the combination of solid-phase extraction on PU-NaDDC with HPLC separation and ICP-MS detection is an effective preconcentration procedure for simultaneous measurement of Hg^{2+} and $MeHg^{+}$ at ultra-trace levels in water samples. The application of the proposed procedure to the determination of mercury species in drinking water sample was investigated. The proposed method clearly gave satisfactory average recoveries between 93.7 and 101.5%.

1. Introduction

Mercury traces are usually determined by cold vapor techniques using atomic spectroscopic detection. However, due to the toxicity differences of the different species of mercury, a speciation analysis is increasingly necessary. Mostly, hyphenated procedures based on systems coupling chromatography separation with atomic spectrometric detection have been proposed [1–3].

For instance gas chromatography (GC) using capillary columns as separation technique has been widely used. However, interferences due to the strong interaction between the polar mercury halides and the column material have been observed [4].

Liquid chromatography (LC) is also proposed for mercury speciation analysis. Among its advantages are the possibility of separating the native mercury species without prior derivatisation and operation at ambient temperature.

For water samples, with extremely low mercury concentrations a preliminary preconcentration step is required [5]. The solid-phase extraction allows the preconcentration from large sample volumes with high yield, as confirmed by some procedures used polyurethane foam with immobilized diethyldithiocarbamate (DDTC) [1,5].

In sediment samples the mercury species are strongly bound to the matrix and have to be released prior to their determination. In total elemental analysis microwave-assisted digestion is a well-accepted technique [6–8]. However, it has rarely been used for organomercury speciation analysis because under the usual conditions (high pressures and temperatures) the compounds are destroyed and all speciation information is lost [9–13].

A popular procedure for selective removal of the organic mercury species from sediment samples is liquid extraction using organic solvents. Most methods consist of an extraction into an organic solvent containing HCl, HBr or HI followed by the subsequent formation of a water-soluble adduct of the organic mercury species with cysteine or thiosulfate. This adduct is then back-extracted to water; the organic mercury species are then liberated by acidification and re-extracted to the organic solvent. However, these procedures are skilful and time consuming, impairing the sample throughput of the whole analytical procedure [14–18].

The aim of the present work was optimization of the quantitative preconcentration of Hg^{2+} and $MeHg^{+}$ in water samples by solid-phase extraction on sodium diethyldithiocarbamate immobilized in polyurethane foam (PU-NaDDC). The extraction of $MeHg^{+}$, $EtHg^{+}$ and $PhHg^{+}$ species from sediment samples was also investi-

gated aiming their posterior separation and determination on-line by HPLC–ICP-MS.

2. Materials and methods

2.1. Apparatus

The chromatographic system used was an HP 1050 model (Hewlett Packard, Waldbronn Germany) equipped with a UV detector (HP 1050 Series, model 79853C) and controlled by HP Chem Station Software (HPLC 2D, reference G2170AA). To perform the Hg speciation, a Nucleosil 100-5 C8 column (5 μm, 10 cm × 4 mm) was used. The mobile phase was composed by 0.06 mol L^{-1} ammonium acetate, 0.005% (v/v) 2-mercaptoethanol, and 3% (v/v) *n*-butanol. In all cases, an eluent flow of 1 mL min^{-1} was employed, and the analytical measurements were performed at 230 nm.

The detector consisted of a PerkinElmer Sciex (ELANTM 5000 ICP-MS spectrometer (Toronto, Canada) equipped with a PerkinElmer Ryton Scott-type spray chamber and cross-flow nebulizer. The optimized instrumental settings are shown in Table 1. The sample solutions were aspirated into the argon plasma via a peristaltic pump, and data were acquired using an IBM PS/2 Model 77 computer.

2.2. Reagents and materials

All reagents used were of the highest purity available and at least of analytical reagent grade. A solution of ammonium acetate (1 mol L^{-1} in *n*-butanol) was used in the sediment extraction procedure, and the ligand sodium diethyldithiocarbamate (NaDDTC) (Fluka, Switzerland) was used as sorbent in the preconcentration procedure.

An Hg^{2+} stock solution (1000 mg L^{-1}) was prepared by dissolving the appropriate amount of $HgCl_2$ (Merck, Darmstadt, Germany) in high purity water (18 MΩ^{-1} specific resistivity) obtained from a MillQ system (Millipore Saint-Quentin Yvelines, France). The $MeHg^+$, $EtHg^+$, and $PhHg^+$ 1000 mg L^{-1} stock solutions were prepared by dissolving their chlorides (Merck, Darmstadt, Germany) in the smallest possible volume of methanol and diluting to volume with nanopure water. High purity ammonium acetate (Scharlau, Spain), 2-mercaptoethanol (Fluka, Switzerland), *n*-butanol (Scharlau, Spain), and chloroform (Normasolv, Spain) were used. High purity argon (C-45 99.995% purity) was supplied by Carburos Metálicos (Barcelona, Spain).

For sieving the sediment samples, a nylon sieve with mesh screen of 0.063 mm (Cole-Parmer Canada Inc., Montreal, Canada) was used.

2.3. Preconcentration of mercury compounds from water samples

Preconcentration of mercury compounds in water samples was performed according to Sonja et al. [1]. Cubical foam pieces 5 mm long were cut from commercially available polyurethane foam. The cleaned and dried foam pieces were soaked in a chloroform solution NaDDTC and then squeezed occasionally until all the solution was retained in the PU cubes. The foam cubes were air dried until the evaporation of the organic solvent.

The NaDDTC-loaded PU foam pieces were transferred to a disposable tube packed with a small wad of cotton wool at its end covered with a filter paper disc. Water samples were passed through the column at a 2 mL min^{-1} flow rate, using a peristaltic pump. After this step the physically immobilized organic chelating ligand, NaDDTC and the analyte–dithiocarbamate complexes formed were completely eluted by *n*-butanol. The performance of the column was stable at least over 15 preconcentration cycles.

Table 1
ICP-MS operating parameters.

Plasma argon flow	9–11 (L min^{-1})
Auxiliary gas	1.4 (L min^{-1})
Nebulizer flow rate	0.8–0.9 (L min^{-1})
Sample flow	1.0 (mL min^{-1})
Forward power	1.10 kW
Sampling cone	Ni, 1.14 mm orifice
Skimmer cone	Ni, 0.89 mm orifice
Total analysis time	600 (s)

2.4. Sediment samples and spiking procedure

The use of certified reference materials (CRMs) is the only viable way to validate current procedures in speciation analysis. Unfortunately, there are only a few CRMs available for limited species and matrices, and those already available may have quite large uncertainties in the certified values [19].

The production of CRMs for organic mercury species has been essentially focused on methylmercury. Thus, there is no standardized method to assess the extraction efficiency of $MeHg^+$, $EtHg^+$, and $PhHg^+$ in sediment samples. However, a recent overview of the certification of total Hg and methylmercury in estuarine sediment recommended the use of standard additions as the best means to establish the efficiency of the method. This is achieved by spiking the material under investigation prior to extraction. However, this method does not guarantee that there is no loss or complete recovery of a given compound from the matrix. It is current practice to apply compensation for these losses by correcting the results with a recovery factor in order to achieve a better approximation to the true value in a material. These correction factors are established after undertaking recovery studies, which are an essential component of the validation of extraction-based techniques [20,21].

The sediment material was collected in Gavião River and Anajé Reservoir, located in the southwest area of the state of Bahia, Brazil. This material was used to prepare the sediment samples to be used in optimization studies. The samples were collected in polyethylene bags and stored at 0 °C. Before the analysis, the sediment samples were dried at 60 °C until a constant mass was reached, as recommended by the EPA [22]. After that, the sediment samples were then ground and sieved through a nylon sieve. The fraction less than 63 μm was spiked with methylmercury, ethylmercury, and phenylmercury according to Vazquez et al. [23]. An amount of 10 g of sediment was mixed with 2 mL of methanol containing a known concentration of $MeHg^+$, $EtHg^+$, and $PhHg^+$, which was slowly added to form a dough that was mechanically stirred for several minutes. The sample was then stored in the dark and allowed to air dry for 1 day. Assuming no losses had taken place during drying or storage, the theoretical concentrations of mercury species were (260.0, 135.7, and 125.2 ng g^{-1} for $MeHg^+$, EtHg, and $PhHg^+$, respectively) on a dry weight basis.

2.5. Extraction of mercury compounds from sediment samples

Spiked samples and sediment samples collected in Gavião River and Anajé Reservoir, located in the southwest area of the state of Bahia, Brazil were extracted as follows: a 1.0 g weight portion was removed from sediment samples that was placed in an extraction container with 10 mL of *n*-butanol containing ammonium acetate (1 mol L^{-1}), and this samples were mechanically stirred for 2 h. After extraction, the sample was filtered through a 0.45 mm filter; the volume was adjusted to 10 mL with *n*-butanol, and it was stored until use at 4 °C.

In order to check the absence of organomercurial in the extraction solution, the sediment samples (P1, P4 and, P9) were selected, because $MeHg^+$, $EtHg^+$ and $PhHg^+$ were not detected in measur-

able quantities in those samples, as shown in Table 5. Each one of the sediment samples was extracted three times with 10 mL of *n*-butanol containing ammonium acetate (1 mol L^{-1}), followed by HPLC/ICP-MS analysis. The chromatogram obtained for those samples was very clean; no interference compounds were present in the extract.

3. Results and discussion

3.1. Performance of the sorbent extraction preconcentration of Hg^{2+} and $MeHg^{+}$ in water samples

In previous work we developed a preconcentration system for the extraction of Hg^{2+} and $MeHg^{+}$ present in water samples. The influence of the pH on the retention of Hg^{2+} and CH_3Hg^{+} on PU-DDTC was studied at different pH varies between 1.0 and 10.0 for the single mercury species solutions. The effect of pH on chelate sorption was different in each case; thus, sorption was maximal at pH 1–7 for Hg^{2+} and 4–7 for CH_3Hg^{+}.

The influence of the flow rate of the samples loaded onto the columns on the retention efficiency of $MeHg^{+}$ and Hg^{+} was investigated in the range of 0.5–3.0 mL min^{-1} using the solutions containing the mercury species at a concentration of 20 ng mL^{-1}. It was established that at a flow rate higher than 2.0 mL min^{-1}, the mercury species uptake lessened successively owing to lower residence time of the sample solution in the column. For that reason, the flow rate of 2.0 mL min^{-1} was considered appropriate for further column operation.

The preconcentration of larger sample volumes at a defined sample flow rate usually results in the enhancement of the enrichment factor expressed as ratio of the volume of the sample loaded onto the column to the volume of an eluent used for the recovery of the analytes retained. For that reason, the influence of sample volume was examined for 200, 300 and 500 mL solutions containing 1.0, 1.5 and 2.5 mg each of the analysed mercury species, respectively. After passage of the test solutions through the columns, the mercury species were recovered using 5 mL of pure *n*-butanol. The resulting 5 mL aliquots of the eluate were measured to determine the concentrations of Hg^{2+} and $MeHg^{+}$ and evaluate the efficiency of the elution procedure.

In order to check the performance of the sorbent extraction preconcentration followed by HPLC–ICP-MS for determination, ten samples of ultrapure water containing Hg^{2+} and $MeHg^{+}$ were passed through the columns. The results showed a good recovery of the two organic species: $92 \pm 2\%$ for Hg^{2+} and $102 \pm 1\%$ for $MeHg^{+}$. Quantitative solid-phase preconcentration of Hg^{2+} and $MeHg^{+}$ on PU-MDC sorbent, was achieved with water samples of up to 500 mL. Hence, considering an elution volume of 5 mL (*n*-butanol) an enrichment factor of 100 was obtained.

3.2. Performance of the solvent extraction of mercury species in sediment samples

The key step of speciation in environmental samples is to extract the target compounds in their original forms without any disturbance. Typically, alkyl mercury species are determined by acid digestion with solvent extraction, followed by several cleanup steps, and then back-extracted into an aqueous phase. However, previous studies have shown that the organomercurials are not stable under very acidic conditions. In this study, three organic solvents (chloroform, methanol, and *n*-butanol) containing ammonium acetate (1 mol L^{-1}) were tested to extract $MeHg^{+}$, $EtHg^{+}$, and $PhHg^{+}$ from spiked sediment samples. The *n*-butanol presented a better recovery of the three organic species. Under the optimum extraction conditions, recoveries of 96.7, 96.3, and 97.3% were obtained for $MeHg^{+}$, $EtHg^{+}$, and $PhHg^{+}$, respectively, from $n = 4$ spiked sediment samples as shown in Table 2.

Table 2
Extraction recoveries in percent of organomercury compounds in four spiked sediment samples.

Ammonium acetate (1 mol L^{-1}) in	$MeHg^{+}$	$EtHg^{+}$	$PhHg^{+}$
Chloroform	89.5 ± 2.1	81.3 ± 2.8	80.5 ± 3.1
Methanol	90.5 ± 2.3	83.2 ± 3.7	77.8 ± 3.8
n-Butanol	96.7 ± 5.7	96.3 ± 7.6	97.3 ± 2.9

3.3. Chromatographic separation of mercury species

Fig. 1a shows the chromatographic separation of a 50 μg L^{-1} mixed standard solution of Hg^{2+}, $MeHg^{+}$, $EtHg^{+}$, and $PhHg^{+}$ by HPLC/ICP-MS detection. The elution sequence is the same as that observed by Dos Santos et al. [24]. The optimized isocratic eluent consists of 3% (v/v) *n*-buthanol and 0.005% (v/v) 2-mercaptoethanol with 0.06 mol L^{-1} ammonium acetate. The eluent flow for the separation was adjusted to 1 mL min^{-1}. During a measuring time of 10.0 min all four peaks appeared well resolved without any other peaks arising from the solvent front or complexing agent. The baseline was stable, and the noise and the drift of the baseline did not increase with increasing concentration of the mobile phase. All the Hg^{2+}, $EtHg^{+}$, $MeHg^{+}$, and $PhHg^{+}$ signals were optimized by varying the carrier gas flow rate and the rf power of the ICP-MS. A mixed standard was injected and the settings for the rf power and carrier gas flow rates on the ICP-MS varied accordingly. The optimum settings were 1100 W and 1.4 L min^{-1}, respectively.

Fig. 1b shows the chromatographic separation of two different mercury species: methylmercury and inorganic mercury with ICP-MS detection. 20 ng mL^{-1} mixed standard solution of inorganic and methylmercury was preconcentrated after complexation by NaDDTC for optimization of the chromatographic conditions. The two species were fully resolved and completely separated in a time of 4 min.

Fig. 1c shows the chromatogram of a sediment sample extracted with *n*-butanol and analysed by HPLC–ICP-MS. In the aforementioned conditions, $MeHg^{+}$, $EtHg^{+}$ and $PhHg^{+}$ were fully resolved and completely separated in a time of 10 min.

3.4. Analytical figures of merit

The analytical performances (accuracy and precision) for the preconcentration procedure of Hg^{2+} and $MeHg^{+}$ in water samples have been checked by added found method. Ultrapure water and mineral water samples were spiked with Hg^{2+} and CH_3Hg^{+} at different ratios and analysed as described. Results obtained are presented in Table 4. The calibration graphs obtained using these conditions were linear with correlation coefficients (r) of 0.9995 and 0.9996 for Hg^{2+} and CH_3Hg^{+}, respectively. The detection limit (LODs), defined as three times the standard deviation of the blank signal ($n = 12$) divided by the slope of each calibration graph, ranged from 4.6 ng L^{-1} for inorganic mercury to 5.2 ng L^{-1} for methylmercury.

The analytical performances for the extraction procedure of $MeHg^{+}$, $EtHg^{+}$ and $PhHg^{+}$ in sediment samples are summarized in Table 3. Precision was evaluated in terms of repeatability (inter-day) and reproducibility (intra-day), and it was determined using the relative standard deviations (RSDs) for five successive injections of spiked extract at 20 μg L^{-1} for each one of the Hg species. Calibration curves for the three mercury compounds were examined under the best experimental conditions between 1.0 and 40.0 μg L^{-1} concentration of each compound. In each case, the peak height was used for quantification. Linear regression curves of the individual

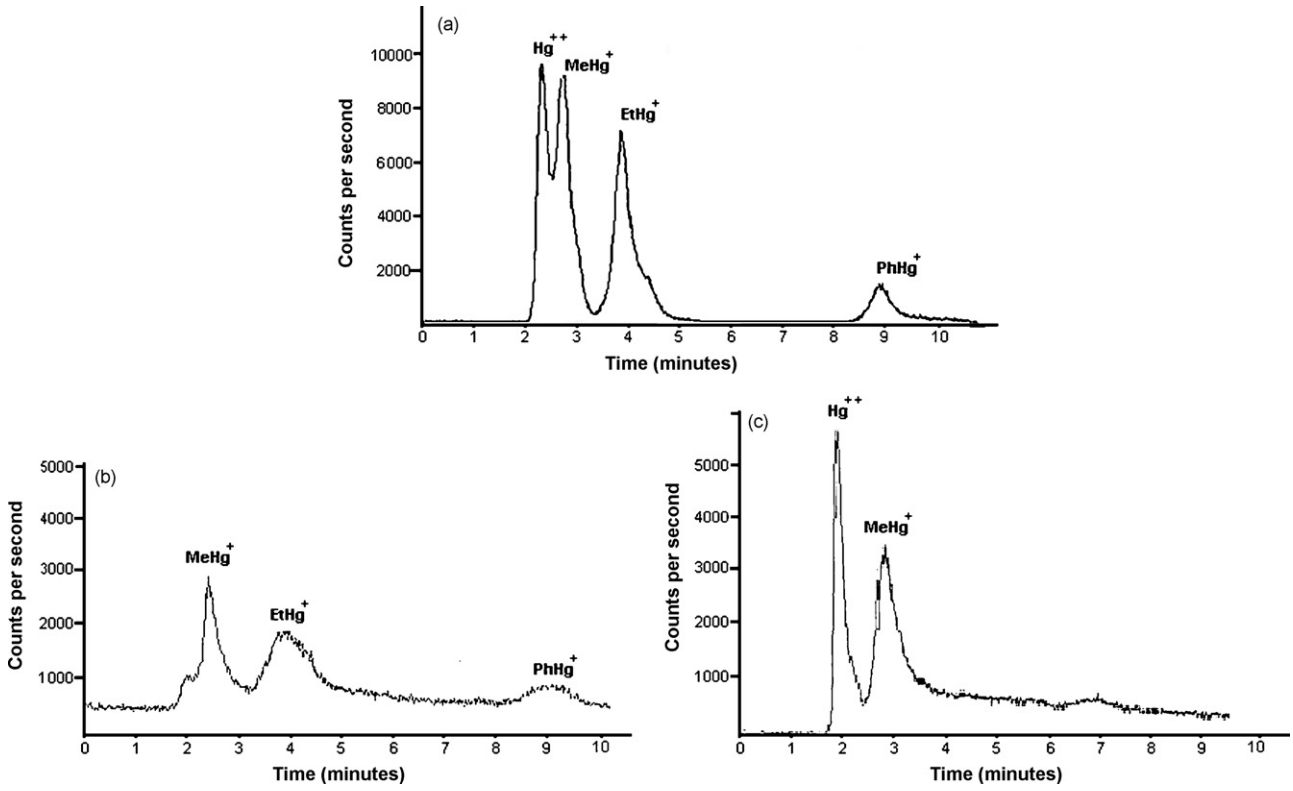

Fig. 1. (a) Chromatogram showing the separation of 50 μg L^{-1} Hg^{2+}, $MeHg^+$, $EtHg^+$ and $PhHg^+$ standards using HPLC/ICP-MS detection. (b) Chromatogram of a sediment sample extracted with *n*-buthanol and analysed by HPLC–ICP-MS. (c) Chromatographic separation of 20 μg L^{-1} Hg^{2+}, $MeHg^+$, ICP-MS detection after preconcentration with NaDDTC immobilized on polyurethane foam. The mobile phase consisting of 3% (v/v) *n*-buthanol and 0.005% (v/v) 2-mercaptoethanol with 0.06 mol L^{-1} ammonium acetate, using the Nucleosil (100 mm × 4 mm) C8 column. (+) Solvent and system peaks.

Table 3
Figure of merit of the extraction procedure method.

Species	LOD (μg L^{-1})	Repeatability (%RSD)	Reproducibility (%RSD)	Correlation
Coefficient				
$MeHg^+$	0.5	2.8	3.0	0.9996
$EtHg^+$	0.8	1.8	2.5	0.9999
$PhHg^+$	1.0	3.0	3.0	0.9994

Table 4
Results for the determination of Hg^{2+} and $MeHg^+$ in drinking water (real sample), ($n = 3$).

Sample	Found ± σ (ng L^{-1})	Added ng L^{-1}	Total found ± σ (ng L^{-1})	Recovery ± σ (%)
Hg^{2+}	30.7 ± 0.6	50	75.6 ± 0.4	93.7 ± 0.3
$MeHg^+$	10.8 ± 0.7	50	61.7 ± 0.5	101.5 ± 0.2

compounds gave correlation coefficients of at least 0.9994. Limits of detection (LODs) were calculated as three times the standard deviation of 12 blank extractions divided by the slope of each calibration graph.

3.5. Analysis of water and sediment samples

The preconcentration procedure was applied to determination of Hg^{2+} and $MeHg^+$ in mineral water samples. The results are summarized in Table 4. The proposed method clearly gave satisfactory average recoveries between 93.7 and 101.5%.

The extraction and determination of $MeHg^+$, $EtHg^+$, and $PhHg^+$ in sediment by HPLC coupled on-line with ICP-MS were applied in river sediment samples. Sediment samples were collected along the Gavião River and Anajé Reservoir (Bahia, Brazil) located in a semi-arid zone (Fig. 2). Table 5 shows the results obtained. Concentration levels of mercury species of a few ng g^{-1} were found for all sam-

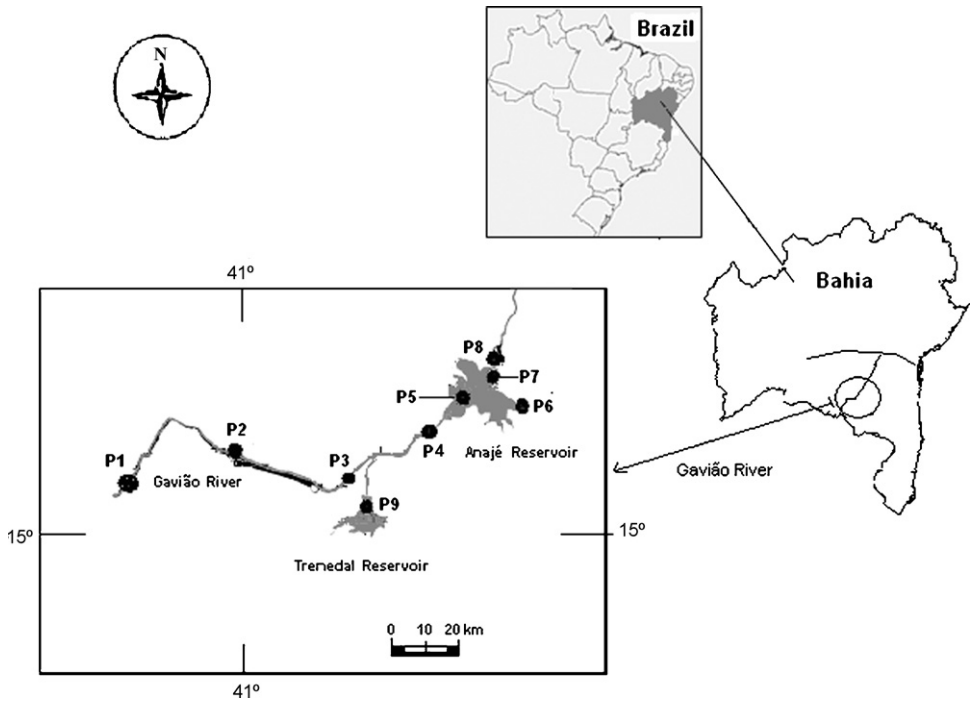

Fig. 2. Map showing the network of sampling sites on Gavião River and Anagé Reservoir.

ples collected along Gavião (P1, P2, P3 and P4). Thus, it is likely that the small variation of mercury species concentrations in the study site is of natural origin. The highest levels of mercury species were detected in sediment samples collected in the Anagé Reservoir (P5, P6, P7 and P8). This can be indicative of pesticides used in crop soil around of the reservoir. Although $EtHg^+$ and $PhHg^+$ are not usually detected in measurable quantities in environmental samples, the concentrations of these two mercury species detected in some sediment samples were consistent with results previously reported in the literature [17,25–27].

4. Conclusions

This study demonstrates that the combination of solid-phase extraction on PU-NaDDC with HPLC separation and ICP-MS detection is an effective preconcentration procedure for simultaneous measurement of Hg^{2+} and $MeHg^+$ at ultra-trace levels in water samples. The application of the proposed procedure to the determination of mercury species in drinking water sample was investigated. The proposed method clearly gave satisfactory average recoveries between 93.7 and 101.5%.

The extraction of mercury species from sediment samples was also investigated. Applying a single organic solvent is a procedure suitable for the simultaneous extraction and determination of methylmercury, ethylmercury, and phenylmercury in sediment by HPLC coupled on-line with ICP-MS. The major advantages in comparison to the extraction procedures currently preferred for mercury speciation are the reduction of the number of sample preparation steps along with a concomitant reduction in the inherent risk of contamination. The reliability of the method was checked by recovery experiments. Recovery values obtained (Table 3) lie in the range of 96.3–97.3%, which demonstrates the applicability of the method to determine alkyl mercury species in sediment samples without any pretreatment.

Determination of uranium and thorium
Mesoporous silica (MCM-41)
Solid phase extraction (SPE)
Inductively coupled plasma optical emission spectrometry (ICP OES)

ABSTRACT

A new synthesized modified mesoporous silica (MCM-41) using 5-nitro-2-furaldehyde (fural) was applied as an effective sorbent for the solid phase extraction of uranium(VI) and thorium(IV) ions from aqueous solution for the measurement by inductively coupled plasma optical emission spectrometry (ICP OES). The influences of some analytical parameters on the quantitative recoveries of the analyte ions were investigated in batch method. Under optimal conditions, the analyte ions were sorbed by the sorbent at pH 5.5 and then eluted with 1.0 mL of 1.0 mol L^{-1} HNO_3. The preconcentration factor was 100 for a 100 mL sample volume. The limits of detection (LOD) obtained for uranium(VI) and thorium(IV) were 0.3 μg L^{-1}. The maximum sorption capacity of the modified MCM-41 was found to be 47 and 49 mg g^{-1} for uranium(VI) and thorium(IV), respectively. The sorbent exhibited good stability, reusability, high adsorption capacity and fast rate of equilibrium for sorption/desorption of uranium and thorium ions. The applicability of the synthesized sorbent was examined using CRM and real water samples.

1. Introduction

Uranium and thorium are important elements not only in industrial application but also in energy and environmental problems. In view of the extensive usage of uranium and thorium for various industrial purposes and their toxicity, precise determination of these elements in environmental and biological samples is a challenging task [1–3]. Both of the metal ions are known to cause acute toxicological effects in human and their compounds are potential occupational carcinogens [4]. The WHO, Health Canada and Australian drinking water guidelines fixed the maximum uranium concentration in drinking waters to be less than 9, 20 and 20 μg L^{-1}. Uranium is present in seawater, in concentration of approximately 3 μg L^{-1} [1,5].

The low concentration of these ions in the presence of relatively high concentration of divorce ions makes it difficult to determine directly uranium and thorium ions. So, a separation and preconcentration is mandatory prior to their determination by highly versatile techniques such as inductively coupled plasma optical emission spectrometry (ICP OES).

Many separation and preconcentration techniques for metal ions have been developed such as liquid–liquid extraction [6,7] and solid phase extraction (SPE) [8–18]. Among these methods, SPE was used widely in separation and preconcentration systems. Compared with traditional technologies, SPE offers several advantages such as faster, higher enrichment factor, inexpensive and less polluting to the environment [19,20]. In SPE technique, it is important to select a suitable adsorption material, which can not only enrich the analytes, but also eliminate the matrix interference effectively. Several solid phase sorbents such as organic chelating resin [21–25], modified activated carbon [26], modified silica gel [27,28] and polyurethane foam [29–31] have been employed for the separation and preconcentration of uranium(VI) and thorium(IV).

The rapid development of mesoporous materials such as MCM-41 has attracted much attention in various scientific areas including physics, chemistry and material science. The advantages of large surface area, well-defined pore size, excellent mechanical resistance, non-swelling, excellent chemical stability and easy to modify, make the ordered mesoporous materials an ideal supporting material in SPE. They are synthesized with surfactant used as template.

Th wavelength (nm)	339.203

The structure of the wall of the pores consists of a disordered network of siloxane bridges and free silanol groups that could act as reacting site against appropriate organic chemical species. This fact allows MCM-41 material can be functionalized with different organic groups. By functionalizing the surface of mesoporous materials, selectivity of these sorbents for metal ions can be improved. Modified mesoporous materials have been successfully used for the preconcentration and separation of trace metals recently [32–40].

In this work, mesoporous silica, MCM-41 was chemically modified by (3-aminopropyl) triethoxysilane groups and fural as a new solid phase extractant. Solid phase extraction in batch mode using this new synthesized sorbent was applied for simultaneous preconcentration and determination of uranium and thorium by ICP OES in water samples.

2. Experimental

2.1. Instrumentation

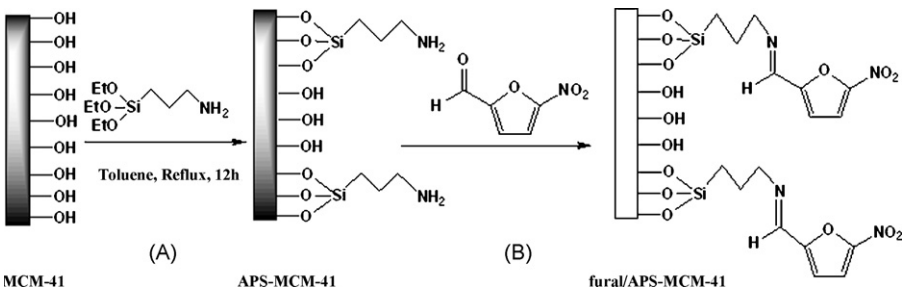
A simultaneous inductively coupled plasma optical emission spectrometry (ICP OES, Varian Vista-MPX, Australia) equipped with a charge-coupled device detector (CCD), a peristaltic pump and a cyclonic spray chamber with a concentric nebulizer was used for simultaneous determination of the target elements. The argon gas with 99.999% purity for ICP OES was purchased from Roham Gas Company (Tehran, Iran). The operation conditions and analytical wavelength were summarized in Table 1. A Metrohm digital pH-meter (model 692, Herisau, Switzerland), equipped with a glass-combination electrode was used. Separation of sorbent was assisted using a centrifuge equipped with a swing out rotor (Universal 320R).

2.2. Reagents and solutions

All chemicals used in this work were of analytical grade of Merck (Darmstadt, Germany) or Aldrich (Chemical Co., Milwauke, WI, USA). All aqueous solutions were prepared in double-distilled deionized water. All organic solvents (HPLC grade) were purchased from Aldrich. Stock standard solutions (1000 mg L^{-1}) of uranium(VI) and thorium(IV) were prepared by dissolving the appropriate amounts of uranyl nitrate hexahydrate and thorium nitrate tetrahydrate, respectively, in deionized water containing 1% HNO_3. The pH adjustment was made with nitric acid (for acidic pH values) or sodium hydroxide (for basic pH values) or standard acetic acid/acetate buffer solution (pH 5.5). The glassware used were kept in 10% nitric acid overnight and subsequently washed several times with double-distilled deionized water before using.

2.3. Preparation of MCM-41 and (3-aminopropyl) triethoxysilane modified MCM-41 (APS-MCM-41)

Mesoporous molecular sieve MCM-41 was prepared according to reported method [41]. Modification of the prepared MCM-41 was performed as followed (Scheme 1A): MCM-41 (2 g) was suspended in dry toluene (70 mL) and then 1 g of (3-aminopropyl) triethoxysilane (APS) was added under dry nitrogen atmosphere and the mixture was refluxed for 12 h. The solid was filtered, washed with dichloromethane and ethanol and dried. It was then soxhlet extracted with a mixture of ethanol and dichloromethane (1:1) to remove the silylating reagent residue and was vacuum dried at 343 K. Characterization of APS-MCM-41 was performed using FT-IR spectroscopy and X-ray diffraction.



2.4. Preparation of fural/APS-MCM-41

For preparation of 5-nitro-2-furaldehyde (fural) modified MCM-41 (Scheme 1B), APS-MCM-41 (2 g) was suspended in 100 mL of methanol and to this mixture was added excess of 5-nitro-2-furaldehyde (1.35 g, 9.58 mmol) and refluxed for 8 h. The yellow solid was filtered, dried and then soxhlet extracted with ethanol and dried under vacuum at 343 K (Scheme 1). FT-IR spectrum shows that the Schiff-base group was covalently grafted to the silica successfully (characteristic C=N stretching at 1650 cm^{-1}) after the co-condensation process.

The molecular formula of the complexes has been assigned on the basis of the results of their elemental analyses. A preliminary identification of the metal complexes was made on the basis of their IR spectra, which exhibited no bands characteristic of free primary amine, thus supporting the proposed ligand skeleton. The C, H, N analysis results (Found—C: 9.34; H: 0.96; N: 2.79; C/N: 3.35%) showed close similarity to the theoretical values (Anal—C: 53.04; H: 5.01; N: 15.46%). The molecular formula of the ligand has been assigned on the basis of the results of their elemental analyses. A preliminary identification of the ligand was made on the basis of their IR spectra, which exhibited no bands characteristic of free primary amine, thus supporting the proposed skeleton.

2.5. Procedure

Batch method was performed for the extraction and preconcentration of uranium and thorium ions. The general procedure for the extraction of these ions by modified MCM-41 was as follows: an aliquot of 10 mL buffered sample solution (pH 5.5) containing ura-

Scheme 1. (A) Preparation of APS-MCM-41. (B) Preparation of fural/APS-MCM-41.

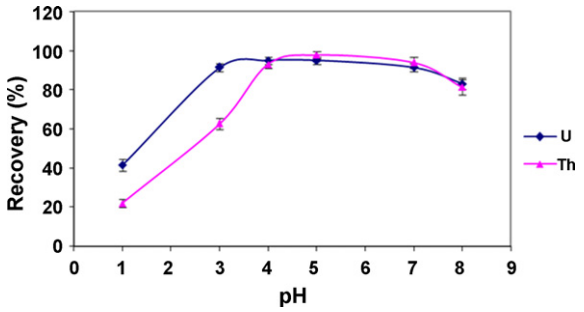


Fig. 1. Effect of pH on the recovery of U(VI) and Th(IV). Amount of metal ions: 1.0 μg, sample volume: 10 mL, amount of sorbent: 20.0 mg, eluent (HNO_3) concentration: 1.0 mol L^{-1}, eluent volume: 1.0 mL.

nium and thorium and 20.0 mg of modified MCM-41 was added to a test tube. The mixture was shaken manually for about 1 min. After that, test tubes were placed in centrifuge and separation of sorbent was achieved by centrifugation for 2 min at 3000 rpm. The aqueous phase was easily decanted by simply inverting the tube. Desorption of target ions was performed by adding 1.0 mL of 1.0 mol L^{-1} HNO_3 solution to sorbent. After shaking manually, the sorbent was separated by centrifugation (2 min at 3000 rpm) and the concentration of uranium and thorium in acidic aqueous phase was determined by ICP OES.

3. Results and discussion

The solid phase extraction of 1.0 μg of uranium and thorium presented in 10 mL of aqueous solution with the modified MCM-41 and non-modified MCM-41 was investigated. The results showed that the modified MCM-41 gave quantitative enrichment while non-modified alone gave a recovery of ~6% and ~9% of uranium and thorium, respectively.

The extraction recovery was defined as the percentage of the total amount of analyte (m), which was extracted into the eluent (acidic aqueous phase):

$$R\% = \left(\frac{m_e}{m_s}\right) \times 100 = \left(\frac{C_e V_e}{C_s V_s}\right) \times 100$$

where V_e, V_s, C_e and C_s are the volume of eluent, volume of sample solution, initial concentration of analyte in aqueous sample and concentration of analyte in eluent, respectively.

3.1. Effect of pH

In order to evaluate the effect of pH on the recovery, the pH was investigated in the range of 1–8 by adding nitric acid or sodium hydroxide solutions. The results of the effects of pH on the recoveries of studied ions were shown in Fig. 1. As can be seen, the pH of maximum recovery for uranium and thorium were found to be 4.0–7.0 and 5.0–7.0, respectively. So, pH 5.5 was chosen as the optimum value for extraction. In all subsequent studies, the pH was adjusted to 5.5 (±0.2) by the addition of acetic acid–acetate buffer solution.

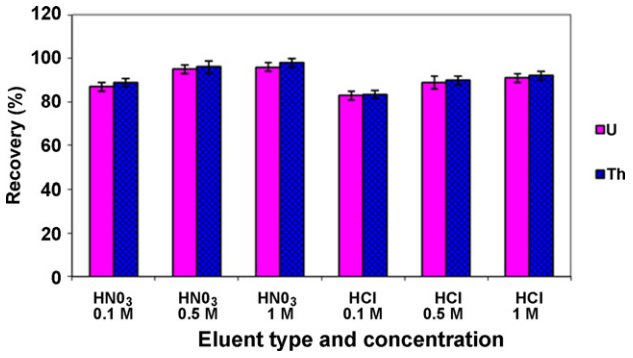

Fig. 2. Effect of eluent type and concentration on the recovery of U(VI) and Th(IV). Amount of metal ions: 1.0 μg, sample volume: 10 mL, pH: 5.5, amount of sorbent: 20.0 mg.

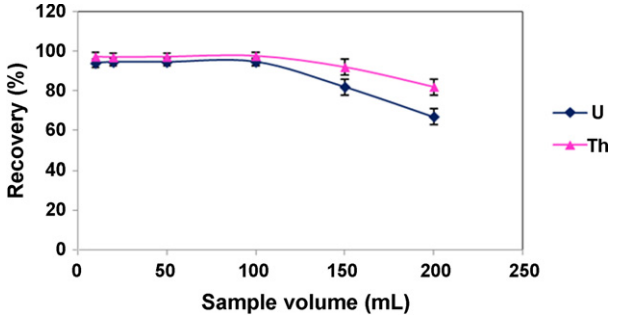

Fig. 3. Effect of sample volume on the recovery of U(VI) and Th(IV). Amount of metal ions: 1.0 μg, pH: 5.5, amount of sorbent: 20.0 mg, eluent (HNO_3) concentration: 1.0 mol L^{-1}, eluent volume: 1.0 mL.

3.2. Choice of eluent: type, concentration and volume

In order to choose a proper eluent, the metal ions were desorbed with different concentrations of nitric acid and hydrochloride acid. The results were shown in Fig. 2. As can be seen, quantitative elution was possible with nitric acid at a concentration of 1.0 mol L^{-1}. So, nitric acid at a concentration of 1.0 mol L^{-1} was selected as eluent for the subsequent experiments.

By using 1.0 mol L^{-1} HNO_3 as eluent, the effect of eluent volume was studied with 1.0–3.0 mL of eluent. The results showed that the recoveries were not influenced noticeably by increasing the eluent volume. So, for obtaining higher preconcentration factor, 1.0 mL of nitric acid (1.0 mol L^{-1}) was selected for the subsequent experiments.

3.3. Effect of sample volume

In order to investigate the effect of sample volume on the sorption of uranium and thorium ions, aliquots of 10, 20, 50, 100, 150 and 200 mL of sample solution containing 1.0 μg of these ions and 20.0 mg of modified MCM-41 were used and the general procedure was applied. It was found that the quantitative recovery of uranium and thorium ions was obtained for sample volume up to 100 mL (Fig. 3).

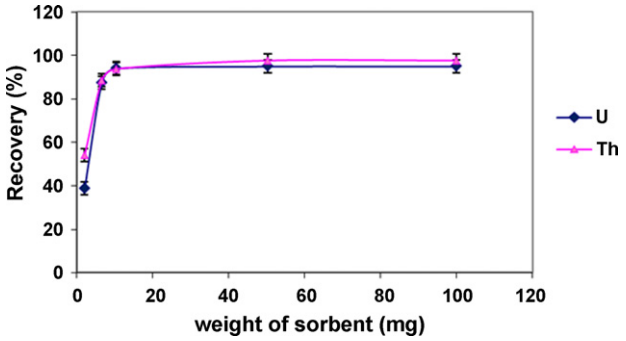

Fig. 4. Effect of sorbent amount on the recovery of U(VI) and Th(IV). Amount of metal ions: 1.0 μg, sample volume: 10 mL, pH: 5.5, eluent (HNO_3) concentration: 1.0 mol L^{-1}, eluent volume: 1.0 mL.

[a] Limit of detection. Calculated as three times the S.D. of the blank signal to slope of calibration curve ratio.
[b] Using sample volume of 100 mL.
[c] Ions concentration: 10 $\mu g\,L^{-1}$.

3.4. Effect of amount of modified MCM-41

The effect of amount of modified MCM-41 on the recovery of uranium(VI) and thorium(IV) ions was examined by varying the amounts of the modified MCM-41 in the range of 2.0–100.0 mg. The results were shown in Fig. 4. As can be seen, the extraction of these ions was quantitative by using 10.0 mg of modified MCM-41. Subsequent extraction experiments were carried out with 20.0 mg of modified MCM-41 in order to achieve high capacity and account for other extractable species.

3.5. Adsorption capacity

For investigation of adsorption capacity of sorbent, aliquots of 10 mL of sample solution with different concentrations of uranium(VI) and thorium(IV) ions were contacted with 20.0 mg of sorbent. The adsorption capacity (a_E, mg g^{-1}) was calculated as

$$a_E = (C_0 - C_E)Vm^{-1}$$

where C_0 and C_E are the initial and equilibrium concentrations (mg L^{-1}) of analyte ions in the solution, respectively. The equilibrium concentration (the remaining uranium(VI) and thorium(IV) in the solution) was determined directly by ICP OES. m is the weight of the sorbent in g and V is the volume of the aqueous solution in L. The mg of uranium(VI) and thorium(IV) sorbed per gram of sorbent, a_E, versus equilibrium concentration as adsorption isotherm is shown in Fig. 5. According to these results, the maximum amount of uranium and thorium ions that can be sorbed by modified MCM-41 was found to be 47 and 49 mg g^{-1}, respectively.

Table 4
Uranium(VI) and thorium(IV) levels of Montana I Soil CRM (NIST-SRM 2710).

	Certified value ($\mu g\,g^{-1}$)	Measured value ($\mu g\,g^{-1}$)[a,b]
U(VI)	25	25.3 ± 2.9
Th(IV)	13	12.6 ± 2.5

[a] Mean of three replicate experiments.
[b] The standard deviation values were calculated at 95% of confidence level.

3.6. Effect of equilibrium time

In order to investigate the effect of shaking time on the extraction recovery, extraction experiments for series of solution containing 1.0 μg U(VI) and Th(IV) were carried out. The results showed that the shaking time from 30 s to 3 min has no effect on the extraction recovery of uranium and thorium. In subsequent experiments, the mixtures have been shaken for at least 30 s.

3.7. The effect of ionic strength and coexisting ions

The effect of ionic strength on the extraction of uranium and thorium was studied in the presence of electrolytes like KNO_3 and NaCl with various concentrations from 0.5% to 5% (w/w), as these salts are the main electrolytes present in nuclear spent fuel waters and environmental samples, respectively [42]. The limit of tolerance defined as the amount of electrolyte ions causing an error of 5% in the recovery of metal ions. Results have shown that there is no interference in the presence of KNO_3 and NaCl up to 5% (w/w).

The effect of commonly occurring ions in water samples has been studied on the recovery of uranium and thorium ions. 10 mL of sample solutions containing 1.0 μg of the target ions and foreign ions in different interference-to-analyte ratios were subjected to the extraction procedure. The obtained results showed that under the conditions specified in the procedure, the major ions in the water samples had no obvious influence on the recovery of the target ions; the alkali and alkaline earth metal ions did not show interferences at the concentration of 10,000 times higher than that

of uranium and thorium concentration, and Cu(II), Ni(II), Cd(II), Pb(II), Zn(II), Co(II), Mn(II), Ce(IV), La(III), Mo(VI), Al(III), Fe(III), Zr(IV), $C_6H_5O_7^{3-}$ (citrate), CN^-, SCN^-, SO_4^{2-}, and CH_3COO^- did not show interference at the concentration 1000 times higher than that of analytes. From the recovery data, it can be seen that the modified MCM-41 shows high selectivity towards the studied analytes when compared to other divorce ions.

3.8. Reusability of modified MCM-41

The modified MCM-41 reusability was examined by shaking 40.0 mg of the sorbent under recommended procedure. After desorption of uranium and thorium ions with 1.0 mol L^{-1} HNO_3, the sorbent was washed with double-distilled water to remove acid. A series of sorption/desorption experiments were performed with the same sorbent and it was found that the modified MCM-41 was able to extract metal ions quantitatively more than 8 cycles.

3.9. Analytical performance

Calibration curves were obtained by preconcentrating 100 mL of sample standard solutions containing 20.0 mg of the sorbent and known amounts of the target ions at optimum conditions of the method. Table 2 shows the analytical characteristics of the method. The preconcentration factor is defined as the ratio of the volumes of the solutions, before and after extraction.

A comparison between the figures of merit of this method with other SPE methods that are used for preconcentration/separation of uranium and thorium were summarized in Table 3. As can be seen, the new synthesized sorbent has high capacity for uranium and thorium. Also, the obtained LODs are better than those obtained by some presented methods and higher than WHO and Health Canada and Australian drinking water guideline levels [5]. Higher LOD levels of the proposed method comparing to the inductively coupled plasma-mass spectrometry (ICP-MS) method are related to the higher sensitivity of the ICP-MS instrument.

3.10. Real sample analysis

The validation of the presented procedure was performed by the analysis of Montana I Soil certified reference material (CRM) (NIST-SRM 2710). 0.2 g of CRM was digested according to Ref. [10] and diluted to 100 mL with double-distilled deionized water. pH of this solution was adjusted to 5.5, then the proposed preconcentration procedure was applied. The certified and observed values for NIST-SRM were given in Table 4. The results found were in good agreement with the certified values of CRM.

In order to demonstrate the applicability of the method, seawater and two different water samples taken from the springs near the uranium mines of Tashk (Bandar Abbas, Iran) and Anarak (Yazd, Iran) were analyzed and the results obtained were summarized in Table 5. Water samples were filtered using a 0.45 μm pore size membrane filter to remove suspended particular solids. Aliquots of 100 mL of each sample were used for extraction of uranium and thorium under optimal conditions of the method. The results of triplicate analysis of each water sample showed that the recovery values were almost quantitative.

4. Conclusion

A new modified mesoporous silica (MCM-41) was synthesized using 5-nitro-2-furaldehyde and applied as an effective sorbent for the solid phase extraction of uranium(VI) and thorium(IV) ions in batch mode. This sorbent exhibited fast adsorption/desorption kinetics and high adsorption capacity. The method has given very low detection limits and good R.S.D. values. Comparative information from some recent studies on solid phase extraction of uranium(VI) and thorium(IV) for the figure of the merits is given in Table 3. The analytical performance of the presented method is comparable with other works. The results of this study clearly showed the potential of this method, which could apply to determination of uranium and thorium in various samples.

ABSTRACT

An impedimetric immunosensor was fabricated for rapid and non-labeled detection of sulfate-reducing bacteria, *Desulforibrio caledoiensis* (SRB) by immobilizing lectin-Concanavalin A using an agglutination assay. The immobilization of lectin was conducted using amine coupling on the surface of a gold (Au) electrode assembled with 11-Mercaptoundecanoic acid. Electrochemical impedance spectroscopy (EIS) was used to verify the stepwise assembly of the sensor system. The work conditions of the impedimetric immunosensor, such as pH of the buffer solutions and the incubation time of lectin, were optimized. Faradic impedance spectra for charge transfer for the redox probe $Fe(CN)_6^{3-/4-}$ were measured to determine SRB concentrations. The diameter of the Nyquist diagram that is equal to the charge-transfer resistance (R_{ct}) increased with increasing SRB concentration. A linear relationship between R_{ct} and SRB concentration was obtained in SRB concentration range of 1.8 to 1.8×10^7 cfu/ml. The variation of the SRB population during the growth process was also monitored using the impedimetric immunosensor. This approach has great potential for simple, low-cost, and time-saving monitoring of microbial populations.

1. Introduction

Sulfate-reducing bacteria (SRB) are anaerobic microorganisms that use sulfate as a terminal electron acceptor, resulting in the production of sulfide [1]. Sulfide is highly corrosive and toxic, thus it can be a serious problem for industries, economies, and ecological systems, such as the offshore oil industry. Therefore, a rapid and easy method for monitoring SRB populations is essential for the control of microbiological-induced corrosion and environmental contamination.

In general, conventional methods for monitoring microbial SRB populations, such as the most probable number (MPN) method, involve a pre-enrichment step or a selective enrichment step followed by a biochemical test, and the sophisticated series of assays required can take up 15 days to complete [2,3]. A variety of protocols have been presented for monitoring microbial SRB populations, including the MPN-improved method [4], the enzyme-linked immunosorbent assay (ELISA) [5], and pertinent molecular techniques such as polymerase chain reaction (PCR) [6] or fluorescence in situ hybridization (FISH) [7]. Although promising, these techniques are still the development phase, and several problems occur when they are used in situ and in real time. For example, because of the longer exponential growth phase of SRB compared to other microorganisms, it may take several days for these bacteria to produce an adequate amount of metabolic product; this makes the MPN-improved method very time-consuming and of little practical use when real-time monitoring is required. Although bovine serum albumin has been used in the ELISA method in an attempt to block non-specific binding sites, it is far from completely effective. In addition, the phylogenetic tree based on nearly complete 16S rRNA sequences reveals a total of 33 members of the phylum and domains of SRB [8].

Various sensitive, reliable, and more rapid methods have been reported for determination and monitoring of microorganisms, including surface plasma resonance (SPR) [9,10], flow cytometry [11], epifluorescence microscopy [12], quartz crystal microbalance (QCM) [13,14], mass spectrometry [15,16], and insulator-based dielectrophoresis [17]. Other methods use gold- or silver-nanoparticles [18,19] or quantum dots [20,21] as detecting mediators, and still others selectively detect cellular compounds such as ATP [22], nucleic acids [23], and whole cells with specific antigens [24,25] or typical structures of the carbohydrate domain [26]. For example, lectin is a structurally diverse protein that can selectively and reversibly integrate with carbohydrate structure domains in the cell membrane of microorganisms, and this process can be recognized by an agglutination test [27]. Agglutination has been used previously as a method for identifying bacteria because the clumping reaction occurs quickly and is easy to produce. Wang [28] and Danielsson [29] reported that a carbohydrate non-labeled

mass sensor in combination with lectin-bacterial antigen recognition can be used to detect *Escherichia coli* using QCM.

Recently, a very promising protocol that uses electrochemical impedance spectroscopy (EIS) was reported; this method involves immobilizing antibodies that are specific to the target microorganisms on the surface of electrodes to detect minute microorganisms. In fact, EIS assays were developed initially for detection of bacteria based on impedance changes due to the release of ionic metabolites from live cells [30]. Currently, the impedance system equipped with a redox probe is regarded as an effective and efficient method for characterizing changes in the interfacial properties of a modified electrode. Initially, impedance biosensor chips in the presence of $Fe(CN)_6^{3-/4-}$ were fabricated for the detection of *E. coli* O157:H7 using antibody-modified indium tin oxide electrode chips [31]. EIS has been used to study bacteria, but until now it has not been used to monitor the growth process of microbial population.

In this study, we fabricated an impedimetric immunosensor based on the self-assembly technique to detect SRB and to monitor microbial populations. To build this biosensor, we used a self-assembled monolayer (SAM) on a gold (Au) electrode surface. Subsequently, lectin immobilized on the SAM-modified Au electrode was used to selectively recognize elements to specifically bind to SRB.

2. Materials and methods

2.1. Chemicals

11-Mercaptoundercanoic acid (MPA), *N*-hydroxysuccinimide (NHS), 1-ethyl-3[3-dimethylaminopropyl] carbodiimide hydrochloride (EDC), and a freeze-dried lectin: Concanavalin A (ConA) were purchased from Sigma. For the ConA solution, 0.1 mg/ml ConA was dissolved in 10 mM phosphate buffer solution (PBS, pH 7.4) containing 1 mM Ca^{2+} and 1 mM Mn^{2+}. The PBS was prepared from analytical grade K_2HPO_4 and KH_2PO_4 (Sinopharm Chemical Reagent Co., Ltd.), and water purified by an ultrapure water system (Mili-Q, 18.2 MΩ). Potassium ferricyanide $[K_3Fe(CN)_6]$ and potassium ferrocyanide $[K_4Fe(CN)_6]$ were also supplied by Sinopharm Chemical Reagent Co., Ltd., as were the analytical grade $MgSO_4$, NH_4Cl, Na_2SO_4, $CaCl_2$, Na_2HPO_4, NaOH, sodium lactate, and yeast extract used to prepare the modified Postgate's medium. The Postgate's medium was filtered with a 0.2 μm pore size filter.

2.2. Culture of SRB

The seed bacteria were isolated from marine mud collected from the Bohai Sea, China. The pure SRB culture was grown in modified Postgate's medium at 30 °C for 4 days [32]. Before measurements, SRB samples were stored in the refrigerator at 4 °C for slow growth. The culture was serially diluted with physiological saline solution, and viable cell number was determined by the MPN method according to the American Society of Testing materials standard D4412-84.

2.3. Fabrication of impedance biosensor

Before use, an Au electrode (CH Instruments, Inc.) was polished with silicon carbide paper and then alumina powder, cleaned ultrasonically in absolute ethanol, rinsed with Mili-Q water, and dried in a flow of air. The electrode was then electrochemically pretreated by cycling the potential range from −0.2 to 1.6 V in a 0.05 M H_2SO_4 solution at a scan rate of 10 V s^{-1} until a steady cyclic voltammogram was obtained [33].

The MPA-modified Au electrode (MPA/Au electrode) was fabricated by immersing the freshly polished Au electrode into an ethanol solution containing 10 mM MPA solution for 2 h [34]. The electrode then was rinsed with ethanol to remove the physically

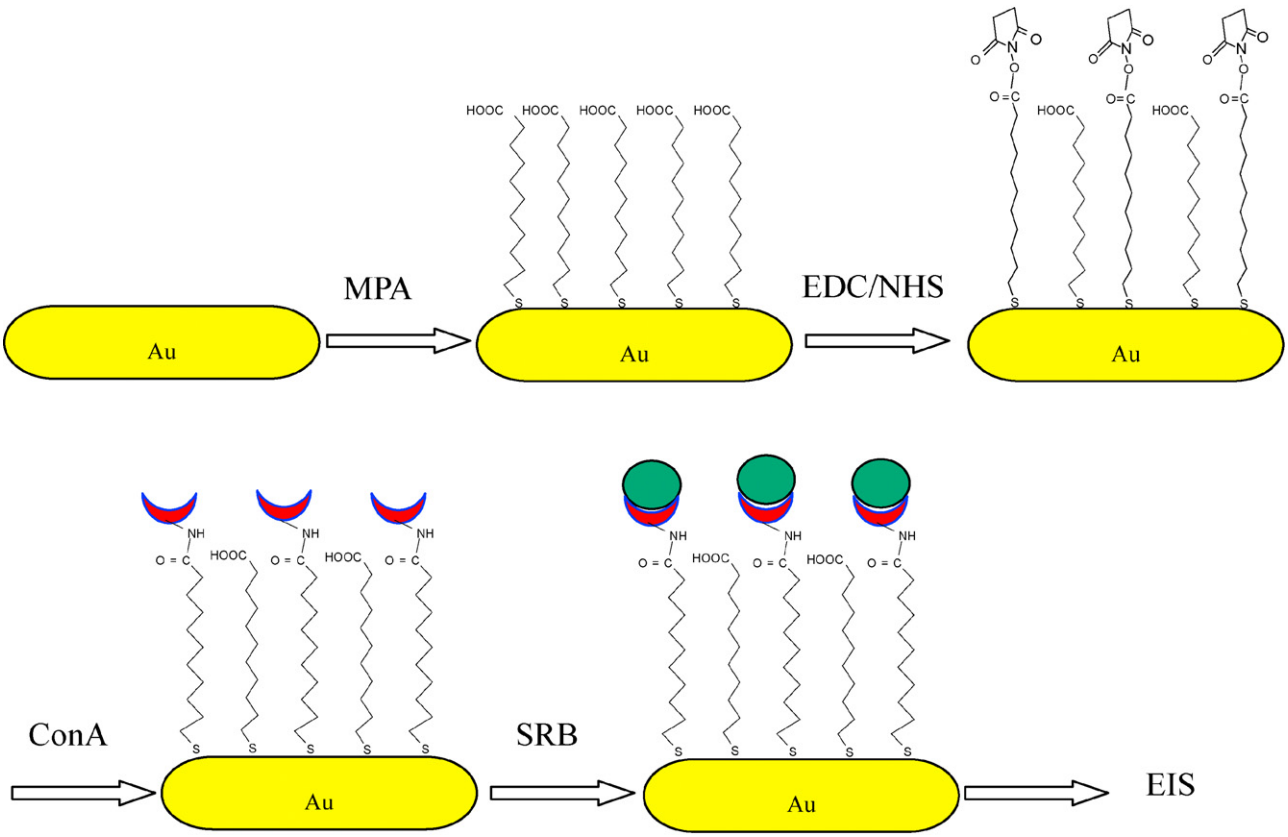

Fig. 1. Scheme showing the binding reactions involved in this study: MPA assembly, EDC/NHS activation, ConA immobilization, and SRB detection.

adsorbed MPA prior to use in the following procedure. As shown in Fig. 1, the ConA/MPA-modified biosensor was prepared by soaking the MPA/Au electrode in an aqueous solution of 40 mM EDC and 10 mM NHS to activate the carboxylic groups onto the surface of the NHS/MPA/Au electrode. Next, ConA was introduced onto the NHS/MPA/Au electrode by dropping 10 μl of 0.1 mg/ml ConA in PBS onto the electrode and allowing it to incubate at 4 °C for at least 2 h in a humidified glass chamber. After the immobilization of ConA, the modified ConA/MPA/Au electrode was rinsed with PBS solution (pH 7.4) to remove the excess non-chemisorbed lectin.

2.4. Electrochemical measurements

All experiments were conducted at room temperature. Electrochemical measurements were made using a CHI760C (CH Instruments, Inc.) conventional three electrode system that included a platinum wire and an Ag/AgCl, 3 M KCl wire as the counter electrode and a reference electrode, respectively. The functionalized Au electrode was used as the working electrode.

EIS was used to characterize the stepwise modification process of the functionalized electrodes. After preparing the multilayer biosensor surface, SRB detection was performed by EIS. The ConA/MPA/Au electrode was immersed in culture containing SRB in a series of concentrations ranging from 1.8 to 1.8×10^7 cfu/ml; incubation time was 2 h. The functionalized work electrode (SRB/ConA/MPA/Au electrode) was then cleaned by PBS, and the Faradic impedance spectra were measured at the open circuit potential.

EIS was conducted in 10 ml PBS in the presence of the redox probe with 5 mM $K_3Fe(CN)_6$ and 5 mM $K_4Fe(CN)_6$ (1:1) at the open circuit potential vs. Ag/AgCl, 3 M KCl and an alternating potential with amplitude of 10 mV at the frequency range from 0.1 Hz to 100 kHz. The experiments were repeated three times. The reproducibility of the impedance responses is represented by the error bar, which was obtained from the standard deviation for the three replicates.

2.5. Monitoring microbial population

The microbial SRB population during the growth process was monitored using the impedimetric immunosensor. The microorganisms were taken out of the incubator to detect impedance shifts on each day from exponential phase to stationary phase (from the 1st to the 6th day). Test samples were incubated at 30 °C for all experiments. The MPN method was used in a control experiment to monitor the variation of the microbial population.

3. Results and discussion

3.1. Measurement principle

EIS has been applied in biosensor studies as a sensitive and reliable tool to measure changes in biological/chemical molecules at electrode interfaces. Faradic impedance spectra often are simulated using the modified Randles circuit (Fig. 2) and used as a model for a reaction controlled by electron transfer and diffusion processes. In the modified Randles circuit, the ohmic resistance of an electrolyte solution between the working electrode and the counter electrode is represented by R_S; C_{dl} is the double layer capacitance; and R_{ct} is the charge-transfer resistance of the $Fe(CN)_6^{3-/4-}$ redox couple. The Warburg impedance (Z_W) with a semi-infinite diffusion mechanism in the measurement system arises from the diffusion resistance of the $Fe(CN)_6^{3-/4-}$ redox probe between the bulk solution and the interface of the modified work electrode. The R_{ct} value can be directly obtained from the Nyquist plots based on the intercept of the semicircle with the real axis, which is the most sensitive and straightforward parameter used to characterize the recognition events that occur on the surface of the work electrode.

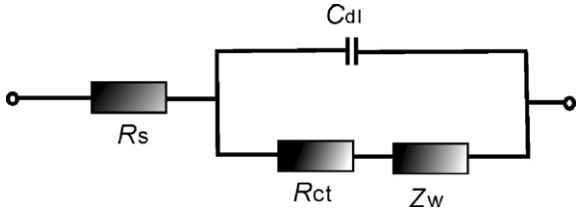

Fig. 2. Equivalent circuit diagram used to fit the experimental impedance spectra.

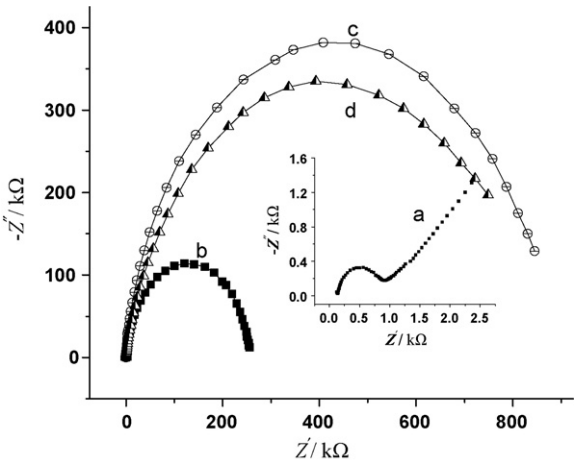

Fig. 3. Nyquist diagram obtained in pH 7.4 PBS containing 5 mM $[Fe(CN)_6]^{3-/4-}$ (1:1 mixture) on bare Au (a), MPA/Au (b), NHS/MPA/Au (c), and ConA/MPA/Au (d) electrodes.

3.2. Biosensor fabrication

Fig. 3 shows the Faradic impedance spectra for the redox of $Fe(CN)_6^{3-/4-}$ measured in the stepwise modification processes of the Au electrode. The diameter of the semicircle represents the magnitude of R_{ct} on the electrode surface. The impedance response on the bare Au electrode reveals a very small domain, implying a low R_{ct} of the redox probe (curve a, 0.778 kΩ). After the electrode was assembled with MPA, the R_{ct} distinctly increased (curve b, 254.7 kΩ) because the SAM retarded the charge-transfer process. Subsequently, NHS/EDC was covalently immobilized on the MPA/Au electrode and a remarkable rise in the R_{ct} was observed (curve c, 834.5 kΩ) because of the spatial hindrance effect of NHS. Additionally, the impedance response on the ConA/MPA/Au electrode (curve d, 633.0 kΩ) was slightly reduced compared to curve c because ConA was combined on the SAM because of the EDC/NHS-mediated amidation/coupling and because the NHS esters completely hydrolyzed within 4–5 h.

3.3. Optimization of the assay conditions

The influence of pH on the response of the impedance biosensor was investigated using 0.1 M PBS containing 5 mM $Fe(CN)_6^{3-/4-}$ to optimize the assay conditions. As seen in Fig. 4, the R_{ct} response increased when pH increased from 6.0 to 7.4 but then decreased at pH > 7.4. We also studied the variation of the R_{ct} response on the bare Au electrode under the same solution conditions (data not shown). The R_{ct} responses on the bare Au electrode barely changed; this finding indicates that changes in pH do not affect the R_{ct} on the bare Au electrode, but they do influence the response of the

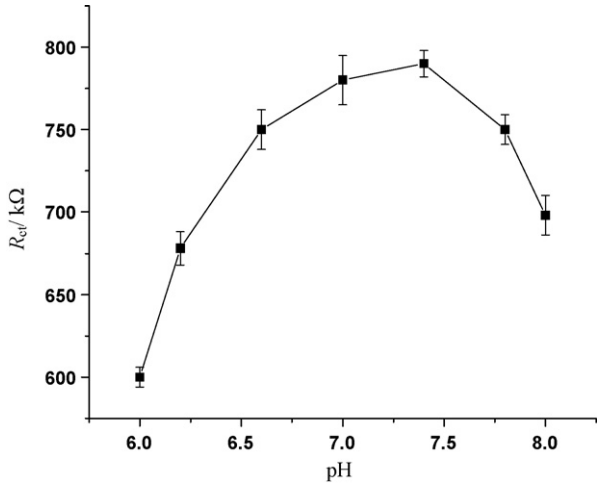

Fig. 4. A plot of R_{ct} response on SRB/ConA/MPA/Au electrodes in PBS with different pH values. Error bars represent one standard deviation of three parallel replicates.

biosensor system for detecting SRB. Therefore, the optimized pH level of 7.4 was used in our study for the detection of SRB.

The incubation time of the MPA-activated electrode in the ConA solution is critically important for the agglutination assay of SRB. Fig. 5 illustrates the dependence of the incubation time and R_{ct} response when a fixed SRB concentration (10^2 cfu/ml) was maintained. As the incubation time increased, the R_{ct} response was rapid and almost linear at first, but then it leveled off until a stable platform (ca. 800 kΩ) was reached after 2 h. Therefore, we used an incubation time of 2 h for the subsequent experiments.

The agglutination assay time between ConA and SRB to take place also play a key role in the detection of SRB. When the agglutination reaction time was less than 1.5 h, the R_{ct} response increased with increasing reaction time. When the reaction time was more than 3 h, the R_{ct} response decreased with increasing reaction time due that the complex of ConA and SRB cell became unstable at room temperature. Therefore, 2 h was selected as the optimal agglutination assay time in this study.

3.4. Specificity of the impedimetric immunosensor

The specificity of biosensor was investigated in relation to other bacteria such as Gram-negative bacteria, *V. anguillarum* as marine

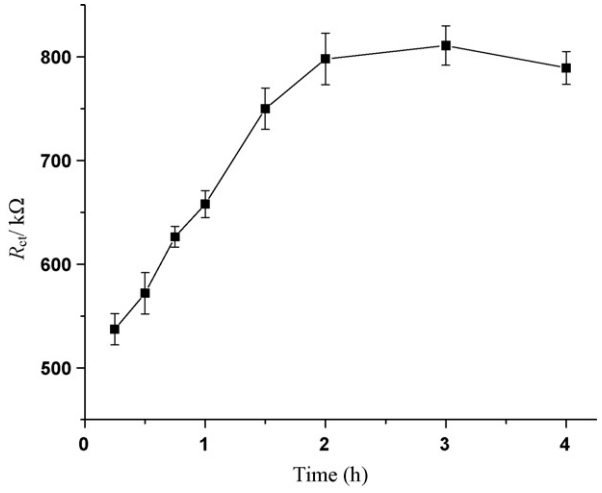

Fig. 5. Effect of the incubation time in ConA solution containing 1 mM Mn^{2+} and 1 mM Ca^{2+} on the R_{ct} response. Error bars represent one standard deviation of three parallel replicates.

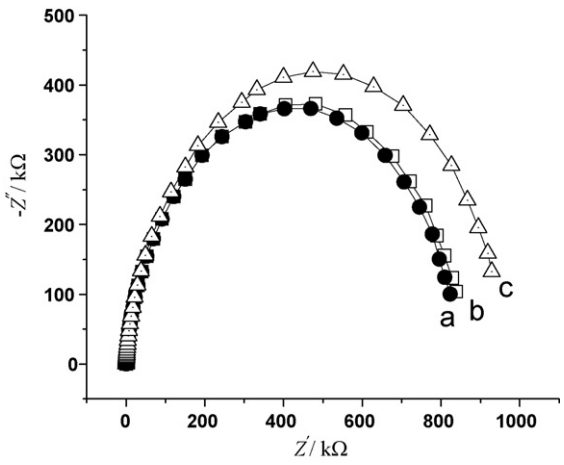

Fig. 6. Impedimetric spectra obtained in pH 7.4 PBS containing 5 mM $[Fe(CN)_6]^{3-/4-}$ (1:1 mixture) on ConA/MPA/Au electrodes before (a) and after their incubation with *V. anguillarum* (b) and SRB (c) culture sample with a fixed concentration of 1.8×10^2 cfu/ml for 2 h.

pathogenic bacteria. Fig. 6 are impedimetric spectra obtained in pH 7.4 PBS containing 5 mM $[Fe(CN)_6]^{3-/4-}$ (1:1 mixture) on ConA/MPA/Au electrodes before (curve a) and after their incubation with *V. anguillarum* (curve b) and SRB (curve c) culture sample with a fixed concentration of 1.8×10^2 cfu/ml for 2 h. It is clearly that the R_{ct} response changes are different between the ConA/MPA/Au electrode incubated with SRB and *V. anguillarum*. The R_{ct} response change for ConA-modified electrode after and before immersing in *V. anguillarum* is 14 kΩ, but the R_{ct} response change for the ConA-modified electrode after and before immersing in SRB increases distinctly to 161 kΩ. Different species bacteria with same concentration induce the different change of R_{ct} value, which lead to the variation of the slope of the R_{ct} value versus bacterial concentration curve. The special slope of the R_{ct} value versus bacterial concentration curve is shown in Fig. 8.

3.5. Detection of SRB

Fig. 7 shows the Faradic impedance spectra obtained on the SRB/ConA/MPA/Au electrodes prepared with different SRB concentrations. The diameter of the Nyquist plots increased regularly with the increase of the SRB concentration, indicating that SRB were adsorbed on the surface of the ConA/MPA/Au electrode to produce

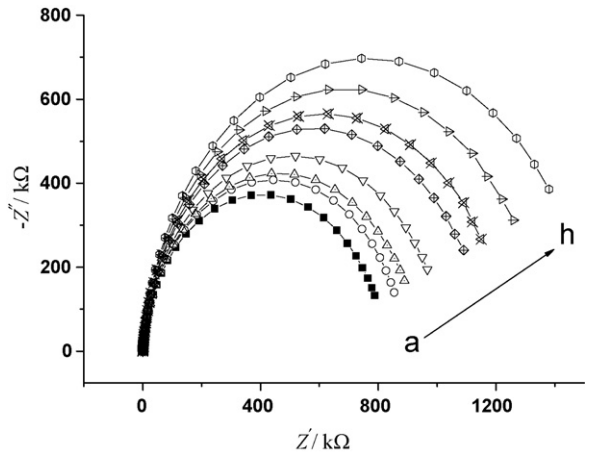

Fig. 7. Faradic impedance spectra obtained on SRB/ConA/MPA/Au electrodes. Curves a–h represent SRB concentrations of 1.8×10^0, 1.8×10^1, 1.8×10^2, 1.8×10^3, 1.8×10^4, 1.8×10^5, 1.8×10^6, and 1.8×10^7 cfu/ml, respectively.

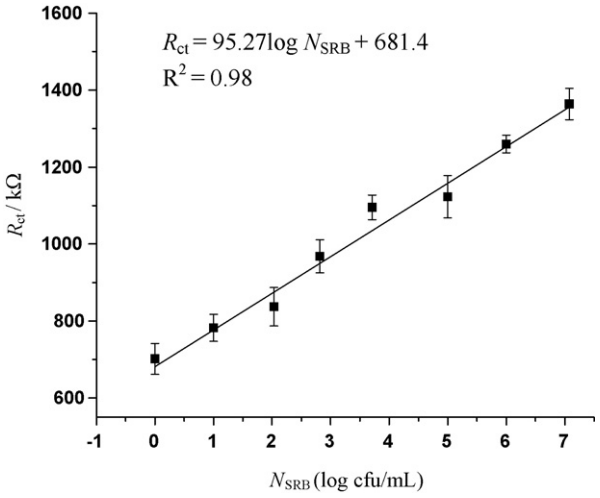

Fig. 8. Concentration of SRB (log cfu/ml) versus the R_{ct} values obtained from Fig. 7. Error bars represent one standard deviation of three parallel replicates.

a packed film that showed electron transfer for the redox probe. Other research groups reported similar results for the detection of *Saccharomyces cerevisiae* by directly binding yeast cells on a gold surface modified with an alkanethiolate SAM [35]. Geng et al. also prepared an electrochemical impedance immunosensor for determination of *E. coli* by immobilizing antibodies on an MPA-modified electrode [36].

Fig. 8 displays the R_{ct} values calculated from Figs. 2 and 7 on SRB/ConA/MPA/Au electrodes prepared with a series of SRB concentrations. A linear relationship between R_{ct} values and the logarithm of the SRB concentrations was obtained for the SRB concentration range of 1.8 to 1.8×10^7 cfu/ml, with a slope of 95.27 and a correlation coefficient of 0.98. These results illustrate that the fabricated Faradic impedance biosensor has a wider detection range compared to the aforementioned immunosensors [35,36]. However, the variation of the slopes obtained using different immobilization methods for detection of bacteria using impedance measurements implies that the different chemical/biological anchors for bacterial cells have very different affinities. For example, the affinity constant of the peanut protein Arah h 1 and its antibody recently was investigated based on a Langmuir adsorption isotherm using an impedance biosensor [37]. The slope of the standard curve for bacteria detection was 16.0 for mercaptopropionic acid directly binding the yeast cells [35] and 1288.9 for the antibody immobilizing *E. coli* [36]. With greater affinity, the slope becomes steeper. In other words, the specific affinity of lectin for the bacterial cells is less than that of its antibody.

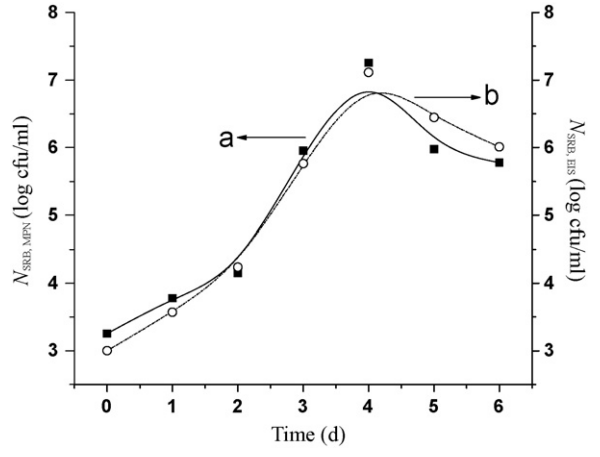

Fig. 9. The variation of the SRB population monitored by the MPN method (a) and by the impedance immunosensor (b).

3.6. Monitoring microbial populations

The impedimetric immunosensor designed in this study was used to monitor the variation in a microbial SRB population that was isolated from marine mud. As shown in Fig. 9(a), the growth curve had two phases: exponential and stationary. In the exponential phase, the microbial population increased rapidly from 2.3×10^3 to 1.3×10^7 cfu/ml in 0–4 days; then it remained constant in the stationary phase. This trend displays a typical bacterial growth process. In addition, the MPN method was used as a control experiment to monitor the growth of the SRB population; the obtained growth curve was similar to that measured with the impedance immunosensor.

4. Conclusion

We have described a simple and reliable method suitable for determination and monitoring of microbial SRB populations; this method uses ConA on a carboxylic-terminated alkanethiolate-modified Au electrode and Faradic impedance measurements. A linear relationship between R_{ct} values and the logarithm of the SRB concentrations was observed in the SRB concentration range of 1.8 to 1.8×10^7 cfu/ml. Our lectin-based impedance biosensor can perform direct, sensitive, and rapid label-less monitoring of the SRB bacterial populations. This technique is a promising alternative to the traditional MPN method for monitoring microbial populations.

ABSTRACT

A novel biosensor based on the silica-coated gold nanorods (GNRs@SiO_2) and hydrophilic room temperature ionic liquid (RTIL) 1-butyl-3-methylimidazolium tetrafluroborate ([bmim][BF_4]) was fabricated for the determination of hydrogen peroxide (H_2O_2) and nitrite. GNRs@SiO_2 can not only act as a binder to hinder [bmim][BF_4] (RTIL) leaking from the electrode surface, but also provide a favorable microenvironment for direct electrochemistry of myoglobin (Mb). A pair of well-defined and quasi-reversible redox peaks of Mb was obtained at the GNRs@SiO_2–Mb/RTIL–sol–gel composite film modified GCE (GNRs@SiO_2–Mb/RTIL–sol–gel/GCE) through direct electron transfer between Mb and the underlying electrode. This biosensor showed an excellent electrocatalytic activity towards hydrogen peroxide and nitrite. The linear range for the determination of H_2O_2 was from 0.2 to 180 μM with a detection limit of 0.12 μM based on the signal-to-noise ratio of 3. In addition, the biosensor also exhibited high selectivity, good reproducibility, and long-term stability. Therefore, this kind of composite film can provide an ideal matrix for protein immobilization and biosensor fabrication.

1. Introduction

The direct electron transfer between redox proteins or enzymes and underlying electrodes is of great significance in the construction of third-generation biosensors. Myoglobin (Mb) is a small heme protein found in muscle cells. Mb functions physiologically in the storage of oxygen and in the enhancement of the rate of oxygen diffusion, and has catalytic activity for H_2O_2 similar to horseradish peroxidase (HRP) [1]. It is an ideal model molecule for the electron transfer study of heme proteins and for biosensing and biocatalysis. However, Mb does not easily undergo facile redox reactions at electrode surfaces because of its electroactive centers embedded deeply in the protein structure. Hence, various materials such as surfactants [2], polymers [3] and nanoparticles [4–6] were exploited to modify the electrodes. Their properties of hydrophilicity, nontoxicity, excellent film-forming ability and remarkable biocompatibility offer excellent prospects for direct electrochemistry of redox proteins.

Room temperature ionic liquid (RTIL) entirely comprised of ions at ambient temperature has attracted extensive attention because of its unique chemical and physical properties such as negligible vapor pressure, low toxicity, wide potential windows, relatively high ionic conductivity and good chemical and thermal stabilities [7]. It has been widely used in synthetic chemistry [8], phase transfer catalysis [9], materials science [10] and electrochemistry [11]. Particularly in electrochemistry, the high ionic conductivity and the ability of retaining and enhancing the enzyme activity make RTIL as a kind of interesting material to modify electrodes and construct new biosensors. For example, Li et al. [12] proposed a novel chitosan–RTIL composite and used as an immobilization matrix to entrap proteins. Zhao et al. [13] used a RTIL modified basal plane graphite (BPG) electrode to immobilize hemoglobin (Hb) and investigated its electrocatalytic ability.

Recently, much attention has been paid to modify electrodes with RTIL and nanocomposites for combining their unique advantages. Sun et al. [14] investigated the electrocatalysis of Hb in a Nafion/nano-$CaCO_3$ film on an ionic liquid modified carbon paste electrode, and found that the immobilized Hb kept its native structure and showed good electrochemical behavior. Cai et al. [15] studied the direct electron transfer of heme-containing proteins immobilized in a single-walled carbon nanotube supported room temperature ionic liquid matrix. However, it is still a challenge for the combinations of RTIL with the nanoparticles to fabricate novel biosensors.

Silica-coated gold nanorods (GNRs@SiO_2) are a kind of novel biocompatible nanocomposite, which has been widely used as the immobilization matrix for biosensors [16] and biocatalysis [17]. On the other hand, sol–gel method has been demonstrated to be an alternative way to immobilize proteins or enzymes [18]. In this

paper, a novel biocomposite film based on GNRs@SiO_2, RTIL and silica sol–gel was prepared and further used to construct an excellent electrochemical biosensor for the determination of H_2O_2 and nitrite. Two chief aspects for the work have been highlighted. First, adding the GNRs@SiO_2 into RTIL–sol–gel can improve adhering ability of the composite film on electrode surface and provided an ideal matrix for protein immobilization and biosensor fabrication. Second, doping RTIL in GNRs@SiO_2/sol–gel can greatly enhance the conductivity of the composite film, and enzyme activity. The method by entrapping enzyme into biocompatible GNRs@SiO_2 and RTIL–sol–gel composite provided an effective means for realizing direct electrochemistry and electrocatalysis of enzymes along with good stability.

2. Experimental

2.1. Chemicals and reagents

Mb (horse heart) and cetyltrimethylammonium bromide (CTAB) were purchased from Sigma. Hydrogen peroxide (H_2O_2, 30%), $HAuCl_4{\cdot}4H_2O$ and tetraethoxysilane (TEOS) were from Shanghai Chemical Reagent Co. (Shanghai, China). Sodium borohydride ($NaBH_4$), sodium nitrite ($NaNO_2$) and ascorbic acid (AA) were obtained from Tianjin Reagent Factory (Tianjin, China). Ionic liquid 1-butyl-3-methylimidazolium tetrafluroborate ([bmim][BF_4]) was purchased from Acros Organics and used as received. All other chemicals were of analytical grade. All aqueous solutions were prepared with doubly distilled water and were deaerated with high purity nitrogen before performing the experiments.

2.2. Apparatus

Electrochemical measurements were performed on a CHI 660a workstation (Shanghai Chenhua, Shanghai, China) with a conventional three-electrode system comprised of a platinum wire as the auxiliary, a saturated calomel electrode as the reference and the modified glass carbon electrode (GCE) as the working electrode. Electrolyte solutions were deoxygenated by bubbling highly pure nitrogen for at least 10 min, and a nitrogen atmosphere was kept over the solution during measurements. Electrochemical impedance spectroscopy (EIS) was performed with an Autolab Electrochemical Analyzer (Eco Chemie, Netherlands) in 10 mM $K_3Fe(CN)_6$/$K_4Fe(CN)_6$ (1:1) mixture with 1.0 M KCl as supporting electrolyte, using an alternating current voltage of 5.0 mV, within the frequency range of 0.1 Hz–100 KHz. Transmission electron micrographs (TEM) were measured on a JEOLJEM 200CX transmission electron microscope, using an accelerating voltage of 200 KV. Scanning electron micrographs (SEM) were obtained with a Hitachi S4800 scanning electron microscope. Fourier transform infrared (FT-IR) spectra were recorded on a Vector 22 FT-IR spectrometer (Bruker). The real surface area (A) of the GC electrode could be obtained by cyclic voltammetry using 1 mM $K_3Fe(CN)_6$ as a probe at different scan rates. A straight line of peak currents (I_{pa}) vs. scan rates ($\upsilon^{1/2}$) could be obtained according to the equation of $I_{pa} = 299(\alpha n_a)^{1/2} A D_R^{1/2} C_o^* \upsilon^{1/2}$ (T = 298.2 K), and the value of A for the bare GC was estimated to be 0.097 cm^2 from the slope of the line.

2.3. Synthesis of GNRs@SiO_2 nanocomposite

GNRs were prepared according to the seed growth method as described in the reference [19]. GNRs@SiO_2 nanocomposite was prepared using an improved Stöber method. Briefly, the as-prepared GNRs were first washed by centrifugation twice at 9000 rpm for 10 min and redispersed in pure water. Then pH of the GNRs dispersion was adjusted to ca. 10 with ammonia (28 wt%), followed by the addition of appropriate amount of TEOS. The reaction was allowed to continue for 24 h at a constant temperature of 37 °C under vortex mixing. After the reaction was over, the GNRs@SiO_2 nanocomposites were collected by centrifugation at 9000 rpm for 10 min and further washed with abundance water.

2.4. Preparation of the GNRs@SiO_2–Mb bioconjugates and RTIL–sol–gel solution

The GNRs@SiO_2–Mb bioconjugates were prepared by adding 20 mg of GNRs@SiO_2 composites into 5 mg mL^{-1} Mb solution under vortex mixing. The resulting solution was further allowed to react for 24 h, followed by centrifugation and washing with water twice. We found that about 630 μg of Mb was immobilized onto 1 mg of GNRs@SiO_2 nanocomposite by calculating the difference in the concentration of the protein before and after adsorption.

A homogeneous RTIL–sol–gel solution was prepared by mixing 600 μL of ethanol, 50 μL of TEOS, 10 μL of 5 mM NaOH, 60 μL of H_2O and 50 μL of [bmim][BF_4] in a small test tube at room temperature. After being sonicated, the RTIL–sol–gel was formed and stored at 4 °C.

2.5. Construction of GNRs@SiO_2–Mb/RTIL–sol–gel/GCE biosensor

Prior to modification, the GCE (3 mm diameter) was first polished with 0.05 μm alumina slurry, then sonicated in nitric acid (1:1), ethanol and redistilled water in turn. The mixture containing 10 μL of biconjugates and 10 μL of RTIL–sol–gel was mixed round for 15 min, and then a 10 μL aliquot of the as-prepared GNRs@SiO_2–Mb/RTIL–sol–gel composite was dropped onto the pretreated GCE. The electrode was left to dry in a silica gel desiccator and stored at 37 °C overnight. As a comparison, the electrodes modified by GNRs@SiO_2/RTIL–sol–gel and GNRs@SiO_2–Mb/sol–gel were also prepared by the similar manner.

3. Results and discussion

3.1. Characterization of GNRs@SiO_2 and GNRs@SiO_2–Mb/RTIL–sol–gel bioconjugates

A method for silica coating GNRs with the Stöber technique was previously reported. However, in the preparation, besides prepared GNRs@SiO_2, some free silica is still observed [17]. In order to obtain a more homogeneous mixing, vortex mixing rather than mechanical

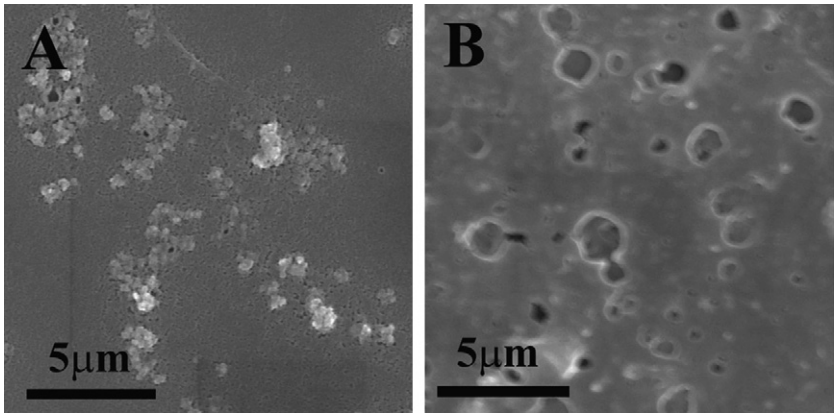

Fig. 2. SEM images of the GNRs@SiO_2–Mb/sol–gel biocomposite film (A) and the GNRs@SiO_2–Mb/RTIL–sol–gel biocomposite film (B).

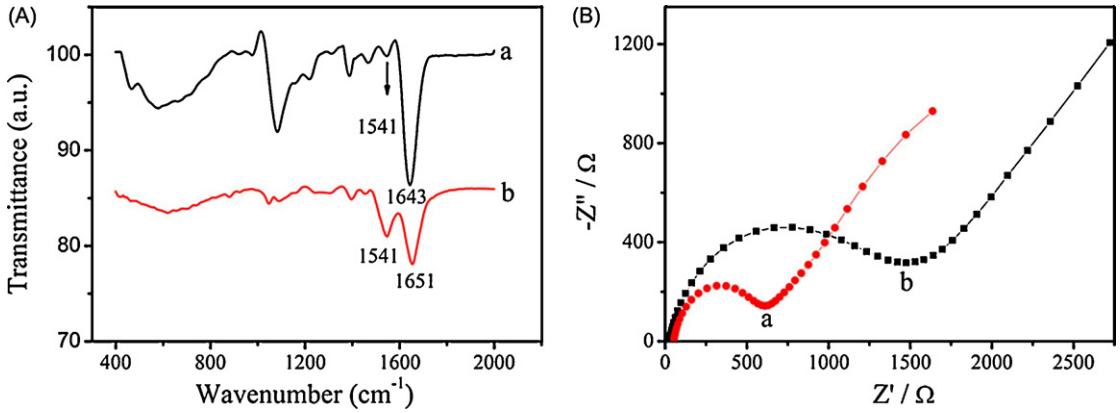

Fig. 3. (A) FT-IR spectra of (a) GNRs@SiO_2–Mb and (b) Mb. (B) EIS for (a) GNRs@SiO_2–Mb/RTIL–sol–gel biocomposite and (b) GNRs@SiO_2–Mb/sol–gel biocomposite modified GCE.

mixing and magnetic stirring was adopted. In addition, the reaction temperature was controlled at 37 °C to avoid the nucleation of free silica in solution. Fig. 1 shows a representative TEM image of the nanocomposite with an average aspect ratios of 2.1 (length: ca. 44 nm, width: ca. 21 nm) for the GNRs cores and a uniform thickness of the silica shell (ca. 18 nm). The homogeneous silica shell not only can control the dipolar interactions between GNRs, but also can enhance the versatility of the particles in biosensing.

SEM images were used to characterize and compare the morphologies of the GNRs@SiO_2–Mb/sol–gel and the GNRs@SiO_2–Mb/RTIL–sol–gel biocomposite film as shown in Fig. 2. It was found that the GNRs@SiO_2–Mb/sol–gel film in Fig. 2A exhibited an isolated and irregularly shaped surface, while the GNRs@SiO_2–Mb/RTIL–sol–gel film in Fig. 2B exhibited a highly porous surface with regularly network-like structure. This porous structure was attributed to the incorporated of RTIL into the composite film. The RTIL–sol–gel matrix provided a non-aggressive Mb enzyme immobilization approach at room temperature, which can improve the enzyme activity, biosensor sensitivity and the response signal.

(B) CVs of GNRs@SiO_2–Mb/RTIL–sol–gel/GCE in 0.1 M PBS solution (pH 7.0) at the scan rates of 0.02, 0.05, 0.08, 0.1 and 0.15 V s^{-1} (from inner to outer). Inset is the plot of cathodic and anodic peak currents vs. scan rate.

FT-IR spectroscopy is sensitive to the secondary structure of the protein. The characteristic amide I and amide II bands of protein provide detailed information on the secondary structure of polypeptide chain [20]. The amide I (1700–1600 cm^{-1}) was ascribed to C=O stretching vibrations of peptide linkages in the protein backbone. The amide II band (1600–1500 cm^{-1}) was attributed to a combination of N–H in plane bending and C–N stretching of the peptide groups. As shown in Fig. 3A, the spectra of amide I (1643 cm^{-1}) and II (1541 cm^{-1}) of Mb in the GNRs@SiO_2–Mb/RTIL–sol–gel biocomposite was nearly the same as those of native Mb. The slight shift of amide I bands from 1651 to 1643 cm^{-1} revealed the interaction between Mb and the GNRs@SiO_2 hybrids. Therefore, Mb retained the essential features of native secondary structure in the porous composite film.

Furthermore, EIS was employed to characterize the electrode surface impedance. Fig. 3B shows the Nyquist plots of EIS for the GNRs@SiO_2–Mb/RTIL–sol–gel and the GNRs@SiO_2–Mb/sol–gel biocomposite modified GCE. Significant differences in the impedance spectroscopy were observed. By mixing the GNRs@SiO_2–Mb/sol–gel with RTIL, the electron transfer resistance (Ret) of the composite film decreased from 1622 to 605 Ω, indicating that the RTIL–sol–gel composite film had good ionic conductivity and obviously improved the diffusion of ferricyanide toward the electrode surface.

3.2. Direct electrochemistry of Mb immobilized in GNRs@SiO_2/RTIL–sol–gel composite film-modified GC electrode

The direct electrochemistry of Mb modified electrode was studied by cyclic voltammetry. As shown in Fig. 4A, the GNRs@SiO_2/RTIL–sol–gel/GCE did not exhibit discernible peaks under the given conditions. However, when the GNRs@SiO_2–Mb/sol–gel/GCE was immersed in PBS, a pair of ill-defined and not symmetric redox peaks (curve b) corresponding to $MbFe^{III}/Fe^{II}$ redox couple was showed in cyclic voltammograms (CVs). This indicated that GNRs@SiO_2 could provide a favorable microenvironment for Mb to retain its natural structure and realize its direct electrochemistry. After the mixing [bmim][BF_4] with composite-sol–gel film, a remarkable enhanced electrochemical response was observed (curve c) with nearly the same value of anodic and cathodic peak current. A stable, well-defined and quasi-reversible redox peaks with the reduction and oxidation peak potentials appeared at −0.271 and −0.217 V at a scan rate of 200 mV s^{-1}, respectively. Compared with curve b, the current responses of Mb in curve c were remarkable increased, demonstrating that the presence of [bmim][BF_4] could greatly enhance the electron transfer process between Mb and the electrode surface. Moreover, it should be noted that the redox peaks of Mb almost disappeared after continuous potential cycling without GNRs@SiO_2 in RTIL–sol–gel film, indicating GNRs@SiO_2 could act as a binder to hinder [bmim][BF_4] leaking from the electrode surface. Thus, both biocompatibility of GNRs@SiO_2 and inherent conductivity of [bmim][BF_4] enable the composite to become an excellent matrix for realizing the direct electrochemistry of Mb.

The effect of scan rate on electrochemistry of the immobilized Mb was shown in Fig. 4B. With an increasing scan rate, the anodic peak potential of Mb shifted to a more positive value and the cathodic peak potential shifted in a negative direction. Furthermore, both the cathodic and anodic peak currents are linearly proportional to the scan rate in the wide range from 20 to 400 mV s^{-1} (inset of Fig. 4B), indicating a surface-controlled quasi-reversible process. The electron transfer rate constant (ks) between Mb and electrode was estimated to be 4.7 s^{-1} according to Laviron method [21]. It is higher than the 3.08 s^{-1} at Mb–TiO_2/MWCNTs/GC electrode [22], 1.0 s^{-1} at Mb/nanoporous ZnO/graphite electrode [23] or 0.34 s^{-1} at Mb/NiO NPs/GC electrode [24]. This faster ks indicates that the GNRs@SiO_2/RTIL–sol–gel composite film is an excellent promoter for the electron transfer between Mb and the electrode. The integration of the reduction peaks at different scan rates gave nearly constant charge values. According to Faraday's law, the average surface concentration of electroactive Mb in GNRs@SiO_2/RTIL–sol–gel/GCE was calculated to be 7.65×10^{-9} mol cm^{-2}. The result was larger than the theoretical monolayer coverage of 1.58×10^{-11} mol cm^{-2} for Mb [25], showing that several layers of Mb entrapped in the composite film participated in the electron transfer process.

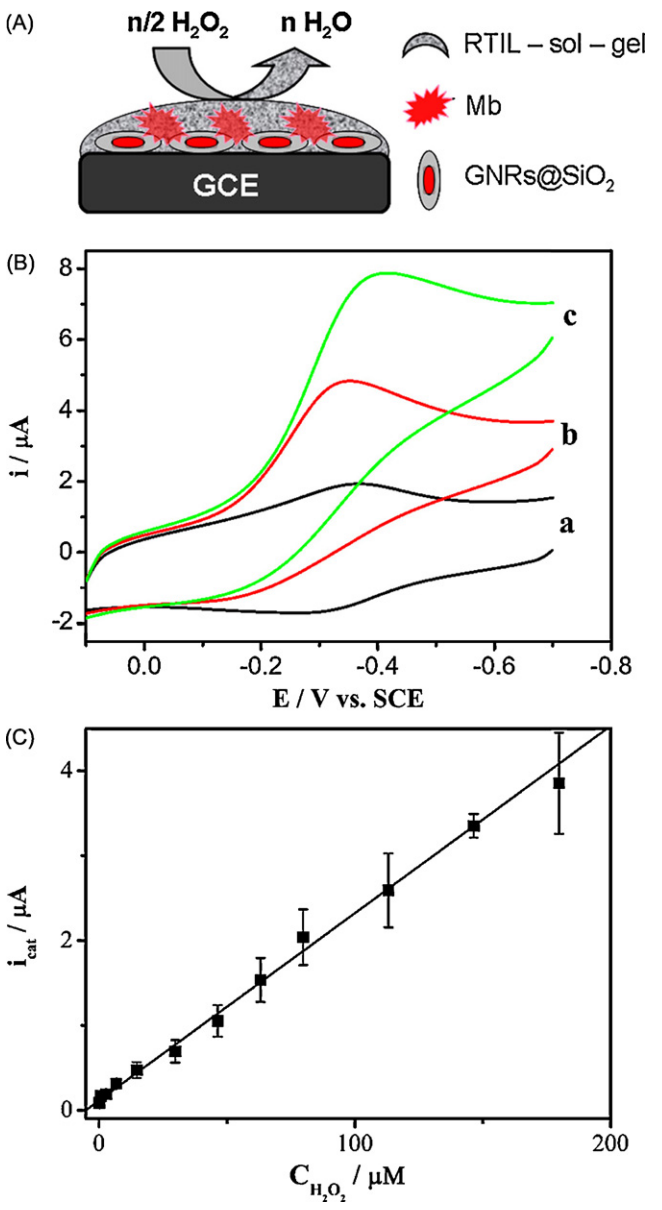

Fig. 5. (A) Schematic of the modification of GCE with GNRs@SiO_2, Mb and RTIL–sol–gel for efficient detection of H_2O_2. (B) CVs of GNRs@SiO_2–Mb/RTIL–sol–gel/GCE in 0.1 M PBS (pH 7.0) containing different concentration of H_2O_2 (a) 0, (b) 113.1 μM, and (c) 346.5 μM. (C) Linear plots of catalytic current (i_{cat}) vs. H_2O_2 concentration.

3.3. Electrocatalysis of GNRs@SiO_2–MbRT/IL–sol–gel/GCE to reduction of H_2O_2

It was reported that enzymes and proteins containing heme groups were able to reduce hydrogen peroxide electrocatalytically [26]. A possible mechanism of H_2O_2 catalyzed by

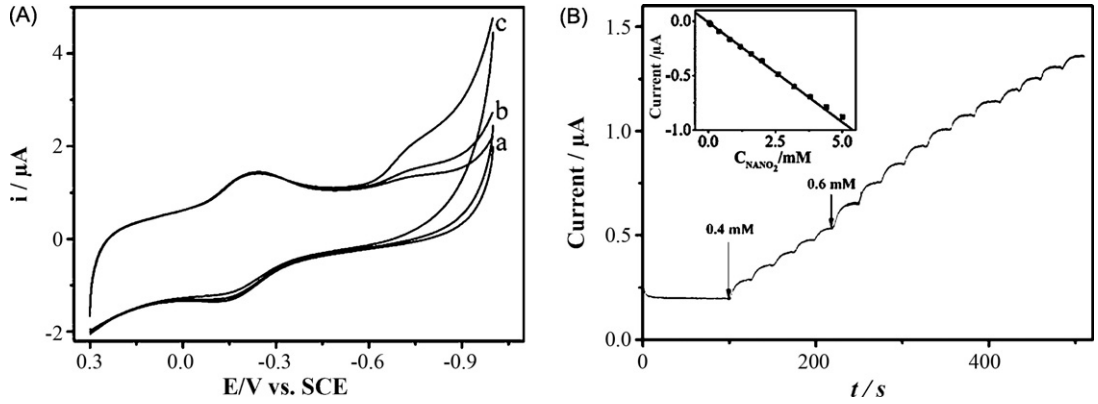

Fig. 6. (A) CVs of GNRs@SiO_2–Mb/RTIL–sol–gel/GCE in 0.1 M pH 5.0 acetate buffer containing different concentration of $NaNO_2$ (a) 0, (b) 100 μM and (c) 400 μM. (B) Typical amperometric current–time response curves of the biosensor upon successive addition of $NaNO_2$ into pH 5.0 acetate buffer solution. Applied potential: −0.7 V. Inset: linear relation between the amperometric response and NO_2^- concentration.

GNRs@SiO_2–Mb/RTIL–sol–gel modified electrode is postulated as shown in Fig. 5A. Fig. 5B shows the cyclic voltammograms of the GNRs@SiO_2–Mb/RTIL–sol–gel/GCE in a 0.1 M pH 7.0 PBS in the absence and presence of H_2O_2 at a scan rate of 200 mV s^{-1}. Upon addition of H_2O_2 to the solution, the reduction peak current increases obviously, while the oxidation peak current decreases with increasing the H_2O_2 concentration, showing a typical electrocatalytic reduction process to H_2O_2. Furthermore, the cathodic peak potentials shifted to negative value slightly with increasing the concentration of H_2O_2. As shown in Fig. 5C, the electrocatalytic peak current (i_{cat}) had good linear relationship with the concentration of H_2O_2 in the range of 0.2–80 μM. The linear regression equation was I (μA) = 0.115 + 0.022c (μM) (R = 0.997, n = 12) with a detection limit of 0.12 μM at 3σ. Thus, the entrapped Mb molecules are of good electrocatalytic activity, and the substrates for enzyme reaction can freely enter the porous RTIL–sol–gel film. The possible mechanism of electrocatalytic reduction of H_2O_2 at Mb-based enzyme electrode has been reported [27], which can be expressed as follows:

$$\mathrm{MbFe} + \mathrm{H_2O_2} \rightarrow \mathrm{CompoundI} + \mathrm{H_2O}$$

$$\mathrm{Compound\,I} + \mathrm{e^-} + \mathrm{H^+} \rightarrow \mathrm{Compound\,II}$$

$$\mathrm{Compound\,II} + \mathrm{e^-} + \mathrm{H^+} \rightarrow \mathrm{MbFe} + \mathrm{H_2O}$$

When the concentration of H_2O_2 was higher than 180 μM, a platform emerged in the catalytic peak current, showing the characteristics of Michaelis–Menten kinetics. The Michaelis–Menten constant (K_m^{app}), which gives an indication of the enzyme–substrate kinetics, is 0.42 mM as calculated from the electrochemical version of the Lineweaver–Burk equation $1/I_{ss} = 1/I_{max} + K_{app}^{m}/I_{max}C$, where I_{ss}, I_{max} and C stand for steady-state current, maximum current and the bulk concentrate of the substrate. This value was smaller than Hb on the sol–gel film modified CPE [28] or HRP on the chitosan/carbon microsphere/GCE [29], implying that Mb in the porous composite film is of a higher affinity to H_2O_2.

3.4. Amperometric response of the biosensor for nitrite

As is well known, nitrite is a carcinogen that widely exists in antiseptic food and polluted water. So the quantitative determination of nitrite concentrations is of rapidly increasing interest. In this study, electrochemical catalytic reduction of nitrite was also observed at the GNRs@SiO_2–Mb/RTIL–sol–gel modified electrode. After the addition of $NaNO_2$ into pH 5.0 acetate buffer solutions, a new reduction peak at about −0.7 V appeared (Fig. 6A), while direct reduction of NO_2^- at GNRs@SiO_2/RTIL–sol–gel/GCE showed a peak potential at about −1.3 V. Thus, the presence of Mb in the film decreased the reduction overpotential of NO_2^- for at least 0.6 V. Furthermore, the reduction current increases with an increase of NO_2^- concentration.

Fig. 6B shows the amperometric response of the biosensor with successive additions of $NaNO_2$ to 0.1 M pH 5.0 acetate buffer solutions at an applied potential of −700 mV. The current is produced from the reduction of NO that came from the disproportionation reaction of nitrite in acidic solution [30]. Upon addition of $NaNO_2$, the biosensor responded rapidly to the substrates and could achieve 90% of the steady-state current within 5 s, indicating a fast amperometric response to NO_2^- reduction. Such a rapid response can be attributed to the fast diffusion of the substrate in the porous and open frameworks of RTIL–sol–gel composite film. The amperometric response showed a linear relation with nitrite concentration from 0.04 mM to 5.0 mM with a correlation coefficient of 0.995 (n = 11) (inset of Fig. 6), which is wider than the previous nitrite sensors. The detection limit was estimated to be 0.02 mM at a signal-to-noise of 3. It is notable that this detection limit is obviously lower than the results obtained at some nitrite biosensors such as Mb–zirconium phosphate nanosheets film modified GCE [31] or Mb/clay–chitosan–gold nanoparticle nanohybrid modified GCE [32], indicating that the fabricated sandwich structured biosensor can potentially be used for monitoring of the concentration of nitrite sensitively. When the concentration of NO_2^- was higher than 5.0 mM, a plateau was observed, showing the characteristics of the Michaelis–Menten kinetics. The Lineweaver–Burk plot showed that Michaelis–Menten constant (K_m^{app}) was about 10.5 mM.

3.5. Reproducibility and stability of hydrogen peroxide biosensor

The reproducibility of the developed biosensor was examined at a H_2O_2 concentration of 1 μM, and the relative

Table 1
Interference experiment with the hydrogen peroxide biosensor.

External matters	Current ratio[a]	R.S.D. (%)
Glucose	0.931 ± 0.041	1.7
Glycin	0.997 ± 0.036	1.5
Ascorbic acid	1.02 ± 0.07	2.8
Citric acid	0.971 ± 0.028	1.6
Enthanol	0.958 ± 0.073	3.0
Acetic acid	1.02 ± 0.12	5.0

[a] Each value (mean of six measurements) was obtained by comparing the current for a mixture of a 20 μM interfering substance and 10 μM H_2O_2 with that for 10 μM H_2O_2 alone.

Table 2
Comparison of the developed H_2O_2 biosensor with other protein–RTIL-based biosensors.

Types of H_2O_2 electrode	Linear range (μM)	Detection limit (μM)	Stability	Reference
GNRs@SiO_2–Mb/RTIL–sol–gel/GCE	0.2–180	0.12	93%/21d	This work

Table 3
Determination of H_2O_2 concentration in an eyedrop sample with the biosensor and the $KMnO_4$ titration method, respectively.

H_2O_2 found by the biosensor (mM)			Average value (mM)	R.S.D. (%)	H_2O_2 average value found by $KMnO_4$ titration (mM)
0.8546	0.7136	0.8477	0.8220	7.8	0.8450
0.8193	0.8750				

standard deviation (R.S.D.) was 4.2% for six successive assays. To evaluate the electrode-to-electrode reproducibility, six GNRs@SiO_2–Mb/RTIL–sol–gel/GCEs were prepared under the same conditions independently. The R.S.D. of the prepared biosensors was 9.7%. The storage stability of the biosensor was also studied. When not in use, the electrode was suspended at 4 °C in a refrigerator. The response to 10 μM H_2O_2 retains 92.6% of its initial currents after three weeks storage. The good long-term stability could be mainly attributed to the excellent biocompatible microenvironment around the myoglobin provided by the composite film and the three-dimensional network structure of the RTIL–sol–gel film preventing the leaking of the biomacromolecules. Due to the good biocompatibility of GNRs@SiO_2 and inherent conductivity of [bmim][BF_4], the novel composite film could provide an excellent biosensing platform for realizing direct electrochemistry and electrocatalysis of Mb along with good stability. The analytical performance of the GNRs@SiO_2–Mb/RTIL–sol–gel/GCE developed in this study was compared with other protein–RTIL-based biosensors as shown in Table 2. As can be observed, our proposed biosensor exhibited excellent performance in terms of wide linear range, low limit of detection and high stability, which fulfill the requirement of in vivo or on line tracking of H_2O_2 concentration.

3.6. Selectivity and real sample analysis of the H_2O_2 biosensor

Selectivity is also important in practical use of the biosensor. In our experiment, six interfering substances were tested and the results are listed in Table 1. It can be observed that glucose, glycin, ascorbic acid, citric acid, ethanol, and acetic acid did not cause significant interferences to the determination of H_2O_2. The high selectivity of GNRs@SiO_2–Mb/RTIL–sol–gel/GCE verified its applicability of the proposed biosensor for real sample analysis Table 2.

To further assess the possible application of our proposed biosensor for real analytical usefulness, we investigated the concentration of H_2O_2 in commercial eyedrops. As listed in Table 3, using the proposed biosensor, the mean concentration of H_2O_2 in the sample was detected to be 0.822 mM, which was close to the actual concentration determined by the potassium permanganate titration method. This suggests that the developed biosensor is reliable and effective to determine H_2O_2 in industry or medicine sample.

4. Conclusions

In this work, a novel nanocomposite film based on biocompatible GNRs@SiO_2, conductivity [bmim][BF_4] and silica sol–gel was prepared and applied in Mb immobilization and biosensor construction. Due to the excellent biocompatible microenvironment and good conductivity provided by GNRs@SiO_2 and RTIL–sol–gel film, direct electrochemistry of the immobilized Mb was realized. The electrochemical results revealed that the GNRs@SiO_2–Mb/RTIL–sol–gel/GCE showed good bioelectrocatalytic activity in the reduction of both H_2O_2 and NO_2^-. The resulting biosensor exhibited excellent analytical performance in the determination of H_2O_2 and NO_2^-, with wider linear range, lower detection limit, and smaller K_m^{app} value than previously reported materials. The biosensor also showed good precision, reproducibility and storage stability, and acceptable accuracy for real samples determination. Therefore, the GNRs@SiO_2/RTIL–sol–gel hybrid material provides a promising matrix for the fabrication of electrochemical biosensors, and may find wide potential applications in biomedical detection and environmental analysis.

ABSTRACT

Methods for the detection and estimation of diphosgene and triphosgene are described. These compounds are widely used phosgene precursors which produce an intensely colored purple pentamethine oxonol dye when reacted with 1,3-dimethylbarbituric acid (DBA) and pyridine (or a pyridine derivative). Two quantitative methods are described, based on either UV absorbance or fluorescence of the oxonol dye. Detection limits are ~4 μmol/L by UV and <0.4 μmol/L by fluorescence. The third method is a test strip for the simple and rapid detection and semi-quantitative estimation of diphosgene and triphosgene, using a filter paper embedded with dimethylbarbituric acid and poly(4-vinylpyridine). Addition of a test solution to the paper causes a color change from white to light blue at low concentrations and to pink at higher concentrations of triphosgene. The test strip is useful for quick on-site detection of triphosgene and diphosgene in reaction mixtures. The test is easy to perform and provides clear signal readouts indicative of the presence of phosgene precursors. The utility of this method was demonstrated by the qualitative determination of residual triphosgene during the production of poly(bisphenol-A carbonate).

Phosgene and its safer derivatives – diphosgene and triphosgene – are industrially important chemicals used in the manufacture of polyurethanes [1] and polycarbonates [2] and in the synthesis of various active pharmaceutical ingredients [3]. This market sector generates approximately 8 million tons of products and the global demand for phosgene is about 5 million tons per year [4]. Phosgene is very corrosive and has a high acute toxicity if inhaled. The danger of inhalation poisoning is particularly grave, since phosgene can be lethal before its odor is recognizable [5].

Current methods for the detection of phosgene are predominantly electrochemical and spectrophotometric [6,7]. A cellulose tape impregnated with 4-nitrobenzylpyridine and benzylaniline has been developed for monitoring phosgene in air [8]. It has also been shown that 1,2-bis-nucleophiles like 2-aminophenol can be used to detect phosgene by mass spectrometry [9].

Over the past few decades, safer alternatives to phosgene, e.g. diphosgene [10,11] and triphosgene [12,13], have been developed. Diphosgene (trichloromethyl chloroformate), is a liquid and triphosgene (bis-(trichloromethyl) carbonate), a solid, at room temperature, making them much easier to handle than gaseous phosgene. In addition, they are more stable to decomposition. Recently colorimetric methods for the detection of diphosgene vapors were reported [14,15] and a FRET (Förster resonance energy transfer) method was developed for triphosgene [16].

In spite of these advances, there is still a need for a quick and reliable test to detect phosgene precursors *in-situ*. In addition, since triphosgene is increasingly used as a reagent in chemical synthesis, it would be advantageous for the user to have a simple and quick method to detect triphosgene in reaction mixtures. In the current work, we demonstrate efficient detection systems for diphosgene and triphosgene, which have rapid response times and stable reaction products.

Kohn and coworkers developed a spectrophotometric method for the detection of organic cyanates [17] and carbodiimides [18] based on work by König [19] on colored oxonol dyes. They have shown that organic cyanates react with dimethylbarbituric acid in pyridine–H_2O to produce an intensely colored purple oxonol dye. The mechanism of color formation is based on the nucleophilic reaction of pyridine with an activated electrophilic species. This reaction is also used for the detection and determination of HCN [20]. A similar reaction between phosgene precursors and pyridine, and the subsequent reaction of the resulting intermediate with dimethylbarbituric acid is employed here to detect nanomole quantities of diphosgene and triphosgene. In pyridine–H_2O, the oxonol dye can be detected by absorbance or fluorescence, the latter extending detection limits for triphosgene to <0.4 μmol/L (or 0.4 nmoles of analyte in a 1 mL cuvette). Additionally a methodology for the preparation of a test strip is illustrated, which can be

used for rapid visual detection and semi-quantitative estimation of triphosgene.

1. Experimental

1.1. Materials

1,3-Dimethylbarbituric acid, 3-cyanopyridine, 4-(4-nitrobenzyl)-pyridine and poly(4-vinylpyridine) were obtained from Sigma Aldrich. 4-Cyanopyridine, 4,4′-bipyridine, 2,2′-bipyridine, cyanuric acid and dimethylaminopyridine and pyridine were obtained from Acros Chemicals.

1.2. Spot test

Silica gel plates (0.5 cm × 5 cm) were dip coated with a solution of 1,3-dimethylbarbituric acid (20 mg/mL) and poly(4-vinylpyridine) (15 mg/mL) in ethanol and air-dried overnight. Selectivity for various triphosgene type reagents was tested by spotting a solution (5 mg/mL) of each test compound on a silica gel plate previously moistened with a mist of water.

1.3. System 1: absorbance method

All absorption measurements were carried out on a Thermo-Fisher Evolution 100 UV–VIS spectrophotometer using 1 cm quartz cuvettes at room temperature.

(i) Reaction of triphosgene with pyridine and 1,3-dimethylbarbituric acid: Triphosgene solutions of various concentrations (0.25–2 mg/mL) were prepared in CH_2Cl_2 and aliquots (5–50 μL) were added to solutions of 1,3-dimethylbarbituric acid (30 mg, 0.19 mmol) in 1 mL of pyridine–H_2O (9:1, v/v). An intense blue colored solution with a red fluorescence developed instantly.

(ii) Reaction of triphosgene with pyridine derivatives and 1,3-dimethylbarbituric acid in methanol–H_2O: Triphosgene solutions of various concentrations (0.25–2 mg/mL) were prepared in CH_2Cl_2 and aliquots (5–50 μL) were added to solutions of 4,4′-bipyridine (30 mg, 0.19 mmol) and 1,3-dimethylbarbituric acid (30 mg, 0.19 mmol) in 1 mL of methanol–H_2O (9:1, v/v). A pink color developed within 10 s, which then changed to an emerald (greenish blue) color within 1 min. The same protocol was used for the other pyridine derivatives. The absorption maximum was dependent upon the pyridine derivative.

1.4. System 2: fluorescence method

Fluorescence spectra were recorded on a Varian Eclipse spectrofluorimeter using a 1 cm quartz cuvette at room temperature. The emission spectrum was collected between 600 and 700 nm. All spectra were recorded at identical PMT voltage and slit widths.

Reaction of triphosgene with 1,3-dimethylbarbituric acid in pyridine–H_2O: Triphosgene solutions of various concentrations (0.025–0.2 mg/mL) were prepared in CH_2Cl_2 and aliquots (5–50 μL) were added to solutions of 1,3-dimethylbarbituric acid (30 mg, 0.19 mmol) in 1 mL of pyridine–H_2O (9:1, v/v). An intense blue colored solution with a red fluorescence developed instantly.

1.5. System 3: test strips

(i) For higher concentrations of triphosgene: 3-cyanopyridine (42 mg), poly(4-vinylpyridine) (14 mg) and 1,3-dimethylbarbituric acid (43 mg) were dissolved in ethanol (2 mL) and coated onto a filter paper (VWR 413) by dripping the solution as evenly as possible over the paper. The filter paper was dried. Prior to the test, the paper was moistened with a mist of water and drops of triphosgene solutions at two different concentrations (0.84 and 6.72 mM) were added onto the paper. Within 1–2 min, the filter paper became pink at the higher concentration of triphosgene and light blue at the lower concentration.

(ii) For lower concentrations of triphosgene: poly(4-vinylpyridine) (30 mg) and 1,3-dimethylbarbituric acid (40 mg) were dissolved in ethanol (2 mL) and coated onto a filter paper (VWR 413) by dripping the solution as evenly as possible over the paper. Drops of triphosgene solutions (0.84 and 6.72 mM) were added onto the paper and both the lower and higher concentrations of triphosgene gave a blue color to the test strip. The blue color was more intense for the higher concentration of triphosgene.

2. Results and discussion

Phosgene precursors react with 1,3-dimethylbarbituric acid (DBA) in pyridine–H_2O (9:1, v/v) to produce an intense blue colored solution (λ_{max} 598 nm) with a red fluorescence. As shown earlier by Kohn et al. [17], for organic cyanates and carbodiimides, the species at 598 nm is the pentamethine oxonol dye that is formed by the reaction with DBA in pyridine–H_2O. From the proposed mechanism, phosgene precursors should react with DBA similarly to the cyanates and carbodiimides to produce the same oxonol dye (Scheme 1). Support for this comes from the similarity of the absorption spectra of the oxonol dye (prepared by Kohn et al.) in pyridine–H_2O (9:1) and that of the reaction between triphosgene and DBA in pyridine–H_2O (9:1) (Fig. 1).

First, the selectivity of the assay was established by comparing the reaction of various phosgene substitutes phosgene on silica gel plates that were dip coated with a solution of 1,3-dimethylbarbituric acid and poly(4-vinylpyridine). Each test solution (5 mg/mL) was spot tested on the silica gel plates using a capillary tube. The solution of triphosgene gave a purple spot that turned to a blue spot in <1 min. Diphosgene also gave a purple/pink spot instantly. 1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC) and *N*,*N*′-dicyclohexylcarbodiimide (DCC) also gave a purple spot, although the color formation with carbodiimide was much slower (2–3 h). Acetyl chloride, di-t-butyl dicarbonate (Boc_2O) and benzylchloroformate gave a faint yellow color, and all other compounds failed to produce any color (Table 1). This established the potential of the current assay for the rapid and selective detection of diphosgene and triphosgene. We then developed three different analytical methods.

2.1. System 1: absorbance measurements

Two quantitative assays for triphosgene were developed. The first method was based on the reaction between triphosgene and

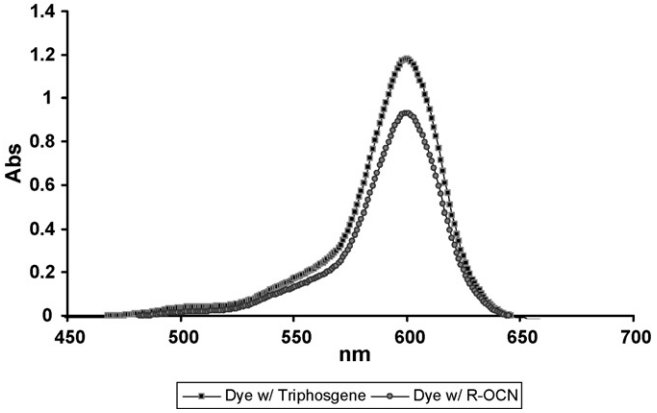

Fig. 1. Comparison of absorption spectra of the dye prepared by the method in Ref. [16] and that of the reaction product of triphosgene and DBA in pyridine–H_2O.

Table 1
Selectivity of the assay.

Test compound	Test result
Triphosgene (TP)	Purple spot turning to blue spot in ~20 s
Diphosgene	Pink spot
DCC	Pink spot; slower response time (2–3 h)
EDC	Pink spot; slower response time (2–3 h)
Acetyl chloride	Faint yellow spot
Benzyl chloroformate	Faint yellow spot
FMOC-Cl	Faint yellow spot
Di-t-butyl dicarbonate (Boc_2O)	Yellow spot
Oxalyl chloride	Colorless
Carbonyldiimidazole (CDI)	Colorless
Disuccinimidyl carbonate (DSC)	Colorless
Trifluoroacetic anhydride	Colorless
PyBOP	Colorless
Choline chloroformate HCl	Colorless

pyridine and the subsequent reaction with 1,3-dimethylbarbituric acid in pyridine–H_2O, which yields an oxonol dye with λ_{max} at 598 nm. Quantitative determination of triphosgene concentration was established by monitoring the absorbance of the oxonol dye at this wavelength. As seen in Fig. 2, the detection limit was about 2 μmol/L, and the dynamic range extends to 80 μmol/L.

In order to extend the dynamic range, we evaluated other pyridine derivatives. In agreement with the proposed mechanism, the λ_{max} of the absorbing species depends upon the pyridine derivative. Noteworthy is the fact that derivatives that contain electron-withdrawing groups give a positive test, (4-cyanopyridine λ_{max} 648 nm; 4-(4-nitrobenzyl)pyridine λ_{max} 624 nm; 3-cyanopyridine λ_{max} 563 nm; 4,4′-bipyridine λ_{max} 618 nm), while those that contain electron-donating groups like dimethylaminopyridine do not produce colored products.

For development of an analytical method we selected 4,4′-bipyridine due to its relatively quick response time (<1 min), high absorbance and stability of the colored product (12–18 h). Immediately after the addition of triphosgene to a solution of 4,4′-bipyridine and DBA in MeOH–H_2O (9:1, v/v), a pink solution forms that turns to an emerald (greenish blue) colored solution within 1 min. As expected from the proposed mechanism, the absorbance maximum of the oxonol dye is red shifted to 618 nm due to a more delocalized structure resulting from 4,4′-bipyridine. The quantitative determination of triphosgene was established by monitoring the absorbance of the oxonol dye at this wavelength. The range of detection of triphosgene is between 4 and 230 μmol/L of triphosgene (Fig. 3). Similar results were obtained when the experiment was done in ethanol–H_2O, isopropanol–H_2O or sec-butanol–H_2O.

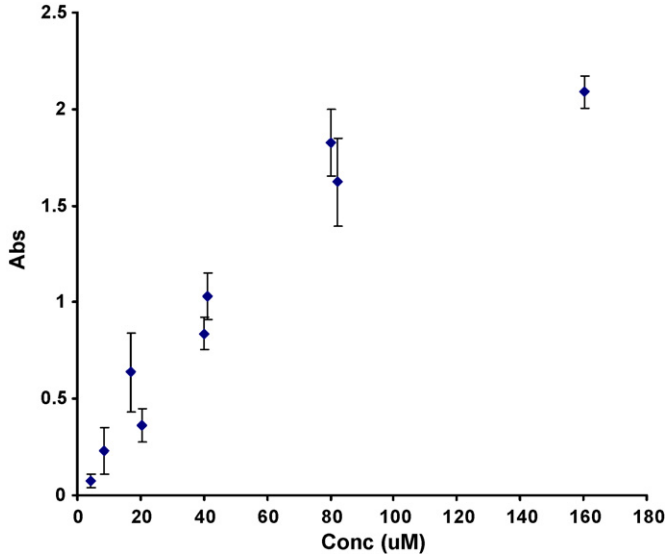

Fig. 2. Dynamic range of detection of triphosgene utilizing the 1,3-dimethylbarbituric acid/pyridine–H_2O method showing breakdown of linearity at 80 μM.

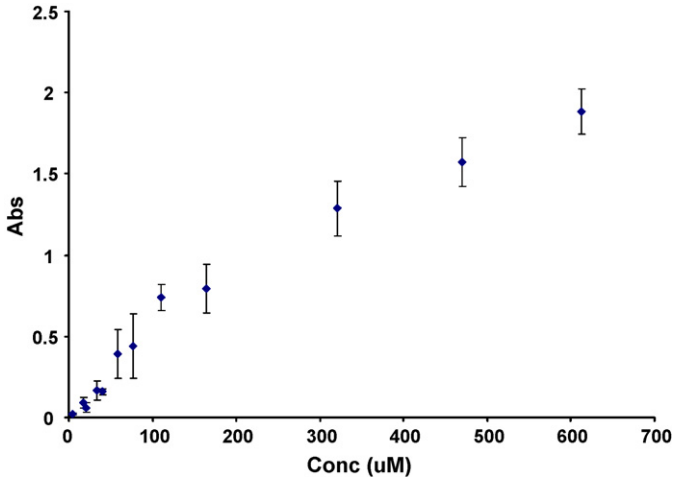

Fig. 3. Dynamic range of detection of triphosgene utilizing the 1,3-dimethylbarbituric acid/4,4′-bipyridine in MeOH–H_2O method showing enhanced linearity over system shown in Fig. 1.

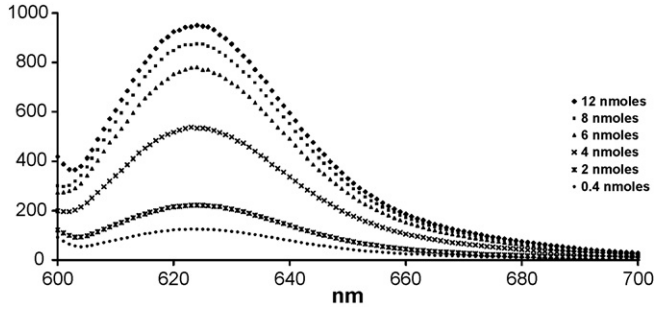
2.2. System 2: fluorescence measurements of the reaction of triphosgene with 1,3-dimethylbarbituric acid in pyridine–H_2O

The high sensitivity of fluorescence based detection methods have resulted in their use for the detection of a wide variety of chemicals [21]. The reaction of triphosgene with 1,3-dimethylbarbituric acid in pyridine–H_2O produces an oxonol dye, which has a very high extinction coefficient and is also highly fluorescent. Hence the possibility of detecting and estimating the amount of triphosgene from the fluorescence of the pentamethine oxonol dye was examined. The fluorescence was recorded between 600 and 700 nm and the λ_{max} of the emission peak is at 624 nm. As seen in Fig. 4, even a concentration of 0.4 μmol/L of triphosgene can be reliably measured and the resulting plot of fluorescence intensity and concentrations has a high correlation. Potentially, an even lower amount of triphosgene can be detected by increasing the amount of DBA in the reaction mixture and/or increasing the sensitivity of the instrument. A recent study [16] has shown that triphosgene can be detected by FRET at concentrations of 5×10^{-5} M. The detection limit of this current spectrofluorimetric method is significantly lower.



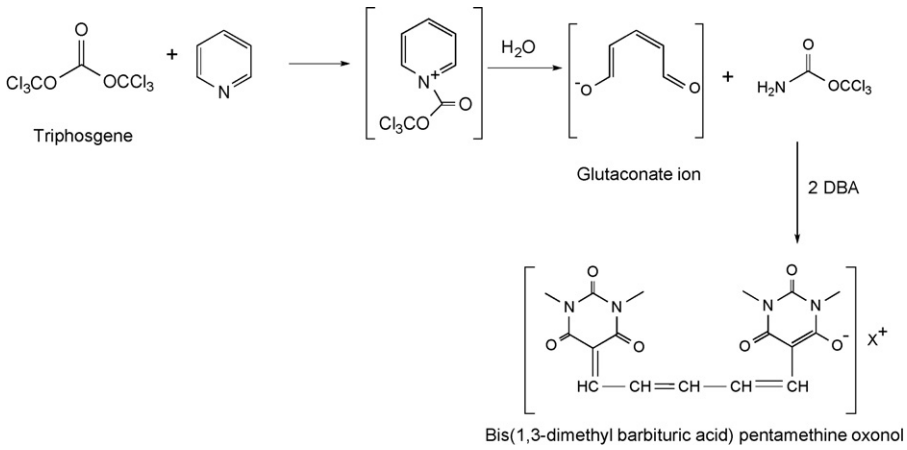


Fig. 4. Fluorescence spectra of pentamethine oxonol dye formed from the reaction of triphosgene, 1,3-dimenthylbarbituric acid (DBA) in pyridine–H_2O (9:1). Shown are spectra taken upon addition of aliquots of a triphosgene solution to a solution of DBA in pyridine–H_2O.

Scheme 1. Mechanism of formation of pentamethine oxonol dye.

2.3. System 3: fabrication of test strips for the detection and estimation of triphosgene

A test strip, similar to pH paper, a glucose test [22] or a pregnancy test [23] is widely used and highly desirable for simple and rapid monitoring. In order to facilitate the adoption of our methodology by end users – for example chemists using triphosgene as a reagent, it would be advantageous to develop a test where the user adds a drop of the reaction mixture to the test strip and determines the presence of a phosgene precursor by the color of the strip. To develop such a test strip, we employed the pyridine derivative – poly(4-vinylpyridine).

A filter paper (VWR 413) was coated with a solution of poly(4-vinylpyridine) (15 mg) and DBA (20 mg) in 1 mL ethanol, which was then dried. Addition of a triphosgene test solution (in CH_2Cl_2) to the strip (pre-moistened with a mist of water) produces a blue color within 1 min. This method was able to clearly indicate the presence of triphosgene since the color change is very discernible from white to light blue (Fig. 5).

Fig. 5. Test strips contain PVP and DBA (1, 2) or PVP, 3CN-Py and DBA (3, 4) embedded within a filter paper. The tests show a difference in color with and without 3CN-Py. PVP: poly(4-vinylpyridine); 3CN-Py: 3-cyanopyridine; DBA: dimethylbarbituric acid; TP: triphosgene.

Although this is a powerful 'yes' or 'no' method for the presence of triphosgene, it is not very useful for the semi-quantitative estimation of triphosgene. To generate a more quantitative method, a system that produces different colors for two different concentrations of triphosgene was designed.

Test strips were prepared using a combination of polyvinylpyridine (14 mg) and 3-cyanopyridine (42 mg) along with DBA (43 mg) in 2 mL ethanol. A triphosgene solution at a concentration of 6.7 mM resulted in a pink color on the paper, while a triphosgene concentration of 0.84 mM produced a blue color. Without the 3-cyanopyridine, both the higher and lower concentrations of triphosgene give a blue color although the intensity of the color is less for the lower concentration. These results provide the basis to develop semi-quantitative methods for the determination of the amount of triphosgene. Due to the non-homogeneous nature of our coating process, there is variability in the color generated on various parts of the paper. However this is a simple and promising method for the semi-quantitative detection and estimation of triphosgene. In contrast, the published cellulose tape method for the estimation of phosgene shows only a single color at all concentrations.

This test strip also works for phosgene vapors. The decomposition of a 5% solution of diphosgene in toluene was initiated with triethylamine and a test strip positioned above this solution turns red immediately. However, the test strip decolorizes within a few minutes due to the presence of HCl vapors.

2.4. Utilization of the assay to indicate the end-point of polycarbonate synthesis

Polycarbonates such as poly(bisphenol-A carbonate) and tyrosine derived polycarbonates, are commercially valuable materials that are efficiently synthesized using triphosgene [24,25]. Due to its toxicity, it is crucial that all excess triphosgene be quenched prior to work up and precipitation of the polymer. The utility of the current assay was demonstrated by using it to test for the presence of triphosgene during the polymerization reactions of poly(bisphenol-A carbonate) and tyrosine polycarbonates and to confirm that all the triphosgene was quenched prior to precipitation of the polymer. During the course of the reaction, aliquots of the reaction mixture were taken and added to solutions of 1,3-dimethylbarbituric acid (30 mg) in pyridine–H_2O, and the presence of triphosgene was indicated by the formation of a blue solution. After the reaction was quenched, the same test produced a colorless solution indicating that the triphosgene has been consumed (within the limits of detection of this test).

2.5. Comparison between the current assay and an established method

A published method for the determination of phosgene is to use a mixture of 4-(4-nitrobenzylpyridine) and *N*-phenylbenzylamine, which produces a yellowish-orange color to indicate the presence of phosgene. Although the above protocol is most commonly used for the detection of phosgene or diphosgene in air samples, we compared our assay with this published procedure under the same experimental conditions. In the experiment, aliquots of triphosgene in CH_2Cl_2 were added to either a solution of 1,3-dimethylbarbituric acid in pyridine–water (test method) or to a solution of 4-(4-nitrobenzylpyridine) and *N*-phenylbenzylamine (control method) in methanol. In the test method, the change in color was obvious and readily discernable – from a clear solution to a blue/red solution while in the control method the change in color before (light yellow) and after (yellowish-orange) addition of triphosgene was sutble and more difficult to detect. Hence the assay developed here presents a clearer indication of the presence of phosgene precursors.

3. Conclusion

Due to the increased use of phosgene precursors (notably diphosgene and triphosgene) in industrial and academic laboratories, and their potential toxicity, methods for *in-situ* detection and estimation of these reagents are very useful. The reaction system consisting of pyridine and dimethylbarbituric acid system described here is an efficient method for *in-situ* detection and estimation of diphosgene and triphosgene. The long wavelength absorbance (or fluorescence) of the resulting oxonol dye decreases the possibility of interference from other chemicals in the reaction mixture. In addition, this reaction system is highly sensitive, allowing the detection of phosgene precursors in nanomole quantities of analyte. Three different protocols were developed which makes it feasible for the end user to adopt a method based on the user's needs and available instrumentation.

ABSTRACT

This paper describes the optimization and validation of an analytical methodology for the determination of losartan potassium in capsules by HPLC using 2^{5-1} fractional factorial and Doehlert designs. This multivariate approach allows a considerable improvement in chromatographic performance using fewer experiments, without additional cost for columns or other equipment. The HPLC method utilized potassium phosphate buffer (pH 6.2; 58 mmol L^{-1})–acetonitrile (65:35, v/v) as the mobile phase, pumped at a flow rate of 1.0 mL min^{-1}. An octylsilane column (100 mm × 4.6 mm i.d., 5 μm) maintained at 35 °C was used as the stationary phase. UV detection was performed at 254 nm. The method was validated according to the ICH guidelines, showing accuracy, precision (intra-day relative standard deviation (R.S.D.) and inter-day R.S.D values <2.0%), selectivity, robustness and linearity (r = 0.9998) over a concentration range from 30 to 70 mg L^{-1} of losartan potassium. The limits of detection and quantification were 0.114 and 0.420 mg L^{-1}, respectively. The validated method may be used to quantify losartan potassium in capsules and to determine the stability of this drug.

1. Introduction

Losartan potassium, chemically described as 2-butyl-4-chloro-1-[*p*-(*o*-1*H*-tetrazol-5-ylphenyl)benzyl] imidazole-5-methanol monopotassium salt [1], is an angiotensin II receptor (type AT1) antagonist for the treatment of hypertension. Losartan has been demonstrated to be superior to previous peptide receptor antagonists and angiotensin converting enzyme (ACE) inhibitors because of its enhanced specificity, selectivity and tolerability [2,3]. Losartan potassium has a molecular weight of 461, a p*K*a value of 4.9 and an aqueous solubility of 3.3 mg mL^{-1} at pH 7.8 [4].

Several methods have been reported for the analysis of losartan potassium and its degradation products. In biological fluids, the active principle has been determined by high performance liquid chromatography (HPLC) methods [5–8]. For applications in pharmaceutical products, there are methods that make use of HPLC [9–18], high performance thin layer chromatography (HPTLC) [19,20], capillary electrophoresis (CE), capillary electrochromatography (CEC) [21] and spectrophotometry [22–24]. Recently, there have been reports in the literature of the employment of HPLC for bioequivalence studies of tablets containing losartan potassium [25,26]. The HPLC methods described employ different conditions and columns, which result in different performances. The drug substance monograph on losartan potassium provided by the United States Pharmacopoeia [1] recommends an HPLC method on a C-18 (4.0 mm × 25 mm) column with a 0.1% solution of phosphoric acid in water and acetonitrile (60:40, v/v) as the mobile phase, flow rate at 1 mL min^{-1}, column temperature at 35 °C, methanol as diluent and detection at 254 nm.

Despite the variety of analytical methods for losartan potassium in pharmaceutical products or biological fluids, a routine pharmaceutical analysis laboratory may encounter difficulty in applying a described method due to a limited availability of chromatographic columns or equipment. This challenge points to the necessity of analytical method development using conventional materials, reagents and equipment. Moreover, in spite of the utility and benefits of the modern focus of method development in pharmaceutical analysis on enhancing analytical performance, reducing costs for routine analysis is also an important concern.

A good tool to be included in method development strategies or in the improvement of analytical performance is the multivariate approach, which without additional costs can yield a reduction in the number of experiments and, consequently, in the analysis time. Furthermore, the multivariate approach allows investigation of the interaction effects between parameters, which is not possible with a univariate approach [27].

Considering the variability of chromatographic conditions used in analysis of losartan potassium and the necessity of cost reductions in routine pharmaceutical analysis, the aim of the present work was to develop and validate a simple and reliable HPLC method for analysis of losartan potassium in capsules, as an alternative to existing methods. A multivariate approach was adopted as an analytical tool to study the influence of different chromatographic conditions and to improve chromatographic performance, using the available resources in our laboratory.

2. Experimental

2.1. Chemical and reagents

All reagents used in the experimental work were of analytical grade. Potassium dihydrogenphosphate (KH_2PO_4), phosphoric acid, sodium hydroxide, hydrochloride acid and HPLC grade acetonitrile were purchased from Vetec® (Rio de Janeiro, Brazil); reverse osmosis water obtained using a reverse osmosis water purifier OS 10 LTH (Gehaka®, São Paulo, Brazil) was used to prepare the mobile phase. Losartan potassium salt of 98.90% purity was supplied by IPCA Laboratories Limited® (Athal, India). Losartan potassium capsules were supplied by three local drug stores, coded as A, B and C. They were described as containing 50 mg losartan potassium (as the anhydrous base of the drug) and the following inactive excipients: magnesium stearate, aerosil, sodium dodecyl sulphate, talc, starch and microcel MC-102 1. The placebo mixture, containing pharmaceutical grade excipients with the same quantitative composition as the pharmaceutical formulations, was also obtained from local drug stores A, B and C.

2.2. Apparatus and chromatographic conditions

Chromatographic separations were carried out using a Shimadzu® HPLC system (Kyoto, Japan) series LC-10A, consisting of a LC AVP pump, a CLASS-VP 5.02 integration system, a DGU-14 A degasser, a 7725i manual injector with a 20 μL loop (Rheodyne®, California, USA), a SPD-10AVP integrated UV detector, a FCV-10ALVP valve, a CTO-10AVP column oven and a SCL-10 AVP controller. The peak purity was determined on a SPD-M 10A VP photodiode-array (PDA) detector. Chromatographic columns and equipment consisted of a LiChroSpher RP-18 (Merck®, Darmstadt, Germany) packed column (100 mm × 4.6 mm i.d., 5 μm particle size) combined with a guard column (10 mm × 4.6 mm i.d.) and a Nucleosil C8 analytical column, 5 μm particle size, 125 mm × 4.6 mm i.d. (Macherey Nagel®, Düren, Germany) with a guard column (20 mm × 4.6 mm i.d., 5 μm); digital pH meter PA 200 (Marconi® S.A., Piracicaba, Brazil); ultrasonic Bath model USC2800A (Unique®, São Paulo, Brazil); analytical balance model 410 (Kern®, Kern, Germany); reverse osmosis water purifier OS 10 LTH (Gehaka®, São Paulo, Brazil); vacuum filtration system (Millipore®, Bedford, USA); and PTFE membrane filters with a pore size of 0.45 μm and diameter of 13.0 mm (Millipore®, Bedford, USA). Peak identify was confirmed by retention time comparison.

The mobile phase was composed of acetonitrile and phosphate buffer. The proportions of these mobile phase components as well as the phosphate buffer pH were changed according to each level of the multivariate optimization. The mobile phases were prepared daily, filtered through a 0.45 μm membrane filter Millipore and degassed using the degasser of the chromatographic system prior to use. The UV detection was carried out at 254 nm wavelength, and the injection volume was 20 μL.

2.3. Preparation of solutions

2.3.1. Stock and working standard solutions of losartan potassium

Stock standard solution of 0.5 mg mL^{-1} of losartan potassium was prepared by accurately weighing approximately 25 mg of losartan potassium (98.90% purity) into a 50 mL volumetric flask and diluting to volume with mobile phase.

Working solutions were prepared immediately before use by suitable dilutions of the corresponding stock solutions to appropriate concentration levels, using mobile phase as the diluent.

2.3.2. Sample capsules solution

Pharmaceutical formulations from three different local drug stores were used and coded as A, B and C. In each case, 20 capsules were weighed and the content of the capsules was removed. The emptied shells were weighed, and the average weight of the contents was obtained by subtracting the weight of the shell from the weight of the full 20 capsule, as recommended by the United States Pharmacopeia [1]. The weight equivalent to 0.5 average dosage unit of each product was transferred into a 50 mL volumetric flask and diluted to volume with mobile phase. The solution was filtered, then diluted immediately before use to appropriate concentration levels, using mobile phase.

2.3.3. Losartan potassium excipient solutions

Excipients solutions (A, B and C) were prepared by transferring a homogeneous mixture of the placebo mixture with the same quantitative composition as the pharmaceutical formulations (A, B and C) into a 50 mL volumetric flask and diluting to volume with mobile phase. This solution was filtered, and 1 mL was transferred to a 10-mL calibrated flask and diluted to the mark with mobile phase.

2.4. Screening design to investigate the chromatographic parameters

The experimental approach adopted in this work was carried out according to the literature [28] in order to investigate which experimental factors are the most important and which factors do not significantly affect the experimental results. Five variables were examined in two levels, lower (−) and upper (+). The factors and their levels were as follows: pH of buffer used in the mobile phase (2.5 and 7.0), proportion of the phosphate buffer in the mobile phase (60% and 70%), column temperature (25 °C and 35 °C), mobile phase flow rate (0.8 and 1.2 mL min^{-1}) and column type (silica C8 and RP-18). A losartan potassium work standard solution at 50 mg L^{-1} concentration was utilized in these experiments (Section 2.3.1).

The analytical response used in this experimental design was based on the theoretical plates/retention time ratio (TP/RT), in order to optimize analytical performance with a reduced analysis time. The number of theoretical plates was calculated according to chromatographic theory, via Eq. (1):

$$\mathrm{TP} = 16\left(\frac{tr}{Wb}\right)^2 \quad (1)$$

where *tr* is retention time of the losartan potassium and *Wb* is width of the peak at its base, obtained by extrapolating the relatively straight sides of the peak to the baseline.

After establishment of answers based on the theoretical plates/retention time ratio, a 2^{5-1} fractional factorial design was chosen with a total of 16 experiments, and each experiment was carried out twice in random order. In Table 1, the combinations of

Estimated error	23.03

factors and their levels are shown with the results of each experiment.

The values of responses were used to calculate the mean values of the analytical responses, as well as the variance of each experiment (Table 1). The variance of each experiment was obtained using Eq. (2):

$$s^2 = \frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})^2, \tag{2}$$

where n is the number of times that the assay was repeated, x_i represents the analytical responses of each assay (theoretical plates/retention time), and $\bar{x}$ represents the mean value of the analytical responses. The analytical responses were also used to calculate the estimated contrast of each factor (Table 2). Estimated contrast, like the effect of each factor, is the average of all the values obtained (in this case, theoretical plates/retention time) when the factors were at the positive level, minus the average of the values corresponding to the lines where there are negative levels. For example, the estimated contrast for phosphate buffer proportion is obtained from: [(1/8)(368.55 + 499.25 + 545.73 + 1205.60 + 557.64 + 568.69 + 1245.94 + 789.18) − [(1/8) (1035.77 + 1062.29 + 1411.91 + 1166.70 + 1230.17 + 1372.57 + 1283.19 + 1802.09] = −573.02. The estimated contrasts of the interaction were calculated similarly to the main estimated contrasts. The levels column (−1 and +1) of the interaction factors is equal to the product of the columns of the main factors, element to element on the same row.

In order to determinate the statistical significance of the factors and their interactions, the standard variance (s_p^2) was calculated via Eq. (3):

$$s_p^2 = \frac{(n_A - 1)s_A^2 + (n_B - 1)s_B^2}{(n_A - 1) + (n_B - 1)} \tag{3}$$

where n is the number of times the assay was repeated and s^2 is the variance obtained in each assay. Moreover, the estimated variance of the contrast was obtained from Eq. (4):

$$V(\text{estimated}) = \frac{s_p^2}{n} + \frac{s_p^2}{n} \tag{4}$$

where s_p^2 is the standard variance and n is the number of assays with low and high levels ($n = 8$). The error of the estimate of the contrast was obtained by extracting the root of the variance. By multiplying the error by the critical $t_{16\text{-}1}$ (2.120) for a confidence interval of 95%, the estimated error was obtained.

2.5. Final optimization by Doehlert design

After establishing the significant factors from the fractional factorial design, the final optimization was further carried out using a Doehlert design, which comprises seven conditions, with the central point carried out in triplicate [27]. The factors and their levels were the pH of buffer used in the mobile phase (2.0; 3.25; 4.5; 5.75 and 7.0) and the proportion of the phosphate buffer in the mobile phase (60%; 65% and 70%). From this design, it was possible to apply the response surface method (RSM) to optimize the factors' levels. All data were processed using the STATISTICAL package software (version 6.0; StatSoft, Inc., Tulsa, OK, USA).

2.6. Chromatographic conditions after optimization

After method optimization, HPLC analyses were carried out using potassium phosphate buffer (pH 6.2; 58 mmol L^{-1}) and acetonitrile (65:35, v/v) as mobile phase, flow rate at 1.0 mL min^{-1} with column temperature of 35 °C, Nucleosil C8 analytical column, UV detection wavelength at 254 nm and 20 μL of injection volume.

2.7. Method validation

Method validation was performed following ICH and FDA specifications [29,30] for selectivity, linearity, accuracy, precision, robustness, detection limit and quantitation limit.

3. Results and discussion

3.1. Method development and optimization

Different methods are described for the analysis of losartan potassium in pharmaceutical products by using different chromatographic conditions. The pharmacopoeia method for analysis of drug substance [1], when applied for the determination of losartan potassium in capsules, yields a smaller number of theoretical plates than expected (less than 2000). This phenomenon was attributed to the differences between the analytical column recommended by USP and the available columns in our laboratory. Therefore, we decided to develop an HPLC analytical method for analysis of losartan potassium capsules, taking into consideration the influence of chromatographic parameters on the method and aiming to improve the chromatographic efficiency, with the available resources, through a multivariate approach.

Since theoretical plate number is indicative of column efficiency, we decided to use this parameter as analytical response. However, as expected, it was observed experimentally that the number of theoretical plates increased with the increase of retention time. Considering that retention time should be short in order to decrease analysis time and mobile phase consumption, the response based on TP/RT ratio was successfully employed as a compromise between the higher required theoretical plates and low run time. This condition is appropriate for application by routine quality control laboratories.

The results of the factorial design are shown in Table 2. When the estimated contrasts of factorial design exceed the estimated error, this effect becomes statistically significant [28]. Furthermore, variables with positive estimated contrasts indicate that an increase of their level provides a significant increase in the analytical response, and negative effects mean that a higher TP/RT ratio is obtained with a decrease in the levels of the variables.

Comparing the results of the estimated contrast with the estimated error (Table 2), it was concluded that all factors were statistically significant. The positive estimated contrasts for temperature, pH of the buffer and mobile phase flow rate indicate that the analytical signal increases significantly with increase of these factors' levels. On the other hand, the estimated contrasts for proportion of the phosphate buffer and column type are negative, which indicates that a higher analytical signal will be achieved by decreasing their levels. As column type is a qualitative factor, we decided to adopt the C8 column for the subsequent studies. Column temperature values above 35 °C were not tested because the use of mobile phase at high pH and high temperatures can damage the silica of the stationary phase. Thus, column temperature was set at 35 °C. The increase in the analytical response observed with the increase of the mobile phase flow rate was attributed to the decrease in retention time and, of course, accompanied by the decrease of the theoretical plates. A very high increase of the mobile phase flow rate is not beneficial, because it can harm the process of diffusion of the losartan potassium between the stationary and mobile phases. Therefore, the mobile phase flow rate was fixed at an intermediate value (1 mL min^{-1}).

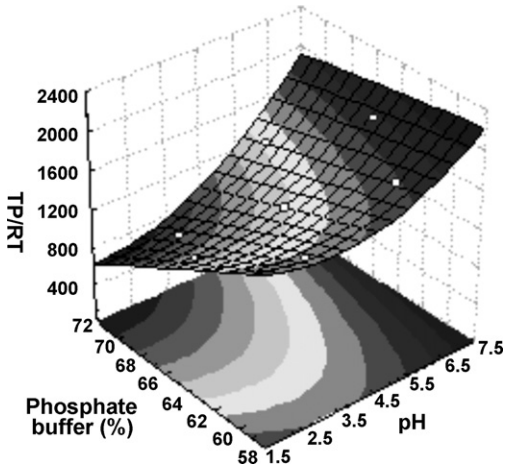

Fig. 1. Response surface of the theoretical plates divided by retention time (TP/RT). The selected working conditions were 65% of 58 mmol L^{-1} phosphate buffer (pH 6.2).

Due to the significant interaction between proportions of the components in the mobile phase and the pH of the buffer used in the mobile phase, a final optimization of these factors was accomplished by Doehlert design (Section 2.5). From this design, the response surface was obtained using the STATISTICAL package software. As verified in Fig. 1, the decrease in proportions of phosphate in the mobile phase when the pH value is low leads to a significant improvement of the analytical signal. On the other hand, when pH is maintained at a high value, for instance pH 7.0, the decrease in proportions of phosphate is only slightly significant. Therefore, using high pH values within the experimental domain, any proportion of phosphate could be employed without significant change in analytical response. In addition, it must be emphasized that such results could never have been observed if a univariate method had been used. So, although high pH values provide the best results, we decided to adopt a phosphate buffer at pH 6.2 in order to preserve the lifetime of the column, while the proportion of phosphate in the buffer at pH 6.2 was fixed at 65%. Smaller ratios of buffer mobile phase content were not used, since it was experimentally observed that this condition can cause a very low retention time.

Therefore, the method developed for the determination of losartan potassium capsules has the following chromatographic parameters: potassium phosphate buffer (pH 6.2; 58 mmol L^{-1})–acetonitrile (65:35, v/v) as mobile phase, flow rate at 1.0 mL min^{-1} with column temperature of 35 °C, C8 analytical column, UV detection wavelength at 254 nm and 20 μL of injection volume.

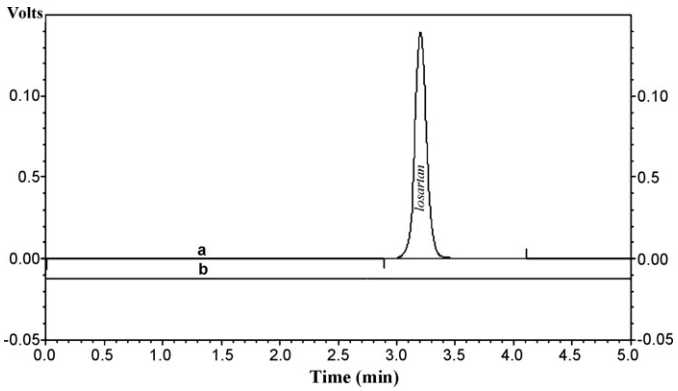

Fig. 2. Chromatogram of losartan potassium capsules (a) and placebo (b).

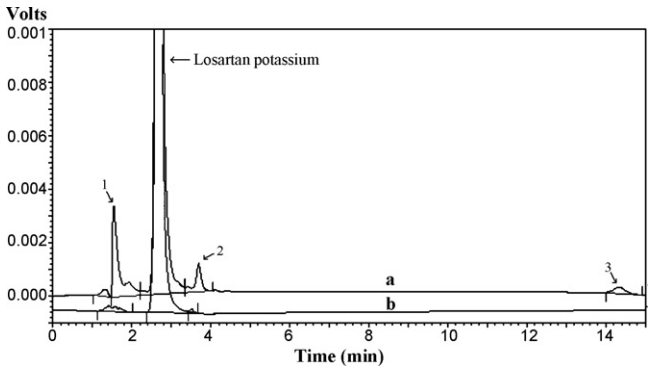

Fig. 3. Chromatogram of losartan potassium reference substance after reflux at 105 °C for 2 h in 1.0 hydrochloric acid (a) and under normal conditions (b).

3.2. Method validation

3.2.1. System suitability testing

System suitability testing was carried out by injecting six replicates of a work standard solution of losartan potassium (Section 2.3.1) containing 50 mg L^{-1} (100% level). According to the FDA [30], the capacity factor (k') must be higher than 2, tailing factor less than 2 and theoretical plate number higher than 2000. These parameters were calculated using CLASS-VP 5.02 software. The observed retention time was 3.19 min; theoretical plates higher than 4900; capacity factor higher than 2.19; and asymmetry of 1.06. All parameters are in accordance with FDA recommendations [30].

3.2.2. Selectivity

Selectivity of the method was evaluated by observing the chromatograms of losartan potassium excipient solutions (Section 2.3.3) and losartan potassium work standard solution at a concentration of 50 mg L^{-1} (Section 2.3.1). The chromatogram depicted in Fig. 2 shows that the excipients have negligible contribution to the losartan potassium peak.

In order to evaluate selectivity of the method for potential degradation products, 25 mg of losartan potassium standard was accurately weighted and diluted in 1.0 mol L^{-1} HCl to a concentration of 50 mg L^{-1}. This solution was heated under reflux at 105 °C for 2 h, then neutralized by adjusting the pH to 7.0 using sodium hydroxide 1 mol l^{-1} solution. The solution was filtered and injected into HPLC. This procedure was performed based on previous reported works [12,17,18], in which degradation products for losartan potassium were observed under the same stress conditions. Other conditions that usually cause degradation were not performed because in those studies no degradation products were obtained under those conditions.

The chromatogram depicted in Fig. 3 shows that after this stress study, additional peaks were observed that were attributed to possible degradation products. They were numbered 1, 2 and 3, based on the order of elution. Through PDA purity study, the losartan potassium peak was found to be pure. The peak purity index was 0.9973. Moreover, the resolutions between losartan and potential degradation products 1, 2 and 3 were 1.70, 1.64 and 14.70, respectively, indicating adequate separation of losartan potassium from each other peak. This separation confirmed the selectivity of the method.

3.2.3. Linearity

Linearity was evaluated by the analysis of working standard solutions of losartan potassium (Section 2.3.1) in five replicates in the final concentrations of 30, 40, 50, 60 and 70 mg L^{-1} of losartan potassium (ranging from 60% to 140% of a 50 mg nominal dose in capsules). The data of peak area versus drug concentration were examined by linear least square regression analysis. The response for the drug was linear in the concentration range between 30 and 70 mg L^{-1}. The calibration equations and determination coefficient obtained were $A = 20321[\text{losartan potassium}] + 2917.2$ and 0.9998, respectively. The relative standard deviations for each point ($n = 5$) were smaller than 2%.

3.2.4. Precision

Precision was evaluated with respect to both repeatability and intermediate precision. Repeatability was evaluated by analyzing six replicates of losartan potassium work standard solutions at a concentration of 50 mg L^{-1} (Section 2.3.1). This procedure was repeated over a short period of time on the same day. Intermediate precision also was evaluated by injection of six independent solutions of losartan potassium at 50 mg L^{-1}, but this procedure was repeated on different days. All samples were prepared and evaluated daily. The observed R.S.D. values for repeatability and intermediate precision were <2%, confirming that the method is sufficiently precise (Table 3).

3.2.5. Accuracy

The accuracy of the losartan potassium capsules method was determined by measuring the reference standard recovery in triplicate at three levels from 80% to 120% of the method concentration (50 mg L^{-1}), added at the beginning of the procedure, according to ICH recommendations. The mean recoveries, expressed in terms of percent recovery of the pharmaceutical dosage forms by the assay and the respective relative standard deviation (R.S.D.), were determined. As shown in Table 4, the mean percentage recoveries of products A, B and C were 98.2, 102.1 and 99.7, respectively, indicating the suitability of the developed method in quantifying the concentration of losartan potassium in pharmaceutical capsules.

Table 3
Results for losartan potassium capsules method precision.

Level	Conditions	Concentration level (mg L^{-1})	Mean of the areas	R.S.D (%)
Repeatability	Series 1	50	1 023 643.83	1.46 ($n = 6$)
	Series 2	50	1 036 100.50	1.21 ($n = 6$)
				1.43 ($n = 12$)
Intermediated precision	Day 1	50	1 043 889.67	0.74 ($n = 6$)
	Day 2	50	1 030 716.67	1.55 ($n = 6$)
				1.33 ($n = 12$)

Table 4
Results for losartan potassium capsules method accuracy.

Sample	Final concentration (mg L^{-1})		R.S.D. (%) ($n = 3$)	Mean recovery (%)
	Added	Found		
A	40	39.3	1.32	98.2
	50	48.7	1.08	
	60	59.4	0.26	
B	40	39.0	1.95	102.1
	50	54.6	1.14	
	60	59.7	0.92	
C	40	42.2	0.10	99.7
	50	51.0	0.95	
	60	54.9	1.86	

Table 5
Assay of losartan potassium in pharmaceutical capsule samples A, B and C.

	Standard	Sample A	Sample B	Sample C
Mean of the areas	948 455.33	913 982.80	928 446.40	944 336.80
R.S.D. (%)	0.39 ($n = 5$)	0.34 ($n = 5$)	0.53 ($n = 5$)	0.48 ($n = 5$)
Losartan (%)	98.90	95.31	96.81	98.47
Losartan (mg)	–	48.19	48.94	49.78

3.2.6. Robustness

The robustness of the method was evaluated by analyzing recovery values data after varying, individually, mobile phase phosphate buffer pH (6.0 and 6.4); organic solvent content (30% and 40%); and column temperature (33 °C and 37 °C). Losartan potassium work standard solutions (Section 2.3.1) at a concentration of 50 mg L^{-1} (100% level) were used in this experiment. According to literature, deliberate variations of HPLC parameters should cause relative errors of less than ±5.0% in analyses of synthetic samples at the 100% level [31]. Recovery values obtained at the 100% level confirmed the robustness of the HPLC assay, since the obtained values were within the acceptance limits (95.0–105.0%) in all cases.

3.2.7. Detection limit and quantitation limit

Detection limit (DL) and quantitation limit (QL) parameters were established based on signal-to-noise (3:1 for DL and 10:1 for QL), according to ICH recommendations [29]. The noise was measured from chromatograms of blank (by injection of the mobile phase) in the same regions as the peaks of the analytes. Using this approach, DL and QL values were found to be 0.114 and 0.420 mg L^{-1}, which demonstrated that the analyses were being performed in a region above the quantitation limit value. Furthermore, these results are in agreement with the literature values of 0.023 and 0.420 mg L^{-1} for the DL and QL, respectively [5].

3.2.8. Analysis of the marketed products

The validated method was applied for determination of losartan potassium in capsule dosage forms. Five samples from each local drug store (A, B and C) were analyzed. The results, expressed as percentage drug related to label claim, are shown in Table 5. The results for the drugs assayed were in good agreement with the label claims.

4. Conclusion

In this study, the application of a multivariate approach using factorial design and the Doehlert matrix was a useful tool for simultaneous study of the five factors that play important roles in chromatographic separation. This strategy produces considerable improvement in HPLC efficiency and, therefore, could be applied in analytical laboratories that are looking to improve chromatographic performance without additional cost for columns or equipment. Another advantage we have noted is the reduction in the total number of simulations necessary to obtain a satisfactory result. The proposed and validated HPLC method was shown to be useful, simple and efficient for determination of losartan potassium in pharmaceutical capsules and could effectively separate the drug from its degradation products. All parameters meet the acceptance criteria for method validation. Therefore, the method is demonstrated to be in compliance with the requirements of quality control.

Food analysis

ABSTRACT

A rapid and sensitive flow injection fluorometry has been developed for the determination of formaldehyde based on the microwave on-line accelerating its Hantzsch reaction with cyclohexane-1,3-dione. Under the optimized conditions, the fluorescent intensity is proportional to formaldehyde content in the range from 0.05 ng/mL to 2.000 μg/mL. The detection limit (S/N = 3) is 0.02 ng/mL and the analytical frequency is 28 injections per hour. The relative standard deviations are 2.2% and 3.1% for eleven injections of 0.100 and 0.001 μg/mL of formaldehyde, respectively. With the assistance of microwave irradiation, a best sensitive fluorometry was established for the determination of formaldehyde at a high analytical frequency. This method was successfully applied to food analysis without requiring any sample pretreatment, and the determination results were correlated well with those obtained by the standard method with a sample pretreatment of steam distillation.

1. Introduction

Formaldehyde is a most widespread carbonyl compound coming from combustion and oxidation of hydrocarbons [1]. The toxicity of formaldehyde to man and animals is well known [2–4], and recently the International Agency for Research on Cancer (IARC) classified it as "carcinogenic to humans" in the Group 1 [5]. An acceptable daily intake (ADI) of 0.2 mg/kg body weight has been set by the US Environmental Protection Agency (EPA) for formaldehyde [6]. Acute toxicity after ingestion of a large amount can cause severe abdominal pain, vomiting, coma, renal injury and possible death. Formaldehyde is found as a contaminant in many foods. The common incriminated food items are beverages like beer and juices, meat, mushroom, bean curd, vermicelli, and hydrated food such as fish, tripe, chicken claws, etc. The formaldehyde content in foods depends on methods of cooking or processing. Sometimes it is added inappropriately in food processing, such as in the process of brewing beer to eliminate unpleasant odour.

In recent years, the determination of formaldehyde has received a great deal of attention. A large number of analytical methods have been reported, such as high-performance liquid chromatography (HPLC) [7,8], biosensors [9], catalytic [10–14] and solid-phase [15,16] photometry, solid-phase microextraction in conjugation with isotope dilution mass spectrometry (ID-MS) [17], GC–MS [18] and capillary zone electrophoresis [19]. The spectrophotometry and fluorometry with Hantzsch reaction are commonly used for the determination of formaldehyde. Cyclohexane-1,3-dione (CHD) [20,21], 2,4-pentandione [22], acetylacetone [23] and Fluoral-P [24] have been used as Hantzsch reaction reagents. Although these methods are sensitive and selective, the derivatization reaction mostly requires high temperature. A spectrofluorometry based on the reaction with acetoacetanilide at room temperature was proposed for the determination of formaldehyde in water [25], and a detection limit of 0.09 ng/mL was reported.

Flow injection analysis (FIA) shows many advantages on rapidity, reproducibility, simplicity and less reagent consumption because it goes along at the nonequilibrium state. Flow injection fluorometry was also reported for the determination of formaldehyde based on Hantzsch reaction. However, the relatively slow derivatization reaction rate limits the development of sensitivity in flow injection system. Though reducing flow rate [20] and extending length of reaction coil [21] could prolong the residence and reaction time, the former would bring bad precision and the latter would increase the dispersion of sample zone. A flow injection fluorometry adopting stopped-flow technique was recently reported and a detection limit of 0.04 ng/mL was reached [26].

As to the determination of formaldehyde in beverages and foodstuffs, a sample pretreatment process, such as steam distillation [11–13,27,28] and extraction [8,18], was necessary for most of the current methods on account of lower detecting sensitivity and the serious effect of sample matrixes. Though a catalytic method was reported for the determination of formaldehyde in beers, it is not suitable for black beers because of the absorption of sample matrix at measuring wavelength [14]. Another method without

doi:10.1016/j.talanta.2009.06.066

sample pretreatment was a flow injection fluorometry with Fluoral-P derivatization reaction used for determination of formaldehyde in alcoholic beverages [24].

Microwave energy has been applied to the field of analytical chemistry, primarily dealing with rapid sample digestion [29–31] and extraction [32,33]. The microwave FIA method not only has the features of FIA but also has the advantage of on-line rapid heating. More importantly, some slow reactions could not proceed in the FIA with conventional heaters because of requiring a long heating time, while microwave radiation on-line assistance makes these reactions suitable for the FIA system [34].

Based on the reaction of formaldehyde with CHD and ammonium to produce a strong fluorescence derivative, the present work combines the selectivity of fluorometry with the effectiveness of microwave-accelerated reaction in a flow injection system to develop a rapid and sensitive method for determination of formaldehyde. Due to the sufficient selectivity and sensitive, proposed method was directly applied to the determination of formaldehyde in black and draft beers, fruit and alcoholic beverages, and extraction solutions of dried food without requiring any sample pretreatment.

2. Materials and experiment

2.1. Apparatus

The manifold of the instrument system established for this work is illustrated in Fig. 1. It consists mainly of a flow-injection analyzer, a microwave oven and a fluorescence detector. An IFIS-C intelligent flow-injection analyzer (Xi'an Ruilian Electronic, China) equipped with two peristaltic pumps and an injection valve was used for sampling and transporting solution. The pumps and valve were controlled by a microprocessor. A 2475 Multi λ Fluorescence detector (Waters Corporation, USA) equipped with a 150 W continuous xenon lamp and a flow cell of 8 μL was used for recording fluorescence spectra and measuring fluorescence intensity. A model XH-100B microwave preparation system (Xianghu Science and Technology Co. Ltd., Beijing, China) was employed for providing microwave irradiation to accelerate the chemical reaction. The power level of the microwave oven could be adjusted from 100 to 800 W. All flow tubes used were 0.9 mm i.d. PTFE. A Model 868 pH meter (Thermo Orion, USA) was used for adjusting solution pH.

2.2. Reagents

All chemicals used in this work were of analytical reagent grade, and water used for the preparation of all solutions was purified with a Milli-Q Labo (Millipore, USA). The formaldehyde standard stock solution (1 mg/mL) was prepared by diluting 2.57 mL of formaldehyde (36%) to 1000 mL with water, and the accurate concentration was standardized with iodimetry. The working standards were daily prepared by accurately diluting the standard stock solution. A buffer solution of acetic acid–ammonium acetate was prepared by dissolving 15 g of ammonium acetate in 500 mL of water and adjusting pH to 5.0 with acetic acid. The CHD solution of 0.150 mg/mL was prepared daily by dissolving 0.0300 g of cyclohexane-1,3-dione (J&K Chemica, USA) in 200 mL of acetic acid–ammonium acetate buffer solution.

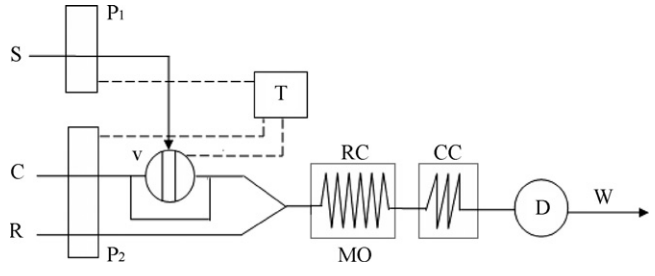

Fig. 1. Schematic diagram of microwave-assistant flow-injection manifold used for determination of formaldehyde. S: sample solution; C: carrier (water); R: reagent solution (0.150 mg/mL CHD in acetic acid–ammonium acetate buffer solution, pH 5.0); P_1, P_2: peristaltic pumps; V: injection valve; T: timer (microprocessor); RC: reaction coil (0.9 mm × 150 cm); CC: cooling coil (0.9 mm × 90 cm, in water bath of 10 °C); MO: microwave oven; D: fluorescence detector; W: waste.

2.3. Flow injection fluorometric procedure

The carrier (water) and the CHD solution are delivered at a flow rate of 0.76 mL/min. The sample of 250 μL is injected into the carrier by means of injection valve V and mixes with the CHD solution. The derivatization reaction of formaldehyde with CHD and ammonium occurs in a reaction coil (150 cm) which was located in the cavity of microwave oven. After derivatization, the mixture stream flows through a cooling coil (90 cm), and then the relative fluorescence intensity of the derivatives is monitored at excitation and emission wavelength of 397 and 465 nm. At the same time, valve V turns to the sampling position and pump 2 runs 35 s for the next sample to be loaded.

2.4. Sample solution preparation

Samples of dried food (mushroom, vermicelli and been curd) were purchased from local market. 5.000 g of portion of each sample was minced and transferred to a 100 mL volumetric flask. Then the flask was filled to 100 mL with water and ultrasoniced for 1 h. After filtrating with micropore membrane, the filtrate was dimensioned to 100 mL with water and the sample solution was obtained. The only further treatment needed is appropriately diluting with water before analysis. Several kinds of drink were randomly collected from different local stores. The test solutions were obtained by direct diluting samples with 20 times water.

For the recovery test, a known amount of formaldehyde standard solution was added into the samples, and then treated as mentioned above.

3. Results and discussion

3.1. Effect of microwave power

The available power in the microwave oven could be calculated using the following equation [29]:

$$\mathrm{Wa} = (Kcm\Delta T)/t$$

where Wa is the available power in the microwave cavity, K the conversion factor, c the heat capacity of water, m the mass of water loading, ΔT the temperature difference between the initial temperature and the final temperature, and t is the heating time. For each segment of the solution in the reaction coil, the K, c and m are identical, considering the reactor length and the flow rate have been fixed, the temperature increase of each segment lies on the irradiation power. The irradiation power was studied from 100 to 600 W (Fig. 2). Though the fluorescence intensity increased with microwave irradiation power enhancing, a great deal of vapour bubbles would be produced due to overmuch temperature enhancing and the repeatability would be poor when irradiation power was higher than 300 W. Therefore, a microwave irradiation power of 300 W was chosen.

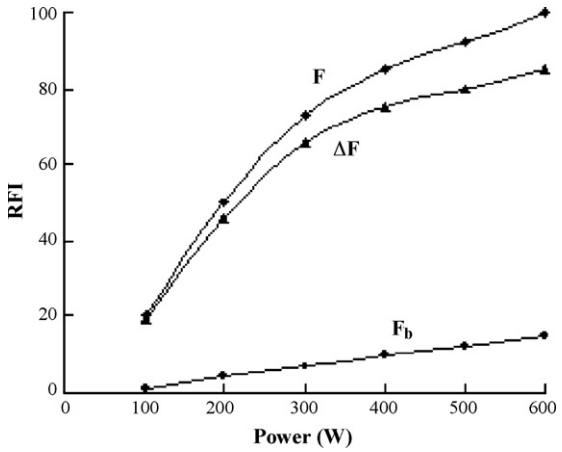

Fig. 2. Effect of microwave irradiation power on the relative fluorescence intensity (RFI). F_b: 0.15 mg/mL CHD; F: 0.100 μg/mL of formaldehyde with 0.15 mg/mL CHD; ΔF: $F - F_b$.

3.2. Effect of chemical variables on the microwave-accelerated derivatization reaction

The effect of the pH was studied in the range 3.5–7. The highest fluorescence intensity was obtained at pH 5.0; further enhancing the pH value drastically decreased the fluorescence intensity because the deprotonation of nitrogen inhibited fluorescence intensity. Hence, the buffer solution of pH 5.0 was chosen to dissolve CHD and prepare CHD solution.

The influence of the CHD concentration was investigated from 0.01 to 0.5 mg/mL (Fig. 3). The fluorescence intensity increased with the concentration increase both for background and formaldehyde. However, the difference of fluorescence intensity between background and formaldehyde (ΔF) retained constant over 0.15 mg/mL of CHD. Therefore, a concentration of 0.150 mg/mL CHD was chosen for the analysis. Compared with previous method [26], a higher CHD concentration was allowed because microwave power accelerated the derivatization reaction rate of formaldehyde and depressed relatively the background.

The effect of concentration of ammonium acetate was studied in the range 1–20% (w/v). It was found that an appropriate peak signal was obtained at an ammonium acetate concentration of 3%. If the concentration was higher, the repeatability would decrease.

3.3. Optimisation of the FI parameters

Under the assistance of microwave power to on-line derivatization, it was necessary to cool the reaction mixture in a cooling bath to obtain a stronger and reproducible fluorescence signal. The FI parameters investigated were the flow rate of sample, carrier and reagent, both lengths of the reaction coil and cooling coil, and the sample volume injected.

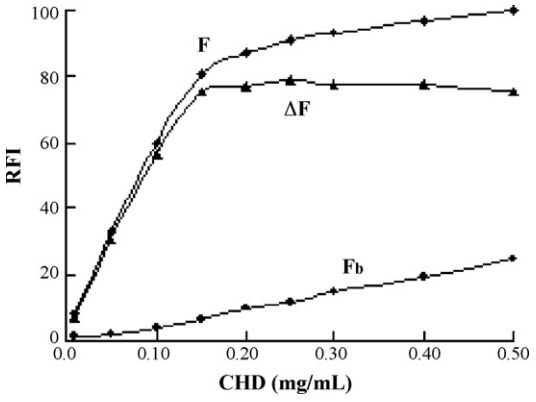

Fig. 3. Effect of CHD concentration on the relative fluorescence intensity (RFI). F_b: background; F: for 0.100 μg/mL of formaldehyde; ΔF: $F - F_b$.

The sensitivity for the determination of formaldehyde obviously depended on the reaction time because of the lower rate of the derivatization reaction. Lower flow rates and a longer reaction coil could give a longer reaction time, but under the assistance of microwave power, too long a reaction time would result in the temperature to be high enough to cause a lot of vapour bubbles. Moreover, too low a flow rate could lead to poor reproducibility and low sample frequency. As a compromise of sensitivity and reproducibility, a flow rate of 0.76 mL/min and a reaction coil of 150 cm were chosen to continue the experiment. The flow rate for sampling was fixed at 2 mL/min to fill the sampling loop with sample solution during the fluorescence measurement (35 s). After heating with microwave, the mixture was cooled in a cooling coil to enhance the fluorescence signal and to reduce the interference of generated bubbles. The cooling coil was immersed in a water bath at 10 °C, and a length of 90 cm was chosen to get an accepted reproducibility without too much dispersion. The fluorescence intensity increased as the injection volume increased across a range of 100–250 μL, and an injection volume of 250 μL was chosen. A period of determination would take 130 s, and the analytical frequency was 28 injections per hour.

3.4. Analytical characteristics

Under the optimized conditions, the calibration graph obtained by plotting fluorescence intensity versus formaldehyde concentration was linear in the range from 0.05 ng/mL to 2.000 μg/mL of formaldehyde, and fitted with the regression equation:

$$\mathrm{RFI} = 738.05 \pm 17.46C + 1.35 \pm 0.04, \quad r = 0.9994$$

where RFI is relative fluorescence intensity, and C is the concentration of formaldehyde in μg/mL. The detection limit calculated from three times the standard deviation of the blank was 0.02 ng/mL. The relative standard derivations for 11 replicate determinations of 0.100 and 0.001 μg/mL of formaldehyde solutions were 2.2% and 3.1%, respectively.

3.5. Interference study

The effect of foreign species concurrently presented in drinks and foods was studied. A similar result with previous work [26] was obtained. It shows that the developed method can be used directly for the determination of formaldehyde in drink and food products.

3.6. Sample analysis

The method has been applied to the determination of formaldehyde in some drink and food products, and was validated with a standard reference method of steam distillation-acetyl acetone spectrophotometry [28].

The determination results of real samples are shown in Table 1 for both proposed method and reference method. The results for recovery tests are also shown in Table 1. It can be seen from Table 1 that the determination results with proposed method are consistent with those obtained with the reference method. The t-test results showed that no significant difference is found between two methods at a confidence level of 95%.

Table 1
Result for the determination of formaldehyde in some drink and food products.[a].

4. Conclusions

The application of microwave irradiation accelerates considerably the derivatization reaction of formaldehyde with CHD, and allows attaining a higher sensitivity for the determination of formaldehyde in a shorter derivatization reaction time than using the water bath to heat reaction. Therefore, the sensitivity of proposed method is enhanced about one order of magnitude than the references with the same derivatization reagent of CHD [20,21], and a best sensitive FI fluorometry is developed at a high analytical frequency. Owing to the higher sensitive and selective, the procedure excludes the influence of sample matrixes, and allows the direct determination of formaldehyde in several kinds of drink, including black and draft beers; alcoholic, fruit and cola beverages; and some dried food extracts without requiring any sample pretreatment. Compared with stopped-flow method [26], the detection limit descends from 0.04 to 0.02 ng/mL with an increase in analytical frequency from 18 into 28 per hour, and the operating procedure is simpler without preheating the water bath to a controlled higher temperature. The proposed method could be an alternative method for rapid determination of low levels of formaldehyde in drink and food products.

ABSTRACT

Gold nanoparticles (AuNPs) were assembled on the surface of polystyrene (PS) and polyaniline (PANI) core–shell nanocomposite (PS@PANI) for the immobilization of HL-60 leukemia cells to fabricate a cell electrochemical sensor. The immobilized cells exhibited irreversible voltammetric response and increased the electron transfer resistance with a good correlation to the logarithmic value of concentration ranging from 1.6×10^3 to 1.6×10^8 cells mL^{-1} with a limit of detection of 7.3×10^2 cells mL^{-1} at 10σ. This biosensor was simple, low cost and disposable, which implied that the PS@PANI/Au composites can regard as the potential applications for clinical applications.

1. Introduction

In recent years, there is an increasing demand to use rapid and simple procedures for the detection of cells viability and proliferation. A series of important biochemical and physiological processes in a living cell involve electron generation and transfer. Therefore, the electrochemical and photoelectric techniques have attractive considerable attention for studying efficiently intact living cells [1,2]. For example, the voltammetric responses of the redox centers in living cells usually show irreversible electron transfer processes [3]. This has been used to characterize the viability of cells in homogeneous solution. However, the anodic peak currents in cyclic voltammograms of cells were generally weak. It is important for searching some methods to improve the electrochemical response signal.

With unique chemical and physical properties, gold nanoparticles (AuNPs) are nowadays the subject of a wide field of research [4,5]. Particularly, there is an enormous interest in exploiting gold colloids in biotechnology for biosensing, imaging, and drug delivery [6,7]. Incorporation of AuNPs with polymers or inorganic materials has attracted increasing interest in improving the stability and biocompatibility to enhance the capability of immobilization. Among these materials, polyaniline (PANI) has been proven particularly useful in the development of biosensors, because of its low cost, readily film forming ability, chemical and electrochemical stability [8]. Polystyrene (PS) latex beads are a kind of functional polymer materials, which have many admirable properties such as biocompatibility, nontoxicity, high surface area and chemical inertness. Taking into account the advantages of PS, PANI and AuNPs, the core–shell nanocomposite has been fabricated, and was applied to assemble a glucose biosensor [9]. As far as I know, it was not used for the detection of cells concentration and monitoring the growing states of tumor cells.

Electrochemical impedance spectroscopy (EIS) is usually regarded as an effective way for probing the interfacial properties and has been used to develop the cell sensors [10–12]. Herein, gold nanoparticles were combined with core–shell nanocomposite (PS@PANI) to form a novel 3D architecture conjunction (PS/PANI/Au), which can be further used to immobilize HL-60 leukemia cells to fabricate a cell electrochemical sensor. The biosensor was more effective for the rapid determination of cell concentration ranging from 1.6×10^3 to 1.6×10^8 cells mL^{-1} with a limit of detection of 7.3×10^2 cells mL^{-1} at 10σ. Moreover, the 3D architecture interface can be used for the electrochemical monitoring of the cells adhesion and proliferation, leading a rapid, simple, and more importantly, convenient way to study and monitor the viability of living tumor cell.

2. Experimental

2.1. Materials

Aniline, styrene, ammonium persulfate ($(NH_4)_2S_2O_8$, APS), potassium persulfate ($K_2S_2O_8$, KPS), $HAuC1_4$ and trisodium cit-

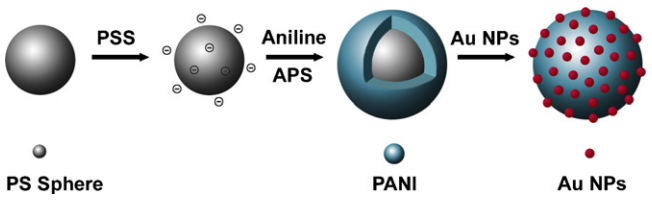
rate ($C_6H_5O_7Na_3{\cdot}2H_2O$) were purchased from Shanghai Chemical Reagent Company. Aniline and styrene were distilled under reduced pressure before use. Poly(sodium 4-styrenesulfonate) (PSS, M_w ~70,000) was from Aldrich Chemical Company. Phosphate buffer solution (PBS) (pH 7.4) containing NaCl 137 mM, KCl 2.7 mM, $Na_2HPO_4{\cdot}12H_2O$ 87.2 mM, and KH_2PO_4 14.1 mM was used as electrolyte. All other reagents were of analytical grade and used without further purification.

2.2. The preparation of the core–shell PS/PANI/Au nanocomposite interface

The glass carbon electrode (GCE) was first polished with 1.0, 0.3, and 0.05 μm alumina slurry successively, and then rinsed with doubly distilled water. The PS/PANI/Au nanocomposite was prepared according to the literature [9]. The obtained nanocomposite was then dispread in water to form a 5.0 mg mL^{-1} solution by sonication. Finally, 5 μL of PS/PANI/Au sol was dropped onto the GCE to form a nanocomposite film (PS/PANI/Au/GCE). The modified electrode was stored in air prior to use.



2.3. Cells culture and immobilization

HL-60 cells were cultured in a flask in RPMI 1640 medium (GIBCO) supplemented with 10% fetal calf serum (FCS, Sigma), penicillin (100 μg mL^{-1}), and streptomycin (100 μg mL^{-1}) at 37 °C in a humidified atmosphere containing 5% CO_2. At the growth retardation stage 3 days, the cells reached a number of 1.0×10^7 cell mL^{-1}, which was determined using a Petroff–Hausser counter (USA). They were collected and separated from the medium by centrifugation at 1000 × *g* for 10 min, followed by washing twice with a sterile PBS (pH 7.4) and resuspending in PBS to obtain cell suspension. Finally, 5 μL of the cell suspension was dropped on the PS/PANI/Au modified GCE, and was incubated at 37 °C for 2 h to achieve cell immobilization.

2.4. Apparatus

The morphologies of the PS/PANI/Au nanocomposite were characterized by scanning electron microscopy (SEM, LEO1530VP) and transmission electron microscopy (TEM, JEOLJEM-200CX).

Cyclic voltammetric and amperometric experiments were conducted with a CHI660B workstation (Shanghai Chenhua, Shanghai).

Scheme 1. Schematic illustration of the synthesis of complex PS/PANI/Au.

All experiments were carried out using a conventional three-electrode system in 0.1 M PBS, where nanocomposite-modified GCE was used as working electrode, a platinum wire as auxiliary electrode and a saturated calomel electrode (SCE) as reference electrode. EIS measurements were carried out on a PGSTAT30/FRA2 system (Autolab, Netherlands) using the three-electrode system in solution containing 10 mM $Fe(CN)_6^{3-/4-}$ and 1.0 M KCl. The impedance spectra were recorded within the frequency range of 10^{-2} to 10^6 Hz. The amplitude of the applied sine wave potential in each case was 5 mV. The applied DC potential was about 0.18 V.

3. Results and discussion

3.1. Characterization of the PS/PANI/Au nanocomposite

The formation of the three-component nanocomposite was described in Scheme 1. Briefly, PSS was modified onto the surface of PS beads for the purpose of increasing the negative charges. Then the positive charged aniline monomer was adsorbed onto the PSS modified PS beads. Through in situ polymerization, PS/PANI core–shell structural composite could be obtained. The Au-decorated PS/PANI nanocomposite was finally formed by an electrostatic effect after introducing PS/PANI into the negative charged Au colloid. Fig. 1 shows the typical TEM and SEM images of the PS/PANI/Au nanocomposite. The PS/PANI/Au nanocomposite with an average diameter of 500 nm was uniform in size and morphology. The numerous individual dark nanodots spread along the grey nanospheres in Fig. 1A and the corresponding outside particles in Fig. 1B are AuNPs, which indicates that well-dispersed AuNPs decorate the core–shell structured PS/PANI surface quite uniformly. The nanoparticle-decorated core–shell nanocomposite can be used to fabricate a cell-based biosensor due to the excellent conductivity of PANI and prominent biocompatibility of AuNPs. The biocom-

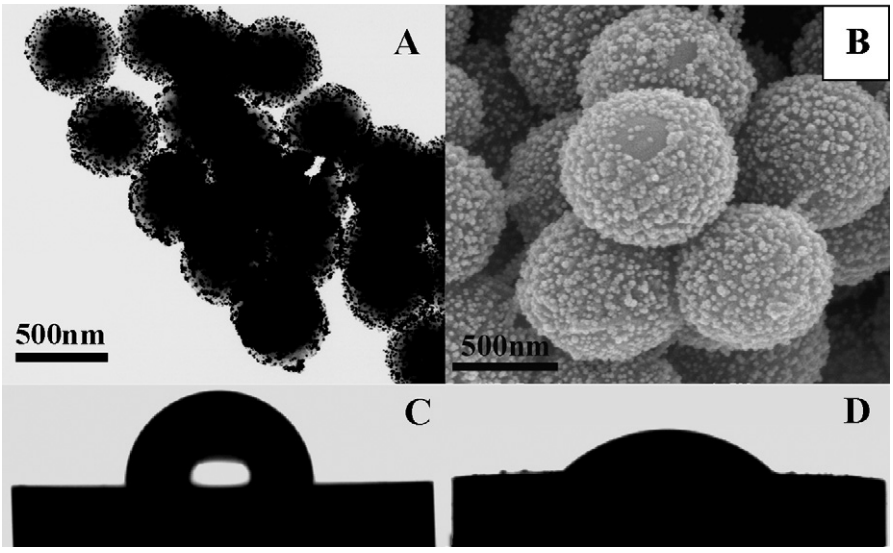


Fig. 1. (A) TEM and (B) SEM images of the PS/PANI/Au nanocomposite. Contact angle of bare electrode (C) and PS/PANI/Au modified electrode (D).

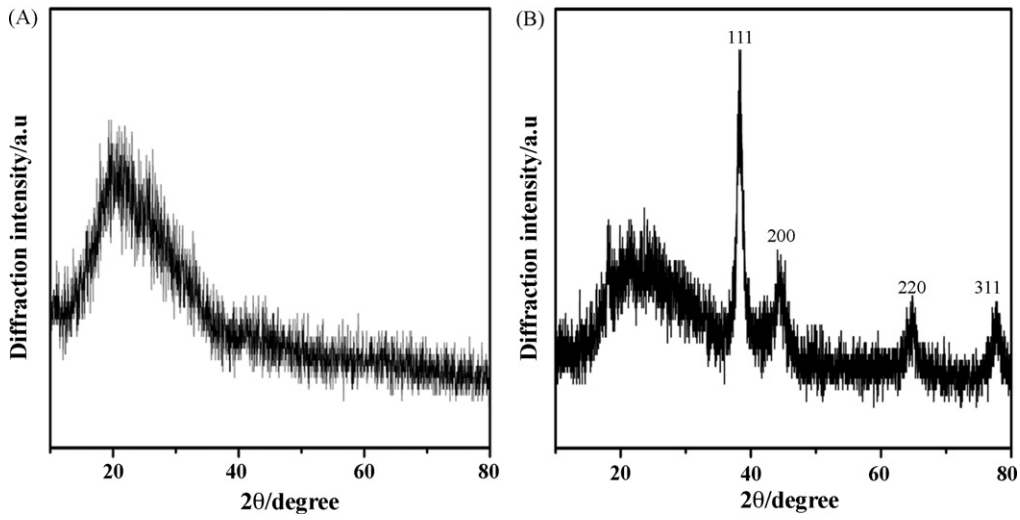

Fig. 2. The XRD patterns of the PS/PANI nanocomposite (A) and the PS/PANI/Au nanocomposite (B).

patibility for loading biomolecules and preserving their bioactivity could be characterized by the hydrophilicity, which could be measured by the contact angle of the substrate. As shown in Fig. 1 (C and D), the contact angle of the bare and PS/PANI/Au modified electrode surface was of 92° (C) and 46° (D) respectively, which indicates the high hydrophilicity of PS/PANI/Au. Thus, the prepared nanocomposite could offer a high hydrophilic surface for promoting cell adhesion and retaining cell activity.

In order to prove Au NPs have been attached on the PS/PANI nanospheres, XRD measurement was carried out. Fig. 2A shows the XRD pattern of the PS/PANI nanospheres, and there was only a broad peak at 22°, which can be assigned to the periodicity parallel to the polymer chains of PANI. While in Fig. 2B, which indicates the XRD pattern of PS/PANI/Au nanocomposite, four additional peaks located at about 38°, 44°, 65°, and 77° are observed besides the broad peak located at 22°. Those peaks can be assigned to the (1 1 1), (2 0 0), (2 2 0), and (3 1 1) lattice planes of fcc-Au.

3.2. Cyclic voltammetric behavior of HL-60 cells on modified electrode

It is well known that many important processes in living cells possess certain electrochemical characteristics. Electron generation and charge transfer exist in all living cells due to the redox reactions and the changes of ionic composition and concentration in life processes [13]. Fig. 3 shows the electrochemical behavior of living cells immobilized on PS/PANI/Au modified electrode. Owning to the larger accessible surface area of the modified electrode, the background current of the PS/PANI/Au modified GCE (Fig. 3b) was greater than that of bare GCE (Fig. 3a). At the modified GCE, the HL-60 tumor cell suspension showed a well-defined irreversible oxidation peak at +0.87 V, while no peak was observed on both bare and PS/PANI/Au (Fig. 3c) modified GCE. The irreversible oxidation peak disappeared in the second scan, and no corresponding reduction peak appeared in the inverse scan, which is the characteristic of an irreversible electrode process. The conversion of guanine in cell cytoplasm to 8-oxo-guanine led to the irreversible electrochemical response of HL-60 tumor cells. In the electrochemical process, the guanine molecules could go through the cell membrane rapidly [14]. Considering the irreversibility of the electrode process of HL-60 cells, the peak current on the first scan was applicable to study tumor cells viability.

3.3. Impedance characteristics of modified electrodes

The electrochemical impedance spectra (EIS) of the modified electrodes were shown in Fig. 4. The electron transfer resistance (R_{et}) was extracted parameters by fitting the EIS data into a suitable equivalent circuit on each independently fabricated electrode. The R_{et} can be used to describe the interface properties of the electrode [15]. At a bare GCE, the redox process of the probe showed a low electron transfer resistance 41.2 Ω (Fig. 3a). When PS/PANI/Au

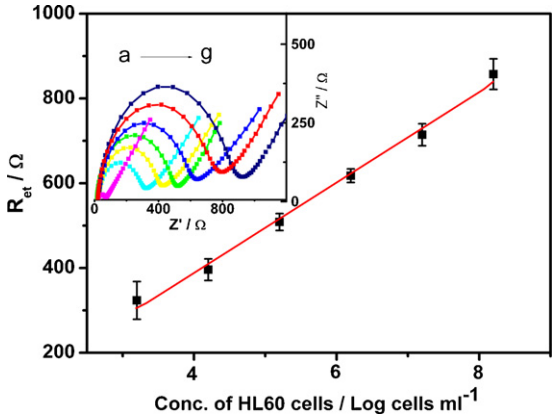

Fig. 6. Linear relationship between electron transfer resistance and logarithm of HL-60 cells concentration. Inset: Nyquist diagrams of PS/PANI/Au modified GCE after immersed in (a) 0 cells mL^{-1}, (b) 1.6×10^3 cells mL^{-1}, (c) 1.6×10^4 cells mL^{-1}, (d) 1.6×10^5 cells mL^{-1}, (e) 1.6×10^6 cells mL^{-1}, (f) 1.6×10^7 cells mL^{-1}, and (g) 1.6×10^8 cells mL^{-1} HL-60 cells suspension.

was assembled on the bare electrode, the semicircle increased dramatically (Fig. 3b). The R_{et} value was about 133.3 Ω, suggesting that the assembly of the nanocomposite layer on the electrode surface inhibited the interfacial electron transfer. When cells were attached to the PS/PANI/Au/GCE, a barrier of the cell membrane would further hinder the redox probe close to the electrode surface and increase the R_{et} value to 601.0 Ω (Fig. 3c). The increasing impedance depended on the surface coverage of the cells, which was proportional to the concentration of the cells used in the adhesion process.

3.4. Monitoring of cell proliferation on electrode surface

EIS measurement was further used to monitor the change of support surface resulting from cell proliferation. Electrochemically monitoring of cell proliferation could be achieved conveniently by placing a set of cells/PS/PANI/Au in culture medium in batch, and measuring at different incubation times. As seen from Fig. 5, with the increasing incubation time, the electron transfer resistance of the redox probe at the produced electrode increased (curves a–e). Obviously resulted from the cell proliferation on the electrode, the increasing amount of cells could lead to a greater barrier for electrochemical process. The inset in Fig. 5 indicates that the R_{et} increased gradually up to the incubation time of 48 h and then tended to a relatively steady value during the incubation time of 48–96 h. After 96 h a sharply increasing resistance was observed, indicating that a majority of HL-60 cells was already dead. This change might be related to the apoptosis of cells, which was congregated on the electrode surface.

3.5. Impedance detection of HL-60 cells

The PS/PANI/Au/GCE could be used for the detection of HL-60 cell concentration. With the increasing concentration of HL-60 cells, the R_{et} value increased, showing increasing diameter of the semicircle on the Nyquist diagram (inset of Fig. 6), implying a higher amount of HL-60 cells immobilized on the electrode. The R_{et} value was proportional to the logarithm of HL-60 cells concentration ranging from 1.6×10^3 to 1.6×10^8 cells mL^{-1} (Fig. 6), with a correlation coefficient of 0.9965. The limit of detection was calculated to be 7.3×10^2 cells mL^{-1} at 10σ, which was comparable with those of several methods developed by other researchers such as the impedance immunosensor for *Escherichia coli* O157:H7 [11] and EIS technique for leukemia K562 cells [16]. Five different biosensors were tested independently for the detection of cells concentration, providing the RSD value of 2.47%.

4. Conclusions

While fabricating a sensitive impedance cell sensor, we took the advantageous features of PANI and gold nanoparticle to construct a nontoxic biocompatible interface for immobilization of tumor cells. Gold nanoparticles with excellent biocompatibility was used to modify leukemia HL-60 cells, which could not only efficiently preserve the activity of tumor cells, but also accelerate the electron transfer between electrode and the immobilized cells. The cell-based impedance sensor showed the wide detection range, low detection limit, good detection precision and simple fabrication process, which could be further developed as a convenient means for the study of cells adhesion, proliferation and apoptosis.

Supported ionic liquid phases
Solid-phase extraction
Anion exchange sorbent
Acidic compounds
Aqueous samples

ABSTRACT

This study reports a material that is based on the concept of ionic liquid analogue: a slightly crosslinked polymer-supported imidazolium trifluoroacetate salt (IL-CF_3COO^-) that favorably combines the properties of ionic liquids (ILs) and the advantages of a solid support.

The ionic liquid-supported material was evaluated for the first time as a solid-phase extraction (SPE) sorbent for selectively and quantitatively extracting pharmaceuticals from aqueous samples.

The novel IL-CF_3COO^- was evaluated under reversed-phase (RP), weak anion exchange (WAX), strong anion exchange (SAX) and strong cation exchange (SCX) SPE procedures, and we found that SAX conditions are the most suitable for investigating the behaviour of the IL-CF_3COO^- material. Under SAX conditions, the IL-CF_3COO^- material was capable of selectively and quantitatively extracting a group of acidic compounds from aqueous samples, while washing basic analytes that were also present in the sample.

The SPE method using IL-CF_3COO^- material was used to analyse 1000 ml of different aqueous samples (ultrapure, tap and river) with complete recovery of the acidic compounds studied. Moreover, the method provided clean chromatogram and high recoveries when percolating complex real samples, such as 1000 ml of river water and 250 ml of effluent wastewater from a sewage treatment plant spiked at low levels with the analytes studied.

1. Introduction

Ionic liquids (ILs) are inorganic and organic salts with a melting point below 100 °C. The most characteristic features of IL are of negligible volatility and high polarity, comparable to the polarity of lower alcohols [1]. Most organic IL are made up of large cations such as imidazolium, pyridinium, quaternary ammonium and quaternary phosphonium and a suitable anion such as chloride, bromide, trifluoroacetate, trifluoromethane sulfonate, p-toluenosulfonate, etc. By using a proper combination of the cation and anion either hydrophilic ionic liquids or hydrophobic ionic liquids can be obtained. However, even relatively hydrophobic ILs are not totally immiscible with water. The features of high polarity and very low miscibility with water make it possible to use ILs in solvent extraction processes.

In this sense, several examples of IL applications in separation techniques have been reported [2–13]. Thus, ILs are used in many chromatographic applications: as stationary phases in gas chromatography [5–7], as mobile phase additives or stationary phases in liquid chromatography [8,9,14,15], as chemical modifiers in capillary electrophoresis or stationary phases in electrochromatography [16]. Another attractive application is as an extraction solvent, in liquid–liquid extraction for benzene derivatives [2] or for phenol, tyrosol and p-hydroxybenzoic acid [3] or for polyaromatic hydrocarbons in direct-immersion and headspace liquid-phase microextraction [10,11] or in single-drop microextraction [12,13]. The excellent sorptive properties of ionic liquids towards such groups of organic compounds as benzene derivatives [2,12,13], polyaromatic hydrocarbons [10] and alkylphenols [17] prompted some of us to investigate the possibility of polymer-supported imidazolium type ionic liquids [18] and the sorptive properties of such material. We found [18] that the polymer-immobilized imidazolium salts have very good capacity to extract benzene derivatives from aqueous phase. The polymer-supporting of imidazolium salts opens up new possibilities because it solves the problem of the small but measurable solubility of IL, what is an obvious disadvantage in extraction.

Another field of application in which ILs show potential is solid-phase extraction (SPE), the most widely used preconcentration technique largely because of the variety of different materials that can be used as SPE sorbents [19,20]. To date, polymeric

doi:10.1016/j.talanta.2009.06.068

sorbents are regarded as the best SPE materials since they can enhance capacity (i.e. hydrophilic polymers and polymers with high specific surface areas) [21], selectivity (molecularly imprinted polymers—MIPs) [22,23] or both (mixed mode ion-exchange polymers) [24] and, therefore, enlarge the type of sample and the analyte to be extracted. To the best of our knowledge, just two studies [25,26] reported in 2009 the application of immobilized IL onto silica sorbents to isolate tanshinones [25] or enrich polyunsaturated fatty acid methyl esters [26] from complex samples.

In this paper we present a step forward in SPE sorbent technology: we prepared a new material based on the novel concept of ionic liquid-supported phase onto polymer phase, and then pioneered its evaluation as a SPE sorbent to evaluate pharmaceuticals, which are emerging pollutants in the environmental field.

2. Experimental

2.1. Reagents and standards

The reagents used for the supported ionic liquid syntheses were vinylbenzyl chloride (VBC), divinylbenzene (DVB), N-methylimidazole, trifluoroacetic acid and formic acid (HCOOH), all purchased from Sigma–Aldrich (Steinheim, Germany). The VBC (mixture of isomers) was distilled under vacuum before polymerization. DVB (80%) was extracted with 2 M sodium hydroxide (NaOH), washed a few times with water and dried over sodium sulfate. Other reagents were used as received.

The analytes selected to evaluate the sorbents were: salicylic acid, 4-nitrophenol (4-NP) carbamazepine, nalidixic acid, flumequine, naproxen, fenoprofen, diclofenac sodium, ibuprofen and gemfibrozil, all obtained from Aldrich. The structure and pK_a values of all the analytes are shown in Fig. 1.

Standard stock solutions at 1000 mg l^{-1} were prepared for each analyte in methanol (MeOH), except nalidixic acid, which was prepared in 0.1 M NaOH aqueous solution, and flumequine, which was prepared in 50/50 (v/v) MeOH/H_2O at basic pH with NaOH. Working solutions of the mixture of all the compounds were all prepared in 50/50 (v/v) MeOH/H_2O. All the solutions were stored at 4 °C.

Ultrapure reagent water purified by a Milli-Q gradient system (Millipore, Bedford, MA, USA) was used throughout. Acetonitrile (ACN) and MeOH were purchased from SDS (Peypin, France). Other reagents used in the SPE procedures were: phosphoric acid (H_3PO_4) (Merck, Barcelona, Spain), ammonium hydroxide (NH_4OH) (Merck), HCOOH (Probus, Barcelona, Spain), sodium acetate (CH_3COONa) (VWR, Mollet del Vallès, Spain), acetic acid (CH_3COOH) (SDS) and nitrogen of 99.995% purity (Carburos Metálicos, Barcelona, Spain).

2.2. Resin preparation and characterization

The starting polymer was obtained by suspension polymerization of VBC and DVB (2 wt.%) in the presence of 20 wt.% of toluene. The reaction was catalyzed with 0.5 wt.% of benzoyl peroxide and was carried out at 60 °C for 1 h, 70 °C for 1 h, and 85 °C for 2 h and it finished after 5 h at 95 °C. After the polymerization, the material obtained was washed with hot water and acetone, dried and then extracted with toluene in a Soxhlet apparatus.

The VBC/DVB was reacted with the excess of N-methylimidazole. Thus, 15.0 g of dry polymer was placed in the round bottom flask and refluxed with the excess of neat N-methylimidazole for 17 h. After this time the polymer was placed in the column and subjected to a conditioning with: water, 1 M HCl, water, 1 M NaOH, water, 0.1 M CF_3COOH and water at a neutral pH.

The chlorine content in polymers was determined by the Volhard method after the samples (ca. 20 mg) had been burned in

oxygen and the fumes absorbed in 20 ml of H_2O_2 solution. The nitrogen content was determined by the Kjeldahl method.

2.3. Instrumentation

The chromatographic experiments were performed with two LC-10AD$_{VP}$ pumps, a DGU-14A degasser and a CTO-6AS column oven (all from Shimadzu, Tokyo, Japan), an injection valve with a 20 μl loop and a Hewlett-Packard (Avondale, PA, USA) Series 1100 UV spectrophotometric detector. The analytical column was a 250 mm × 4.6 mm i.d. stainless-steel column packed with Kromasil 100 C_{18}, 5 μm (Teknokroma, Sant Cugat del Vallès, Spain).

2.4. Chromatographic conditions

The mobile phase was: ultrapure water adjusted to pH 2.8 with H_3PO_4 and acetonitrile (ACN). The flow-rate was 1 ml min^{-1} and the temperature of the column oven was set at 30 °C. The gradient profile was 40% initially for 8 min, which was increased to 60% ACN in 12 min, and to 100% ACN in 8 min (held for 2 min). The mobile phase was then returned to the initial conditions (40% ACN) in 2 min.

The wavelength used to detect all the compounds was set at 210 nm throughout the analysis.

2.5. Solid-phase extraction procedure

The SPE evaluation was performed in an off-line mode using 500 mg of IL-CF_3COO^- resin packed into 6 ml polypropylene cartridges equipped with two polyethylene frits (Symta, Madrid, Spain). The cartridges were connected to an SPE manifold (Teknokroma), which was connected to a vacuum pump.

The laboratory-synthesized IL-CF_3COO^- resin was compared to the commercially available sorbent Oasis MAX (500 mg) from Waters (Milford, MA, USA).

The SPE protocols used depended on whether the sorbent was being evaluated as reversed-phase (RP), weak anion exchange (WAX), strong anion exchange (SAX), or strong cation exchange (SCX). They are listed in Table 1 and are all adapted from standard SPE procedures [27,28]. After the optimization studies, the sorbent was evaluated under SAX conditions and using the following protocol: sample: ultrapure water at pH 7; equilibration: 1 ml of 25 mM CH_3COONa, pH 5; washing: 20 ml of MeOH; elution: 10 ml of 5% HCOOH in MeOH; regeneration: 5 ml of 5% HCOOH in MeOH.

In real water samples, the optimum protocol was used, but, the two eluates from the washing and the elution steps were reduced to dryness under a stream of nitrogen and the respective residues were redissolved with 0.5 ml 50/50 (v/v) MeOH/H_2O to decrease the analyte concentration levels as close as possible to the low levels found in the environmental water samples.

2.6. Sample collection and preparation

Real water samples (tap water from Tarragona, Ebro river water and effluent waste water from a treatment plant in Tarragona) were acidified and kept in the fridge at 4 °C. Before analysis they were readjusted to pH 7 with NaOH and filtered through 0.45 μm nylon membranes (Osmonics Inc., Minnetonka, MN, USA) to remove the particulate matter before the SPE step.

3. Results and discussion

3.1. Preparation and characterization of the IL-CF_3COO^- material

The polymer-immobilized imidazolium salt was prepared in a one-step simple reaction of VBC–DVB copolymer with N-methylimidazole (Fig. 2). The elemental analysis gave 0.32 mmol of residual Cl per g and 5.47 mmol of N per g of dry material in the form of CF_3COO^-, which corresponds to 2.73 mmol of imidazolium groups per g. These results show that the modification leading to the immobilized imidazolium salt proceeds with very high yield and the resultant material contains almost the maximum possible amount of immobilized salt. After the reaction (Fig. 2), the polymer contains the Cl^- groups but these groups can be easily substituted by an ion-exchanger to the desired ionic form. These forms, chosen for the purpose of this research, were trifluoroacetate and formate. The former is used in ionic liquid chemistry, and the latter was tried because HCOOH is being used in the elution solutions of SPE experiments. The high water content (2.55 and 4.26 g of water per g of polymer for trifluoroacetate and formate, respectively) ensures the good kinetics of solute diffusion within the polymeric beads. Moreover, a copolymer with 2 wt.% of crosslinking agent was used to ensure that the resulting material swelled appropriately and to provide sufficient mechanical strength.

For the experimental conditions, see text. % Relative standard deviation (RSD) ($n = 3$) were lower than 4% when % recovery >15%.

3.2. Selection of the optimum protocol in SPE

We first tested several SPE procedures in order to determine which retention mechanisms the interaction of IL-CF_3COO^- with the analytes is based on. For this, in order to test a wide range of interactions we selected a group pharmaceuticals considered emerging contaminants of environmental interest (see Fig. 1), and also 4-NP. The studied compounds include polar analytes with different basic–acidic properties, and particularly acidic compounds.

We tested four SPE protocols: reversed-phase (RP), weak anion exchange (WAX), strong anion exchange (SAX) and strong cation exchange (SCX). Table 1 summarizes the conditions in each of the procedures tested. At the end of each SPE procedure, an extra 10 ml of 2% HCOOH in 80/20 (v/v) MeOH/ACN (called elution 2) was passed through the cartridge to ensure that the compounds, mainly the acidic ones, had completely eluted from the sorbent, since the acidic solution ensures the protonation of the analytes – which at loading sample pH (pH 7) might be in their anionic form – and releases them from the sorbent.

Table 2 summarizes the % recovery values provided in each respective protocol, which point out that the SAX protocol is the more efficient, since all the most acidic compounds studied (pK_a < 5) eluted during the elution step with recovery values ranging between 90 and 100% in all instances. The less acidic compounds (pK_a > 5) also eluted (% recoveries from 87 to 69% for all this type of compounds, and 45% for 4-NP) in the washing step. All the analytes, then, completely eluted during the washing and elution steps, and none (or just traces) of the analytes were recovered in elution 2. On the other hand, when the other three protocols were used (i.e. RP, WAX and SCX), the analytes did not elute in either the washing or the elution step, and the extra step (elution 2) was required to completely elute all the analytes from the sorbent.

If the SAX conditions are the most suitable for extracting acidic analytes, this means that the IL-CF_3COO^- resin retains the analytes through ionic interactions with its imidazole groups (which involves SAX interactions). Therefore, we shall now focus on the extraction of the most acidic compounds, but we shall maintain all the initial compounds (i.e. including the basic and less acidic ones) in order to provide as much information as possible about how IL-CF_3COO^- behaves with compounds of different characteristics.

3.3. Optimisation of the SAX protocol

Once SAX had been seen to be the optimal procedure for eluting the analytes studied from IL-CF_3COO^-, our next aim was to tune the conditions. For these experiments, we increased the sample volume to 250 ml in order to study the effect of each parameter at conditions more pertinent to the off-line SPE extraction.

3.3.1. Loading sample conditions

The loading step was fixed at pH 7 in order to ensure the deprotonation of the most acidic compounds (pK_a < 5) and retain them in the resin (which is charged) through ionic interactions.

The ionic strength of the sample was also tested, to do this, we compared the recovery results of two type of samples both adjusted to pH 7 with H_3PO_4: one based on ultrapure water and another based on isotonic saline buffer. The results were better when the sample was prepared merely with ultrapure water adjusted to pH 7, which may be due to the lower ionic strength of this type of sample.

3.3.2. Elution solution

We increased the percentage of the HCOOH (2%, 5% and 10%) in the solution and then we changed the solvent in the solution (20/80 (v/v) MeOH/ACN or pure MeOH) in order to completely elute the most acidic compounds with the minimum volume of solvent. We found that 5% HCOOH solution in either 20/80 (v/v) MeOH/ACN or pure MeOH provided the best results (data not shown). We finally chose 5% HCOOH in MeOH as the elution solution because it is more straightforward to prepare.

To determine the optimum elution volume, we tested volumes from 1 to 15 ml of 5% HCOOH in MeOH, and the minimum volume to ensure the complete elution of all the acidic compounds was 10 ml of this acidic solution.

3.3.3. Washing step

In order to enhance the selectivity of the whole extraction process, another parameter that had to be optimized is the type and volume of solvent in the washing step. We had already used 1 ml of MeOH as washing solvent, but we were interested in increasing the volume to more effectively wash out the interferences, so we tested up to four aliquots of 5 ml of MeOH (total 20 ml of MeOH). With 20 ml of washing solvent, none of the most acidic analytes underwent any loss during the washing step and they were completely recovered in the elution step (data not shown). On the other hand, when 20 ml of MeOH was used as washing solvent, the less acidic compounds partially eluted in the washing step (as expected, since they are just retained by reversed-phase interactions) and completed their elution in the elution step. However, increasing the volume of washing solvent further led to the elution of some acidic compounds, such as gemfibrozil, but other less acidic compounds still did not elute.

We also tested the effect of combining two types of washing solvents – 10 ml of 5% NH_4OH in MeOH followed by 10 ml of MeOH – to check whether the addition of a basic solution helped to completely elute the basic and neutral compounds in the washing step. However, we ruled out this possibility since we could not see any

Table 3
% Recovery values of the analytes with the different sorbents studied (IL and Oasis MAX) after extracting 1000 ml of ultrapure, tap and Ebro river water sample at pH 7 with the analyte mixture spiked at 10 μg l^{-1}.

Salicylic acid	3	0	68	0	99	0	76	0	20	2	63	0	100

For the experimental conditions, see text. % Relative standard deviation (RSD) (n = 3) were lower than 4% when % recovery >25%.

improvement, and some of the less acidic compounds continued eluting in the elution step.

3.3.4. Regeneration of the ILs

Another point to consider was the regeneration of the IL after each extraction. We tried to regenerate the cartridge by passing the stoichiometric amount of CF_3COOH, to maintain the IL-CF_3COO^- form, or 5 ml of 5% HCOOH in MeOH (also used in the elution step) to maintain the IL-$HCOO^-$ form, and the results obtained in the following respective SPE experiments were the same. Thus, we predict that the important point is to maintain the IL in the protonated form, but we can use any counter-ion to do so. Moreover, in view of the water content (Section 3.1) of the $HCOO^-$ form in comparison with that of the CF_3COO^- form, we decided to use 5 ml of 5% HCOOH in MeOH as the regeneration solution to maintain the imidazole moiety in its charged form and at the same time to continue working with the more suitable IL-$HCOO^-$ form.

3.3.5. Sample volume

After the different conditions that might affect the extraction had been evaluated, the following optimized conditions were selected for all further experiments: sample: ultrapure water at pH 7; equilibration: 1 ml of 25 mM CH_3COONa, pH 7; washing: 20 ml of MeOH; elution: 10 ml of 5% HCOOH in MeOH; regeneration: 5 ml of 5% HCOOH in MeOH.

Once the SPE protocol had been established, we tested different sample loading volumes (i.e. 250, 500 and 1000 ml) and the recovery results were similar for all the tested volumes. Table 3 lists the recoveries (%) obtained after loading 1000 ml of ultrapure water sample (pH 7) spiked at 10 μg l^{-1} with the analyte mixture through IL material. All the most acidic compounds provided % recoveries ~100%, with the exception of salicylic acid, which polarity let its recoveries to fall to 68%. Previous studies [29,30], where it used conventional SPE sorbents, also reported problems in the extraction of salicylic acid.

As far as the less acidic compounds studied are concerned, 4-NP showed partial elution with the IL-CF_3COO^- during the elution step, which might be because it interacts through the nitro moiety (see the structure of 4-NP in Fig. 1) and the amine moiety in the imidazole ring of IL-CF_3COO^-. On the other hand, carbamazepine is almost lost during the loading step when extracted with IL-CF_3COO^-, because it is retained by the sorbent as a result of the π–π interactions between the aromatic rings in the analyte (see structure in Fig. 1) and the ones in the sorbent structure (Fig. 2). However, the SAX protocol used enhanced ionic interactions with the analytes rather than RP, which are more suitable for extracting this basic compound.

3.3.6. Comparison to conventional sorbent

For purposes of comparison, we also evaluated the SPE performance of Oasis MAX, which is a commercially available polymeric sorbent based on N-vinylpyrrolidone–DVB with a specific surface area of ~800 m^2 g^{-1} and it contains quaternary ammonium moieties, so it behaves like a SAX sorbent.

Table 3 also summarizes the recovery values obtained for Oasis MAX under the same conditions as those listed for IL-CF_3COO^-. From these recoveries, we can see that the performance of the IL-CF_3COO^- sorbent is comparable to that of the Oasis MAX sorbent in the extraction of the studied compounds. With this comparison, we demonstrate that polymer-supported IL (with just a 2% crosslinking degree) performance is as good as other established polymeric SPE sorbents that use macroporous resins with crosslinking degrees up to 80%.

3.4. Application to real samples

To assess the applicability of IL-CF_3COO^- in real water samples, we evaluated tap river and wastewater samples. As with the ultrapure water, we initially percolated 1000 ml of each sample spiked at 10 μg l^{-1} and then followed the rest of the SPE procedure as described above. Table 3 shows that the recoveries for real samples are similar to those in ultrapure water, but, in tap water the recoveries slightly decrease, i.e. 60% for gemfibrozil. This decrease in recovery values in tap water samples might be attributed to the chloride content in this type of sample, which might block the amine moiety and prevent interaction with the target analytes. More interesting are the results with river water, the recoveries of which are close to 100%, except for salicylic acid and ibuprofen (63% in both cases). The decrease in the recovery of these two acidic compounds is not surprising; in fact, salicylic acid recoveries are similar to those obtained in ultrapure water and several studies have shown that ibuprofen has more recovery problems than other compounds with similar acidic and polar characteristics when it is extracted with such neutral polymeric sorbents as Oasis HLB [31–33] and Strata-X [34] or weak anion exchange polymeric sorbent Oasis WAX [27].

For purposes of comparison, we also ran the same experiments using Oasis MAX as the sorbent (see Table 3 for the % recovery values). The results obtained for the most acidic compounds when Oasis MAX was used in tap water samples are slightly lower (about 50–60% compared to 60–70% for IL-CF_3COO^-) and in river water samples they are slightly higher (values about 100% for all the compounds studied while the recoveries of salicylic acid and ibuprofen fall to 63% when IL-CF_3COO^- is used) than those obtained with IL-CF_3COO^-.

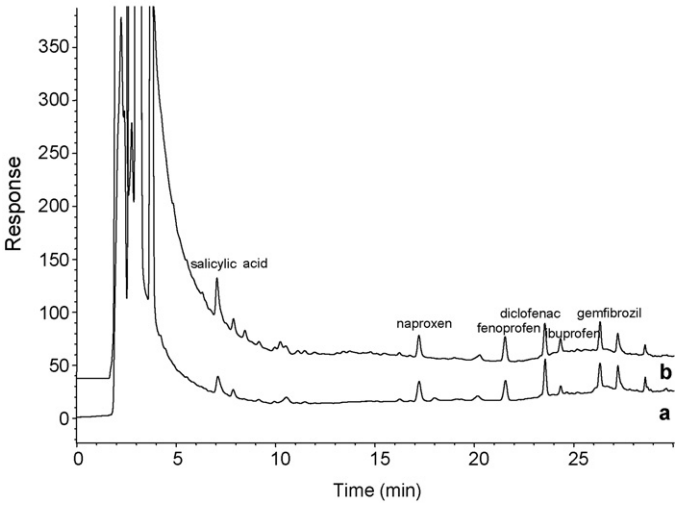

Fig. 3. Chromatograms obtained after off-line trace enrichment of 1000 ml of Ebro river water sample with the addition of a 0.5 $\mu g\,l^{-1}$ level of the analyte mixture followed by the washing step and elution of the most acidic compounds using IL-CF_3COO^- (a) and Oasis MAX (b).

As expected, the less acidic compounds studied followed the same trends as in ultrapure water.

The next experiments in real water samples consisted of decreasing the analyte concentrations at 0.5 $\mu g\,l^{-1}$ so that they reassembled those found in the environment. In order to determine lower concentrations, in this set of experiments the SPE eluate was evaporated to dryness and then reconstituted with 0.5 ml of 50/50 (v/v) H_2O/MeOH solution. With the evaporation step, an additional concentration factor of 20 was achieved. Recovery values were similar to those of the extraction of the Ebro river water sample spiked at higher concentration (i.e. 10 $\mu g\,l^{-1}$). Fig. 3 shows the chromatograms obtained after preconcentrating 1000 ml of Ebro river water on IL-CF_3COO^- (a) and Oasis MAX (b) with the addition of the analyte mixture at 0.5 $\mu g\,l^{-1}$, and performing first the washing step and then the elution. It is worth mentioning that non-spiked sample chromatograms (not shown) were run with each respective sample, and neither any compounds studied nor any important interference were detected. We can also see that the chromatogram profile for IL-CF_3COO^- (Fig. 3a) shows a smaller initial hump than Oasis MAX (Fig. 3b), which might help to quantify the analytes that appear at the initial retention times, such as salicylic acid.

To further show the capacity of ILs material to selectively extract acidic compounds, we used the IL-CF_3COO^- to percolate much more complex aqueous samples, such as effluent water from the waste water treatment plant (WWTP) in Tarragona. Table 4 summarizes the recovery results after 250 ml of effluent WWTP sample at pH 7 were extracted spiked at 5 $\mu g\,l^{-1}$ with the analyte mixture. At this point, we would like to clarify that the sample volume was decreased to 250 ml because the WWTP sample is much more complex than the rest of water samples analyzed. The SPE material IL-CF_3COO^- and Oasis MAX were used for purposes of comparison. The results for IL-CF_3COO^- are satisfactory and comparable to those for Oasis MAX, though slightly lower in the case of ibuprofen and gemfibrozil (~75% for IL-CF_3COO^- compared to ~100% for Oasis MAX) and salicylic acid (~55% for IL-CF_3COO^- compared to ~100% for Oasis MAX). In fact, these compounds have also shown some recovery problems in the other matrices analyzed in this study; and when samples are more complex, the weaker retention of these compounds might be further weakened by the presence of interferences that mask the interaction points of the sorbent, thus preventing proper interaction with the target compounds.

Table 4
% Recovery values of the studied analytes with IL sorbent and Oasis MAX in SPE after percolating 250 ml of effluent WWTP water sample at pH 7 spiked at 5 $\mu g\,l^{-1}$ with the analyte mixture.

Solutes	pK_a	% Recovery			
		IL		OASIS MAX	
		Wash	Elution	Wash	Elution
Carbamazepine	13	43	0	104	0
4-NP	7.1	0	81	0	57
Nalidixic acid	6.5	61	0	79	0
Flumequine	6	2	0	84	0
Gemfibrozil	4.7	0	72	0	97
Ibuprofen	4.6	0	77	0	99
Fenoprofen	4.5	0	93	0	102
Naproxen	4.2	0	101	0	100
Diclofenac	3.9	0	101	0	99
Salicylic acid	3	0	55	0	94

For the experimental conditions, see text. % Relative standard deviation (RSD) ($n = 3$) were lower than 7%.

Fig. 4 shows the chromatograms obtained after preconcentrating 250 ml of effluent WWTP sample on IL-CF_3COO^- (a and b) and Oasis MAX (c and d) with the addition of the analyte mixture at 5 $\mu g\,l^{-1}$ (b and d). The most acidic compounds of the group studied were first washed and then eluted (see chromatograms). Fig. 4 also shows the non-spike sample chromatograms (a and c) for each SPE material evaluated (i.e. IL-CF_3COO^- (a) and Oasis MAX (c)), which display some unknown peaks and two peaks at the same retention time as diclofenac and gemfibrozil; therefore, we took them into account in the quantification of these compounds. The chromatograms in Fig. 4 show that, although the samples are complex, the baseline is flatter and allows the most acidic analytes to be properly quantified at low concentration levels, which might be partially attributed to the effective washing step that can be performed in this type of material. Again, a comparison of the chromatograms reveals a smaller initial hump in the IL-CF_3COO^- (Fig. 4a and b) than in the Oasis MAX (Fig. 4c and d), due to the contribution of the non-specific RP interactions of Oasis MAX material. It should also be pointed out that the chromatograms are clean thanks to the material used in the SPE, and that both the cleanliness and the sensitivity achieved with this type of complex samples could be further enhanced by using a more powerful detection technique, such as mass spectrometry.

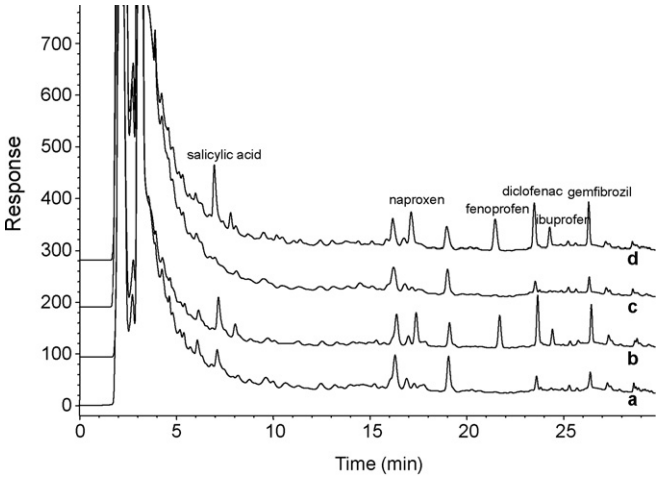

Fig. 4. Chromatograms obtained after off-line trace enrichment of 250 ml of effluent WWTP sample without (a and c) and with (b and d) the addition of a 5 $\mu g\,l^{-1}$ level of the analyte mixture followed by the washing step and elution of the most acidic compounds using IL-CF_3COO^-: without (a) and with (b), and Oasis MAX: without (c) and with (d), the addition of the analyte mixture.

4. Conclusions

This paper describes a pioneering study of the synthesis, evaluation and application of polymer-supported ILs as SPE material, which effectively extracts a group of acidic compounds from complex aqueous samples.

The imidazolium trifluoroacetate was linked to a 2% crosslinked resin in order to combine the advantages of ionic liquid properties and those of a solid material.

We tested the different functional groups of the ionic liquid resin and their capacity to interact with the analytes selected by using various SPE protocols. We found that the SPE performed best when using the SAX interaction that the imidazole group provides with the acidic compounds studied.

We have shown that the IL-CF_3COO^- is a good alternative for extracting acidic analytes at low concentration levels from complex samples (tap, river and effluent WWTP), since it presented clear chromatograms and high recoveries; using ILs as a SPE material is sometimes even a better option than such well-established anionic exchange SPE sorbents as Oasis MAX sorbent.

We have, then, described a novel application of these promising media, which are still in the process of being explored. This study is just the first step towards new applications of these materials in the sorptive extraction field.

LC–ESI-MS

ABSTRACT

Produced formation waters (PFWs) represent the largest aqueous wastes that are normally discharged into the marine environment during the offshore gas production processes. The chemical additive diethylene glycol (DEG) is widely used in the gas production line and therefore can be found in the PFW, becoming of environmental concern. In this study, a new method has been developed for trace determination of DEG in sea water samples collected around offshore gas platforms. The method is based on liquid chromatography coupled to electrospray ionization mass spectrometry (LC–ESI-MS). Prior to analysis, water samples were derivatized using the Schotten–Baumann method for the benzoylation of glycols. The derivatization procedure allowed us to maximize the ESI-MS response of DEG and minimize the influence of interfering compounds. The method was validated and allowed a quantification of DEG in sea water samples with a method LOD of 0.4 ng/mL. The applicability of the procedure was demonstrated by analyzing sea water samples collected around eight gas platforms located in the Adriatic Sea (Italy).

1. Introduction

Diethylene glycol is a widely used industrial chemical, which is well known for causing acute toxicity phenomena in humans [1–5]. Due to its extensive use this compound primarily enters the environment from manufacturing effluents and emissions, and upon release during its use in commercial products [6–12]. Regarding the marine environment, an important source of contamination from DEG can be found in the gas extraction offshore platforms.

Produced formation waters (PFWs) are the largest aqueous wastes that are normally discharged into the marine environment during the offshore gas production processes. It has been estimated that about 7 million cubic meters of water are produced and discharged daily by offshore platforms [13]. The chemical composition of PFWs is complex and strongly field-dependent. It also depends upon time period over which hydrocarbons have been produced from a particular field [14–16] and the production practice [15]. Offshore platforms extensively use DEG as inhibitor of the gas hydrate formation and as dehydrating additive to eliminate water vapors that normally saturate the extracted gas [16,17]. The dehydrating process is also necessary to avoid the corrosion and clogging of the gas transport lines. Sometime DEG can also be injected as antifreeze additive in wellhead or/and into oilwell. Sorensen et al. [18] describe the generation, handling, and disposal of gas dehydration discharges as well as how those wastes may be introduced into the subsurface environment. Large volumes of produced formation water (PFW), used to maintain gas reservoir pressure and additioned with corrosion inhibitors, demulsifiers, defoamers as DEG, are discharged directly into the marine environment [15,16]. After discharge into the sea, the PFW will be diluted depending on local conditions and biodegradation processes will change their composition [19–21]. Dissolved and particulate components from produced water are found both in the water column and in the marine sediment, and are thus available to the total ecosystem. For this reason, chronic and toxic effects of oil and gas platforms wastes have been monitored by regular surveys of benthic communities around the platforms [22]. Published data regarding the environmental impact of PFW have been addressed to the investigation of released pollutants such as heavy metals and hydrocarbons coming from the water reservoir, antifoams (e.g. fluorosilicone-based products), biocides (e.g. formaldehyde and glutaraldehyde-based compounds), demulsifies (e.g. phenol formaldehyde resin ethoxylates) [16,22–26]. However, exhaustive information regarding biodegradability, fate and toxic effects of wastes associated with DEG are still lacking [19,27]. Recent findings regarding the impact of glycol-based gas dehydration units on ground water demonstrated that glycols could act as a co-solvent for other pollutants (e.g. benzene, toluene, ethylbenzene and xylenes), thus greatly increasing the transport of such contaminants [18]. Failure to consider this co-solvent property of DEG and other glycols may result in underestimation of the risk associated to PFW discharges.

Due to its specificity, gas chromatography coupled to mass spectrometry (GC–MS) represents the widely used assay for the determination of glycols [9,10,28,29]. However, the hydrophilic character of DEG makes the trace determination of this compound in water samples a substantial analytical problem. Sample preparation represents the major drawback in the development of methods characterized by acceptable sensitivity. In fact, most of the protocols based on solid phase extraction (SPE) or liquid–liquid extraction (LL) are characterized by low recoveries due to the difficulty of finding adequate adsorbent materials and to the final elution step in an organic solvent [30]. In order to overcome these problems, in one previous work we proposed a new approach for detecting DEG in PFW wastes and seawater samples collected around offshore gas platforms [31]. The experiments were performed exploiting an innovative instrumentation, the Direct–EI interface, totally developed in our laboratory [32–34]. The Direct–EI interface is able to couple a liquid chromatograph with an electron ionization ion source of a mass spectrometer. The Direct–EI capability to acquire EI spectra and operate in SIM mode allowed us to detect DEG in sea water with a method limit of detection (LOD) of 31 ng/L. However, the lack of commercial availability of the interface makes the proposed method not yet universally applicable for a routine monitoring of DEG. For this reason, the aim of this study was to develop an alternative analytical approach for trace determination of DEG in PFW discharges and sea water. The new method is based on the use of a conventional LC–ESI-MS system. ESI represents a powerful technique for the quantitation of polar pollutants in aqueous matrices [23,35]. However the sensitivity of this technique for low molecular weight compound, such as glycols, is reduced due to the matrix effects (ME) and to the formation of adduct ions coming from the mobile phase that increase the background noise signal [36–38]. A derivatization process using benzoyl chloride has been used by Holčapek et al. [30] to minimize this phenomenon. This procedure was successfully applied for trace determination of several glycols in bitumen samples. In this work, the derivatization process has been modified enhancing the quality of the results. The method has been validated considering selectivity, limit of detection (LOD), limit of quantitation (LOQ), linearity, working range, precision and evaluation of ME, and it has been applied to the analysis of sea water samples collected around eight offshore gas platforms located in the Adriatic Sea.

2. Experimental

2.1. Sampling procedure

Samples collection was carried out during summer 2007 by the Research Vessel ASTREA of the High Institute for the Environmental Protection and Research (ISPRA, Rome, Italy). They were all collected around gas platforms situated in the Adriatic Sea. Sampling was conducted at different distances from the PFW diffuser and at different deep. Mercury chloride was added to the samples until saturation to inhibit bacterial activity. Samples were stored in refrigerator at 4 °C in dark glass bottles.

2.2. Reagents and derivatization procedure

Diethylene glycol, pentane, benzoyl chloride, benzyl alcohol were purchased from Sigma–Aldrich (Milan, Italy). Acetonitrile HLPC-grade and sodium hydroxide were obtained from VWR (Milan, Italy). A milliQ water purification system (Millipore, Bedford, MA, USA) was used to obtain reagent grade water. A 10 mg/mL DEG standard solution was prepared in water and stored at 4 °C. This stock solution was diluted appropriately to prepare the working solutions used for the method validation experiments. The internal standard (IS) benzyl alcohol solution was prepared in milliQ water at a concentration of 1 mg/mL.

The Schotten–Baumann method of the benzoylation of glycols in aqueous solution using an excess of the derivatization agent in a strongly alkaline medium was employed to derivatize DEG [39]. The reaction follows this scheme:

$$(1)R(OH_2) + 2C_6H_5COCl + 2NaOH \rightarrow R(OCOC_6H_5)_2 + 2NaCl$$

2.5 mL of a sample or working solution were added with 12.5 μL of the IS solution, 1.75 mL of 30% NaOH, and 50 μL of benzoyl chloride. The mixture was shaken for 2 min and incubated at ambient temperature for 10 min. After that, a liquid–liquid extraction was conducted utilizing 2.5 mL of pentane collected after shaking vigorously. This procedure was repeated twice. Then, the two collected aliquots of about 2.5 mL were mixed and was evaporated to dryness under a gentle stream of nitrogen at ambient temperature. The residue was dissolved in 250 μL of a mixture of acetonitrile:water (50:50), with a net preconcentration factor of 10. Respect to the procedure of Holčapek, the volumes of samples and reagents were modified and benzyl alcohol was used as the internal standard (IS).

2.3. LC–ESI-MS conditions

Chromatographic separations were conducted with a SpectraSystem P2000 binary gradient pump (ThermoFisher Corporation, San Josè, CA) equipped with a Waters Nova-Pack Column (150 mm × 2.1 mm i.d., 5 μm particle size) obtained from Waters (Milford, MA). Instead of an isocratic elution (30), a gradient elution program was used starting from 90% water and 10% acetonitrile to 100% acetonitrile in 8 min. The flow rate was set at 300 μL/min, and the injection volume was of 5 μL. The eluent coming out from the column was introduced on an ion trap mass spectrometer equipped with an ESI source (LCQDuo, ThermoFisher Scientific, San Josè, CA). Derivatized DEG and IS, benzyl alcohol, gave a better response in positive ion mode. Chromatographic separation was necessary to separate DEG from the IS and from the eventually present co-eluted interfering compounds maximizing the selectivity and the specificity of the method and eliminating any possible matrix effects. HPLC-MS analyses were conducted in Selected Ion Monitoring (SIM) on the m/z 235 (sodium adduct ion of the derivatized IS) and 337 (sodium adduct ion of the derivatized DEG). Three microscan of 500 ms were summed to obtain the entire scan. The voltage between the needle and the transfer capillary was set to 4.5 kV. The heated capillary voltage and temperature were kept to 10 V and to 225 °C respectively. To assist the nebulization and desolvation processes, nitrogen was used as sheath gas (60 arbitrary unit) and as auxiliary gas (20 arbitrary unit).

3. Results and discussion

This work is focused on quantification of DEG in marine water samples collected nearby offshore gas extraction platforms. These industrial plants use large quantity of DEG in their application processes and sometimes this chemical is discharged with PFWs creating potential impact on the marine ecosystem. Many authors have studied composition and effects of the PFW wastes [16,24,25] but from our knowledge nobody has applied LC–ESI-MS for the investigation of the chemical composition of the sea water surrounding the platforms. LC–ESI-MS represents the method of choice for the analysis of polar compounds in water matrices. However, as reported in Section 1, this analytical approach has a low sensitivity for glycols. This disadvantage is mainly due to the mobile phase background, which interferes with the signal of these low molecular weight compounds [30]. In addition, when dealing with matrices such as sea water, detection drawbacks can arise for the

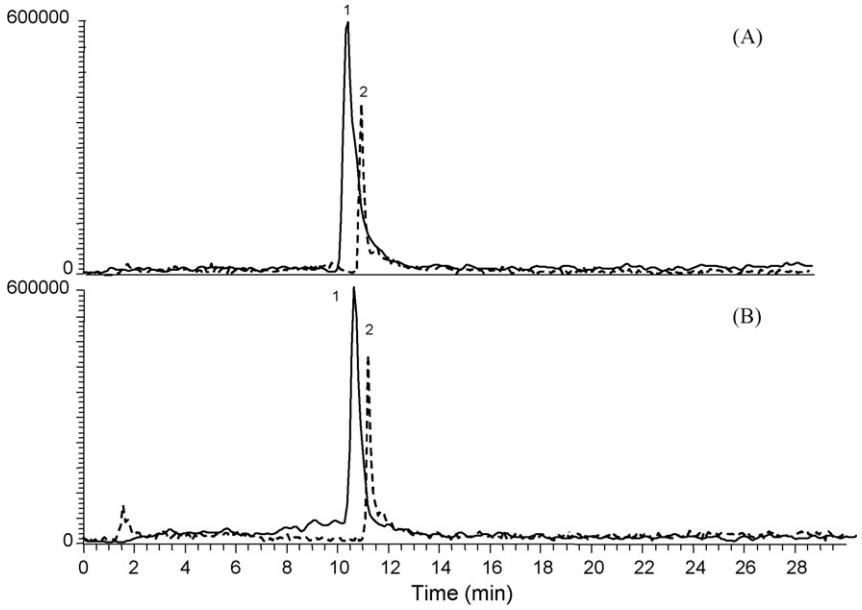

Fig. 1. Chromatograms relative to the separation of two extracts from: (A) a standard mixture in milliQ water containing DEG at a concentration of 0.4 μg/mL; (B) a blank sea water sample spiked with DEG at the same concentration of the standard mixture. Peaks: (1) derivatized DEG; (2) derivatized IS.

contemporary presence of salts which can co-elute with glycols in reversed phase chromatography, thus leading to ion suppression phenomena into the ESI source. In this work we applied a glycol benzoylation procedure as an efficient tool to overcome the above mentioned limitations. Respect to the underivatized DEG, its benzoyl derivative is characterized by a lower polarity and a higher molecular weight. The decreased polarity allows to facilitate the extraction procedure from the aqueous matrix and to improve the chromatographic separation from inorganic salts, preventing ME [36,37].

The optimization of chromatographic and mass spectrometric conditions was performed using a standard solution containing the derivatized DEG and benzyl alcohol at a concentration of 1 μg/mL. As widely reported in the literature [37,39,40], to compensate for possible ME, the target analyte and its IS must have identical or very close retention time. In these conditions, both compounds will be subjected to the same interferences, thus correcting for the degree of ME (Fig. 1). Mass spectrometric conditions were carefully optimized with the aim of achieving the best response for both derivatized compounds.

3.1. Method validation

Method performance was carefully evaluated taking into account *selectivity*, *linearity*, working range, *precision* and *matrix effects evaluation*. Selectivity was defined as the ability of the method to measure an analyte in the presence of interferences that may be expected to be present in the sample matrix [41]. A first step in obtaining the required method *selectivity* was obtained through the derivatization procedure, which was able to modify only the analytes reacting with benzoyl chloride excluding most of the other interfering substances. Subsequently, a pentane liquid–liquid extraction was carried out with the purpose of separating the DEG and IS derivatives from the sea water salts, benzoyl reagent and reaction by-products. The extract was finally analyzed by LC–ESI-MS in SIM mode. As reported in Fig. 2, the spectrum in scan mode of the dibenzoyl DEG is characterized by the presence of the sodium adduct ion at m/z 337. During the chromatographic separation, SIM detection enhances instrumental selectivity for both derivatives of DEG and of the IS ($[M+Na]^+$ at m/z 235). Fig. 1 reports the chromatograms relative to the separation of two extracts from: (A) a standard mixture in milliQ water containing benzyl alcohol and DEG at known concentration; (B) a blank sea water sample spiked with DEG and IS at the same concentration of the standard mixture. As it can be seen, the presence of the selected ion at the same retention time of the standard is a first satisfactory criterion in confirming the presence of DEG in the sea water sample. Moreover, as it will be demonstrated afterwards, the absence of ME represents the last goal in achieving a satisfactory selectivity.

The detection limit of the method was calculated taking into account the recovery of both extraction and derivatization procedures, the initial volume of the sample, the final volume of the extract and the instrumental LOD. Accordingly to the work of Holčapek [30] the percentage of recovery of the liquid–liquid extraction is very high (only less than 0.16% of the derivatives are lost). Different is the case of derivatization, where the recovery is about 40%, showing that the process is not complete. However, the reproducibility of this result and the use of an IS improve quality of quantitative results. In order to evaluate the instrumental LOD and LOQ, diluted working solutions containing DEG were subjected to the derivatization procedure and analyzed as reported in Section 2. The instrumental LOD was expressed as the minimum analyte amount that the instrumentation can detect with a signal-to-noise ratio (S/N) of 3, while the LOQ was defined as the amount that can be detected with a S/N of 10. Considering the derivatization process efficiency of 40% [30], these experiments demonstrated an instrumental LOD and LOQ of 4 and 12 ng/mL respectively (Table 1). Based on the above results, the proposed method has a limit of detection of 0.4 ng/mL.

To calculate the *linearity and working range*, calibration curves were constructed by plotting the peak area ratio of the dibenzoyl DEG to the derivatized IS versus the DEG concentration. The linear regression lines demonstrated a good linearity for 3 orders of magnitude starting from the instrumental LOD (Table 1). These experiments were carried out on column using the same conditions reported in Section 2. A correlation coefficient (R^2) of 0.9990 was achieved in the working range from 4 ng/mL to 4 μg/mL.

Precision was evaluated in terms of intraday and interday repeatability as the relative standard deviation percentage (RSD) of the peak areas of an LL extract containing the derivatized DEG at

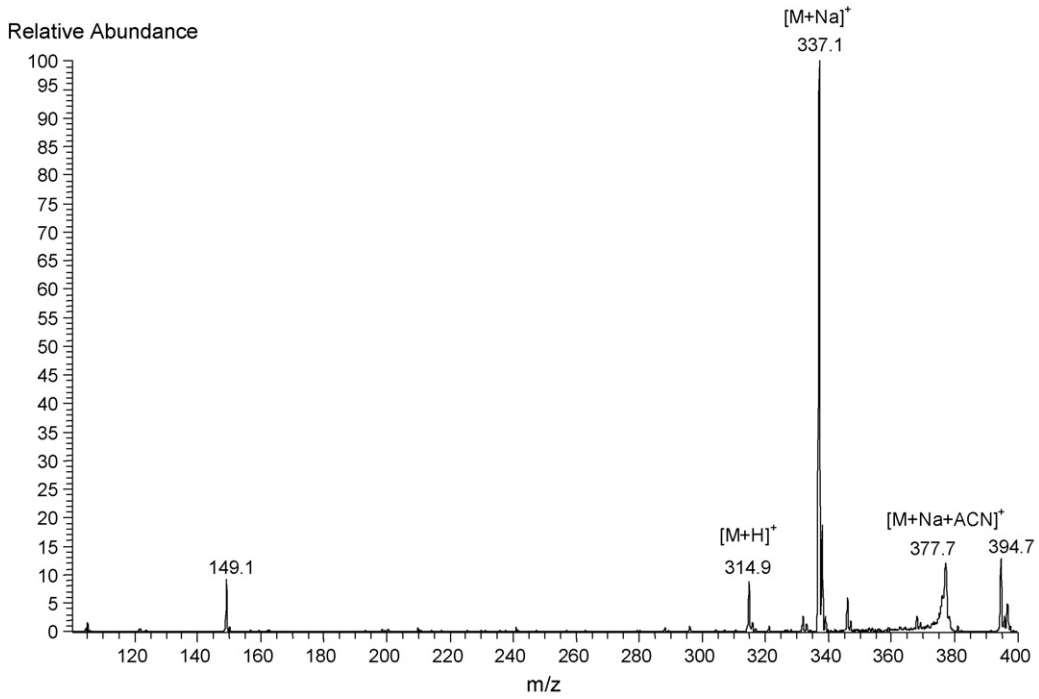

Fig. 2. ESI-MS spectrum obtained in infusion of a 10 μg/mL derivatized DEG solution.

a concentration of 0.1 μg/mL DEG solution. For the determination of the intraday repeatability, five replicates were analyzed in one day. The interday repeatability was evaluated injecting the solution on a working period of five days (three injections/day with a total of 15 replicates). RSD values together with all the other validation parameters are reported in Table 1.

A major limitation in quantitative analysis with LC–ESI-MS is represented by ME in which the matrix co-extracted with the analytes can alter the signal response, causing either suppression or enhancement [36,37]. This phenomenon can heavily affect the performances of the analytical method leading to erroneous quantitation [38–43]. For this reason, a careful evaluation of ME represents an important step in the development and validation of an LC–ESI-MS method. The exact mechanism of ME is still unknown. It is assumed that the co-eluted matrix can influence signal intensity in a possible competition for the available charges and for the access to the droplet surface for gas-phase emission. Due to the high salts concentration, ME represents one of the major drawback when analyzing sea water samples by LC–ESI-MS [44,45]. In order to investigate the capability of our derivatization method to overcome ion suppression phenomena due to the presence of salts, ME was carefully evaluated. In the literature, ME is usually calculated performing a comparison between the signal of an analyte in a pure solution and a matrix-matched standard [46,47]. In the present work, ME effect evaluation was carried out performing two different set of experiments. In the first set, three samples of milliQ water were spiked with DEG at a concentration of 0.4 μg/mL. Each spiked sample was then subjected to the IS addition and derivatization protocol described in Section 2. In the second set of experiments the derivatization procedure was carried out on three different aliquots of blank sea water sample spiked with DEG at a concentration of 0.4 μg/mL, and mercury chloride was added until saturation, as required by the sample collection procedure used for the real samples. The value of the ratio between the signal of the derivatized DEG and of the derivatized IS were then estimated in all the investigated samples. Finally, the ME was calculated in percent as the ratio between B and A multiplied by 100 (A = average peak area of the derivatized DEG/derivatized IS in pure water; B = average peak area of the derivatized DEG/derivatized IS in sea water). A ME value >100% indicates ionization enhancement, while a value <100% indicates ionization suppression. The final results indicate that an average ME of 90% was obtained, thus demonstrating that the proposed protocol exhibits an excellent performance toward the presence of matrix interferences.

3.2. Analysis of seawater samples

The method has been applied to the analysis of 48 seawater samples collected around eight gas platform located in the Adriatic Sea. DEG was extensively used as production chemical during the extraction processes of the investigated platforms. DEG identification in real samples was confirmed by chromatographic retention time and mass spectrometric SIM response. Quantification was based on the calibration curve values with the method of internal standard, that can correct instrumental and procedure fluctuations. The results are reported in Table 2. The variability of DEG concentrations on samples is due to the distance and deepness of the sampling locations respect to the discharge diffuser. Anyway, the values obtained show the presence of DEG at concentration that does not exceed the toxicity threshold for these substances in sea water [19].

4. Conclusions

From the results obtained, it can be concluded that the direct benzoylation of DEG followed by LC–ESI-MS can be proposed as a convenient experimental approach for monitoring the levels of this chemical in sea water. Validation parameters such as selectivity, linearity, instrumental LOD and LOQ were relevant to environmental analysis. This method was successfully applied in a real world application regarding the analysis of marine water collected around offshore gas platforms. Because of the relative simplicity and robustness, this method can be proposed as a routine protocol in monitoring programs addressed at the investigation of the glycols environmental impact during gas extraction processes.

VOC sensing

ABSTRACT

The effect of volatile organic compounds (VOCs) such as acetone, methanol, ethanol, chloroform, carbon tetrachloride, dichloromethane, and hexane on electrical conductivity of thin films of bis[tetrakis(alkylthio)phthalocyaninato]lutetium(III) double decker complexes $[(C_nH_{2n+1}S)_4Pc]_2Lu(III)$ was investigated. The $[(C_nH_{2n+1}S)_4Pc]_2Lu(III)$ molecules substituted with different alkylthia chains (n = 6, 8, 10, 12, and 16) were coated on interdigital transducers using a jet spray technique. A change (increase or decrease) in the conductivity of the $[(C_nH_{2n+1}S)_4Pc]_2Lu(III)$ films was observed depending on the concentration of the VOCs, which was ranging from 500 to 5000 ppm. The decrease in the conductivity of the sensors for the dissolvent of the compounds (chloroform, carbon tetrachloride, dichloromethane and hexane) could be related to swelling of the films. On the other hand, the increase in the conductivity of the sensors for the other VOCs (acetone, methanol and ethanol) could be resulted from that the VOCs act as electron donors and/or acceptors in the films. A linear relationship between the sensor response and concentration of the VOC vapors is obtained. The sensitivities of the $[(C_nH_{2n+1}S)_4Pc]_2Lu(III)$ films were in the range of 2.10^{-4}–3.10^{-3}%/ppm.

1. Introduction

During the past decade, metalophthalocyanines (MPcs) have attracted considerable attention in solar cells, photo dynamic therapy, gas sensors, as liquid crystal, and electrochoromic displays because of their remarkable optical, and electrical properties, the conjugated π system, as well as chemical, and thermal stability [1–3].

Several review papers about chemical sensing properties of the MPcs have been published [4–8]. The MPcs may be utilized for different types of chemical sensors, including in particular electronic sensors (such as resistive sensor, field-effect transistors (FET), solid-state ionic, and capacitance sensors), mass-sensitive sensors utilizing a quartz crystal microbalance (QCM) or surface acoustic-wave (SAW) sensors, and optical sensors. It is well known that the sensor response, stability and other sensing characteristics of the MPc films are affected by many factors, such as film morphology, molecular orientation and so on. To achieve optimal sensor performance, requirements for coating properties of the MPc films are good control of thickness, uniformity, viscosity and adhesive strength of the film. Various techniques are used to prepare MPc thin films, such as vacuum deposition, spin-coating and Langmuir–Blodgett technique depending on the structure and solubility of the used MPc molecule.

Most researchers studying the gas sensitivity of MPcs using chemoresistive sensors are focused on oxidizing and reducing gases such as NO_2, O_3, and Cl_2 which have strong electron interactions with the phthalocyanine film [4–9]. However, only a few papers were published on chemoresistive gas sensors for non-oxidizing gases such as volatile organic compounds (VOCs). The main reason is that the exposure of a MPc film to a gas leads to variations in the charge carrier density in the molecular units of the film. These types of organic compounds generally are not so strong electron donors or acceptors, and hence the changes are less intense when compared with those observed with the inorganic gases mentioned above [10].

Among the large family of the phthalocyanines, lanthanide bisphthalocyanines, and especially the lutetium derivatives have been subject of extensive investigations because of their characteristic properties such as intense color, redox activity, and high thermal stability [2,3]. There are special properties of this class of compounds that make them suitable for applications in the field of

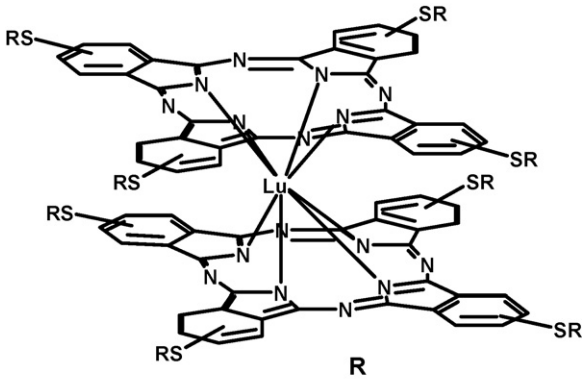
molecular electronics such as photovoltaic cells [3], organic light emitting diodes [11,12], and sensor devices for industrial and environmental applications [13]. de Saja and coworkers have been working for several years extensively with lanthanide phthalocyanines which are sandwich type complexes for chemoresistive sensor applications [8,10,14–16]. However, the sensing mechanism between MPc and VOCs is not yet well understood [8].

In this work we have investigated the effect of VOCs on the electrical conductivity of thin films of bis[tetrakis (alkylthio)phthalocyaninato]lutetium(III) double decker complexes $[(C_nH_{2n+1}S)_4Pc]_2Lu(III)$ and have explained VOCs sensing mechanism.



2. Experimental details

The synthesis procedure of bis[tetrakis(alkylthio)phthalocyaninato]lutetium (III) double decker complexes, $[(C_nH_{2n+1}S)_4Pc]_2Lu(III)$ (n = 6, 8, 10, 12, 16), has been extensively described in Ref. [17]. The chemical structure and the sample notation (**1–5**) of the compounds are given in Fig. 1 [17].

The interdigital transducer (IDT) used in the experiment consists of an array of metal electrodes photolithographically patterned on pre-cleaned microscope slides. Before vacuum evaporation, microscope slides were thoroughly cleaned with soap (micro 90), pure acetone and deionized water (18 MΩ) by an ultrasonic cleaner and then coated with ca. 20 nm of chromium followed by 130 nm of gold in a Leybold Univex 450 coater system with a Inficon Deposition Monitor (XTM/2). The film is patterned photolithographically and etched to provide 10 finger pairs of electrodes having a width of 100 μm, spaced 100 μm from the adjacent electrodes. The finger overlap distance was 5 mm. Gold was selected as the electrode material, since it is well-known metal which forms ohmic contacts with the phthalocyanines.

Thin films of the compounds were coated onto the IDTs using a homemade air brush system in an inert ambient from a solution of the compounds in chloroform. The thickness of the films determined by a Surface Profilometer (Veeco, Dektak 6) was approximately 150 nm. The films used on the sensors were annealed at 150 °C in high purity dry nitrogen ambient to get a liquid crystal order of the film before gas sensing measurements.

The sensor devices were mounted in a homemade aluminum test chamber of a volume of 1 l which was connected with MFC controlled high purity N_2 lines. All measurements were done in dark because it is known that with a glass chamber, light can induce the formation of ozone whose presence, even at very low concentration (10 ppb), can increase the density of charge carriers in the radical lutetium bismacrocyclic derivatives, then the measured conductivity [13,18]. A constant bias voltage of 1 V was applied to the devices and the dc current was measured with a Keithley 6517A Electrometer/High Resistance Meter. The dc current (sensor responses) was monitored continuously under N_2 atmosphere to establish the baseline of the device and recorded using an IEEE 488 data acquisition system incorporated to a personal computer. The high purity N_2 stream flowed through the test chamber until the electric current reached a steady value and then the valves of the chamber were closed. A certain amount of volatile organic compound (from 15 to 150 μmol, resulting in concentrations of 500, 1000, 2000, 3000, 4000, 5000 ppm consequently) was injected into the test chamber through a septum with a gas tight micro syringe. The VOCs exposed to the sensors were the dissolvent of the compounds such as chloroform, carbon tetrachloride, dichloromethane, and hexane, and other VOCs such as acetone, methanol, and ethanol.

3. Results and discussion

It is well known that when an analyte gas molecule is adsorbed on the surface of a phthalocyanine film it causes a variation in the physical or chemical properties of the film, such as swelling, capacity or conductivity changes, etc. In order to measure the effect of different VOC vapors on the conductivity of the Pc films, after the baseline current reached a steady state value, the films were exposed to atmospheres containing a certain amount of them (500, 1000, 2000, 3000, 4000, 5000 ppm). Fig. 2a shows the current versus time behavior of compound **1** exposed to 3000 ppm of the dissolvent chloroform, carbon tetrachloride, dichloromethane and hexane at room temperature. After the dissolvent exposure (3000 ppm), the current decreased sharply for a few minutes and then the rate of decrease slowed down and then the current reached a steady value. When the dissolvent vapors are removed with high purity N_2 flow, the recovery shows a rapid increase and then the rate of increase slows down. A drift in the baseline is observed while monitoring the operation of the sensors. This type of behavior has been previously reported [19] for other sensors based on phthalocyanine derivatives, and has been attributed to an incomplete recovery of the original properties of the films. This problem could be overcome by heating the samples in order to facilitate the desorption of the vapors from the sensing layer. It is obviously seen in Fig. 2a that the sensor response is in the order: chloroform > hexane > dichloromethane > carbon tetrachloride.

Fig. 2b shows a typical current versus time of compound **1** exposed to 500–5000 ppm of chloroform at room temperature which is a dissolvent of the compounds (**1–5**). After first exposure (500 ppm), the current decreased sharply for a few minutes and finally the rate of decrease slowed down and then the current reached a steady value. Similar behavior is observed for second and further exposures to chloroform (1000–5000 ppm). When the chloroform vapor is removed with high purity N_2 flow, the recovery shows a rapid increase and then the rate of increase slows down. Similarly, as can be seen in Fig. 3 a decrease in the current is obtained when the dissolvent chloroform is exposed to the other four compounds (**2–5**). After every indicated concentration of chloroform exposed to the sensors, the current decreased sharply for a few minutes and finally the rate of decrease slowed down and then the current reached a steady value. If we pay attention to the current scale in Fig. 2b and Fig. 3, it is clearly seen that the amplitude of the current is depending on the length of alkyl chain. The relationship between conductivity and the length of alkyl chain is previously given in Ref. [17].

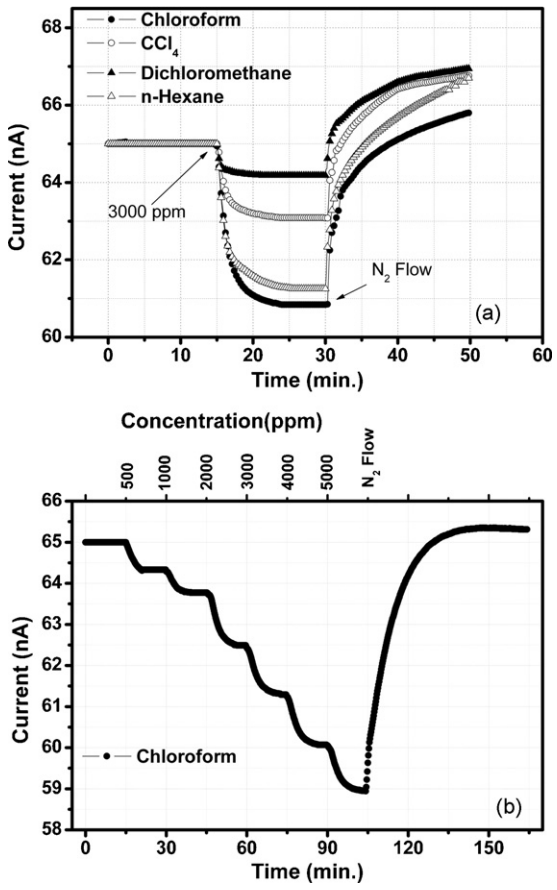

Fig. 2. Current versus time of a film of compound **1** exposed to the 3000 ppm of the dissolvents chloroform, carbon tetrachloride, dichloromethane and hexane at room temperature (a) and current versus time of compound **1** at room temperature as a function of chloroform concentration (b).

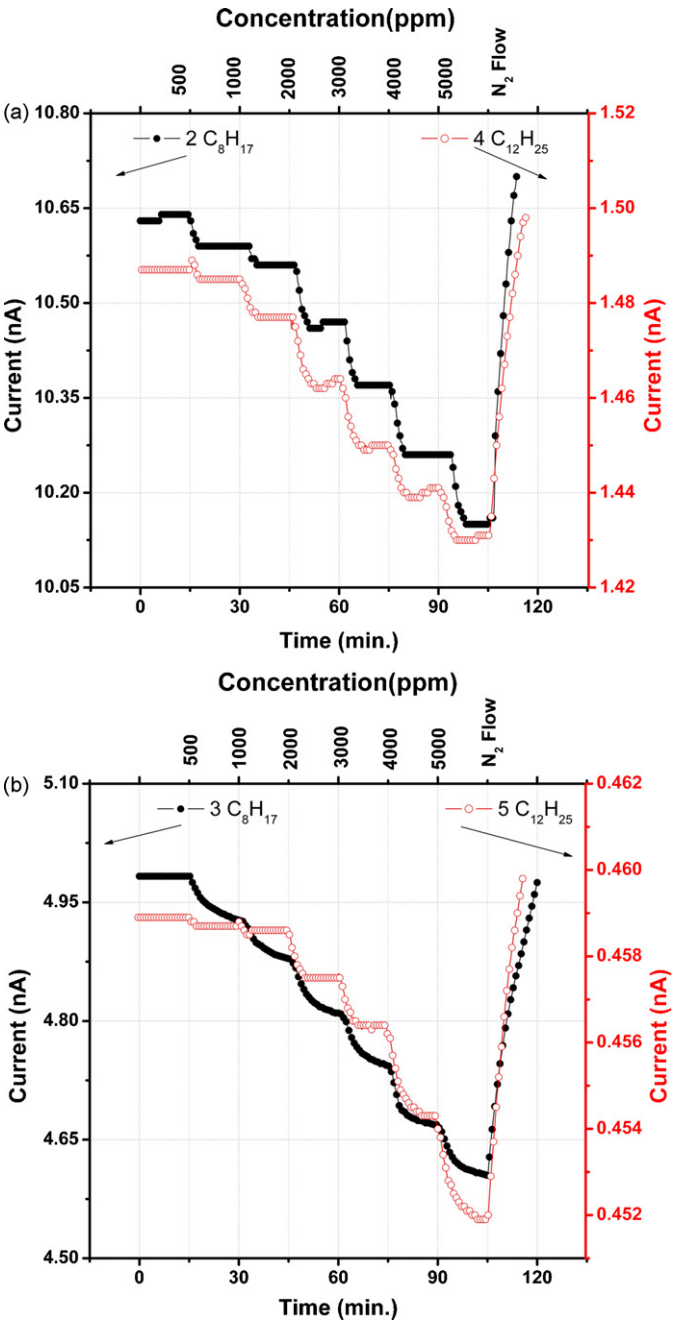

Fig. 3. Current versus time of films of compounds (**2–5**) exposed to 500–5000 ppm of chloroform at room temperature. (a) and (b) represent the response curves of compounds **2**–**4** and **3**–**5**, respectively.

Fig. 4 shows typical current versus time curves of a sensor of compound **1** exposed to 500–5000 ppm of the three different VOCs acetone, methanol and ethanol. After first exposure to the VOCs (500 ppm), the current increased sharply in a few minutes and then the rate of increase slowed down and then the current reached a steady value (saturation). Similar behavior is observed for the second and so on exposures to the VOCs (1000–5000 ppm). When the VOCs are purged with a high purity N_2 flow, the sensor response goes back to the baseline. The recovery curve shows a rapid decrease and then the rate of decrease slows down. A slight drift in the baseline is observed while monitoring the operation of the sensors such as for the dissolvent VOCs of the compounds. If two alcohols are compared, the sensitivity to ethanol is higher than of the methanol. This effect can be explained by looking at the electric dipole polarizabilities of the alcohols; ethanol has a greater polarizability than methanol (5.41×10^{-24} and 3.23×10^{-24} cm^3, respectively). For the other four compounds (**2–5**) similar results are obtained. In generally, the conductivity changes as determined using interdigital transducers may result from changes of the relative dielectric coefficients in the gas phase, in the sensitive layer and/or from the changes of the effective thickness of the sensitive layer (swelling). So, the increase in the current could be naively interpreted bearing in mind that phthalocyanines are p-type semiconductors and that electron donor molecules can oxidize the phthalocyanine molecules.

A different behavior for the dissolvent of the compounds (**1–5**) such as chloroform, carbon tetrachloride, dichloromethane and hexane from the other VOCs has been observed. While the dissolvent is exposed to the sensor the current decreases, but for the other VOCs exposed the current increases. In the literature, de Saja and coworkers have investigated chemoresistor sensors based on Pc_2Lu for VOCs sensing. They obtained a decrease in the conductivity, when the sensors were exposed to the VOCs such as hexanol, hexanal, *n*-butyl acetate, acetic acid [8,10], trimethylamine [14], and olive oil aroma [15]. Miller et al. obtained a similar behavior for cobalt phthalocyanine (CoPc) which was exposed to dimethylmethylphosphonate, methanol, water, and toluene [20]. In our case, the decrease of the conductivity would be the result of the swelling effect caused by the diffusion of dissolvent of the compounds that would lead to a decrease in the mobility of the charge carriers. The investigation of the mesoscopic phase under VOC vapors under polarized microscope showed us, the dissolvent of the compounds disturbed the ordered structure of the films which leads to decrease

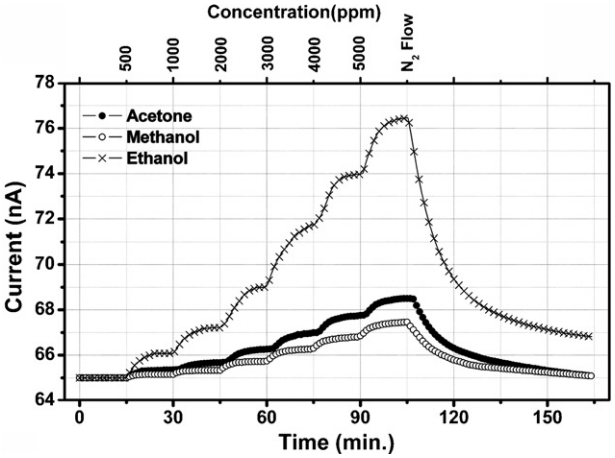

Fig. 4. Current versus time of a film of compound **1** exposed to 500–5000 ppm of three different VOCs at room temperature.

in conductivity, but other VOCs have no effect on the film structure. Fig. 5 shows the polarized microscope photos of the thin film of compound **1** when the compound **1** was exposed to dry air, 10,000 ppm acetone and 10,000 ppm chloroform. There is no structural metamorphosis when the compound **1** was exposed to acetone but it is clearly seen a change in the structure when the compound **1** was exposed to chloroform. Dark lines or dark parts are gold electrode fingers under the thin film as seen in Fig. 5. The mesophase of the compound **1** was disappeared when the compound 1 was exposed to chloroform (Fig. 5c).

On the other hand, Gorbunova et al. have obtained an increase in the conductivity for chemoresistor sensors based on samarium bisphthalocyanine, when the sensors were exposed to VOCs such as hexanol, hexanal, *n*-butyl acetate and acetic acid [16] like our results for acetone, methanol and ethanol. Similarly Bekaroglu and coworkers acquired an increase in the conductivity for chemoresistor sensors based on zinc phthalocyanine (ZnPc) [21,22] and CoPc [21] exposed to VOCs such as chloroform, acetone, carbontetrachloride, methanol, ammonia, and ethanol. Similar results were obtained by Ma et al. for the ZnPcs zinc hexadecafluorophthalocyanine [23], zinc tetraphenylporphyrin, and zinc meso-tetra(2,3,4,5,6-pentafluorophenyl)-porphyrin [24]. Gupta and Misra observed an increase in conductivity for manganese phthalocyanine when trimethylamine was exposed to the sensor [25]. In our results the increase in the conductivity of the sensors for the other VOCs (acetone, methanol and ethanol) could be naively interpreted to electron-donating to the films.

A linear relationship between the sensor response and concentration of VOC gases, which is based on the low concentration region of a Langmuir adsorption model, is observed in the concentration range 500–5000 ppm at room temperature. The sensor response is defined as

$$R = \frac{\Delta I}{I_0} 100 \quad (1)$$

where ΔI is the change in current and I_0 is the reference value of the coated devices exposed to dry nitrogen. Fig. 6a shows the sensor

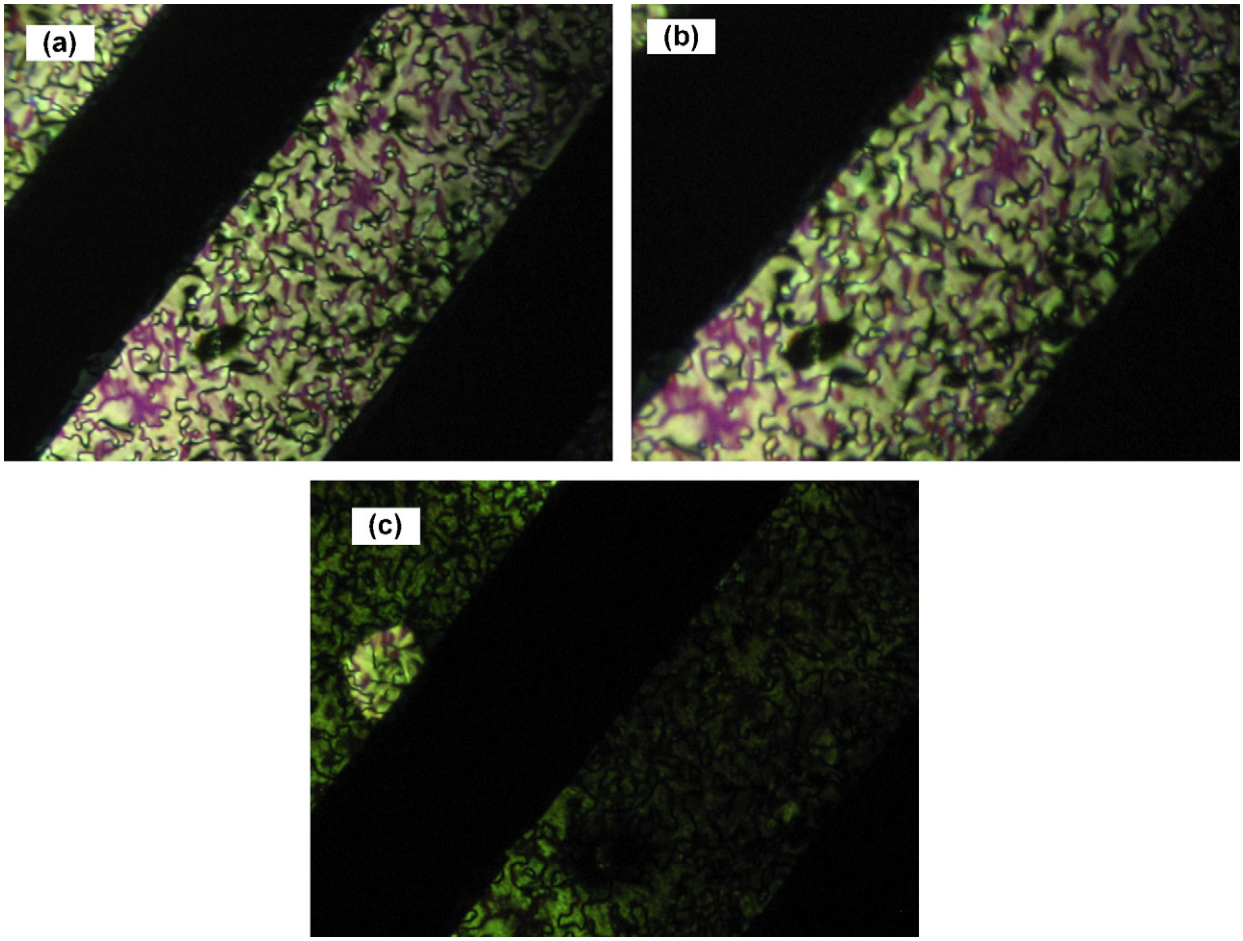

Fig. 5. The polarized microscope photos of the thin film of compound **1** when the compound **1** was exposed to dry air (a), 10,000 ppm acetone (b) and 10,000 ppm chloroform (c). Dark lines are gold electrodes fingers under the thin film.

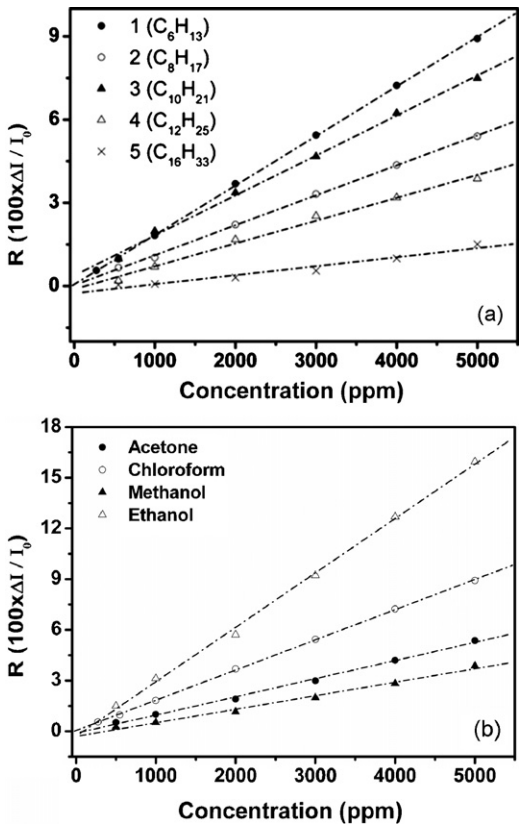

Fig. 6. Sensor response versus concentration of chloroform for all compounds (**1–5**) (a) and for all VOCs for compound **1** (b) at room temperature. The side chain formula of the compounds is represented in the parentheses.

responses versus concentration of chloroform for all compounds (**1–5**) at room temperature. The sensor response decreased with increasing length of the alkyl chain, except for compound **3**. It can be clearly seen from Fig. 6a that the maximum sensor response is observed for compound **1** which has the shortest alkyl chain and the minimum sensor response is observed for compound **5** which has the longest alkyl chain. However, no relationship between sensor response and the length of alkyl chain was observed for the other VOC vapors. Fig. 6b shows the sensor response versus concentration of VOCs for a film of compound **1**. The electric dipole polarizability of chloroform, acetone, ethanol and methanol is 8.23×10^{-24}, 6.33×10^{-24}, 5.41×10^{-24}, and 3.23×10^{-24} cm^3, respectively [26]. There is no relationship between the electric dipole polarizability of VOCs and the sensor response (Fig. 6b), because the sensitivity is not only depending on polarizability but also depends on polarity, acidity, basicity, dispersion, etc. of the VOCs. For the other four compounds (**2–5**) similar results are obtained.

The sensing properties of these films were compared by sensitivity. The sensitivity is defined as

$$S = \frac{\Delta R}{\Delta C} \quad (2)$$

where ΔR is the change in sensor response and ΔC is the change in the concentration of the VOC. Fig. 7 depicts the sensitivity of compounds **1–5** for acetone, chloroform, methanol and ethanol at room temperature. It is clearly seen from Fig. 7 that if alcohols are compared, the sensitivity for the ethanol is higher than of the methanol for all compounds. The sensitivities of the $[(C_nH_{2n+1}S)_4Pc]_2Lu(III)$ films were in the range of 2.10^{-4}–3.10^{-3}%/ppm. Previously, a logarithmic relationship between the dc conductivities of the compounds and the length of the alkyl chains on the periphery of the compounds was observed [17] and self-orientation of

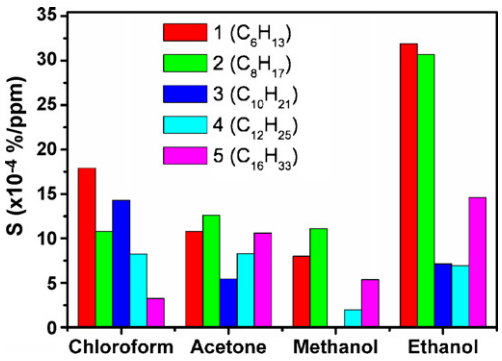

Fig. 7. Sensitivity of compounds **1–5** for VOCs at room temperature. The side chain formula of the compounds is represented in the parentheses.

$[(C_nH_{2n+1}S)_4Pc]_2Lu(III)$ films after heated to liquid crystal phase region caused a decrease in the conductivities of the films [27]. However, we did not obtain such a relationship between the sensitivity and the length of the alkyl chains on the periphery of the compounds except for dissolvent chloroform. Fig. 7 shows that the sensitivities of the $[(C_nH_{2n+1}S)_4Pc]_2Lu(III)$ films are varying. This could be related to different reorganizations of the $[(C_nH_{2n+1}S)_4Pc]_2Lu(III)$ films after heating to 150 °C as the $[(C_nH_{2n+1}S)_4Pc]_2Lu(III)$ compounds have various phase and phase transition temperature up to 150 °C. The phase and phase transition temperature of the all compounds were given in Ref. [17].

4. Conclusions

The use of the tetrakis(alkylthio)-substituted lutetium(III) bisphthalocyanines can contribute greatly to the development of VOC monitoring systems. The behavior of the sensing elements when exposed to VOCs has been analyzed. The sensing units give rise to fast and reproducible signals, without a noticeable loss of their properties. The reproducibility and complete reversibility of the signals further encourage the development of these in-situ detectors for VOCs.

The linear relationship between the sensor response and concentration of VOC vapors allows the quantification of trace amount of VOCs. A different sensing behavior for the dissolvent of the compounds such as chloroform, carbon tetrachloride, dichloromethane and hexane from the other VOCs has been observed depending on the swelling effect caused by the diffusion of dissolvent of the compounds that leads to a decrease of the mobility of the charge carriers. For the other VOCs (acetone, methanol and ethanol), the increase in the conductivity of the sensors can be related to the electro-donating and -accepting properties of the films.

Method optimization and validation

ABSTRACT

A rapid and reliable analytical method for quantification of flavonoids in onions was developed and validated. Five extraction methods were tested on freeze-dried onions and subsequently high performance liquid chromatography (HPLC) with UV detection was used for quantification of seven flavonoids.

The extraction efficiencies were lowest for the conventional water bath extraction compared to pressurized liquid extraction (PLE), ultrasonication, ultrasonic liquid processor, and microwave extraction, which yielded similar efficiencies. The reproducibility was in the same range (RSD: 1–11%) for all tested extraction methods. However, PLE was the preferred extraction method because the method can be highly automated, use only small amounts of solvents, provide the cleanest extracts, and allow the extraction of light and oxygen-sensitive flavonoids to be carried out in an inert atmosphere protected from light.

The method parameters: extraction temperature, sample weight, flush volume and solvent type were optimised, and a clean-up step was integrated in the PLE procedure by in-cell addition of C18-material to the extraction cells, which slightly improved the recovery and reproducibility of the method. The one-step PLE method showed good selectivity, precision (RSDs = 3.1–11%) and recovery of the extractable flavonoids (98–99%). The method also appeared to be a multi-method, i.e. generally applicable to, e.g. phenolic acids in potatoes and carrots.

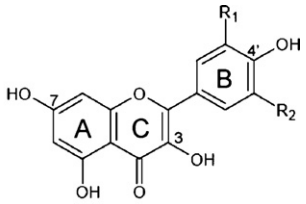
1. Introduction

Flavonoids belong to the group of polyphenols and are secondary metabolites [1], which play an important role in the normal growth, development and defence of plants [2]. Polyphenols in general have antioxidant properties and are proposed to have beneficial health effects such as decreasing the risk of heart diseases and protection against cancer [3–5].

Onions are a rich source of flavonoids [6,7], which generally occur widely in the plant kingdom [3], and onions are one of the main sources of polyphenols in daily food intake [8–10]. The content of polyphenols varies in different plant parts [11,12] and between varieties due to genetic factors [13–15], environmental and cultural factors [1], as well as time of harvest, processing and storage [16].

The main flavonoids in onions are quercetin mono- and diglucosides [17,18], which account for up to 80% of the total content of flavonols, but kaempferol [17] and isorhamnetin derivates [18,19] as well as myricetin [2] have also been found (see chemical structures in Fig. 1).

Conventional liquid extraction methods, e.g. water bath or ultrasonication, with aqueous methanol or acetonitrile have been widely used as simple and easy methods for analysis of flavonoids [20,21]. Extraction of flavonoid aglycones has most often been done by acid hydrolysis [2,22,23], but harsh extraction conditions (e.g. acid or heating) should be avoided if intact flavonoid-glycosides are desired [21]. An increased risk of degradation is often seen with conventional extraction methods owing to long extraction times, where samples are exposed to light and oxygen, which facilitate the degradation of flavonoids [24,25].



More rapid and automated methods have recently been used, e.g. supercritical fluid extraction (SFE), pressurized liquid extraction (PLE) or microwave-assisted extraction (MAE). They are advantageous compared to conventional methods because they can be carried out in the absence of light and protected from oxygen, cope with the demand for a reduction in organic solvent consumption and improve the extraction time due to the possibility of working at elevated temperatures and/or pressures in inert atmospheres [26].

SFE has been used for extraction of polyphenols in grapes [27]. However, SFE of polyphenols requires a high percentage of organic modifiers, which is a disadvantage as it decreases the method selectivity [25]. PLE is advantageous because high temperatures and pressures can be applied, which accelerate the extraction [25], but its application in food analyses has been limited although it

Fig. 1. Chemical structures of selected flavonols. The full chemical names are listed in the footnotes.

has been used to extract polyphenols from various food products [28,29]. MAE has been used for extraction of polyphenols from food products and plants and has the advantage of being rapid with a low solvent-consumption [32]. Another promising technique is Ultrasonic Liquid Processing (ULP), which has so far not been used for extraction of polyphenols from plants. The principle of ULP is the same as sonication, but shorter extraction times are expected due to a more intense cavitational action and greater disruption of the sample [33].

The objective of our study was to develop a rapid, sensitive and robust analytical method, which sets a new standard for extraction of flavonoids in onions. The recommended method of choice should be based on a comparison of the efficiency, reproducibility and sensitivity of conventional methods (water bath and ultrasonication) with more modern extraction methods (PLE, MAE and ULP). The best extraction method will be optimised with regards to relevant extraction parameters and validated.

2. Materials and methods

2.1. Reagents and chemicals

Methanol (HPLC-grade, Rathburn Chemicals Ltd., Scotland) and Milli-Q water (18 MΩ, Millipore, USA) were used for standards and eluents. Dimethyl sulfoxide (DMSO, >99%) and formic acid (98–100%) were purchased from Merck (Germany). The following standards were purchased: quercetin (Q) and isorhamnetin (I) from Extrasynthése (France), quercetin-3,4′-diglucoside (Q-3,4′-diglu) from Polyphenols (France), quercetin-7,4′-diglucoside (Q-7,4′-diglu) from Apin (United Kingdom), quercetin-4′-glucoside (Q-4′-glu) from Plantech (United Kingdom), and quercetin-3-glucoside (Q-3-glu, purity >90%), chlorogenic acid (ChlAcid, purity >95%) and caffeic acid (CafAcid, purity >99%) from Sigma–Aldrich (Germany).

Individual standard stock solutions were prepared by dissolving the solid compounds in DMSO (100 μg/mL). Working solutions were prepared by 10-times dilutions of the stock solutions with methanol. Stock solutions were stored at −80 °C (<1 year), while the working solutions were prepared shortly before analyses and kept at −20 °C until analyses.

2.2. Samples

The onion sample (*Allium cepa* var. *zittauer*, 40–60 mm, Soeris I/S) used for comparison of extraction methods and PLE method optimisation was organic and purchased in a local supermarket. The onion (*Allium cepa* var. *hytech*), carrot (*Daucus carota* var. *bolero*), potato (*Solanum tuberosum* var. *sava*) and white cabbage (*Brassica oleracea* var. *impala*) samples used for method validation were internal reference samples. Only the bulb of the onion sample was used for analysis comprising the eatable part by removing the top, bottom and outer leaves. The stalk and outer leaves of the white cabbage heads were also removed. The top and bottom of the carrots were discarded and both carrots and potatoes peeled. The samples were freeze-dried at 1×10^{-3} bar for approximately 2 days and afterwards crushed and homogenised in a blender. The samples were stored at −20 °C in a nitrogen atmosphere until analysis. In general, the samples were protected from light and oxygen during the entire sample preparation.

2.3. Extraction methods

Throughout the entire method comparison 60% aqueous methanol was used as extraction solvent because it has previously been used successfully in our conventional water bath method (data not shown).

2.3.1. Ultrasonication

The sample material (0.1 g) was mixed with 5 mL solvent and sonicated at room temperature for 60 min (Branson 5200 Ultrasonic Cleaner, 120 W) following the procedure suggested by Lin and Harnley [34].

2.3.2. Water bath

The sample material (0.5 g) was extracted with 50 mL solvent at 30 °C for 60 min in a shaking-water bath (Julabo SW 23). The extracts were then filtered through a filter paper (Whatman1) and evaporated close to dryness *in vacuo* at 30 °C on a rotary evaporator. The residue was redissolved in 5 mL solvent.

2.3.3. Microwave-assisted extraction

The sample material (0.1 g) was transferred to a glass tube and 5 mL solvent was added. The extraction was carried out in the tubes on a Microwave Synthesizer (Initiator, Biotage, 15 watt) at 60 °C for 2 min.

2.3.4. Ultrasonic liquid processor

The sample material (0.1 g) was transferred to a glass tube and 5 mL solvent was added. The microprobe was immersed into the tube and the extraction was performed at room temperature for 30 s using an ultrasonic liquid processor (Microson XL 2000, Misonix, 10 W).

2.3.5. Pressurised liquid extraction

The extractions were carried out using an ASE-200 (Dionex). The sample material (0.1 g) was mixed with 3 g of glowed and chemically inert Ottawa sand (particle size 20–30 mesh, Fisher Chemicals) and added to 5 mL extraction cells. Two glass fiber filters (90 mm, Advantec) were placed at the bottom and one at the top of the extraction cell, which was filled with Ottawa sand. The extraction parameters were: temperature: 40 °C, pressure: 1500 psi, pre-heating time: 1 min, static extraction time: 5 min, heating: 5 min, static cycles: 2, flush volume: 100% of cell volume, purge time with N_2: 60 s. The extracts were collected in vials and

the volume adjusted to 20 mL with extraction solvent in volumetric flasks.

All extracts were filtered through a 0.20 μm filter (Sartorius Minisart) before chemical analysis.

2.4. Quantification of flavonoids by HPLC–UV

A Waters 2695 Alliance Separation Module was used for the chemical analysis of flavonoids in combination with a Waters 2996 Photodiode Array Detector (PDA) and a Waters 2487 Dual λ Absorbance Detector. Empower 2 was used for instrument control and data acquisition. The chromatographic separation was carried out at a flow rate of 1.0 mL/min at 30 °C with an injection volume of 20 μL (temperature of autosampler: 5 °C). The column was a Phenomenex Prodigy RP-C18 column (4.6 mm × 250 mm, 5 μm). The A-eluent was a mixture of 0.1% formic acid in Milli-Q water (v/v) and methanol (90:10, v/v) and the B-eluent was 100% methanol. The gradient program was as follows: 5% B for 1 min, a linear gradient to 50% B for 34 min, a linear gradient to 100% B for 5 min, isocratic elution for 4 min, followed by a 1-min ramp back to 5% B and re-equilibration for 6 min giving a total run-time of 51 min. The PDA collected data from 190–500 nm (sampling rate: 1.0 spectra/s and resolution: 1.2 nm). The Dual λ Absorbance Detector was used for quantification and set at 254 nm (sampling rate: 1.0/s), which is in the range of the first UV-maximum of flavonoids (240–285 nm) [21]. The flavonoids were quantified relative to quercetin and it is common practise in analyses of bioactive compounds to quantify relative to one or more selected reference compounds [20].

2.5. Identification of flavonoids by HPLC–MS and MS/MS

Structure elucidation of flavonoids in onions was based on accurate mass measurements, isotopic pattern fit of measurement compared to theoretical (i-FIT values, Elemental Composition version 4.0 in MassLynx software version 4.1, Waters, USA) and MS/MS fragmentation patterns. An ultra performance liquid chromatograph (UPLC) interfaced to a quadropole time of flight tandem mass spectrometer (qTOF) was used for exact mass determinations and an HPLC interfaced to a triple quadropole mass spectrometer (HPLC–QqQ) was used to study fragmentation patterns. Afterwards, the identities were confirmed with available and affordable standards by comparison of retention times, UV and MS data.

2.5.1. UPLC–qTOF

The same mobile phases as those used for the HPLC–UV analyses were used for the UPLC (Waters) analyses. The column was a Waters Acquity BEH-C18 column (2.1 mm × 100 mm, 1.7 μm), which was retained at 30 °C. The HPLC gradient was scaled according to the column dimensions and gradient flow rate applied in UPLC in order to obtain a UPLC gradient with the same number of column volumes and linear velocity. The gradient program was as follows (flow rate of 0.2 mL/min): 5% B until 0.4 min, a linear gradient to 50% B until 14.6 min, a linear gradient to 100% B until 15.4 min, isocratic elution until 17.5 min, a 0.4 min ramp back to 5% B and re-equilibration for 2.1 min giving a total run-time of 20 min. A sample volume of 8 μL was injected using the partial loop with needle overfill mode. The qTOF (Waters/Micromass qTOF Ultima Global) used electrospray ionisation in negative ion mode. The operating conditions were: ion source temperature: 120 °C, desolvation gas (N_2): 350 °C, 600 L/h, cone gas: 50 L/h, capillary voltage: 3 kV, scan time: 1.0 scan/s and inter-scan delay time: 0.1 s. MassLynx software version 4.1 was used for instrument control and data acquisition and leucine enkephaline (554.2615 g/mol) was used as lock-spray mass (reference standard). External mass calibration (*m*/*z* 150–1000) was carried out before the analyses using a sodium formate solution containing 10 mM sodium hydroxide in isopropanol/0.2% formic acid (1:1, v/v).

2.5.2. HPLC–QqQ

A Waters 2699 Alliance Separations Module combined with a PDA (Waters 2996) and a QqQ (Waters Micromass Quattro LC) mass spectrometer with an electrospray interface was used for analyses. The same chromatographic conditions as in the quantitative analyses (see section above) were used. The initial scanning for flavonoids in onions included both negative and positive full scan (single MS) mode at different cone voltages (±10, 30, 50 and 70 V; *m*/*z* 100–850). MS/MS analyses were carried out at different collision energies (±10, 30 and 50 V) with a cone voltage of 30 V. The operating conditions were: ion source temperature: 120 °C, desolvation gas (N_2): 300 °C, 580 L/h, nebulizer gas: 90 L/h, capillary voltage: 3 kV, scan time: 1.0 scan/s and inter-scan delay time: 0.10 s. MassLynx software version 4.1 was used for instrument control and data acquisition.

2.6. Optimisation and validation of PLE method

The following PLE parameters were optimised: temperature (40, 75 and 100 °C), sample weight (0.1, 0.3 and 0.5 g), flush volume (100,

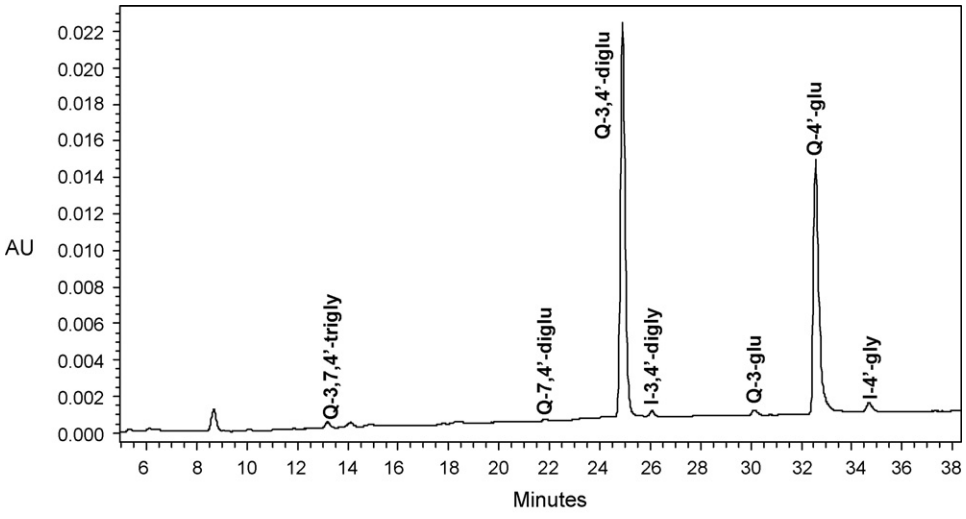

Fig. 2. Chromatogram of an onion extract (HPLC–UV, 254 nm).

125 and 150%) and solvent type (30, 40, 50, 60, 70, 80 and 90% aqueous methanol). It was also tested whether a clean-up step by in-cell addition of 0.5 g C18-material (Sepra E-C18, 50 μm, Phenomenex, Denmark) to the extraction cells would improve the method selectivity and reproducibility. Each sample was extracted three times during the optimisation experiments.

The PLE method was validated. The selectivity was determined from blank samples containing Ottawa sand and the reproducibility by two replicate analyses in four series. The limit of detection (LOD) and quantification (LOQ) was determined as three and ten times the standard deviation. Diluted reproducibility samples with a concentration close to the expected LOQ were used for determination of LOD and LOQ. The trueness of the method was determined by recovery experiments using the internal onion reference sample because no samples were available without or with a low concentration of the relevant flavonoids. The recovery was determined by extraction of five onion samples with and without addition of flavonoid standards. Linearity, sensitivity and range of measurements were determined for Q-7,4′-diglu, Q-3,4′-diglu, Q-4′-glu, Q-3-glu and Q (10 μg/mL) by varying the injection volumes of the standards, which provided comparable results to serial dilution of standards. We did not use an internal standard in the analysis because it was not possible to find a reference standard, which had similar chemical and physical properties, did not co-elute with the compounds of interest and was not present in the matrix.

3. Results and discussion

3.1. Identification of flavonoids (HPLC–MS and MS/MS)

An HPLC chromatogram confirmed that onions are a rich source of quercetin compounds (Fig. 2). The two most abundant compounds were Q-3,4′-diglu and Q-4′-glu in agreement with previous studies [12,18,35], but Q-3,7,4′-trigly, Q-7,4′-diglu and Q-3-glu were also present. Two isorhamnetin compounds, I-3,4′-digly and I-4′-gly were also identified in the onions. The flavonoid profile was similar to that found in southern Italian red onions [18] and white onions [12]. Neither aglycone quercetin (retention time (t_R): 37.1 min) nor isorhamnetin (t_R: 40.5 min) were detected in the onion extract indicating that hydrolysis of glycosides did not take place during sample preparation and analysis [35].

Two absorption maxima were observed in the UV spectra of the identified flavonoids at 345–363 nm (band I) and 253–256 nm (band II) (Table 1) associated with the absorption owing to the cinnamoyl B-ring and benzoyl A-ring, respectively [18]. The UV spectra were in agreement with previously obtained spectra of similar compounds [18,34] and confirmed the characteristic maxima of flavonols [36].

The glucosidic compounds showed loss of glucosyl moieties (162 amu per glucose moiety) in the mass spectral data leading to the aglycone fragment of quercetin (*m*/*z* 301/303 in ESI−/ESI+) or isorhamnetin (*m*/*z* 315/317) as earlier observed with similar compounds [12,18]. We observed fragments at *m*/*z* 151/153, which are typical for flavonoids and results of a retro-Diels–Alder fragmentation [21,37,38]. The fragments at *m*/*z* 107/109 are also characteristic, especially in negative mode [21].

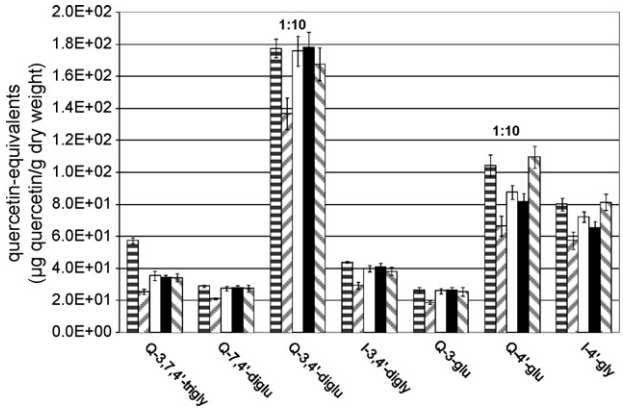

Fig. 3. Efficiency (expressed in quercetin equivalents) of the tested extraction methods. The concentrations of Q-3,4′-diglu and Q-4′-glu have been reduced by a factor of 10 to improve the visualisation of the remaining five less abundant flavonoids. (▤) Ultrasonication, (▨) water bath, (□) microwave-assisted extraction, (■) ultrasonic liquid processor, (▧) pressurised liquid extraction. The error bars describe the standard deviation ($n = 3$).

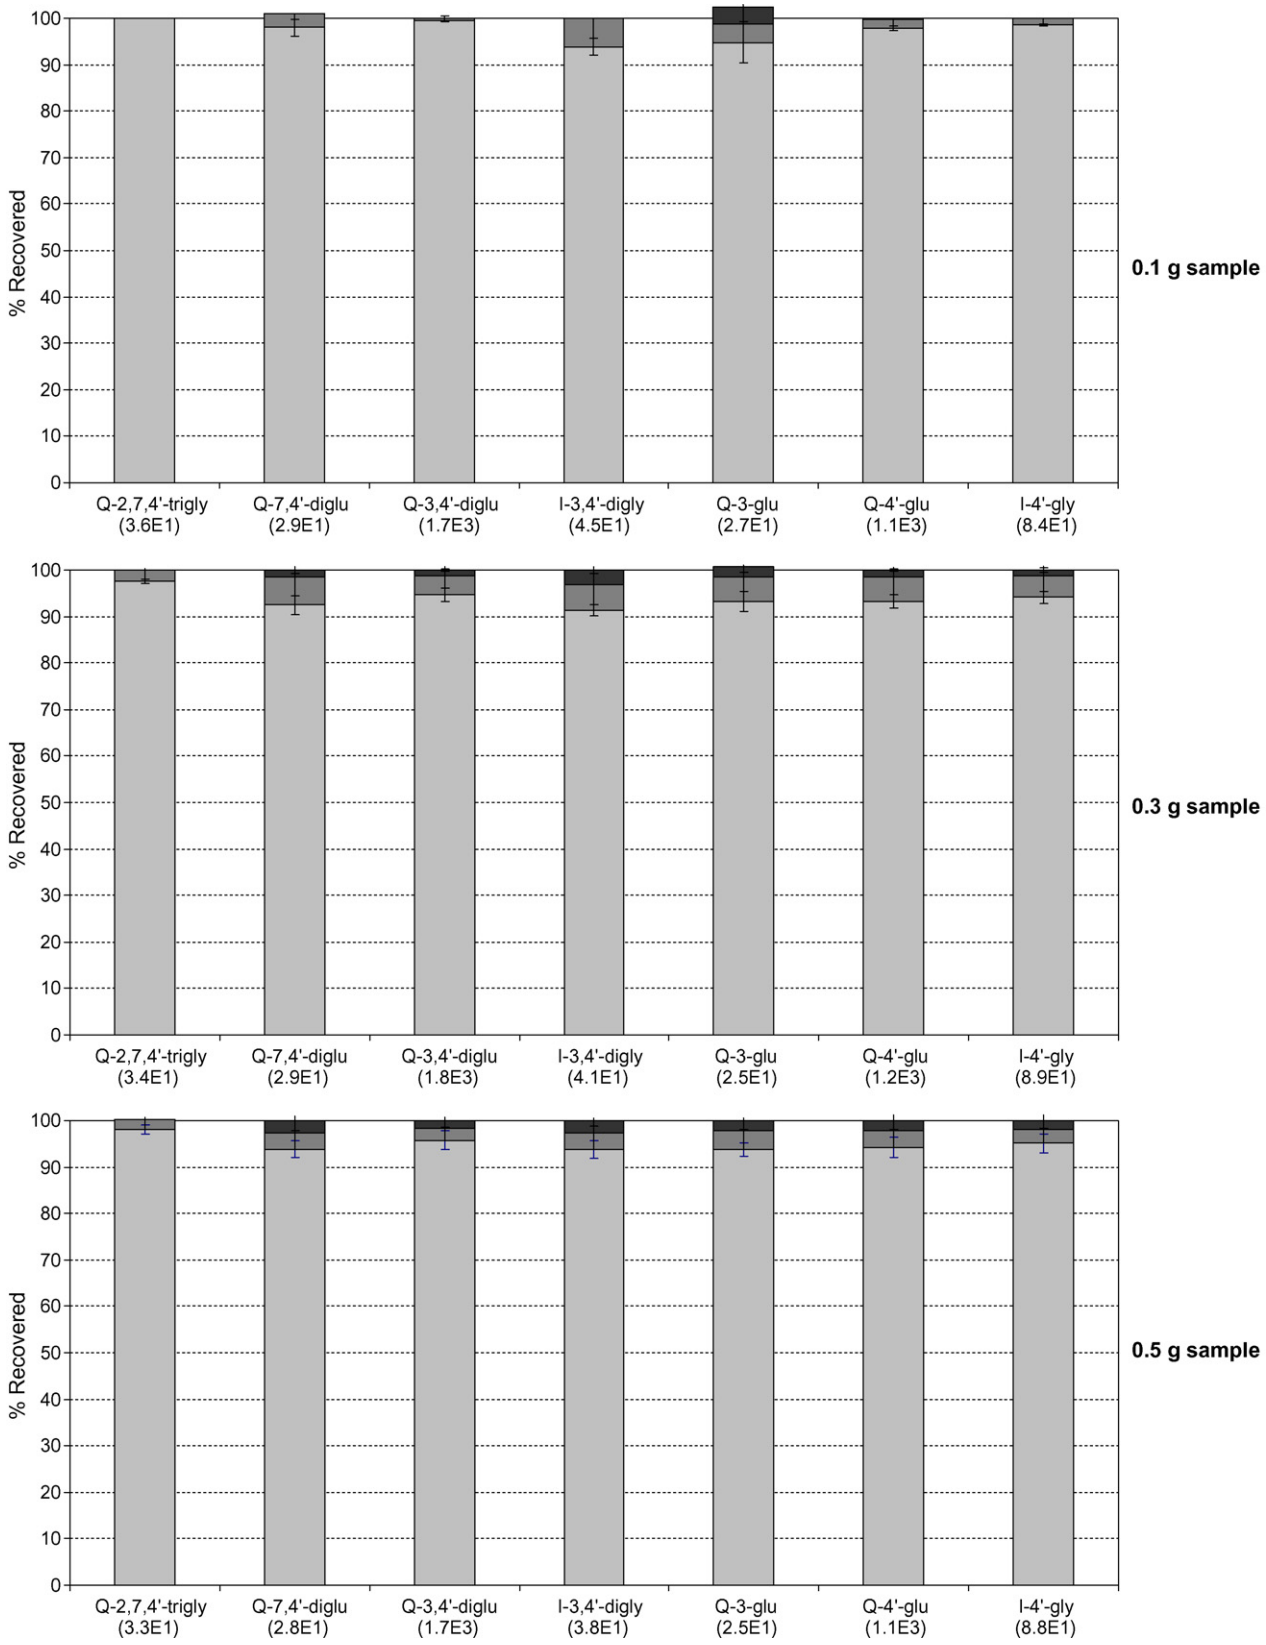

Fig. 4. Effect of sample weight on recovery in the three collected extracts (pressurised liquid extraction). (▒) 1st extract; (▒) 2nd extract and (■) 3rd extract. The total recovery in all three extracts (μg quercetin-equivalents/g dry weight) is shown in parenthesis below each compound. The error bars describe the standard deviation ($n = 3$).

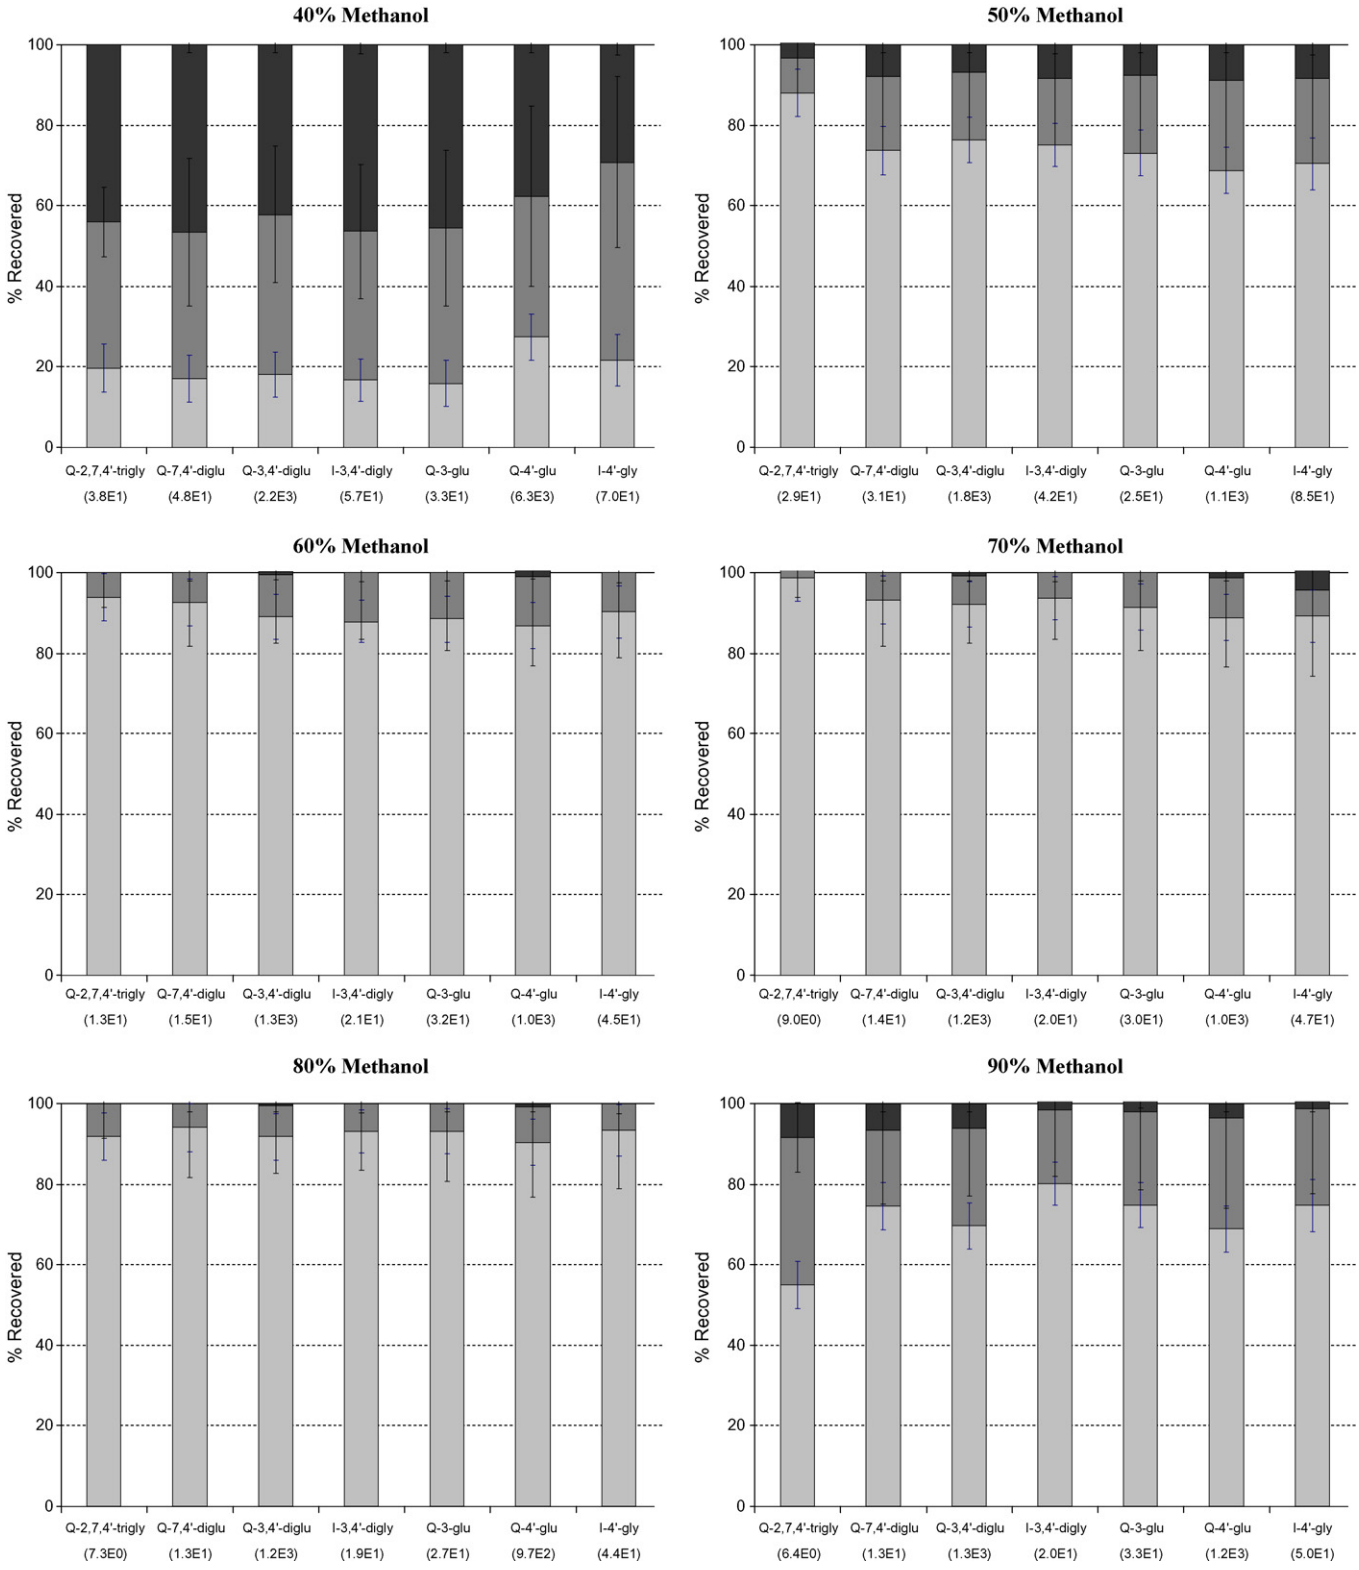

Fig. 5. Effect of solvent type on recovery in the three collected extracts (pressurised liquid extraction). (▒) 1st extract; (▓) 2nd extract; (■) 3rd extract. The total recovery in all three extracts (μg quercetin-equivalents/g dry weight) is shown in parenthesis below each compound. The error bars describe the standard deviation ($n = 3$).

The identified isorhamnetin glycosides might contain glucose as the sugar moiety, but also other sugars like galactose and mannose are possible (loss of 162 amu). However, glucose is the most frequently found sugar moiety in flavonoids [21], but it was not possible to determine the exact identity of the sugars and the linkage positions for the attached sugars. The loss of a methyl radical $[M\pm H\text{-}15]^{\bullet+/-}$ is often seen for methoxylated flavonols such as isorhamnetin [21,39], but was not observed in our experiments. Nevertheless, the identification is supported by previous studies, where both I-3,4′-digly and I-4′-gly have been identified in red [18] and white onions [12], respectively, with similar relative retention time and in other studies of onions [12,15].

3.2. Comparison of extraction methods

The efficiencies of MAE and ULP were comparable and at the same level as ultrasonication and PLE (Fig. 3) despite an expected strong disruption of the tissue structure with MAE and ULP due to the powerful shock waves radiating throughout the sample. Lower extraction efficiency was observed for the water bath extraction method. However, lower and thus better LODs were obtained with the water bath extraction method owing to the required preconcentration step of this method. An increase in sample weight and flush volume in PLE is expected to improve the LODs, which were otherwise the highest among the methods. The reproducibilities of the extraction methods were in a similar range (relative standard deviation (RSD): 1–11%, $n = 3$), which is generally considered acceptable for this type of analyses.

Ultrasonication is a fast and easy method, but difficulties were observed during the filtration of extracts as with MAE and ULP, so an additional sample preparation step (e.g. centrifugation) was needed. In contrast, PLE yielded clean extracts, which could be filtered directly after extraction. We also observed an increase in sample temperature during ultrasonication, which is a disadvantage as heating should be avoided during extraction [21]. High temperatures accelerate the oxidation of flavonoids [25] though no effects on recovery were observed in this study.

Higher efficiencies of MAE in comparison with conventional extraction methods have previously been obtained in extraction studies of anthocyanins from raspberries [30] and isoflavonoids and saponins from Chinese medicinal plants [31]. However, we did not observe such superior efficiencies, maybe because some cell structures were already destroyed during the freeze-drying process, which might also explain the non-superior efficiencies obtained with ULP.

An advantage of PLE is that it is a highly automated extraction process carried out in an inert atmosphere and protected from light. High extraction temperatures in PLE should yield improvements relative to time and solvent usage [40]. Flavonoids are temperature-sensitive [25], but the extraction can be carried out at high temperatures in PLE because it is performed in an inert atmosphere, which decreases the risk of chemical degradation [25]. The efficiencies of PLE were similar or higher than those found for the other tested methods. The solvent consumption (20 mL) was also decreased by its application in comparison with the conventional water bath method (50 mL), whereas the solvent consumption was lower for the other methods (5 mL). Altogether, we recommend PLE as the method of choice for extraction of flavonoids from onions because it shows several advantages and possibilities, e.g. simultaneous extraction and clean-up, which can otherwise be very time-consuming.

3.3. Optimization of PLE method

Extraction temperatures of 40, 75 and 100 °C were tested, but no significant differences in the efficiencies were observed. So, we decided to carry out the extractions at 40 °C in agreement with the temperatures used in previous PLE studies [28,41] and because of the known temperature-sensitivity of polyphenols [25].

Decreases in the LODs were observed as the sample weight increased and the total efficiencies after three extractions at all tested sample weights (0.1, 0.3 and 0.5 g) were comparable. The recoveries in the first extract were always greater than 91%, but increased with sample weight for the second and third extract (Fig. 4). The RSDs were acceptable (0.1–6.2%), but a slight tendency towards lower RSDs with higher sample weights was observed. So, 0.5 g is the recommended sample weight due to the improved LODs as well as acceptable recovery (98–99% of the total extracted with two extraction cycles) and reproducibility. Larger sample weights have been used in previous studies in combination with larger extraction cells [25,29,42], but larger sample weights caused clogging of our system due to the fine freeze-dried powder used.

Neither the total efficiency nor the efficiency in each extract was affected by the flush volumes (viz. 100, 125 and 150%) tested in this study (see Figure S1 in supporting information). A further increase in flush volume would have been interesting; however, the ASE-200 system does not allow flush volumes above 150%. A 100% flush volume is in accordance with flush volumes used by others [43,44] and was preferred because lower extract volumes were obtained at lower flush volumes, which leads to an improvement in the LODs.

The total extraction efficiencies were almost constant using a solvent composition of methanol between 50 and 90%, while slightly higher efficiencies were obtained at lower percentages of methanol. However, the results showed lower RSDs at methanol percentages below 50 as well as above 80% and the largest percentages were recovered in the second and third extracts, while only 1% of the total extracted flavonoids were recovered in the third extract with 60–80% methanol, except I-4′-gly with 70% methanol (Fig. 5). The decreased reproducibility when using solvents with high percentages of water has also previously been observed in another PLE study of polyphenols in apples [42]. An interfering compound was observed in the chromatogram of the second extract with 70–90% methanol (data not shown) and it more or less co-eluted with Q-3,4′-glu. Hence, the optimum solvent type appeared to be 60% methanol, but 65% methanol was afterwards tested. The recommended extraction solvent was 65% methanol owing to the obtained recovery as well as no co-eluting compounds in the HPLC analyses were observed (results not shown).

A clean-up step was included in the extraction by in-cell addition of C18-material, which has often been used as sorbent for solid-phase extraction (SPE) of flavonoids [21]. The total recoveries were improved with 13–35% in the samples added C18-material (data not shown). The RSDs were slightly higher (0–19%) for the majority of compounds in the samples without addition of C18-material, especially the more polar compounds (Table 2). This might be because of reduced interferences and/or increased selectivity. However, the HPLC–UV chromatograms did not reveal any immediate differences with respect to interference or noise. The simultaneous extraction and clean-up is a considerable improvement because the alternative SPE can be very time and solvent consuming and additional sample handling increases the risk of chemical degradation, though it has previously been used for clean-up of onion-extracts [19,22].

Our results show that two extraction cycles were sufficient and the third extract only contained 1–2% of the total extracted flavonoids in the three extracts. The optimum number of extraction cycles is in accordance with previous used extraction cycles (1–4) in PLE studies of polyphenols from plant materials [29,41,42] and so is the recovery, which in other similar PLE studies ranged from 81 to 100% of the total extractable polyphenols [25,41,42].

Table 2
Precision in extractions with and without addition of C18-material to the extraction cells ($n = 3$).

Compound	RSD (%)	
	Addition of C18-material	No addition of C18-material
Q-2,7,4′-triglu	5.8	25
Q-7,4′-digly	4.3	7.7
Q-3,4′-digly	3.8	7.0
I-3,4′-diglu	3.8	9.0
Q-3-gly	9.9	7.3
Q-4′-gly	6.8	6.8
I-4′-glu	9.9	9.7

Table 3
Limit of detection (LOD) and quantification (LOQ) as well as the precision (expressed as the relative standard deviation, RSD) of the analysis of polyphenols in vegetables ($n = 8$).

Compound	Vegetable	LOD (μg q-eq/g dw)	LOQ (μg q-eq/g dw)	Precision (RSD, %)	Concentration (μg q-eq/g dw)
Q-2,7,4′-trigly	Onion	3.0	20	11	4.6×10^1
Q-7,4′-diglu	Onion	1.4	60	10	2.5×10^1
Q-3,4′-diglu	Onion	0.90	20	3.1	2.7×10^3
I-3,4′-digly	Onion	1.5	20	8.6	4.5×10^1
Q-3-glu	Onion	2.0	20	4.9	4.6×10^1
Q-4′-glu	Onion	1.1	20	5.7	2.0×10^3
I-4′-gly	Onion	4.8	20	9.6	9.1×10^1
Chorogenic acid	Potato	0.4	20	1.8	1.2×10^2
Chorogenic acid	Carrot	1.5	20	7.3	1.3×10^2
Caffeic acid	Potato	2.7	20	–[a]	<LOQ

The average concentration of the compounds in the vegetables used for precision measurements can be seen in the last column. The LOD, LOQ and concentrations are expressed in μg quercetin-equivalents/g dry weight (μg q-eq/g dw).

[a] Precision was not determined because the concentration was below LOQ.

3.4. Method validation

The selectivity of the method was studied by extraction of blank samples (Ottawa sand) because onion samples without flavonoids were not available. The selectivity was good as interfering compounds were neither immediately detected in blank samples nor in the alternative analysis by LC–MS with electrospray ionization in negative ionization mode. The linearities of the standard curves of selected flavonoids (Q-7,4′-diglu, Q-3,4-diglu, Q-4′-glu, Q-3-glu and Q) were in the range of 0.5–10 μg/mL (equal to 20–400 μg/g dry weight), except for Q-7,4′-diglu (linearity between 1.5 and 10 μg/mL), and regression coefficients (R^2) were above 0.998. The sensitivity (measured in area/(μg/mL)) ranged from 2.2×10^4 to 7.0×10^4.

LODs ranged from 0.9 to 4.8 μg quercetin-equivalents/g dw (μg q-eq/g dw) and LOQs were equal to the lower limit of the linear range (20 μg q-eq/g dw), except for Q-7,4′-diglu (i.e. LOQ of 60 μg q-eq/g dw) (Table 3). The precisions were in an acceptable range for our purpose (RSD: 3.1–11%, Table 3).

Recovery experiments were used to estimate the trueness of the method, but the experiment was only of relevance for Q-7,4′-diglu and Q-3-glu due to insufficient amounts of pure standards in comparison with the high content of flavonoids in the reference sample. The recovery of Q-7,4′-diglu and Q-3-glu were 127% and 98%, respectively., which we consider acceptable though it is in the higher range for Q-7,4′-diglu. Furthermore, as previously stated the PLE method prior to optimization yielded satisfactory recoveries compared to the other tested extraction methods (Fig. 3) and 98–99% of the extracted flavonoids were recovered within two consecutive extraction cycles.

Our method was also applicable to other matrices and groups of polyphenols, e.g. extraction of phenolic acids from potatoes and carrots. The reproducibility (RSD: 1.3–7.3%, Table 3), linearity (0.5–10 μg/mL equal to 20–400 μg/g dw, $R^2 > 0.998$) and sensitivity ($2.4–4.6 \times 10^4$ area/(μg/mL)) of phenolic acids were in the similar range of flavonoids in onions. The LODs of chlorogenic acid and caffeic acid were between 0.4 and 2.7 μg q-eq/g dw, while LOQs of 20 μg q-eq/g dw were obtained (Table 3). Extraction of white cabbage was also possible, but the compound identification is ongoing.

4. Conclusion

Five extraction methods (water bath extraction, pressurized liquid extraction (PLE), ultrasonication, ultrasonic liquid processor and microwave extraction) were tested and PLE was the preferred extraction method. The PLE method sets a new standard for analyses of flavonoids from onions and showed considerable improvements, especially the simultaneous extraction and clean-up by in-cell addition of a stationary phase (in this case C18-material) improved the extraction efficiency and reproducibility. However, the integration of extraction and clean-up into one combined analytical step can also be advantageous in future development of PLE methods for rapid and reliable extraction and clean-up of bioactive compounds from various food products. The PLE method yielded similar efficiency and reproducibility in comparison with the other modern extraction methods (ULP and MAE), but it is advantageous because it can be highly automated, small amounts of solvents are used, the cleanest extracts are obtained and the extraction of the light and oxygen-sensitive flavonoids is carried out in an inert atmosphere protected from light. The optimised and validated method is rapid, reliable, sensitive and its application can be extended to other food matrices and polyphenols, e.g. phenolic acids in potatoes and carrots.

Acknowledgements

We acknowledge the International Centre for Research in Organic Food Systems (ICROFS, former the Danish Research Centre for Organic Farming and Food Systems (DARCOF)) for financial support through the OrgTrace project (http://www.orgtrace.elr.dk/uk) and the COWI Foundation and Ib Henriksens Foundation for funding of the ASE-200 instrument. We also thank Kasper Kildegaard Sørensen for technical assistance with the microwave-assisted extraction and Lawrence White for thorough proof-reading.

ABSTRACT

Diazepam is frequently used as an adjuvant during antidepressant therapy. Recently, some studies have suggested that the treatment with benzodiazepines could have different efficacy in depressed patients as opposed to non-depressed ones. To clarify the matter, a study is currently underway, regarding the drug metabolism in rats. In order to obtain a more complete and significant set of data, the main diazepam metabolites have also been considered, namely: nordiazepam, temazepam and oxazepam. A feasible and reliable HPLC method has been developed for the simultaneous determination of these compounds in plasma and brain tissue of rats. The method has been applied to "normal" rats and to genetic rat models of depression in order to estimate drug metabolism in different breeds. Analyte separation was achieved on a C8 reversed phase column using an acidic phosphate buffer/acetonitrile mixture as the mobile phase. The detection wavelength was 238 nm. An original sample pre-treatment, based on solid-phase extraction (SPE) was developed in order to eliminate endogenous interference, using only 250 μL of matrix (brain homogenate or plasma) for a complete analysis. The method has been validated with good results in terms of precision, extraction yield, sensitivity, selectivity and accuracy on both matrices and has been successfully applied to samples from some rats subjected to the preliminary study. The obtained data will hopefully contribute to the clarification of possible differences between depressed and non-depressed subjects with respect to benzodiazepine biotransformation.

1. Introduction

Diazepam (DZP, Fig. 1a) was the second benzodiazepine to be introduced into clinical practice, after chlordiazepoxide, and is still one of the most frequently prescribed drugs of this class. It is widely used for the treatment of anxiety and insomnia, but also for seizures (especially *status epilepticus*), alcohol withdrawal and muscle spasms [1]. In the therapy of major depressive syndromes, DZP is often prescribed as an adjuvant to control anxious symptoms and to treat anxiety associated with the beginning of treatment with second-generation antidepressants [2]. DZP is a core medicine in the World Health Organization's (WHO) "Essential Drugs List", which is a list of minimum medical needs for a basic health care system [3].

Like all 1,4-benzodiazepine drugs, DZP acts by allosterically interacting with neuronal $GABA_A$ receptors, thus facilitating the interaction between the receptor and the neurotransmitter, which in turn leads to a decrease in neuronal activity. For this reason, benzodiazepines are generally considered much safer than the older sedative barbiturates (which are direct GABA agonists), especially in case of overdose. However, side effect such as somnolence, amnesia, dizziness and impaired concentration are commonly reported. Furthermore, DZP and other benzodiazepines induce tolerance during chronic administration and an abstinence syndrome upon discontinuation. Consequently, pure DZP is considered a controlled substance in several Western countries (it is a schedule IV drug according to the convention on psychotropic substances) [4].

DZP is mainly metabolised by cytochrome P450 (CYP) enzymes. Hepatic *N*-demethylation results in the formation of an active metabolite, desmethyldiazepam (also known as nordiazepam, NDZ, Fig. 1b). This metabolite is hydroxylated to form oxazepam (OXZ, Fig. 1c), which is also active and is metabolised to form oxazepam glucuronide. A minor active metabolite is temazepam (TMZ, Fig. 1d), which can be in turn demethylated to oxazepam or glucuronidated [5]. The main active species found in blood are DZP and NDZ [6].

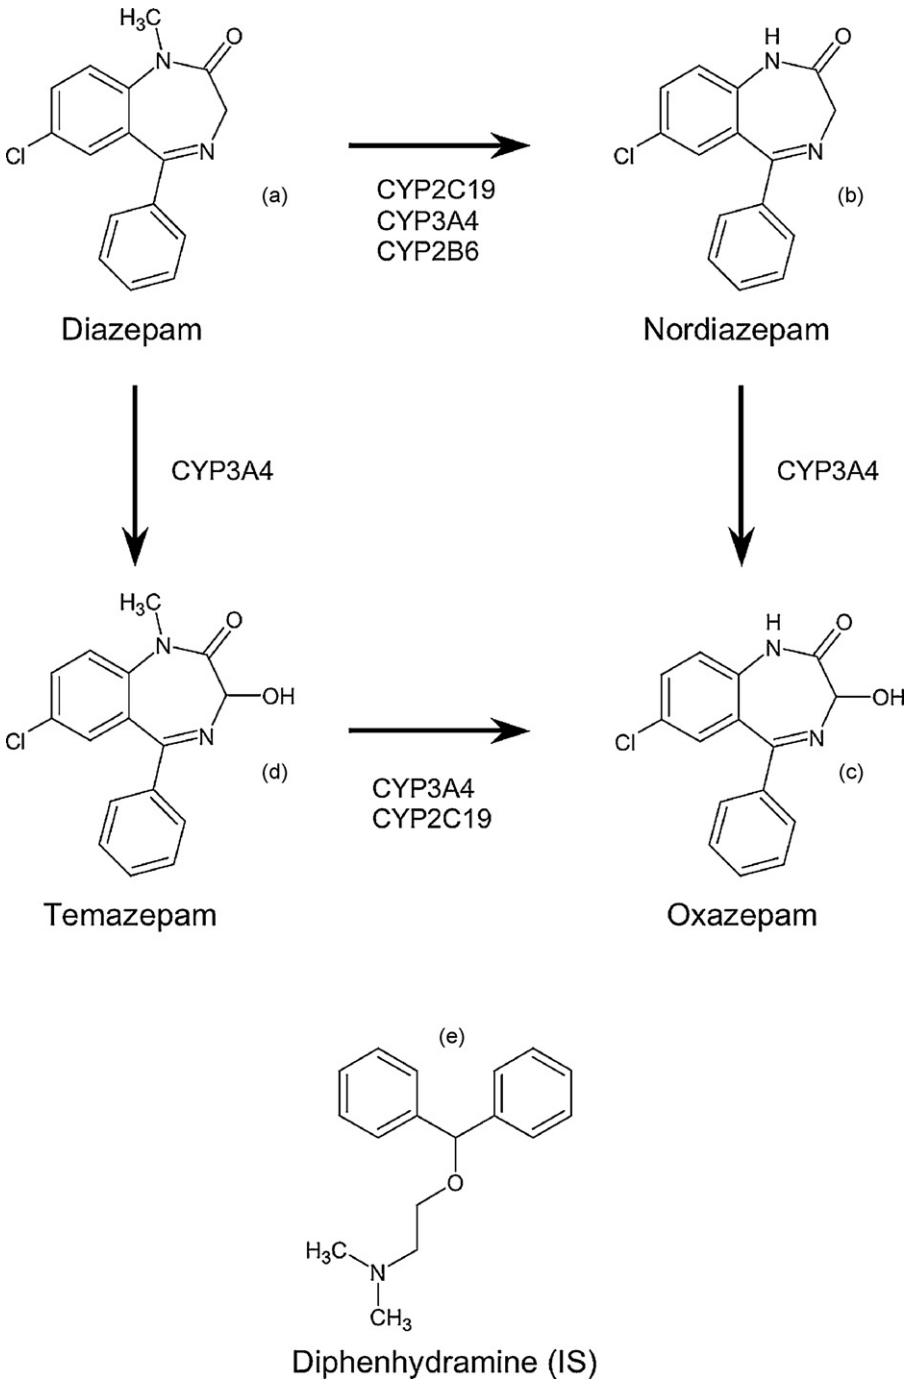

Fig. 1. Main metabolic pathways of DZP with (a–d) the chemical structures of its main metabolites; (e) chemical structure of diphenhydramine (IS).

Since all these metabolites are pharmacologically active and have a long half-life, they can significantly contribute to the pharmacological effect of DZP administration.

Recent studies have found a hyper-responsivity to DZP treatment in some animal models of depression, and in particular in the Flinders sensitive line (FSL) rats. FSL animals are spontaneously showing a behaviour corresponding to the animal model of depression (e.g., immobility in the forced swim test). These two facts combined point out to possible pharmacokinetic or pharmacodynamic differences between depressed and non-depressed subjects with respect to DZP treatment. Thus, an interdisciplinary research has been started, aiming to discover the mechanism(s) underlying the hyper-responsivity to DZP. Here, an original analytical method is presented for the simultaneous determination of DZP and its main phase I metabolites NDZ, OXZ and TMZ. Of course, the determination of the metabolites is necessary to obtain a complete idea of the metabolic state of the subject and thus of the causes leading to different responses. The method has been validated and applied to the quantification of the analytes in plasma and brain tissue of FSL and control (Sprague–Dawley, SD and Flinders resistant line, FRL) rats.

Several methods can be found in the literature regarding the determination of these metabolites in plasma of humans [7–10] or animals [11], by HPLC coupled to mass spectrometric (MS) [7,11] or UV [8–10] detection. One method deals with rat cerebrospinal fluid using HPLC-MS [12]. Other methods only analyse diazepam

and one or two metabolites in human plasma [13–16], in rat plasma and urine [17] or plasma and brain tissue [18] and in dog plasma [19].

As one can see, none of these methods is suitable for the purposes of this study, since none of them simultaneously determines all analytes in both matrices.

2. Experimental

2.1. Chemicals

The analytes DZP, NDZ, OXZ and TMZ were purchased from LGC Standards (Teddington, UK) as methanolic solutions (1 mg mL^{-1}). The internal standard diphenhydramine (IS, Fig. 1e) and bovine serum albumin were purchased from Sigma Chemicals (St. Louis, MO, USA).

Disodium hydrogen phosphate anhydrous (Na_2HPO_4), phosphoric acid, methanol and acetonitrile were analytical grade from Carlo Erba (Milan, Italy).

Ultrapure water (18.2 MΩ cm) from a MilliQ apparatus by Millipore (Milford, Mass., USA) was used.

2.2. Apparatus and chromatographic conditions

The chromatographic system was composed of a Jasco (Tokyo, Japan) PU-980 chromatographic pump and a Jasco UV-975 spectrophotometric detector set at λ = 238 nm.

Separations were obtained on an Agilent (Waldbronn, Germany) Zorbax Eclipse C8 reversed-phase column (150 × 4.6 mm ID, 5 μm) kept at room temperature. The mobile phase was a mixture of acetonitrile (38%, v/v) and a pH 2.5, 30 mM phosphate buffer containing 0.3% triethylamine (62%, v/v). One litre of mobile phase was prepared as follows: 1.25 mL of 85% phosphoric acid and 1.9 mL of triethylamine were added to about 500 mL of water, then the pH of the solution was brought to 2.5 with diluted phosphoric acid. The solution was made up to 620 mL with water and mixed with 380 mL of acetonitrile.

The mobile phase was filtered through a Phenomenex (Torrance, CA, USA) membrane filter (47 mm nylon membrane, 0.2 μm) and degassed by an ultrasonic bath. The flow rate was 1.0 mL min^{-1} and the injections were carried out through a 50 μL loop. Data processing was handled by means of a Varian (Palo Alto, CA, USA) Star Chromatography 4.0 software.

Solid-phase extraction (SPE) was carried out on a Varian VacElut apparatus. A Crison (Barcelona, Spain) Basic 20 pH meter and a Hettich (Tuttlingen, Germany) Universal 32 R centrifuge were used.

2.3. Solutions

Stock solutions of the analytes and the IS were 1 mg mL^{-1} and were stored at −80 °C in actinic glass vials. The stock solution of the IS was prepared by dissolving 2.0 mg of the substance in 2.0 mL of methanol. Standard solutions were prepared daily by diluting the stock solutions with the mobile phase.

2.4. Sample collection

The study was carried out in collaboration with the Department of Human Physiology and Pharmacology, "Sant'Andrea" Hospital of the Sapienza University, Rome, Italy. Flinders sensitive line (FSL, kindly provided by Dr. A.A. Mathè, Department of Psychiatry, Karolinska Institute, Stockholm, Sweden), Flinders resistant line (FRL) and Sprague–Dawley (SD) rats were housed in groups of three under controlled conditions of light (from 07.00 to 19.00 h), temperature (22 ± 2 °C) and humidity (65%) and were allowed free access to standard laboratory diet and tap water. The experimental protocol was approved by a local bioethical committee and the procedures and animal comfort were controlled by the University Veterinary Service. All efforts were made to minimise suffering and the number of animals used was kept to a minimum by experimental design. They were divided into two groups: the "control" rats were not subjected to any pharmacological treatment, while the "treated" rats were subjected to one intraperitoneal diazepam dose (0.3 mg/kg). The rats were weighed, anaesthetised and sacrificed by decapitation. Blood was collected from the carotid arteries in glass tubes containing EDTA as the anticoagulant, then centrifuged at 5000 × *g* for 15 min; the supernatant (plasma) was transferred to polypropylene test tubes and stored at −80 °C until HPLC analysis. The brain was removed and separately weighed (mean weight: 2 g), rinsed with saline and homogenized with 5 mL of methanol. After centrifugation (9000 × *g* for 15 min), aliquots of the supernatant were stored at −80 °C until analysis.

2.5. Sample pre-treatment: SPE procedure

The sample pre-treatment procedure was carried out on plasma by means of solid-phase extraction (SPE) on IST International (Hengoed, UK) Isolute C2 (50 mg, 1 mL) cartridges; for brain tissue, polymeric Strata-X (30 mg, 1 mL) cartridges from Phenomenex were used.

- Plasma: the C2 cartridges were activated and conditioned with 2× 1 mL of methanol and 2× 1 mL of water, respectively. After adding 50 μL of the IS standard solution (2.5 μg mL^{-1}) and 500 μL of water to 250 μL of plasma, the resulting mixture was loaded onto the previously conditioned cartridge. It was then washed with 2× 1 mL of water and 50 μL of methanol and dried applying full vacuum (−30 kPa) for 1 min. Analyte elution was carried out with 1 mL of methanol, applying full vacuum again for 1 min. The eluate was brought to dryness with a rotary evaporator and the residue was re-dissolved in 125 μL of mobile phase.
- Brain tissue: the activation, conditioning and loading steps were identical to those used for plasma (loading was carried out with 250 μL of brain homogenate supernatant). The cartridges were then washed with 2× 1 mL of water, 1 mL of water/methanol (80/20, v/v) mixture and 50 μL of methanol. Elution, drying and re-dissolution were carried out as for plasma.

2.6. Method validation

2.6.1. Linearity

Analyte standard solutions at seven different concentrations were added to 250 μL of blank sample, subjected to the SPE procedure and analysed. The volume of standard solution added was 50 μL and each spiked blank sample was prepared in triplicate. The analyte/IS peak area ratios were plotted against the corresponding concentrations and the calibration curves were set up by means of the least-squares method.

2.6.2. Limit of quantitation and limit of detection

According to international guidelines [20,21], limit of quantitation (LOQ) and limit of detection (LOD) values were determined as the analyte concentrations which give rise to peaks whose height is 10 and 3 times that of the baseline noise, respectively. Decreasing concentrations of samples (standard solutions or spiked blank plasma) were injected and the heights of the resulting analyte peaks were compared to the baseline noise, as calculated by the integration software. The concentrations that produced analyte peaks equal to 10 times the baseline noise were prepared and injected six times in order to evaluate the R.S.D.% of peak areas. These values should be lower than 20%.

2.6.3. Extraction yield (absolute recovery)

Spiked blank samples were prepared and analysed as described under Section 2.6.1, however, three concentrations were prepared and analysed for each analyte, corresponding to the lower limit, middle point and upper limit of the corresponding linearity curve. The analyte peak areas thus obtained were compared to those obtained from standard solutions at the same concentration, and the percentage extraction yield was calculated.

2.6.4. Precision

Spiked blank samples were prepared and analysed as described under Section 2.6.3. The procedure was repeated six times within the same day to obtain repeatability (intraday precision) values and six times over six different days to obtain intermediate (interday) precision values, both expressed as percentage relative standard deviation (R.S.D.%).

2.6.5. Selectivity

Six different blank samples were subjected to the SPE procedure and analysed. The acceptance criterion was: no peak should be detected at the retention times of the analytes or the IS, with an area larger than that of a LOQ peak.

2.6.6. Accuracy

Analyte standard solutions at three different concentrations were added to 250 μL of plasma or brain tissue homogenate (in order to obtain analyte additions corresponding to the lower limit, middle point and a high level of each calibration curve) and the mixture subjected to the SPE procedure. Recovery values were calculated according to the following formula: 100 × ([after spiking] − [before spiking])/[added]. The procedure was repeated three times at each concentration level to obtain standard deviation (S.D.) values.

3. Results and discussion

3.1. Choice of the chromatographic conditions

Our previous work on the simultaneous determination of fifteen benzodiazepines [22] (which did not include TMZ nor NDZ) prompted us to develop a new, narrower method only for DZP and its four metabolites. When the previously published conditions (C8 column, mobile phase composed of pH 3.0 phosphate buffer and 35% acetonitrile) were applied to this different set of analytes, however, NDZ and TMZ were not baseline resolved. Moreover, their peaks showed a moderate degree of tailing. To reduce it, triethylamine was added to the mobile phase. To increase peak resolution, it was decided to exploit the differences in pK_a values between NDZ (pK_a = 3.5) and TMZ (pK_a = 1.9), lowering the pH of the mobile phase to 2.5 to retain the protonation of TMZ while increasing that of NDZ. In this way, the retention of NDZ should become significantly lower, since its protonation disrupts the lipophilic interactions with the C8 sorbent. For this reason, a Zorbax Eclipse column was chosen, since it has increased stability under acidic conditions (down to pH 2.0) with respect to other silica-based columns. These changes allowed the complete separation of all analytes with good efficiency and within reasonable run times, without compromising the stationary phase stability.

Among the different compounds tested as possible ISs, diphenhydramine was chosen for its retention time, similar but not identical to those of the analytes, and its good peak efficiency.

The chromatogram of a standard solution containing OXZ (50.0 ng mL^{-1}), NDZ (50.0 ng mL^{-1}), TMZ (50.0 ng mL^{-1}), DZP (50.0 ng mL^{-1}) and the IS (1.0 μg mL^{-1}), analysed under the chosen chromatographic conditions, is shown in Fig. 2. As one can see, all peaks are baseline resolved and one complete chromatographic run lasts about 12 min.

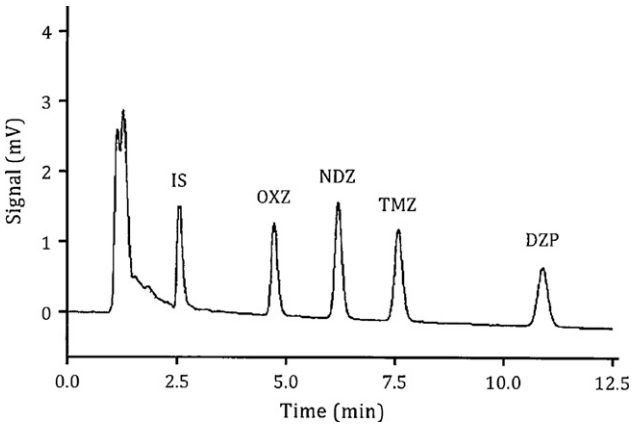

Fig. 2. Chromatogram of a standard solution containing DZP (50 ng mL^{-1}), NDZ (50 ng mL^{-1}), OXZ (50 ng mL^{-1}), TMZ (50 ng mL^{-1}) and the IS (1 μg mL^{-1}).

3.2. Application to standard solutions

Calibration curves were built for all analytes by injecting standard solutions at different concentrations, containing the IS at a constant concentration. The analyte/IS peak area ratios thus obtained were plotted against the corresponding analyte concentrations and the calibration curves set up by means of the least-squares method. Good linearity values ($r^2 > 0.9997$) were found for all analytes in the following concentration ranges: 4.0–250.0 ng mL^{-1} for OXZ, 3.0–250.0 ng mL^{-1} for NDZ, 4.0–250.0 ng mL^{-1} for TMZ and 5.0–250.0 ng mL^{-1} for DZP. LOD values were between 1.0 and 1.7 ng mL^{-1} and LOQ values between 3.0 and 5.0 ng mL^{-1}.

Precision values were also satisfactory, with R.S.D. values always lower than 3.0% for repeatability and lower than 3.3% for intermediate precision.

3.3. Development of the sample pre-treatment procedure

Several different kinds of sorbents were tested for the development of the SPE procedure: C2, C18, cyanopropyl (CN), phenyl (PH) and hydrophilic–lipophilic balance (HLB). Only the C2 sorbent suitably retained all the analytes while giving good purification of the plasma matrix. Of the two cartridge sizes tested (100 and 50 mg, 1 mL), the smaller one granted better extraction yields and an easier elution of the analytes. For this reason, C2 (50 mg, 1 mL) cartridges were chosen for all subsequent assays on rat plasma, using 250 μL of matrix. Unfortunately, the same (or a similar) procedure was not suitable for the extraction of the analytes from brain tissue: severe interference was detected when injecting this matrix, irrespective of the sorbent used. On the other hand, adding a further washing step with a water/methanol mixture caused a sharp drop in extraction yields. Thus, a completely different kind of sorbent was tested for the analysis of brain samples, and namely the Strata-X reversed phase polymer. According to the manufacturer [23], this sorbent is a surface modified styrene divinylbenzene polymer with superior H-bonding and π–π bonding capabilities for enhanced retention of polar and aromatic analytes. Thus, it should be suitable for the extraction and purification of both polar metabolites and less polar parent compounds. Moreover, its multimode retention

mechanisms lend themselves to strong washing with organic solvents without dramatically affecting analyte recovery. The Strata-X sorbent proved to be efficient in adequately retaining the analytes even when an additional washing step (with methanol/water) was added to obtain a good purification from endogenous constituents of the brain matrix. Both matrices were then subjected to a final washing step with a small volume of methanol, which increases matrix clean-up without significantly lowering extraction yields. Elution was carried out with 1 mL of methanol, followed by drying under vacuum and re-dissolving in 125 μL of mobile phase. Thus, the pre-treatment procedure concentrates the analytes two times.

Preliminary assays were carried out on blank samples (both of brain tissue and of plasma) from all three rat strains (FSL, FRL and SD); the purification and extraction results obtained were statistically not significantly different among strains.

The chromatogram of a blank plasma sample spiked with the analytes and the IS and subjected to SPE is shown in Fig. 3a, while the chromatogram of a blank brain sample spiked with the same concentrations of the analytes and the IS is reported in Fig. 3b. As one can see, a good purification of the matrix and neat, symmetrical peaks for all analytes are obtained in both cases.

With regard to stability, a formal, complete study was not carried out, since benzodiazepines are usually considered stable under the mild conditions used in our method. However, all spiked blanks and samples were analyzed more than once, storing them for 1–4 weeks at −20 °C. No significant change in peak areas was observed. Moreover, no significant change was observed when storing samples after SPE (i.e., ready to be injected) for up to 1 h at 4 °C.

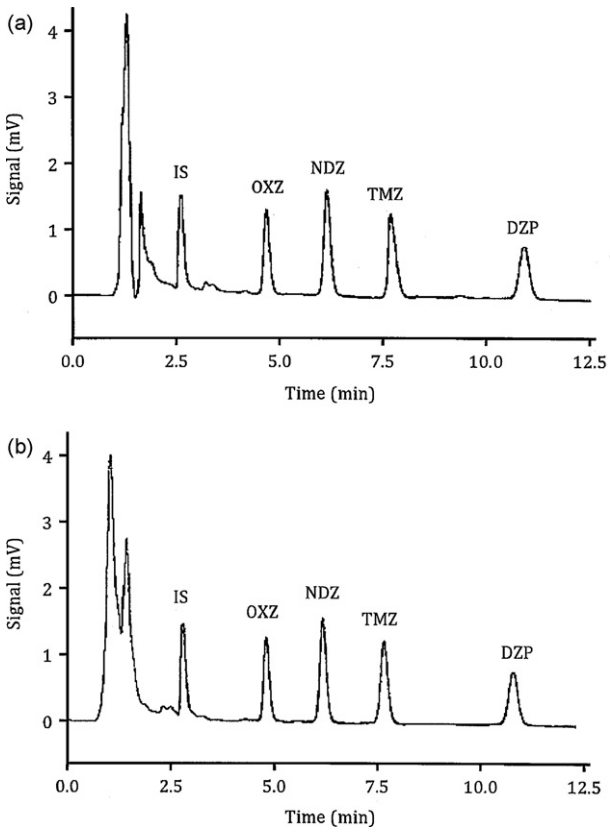

Fig. 3. Chromatograms of: (a) a blank rat plasma sample spiked with DZP (25 ng mL^{-1}), NDZ (25 ng mL^{-1}), OXZ (25 ng mL^{-1}), TMZ (25 ng mL^{-1}) and the IS (0.5 μg mL^{-1}); (b) a blank rat brain sample, spiked with the same concentrations of the analytes and the IS. Concentrations in the injected solutions are twice those reported. Brain concentrations are calculated in the homogenate supernatant.

3.4. Method validation

3.4.1. Method linearity, LOQ and LOD values

Calibration curves were set up on blank plasma and brain tissue by adding to the matrix known amounts of analyte standard solutions at different concentrations (and of IS standard solution at constant concentration) and subjecting the resulting mixture to the SPE procedure.

Calibration curves were set up in the expected concentration ranges. Good linearity values ($r^2 > 0.9992$) were found for all analytes in plasma and brain, with LOQ values ranging from 1.5 to 2.5 ng mL^{-1} (R.S.D. always lower than 20%) and LOD values ranging from 0.5 to 0.8 ng mL^{-1} for both matrices. Complete linearity, LOQ and LOD details are reported in Table 1.

3.4.2. Extraction yield and precision

Extraction yield (absolute recovery) and precision assays were carried out on blank plasma and brain tissue spiked with analyte concentrations corresponding to the lower limits, middle levels and upper limits of the respective calibration curves. The results of these assays are reported in Table 2.

As one can note, mean extraction yields were always higher than 91%. Precision results were also satisfactory: R.S.D. values for repeatability were always lower than 3.3% on plasma and 3.4% on brain tissue; R.S.D. values for intermediate precision were lower than 3.8% on plasma and 3.7% on brain tissue.

3.4.3. Method selectivity

Selectivity was evaluated by injecting into the HPLC six different samples of blank rat plasma and brain tissue after subjecting it to the SPE procedure. In all cases, no significant peak was observed at retention times corresponding to those of the analytes, as can be seen from Fig. 4a and b.

3.5. Analysis of rat plasma and brain samples

Having thus successfully validated the method, it was applied to the analysis of DZP and its metabolites in plasma and brain tissue of FSL, FRL and SD rats treated with DZP 0.3 mg/kg, as well as in plasma and brain tissue of control rats, which received

Table 1
Linearity parameters for DZP and metabolites on spiked blank plasma and brain tissue.

Analyte	LOD[a] (ng/mL)	LOQ[a] (ng/mL)	Linearity concentration range[a] (ng/mL)	Plasma			Brain tissue		
				Linearity equation ($y = a + bx$)		r^2	Linearity equation ($y = a + bx$)		r^2
				a	b		a	b	
OXZ	0.7	2.0	2.0–125	0.0024	0.0007	0.9997	0.0028	0.0008	0.9996
NDZ	0.5	1.5	1.5–125	−0.0017	0.0015	0.9996	0.0033	0.0012	0.9993
TMZ	0.7	2.0	2.0–125	0.0018	0.0014	0.9995	0.0011	0.0013	0.9995
DZP	0.8	2.5	2.5–125	−0.0012	0.0016	0.9996	0.0004	0.0013	0.9996

[a] LOD, LOQ and linearity range values were identical for the two matrices.

only saline. A chromatogram of a plasma sample from a FSL rat treated with DZP is reported in Fig. 4c, while a chromatogram of a brain sample is shown in Fig. 4d. As can be seen, the sample pretreatment allows obtaining chromatograms devoid of interference from the biological matrix. The plasma sample shown in Fig. 4c contained the following analyte concentrations: OXZ 4.3 ng mL^{-1}, NDZ 3.4 ng mL^{-1}, TMZ 4.0 ng mL^{-1}, DZP 12.6 ng mL^{-1}; analyte concentrations in the brain sample shown in Fig. 4d were: OZP 3.3 ng g^{-1}, NDZP 12.5 ng g^{-1}, TZP 26.3 ng g^{-1} and DZP 12.6 ng g^{-1}.

3.6. Accuracy

Method accuracy was evaluated by means of recovery studies at three different concentration levels ($n = 3$ for each level), corresponding to the lower limit, the middle point and a high point of the respective calibration curve. Results were satisfactory: mean recovery values were always higher than 90% and standard deviation values were also good, always lower than or equal to 3%. Complete detailed results are reported in Table 3.

4. Conclusion

An original HPLC-UV method has been developed for the simultaneous analysis of DZP and its main active metabolites NDZ, OXZ and TMZ in rat plasma and brain tissue. The SPE procedures implemented for the sample pre-treatment allowed obtaining good extraction yields (>91%) and precision values (R.S.D. < 3.8%) for all analytes and in both matrices, as well as a satisfactory purification form endogenous interference. The method has been successfully applied to the analysis of DZP and metabolites in samples from different strains of rats (FSL, FRL and SD), with good accuracy (recovery >90%), sensitivity and selectivity.

Among the numerous methods reported in the literature for the determination of these analytes, none had been developed, validated and applied to these two specific matrices. Furthermore, some of them [7,11,18] require very expensive instrumentation (such as MS/MS detectors), which is not always available in clinical analysis laboratories. Others give less satisfactory precision and extraction yield results, using less feasible and more polluting procedures (such as liquid–liquid extraction) [8], or have lower sensitivity [9]. Thus, the proposed method has significant advantages with respect to those available in the literature.

The method has been applied to the simultaneous determination of DZP and its metabolites in the tissues of rats within a study regarding differences in responsivity to DZP treatment. This will allow obtaining a complete idea of the metabolic state of the laboratory animals, possibly contributing to the clarification of the causes leading to different therapeutic responses.

Musical instrument

ABSTRACT

The analysis of various varnishes from different origins, which are commonly found on historical musical instruments was carried out for the first time with both fluorescence excitation emission spectroscopy and laser-induced time-resolved fluorescence spectroscopy. Samples studied include varnishes prepared using shellac, and selected diterpenoid and triterpenoid resins from plants, and mixtures of these materials. Fluorescence excitation emission spectra have been collected from films of naturally aged varnishes. In parallel, time-resolved fluorescence spectroscopy of varnishes provides means for discriminating between short- (less than 2.0 ns) and long-lived (greater than 7.5 ns) fluorescence emissions in each of these complex materials. Results suggest that complementary use of the two non destructive techniques allows a better understanding of the main fluorophores responsible for the emission in shellac, and further provides means for distinguishing the main classes of other varnishes based on differences in fluorescence lifetime behaviour. Spectrofluorimetric data and time resolved spectra presented here may form the basis for the interpretation of results from future in situ fluorescence examination and time resolved fluorescence imaging of varnished musical instruments.

1. Introduction

Fluorescence spectroscopy is particularly useful for the examination of works of art and historic musical instruments, as many binding media [1–5], modern pigments [6] and colorants [7] may be luminescent. With the advantage of not requiring any sample and being non-contact, fluorescence spectroscopy can also be coupled with multispectral and time-resolved fluorescence imaging techniques for the analysis of painted surfaces [8–10], thus increasing the utility of fluorescence spectroscopy for the characterisation of materials and works of [11]. In this work, time resolved and fluorescence excitation emission spectroscopy have been employed for the first time for the analysis of selected musical instrument varnishes.

The conservation and assessment of musical instrument varnishes may require the characterisation of their constituent materials. Varnishes represent a sensitive interface between painted or unpainted wooden surfaces and their environment, serving to protect an instrument, as well as to enhance and change the object's appearance. While paintings and musical instruments are significantly different in terms of their use, history and technique, parallels between the materials used for the construction and varnishing of historical string instruments and polychromy are apparent [5]. Paintings are often coated with multiple and thin layers of natural resins (from a variety of animal and plant sources) dispersed in a solvent as a varnish or surface coating, as described in historical treatises on painting and gilding [12], and varnishes are often applied to paintings during conservation or restoration. Recent analysis of Leonardo's *Mona Lisa* has suggested the presence of multiple layers of oxidised and yellowed varnish, which significantly alter the appearance of the masterpiece, but which have been retained for their historical value [13]. On the other hand, an integral part of the construction of stringed instruments (including lutes and violins, among others) is the varnishing and finishing of the wooden surface, which contributes to the appearance (colour and gloss) and to the protection of an instrument, and, hypothetically, to the quality of sound produced [14].

The presence of different varnishes and other conservation materials on musical instruments is easily appreciable due to the variation in fluorescence emissions from the surface of instruments which may increase with age [1]. In fact, due to their composition and degradation, many varnishes are naturally fluorescent or develop fluorescence upon ageing (which may also be accom-

doi:10.1016/j.talanta.2009.06.063

panied by yellowing). The visual assessment of the fluorescence from musical instruments (as well as paintings) with UV excitation using a Wood lamp (emitting a broad band around 365 nm) is widespread, providing immediate indications to conservators and curators regarding the potential presence of retouching, repainting and surface heterogeneity. For example, it is common to inspect the abrasion or wear on the back of some stringed instruments, where varnish may be consumed due to cumulative use. Indeed, some violin experts claim that they can recognise specific "fluorescing colours" on varnishes of famous violins from Cremona, which include those by Amati and Stradivari.

Although UV-excitation is commonly used in museums for the examination of musical instruments, the spectrofluorimetric analysis of varnishes found on the surfaces of stringed instruments and paintings is relatively limited: laser induced fluorescence (LIF) of varnishes has highlighted significant differences in emissions of common varnishes [2,15] and recently spectrofluorimetry has been proposed for the differentiation between sandarac, mastic and dammar [4]. Because of the complex chemistry and large number of sensitive molecules present in most varnishes it has not been possible to attribute or fully interpret fluorescence spectra.

In most cases, the determination of the chemical composition of varnishes is carried out using sensitive and highly specific chromatographic/spectrometric analysis [16–20], providing indications regarding original composition, mixtures of materials and degradation mechanisms associated with ageing and light exposure; indeed, results from analysis form the basis for the differentiation of many organic materials, including varnishes, and also provide the framework for the rationalisation of results from other complementary spectroscopic techniques, including fluorescence spectroscopy in this work. Alternative and complementary non-destructive techniques, which can provide information about the surface of musical instruments, are particularly advantageous; sampling is not limited by access to fragments, and when it is possible to integrate punctual analysis with imaging, more representative indications regarding the composition surfaces may be obtained. The specificity of most non-invasive techniques can be limited to the elemental level (for example X-ray fluorescence spectrometry) [21] or to the detection of broad classes of molecular materials (using Fourier-transform infrared spectroscopy) [22].

In this work, fluorescence spectroscopy integrated with time-resolved fluorescence analysis is investigated on model samples of vanishes. For a more complete visualisation of the contribution from multiple-fluorophores present in the complex systems found in varnishes, where variations in fluorescence may be small and not related directly to the position of the maximum [4], maps of the fluorescence emissions as a function of excitation wavelength have been generated. Studies of different materials from food have demonstrated the potential of fluorescence excitation emission (EE) spectroscopy, in which a series of emission spectra that have been collected over a range of excitation energies, allowing the discrimination between complex multiple protein [23] and multiple oil-based systems [24]. In addition to EE spectra, the modelling of the nanosecond decay of fluorescence can be particularly helpful for the analysis of complex systems which contain multiple fluorophores, as has been demonstrated for binding media used in paintings [11]. Various portable instruments based on LIF devices have been developed and time-resolved fluorescence spectroscopy and imaging have been used to examine complex inorganic and organic painted surfaces [9] and sculptures [25], with significant advantages for the detection of the presence of superimposed organic materials. However no time-resolved fluorescence spectra of varnishes found on paintings or musical instruments have been published.

Therefore, in this work, both fluorescence EE spectra and time-resolved fluorescence spectra of varnishes are presented for the first time. Films of selected varnishes were prepared according to historical treatises [12,26] by a lacquer conservator at the Musée de la Musique to replicate typical thickness and surface morphology of varnishes found on musical instruments. The aim of this work is to measure fluorescence properties of these materials and to assess the potential of such measurements for material classification, thus providing a useful framework for the interpretation of fluorescence imaging of instruments.

2. Experimental

2.1. Description of samples

The materials analysed in this work were specifically chosen to reflect commonly found varnishes used for historical musical instruments. While most varnishes typically used in violin manufacture [26,27] are obtained from plants, shellac is excreted by the *Kerria lacca* insect and may be red-brown in colour prior to purification. Two different shellac samples have been considered in this work: cherry shellac which has not been extensively purified and which yields a slightly yellow varnish film, and platina shellac, which is bleached and colourless, having been washed and treated prior to use. Other varnishes studied can be broadly grouped into two categories based on their terpenic chemical composition. The triterpenoids considered are elemi and mastic. Diterpenoid varnishes included colophony, Venice turpentine, sandarac, and copal from two sources, Manila (Philippines) and Congo.

For this research samples have been prepared from the restoration materials stored at the laboratory of the Musée de la Musique and purchased more than 10 years ago from local suppliers (Prolabo, HMB and Art & Conservation, Paris). Most of these materials have been previously analysed with GC/MS [14].

Varnish solutions have been prepared by dissolving each of the following resins in ethanol (1:2, w/w), and undissolved residual materials were decanted. Further, mixtures of equal parts of colophony:sandarac, colophony:elemi, elemi:sandarac and colophony:elemi:sandarac were also prepared. Varnishes were painted out in single layers on non-fluorescent quartz slides. The choice of a smooth non-fluorescent substrate for an assessment of fluorescence of varnishes is important for two main reasons. First, only fluorescence from the varnish (and not from the substrate) is assessed. Second, coloured surfaces may selectively reflect photons generated during fluorescence, which may compromise the detection of fluorescence emissions [28].

Varnishes were prepared in 2006 and were analysed with fluorescence devices in 2008. Therefore, while natural and artificial ageing are both recognised as significant factors in the oxidation of varnishes [18], which may influence fluorescence emissions [1,4], for this work only naturally aged reference samples have been considered in an effort to assess if fluorescence spectroscopy can allow the differentiation between naturally aged materials.

2.2. System set-up and data analysis

2.2.1. Fluorescence excitation emission spectroscopy

EE spectra of films of varnishes were acquired using a scanning spectrofluorimeter with excitation provided by a Xenon arc lamp (Fluorolog, Jobin-Yvon/Horiba); a front-face geometry was employed during collection (detection at 23° with respect to the excitation slits) and the detected signal was automatically corrected for excitation and detection efficiency. Spectra matrices were constructed by recording a series of synchronous fluorescence spectra with variable excitation between 300 and 500 nm (resolution of 1 nm), with synchronous fluorescence offsets between 10 and 250 nm in 5 nm steps, and with slits of 1 nm (excitation) and 5 nm (emission). The precision of the measurement is thus ±1 nm for the

excitation monochromator and ±5 nm for the emission wavelength (and hence ±6 nm for Stokes Shift). Matrices were then transformed into EE spectra using Matlab (Mathworks) and have been plotted as contour plots with 20 different levels of intensity from the maximum (white) to 10% of the maximum intensity (black). The maximum peak is defined by the excitation and emission wavelengths at the maximum emission intensity. Peaks are reported in the text as ($\lambda_{excitation}$/nm:$\lambda_{emission}$/nm).

2.2.2. Time-resolved fluorescence spectroscopy

Time-resolved fluorescence spectra were recorded using an Optical Multichannel Analyser working in nanosecond gated mode, as described previously [9] and briefly summarised below.

UV pulsed excitation was provided by a nanosecond N_2 laser with 337 nm excitation; the emitted fluorescence was collected through a monochromator, with sensitivity between 400 and 650 nm and a spectral resolution of 1 nm, coupled to a time-gated multichannel analyser. The time-resolved detector is associated with a temporal gate of 10 ns and a jitter below 0.5 ns.

The kinetics of the emission was analysed by recording a set of fluorescence spectra with increasing delays with respect to the excitation pulse. Following data acquisition, spectral data are automatically corrected for the detection efficiency and are pre-processed with a moving average smoothing filter in order to reduce the level of noise. The fluorescence decay is then analysed at each wavelength by using a procedure based on a non-linear regression least-squares fit.

When using conventional fluorimetric techniques, the presence of a variety of fluorophores in complex fluorescent materials is indicated by the dependency of the fluorescence emission on the excitation wavelength. Moreover, the fluorescence spectra are composed of one or several broad band emissions generated by contributions from numerous fluorophores. In terms of fluorescence decay, a complex fluorescent material commonly shows a multi-exponential decay where the emission from each one of the main emitting species or group of fluorophores can be modelled as a single-exponential decay characterized by a specific lifetime and emission. Hence, the analysis of the decay kinetics of the emission spectrum of a complex material can provide a way for distinguishing amongst its main emitting fluorophores characterized by different lifetimes.

In this work, the analysis of the nanosecond emission decay following excitation at 337 nm was performed considering three different models: a mono-, a bi- and a tri-exponential decay. For all the selected materials, whereas the application of the bi-exponential decay model highly improves the result of the fitting procedure with respect to the mono-exponential model, the use of a tri-exponential decay model does not yield significant information. Therefore, in the following section, only results from the application of a bi-exponential model will be discussed.

Specifically, the application of a bi-exponential fitting procedure assumes that the optical fluorescence fluence $f(t, \lambda)$ which is emitted t seconds after the excitation pulse at the emission wavelength λ can be modelled as:

$$f(t,\lambda) = A_{SHORT}(\lambda)\ \exp\left(\frac{-t}{\tau_{SHORT}(\lambda)}\right) + A_{LONG}(\lambda)\ \exp\left(\frac{-t}{\tau_{LONG}(\lambda)}\right) \quad (1)$$

where $A_{SHORT}(\lambda)$ and $A_{LONG}(\lambda)$ indicate the wavelength-dependent amplitudes of the short-lived and long-lived fluorescent components identified in the emission, and $\tau_{SHORT}(\lambda)$ and $\tau_{LONG}(\lambda)$ are the associated wavelength-dependent lifetimes. Following a suitable non-linear regression least-squares fitting procedure, $A_{SHORT}(\lambda)$, $A_{LONG}(\lambda)$, $\tau_{SHORT}(\lambda)$ and $\tau_{LONG}(\lambda)$ are estimated, and the mean reduced χ^2 value is used for assessing the reliability of the fit. Generally, with this model, while the wavelength-dependent functions $A_{SHORT}(\lambda)$ and $A_{LONG}(\lambda)$ are associated with spectral shapes characterized by distinct spectral features, $\tau_{SHORT}(\lambda)$ and $\tau_{LONG}(\lambda)$ are associated with relatively constant spectral behaviour. In principle, $A_{SHORT}(\lambda)$ and $A_{LONG}(\lambda)$ describe the emission spectrum of the two main emitting groups of fluorophores present in each one of the materials studied.

In the following section, the outcome of the bi-exponential fitting procedure is shown in terms of $A_{SHORT}(\lambda)$ and $A_{LONG}(\lambda)$, which, for an easier comparison, are always shown normalized to their maximum value. The mean lifetime τ_{SHORT} and τ_{LONG} associated with each one of the reconstructed components is further indicated, together with the ratio R between the total intensity of the short-lived and long-lived component, calculated according to the following formula:

$$R = \frac{\int A_{SHORT}(\lambda)\ d\lambda}{\int A_{LONG}(\lambda)\, d\lambda} \quad (2)$$

Hence, in each varnish studied, in addition to picosecond lifetime components that cannot be resolved with the instrumentation employed here, two main emitting groups can be well separated.

3. Results

EE spectra of the materials studied can be classified based on the number of evident peaks in the contour plots, the position of the maximum emission and excitation wavelengths and the general shape of the excitation/emission contours present in the spectra. Spectra below can be divided into three basic groups: those from (1) shellac, (2) triterpenoid and (3) diterpenoid varnishes and are presented in this order in the following subsections. Finally the EE and time-resolved spectra of mixtures of selected varnishes are shown.

3.1. Shellac

Shellac is composed of a resinous fraction and of a solid colorant fraction, containing various laccaic acids. The differences between the distinctly red cherry shellac and the colourless platina shellac are likely due to the extraction of red-coloured laccaic acids during the washing and bleaching process associated with the production of platina shellac. EE spectra of purified (platina) shellac, and red-coloured (cherry) shellac are seen in Fig. 1. Although of similar origin, the different shellac varnishes exhibit significantly different EE spectra. Specifically, while the former is associated with one broad emission centred at (307:487), as well as significant fluorescence at longer excitation wavelengths, the latter has multiple fluorescence bands: a broad fluorescence pattern centred at (307:410) with the addition of intense peaks at (307:554) and (465:635) [2,29]. The last two peaks may be attributed to the fluorescent laccaic acids. The fluorescence of shellac is clearly dependent on its degree of purification.

The analysis of the kinetics of the fluorescence emission decay confirms the differences ascribable to the two materials and further provides indications on the presence of secondary fluorescent compounds in each one of the two different shellacs studied. In detail, in Fig. 2 the fluorescence spectra of the short- and long-lived components of the emission from the two shellacs are shown: emission from the purified platina shellac is characterised by a short-lived component with a major peak at 420 nm and a further broad emission centred around 600 nm, possibly ascribable to residual laccaic acids. In the long-lived component the red-emission almost disappears and instead a broad emission at 440 nm with a shoulder at 520 nm is evident. Cherry shellac is characterised by an intense short-lived component with two peaks at 420 and 600 nm, similarly to those observed in the platina shellac, but in this case the emission ascribed to laccaic acids is predominant. The long-lived

Fluorescence spectra of the short- and long-lived components of the emission from naturally aged films of shellac following a bi-exponential fit of time-resolved spectral data: (a) short-lived and (b) long-lived component of platina shellac; (c) short-lived and (d) long-lived component of cherry shellac. For an easier comparison fluorescence amplitudes are shown normalized to the maximum value and values of τ_{SHORT}, τ_{LONG} and R are provided. Dashed vertical lines indicate the main peak wavelength of each fluorescent component.

component of the emission of cherry shellac shows further emission in the red with a peak at 630 nm, again possibly ascribable to laccaic acids.

3.2. Triterpenoid varnishes

The EE spectra of two triterpenoid varnishes elemi and mastic (Fig. 3) reflect small difference in their chemical composition, which may be related to the presence of specific terpenic acids [17]. In detail, EE spectra of elemi and mastic have symmetrical fluorescence emission bands and both varnishes are associated with maximum emission at excitation around 310 nm. However the emissions of the two varnishes differ significantly, with Stokes shifts of 85 and 135 nm, respectively, suggesting that the materials are characterised by a different group of fluorophores which may have similar absorption spectra. The EE spectra of mastic and elemi also indicate the presence of significant visible fluorescence at longer excitation wavelengths and the shape of the contours is relatively similar for both materials. While specific fluorophores have not been identified for either varnish, these results are comparable with fluorescence reported by others who suggest emissions in mastic at 440–460 nm [1,4,15]. Moreover, excitation at 365 nm of samples of mastic aged naturally for 50 years has been reported with emission spectra similar to those represented above [1]. It is further of interest that elemi and platina shellac have a common excitation-emission maximum (as can be observed in Table 1), but EE spectra of the two varnishes are completely different.

The analysis of the kinetics of the emission at 337 nm excitation in shown in Fig. 4. Fluorescence emissions from elemi appear

Colophony:elemi	320	412	92	410	490	1.9	8.2	0.011	0.160
Elemi:sandarac	310	395	85	410	460	2.0	8.4	0.005	0.088
Colophony:elemi:sandarac	310	405	95	420	480	2.0	8.6	0.006	0.071

characterised by an intense short-lived component with a strong and narrow peak at 410 nm, whereas in the long-lived component a broader emission centred at 480 nm is evident. In turn, mastic is characterised by a short-lived component peaked at 430 nm with a shoulder at 410 nm and a long-lived component peaked at 460 nm, which, compared to that of elemi, is much narrower. Nevertheless, despite some detectable differences in their time-resolved spectra, the two materials clearly show common features related to their similar chemical composition. Moreover, differences between the results of time-resolved analysis of triterpenoid-based and shellac-based materials indicate these two classes of varnishes can be distinguished easily.

3.3. Diterpenoid varnishes

The EE spectra of the diterpenoid varnishes analysed (Fig. 5) vary in terms of the position of the emission maximum, with the exception of sandarac and copal. Moreover, in comparison with the emission from triterpenoid varnishes, the distribution of fluorescence is significantly different; specifically, more intense fluorescence is observed at longer excitation wavelengths, providing an immediate means of distinguishing between diterpenoids and triterpenoids analysed.

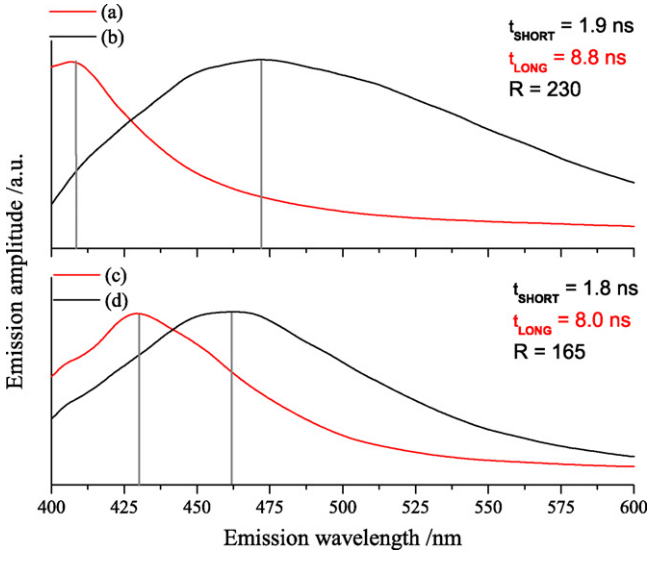

Fig. 4. Fluorescence spectra of the short- and long-lived components of the emission from naturally aged films of varnishes following a bi-exponential fit of time-resolved spectral data: (a) short-lived and (b) long-lived component of elemi; (c) short-lived and (d) long-lived component of mastic. For an easier comparison fluorescence amplitudes are shown normalised to the maximum value and values of τ_{SHORT}, τ_{LONG} and *R* are provided. Dashed vertical lines indicate the main peak wavelength of each fluorescent component.

The most distinctive and complex EE spectrum of the diterpenoid-based varnishes studied in this work is associated with colophony, the solid residue obtained after filtration and distillation of pine turpentine. Indeed, two different groups of fluorophores have been assigned to the bands present: (370:480) and another stronger peak at around (310:505). Multiple groups of fluorophores which are characterised by different bands are likely present in the sample. In contrast, the resin from larch trees, commonly known as Venice turpentine, is associated with a similar maximum emission band but has fewer contributions to fluorescence at longer excitation wavelengths. This phenomenon may be related to variation in extraction and processing of the resins or to variation in the polymerisation of the varnish films [20].

Sandarac and copals (Fig. 5(c and d)) are other diterpenoid conifer resins, and form cross-linked fraction of polycommunic acids upon oxidation, but differ in terms of the age of the collected tree-resins prior to their use as varnishes. Sandarac is harvested directly from the tree while copal is a semi-fossilised resin collected from the ground and the two materials share common chemical markers: agathic acid and related labdane compounds are predominant in copals, and are also present in sandarac [30]. Only subtle differences are observed in the EE spectra of copal and sandarac which are associated with the shape of contours describing fluorescence, and spectra of the two varnishes share a common maximum at approximately (310–20:390–415). Small differences were found in the EE spectra of the two copal-based varnishes (Congo copal not shown); rather than a shift in the position of the fluorescence maximum, fluorescence emissions excited at wavelengths above 400 nm are more apparent in Congo copal (from *Copaifera guibourthiana*) which has a spectrum more similar to sandarac than to that observed in Manila copal (from *Agathis dammar*), likely due to the differences in the source and age between the two semi-fossilised copals. Published spectra of aged sandarac are comparable to those represented in EE spectra [4].

The time-resolved analysis of the emission performed on the five diterpenoid varnishes (Fig. 6) indicates the presence of common features for these materials, ascribable to their similar chemical composition: in particular, it is possible to observe the presence of a common short-lived and intense component peaked between 400 and 420 nm, characterized by a much broader emission with

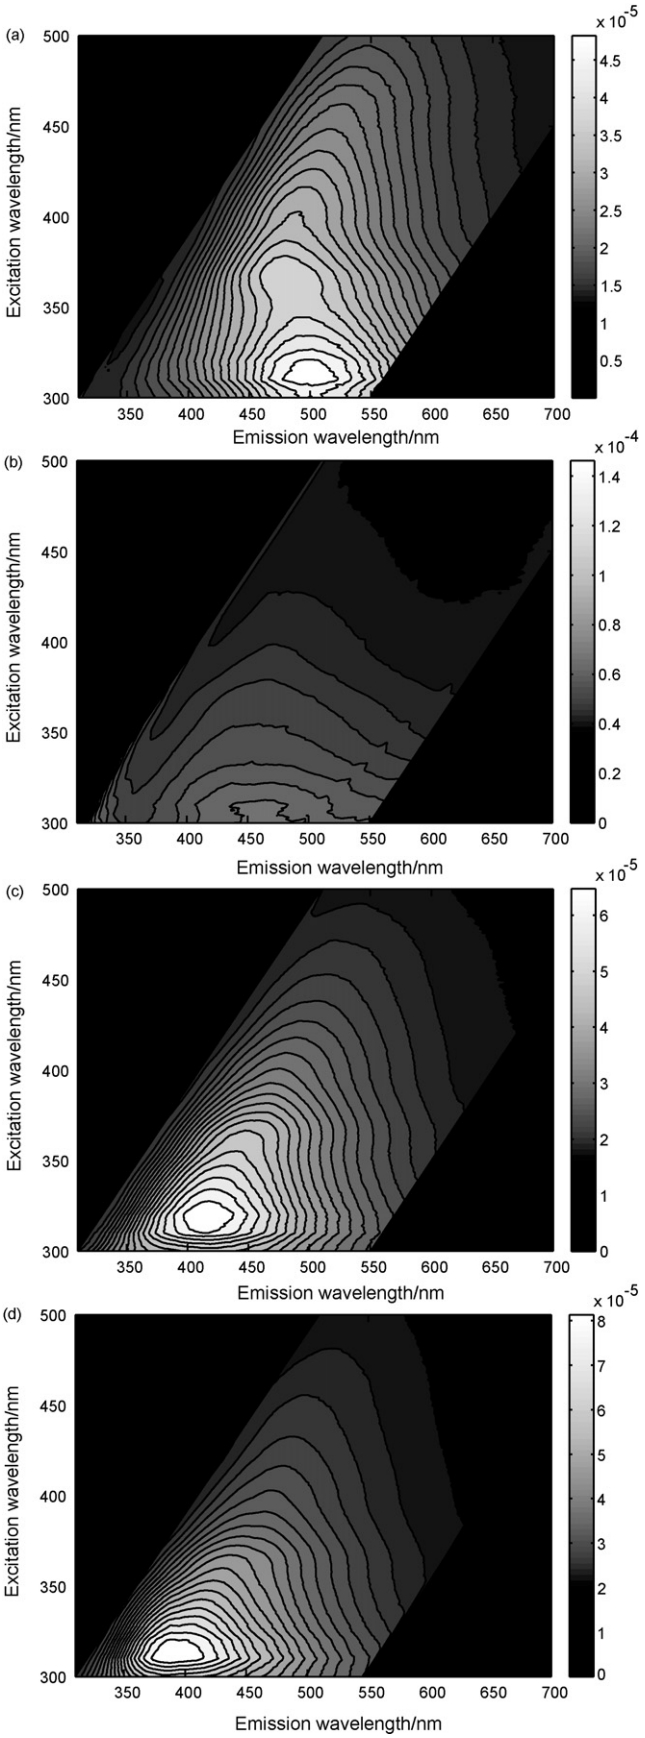

Fig. 5. EE spectra of naturally aged films of varnishes (a) colophony (b) Venice turpentine (c) sandarac (d) Manila copal, where intensity is given in counts and 20 contours represent 90% of the fluorescence of materials as a function of excitation.

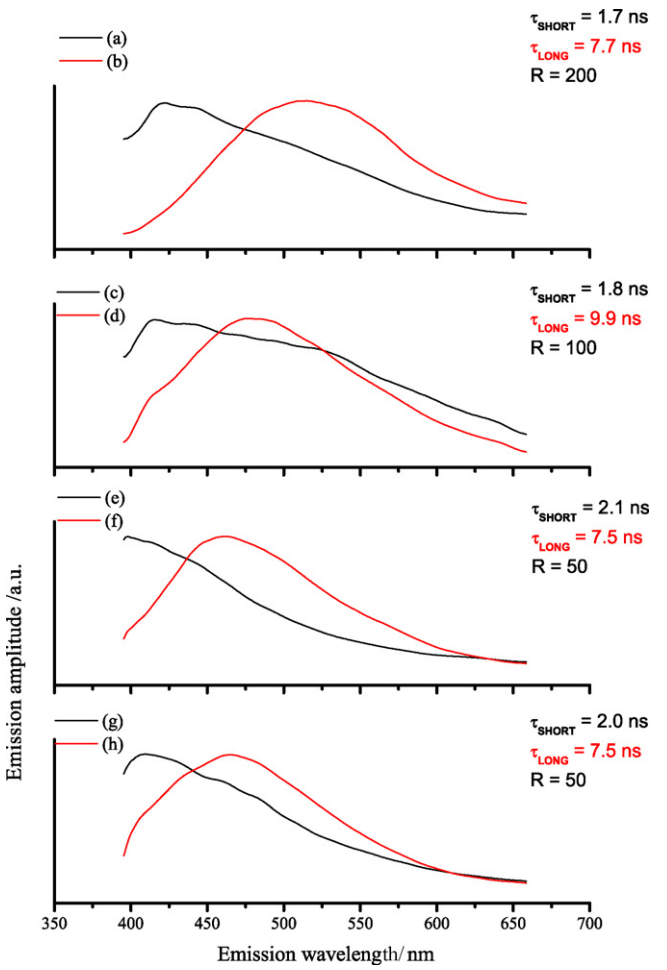

Fig. 6. Fluorescence spectra of the short- and long-lived components of the emission from naturally aged films of varnishes resulting following a bi-exponential fit of time-resolved spectral data: (a) short-lived and (b) long-lived component of colophony; (c) short-lived and (d) long-lived component of Venice turpentine; (e) short-lived and (f) long-lived component of the mixture of sandarac; (g) short-lived and (g) long-lived component of the mixture of Manila copal. For an easier comparison fluorescence amplitudes are shown normalised to the maximum value and values of τ_{SHORT}, τ_{LONG} and R are provided. respect to that observed in the triterpenic varnishes, which extends into the red region of the electromagnetic spectrum in the case of colophony and Venice turpentine and towards the green spectral region in the case of sandarac and Manila and Congo copal. In its turn the long-lived component shows small differences ascribable to the five materials analysed: a broad and symmetric emission peaked at 520 nm for colophony, an emission peaked at 480 nm with a small shoulder at 420 nm for Venice Turpentine and an emission peaked at 460 nm for sandarac (Fig. 6), at 450 nm for Congo copal and at 470 nm for Manila copal.

3.4. Mixtures of different varnishes

Mixtures of varnishes containing colophony, elemi and sandarac yield different EE spectra than those observed in single varnish samples seen in Figs. 3 and 5, however the EE spectra in mixtures (Fig. 7) may retain features from the constituent materials.

In general, the presence of colophony in mixtures contributes to emissions at longer excitation wavelengths (seen in all three mixtures containing colophony). For example in a mixture of colophony:sandarac (Fig. 7a) the maximum emission is observed with similar excitation wavelength as that seen in colophony, but

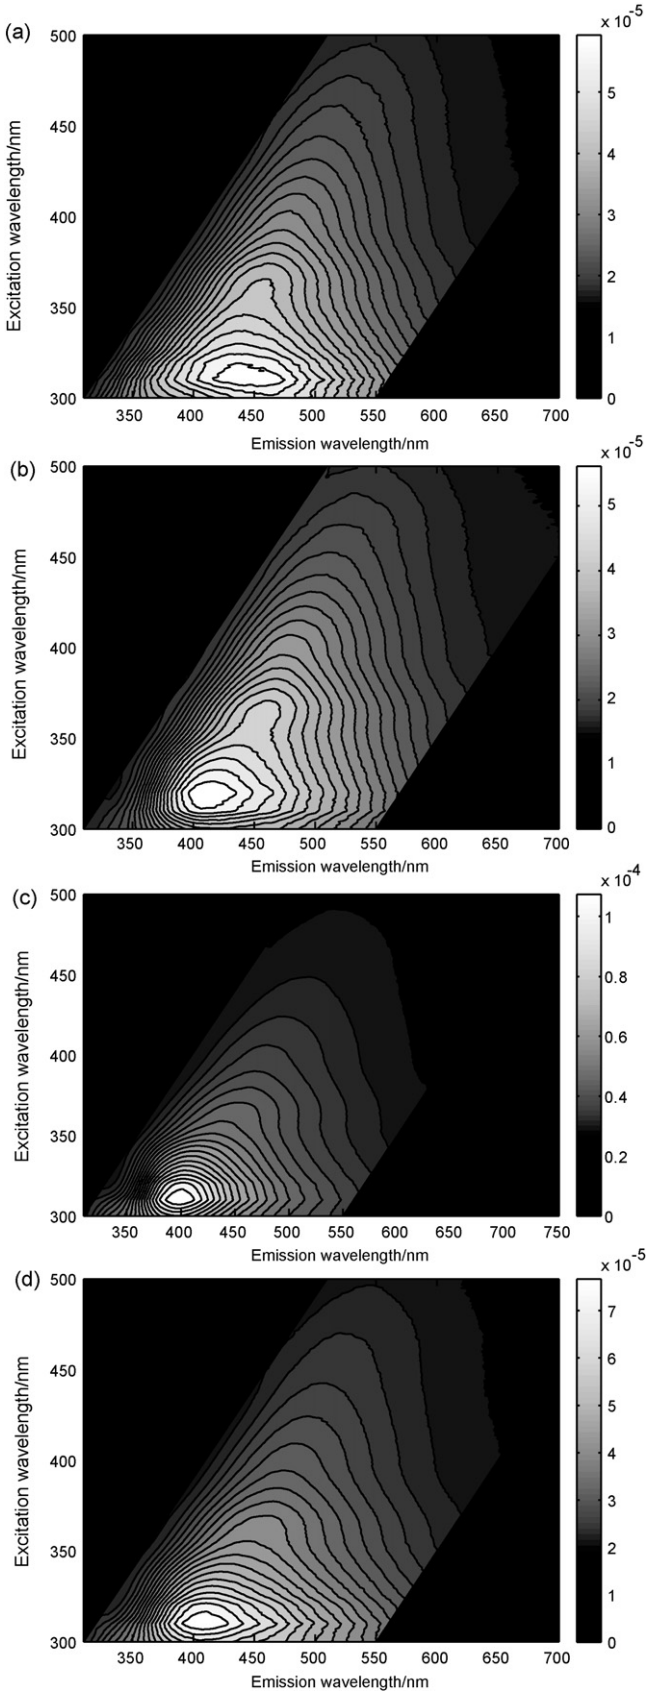

Fig. 7. EE spectra of varnishes made from mixtures of (a) colophony:sandarac, (b) colophony:elemi, (c) elemi:sandarac and (d) colophony:elemi:sandarac.

with a Stokes shift of 90 nm, greater than that seen in sandarac and less than that of colophony. The time-resolved analysis of the emission from the mixtures appears to be quite complicated. In fact, it can happen, as for the case of the mixture of colophony:sandarac, that both the short- and long-lived components of the emission from the mixture are characterised by spectral features which are found between those observed in the pure varnishes forming the mixture, but, in general, it is not possible to easily differentiate fluorescence contributions from mixed varnishes.

In Table 1, the positions of the maximum of the short- and long-lived component of the emission are further summarised.

4. Discussion

While in most cases it is difficult to interpret spectra with reference to specific fluorophores [4], the presence of small but appreciable differences in EE spectra and spectrally resolved fluorescence decays is an indication of the chemical variation among the varnishes analysed, which is ascribed to different sources of materials employed. Importantly, despite the dependence of fluorescence on ageing, spectra of materials reported here are comparable to those published previously by others [1,4,15].

From an initial examination of the maximum excitation and emission wavelengths as shown in Table 1, shellac is easily distinguished from other varnishes. However only small differences in the maximum excitation and emission wavelength are found for diterpenoids and triterpenoids; for example mastic and Venice turpentine have maxima at (305–10:445–65). Mastic, colophony and Venice turpentine seem to present high Stokes shifts ($\geq$135 nm), significantly greater than the other terpenoids. However, in comparison with fluorescence excitation and emission maximum, EE spectra indicate further differences in the emission properties of the varnishes studied, hence corroborating the limitation of considering only maxima in fluorescence spectra. Using a single excitation wavelength, it may still be possible to better distinguish materials with the aid of time-resolved fluorescence spectroscopy.

Since materials analysed are characterized by multiple fluorophores which emit in different spectral bands, bi-exponential modelling of time-resolved data provides a better fit with respect to results obtained with a mono-exponential fit. In detail, in Table 1 the mean reduced χ^2 values for the two exponential models are given, where the mono-exponential fit was carried out by considering only the decay following the first 10 ns after excitation. Indeed, fluorescence lifetime analysis of spectral bands provides a better indication of the presence of emissions from at least two distinct groups of fluorophores in each material: specifically, the emission spectrum of the long-lived component can be used to distinguish colophony from the other terpenic resins, whereas the narrower emission spectrum of the short-lived component of triterpenic varnishes can be used to distinguish them from diterpenoid media.

However, the resolution of mixtures of varnishes using fluorescence spectroscopy indicates that the contribution from one varnish of the mixture is predominant. As a general observation, in many cases time-resolved and EE spectroscopy are not able to separate the fluorescent components of mixed materials, but more refined statistical analyses on spectral and time-resolved data could be carried out to address the resolution of mixtures of multiple varnishes. For example, the combination of colophony:elemi (Fig. 7b) does not yield EE spectra which are easily rationalised, as the position of the maximum shifts and broadens with respect to that of the two varnishes. In turn, the EE spectrum of elemi:sandarac (Fig. 7c) does not differ from that of pure elemi in the position of maximum emission, whereas fluorescence intensity at the maximum is more intense than that of individual varnishes and a change is observed in the shape of the contours. The reason for this phenomenon is

not clear; it is possible that both chemical and physical interactions between the mixed materials occur or that a stratigraphic separation of the components takes place. In this latter case, the use of confocal fluorescence microscopy or other stratigraphic sampling techniques (MALDI) could be investigated.

5. Conclusion

The analysis and identification of varnishes using fluorescence remains a complex problem, which can be addressed, in part, by the integration of excitation emission spectroscopy and complementary time-resolved fluorescence spectroscopy, as shown in this work. Clear differences in EE spectra and short- and long-lived fluorescence emissions are evident and can be employed to better understand the materials responsible of the emission observed in varnishes. Based on the position of emission maximum, as well as the shape of the contours describing fluorescence, it may be possible to classify simple varnishes into groups which correspond to their chemical composition: sesquiterpenoids and polyesters (shellac), triterpenoids and diterpenoids.

The analysis of mixtures has also been carried out, and revealed that in some cases various contributions to the observed fluorescence spectra may be discerned from careful analysis of EE and time-resolved spectra. Further work based on factor analysis (for example PARAFAC), which has been applied to EE spectra of mixtures of fluorophores in food [23], may be used to create a more robust method for the deconvolution of EE spectra of single and multiple varnishes. Such analysis could be strengthened by the precise identification of specific groups of fluorophores present in the complex mixtures of resins employed as varnishes, potentially achievable with chromatographic techniques.

Instrument varnishes may also be mixed with dyes and colorants, as well as pigments (for example cinnabar) [14], which may complicate the interpretation of fluorescence spectra [31]. The presence of underlying varnish and pigmented layers may also compromise the detection of fluorescence; indeed fluorescent or absorbent substrates (wood or painted surfaces) may also modify the observed emission spectrum of materials through scattering and reflectance of emitted photons [28]. Therefore, the role of pigments and colorants in the modification or absorption of fluorescence should be further studied.

Another important factor which has not been directly addressed in this work, but which has been investigated by others [1,4], is the ageing and oxidation of varnishes, which is well-known to produce chemical and physical changes [18], both of which may have significant implications for varnish detection using fluorescence; further work is therefore necessary on a larger set of naturally aged materials which would better reflect materials found on works of art and historical musical instruments.

Finally, within the context of the analysis of both instruments as well as paintings, fluorescence spectroscopy, while unable to provide the specific and definite identification of materials and markers, which is afforded by alternative destructive techniques [15], remains an important tool for analysis. Extensively used in practice by restorers and art historians, fluorescence can indeed provide indications which go beyond the identification of areas of repainting and repairs, and may be used to guide further analytical investigations of musical instruments using selected complementary techniques.

ABSTRACT

beta-Casomorphins (b-CMs) are bioactive peptides derived from casein with opioid agonist effects similar to morphine. The use of electrospray (ESI) with quadrupole ion-trap mass spectrometry (QIT-MS) for these compounds in two matrices, cheese and milk, was examined. It was compared to a liquid chromatography (LC) coupled to mass spectrometry (LC–MS), and a "soft" ionisation technique, NanoMate, with selected ion monitoring (SIM), which are unreliable for the determination of trace casomorphins in derived milk products. b-CM mass fragmentation pathways were done for the four most common b-CMs: β-casomorphin (1-5) bovine (b-CM-5), β-casomorphin (1-7) bovine (b-CM-7), [D-Ala2, D-Pro4,Tyr5]-β-casomorphin (1-5) amide (b-CM-10) and β-casomorphin (1-5) amide [D-Ala2,Hyp4,Tyr5] (b-CM-11). The major product ions obtained in QIT-MS were used to construct fragmentation pathways for b-CMs. The different collision energies using automated nanoelectrospray ion source NanoMate and conventional LC in QIT-MS were studied. Calibration data for b-CMs, using spiked milk or cheese samples (10 g or 10 mL), were: NanoMate/MS (25–1000 μg/L), $r^2 = 0.998$; NanoMate/MS^2 (5–1000 μg/L), $r^2 = 0.9992$; NanoMate/MS^3 (2.5–1000 μg/L), $r^2 = 0.9998$. Reproducibility data (% RSD, $N = 5$) for NanoMate/MS^n mode ranged between 2.0 at 500 μg/L and 7.0 at 10 μg/L.

1. Introduction

Peptides yielded by the digestion of beta-casein have opioid agonist effects similar to morphine. They are named beta-casomorphins (b-CMs) [1]. These bioactive peptides are bound to opioid receptors and exhibit morphine-like effects. They have high content on proline residues which it is related with effects as opioid (casomorphins) antithrombotic, antihypertensive, immunomodulators or mineral carriers [6,5].

Although their effect in adult human is limited to the gastrointestinal tract, as they are not absorbed or are subject to enzymatic degradation in the intestinal wall, in newborns and young infants, the effects presented are more evident, as the widespread hypothesis used to explain autistic symptoms in autism spectrum disorders (ASD) as shown in some studies [2,3]. It has been observed that many children with ASD present gastrointestinal symptoms such as inflammation, diarrhea, gastroesophageal reflux, abdominal pain and increased intestinal permeability [4,5]. It has also been observed that b-CMs induce alteration of the intestinal electrolyte transport, affect the human mucosal immune system, possibly via opioid receptors, and an important function in the digestive process may be served [6]. Investigations have shown that b-CMs significantly inhibited stimulated lamina propria lymphocyte proliferation (LPL) [5,7].

Continued developments in food technology and nutritional scientific interest in food peptides have grown considerably in the last years and in consequence it has given rise to the synthesis or production of potential bioactive peptides. This interest has been increased due to the presence of food component necessaries for organism such as amino acids, nitrogen and nutritional and functional values. In fact in the food industry, peptides derived from whey proteins, sometimes are used as skim milk replacers in ice cream, as fat replacers, as whole eggs replacers, as nondiary dessert products and in enteral, infant and sport nutrition [8,9]. And in consequence, detrimental components are sometimes presented in natural forms in food, but others, some effects on food components could cause effects and provide bioactive peptides because of the development of modern food processing and storage techniques.

Methods used in food processing such as hydrolysis, oxidation, fermentation, pH changes, heat and microbial enzymes can cause structural and chemical changes and synthesis or production of potential bioactive peptides. In the case that it concerns us the biologically active peptides produced from milk proteins are generated in natural way like in fermentation process of milk products. Milk is of great importance in the early years of human life and adult age [6,8], it is one of the basic foods well studied over the years, and its major proportion of nutrient components are proteins, the main source of natural biologically active peptides (b-CMs).

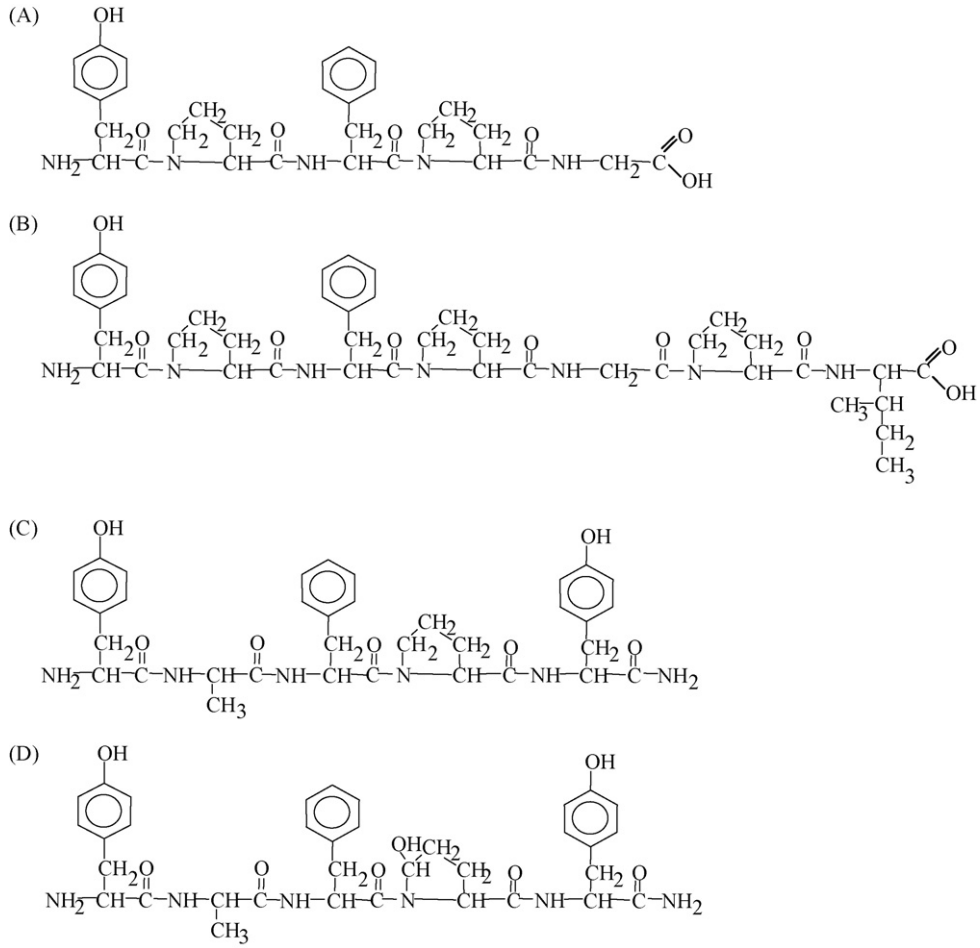

Fig. 1. Structure of the b-CMs studied: (A) β-casomorphin (1-5) bovine (b-CM-5); (B) β-casomorphin (1-7) bovine (b-CM-7); (C) [D-Ala2, D-Pro4,Tyr5]-β-casomorphin (1-5) amide (b-CM-10); and (D) β-casomorphin (1-5) amide [D-Ala2,Hyp4,Tyr5] (b-CM-11).

The beta-CMs have been isolated and identified in different origins of fresh milk: in cow, bovine, ovine, water buffalo and human milk, as well as in dried infant formula [1,10–13] and analytical and preparative separations in food proteins, LC coupled with conventional UV and fluorescence detectors has been the most widely used method. New developments in detection and separation facilities of LC have introduced robust and easy-operating LC–MS instruments capable of providing selective separation on-line with sensitive and selective mass detection.

Knowledge of importance in food derived bioactive peptides and the ionisation provided by analytical tools of the identification with a near complete certainly it has taken us to develop a method based on a quadrupole ion-trap (QIT) MS for identification of different b-CMs (Fig. 1) in milk and cheese samples. These MS instruments are quite specific to allow the identification of unknown analytes with a high degree of confidence, and they have been used for our studies. MS instruments are a powerful tool for the determination of the relative molecular mass of milk proteins as it is shown in some papers [9,14]. It has allowed the sequence of a large number of peptides in a relatively short analysis time and made such analyses by mass spectrometry possible for proteins and peptides with high accuracy [15–18].

Analytical methods for derived milk products using multiple tandem MS with electrospray ionisation (ESI) and nanoESI sources have been developed in this study. The multiple tandem mass spectrometer has been examined for the determination of b-CMs in cheese and milk; a quadrupole ion-trap (QIT) MS permits structural studies on casomorphins since mass fragmentation pathways can be studied using MS^n. An improved detection sensitivity using LC and automated nanoESI (NanoMate), linked to the QIT-MS, applied to determine b-CMs in cheese and milk samples, was reached.

The presented method achieves the identification of different b-CMs (Fig. 1) in milk and cheese samples and it is novel because there is no paper that studies the best conditions for optimal sensitivity and selectivity using the mass analyser QIT-MS to determine b-CMs in milk and cheese, and that establishes the strong points of each instrument that can be profit to more sensitive and selective quantification. It shows best conditions for the most common four b-CMs using LC-QIT/MS, studying the fragmentation pathway of these compounds, and also a comparison between different collision energies used by LC-QIT-MS and NanoMate-QIT-MS. Infusion NanoMate-ESI-MS demonstrates the successful possibility to analyse samples at ng/mL regime.

2. Materials and methods

2.1. Chemicals

β-Casomorphin (1-5) bovine, β-casomorphin (1-7) bovine, [D-Ala2, D-Pro4,Tyr5]-β-casomorphin (1-5) amide and β-casomorphin (1-5) amide [D-Ala2,Hyp4,Tyr5] were obtained from American Peptide Company, Inc. (Sunnyvale, CA, USA) as shown in Fig. 1. Individual standard stock solutions of 1000 mg/mL were prepared in methanol and stored in stained glass-stopper bottles under refriger-

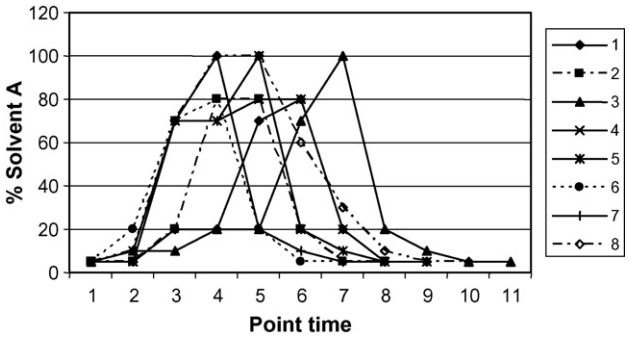

Fig. 2. Diagram of gradient of % solvent A in eight proofs to obtain the best separation of the four b-CMs. Each point time corresponds to a different minute depending on the proof. Time ranged between 50 and 60 min. The definite gradient is not represented, and it is detailed in Section 3.1.

ation at 4 °C. Standard working mixtures at various concentrations were prepared daily by appropriate dilution of aliquots of the stock solutions in methanol. A working standard mixture containing 5 μg/mL of each compound was prepared in methanol to be used as a spiking solution.

All chemicals and solvents used were of analytical grade or HPLC quality. Acetonitrile, water and methanol were purchased from Lab-Scan (Dublin, Ireland). Trifluoroacetic acid (TFA) was obtained from Sigma–Aldrich (Dorset, UK).

2.2. Liquid chromatography

The LC system was a Waters 2690 Alliance (Mildford, MA, USA) that included a thermostated autosampler, operated at 4 °C. The analytical column was a Luna-2 C_{18} (5 μm, 150 mm × 2.00 mm, Phenomenex, Macclesfield, UK) that was maintained at 35 °C. Isocratic chromatography was carried out using water–acetonitrile (70:30) containing 0.05% TFA at a flow rate of 200 μL/min. The injection volume was 5 μL.

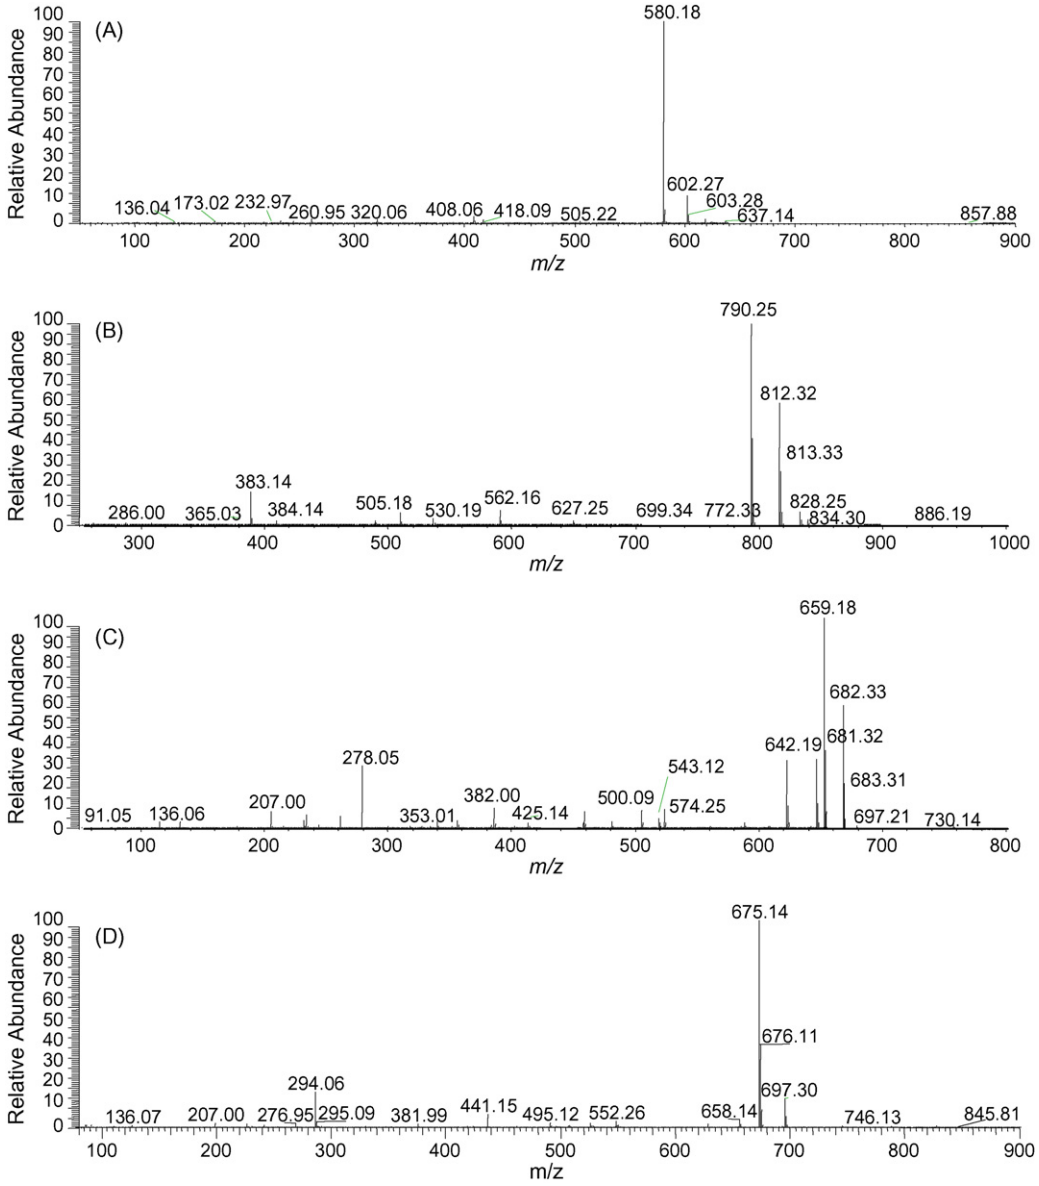

Fig. 3. QIT-full MS of the b-CMs studied by NanoMate: (A) b-CM-5; (B) b-CM-7; (C) b-CM-10; and (D) b-CM-11.

Table 1
Molecular weight, amino acid sequences and formula of the four b-CMs studied.

	Molecular weight	Sequence	Formula
Beta-casomorphin (1-5) bovine	579.7	Tyr-Pro-Phe-Pro-Gly	$C_{30}H_{37}N_5O_7$
Beta-casomorphin (1-7) bovine	789.9	Tyr-Pro-Phe-Pro-Gly-**Pro-Ile**	$C_{41}H_{55}N_7O_9$
Beta-casomorphin (1-5) amide [D-Ala2, D-Pro4,Tyr5]	658.8	Tyr-DAla-Phe-**DPro**-Tyr-NH_2	$C_{35}H_{42}N_6O_7$
Beta-casomorphin (1-5) amide [D-Ala2,Hyp4,Tyr5]	673.8	Tyr-DAla-Phe-**Hyp**-Tyr-NH_2	$C_{35}H_{41}N_6O_8$

Table 2
Ions and relative abundance of b-CMs obtained with NanoMate and LC in ESI mode by QIT-MS (full MS).

Compound	MW	*m/z* (% relative abundance)	
		LC-QIT-MS	NanoMate-QIT-MS
Beta-casomorphin (1-5) bovine	579.7	580 $[M+H]^+$ 100; 213 $[M+2H]^{2+}$ 100; 624 $[M+2Na-H]^+$ 70; 602 $[M+Na]^+$ 85	580 $[M+H]^+$ 100; 602 $[M+Na]^+$ 85
Beta-casomorphin (1-7) bovine	789.9	790 $[M+H]^+$ 100; 834 $[M+2Na-H]^+$ 15; 812 $[M+Na]^+$ 25	790 $[M+H]^+$ 100; 812 $[M+Na]^+$ 80
Beta-casomorphin (1-5) amide [D-Ala2, D-Pro4,Tyr5]	658.8	659 $[M+H]^+$ 25; 681 $[M+Na]^+$ 100; 697 $[M+K]^+$ 10	659 $[M+H]^+$ 100; 681 $[M+Na]^+$ 70; 697 $[M+K]^+$ 10
Beta-casomorphin (1-5) amide [D-Ala2,Hyp4,Tyr5]	673.8	675 $[M+H]^+$ 45; 697 $[M+Na]^+$ 100	675 $[M+H]^+$ 100; 697 $[M+Na]^+$ 20

2.3. Quadrupole ion-trap mass spectrometer (QIT-MS) conditions

Experiments were carried out using a Finnigan MAT LCQ Classic ion-trap mass spectrometer system (Thermo-Finnigan, San Jose, CA, USA) equipped with electrospray ionisation (ESI) Finnigan Xcalibur™ Rev. BXCALI-97001 software of ThermoQuest Corporation trademark and Data Analysis BioWorks™ ver. 3.1. The coupling of LC to QIT-MS was carried out using the binary pump and through its ESI interface in positive mode using the standard scan at normal resolution.

The sample was introduced from the HPLC into the ion-trap mass spectrometer using an uncoated fused-silica capillary (Metal Services Ltd.) with a length of 18 cm, at room temperature, 100 μm I.D., and 200 μm O.D. The polyamide coating was removed from the end of the capillary (ca. 5 mm) to maintain a stable electrospray. The voltage on the ESI needle was set at 4 kV, producing a spray current of approximately 80 μA. The capillary voltage was set at 10 V and the temperature of the heated capillary was 200 °C. The sheath gas flow rate used was 60 (arbitrary units). The QIT-MS was tuned for b-CMs and the voltages on the lenses were optimised in TunePlus (Excalibur Software) whilst infusing a standard solution (1 μg/mL methanol) at the rate of 3 μL/min. The optimised lens voltages were as follows: tube lens offset (0.0 V); octapole 1 offset (−3.0 V); octapole 2 offset (−7.0 V); inter-octapole lens voltage (0–16.0 V); trap DC offset voltage (−10.0 V). The microscan value was set at 3 ms and the maximum inject time was 50 ms.

Multiple tandem MS spectra, produced by collision-induced dissociation (CID), were obtained using the primary and majority ion provided at the conditions above mentioned. For most of the b-CMs studied compounds the protonated molecule $[M+H]^+$ was obtained.

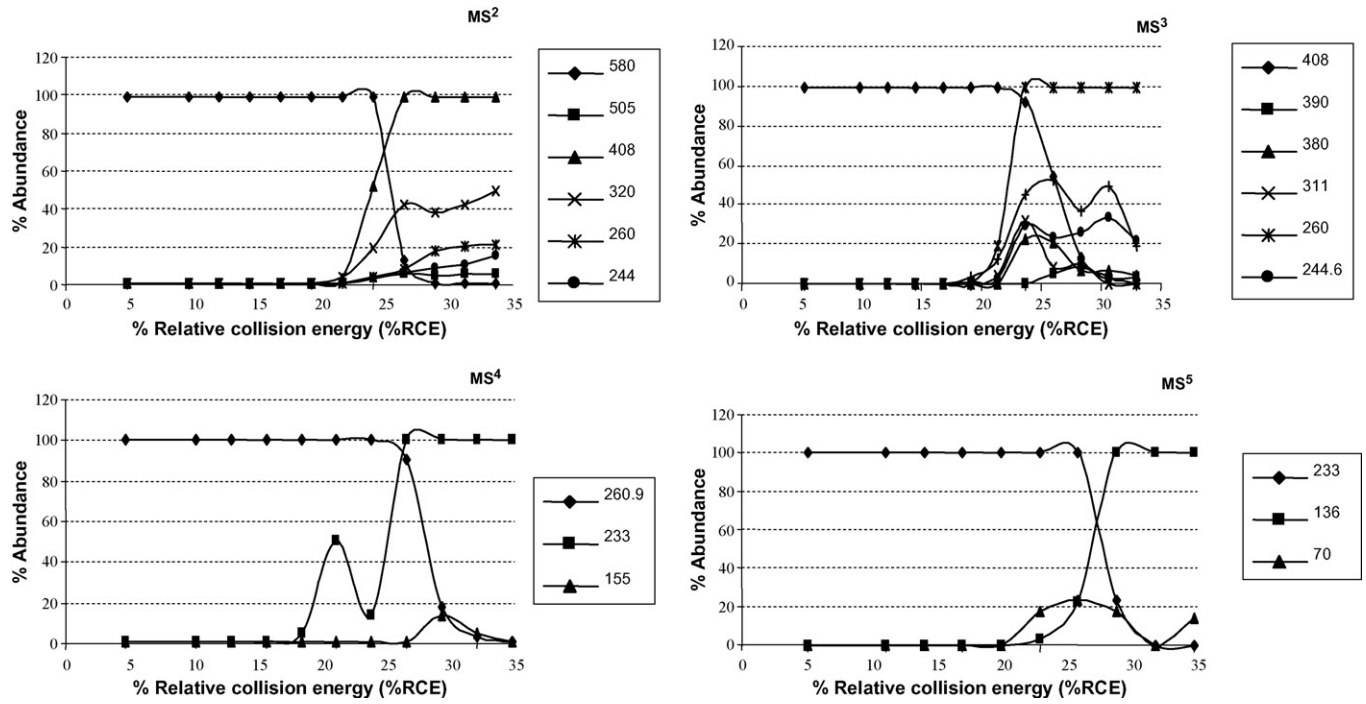

Fig. 4. Abundance of product ions from the reaction of protonated b-CM-5 with helium in the quadrupole ion-trap as a function of relative collision energy (RCE).

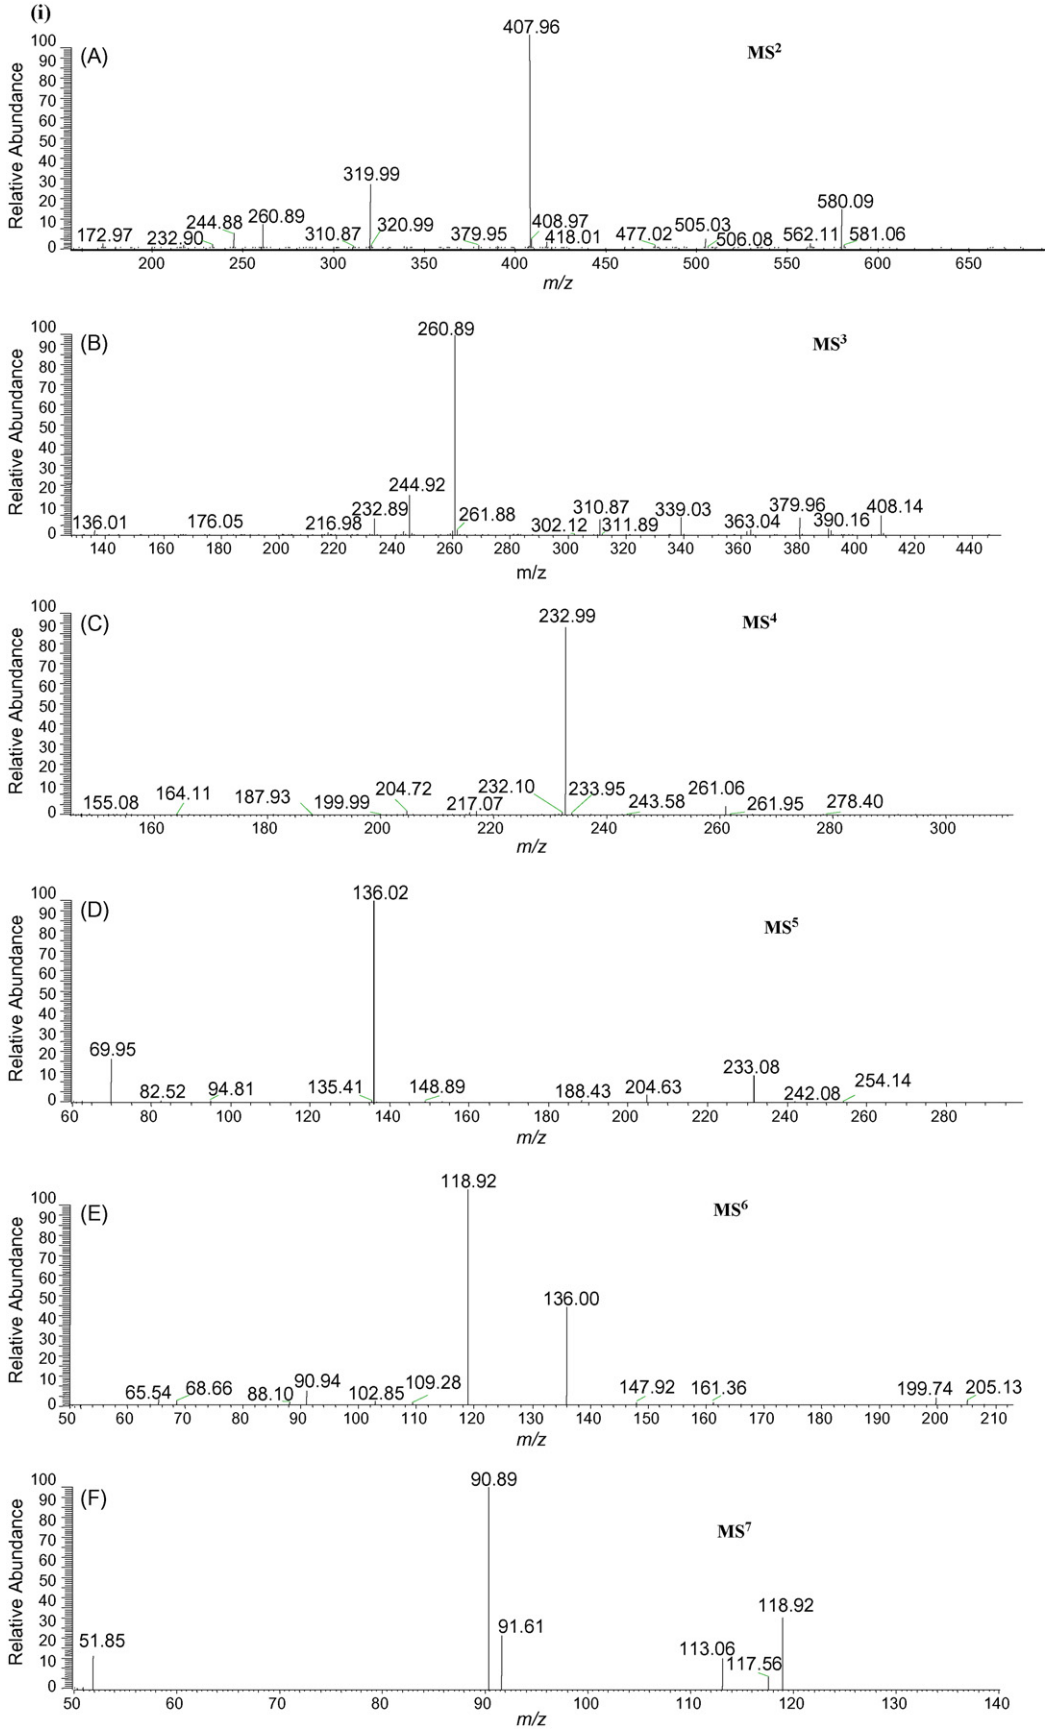

Fig. 5. Positive ion NanoMate-ESI mass spectra of (i) b-CM-5 and (ii) b-CM-11. CID product ion spectra of b-CM-5: (A) MS^2; (B) MS^3; (C) MS^4; (D) MS^5; (E) MS^6; and (F) MS^7, and of (ii) b-CM-11: (A) MS^2; (B) MS^3; (C) MS^4; (D) MS^5; (E) MS^6; (F) MS^7; and (G) MS^8. The selected ions for trapping and fragmentation, together with the optimised RCE, are shown in Table 3.

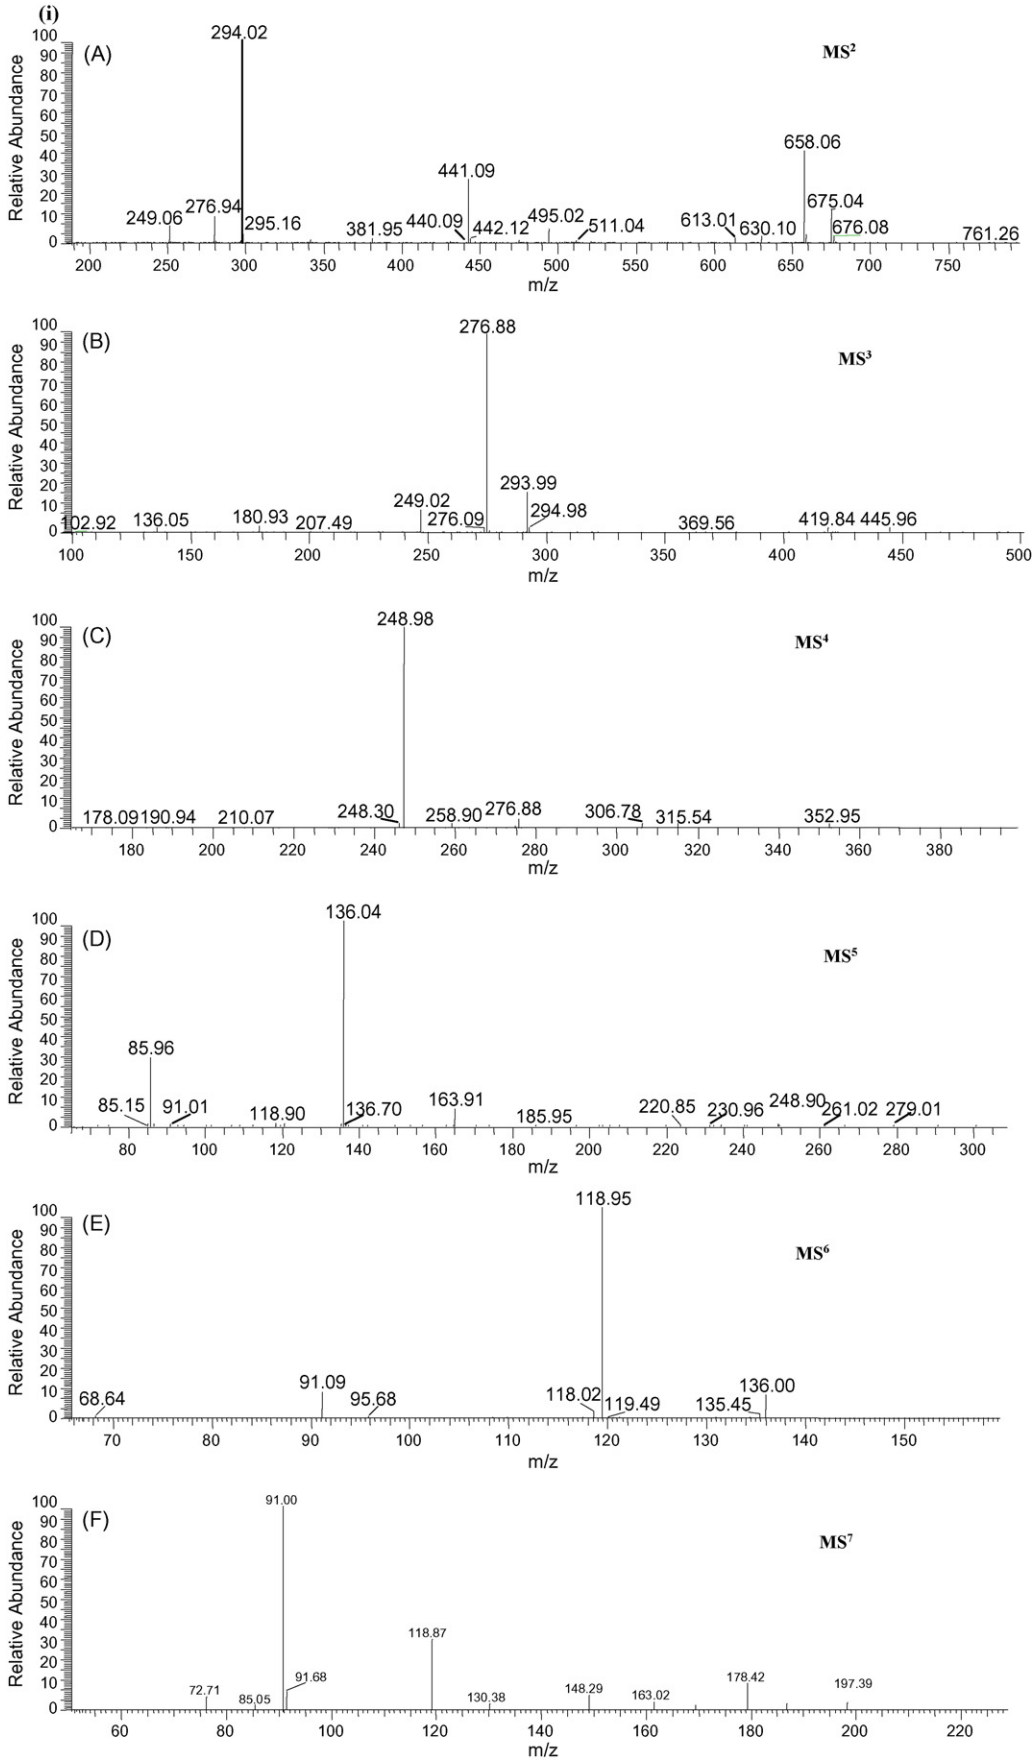

Fig. 5. (*Continued*)

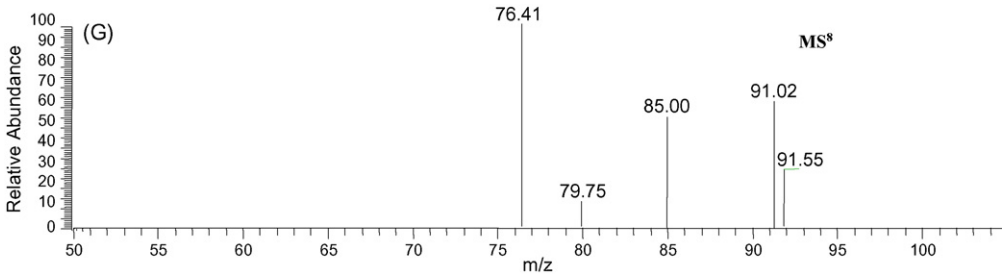

Fig. 5. (*Continued*).

All separations were conducted using 2 mL sample glass vials. The sample volume injected was 10 μL with a syringe draw rate of 0.50 μL/s.

The sheath liquid was water:trifluoroacetic acid 0.05% (A) and acetonitrile:trifluoroacetic acid 0.05 (B) with 70:30 (A:B, v/v), delivered at 200 μL/min. Electrospray ionisation/MS was conducted in the positive ion mode, and the capillary voltage was set at 4.0 kV. Dry nitrogen gas was heated to 250 °C and delivered at a flow rate of 7 L/min. The pressure of nebulizing nitrogen gas was set at 10 psi.

The parameters in the LCQ Classic ion-trap mass spectrometer system were recorded using full-scan event with a mass range *m*/*z* 50–1000 with a scan time of 0.75 s and acquisition data time of 4 min, or selected ion monitoring (SIM) ($[M+H]^+$ molecules at *m*/*z*, 580 for β-casomorphin (1-5) bovine, *m*/*z* 790 for β-casomorphin (1-7) bovine, *m*/*z* 659 for [D-Ala2, D-Pro4,Tyr5]-β-casomorphin (1-5) amide, *m*/*z* 674 for β-casomorphin (1-5) amide [D-Ala2,Hyp4,Tyr5] with a gain of 3, fragmentor voltage of 90 V, and dwell time of 63 ms. CID was performed on the ion of interest by collision with the helium background gas present in the trap for 50 ms. The fragmentation steps for each compound were optimised visualizing the changes in the intensities of fragment ions.

The HPLC and ion-trap MS instruments were connected and synchronized by signal programmed from the Software.

2.4. Chip based nanoelectrospray emitters

Nanoelectrospray infusion analysis was achieved using a NanoMate 100 (Advion BioSciences, Ithaca, NY), an automated chip based nanoelectrospray device using a disposable ESI-Chip with a fully integrated array of 10 × 10 nozzles etched from the surface of a silicon wafer. This system holds a 96-well plate, a rack of 96 disposable conductive pipette tips, and the nanoelectrospray mentioned above. During infusion analysis, the system sequentially picks up a pipette tip, aspirates 1–5 μL of sample from one position of the 96-well plate, and then delivers the sample to the inlet side of the ESI chip. In this study, 5 μL of sample solution was delivered to the back lane of the nanoESI chip. The electrospray process was initiated by applying 1.67 kV and approximately 0.6 psi nitrogen head pressure to the sample in the pipette tip to ensure constant sample flow to the chip. These settings gave an approximate sample flow rate of 150–200 nL/min for samples prepared in methanol. The nanoelectrospray chip was positioned directly in front of the aperture in the curtain plate. Samples were analysed in approximately 60 s

intervals using ChipSoft 6.4.2 software (Advion Biosciences), which controlled the automated nanoESI system.

2.5. Sample preparation

20 samples, 10 of milk and 10 of cheese, of different local markets from Cork, Ireland were collected. 12 g of sample was mixed with 12 mL of water:trifluoroacetic acid (TFA) 0.1%. 2 mL was taken and 2 mL of water:TFA 0.1% was added, homogenized and centrifuged at 4024 g for 5 min. The resulting supernatant was collected and 4 mL of methanol was added, mixed and filtered through a Buchner funnel. The extract obtained was passed through SPE C_{18}, X-Strata cartridges at a flow rate of 2 mL/min. These cartridges were previously conditioned with 5 mL of methanol and 5 mL of water. The sample was transferred to the cartridge and b-CMs were eluted using 4 mL of methanol and the solvent was removed at 40 °C, under stream of nitrogen until 1 mL. The sample was filtered prior to analysis.

3. Results and discussions

3.1. Separation of b-CMs

The direct combination of LC with MS reduces the emphasis on chromatographic separations due to the mass selectivity and distinctive fragmentation patterns. There are some previous studies showing satisfactory chromatographic separation of two b-CMs (b-CM-5 and b-CM-11), among the four studied in this work [6]. However poor peak shapes, low or variable retention and high retention time were observed for the above b-CMs analysed in the study.

Some of the b-CMs found in the literature differ only in one unity of the molecular weight, and polarity of them is similar, so it made the separation more difficult. In this study more attention was paid to the b-CMs that were usually studied and well known, as it has been mentioned in Section 1, which are b-CM-5, b-CM-7, b-CM-11 and b-CM-10 and different molecular weights they present.

Prior to the analysis with quadrupole ion-trap the four b-CMs, were injected separately in a conventional LC-UV Shimadzu to optimise its separation. This separation was studied with two different length columns 150 mm × 2.00 mm and 250 mm × 4.60 mm. Different mobile phases were tested to obtain the best separation of b-CMs as shown in Fig. 2.

The four b-CMs studied were successfully separated at a flow of 1 mL/min: starting at 5% of B, increased to 10% in 5 min and maintained for 1 min. B was increased until 20% in 1 min, maintained for 7 min and in 10 min 70% of B was reached. After that, 100% was reached with the high proportion of solvent B in 1 min. The return to the initial conditions was from 100% to 20% in 5 min, in 2 min to 10% and in 2 min more to 5%. The total time employed was 34 min, and the four b-CMs were resolved in 25 min.

3.2. MS spectrum of b-CMs

QIT multi-stage mass spectrometry (MS^n) has previously been applied for the determination of many organic contaminants in different matrices. These studies have now been extended to a wide variety of compounds and degradation products since QIT-MS

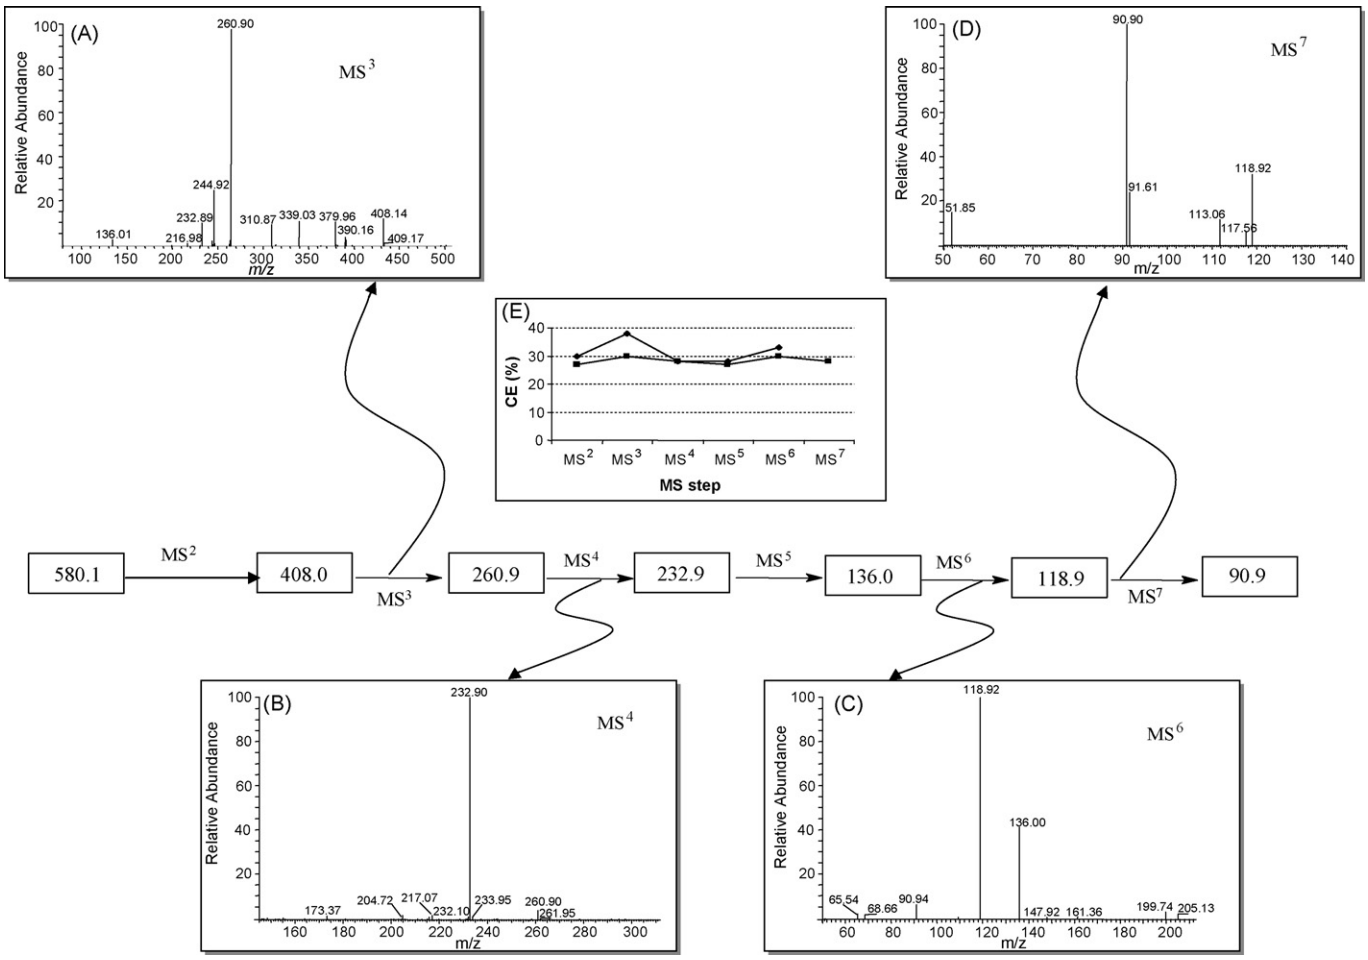

Fig. 7. Fragmentation scheme of b-CM-5: (A) MS^3; (B) MS^4; (C) MS^6; (D) MS^7; (E) collision energy (CE) diagram in LC (♦) and NanoMate (■).

permits the elucidation of fragmentation pathways. The coupled NanoMate-electrospray ionisation (ESI), a valuable source that enables detailed MS studies carried out on very small quantities, is particularly relevant to these studies since only micrograms of most of the b-CMs were extracted.

The b-CMs examined in this work are illustrated in Fig. 1. As it can be appreciated structural variants involve the union of different amino acids, see also Table 1. The ESI mass spectra of b-CMs are relatively simple and it can be observed in Fig. 3 by NanoMate. The molecular-ion species formed in positive mode in the acidic mobile phase are mainly protonated molecules, but some sodium adducts could also be observed. High background signals and potential interferences warranted additional characteristic fragmentation of the analytes. Quantification was done on the most intense ion transition.

The abundance of $[M+H]^+$ is greater than that of $[M+Na]^+$ for most of the b-CMs. In general, the maximum abundances of both $[M+H]^+$ and $[M+Na]^+$ ions were observed when the CID voltage was set around 30 V. The ESI-MS spectra of b-CMs are shown in Fig. 3. At a lower voltage, low ion intensity was measured. When the voltage was higher than 35 V, less $[M+H]^+$ and $[M+Na]^+$ ions, and more fragmented ions were detected. That is the reason to set at 30 V the fragmentor voltage.

3.3. Multiple tandem MS experiments

In the ThermoFinningan LCQ, relative collision energy (RCE) is the energy that is applied to trapped ions in the mass analyser. The RCE value varies in the range 0–100% and corresponds to 0–5 V peak-to-peak of resonance excitation RF voltage. Different scan events were prescribed to run simultaneously in the instrument. The first scan event was full-scan MS to acquire data on ions in the range m/z 50–1500. The optimum RCE value was studied ramping with an initial point of 10% to reveal the major fragmentation pathways and to ascertain the energy required to generate the optimum population of target ions for subsequent MS stages. The predominant product ions, acquired at the optimised RCE value, were selected for MS^3 experiments where the RCE was again ramped to establish the next generation of product ions. The ions selected in the ramped RCE studies are shown in Table 2. The difference between the two MS^2 experiments carried out for each b-CM was the initial ion, because the $[M+H]^+$ ions and sodium adduct $[M+Na]^+$ in all b-CMs, and $[M+2Na-H]^+$ adduct in b-CM-5 and b-CM-7, and potassium adduct in b-CM-10 were studied.

All these experiments were also carried out by using the nano-electrospray NanoMate 100 and as it would be observed further different RCE values were necessary for each MS step and the step number reached it could be observed in the figures presented.

3.4. MS fragmentation studies of b-CMs

The fragmentation of b-CM was examined using TFA as a buffer for positive ion mode operation. In this study, multiple tandem MS (MS^n) was used for the repeated trapping and fragmenting ions. An advantage of the ion-trap MS instruments is the ability to switch between a full-scan MS and MS^n scan of fragments without a signif-

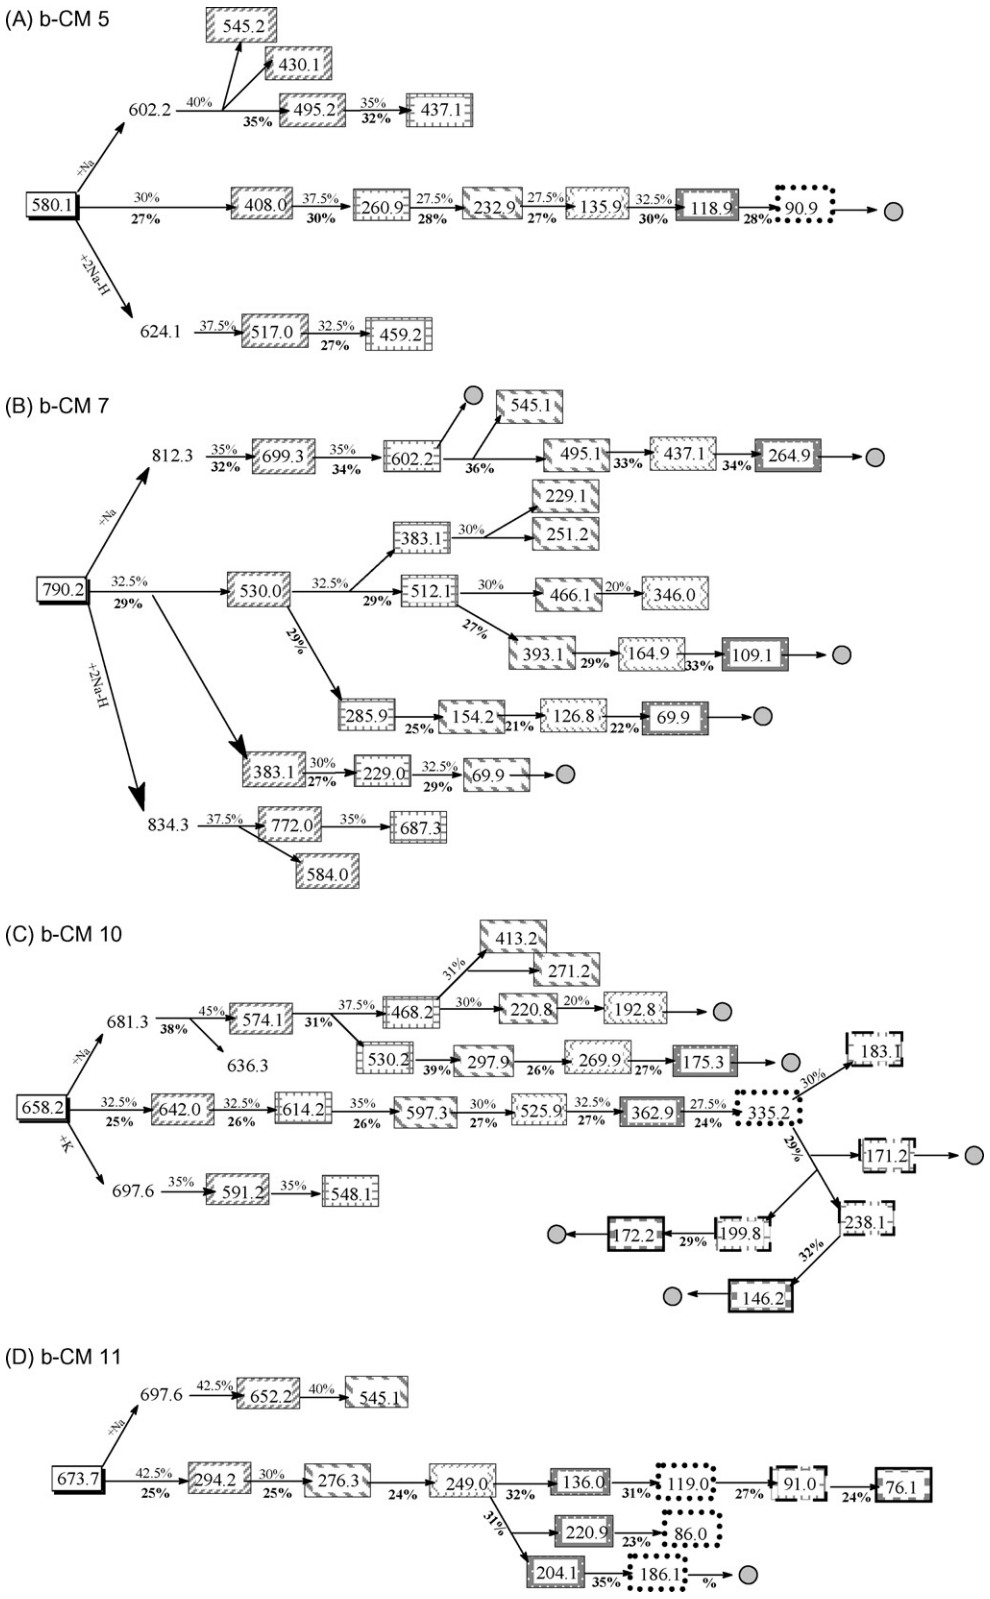

Fig. 8. Scheme of the proposed pathway for the b-CMs studied. Each colour box belongs to one MS step; MS^2 ( ), MS^3 ( ), MS^4 ( ), MS^5 ( ), MS^6 ( ), MS^7 ( ), MS^8 ( ) and MS^9 ( ). It is also indicated the RCE for LC and for NanoMate (in black).

icant loss in sensitivity [19]. Once the precursor ion was selected, explained above and shown in Table 2, the effect of varying the energy of the helium collision processes was determined by plotting the relative abundances of the product ions versus % RCE (Fig. 4) for each b-CM. Fig. 4 shows the product ions plotted for b-CM-5. These data were used to select candidate ions for subsequent MS^n experiments.

For b-CM-5 (Fig. 4), MS^2 gave major fragment ion at m/z 408 $[M-C_7H_{11}N_2O_3+H]^+$ and MS^3 yielded product ions from the m/z 408 fragment ion of b-CM-5 at m/z 261 $[M-C_{16}H_{20}N_3O_4+H]^+$, m/z

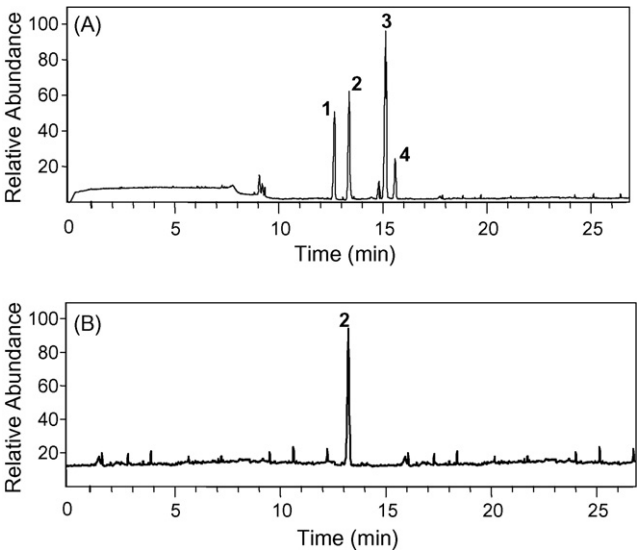

Fig. 10. (A) NanoMate/MS chromatographic separation of standard b-CM-5 (1), b-CM-7 (2), b-CM-11 (3) and b-CM-10 (4) following C_{18} solid phase extraction. (B) NanoMate/MS chromatograms of b-CM-7 identified in a milk sample from local supermarket. Chromatographic conditions: Luna-2 C_{18} (5 μm, 150 mm × 2.00 mm) at 35 °C; mobile phase water:acetonitrile (70:30) containing 0.05% TFA; flow rate 200 μL/min.

233, 244, 176, 136 and 119 (see also Table 3 and Fig. 5). MS^4 experiments, targeting *m/z* 261, gave the product ion *m/z* 233 $[M-C_{17}H_{20}N_3O_5+H]^+$, MS^5 experiments, targeting *m/z* 233, gave the product ion *m/z* 136 $[M-C_{22}H_{27}N_4O_6+H]^+$, MS^6 experiments, targeting *m/z* 136, gave the product ion *m/z* 119 $[M-C_{22}H_{28}N_4O_7+H]^+$ and finally when for MS^7 experiments, targeting *m/z* 119, a majority single ion *m/z* 91 $[C_7H_7]^+$ as can be observed from the spectra shown in Fig. 5(i). A similar fragmentation process was carried out for the other three b-CMs studied.

b-CM-11's mass spectra are also shown in Fig. 5(ii). The ions at *m/z* 136, *m/z* 119 and *m/z* 91 were observed in MS^5, MS^6 and MS^7 spectra for both b-CMs shown in Fig. 6. The fragmentation pathway obtained for b-CM-5 and proposed structures for the major fragment ions observed in the mass spectra are shown in Fig. 6.

3.5. Comparison between LC infusion and NanoMate in QIT fragmentation

The ions formed from the b-CM studied by the initial collision process are shown in Table 2 where it can be seen that both NanoMate and LC gave practically identical initial majority ions for all the b-CMs studied.

The most abundant ion obtained in the spectra of all b-CMs, when NanoMate system was used, was the protonated molecule $[M+H]^+$. However, this phenomenon only happens for b-CM-5 and -7, when LC system was used.

Sodium adducts are important, and needs to be taken into account because relative abundance ranged between 85–20% and 100–25% for NanoMate and LC systems respectively was obtained. The sodium adduct $[M+Na]^+$ was the majoritary ion for b-CM-10 and -11 not been in that way for NanoMate, where no b-CM presented the sodium adduct as majoritary ion. Otherwise some other adducts as potassium $[M+K]^+$ or two molecules of sodium added to the molecule, $[M+2Na-H]^+$ were also observed and they were taken into account for b-CM-5 and -7 analyses.

The potassium adduct was observed although in a low relative abundance, only at 10%, in b-CM-10 when LC system and NanoMate system were used and in consequence a fragmentation study with increasing collision energies was carried out, however this adduct ion did not appear for any of the other b-CMs studied, b-CM-5, -7 and -11 when NanoMate or LC system was used. The $[M+2Na-H]^+$ adduct was formed and observed in relevance only for b-CM-5 and -7 ranged from 70% to 15% of relative abundance as it was mentioned above, when LC system was used, but no $[M+2Na-H]^+$ was observed for any of the b-CM when NanoMate system was used.

Table 3 shows the MS steps achieved for each b-CM and the relative collision energy necessary to obtain the next MS step is shown in brackets. To be focused in b-CM-5 identical fragment ions are presented in all stages with LC and NanoMate system respectively, however with this last system (NanoMate) was possible to achieve one stage higher than with LC, arriving until MS^7. In Fig. 7 a fragmentation scheme of b-CM-5, the collision energy diagram (see also Fig. 8) and the MS spectra obtained are shown. However for b-CM-11, the information of the fragmentation pathway was more different when both system NanoMate and LC were compared. Likewise, only MS^3 was achieved in LC system and MS^8 when NanoMate system was used. In Figs. 9 and 8 the fragmentation scheme is shown.

In b-CM-7 the obtained ions were different between NanoMate and LC systems once MS^3 for the studied ion *m/z* 512 was obtained. For b-CM-10 the fragmentation pathway proposed allows to achieve MS^9 with NanoMate system; however, once MS^7 is achieved with LC system for this b-CM the predominant product ion was different from the same step in NanoMate. For b-CM-7 and -10 the scheme is represented in Fig. 8.

Figs. 7 and 9D also indicate and represent the relative collision energy necessary to reach each MS step. As it could be observed, in general, collision energies are higher by using LC than using NanoMate. This is the first reported study where a comparison between LC and NanoMate collision energies is carried out, the first in which high MS steps could be reached and a comparison between LC and NanoMate MS steps is done and the first reported study of the most common b-CMs to employ QIT and the CID spectra for the four compounds is shown in Fig. 3.

3.6. NanoMate/MS^n

Good linear correlations were obtained for the b-CMs in each MS mode. The selected ions (Table 2) were generated by trapping and fragmenting the product ions from the MS stage, *m/z* 580 (b-CM-5), *m/z* 790 (b-CM-7), *m/z* 659 (b-CM-10) and *m/z* 675 (b-CM-11).

The calibration data for standard b-CM, spiked into milk or cheese (10 g or 10 mL), were: NanoMate/MS (25–1000 μg/L), $r^2 = 0.998$; NanoMate/MS^2 (5–1000 μg/L), $r^2 = 0.9992$; NanoMate/MS^3 (2.5–1000 μg/L), $r^2 = 0.9998$. Good reproducibility data were obtained for b-CM using the NanoMate/MS^3 and the NanoMate/MS^4 modes, with the latter being slightly better. The relative standard deviation (% RSD) values for NanoMate/MS^5 were ≤2.0 at 500 μg/L and ≤7.0 at 10 μg/L ($N = 5$). Although valuable structural data were acquired at the MS^8 or even at MS^9 stages, using the product ions above mentioned for each b-CM for fragmentation, reproducible data were not obtained with spiked cheese and milk samples.

3.7. Analysis of the b-CMs in cheese and milk

To demonstrate the utility of this NanoMate/MS^n analytical protocol for the determination of the b-CMs, in milk and cheese samples, 20 samples were examined using each NanoMate/MS^n method. Fig. 10 shows the NanoMate/MS^3 chromatograms obtained for a milk sample from a local supermarket in Cork, Ireland. b-CM-7 was identified in this milk sample, at 14 μg/L. MS^1 to MS^4 spectra were obtained simultaneously and compared with those obtained from the isolated standard of b-CM-7 to confirm the presence of this bioactive peptide.

4. Concluding remarks

Under the hypothesized that b-CMs are the cause of sudden infant death syndrome, and that bonded to the opioid receptors could exhibits morphine-like effects and many other consequences, most of them unknown, it is necessary to develop sensitive techniques that unequivocal confirm of the presence of b-CMs in milk and cheese samples. The use of the NanoMate nanoelectrospray device enabled fast and easy analysis of b-CMs from milk and cheese sample. The infusion conditions can be adjusted very easily to the analyte in order to obtain optimal fragments for the MS experiments

QIT-ESI-MS has permitted to elucidate the main fragmentation pathways for b-CMs and structures for the major fragment ions that were observed in the mass spectra, as shown for b-CM-5 and b-CM-11.

Specificity

ABSTRACT

Quantum dots (QDs) are widely used in the immune detection. Yet, the sensitivity and specificity of the immune detection are not satisfactory because the binding sites of QDs onto antibody (Ab) are often arbitrary and the influence of the large surface electronic potential energy of QDs on the directly conjugated Ab is nonnegligible. In this work, we provide a "flexible" coupling method, in which protein G (PG) is selected as the flexible bridge between the QDs and the Hepatitis B virus surface antibody (HBsAb), to improve the sensitivity and specificity of the fluoroimmunoassay compared to the directly covalent conjugation. Successful coupling of the HBsAb to our highly luminescent CdTe/CdS core/shell QDs is proven with Gel electrophoresis and atomic force microscopy (AFM). The assay results, based on the microelisa well plate as matrix to immobilize the sandwich structure, show that both sensitivity and specificity can be improved greatly through the flexible coupled QDs–PG–Ab conjugates.

© 2009 Published by Elsevier B.V.

1. Introduction

Quantum dots (QDs) hold immense promise for optoelectronical and biological/biomedical applications due to their unique optical properties, such as size-tunable photoluminescence (PL), high PL quantum yields (QY), narrow emission line width, broad absorption profile, superior photostability, and flexible solution-processing [1–3]. Compared to organic fluorophores, the QDs also have high resistance to chemical degradation and photodegradation [4]. The number of publications on applications of QDs in bio-labeling and bio-detection has increased enormously during the recent years [3,5–12]. Attempt of in vivo applications, e.g., cell-imaging with the glutathione capped CdTe QDs has been reported [7]. In the mean time, focus has been given on in vitro applications based on the toxicity concern of the QDs. Mattoussi's group reported the detection of pathogens by using the conjugates of dihydrolipoic acid capped CdSe/ZnS QDs and the recombinant maltose binding protein [8,9]. Peng et al. improved the sensitivity of pathogens detection to be as low as 5 ng/ml via CdSe/ZnS dendron QDs and a porous membrane immunofilter [10]. In spite of these efforts, the large surface electronic potential energy and the resulting influence of the QDs on the antibody (Ab) are still large, which will ultimately reduce the immunoreactivity and increase the nonspecific binding of the labeled antibody. This disadvantage will be reduced by applying "flexible" coupling where a proper soft bridge is built up providing a single coupled site to the Ab and the single site linkage can minimize the orientation alteration of the Ab, thus maintaining its native immunoreactivity.

The biotin–avidin system (BAS) has been widely applied in the bio-conjugation of QDs and proteins as a "bridge" [4,8]. However, this requires the antibody (or antigen) to be conjugated to biotin molecules, the non-epitaxial conjugation will finally sacrifice the sensitivity and specificity of the bio-detection. It is well known that the Fab fragments of the antibody contain the antigen binding regions. And protein G (PG) is an immunoglobulin-binding protein expressed in group C and G streptococcal bacteria. It is a cell surface protein that has found application in purifying or coupling antibodies because the $\beta 2$ domain of PG can bind strongly with the Fc fragment of the antibody [9]. The fluorescent labels can thus be connected to the antibodies through protein G – a "flexible bridge" – without occupying the Fab domain and influencing the bio-specificity of the Ab. Early in 2002, Mattoussi et al. reported the detection of explosive 2,4,6-trinitrotoluene with conjugates of

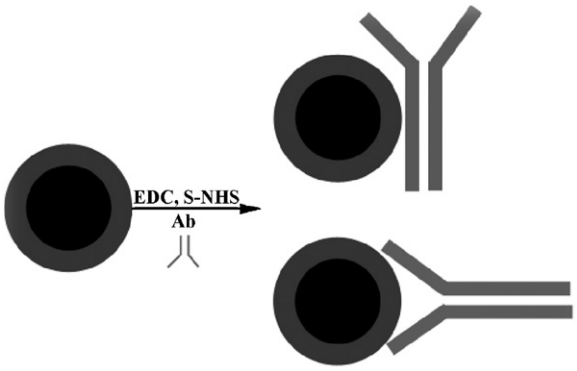
QDs and a specific antibody using PG as a bridge [13], however, they did not give a systematical discussion and manifestation on the high-specificity of the fluoroimmunoassay. In this work, flexible conjugation is realized by covalently coupling carboxylic highly luminescent aqueous CdTe/CdS core/shell QDs with PG to form a QDs–PG complex which is then bounded to the antibodies. The effect on the specificity and sensitivity of detection based on the sandwich structure is studied with choosing microelisa well plate as the matrix for antibody immobilization. As far as virus is concerned we have chosen Hepatitis B virus (HBV)—known to be one of the leading causes of death worldwide [14]. In our experiments, Hepatitis B surface antigen (HBsAg) are detected with much lower detect limitation and non-specificity when the flexible coupling is realized of the HBsAb with highly luminescent CdTe/CdS QDs.

2. Experimental

2.1. Materials



1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC) (99%), sulfo-N-hydroxysulfosuccunimide (sulfo-NHS) (98.5%), aminopropyltriethoxysilane (APTES) (98%) and glutaraldehyde (Glu) were purchased from Aldrich. Protein G, HBsAb, HBsAg, Bovine serum albumin (BSA) and the microelisa well plate were all subscribed from Beijing DingGuo Biotechnology co. Ltd. All the reagents were used without further purification. Deionized water was purified through Milli-Q water purification system and the resistivity was 18.2 MΩ cm.

2.2. Apparatus

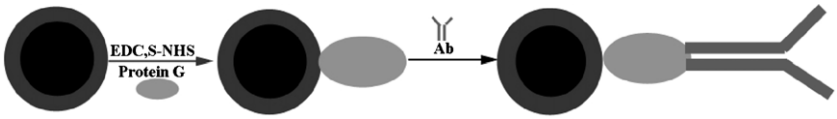
Ultraviolet–visible (UV–vis) absorption and fluorescence spectra were measured at room temperature (RT) by a UV-3101 spectrophotometer and a Hitachi F-4500 fluorescence spectrofluorimeter, respectively. Unless claimed otherwise, the excitation wavelength was set to 350 nm and the excitation and emission splits are 5 nm. The QY of nanocrystal solutions was determined using Rhodamine 6G in ethanol as a standard. The sizes and concentration of CdTe QDs were calculated based on the wavelength of the first excitonic absorption peak [15]. The photo-irradiation experiments were performed under ambient condition and irradiation from a 365 nm ultraviolet lamp at certain time intervals. The samples were prepared by the 1:200 dilution of a stock solution.

2.3. Synthesis of highly luminescent CdTe/CdS core/shell QDs

CdTe/CdS core/shell QDs were prepared according to our previous publication [16]. The CdTe QDs were capped with 2 monolayers (ML) of CdS shell with a 530 nm emission and QY of 40%. The average size of the aqueous core–shell QDs was calculated to be only about 3 nm, which successfully discards the drawback of the large size (12–20 nm) water-soluble QDs after the multilayer coating, e.g., phospholipids [17], silica [2,18], or polymer [19,20], etc. This is because that the small dimension would dramatically improve the biological labeling and detection efficiency.

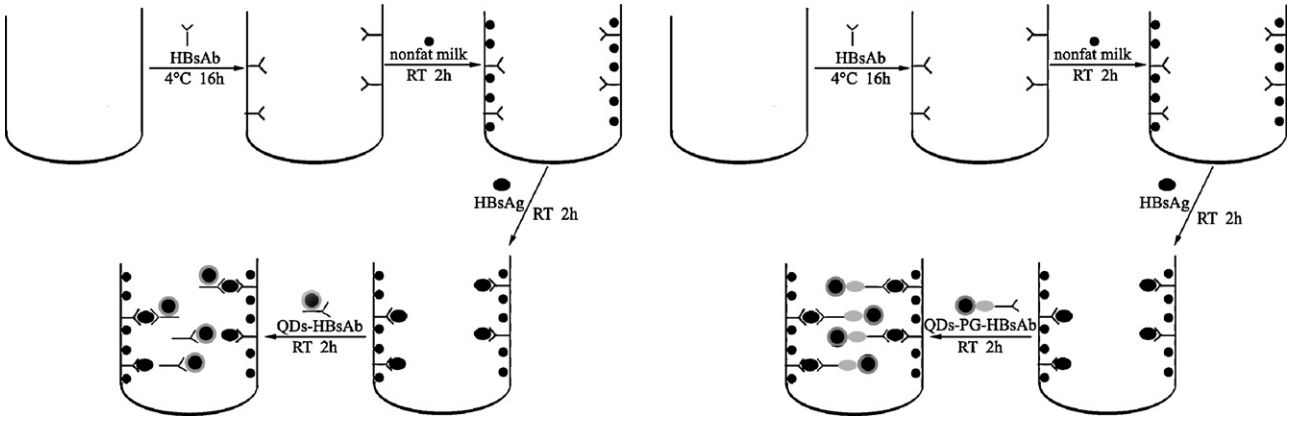
Scheme 1. Covalent conjugation of CdTe/CdS QDs and HBsAb.

2.4. Conjugation of antibody onto CdTe/CdS QDs



The HBsAb was conjugated to the CdTe/CdS QDs classically by using EDC and sulfo-NHS (S-NHS) as crossing-linking reagent [10]. The schematic route of the conjugation is shown in Scheme 1. Firstly, 0.1 ml of QDs (60 μM) was mixed with 10 μl of EDC and sulfo-NHS in phosphate buffer saline (PBS, pH 7.4) with the molar ratio of 1:100:200. After 30 min of magnetic stirring, 3 nmol HBsAb was added into the reacted bottle and stirred at room temperature for another 2 h. In this way, the amide linkage can be formed through the amino of the Ab and the active carboxyl of QDs. In order to remove the excess small molecules, e.g., EDC and sulfo-NHS, the resulting samples were centrifuged in Microcon Centrifugal Filter Devices (50,000 Nominal Molecule Weight Limit). Afterwards, the product was purified by sephadex-150 filtration column chromatography. The conjugation of Ab and QDs was confirmed by the agarose gel (0.8%) electrophoresis technique.

2.5. Flexible conjugation of antibodies onto CdTe/CdS QDs



The HBsAb was conjugated with QDs flexibly by using protein G as a bridge. Firstly, the PG was covalently linked with QDs by an EDC-mediated coupling reaction as described above. Then the complex was purified by centrifugation in Microcon Centrifugal Filter Devices (50,000 Nominal Molecule Weight Limit). Afterwards, the HBsAb was added into the QDs–PG PBS solutions with equal molar ratio under stirring for 2 h. Because the $\beta 2$ domain of protein G can bind with the Fc domain of the Ab specially, the Ab can be oriented as shown in Scheme 2. The product was then purified by sephadex-150 filtration column chromatography to separate the by-products and the excessive QDs. The conjugation of Ab and QDs was also confirmed by the agarose gel (0.8%) electrophoresis technique.

2.6. Fluorescent immune detection

As depicted in Scheme 3, firstly, 200 μl designed amount of monoclonal HBsAb was planted into the transparent microelisa well plate and incubated at 4 °C for about 16 h. Then, the solution was discarded away and 200 μl 5% (w/v) nonfat powdered milk in PBS was added into the well to block the plates. After 2 h of blocking time at RT, the nonfat dried milk solutions were also discarded and the wells were rinsed with PBS for 3 times. Afterwards, 200 μl series of

Scheme 2. Flexible coupling of CdTe/CdS QDs and HBsAb by using PG as a bridge.

Scheme 3. Immune microelisa well plate detection route of HBsAg based on the normal (left) and flexible (right) coupling of HBsAb and QDs.

dilutions of HBsAg solutions were dropped into the well for about two hours' specific adsorption reaction and then the solutions were removed again and rinsed with PBS for 3 times. Control well was always included in which no HBsAg was added to capture the Ab adsorbed on the walls of the wells. At last, the designed concentration of QDs labeled HBsAb was added into the well and reacted specifically with HBsAg for 2 h. The solutions were taken out for additional PL measurement to obtain the detection curves.

2.7. AFM measurement

The atomic force microscopy (AFM) (Veeco Instrument, DI-3100) was measured via immobilizing the QDs labeled Ab covalently onto the silicon slice to evaluate the flexible coupling. Tapping mode silicon probe with spring constants of ~180 N/m and resonance frequencies of ~1 kHz was used. Prior to silanization, the silicon slice surface was pre-cleaned by treatment in $HCl:CH_3OH = 1:1$ solution, followed by strong vitriol for 30 min and being boiled for 10 min, then extensive rinsing with deionized water, and were stored in 25% ethanol. Chemically cleaned silicon slice surface was reacted with an acetone solution of APTES for 90 min at RT, followed by rinsing several times with acetone, and dried with nitrogen flowing and baked for 2 h at 120 °C in a vacuum oven. Finally, the APTES-treated silicon slice was immersed in the 10% solution of glutaraldehyde in PBS (pH 7.4) for 2 h, followed by rinsing with PBS (pH 7.4). QDs labeled Ab was immobilized on the APTES-Glu surface by incubation at 4 °C with an aqueous solution overnight. The QDs labeled Ab was covalently immobilized on this surface by an imine linkage between the aldehyde group on surface and primary amine of the Ab. The images were obtained in air after drying the samples in a gentle stream of nitrogen.

3. Results and discussion

The absorption and emission spectra of bare CdTe and CdTe/CdS core/shell QDs are shown in Fig. 1a, the calculated QY of the CdTe QDs increases from 15 to 40% after growing 2 monolayers CdS shell. The photo-irradiation experiments of the diluted samples (0.3 μM) were performed under ambient condition and irradiation from a 365-nm ultraviolet lamp at certain time intervals. It is reported that the PL peak will shift to blue side with time under ultraviolet light irradiation due to photo-oxidation reaction of the diluted samples [21]. In our experiments, a blue-shift of 39.6 nm of the PL spectrum of the CdTe bare core is observed after four hours' photo-irradiation, however, the blue-shift of the CdTe/CdS core/shell QDs is only 2.8 nm under the same conditions (cf Fig. 1b). In fact, these aqueous core/shell QDs are found to be stable and the optical properties of them in a sealed vial remain invariable over one year's storage under ambient condition. Therefore the core/shell QDs are capable to act as the fluorescent marker in the immunoassay.

In order to purify the QDs–Ab complexes and investigate the combination of proteins and CdTe/CdS QDs, the sephadex G-150

gel filtration column chromatography is employed. After collection of first peaks, QDs–Ab and QDs–PG–Ab are collected and condensed for the next electrophoresis and detection experiment. In general, electrophoretic analysis can be used to confirm the conjugation of biomolecules to QDs [22,23]. The agarose gel electrophoresis (AGE) technique is applied here to further identify the bio-conjugation of QDs and proteins. Because the COOH-QDs carry a high negative charge density, they migrate quickly through the gel matrix under an electric field. The mobility of the proteins in electrophoresis is determined by the mass/charge ratio of proteins. As shown in Fig. 2, the green luminescence bands of QDs and QDs labeled proteins are observed under the excitation of a 365-nm ultraviolet lamp. Because the sizes (equal to the mass/charge ratio) of QDs–Ab, QDs–PG and QDs–PG–Ab bio-conjugates are larger than the QDs, they all migrate more slowly than pure QDs and separate well in 0.8% agarose gels, which strongly suggests the presence of the corresponding conjugates. Considering that PG is a kind of small molecular protein than HBsAb, the electrophoretic mobility of QDs–PG is slightly slower than that of QDs (Fig. 2B) and faster than that of QDs–Ab (Fig. 2A). The fluorescent band of QDs–PG–Ab migrates most slowly (Fig. 2C), which is due to the fact that the highest molecular-weight QDs–PG–Ab complexes have formed.

AFM is a powerful technique for studying biomolecule interactions and it provides topographic images with high resolution [24]. The AFM imaging has previously been used to characterize the size of QDs [25]. In this work, AFM imaging is used to demonstrate the success in flexible conjugation of the QDs to Ab based on the fact that the height of the flexible coupling should be higher compared to that of the normal covalent coupling. In order to keep the proteins stable on the silicon surface, covalent immobilization is a preferred method. APTES surfaces are used to immobilize the proteins covalently, because the amido groups on their surfaces can react with glutaraldehyde, yielding aldehyde groups that could form an imine linkage with the primary amine groups on the surface of the proteins. The size of a protein measured from AFM is directly correlated to its molecule weight [26]. Hence, AFM can be used to study the binding behavior of Ab to QDs. Fig. 3 is the AFM image of QDs–Ab and QDs–PG–Ab bio-conjugates. Because the binding sites of QDs onto Ab are arbitrary, the conformational dimension of QDs–Ab complex must be tanglesome. On the contrary, the conformational dimension of QDs–PG–Ab complex should be uniform. In our image, the QDs–Ab exhibits a heterogeneous and dissymmetrical shape with the AFM height of approximately 6–8 nm, and reversely, the QDs–PG–Ab exhibits a homogeneous and symmetrical shape with the AFM height of approximately 10–12 nm. Considering that the sizes of QDs, Ab and PG are 3, 7 and 3 nm, respectively, the result from AFM match closely with the heights of QDs–Ab and QDs–PG–Ab with only a few nanometers less, and this shortening can be ascribed to the fact that Ab protein molecules on QDs surface can be compressed by the imaging process due to forces applied to the samples [27,28]. In line with this idea, the average AFM heights of QDs–Ab and QDs–PG–Ab are a little smaller than the estimated ones. In any case, the height of QDs–PG–Ab is obviously higher than that of QDs–Ab, which can be used to efficiently testify the flexible coupling between QDs and Ab via PG bridges.

The fluorescent immune detection is based on the sandwich method with bright and robust CdTe/CdS QDs as the indicator. In order to enhance the efficiency of the immunoreaction between Ab and Ag, shorten the detection time, and reduce the detection limit, the flexible coupling based immunoassay is employed with microelisa well plate as the matrix. The microelisa well plate can provide a large surface area for protein immobilization and proper-sized pores in the plate to force the immunoreaction between Ab and Ag in a limited space that is small but sufficiently large for the volume of the sample solution. In order to immobilize the Ab sufficiently, the adsorption time of the Ab on the pores should be enough (not less than 12 h). The detecting signal of the HBsAg is based on measuring the subtraction between the PL intensity of the control value of the QDs–Ab without any Ag injection and the value of the excessive unreacted QDs–Ab on the sandwich immunoplexes of the wells. The schematic bio-detection of HBsAg by using the microelisa well plate is given in Scheme 3, whereas Fig. 4 illustrate the PL spectra of the normal coupling (QDs–Ab) and flexible coupling (QDs–PG–Ab) with different concentrations of the HBsAg. Fig. 4C and D show the experimental results where

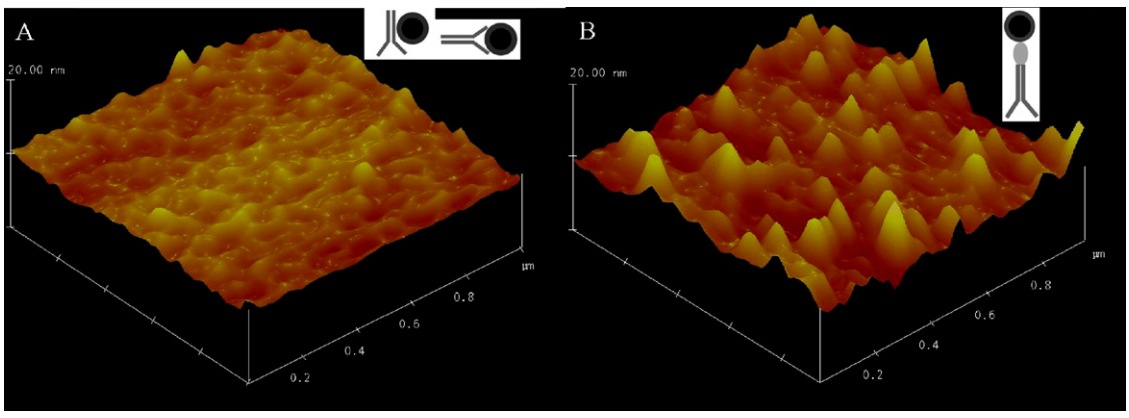

Fig. 3. AFM images of the complexes of QDs–HBsAb (A) and QDs–PG–HBsAb (B).

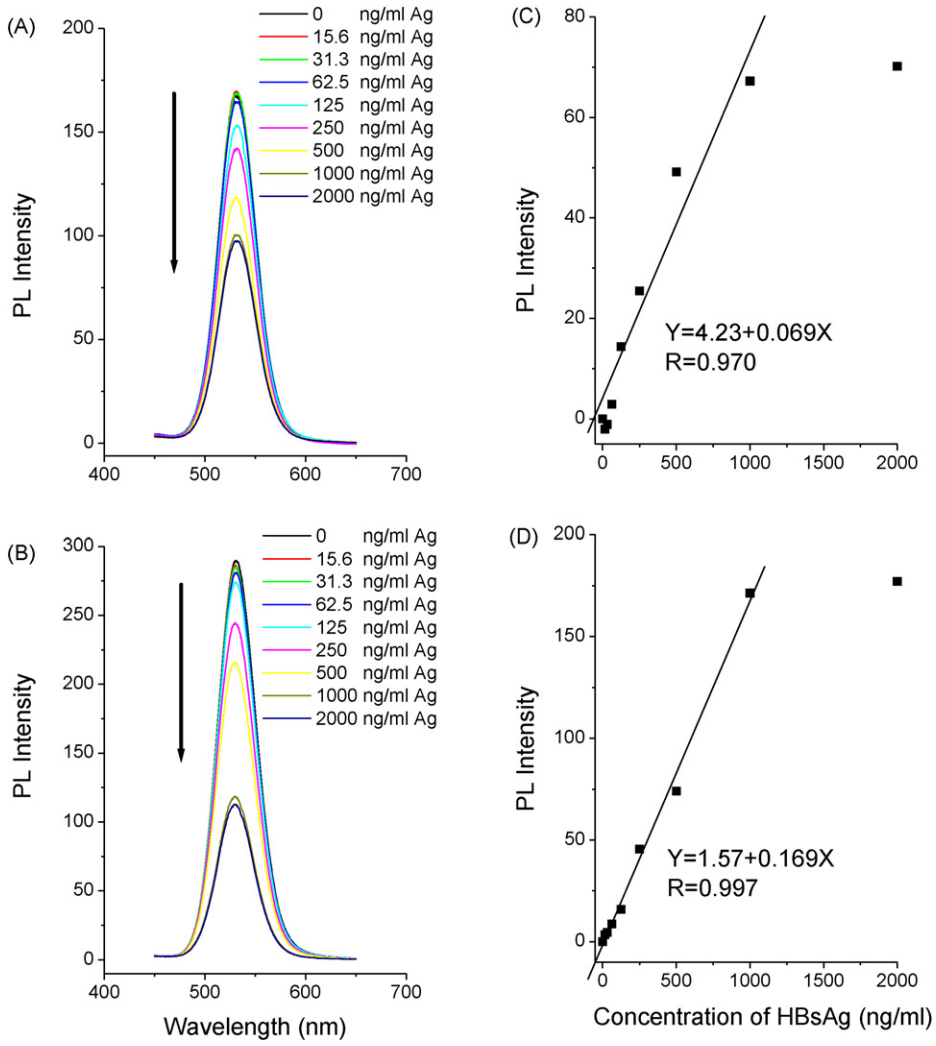

Fig. 4. PL spectra (A and B) and the detection curves (C and D) of the PL intensity vs the concentration of HBsAg. A and C show the results based on the normal coupling product of QDs–Ab, B and D show the results based on the flexible coupling product of QDs–PG–Ab. C and D are the PL intensity difference between control (without antigen) and the sample (with antigen). The fitted linear equations are also shown.

the PL intensity from bound HBsAb conjugate is measured over a range of HBsAg concentration till 2000 ng/ml. It should be noted that the signal increases monotonically with the increase of the concentration of HBsAg until saturation is reached at ~1000 ng/ml. The detection limit can be defined as the lowest concentration of detected sample that give positive value of the PL intensity difference between control (without antigen) and detected sample (with antigen) [4,13]. It can be clearly seen from Fig. 4 that the subtracted PL intensity is still discernable to be positive even when the concentration of HBsAg is as low as 62.5 ng/ml for normal conjugation and 15.6 ng/ml for flexible conjugation, which indicates that the sensitivity of detection is improved due to flexible coupling. The lower detection limit and broad working range in the flexible situation result from high capturing efficiency of QDs with the microelisa well plate. The higher capturing efficiency is due to the flexible coupling of QDs and Ab (as shown in Scheme 2) which enables sufficiently mutual affinity between QDs labeled HBsAb and the HBsAg immobilized onto the pores of the well plates. On the contrary, the normal coupling are commonly accompanied with certain non-efficient conjugation by occupying the specific site or influencing the bioactivity of the Ab (as shown in Scheme 1), which will reduce the ability of the recognition between the QDs labeled Ab and the detected Ag consequently and result in a lower detection sensitivity.

The specificity of an immunoassay system mainly depends on the immunoreactivity of the labeled monoclonal Ab. However, due to the larger surface electronic potential energy of the nanocrystals, the property of the Ab can be easily manipulated by the nature of the fluorescence labels. PG acts as a “flexible bridge” for connecting the QDs with Ab to avoid the non-specific and null combination, and thus to increase the specificity of the immunoassay. As is shown in Fig. 4C, detect signal shows negative value at certain low cencentrations, which is not observed in Fig. 4D. The negative value is mainly a consequence of the non-specific adsorption between QDs–Ab and the blocking molecules immobilized on the wall of the well. To further validate the specificity enhancement based on the flexible coupling, a control experiment was designed by using a 1% BSA PBS solution as the detected sample. The results are given in Fig. 5, in which the PL intensity is normalized to the value of HBsAg detection. When the QDs–Ab is used to monitor the nonspecific binding of the BSA molecules, a low PL intensity can be obtained, which indicates that there is 31.5% non-specific adsorption of BSA molecules during the detection process. Comparably, when the QDs–PG–Ab is used to monitor the nonspecific binding of the BSA molecules, only a small PL signal is observed under the same detection condition, which indicates that only 2.4% non-specificity with BSA exists. Clearly the immunoassay using the QDs–PG–HBsAb conjugate is much

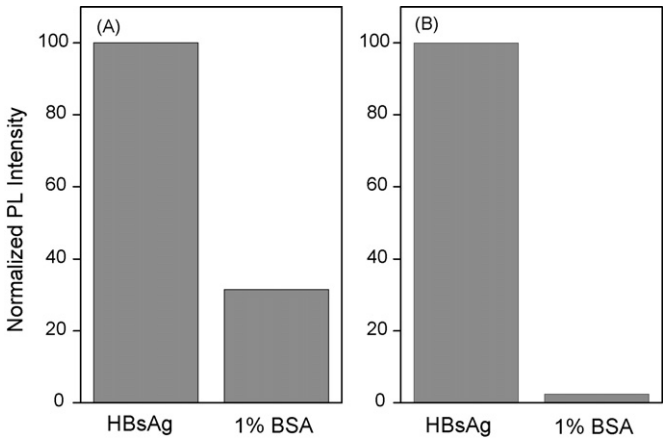

Fig. 5. The normalized PL intensity on the non-specific adsorption experiments of 1% BSA solution using the normal coupled QDs–Ab product (A) and the flexible coupled QDs–PG–Ab product (B).

more specific for HBsAg than that using the QDs–HBsAb conjugate.

4. Conclusions

Highly luminescent aqueous CdTe/CdS core/shell QDs are covalently conjugated with HBsAb and PG by using EDC and S-NHS as cross-linking reagents. The flexible coupling using protein G as a bridge between the QDs and HBsAb is characterized by the gel electrophoresis technique and AFM measurement. The fluoroimmunoassay based on the microlisa strip plates via the conjugates of QDs and HBsAb is applied to detect the HBsAg. The detect limitation can reach about 15.6 ng/ml and 62.5 ng/ml by using the complexes of QDs–PG–Ab and QDs–Ab, respectively. In addition, the immune detection using QDs–PG–Ab conjugate shows higher specificity, accompanied with the higher sensitivity. Therefore, the flexible coupling by using PG as a bridge is feasible and the fluorescent immune detection via microelisa well plate based on the coupling of the highly luminescent aqueous CdTe/CdS QDs and biomolecules is also acceptable and can be applied into the future biological diagnosis.

ABSTRACT

Matrix-assisted laser desorption ionization mass spectrometry (MALDI-MS) is powerful in characterizing and identifying bacterial isolates. However, sufficient quantities of bacterial cells are required for generating MALDI mass spectra and a procedure to isolate and enrich target bacteria from sample matrix prior to MALDI-MS analysis is often necessary. In this paper, anion-exchange superparamagnetic nanoparticles (NPs), i.e., fluidMAG-DEAE and fluidMAG-Q, were employed to capture *Aeromonas*, *Salmonella*, *Pseudomonas*, *Enterococcus*, *Bacillus*, *Staphylococcus* and *Escherichia coli* from aqueous solutions and fresh water. The magnetically isolated bacteria were then characterized by whole cell MALDI-MS. The capture efficiency was found to be dependent on bacterial species, medium pH, the functional group and concentration of the NPs. The experimental results demonstrated that fluidMAG-DEAE and fluidMAG-Q were broad spectrum probes for bacteria. Furthermore, both dead and live bacteria could be captured by the NPs, and the live bacteria captured remained viable. Membrane filtration prior to the magnetic isolation could increase enrichment factor and eliminate potential matrix interference. A detection limit of 1×10^3 cfu/ml was achieved for the bacteria spiked in tap water and reservoir water, and the analytical time was around 2 h.

1. Introduction

Pathogenic bacteria are often found in clinical isolates, spoiled food and contaminated water. Some of them are considered as potential bioterrorism agents [1]. Rapid identification of bacteria is important for surveillance, prevention and control of disease outbreaks. MALDI-MS has become a powerful technique for rapid characterization and identification of microorganisms, especially bacteria [2–14]. In whole cell MALDI-MS, characteristic mass spectral fingerprints of bacteria can be employed for bacterial identification [9,14]. The mass spectrum of an isolate can be searched against a well-established mass spectral library of bacterial strains following an appropriate preparation protocol. The comparison will produce the most matching results as well as related evaluation. However, sufficient amount of bacterial cells (typically, $\sim 10^4$ cells per MALDI well) are required to generate MS signals, and a time-consuming culture step is often involved. In contrast, preconcentration of target bacteria from a big sample volume to a small volume provides a much faster alternative to increase the levels of bacterial cells [15]. A combination of enriching/isolating technique and MALDI-MS has been demonstrated as an efficient strategy for accurate identification of target bacteria. For example, immobilized lectins on different substrates [16–18], antibodies coated magnetic beads [19–22], immunoglobulin- [23], vancomycin- [24] or pigeon ovalbumin-conjugated magnetic nanoparticles (NPs) [25] have been used as affinity probes to capture bacteria from food, clinical, biological and environmental samples. Compared with common separation techniques, such NPs-based magnetic separation is rapid and simple. However, specific affinity separation has a limitation in the enrichment of unknown target bacterial species.

Magnetic ion-exchange microparticles and NPs have previously been applied in cell- and drug-targeting experiments, gene transfection studies, and novel DNA extraction [26]. It is interesting to note that anion-exchange particles are potentially non-selective ligands to bacteria since the outer membranes of bacterial cells are generally negatively charged [27]. With such a merit, magnetic separation of bacteria could be carried out [28]. In this paper, we proposed to study the interaction of anion-exchange magnetic NPs, i.e., fluidMAG-DEAE and fluidMAG-Q [29], with several genera of bacteria and the potential to use them to enrich and isolate bacteria. *Escherichia coli*, *Aeromonas*, *Salmonella*, *Pseudomonas*, *Staphylococcus*, *Enterococcus* and *Bacillus* strains were used as target bacteria. Furthermore, we integrated membrane filtration, magnetic isolation and whole cell MALDI-MS for rapid analysis of bacteria in tap water and reservoir water.

Scheme 1. The process employed for bacterial separation and MALDI-MS characterization.

2. Experimental

2.1. Materials and bacteria

FluidMAG-DEAE and fluidMAG-Q NPs (particle size, 250 nm; particle weight, 50 mg/ml; particle number, 1.1×10^{14} g^{-1}; density, 1.25 g/ml) and MagnetoPURE magnetic separator were purchased from Chemicell (Berlin, Germany). α-Cyano-4-hydroxycinnamic acid (CHCA), 3,5-dimethoxy-4-hydroxycinnamic acid (sinapinic acid, SA, for MALDI-MS), acetonitrile (HPLC grade) and trifluoroacetic acid (TFA, ≥99%, for protein sequencing) were obtained from Sigma (St. Louis, MO, USA). Deionized (DI) water (18.2 MΩ cm) from a Milli-Q Plus pure water system (Millipore, Bedford, MA, USA) was autoclaved before use.

All bacterial strains used in this study were purchased from the National Collection of Type Cultures (NCTC), UK, and the American Type Culture Collection (ATCC), USA. Table S1 of the Supplementary material lists the details of the strains used. Pure strains were cultured on Columbia blood agar (CBA) plates (Oxoid, Basingstoke, UK) for 24 h at 37 °C. Plate counting was used to check concentrations of bacteria in suspensions [30]. Phosphate-buffered saline (PBS) was used to dilute bacterial samples. All microbiological procedures were carried out in a Biosafety Level 2 cabinet (Nuaire, Plymouth, MN, USA).

2.2. MALDI plate preparation for direct bacterial analysis

A few bacterial colonies were harvested from a CBA plate with a sterilized loop and placed in a microcentrifuge tube with 2 ml of DI water. The suspension was vortexed for 1 min and centrifuged at 8000 rpm for 5 min. The pellets were washed twice with DI water and re-suspended in 20 μl of DI water. One microliter of the bacterial suspension was deposited into a well of a MALDI plate (12 wells for a sample), air-dried and overlaid with 1 μl of SA (10 mg/ml in 7:3 acetonitrile–0.1% TFA). The MALDI plate was air-dried again prior to MALDI-MS running.

2.3. Microfiltration and magnetic separation of bacteria

Scheme 1 represents the process of the separation and MALDI-MS analysis of bacteria in water. A portion of tap water or reservoir water sample was first filtered through a cellulose nitrate membrane (0.45-μm pore size, 47-mm diameter) under negative pressure. After filtration, the membrane was transferred into a test tube. It was washed with PBS (1 ml × 2) with gentle vortex for 1 min. The supernatant was transferred to a microcentrifuge tube and incubated with 2.5 μl of fluidMAG-Q or 5.0 μl of fluidMAG-DEAE for 30 min with gentle vortex. The tube was then seated with a MagnetoPURE magnetic separator for a few minutes to separate the NPs-bacteria aggregates from the liquid. The supernatant was removed by pipetting carefully. The isolated NPs-cell aggregates were washed with DI water (200 μl × 3) to remove unbound impurities. Subsequently, the NPs-bacterial cell aggregates were re-suspended in 20 μl of DI water. One microliter of the suspension was deposited into a MALDI well, overlaid with 1 μl of SA solution and air-dried for MALDI-MS analysis.

2.4. Instrumentation

All MALDI mass spectra were obtained at the *m*/*z* range of 1000–20,000 using a Micro MX MALDI time-of-flight mass spectrometer (Waters Micromass, Manchester, UK) equipped with a 337-nm nitrogen laser beam (maximum 350 μJ) and a 96-well MALDI target plate. The system had a mass accuracy (RMS error) of ≤300 ppm (using linear external calibration) and a mass resolution of ≥1000 for cytochrome *c* (MH^+ 12361) in linear positive mode. MALDI-MS analyses of whole cell bacteria were conducted in linear positive mode. The accelerating voltage was set to 12,000 V while the laser radiation, pulse voltage and detector voltage were adjusted to obtain good resolutions and high intensities. The raw data was processed with MassLynx 4.0. A JEM-2100 transmission electron microscope (TEM) (JEOL, Tokyo, Japan) was employed to obtain TEM images of the NPs after trapping the bacteria.

3. Results and discussion

3.1. Optimization of the MALDI-MS analysis conditions

A number of researchers [8,9,11,13] have found that experimental factors can influence mass spectral characteristics, signal intensity and reproducibility of whole cell MALDI-MS to different extents. Hence, optimizing experimental parameters can produce informative and reproducible spectra for specified bacteria. We have developed a protocol for whole cell MALDI-MS characterization of aerobic bacteria [31], including all those involved in current study. SA was found more suitable than ferulic acid, CHCA and 5-chloro-2-mercaptobenzothiazole as the MALDI matrix to produce more peaks at m/z >4000 in bacterial mass spectra.

The amount of NPs and the incubation time of bacterial cells with the NPs were also optimized. The capture efficiency of bacteria increased when the incubation time was increased, but the increase was slight in short period (within 3 h). For a 2-ml aqueous solution containing $\sim 10^7$ cfu/ml bacteria, 2.5 μl of fluidMAG-Q (1.4×10^{10} NPs) or 5.0 μl fluidMAG-DEAE (2.8×10^{10} NPs) was added and an incubation of 30 min was necessary to obtain good MALDI mass spectra. Hence, all the capture experiments were under this condition unless otherwise stated.

3.2. Capture of Escherichia coli using anion-exchange nanoparticles

After fluidMAG-DEAE and fluidMAG-Q were separately incubated with aqueous *E. coli* ATCC 700891 suspension, the isolated cells-NPs aggregates were characterized by whole cell MALDI-MS with SA as the MALDI matrix. Their mass spectra were compared with the spectrum of *E. coli* cells directly suspended in DI water at a much higher concentration (without being treated with NPs). Some ions appeared at m/z 3576, 4538, 4876, 5996, 6862, 7714, 9070, 9752, 10,466, 11,987, 13,496, 15,115 and 18,145 as shown in the spectrum of the pure bacterial suspension (Fig. 1). They were potential biomarkers of this species or strain. The *E. coli* cells treated with fluidMAG-DEAE and fluidMAG-Q had very similar MS profiles to corresponding "intact" cells, although their relative intensities were different.

Fig. 2. TEM image obtained after incubation of *E. coli* ATCC 700891 with fluidMAG-DEAE NPs and magnetic isolation.

When the concentration of *E. coli* suspension was lowered to 4.7×10^6 cfu/ml and 8.3×10^5 cfu/ml, the spectra of captured cells by fluidMAG-DEAE consistently retained the peaks at m/z 3576, 4538, 4876, 5996, 6857, 7714, 9063, 9742, 10,466, 11,988, 13,496, 15,115 and 18,145 (Fig. S1 of the Supplementary material). The same phenomenon was observed for cells captured with fluidMAG-Q from low concentrations of spiked solutions. The results demonstrated that neither the capture process nor the magnetic NPs bound to the cells influenced the MALDI-MS characterization of the bacteria. Fig. 2 shows a TEM image obtained after incubating fluidMAG-DEAE with *E. coli* ATCC 700891 and the subsequent magnetic isolation. A few bacterial cells-NPs conjugates were visible, which proves that the NPs successfully captured the bacteria.

3.3. Capture of various bacteria using fluidMAG-DEAE and fluidMAG-Q

Besides *E. coli* ATCC 700891, other bacteria involved in the capture experiments from aqueous solutions were *Aeromonas hydrophila*, *Aeromonas sobria*, *Pseudomonas aeruginosa*, *Salmonella enterica subsp. arizonae*, *Salmonella enterica subsp. enterica*, *Staphylococcus aureus subsp. aureus*, *Bacillus subtilis*, *Enterococcus faecalis* and *E. coli* ATCC 700609. The comparison of the MALDI mass spectra

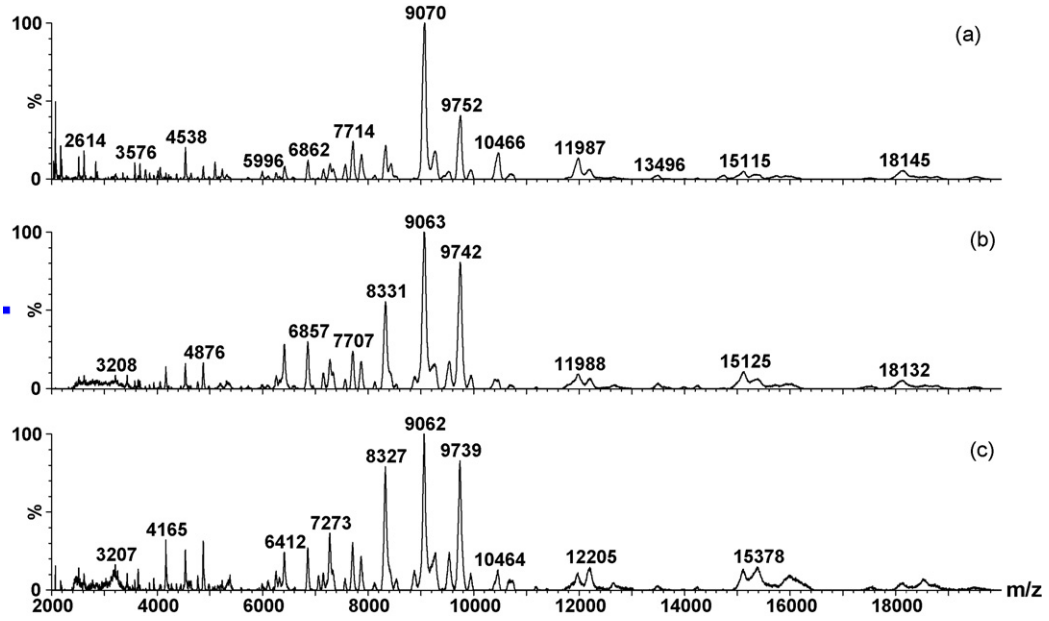

Fig. 1. MALDI spectra of *E. coli* ATCC 700891: (a) pure culture; concentrated from aqueous solution of 4.7×10^7 cfu/ml (b) with fluidMAG-DEAE; and (c) with fluidMAG-Q.

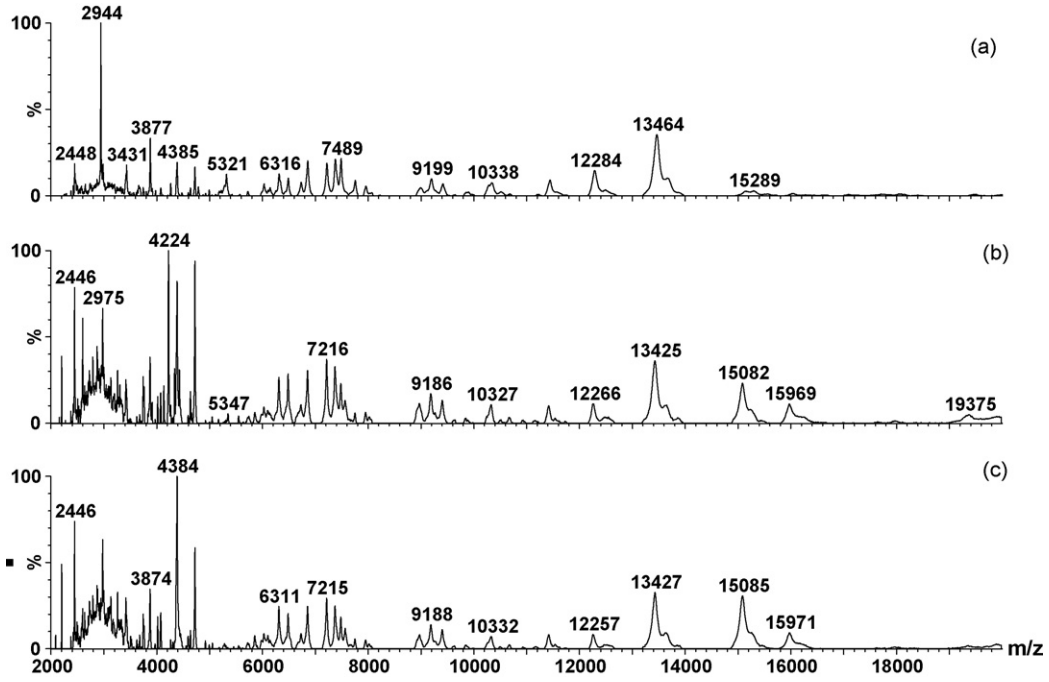

Fig. 3. MALDI mass spectra of *Aeromonas hydrophila* NCTC 8049: (a) pure culture; concentrated from aqueous solution of 8.6×10^7 cfu/ml (b) with fluidMAG-DEAE; and (c) with fluidMAG-Q.

of respective cells with and without the NPs-based magnetic isolation indicated that fluidMAG-DEAE and fluidMAG-Q were capable of recognizing all the bacteria examined and capturing them from aqueous solutions. For example, Fig. 3 shows the MALDI mass spectra of *A. hydrophila* NCTC 8049. Although bacteria with and without NPs treatment yielded ions with different intensity, they were still located at the same *m*/*z* positions (within mass error). Table 1 lists the ions that reproducibly appeared in the MALDI mass spectra of the bacterial strains investigated in this study. Whole cell MALDI-MS clustering analysis is mainly based on the mass spectral peak

Table 1
MALDI mass peaks of bacteria (pure cultures and trapped by the nanoparticles).

Bacteria	Position (*m*/*z*) of peaks	Percentage of signals reproducibly present in the spectra of pure cultures[a]	Percentage of signals reproducibly present in the spectra of isolated cells-NP aggregates[a]
Escherichia coli ATCC 700891	3207, 3576, 4165, 4537, 4876, 5235, 5996, 6412, 6862, 7273, 7711, 8327, 9068, 9744, 10,466, 11,981, 12,205, 13,496, 15,140, 15,378, 18,139	90.5	91.7
Escherichia coli ATCC 700609	3209, 3677, 4369, 4773, 5101, 6261, 6418, 6862, 7339, 7714, 7876, 9541, 10,904, 12,212, 13,481, 15,103, 15,995	91.9	95.6
Aeromonas hydrophila NCTC 8049	3430, 3744, 3874, 4018, 4074, 4224, 4384, 4722, 5321, 6311, 6486, 6854, 7215, 7374, 7565, 8972, 9188, 9401, 10,332, 11,418, 12,257, 13,427, 15,085, 15,971	91.7	90.6
Aeromonas sobria ATCC 11217	3934, 4103, 4976, 6102, 6308, 6484, 6862, 7214, 7369, 7558, 8690, 9184, 9372, 10,334, 10,467, 11,319, 12,189, 13,483, 15,072	94.7	96.7
Pseudomonas aeruginosa NCTC 10662	3162, 3644, 3792, 5740, 6190, 6351, 6981, 7206, 7332, 7582, 8567, 8973, 9303, 10,268, 11,731, 12,356, 13,925, 15,076, 15,974, 17,426, 19,705	95.2	94.6
Pseudomonas aeruginosa NCTC 12924	3178, 3630, 3751, 3794, 4670, 5728, 6191, 6353, 7005, 7209, 7584, 9278, 10,274, 11,679, 12,356, 13,135, 13,972, 15,085, 15,976, 17,267, 19,821	95.4	93.5

Salmonella enterica subsp. enterica ATCC 14028	3685, 4085, 4312, 4553, 4967, 5220, 6098, 6390, 7276, 7562, 7663, 7871, 8009, 8418, 9405, 10,176, 10,952, 12,211, 13,424, 15,094, 15,979	90.5	90.5
Staphylococcus aureus NCTC 13131	3007, 4300, 4827, 5028, 5523, 6422, 6886, 8139	99.2	98.5
Bacillus subtilis ATCC 6051	3404, 3880, 4316, 4522, 4601, 4828, 5059, 5255, 5430, 5716, 6040, 6506, 7556, 7714, 9886, 10,855, 15,085	97.5	96.3
Enterococcus faecalis ATCC 7080	3430, 3695, 4426, 4714, 5212, 5351, 5450, 5540, 6136, 6220, 6397, 6856, 7326, 7571, 8109, 8874	98.1	97.6

[a] Average percent frequency of the peaks listed observed in 12 replicate spectra.

positions rather than peak intensities [11]. The absence of one or even a few small peaks in the spectra of isolated cells could decrease the confidence or probability of the bacterial identification, but did not hamper the correct alignment of bacterial identity. The obtained spectra may be used for bacterial identification by searching against the mass spectral databases already available. However, it should be pointed out that a MALDI mass spectral database has been set up by following a specified sample preparation protocol and a mass spectral algorithm processing. To obtain correct identification, the mass spectra should be acquired under same conditions. When the mass spectra acquired from the isolated cells were searched against a Microbelynx-based database developed by the Manchester Metropolitan University (MMU) [9], the searching results did not always match to the real. This was because that we used a different sample preparation protocol and a different mass range to acquire the mass spectra and such factors could contribute to the mass spectral variation. The mass range for the mass spectral entries in the MMU database was m/z 1000–10,000, while fluidMAG-Q and fluidMAG-DEAE had some strong peaks at $m/z < 3000$. It is necessary to change the mass range setting of automated searching to avoid potential interference from the peaks of NPs.

Wide mass shifts were observed in the spectra under different occasions. For example, the signal at m/z 9752 in Fig. 1 corresponded to those reported in Fig. S1 at m/z 9742 in panel (a) and at m/z 9739 in panel (b). The spectra were acquired on different days. The MALDI-MS system used in this study had a mass accuracy of ≤300 ppm (using linear external calibration). That means a typical mass shift of $m/z \leq \pm 3$ for a signal at m/z 10,000 may occur. Actually, bigger mass shifts of ≥±5 were possible. During the implementation of this study, the system underwent several repair and maintenance services, which may affect the mass accuracy. Such mass shifts were also observed by other researchers [11]. That was why the ions within m/z ±20 of each other were binned together for peaks at $m/z > 9000$ in the peak list [11]. To avoid big mass shifts, it is recommended to use a bacterial strain [11] or internal standards covering whole m/z range [13] to calibrate the mass spectra of the samples.

The culture tests showed that the live cells going through the magnetic separation with fluidMAG-DEAE and fluidMAG-Q remained viable and cultivable. Dead bacterial cells (colonies after heating) could also be isolated with the NPs and further characterized by MALDI-MS.

3.4. Effect of medium pH

The surface charges of bacteria originate from the ionization of surface molecules and the adsorption of ions from the solution [32]. Bacterial cell walls and membranes contain a variety of proteins, lipids, teichoic acids and lipopolysaccharides. Carboxyl, phosphate and hydroxyl groups, with pK_a values of 4.82 ± 0.14, 6.9 ± 0.5 and 9.4 ± 0.6, respectively [27], exposed on the outer surface of the cell wall will result in the negative charge of bacteria at neutral medium [27,33,34]. Amino groups in the cell membrane molecules are positively charged at low pH values while neutral at high pH values. They are unlikely to contribute significantly to the surface charge of the bacteria at high pH values. Therefore, medium pH has significant influence on the bacterial surface charges and their adherence to different materials [27,33–37]. Here, the effects of pH on the interaction of the two magnetic NPs with *E. coli* ATCC 700891, *S. enterica* ATCC 13314 and *S. aureus* NCTC 13131 were examined over the range of pH 2–12.

The MALDI mass spectra of *E. coli* ATCC 700891 separated with fluidMAG-DEAE from aqueous solutions at pH 4.3 and pH 7.3 were much better than those obtained at pH 2.0, pH 10.0 and pH 12.0 (Fig. S2 of the Supplementary material). At pH 2.0, the bacterial surface became less negatively charged which would reduce the interactions between bacterial cells and the particles. Meanwhile, a part of the superparamagnetic NPs were dissolved in acidic solution. Therefore, fewer particles were left as anion-exchanger to be isolated by an external magnet. At pH 10.0 and pH 12.0, the anion-exchange groups of the NPs could not function well although the bacterial surface seemed more negatively charged. In contrast, at pH 4.3 and pH 7.3, the bacterial surface became more negatively charged and the functional groups of NP were oppositely charged. As a result of stronger electrostatic attractive forces, the capture yield has been improved.

For *S. aureus* NCTC 13131 and *S. enterica* ATCC 13314, the best spectra were obtained at pH 7.0, followed by those obtained at pH 10.0. No spectrum was observed at pH 2.0 and pH 12.0. In summary, the magnetic separation worked well only in a nearly neutral medium. Therefore, DI water and fresh water were not pH-adjusted during the experiments.

3.5. Reproducibility of the MALDI-MS spectra

Reproducibility of MALDI-MS spectra is very important for reliable microbial identification and has been addressed in a number of studies [8–14]. It can be evaluated with the frequency of appearance for ions in the mass spectra when the spectra were collected from replicate MALDI wells (well-to-well) or from same bacteria samples prepared on different days (day-to-day). Ions with at least 10% of the strongest ion intensity observed in the spectra within an m/z difference of ±10 were considered reproducible. In this study, we compared the MALDI mass spectra of magnetically isolated bacteria deposited on 12 MALDI wells in a same batch and on three separate days. Table 2 displays the reproducibility of peaks of *E. coli* ATCC 700891 and *S. enterica* ATCC 13314 from different MALDI wells in a batch and on different days. The results showed that the integrated separation-characterization method was reproducible.

3.6. Capture efficiencies of bacteria

The capture efficiencies of bacteria by the anion-exchange NPs were evaluated by counting the colonies grown on the nutrient broth agar plates from the isolated supernatant and the initial bacterial suspension. In these experiments, fluidMAG-Q (2.5 μl) or fluidMAG-DEAE (5.0 μl) was added to a 2-ml suspension containing ~10^7 cfu/ml of specific bacteria. As Table 3 displays, the capture efficiency was obviously dependent on both the NPs functional groups and the bacterial surface charges. The enrichment factor

Table 2
Reproducibility of the MALDI-MS spectral peaks.

Bacteria	Peak m/z (average ± SD)[a]
Salmonella enterica ATCC 13314	2622 ± 1.0
	3645 ± 1.0
	5742 ± 2.0
	6355 ± 2.2
	7584 ± 3.0
	8572 ± 3.5

Table 3
The efficiency of bacterial capture with fluidMAG-DEAE and fluidMAG-Q (incubation time of 30 min).

Bacteria	Capture efficiency (%)[a]	
	FluidMAG-DEAE (5.0 μl)	FluidMAG-Q (2.5 μl)
Escherichia coli ATCC 700891	21.9 ± 1.8	23.1 ± 0.4
Escherichia coli ATCC 700609	21.6 ± 0.9	24.6 ± 0.7
Staphylococcus aureus NCTC 13131	14.3 ± 0.7	19.2 ± 1.5
Salmonella enterica ATCC 13314	20.3 ± 0.4	25.7 ± 0.3
Aeromonas sobria NCTC 11217	8.0 ± 0.5	10.6 ± 0.8
Aeromonas hydrophila NCTC 8049	9.2 ± 0.6	11.6 ± 0.3
Bacillus subtilis ATCC 6051	24.8 ± 1.3	28.4 ± 0.6
Enterococcus faecalis ATCC 7080	15.4 ± 0.8	18.4 ± 1.1

[a] Expressed as average ± standard deviation ($n = 3$).

is equal to the capture efficiency times the volume change factor (i.e., 100 for magnetic isolation only). For example, it was 23.1 ± 0.4 for *E. coli* with fluidMAG-Q under the conditions examined. Both fluidMAG-Q and fluidMAG-DEAE had higher capture efficiencies for *E. coli*, *S. enterica* and *B. subtilis* than for *S. aureus*, *A. hydrophila* and *A. sobria*. FluidMAG-Q had a higher efficiency for each of the bacterial species than fluidMAG-DEAE, even when the number of particles used to capture bacteria was half of fluidMAG-DEAE's. This efficiency difference can be explained in terms of interaction mechanism between the NPs and bacteria. The binding force between bacteria and the NPs is mainly electrostatic force. FluidMAG-Q has a polymer structure with more positive charges at its surface [37] while fluidMAG-DEAE has a linear structure with only one positive charge at the surface [26].

The capture efficiency was also found to be related with the concentration of the magnetic NPs. Fig. 4 shows a much higher efficiency, even up to 99%, was obtained for *E. coli* ATCC 700891 (3.4×10^7 cfu/ml) with increasing amount of NPs used. During the capture process, there is a dynamic equilibrium between the NPs and bacterial cells [10]. When the concentration of the NPs is higher, more bacterial cells would be bound by the particles. However, high capture efficiency does not ensure good MALDI mass spectra of captured cells. Too many particles may "dilute" the bacterial cells in a MALDI spot, and also affect the interaction among laser radiation, MALDI matrix molecules and bacterial cells.

In view of the enrichment factor, the NPs-based magnetic separation lowered the detection limit of bacteria by 8–28-folds. The detection limit was also related to the MALDI-MS system used. For the equipment we used, it was ~10^5 cfu/ml for all bacteria investigated. To further lower the detection limit, microfiltration using 0.45-μm membrane was introduced into the procedure for analysis of water samples.

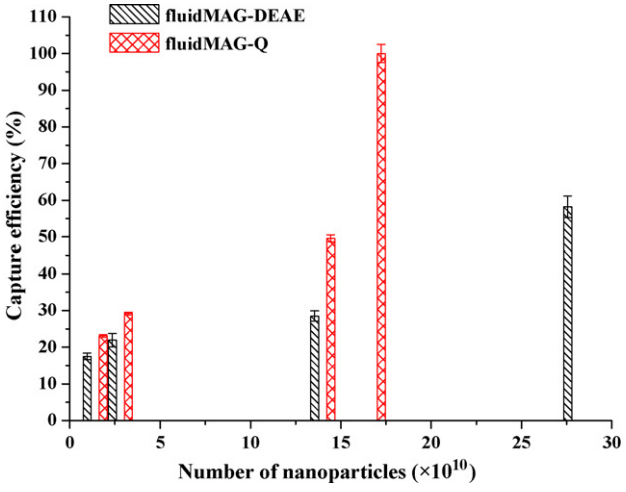

Fig. 4. Relationship between capture efficiency and the amount of the nanoparticles used. The nanoparticles were incubated with 3.4×10^7 cfu/ml of *E. coli* ATCC 700891 for 30 min.

3.7. Separation of the bacterial mixtures

It was worthwhile to check whether fluidMAG-Q and fluidMAG-DEAE preferred certain bacteria to others during the capture. Therefore, six aqueous suspensions were prepared by mixing two bacterial species with similar concentrations in DI water. After the magnetic separation, the mass spectrum for each mixture was found as the mass spectral addition of two spiked species. For example, in the spectra (Fig. S3 of the Supplementary material) of the mixture of *S. aureus* NCTC 13131 (Gram-positive) and *E. coli* ATCC 700891 (Gram-negative), the peaks positioned at $m/z < 4000$ and peaks at $m/z > 7000$ were mainly attributed to *S. aureus* NCTC 13131 and *E. coli* ATCC 700891, respectively. Fig. S4 shows the mass spectra of the mixture of two Gram-negative bacteria, *S. enterica* ATCC 13314 and *E. coli* ATCC 700891. Similarly, the peaks from both species were observed. The results indicated that fluidMAG-DEAE and fluidMAG-Q were non-specific and broad spectrum isolation materials for both Gram-positive and Gram-negative bacteria.

3.8. Analysis of bacteria in spiked waters using the integrated method

Bacterial analysis is important in many areas including food quality, clinical diagnosis and water quality monitoring. In this study, we were more interested in the applicability of MALDI-MS coupled with separation in the identification of bacterial contamination in fresh water. Reservoir water and tap water, i.e., source and finished drinking water, is more meaningful to drinking water supply than other high ion strength water (e.g., wastewater and seawater). Three concerns would arise when fluidMAG-DEAE and fluidMAG-Q NPs were used to directly concentrate bacteria in fresh water and the obtained isolates were subsequently detected by MALDI-MS. Firstly, bacteria in contaminated water were commonly below ~10^4 cfu/ml. That means the pre-concentration step would require a bigger volume (a few liters rather than a few milliliters) for each sample. Secondly, inorganic ions and negatively charged organic compounds in water have potential interferences on the magnetic separation. Thirdly, it is impractical to conduct magnetic separation from a big-volume sample. In order to overcome such issues, water samples were subjected to microfiltration using 0.45-μm cellulose nitrate membrane filter prior to the magnetic separation. To evaluate the applicability of the proposed approach, *E. coli*, *S. enterica*, *A. hydrophila*, *P. aeruginosa*, *S. aureus* and *B. subtilis* were individually spiked into 2 L of tap water or reservoir water to a final concentration in the range of 10^2–10^5 cfu/ml. Table S2 of the Supplementary material lists the main matrix components and contaminants of the water samples. Finally, the bacteria were detected with the detection limit of 1×10^3 cfu/ml. Figs. 5 and 6 display two examples: *B. subtilis* ATCC 6051 spiked in reservoir water and *P. aeruginosa* NCTC 12924 spiked in tap water. The peaks from the captured cells matched well with those from the pure bacteria and no sample matrix peaks were found. An additional example is provided as Fig. S5 of the Supplementary material. Furthermore, the current method was also applied to a tap water sample and a reservoir water sample. In their mass spectra (Fig. S6), no peaks except those for the NPs were observed. This indicated that bacteria in the water samples examined were non-detected, i.e., lower than the detection limit. Compared with the traditional culture method, the current method requires a running time of around 2 h.

The detection limit of bacteria by the proposed method is 1×10^3 cfu/ml, and contaminated water with bacteria concentration higher than the detection limit can be rapidly tested.

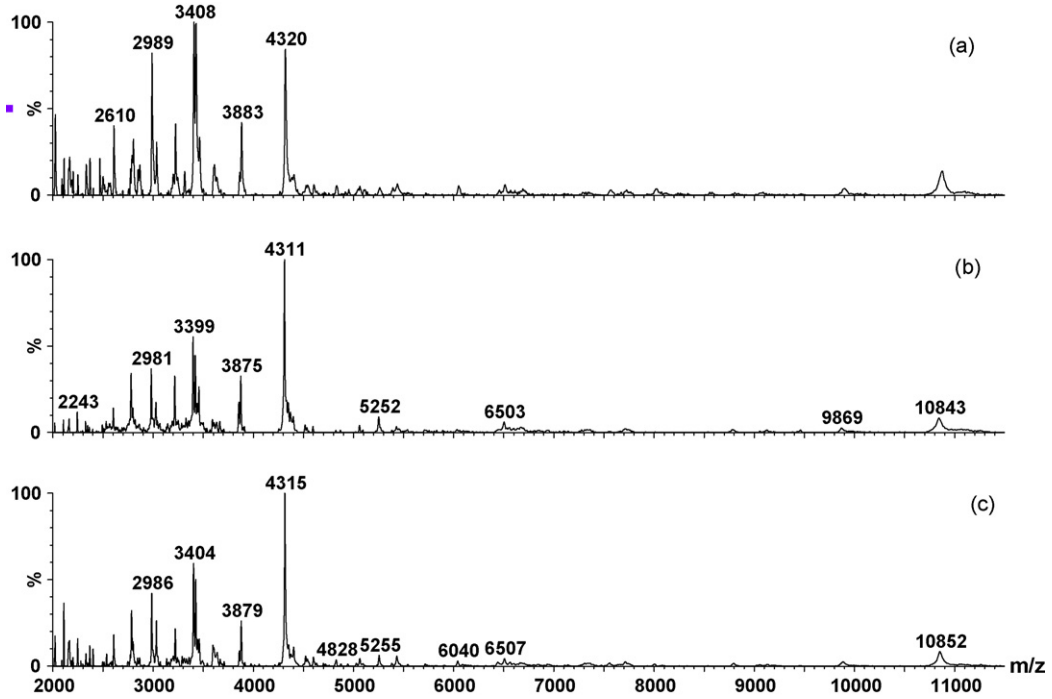

Fig. 5. MALDI mass spectra of *Bacillus subtilis* ATCC 6051: (a) pure culture; (b) membrane filtered and separated with fluidMAG-DEAE from reservoir water spiked at 1×10^3 cfu/ml; and (c) membrane filtered and separated with fluidMAG-Q from reservoir water spiked at 1×10^3 cfu/ml.

Otherwise, the results would be non-detected. In this term, pre-enrichment on a selective culture media can be avoided. When different bacterial species are present in a sample, as discussed above, they are concentrated together and a combined spectrum is produced. By comparing with the blank, it is easy to justify the existence of bacteria. But when searching using an algorithm or software against a mass spectral library of pure bacterial species or strains, the result of bacterial identity may not be correct. In this case, the identification strategy on the basis of specific ions (biomarkers) is more reliable [38,39].

When 5-ml human urine samples were individually spiked with 10^6 cfu/ml of *E. coli* ATCC 700891, *S. enterica* ATCC 13314 and *S. aureus* NCTC 13131 and then processed through magnetic separation (without membrane filtration), the analytical results were not satisfactory. Extra peaks appeared in the mass spectra for spiked urines, compared with pure cultures. Urine is a more complicated

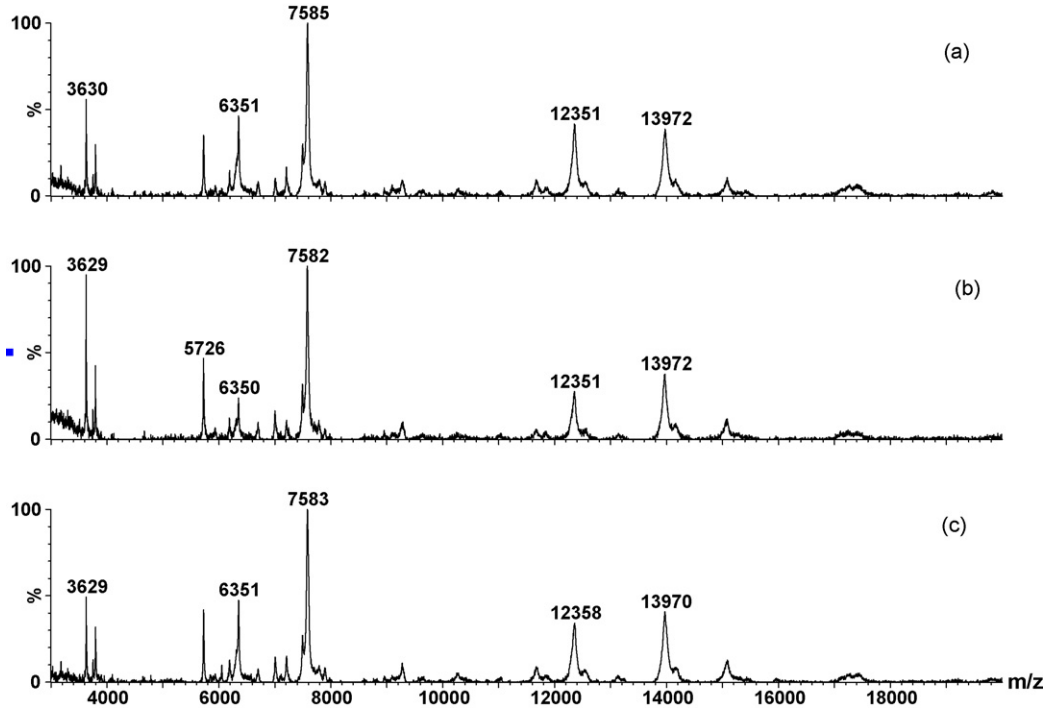

Fig. 6. MALDI mass spectra of *Pseudomonas aeruginosa* NCTC 12924: (a) pure culture; (b) membrane filtered and separated with fluidMAG-DEAE from a tap water spiked at 2×10^3 cfu/ml; and (c) membrane filtered and separated with fluidMAG-Q from a tap water spiked at 2×10^3 cfu/ml.

matrix than fresh water. A number of inorganic ions and negatively charged organic compounds were easily found in urine, and they have potential interferences on the magnetic separation and MALDI-MS spectra. The current method does not apply to urine analysis.

4. Conclusions

This paper addressed a combination of microfiltration, magnetic separation using anion-exchange NPs to concentrate bacteria from aqueous suspensions and fresh water, and the characterization of the isolates by whole cell MALDI-MS. Various bacteria, e.g., *E. coli*, *Salmonella*, *Aeromonas*, *Pseudomonas*, *Staphylococcus*, *Bacillus* and *Enterococcus*, were analyzed in this strategy. Bacterial species, medium pH, concentration and functional group of the NPs were found to influence the capture efficiency. With fluidMAG-DEAE and fluidMAG-Q, bacteria could be enriched and magnetically isolated from simple matrix solutions without affecting their vitality and cultivability. With such an integrated method, bacteria in fresh water could be analyzed in 2 h with a detection limit of 1×10^3 cfu/ml. Rapid and accurate identification of bacterial contamination in water can be expected up to species level by the proposed method when a MALDI library of bacterial strains has been established.

Reject option

ABSTRACT

Microarrays are used to simultaneously determine the expressions of thousands of genes. An important application of microarrays is in the classification of samples into classes of interest (e.g. either healthy cells or tumour cells). Discriminant partial least squares (DPLS) has often been used for this purpose. In this paper, we describe an improvement to DPLS that uses kernel-based probability density functions and the Bayes rule to classify samples whilst keeping the option of not classifying the sample if this cannot be done with sufficient confidence. With this approach, those samples outside the boundaries of the known classes or from the ambiguity region between classes are rejected and only samples with a high probability of being correctly classified are indeed classified. The optimal model is found by simultaneously minimizing the misclassification and rejection costs. The method (*p*-DPLS with reject option) was tested with two datasets. For the human cancers dataset the accuracy (obtained by leave-one-out cross-validation) was improved from 97% to 99% when compared to *p*-DPLS without reject option. For the breast cancer dataset, *p*-DPLS with reject option was able to reject 100% of the test samples that did not belong to any of the modelled classes. These samples would have been misclassified if the reject option had not been considered.

1. Introduction

Supervised classification is increasingly being applied to microarray gene expression data in order to predict tumour types [1–3], to differentiate between healthy and tumour samples [4–6] and to differentiate between pharmacological mechanisms [7], among other applications. Microarray data are characterized by thousands of variables (genes) and few samples, resulting in high redundancy and a high number of non-informative measurements. There has been a lot of interest in using factor-based multivariate classification methods such as discriminant partial least squares (DPLS) to analyze these data [8,9]. The DPLS uses a few latent variables rather than a lot of measured variables and this brings with it a series of advantages. DPLS takes variable correlations into account, filters noise and leads to classification rules with good predictive performance, especially when DPLS is implemented together with variable selection methods. DPLS has been used to differentiate between samples before and after chemotherapy [10], to determine the different states of a breast cancer tumour [11], to predict the efficacy of a drug by using expression data biomarkers [12], and to predict the quality of DNA-microarray spots [13].

Like other classification rules, DPLS must have two main qualities: it must provide reliable classifications of forthcoming samples and it must minimize the number of misclassifications (i.e. the expected error rate). Both of these are improved if the classifier is allowed to reject doubtful samples instead of always being forced to classify them in one of the modelled classes. By classifying only the most well-defined cases, both the accuracy of the classifier and the reliability of each classification are improved.

In this paper we implement the reject option in the recently developed *p*-DPLS classifier and show how it can be used for microarray data classification. *p*-DPLS is a variant of DPLS, which uses kernel functions to calculate a probability density function (PDF) for each class. This allows a flexible implementation of the Bayes rule for classification, and also provides a measure of the reliability of the classification. Reliability is a primary concern in statistical classification, especially when this classification is used in critical health applications such as cancer diagnosis [14], an issue which has also led to several other studies [15].

In classification, rejection is advantageous when: (a) the new sample does not belong to any of the trained classes, (b) the new sample belongs to one of the classes but is very different from the samples used for training the classifier, or (c) the sample is in the boundary region between classes. Situation (a) occurs when the sample is an outlier. Forcing the classifier to decide among one of the modelled classes will produce a classification error (e.g. a cell does not belong to any of the modelled cell types but it is classified

doi:10.1016/j.talanta.2009.06.072

as one of them). Situation (b) typically arises when the sampling of the training samples is incomplete or not representative. Finally, situation (c) may arise, for example, because of the limited discriminative power of the measured variables or because the classification algorithm has limited discriminative power. Although samples in situations (b) and (c) might finally be classified correctly, they might also be classified incorrectly because either they are unique samples or they are ambiguous samples and can belong to either of the classes, respectively.

The reject option aims to overcome situations (a) to (c) by rejecting the sample and not classifying it when the probability of error is too high. This is a safeguard against errors and improves the accuracy of the classifier, which is evaluated as the percentage of samples correctly classified among the number of samples classified [16]. This in turn leads to greater confidence in the samples that are finally classified. The reject option can be fine-tuned in order to avoid rejecting too many samples that would otherwise be classified correctly. Since too high a rejection rate would decrease the usefulness of the classifier, a compromise must be reached between improving the accuracy and reducing the usefulness of the classifier. There has been extensive research into the theoretical aspects of the reject option [14,17–28], most of which relates to Chow's reject option [29], which implemented the reject option for the Bayes rule. Chow's reject option has recently been used to microarray expression data [30].

There are still two limitations to jointly applying the Bayes and Chow rules. First, they are not adequate for the extreme (outlying) samples (situations (a) and (b)) which are typically found at the extremes of the probability density functions (PDFs). These samples must be rejected according to a different criterion. Second, both rules require knowledge of the *a priori* probabilities and the PDFs of the classes [31], which makes applying these rules more difficult. In this paper, the first limitation is overcome by including distance based thresholds, which is equivalent to selecting a confidence interval around each class and rejecting samples outside this interval [17]. The second limitation is overcome by the calculating PDF-like functions in *p*-DPLS [32], which makes an approximate Bayesian classification easier.

2. Methods

2.1. Probabilistic DPLS

The DPLS method applies partial least squares (PLS) regression to binary classification problems, in which the dependent variable y codifies the class of each sample [8,33]. A DPLS model is calculated by regressing $\mathbf{y}$ on $\mathbf{X}$ using the adequate number of factors. For microarray gene expression data, $\mathbf{X}$ is an $n \times p$ matrix of n samples and p gene expressions and $\mathbf{y}$ is a $n \times 1$ vector of ones and zeros, where the integer 0 codifies the sample as belonging to class ω_0 (e.g. "cancer of type I") and the integer 1 codifies the sample as belonging to class ω_1 (e.g. "cancer of type II"). For a sample i, the value predicted by the PLS model is $\hat{y}_i = \mathbf{x}_i{}^{\mathrm{T}}\mathbf{b}$, where the b's are the regression coefficients for the model of A factors and the adequate preprocessing is implicit (e.g. if the b's had been calculated from mean-centred data, then $\mathbf{x}_i$ should be mean-centred, and the predicted $\hat{y}_i$ should be unprocessed accordingly). With the coding of y, the prediction for a sample should be close to 0 if the sample belongs to class ω_0, and it should be close to 1 if the sample belongs to class ω_1. In order to better define the cut-off value between classes, Pérez et al. [32] developed *p*-DPLS, a probabilistic version of the DPLS in which the uncertainty of the predicted value $\hat{y}$ is accounted for in the calculation of the model. This method is described here for completeness. The method starts by calculating a DPLS model of A factors with $\mathbf{X}$ and $\mathbf{y}$. Then, this model is used to predict the training samples and, for each training sample i, a Gaussian function centred at the predicted value $\hat{y}_i$ is calculated as:

$$f_i(\hat{y}) = \frac{1}{\mathrm{SEP}_i\sqrt{2\pi}} \cdot e^{-\frac{1}{2}\left(\frac{(\hat{y}-\hat{y}_i)}{\mathrm{SEP}_i}\right)^2} \tag{1}$$

$$\mathrm{SEP}_i = \mathrm{RMSEC}\sqrt{1+h_i} \tag{2}$$

$$\mathrm{RMSEC} = \sqrt{\frac{\sum_{i=1}^{n}(\hat{y}_i - y_i)^2}{n-A-\delta}} \tag{3}$$

where SEP_i is the standard error of prediction for sample i, h_i is the leverage of the sample, RMSEC is the root mean square error of calibration, y_i is the known class of the training sample i (i.e. value 0 for a sample of class ω_0 and value 1 for a sample of class ω_1) and δ is 1 if the data has been centred and 0 if it has not. Fig. 1 shows the Gaussian functions calculated from the predictions of three training samples of class ω_0 and four samples of class ω_1. Note that the width of the Gaussian kernel for sample i depends on SEP_i, which is particular to that sample, and depends on the relative position of the sample in the multivariate space. Then, for classes ω_0 and ω_1, a PDF is calculated as the average of the individual kernel functions of the training samples of each class:

$$p(\hat{y}|\omega_0) = \frac{1}{n_0}\sum_{i=1}^{n_0} f_i(\hat{y}) \tag{4}$$

$$p(\hat{y}|\omega_1) = \frac{1}{n_1}\sum_{i=1}^{n_1} f_i(\hat{y}) \tag{5}$$

where n_0 and n_1 are the number of samples of class ω_0 and class ω_1 respectively.

2.2. Bayes rule for classification

In *p*-DPLS, the predicted class for sample i is obtained using the Bayes rule. The prediction $\hat{y}_i$ for that sample is used to obtain the *a posteriori* probabilities $P(\omega_0|\hat{y}_i)$ and $P(\omega_1|\hat{y}_i)$. These are the probabilities that the sample belongs either to class ω_0 or to class ω_1, once it is known that the sample's prediction is $\hat{y}_i$. For the two-class classification problem:

$$P(\omega_0|\hat{y}_i) = \frac{p(\hat{y}_i|\omega_0)\cdot P(\omega_0)}{p(\hat{y}_i)} \tag{6a}$$

$$P(\omega_1|\hat{y}_i) = \frac{p(\hat{y}_i|\omega_1)\cdot P(\omega_1)}{p(\hat{y}_i)} \tag{6b}$$

where $p(\hat{y}_i|\omega_0)$ and $p(\hat{y}_i|\omega_1)$ are the *conditional* probabilities evaluated from the PDFs of classes ω_0 and ω_1 and $P(\omega_0)$ and $P(\omega_1)$ are the *a priori* probabilities. Both *a priori* probabilities may be estimated as the proportion of samples of each class in the training set, provided that the set is representative of the overall population. That is, $P(\omega_0) = n_0/n$ and $P(\omega_1) = n_1/n$ where $n = n_0 + n_1$. The denominator of Eqs. (6a) and (6b) is:

$$p(\hat{y}_i) = p(\hat{y}_i|\omega_0)\cdot P(\omega_0) + p(\hat{y}_i|\omega_1)\cdot P(\omega_1) \tag{7}$$

The Bayes rule assigns the sample to the class in which it has the highest *a posteriori* probability [31]. The rule is:

$$\begin{array}{lll} \text{Assign the sample to} & \text{class } \omega_0 & \text{if } P(\omega_0|\hat{y}_i) > P(\omega_1|\hat{y}_i) \\ & \text{class } \omega_1 & \text{if } P(\omega_1|\hat{y}_i) > P(\omega_0|\hat{y}_i) \end{array} \tag{8}$$

Although this rule is optimal in the sense that no other rule can yield a lower error probability, it is not always satisfactory. For example, when the $\hat{y}_i$ is at one of the extremes of the PDF (Fig. 2), both $p(\hat{y}_i|\omega_0)$ and $p(\hat{y}_i|\omega_1)$ are low, and the products $p(\hat{y}_i|\omega_0)\cdot P(\omega_0)$ and $p(\hat{y}_i|\omega_1)\cdot P(\omega_1)$ are also low but the *a posteriori* probability for one

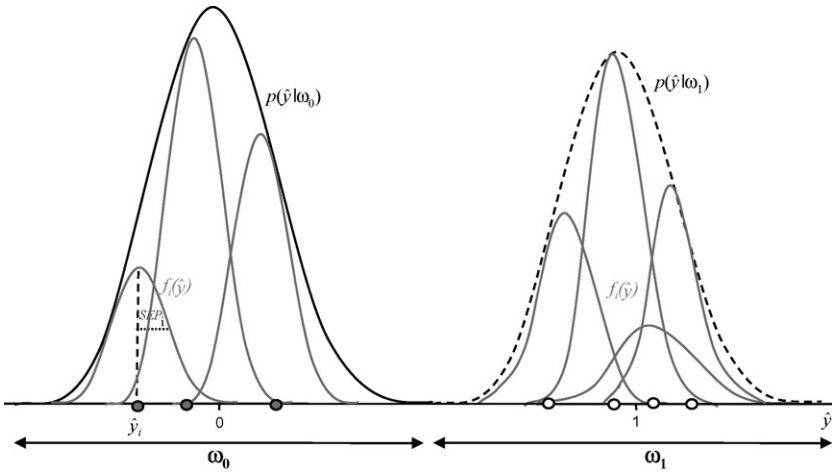

Fig. 1. Simulated PDFs of class ω_0 and class ω_1 obtained from Eqs. (4) and (5). The kernel functions (Eq. (1)) are centred on prediction $\hat{y}_i$ of each training sample. According to the code assigned to the classes, the sample predictions of class ω_0 and class ω_1 should be located around the values 0 and 1 respectively.

of the classes (the ratio in Eqs. (6a) and (6b)) is high. This means that the further the prediction $\hat{y}_i$ is from one class, the more likely it will be allocated to the other class. This is a reasonable result since the classifier only expects to receive samples from the two modelled classes. In most multivariate applications, however, samples from non-modelled classes (outliers) may also be inadvertently submitted to the classifier. The predictions for those samples will most probably be found at the tails of a PDF, and, hence give a misleading high *a posteriori* probability for one of the classes. Consequently, forcing the two-class Bayes rule to classify any input sample may involve a high risk because outliers may be erroneously classified in one of the modelled classes.

Another situation in which the usefulness of the Bayes rule is limited occurs when the predicted value $\hat{y}$ is in the boundary between classes (the ambiguity region). The dot in the centre of Fig. 2A represents a sample whose characteristics are similar for both classes, with the result that the model cannot clearly distinguish whether it belongs to one class or to the other. Again, the sample will be assigned to the class to which, according to the Bayes rule, it has the highest probability of belonging. However, since the probability that the sample belongs to class ω_0 is similar to the probability that it belongs to class ω_1, there is a high risk of misclassification and the reliability of the classification is low.

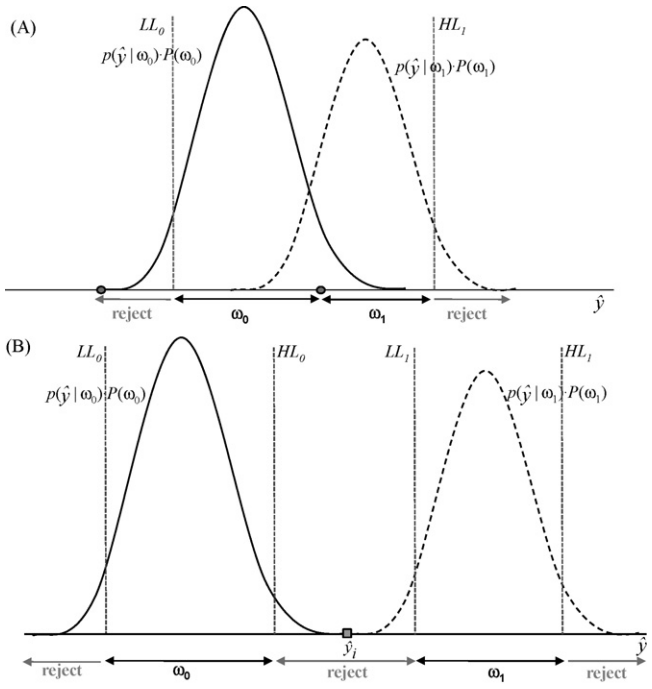

Fig. 2. Possible distributions of class ω_0 and class ω_1 with the distance reject limits: (A) overlapped classes and (B) well separated classes. ● and □ indicate possible predictions of unknown samples for which the Bayes rule gives questionable results. LL_0, HL_0, LL_1 and HL_1 are the limits for rejection based on the distance reject option.

These situations show that the reject option might be an advantageous addition to the decision rule. In this paper, we implement the reject option in *p*-DPLS. Both the classification reliability and accuracy of the *p*-DPLS model are improved by identifying unreliable classifications and rejecting the sample instead of running the risk of misclassifying it.

2.3. Implementation of the reject option in p-DPLS

The reject option in the case of classification ambiguity (i.e. for overlapped PDFs) can be derived by adapting Chow's rule to the PDFs obtained in *p*-DPLS. Chow's rule sets a threshold t so that the sample is rejected if the highest *a posteriori* probability is lower than $1-t$. In other words, the sample is classified only if:

$$\max(P(\omega_0|\hat{y}_i), P(\omega_1|\hat{y}_i)) > (1-t) \tag{9}$$

Thus, only those samples whose classification is reliable enough are indeed classified. The other samples are rejected because they could be misclassified. The threshold that optimizes the trade-off between the error rate and reject rate can be derived from the costs associated with each classification result [29]:

$$t = \frac{\lambda_r - \lambda_c}{\lambda_e - \lambda_c} \tag{10}$$

where λ_e, λ_r, and λ_c, are the costs of incorrect classification, of rejection and of correct classification, respectively. The values that are assigned to these costs make the reject option tuneable. The cost of being wrong is higher than the cost of both rejecting and classifying correctly ($\lambda_e > \lambda_r > \lambda_c$). In fact, it is preferable to reject a sample and gather additional information than to classify the sample incorrectly. It is also generally assumed that classifying correctly has no cost ($\lambda_c = 0$). Note that Eq. (9) is a generalization of the standard Bayes rule. In particular, for the extreme case in which the cost of rejection λ_r equals the cost of misclassification λ_e, the reject threshold is $t = 1$ and Chow's rule is reduced to the standard Bayes rule, in which samples are never rejected. A sample is also not rejected if $t > 1/C$, where C is the number of possible classes ($C = 2$ for a binary classification) [34].

The second reason for using the reject option is to avoid classifying extreme samples that have a large *a posteriori* probability but low values at both PDFs. In order to solve this problem, Dubuisson and Masson [18] added a distance reject criterion to Chow's ambiguity reject option. This idea is implemented here for the *p*-DPLS model by imposing limits on the $\hat{y}$ values, which define the extreme regions in which the samples will be rejected. The limits are chosen so that the sum of the area in the tails of each PDF is five percent of the total area of the distribution (i.e. the distance reject probability equals 0.05 for each class, see Fig. 2) [19]. Since the limits depend on the shape of the distributions of each class, they are particular for each *p*-DPLS model with a given number of factors. In practice, when the PDFs are overlapped we have two operative limits, a High Limit (HL) and a Low Limit (LL) and when the PDFs are separated we have four limits (HL and LL for each class, see Fig. 2).

Assuming the constraints for the distance reject and the ambiguity reject, the Bayes rule with reject option is:

$$\begin{array}{lll} \text{Reject} & \text{if} & \hat{y}_i < \mathrm{LL}_0 \\ & \text{or if} & (\mathrm{HL}_0 < \hat{y}_i < \mathrm{LL}_1) \\ & \text{or if} & \hat{y}_i > \mathrm{HL}_1 \\ & \text{or if} & \max(P(\omega_0|\hat{y}_i), P(\omega_1|\hat{y}_i)) < (1-t) \\ \text{Otherwise} & & \\ \text{classify into } w_0 & \text{if} & P(\omega_0|\hat{y}_i) > P(\omega_1|\,\hat{y}_i) \\ \text{or into } w_1 & \text{if} & P(\omega_1|\hat{y}_i) > P(\omega_0|\hat{y}_i) \end{array} \quad (11)$$

2.4. Evaluation of the classification method performance

The *p*-DPLS models can be calculated for a different number of factors that are needed to explain the relevant information. Thus, every *p*-DPLS model will produce different $\hat{y}$ predictions for the calibration samples and, therefore, for the different PDFs, which, in turn, will influence the performance of the classifier. The performance of a classifier is commonly characterized by its error rate (or the classification rate, which is the percentage of correctly classified samples) when classifying a test set of unseen samples that were not used during the training phase. The actual class of every sample in the test set is compared to the class to which it is assigned by the classifier. In general terms, however, it is not the misclassification (and rejection) rate that we want to minimize, but the misclassification (and rejection) cost [35], since the cost more accurately reflects the objective of the classification rule [36]. The cost is here defined as:

$$\text{Cost} = \lambda_r \cdot N_r + \lambda_e \cdot N_e \quad (12)$$

where N_r is the number of rejected samples and N_e is the number of misclassified samples. The cost of correctly classifying a sample has been set to zero. Here, the minimization of the cost will be used to decide on the optimal number of factors in the *p*-DPLS model.

3. Results and discussion

3.1. Datasets

The proposed classification rule (Eq. (11)) was applied to two datasets, the human cancers dataset [37] and the breast cancer dataset [38]. These datasets have been studied extensively in the literature [39,40] and also used to evaluate the performance of classification models [41–44]. The human cancers dataset consists of 282 microRNA (miRNA, non-coding RNA species) normalized expression profiles for 218 samples, including 46 healthy samples (class ω_0) and 172 tumour samples (class ω_1) from several healthy and tumour tissues (ovary, colon and lung to mention a few). The dataset was divided into a training set and a test set by applying the Kennard–Stone algorithm [45] to the scores of the first 20 Principal Components (PCs), which were obtained from the Principal Component Analysis (PCA) of the raw gene expression matrix. For this dataset, the training set contained 153 samples (116 samples of class ω_1 and 37 samples of class ω_0), and the test set had 65 samples (56 of class ω_1 and 9 of class ω_0). The breast cancer dataset consists of 5361 normalized gene expression ratios. These were used in [38] to prove that a hereditable mutation influences the gene expression profile of breast cancer. Seven samples of the BRCA1 mutation were used as class ω_0, eight samples of BRCA2 mutation were used as class ω_1, and six samples of sporadic mutation were used as test samples.

3.2. Human cancers dataset

Although *p*-DPLS is a full-variable method, it can often be improved by carefully selecting the variables and removing irrelevant miRNA expressions that interfere with the discriminative power of the relevant miRNA [46]. For this dataset, the 100 variables with the highest VIP values (variable importance for the projection) were considered. VIP values were calculated as described in [8,47]. These values quantify how each variable influences the response summed over all components and classes.

For the selected variables, six *p*-DPLS models were calculated with 1–6 factors using mean-centred miRNA expression patterns (we will denote each model as *p*-DPLS$_A$, where A is the number of factors). The *a priori* probabilities for these six models were $P(\omega_0) = 37/153 = 0.24$ and $P(\omega_1) = 116/153 = 0.76$.

The PDF of classes ω_0 and ω_1 were calculated for each *p*-DPLS model (Eqs. (1)–(5)). The test sample was classified by obtaining its $\hat{y}$ prediction and then calculating the *a posteriori* probabilities (Eqs. (6a) and (6b)). Finally, the sample was either rejected or classified in the class with the highest *a posteriori* probability (Eq. (11)). In this dataset, the high and low limits (HL and LL) for $\hat{y}_i$ were defined so as to retain the five percent of the total area of the PDF in the tails of the distributions. The costs were arbitrarily set to $\lambda_c = 0$, $\lambda_r = 0.25$, and $\lambda_e = 1$ because no information was available about the costs of each classification decision. Note that these costs are relative, and indicate that it is preferable to reject four samples than to classify one wrongly. These values are illustrative and should be adjusted for each particular classification problem. With these values, the threshold value for rejection in the ambiguity zone is $t = 0.25$ (Eq. (10)). The models with $A = 1$–6 factors were validated by leave-one-out cross-validation (CV). In this process, sample *i* was left out of the training set, the *p*-DPLS$_A$ model was calculated, and the prediction $\hat{y}_i$ for the left-out sample was obtained (note that the *a priori* probabilities were recalculated to take into account that one sample had been left out). This procedure was repeated for all the samples of the training set and for all the *p*-DPLS models.

Fig. 3 and Table 1 show the cross-validation results obtained for the different *p*-DPLS models when the reject option (Eq. (11)) is considered. Note that predictions for samples in class ω_0 are around 0 and predictions for samples in class ω_1 are around 1, but that the predictions partially overlap in models with less than four factors (underfitted models). As a result of the overlap, many samples are either rejected or wrongly classified and the cost of these models (Table 1) is high. For example, for *p*-DPLS$_2$, 51% of the samples in class ω_0 were rejected by CV and 27% were misclassified. On the other hand, the predictions from the models with four to six factors are grouped tighter together. Consequently, these models have fewer misclassifications, fewer rejections, and lower classification costs.

In terms of classification cost, the optimal model is *p*-DPLS$_5$ since no further improvement is obtained for the model of six factors. The PDFs for this model are presented in Fig. 4A and the *a posteriori* probabilities across the $\hat{y}$ domain are presented in Fig. 4B. The limits were found to be $\mathrm{LL}_0 = -0.43$ and $\mathrm{HL}_1 = 1.42$. Thus, samples with a predicted value $\hat{y}_i < -0.43$ or $\hat{y}_i > 1.42$ would be flagged as

Table 1
Classification of validation samples by leave-one-out cross-validation and test samples for the different p-DPLS models for $t = 0.25$. In brackets, classifications performed without considering the reject option.

Factors	Cost	Cross-validation samples					Test samples				
		Wrongly classified	Rejected	Correctly classified	Wrongly classified	Rejected	Correctly classified	Wrongly classified	Rejected	Correctly classified	Wrongly classified	Rejected	Correctly classified
		Samples of class ω_0			Samples of class ω_1			Samples of class ω_0			Samples of class ω_1

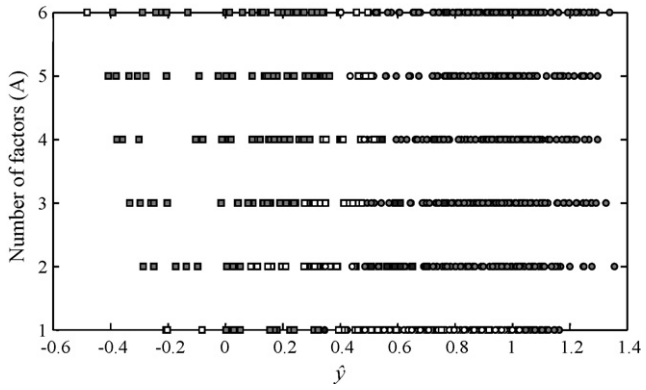

Fig. 3. Prediction of the training samples by CV for the different p-DPLS models with reject option. *Squares*: healthy samples (class ω_0). *Circles*: tumour samples (class ω_1). *Grey*: samples correctly classified. *White*: samples rejected. *Black*: samples wrongly classified.

outliers and rejected. These limits were different for each p-DPLS$_A$ model because the training sample predictions changed. According to the rejection criterion, eight samples (four from class ω_0 and four from class ω_1) were rejected, all of them in the ambiguity region (Table 1). As an example, the dot in Fig. 4 corresponds to the sample T_BRST_2 (tumour sample, class ω_1) during the leave-one-out process. The prediction is $\hat{y}_i = 0.44$ and the calculated *a posteriori* probabilities are $P(\omega_0|\hat{y}_i) = 0.59$ and $P(\omega_1|\hat{y}_i) = 0.41$ (Eqs. (6a) and (6b)). Since both probabilities are similar, the confidence (reliability) that the classification is correct is low because a slight shift in $\hat{y}_i$ due to measurement errors could have changed the assigned class. The application of the classic Bayes rule (Eq. (8)) would assign the sample to the class with the highest *a posteriori* probability, meaning that the sample would be wrongly classified into class ω_0. By allowing the reject option, defined here by Chow's rule (with $t = 0.25$), the sample was rejected and not classified because the highest *a posteriori* probability was below $1 - t$ (i.e. $\max(P(\omega_1|\hat{y}_i), P(\omega_0|\hat{y}_i)) < 0.75$). In this case, the reject option prevented us from classifying a tumour sample as a healthy sample, and the expert would be prompted to make more tests before the final diagnosis. It is interesting to note, as we indicated before, that the reject option's performance depends on the relative costs assigned to the classification results. Thus, by setting different costs, the threshold (and hence the number of samples rejected) will be tuned to meet the experimenter's needs.

For comparison, Table 1 shows in brackets the classification results when the classical Bayes rule is applied. For the model that best minimizes the cost, that is, p-DPLS$_5$, five samples were misclassified if the reject option was not applied, whereas only one sample was misclassified (a healthy sample) when the reject constraints were applied. Thus, this model's classification accuracy (i.e. the ratio of samples well classified and the number of samples classified) was improved from 97% (148/153) to 99% (144/148). Notice, however, that the reject option also rejected some samples that would otherwise be correctly classified: the number of samples well classified decreased from 148 to 144. This reduction in the number of well classified samples is the price to pay for safeguarding against errors, and follows the trend of the suggested costs of classifications, in which rejecting four samples was preferable to misclassifying one.

Different reject thresholds were tested by varying the classification costs (Table 2). When $\lambda_r = 0.10$, $\lambda_e = 1$ and $\lambda_c = 0$, the threshold was $t = 0.10$. As expected, the number of rejected samples increased because the cost of doing so decreased (i.e. we preferred to reject ten samples rather than classify one wrongly). However, the number of misclassified samples did not change, which means that the rule rejected samples that would have been correctly classi-

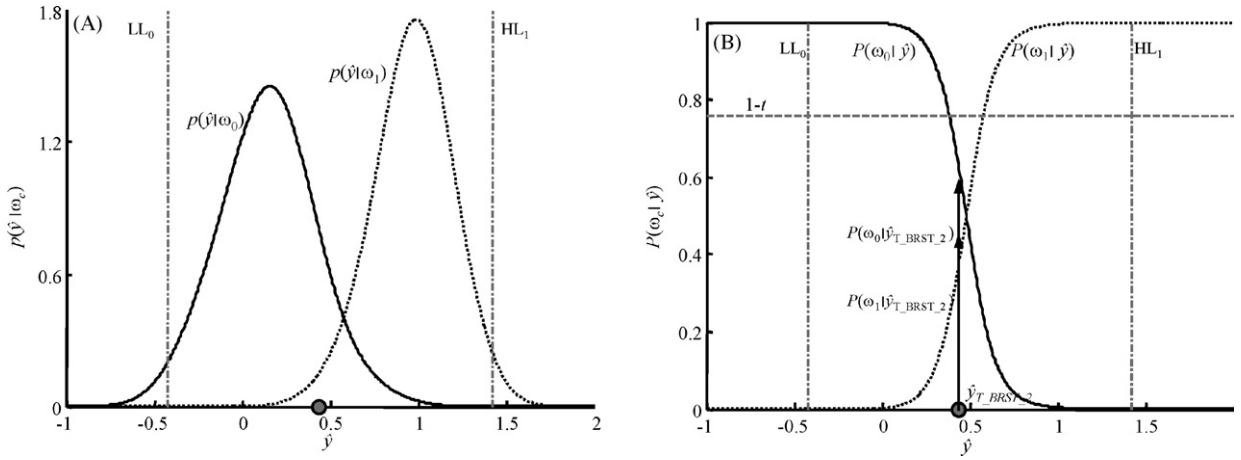

Fig. 4. (A) PDFs for the five factor *p*-DPLS model obtained from the training samples during the LOOCV process when T_BRST_2 is used as the validation sample. (B). *A posteriori* probabilities across the $\hat{y}$ domain (Eq. (6a) and (6b)) derived from the PDFs in (A). The prediction and the *a posteriori* probability for sample T_BRST_2 during the LOOCV process are also shown.

fied with $t = 0.25$. Thus, decreasing t to below 0.25 did not improve the model's classification performance for this dataset. On the other hand, when t was set to 0.35 (i.e. $\lambda_r = 0.35$, $\lambda_e = 1$, $\lambda_c = 0$), the results (not shown) were the same as those obtained for $t = 0.25$. Hence, $t = 0.25$ was considered optimal for this p-DPLS$_5$ model.

The samples of the test set were also classified according to Eq. (11). For the p-DPLS$_5$ model using $t = 0.25$, 100% of the samples were well classified and there were no rejects (Fig. 5 and Table 1). By setting the threshold to $t = 0.10$, two correctly classified healthy samples turned into rejects (Table 2). This was seen in the classification of the training samples above and highlights the need to set an adequate reject threshold in order to obtain an adequate trade-off between the rejects and the misclassifications. This will depend on the needs of the experimenter and the cost constraints in each particular application.

3.3. Breast cancer dataset

This dataset demonstrates the rejection of test samples that are outside the class limits. The same methodology as for the human cancers dataset was used except that the Kennard Stone algorithm was not applied. Instead, the samples of mutations BRCA1 and BRCA2 were used as a training set and the sporadic mutation samples were used as a test set. The aim was to show that the classification rule could reject prediction samples from non-modelled classes. This would prevent the classification error that would otherwise occur if the classifier had to assign the samples to one of the two modelled classes. Detecting this type of outlier is fundamental to the application of any classification rule.

Probabilistic DPLS models were calculated for one to three factors by using $\log_2$ mean-centred gene expression data from BRCA1 (class ω_0) and BRCA2 (class ω_1) mutation samples. This data consisted of the 51 most relevant gene expressions according to [38]. These genes were found to be the most discriminative between the three mutations. The costs of classifying correctly, rejecting and misclassifying were set at $\lambda_c = 0$, $\lambda_r = 0.25$, and $\lambda_e = 1$ respectively. The one factor p-DPLS model (p-DPLS$_1$) was the optimal model with the lowest cost (i.e. cost of 0.5). Models with two and three factors were overfitted, with costs of 2.5 and 3.25 respectively. These higher costs are due to the fact that most of the samples are rejected and, although there are no misclassifications, the classifiers become useless. For example, for the p-DPLS$_2$ model, 10 of the 15 training samples were rejected during LOOCV. Similarly, the p-DPLS$_3$ model rejected 13 of the training samples.

The p-DPLS$_1$ calculated with the 51 gene expressions selected in the bibliography was able to distinguish the samples of class ω_0 from those of class ω_1, thus providing well separated PDFs (Fig. 6). Only the sample *s1252_P2*, of class ω_0, and the sample *s1816_P13*, of class ω_1, were rejected during LOOCV. The predictions of both samples were outside the limits of the classes (i.e. $\hat{y}_{s1252_P2} > HL_0$ and $\hat{y}_{s1816_P13} > HL_1$). Notice that because the PDFs were not overlapped,

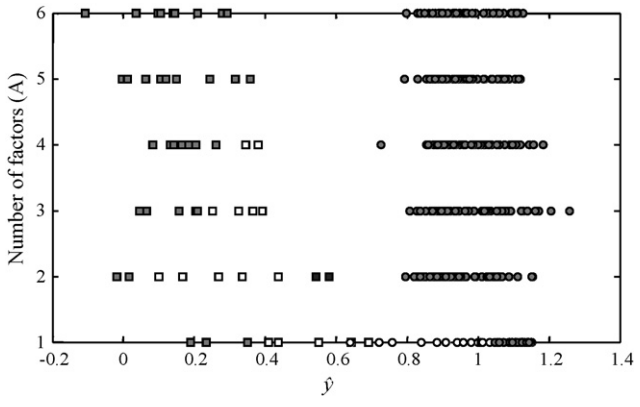

Fig. 5. Classification of test samples for the different *p*-DPLS models with reject option. *Squares*: healthy samples (class ω_0). *Circles*: tumour samples (class ω_1). *White*: correctly classified. *Grey*: rejected. *Black*: wrongly classified.

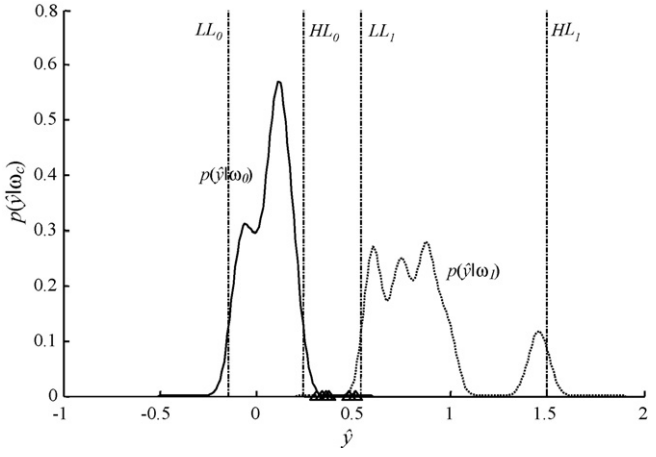

Fig. 6. PDFs for the one factor *p*-DPLS model. Limits on $LL_0 = -0.15$, $HL_0 = 0.24$, $LL_1 = 0.54$ and $HL_1 = 1.50$. *Triangles* represent the test samples classified with p-DPLS$_1$.

Table 2
Classification of validation samples via leave-one-out cross-validation and test samples for the different p-DPLS models for $t = 0.10$.

Factors	Cost	Cross-validation samples						Test samples					
		Wrongly classified	Rejected	Correctly classified	Wrongly classified	Rejected	Correctly classified	Wrongly classified	Rejected	Correctly classified	Wrongly classified	Rejected	Correctly classified
		Samples of class ω_0			Samples of class ω_1			Samples of class ω_0			Samples of class ω_1		
1	16.1	0	36	1	1	115	0	0	9	0	0	56	0
2	6.5	2	31	4	0	14	102	0	9	0	0	0	56
3	5.9	3	23	11	0	6	110	0	7	2	0	0	56
4	3.5	1	17	19	0	8	108	0	3	6	0	0	56
5	3.3	1	14	22	0	9	107	0	2	7	0	0	56
6	2.9	1	13	23	0	4	110	0	2	7	0	0	56

there was no ambiguity region and the limits of the classes were defined by four operative limits. The classification performance of the p-DPLS$_1$ did not change when the reject threshold was varied to $t = 0.35$ and 0.10.

The p-DPLS$_1$ model was used to classify the six test samples of sporadic mutation of breast cancer. This mutation was not modelled in the training step; hence, all these samples should be pointed as outliers and not classified. Classifying these samples in any of the two modelled classes would result in a classification error. Fig. 6 shows the PDFs (Eqs. (4) and (5)) of class ω_0 and class ω_1 for p-DPLS$_1$ together with the predictions for the test samples. According to Eq. (11), all test samples were correctly detected as outliers and rejected since their predictions $\hat{y}$ were between the limits HL$_0$ ($\hat{y} = 0.24$) and LL$_1$($\hat{y} = 0.54$). If the reject constraints had not been applied, the classifier would have assigned the test samples to the class with the highest *a posteriori* probability. In this case, the samples *s1572_P16* and *s1324_P17* would have been incorrectly classified into class ω_1 (i.e. as BRCA2 mutation samples) and the remaining samples (*s1649_P15*, *s1320_P18*, *s1542_P19* and *s1281_P21*) would have been incorrectly classified into class ω_0 (as BRCA1 mutation samples). For these samples, the *a posteriori* probability for one class was near 1. For example, sample *s1572_P16* had $p(\hat{y}_i|\omega_0) = 6 \times 10^{-6}$ and $p(\hat{y}_i|\omega_1) = 2 \times 10^{-3}$ which results in $P(\omega_0|\hat{y}_i) \approx 0$ and $P(\omega_1|\hat{y}_i) \approx 1$. Therefore, if it is believed that the *a posteriori* probability demonstrates the classification's reliability, then the high values of probability obtained for the test samples would suggest that we can trust the classifications, despite the fact that all of them were incorrect. This shows that the classic Bayes rule is unreliable when both conditional probabilities $p(\hat{y}_i|\omega_0)$ and $p(\hat{y}_i|\omega_1)$ are low. Moreover, it should be noted that the predicted values are not as extreme as those expected for outliers. Hence, these are not directly suspicious samples because of their $\hat{y}_i$ values. It was the reject option, which set limits on the classes, which allowed these samples to be detected.

4. Conclusions

Recently, the DPLS method has received much attention in the field of gene expression data analysis. We have applied a new version of DPLS, namely probabilistic DPLS (p-DPLS), to classify biological samples using their microRNA (miRNA) expression patterns and cDNA-microarray data. p-DPLS takes into account the uncertainty of the PLS predictions in the definition of the classification model. In this version, the possibility of rejection has been introduced. p-DPLS with reject option performs better than the original p-DPLS, because only those samples that have the highest probability of being correctly classified are indeed classified, whereas doubtful cases are rejected. The methodology involves evaluating the probability of each classification together with the overall cost of the classifications performed for each model. In addition, the reject option allows us to deal with situations in which the results of the Bayes rule may be questioned. Moreover, the classification rule with reject option can help the experimenter to check that a sample does not belong to any of the classes modelled in the training step and therefore to ensure that it is rejected rather than misclassified. Thus, the reject option enables the classifier to detect outliers, and this in turn provides a new approach for improving outlier detection methods in the near future.

ABSTRACT

In 2008, the first Proficiency Testing Scheme of Chemical Oxygen Demand (*1st COD-PT^{ADG}*) was conducted to assess the results obtained for different research groups whose field work is mainly anaerobic digestion. This study was performed using four samples, two solid samples as raw materials and two solid samples to prepare high concentration suspended solid solutions. Invitations were sent to a large number of laboratories, mainly to anaerobic digestion research groups. Finally, thirty labs from sixteen countries agreed to participate, but for different reasons four participants could not send any data. In total, twenty-six results were reported to the *COD-PT* coordinator.

This study showed the importance of continuous participation in proficiency testing (PT) schemes in order to compare the results obtained. Taking into account the lack of a general standard method and high quality certified reference materials (*CRMs*), the traceability of COD determination is not currently easy to check. In addition, the spread of participants' results obtained was high and pointed to the advisability of using consensus values due to their unreliability. Therefore, the theoretical oxygen demand (ThOD) values were considered as assigned values for all the samples analysed. On the other hand, in this PT the established standard deviation (*ESD*) has been determined by the Horwitz modified function.

Participants of this *1st COD-PT^{ADG}* were asked to give a short report on the analytical method used. Although all the participants used potassium dichromate as their oxidant reagent, their experimental procedures were very different. With the purpose of comparing the results obtained, the different experimental conditions used were classified into five methods, corresponding to two main categories, open and closed reflux. The performance of laboratories was expressed by the *z*-score, whose value is considered satisfactory when *z*-score $\leq \pm 2$. The overall analytical data evaluation showed that 64% of *z*-scores obtained were outside the accepted limits.

1. Introduction

There are a large number of laboratories that can measure the chemical oxygen demand (COD). COD is an empirical determination

used worldwide to find out the index of pollution of any aqueous sample, although it is also used to determine the organic content of solid substrates. For COD determinations, a wide range of chemicals has been used as oxidizing agents, including dichromate, permanganate, ceric acid, iodate and persulphate. The dichromate method is preferable to other methods using different oxidants because of its superior oxidizing ability, its applicability to a wide variety of samples and its easy manipulation. In the COD reference method, samples are oxidised by potassium dichromate in an acid sulphuric medium. Silver sulphate and mercury sulphate are added to catalyse the oxidation and to suppress the interference effects of chloride, respectively. The resulting mixture is refluxed for 2 h and the residual dichromate reagent is determined by titration with standardised ferrous ammonium sulphate or spectrophotometrically. The amount of dichromate reduced is expressed as COD in the form of milligrams of oxygen consumed per litre or gram of sample.

Proficiency testing (PT) is an essential element of laboratory quality assurance. The interlaboratory comparison of an external quality control test material allows individual laboratories to compare their analytical results with those from other laboratories whilst providing them with objective standards to perform with.

The performance evaluation of anaerobic digestion processes is based on chemical analysis measurements. Accurate and precise results are essential when monitoring anaerobic reactors because only reliable analytical results can serve as a basis for drawing meaningful conclusions about the situation of the biological process and thus avoid misinterpretation. However, the COD determination of samples typically from anaerobic reactors, as solid substrates and liquid samples with a high concentration of suspended solids, is currently in the following situation:

- no companies organise COD-PT schemes.
- no appropriate certified reference materials are available for this determination.
- no references of COD analytical methods are cited in the literature.
- the frequent use of the APHA-AWWA-WPCF standard methods [1] for COD determination of solid samples and high concentration suspended solids solutions by dilution of the sample, with the consequent inaccuracy in the final results obtained.

No previous interlaboratory studies are reported in the literature about the quality of COD measurements obtained in such types of samples. For this reason, a PT was organised. The aim of this *1st COD-PT* was to take some information from the results obtained for all participants, testing the different analytical methods used and comparing the results reported in order to check their day-to-day analytical performances and improve their quality. The objective of this PT was not the evaluation of participants by a general proficiency ranking. Therefore, the ranking of participants was totally rejected and not reported.

2. Organisation of proficiency testing scheme

This study is the first attempt of a COD worldwide interlaboratory comparison using solid samples and high concentration suspended solids solutions. The scheme was organised by the Spanish National Research Council (CSIC) through the Instituto de la Grasa, specifically by the Water and Wastewater Treatment group. The PT coordinator and collaborators were responsible for designing the scheme, the preparation and validation of test materials, the production and distribution of instructions and test materials to participating laboratories, the collection and statistical analysis of the data obtained from the PT and feedback of the results to the participants.

This PT was carried out according to the International Harmonised Protocol for the PT of Analytical Chemistry Laboratories [2]. The exercise took place from September 2008, when the samples were shipped to the laboratories for analysis, to the beginning of October 2008, when the last reports of the results were received. The deadline for the reporting of results was extended upon the request of eight participants so as not to exclude their results. Although initially, thirty groups from sixteen countries agreed to participate, finally four participants could not send any data: 1 lab never received the samples, 2 labs admitted to being unable to determine the samples and 1 lab gave no explanation. Finally, twenty-six results were reported to the *COD-PT* coordinator. Firstly, the individual lab reports, including the specific results of each participant, and secondly a draft general report with the whole results were sent to participants.

The determination of COD does not require great laboratory skills or highly selective and sensitive analytical techniques and procedures with difficult validation or accreditation by recognized bodies. Therefore, no information was required to participants about their accreditation status for COD parameter according to ISO/IEC 17025 [3], or their participation in previous PTs.

3. Materials and methods

3.1. Materials

3.1.1. Description of samples

All laboratories participating in the PT to assess the COD measurement quality were required to analyse four different samples. The samples were divided into two main groups; solids samples (SS) and high concentration suspended solid samples (HC3S).

Theoretical oxygen demand (mg O_2 g^{-1} TS)	988	1210	1239

3.1.1.1. Sample 1 (SS-1) – certified reference material (CRM). This sample is a sewage sludge provided by LGC Promochem as the certified reference material 055-050 (it included the certified values of 19 metals plus COD, Kjeldahl nitrogen and total phosphorus). This CRM was produced and certified by Resource Technology Corporation (USA and UK). The COD certified value was 771 ± 192 mg O_2 g^{-1} total solids (dry-weight basis). This value was rejected as the assigned value due to significant discrepancy with theoretical oxygen demand (ThOD) and disagreements with the data reported by the company organising the material-certification study.

3.1.1.2. Sample 2 (SS-2) – Quinoa (Qu). This substrate is a species of goosefoot (*Chenopodium quinoa*) grown as a crop primarily for its edible oil, but its leaves can also be used as food. Quinoa is also named Andean rice because it originates from the Andean region of South America where it had the greatest nutritional importance in pre-Columbian Andean civilizations. It is a pseudo-cereal rather than a true cereal as it is not a grass.

3.1.1.3. Samples 3 and 4 (HC3S-1 and HC3S-2) – sunflower oil cake (SuOC). SuOC is a by-product made up of what remains after the oil extraction processes of whole sunflower seeds. It is a heterogeneous substrate that can be broken down into three main components: a proteinaceous fraction, a lignocellulosic fraction and a soluble fraction.

Table 2
Homogeneity of solid substrates—summary of statistical parameters obtained.

Sample	Test	Experimental value	Critical value	Result
(*CRM*)	Cochran	0.31833	0.5410	Pass

	Homogeneity	0.00014	0.00021	Pass

3.1.2. Preparation of samples

To ensure that identical samples were analysed for all participating laboratories, the preparation of samples is a fundamental and critical step of the PT scheme.

The commercially available *CRM* was re-bottled and re-labelled without further manipulation, and could be analysed as raw material. The two remaining substrates were sieved prior to subsampling in order to keep only the particles of desired size and, consequently, to avoid the lack of uniformity in the samples tested.

Samples 3 and 4 were two spiked suspensions with different substrate concentration levels of. These samples required in-lab

Table 3
Summary of participants' analytical procedures.

Lab	Method	Digestion reagent		Acid reagent			$HgSO_4$	Water	End-point

suspension immediately before analysis, by adding 200 mL of distilled water to the exact weight of substrate previously packaged, specifically 4 and 10 g of total solids (dry-weight basis), respectively. Additionally, in order to avoid variability in the preparation, all participants were advised to stir the samples (1 h) before analysis and during the sampling procedure.

3.1.3. Characterisation of samples

General characterisations of the different substrates selected for this PT were carried out. The substrates were analysed in triplicate, including moisture, chemical composition, elemental analysis and theoretical oxygen demand. Table 1 presents the results obtained.

3.1.4. Homogeneity of samples

Testing the homogeneity of samples is time-consuming and expensive, but the significance of sample homogeneity is very important for the effectiveness of the PT scheme. Therefore, the samples were tested for sufficient homogeneity by the COD-PT coordinator immediately after packaging the samples, using the standard analytical method developed in this lab and used on a routine basis. To check for sufficient homogeneity the protocol devised by Fearn and Thompson [6] was used. Following the author's approach, three tests were carried out to estimate the corresponding experimental statistical parameters and compared with their theoretical critical values: (i) Cochran's test procedure for duplicate results or the detection of outliers by differences between pairs; (ii) precision of the analytical method used; (iii) homogeneity test or test for acceptable between-sample variance.

For this purpose, the duplicated results for 12 distribution units of solid substrates were randomly selected to analyse the COD and values were statistically evaluated. Results obtained in the statistical analysis of homogeneity data are summarized in Table 2, which shows that substrates selected were homogeneous enough to be used in this PT.

3.2. Methods

3.2.1. Analytical methods

3.2.1.1. Chemical oxygen demand. The participating laboratories were free to choose the analytical method that they consider appropriate to perform the COD analysis, but were advised to analyse samples using their usual techniques. Each participant was required to include detailed information about the methodology used. A summary with all the experimental conditions of the analytical methods used are compiled in Table 3.

All participants of this PT have used the standard procedure that uses potassium dichromate as the oxidizing agent. However, there are some experimental conditions that define specifically the

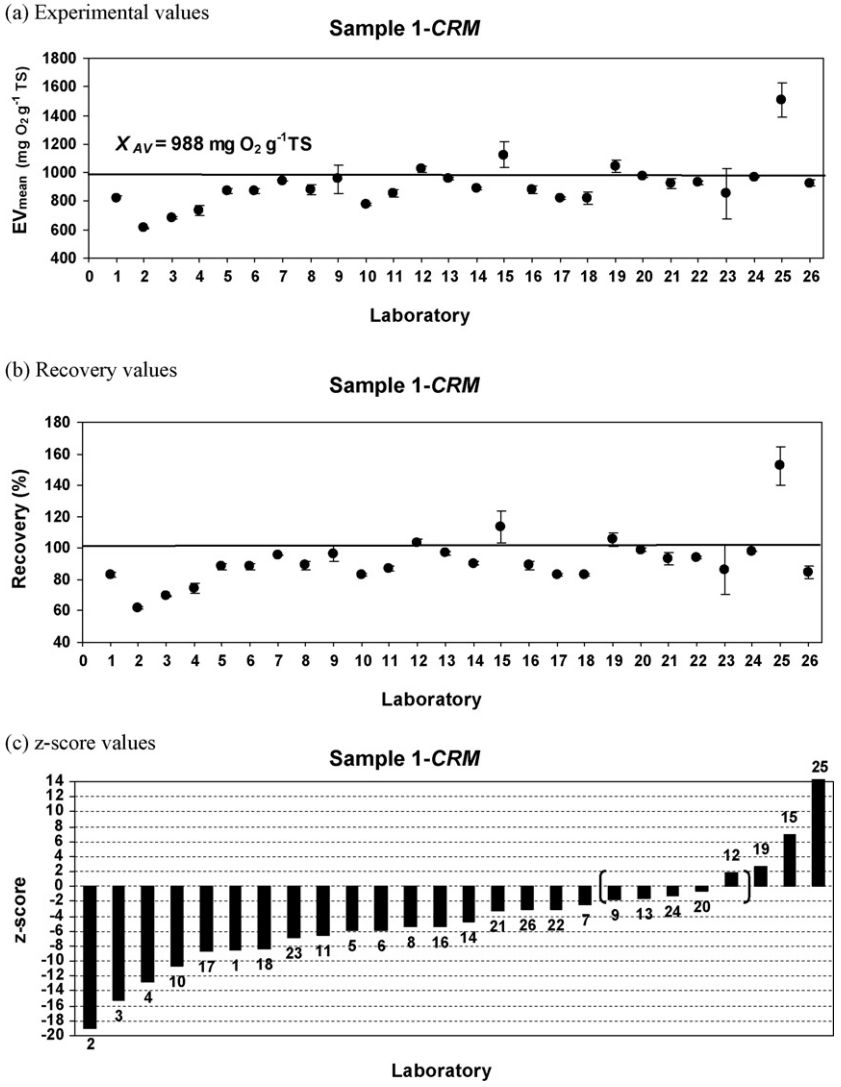

Fig. 1. Participants' results of sample 1 (*CRM*). (a) Experimental values. (b) Recovery values. (c) *z*-Score values.

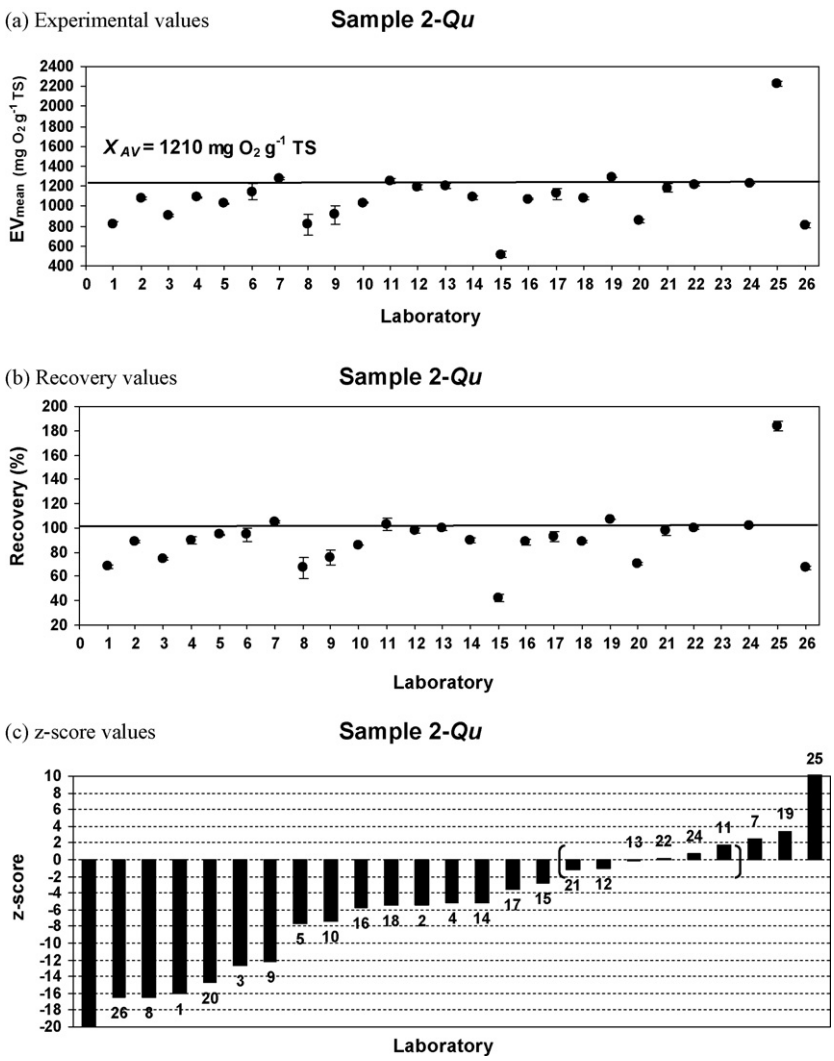

Fig. 2. Participants' results of sample 2 (*Qu*). (a) Experimental values. (b) Recovery values. (c) *z*-Score values.

method used: (i) volume and concentration of oxidant reagent; (ii) volume and concentration of the mixture H_2SO_4–Ag_2SO_4 reagent; (iii) volume of water/sample used; (iv) use of $HgSO_4$; (v) visualisation of end-point redox system by titration (total or partial) or spectrophotometrically; (vi) the reflux system. With the purpose of comparing the results obtained, the thirty-two variants of the standard procedure reported to determine this parameter have been classified, firstly in two main groups and secondly in five methods:

I. Open reflux (*OR*)
(1) *OR-LCM.* Low concentration of $K_2Cr_2O_7$ ($N < 1$)
(2) *OR-HCM.* High Concentration of $K_2Cr_2O_7$ ($N \geq 1$)
II. Closed reflux (*CR*)
(3) *CR-TM.* End-point by titration
(4) *CR-SM.* End-point by spectrophotometric determination
(5) *CR-KM.* Kits

Samples 1 and 2 were analysed in duplicate, whilst samples 3 and 4 in triplicate. The results must be reported on a dry-weight basis. The percentages of each method used were as follows: *OR-LCM* (38%), *OR-HCM* (25%), *CR-TM* (6%), *CR-SM* (19%) and *CR-KM* (12%). An interesting point is that although the *OR-LCM* was the main method used, any of twelve experimental conditions reported were repeated by the participating labs. On the other hand, the eight experimental conditions of *OR-HCM* were very similar, only five of which used different volumes of water added and two were exactly the same (labs 13 and 24). The experimental conditions followed in *CR-TM* and *CR-SM* were also very similar (only lab 20 reported a different method). Finally, two commercial kit brands (Hach and Merck) were used to apply the *CR-KM.*

3.2.1.2. Other parameters. Moisture was obtained by dryness at 105 °C and organic content by calcination at 550 °C [1]. Fat was determined by extraction with hexane using a soxhlet system. Protein and elemental composition was analysed by LECO CHNS-932 elemental analyzer, using sulphametazine as standard substrate. Fibre content was obtained using the method reported by Lee et al. [4]. Carbohydrates content was reported by subtraction of fat, protein and fibre contents. Theoretical oxygen demand was calculated according to ISO 10707 [5].

3.2.2. Data treatment

All results from the participating laboratories were considered. No randomization tests for quantitative results, such as Grubb's or Cochran's tests, were performed for the detection of possible outliers. Robust statistics have been applied to the estimation of average values and standard deviations from data reported.

The performance of each individual participating laboratory was assessed by the internationally accepted *z*-score. A participant's

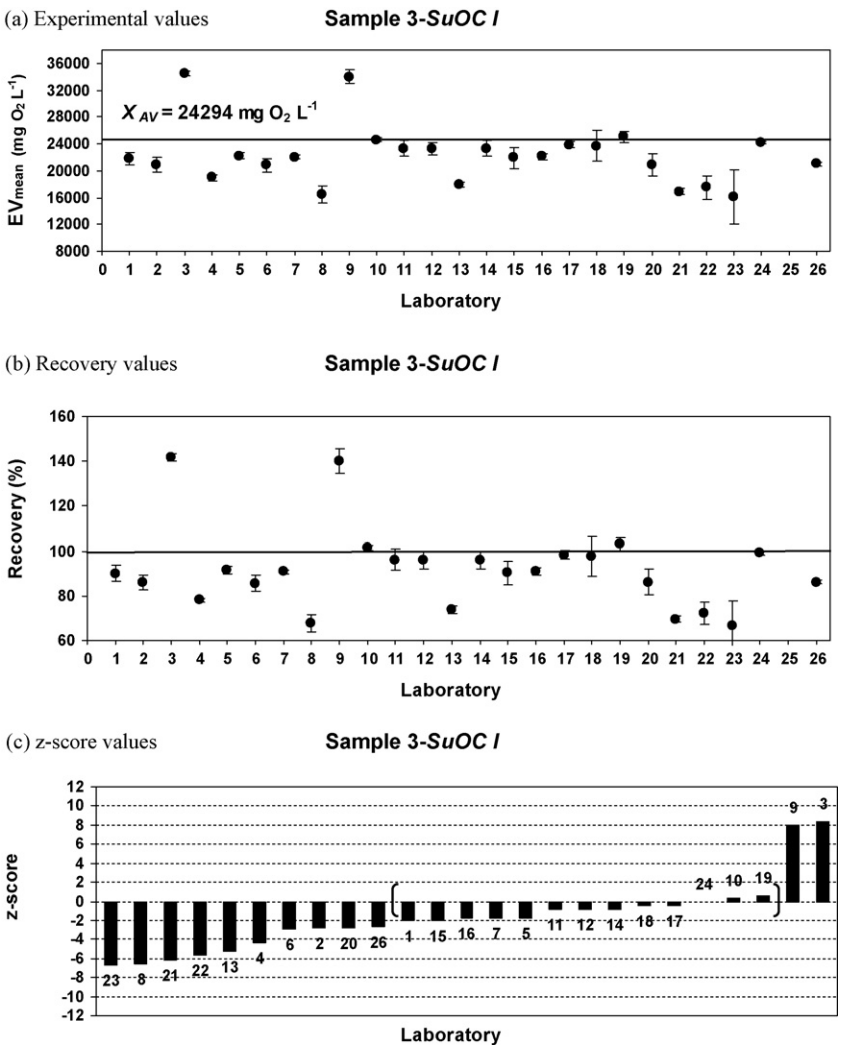

Fig. 3. Participants' results of sample 3 (*SuOC I*). (a) Experimental values. (b) Recovery values. (c) *z*-Score values.

result is converted into a *z*-score according to the following equation:

$$z\text{-score} = \frac{(X_{EV} - X_{AV})}{ESD}$$

where X_{EV} is the laboratory experimental value, X_{AV} is the assigned value (estimation of the true value of the measurand that is used for the purpose of calculating scores), and *ESD* is the fitness for purpose-based "established standard deviation for proficiency assessment", defined as a target value for the acceptable deviation from the assigned value. It means that the *z*-score compares the participant's deviation from the reference value with *ESD*.

The *z*-score values can be used for assessing the acceptability of the results reported according to the following generally accepted limits:

- *z*-score = 0 (rarely happens). Perfect result.
- *z*-score $\leq \pm 2$ (95%). Satisfactory or acceptable result. No action is required.
- $\pm 2 <$ *z*-score $\leq \pm 3$ (5%). Questionable or doubtful result. Preventive action is required.
- *z*-score $> \pm 3$ (unusual). Unsatisfactory or unacceptable result. Corrective action is required.

In this PT, the X_{EV} value was the mean value for each sample, independently of the analytical method used. The X_{AV} and *ESD* values were assigned as follows:

3.2.2.1. Establishing the assigned value (X_{AV}). There are various procedures available for establishing the assigned values. The most common are listed as follows: (i) known values; (ii) certified reference values; (iii) reference values; (iv) consensus values from expert laboratories; (v) consensus values from participating labs.

Taking into account the lack of a general standard method and high quality CRMs, the traceability of the COD determination is not currently easy to check. In addition, the spread of participants' results obtained was high and pointed to the advisability of using consensus values due to their unreliability. Therefore, the assigned values in this PT cannot be obtained for any of the earlier procedures described. With this situation in mind, a useful alternative, previously reported by Raposo et al. [7], was to consider the ThOD values as assigned values. The X_{AV} for samples 1 and 2 were 988 and 1210 mg O_2 g^{-1} TS, respectively. For liquid samples (samples 3 and 4) which were prepared gravimetrically (which required correction for the solid substrate volume occupied), were 24 294 and 59 855 mg O_2 L^{-1}, respectively.

3.2.2.2. Setting the established standard deviation (ESD). This parameter was previously defined as a target value for the acceptable deviation from the assigned value. It is determined in advance by the PT organisation in order to describe their notion of fitness for purpose; it does not depend in any way on the results obtained by the participants.

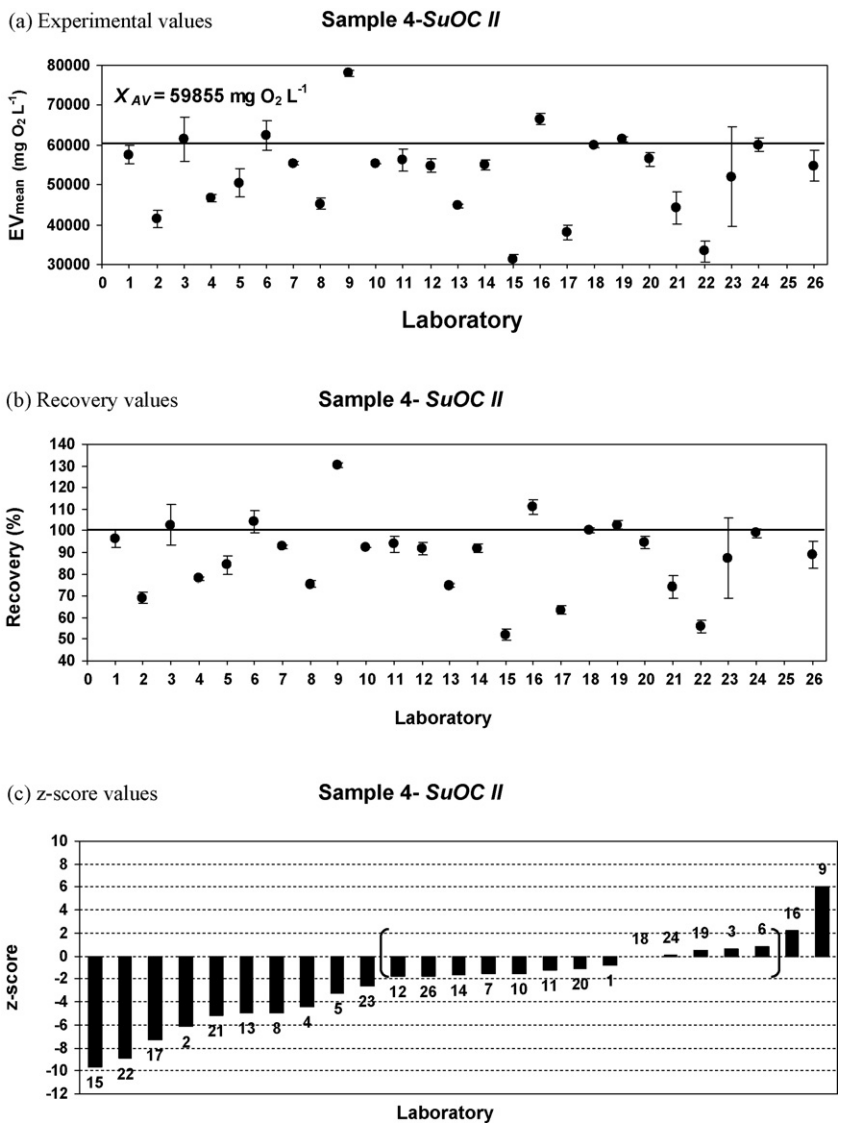

Fig. 4. Participants' results of sample 4 (*SuOC II*). (a) Experimental values. (b) Recovery values. (c) *z*-Score values.

In this PT, the *ESDs* have been determined as suggested by Thomson [8] by the Horwitz modified function, a useful generalisation about the reproducibility standard deviation expected in a collaborative trial. This equation predicts a standard deviation from a given concentration level of analyte, and requires the expression of this amount as a dimensionless mass ratio (e.g. 1 ppm = 10^{-6}, 1% = 10^{-2}).

In this PT, the theoretical *ESDs* for SS and HC3S obtained were 1% and 4%, respectively. In order to avoid a larger number of *z*-scores >± 2, the experimental values used for performance calculation were slightly increased for SS and HC3S up to 2.5% and 5%, respectively.

4. Results and discussion

4.1. Individuals results

Participants' results are summarized in graph form (Figs. 1–4) by a set of three figures for each sample analysed, including experimental values, recoveries and *z*-scores. In general, the repeatability of duplicate or within-laboratory variability expressed by repeatability relative standard deviation (RSD_r) was good. In the present PT, only 1–2 labs reported values of RSDr higher than 10% for each sample analysed.

4.2. Evaluation of results obtained for different analytical methods

To evaluate and compare the participants' results reported for different analytical methods, all the data have been summarized in Table 4. In order to compare the results obtained for samples analysed, firstly the data has been detailed by specific analytical method and secondly grouped in two main categories, open reflux methods (*OR-M*) and closed reflux methods (*CR-M*).

At first sight, it can be seen that averages values are not too bad, but closer inspection of the data using the *z*-scores reveals that most of the results obtained can be considered as unacceptable.

4.2.1. Comparison of averages values

No major differences among the methods used in this PT were observed during the evaluation of average values. Based on the results reported, it can be stated that the individual performance of participants was not good. Compared with assigned values, the mean values obtained were always lower. The underestimation of samples analysed might be related to negative bias in the analytical methods used. Therefore, only few labs reported positive recoveries compared to a general trend of numerous negative recoveries. In addition, some of the positive recoveries were obtained after

Table 4

	Total	26	100	52903	10553	20	88	13	50	2	8	11	42

processing potential outliers. The general values of recovery were very similar and ranged from 88% to 92%, which is too low. On the other hand, the reproducibility of between-laboratory variability, expressed by reproducibility relative standard deviation (RSD_R), showed an extremely high variation. The precision obtained in 3 out of 4 samples analysed was low and very similar (18–20%), whilst the largest substrate (sample 2) gave a higher total value (27%), achieving up to 53% for *CR-SM*.

Sample 1 (*CRM*): The total average value was 910 ± 163 mg O_2 g^{-1} TS, with an RSD_R of 18% and a recovery of 92%. The accuracy of *OR-M* was lower than *CR-M*, mainly due to the compensatory effect of the data reported by lab 25, which could be considered as clear outlier. The precision of both groups of methods was very similar, being slightly better for *OR-M* (14% versus 20%).Considering only the results of *OR-M*, the accuracy and precision of *OR-HCM* (91–12%) were slightly better than *OR-LCM* (84–15%).

Sample 2 (*Qu*): The total average value was 1097 ± 298 mg O_2 g^{-1} TS, with an RSD_R of 27% and a recovery of 91%. The accuracy of *OR-M* (94%) was higher than *CR-M* (85%). In addition, the precision of *OR-M* (9%) was better than *CR-M* (48%). The results can be attributed to the difficulties found in sampling when a substrate with no powder form was analysed.Considering only the results of *OR-M*, the accuracy (96% versus 92%) was slightly better for *OR-HCM* as was the precision (6% versus 11%) for *OR-LCM*.

Sample 3 (*SuOC I*): The total average value was $22\,301 \pm 4428$ mg O_2 g^{-1} TS, with an RSD_R of 18% and a recovery of 92%. The accuracy of both groups of methods was very similar, although the influence of two potential outliers (labs 3 and 9) in the average values of *CR-M* must be mentioned. The precision was also better in the *OR-M*, nearly three times less than *CR-M* (11% versus 28%). The comparative study of the *OR-M* did not show any significant difference.

Sample 4 (*SuOC II*): The total average value was $52\,903 \pm 10\,553$ mg O_2 g^{-1} TS, with an RSD_R of 20% and a recovery of 88%. The accuracy of *OR-M* was slightly lower than *CR-M* (85% versus 92%), due to low values of *OR-LCM* (83%) compared with *OR-HCM* (92%) and also to the influence of some potential outliers.

4.2.2. Comparison of z-score values

The statistical parameter used to measure the COD performance was the *z*-score. The general trend of data obtained showed a few positive *z*-scores compared to the numerous negative *z*-scores. Moreover, some labs obtained *z*-scores excessively out of range, with values ranging between −30 and +40. The data of this PT show that overall there is a clear difference between the methods, with *CR-M* normally providing worse results than *OR-M*, whilst *OR-HCM* usually provides better results than *OR-LCM*. The cause of these results could be attributed to the amount of sample taken for each analytical method, so it should be ensured that test samples (portion or aliquot) are representative of the laboratory sample. For solid

samples, the amount ranged between 100–200 mg, 30–50 mg and 4–6 mg for *OR-HCM*, *OR-LCM* and *CR-M,* respectively. At the same time, for liquid samples *OR-HCM* uses a volume of 1–10 mL directly whilst *OR-LCM* and *CR-M* use a previous dilution of the sample.

Sample 1 (*CRM*): This sample presented the worst results, with only 5 labs (19%) reporting satisfactory results, 2 labs (8%) questionable results and 19 labs (73%) unsatisfactory results. Nevertheless, no differences between either group of methods were found.
Sample 2 (*Qu*): The results were similar to earlier samples, with 6 labs (23%) reporting satisfactory results, 2 labs (8%) questionable results and 18 labs (69%) unsatisfactory results. This sample showed differences between the groups of method used; the acceptable results of *OR-M* against *CR-M* were 31% and 10%, whilst unacceptable results were 56% and 90%, respectively. The possible influence of substrate size again was reflected in the results obtained.
Sample 3 (*SuOC I*): According to the *z*-score approach, 13 labs (50%) reported acceptable results, 3 labs (12%) doubtful results and 10 labs (38%) unacceptable results. Once again, differences between O*R-M* and C*R-M* were appreciated, with the percentages for acceptable results being 64% as against 33% and unacceptable results being 29% as against 50%.
Sample 4 (*SuOC II*): Considering the *z*-score for this sample, 13 labs (50%) reported satisfactory results, 2 labs (8%) questionable results and 11 labs (42%) unsatisfactory results. The results obtained comparing both groups of methods were not like the earlier sample, although *OR-M* reflected better satisfactory results than *CR-M* (57% against 42%).

To outline the results obtained in this PT the substrates analysed were firstly divided into two main categories, as solid and liquid samples, and finally grouped as total samples:

Solid samples: 11 *z*-scores (21%) were satisfactory, 4 (8%) doubtful and 37 (71%) unacceptable. Only 3 labs (12, 13 and 24), which represents 12% of participants, reported good values for both samples. All of them used *OR-M.* Special attention should be brought to the situation of labs 13 and 24 – they used the same method and reported in agreement with expected values.
Liquid samples: 26 *z*-scores (50%) were satisfactory, 5 (10%) doubtful and 21 (40%) unacceptable. For this type of samples, 9 labs (1, 7, 10, 11, 12, 14, 18, 19 and 24), which represents 35% of participants, reported good values for both samples. The methods used were *OR-LCM* (4 of 9), *OR-HCM* (3 of 9) and *OR-SM* (2 of 9).
Total samples: 37 *z*-scores (36%) were satisfactory, 9 (9%) doubtful and 58 (55%) unacceptable. In summary, the present PT revealed that about two thirds of results reported did not agree with the expected values. Only 2 labs (12 and 24), which represents 8% of participants, reported the four samples adequately.

5. Conclusions

In order to assess the results obtained for the performance of laboratories determining the COD of solid substrates and liquid samples with high suspended solid content, a PT scheme was organised. The interest in this PT was very high taking into consideration the numbers of labs participating. In addition, the results were representative of sixteen countries, reflecting the current situation in the analytical laboratories COD performances, mainly related to anaerobic research groups.

The present study demonstrates the current lack of uniformity in the analytical methods used to determine the COD of solid samples and liquid samples with high concentration of suspended solids. On the other hand, the PT allowed the study of some variables that can influence COD determination, such as the clear influence of substrate size. Furthermore, the study of the suspended solid concentration influence shows that bias was not concentration-dependant, and therefore it was totally rejected as a reason for obtaining unsatisfactory results.

Results from PT performance using the *z*-score indicated that only 36% of the results (from a total of 104 reported results) were satisfactory, with 9% doubtful and 55% unacceptable. This suggests that the majority of participating laboratories obtained inappropriate performances. Specifically, only two out of twenty-six participants reported a full set of acceptable *z*-scores.

Potentials reasons for achieving unsatisfactory results might be:

- Lack of experience with this type of samples.
- Sampling procedures. The analysis should be undertaken on homogeneous sub-samples. It should be ensured that test samples (portions or aliquots) are representative of the laboratory sample.
- Additional calculation errors. Only moisture content could be considered when correcting the results obtained. In fact, one lab stated the fault in moisture content determination as the cause of the unsatisfactory results obtained.
- The application of improper analytical methods. The detailed study of labs performance for the type of samples used in this PT showed that in general C*R-M* provides worse results than *OR-M*, whilst *OR-HCM* usually provides better results than *OR-LCM*. This fact could not be demonstrated without the participating in a PT, because the substrates (potassium hydrogen phthalate, glucose and cellulose) used as standard for COD determination are easily oxidizable compounds. For this reason, the oxidation of these substances is complete even in the absence of a catalyst, achieving recoveries close to 100% [9]. In this way, all the experimental conditions reported by participants obtained excellent standard's recoveries. To sum up, the laboratory internal quality control procedure failed because these standard substrates are poorly matched to the test material analysed.

Finally, the interlaboratory study showed the importance of a PT as an additional way to verify that all aspects of the laboratory measurement system are reliable in order to guarantee the production of analytical data of adequate quality.

Acknowledgements

The participating research groups are acknowledged for their contribution in running this *1st COD-PT^{ADG}* and their interest in its overall objectives. All the individual analysts are acknowledged to contribute with their work in the results obtained.

Enzyme-linked immuno-sorbent assay (ELISA)
Immunosensor
Optical fiber immunosensor (OFIS)
Silane coupling agent (SCA)

ABSTRACT

Immunosensors are powerful analytical tools in clinical and veterinary diagnostics. This has led us to design a chemiluminescent immunosensor aimed at identifying anti-*Brucella* antibodies using optical fibers as the transducer. In order to develop the optimal transducer, to achieve an optimal chemical modification thereby allowing an optimal covalent binding of the protein receptor, several cleaning strategies and silane coupling agents were investigated. *Brucella* killed organisms were used as a model receptor for quantifying anti-*Brucella* IgG antibodies in a suspension compared to conventional colorimetric and chemiluminescent ELISA. A silane–benzophenone derivative was selected as the best performing silane coupling agent: the optical fiber immunosensor (OFIS) has showed the lowest limit of detection at 0.207 μg/ml, compared to 0.828 μg/ml and 0.414 μg/ml achieved by colorimetric and chemiluminescent ELISAs, respectively. These results, together with the additional advantages of rapidity, lower reagent volumes and moderate operating conditions, have set the grounds for further study in order to adapt this platform for on-site diagnostics of brucellosis disease markers.

1. Introduction

The selective recognition between an elicited antibody and its specific antigen is the basis of a humoral immune response. Based on this principle, immunosensors have been designed by measuring the analyte binding to its corresponding immobilized biospecific recognition entity on the surface of a transducer and ensuring a signal obtained by this recognition given as a measured value. Immunosensors are being exploited in recent years for clinical diagnosis and environmental monitoring [1–3].

One such technology is based on optical fibers [4] which are ideal transducers governed by Snell's law. Fiber optics have many advantages reviewed before [5], including: (1) high efficiency in the blue region that is ideal for chemiluminescence [6], (2) their silica composite enables macromolecular conjugation via silanization [7], and (3) as an optrode system, they are polyvalent and can be easily adapted to different biorecognition systems, especially for the detection of antibodies [8–12], antigens [13], nucleic acids and toxins [14,15] with high sensitivity and specificity.

However, one of the greatest challenges in the field of immunosensors, and in particular when the transducer is an optical fiber, is the covalent immobilization of the receptor molecule to the solid phase transducer. One of the most common methods used to immobilize molecules on the transducer's surface is achieved by silanization with a silane coupling agent (SCA), [17], a bi-functional silane with the general structure [Y–$(CH_2)_n$–Si–X_3]. Y stands for the tail functional group that will further bind to the protein receptor and X stands for the head hydrolysable group, usually an alkoxy or a chloro, used in the covalent binding of the silane to the glass surface after physisorption, hydrolysis, formation of siloxane bonds and cross linking, or curing, between neighboring alkyl chains [7,16]. Compared to adsorption or entrapment, silanization suffers from fewer problems of leakage and diffuse controlled reaction [18,19]. Further, it allows for robust, covalent, stable and durable attachment of a proteinaceous receptor [20].

In order to compare the different chemical modification methods of the optical fiber and suitability of the modified fibers to serve as a platform for a chemiluminescent optical fiber immunosensor (CL-OFIS), a model analyte anti-*B. melitensis* IgG antibody immunosensor for was used.

Brucellosis was selected as a useful model of interest to many end-users because it is a worldwide bacterial zoonotic disease caused by the genus *Brucella* [21], and is considered to be a

doi:10.1016/j.talanta.2009.06.070

re-emerging problem in several countries of the Middle East, Africa, the Far East and Central and South America [22–24]. As a highly contagious and costly disease, with putative bioterror potential [25], rapid and accurate diagnosis of brucellosis is important.

The gold test that confirms brucellosis is bacterial isolation of the strain from suspected samples. However, the diagnosis succeeds in only 50–90% of the cases due to the low persistent number of cells in some of the infected materials, the intracellular localization of the organisms in the host and, and sometimes *Brucella* exhibits a slow or fastidious growth [26,27]. Serodiagnosis of IgM and IgG antibodies is a common diagnostic approach and indirect enzyme-linked immuno-sorbent assays (i-ELISA) have become a preferred method that allows mass surveillance of the population without loosing the sensitivity and specificity required for an accurate diagnosis [28–31].

We report the comparison of several types of SCA-modified optical fiber surfaces and the development of a prototype CL-OFIS for the detection of anti-*Brucella* IgG antibodies. The performances of the OFIS, as well as its ability to serve as a future analytical tool, were superior to conventional colorimetric and CL-ELISA using the same immunological rationale.

2. Experimental

2.1. Chemicals and biochemicals

2.1.1. Commercial chemicals

Allylbromide (A29585), potassium carbonate (P1472), sodium sulphate anhydrous (71962), triethylamine (T0886), sodium cyanoborohydride (71435), sodium m-periodate (S1878), sodium phosphate (S9390), potassium phosphate (P0662), potassium chloride (P9333), glycine (241261), chromium (VI) oxide (27081), 4-hydrozybenzophenone (54800), dichloromethylsilane (440248), (3-mercaptopropyl)trimethoxysilane (MPTS) (A1521), (3-aminopropyl)trimethoxysilane (AMPTS) (181778), (3-glycidyloxypropyl)trimethoxysilane (GOPS) (440167), (T0886), 3,3′,5,5′-tetramethylbenzidine (TMB) (T0440), skim milk powder (SM) (70166), 6-maleimidohexanoic acid *N*-hydroxysuccinimide ester (EMCS) (M9794), 30% (v/v) hydrogen peroxide solution (H1009), 50% (v/v) gluteraldehyde solution (G7651), polyoxyethylene-sorbitan monolaurate (Tween® 20) (P7949), dimethyl sulfoxide (DMSO) (41650) and rabbit anti-bovine IgG HRP conjugated (A5295) and all other chemicals were purchased from Sigma.

Luminescence measurements were carried out using the Western Blot Chemiluminescence Reagent kit (Immuno-star-HRP™) from BIO-RAD Laboratories (170-5040).

2.1.2. Synthesis of 4-(3′-dichloromethylsilyl)propyloxybenzophenone (DCBZS)

Silane–benzophenone derivative was synthesized in a two-step process as described before [32]. The first step, synthesis of 4-allyloxybenzophenone, had 65% yield. The second step, synthesis of 4-(3′-dichloromethylsilyl)propyloxybenzophenone (DCBZS), had a 72% yield (see supplemental information section 1 (SI.1)).

2.2. Preparation of the Brucella antigen solution

B. abortus strain B1119 (a strain used in antigen production for serological tests) and *B. melitensis* strain Huddleson (a laboratory strain) were provided by the Israeli National Brucellosis Center, also serving as an OIE Reference Laboratory, Kimron Veterinary Institute, Bet Dagan, Israel. The *Brucella* strains stored as a freeze-dried culture as part of the national collection were reconstituted in water, propagated in tryptic soy agar (TSA) enriched with serum-dextrose (1% and 5% (v/v), respectively), and incubated at 37 °C in atmospheric air containing 5% CO_2 (v/v) till growth to a logarithmic phase [33]. Bacteria were then harvested in saline and the bacterial suspensions at concentration of 10^8 bacteria/ml were heat-killed at 70 °C in 0.5% (v/v) phenol–saline solution.

2.3. Preparation of bovine anti-Brucella IgG serum

A large volume of anti-*B. melitensis* biovar 1 bulk serum was collected from a *B. melitensis* biovar 1 infected cow on August 15, 1990. Serum was frozen at −20 °C until IgG purification. The IgGs were purified from the bulk sera by Dr. Gil Korner, Kamada, Kiryat Weizmann, Rehovot 76327, Israel, using an industrial pipeline, and eluted from the column by 0.3 M glycine solution. The purification grade was determined by HPLC as 99.8% and the protein concentration was determined to be 21.2 mg/ml. The presence of anti-*Brucella* antibodies in the original serum sample and the purified IgG fraction was confirmed by serological tests that were carried out in the National Reference Laboratory for Brucellosis. The original serum was positive by rose bengal test (RBT) and produced 1:640 and 1:320 positive titers by plate-micro-agglutination test (MAT) and complement fixation test (CFT), respectively. The purified fraction produced MAT titers of 1:640 and 1:40 using *B. melitensis* strain Huddleson and *B. abortus* strain 1119 antigens, respectively. The IgG fraction was positive by fluorescence polarization assay using Diachemix Sentry 100 reader and Brucella O-polysaccharide fluorescing tracer.

2.4. Detection of anti-Brucella IgG antibodies by i-ELISA and CL-ELISA

An indirect ELISA (i-ELISA) was performed using the same rationale as described before with some modifications (Fig. 1E) [30,34] and after selecting the optimal reagents and concentrations (data not shown). 100 μl volume of a 1:1 (v/v) mixture of the *B. abortus* and *B. melitensis* antigens, diluted 1:20 (v/v) in phosphate buffer saline (PBS) (80 g l^{-1} NaCl, 5 g l^{-1} Na_2HPO_4 11.2 g l^{-1} KCl and 2 g l^{-1} KH_2PO_4 adjusted to pH 7.2 with NaOH/HCl), was added into each well of a 96-well microtiter plate (MaxiSorp, Nunc). The plate was sealed to avoid evaporation and a coating of *Brucella* cells was allowed to take place overnight at 4 °C. After the incubation, the coating buffer was decanted and the plate was blocked by adding 100 μl/well of blocking solution, 5% (w/v) SM–0.1% (v/v) PBS-Tween (PBST) (pH 7.2). A blocking step was allowed for 1 h at 37 °C in order to reduce the overall background and to increase the sensitivity of the assay. Following blocking, the wells were washed thrice with PBST. Then, 50 μl/well of milk samples that included serum dilutions ranging from 10^{-1} to 10^{-7} or milk as negative control were added in triplicates and the plate was incubated for 1 h at 37 °C. The wells were then washed thrice with PBST and 50 μl/well of the rabbit anti-bovine IgG HRP conjugated antibodies diluted 1:10,000 (v/v) in 1% (w/v) SM–PBST were added and the plate incubated at 37 °C for 1 h. After incubation, the plate was prepared for reading by washing the wells thrice with PBST.

Colorimetric i-ELISA measurements were accomplished by adding a volume of 100 μl of chromagen (TMB) into each well and the plate was incubated at room temperature for 30 min in the dark. Then, 50 μl/well of 2N H_2SO_4 were added and the absorbance at 450 nm was determined with the Labsystems Multiscan RC ELISA reader after 10 s shaking. The data was collected by using the Labsystems Transmit software and the mean and the standard deviation of the triplicates were calculated for each point.

Chemiluminescence i-ELISA measurements were accomplished by adding oxidizing reagent and enhanced luminol reagent solutions into each well in a 1:1 ratio before each measurement. A total

of 20 measurements were performed with a gap of 1 s between each reading. The data were collected with the Luminoskan Ascent Software, the mean and the standard deviation of each triplicate were calculated and the signal reported in RLU (relative light units).

2.5. Chemical modification of the optical fiber

2.5.1. Optical fibers

All fibers used were SFS400/440B Superguide G UV-Vis (Fiberguide Industries, Stirling, NJ, USA) with an original numerical aperture (NA) of 0.22. Their core was 400 μm in diameter (refractive index of 1.457 at 633 nm) and surrounded by a 40 μm silica cladding (refractive index of 1.44 at 633 nm), followed by a 150-μm thick silicon buffer and finally a 210-μm thick black Tefzel® jacket. The length of any single fiber used in the experiments was approximately 25 cm. The black Tefzel® jacket and silicon buffer were stripped away mechanically using a fiber stripping tool (Micro-Strip®, from Micro-Electronics Inc., MA, USA), leaving a 1 cm nude optical fiber core tip.

2.5.2. Cleaning procedures

Several cleaning strategies were evaluated ($n = 15$ for each method) using different combinations of acid treatments (Table 1, part A). In order to assure the complete removal of the silica cladding, fibers were soaked in 48% (v/v) hydrofluoric acid for 5 min at room temperature (RT), washed thrice with deionized water, once with absolute ethanol and blow dried with air flow. Removal of major micro-contaminants from the newly exposed fiber was done by either soaking in 5 M chromic acid for 1 h at 90 °C, rinsing five times in deionized water, and blow dried with air flow or sonicating the fibers in 1:1 (v/v) methanol/97% HCl solution for 5 min, soaking in fresh 1:1 (v/v) methanol/97% HCl solution for 45 min at 90 °C and finally blow dried with air flow.

Enhancement of hydroxyl groups exposed on the clean silica surface of the fiber tips was achieved by either soaking in 95% (v/v) sulfuric acid for 45 min at RT; or in piranha solution of 7:3 (v/v) 96% sulfuric acid and 30% hydrogen peroxide for 60 min at 90 °C and then blow dried with air flow.

2.5.3. Silanization procedures

Four SCAs were used for the silanization procedure: MPTS [8,11,12,35], AMPTS [36], GOPS [5,37], and DCBZS [10,13], using different silanization methods ($n = 15$ for each method). The first five methods were liquid phase deposition and included soaking the fibers for 1 h at 90 °C in a solution of 100%, 25%, 3%, 1% or 0.3% (v/v) silane in dry toluene, followed by a quick rinse with deionized water and blow dried with air flow. The sixth method was a vapor phase deposition. Fibers were placed in a pre-saturated silane reactor chamber with 1 ml silane injected to the bottom of the reactor and 1.2 l/min argon flow for 30 min (see SI.2) at ambient pressure and temperature. These methods were all employed for the commercial SCAs. When home-made DCBZS was used as SCA, only dilute liquid phase deposition methods were employed in order to economize the precious amount of silane and because of the much fewer procedures used in previous manuscripts then the commercial SCAs. The fibers were left to stand overnight at RT with gentle shaking in a solution of 3%, 1% or 0.3% (v/v) DCBZS in toluene and 0.5% (v/v) triethylamine as a catalyst and acid scavenger, followed by rinsing with fresh toluene and then with PBS.

Table 1
Comparison of different cleaning and activation methods. Five different methodologies were evaluated by a simple i-ELISA for the detection of anti-*Brucella* IgG antibodies after silanization with 25% AMPTS.

#	(A) Treatment			(B) i-ELISA signals		
	De-cladding[a]	Cleaning[b]	Activation[c]	Positive[d]	Negative[d]	S/N
1	HF	CrO_3	Piranha	34,559 (25.3)	142 (19.4)	242.8
2	HF	MeOH:HCl	Piranha	3,133 (64.6)	109.5 (29.6)	28.6
3	HF	MeOH:HCl	H_2SO_4	34,564 (26.5)	94.4 (16.0)	366.2
4	None	MeOH:HCl	H_2SO_4	46,332 (9.7)	116.0 (19.6)	398.3
5	None	CrO_3	H_2SO_4	35,874 (46.30)	122.9 (15.6)	292.6

[b] Cleaning step for the removal of micro-contaminants.
[c] Activation step for enhancement of hydroxyl groups.
[d] Number in brackets indicates the coefficient of variance of groups of 10 fibers.

2.6. Detection of anti-Brucella IgG antibodies using the optical fiber immunosensors

2.6.1. Cross linking using the four used silane coupling agents

After silanization, the strategy for cross linking of the capture protein, 1:1 (v/v) *B. abortus* and *B. melitensis* antigens diluted 1:20 (v/v) in PBS, was dependent on the type of silane used and was done similar to previous reports.

MPTS cross linking employed the hetero-bi-functional cross linker, EMCS and was achieved simply by immersing the fibers in 4 mM EMCS in 1:9 DMSO/PBS pH 7.2 (Fig. 1A). The maleimide group of the EMCS reacted strongly with the thiol group of the silane to form a covalent bond [8,11,12,35].

AMPTS cross linking employed gluteraldehyde (Fig. 1B), and was achieved by immersing the fibers in 2.5% gluteraldehyde in PBS pH 7.2. The two aldehyde groups form amide bonds with the AMPTS's amine from one side and with the receptor from the other one [36].

GOPS facilitates direct linking using several steps of chemical reactions (Fig. 1C). In brief, vicinal diols were formed by treating the fibers in 12 mM hydrochloric acid for 60 min and oxidized to aldehyde using 100 mM sodium m-periodate dissolved in 10% (v/v) acetic acid for 60 min at RT. Then the fibers were rinsed with deionized water. Finally, fibers were incubated overnight at 4 °C with the capture protein, un-reacted aldehyde groups were blocked using 1 M glycine for 30 min at RT and the unsaturated amines were stabilized by a Schiff base by dipping the fibers in 0.3 M sodium-cyanoborohydride for 60 min at RT [5,37].

DCBZS also does not require a cross linker and direct linking of the receptor is achieved via photo-immobilization (Fig. 1D). The photo-immobilization is achieved by activation of the benzophenone groups using a 345-nm wavelength light input, with light intensity of 80 mW cm^{-2}, projected for 7 min into the far end of the DCBZS coated fiber soaked in the capture protein solution. This resulted in binding neighboring *Brucella* cells from the surrounding solution to the optical fiber [10,13].

2.6.2. Detection of anti-Brucella IgG antibodies using CL-OFIS

Following the cross linking of the receptor *Brucella* killed cells and its fragments onto the optic-fibers, the following conventional ELISA steps as detailed in Section 2.5 were performed from the blocking step (using AMPTS, MPTS and DCBZS) or from the sera step (using GOPS) with slight modifications: incubation steps were carried out for 30 min at RT using 250 μl per sets of five fibers and double rinsing, each for 5 min, carried out after each treatment.

2.6.3. Signal measurements of the chemiluminescent optical fiber immunoassay

The instrument set-up for the fiber chemiluminescence measurements has previously been described [15,38,39]. A Hamamatsu HC135-01 Photo Multiplier Tube (PMT) Sensor Module was used for chemiluminescence measurements in a light-tight box. The far end of the fiber was held by a fiber holder (FPH-DJ, Newport) and placed into an adjustable single-fiber mount (77837, Oriel). Monitoring the chemiluminescent signal and data handling at real time was performed by using LabView (version 3.1, National Instruments Corporation). During measurement, each fiber optic was placed in a 400-μl sample tube containing the combined oxidizing reagent, and enhanced luminol reagent solutions in a 1:1 (v/v) ratio. The chemiluminescence readings were integrated for 1 s and each measurement was obtained by taking a mean value of photon counts during 15 s. The mean and standard deviation were calculated for each dilution and reported as RLU (Relative Light Units).

2.7. Stability and short term storage conditions

On-site field diagnostics must be as fast as possible. Thus, examination of the ready to use immunosensor (after silanization, cross linking of the receptor and blocking steps) shelf life was done. Following the blocking step, the fibers were soaked in a stabilizing solution of 5% (w/v) trehalose–0.02% (w/v) sodium azide–0.1% (w/v) skim milk in PBS [40] for 4 h at RT, blow dried with air flow and stored at 4 °C, RT and 37 °C for 1, 2, 4, 7, 14 and 30 days.

2.8. Fiber surface characterization techniques

2.8.1. Scanning electron microscopy (SEM)

Scanning electron microscopy (SEM) micrographs were taken by a JEOL JSM-7400F system with 129 eV resolution of detector (Si) and exposure time of 100 s. The specimens were analyzed using energy-dispersive X-ray spectrometry (EDS) microanalysis analytical equipment installed in the scanning electron microscope.

2.8.2. Atomic force microscopy (AFM)

AFM measurements were performed in non-contact mode at ambient conditions using a Nanonics NSOM/AFM 100 system (Jerusalem, Israel) with a flat scanner, which allows two optical microscopes to examine the sample simultaneously, from above and below.

3. Results and discussion

3.1. Cleaning methodology

As SCAs react with exposed hydroxyl groups on the glass surface, the creation of a uniform, reproducible and functional silane layer also depends on glass pre-treatments: elimination of contamination and hydroxylation of the surface [41].

There is no universal protocol for glass cleaning, therefore five combinations of common acid pre-treatments (Table 1, part A) were evaluated. SEM–EDS (SI.3) was used in evaluating surface structures and composites and i-ELISA procedure (Table 1, part B) for evaluating the influence of silanization with 25% AMPTS over the immunosensor. SEM-EDS revealed that the smoothest surface with the minimal non-silanol molecules was achieved using MeOH:HCl for cleaning and H_2SO_4 for hydroxylation. This method was therefore chosen for all of the next experiments, which also included the fact that it gave the highest S/N ratio [42] and the lowest coefficient of variance in the bioassay, as well as being relatively simple, environmentally friendly and safe.

3.2. Comparison of silanization techniques

The effectiveness of various silianization strategies using all of the SCAs was compared using several methods.

First, SEM micrographs (SI.3 and Fig. 3) provided a qualitative measure of the homogeneity of the modified surface. It was seen that each SCA, in each silanization technique, generated a different morphology without directly correlating to SCA type and concentration. Yet, AMPTS and MPTS, in all of the silanization techniques, provided a relatively homogenous yet thick multi-layer surface. The DCBZS provided a relatively homogenous coverage with aggregates fairly equally distributed over the modified surface.

Secondly, AFM (insets, Fig. 3) provided complementary semi-quantitative data. It is not possible to deduce the exact thickness of the silane layer mainly because of the fiber curvature and only the comparison of roughness reflecting homogeneity was achieved. DCBZS modified surface had the lowest roughness values (102, 293

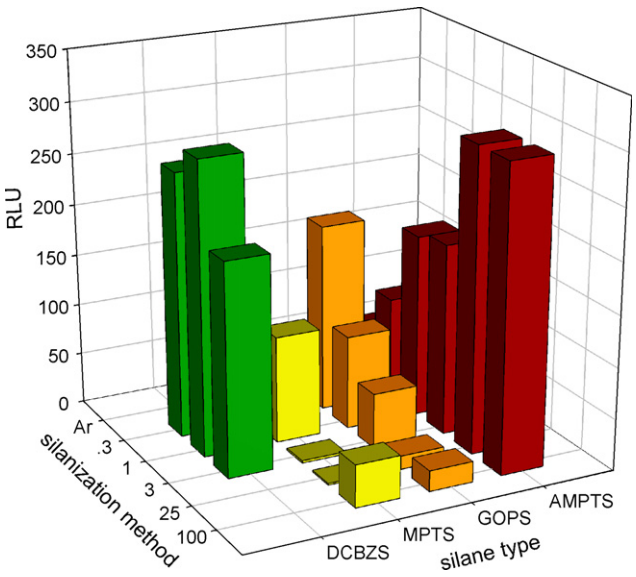

Fig. 2. S/N values in an i-ELISA for detecting anti-*Brucella* IgG antibodies. Several commercially available silane coupling agents and home-made silane coupling agents were tested in different silanization conditions.

and 595 nm for DCBZS, AMPTS and MPTS modified surfaces, respectively), thus demonstrated maximal surface homogeneity.

Thirdly, EDS analysis was executed only on the surfaces modified with SCA which has a unique functional group (–SH of MPTS and –NH of AMPTS (SI.3)). The two representative scans validated the cleaning effectivity per method (no foreign atoms), and that the C:N and C:S ratios were 1:2.2 and 1:3.3 for AMPTS and MPTS surfaces, respectively, which is close to the theoretical value of 1:3 (in case of densely packed SAM formation). The exception from the theoretical value can be explained by incomplete hydrolysis and condensation, thus forming lateral and vertical polymerization in parallel, with excess of methoxy groups [7,16,19,43,44].

Finally, OFIS was used to test the modified surface suitability for an immunosensor (Fig. 2). Significant S/N values were obtained using all the SCA, and the best (about 285) was achieved using between 25–100% AMPTS and 1% DCBZS solutions.

The improvement in the immunosensor performances using DCBZS over the other SCAs can be explained by the efficiency of the cross linking methodology, with high yield for photo-immobilization [32,45], or by the nature of the silane hydrolysable group, with the hydrolysis of the chloro group being more efficient than the methoxy group, thus allowing for a more stable and homogenous coverage [17,43,46].

Only the best three silanization methods, according to those results, were further employed for the calibration curve: 25% AMPTS and 1% DCBZS in liquid phase silanization and Ar phase silanization using MPTS. Although the last was not found best in means of S/N values, it was selected because it is routinely used in our Biosensors Laboratory.

3.3. Immunosensor performances

Three OFIS techniques (having the best silanization as discussed in Section 3.2) and two conventional ELISA techniques were employed. The methods were compared using a model for the detection of anti-*Brucella* IgG antibodies with the same assay principles as for i-ELISA. The respective calibration curves (Fig. 3) were reproducible and demonstrated the essential parameters of any biosensor: dynamic range, sensitivity and lower limit of detection [47].

3.3.1. Calibration curves

The calibration curves describing the general detection of the anti-*Brucella* IgG antibodies were derived using various concentrations of the analyte in milk solutions, ranging in dilutions from 10^{-1} to 10^{-8} of the original concentration, correlating to 2.12 mg/ml to 0.212 ng/ml of the total IgGs per sample, respectively. The calibration curves were calculated by analyzing the data with SigmaPlot 8.2 (Systat) and by applying the sigmoid logistic four parameters model described by Eq. (1), where x and y represent the measured titer of the antigen, respectively:

$$y = \frac{y_0 + a}{(x + x_0)^b} \quad (1)$$

Results are shown in Fig. 3 and the mathematical parameters are reported in Table 2. The applied mathematical model proved to be a good description of the relation between the anti-*Brucella* IgG antibody reported by the signal as shown by the r^2 values.

Influence of non-specific interactions over the colorimetric or chemiluminescent responses was examined using a set of control experiments, each lacking one step of the complete assay. The results (SI.4) showed that the responses obtained in the lack of capture *Brucella* cells, anti-*Brucella* IgG antibodies (the analyte) and secondary labeled antibodies were all relatively negligible, thus the designed immunosensor did not exhibit non-specific binding. High values obtained in the absence of a blocking step reflect the necessity of a blocking step to avoid receptor unsaturated sites of receptors, thus avoiding background noises. High values in the absence of SCA can be explained by the high reactivity of a silane surface towards protein adsorption using van der Walls, polar and ionic interactions. However, those interactions are weaker and less stable and durable compared to covalent attachment of the receptor using SCA [19,20,48]. The signals in the absence of cross linker can be explained by the exclusivity of the cross linker active groups: thiol of MPTS can form disulphide bonds with the receptor, amine of AMPTS can form amide bonds with carboxyl groups in protein, and the benzophenone of the DCBZS can utilize ambient surrounding UV light [32].

3.3.2. Dynamic ranges

The dynamic range is the anti-*Brucella* IgG antibodies titer range where the detection system displays a linear relationship between analyte concentration and measured signal. The dynamic range can be calculated from the previous results by applying a two-parameter linear regression analysis of the data according to Eq. (2):

$$y = y_{01} + d\ \ln(x) \quad (2)$$

Dynamic ranges can be visualized in the upper right corner of each graph in Fig. 3 and the mathematical data are reported in Table 2. The dynamic ranges were with good reliability according to their high r^{2*} values and calculated to be 3.31–0.53 μg/ml, 53–0.42 μg/ml, 212–0.21 μg/ml, 2120–6.65 μg/ml and 106–2.12 μg/ml for colorimetric ELISA, CL-ELISA and MPTS, AMPTS and DCBZS based CL-OFIS methodologies, respectively.

3.3.3. Lower detection limit

The lower detection limit of the immunosensor is defined as the amount (or concentration of the analyte) that gives a response (YDL) significantly different (three standard deviations, STD) from the background analysis obtained from negative control milk (NEG). Therefore, the lower detection limit (LDL) was calculated using Eq. (3) and the sample response considered positive according to Eq. (4):

$$\mathrm{LDL} = 3(\mathrm{STD}) + \mathrm{NEG} \quad (3)$$

$$\mathrm{YDL} > \mathrm{LDL} \quad (4)$$

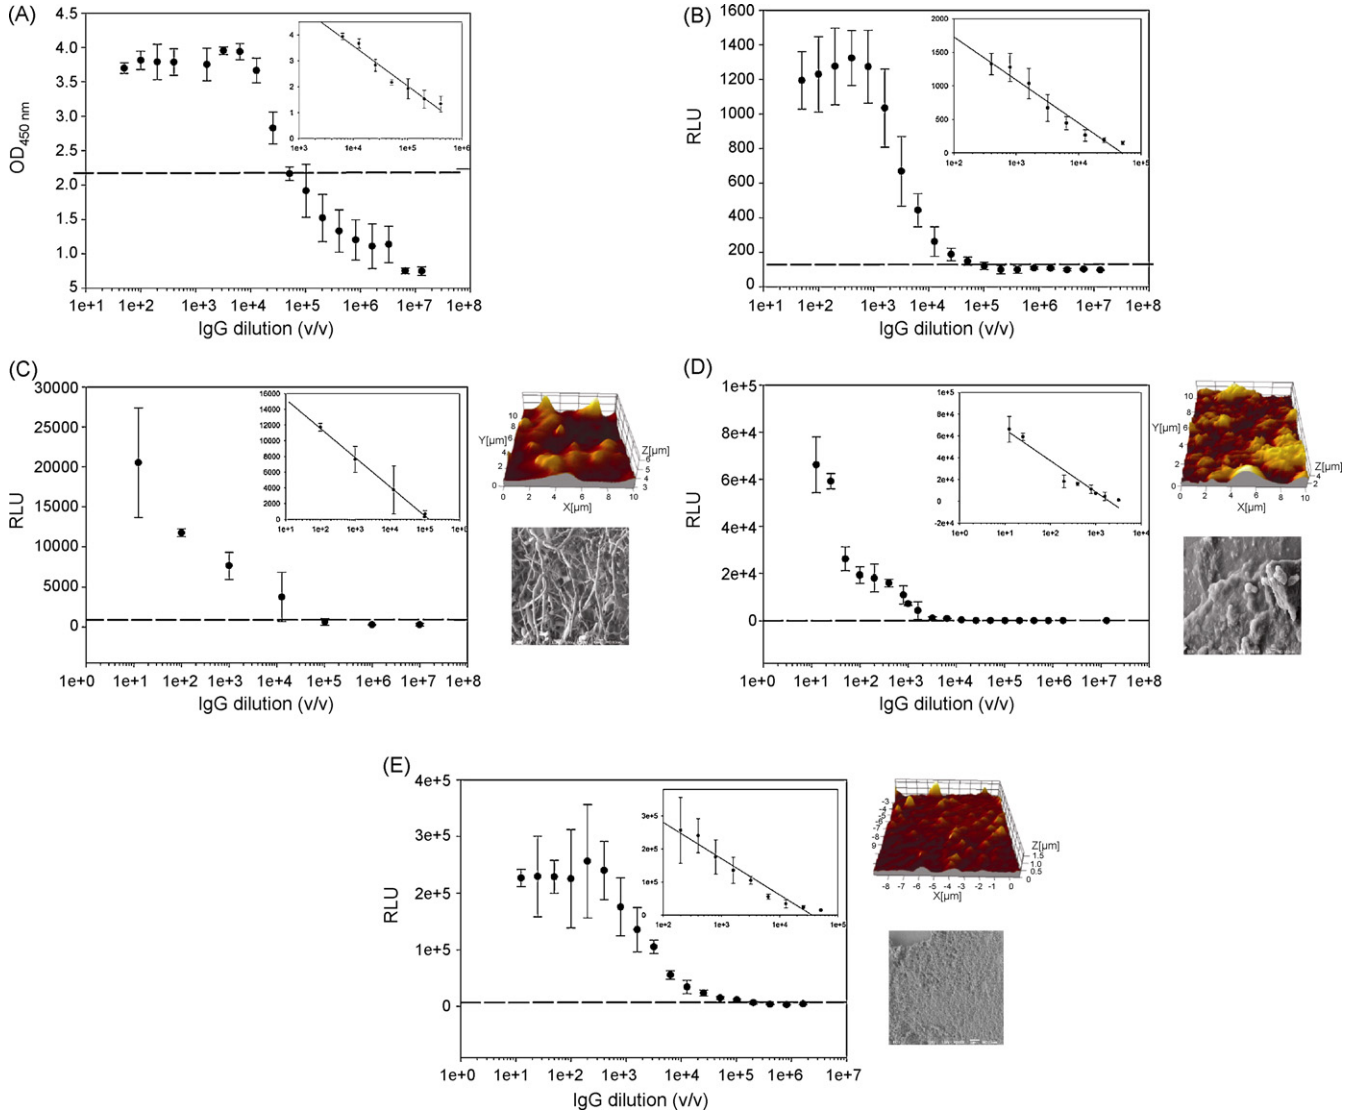

Fig. 3. Calibration curves for detecting anti-*Brucella* IgG antibodies in spiked milk. (A) Colorimetric ELISA. (B) Chemiluminescent ELISA. (C) OFIS using MPTS as silane coupling agent. (D) OFIS using AMPTS as silane coupling agent. (E) OFIS using DCBZS as silane coupling agent. In all of the graphs, linear range is shown in the upper right corner, the lower detection limit is plotted in a dashed line and fitting curve in a dotted line. Insets: AFM and SEM micrographs (top and bottom, respectively) of the optical fiber after modification with the silane coupling agent.

Table 2
Different immunosensors for the detection of anti-*Brucella* IgG antibodies. Summary of all mathematical models and performance description of the methodologies.

Characteristics	Colorimetric ELISA	Chemiluminescent ELISA	OFIS using MPTS	OFIS using AMPTS	OFIS using Si–Bz
Curve mathematical model parameters (Eq. (1))					
a	2.476	948.115	10,399.445	37,093.540	190,223.203
b	1.533	2.224	0.944	1.318	1.684
x_0	62,625.696	4525.673	4708.998	235.128	3129.734
y_0	1.026	119.131	291.321	633.202	9609.924
r^2	0.956	0.881	0.671	0.692	0.879
Linear domains parameters (Eq. (2))					
d	−0.671	−278.275	−18,984.812	−12,470.578	−47,558.486
y_{01}	9.756	2009.959	−1610.143	94,729.801	499,477.653
r^{2*}	0.995	0.984	0.999	0.976	0.984
Performance criteria of methodology					
Linear range	3.31–0.53 μg/ml	53–0.42 μg/ml	212–0.21 μg/ml	2120–6.65 μg/ml	106–2.12 μg/ml
Sensitivity	0.176/ln	0.210/ln	0.078/ln	0.188/ln	0.186/ln
LDL	0.828 μg/ml	0.414 μg/ml	2.120 μg/ml	1.656 μg/ml	0.207 μg/ml
Maximum response	3.810	1323.500	20,520.580	66,142.640	256,278.300

The LDL was calculated for each method and plotted in Fig. 3 as a dotted line. The LDL was 0.828 μg/ml, 0.414 μg/ml, 2.12 μg/ml, 1.656 μg/ml and 0.207 μg/ml, for colorimetric ELISA, CL-ELISA and MPTS, AMPTS and DCBZS based CL-OFIS methodologies, respectively. The OFIS methodology using DCBZS gave two times lower LDL than the CL-ELISA, and four times lower than the colorimetric ELISA. This OFIS methodology is therefore more sensitive and subject to less background noise.

The amount of the immobilized antigen on the solid phase immunoassays has greatly influenced the LDL of the test. This parameter depends on both the binding surface available and the chemistry used to immobilize the biological molecules. Though the binding surface of the microtiter wells is 6.5 times greater than on the OFIS (79 mm^2 and 12 mm^2, respectively), the DCBZS based OFIS showed the best LDL. Major reasons for the improved results are: (1) the proteins are covalently attached to the fiber optic and not only adsorbed on the surface which may increase the stability of the antigen–antibody complex on the optical fiber surface, (2) the CL reaction occurs with high proximity to the transducer surface and enhances light collection efficacy, and (3) the washing method in ELISA technique is manual and passive, and with OFIS the washing steps are more active, the fibers being dipped in the washing solution. This may enhance removal of non-specific binding and decrease noise level.

3.3.4. Sensitivity

The sensitivity is defined as the slope of the linear range, representing the ability of the system to discriminate between two different concentrations *A* and *B* in the solution. It is based on the ratio $(Y_A - Y_B)/(X_A - X_B)$, where *Y* represents the measured signal and *X* represents the concentration. In order to compare the sensitivity of the five different methodologies, each having a different scale, the results were normalized by dividing the signal obtained in the linear range by their respective maximal responses. It was found that all methodologies had similar sensitivity indicating the reliability of the developed OFIS.

3.3.5. Short term shelf life

After preparation, the ready-to-use probes were kept dried at the different temperatures until use. Results (data not shown) revealed that even after a 30-day storage, probes retained similar activity, and the intensities of the signals ranged between 298% and 397%, 109% and 124%, and 85% and 105% from the initial signal for MPTS, AMPTS and DCBZS modified probes, respectively. This stability, confirmed for a minimum of 30 days period that was tested, has shown the reliability of the different techniques, AMPTS and DCBZS modified fibers, at the different storage temperatures. Further work needs to be carried out to establish longer shelf life stability but this was out of the scope of the present study.

4. Conclusions

The chemical modification step is one of the most crucial steps in designing a silanization based immunosensor as it allows the introduction of a new reactive group on the optical fiber in a covalent manner for further immobilization of the bio-receptor. The results have clearly shown that CL-OFIS based on in-house DCBZS modified fibers was superior to other commercial SCAs and conventional colorimetric and CL-ELISA in detecting anti-*Brucella* IgG antibodies at the lowest LDL, therefore making the immunosensor an appropriate tool for detecting and quantifying antibodies at low protein concentrations. Moreover, this immunosensor makes it feasible to work with lower amounts of reagents and as a result, allowing a price reduction of the reagents used and utilizing smaller volumes of sample. Finally, the rapidity of the fiber based procedures compared to the conventional ELISA platform (2 h versus 4 h) and the moderate working operation (RT versus 37 °C) make OFIS preferable in allowing putative real time on-site testing. While only presenting a prototype of the innovative immunosensor, future developments of the OFIS should focus on adjusting the test for mass surveillance.

From the clinical and veterinary point of view, our developed immunosensor identifies anti-*Brucella* antibodies in terms of protein concentration rather than serological activity. Therefore, this work can set the ground for further work that will enable quantifying low amount of anti-*Brucella* antibodies, irrespective of their serological activity, allowing identification of the disease at the earliest possible time following exposure of the host to the organisms.

Acknowledgments

Dr. Gil Korner, Kamada, Israel, is kindly thanked for his work in purifying the anti-*B. melitensis* IgG bovine antibodies used in this research. Luba Burlaka from the Center for Meso, Nanoscale Science and Technology, Department of Chemical engineering (BGU), is thanked for performing SEM-EDS measurements and Inbal Tsarfati and Dr. Levi Gheber, Department of Biotechnology Engineering (BGU) are thanked for performing the AFM measurements. Gina Hughes is thanked for her editorial help and Dr. Michal Shani-Sekler and Dr. Sebastien Herrmann are thanked for their advice and insights. This work was supported by Yeshaya Horowitz Association, project BioPen #84534101 and the Technical Support Working Group project #T-582.

Method validation

ABSTRACT

A sensitive and efficient method was developed for determination of metoprolol in human plasma by gas chromatography–mass spectrometry (GC–MS). Metoprolol and atenolol (internal standard, IS) were extracted from human plasma with a mixture of ethylacetate and diethylether at basic pH with liquid–liquid extraction. Calibration curves were linear over the concentration range 15–500 ng/ml. Intra- and inter-day precision values for metoprolol in human plasma were less than 6.4, and accuracy (relative error) was better than 8.8%. The analytical recovery of metoprolol from human plasma averaged 91.20%. The limits of detection (LOD) and quantification (LOQ) of metoprolol were 5.0 and 15 ng/ml, respectively. Also the developed and validated GC–MS method was successfully applied to three patients with hypertension who had been given an oral tablet of 100 mg metoprolol.

1. Introduction

Metoprolol, 1-(isopropylamino)-3-[p-(2-methoxyethyl)phenoxy]-2-propanol, is a kind of β adrenaline receptor blocker. It is widely used for the treatment of hypertension, angina, myocardial infarction, arrhythmia, hyperthyroidism and other related diseases [1,2].

Several methods have been reported for determination of metoprolol including gas chromatography–mass spectrometry (GC–MS) [3–5], high-performance liquid chromatography (HPLC) [6–10], LC–MS [11–13] and LC–MS–MS [14] in human plasma and other biological fluids.

β-Blockers have similar chemical structures with highly polar functional groups that yield them unsuitable for analysis by GC methods. Recently the use of mass selective detectors with a capillary GC coupled to mass spectrometry as a mode of detection has considerably increased. Suitable derivatization should improve the gas chromatographic properties of the compounds and yield compounds with mass spectra containing high relative intensity and high-mass fragments suitable for selected ion monitoring (SIM) [15].

The present work describes the O-silylation of the hydroxyl group of metoprolol using *N-methyl-N-(trimethylsilyl)trifluoroacetamide* (*MSTFA*) as a silylating reagent. This is followed by determination of metoprolol after a derivatization procedure in human plasma using internal standard methodology by GC–MS. The developed method was validated by using linearity, stability, precision, accuracy and sensitivity parameters according to International Conference on Harmonization (ICH) guidelines [16]. The advantages of present method include simple and single step extraction procedure using inexpensive chemicals and short run time. Also, this method was used to assay the metoprolol in plasma samples obtained from three patients with hypertension who had been given an oral tablet of Problok (100 mg metoprolol).

2. Experimental

2.1. Chemicals and reagents

Metoprolol tartrate was obtained by Sigma–Aldrich (St. Louis, MO, USA). Atenolol as internal standard (IS) was kindly donated from Abdi Ibrahim Pharmaceutical Industry (Istanbul, Turkey). *N-methyl-N-trimethylsilyl-trifluoroacetamide* (*MSTFA*), ethylacetate, diethylether and acetonitrile were purchased from Sigma–Aldrich (St. Louis, MO, USA). Problok tablet (100 mg metoprolol tartrate) was obtained Terra Pharmaceutical Industry (Istanbul, Turkey).

2.2. Apparatus and analytical conditions

Chromatographic analysis was carried out on an Agilent 6890N gas chromatography system equipped with 5973 series mass selective detector, 7673 series autosampler and Agilent chemstation

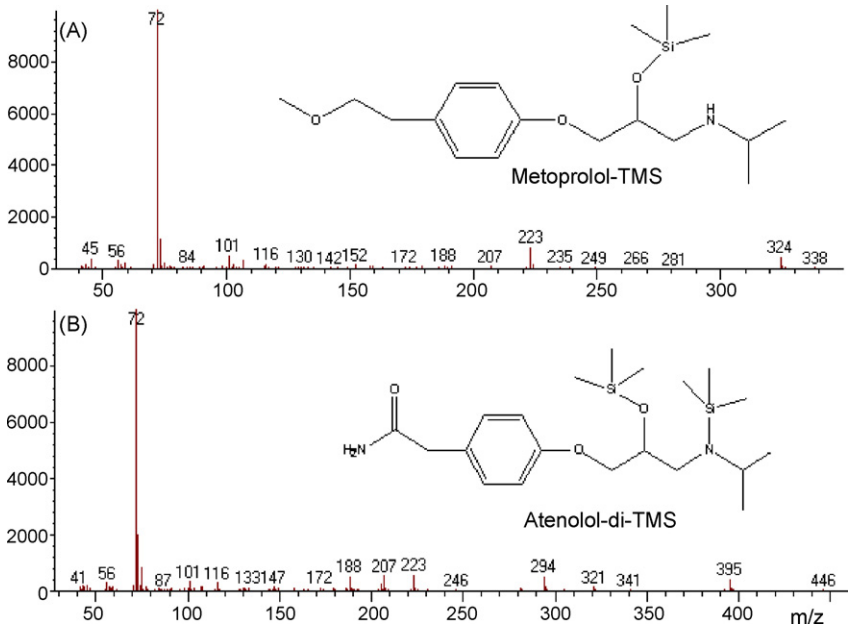

Fig. 1. MS spectra after derivatization of metoprolol (A) and atenolol (IS) (B) with *MSTFA*.

(Agilent Technologies, Palo Alto, CA). HP-5 MS column with 0.25 μm film thickness (30 m × 0.25 mm I.D., USA) was used for separation. Splitless injection was used and the carrier gas was helium at a flow rate of 1.0 ml/min. The injector volume was 1 μl. The MS detector parameters were transfer line temperature 280 °C, solvent delay 3 min and electron energy 70 eV.

2.3. Preparation of stock and working solutions

10 mg metoprolol and IS was weighed, transferred 500 ml volumetric flask, differently. 250 ml acetonitrile was added and the flask was sonicated. The flask was filled to volume with acetonitrile (20 μg/ml). After, 5000 ng/ml standard solution was prepared by diluting with acetonitrile appropriate volumes of 20 μg/ml stock solution and stored at −20 °C under refrigeration. IS working solution was prepared at final concentration of 2500 ng/ml. The working solutions were prepared by diluting the standard stock solution from 15 to 500 ng/ml. Also, quality control (QC) solutions were prepared from stock solution at concentrations of 75, 250 and 450 ng/ml together with 250 ng/ml IS.

2.4. Sample preparation and derivatization procedure

MSTFA is an effective trimethylsilyl (TMS) donor. *MSTFA* reacts to replace labile hydrogens on a wide range of polar compounds with a TMS group and is used to prepare volatile and thermally stable derivatives for GC–MS [17] To increase the performance of the gas chromatographic separation, metoprolol and IS were derivatized using *MSTFA* (Fig. 1). The secondary amine (–NH) and hydroxy (–OH) groups were converted to the corresponding silyl (–N-TMS) and (–O-TMS) groups.

A 0.5-ml aliquot plasma sample was transferred to a 10-ml glass tube. After, a suitable amount of standard metoprolol solutions together with 0.1 ml IS solution (250 ng/ml) and 0.5 ml 1 M sodium hydroxide solution were added. After vortex mixing for 5 s, 3 ml of ethylacetate and diethylether was added (2:1, v/v), the mixture was vortexed for 30 s and then centrifuged at 3000 × *g* for 7 min. The organic layer was transferred into another tube and evaporated to dryness at room temperature under nitrogen gas. The dry residue was dissolved in 100 μl of a mixture of acetonitrile and *MSTFA* (50:50, v/v). The mixture was vigorously shaken and then delayed at room temperature for 10 min. 1 μl sample was injected into the GC–MS system.

3. Results

3.1. Method development

The method development for the assay of metoprolol was based on its chemical properties. The column and acquisition parameters were chosen to be a starting point for the method development. Metoprolol is a polar molecule. Therefore, the capillary column coated with 5% phenyl and 95% dimethylpolysiloxane is a good choice for separation of metoprolol.

The GC/MS parameters used in the method development were based on the boiling point. The injection port and detector temperature was set to 280 °C for GC/MS. Different temperature programs were investigated for method. The end of this investigation, the temperature program of the GC/MS was as follows: initial temperature was 150 °C, held for 1 min, increased to 220 °C at a rate of 20 °C/min held for 1 min, and finally to 300 °C at a rate of 10 °C/min and held for 1 min.

The effects of time and temperature on the reaction were investigated. To confirm the complete derivatization of metoprolol and IS, since only one peak appears on the chromatogram, each compound was derivatized and analyzed separately. After establishing the optimum reaction conditions, the compounds were mixed together and then derivatized in order to perform a simultaneous analysis. To 100 μl of 1000 ng/ml metoprolol and 100 μl of *MSTFA* solution was added and reacted at room temperature, 50 and 75 °C for 5, 10 and 20 min. The resulting samples were quantitated by GC/MS system. The effects of the time and temperature were shown in Fig. 2.

3.2. Validation of the method

The validation was carried out by establishing specificity, linearity, intra- and inter-day precision, accuracy, recovery and sensitivity parameters according to ICH [16] and Center for Drug Evaluation and Research (CDER) guidance for Bio-analytical Method Validation [18].

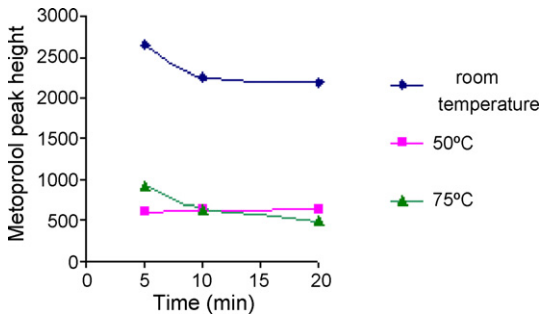

Fig. 2. The effect of reaction time and temperature on derivatization reaction.

3.2.1. Specificity

The specificity criterion tries to demonstrate that the result of the method is not affected by the presence of interferences [19]. The specificity of method was determined by checking the chromatograms obtained from blank plasma samples, and no endogenous interferences were encountered. The fragment ion $[CH_2NHCH(CH_3)_2]^+$ (m/z 72) was used for quantification of metoprolol and IS. The retention time of metoprolol-TMS and IS-di-TMS was approximately 7.8 and 10.6 min in human plasma (Fig. 3).

3.2.2. Linearity

The linearity of an analytical method is its ability within a definite range to obtain results directly proportional to the concentrations (quantities) of an analyte in the sample. The concentrations of the spiked metoprolol in human plasma were 15, 50, 100, 200, 300, 400 and 500 ng/ml with constant concentration of IS (250 ng/ml). The calibration curves were established by plotting the ratio of the peak areas of metoprolol and IS obtained after extraction of the spiked plasma sample. The equation of the calibration curve obtained from seven points was $y = 0.052x + 0.2134$ with a correlation coefficient ($r = 0.998$). The linear regression equation was calculated by the least-squares method using Microsoft Excel® program and summarized in Table 1.

3.2.3. Precision and accuracy

Assay precision was determined by repeatability (intra-day) and intermediate precision (inter-day). Repeatability during the same day and intermediate precision on different days (3 days) were evaluated with six replicates of QC samples. The accuracy of analytic method was assessed as the percentage relative error (% RE). The accuracy and precision of the method were evaluated with QC samples at concentrations of 75, 250 and 450 ng/ml. The intra- and inter-day accuracy and precision results are shown in Table 2. The intra- and inter-day precisions of the QC samples were satisfactory with RSD less than 6.4% and accuracy with RE within ±8.8% (should be less than 15 according to CDER guidance for Bioanalytical Method Validation) [18].

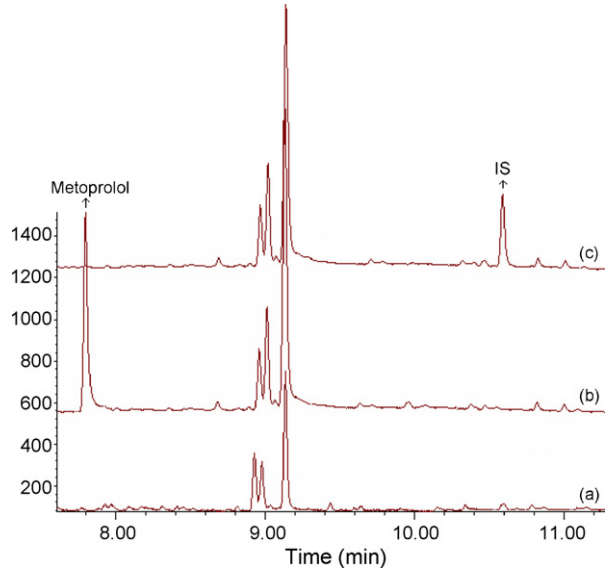

Fig. 3. Typical SIM chromatogram of blank plasma (a), plasma spiked with 100 ng/ml metoprolol (b) and 250 ng/ml atenolol (IS) (c).

Table 1
Linearity of metoprolol in human plasma.

Linearity (ng/ml)	15–500
Regression equation[a]	$y = 0.052x + 0.2134$
Standard deviation of slope	1.62×10^{-3}
Standard deviation of intercept	6.24×10^{-2}
Correlation coefficient	0.998
Standard deviation of correlation coefficient	4.23×10^{-3}
Limit of detection (ng/ml)	5.0
Limit of quantification (ng/ml)	15

[a] Based on three calibration curves, y: peak-area ratio, x: metoprolol concentration (ng/ml).

3.2.4. Sensitivity [limits of detection (LOD) and quantification (LOQ)]

The LOD and LOQ were studied to test the sensitivity of the method. The LOD defined as signal/noise = 3 in method (RSD > 20% for LOD) was found to be 5.0 ng/ml. The LOQ defined as signal/noise = 10 in method (RSD > 10% for LOQ) was found to be 15 ng/ml (Table 1). Both accuracy and precision of these values were well within the proposed criteria (RSD % < 20%).

3.2.5. Recovery

The recovery of an analyte is the extraction efficiency of an analytical process, reported as a percentage of the known amount of an analyte carried through the sample extraction and processing steps of the method [20]. The liquid–liquid extraction was used for the sample preparation in this work. Several solvents (ethylacetate, diethylether, dichloromethane, acetonitrile, butanol and chloroform) were tested for the extraction. Finally, ethylacetate and diethylether mixture (2:1, v/v) proved to be the most efficient in extracting metoprolol from human plasma. After extraction procedure, the dry residue was dissolved in 100 μl of a mixture of acetonitrile and *MSTFA* (50:50, v/v). The mixture was vigorously shaken and then delayed at room temperature for 10 min. Spiked plasma samples were prepared three times at all levels (15, 50, 100, 200, 300, 400 and 500 ng/ml) of the calibration graph of metoprolol. The recovery of metoprolol was determined by comparing the peak areas measured after analysis of spiked plasma samples with those found after direct injection of standard solutions at the same concentration levels. The extraction recoveries of metoprolol from human plasma were between 88.6 and 95.1% as shown in Table 3.

3.2.6. Matrix effect

The matrix effect (ME) was defined as the direct or indirect alteration or interference in response due to the presence of unintended analytes or other interfering substances in the sample [18]. The ME of metoprolol was investigated by comparing amount of metoprolol solutions with processed blank samples reconstituted with metoprolol solutions. The blank plasmas used in this study were from five different batches of healthy human blank plasma. If the ratio <85 or >115%, a matrix effect was implied. The relative matrix effect of metoprolol at three different concentrations (50, 200 and 500 ng/ml) was less than ±10.9% (Table 4). The results showed that

there was no matrix effect of the analytes observed from the matrix of plasma in this study.

3.2.7. Stability

The stability of metoprolol in human plasma was studied under a variety of storage and handling conditions at low (100 ng/ml) and high (500 ng/ml) concentration levels. The short-term temperature stability was assessed by analyzing three aliquots of each of the low and high concentration samples that were thawed at room temperature and kept at this temperature for 8 h. Freeze–thaw stability (-20 °C in human plasma) was checked through three cycles. Three aliquots at each of the low and high concentrations were stored at -20 °C for 24 h and thawed unassisted at room temperature. When completely thawed, the samples were refrozen for 24 h under the same conditions. The freeze–thaw cycles were repeated three times and then analyzed on the third cycle. The long-term stability was determined by analyzing three aliquots of each of the low and high concentrations stored at −20 °C for 1 week. The accuracy of metoprolol stability was obtained for the short-term temperature, freeze–thaw and long-term 97.8, 96.2 and 95.4%, respectively. The stability results indicated that no significant degradation of metoprolol in human plasma was observed under the tested conditions.

3.3. Application of the method

Prior to the study, the clinical protocol was approved by the Ethics Committee of Faculty of Medicine, Ataturk University (2009/Number 41). All volunteer patients were given written informed consent to participate in the study according to the principles of the Declaration of Helsinki. The patients who submitted the agreements to attend this project were medically examined and three patients with hypertension were selected (34.3 ± 1.154 years; 72.7 ± 1.528 kg; 169.3 ± 2.517 cm) for the pharmacokinetics study of metoprolol. The subjects were required to abstain from taking any other drug for 7 days prior the start of test. They were also demanded not to smoke or drink alcohol or xanthine-containing beverages for 24 h before the beginning of the study until its end. Three patients with hypertension received an oral tablet (Problok 100 mg) containing 100 mg of metoprolol. Then, they were allowed to drink water. The total amount of water drunk during the day was 1500 ml. The volunteers were sitting during lunch. They had normal activity (standing or sitting) during the study, but were never in a supine position during the 12 h after administration. Blood samples were taken into EDTA tubes before and 0.5, 1, 1.5, 2, 3, 4, 6, 8 and 12 h after oral administration. The blood was centrifuged 3000 × *g* for 10 min at ambient temperature, extracted and derivatized with *MSTFA*. Representative chromatograms obtained before and after administration of the drug are shown in Fig. 4. Metoprolol plasma concentrations were shown in three patients with hypertension following oral application of Problok in Fig. 5.

3.4. Pharmacokinetic analysis

The present method was used to determine the plasma concentration of metoprolol. The peak plasma level (C_{max}) is the highest observed concentration and T_{max} is the corresponding time of this concentration. The areas under the plasma concentration–time curves (AUC) were calculated with the linear trapezoidal rule. The $AUC_{0-\infty}$ was calculated by dividing the last measured concentration (C_t) by elimation rate constant (k_{el}) and adding the result to the AUC_{0-t}. The elimination rate constant was calculated by the least-squares regression using the last five time points of each curve. The apparent elimination half-life was the quotient of the natural logarithm of 2 and the elimination rate constant [21].

Analysis of metoprolol concentration in plasma samples from three patients following oral administration of 100 mg of Problok provided the following pharmacokinetic parameters (mean ± SD): C_{max}, 104.3 ± 7.09 ng/ml; area under curve (AUC),

$AUC_{0-12\,h}$, 381.4 ± 11.22 h ng/ml; $AUC_{0-\infty}$, 475.4 ± 19.30 h ng/ml; T_{max}, 1.83 ± 0.29 h and elimination half-life, $t_{1/2}$, 4.12 ± 0.16 h.

4. Discussion

Kim et al. [3] have reported GC–MS method after pre-column derivatization with α-methoxy-α-(trifluoromethyl)phenylacetyl chloride as a chiral derivatizing agent for the determination of metoprolol in human urine. Angier et al. [4] have reported the determination of metoprolol with other β-blockers in biological fluids by GC–MS method after pre-column derivatization with pentafluoropropionic anhydride. Gowda et al. [14] have reported LC method with tandem mass detection for the analysis of metoprolol in human plasma. The calibration curve of LC–MS–MS method was linear for metoprolol in the range 5.0–500 ng/ml. Intra- and inter-day precision ranged from 4.82 to 8.42 and from 7.2 to 11.11% for metoprolol, respectively. The maximum recovery of metoprolol was 77.68%. The LOQ and LOD of method were found 5.0 and 1.0 ng/ml, respectively. Detection using LC–MS–MS would be a more sensitive approach but is costly and not yet available for every laboratory.

Albers et al. [6] have reported HPLC method with fluorescence detection for the analysis of metoprolol in human plasma. The calibration curve of the method was linear for metoprolol in the range 2.4–195.2 ng/ml. Precision throughout the whole working range was between 0.6 and 15.5%. Metoprolol recovery was determined at 73.0 ± 20.5, and the LOQ was 2.4 ng/ml.

Today, GC–MS is a powerful technique for highly specific and quantitative measurements of low levels of analytes in biological samples. As compared to HPLC, high-resolution capillary GC has been less frequently used. Because it requires pre-conversion of multifunctional β-blockers into thermally stable volatile derivatives. However, it has inherently high resolving power and high sensitivity with excellent precision and accuracy allowed simultaneous detection of expected and unexpected β-blockers, their metabolites and contaminants. Also, the detection limits were lowered to pg levels by GC combined with MS [22].

The specificity of GC–MS method has been demonstrated by the representative chromatograms for metoprolol in human plasma (Figs. 3 and 4). The recovery of metoprolol was achieved by developed liquid–liquid extraction procedure in human plasma. Metoprolol was extracted from human plasma with a mixture of ethylacetate and diethylether solvents. This solvent mixture gave an excellent recovery. The analytical recovery of metoprolol from human plasma averaged 91.20%. Intra- and inter-day precision values for metoprolol in human plasma were less than 6.4%. Metoprolol was extracted from urine with a solid phase extraction procedure by Chiu et al. [8]. This method is also the most comprehensive method which can extract metoprolol in a single extraction procedure.

In statistical comparison ($p > 0.05$) with other methods in the literature [3,6–8,12,14] the proposed method has indicated high accuracy, precision and recovery.

Metoprolol in plasma, amniotic fluid and capillary blood was analyzed by GC–MS according to Ervik et al. [23]. The minimum determinable concentration at standard deviation of 10% was 1 nmol/l. The present method has the following advantage over the reported method [24]. The LOQ of the reported method was 15.7 ng/ml whereas the present method LOQ was 15 ng/ml. When this method is applied to plasma samples, its sensitivity was found to be adequate for pharmacokinetic studies.

Additionally, this method was applied to three patients with hypertension who had been given an oral tablet of 100 mg metoprolol. The amount of metoprolol was determined between 0 and 12 h in human plasma.

5. Conclusion

In the present work, a simple and sensitive GC–MS method has been developed for the determination of metoprolol in human plasma. Also, the method was completely validated by using sensitivity, stability, specificity, linearity, accuracy and precision parameters for determination of metoprolol in human plasma. Additional advantages of this method include small sample volume (0.5 ml), good extraction recovery from plasma and a readily available internal standard. Also, the extraction and derivatization procedures in this study were simple. Therefore, the proposed method can be used as a therapeutic drug monitoring method in clinic to check the plasma concentration of metoprolol in the patients with hypertension.

ABSTRACT

The paper describes a research of possible application of UTEVA and TRU resins and anion exchanger AMBERLITE CG-400 in nitrate form for the isolation of uranium and thorium from natural samples. The results of determination of distribution coefficient have shown that uranium and thorium bind on TRU and UTEVA resins from the solutions of nitric and hydrochloric acids, and binding strength increases proportionally to increase the concentration of acids. Uranium and thorium bind rather strongly to TRU resin from the nitric acid in concentration ranging from 0.5 to 5 mol L^{-1}, while large quantities of other ions present in the sample do not influence on the binding strength. Due to the difference in binding strength in HCl and HNO_3 respectively, uranium and thorium can be easily separated from each other on the columns filled with TRU resin. Furthermore, thorium binds to anion exchanger in nitrate form from alcohol solutions of nitric acid very strongly, while uranium does not, so they can be easily separated. Based on these results, we have created the procedures of preconcentration and separation of uranium and thorium from the soil, drinking water and seawater samples by using TRU and UTEVA resins and strong base anion exchangers in nitrate form. In one of the procedures, uranium and thorium bind directly from the samples of drinking water and seawater on the column filled with TRU resin from 0.5 mol L^{-1} HNO_3 in a water sample. After binding, thorium is separated from uranium with 0.5 mol L^{-1} HCl, and uranium is eluted with deionised water. By applying the described procedure, it is possible to achieve the concentration factor of over 1000 for the column filled with 1 g of resin and splashed with 2 L of the sample. Spectrophotometric determination with Arsenazo III, with this concentration factor results in detection limits below 1 μg L^{-1} for uranium and thorium. In the second procedure, uranium and thorium are isolated from the soil samples with TRU resin, while they are separated from each other on the column filled with anion exchanger in alcohol solutions. Anion exchanger combined with alcohol solutions enables isolation of thorium from soil samples and its separation from a wide range of elements, as well as spectrophotometric determination, ICP-MS determination, and other determination techniques.

1. Introduction

Determination of uranium and thorium in environmental and biological samples has considerable potential as a tool for assessing human exposure. Despite the relatively low specific activity of natural uranium and thorium isotopes, there exists an important health concern because of their chemical toxicity and radio toxicity of their decay products. These elements, present in soil, rocks, water and other samples, can be incorporated into human food chain through various pathways. The simplest way for their intake is through water and beverages consumption. Therefore WHO recommends that U and ^{232}Th in drinking water should not exceed 15 μg L^{-1} and 1 Bq L^{-1} respectively and for daily water consumption of 2 L per day this limit leaves a considerable safety margin [1]. Furthermore, the European directive requires measurement of radionuclides (prescribes ^{3}H and total indicative dose) in drinking water and in Annex define parameters to perform radioactivity monitoring of water. It could be expected in near future that Directive will define reference values for single radionuclides as well as their limits of detection [2]. These recommendations require a regular monitoring of uranium (as isotopes and element), and consequently, forces the analysts to find rapid, inexpensive and sensitive methods for its determination.

Although a series of methods for determination of uranium and thorium in different kinds of samples have been developed, in consideration of the mentioned requests there is no superior method [3–30]. Direct determination of uranium and thorium isotopes is possible on inductively coupled plasma mass spectrometry

ICP-MS [13,15,16] in solutions (excluding rather sophisticated and expensive techniques of laser ablation ICP-MS or accelerator mass spectrometry which can be used for determination in solid samples). The lower detection limit depends on a number of factors, the main being the occurrence of interferences caused by the structure and concentration of matrix elements. In conditions of low concentrations of matrix elements, it is possible to achieve very low detection limits. However, it is not possible to achieve the same detection result with concentrated samples without removing the interfering factors. In practice, the most frequently used methods are coupling ion chromatography and ICP-MS [10,12,16,18,29]. Nevertheless, IC-ICP-MS also has limitations due to sample structure (column capacity, acidity). Other determination techniques as fluorimetry [16,23] neutron activation analysis [24,25] and alpha spectrometry [11,26–28] can be used for their determination but these techniques require more or less sample preparation (preconcentration and separation from the sample). An exception to the rule is gamma spectrometric determination, which enables direct determination through their decay products [11,25]. Although a rather elegant determination procedure, it requires time in order to establish radio-chemical equilibrium between decay products.

For determination of low concentrations of uranium and thorium, some of the most appropriate techniques are above mentioned methods. However, spectrophotometry is always an acceptable alternative method, due to its acceptable precision and accuracy, associated with its lower cost compared to the some of mentioned techniques [4,5,8]. The critical point against the use of spectrophotometry for determination of uranium and thorium is generally associated with low sensitivity of the spectrophotometric determinations and impossibility of direct determination without sample preparation. Considering the advantages and disadvantages of the existing techniques the set objective is the development of a robust, simple, and relatively cheap determination method that can be used in any laboratory.

Preconcentration and elimination of interfering elements is characteristic almost for all developed methods, so various separation and preconcentration techniques are often employed prior to detection on available instruments [30]. Preconcentration improves the detection limits, increases the sensitivity by several orders of magnitude and enhances the accuracy of the results. The preconcentration techniques hitherto developed for uranium and thorium are based on physico-chemical and chemical principles. Among many others, ion exchange and extraction chromatography are very popular methods due to their applicability to both preconcentration and separation [30]. Horwitz et al. have developed several types of extraction chromatographic resins that can be used for enrichment and separation of uranium and thorium. So it is well known that uranium tetravalent actinide specific resin UTEVA and transuranium specific resin TRU are very applicable for separation of U and Th from various types of samples [31–35]. Also thorium can be chromatographically separated from number of elements on anion exchange column with alcoholic solution of nitric acid [36–38].

Therefore, the main aim of this work is the development of simple methods for preconcentration and separation of uranium and thorium from water samples that can be easily adapted for separation and preconcentration from various types of samples and that will enable their spectrophotometric determination with satisfactory sensitivity and detection limit. It will be shown that a combination of mixed solvent anion exchange and extraction chromatography can ensure a simple and efficient procedure for uranium and thorium separation and preconcentration from various types of samples. Considering the fact that alpha spectrometric determination in general requires separation of uranium and thorium from the sample as well as ICP-MS in some cases, it will be discussed how to use the developed procedure in these determination procedures.

2. Experimental

Based on the literature data [36–38], obtained results and experience, the procedures for isolation of uranium and thorium from the soil, drinking and seawater samples, and their subsequent determination were created. In the first step, the distribution coefficients of the mentioned elements on extraction chromatographic resins TRU and UTEVA and strong base anion exchanger Amberlite CG-400 in nitrate form were determined. In the second step, the optimal conditions for preconcentration and separation of uranium and thorium from other elements in real samples were established. Finally, uranium and thorium were quantitatively determined by spectrophotometry and parallel with ICP-MS and gamma spectrometry. In the first step, the research was conducted with model systems and then with real systems.

2.1. Determination of distribution coefficients and elution curves

The distribution coefficients of uranium and thorium and their elution curves for the TRU and UTEVA resins from nitric and hydrochloric acids and for anion exchanger Amberlite CG-400 (100–200 mesh) in the nitrate form and alcohol solution of nitric acid were determined. For distribution coefficients determination, 10 mL of solution containing 20–50 mg L^{-1} of uranium, thorium or lead were equilibrated with 0.2 g of the mentioned resins or exchanger for 24 h.

Amberlite CG-400 had to be transferred into nitrate form. The distribution coefficients were calculated according to the equation:

$$K_D = \frac{c_0 - c}{c} \cdot \frac{V}{m}$$

where c_0 is the initial concentration of cations, c: concentration after equilibrating, V: solution volume and m: mass of resin or exchanger.

Columns of 0.9 cm in diameter and 25 cm long were used for determination of elution curves. Columns were filled with (1–3) g of extraction chromatographic resins or anion exchanger. The isolation procedures from model and real samples of natural waters and soil were created based on the obtained data.

2.2. Preconcentration of uranium and thorium from model water samples and real samples

In order to determine the efficiency of isolation from seawater and drinking water samples, model samples were tested first. The preconcentration method on TRU and TEVA resin with simultaneous separation of uranium from thorium on the same resin and on the anion exchanger Amberlite CG-400 was tested. As real samples of tap water (Zagreb), mineral water (Studenac) and seawater from Adriatic sea were used. Sample of seawater was taken near the island Vis.

Model sample solution of seawater with known concentration of thorium and uranium was prepared by dissolving of $Th(NO_3)_4{\cdot}5H_2O$ and of $UO_2(NO_3)_2{\cdot}6H_2O$ in artificial seawater. Artificial seawater was prepared by dissolving of salts of Na, Ca, Mg, K in Mili-Q (Millipore) deionised water (18 MΩ) according to Bowen [39]. Model solution of drinking water with known concentration of thorium and uranium was prepared by dissolving of $Th(NO_3)_4{\cdot}5H_2O$ and of $UO_2(NO_3)_2{\cdot}6H_2O$ in model drinking water. Model sample of drinking water was prepared by dissolving of salts of Na, Ca, Mg, K in Mili-Q deionised water. Concentration of Na, Ca and other cations was equivalent to concentration of these elements in bottled spring and mineral water. Final concentration of acid in model samples was obtained by mixing of concentrated acids and

model sample. For 3 mol L^{-1} HNO_3 1 L of water was mixed with 330 mL of 14 mol L^{-1} HNO_3.

2.2.1. Preconcentration on TRU resin and separation on anion exchange resin

1 L of the prepared solution (0.5 mol L^{-1} HNO_3 in sample) was passed through a column (I.D. = 0.9 cm) filled with TRU resin (1.5 g) at a flow rate of (1–2) mL min^{-1}. Before that, the column had to be prepared for separation by passing 50 mL of 3 mol L^{-1} HNO_3. After passing the sample, 50 mL of 3 mol L^{-1} HNO_3 were passed through the column. Thorium and uranium were stripped together with 50 mL of deionised water and then separated on the anion exchange column. Water fraction was reduced (by evaporation) to 1 mL and then prepared for separation on the anion exchange column filled with Amberlite CG-400 in nitrate form. 1 mL sample was mixed with 5 mL of 0.25 mol L^{-1} HNO_3 in methanol and passed through the column filled with 1 g Amberlite CG-400 at a flow rate of 1 mL min^{-1}. Uranium was eluted with 25 mL of 0.25 mol L^{-1} HNO_3 in methanol, and after that thorium was stripped from the column with 5 mL of deionised water. To perform spectrophotometric determination, the volume of uranium and thorium fractions must be reduced by evaporation exactly to 1 mL. The same procedure is applied for isolation from model drinking water. The concentration of acid in the sample is 0.5 mol L^{-1} (see Section 3).

2.2.2. Preconcentration on UTEVA resin and separation on anion exchange resin

1.33 L of the prepared solution (3 mol L^{-1} HNO_3 in sample) was passed through a column (I.D. = 0.9 cm) filled with UTEVA resin (3 g) at a flow rate of (1–2) mL min^{-1}. Before that, the column had to be prepared for separation by passing of 50 mL of 3 mol L^{-1} HNO_3. After passing the sample, 50 mL of 3 mol L^{-1} HNO_3 were passed through the column. Thorium and uranium were stripped together with 50 mL of deionised water and then separated on the anion exchange column. Water fraction was reduced (by evaporation) to 1 mL and then prepared for separation on the anion exchange column filled with Amberlite CG-400 in nitrate form. 1 mL sample was mixed with 5 mL of 0.25 mol L^{-1} HNO_3 in methanol and passed through the column filled with 1 g Amberlite CG-400 at a flow rate of 1 mL min^{-1}. Uranium was eluted with 25 mL of 0.25 mol L^{-1} HNO_3 in methanol, and after that thorium was stripped from the column with 5 mL of deionised water. To perform spectrophotometric determination, the volume of uranium and thorium fractions must be reduced by evaporation to 1 mL exactly. The same procedure is applied for isolation from model sample of drinking water. The concentration of acid in the sample is 3 mol L^{-1} (see Section 3).

2.2.3. Preconcentration and separation on TRU resin

1 L of the prepared solution (0.5 mol L^{-1} HNO_3 in sample) was passed through a column (I.D. = 0.9 cm) filled with TRU resin (1.5 g) at a flow rate of (1–2) mL min^{-1}. Before that, the column had to be prepared for separation by passing of 50 mL of 3 mol L^{-1} HNO_3. After passing the sample, 50 mL of 3 mol L^{-1} HNO_3 were passed through the column. After that, thorium was eluted with 25 mL of 0.5 mol L^{-1} HCl and uranium was stripped with 25 mL of deionised water. To perform spectrophotometric determination, the volume of uranium and thorium fractions must be reduced to precisely 1 mL by evaporation.

2.2.4. Preconcentration and separation on UTEVA resin

1.33 L of the prepared solution (3 mol L^{-1} HNO_3 in sample) was passed through a column (I.D. = 0.9 cm) filled with UTEVA (3 g) at a flow rate of (1–2) mL min^{-1}. Before that, the column had to be prepared for separation by passing of 50 mL of 3 mol L^{-1} HNO_3. After passing the sample, 50 mL of 3 mol L^{-1} HNO_3 were passed through the column. After that, thorium was eluted with 25 mL of 5 mol L^{-1} HCl and uranium with 25 mL of 0.1 mol L^{-1} HCl.

2.3. Preconcentration and isolation of uranium and thorium from drinking and seawater

Drinking water and seawater samples were prepared by mixing 1 L of the sample and 100 mL conc. HNO_3 (1 mol L^{-1} final concentration of nitric acid). Prior to that, water samples had to be filtered through G4 sinter funnel. After passing the sample, 50 mL of 3 mol L^{-1} HNO_3 were passed through the column. After that, thorium was eluted with 25 mL of 0.5 mol L^{-1} HCl and uranium was stripped with 25 mL of deionised water. To perform spectrophotometric determination, the volume of uranium and thorium fractions must be reduced to 1 mL exactly. This procedure was repeated with 2 L of water. In water and seawater samples uranium was also directly determined by ICP-MS.

2.4. Preconcentration and isolation of uranium and thorium from soil samples

Different soil samples for the analysis was used; NIST SRM 2710 Montana soil, IAEA 312 soil and natural soil taken on the island Vis and on the Adriatic coast (terra rossa and dolomite soil). Natural soil samples were prepared for analysis by drying and sieving through 250 μm sieve.

Soil samples require special ways of treatment in order to be transferred in soluble form suitable for isolation of the matrix elements with extraction chromatographic resins or ion exchangers. Soil samples can be dissolved with concentrated acids and hydrogen peroxide in the following sequence (HCl, HNO_3, HF, $HClO_4$, H_2O_2, HNO_3) by heating or using microwave digestion [20]. If 10 g of sediment or soil are destroyed, it requires acid volumes of 100 mL respectively (except HF, which is added twice á 50 mL) and 10 mL of hydrogen peroxide. After final evaporation, the sample is dissolved in the smallest possible volume of desired concentration of HNO_3 (100 mL) and then transferred into the form suitable for separation. For direct determination of U and Th by ICP-MS aliquot of 1 mL solution of NIST, IAEA and natural soil samples was diluted before analysis.

2.4.1. Preconcentration and separation of uranium and thorium on TRU resin

Prepared solution in 3 mol L^{-1} HNO_3 was passed through a column (I.D. = 0.9 cm) filled with TRU resin (1.5 g) at a flow rate of (1–2) mL min^{-1}. Before that, the column had to be prepared for separation by passing of 50 mL of 3 mol L^{-1} HNO_3. After passing the sample, 50 mL of 3 mol L^{-1} HNO_3 were passed through the column. After that, thorium was eluted with 25 mL of 0.5 mol L^{-1} HCl and uranium was stripped with 25 mL of deionised water. To perform spectrophotometric determination, the volume of uranium and thorium fractions must be reduced to precisely 1 mL by evaporation.

2.4.2. Preconcentration and separation of thorium on anion exchange column

The soil after digestion was dissolved in the minimal quantity of 5 mol L^{-1} HNO_3 and mixed with methanol so that the concentration is 0.25 mol L^{-1} in methanol [37,38]. Alcohol solution was passed through a column (I.D. = 0.9 cm) filled with 1 g Amberlite CG-400 in nitrate form. After passing the sample, 100 mL of 0.25 mol L^{-1} HNO_3 were passed through the column in order to separate macroconstituents. Following that, thorium was eluted with 10 mL of deionised water. Since soil samples often contain lead that binds strongly to anion exchanger and is eluted from column with water.

Lead also makes complex with Arsenazo III and interfere with thorium in spectrophotometric determination. Therefore it must be separated from thorium. In order to achieve that, a water fraction of thorium and lead from the anion exchanger was passed through a column filled with 0.2 g of Sr resin (0.1 mol L^{-1} HNO_3). In such conditions, thorium did not bind to the column, while lead bound strongly. To perform spectrophotometric determination, the volume of thorium must be reduced to precisely 1 mL by evaporation. Thorium was also determined by mass spectrometry. For the thorium analysis aliquot of 0.1 mL of water fraction was taken and diluted in deionised water.

2.5. Spectrophotometric and ICP-MS determination of uranium and thorium

Spectrophotometric determination was based on measuring the absorption of the complex compounds with Arsenazo III or Thorin in the visible part of the spectrum from 400 to 800 nm. Measurements were performed according to blind samples. The samples were prepared in flasks of 10 mL by adding of the specific sample volume and 0.8 mL of 0.05% solution of Arsenazo III or 1.2 mL of 0.1% solution of thorin. The pH values were adjusted by adding conc. 10% NaOH or 5 mol L^{-1} HNO_3 or HCl, and the flasks were refilled with water, methanol, or ethanol.

ICP-MS Element 2 mass spectrometer with conical nebuliser (Thermo) and glass spray chamber (Scott-Thermo) was used for the U and Th determination (RF powers 1200 W, Coolant flow 15.5 L min^{-1}, sample gas flow 1.004 L min^{-1}, Resolution LR = 300, MR = 4000, HR = 10 000, sample uptake 1 mL min^{-1}, acquisition mode E-scan, sample time 5 min). Before analysis, the ICP-MS measuring conditions were optimised using a solution containing In and U at a concentration of 1 μg L^{-1}. Calibration standards for ICP-MS determination were prepared by dilution of 10 mg L^{-1} U and Th Merck standards solution in model drinking water and seawater samples. Model samples (without U and Th) were prepared as described previously.

2.6. γ-Spectrometric determination of ^{232}Th and ^{238}U in soil samples

Prior to gamma spectrometry measurement dried soil samples were placed into counting vessel of known geometry, sealed and stored for at least 6 weeks to allow ingrowths of decay products and to equilibrate with their long lived precursor. After that samples were counted on a gamma spectrometer with HPGe broad detector and 8192 channel analyzer. The system was calibrated and validated by using γ-standards (Czech Metrological Institute) and IAEA reference materials IAEA-306, IAEA-311 and IAEA-314. Counting time was 200 000 s and spectra were analysed by GENIE 2000 software (Canberra). ^{232}Th activities were determined from 911.1 keV peak of its progeny ^{228}Ac(Ra). 186 keV peak of ^{235}U (after subtracting of ^{226}Ra overlapping peak) were used for ^{238}U determination taking into account activity ratio ^{235}U/^{238}U of 0.046. Calculated ^{238}U activity was additionally controlled using 1001 keV line of its progeny ^{234M}Pa as well as ^{235}U activities using 143.7 keV and some other lines [26,40,41].

2.7. Instruments

The instruments used for the detection and quantitative determination of cations were the atomic absorption spectrometer PerkinElmer 3110, Varian Cary 3 UV–VIS spectrophotometer with 1 **cm** quartz cells and HR ICP-MS Element 2 (Thermo Finnegan, Germany). Gamma spectrometry system with HPGe Broad detector was used (Canberra).

2.8. Chemicals

The EiChrom extraction chromatographic resins TRU, UTEVA and Sr resin and the Fluka Amberlite CG-400 strong anion exchange resin (100–200 mesh) were used. Arsenazo III and thorin were used as ligands for complexation. All other chemicals used in this paper were of analytical or supra pure grade (Merck).

3. Results and discussions

As we have mentioned in Section 1, the main aim of this paper is the development of methods for uranium and thorium preconcentration and separation from complex samples. On the one hand, these methods will enable their spectrophotometric determination, and on the other hand will improve determination performances (removal of matrix influence) for other methods, primarily for ICP-MS. That means that the creation of an effective and simple procedure for direct binding and preconcentration of uranium and thorium with their mutual separation from matrix elements is required. As we have mentioned, Horwitz and co-workers have developed specific resins for simple binding of uranium and thorium. These resins are TRU and UTEVA (macro-elements and series of other elements can be also bound on these resins), and are now most often used for their isolation. The characteristics of these resins are very well described in literature [31–35]. However, in concrete applications additional research for optimal conditions of binding and separation from the series of other elements are required. Therefore, uranium and thorium binding on the mentioned resins from aqueous solutions of different composition has been studied.

3.1. Binding of uranium and thorium on the TRU, UTEVA resins and anion exchanger Amberlite CG-400

Solutions of nitric and hydrochloric acids in deionised and seawater were chosen for the experiment. Seawater was chosen for its complex composition and the fact that it can be used as a model for binding from other sample types containing large quantities of macro-constituents. Furthermore, uranium is possible to determine in natural and seawater sample directly by ICP-MS but such determination of thorium is not possible due to its low concentration [16,28]. On the other hand ICP-MS provides a rapid and sensitive technique for their determination but high levels of sample matrix can produce interference in the plasma which result in a suppression of analyte ionisation or block the nebuliser or torch due to the deposition of dissolved solids coming out of solution [19,24].

Tables 1 and 2 contain the results of determination of distribution coefficients of uranium and thorium for UTEVA and TRU resins

from the solutions of nitric and hydrochloric acids in deionised water as well as the solutions of nitric and hydrochloric acids in seawater. The results in Table 1 have shown that U and Th bind stronger on the UTEVA resin from the solutions of nitric acid then from solutions of hydrochloric acid. The binding strength of U and Th increases with increasing of concentration of both acids. But it is obvious that binding strength of U and Th depends on presence of matrix ions. So distribution coefficients of Th are higher in deionised water than in seawater for concentration of nitric acid of 0.5–3 mol L^{-1}. On the other hand distribution coefficients of U are similar in both deionised and seawater in the mentioned nitric acid concentration range. But for 5 mol L^{-1} nitric acid K_D of U is three times higher in seawater while Th distribution coefficients is almost same in both solution. For the distribution coefficient of Th in HCl solution there is no difference between deionised water and seawater. Behaviour of U is almost the same except for the 5 mol L^{-1} where K_D of U is three times higher. If these results are compared with Horwitz it can be seen that trend of increasing of binding strength with increasing of acid concentration are the same for both elements in deionised water [31–34]. It should be mentioned that only trend can be compared because of Horwitz gave dependence of capacity factor about concentration of acid. But Horwitz in these articles did not study influence of anions like F^-, Cl^- on the behaviour of U and Th on UTEVA resins or other resins. As seawater contains high concentration of Cl^- ions it can be suppose that differences in K_D of Th and U in seawater and deionised water is result of interaction of Th^{4+} and UO_2^{+} ions with Cl^-, NO_3^- and diamylphosphonate (DAAP) the extractant impregnated on UTEVA resin. DAAP acts as neutral ligand and charge of Th and U can be neutralized by counter ions. Since the major anions are Cl^- and NO_3^- it is possible that Th^{4+} and UO_2^{+} form complexes with these anions. It is well known that nitrate complexes are extracted with UTEVA resin [31–33]. In the case of 5 mol L^{-1} HNO_3 Th nitrate complexes should proceed. As HNO_3 concentration increases NO_3^- concentration also increases and Cl^- concentration decreases due to binding of Cl^- with H^+. This would promote nitrate formation and tend to increase binding strength. In fact it seems that its chloride complex has high Gibbs energy for transfer from aqueous to organic phase and at lower concentration of nitrate ions formation of thorium nitrate was not dominant. This implies that thorium chloride complex is hard to extract with UTEVA resins and presence of chloride ions decrease binding strength. On the other hand U form chloride complexes which can be extracted with DAAP and presence of chloride ions from seawater can additionally stabilized complex formation in resin and increase binding strength [42,43].

Results in Table 2 showed that in the whole range of the tested HNO_3 concentrations, binding of Th and U on TRU resin is very strong for both deionised and seawater sample. It has also been noted that the binding of uranium from seawater samples on TRU resin does not follow the binding trend of thorium. Namely, the results have shown that thorium binds very strongly in the tested range of concentrations and from all acid solutions, while uranium binds less strongly from acid solutions in seawater at lower concentrations of acids. Results in Table 2 also shows that U from the solution of hydrochloric acid binds on TRU resin more strongly, unlike thorium that does not bind, or binds rather weakly from the hydrochloric acid solution of concentration lower than 3 mol L^{-1}. It should be mentioned that U binding strength decreases in seawater solution and difference between binding strength of U and Th on TRU resin from seawater and deionised water can be explained at previous manner but for exact explanation more detailed study is needed. As in previous case our results follows Horwitz results from which can be seen that trend of increasing of binding strength with increasing of acid concentration are the same for both elements [31–34].

Considering that a range of macro-constituents does not bind on UTEVA and TRU resins and that, according to the obtained results, uranium and thorium binding on TRU resin from the solutions of nitric acid is very strong, it can be expected that preconcentration will be successful. Therefore, developing a method of preconcentration and isolation of uranium and thorium from drinking water and seawater will not require a high concentration of acid, since both elements are bound strongly on UTEVA and TRU resin at concentration of 3 and 0.5 mol L^{-1} HNO_3 respectively. Thus, it is possible to perform preconcentration from a great amount of sample, as it will be shown. In order to ensure the conditions for obtaining the accurate results of quantitative determination of uranium and thorium by spectrophotometry, it is necessary to perform 100% isolation and separation of uranium and thorium along with preconcentration.

Uranium and thorium can be isolated from the samples and separated from each other by classical ion exchange on strong base anion exchangers. The procedure requires the usage of concentrated acids and is rather time consuming. However, thorium can be bound on the mentioned exchanger from the alcohol solutions of nitric acid. It should be mentioned that it is possible to selectively bind cations on anion exchanger in nitrate form from alcohol solutions [36–38]. In this case binding is governed by sorption (not ion exchange) of cations on strong base anion exchanger in nitrate form in presence of high portion of alcohol. So Table 3 shows the binding of a range of cations on anion exchanger from the solution of nitric acid in methanol and ethanol. From these results, can be seen that number of elements does not bind on the exchanger at this manner. Furthermore, Tables 4 and 5 show the results of determination of Pb, U and Th distribution coefficients from ethanol and methanol solutions of nitric acid. From these results, we can see that Th binds strongly on anion exchanger, unlike uranium, whose binding is weak. The reason for that is probably in the fact that uranium is in the form of UO_2^{+} ions, while thorium is in Th^{4+} form, so that thorium binding is much stronger due to the difference in ion charges [37,38]. Along with thorium, lead also binds strongly on the anion exchanger. The results have shown that thorium binds more strongly from methanol than from ethanol, and lead behaves in opposite manner. They have also shown that the presence of water decreases binding strength. It is to be expected, since water increases the polarity of the solution. It has to be mentioned that the mechanism of this binding has not been clarified and that some deviations, such as weaker binding of thorium in ethanol solution, cannot be explained by polarity. The presence of water in alcohol mixtures is useful in practical application because of better dissolution of nitrate salts. However, a larger quantity of water prevents binding, so it has to be taken into consideration during the preparation of a real sample solution. If we increase the concentration of acid in alcohol, it also decreases binding strength.

3.2. Separation of uranium and thorium on the chromatographic column

The separation of uranium and thorium is necessary in spectrophotometric determination. The previous results have shown that U and Th demonstrate a pronounced difference in the intensity of binding on UTEVA resin from hydrochloric acid solution in concentration higher than 3 mol L^{-1}, as well as in binding on TRU resin from hydrochloric acid solution in concentration range from 0.5 to 3 mol L^{-1}, which can be applied for the procedure of their separation.

Table 4
Distribution coefficients (K_D/mL g^{-1}) of lead, thorium and uranium for Amberlite CG-400 in nitrate form and alcoholic–water solution of 0.25 mol L^{-1} nitric acid.

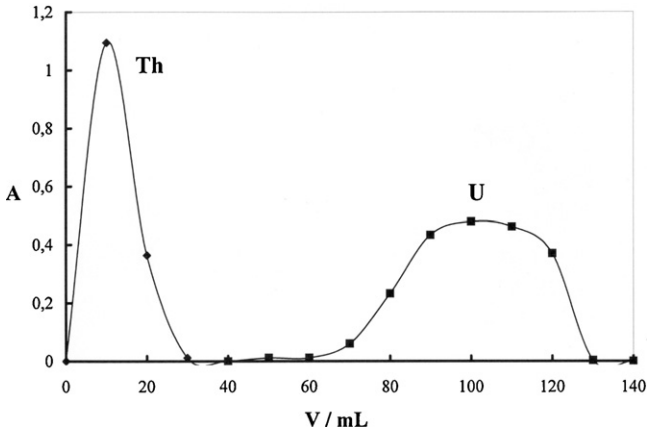

Fig. 1. Separation of uranium from thorium on TRU column (I.D. = 0.9 cm, 10.6 cm bed height, 2 g TRU resin, flow rate 1.7 mL min^{-1}) by elution with 0.5 mol L^{-1} HCl.

Based on the previous results, elution curves are determined. It can be seen from Fig. 1 that uranium can be easily separated from thorium on TRU column by elution with 0.5 mol L^{-1} of hydrochloric acid because, in given conditions, uranium is much more strongly bound than thorium. However, a large quantity of 0.5 mol L^{-1} HCl is needed for elution, which is not acceptable in cases when preconcentration of the sample has been applied. In this case, uranium can be eluted with 0.1 mol L^{-1} of HCl or deionised water in two column volume.

Based on the obtained results for TRU resin, we have developed a procedure of isolation and simultaneous separation of uranium and thorium from natural samples, which is described in detail in the experimental part of the paper. In the previous part, we have also tested binding of these elements on UTEVA resin and determined the elution curves presented in Fig. 2. The separation of uranium from thorium on the column filled with UTEVA resin, in the given conditions for 1 g of resin, cannot be achieved by eluting with hydrochloric acid. However, it is possible to achieve better separation results by increasing the height of resin in the column, which suggests that it could be possible to perform a complete separation—see Fig. 2. Nevertheless, this procedure should be avoided if preconcentration is performed.

A complete separation of uranium from thorium on the given resin can be achieved by eluting with 5 mol L^{-1} of hydrochloric acid due to their significant difference in distribution coefficients. Due

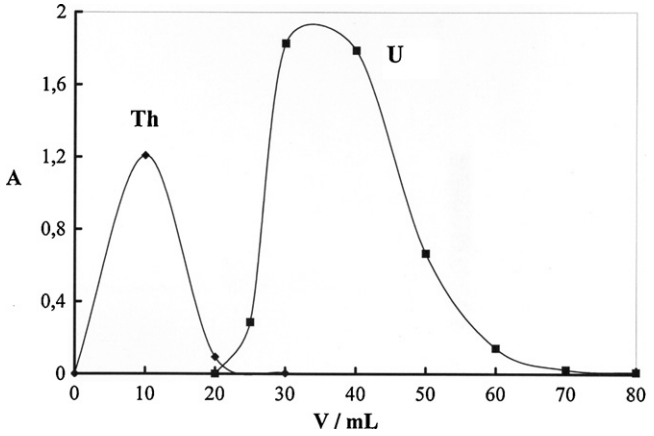

Fig. 2. Separation of uranium from thorium on UTEVA column (I.D. = 0.9 cm, 10.6 cm bed height, 2 g UTEVA resin, flow rate 1.2 mL min^{-1}) by elution with 3 mol L^{-1} HCl.

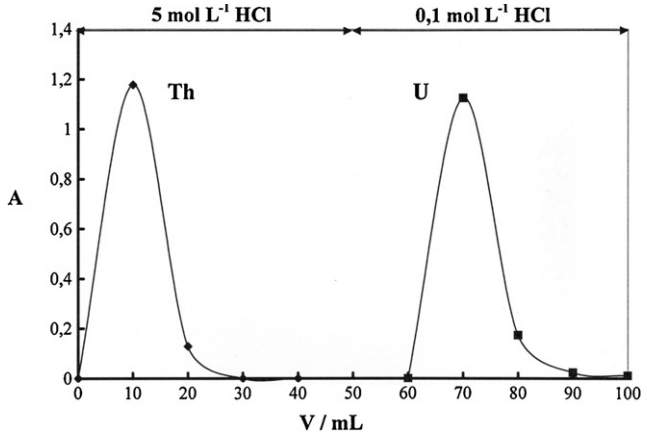

Fig. 3. Separation of uranium from thorium on UTEVA column (I.D. = 0.9 cm, 10.6 cm bed height, 2 g UTEVA resin, flow rate 1.4 mL min^{-1}) by elution with 5 mol L^{-1} HCl and 0.1 mol L^{-1} HCl.

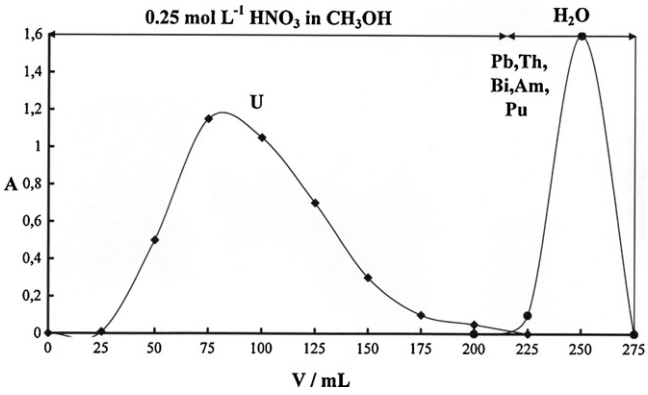

Fig. 4. Separation of uranium and thorium on anion exchange column (I.D. = 0.9 cm, 15 cm bed height, 5 g of Amberlite CG-400 in nitrate form, flow rate 1 mL min^{-1}) by elution with 0.25 mol L^{-1} HNO_3 in methanol.

to its weak binding on the resin, thorium is first eluted from the column with a small eluents volume—Fig. 3.

However, certain elements that can interfere with spectrophotometric determination also bind on TRU and UTEVA resins together with uranium and thorium. Furthermore, extraction chromatographic resins are expensive compared to ion exchangers, and it is possible to remove the extraction medium from the inert carrier during preconcentration and separation. As it has been shown by previous results, uranium and thorium are bound on anion exchanger in nitrate form from alcohol solutions of nitric acid. Thus, it is possible to separate them on the chromatographic column. Since zirconium, which binds on UTEVA resin [43], does not bind on anion exchanger, it can be separated from thorium in the described manner. The elution curves given in Fig. 4 show that it is possible to separate uranium from zirconium, thorium, and lead on the column filled with Amberlite CG-400 (NO_3^- form) [38].

3.3. Spectrophotometric determination of uranium and thorium

The elution of uranium and thorium from chromatographic resins (Amberlite CG-400, TRU and UTEVA) depends on the kind of acid and its concentration, as well as on the type and the mass percent of the used alcohol. Because of this, the influence of the solution composition on the colour development in optimal conditions for complex formation has been investigated. The calibration graphs obtained under optimal conditions for U-Arsenazo III obeyed the Beer's law in the range (0–8.00) mg L^{-1}. The colour reaction has almost the same sensitivity in water solution of hydrochloric or nitric acids. However, it has been found that in the alcohol solutions the absorptivity of U-Arsenazo III decreases, especially when the solution contains methanol. For Th–thorin complex, a linear relationship between absorbance and concentration is obtained between (0 and 12.0) mg L^{-1}. The obtained results in Table 6 show that the absorptivity of Th–thorin method has larger value in nitric than in hydrochloric water solution. In addition, the sensitivity of the method increases in alcohol solution—Table 6. For Th–Arsenazo III complex, a linear relationship between absorbance and concentration is obtained between (0 and 8.0) mg L^{-1}. The obtained results show that the absorptivity of Th–Arsenazo III method has larger value in nitric than in hydrochloric water solution. In addition, the absorptivity increases very little in methanol–nitric acid solution—Table 6. It has to be mentioned that the absorptivity is almost twice as high for Th–Arsenazo III than for Th–thorin complex.

Due to the fact that the binding strength of uranium and thorium onto ion exchanger depends on the water content in alcohol mixture, it is necessary to know how the absorptivity depends on the composition of water–alcohol mixture. We attempted to connect the relation between absorptivity and volume portion of alcohol in solution with simple linear relation. It can be assumed that the absorptivity of the coloured species in water–alcoholic mixture depends on portion of alcohol according the following equation:

$$a = X_A \cdot a_A + X_B \cdot a_B$$

X_A: volume portion of water; a_A: absorptivity in water solution; X_B: volume portion of alcohol; a_B: absorptivity in alcoholic solution.

The calculated value for the absorptivity is compared with the experimental data obtained by measuring the absorbance of the coloured species in solutions containing various portion of alcohol. On one hand, it can be seen from the obtained results that the sensitivity of the uranium–Arsenazo III method decreases with increasing the alcohol portion in the solution. On the other hand, the sensitivity of thorium–thorin method is larger in the alcohol solution. The deviation data calculated according to above mentioned equation from experimental data are in range of maximal 6% for methanol and 10% for ethanol—Table 7. However, in thorium–arsenazo complex, the presumed relation cannot be discussed because the presence of alcohol causes a great deviation from the Beer's law, which can be seen in Fig. 5 .

Since the concentration of uranium and thorium in environmental samples is very low, it is necessary for the spectrophotometric analysis to know the smallest concentration that can be reported with a certain level of confidence. Such a concentration can be cal-

culated from the Curie statistical treatment [44] of the experimental data—Table 8. The level of detection was obtained from critical level for blank fluctuation ($L_c = 2.33\sigma_b$, $L_d = 4.65\sigma_b$, $L_Q = 14.1\sigma_b$). Limit of determination LOD (C in mg L^{-1}) was estimated from absorptivity coefficient a (assuming negligible error) and quantification level ($L_Q = aC$). L_Q was chosen in order to obtain a precision as small as 10%. Limit of determination in Table 8 is given for spectrophotometric determination. Considering that the absorptivity coefficient for thorium–arsenazo III is almost twice as high as for thorium–thorin, for quantitative determination and detection Arsenazo III form was used.

3.4. Isolation and determination of uranium and thorium in model water samples

It has to be said that uranium in surface seawater exist in the hexavalent oxidation state and anionic uranium carbonato complexes. Acidification of samples results in destabilization of carbonato complexes and formation of uranium (VI)–aqua-complexes. At pH = 1 only UO_2^{2+} is present [16,40,45]. Thorium is presented in water in

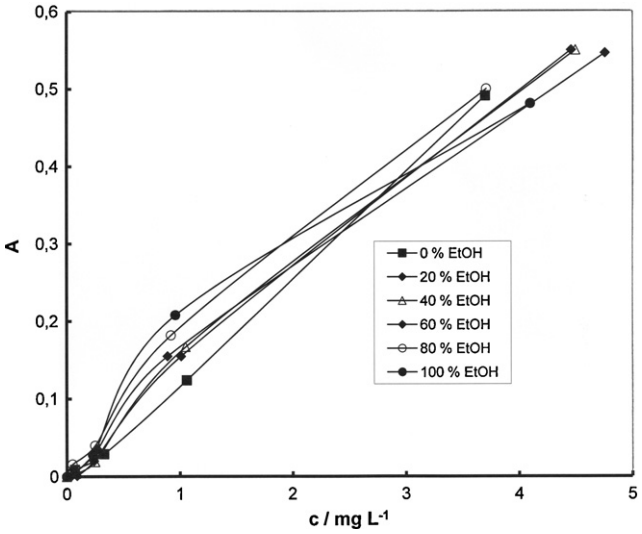

Fig. 5. Dependence of thorium–arsenazo III complex absorptivity on ethanol contents.

quadrivalent state but due to low solubility it will be present in water as suspended particles. Soluble thorium ions in water will hydrolyse at pH above 5 forming $Th(OH)_4$ precipitate or hydroxy complexes. The hydroxy complexes will be adsorbed by particulate matter in water, with the results that most of the thorium is presented in suspended matter or sediment and concentration of soluble thorium in water is very low, but in some cases due to formation of soluble complexes with carbonate and other ligands concentration can increase [28,46].

The procedure of preconcentration and separation of uranium and thorium from water samples is described in the experimental part of the paper. In order to test the proposed methodology, uranium and thorium were first isolated from model samples by concentration on TRU and UTEVA resins from 0.5 and 3 mol L^{-1} HNO_3, and then separated from each other on Amberlite CG-400 (NO_3^-) exchanger with 0.25 mol L^{-1} HNO_3 in methanol. Model samples contained the known concentrations of uranium and thorium. After preconcentration and separation, thorium and uranium were determined by spectrophotometry. Sample volume was 1.33 L for UTEVA resin and 1.04 L for TRU resin, while concentration of uranium and thorium was about 10 μg L^{-1}. At the beginning "high" concentration was used due to easier and accurate spectrophotometric determination. Concentration of U and Th was also determined by ICP-MS in model samples. Table 9 provides the results of uranium and thorium determination before and after completing the procedure. The results have shown that the isolation is quantitative for both resins from both samples (recovery is 90–100%). It has to be said that ICP-MS analysis of uranium and thorium fractions was performed. The thorium has not been found in uranium fraction and vice versa.

The other way of isolating uranium and thorium from model drinking water and seawater samples was by using the TRU resin on

which U and Th are bound from 0.5 mol L^{-1} HNO_3 in drinking water or seawater. Thorium was eluted with 0.5 mol L^{-1} of HCl, and uranium with 0.1 mol L^{-1} of HCl or with deionised water. The obtained results in Table 10 have shown that uranium and thorium can be preconcentrated and simultaneously separates on TRU resin in the separation procedure from water samples where they are present in low concentrations. These results show that it is possible to isolate quantitatively uranium and thorium from water samples. But results also suggest that it is possible to acquire thorium losses that can lead to determination error. Losses are probably caused due to low cation and acid concentration in water sample. It must be said that certain losses of extraction medium into mobile phase may be acquired in the course of isolation during the eluting procedure (considering the fact that binding of the extraction medium on the carrier is not of covalent nature, but an absorption), which results in shorter retention on the resin and earlier elution.

The results in Table 10 have also shown that uranium and thorium can be preconcentrated from water samples where they are present in low concentrations. But spectrophotometric determination is limited on the concentration over LOD. As we seen earlier LOD for the U and Th in our case are 0.24 and 0.43 mg L^{-1} respectively. As concentration of U and Th are far below these values, even in case of concentration by 1000 times (volume reducing from 1 L to 1 mL) U and Th could not be determined. Therefore concentration was determined by ICP-MS. U and Th was determined by spectrophotometry only in samples with highest concentration (0.2 μg L^{-1} of U and 0.4 μg L^{-1} of Th) after the separation from 2 L of water and reducing a volume of to 1 mL (2000 times). In this case obtained concentration of U and Th was 0.17 and 0.37 μg L^{-1}.

3.5. Determination of uranium and thorium in real water samples

Based on the previous results, a procedure for isolation and determination of uranium and thorium from seawater and drinking water samples (spring and mineral water) was created. Uranium and thorium were bound from 1.5 mol L^{-1} HNO_3 on TRU resin. 1.5 mol L^{-1} of HNO_3 was chosen based on the previous results of K_D determination and the results obtained from model solutions, as an optimal concentration that, on one hand, enables quantitative isolation, and on the other, decreases the consumption of concentrated acid. Prior to isolation, uranium was determined in drinking water and seawater on ICP-MS before and after processing. Thorium could not be determined directly on the available instrument. The isolation was performed from 2 L of water. Uranium and thorium were separated with 0.5 mol L^{-1} HCl, and then determined by spectrophotometry. U and Th were also determined on ICP-MS. Obtained results can be seen from Table 11. From these results it can be seen that thorium was determined only in seawater by ICP-MS after preconcentration (factor 1000) and separation on the columns. Results also show that concentration of U which can be determined by spectrophotometry after the separation from 2 L sample lie below 1 μg L^{-1}. In addition obtained results correspond with results of other authors (2.1 μg L^{-1} U in seawater and 0.99 μg L^{-1} in mineral water) [40,48].

Table 11
Determination of U and Th after the preconcentration and separation on TRU column.

	ICP-MS		Proposed method

3.6. Determination of uranium and thorium in NIST and IAEA soil sample

For the test of the method for the determination of U and Th in soil sample NIST SRM 2710 and IAEA-312 soils were used. After dissolving of the 10 g soil sample in acids, and filtering through G4 sinter funnel, 100 mL of 3 mol L^{-1} HNO_3 of sample solution was passed through a TRU column, and uranium and thorium were isolated from other elements by eluting with 50 mL of 3 mol L^{-1} HNO_3 and separated from each other with HCl solution as it has been described earlier and determined by spectrophotometry and on ICP-MS. For the direct ICP-MS determination an aliquot of 1 mL of original solution of samples was used. As it well known one of the major problems in determining trace elements by ICP-MS in soil is the matrix effects caused by major constituent elements Ca, Mg, Al and Fe. The matrix effect caused by these elements has been carefully studied by Shinotsuka and Ebihara [24]. As a result, a dilution factor was proposed for the U and Th determination. In our case we have used different dilution factor depending on U and Th concentration in sample and reference sample composition. The obtained results are shown in Table 12. By comparison of obtained results it can be concluded that ICP-MS results match well with oriented value. Results obtained by spectrophotometer determination are satisfactory in relation to oriented results. But it should be mentioned that in case of chemical separation it is visible that all obtained results are below the oriented value. Reason for that can be some loses of U and Th during the separation procedure.

As we have already said, thorium can be isolated rather easily on a column filled with anion exchanger in the procedure described in experimental part of the paper. This procedure was used for isolation of thorium from the soil samples, and determined by spectrophotometry and ICP-MS. The results obtained are also shown in Table 12. Specifically, thorium is strongly bound from alcohol solutions on exchanger Amberlite CG-400 (NO_3^- form) and easily separated from a range of elements, except from lead. However, it is easily separated from lead on the small quantity of Sr resin. Considering the given characteristics, in this procedure, the smallest risk of losses occurs during concentration and isolation.

3.7. Determination of uranium and thorium in soils

As in previous case after dissolution in 3 mol L^{-1} HNO_3, and filtering through G4 sinter funnel, the solution was passed through a TRU column, and uranium and thorium were isolated from other elements by eluting with 50 mL of 3 mol L^{-1} HNO_3, separated from each other as it has been described earlier, and determined by spectrophotometry. The same procedure was applied to determination on ICP-MS. Both uranium and thorium were also determined by high-resolution gamma spectrometry as described in experimental part. The obtained results are shown in Table 13. It is shown that deviations for both elements and for all three methods amount to 25%. Similar to the previous case, the results obtained by spectrophotometric determination are, as a rule, lower than those obtained by gamma spectrometric determination. It should be mentioned that results in table are given as mean from three determinations and error is expressed as standard deviation.

In our paper uncertainty for single spectrophotometric determination is not discussed because an overview of the most important uncertainty sources that affect analytical UV–VIS spectrophotometric measurements was described and generic uncertainty budget for absorbance was presented elsewhere [49]. It was demonstrated that the well-known intrinsic sources of uncertainty that originate from the instrument itself (repeatability of spectrophotometer reading, spectrophotometer drift, stray light, etc.) often have significantly lower contributions to the combined uncertainty of the result than the "chemical" sources of uncertainty that originate from the object under study (interference from the constituents of the matrix, decomposition of the photometric complex, etc.).

At the end it can be said that spectrophotometric determination in combination with preconcentration and separation step is time consuming. Nevertheless, the determination is simple and can meet the requirements regarding detection limits prescribed by the authorised institutions, since the obtained detection limits in water samples are lower than 1 $\mu g\,L^{-1}$ for uranium and thorium. In addition, it is a cheaper method if compared to ICP-MS. In case when ICP-MS determination requires removing of the matrix elements for some types of samples, the proposed separation methods can successfully used. Moreover, it is possible to use the TRU isolation method for determination of uranium and thorium by other method (polarography, alpha spectrometry) in different samples [27,28,47]. Also mixed solvent anion exchange method can be used for thorium isolation and its determination.

4. Conclusion

The results of determination of distribution coefficients have shown that uranium and thorium are bound on TRU and UTEVA resins from the solutions of nitric and hydrochloric acids, and that the binding intensity increases parallel with increasing the acids' concentration. Uranium and thorium are bound very strongly on TRU resin from nitric acid in concentration ranges from 0.5 to 5 mol L^{-1}, and large quantities of other ions present in the sample do not influence the binding strength. Due to the difference in binding strength in HCl and HNO_3, uranium and thorium can be easily separated from one another on the columns filled with TRU resin. Furthermore, thorium binds very strongly, while uranium binds rather weakly, on the anion exchanger in nitrate form from alcohol solutions of nitric acid, so they can be separated rather easily. These results render possible the creation of flexible and simple preconcentration and isolation procedures for uranium and thorium from the samples of drinking water, seawater, soil and sediments. In combination with spectrophotometric determination with Arsenazo III at concentration factor 1000, which can be achieved easily, we obtain determination limits below 1 $\mu g\,L^{-1}$. The developed procedures are easy to apply in any laboratory.

Pressurized liquid extraction
Liquid chromatography–tandem mass spectrometry

ABSTRACT

A simple and sensitive method for simultaneous analysis of 43 pharmaceutical compounds in sewage sludge and sediment samples was developed and validated. The target compounds were extracted using pressurized liquid extraction (PLE) and then purified and pre-concentrated by solid phase extraction (SPE) using a hydrophilic–lipophilic balanced polymer. PLE extraction was performed on temperature of 100 °C, with methanol/water mixture (1/2, v/v) as extraction solvent. The quantitative analysis was performed by liquid chromatography tandem mass spectrometry using a hybrid triple quadrupole-linear ion trap mass spectrometer (LC–QqLIT-MS). Data acquisition was carried out in selected reaction monitoring (SRM) mode, monitoring two SRM transitions to ensure an accurate identification of target compounds in the samples. Additional identification and confirmation of target compounds were performed using the Information Dependent Acquisition (IDA) function. The method was validated through the estimation of the linearity, sensitivity, repeatability, reproducibility and matrix effects. The internal standard approach was used for quantification because it efficiently corrected matrix effects. Despite the strong matrix interferences, the recoveries were generally higher of 50% in both matrixes and the detection and quantification limits were very low. Beside the very good sensitivity provided by LC–QqLIT-MS, an important characteristic of the method is that all the target compounds can be simultaneously extracted, treated and analysed. Hence, it can be used for routine analysis of pharmaceuticals providing large amount of data. The method was applied for the analysis of pharmaceuticals in river sediment and wastewater sludge from three treatment plants with different treatment properties (i.e. capacity, secondary treatment, quality of influent waters). The analysis showed a widespread occurrence of pharmaceuticals in the sludge matrices.

1. Introduction

The pharmaceutical products have an important role in the treatment and prevention of disease in both humans and animals. They are designed either to be highly active and interact with receptors in humans and animals or to be toxic for many infectious organisms. Because of the nature they can also have unintended effects on animals and micro-organisms in the environment. Although the effects of the pharmaceuticals are investigated through safety and toxicology studies, the potential environmental impacts of their production and use are less understood and have recently become a topic of research interest [1].

The main point of collection and subsequent release of pharmaceuticals into the environment are wastewater treatment plants (WWTP), where they enter via domestic and hospital sewages or through industrial discharges. The studies of effluent waters and river sediment show that wastewater treatment achieves only partial removal of organic pollutants [2–4]. The analysis of effluent and receiving waters itself is not enough to understand comportment of pharmaceuticals during the whole wastewater treatment. Occurrence and distribution of pharmaceuticals in sewage sludge demands detailed investigations, especially because the digested sludge is disposed to landfills or used as agricultural fertilizer. This is another significant route of these micro-pollutants to the environment [5]. It is very difficult to presume the comportment of pharmaceuticals in wastewater treatment because the pharmaceutical products belonging to the same therapeutic groups do not

doi:10.1016/j.talanta.2009.06.077

show the similar removal. This is caused by the fact that they have different chemical structure and thus they differ in issue. The available data just give very general overview. The existing analytical methods are mostly focused on specific therapeutic classes, paying special attention to the antibiotics due to their potential for antibiotic resistance [6]. But with the quantity and variety of pharmaceuticals and organic pollutants in general, the interactive and synergetic effects in environment are very possible. For this reason, new trends in analytical chemistry are focused on development of methods for simultaneous analysis of many various compounds. The qualitative and quantitative analysis is a good starting point for the further planning of wastewater treatment as well as the establishment of new regulations related to this subject.

Recent development of the advanced instruments and improved analytical methodologies made possible detection of pharmaceuticals in low levels in different environmental matrixes [5,7–11]. Several methodologies have been developed for determination of pharmaceuticals in solid environmental samples. In recent years, the target compounds have usually been extracted by liquid partitioning with ultrasonication (USE) [6,12–15], microwave assisted extraction (MAE) [16] or the more advanced pressurized liquid extraction (PLE). In order to minimize interferences with matrix components and to pre-concentrate target analytes, solid phase extraction (SPE) has been introduced in preparation procedure as a clean-up step. The combination of pressurized liquid extraction (PLE) with solid phase extraction (SPE) as clean-up step becomes mostly employed technique for preparation of solid samples for instrumental analysis. The PLE technique provides good recoveries, saves time and organic solvent, which makes this technique being preferred one for these kind of samples [5,17–21]. Recently, Radjenović et al. [7] used the PLE–SPE combination for the isolation of 31 pharmaceuticals from sludge samples proceeding from the conventional activated sludge treatment and pilot-scale membrane bioreactors. Barron et al. [5] used the same approach for sample preparation for analysis of 27 pharmaceuticals in soil and treated sludge. Also, Nieto et al. [17] and Göbel et al. [22] extracted the target compounds from sludge samples using the PLE–SPE. In all the mentioned methods a hydrophilic–lipophilic balance (HLB) reversed-phase sorbent was used as SPE packaging. This sorbent has been found suitable for multi-residue methods in neutral pH condition, with a proper selection of the eluent (solvent) [23–25].

The majority of current analytical methods for separation and detection of pharmaceuticals uses liquid chromatography–tandem mass spectrometry (LC–MS/MS) because of its versatility, specificity and selectivity [26]. Triple quadrupole (QqQ) [7,12,17,27] and ion trap MS (IT) [5,6,15] have been widely applied in quantitative target analysis. Recently, a hybrid instrument consisting of a quadrupole and a linear ion trap (QqLIT) have been applied for analysis of pharmaceuticals in waters, thus good results related to analysis of pharmaceuticals in sludge could be expected. This instrument allows powerful scan combinations which lead to rapid identification and confirmation of analytes [8,24,28,29].

The objective of the present study was to develop and validate a sensitive multi-residual method for determination of 43 pharmaceuticals in sludge and sediment. The target compounds belong to different therapeutic groups of pharmaceuticals. They are listed in Table 1 classified according to their therapeutic effects. The pharmaceuticals are extracted using PLE and purified by SPE (Oasis® HLB). High performance liquid chromatography (HPLC) coupled to a QqLIT-MS has been applied for separation and determination of the target pharmaceuticals. Quantitation was performed by the internal standard approach. The performance of the method was evaluated through the estimation of the linearity, sensitivity, repeatability, reproducibility and matrix effects.

The developed method offers simple and simultaneous extraction, treatment and analysis of 43 pharmaceutical compounds in sludge and sediment. Comparing to the previously published methods for determination of pharmaceuticals in environmental solid matrices this method exhibits significantly improved sensitivity due to the QqLIT capabilities. Finally, the method was successfully applied for analysis of pharmaceuticals in sludge from three WWTPs which proves that it can be used for routine analysis of pharmaceuticals providing a large amount of data.

2. Experimental part

2.1. Chemicals

All the pharmaceutical standards for target compounds were of high purity grade (>90%). Ibuprofen, neproxen, ketoprofen, diclofenac and gemfibrozil were supplied by Jescuder (Rubí, Spain). Acetaminophen, indometacin, mefenamic acid, phenazone, bezifibrate, mevastatin, fenofibrate, Pravastatin (as sodium salt), carbamazepine, famotidine, ranitidine (as hydrochloride), cimetidine (as hydrochloride), erythromycin (as hydrate), azithromycin (as dehydrate), roxitromycin, clarithromycin, josamycin, tylosin A, sulfamethazine, trimethoprim, chloramphenicol, atenolol, sotalol, metoprolol (as tartrate), timolol, pindolol, nadolol, salbutamol, clenbuterol (as hydrochloride), enalapril (as maleate), glibenclamide, furosemide, hydrochlorothiazide and metronidazole were purchased from Sigma–Aldrich (Steinheim, Germany). Standard atorvastatin (as calcium salt) was provided by LGC Promochem (London, UK), while diazepam, lorazepam and butalbital were from Cerilliant (Texas, USA).

Isotopically labelled compounds, used as internal standards, were sulfathiazole-d_4 from Toronto Research Chemicals, diazepam-d_5 and phenobarbital-d_3 from Cerilliant (Texas, USA), atenolol-d_7, carbamazepine-d_{10}, ibuprofen-d_3, clotrimazole-d_5, enalapril-d_5, hydrochlorothiazide-d_2, glyburide-d_3, albuterol-d_3, cimetidine-d_3, ethyl clofibrate-d_4, antipyrine-d_3, acetaminophen-d_4, diclofenac-d_4 from CDN Isotopes (Quebec, Canada), mecoprop-d_3 from Dr. Ehrenstorfer (Augsburg, Germany) and ^{13}C-erythromycin and ^{13}C-phenacetin from Sigma–Aldrich (Steinheim, Germany).

The solvents, HPLC grade methanol, acetonitrile, water (Lichrosolv) and formic acid 98% were provided by Merck (Darmstadt, Germany). Nitrogen used for drying from Air Liquide (Spain) was of 99.995% purity.

The cartridges used for solid phase extraction were Oasis® HLB (200 mg, 6 ml) from Waters Corporation (Milford, MA, USA). The syringe filters of 0.45 μm pore size were purchased from Pall Corp (USA).

The individual standard solutions as well as isotopically labelled internal standard solutions were prepared on a weight basis in methanol. Furosemide and butalbital were obtained as solutions in acetonitrile, while lorazepam and diazepam were dissolved in methanol, at a concentration of 1 mg/ml. The solutions were stored at −20 °C. Fresh stock solutions of antibiotics were prepared monthly due to their limited stability while stock solutions for the rest of substances was renewed every three months. A mixture of all pharmaceuticals was prepared by appropriate dilution of individual stock solutions in methanol–water (25:75, v/v) and it was renewed before each analytical run. A separate mixture of isotopically labelled internal standards, used for internal standard quantification, was prepared in methanol and further diluted in methanol–water (25:75, v/v) mixture.

2.2. Sample pretreatment

River sediment and sludge samples, provided from three wastewater treatment plants (WWTP), were used for development

and validation of the method. The sludge samples are products of aerobic (WWTP Tudela) and anaerobic digestion (WWTP Arazuri and WWTP Terrassa) of sludge.

The sediment was collected from the middle course of river Ebro (Spain) in 2004. The samples from WWTP Tudela (Sludge I) were collected in October 2007 and July 2008. This plant serves 37,300 inhabitants, with a total capacity of 110,000 equivalent inhabitants. Sludge processing is based on thermophilic aerobic digestion in bacterial beds with approximately 9 days of retention time. The samples from WWTP Arazuri (Pamplona) (Sludge II) were collected in October 2007 and from WWTP Terrassa in April 2007. The WWTP Arazuri serves around 356,000 inhabitants, with a total capacity of 722,000 equivalent inhabitants in 2007. The sludge treatment involves anaerobic digestion with retention time of 19 days. The WWTP Terrassa has a total treatment capacity of 277,000 equivalent inhabitants. The sludge is treated by anaerobic digestion with the solid retention time of approx. 10 days.

All the solid samples were freeze-dried (LioAlfa 6, Telstar) at −40 °C and with 0.044 bar vacuum and stored at −20 °C until the analysis.

2.3. Extraction and clean-up

The samples of sludge and sediment were extracted by PLE using ASE 300 accelerated solvent extractor (Dionex, Sunnyvale, CA) equipped with 11 ml stainless extraction cells. Aliquots of freeze-dried and grinded sludge and sediment (1 g) were mixed in the extraction cells with Hydromatrix. This dispersing agent is used

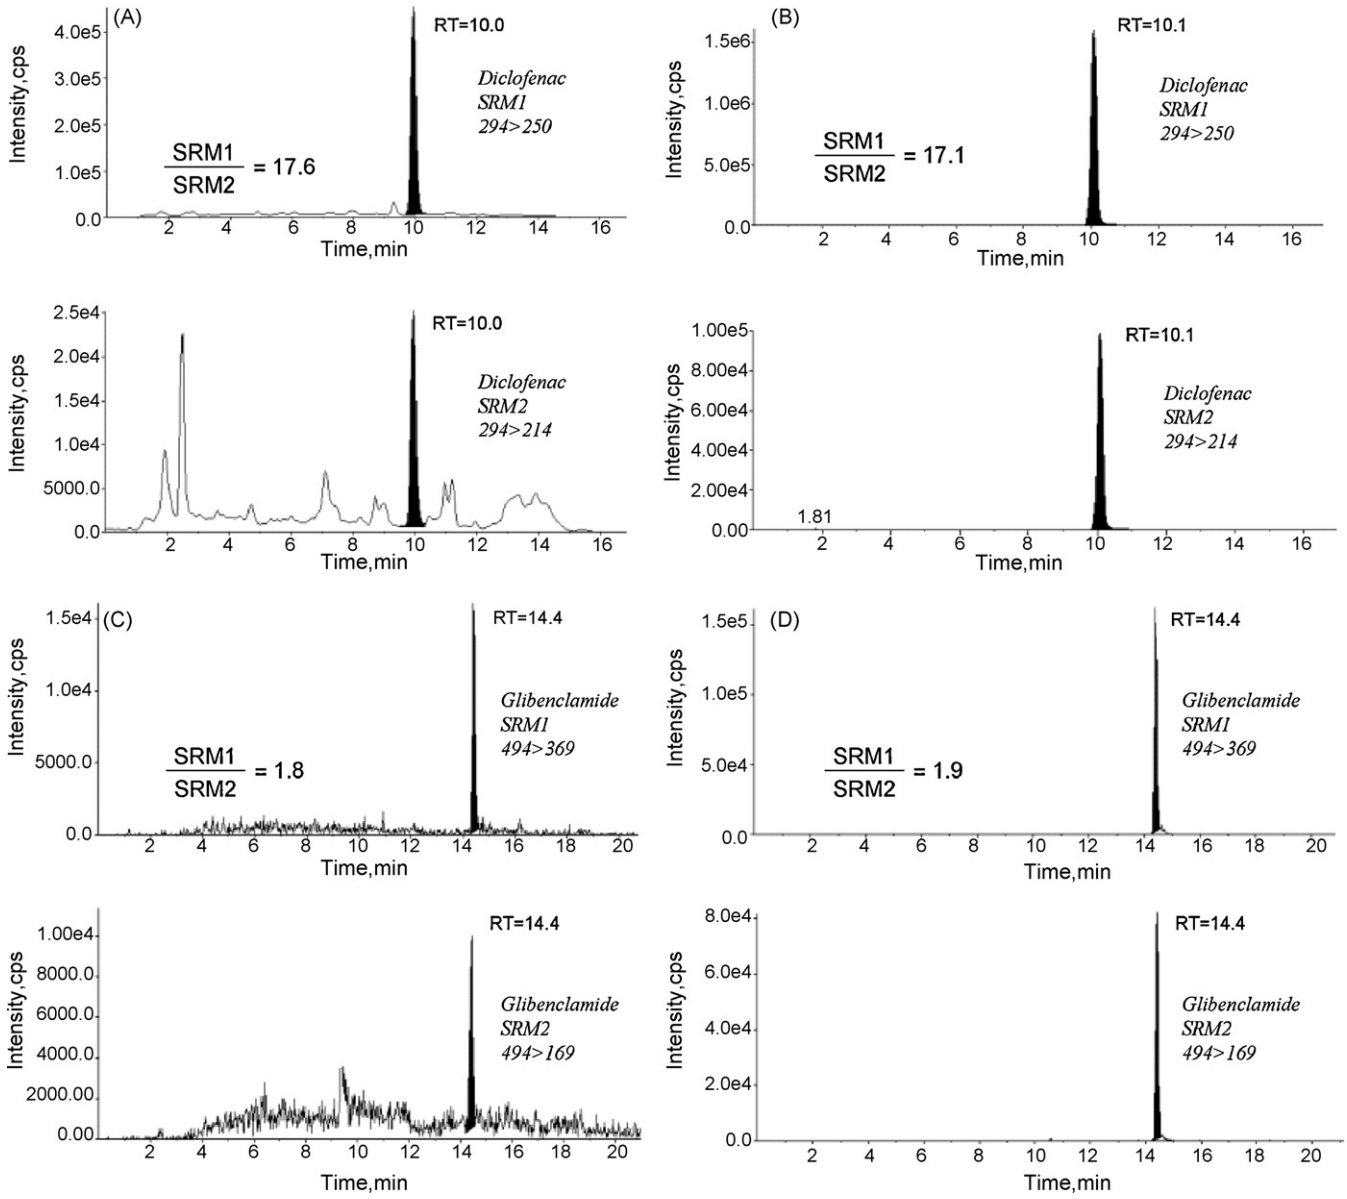

Fig. 1. Chromatograms of the two SRM transitions of diclofenac and glibenclamide in Sludge II (A and C, respectively) and in standard solution (B and D).

to prevent aggregation of sample particles and reduce interstitial volume in the cells [30]. Optimization of extraction parameters included selection of solvent and variation of temperature, time and number of extraction cycles. The extraction method was established with the following parameters: methanol/water, 1/2 (v/v) as extraction solvent, temperature of 100 °C, a preheating period of 5 min, 3 static cycles, each lasting 5 min, total flush volume of 100% of cell with 60 s of nitrogen purge.

The extract obtained in PLE (~22 ml) was diluted in 500 ml of HPLC water (methanol < 5%), and processed by SPE. Oasis HLB cartridges (200 mg, 6 ml) from Waters Corporation (Milford, MA) were used for clean-up. The cartridges were conditioned with 5 ml of methanol followed by 5 ml of HPLC water at neutral pH. Then the dilution of ASE extract was percolated through the cartridges using a Baker vacuum system (J.T. Baker, The Netherlands). Finally, the compounds were eluted with 8 ml of methanol at a 1 ml min^{-1} flow and then the SPE extracts were evaporated under a nitrogen stream and reconstituted with 1 ml of methanol–water mixture (25:75, v/v). Prior to the LC–MS/MS analysis, the samples were passed through 0.45 μm filters and fortified with a standard mixture of the internal standards to the concentration of 20 ng ml^{-1}.

2.4. LC–ESI-(QqLIT)-MS^2 analysis

LC analysis was performed using Symbiosis™ Pico (SP104.002, Spark, Holland), equipped with an autosampler and connected in series with a 4000 QTRAP hybrid triple quadrupole-linear ion trap mass spectrometer equipped with a Turbo Ion Spray source (Applied Biosystems-Sciex, Foster City, CA, USA). Chromatographic separation was achieved with a Purospher Star RP-18 endcapped column (125 mm × 2.0 mm, particle size 5 μm) preceded by a C_{18} guard column (4 × 4, 5 μm), both supplied by Merck (Darmstadt, Germany).

Knowing that an aqueous, purified and pre-concentrated extract of a solid environmental sample is quite similar to a water sample, already established protocol by Gros et al. [8] was used for quantitative analysis of water samples.

The elution gradients were adapted for the LC by Symbiosis™ Pico. For the analysis in negative ionization mode, solvent A was a mixture of acetonitrile–methanol (1:1, v/v) and solvent B was HPLC water. The elution started with 20% of eluent A, increasing to 80% in 15 min, raising to 90% in 2 min and then back to initial conditions within 3 min. The column was re-equilibrated for 10 min before another injection. The analysis in positive ionization mode was performed using acetonitrile as solvent A and HPLC water with 0.1% formic acid as solvent B. The elution started with 5% of eluent A, increasing to 95% in 20 min, raising to 100% in the following 2 min and then back to initial conditions within 5 min. The re-equilibration time was 10 min. The sample injection volume was set at 20 μl and the flow on 0.2 ml/min in both modes.

Data acquisition was performed in selective reaction monitoring (SRM) mode. For each compound two SRM transitions between the precursor ion and two most abundant fragment ions were monitored, as illustrated in Fig. 1. Only one transition was monitored for the isotopically labelled standards since they are normally not present in environmental samples. In total, 70 transitions in positive ionization mode (corresponding to 30 compounds and 12 internal standards) and 29 transitions in negative ionization mode (13 compounds and 7 internal standards) were monitored. In order to obtain additional confirmation, especially for compounds showing poor fragmentation, an Information Dependent Acquisition (IDA) experiment was performed, with SRM as the survey scan and an enhanced product ion scan (EPI), at three different collision energies, as dependent scan. The obtain spectra were compared with library data based on EPI spectra at the three collision energies used. This allows broad accomplishment of the requirements set by the EU regulations (EU Commission Decision 2002/657/EC) [31] related to identification and confirmation of pharmaceuticals in LC–tandem MS analysis.

2.5. Method validation

The performance of the method was evaluated through estimation of the linearity, sensitivity, repeatability, reproducibility and matrix effects of the method.

Quantification, based on peak areas, was performed by internal standard calibration. The internal standards used for quantification of the compounds were following: sulfathiazole-d_4, diazepam-d_5, phenobarbital-d_3, atenolol-d_7, carbamazepine-d_{10}, ibuprofen-d_3, clotrimazole-d_5, enalapril-d_5, hydrochlorothiazide-d_2, glyburide-d_3, albuterol-d_3, cimetidine-d_3, ethyl clofibrate-d_4, antipyrine-d_3, acetaminophen-d_4, diclofenac-d_4, mecoprop-d_3, ^{13}C-erythromycin and ^{13}C-phenacetin. Seven-point calibration curves (0.5–100 ppb) were generated using linear regression analysis. The linearity was qualified by linear correlation coefficient, r^2.

To determine the recoveries, sediment and sludge samples were spiked in triplicate with a standard mixture of analytes in methanol/water, 25/75 (v/v) to 50 ng g^{-1} concentration. The spiked samples were stirred vigorously in order to enable better contact of analytes with the matrix. After 24-h equilibration, these samples together with the correspondent blank samples were extracted and treated by the previously described protocol. The internal standards for correcting matrix effects were added to the final sample extract. The recoveries were determined in triplicate comparing the obtained concentrations, after subtraction of concentrations found in blank samples, with the initial spiking level.

Method detection limits (MDL) and method quantification limits (MQL) were determined as the minimum detectable amount of analyte with a signal-to-noise of 3 and 10, respectively.

Intra-day and inter-day precision were determined from five repeated injections 50 ng g^{-1} standards during the same day (repeatability) and in five successive days (reproducibility). These two parameters were expressed as relative standard deviation of result (RSD, %).

Matrix effect was evaluated. In order to express it as percentage of suppression or enhancement, Eq. (1) was applied. The peak-areas from the analysis of spiked sludge and sediment extracts ($\text{area}_{\text{matrix}}$) reduced by the peak areas corresponding to the native analytes present in the sample ($\text{area}_{\text{blank}}$), were compared with the peak areas from spiked solvent at the same concentration ($\text{area}_{\text{solvent}}$). The spiked concentration was 25 ng g^{-1} for all the solid samples.

$$\text{signal suppression } (\%) = 100 - \left(\frac{(\text{area}_{\text{matrix}} - \text{area}_{\text{blank}}) \times 100}{\text{area}_{\text{solvent}}}\right) \quad (1)$$

The efficiency of internal standard and standard addition calibration were evaluated comparing the relations of calibration curves made in pure solvent with those prepared in matrix extracts.

3. Results and discussion

3.1. PLE conditions

The combination of solvent, temperature, flush volume, number and time of extraction cycles were investigated in order to obtain optimum extraction conditions for analysis of 42 pharmaceutical compounds. This method is one step forward in development of multi-residual analytical methods in our group [7,8]. Thus the starting point for PLE extraction were conditions reported by Radjenović et al. [7], adopted for the extraction of extended list of compounds.

The influence of the parameters was investigated simultaneously. The experiments were organized combining different solvent mixtures with different temperatures in 30 extractions, and then the other parameters were examined (time and number of cycles). Extraction pressure was set to 1500 psi for all PLE experiments, because it is not considered as a critical experimental parameter and it has negligible impact on analytical recovery [30].

Solvent: The solvent must be able to solubilize the target analytes leaving the sample matrix integrate. Since the analysed pharmaceuticals vary in physicochemical properties, the choice of the solvent mixture was limited and it could not match all the compounds in their polarity. The neutral conditions were required. In this study the following extraction solvents tested were: methanol/water (1/1, 1/2, 1/3, 2/1, 3/1, v/v) and acetonitrile/water (1/1, 1/2, 1/3, 2/1, 3/1, v/v). The combination methanol/water, 1/2, (v/v) yielded relatively better recoveries than other ones. For enalapril, metronidazole, bezifibrate and chloramphenicol, higher percent of water (i.e. methanol/water, 1/3, v/v) gave higher recoveries. More methanol (i.e. methanol/water, 1/1, v/v) gave better results for gemfibrozil, sulfamethazine and erythromycin. In the group of experiments with mixtures of acetonitrile and water, the best ratio was 1/2 (v/v) as well, but still it gave lower recoveries than methanol/water combination.

Temperature: This is very important parameter in PLE extraction. Application of higher temperature in PLE decreases the viscosity of solvents, thus allowing its better penetration into the sample matrix. The increase of temperature decreases significantly the dielectric constant of the water so the organic solvents can be used in smaller amount or avoided. But too high temperature can lead to degradation of the compounds or loss in method selectivity due to more efficient extraction of interfering matrix components. In the described experiments, all the combinations of the solvents on three extraction temperatures were tested: 60, 80 and 100 °C. The temperature higher of 100 °C was not tested since thermal

degradation can occur at higher temperatures [22]. The recoveries obtained on 60 °C were low for most of analysed compounds. Salbutamol, gemfibrozil, mefenamic acid and diazepam gave better recoveries at temperature of 80 °C. For the compounds that were recovered in small or exaggerated percent is difficult to conclude which temperature suits better (i.e. prevastatine, atorvastatine, macrolides).

Extraction cycles: Optimization of the conditions included the screening of number and duration of static cycles. Each static cycle introduce fresh solvent which is very useful for the samples with complex matrix as sludge, while the longer time of a cycle can allow better diffusion of analytes into the extraction solvent. It is recommended to divide the extraction into more cycles [30]. The extracts of individual cycles of 5 min were collected as well as extracts from 2 and 3 cycles. Through the first and second fraction had almost all the compounds extracted completely, the third cycle was introduced to insure the complete extraction of diclofenac, indometacin, mefenamic acid, gemfibrozil, bezifibrate and lorati-

dine. With the three-cycle extraction, it is presumed that all the spiked and native analytes were removed. Finally, the PLE extraction was performed under the following conditions: 1 g of sample, temperature of 100 °C, as extraction solvent—methanol/water, 1/2 (v/v), a preheating period of 5 min, 3 static cycles, each lasting 5 min, total flush volume was 100% of cell with 60 s of nitrogen purge.

3.2. Method validation

The quantification was based on peak area. The shift of peaks in both transitions was noticed in the matrices comparing to the position in pure solvent. But, the retention times for all the analytes in the matrix varied less than 1%. In Fig. 1 are illustrated the chromatographic peaks of the two SRM transitions of diclofenac and glibenclamide in sludge and standard solution. The parts of the figure marked by A and C stand for the chromatograms of analytes in Sludge II, and B and D for chromatograms of standard solutions of diclofenac and glibenclamide, respectively. As illustrated, the retention times and SRM ratios concord well. Reproducibility and repeatability expressed as relative standard deviation, RSD%, were lower than 13% for intra-day and 15% for inter-day analysis, respectively (Table 2). Seven points calibration curves gave very good fits, $r^2 > 0.99$, over the established concentration range of 0.5–100 ng g^{-1} for all the compounds in all the matrices. The limits of detections in sludge and sediment were lower than 1 ng/g for the most compounds. The method provided lower sensitivity for phenazone, fenofibrate, prevastatine, mevastatine, diazepam, lorazepam, erythromycin, roxitromycin and

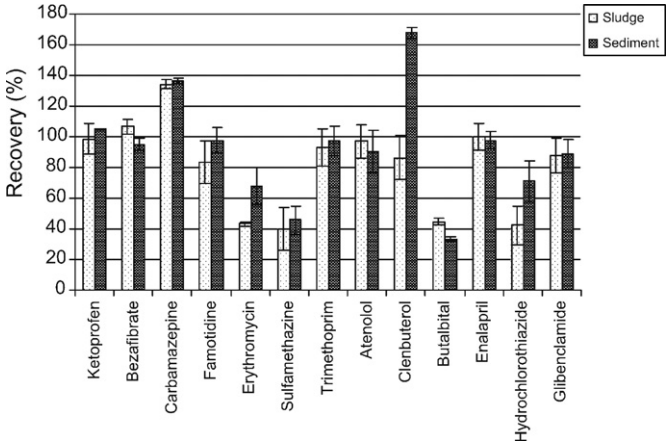

Fig. 2. Recoveries obtained for the representative compounds of each therapeutic group.

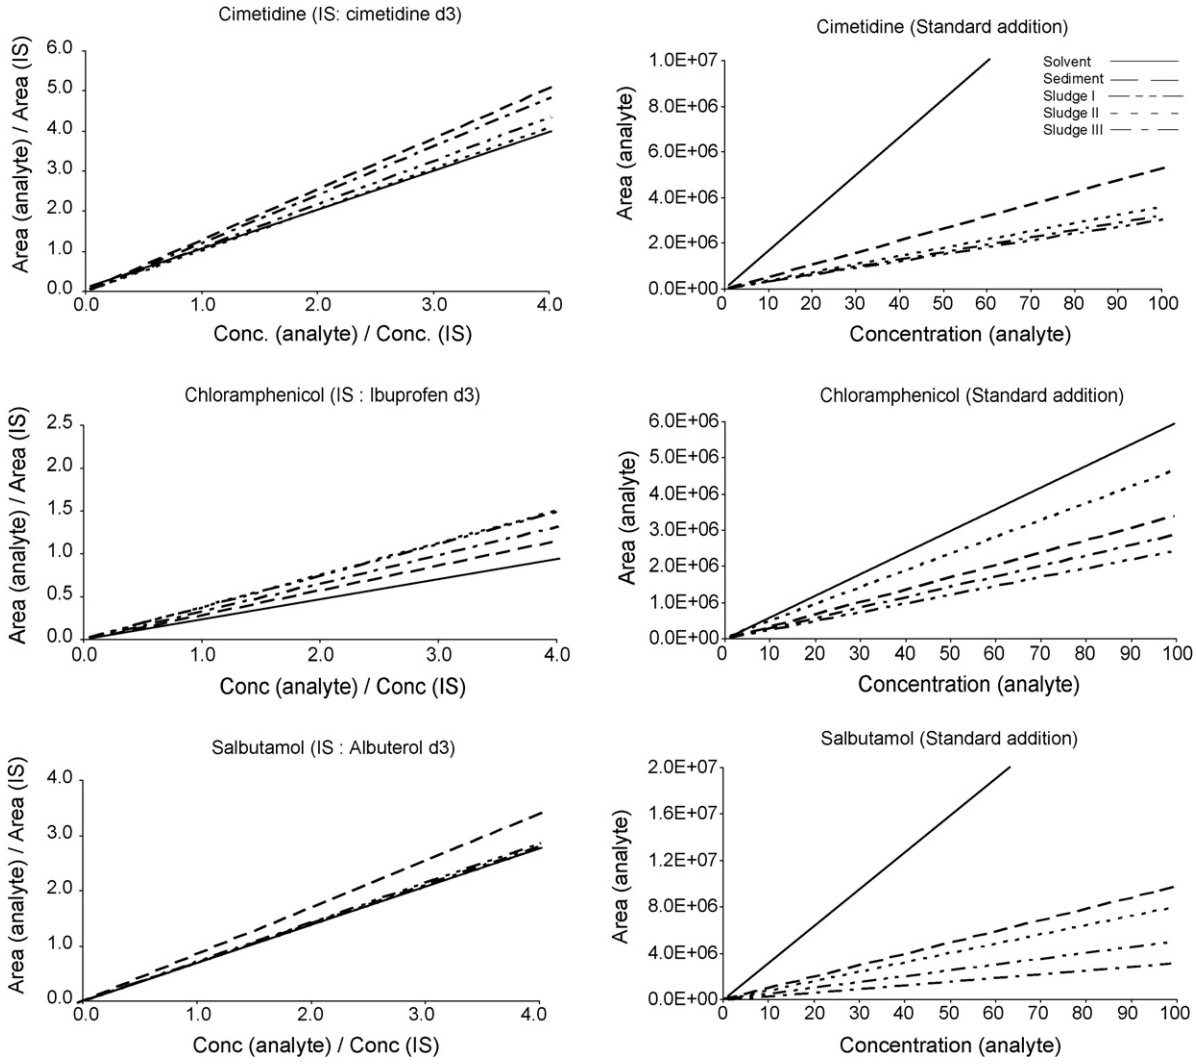

Fig. 3. Internal standard calibration curves (left) and standard addition calibration curves (right) of spiked solvent and extracts of sludge and sediment for cimetidine, salbutamol and chloramphenicol.

clarithromycin in sludge (1.12 < MDL < 6.75) and for mevastatine, gemfibrozil, lorazepam in sediment samples (1.24 < MDL < 3.20). Generally, the sensitivity was lower for sludge than for sediment samples, due to the more complex matrix. The values of MDL and MQL for sludge (Sludge I) and sediment are presented in Table 2. Compared to the method detection limits obtained for pharmaceuticals in solid matrices using some other instruments [5,7,12,13,32], with the LC–QqLIT-MS the improvement in sensitivity is significant.

In Table 2 are listed only the recovery results obtained for Sludge I and sediment, with the corresponding relative standard deviations. The RSD% was less than 15% for all the compounds in both matrices, which is considered as good method precision. The recoveries varied significantly depending on compound and matrix. For the pharmaceuticals in Sludge I only acetaminophen (40.7%), josamycin (42.1%), sulfamethazine (40.3%) and hydrochlorthiazide (42.3%) had recoveries <45%, wherein acetaminophen and hydrochlorthiazide were quantified with their deuterated standards. For the samples of sediment, recoveries were <50% for atorvastatin (34.6%), sulfamethazine (45.7%), metronidazole (41.7%) and butalbital (33.2%). In Fig. 2 are illustrated the results for some representative compounds for each therapeutic group, and the rest of the compounds followed a similar pattern. Some compounds yielded extremely high recoveries (»100%) in both matrices, like prevastatine, phenazone, fenofibrate and metoprolol. Elevated recoveries have already been reported in some studies about pharmaceuticals in sludge [5,7,32]. The properties of matrix itself and the complexity of the interaction with analytes, as well as possible errors in procedure could be the reason for the extreme (high or low) recoveries. Hence, it is difficult to give logical explanation and expect certain values of recoveries. If the accurate results are requested, the recoveries in the investigated matrix must be determined prior to quantification.

Matrix effect: The performance of HPLC–ESI-MS/MS analysis is strongly affected by the ionisable impurities coming from matrix (e.g. natural organic matter, salts, ion-pairing agents, non-target contaminants, etc.) that can interfere with the ionization processes. This may result in a signal suppression or enhancement leading to low sensitivity and inaccurate results. These effects are more extensive when the matrix is more complex as sludge matrix, for example. It is advisable to evaluate matrix effect as a part of validation of the method to ensure the reliability of results obtained. In this study, standard addition and internal standard addition experiments were performed to investigate and minimize matrix effect.

The calibration curves obtained from real sludge and sediment extracts with standard addition were compared with those in pure solvent (methanol/water, 25/75, v/v). All curves were linear over the concentration range of 0.5–100 ng g^{-1} with correlation factors $r^2 > 0.99$. For illustration, Fig. 3 (right) presents calibration curves of cimetidine, chloramphenicol and salbutamol in 4 real matrices (sediment and three samples of sludge) and one in solvent. Significant difference in slopes was observed proving the existence of matrix effects.

Fig. 3 (left) shows the calibration curves of the same compounds acquired by isotopically labeled compounds added into sludge and sediment extracts and in the pure solvent. The curves were linear over the concentration range of 0.5–100 ng g^{-1} with good correlation factors of $r^2 > 0.99$. Despite the fact that the matched isotopically labeled standards were not available for all the target compounds, the calibration curves appear to be overlapped well enough. This means that internal standards compensated the matrix effects considerably; therefore the internal standard addition was used for quantification in this study. Although the selected isotopically labeled standards seem to be appropriate for the target compounds (Fig. 3), cannot be expected that they give very accurate results. More precise results could be achieved using the surrogate standards of the target compounds. It is expected that the surrogate standards compensate for any error that can occur during the sample preparation. But since the surrogate standards were not available for all the analysed compounds and the internal standard quantification gave repeatable results, we decided to use only internal standard approach. The application of only one approach allowed more comparable and reproducible results. The lack of fully compatible surrogate/internal standards is considered as the main limitation of one multi-residual method for pharmaceuticals in environmental samples [33].

Matrix effect was quantified comparing the areas of compounds in spiked matrix samples with the areas obtained in spiked solvent (methanol/water, 25/75, v/v). The effect was expressed by percentage of signal suppression/enhancement and the results are summarized in Table 2. Knowing that the nature of matrix effect is pretty varying, the percentage is just a relative indicator of the degree of suppression and enhancement. The percentage varies from 14 to 100% in sludge and from 9 to 98% for sediment samples. The impact of matrix interferences was different for each compound and except acetoaminophen, all the compounds were subjected to ion suppression. Strong MS signal suppression effects were observed for most of the compounds.

3.3. Application of the method

The developed method was applied for determination of pharmaceuticals in sediment from middle course of river Ebro and in the sewage sludge from WWTPs Tudela, Pamplona and Terrassa. Target pharmaceuticals were not detected in sediment samples. Of

BLD and BLQ determined for each matrix individually.
[a] BLD—below limits of detection.
[b] BLQ—below limits of quantification.

43 analysed compounds, 34 were detected in sewage sludge samples from WWTPs. The average concentrations ($n = 5$) determined in those samples are summarized in Table 3. The recoveries and limits of detection and quantification were determined for each kind of sludge individually, prior to quantification. The concentrations below the limits of detection and quantification are not presented. In general, the pharmaceuticals were identified in concentrations of 0.1–120 ng/g. Ibuprofen, acetaminophen, diclofenac, atorvastatin and hydrochlorthiazide were detected in the highest concentrations in samples from all 3 WWTP. These compounds were present in average concentrations from 43.2 to 117 ng g^{-1}, 42.1 to 103 ng g^{-1}, 27.5 to 74.9 ng g^{-1}, 21.4 to 65 ng g^{-1} and 29.0 to 126 ng g^{-1}, respectively. Carbamazepine, mefenamic acid, gemfibrozil, furosemide and glibenclamide were frequently detected as well. The presence of these compounds was reported in recent works related to pharmaceuticals in sludge in similar concentrations [7,13,14]. WWTP Pamplona serves more inhabitants and has higher capacity of treatment than the other two, so the samples from this plant are more contaminated by analysed pharmaceutical residues.

4. Conclusion

The study involved development and validation of a method for simultaneous analysis of 43 pharmaceutical compounds in sludge and sediment. Differences in physicochemical properties of the compounds required neutral experimental conditions. The pharmaceuticals were isolated from solid samples using PLE followed by SPE clean-up step, and submitted to the analysis in LC–QqLIT-MS.

The influence of extraction parameters (i.e. solvent composition, temperature, and number and time of extraction cycles) on the extraction and overall recoveries were evaluated. Strong effects of signal suppression and extreme values of recoveries ($\gg$100%) were noticed as result of matrix interferences. The chosen isotopically labelled compounds compensated for the matrix effects well enough; therefore the internal standard approach was used for quantification. Linearity of the method was satisfactory ($r^2 < 0.99$) in the defined concentration range (0.5–100 ng g^{-1}). The instrument exhibited very good sensitivity with the MDLs and MQLs lower than 1 ng g^{-1} for most of the compounds. The instrumental precision was acceptable with RSDs < 15% for intra- and inter-day analysis and <1% for peak position shifts.

The applicability of the method for routine multi-residue analysis was demonstrated through the analysis of sludge samples from three WWTPs. The recoveries were higher of 50% for most of the compounds and the variance of values was observed depending on the origin of the sludge samples. The presence of 35 pharmaceuticals was confirmed, wherein ibuprofen, acetaminophen, diclofenac, atorvastatin and hydrochlorothiazide were detected in the highest concentrations.

Environmental analysis

ABSTRACT

This paper reports the interest of the novel 4-carboxyphenyl-grafted screen-printed electrodes (4-CP-SPEs) for sub-nanomolar analysis of uranium in water samples. Electrodes were easily prepared via electrochemically reduction of the corresponding diazonium salt. The stability of the grafted layer has been clearly demonstrated. Uranium detection was then achieved by immersing the grafted electrode into the sample solution, followed by the electrochemical measurement of adsorbed U(VI) by square wave voltammetry.

Adsorption time was investigated so as to find the best compromise between analysis time, repeatability and reproducibility. Limit of detection and quantitation reached 7×10^{-10} and 2×10^{-9} mol L^{-1}, respectively. Moreover, interference study was conducted with Zn(II), Cd(II), Pb(II) and Cu(II); no major interference was established. 4-CP-SPEs were finally applied for uranium determination in estuarine water demonstrating the convenience of these electrodes for environmental analysis.

1. Introduction

Trace uranium monitoring in aquatic ecosystem is of a great importance because of its chemical and radiologic toxicity [1]. Although uranium can exist in different oxidation states, from +III to +VI, U(VI) is the oxidation state the most prevalent in oxygenated waters [2]. It would thus be useful to be able to determinate the concentration of U(VI) directly in the sample [3].

Even if extensive efforts have been devoted for developing highly sensitive analytical procedures for uranium determination in natural water samples, the development of portable sensing probes for on site analysis is a growing necessity and therefore a serious challenge to any analytical technique in terms of sensitivity, accuracy and repeatability.

Among the strategies investigated, electroanalytical techniques appear as the most appropriate for direct determination of uranium owing to the portable instrumentation character and low power requirement [4]. The use of calixarenes or ion imprinted polymers has proved to be an excellent choice in ion selective electrodes elaboration [5–7]. Although ion selective electrodes showed large selectivity factors, measurements yield detection limits that were not low enough (2×10^{-8} mol L^{-1}); elsewhere uranium natural concentrations may be as low as 2×10^{-9} mol L^{-1} in river water and 10^{-8} mol L^{-1} in sea water [8,9].

Because of its high sensitivity, adsorptive cathodic stripping voltammetry (ACSV) was widely used to determine uranium at sub-nanomolar level. U(VI) complexes with 8-hydroxyquinoline [10], aluminon [11], N,N′-ethylenebis(salicylidenimine) [12], potassium hydrogen phthalate [13], cupferron (nitrosoarylhydroxylamines) [14], 2,6-pyridinedicarboxylic acid [15]... have been successfully used for uranium detection with mercury drop electrodes. A limitation of these electrodes is their unsuitability for on site analysis. New alternative electrode materials, with similar performances, were thus investigated for this purpose: carbon paste electrodes modified with propyl gallate [16], multi-wall carbon nanotubes modified glassy carbon electrodes (GCEs) [17], mercury film silver-based electrodes [18], lead-coated GCEs [19], bismuth-coated carbon fiber electrodes [20] or iridium-based mercury electrodes [21].

Attention was recently being paid to self-assembled monolayers (SAM's) grafted on gold electrodes [6,7]. However, limitations with regard to the stability of the gold-thiolate covalent bound and hence the stability of the resultant SAM's have been demonstrated [22]. Another approach consists in reduction of diazonium salts. Indeed, grafting of aryldiazonium is a versatile method allowing stable grafted organic layers bearing a wide range of functional groups on many conductive surfaces [23–34].

We have recently reported the elaboration of 4-carboxyphenyl-grafted screen-printed electrodes (4-CP-SPEs) for copper analysis [35]. Screen-printed electrodes (SPEs) were easily functionalized via electrochemically reduction of 4-carboxyphenyldiazonium salt. Copper analyses were achieved by direct immersion of the grafted electrode into the sample solution for a specific time, followed by

the electrochemical reduction of accumulated Cu(II) by square wave voltammetry. Detection limit reached 5×10^{-9} mol L^{-1} and 4-CP-SPEs were successfully used for environmental analysis.

The main purpose of this paper is to show the benefit of 4-CP-SPEs for sub-nanomolar uranium determination. The stability of the grafted layer was considered. Electrode performances and reliability were investigated for the determination of the total concentration of uranium in environmental sample. Adsorption time was studied so as to find the best compromise between analysis time, repeatability and reproducibility. Zn(II), Cd(II), Pb(II) and Cu(II) interference study was also examined. Analyses were then performed in natural water sample.

2. Experimental

2.1. Materials and reagents

Suprapur CH_3COONH_4 (5 mol L^{-1}), H_2SO_4 (0.1 mol L^{-1}) and suprapur standards solutions: $Cd(NO_3)_2$, $Cu(NO_3)_2$, $Pb(NO_3)_2$, $Zn(NO_3)_2$ (1 g L^{-1}) were purchased from JT Baker; certified estuarine water (NRC-CNRCSLEW-3) from Sodipro.

4-carboxyphenyldiazonium tetrafluoroborate (DCOOH) was synthesized as previously described [36]. Working electrodes were 9.6 mm^2 carbon-based SPEs [37]. SPEs were cleaned by sonication in H_2SO_4 for 10 min before grafting [36].

Experiments were performed with an Autolab (low current PGSTAT12, Metrohm) [38]. All the potentials were measured versus the saturated calomel electrode (SCE). A Pt wire was used as counter electrode.

Grafted layer was generated by the reduction of DCOOH in H_2SO_4 (0.1 mol L^{-1}) either by (i) cyclic voltammetry (CV) (1 scan at 0.1 V s^{-1} between +0.8 and −0.8 V/SCE), leading to a grafted pseudo-monolayer [30,38] or (ii) under chronoamperometry (CA) (−0.6 V/SCE during 300 s), leading to grafted multilayer [30,38]. Once grafted electrodes were rinsed, sonicated for 10 min and stored in H_2SO_4.

2.2. Uranium analysis

Experiments were conducted at constant temperature 21.0 ± 0.5 °C in CH_3COONH_4 (5×10^{-2} mol L^{-1}, pH 7). Analyses were achieved by (i) direct adsorption of U(VI) at the grafted layer followed by (ii) electrochemical reduction of adsorbed U(VI) to U(V) [15]. (i) Adsorption was achieved by immersing the grafted electrode into 10 mL of stirred CH_3COONH_4 containing U(VI). (ii) Electrodes were then transferred to the electrochemical cell containing only CH_3COONH_4 in order to perform square wave voltammetry (SWV) measurements (pulse amplitude: 25 mV, step: 4 mV, frequency: 100 Hz). As otherwise stated SWV was performed in deoxygenated solutions. After use, 4-CP-SPEs were regenerated: electrodes were rinsed with milli-Q water and stored in H_2SO_4 in order (i) to ensure desorption of uranium species that would remain complexed at the working surface and (ii) to be sure of getting data free from memory effect. It was found (by ensuring blanks between successive measurements of U(VI)) that a period of 15 min of storage in H_2SO_4 was enough to remove uranium from the electrode.

3. Results and discussion

3.1. SPEs grafting via electrochemical reduction of diazonium salt

3.1.1. Elaboration of grafted-SPEs

Because they can easily be modified to enhance sensitivity and/or selectivity [35,37,39,40], SPEs appeared particularly well suited for being functionalized. Moreover, due to the very low capacitive current [35], SPEs exhibit fine and well define signal leading to low detection limits. Electrochemical reduction of diazonium salt was selected as the most attractive method to functionalize SPEs working surface because it leads to the rapid formation of organic stable layers covalently bound to conductive substrates [25,28–34,36,38]. In this study, SPEs were grafted via electrochemical reduction of 4-carboxyphenyldiazonium salt. Acetate functions, known for their complexation properties towards U(VI) in solution ($\log \beta_1 = 3.03$, 25 °C, 0 mol L^{-1}) ($\log \beta_2 = 5.57$, 25 °C, 0 mol L^{-1}) [41], are assumed to complex U(VI) at the grafted SPEs. The well shaped peak observed at −0.25 V/SCE in Fig. 1 illustrates the electrochemical reduction of 4-carboxyphenyldiazonium salt at SPEs.

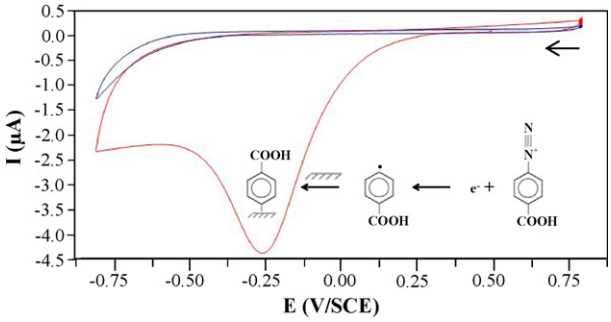

Fig. 1. Blank and reduction of 4-carboxyphenyldiazonium (2×10^{-3} mol L^{-1}) in H_2SO_4 by CV (CV—scan rate: 0.1 V s^{-1} between +0.8 and −0.8 V/SCE).

3.1.2. Stability of SPEs grafted layer

To investigate the stability of the SPEs grafted layer, four SPEs were grafted (the same day) via 4-nitrophenyldiazonium salt chosen for the electrochemical properties of the nitro groups [42–44]. It was previously shown that the oxidation/reduction reaction of the nitro compounds (Ar–NO_2) in acidic solutions should proceed according to the following mechanism [43]:

$$Ar\text{–}NO_2 + 4e^- + 4H^+ \leftrightarrow Ar\text{–}NHOH + H_2O \quad (1)$$

$$Ar\text{–}NHOH + 2e^- + 2H^+ \leftrightarrow Ar\text{–}NH_2 + H_2O \quad (2)$$

$$Ar\text{–}NHOH \leftrightarrow Ar\text{–}NO + 2H^+ + 2e^- \quad (3)$$

Grafted nitro groups can electrochemically be reduced into amine groups (2), via the formation of intermediate hydroxylamine functions (1). Reduction of these functions is not complete so that they can be detected during the reverse oxidation process (3) [44].

In this work, investigation has consisted in comparing the electrochemical signals obtained from freshly grafted SPEs (two electrodes) to those obtained from grafted SPEs (two electrodes) that were stored for 18 days in H_2SO_4. Experiments conducted with nitro-grafted SPEs were achieved by CV in HCl 0.1 mol L^{-1}: each time, 2 cycles were realised, the first one between +0.85 and −0.85 V/SCE, the second one between +0.8 and −0.3 V/SCE. Fig. 2 presents the cyclic voltammograms obtained with (i) freshly grafted SPEs (straight line) and (ii) SPEs that were stored for 18 days in H_2SO_4 (broken line).

The first cycle conducted between +0.85 and −0.85 V/SCE (Fig. 2A) shows an irreversible reduction peak at −0.52 V, unambiguously assigned to the reduction of nitro groups immobilized at the electrode surface in amino and hydroxylamine functions [36]. The oxidation peak located at +0.33 V/SCE is attributed to the oxidation of NHOH. The second cycle (Fig. 2B) conducted between +0.8 and −0.3 V/SCE shows the reversible reduction of NO at the working surface. No significant difference was observed in the shape of the voltammograms, demonstrating the stability of the grafted layer for long time.

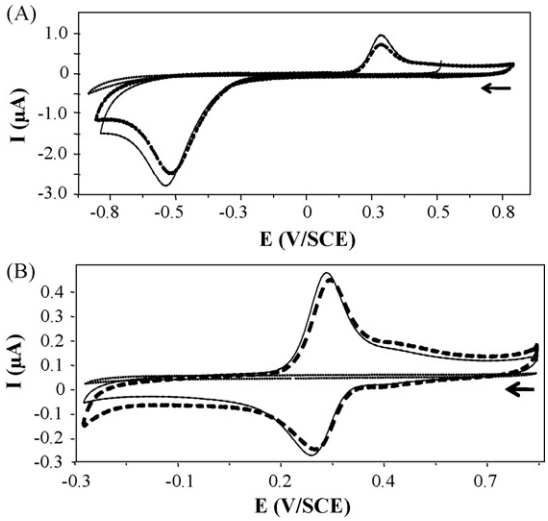

Fig. 2. Cyclic voltammograms obtained at 4-nitrophenyl-grafted SPEs in HCl (0.1 mol L^{-1}) with naked-SPEs (doted line), freshly grafted SPEs (straight line) and grafted SPEs that were stored for 18 days in H_2SO_4 (broken line) (CV—scan rate: 0.1 V s^{-1}). (A) First cycle conducted between +0.85 and −0.85 V/SCE. (B) Second cycle conducted between +0.8 and −0.3 V/SCE.

3.2. U(VI) electrochemical behaviour on SPEs

Uranium stable oxidation state is U(VI) in oxygenated waters. It would obviously be useful to be able to determinate the concentration of U(VI) directly in the sample [3].

The feasibility of qualitative analysis was investigated by studying the analytical signal obtained after the direct electrochemical reduction of uranium in a solution containing U(VI) 10^{-4} mol L^{-1}. U(VI) reduction was examined with both naked-SPEs and 4-CP-SPEs. Voltammograms are presented in Fig. 3. In accordance with Gholivand et al. who studied the U(VI) electrochemical behaviour by CV in acetate media (pH 6.7) [15], the single peak observed at −0.37 V/SCE with naked-SPEs is attributed to the reduction of U(VI) to U(V) (E° = −0.175 V/SCE [13]). With 4-CP-SPEs, the shift of 0.13 V/SCE in the reduction peak towards more negative values is assumed to the presence of the grafted complexing layer. Even if

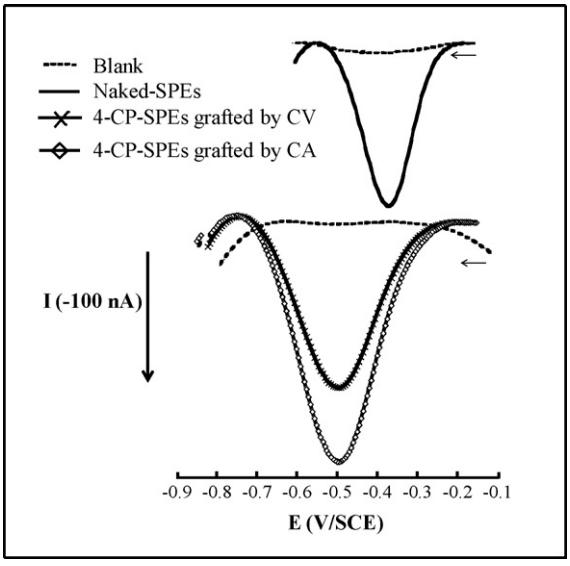

Fig. 3. U(VI) reduction peak obtained with naked-SPEs and 4-CP-SPEs after the direct reduction of U(VI) 10^{-4} mol L^{-1} by SWV in CH_3COONH_4 (SWV—pulse: 25 mV, step: 4 mV, frequency: 25 Hz).

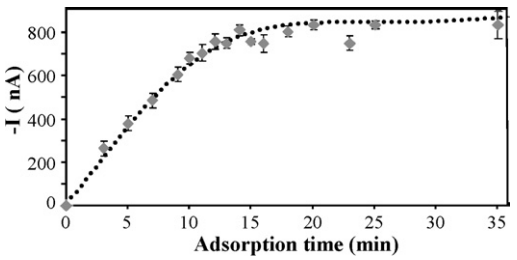

Fig. 4. Influence of adsorption time for U(VI) 3.5×10^{-8} mol L^{-1} (SWV—pulse: 25 mV, step: 4 mV, frequency: 100 Hz).

the thickness of the grafted layer does not influence peak potential, it influences peak current. Indeed, in comparison with naked-SPEs, pseudo-monolayer grafted by CV induces an increase in the peak current of 4%; multilayer grafted by CA induces an increase of 50%, demonstrating the interest of the grafting via CA for U(VI) analysis. In other respect, electrodes grafted by CA were shown to lead to a better reproducibility for Cu(II) analysis [35]. For further studies, all 4-CP-SPEs were grafted by CA.

3.3. Adsorption time

Particular attention was paid to the influence of the adsorption time. Experiments were conducted with U(VI) 3.5×10^{-8} mol L^{-1}. As displayed in Fig. 4, peak current increases linearly with adsorption time up to 10 min; the thermodynamical equilibrium was achieved at 12 min. 15 min was retained as optimal time, best compromise between analysis time, repeatability and reproducibility.

3.4. Interference study

Effects of co-existing ions Cu(II) (E° = 0.1 V/SCE), Cd(II) (E° = −0.65 V/SCE), Pb(II) (E° = −0.37 V/SCE) and Zn(II) (E° = −1 V/SCE), noted M(II), which are of great significance in environmental matrices [3], were examined on the behaviour of U(VI) 10^{-8} mol L^{-1}. M(II) ranged from 3.5×10^{-9} to 10^{-7} mol L^{-1} (Fig. 5). Voltammograms are presented in Fig. 5A. It is worth noting that only the voltammogram obtained in the presence of Cu(II) shows a second peak at −0.1 V/SCE attributed to Cu(II) reduction [35]. Moreover, neither U(VI) peak location (Fig. 5A) nor repeatability (Fig. 5B) were affected by the presence of the investigated interfering. According to the standard errors, neither Zn(II), nor Cd(II), nor Pb(II) seems to affect electrodes sensitivity. No major interferences of these ions are thus expected in the determination of uranium in natural water samples in which these trace-elements ambient concentration is lower than 10^{-7} mol L^{-1}. In the case of copper, peak current remained unchanged as long as the concentration of Cu(II) remained three times higher than that of U(VI). For higher concentrations, Cu(II) induces a decrease of the U(VI) analytical response correlated to an increase of Cu(II) peak current showing the competition between U(VI) and Cu(II) at the working surface. In agreement with the repeatability of the analyses, the standard addition method can thus be performed to quantify uranium in natural samples [13].

3.5. Analytical performances

3.5.1. Limit of detection (LOD) and quantitation (LOQ)

The analytical performances were determined from U(VI) calibration curves, in the range of 8.5×10^{-10} to 10^{-7} mol L^{-1} (Fig. 6A). Experiments were carried out with three 4-CP-SPEs and each data was duplicated. In Fig. 6B, only voltammograms related to the lowest concentrations are presented.

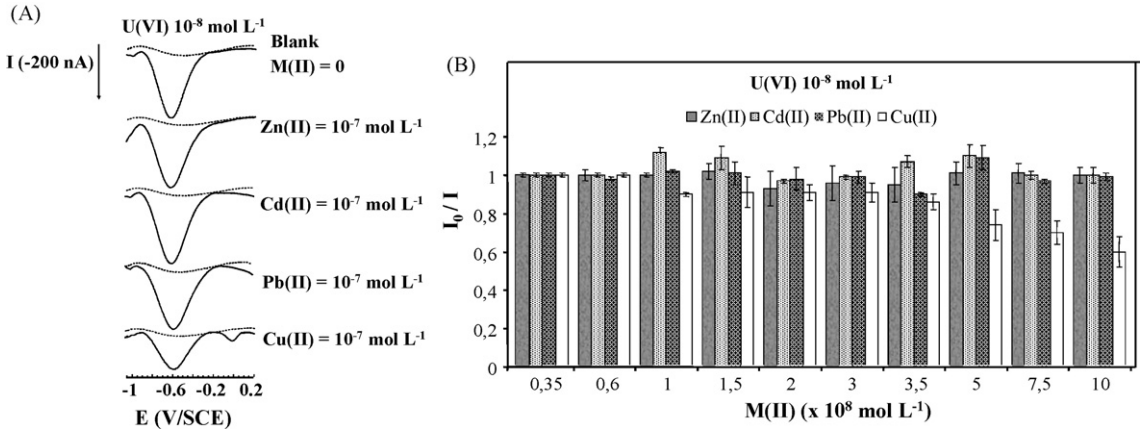

Fig. 5. Influence of Zn(II), Cd(II), Pb(II) and Cu(II), noted M(II), on the analytical response of 4-CP-SPEs. (A) Superposition of U(VI) voltammograms obtained in CH_3COONH_4 in absence and in presence of M(II). (B) U(VI) relative intensity, I/I_0, (where I and I_0 are the U(VI) intensity in presence and in absence of M(II)) versus M(II) concentration (adsorption time: 15 min; SWV—pulse: 25 mV, step: 4 mV, frequency: 100 Hz).

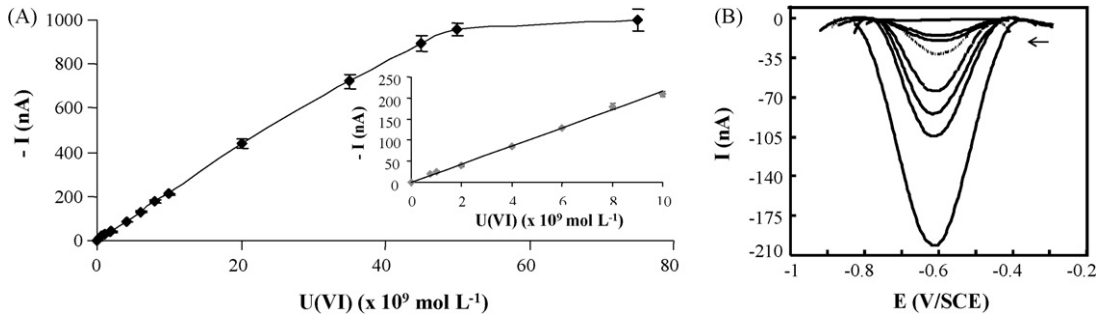

Fig. 6. (A) 4-CP-SPEs U(VI) calibration curve obtained in CH_3COONH_4. (B) SWV voltammograms for U(VI) 0, 8.5×10^{-10}, 10^{-9}, 2×10^{-9}, 4×10^{-9}, 8×10^{-9}, 10^{-8} mol L^{-1} (adsorption time: 15 min; SWV—pulse: 25 mV, step: 4 mV, frequency: 100 Hz).

The calibration plot was found to be linear over the range 8.5×10^{-10} to 5×10^{-8} mol L^{-1}. LOD 7×10^{-10} mol L^{-1}, and LOQ 2×10^{-9} mol L^{-1} were calculated statistically from Norme AFNOR [45]. These performances appeared superior to those obtained with carbon-based electrodes (LOD $\geq 10^{-9}$ mol L^{-1} [16,17]) and reached those obtained with metallic-coated electrodes [18–21] (LOD $\geq 10^{-10}$ mol L^{-1}). In comparison with metallic-coated electrodes (Bi, Pb or Hg-based electrodes), 4-CP-SPEs are non-pollutant. As uranium natural concentrations in water range from 2×10^{-9} to 10^{-8} mol L^{-1} [8,9], electrodes appeared adequate to quantify U(VI) in environmental samples.

3.5.2. Repeatability and reproducibility

Repeatability was verified with repetitive analyses of U(VI) 3.5×10^{-8} mol L^{-1} with single sensor. Well shaped voltammograms were obtained for all experiments; relative standard deviation was 7% after 25 analyses, indicating 4-CP-SPEs can be reusable.

Reproducibility between 4-CP-SPEs was evaluated by performing a series of U(VI) calibration curves with 16 electrodes coming from two different plates on which eight electrodes were printed. Calibration curves were based on two replicates of four concentration levels from 0 to 3.5×10^{-8} mol L^{-1}. Average sensitivity was 21 ± 2 A/(mol L^{-1}). Such performances reach those obtained with usually used SPEs [35,37,39,40], demonstrating the convenience of 4-CP-SPEs.

3.6. Di-oxygen influence

Because removal of O_2 is not suitable for on site analysis, 4-CP-SPEs sensitivity was compared for SWV measurements carried out with or without deoxygenating. Voltammetric responses obtained for U(VI) 3.5×10^{-8} mol L^{-1} in the presence of oxygen showed no loss of sensitivity compared to those obtained in absence of oxygen. In accordance with Brett et al. [46] and Wojciechowski and Balcerzak [47], SWV leads to minimize background oxygen reduction for fast scans. Analyses can thus be performed without deoxygenating during all the procedure, which constitutes a great advantage for on site measurements.

3.7. Natural water sample

4-CP-SPEs performances being proved, experiments were conducted in a certified estuarine water (pH 1.6, salinity 15) which composition was (10^{-9} mol L^{-1}): U(VI) 6.6; Cu 2.4 ± 0.2; Cd 0.42 ± 0.03; Pb 0.040 ± 0.007; Zn 3.05 ± 0.60. The measurement of the total uranium concentration was performed using a conventional approach, sample acidification and UV irradiation [48]. Estuarine water sample was UV digested and adjusted to pH 7 with appropriate amount of CH_3COONH_4 and NaOH. Results $(5.8 \pm 0.2) \times 10^{-9}$ mol L^{-1} were in agreement with those given by ICP-MS comparative analyses $(6.1 \pm 0.2) \times 10^{-9}$ mol L^{-1}, demonstrating the 4-CP-SPEs reliability for U(VI) analysis in natural water samples.

4. Conclusion

These novel and easy to realise 4-carboxyphenyl-grafted screen-printed electrodes (4-CP-SPEs) which have demonstrated their ability for Cu(II) analysis [35], present high performances for U(VI) trace analysis. Electrodes were able to detect and quantify U(VI) as low as 7×10^{-10} and 2×10^{-9} mol L^{-1}. No significant interference of Cd(II), Zn(II) or Pb(II) was established. In the presence of copper, standard addition method can be performed to quantify

U(VI) in natural water samples. It is worth noting that work is in progress to increase electrodes selectivity. The possibility of non-deoxygenating the samples was clearly demonstrated. 4-CP-SPEs were successfully used for trace U(VI) analysis in estuarine water. In comparison with electrodes described in the literature, 4-CP-SPEs appear as the best compromise between reliability, sensibility and environmental compatibility for U(VI) trace analysis in water samples.

Rodalquilar mining district

ABSTRACT

Unsupervised and supervised pattern recognition techniques such as hierarchical cluster analysis, principal component analysis, factor analysis and linear discriminant analysis have been applied to water samples recollected in Rodalquilar mining district (Southern Spain) in order to identify different sources of environmental pollution caused by the abandoned mining industry. The effect of the mining activity on waters was monitored determining the concentration of eleven elements (Mn, Ba, Co, Cu, Zn, As, Cd, Sb, Hg, Au and Pb) by inductively coupled plasma mass spectrometry (ICP-MS). The Box–Cox transformation has been used to transform the data set in normal form in order to minimize the non-normal distribution of the geochemical data. The environmental impact is affected mainly by the mining activity developed in the zone, the acid drainage and finally by the chemical treatment used for the benefit of gold.

1. Introduction

Metals as gold, lead, zinc, copper, etc. have been exploited from immemorial time. Naturally, these elements appear mainly associated to sulphur as part of sulphides, which constitute a minimal proportion of the host rocks. As consequence, their extraction generates important volume of dumps waste, which in contact with air and rainwater could cause acid drainage. In addition, with the extractive activity of mines exploiting metallic minerals, it is frequent to find mineral processing plants focused to obtain mineral concentrate. These plants could also product tailing impoundments. Then, during different processes involved in the extraction and in mineral processing to obtain metals, several products (rocks, metals, chemical products, polluted/unpolluted water,. . .) can be overturned to environment, being these facts, the presence of waste dump and tailing impoundments, a potential inconvenience for environment. Among other environmental impacts, they can be the source for possible contamination of ground waters (turbidity, changes in pH, increasing of dissolved toxic metals, acid mine drainage, etc.). In addition, acid drainage dissolves sulphide and could liberate other elements present in sulphides as trace elements (Cd, Co, Ni, etc.). These metals could also be dissolved and transported in water. Fortunately, environmental policies are increasingly restrictive and the overturned must be produced in a controlled and supervised way.

In the particular case of Rodalquilar mining district (Almería, Southern Spain), the target of the mine activity was mainly the gold, but other metals (Cu, Pb, Zn,. . .) have also been mining [1]. Gold mineralizations occur in outcrops with low ore/barren host rock ratio (e.g., the usual values of ore/host rock ratio for gold are in the range of part per million). Therefore the mining process originates big volumes of dumps waste. In addition, as gold (and other metals) does not appear frequently in nature as native elements, but as part of ore minerals, it is necessary to use some extraction methods, typically amalgamation with mercury or cyanidation [2]. Material from which gold was separated, mixed with residue of chemical products used during extraction processes, was overturned in tailing impoundment being potential sources of contamination.

The use of unsupervised and supervised pattern recognition techniques provide several avenues for exploratory assessment of water quality sets and grouping of water qualities [3–5]. These techniques make it possible to extract information from analytical parameters, allowing (a) to verify associations among variables,

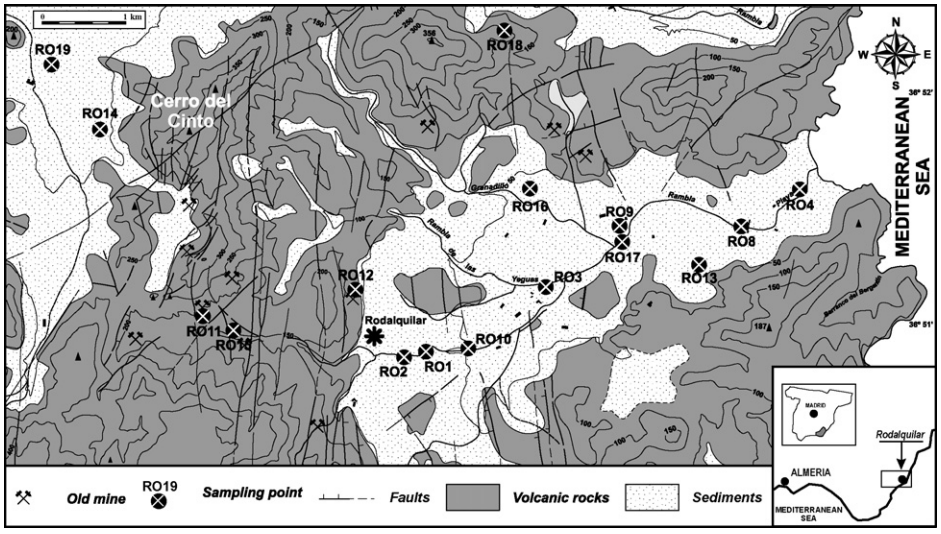

Fig. 1. Location of sampling points on Rodalquilar mining district.

(b) to group or to clusters samples (objects) with respect to comparable chemical descriptors, and (c) to search multivariate data classification on the basis of known class membership of those objects.

In this paper, a data matrix is subjected to different pattern recognition techniques to extract the information about the similarities or dissimilarities between sampling sites, to group the mining area waters in clusters, to identify the important discriminant variables, to classify them in order to evaluate the environmental contamination which could affect in the Rodalquilar mining district.

2. Materials and methods

2.1. Study area

The Rodalquilar gold mining district (Almería, SE Spain) [1] is now an abandoned mining area in which different types of metallic mineralizations appear related with volcanic rocks. In general, mineralizations are quartz veins with different metals (Pb–Zn–Cu–Ag–Au), usually in the form of sulphides or native elements. The area (Fig. 1) is characterized by the presence of small hills of different volcanic materials, often fractured, surrounded in the lower areas of porous sediments. These structures allow the movement of surface waters as well as a permeable behaviour of the rocks, so much by percolation through sediments and also movement through fractures. In the area, some small rivers or streams descend from volcanic rocks (topographically higher than sediments) until the sea crossing the sediments. They received locally the name of "ramblas". Due to the arid climate of the area, watercourses have a particular behaviour: normally there is very little water in the rivers, getting even to be dry, and, occasionally, coinciding with episodes of strong rains, watercourses reach high levels producing avenues and overflows.

From an extractive point of view, this zone has been mining for metals more or less continuously since mid-nineteenth century until 1990 [2], with a maximum between 1943 and 1966, when the mining activity stopped. In the zone, Au was the main exploited ore, but other minor metals (Pb, Ag,. . .) were also mining. The method of benefit of the gold changed throughout the time, from the initial stages of amalgamation with Hg *in situ* or close to mine entrance (until 1930), up to a process with cyanidation tanks (1930–1970, approx.) or using batch leaching (1973–1990). As consequence of this activity, in the zone it is possible to find numerous products with remains of the mining exploitation: dumps, tailings impoundments, two great tailing disposals, situated in the east zone (from cyanidation tanks process) and in the western part (from batch leaching process), etc. (Fig. 1).

In order to study the effect of this mining activity on waters, a field campaign was carried out for sampling. Bearing in mind the zone is quite arid (average annual temperature 18.5 °C, average annual precipitation 150 mm [6]), it was quite difficult to obtain water samples. Nevertheless, there were inspected nineteen points of sampling. Of them, it was impossible to take samples in three cases, whereas sixteen cases turned out to be effective for sampling (see location in Fig. 1 and description in Table 1). These cases reflect diverse activities or phenomena related to the water and cover a wide range: one sample proceeding from a water well, five samples from drill holes, three samples from waterwheel, one sample of a coastal lagoon, one sample of a little pool at foot of a pile of mine waste, one from the nowadays accumulated rainfall in a empty dam used formerly for process with batch leaching of cyanidation, one sample from a domestic cistern, two samples from windlassed wells, and finally one sample from a spring (known locally like "El Granadillo"). These waters have diverse uses: domestic use (although they are not consumed like drink water), irrigation or rural use, ecological (wetland maintenance). In other cases they are waters without use, which in some occasions they have had a former domestic use (even probably like drink water), for irrigation and livestock consumption.

2.2. Monitored parameters and analytical methods

Sampling, preservation and transportation of the water samples to the laboratory were as standard methods [7]. The monitored parameters were the concentrations of Mn, Ba, Co, Cu, Zn, As, Cd, Sb, Hg, Au and Pb. They have been selected according the mineralogy of the zone as possible contamination indicators. The analysis of the samples was done by ICP-MS, the instrument used was a PerkinElmer Sciex-Elan 5000 ICP-mass spectrometer (PerkinElmer, Überlingen, Germany) equipped with quartz torch, nickel sampler and skimmer cones, a peristaltic pump (maintaining a 1 mL min^{-1}) sample uptake rate), a cross-flow type pneumatic nebulizer and a double pass Scott-type spray chamber. Operating conditions are summarized in Table 2. The results obtained expressed as arithmetic means of three replicate of each determination are summarized in Table 3.

Table 1
Sampling points on the Rodalquilar mining district, Southern Spain.

Sample	Brief description	Use
RO-1	Windlassed dug shaft	Without use. Old use for domestic and livestock consumption
RO-2	Domestic cistern	Domestic use, not drinking
RO-3	Well drilled with electric pump	Domestic use in hotel, not drinking
RO-4	Coastal lagoon at the end of the watercourse	Ecological use. Wetland maintenance
RO-8	Excavated well for waterwheel	Without use. Old use for domestic, irrigation and livestock supply
RO-9	Excavated well for waterwheel	Without use. Old use for domestic, irrigation and livestock supply
RO-10	Well drilled with electric pump	Use for irrigation
RO-11	Little pool "at foot" of a pile of mine waste	Without use
RO-12	Well close to installations for gold recovery processes	Use for irrigation. Old public supply of Rodalquilar
RO-13	Well drilled with electric pump with a close irrigation storage reservoir	Use for irrigation
RO-14	Nowadays accumulated rainfall in a empty dam used formerly for process with batch leaching of cyanidation	Without use
RO-15	Excavated well close to a gully	Without use. Old use for domestic consumption
RO-16	Excavated well for waterwheel	Rural use
RO-17	Well drilled with electric pump	Use for domestic, irrigation and livestock supply
RO-18	"El Granadillo" spring	Use for irrigation
RO-19	Windlassed excavated well	Without use. Old use for domestic, irrigation and livestock supply

2.3. Chemical reagents and standards

All ICP-MS standards were prepared from ICP single element standard solutions (Merck, Darmstadt, Germany) after appropriate dilution with 10% HNO_3. For calibration, two sets of multielement standards containing all the analytes of interest at five levels concentrations were prepared using Rhodium as internal standard (based on repeatability variation of the measurements).

HNO_3 acid used (Merck) was analytical grade. All solutions were prepared using Milli-Q ultra pure water (18.2 MΩ cm^{-1}). All the plastic and glassware were cleaned by soaking in dilute HNO_3 and then rinsed with ultra pure water prior to analysis.

2.4. Data treatment and multivariate statistical methods

Assuming environmental data show in general a spatial dependence not normally distributed and they are subject to many potential sources of error involved in sampling, sample preparation and analysis, i.e. detection limit problems, precision–concentration relationship (values are less precise at very low and very high concentrations), and data outliers (some samples with unusually high concentrations) the standardized values of skewness and kurtosis were determined [8]. The statistical analysis of data showed that all of them are not normally distributed and are skewed (the standardized skewness and kurtosis estimated varied from 2.05 to 6.53 and from 0.55 to 13.06, respectively). The Kolmogorov–Smirnov test was used to check the data fit to a normal distribution the test concluded that not all the variables were normally distributed with a 95% confidence interval. This fact made us to study the matrix of the data in detail, observing four anomalous sampling points (RO-04, RO-08, RO-11 and RO-14), in which the values of certain concentrations were excessively high and inconsistent in relation with the other points. These points could be considered different to the rest of sampling points, so they were rejected for this study. Concretely, RO-04 corresponds to a seasonal lagoon, located inside the watercourse, developed in periods of desiccation of the watercourse. This lagoon has around 40–50 m in length and is placed at the end of the watercourse. Thus, the anomalous high values of metals can be considered as a combination of two factors: (i) its location, which could favour the gathering of metals through the crossed materials, and (ii) the local concentration of metals transported in the water, due to its accumulation in the lagoon from evaporation processes of immobilized waters. RO-08 belongs to a deserted waterwheel near the previous one, where filtration processes from the mentioned lagoon are recognized; RO-11 corresponds to a sample of water taken in a little pool located on a pile foot of the mine waste, and subsequently the sample is loaded in metals coming from the leaching of this dump; RO-14 also corresponds to a sample of rainwater, which was accumulated seasonally in a empty dam. This empty dam was used in the last period of the mining operations, for processing with batch leaching of cyanidation.

Table 2
ICP-MS operating conditions.

RF power (W)	1000
Plasma argon (L min^{-1})	15
Nebulizer flow (L min^{-1})	0.9–1
Nebulizer	Cross-flow
Data acquisition	Peak hop transit
Resolution	Normal
Dwell time (ms)	50
Number of replicates	3

The statistical analysis of the remained data showed that, once again, all of them were not normally distributed and were skewed (the standardized skewness and kurtosis estimated varied from 0.22 to 4.89 and from −1.13 to 8.46, respectively). Box–Cox transformation was used to transform the data set into normal form [2,9–11]. The transformation procedure was designed to determine an optimal transformation for Y to fit a linear regression model:

$$W = \beta_0 + \beta_1 X + \varepsilon \quad (1)$$

where W is the transformed variable, X is the regression variable, β_0 and β_1 are the unknown parameters and ε is the error. The dependent variable W is related to Y according to equation:

$$W = 1 + \frac{(Y+\lambda_2)^{\lambda_1} - 1}{\lambda_1 G^{\lambda_1 - 1}} \quad \text{for } \lambda_1 \neq 0 \quad (2)$$

$$W = G\ \ln(Y+\lambda_2) \quad \text{for } \lambda_1 = 0 \quad (3)$$

where λ_1 and λ_2 are the transformation parameters and G is the geometric mean of $Y+\lambda_2$. The optimal transformation is the one that minimizes the mean squared error (MSE) for W. In all the cases, the normality tests used (Kolmogorov–Smirnov; Shapiro–Wilks and skewness score) showed that Box–Cox transformation applied to the analysed metals concentration in the 12 sampling point selected, adjusts them to a normal distribution for a 90% confidence (Table 4). In which, the mean squared error (MSE) diminished in each case when the applied transformations was depicted.

To study the correlation structure between normalized variables the Spearman rank-order correlations (Spearman R coefficient) were used, due the samples are less sensitive to outliers than the Pearson coefficients.

In all the cases, the statistical treatment of the data was performed using with Statgraphich Plus for windows v. 5.1 [12].

2.5. Unsupervised pattern recognition methods

2.5.1. Cluster analysis

Hierarchical agglomerative CA [13] was performed on the normalized data set by means of Manhattan (city-block) distance as similarity measurement and Ward's method as the amalgamation rule. These criterion have been selected with two objectives: (i) to find at each stage those two clusters whose merger gives the minimum increase in the total within group error sum of squares (Ward objective) and, (ii) to dampen the effect of outliers bearing in mind using city-block distance the average differences across dimensions are not squared. The distance between two monitoring point locations using Manhattan distance is given by [12]

$$d(x, y) = \sum_{i=1}^{n} \left| x_i - y_i \right| \tag{4}$$

where $d(x, y)$ denotes the city block distance, i.e. the average difference across dimensions, between two objects represented by x_i, y_i and n the dimensional space of the variables. This distance is a special case of Minkowski distance with $\lambda = 1$ (taxicab geometry).

[b] p value for probability level of 90%.

Cluster analysis was applied to the Box–Cox transformed monitoring (normalized) matrix data set in order to observe the natural grouping of the sampling sites (spatial variability) which are spread over the tested/sampling region.

2.5.2. Principal component (PCA)

PCA is a projection method that reduces the dimensionality in a data matrix while retaining most signification information. The technique transforms the variables into a smaller set of independent (uncorrelated) variables (principal components) without losing much information [13,14]. A reliable model requires a number of PCs, so that over 75% of the total variation can be explained.

As in CA, PCA was applied to the Box–Cox transformed matrix data set in order to display the structure of the normalized data using information about latent relationship within them.

2.5.3. Factor analysis (FA)

FA is a technique of data reduction that examines the interdependence of variables providing knowledge of the underlying structure of data. In this case the factorization type used was principal components which supposes that all the variability (variance) of the data corresponds exclusively to common factors. The orthogonal rotation of the axis defined by PCA, and obtained maximizing (Varimax rotation) produces new groups of variables called varifactors (VFs), which usually group the studied variables in accordance with common features which can include unobservable, hypothetical and/or latent variables [15].

2.6. Supervised pattern recognition methods

These methods permit to obtain suitable classification rules assuming a prior knowledge of the number of groups as well as the group membership of each sample.

2.6.1. Linear discriminant analysis (LDA)

It builds up a discriminant function for each group operating on raw data. The discriminant function has the form:

$$f(G_i) = k_i + \sum_{j=1}^{n} w_{ij} p_{ij} \quad (5)$$

where "i" is the number of groups (G_i), k_i is the constant inherent to each group, n is the number of variables/parameters used to classify a set of data into a given group, w_{ij} the weight coefficient, assigned by LDA to a given selected parameter (p_{ij}). As well as, in the model the classification functions associated to each group established can be used to determine to which group each object/case most likely belongs. Each function allows computing classification scores for each case for each group, by applying the equation:

$$S_i = c_i + \sum_{j=1}^{m} w_{im} x_j \quad (6)$$

where S_i is the resultant classification score, "i" denotes the respective group; c_i is a constant for the i^{th} group, n is the number of

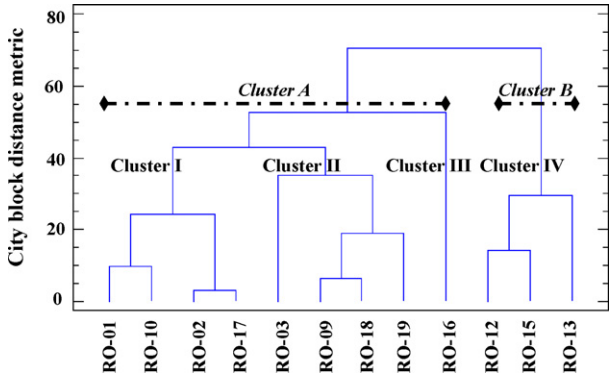

Fig. 2. Dendogram of clustering of sampling according its tributaries using Ward's method and city block distance method.

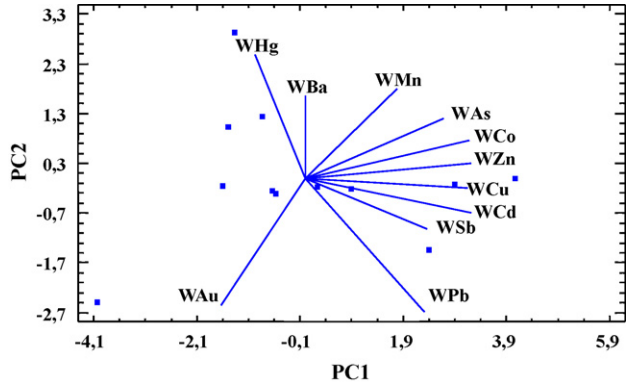

Fig. 3. Principal components biplot on the first and the second PCs.

variables/parameters used to classify the set of data, w_{ij} the weight for the j^{th} variable in the computation of classification score for the i^{th} group; x_j is the observed value for the respective object/case for the j^{th} variable. Subsequently the classification of a case is made assigning it to the group for which it has the highest classification score [16]. In this study LDAs were performed on the Box–Cox transformed monitoring data.

3. Results and discussion

3.1. Spatial similarity and site grouping

The Dendogram of the location pattern resulting from CA (Manhattan distance and Ward's agglomerative method) of normalized data set is represented in Fig. 2. It shows that the sampling points could be initially grouped into two main clusters, Cluster A and Cluster B. Nevertheless, in our opinion it would be possible to distinguish among "*four secondary*" clusters labelled as Clusters I to IV in Fig. 2. Cluster I formed by the sampling points RO-01, RO-10, RO-02 and RO-17, Cluster II by RO-03, RO-09, RO-18 and RO-19. Cluster III formed by RO-16, it is not exactly a cluster due it is an ungrouped sampling point but considered by us as "a group" bearing in mind that would represent a sample with a metals different from the rest. Finally Cluster IV formed by RO-12, RO-15 and RO-13. The grouping of these classes varies with the significance level. It is clearly seen that Cluster II is characterized by the biggest city-block distance (high significance clustering).

The geographical and geological locations of sampling points permit us to associate each group with a possible type of influence of mining activity over the water. Cluster I, Cluster II and Cluster III (Cluster A) all constituted by waters sampled from porous sediments with different metal concentrations. Clusters I and II are located next to main metallic mining area. Cluster I is constituted by samples from sediments located in a watercourse around mineralized areas. This watercourse collected the drained water from mineralized volcanic rocks and canalised downstream. Watercourse is limited by rocks less impermeable that difficult the free movement of waters and, subsequently, these rocks favour a higher accumulation of metals. Cluster II are samples from sediments located in watercourses collecting waters from mineralized areas but with an open circulation that permit dilution of metal concentrations. Cluster III represents a sample located in sediment from a watercourse located in a position less favourable to receive waters coming from main mineralizing areas. In addition, this sampling point is located at the foot of volcanic rock with non-metallic mining activity (alums). Cluster IV (Cluster B) are samples located inside the volcanic rocks and, consequently, conditioned by the regional background of metals characteristic for these volcanic rocks containing the mineralized veins.

3.2. Data structure determination and source identification

Principal component analysis was applied to the normalized data set (11 variables) to compare the composition patterns between the analysed water samples and to identify the factors that influence each one. On the basis of eigenvalues >1 criterion three principal components were developed explaining about 75, 94% of the total variance. This facilitated the explanation, of all the sampling points for the Box–Cox transformed original 11 variables, in a reduced space by three sets of calculated principal components (PCs). Fig. 3 shows the biplot corresponding to our data explaining. The analysis of the data shows that: (a) PC1, which explain the 46.19% of the total variance, is mainly influenced by the normalized concentration of Cd, Zn, Co, Cu, As, Sb and Pb, (b) PC2 (16.33% of the total variance) is influenced by Hg, Mn, Ba, Au and Pb, and (c) PC3 is influenced by Hg, Zn, Cd, As and Ba. This last component explains the 13.43% of the total variance.

The scatter plot (Fig. 4) for the first two calculated factors on the basis on PCA shows four groups of waters in complete accordance with CA. It can be seen also that Group I (Cluster I) is characterized by low values from PC1 and PC2; Group II by negative values for PC1 and high positive values for PC2; Group III by highest negative values for PC1 and PC2, and finally Group IV characterized by high positive values for PC1 and negative values for PC2.

The rotation Varimax of the axes defined by PCs (FA) explains again the 75, 94% of the variability of the normalized data but it partially modifies the weight of the normalized variables in the three varifactors obtained (Fig. 5). It can be seen that: (a) VF1 is mainly influenced by the normalized concentration of Cd, Zn, Cu, Pb, Co and As, (b) VF2 is influenced by Ba, As, Co, and Mn, and (c) VF3

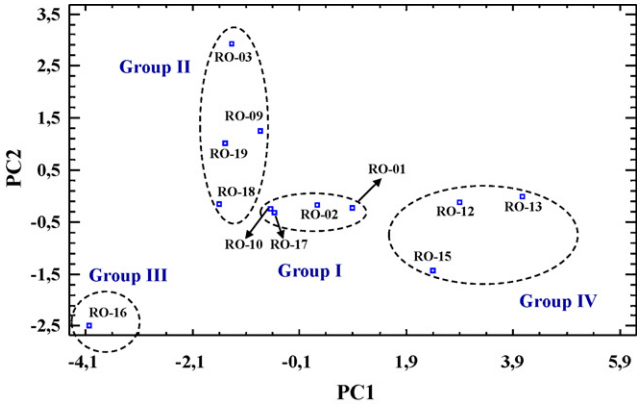

Fig. 4. Scatter plot of the principal components scores for Box–Cox transformed monitoring data.

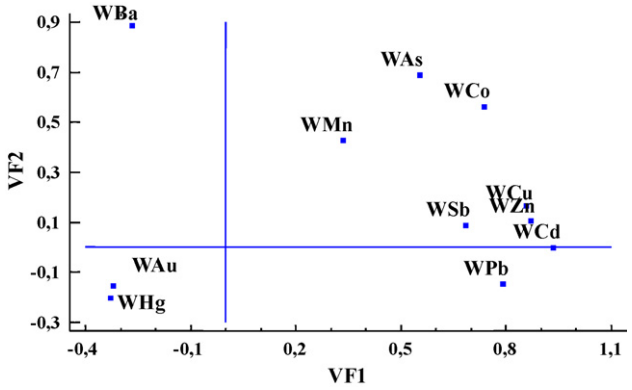

Fig. 5. Varifactors biplot on the first and the second VFs.

is influenced by Hg and Au. The scatter plot (Fig. 6) for the first two varifactor calculated, confirms the existence of two main groups of water samples (denoted initially in CA by Clusters A and B) although do no permit distinguish so clearly the four groups confirmed by PCA.

On the other hand, the Varimax rotation of the axes permits us to assign an influence of the mining activities happened in the studied area over the water samples analysed. Then, VF1 is determined by the behaviour of a group of elements that could come from the metallic mineralization extracted during different stages of the mining in the area. According with bibliography [17], different types of metallic mineralization appears in the area. In this sense, although the mining activity was focused mainly in gold, the veins are bearing of different metallic minerals associated with this element. In short, galena –PbS–, sphalerite –ZnS–, and copper sulphides (mainly chalcopyrite –$CuFeS_2$– and occasionally bornite –Cu_5FeS_4– or digenite –Cu_9S_5–), and also Cu-bearing sulphosalts (tennantite –$(Cu,Fe)_{12}As_4S_{13}$– or tetrahedrite –$(Cu,Fe)_{12}Sb_4S_{13}$–) have been described in the area. Also, it is very possible that this varifactor is not only reflecting the primary phases, but also reflects a group of alteration minerals formed by transformation of the primary phases – supergenic transformation or by way of acid mining drainage – e.g., copper carbonates, azurite –$Cu_3(CO_3)_2(OH)_2$–, malachite –$Cu_2(CO_3)(OH)_2$–, Pb-carbonates, cerusite –$PbCO_3$–, Pb-sulphates, anglesite –$PbSO_4$–, etc., more soluble in water even that the corresponding primary sulphides. The presence of Cd in this component can be justified by the frequent association in the nature of Cd as minor element in the sphalerite structure, being substituted Zn by Cd. That is why this varifactor could reflect the environmental pollution attributable to the mining activity of the zone.

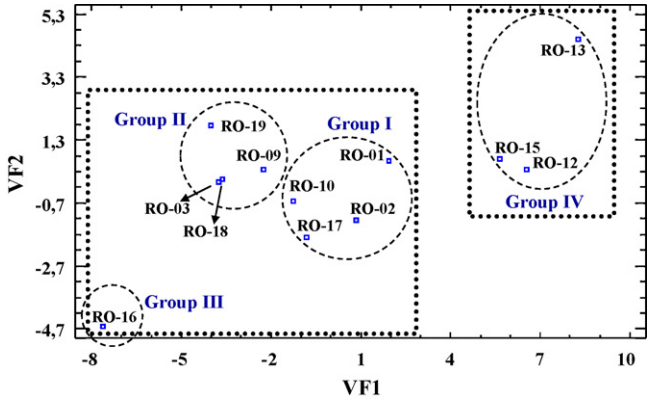

Fig. 6. Scatter plot of the varifactors loadings for Box–Cox transformed monitoring data.

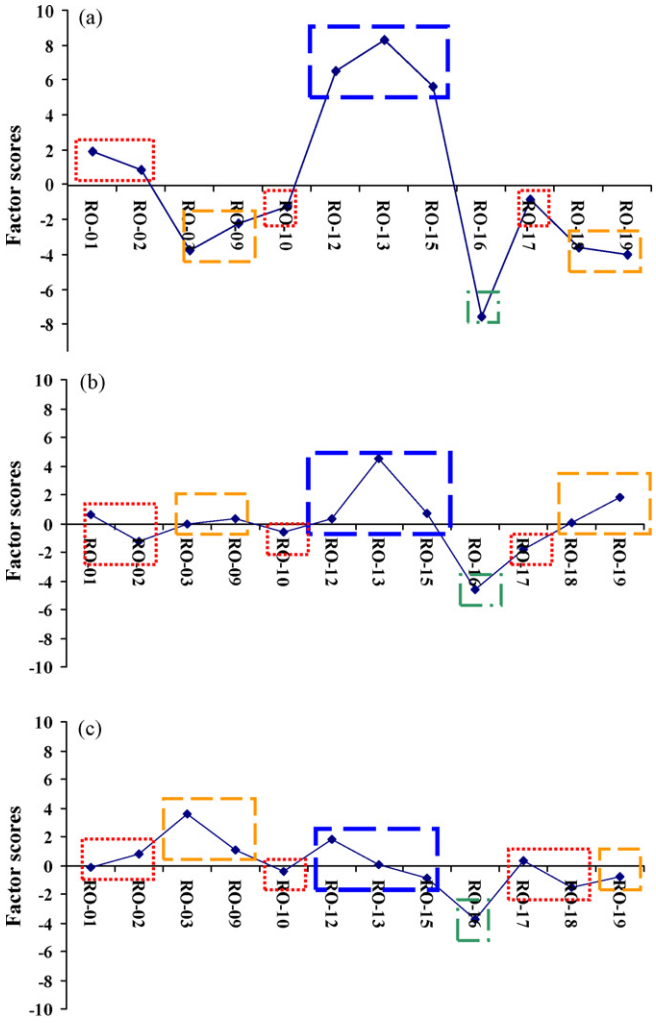

Fig. 7. Factor scores versus sampling points: (a) VF1; (b) VF2; (c) VF3.

VF2 can be justified by the action of acid drainage, as consequent of interaction between sulphides present in mineralized rocks and water. This drainage could mobilize not only Ba but also other metals present in host rock and mineralization (e.g., As, Co and Mn).

VF3 could be clearly anthropogenic, since the amalgamation with Hg was used like method of benefit of Au in different times. This process also could partially amalgamate a portion of Zn and, therefore, the associated with Cd as trace element in the sphalerite.

Fig. 7 shows the representation of the varifactor scores versus sampling location, which may be used in order to identify the pollution sources. In this sense, high scores correspond to high influence of the varifactor on the sampling site. In general the majority of water analysed samples presents an elevated metallic contribution as consequence of the mining activity of the zone. Varifactors 1 and 2 are crucial in water samples included in Group IV, which would indicate that these waters are more affected by the mining activity (Varifactor 1) and the effect of the acid drainage (Varifactor 2). Both varifactors are also important in Group II. Finally, Varifactor 3 is crucial in some water samples belonging to Group II, concretely those that are located in the influence area of the eastern tailing disposal. This fact support an idea about where spread the environmental impact originated by the chemical treatment which the mineral was submitted for the recovery of gold. This varifactor also presents an important load in a well located in the main mining area (RO-12).

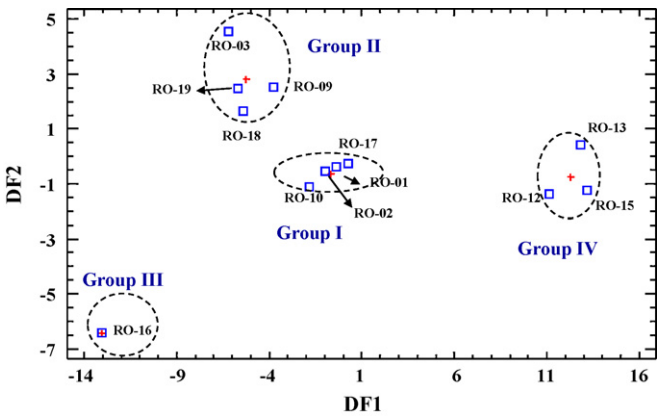

Fig. 8. Representation of the discriminant functions found from analyte concentrations for water samples analysed.

Finally, in order to verify the natural grouping obtained by unsupervised pattern recognition techniques (CA, PCA and FA), a LDA was performed. The discriminant functions were calculated considering the Box–Cox normalized metal concentrations that mainly affect to VF1 (mining activity). On these bases, i.e. WCd, WZn, WCu, WPb, WCo and WAs, three discriminant, orthogonal functions were calculated from which DF1 and DF2 contribute 99.65% to the total discriminant power, although only DF1 is statistically significant with a *p*-value of 0.008 for 95% confidence interval. Fig. 8 shows the scatterplot of monitoring samples locations using the two discriminant functions as axes. It can be observed that these two discriminant functions distinguish perfectly among the four natural groups defined by the non-supervised pattern recognition methods used previously. In this case, Group I is characterized by DF1 and DF2 values close to zero, Group II is characterized by negative DF1 values and highest positive DF2 values, Group III is characterized by the highest negative values for DF1 and DF2 and finally Group IV characterized by the highest positive values for DF1. However, to establish the model as a valid general one, more data should be included in the study.

4. Conclusions

The use of Box–Cox transformation to adjust the geochemical data set (eleven metal(loids) concentrations closely related to sulphide mining activity) in normal distribution form has been shown as a very useful tool to study the environmental impact of mining activity of water samples of the Rodalquilar mining district. Unsupervised pattern recognition methods, as hierarchical CA, grouped samples into four clusters closely related with the geographical and geological locations of the water samples analysed. Also, PCA and FA have allowed confirming this fact. Particularly, FA has been allowed to identify different sources of environmental pollution caused by the abandoned mining industry, i.e., (1) the mining activity developed in the zone—metal(loids) strongly associated with sulphides, (2) the acid drainage, and, (3) the chemical treatment used for the benefit of gold. Finally, the use of LDA as a supervised pattern recognition method has permit to obtain a discriminant function considering the elements associated with the mining activity, which generates classification scores from those it is possible to confirm the natural grouping obtained previously.

ABSTRACT

In this work, design and fabrication of a hybrid micro-device dedicated to the selective detection of hydrogen fluoride vapours is reported. This micro-device is composed by a gas chromatographic micro-column positioned in front of a tin dioxide-based gas sensor. The efficiency of this hybrid micro-system regarding to reproducibility and reversibility for various HF concentrations was investigated. The influence of the HF concentration on the electrical responses of the sensor is also studied. The experimental results show that this hybrid micro-system is efficient since it allows the elution, separation and detection of hydrogen fluoride at a low temperature close to ambient.

1. Introduction

Nowadays, there are increasing demands for the control of toxic chemical compounds in the atmosphere. Environmental standards have made it imperative to develop adequate methods for the analysis of gaseous substances or substances that can be converted to the gaseous state. Among the dangerous chemical compounds for both human and the environment, one can distinguish hydrogen fluoride (HF). HF is involved in a very specific chemical process and can be released in the atmosphere. In this case, it is essential to be able to quickly analyse this molecule in order to prevent possible risks of pollution. Some studies have dealt with the detection of hydrogen fluoride. In the literature, we can find works based on optical method to evaluate and quantify the presence of hydrogen fluoride [1,2]. Moreover, some studies have dealt with the use of chemical gas sensors for the detection of HF. In particular, we notice the use of field-effect gas sensor [3–5], surface acoustic wave sensor [6] or cantilever [7]. At the present time, only two studies have dealt with the use of tin oxide-based gas sensor for the detection of this chemical compound [8,9]. The detection limit of these sensors range from 30 ppm to 50 ppb. Generally, these works allowed to detect this molecule in a controlled atmosphere i.e. without any interfering gases in the surrounding atmosphere of the chemical gas sensor. It is evident that this experimental configuration does not correspond to the real conditions (complex atmosphere).

Since the development of semi-conductor gas sensors, various studies have shown that these chemical gas sensors are sensitive to a wide range of chemical compounds (O_3, CH_4, Volatil Organic Compounds (VOC), H_2, ...). Previous studies completed in our laboratory have shown that SnO_2-based gas sensor is very sensitive to hydrogen fluoride in a controlled atmosphere [9]. The detection limit is a low 50 ppb. Nevertheless, the typical lack of intrinsic selectivity of these chemical gas sensors does not allow using these devices in the presence of interfering pollutants (one or more). In order to detect hydrogen fluoride vapours in a complex atmosphere we developed a gas chromatographic micro-column (GC micro-column) which was positioned in front of the SnO_2-based gas sensor. This GC micro-column was developed in a clean room using the standard techniques of silicon's micro-machining.

The present paper provides a comprehensive description of the performances of a hybrid micro-system for the selective detection of hydrogen fluoride in a VOC complex sample. First a brief description of the GC micro-column used in this experiment will be exposed. Then results obtained for the detection of hydrogen fluoride in presence of some VOC will be presented in order to specify the advantage induced by the coupling of a GC micro-column and a semi-conductor gas sensor (SnO_2).

2. Experimental

2.1. Design and realization of the gas chromatographic micro-column

In this section, we present briefly the miniaturised fluidic device developed in our laboratory in order to eluate and separate chem-

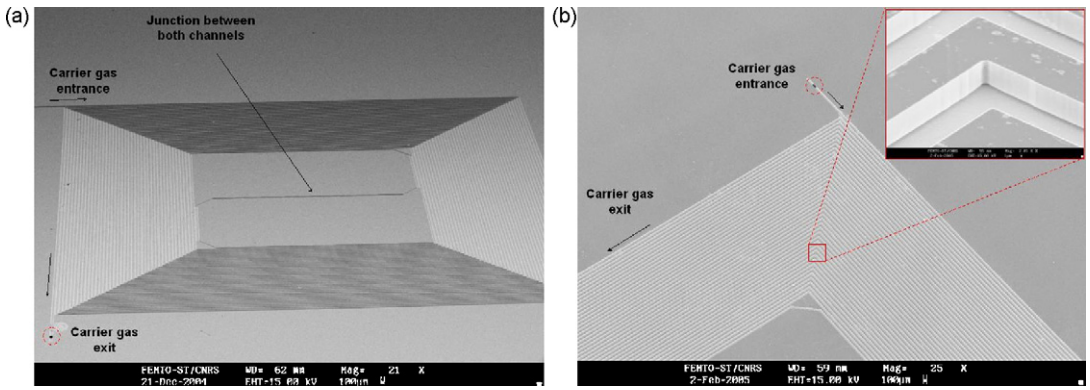

Fig. 1. SEM pictures of the etched micro-structure obtained after the step 1.

ical compounds from gas or vapour mixtures. More details in the manufacturing of this GC micro-column can be found in a previous research paper [10]. We dealt with a column about 2 m long, 50 μm wide and 50 μm deep. The geometry retained for this micro-structure is a rectangular spiral configured as two interlocking structures in order to reduce the final dimensions on the silicon wafer. Three principal steps were involved for the realization of the GC micro-column. The first step is the etching of the silicon substrate. Fig. 1 shows two SEM pictures of the etched micro-structure.

The second step consisted in the anodic bonding of a Pyrex wafer with the etched silicon structure to obtain the final three-dimensional micro-structure. Before this operation, a thin SiO_2 layer was deposited on the silicon substrate allowed the grafting of the future stationary phase. The last step concerned the filling of the GC micro-column with a specific stationary phase (cf. Fig. 2). The chemical formulation of the stationary phase has been obtained by mixing two metal-alkoxyde precursors: Tetraethoxysilane (TEOS) and 1H, 1H, 2H, 2H-perfluorooctyltriethoxysilane (F13-TEOS). The first precursor (TEOS) allowed the formation of a silica matrix grafted onto the internal walls of the GC micro-column. The second precursor (F13-TEOS) was used in particularly to functionalize the whole stationary phase. The principal interest to functionalize the stationary phase with fluorinated groups is to form a chemical compound with a composition identical to Teflon®. The Teflon® is well known for its chemical inertia with respect to HF.

2.2. Experimental set-up

In order to study the possibility of selective detection of HF vapours in a mixture, a special assembly was carried out. Fig. 3 shows the general architecture retained for the analysis of a gas mixture by coupling a GC micro-column with a SnO_2 gas sensor. In this approach, we used synthetic air as carrier gas (80% N_2, 20% O_2, free of moisture). Considering the very small inner volume of the GC micro-column, the volume of sample to be injected into the carrier gas must be very small. Then, the sampling was realized by a chromatographic injector equipped with a split device enabling a high dilution of the analytes before to reach the GC micro-column. For all the studies, we sampled liquid hydrogen fluoride (40%). The high temperature of the injector (250 °C) completely vapourized every chemical compounds that could be contained in the sample.

The separation step is obtained with the GC micro-column positioned into an oven in order to hold the GC micro-structure to a precise temperature. Each chromatographic analysis is carried out in isothermal mode. Previous studies completed in our laboratory have shown that using this gas chromatographic micro-column, best results in terms of separations of the chemical compounds, were obtained at temperature close to 30 °C [11]. The linear velocity of the carrier gas is an important experimental factor that controls the effectiveness of a chromatographic system. Using the chromatographic injector, the carrier gas flow rate in the GC micro-column directly depends on the inlet pressure of the carrier gas applied. Thus, an increase in the pressure imposed, induced an increase in the carrier gas flow rate. This experiment set-up deals with very low linear velocity of the carrier gas. For this experiment, we fixed the carrier gas flow rate at 0.25 mL × min^{-1} (4 bars). This value corresponds to the optimal velocity for the elution and separation of chemical compounds with this GC micro-column [12].

The last part of the experimental device concerns the detection unit. A SnO_2 gas sensor is positioned directly at the end of the GC micro-column and is used as a chromatographic detector. Tin oxide is an ntype semiconductor material, which at typical working temperatures ranging from 200 °C and 500 °C adsorbs oxygen from the surrounding atmosphere leading to an electron-depleted zone. Its

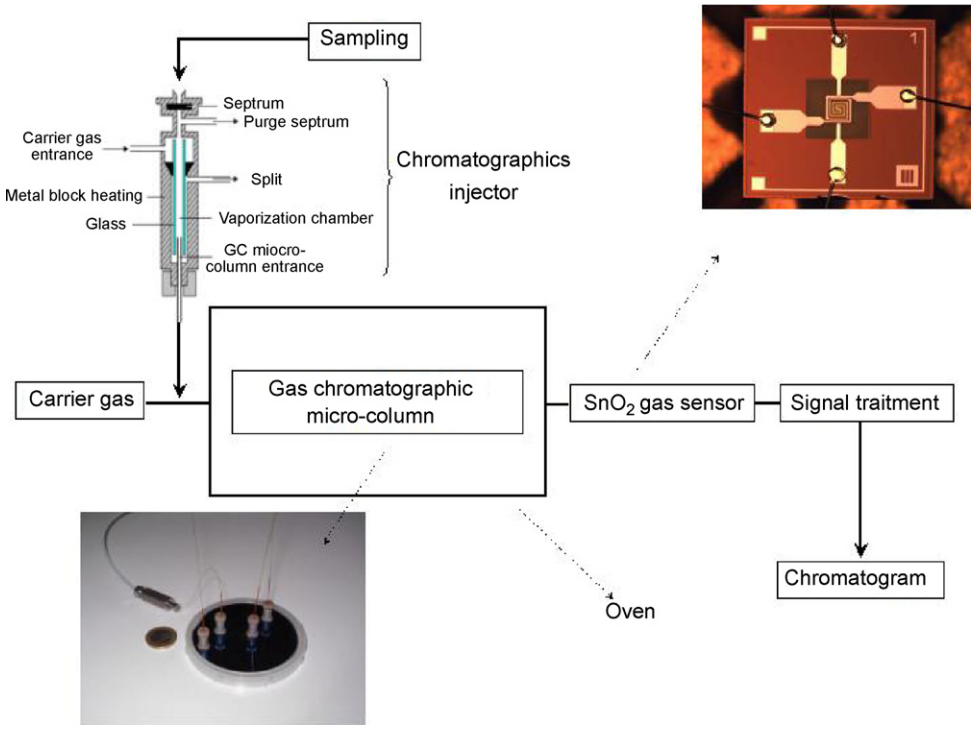

Fig. 3. General achitecture of the experimental set-up used.

electrical resistance decreases in the presence of reducing gases, which react with the pre-adsorbed oxygen leading to an increase in the electronic concentration. The measurement of the change in the resistive value of the sensitive layer due to the chemical reaction induced by gas adsorption serves as sensing signal. The electrical conductance variations of the layer (SnO_2) are connected both with the gas concentration and with the physical–chemical properties of the detected gas. The gas sensor used includes a semi-conducting metal oxide layer (SnO_2) and a silicon substrate with an integrated heater. Before conducting experiments, each sensor was exposed to constant pure air flow for 24 h (conditioning process). This 24 h protocol consists in a linear heating program of the sensitive layer (2.2 °C s^{-1}) for temperatures ranging between 25 °C and 500 °C. This process allowed for the desorption of pollutants chemical compounds adsorbed during the storage stage (organic compounds, water). Fig. 4 represents a 2-h sequence of the conditioning process of a tin dioxide-based gas sensor. We notice a rapid decrease and stabilisation of the gas sensor's conductance. In our

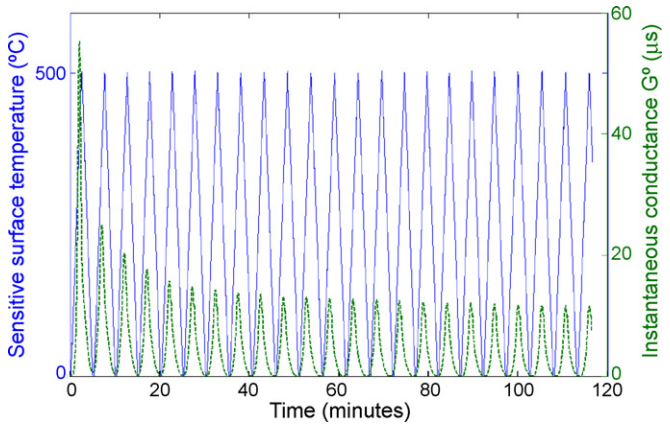

Fig. 4. A 2-hour stage of the conditioning process. Solid line : temperature of the sensitive layer, dash line : instantaneous conductance (µS).

experimental configuration (cf. Fig. 3), the effect of gases on the sensor's electrical properties is recorded by monitoring the variations in the sensor's instantaneous conductance versus time, for a temperature of the sensitive element (SnO_2) fixed at 500 °C [11–12].

3. Results and discussion

3.1. Elution of hydrogen fluoride

After having conditioned the gas sensor and fixed the various experimental parameters (column's temperature and inlet pressure of the carrier gas), one can study the elution and detection of HF with the hybrid micro-system. For this experiment, the sample was made from a hydrogen fluoride solution at 40% which is vapourized inside the injector before its migration in the GC micro-column.

Different dilutions with water have been realized in order to study the influence of the concentration in the sensor's electrical response. Fig. 5 summarized the main chromatograms obtained for the elution of such samples.

These results principally showed that the coupling between a chromatographic micro-column and a SnO_2-based gas sensor allows to first, eluate hydrogen fluoride and second, detect this chemical compound. Let us note two important points regarding these results:

- First, the retention time is very short (15 s) for this chemical compound.
- Second, the temperature of the GC micro-column (30 °C) is very low. This last point is very important particularly for the development of embarked devices.

From this graph, we noticed that the electrical responses of the gas sensor are directly dependant on the hydrogen fluoride concentrations. Higher concentrations give higher electrical responses, exactly like a chromatographic detector. Between each acquisition with the same gas sensor (i.e. for each concentration), no surface

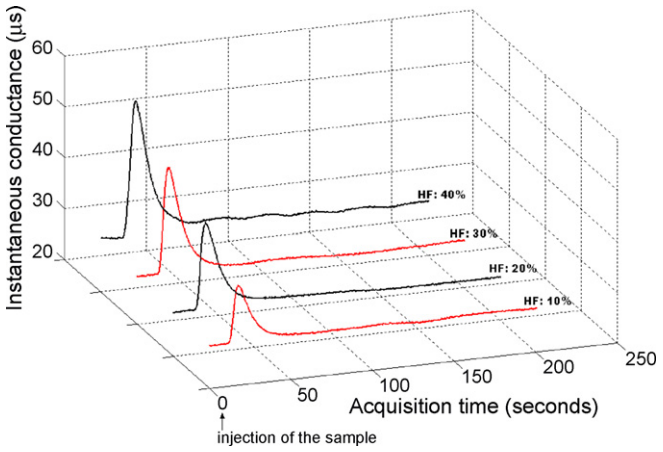

Fig. 5. Chromatograms showing the elution and detection of various hydrogen fluoride concentrations.

treatment of the sensitive layer was made. The sensor's sensitive surface is always maintained at 500 °C under an air flow. Let us specify however that the low temperature of the GC micro-column (30 °C) causes the recondensation of water present in the sample. Thus, water remains "trapped" ahead of the chromatographic micro-column and thus is not detected by the SnO_2 gas sensor. The sensor's electrical response will thus not be disturbed by the presence of water in the SnO_2 surrounding surface.

3.2. Comparison with classic GC

In order to underline the performance of the hybrid micro-system developed in our laboratory, we compared results obtained in the preliminary work completed with a commercial packed chromatographic column filled with a stationary phase which present the same chemical properties (Teflon® stationary phase) [11]. The packed column is 3 m long with a diameter equal to 1/8 in. Fig. 6 represents the hydrogen fluoride's elution peaks for each chromatographic column used (micro-column and packed column). For each experiment, sensor's temperature is equal to 500 °C and synthetic air carrier gas was used. Only the temperature and the linear velocity of the carrier gas of the chromatographic columns are different. For the packed column, the temperature is fixed at 100 °C with a carrier gas flow rate equal to 20 mL × min^{-1}. For the packed column, an injection loop was used to inject 300 µL of hydrogen fluoride at 9.91 ppm in air [11]. In comparison with the classical column for which working temperatures is about 100 °C (optimum condition

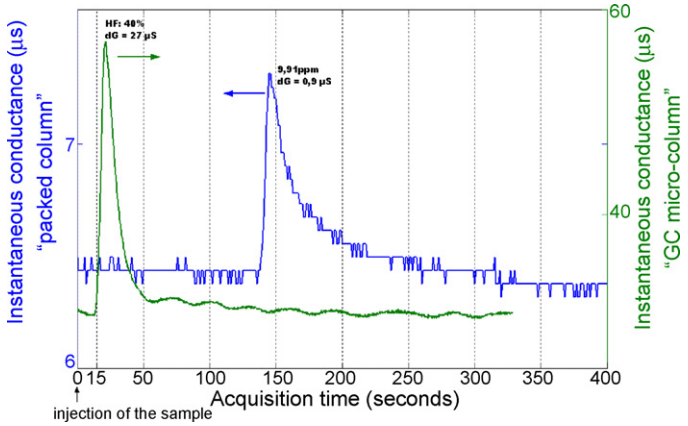

Fig. 6. Elution peaks of hydrogen fluoride from the GC micro-column and a packed column.

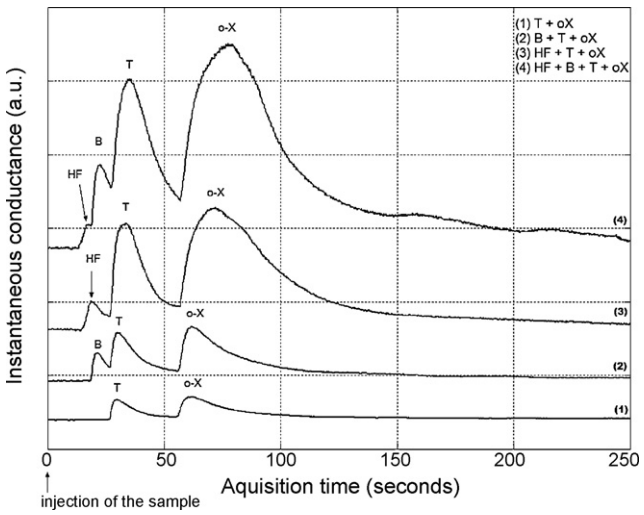

Fig. 7. Chromatograms of VOC mixture and hydrogen fluoride using the GC micro-column coupled with a tin oxide-based gas sensor.

of separation), our GC micro-column works at lower temperature (30 °C). At 30 °C, it is impossible to obtain elution peaks with the packed column. Moreover, the important result obtained with the use of this GC micro-column is the short analysis time for this chemical compound. Fifteen seconds for the GC micro-column against more than 2 min for the classic packed column.

3.3. Separation of hydrogen fluoride in a complex sample

For a complete study of our hybrid micro-system, we prepared various complex samples including volatile organic compounds and hydrogen fluoride. Pure toluene, ortho-xylene and benzene were used in this experimental section. First, samples consisted in an equivolumic mixture of liquid toluene, o-xylene and benzene. Chromatograms obtained when 0.1 µL of these solutions were injected in the chromatographic injector are represented in Fig. 7 (1 and 2). These chromatograms clearly show the presence of peaks, respectively corresponding to each chemical compounds injected ahead of the GC micro-column.

The retention time is the same for each chemical compound. Then, we studied samples constituted of an equivolumic mixture of liquid HF, toluene, o-xylene and benzene. The same volume as previously was injected ahead of the GC micro-column. Chromatograms in Fig. 7 (3 and 4) show the efficient elution and then the detection of the VOC's and hydrogen fluoride in a low isothermal mode (30 °C) for the micro-fluidic device. The first chemical compound emerging from the GC micro-column and detected is hydrogen fluoride. The retention time is, once again, very low for these chemical compounds. These chromatograms do not show any shift in the retention time for each chemical compounds analysed. With this experimental set-up, constituted a GC micro-column and a SnO_2 gas sensor, it is possible to obtain a highly selective gas sensor for various chemical compounds including hydrogen fluoride vapours.

4. Conclusion

The aim of this work was to validate the use of a GC micro-column positioned in front of a semi-conductor gas sensor for the selective detection of hydrogen fluoride vapours in a complex sample. The various tests conducted in this study showed a high selectivity and a good reproducibility in addition to a short response time. This hybrid micro-system provides rapid and discriminative analyses. In comparison with a packed chromatographic

column filled with a Teflon® stationary phase (operating temperature = 100 °C), the GC micro-column developed in this study presents best performances at lower temperature (30 °C). The next step of this study will consist of the development of a micro preconcentrator unit positioned in front of the GC micro-column in order to directly inject sample's vapours in the GC micro-column and determine the detection limit of the system for various pollutants.

Tandem mass spectrometry (MS/MS)

ABSTRACT

We have developed a simple method for extracting and purifying (+)-abscisic acid (ABA) and eight ABA metabolites – phaseic acid (PA), dihydrophaseic acid (DPA), neophaseic acid (neoPA), ABA-glucose ester (ABAGE), 7′-hydroxy-ABA (7′-OH-ABA), 9′-hydroxy-ABA (9′-OH-ABA), ABAaldehyde, and ABAalcohol – before analysis by a novel technique for these substances, ultra-performance liquid chromatography–electrospray ionisation tandem mass spectrometry (UPLC–ESI-MS/MS). The procedure includes addition of deuterium-labelled standards, extraction with methanol–water–acetic acid (10:89:1, v/v), simple purification by Oasis® HLB cartridges, rapid chromatographic separation by UPLC, and sensitive, accurate quantification by MS/MS in multiple reaction monitoring modes. The detection limits of the technique ranged between 0.1 and 1 pmol for ABAGE and ABA acids in negative ion mode, and 0.01–0.50 pmol for ABAGE, ABAaldehyde, ABAalcohol and the methylated acids in positive ion mode. The fast liquid chromatographic separation and analysis of ABA and its eight measured derivatives by UPLC–ESI-MS/MS provide rapid, accurate and robust quantification of most of the substances, and the low detection limits allow small amounts of tissue (1–5 mg) to be used in quantitative analysis. To demonstrate the potential of the technique, we isolated ABA and its metabolites from control and water-stressed tobacco leaf tissues then analysed them by UPLC–ESI-MS/MS. Only ABA, PA, DPA, neoPA, and ABAGE were detected in the samples. PA was the most abundant analyte (ca. 1000 pmol/g f.w.) in both the control and water-stressed tissues, followed by ABAGE and DPA, which were both present at levels ca. 5-fold lower. ABA levels were at least 100-fold lower than PA concentrations, but they increased following the water stress treatment, while ABAGE, PA, and DPA levels decreased. Overall, the technique offers substantial improvements over previously described methods, enabling the detailed, direct study of diverse ABA metabolites in small amounts of plant tissue.

1. Introduction

Abscisic acid (ABA) is an isoprenoid plant hormone that regulates embryonic development and physiological adaptation to various environmental stresses, including water deficiency, osmotic stress, and low temperature [1]. Hence, plant tissue ABA concentrations change under stress and during physiological processes [2].

In plants, ABA can be metabolised by three types of reaction: oxidation, conjugation, and reduction [3,4]. The major oxidative pathway of natural ABA [(+)-S-enantiomer] is through 8′hydroxylation, forming 8′-hydroxyABA, which in turn spontaneously isomerizes to phaseic acid (PA). PA can then be reduced to the major product dihydrophaseic acid (DPA), with minor amounts of *epi*-dihydrophaseic acid (*epi*-DPA). The minor oxidation pathway includes the formation of (+)-7′-hydroxy-ABA (7′-OH-ABA), while the minor reductive pathway produces the unstable ABA 1′,4′-diol [2,4]. A novel ABA 9′-hydroxylation pathway has also been reported [5], yielding the metabolites 9′-hydroxy ABA (9′-OH-ABA) and its cyclised product, neophaseic acid (neoPA). In addition, ABA and its metabolites may be conjugated with glucose, thereby forming corresponding glucose esters at C-1 (ABAGE) or glycosides at C-1′ or C-4′ [2,4]. Two new glucose conjugates, namely *epi*-DPA-β-D-glucoside and 8′-hydroxy-ABA-β-D-glucoside, have also been identified in avocado seeds [6]. Furthermore, a compound identified as 8′-oxoABA has been isolated from corn cell suspension cultures [7]. The isolation and characterization of several new ABA metabolites (8′-oxoDPA, 8′-oxoDPA-GS, 5′-hydroxy-8′-oxoDPA, and 5′-hydroxyDPA) in plums (*Prunus domestica* L.) have also been reported [8].

ABA and its metabolites can be relatively easily and sensitively analysed. For instance, ABA has been detected and quantified in plant tissues by diverse techniques [9], including

doi:10.1016/j.talanta.2009.06.027

radioimmunoassays (RIA) [10–12], enzyme-linked immunosorbent assays (ELISA) [13,14], reversed-phase high performance liquid chromatography (HPLC) with ultraviolet (UV) detection [15–18], gas chromatography with electron capture detection (GC/ECD) [19,20], GC–mass spectrometry (GC–MS) in either selected ion monitoring (SIM) [21,22] or multiple ion monitoring (MIM) modes [23], and LC–ESI-MS via either direct quantification [24,25] or following several purification steps [26,27]. Its metabolites have also been analysed by several techniques (albeit much less frequently than ABA) including: HPLC/UV detection to determine PA and DPA [28,29]; GC/ECD for PA, DPA, *epi*-DPA and ABAGE [19,20], and the cited GC–MS and LC–MS modes for ABAGE [21–27]. However, there is still a need for a convenient, efficient purification procedure prior to their analysis. Purification approaches that have been commonly applied include liquid-phase extraction (LPE) [30], solid-phase extraction [31–34], and solid-phase microextraction [35]. A purification procedure involving use of immunoaffinity chromatography (IAC) prior to single ion monitoring by liquid chromatography electrospray ionisation–mass spectrometry (LC–ESI-MS) analysis has also been recently described [36]. All of these approaches, for both purification and subsequent analysis have some advantages, but also various limitations.

In addition, in recent years, HPLC–tandem mass spectrometry (HPLC–MS/MS) in multiple reaction monitoring mode (MRM) has become increasingly popular for analysing ABA and its metabolites, due to its selectivity and sensitivity. This approach has been used: to measure ABA in *Arabidopsis thaliana* leaves [37] and *Citrus reticulata* leaves and roots [38]; to monitor changes in levels of ABA metabolites during seed development and germination in *Brassica napus* siliques [32], lettuce seeds [31], Western white pine seeds [39,40] and Douglas fir seeds [41]; and to evaluate ABA's role in developmental switches in *Marsilea quadrifolia* [42]. An analytical protocol for quantifying ABA by LC–MS/MS, using non-exchangeable isotope-labelled ABA analogues as internal standards, has also been developed [43] and used to analyse metabolites in the ABA catabolic pathway [39,40,44]. Furthermore, new ultra-performance liquid chromatography (UPLC)-based methods for purifying ABA in plant extracts have been developed very recently [45,46], but no applications of UPLC for analysing ABA metabolites have been previously described.

Here we report the development of an approach (optimised using deuterated internal standards) for isolating, purifying, and measuring ABA and its metabolites (see Fig. 1 for the structures) by UPLC followed by ESI-MS/MS. The method yielded a 10-fold increase in throughput compared to conventional LC–MS analysis, reducing the total time of the analytical procedure for sample preparation and analysis of ABA and its metabolites to just a few hours, rather than days. Thus, the new technique appears to offer fast, highly sensitive, selective, and simultaneous profiling and quantification of ABA and its diverse metabolites in plant tissues.

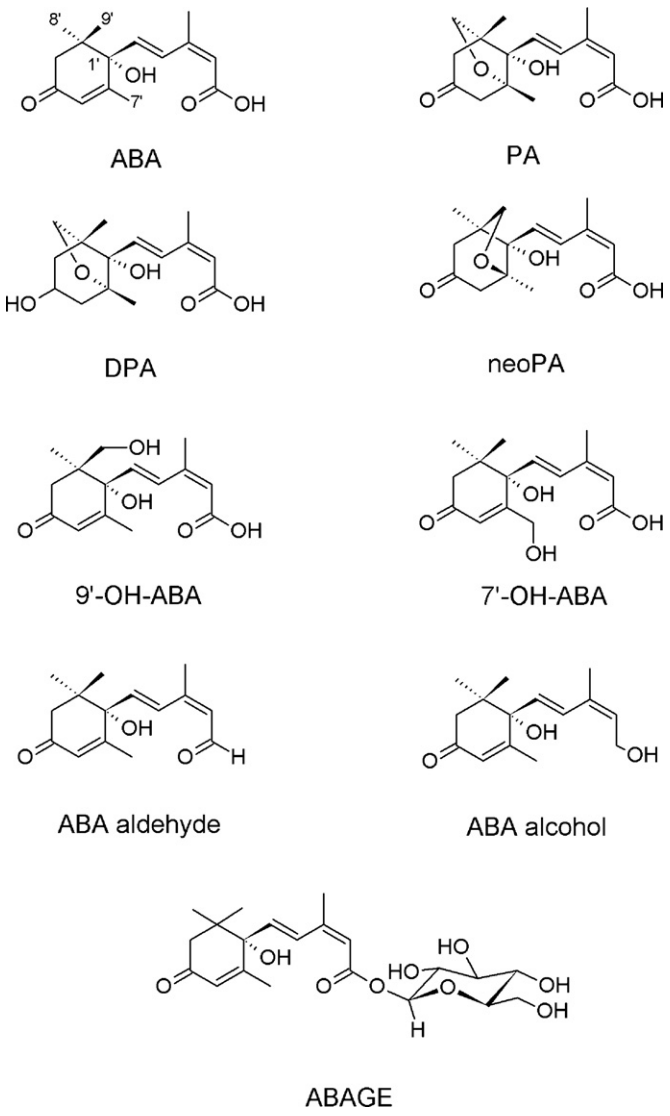

Fig. 1. The structures of ABA and its metabolites.

2. Experimental

2.1. Chemicals

(+)-*cis*,*trans*-ABA was obtained from Sigma (St. Louis, MO, USA); (−)-phaseic acid, (−)-dihydrophaseic acid, (±)-abscisylaldehyde, (±)-abscisylalcohol, (+)-neophaseic acid, (±)-7′-OH-ABA, (+)-9′-OH-ABA, $^{2}H_2$-ABAalcohol, $^{2}H_2$-ABAaldehyde, [(−)-7′,7′,7′-$^{2}H_3$-phaseic acid] (d_3-PA), [(−)-7′,7′,7′-$^{2}H_3$-dihydrophaseic acid] (d_3-DPA), [(−)-8′,8′,8′-$^{2}H_3$-neophaseic acid] (d_3-neoPA), [(+)-4,5,8′,8′,8′-$^{2}H_5$-ABAGE] (d_5-ABAGE), and [(−)-5,8′,8′,8′-$^{2}H_4$-7′-OH-ABA] (d_4-7′-OH-ABA) were kindly provided by Prof. S. Abrams (National Research Council, Saskatoon, Canada). (+)-*cis*,*trans*-ABA methyl ester (ABAMe) and (±)-abscisyl-β-D-glucosylester were generous gifts from Olchemim Ltd. (Czech Republic). Deuterium-labelled (+)-*cis*,*trans*-abscisic acid [(+)-3′,5′,5′,7′,7′,7′-$^{2}H_6$-ABA)] (d_6-(+)ABA) was synthesised using a previously described method [47]. Methanol (HPLC grade) and acetic acid were supplied by Sigma–Aldrich (St. Louis, MO, USA), formic acid by MERCK (Darmstadt, Germany), and Oasis® HLB cartridges (60 mg) by Waters (Milford, USA). The PBS buffer used contained 7.8 g $NaH_2PO_4{\cdot}2H_2O$ and 0.877 g NaCl per liter, adjusted to pH 7.2 using 0.1 M NaOH. Deionised (Milli-Q) water, obtained from a Simplicity 185 system (Millipore, Bedford, MA, USA), was used to prepare all aqueous solutions. The polyclonal antibody based immunoaffinity gel used for the IAC was prepared, used and stored as described previously [36].

2.2. Instrumentation

An Acquity UPLC™ System (Waters, Milford, MA, USA), including a Binary solvent manager, sample manager, and 2996 PDA detector, combined with a Micromass Quattro micro™ API mass spectrometer (Waters MS Technologies, Manchester, UK), was used to analyse ABA and its metabolites. All data acquired were processed using the QuanLynx™ module within the MassLynx™ software (version 4.1, Waters, Milford, MA, USA).

2.3. Biological material

Nicotiana tabacum L. plants were cultivated in a greenhouse at +20 °C under 12-h dark/12-h light cycles. Leaves were harvested from well-watered 8-week-old plants and corresponding plants from which water had been withheld for 4 days prior to sampling. The leaf samples were immediately frozen in liquid nitrogen after harvesting, and then stored at −80 °C until preparation.

2.4. Purification of ABA and its metabolites

The tobacco leaf tissues (1–50 mg f.w.) were powdered using a MM 301 vibration mill at a frequency of 30 Hz for 3 min (Retsch GmbH & Co. KG, Haan, Germany) after adding 3-mm tungsten carbide beads (Retsch GmbH & Co. KG, Haan, Germany). Samples were extracted for 1 h in 750 μL of ice-cold methanol/water/acetic acid (10/89/1, v/v) containing sodium diethyldithiocarbamate (400 $\mu g\,g^{-1}$ d.w.) as an antioxidant. Internal standard mixtures, containing 20 pmol each of d_2-ABAalcohol, d_2-ABAaldehyde, d_3-PA, d_3-DPA, d_3-neoPA, d_4-7′-OH-ABA, d_5-ABAGE, and d_6-(+)ABA were also added to the samples. The homogenates were centrifuged (21 000 × *g*, 10 min, 4 °C) after 1 h of extraction, and the resultant pellets were then re-extracted in the same way for 30 min. The combined extracts were transferred by a pipette onto 3 mL Oasis® HLB cartridges (60 mg, Waters, Milford, MA, USA), that had been conditioned with 2 mL methanol and equilibrated with 2 mL methanol/water/acetic acid (10/89/1, v/v). The samples (ca. 1.5 mL) were loaded onto the cartridges, washed with 1 mL methanol/water/acetic acid (10/89/1, v/v) and eluted with 3 mL methanol/water/acetic acid (80/19/1, v/v), then the eluates were dried under vacuum.

Four purification procedures were tested. In the first, the evaporated samples were directly analysed by UPLC–ESI(−/+)-MS/MS. In the second, the samples were purified with a preimmune column and processed by (+)ABA-specific IAC, as previously described [36]. The purified samples were then evaporated to dryness in a Speed-Vac (UniEquip) and analysed by UPLC–ESI(−/+)-MS/MS. In the third procedure, the extracts were methylated using excess diazomethane for 10 min at room temperature, then dried under a nitrogen stream and finally analysed by UPLC–ESI(+)-MS/MS. In the last procedure, the evaporated samples were methylated, purified by IAC [36], and analysed by UPLC–ESI(+)-MS/MS.

2.5. Immunoaffinity purification

An immunoaffinity gel (IAG) containing immobilized anti-ABA antibodies was used to purify the ABA metabolites in the samples, as previously described [36]. Initially, the capacity of the IAG was tested using standard solutions, in triplicate, containing eight methylated ABA standards in equal amounts at concentrations (per standard) ranging from 5 to 300 pmol in ethanol:PBS buffer (5:95, v/v). The eluates were analysed by UPLC–ESI-MS/MS, and the whole experiment was repeated twice.

2.6. UPLC–ESI-MS/MS conditions

The dried samples were reconstituted in 30 μL of mobile phase (initial conditions), and 15 μL of each sample was then injected onto a reversed-phase column (BEH C18, 2.1 mm × 150 mm, 1.7 μm; Waters) coupled to an ESI-MS/MS system. The fractions containing ABA and the related acids were analysed in negative ion mode $[M-H]^-$, ABAGE was measured in negative and positive modes, while ABAalcohol, ABAaldehyde, and the methylated acids were determined solely in the positive ion mode $[M+H]^+$. In the first and second purification approaches, non-methylated compounds were separated by a linear gradient of methanol (A) and 10 mM formic acid (B), from 30:70 A:B (v/v) to 50:50 (v/v) over 7.5 min. Finally, the column was washed with 100% methanol (1 mL) and equilibrated to initial conditions (30:70 A:B, v/v) for 3.5 min. The retention time of ABA was 8.85 ± 0.02 min, and those of its metabolites DPA, ABAGE, PA, 9′-OH-ABA, 7′-OH-ABA, neoPA, ABAalcohol and ABAaldehyde were 4.44 ± 0.03, 5.25 ± 0.02, 5.39 ± 0.03, 5.97 ± 0.01, 6.83 ± 0.02, 7.39 ± 0.03, 8.01 ± 0.01, 8.20 ± 0.01 min, respectively. Methylated samples generated using the third and fourth purification procedures (see above) were separated using a linear methanol gradient, from 35 to 65% over 8 min, after which the column was washed with 100% methanol (1 mL) and equilibrated to initial conditions for 3.5 min. The retention times of ABAGE, DPAMe, ABAalcohol, PAMe, ABAaldehyde, 7′-OH-ABAMe, neoPAMe and ABAMe were 4.11 ± 0.02, 5.48 ± 0.01, 5.76 ± 0.01, 6.09 ± 0.01, 6.22 ± 0.01, 6.82 ± 0.01, 7.51 ± 0.01 and 8.56 ± 0.01 min, respectively. Calibration curve were created from triplicate analysis of free and methylated ABA metabolites by plotting the known concentration of each unlabeled analyte against the calculated response area of the analyte/IS ratio 0.15, 0.75, 1.5, 7.5, 15, 75 and 150 pmol/7.5 pmol and 0.015, 0.075, 0.15, 0.75, 1.5, 7.5, 15, 75

and 150 pmol/7.5 pmol, respectively, where IS concentration is the known amount of the internal standard added.

For both non-methylated and methylated analytes, the column temperature and flow rate were kept constant at 40 °C and 0.20 mL min^{-1}, respectively, the eluant was introduced into a UV-diode array detector (scanning range: 210–400 nm, resolution: 1.2 nm, sampling rate: 10 spectra s^{-1}) and the MS/MS without post-column splitting. The eluting parent ions and the appropriate product ions were measured by MRM in either negative ion mode ($[M-H]^-$), for ABAGE and the free ABA acids, or positive ion mode (ABAGE as $[M+H]^+$; ABAalcohol, ABAaldehyde, and the methylated ABA acids as $[M+H-H_2O]^+$). The optimised conditions for the selective MRM analyses were: capillary voltage: 1.0 kV, source/desolvation gas temperature: 100/350 °C, cone/desolvation gas: 2.0/500 L h^{-1}, LM/HM resolution: 12.5, ion energy 1: −0.3 V, ion energy 2: −1.5 V, entrance and exit potentials: 2.0 V, and multiplier voltage: 650 eV. The collision cell pressure was 5.10^{-3} mbar (maintained using argon), and the dwell time, cone voltage, and collision energies depended on the compounds under investigation (see Table 1). In addition, the dwell time of each MRM channel was calculated to provide 16 scan points per peak, with an inter channel delay of 0.1 s.

3. Results and discussion

3.1. Immunoaffinity chromatography of ABA metabolites

A mixture of high affinity C1ABA1 and C1ABA2 antibodies was used to prepare the IAG, which has been previously shown to bind up to 1.7 ± 0.2 nmol (+)-*cis*,*trans*-ABA and 8.0 ± 0.9 nmol of (+)-*cis*,*trans*-ABAMe in the presence of a single free competitor [36]. However, for the immunoaffinity isolation of ABA metabolites to provide reliable results when several cross-reacting metabolites are present, the capacity and recovery must remain high for each of the target metabolites. Hence, since the previous cross-reactivity study only investigated antibody binding parameters in the presence of a single free competitor, we used IAC–UPLC–ESI-MS/MS to determine the extent of cross-reactivity when the immobilized antibody was exposed to a mixture of potentially cross-reacting compounds. For this purpose, solutions containing mixtures of eight equal amounts of methylated ABA acids and metabolites at levels ranging from 5 to 300 pmol (Fig. 3B) were purified using 500 μL IAC gel, as described in [36], and the resultant eluates were analysed by UPLC–ESI-MS/MS. This procedure allowed the effects of competition between the compounds with differing affinities on their recoveries to be determined (Fig. 2).

The following five ligands were retained with high recoveries over the concentration range tested: ABAMe, its glucosylester, 7′-OH-ABAMe, PAMe, and neoPAMe, and all of these substances showed slow concentration-dependent losses. The binding capacity of the IAC gel was estimated to be about 1.1 nmol/mL gel for the tested standard mixture. Metabolites that had extremely low affinity for the sorbent (detection limits <5 pmol) included DPAMe; the IAG showed little (if any) concentration-dependent binding of this substance, and only trace amounts of it were detected in the eluate by the UV and MS systems (data not shown). Virtually no retention of ABAaldehyde and ABAalcohol was observed at 5 pmol either, but both became temporarily coupled at levels exceeding 50 pmol. Recoveries higher than 90% were obtained for ABAMe in the range 5–50 pmol, and the recoveries were still higher than 50% up to 300 pmol. However, the recovery of ABAMe declined very rapidly beyond this limit. The results of these experiments indicated that the IAC gel's maximum capacity for ABAMe, and hence its recovery, may vary depending on the other ABA-type ligands present in natural samples. In addition, the capacity per mL of our

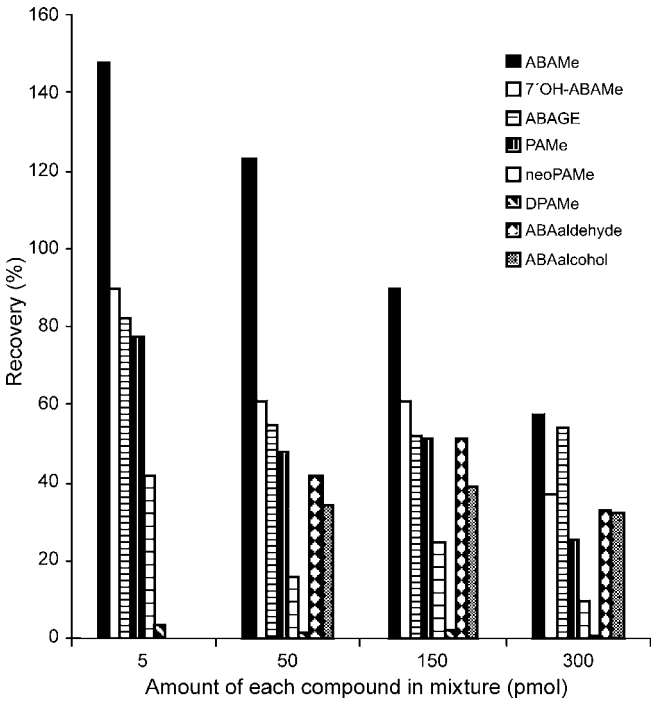

Fig. 2. Binding capacities of anti-ABA antibodies for eight methylated ABA metabolite standards in mixtures containing various, equimolar concentrations of the metabolites.

gel, expressed according to [48], was similar to previously published values [49–51]. On the other hand, at all concentrations tested, the differences in individual metabolite capacities were not fully parallel with previous observations of the metabolites' cross-reactivities in ELISAs (see [36] for comparison), hence the binding capacity of the antibodies appears to be influenced by their immobilization to varying degrees, depending on the metabolite. The binding capacities were also probably influenced by the high availability of free antibody binding sites at the low tested concentrations. The cross-reactivity parameters for a complex mixture may differ from those of the primary antigen for a number of reasons, including: (1) differences between the K_a values of antibodies for the cross-reacting substance and the antigen, (2) differences in the binding parameters of the immobilized antibodies on the gel, and (3) differences in the concentrations (relative and absolute) amongst cross-reacting substances in real samples [49]. Nevertheless, there are several reported advantages of using IAC for purifying ABA from plant tissue extracts, notably the immunoaffinity purification can significantly increase the selectivity and sensitivity (more than 10-fold) of subsequent LC–ESI-MS analysis [36]. Furthermore, we have shown the IAC gel to be highly specific for ABA, certain C1-ABA metabolites, and other structurally related compounds, making it highly useful for purifying ABA-like substances in complex plant extracts, which is often essential since total amounts of ABA metabolites in non-stressed plant material range from 5 to 50 pmol per gram fresh weight. Unfortunately, however, this approach cannot be used to isolate ABA metabolites like DPA, neoPA, and 7′-OH-ABA, due to their low affinity for the IAC gel.

3.2. Extraction and purification procedure

In order to identify and quantify ABA and its metabolites in plant tissue the samples must first be homogenized and extracted with a suitable solvent. These substances have generally been extracted using methanol or acetone acidified with 0.5–2% acetic acid (70–100%) [24,32,43,52,53], although other solvents, such as

Table 2
Levels of ABA and its metabolites in water-stressed *Nicotiana tabacum* L. leaves. Plant tissues (50 mg f.w.) were extracted with methanol/water/acetic acid (10/89/1, v/v), purified by HLB column chromatography and (a) directly analysed by UPLC–ESI(−/+)-MS/MS, (b) purified by immunoaffinity chromatography and analysed by UPLC–ESI(−/+)-MS/MS, (c) methylated and analysed by UPLC–ESI(+)-MS/MS, or (d) methylated, processed by immunoaffinity chromatography, and analysed by UPLC–ESI(+)-MS/MS. Data shown are means ± SE of three replicates.

[b] n.c.—no cross-reactivity with anti-ABA antibodies.

40% ethanol [36] and water [36,38], have also been used. We extracted ABA and its metabolites from water-stressed *N. tabacum* leaves using acidified 10% methanol, and then purified them using Oasis® HLB columns (see Tables 2 and 3). This procedure gave practically identical results to the classical method of 80% methanol extraction followed by purification using C18 cartridges (compare data presented in column (a) of Table 2 to the following values obtained following extraction by acidified 80% methanol: 84 ± 4, 203 ± 12, 848 ± 84 and 168 ± 23 pmol/g f.w. for ABA, ABAGE, PA and DPA, respectively). Furthermore, extraction by 10% methanol recovered 67% of the added internal standards, on average (Table 2), whereas recoveries of around 55% were obtained using the more commonly applied 80% methanol (data not shown). Extraction with an aqueous solution of methanol with a higher water content was also preferred due to the relatively low pigment content of our crude plant extracts, which is very advantageous for subsequent LC–ESI-MS/MS analysis when no immunoaffinity purification procedure is applied. Consequently, the 10% methanolic solvent was used for extraction in all subsequent optimisation procedures.

Samples usually require purification after extraction, which can be performed by reversed-phase chromatography, to remove lipids and chlorophyll, or by immunoaffinity columns, which allow almost complete purification of the samples. Furthermore, ABA and its metabolites have been purified using Oasis® HLB cartridges [31,32]. An Oasis® HLB can also be used to purify other plant hormones, such as gibberellins and indole-3-acetic acid [32]. Therefore, in the presented study purifications with both Oasis® HLB cartridges and an IAC gel were tested to examine their influence on subsequent UPLC–ESI-MS/MS analysis, again using the water-stressed *N. tabacum* leaves.

The yield and efficiency of the following purification protocols were compared (Table 2): (a) purification with Oasis® HLB cartridges, (b) combined Oasis® HLB and IAC, (c) Oasis® HLB purification followed by methylation, and (d) Oasis® HLB combined with methylation and the IAC step. The levels of ABA metabolites in *N. tabacum* leaves, determined by UPLC–ESI-MS/MS following each of these purification approaches are shown in Table 2. ABA and ABAGE concentrations detected by UPLC–ESI-MS/MS following all of the purification procedures (a–d) varied between 69 ± 2 and 87 ± 13 pmol/g f.w. and 133 ± 2 and 194 ± 19 pmol/g f.w., respectively. PA levels determined following three of the purification methods (a, c, d) ranged from 754 ± 39 pmol/g to 844 ± 78 pmol/g f.w., but this metabolite was undetectable after purification with the second method (b). DPA was only detected after use of the first and third purification methods (a and c), which did not involve an IAC step. Endogenous neoPA (31 ± 4 pmol/g f.w.) was detected only in those samples subjected to Oasis® HLB purification and methylation (c). The other metabolites, such as 7′-OH-ABA, 9′-OH-ABA, ABAalcohol, and ABAaldehyde, were undetectable in the *N. tabacum* leaf samples.

We also compared the recoveries of the internal standards from the samples. About 67% of the internal standards were recovered following the first purification procedure (Table 2a), which involved direct analysis of crude *N. tabacum* tissues by UPLC–ESI-MS/MS; similar to the values obtained by Zhou et al. [32]. The second purification procedure yielded recoveries of ca. 57% of

Table 3
Levels of ABA and its metabolites in varied amounts of tobacco leaves. Plant tissues were extracted with methanol/water/acetic acid (10/89/1, v/v), purified by HLB column chromatography and either (A) directly analysed by UPLC–ESI(−/+)-MS/MS or (B) methylated by ethereal diazomethane and then analysed by UPLC–ESI(+)-MS/MS. NeoPA, 7′-OH-ABA, ABAaldehyde, and ABAalcohol were not detected (n.d.) in tobacco leaves.

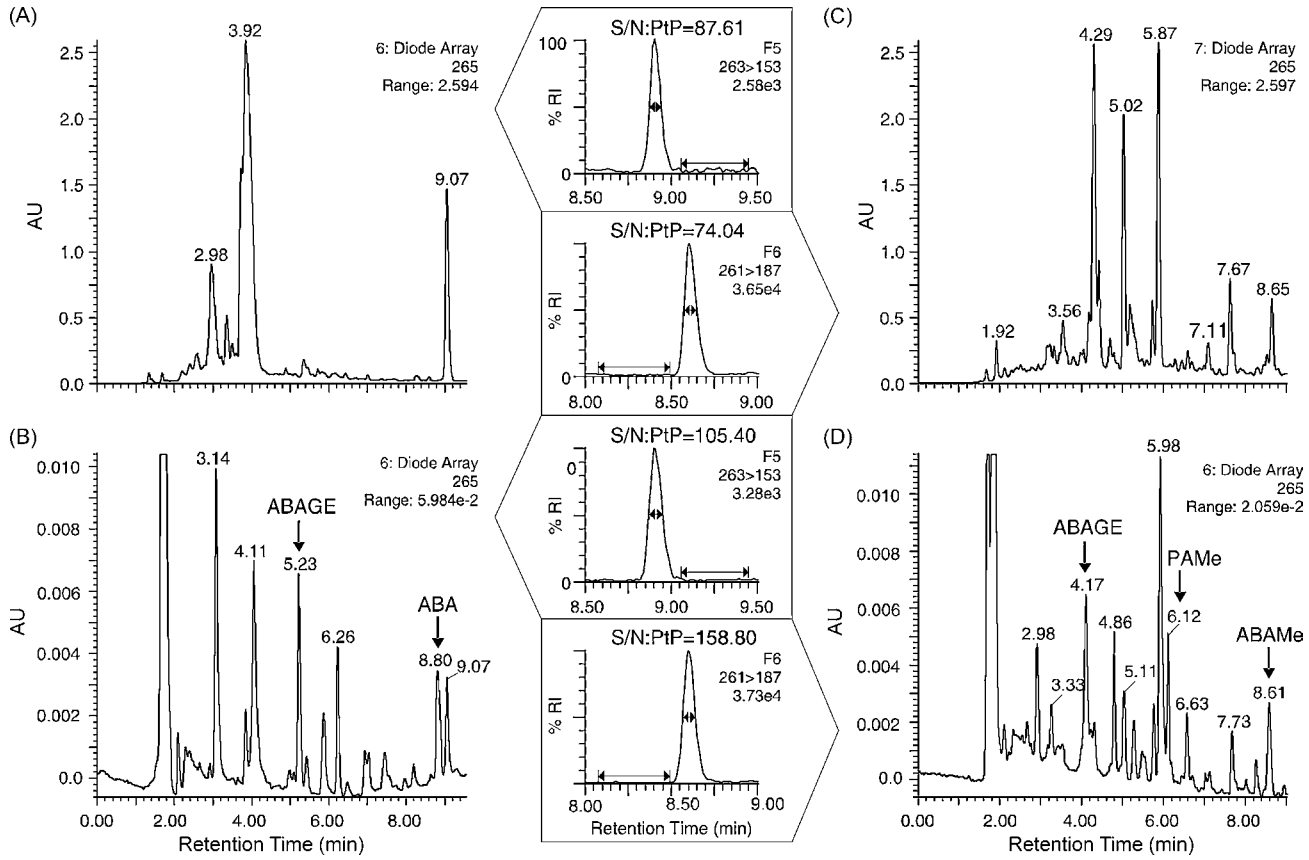

Fig. 3. Effects of immunoaffinity purification on the selectivity and sensitivity of subsequent ESI-MS/MS analysis. Comparison of UV (265 nm) and MRM chromatograms of authentic ABA present in 50 mg *Nicotiana tabacum* non-methylated (A and B) and methylated (C and D) extracts, before (A and C) and after using IAC (B and D).

the labelled d_6-(+)ABA, 59% of d_5-ABAGE, 51% of d_2-ABAaldehyde, and 14% of d_2-ABAalcohol (Table 2b). The other ABA metabolites could not be detected following this procedure due to the negligible cross-reactivity of the polyclonal anti-ABA-antibodies with PA, DPA, neoPA and 7′-OH-ABA [36]. Therefore, the combination of IAC and solid-phase extraction was wholly unsuitable for purifying these weakly immunoaffinity-binding analytes. The third procedure, based on purification of methylated samples by Oasis® HLB, recovered about 50% of each of the internal standards, while the subsequent introduction of the IAC step (4th procedure) resulted in only ca. 31% recoveries (Table 2c and d). Thus, once again, using IAC after sample methylation hindered measurement of metabolites other than ABAMe, ABAGE, and PAMe. On the other hand, non-significant variations were seen in the estimated levels of the analytes following each of the four purification protocols (as illustrated in Table 2). The rapid purification by each of these approaches, validated by the internal standardization procedure, allowed such differences to be accounted for, thereby enabling accurate quantification of endogenous ABA metabolites by UPLC–ESI-MS/MS. Adding labelled analogues to the extracts further facilitated the detection of natural ABA and the metabolites, providing better resolution of analytes eluting close together and

[b] Mean value of four independent measurements ± standard deviation.

measures of their recovery throughout the purification procedure. The results also corroborate the value of using specific recovery markers for each hormone metabolite measured [31].

However, the results also showed that the IAC step enhanced the purification of ABA, ABAGE and PA (Fig. 3), despite the losses of certain compounds (DPA and neoPA) from the profile of analysed tobacco leaf ABA metabolites. The UPLC chromatograms obtained before (0.1–2.5 AU) and after (0.001–0.01 AU) IAC purification confirmed that large proportions of potentially interfering UV-absorbing substances present in the plant extracts were removed. IAC also increased the selectivity and sensitivity of the subsequent high-throughput UPLC–ESI-MS/MS analysis, and reduced the need for frequent system clean-up, since interference by the sample matrix was reduced, resulting in an increased signal-to-noise ratios (e.g. 88/105 and 74/159 for ABA and ABAMe, respectively). Similar trends were observed for ABAGE and PA, although the IAC did not isolate all of the ABA metabolites (Table 2). The advantages of using IAC prior to LC–ESI-MS for the analysis of ABA, as well as other plant hormones, have been described in previous studies [36,47,54].

3.3. Optimisation of the UPLC–ESI-MS/MS methods

The masses of the diagnostic precursor-to-product ions for (non)methylated ABA, its metabolites, and their internal standards are shown in Table 1, while corresponding UPLC chromatograms are shown in Fig. 4. Fig. 4A shows the separation of a mixture of nine standards on a short reversed-phase column (2.1 mm × 150 mm) over 9 min, as monitored by diode array detection at 265 nm. The whole series of standards was eluted in 5 min, starting with DPA at 4.44 ± 0.03 min and ending with ABA at 8.85 ± 0.02 min, and the method provided baseline separation of all of the ABA compounds under investigation. Fig. 4B shows the separation of the standard mixture on the same reversed-phase column after methylation. In accordance with the mobile and solid phases used, the most polar ABA conjugate (ABAGE) was eluted in the first retention window and the polarity of the eluted compounds decreased as the chromatographic process continued. The polarity of the ABA acids was decreased by methylation, so ABAGE, ABAalcohol, and ABAaldehyde eluted earlier in the UPLC separation using the methanol gradient (see Fig. 4). Furthermore, the run-time of the analysis was reduced up to 3-fold compared to the previously published HPLC method (30 min in [36]). The retention times were also much more consistent (with RSDs between 0.1 and 0.7% for all compounds) than those of the previously published LC method (e.g. the mean and standard deviations of the ABA and ABAMe retention times were 13.53 ± 0.03 and 17.01 ± 0.04 min, respectively). This allowed the chromatographic runs to be split into five retention windows for non-methylated compounds (4.0–4.8, 4.8–5.7, 5.7–7.7, 7.7–8.5, 8.5–9.5 min) and six retention windows for methylated compounds (3.0–4.6, 4.6–5.9, 5.9–6.4, 6.4–7.1, 7.1–8.0, 8.0–9.0 min), which increased the sensitivity of the subsequent ESI-MS/MS measurements.

The MS parameters (ion mode, capillary voltage, cone voltage, collision energy, and dwell times) were optimised to maximise the overall sensitivity of the analysis, according to the analyte peak areas, and strong consistency was found between the MRM transitions obtained here and those previously acquired for ABA, ABAGE, and 7′-OH-ABA [31,37,43]. In the presented study, ABAGE and the free acids were measured in negative ion mode, which yields strong molecular deprotonated $[M-H]^-$ ions of these substances. Conversely, positive ion mode had more advantages for measuring ABAalcohol, ABAaldehyde, ABAGE and ABA acid methylesters. In positive ion mode, the most intense parent ions for these analytes were $[M+H]^+$ ions, followed by $[M+H-H_2O]^+$, and $[M+Na]^+$ ions. However, while the $[M+Na]^+$ ions were the most prominent, their high stability hindered their fragmentation and thus their utility as precursor ions in MRM analysis (data not shown). Hence, the second most prominent ions were chosen as precursors; $[M+H]^+$ for ABAGE and $[M+H-H_2O]^+$ for ABAalcohol, ABAaldehyde, and the methylesters. Product ion scans of each of the selected precursor ions showed several product fragments similar to those observed by other groups [31,37], and the predominant fragment generated from each precursor was chosen as a corresponding product ion for MRM transition. Each analyte, and the corresponding deuterated analogue, was scanned to confirm its retention time and optimised MRM transition characteristics (Table 1).

Limits of detection (LOD) and quantification (LOQ), defined as concentrations yielding signal-to-noise ratios of 3 and 10, respectively, were determined for the UPLC–ESI-MS/MS analysis of ABA and all of the investigated analytes. Analysis of ABA by IAC–LC–ESI(+)/MS has been previously described, with detection limits of 0.25 and 0.1 pmol for ABA and ABAMe, respectively [36]. The UPLC–ESI-MS/MS method presented here provided LODs ranging between 0.1–1.0 and 0.01–0.05 pmol for the free and methylated analytes, respectively (Table 4), while the LOQs ranged from 0.025 pmol (ABAaldehyde) to 2.5 pmol (7′-OH-ABA, 9′-OH-ABA). In comparison, ABA has been previously analysed by LC–ESI(−)-MS/MS in *B. napus* siliques [32], *A. thaliana* leaves [37] and *C.*

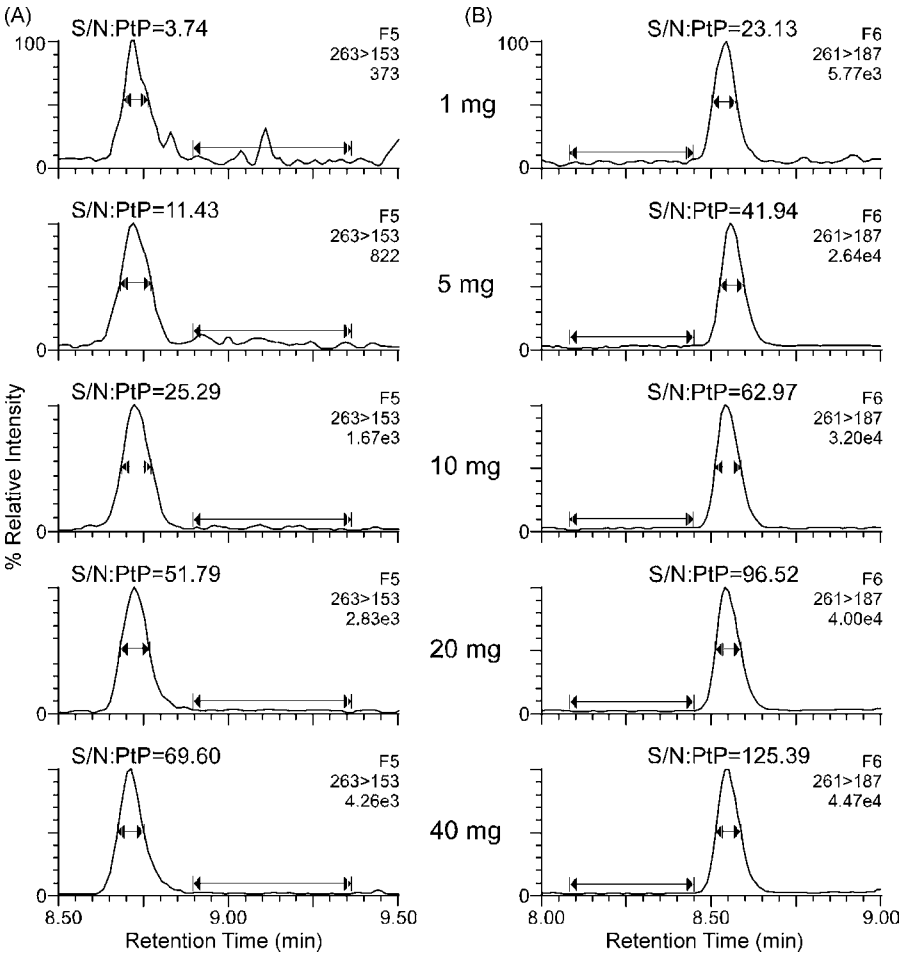

Fig. 5. Chromatograms showing the increase in sensitivity of subsequent UPLC–ESI(+)-MS/MS analysis afforded by the methylation of analytes in small amounts of tobacco plant tissues (1, 5, 10, 20, and 40 mg f.w.).

reticulata leaves and roots [38], with reported detection limits of 0.76, 3.8 and <50 pmol/g d.w., respectively. The cited study of *B. napus* siliques also reported detection limits for ABAGE, PA and DPA of 6.32, 1.79 and 2.49 pmol/g d.w., respectively [32].

Finally, the sensitivity of the analytical procedure for analyses of real plant tissue samples was examined by extracting samples of tobacco leaf material ranging from 1 to 40 mg (f.w.) in the presence of an internal standard mixture (20 pmol per standard). The samples were then purified by Oasis® HLB columns alone, and subjected to either direct analysis by UPLC–ESI(−/+)-MS/MS or UPLC–ESI(+)-MS/MS following methylation. The results of these experiments, presented in Table 3, show that methylation of the samples considerably increased the analytical sensitivity of UPLC–ESI(+)-MS/MS (Fig. 5). In addition, the use of small amounts of plant tissue reduced the analyte ion-suppressing effects of the matrix, and in combination with the methylation step enhanced the signal-to-noise ratios of the MS/MS measurements up to 6-fold. Furthermore, the results demonstrate that less than 5 mg of tissue is sufficient for determining ABA, ABAGE, and PA, although DPA analysis would require 10 mg of tissue (Table 3A). The results of analyses following Oasis® HLB purification and methylation (Table 3B) show that the minimum amount of tissue required for detecting all the analytes found in the material (ABA, ABAGE, PA and DPA) using this preparation procedure was 1 mg. Therefore, the analysis of ABA and its metabolites should be carried out with a minimum of 1 mg plant tissue when methylation is used, and 10 mg when it is not. In comparison, relatively high amounts (20–1000 mg) of fresh plant tissue [see, for example [36,37,55]], or 10–100 mg of dry seeds [32,33,39,43,46], have to be used to obtain measurable amounts of the ABA analytes when using the LC technique. Furthermore, LC requires a complex purification procedure involving several steps.

3.4. Validation of the UPLC–MS/MS method

To validate the UPLC method for the analysis of tissue samples, endogenous ABA and its metabolites were measured in replicates ($n = 4$) of water-stressed *N. tabacum* leaf extracts, using calibration curves generated from analyses of solutions with varied amounts of each unlabelled analyte and fixed amounts of the corresponding deuterium-labelled internal standards. This method gave a broader linear range with the methylated compounds, spanning at least four orders of magnitude. Furthermore, the resultant calibration curves were mostly linear, across concentration ranges of 0.25–2.5 to 150 pmol for the free substances and 0.025–0.5 to 150 pmol for the methylated analytes, with correlation coefficients (R^2) varying between 0.9975 and 0.9994 (Table 4).

The results demonstrate that either Oasis® HLB chromatography followed by UPLC–ESI(−/+)-MS/MS or Oasis® HLB purification followed by methylation and UPLC–ESI(+)-MS/MS can be used to reduce sample matrix effects and enhance the analytical accuracy sufficiently to reliably determine levels of the analytes in small samples of *N. tabacum* tissue (25 mg f.w., Table 4). Furthermore, the

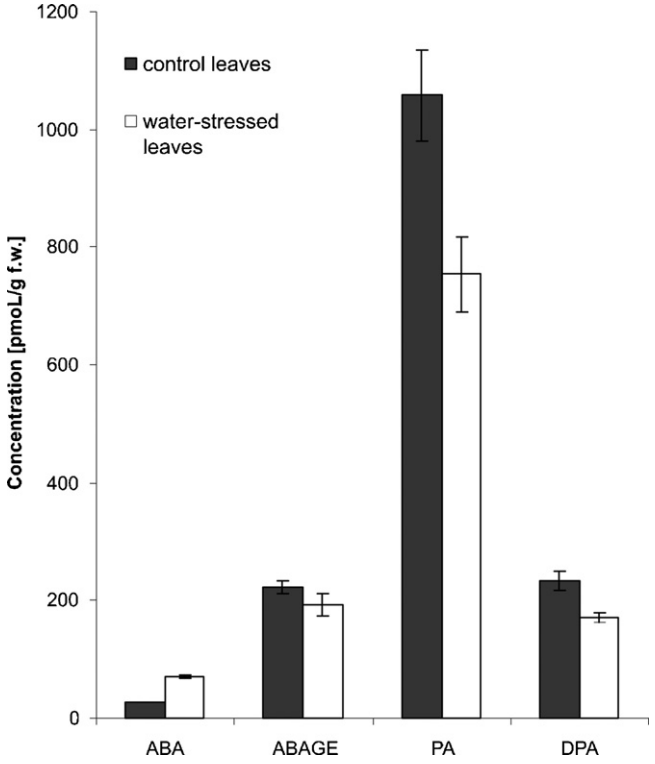

Fig. 6. Levels of ABA and its metabolites (ABAGE, PA and DPA) in control and water-stressed *Nicotiana tabacum* L. leaves (mean ± SE, $n = 3$).

accuracy of the method was validated by the "standard addition method", using two sets of samples: purified extracts of tobacco leaves (25 mg of 4 days water-stressed leaves) with and without the addition of a standard mixture (50 and 150 pmol each). The UPLC–ESI-MS/MS measurements were practically identical, regardless of the inclusion of the methylation step, as shown by the average results obtained using the two procedures in Table 4. The percentages of the analytes recovered were also calculated for ESI-MS/MS analysis in both positive and negative ion modes ($n = 4$), and were found to be 60 ± 7 and 77 ± 3%, on average, respectively. Hence, the data show that the method was satisfactory for measuring these trace components in a complex plant matrix [56]. Assessments of analytical accuracy using spiked tobacco extracts showed that estimated amounts of the ABA metabolites (after adjustments based on the results for the standards) were generally within ±25% of the true amounts.

3.5. Quantification of abscisic acid and its metabolites in water-stressed tobacco leaves
