Levels of abscisic acid and its metabolites in leaves of control and 4 days water-stressed tobacco plants were quantified using the UPLC–ESI-MS/MS method in conjunction with standard isotope dilution measurements, which generally provide quantitative results with high accuracy and precision [57]. As shown in Fig. 6, the samples from the control and stressed leaves had ABA concentrations of 27 and 70 pmol/g f.w., respectively. Conversely, the control plants contained higher levels of ABAGE, PA, and DPA than the water-stressed plants. PA was the most abundant ABA metabolite in both control and water-stressed plants, followed by ABAGE and DPA, which were present at approximately 5-fold lower concentrations. Furthermore, ABA levels were at least 100-fold lower than PA concentrations, but its endogenous levels increased after water stress, while ABAGE, PA, and DPA concentrations decreased. The other ABA metabolites such as neoPA, 7′-OH-ABA, 9′-OH-ABA, ABAalcohol and ABAaldehyde were not detected, even in the water-stressed plants. Previous authors have reported contents of ABA and related compounds (PA, DPA, neoPA, ABAGE and 7′-OH-ABA) in seeds of various species, including western white pine (*Pinus monticola*) seeds during dormancy breakage (by moist chilling) and germination [39,40], thermodormant and germinating lettuce (*Lactuca sativa* L.) seeds [31], and in canola (*B. napus*) siliques (valves and seeds) [32]. In addition, the effect of parasitism on ABA metabolism during the early development of Douglas fir seeds has been described [41]. However, this is the first published study in which endogenous ABA and its metabolites have been analysed in leaves of *N. tabacum*, or any other species.

4. Conclusion

In the presented study we developed a UPLC–ESI-MS/MS method and combined it with a convenient procedure for extracting and purifying plant samples. This method was then successfully applied to the analysis of ABA and its metabolites in water-stressed *N. tabacum* leaves, and unstressed controls. The extraction procedure, which combines solvent extraction followed by solid-phase purification, allows samples to be prepared much more simply and rapidly than possible using previous protocols, permitting more than 70 samples per day to be extracted and purified. Overall, the methodology is less time-consuming and much more effective than other LC techniques. The liquid chromatographic separation and analysis of nine ABA derivatives by UPLC–ESI-MS/MS also provides accurate and reproducible quantification of most ABA metabolites. Furthermore, the approach enables the detailed and direct study of ABA and various ABA metabolites in small amounts of leaf tissues, which was not previously possible. Therefore, this newly developed UPLC–ESI-MS/MS method should be useful for studying the physiological roles, metabolism, and modes of action of ABA derivatives in plants.

ABSTRACT

A rapid non-destructive sampling technique for the analysis of volatile organic compounds (VOCs) emitted by paper sheets is described. A capillary, which is connected to a microcolumn packed with Tenax TA, is inserted between two sheets at the centre of a paper stack encapsulated inside a PET/Al/PE composite foil. The other end of the microcolumn is connected to a gas-tight syringe and an appropriate volume of gaseous phase is aspirated. The microcolumn is then thermally desorbed in a modified GC inlet (modification is presented) and analysed by gas chromatography–mass spectrometry (GC–MS). In the chromatogram from the analysis of artificially aged paper sample 21 compounds were identified. Advantages of the method including the short sampling time (1 min), simplicity and economic aspect are discussed.

1. Introduction

Paper emits a complex mixture of volatile organic compounds (VOCs) as it ages. Its composition depends on the nature of the paper, the degree of its degradation, and the pathway by which it degrades [1]. Identification, determination and evaluation of the ratios of different degradation products can be used for the evaluation of condition of aged paper material and it can be suitable for the comparison of the used and newly developed paper modification processes.

Analytical methods applied for the evaluation of paper material condition and degree of its degradation can be divided into destructive (size-exclusion chromatography, viscosity measurements, etc.) and non-destructive ones (e.g. headspace methods) [2]. However, the non-destructive ones are the most suitable for examination of valuable artefacts. Recently, a non-destructive solid-phase microextraction (SPME) method has been applied to the trapping and analysis of VOCs emitted during ageing of books [3,4]. The contact SPME coupled to GC–MS allowed the characterisation of more than 50 individual organic constituents and enabled to monitor relative abundances of the main degradation products.

The aim of this work was the application of another recently introduced non-destructive sampling technique, the headspace solid-phase microcolumn extraction (HS-SPMCE), for the analysis of VOCs emitted by paper [5–7]. In the presented method, the loaded microcolumn was thermally desorbed in a modified GC inlet and VOCs were separated and detected by GC–MS.

2. Experimental

2.1. Sample and sampling procedure

A sample of a newsprint paper (Jihočeské papírny, Větřní, Czech Republic) was conditioned for 24 h according to ISO 187 at 23 ± 1 °C, and at relative air humidity of 50 ± 1% [8]. Seventy-five sheets of paper (A5 format) were then encapsulated inside a polyethylene terephthalate/aluminium/polyethylene (PET/Al/PE) composite foil (Tenofan Al/116S) using Polystar 30D impulse tong sealer (Rische + Herfurth, Hamburg, Germany). The sample was submitted to accelerated temperature ageing at 98 ± 2 °C during 15 days according to the ASTM D 6819-02 standard test method [9] in which sealed glass tubes were replaced by the PET/Al/PE foil.

The PET/Al/PE foil was pierced and a deactivated fused silica capillary column (12 cm long, 0.25 mm I.D.) equipped with a glass press-fit connector (to protect the paper surface) was inserted

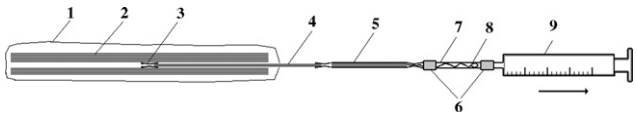

Fig. 1. Sampling procedure: (1) PET/Al/PE foil, (2) sheets of paper, (3) press-fit connector, (4) fused silica capillary, (5) sorbent-packed microcolumn, (6) short flexible tubing, (7) glass tube, (8) wire for microcolumn manipulation and (9) gas-tight syringe.

10 cm deep between two sheets at the centre of a paper stack (Fig. 1). The exit end of the capillary was gas-tightly connected to the entrance end of the microcolumn. The other end of the microcolumn was attached to a 20-mL all-glass gas-tight syringe (Poulten & Graf, Wertheim, Germany) and 10 mL of gaseous phase was aspirated through it.

2.2. Apparatus

Analyses were conducted using a Hewlett–Packard 6890GC–5972 MS system (Palo Alto, CA, USA) combination equipped with a modified split/splitless (S/SL) inlet. The inlet modification is shown in Fig. 2A (see also in [7]) and the Tenax TA (30 mg) packed glass microcolumn (specified in [5]) and the parts employed are shown in Fig. 2B. The inside of the entrance end of the microcolumn is conically broadened (as in glass press-fit connectors) to make a gas-tight connection when it is put on the end of a capillary column inserted into the bottom part of a glass tube chamber. To place a loaded microcolumn into the glass tube chamber, the modified upper part of the S/SL insert weldment with tubing has previously to be taken out and then replaced. For the separation of analytes a 60 m × 0.32 mm I.D. fused silica HP-VOC/MS capillary column with a film thickness of 1.8 μm was used. The GC column was temperature programmed from 50 °C (2 min) to 120 °C at 7 °C/min and then to 270 °C (10 min) at 14 °C/min. Desorption of the loaded microcolumn was accomplished at the inlet temperature of 250 °C and a carrier gas (helium) pressure of 5 kPa during 1 min. After desorption, the carrier gas pressure was increased to 50 kPa at 100 kPa/min and maintained at this value for the rest of the analysis. The split ratio in the modified inlet was adjusted to 100:1. Gas chromatographically separated compounds were detected by MS operating in the scan mode scanning from 10 μ to 300 μ at 2.59 scans/s. Temperatures of the MS ion source and of the GC–MS interface were 170 °C and 280 °C, respectively. Identification of mass spectra of the detected compounds was carried out by computer matching against an Agilent Wiley7n mass spectra library (Agilent Technologies, USA).

3. Results and discussion

As an example of the method application, a chromatogram from the analysis of the headspace of the artificially aged paper sample is shown in Fig. 3A. In 10 mL of the gaseous phase that had been in contact with the paper stack, 21 organic compounds were identified. The chromatogram (Fig. 3B) of the blank SPMCE–GC–MS analysis of 10 mL of air taken from the empty composite foil bag was clean. The obtained qualitative data together with information on relative abundances of degradation products can be used for the characterisation of the paper condition [2–4]. So far, no method is available in the literature which would allow the determination of the VOCs content in paper material quantitatively on the basis of their concentration in the gaseous phase. For the quantitative VOCs analysis in paper destructive methods can be used, too. However, those are not appropriate for the testing of valuable historic documents.

The advantage of using microcolumn adsorption lies in short sampling times (in our case 1 min) in comparison with the SPME

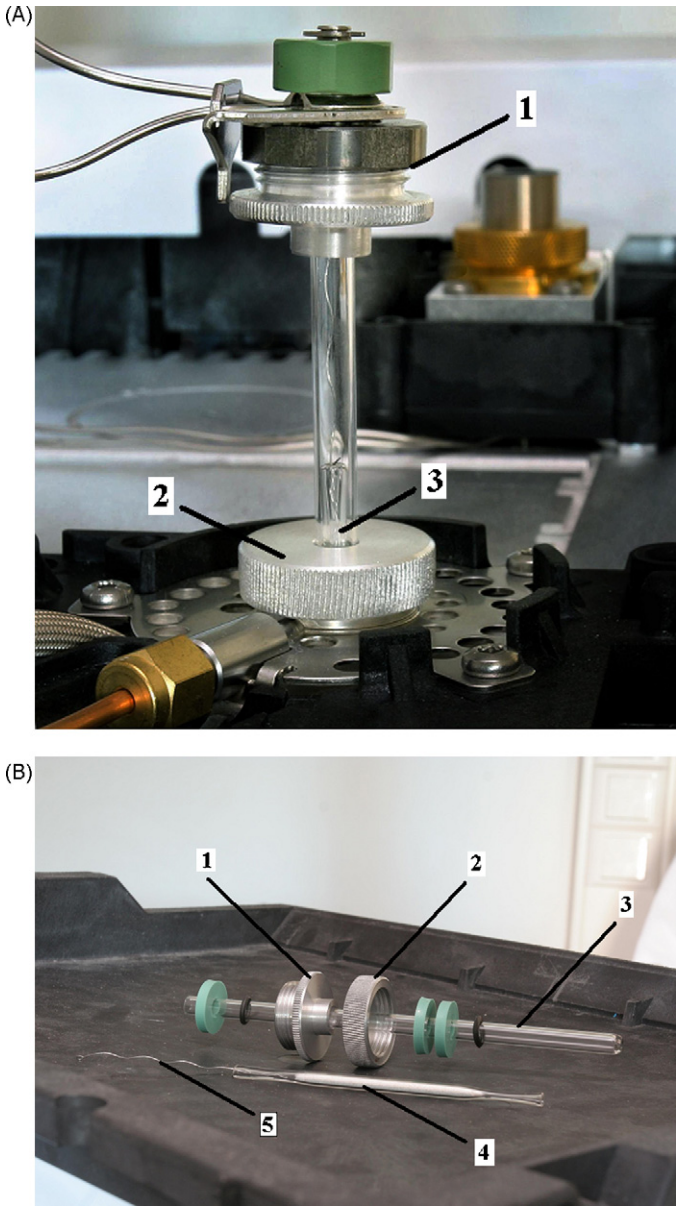

Fig. 2. (A) The split/splitless inlet modification for thermal desorption of a microcolumn: (1) upper part of S/SL insert weldment with tubing, (2) lower nut, (3) inserted microcolumn. (B) The sorbent-packed glass microcolumn and parts employed: (1) upper nut, (2) lower nut, (3) glass tube chamber, (4) microcolumn and (5) wire for microcolumn manipulation.

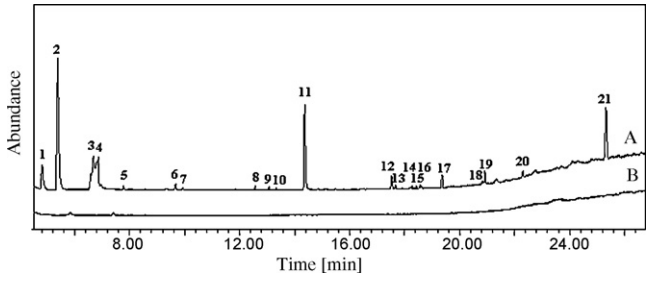

Fig. 3. Chromatograms from the SPMCE–GC–MS analysis (A) of the headspace of the artificially aged paper sample and (B) of the blank run. Peaks: (1) acetone; (2) methyl acetate; (3) 2,3-butanedione; (4) acetic acid; (5) methyl propanoate; (6) 2,3-pentanedione; (7) pentanal; (8) toluene; (9) octane; (10) hexanal; (11) furfural; (12) decane; (13) 2-pentylfuran; (14) alpha-terpinene; (15) 1,2,3,4-tetramethylbenzene; (16) limonene; (17) undecane; (18) benzoic acid; (19) dodecane; (20) tridecane; (21) 1-methylethyl tetradecanoate.

method, in which sampling takes tens of minutes. In the studies [3,4] describing the use of contact SPME for the analysis of VOCs emitted by naturally aged book, the applied sampling times varied from hours to several days, which is not convenient for practical purposes. Another advantage of a method operating up to the adsorbent packing breakthrough capacity, is that the amount ratios of analytes trapped in the microcolumn are comparable with the ratios in the aspirated gaseous phase. In the case of SPME the ratios of the fibre-sorbed analytes depend on the sampling time and the equilibrium is shifted towards the higher boiling components with increasing time. As a result, the use of the microcolumn method is more advantageous for trapping of more volatile compounds.

The simple modification of the GC inlet presents an inexpensive alternative to the commercially available thermal desorption systems. The modified inlet can be reversed to its initial S/SL status in a few minutes. During the analysis run, the microcolumn remains inside the GC inlet and is flushed by the carrier gas, so there is no need of subsequent conditioning of the adsorbent. In the case of analysis of higher concentrations of less volatile compounds, the carryover can be eliminated by repeating the thermal desorption of the microcolumn. The microcolumn makes it possible to analyse hundreds of samples without significant distortion.

ABSTRACT

The bionanocomposite film consisting of glucose oxidase/Pt/functional graphene sheets/chitosan (GOD/Pt/FGS/chitosan) for glucose sensing is described. With the electrocatalytic synergy of FGS and Pt nanoparticles to hydrogen peroxide, a sensitive biosensor with a detection limit of 0.6 μM glucose was achieved. The biosensor also has good reproducibility, long-term stability and negligible interfering signals from ascorbic acid and uric acid comparing with the response to glucose. The large surface area and good electrical conductivity of graphene suggests that graphene is a potential candidate as a sensor material. The hybrid nanocomposite glucose sensor provides new opportunity for clinical diagnosis and point-of-care applications.

1. Introduction

Graphene has recently emerged as an interesting material in a myriad of applications because of its unique mechanical and electronic properties [1–5]. Most of the graphene studies have focused on its physical properties, such as its electronic properties, and these studies have demonstrated some applications in gas sensors [6,7] and pH sensors [8]. However, using graphene for biosensors has not received much attention. Graphene exhibits excellent electrical conductivity, high surface area, and strong mechanical strength [2,4,9]. Such properties indicate that graphene may be a good support for electrocatalysts. Recently, we developed a new approach for producing functionalized graphene sheets (FGSs) in mass quantities through the thermal expansion of graphite oxide to yield single graphene sheets with epoxy, hydroxyl, and carboxyl groups as well as Stone-Wales and 5–8–5 lattice defects [10]. Such functional groups and their lattice defects may play a significant role in preparing graphene-based electrocatalysts. Furthermore, these FGSs are more dispersible and biocompatible than other carbon-based materials due to their functional groups. These advantages of FGSs make them an ideal material for sensor and fuel cell applications. In fact, due to their planar morphology and thus larger accessible surface area, FGSs may perform better than any other carbon-based electrode as a sensor material. Another advantage of graphene is its potential low manufacturing cost as compared to other nanostructured carbon materials, such as carbon nanotubes. Recently, graphene has been used as electrode material for direct electrochemistry of glucose oxidase, battery, and fuel cell [11–13].

Noble nanoparticles (NPs), such as platinum, exhibit electrocatalytic behavior to hydrogen peroxide (H_2O_2) and have been widely used for sensing applications [14–16]. It will be attractive to prepare nanoparticle-functionalized FGS, e.g., platinum nanoparticles (Pt NP)/FGS nanocomposite, because such a functionalized FGS may generate synergy on electrocatalytic activity and thus enhance the sensitivity of the biosensor.

In this work, we report a FGS-based bionanocomposite film and demonstrate its application for sensitive glucose sensing. This bionanocomposite film was prepared by the following routes: chemically controlled modification of FGSs by electrodeposition of Pt NPs followed by physical modification of the Pt/FGS nanocomposite with enzymes. The FGS used here was prepared as described elsewhere [10]. The FGSs were first dispersed in a solution containing 0.2% chitosan and then cast on a glassy-carbon electrode (GCE). By using the potentiostatic electrodeposition in a platinum-containing solution, platinum nanoparticles were modified on the FGS/chitosan/GCE. Then glucose oxidase (GOD) was immobilized on Pt/FGS/chitosan/GCE, forming a bionanocomposite film.

2. Experimental

2.1. Chemicals

GOD, D-glucose, chitosan, phosphate buffer saline, potassium chloride, acetic acid, chloroplatinic acid, sulfuric acid, H_2O_2, ascorbic acid, and uric acid were all purchased from Sigma–Aldrich (St. Louis, USA). All solutions used in the experiments were prepared with ultra-pure water (18.3 MΩ cm, Nanopure, Barnstead, USA).

2.2. Materials

The graphene used in our study was made by thermal exfoliation of graphite oxide [10], which starts with the chemical oxidation of graphite flakes to increase the *c*-axis spacing from 0.34 nm to 0.7 nm. The resulting graphite oxide is split apart through rapid thermal expansion to yield a single but wrinkled graphene sheet functionalized with hydroxyl and epoxy sites.

2.3. Preparation of FGS/chitosan/GCE

The suspension of FGS was prepared by dispersing 1 mg graphene in 1 mL of 0.2% chitosan solution (pH 5). The mixture was sonicated 1 h to obtain a homogeneous dispersion. The FGS suspension was cast on the surface of a GCE (∅ = 3 mm) to prepare the FGS-modified electrode. Six microliters of 1 mg/mL FGS suspension was cast on the pretreated GCE and dried at room temperature.

2.4. Preparation of Pt/FGS/chitosan/GCE

Platinum nanoparticles were electrochemically deposited on the FGS/chitosan/GCE with constant potential at −0.25 V for a desired time in a 5-mL solution containing 1 mM H_2PtCl_4 and 0.5 M H_2SO_4. After the deposition, the electrode was thoroughly rinsed with water and allowed to dry at room temperature for further modification.

2.5. Preparation of GOD/Pt/FGS/chitosan/GCE

GOD was dissolved in a 0.2% chitosan solution, and the GOD concentration was 10 mg/mL. Six microliters of the solution were cast on the as-prepared Pt NP/FGS/chitosan/GCE. Right after casting, the GOD-modified electrode was moved into a refrigerator and kept at 4 °C to dry overnight. During the experimental period, the modified electrodes were stored at 4 °C until use.

2.6. Instrumentation

Cyclic voltammetric and amperometic measurements were performed on a CHI 824 electrochemical workstation (CHI Instruments, Inc., Austin, TX) connected to a personal computer. A three-electrode cell (10 mL) was employed with a modified GCE as the working electrode, an Ag/AgCl electrode as the reference electrode, and platinum wire as the auxiliary electrode. An amperometric response of the GOD/Pt/FGS/chitosan/GCE to the sequential addition of a desired amount of glucose was measured at +0.4 V with continuous gentle stirring in a 5-mL buffer solution containing 0.01 M PBS. The transmission electron microscope (TEM) images were recorded on a JEOL JEM 2010 microscope with a specified point-to-point resolution of 0.194 nm. The operating voltage on the microscope was 200 keV. The FGS sample was prepared by dropping a diluted FGS suspension onto the Cu–C grid. The Pt/FGS/chitosan nanocomposite sample was prepared by peeling the hybrid Pt/FGS/chitosan nanocomposite off the GCE and was transferred to a Cu–C grid. All images were digitally recorded with a slow-scan charge-coupled device camera (image size 1024 × 1024 pixels), and image processing was carried out using a Digital Micrograph (Gatan).

3. Results and discussion

The chitosan dispersed FGSs were prepared and characterized with TEM. Fig. 1(A) shows an image of FGSs dispersed in chitosan. As shown in this figure, the FGSs exhibit wrinkled graphene sheets. This wrinkled nature of FGSs is highly beneficial in maintaining a high surface area on the electrode since the sheets cannot readily collapse back to a graphitic structure. The inset in Fig. 1(A) displays a selected-area electron diffraction (SAED) of the nanocomposite material, yielding a double six-spot-ring pattern from a graphene sheet [17].

Pt nanoparticles were electrochemically deposited on FGS/chitosan film. Fig. 1(B) is a TEM image of Pt NP-modified FGSs. It can be seen from this figure that Pt NPs are uniformly deposited on the graphene surface with a size of less than 50 nm.

In the current study, the electrochemical response of the graphene-based glucose biosensor was coming from the anodic oxidation current of the enzymatic product H_2O_2. It is well known that H_2O_2 undergoes electrochemical oxidation processes at the solid electrodes, but the oxidation or reduction occur at relatively high potentials that cause high background current and interference from other electroactive compounds. Noble nanoparticles, such as platinum, have been widely used as electrocatalysts for oxidation and reduction of H_2O_2. To study the electrocatalytic effect of the FGS/chitosan and Pt/FGS/chitosan films to H_2O_2, cyclic

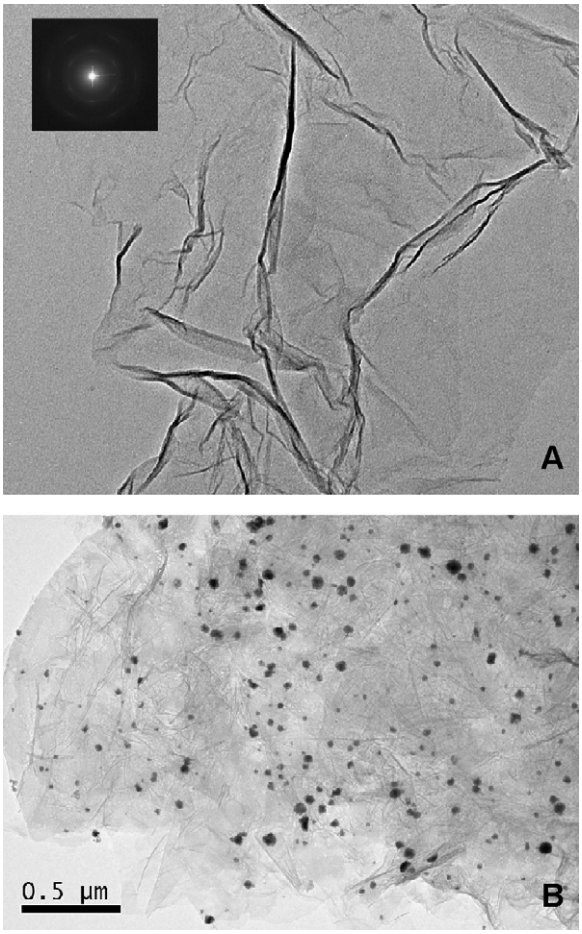

Fig. 1. (A) TEM image of FGS (inset: SAED of FGS). (B) TEM image of platinum nanoparticles deposited on a graphene sheet.

voltammetry was performed. Fig. 2(A) shows the cyclic voltammograms obtained at the modified GCE with a hybrid Pt/FGS/chitosan nanocomposite film in a 10-mM phosphate-buffered saline (PBS) solution containing 1.5 mM H_2O_2 in comparison with a bared GCE and FGS/chitosan GCE. The electrochemical responses of all these electrodes are negligible in the solution in the absence of H_2O_2 (data not shown). As shown in this figure, the oxidation and reduction currents from H_2O_2 at the bare GCE are quite small, and the oxidation of H_2O_2 at the bare GCE starts at 0.6 V. However, the electrochemical responses obtained at the FGS/chitosan/GCE and the Pt/FGS/chitosan/GCE are much larger than that obtained at the GCE. Moreover, it can be seen that the oxidation of H_2O_2 started at ~0.3 V, and the oxidation current increased as the potential increased at these modified electrodes. It can also be seen that the reduction of H_2O_2 started at 0.1 V at the modified electrode, and the reduction current increased as the potential decreased. The decrease of the overpotential of H_2O_2 is ascribed to the electrocatalytic activity of the platinum NP and graphene. Furthermore, it can be seen that the magnitude of the electrochemical response at these different electrodes increased in the following order: Pt/FGS/chitosan/GC > FGS/chitosan/GC > GC. It was concluded that the hybrid nanocomposite film with both graphene and platinum nanoparticles showed a synergistic effect on the electrocatalytic activity to H_2O_2. Therefore, the hybrid Pt/FGS/chitosan/GCE exhibited the highest electrocatalytic activity toward H_2O_2. The data from hydrodynamic voltammograms shown in Fig. 2(B) further confirmed the results in Fig. 2(A). Fig. 2(B) illustrates that the FGS-modified electrode improved the electrocatalytic activity to H_2O_2 (Curve b) compared with that at the GCE (Curve a). It can be seen that the Pt/FGS/chitosan nanocomposite had the highest electrochemical response to H_2O_2 and showed a significant synergistic effect on the electrocatalytic activity to H_2O_2 (Curve c).

The effect of the Pt electrodeposition time on the electrocatalytic activity of Pt/FGS/chitosan/GCE to H_2O_2 was studied. The electrocatalytic activity of the prepared electrode was measured at 0 V in a solution containing 0.6 mM H_2O_2. It was found that the response current increased as the deposition time increased until it reached the plateau at 200-s deposition. Then the signal started to decrease with more deposition time, which may be ascribed to the reduced electrochemical active surface area because large-sized particles may be deposited on the electrode surface with a long deposition time. A 200 s deposition time was chosen for this work.

Amperometric technique was used for the evaluation of the graphene-based biosensor for glucose detection. Fig. 3(A) shows the typical amperometric response of GOD/Pt/FGS/chitosan/GCE to successive additions of 0.15 mM glucose with an applied potential at 0.4 V. As can be seen from Fig. 3(A), the electrochemical response increased as the glucose concentration increased. From the inset in Fig. 3(A), it can be seen that the sensor is responsive to a low

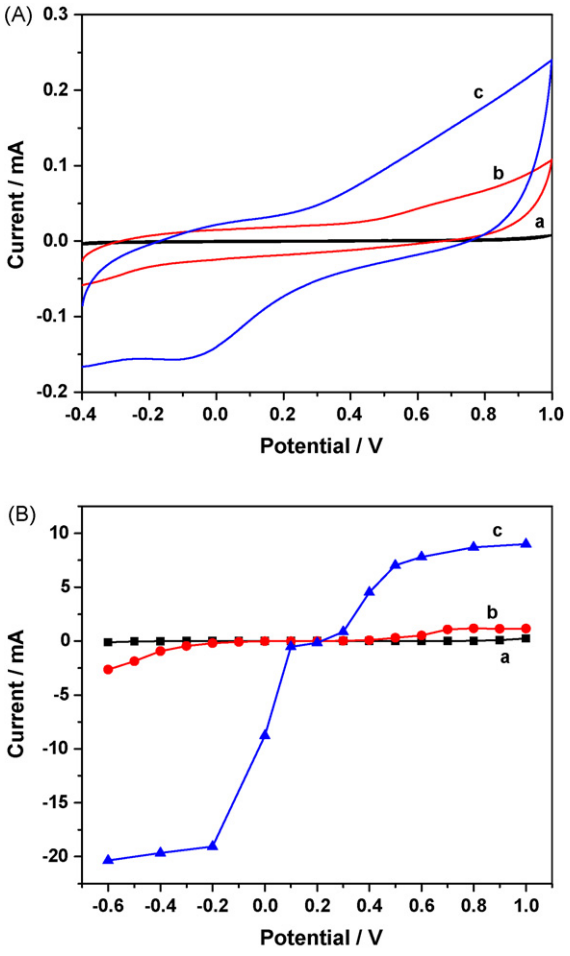

Fig. 2. (A) Cyclic voltammograms obtained at (a) bare GCE; (b) FGS/chitosan/GCE; (c) Pt/FGS/chitosan/GCE in 10 mM PBS buffer solution containing 1.5 mM H_2O_2. (B) Hydrodynamic voltammograms obtained at (a) bare GCE; (b) FGS/chitosan/GCE; (c) Pt/FGS/chitosan/GCE in 10 mM PBS buffer solution containing 0.12 mM H_2O_2.

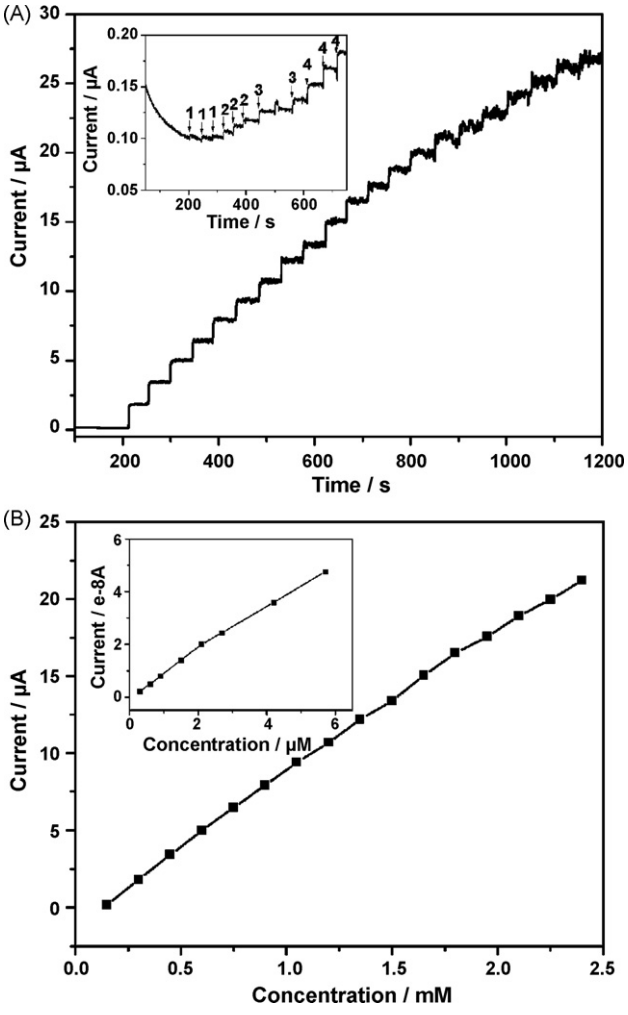

Fig. 3. (A) Amperometric response of GOD/Pt/FGS/chitosan/GCE to sequential addition of a series of glucose concentrations from 0.15 mM to 4.2 mM at +0.4 V. Inset (b) is the lower range of the calibration curve.

concentration of glucose, such as 0.6 μM glucose. Fig. 3(B) displays the plot of the electrochemical response vs. the glucose concentration. It can be seen from this figure that this sensor shows a wide linear range from sub-μM to 5 mM glucose. The detection limit of the glucose sensor is 0.6 μM based on the three times of signal-to-noise ratio. Such a sensitivity of the biosensor might be attributed to a large surface area, a fast electron transfer activity of FGS, and the electrocatalytic synergy from platinum and graphene. Within the nanocomposite, GOD can contact both graphene and platinum, which facilitates the fast electron transfer with a relatively low barrier between the enzyme and the electrode. The glucose sensor based on Pt NP/FGSs achieved a better detection limit in comparison with the Pt/Pb alloy NP/carbon nanotube-based glucose sensor [16] (a detection limit of 7 μM) and the Pt nanowire/carbon nanotube-based glucose sensor [15] (a detection limit of 3 μM). The sensitive biosensor was also accompanied with good reproducibility. The relative standard deviation (RSD) of the biosensor in response to 15 μM glucose was 6% for five different electrodes, indicating the good reproducibility of the biosensor. The long-term stability of the glucose sensor was examined with two electrodes for 2 weeks. The data showed that the enzyme maintained 86% of its activity during the first week and 75% during the second week. We also evaluated the potential interference from other electroactive biomolecules, such as ascorbic acid and uric acid, with concentrations similar to physiological fluid. Results indicate that the responses from these interferents are negligible. The sensor was also validated with glucose-spiked human plasma samples, and the recovery of the spike sample was 101%. These results indicate that the biosensor developed in this work has high sensitivity and selectivity for detecting blood glucose level.

4. Conclusion

We present a novel bionanocomposite film consisting of GOD/Pt/FGS/chitosan for glucose sensing. The biosensor exhibits good sensitivity with a detection limit of 0.6 μM glucose. Such a sensitivity is attributed to the synergy of FGS and Pt nanoparticles on the electrocatalytic activity to H_2O_2. The glucose biosensor has good responses because of the large surface area and fast electron transfer of graphene and Pt nanoparticles. The biosensor also has good reproducibility and long-term stability. The interfering signals from ascorbic acid and uric acid are negligible compared with the response to glucose. Human plasma samples were tested with the glucose sensor, and good recovery was achieved with the spiked samples. This work shows that the hybrid GOD/Pt/FGS/chitosan nanocomposite-based biosensor has great potential for clinical utility and home care for a rapid monitoring of glucose. The graphene-based biosensor fabrication method demonstrated in this work is readily applicable to the fabrication of other biosensors based on oxidases, such as biosensors for cholesterol, alcohol, lactate, acetylcholine, hypoxanthine, and xanthine [18,19].

ELISA

ABSTRACT

An indirect inhibitive surface plasmon resonance (SPR) immunoassay was developed for the microcystins (MCs) detection. The bioconjugate of MC-LR and bovine serum albumin (BSA) was immobilized on a CM5 sensor chip. A serial premixture of MC-LR standards (or samples) and monoclonal antibody (mAb) were injected over the functional sensor surface, and the subsequent specific immunoreaction was monitored on the BIAcore 3000 biosensor and generated a signal with an increasing intensity in response to the decreasing MCs concentration. The developed SPR immunoassay has a wide quantitative range in 1–100 $\mu g\,L^{-1}$. Although not as sensitive as conventional enzyme-linked immunosorbent assay (ELISA), the SPR biosensor offered unique advantages: (1) the sensor chip could be reusable without any significant loss in its binding activity after 50 assay-regeneration cycles, (2) one single assay could be accomplished in 50 min (including 30-min preincubation and 20-min BIAcore analysis), and (3) this method did not require multiple steps. The SPR biosensor was also used to detect MCs in environmental samples, and the results compared well with those obtained by ELISA. We conclude that the SPR biosensor offers outstanding advantages for the MCs detection and may be further developed as a field-portable sensor for real-time monitoring of MCs on site in the near future.

1. Introduction

Microcystins (MCs) are a family of cyclic heptapeptides produced mainly by some freshwater cyanobacteria such as *Microcystis*, and are hazardous to humans and animals due to their hepatotoxicity and tumor-promoting activity [1,2]. Among the MCs variants, MC-LR is the most common and well investigated. To reduce the adverse effects on humans and animals, World Health Organization (WHO) has established a maximum permissible concentration of 1 $\mu g\,L^{-1}$ of MC-LR in drinking water [3]. It is therefore necessary to develop a rapid and reliable method for MCs detection in environmental monitoring. Recently, a series of biochemical and physicochemical methods have been developed for MCs detection such as protein phosphatase inhibition assay (PPiA), enzyme-linked immunosorbent assay (ELISA), high-performance liquid chromatography (HPLC) and liquid chromatography with mass spectrometry (LC/MS) [4]. However, these methods require either complex operation or expensive materials and devices. To circumvent these drawbacks, several research groups have made the attempts to develop biosensors for MCs detection, such as molecularly imprinted polymer (MIP)-based sensor [5], electrochemical immunosensors [6–9], and evanescent wave all-fiber immunosensors [10,11]. There have been the reports that described the application of test strips for rapid MCs analysis *in situ* [12,13]; however, it is still challenging to develop a simple, rapid, and sensitive method for MCs analysis.

Recently, the optical biosensor based on the surface plasmon resonance (SPR) has received more and more attention because of its own outstanding advantages: allowing rapid and real-time analysis, owning reusable sensor chip, and requiring low amounts of reagents without chemical labels. And it has been successfully and widely employed to detect small molecules of biomedical, food and environmental interest [14]. In this paper, we developed an indirect inhibitive SPR immunoassay for the MCs detection. The sensor chip was firstly functionalized by the amine-coupling method, and then the MCs detection was performed with indirectly measuring the inhibition by MCs in samples. The regeneration of the sensor chip was investigated. Moreover, the SPR biosensor was also used to detect MCs in environmental samples, the results were discussed and compared with the conventional ELISA.

2. Experimental

2.1. Materials and sample preparation

MC-LR with >95% purity (HPLC-grade), the (MC-LR)–BSA bioconjugate, and anti-(MC-LR) monoclonal antibody (mAb) were prepared in our laboratory, the cross-reactivity of mAb with MCs variants has been tested in our previous work [15]. *N*-hydroxysuccinimide (NHS), 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride (EDC), ethanolamine, and Tween-20 were purchased from BIAcore (Amersham Pharmacia Biotech, Uppsala, Sweden). All other chemicals used in the experiment were of analytical grade. All the solutions were prepared using deionized water (18.2 MΩ cm), which was obtained from a Milli-Q System (Millipore, Bedford, MA).

Natural water samples and fish tissue extractions were collected, pretreated, and extracted according to our previous procedure [16].

2.2. Instrumentation

The SPR immunoassay was performed with a BIAcore™ 3000 instrument (BIAcore, Uppsala, Sweden). The molecular weight (MW) of BSA and (MC-LR)–BSA were determined by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) instrument (Bruker Daltonic Reflex™ III mass spectrometer, Bruker Doltonic, Bremen, Germany).

2.3. Immobilization protocol

Before the immobilization, the molecular weight (MW) of BSA and (MC-LR)–BSA were determined to be 66,354 and 68,708, respectively. The difference of MW between BSA and (MC-LR)–BSA (2354) indicated that the molar ratio of MC-LR to carrier protein BSA was 2.4 in this work, which was suitable for further immobilization. Then the CM5 sensor chip was functionalized by the EDC–NHS amine coupling as follows: the sensor chip was activated twice by mixing equal volumes of NHS (0.1 M) and EDC (0.4 M) and injecting the mixture over the sensor chip for 10 min at a flow rate of 10 μL min^{-1}. (MC-LR)–BSA (100 μg mL^{-1}) was dissolved in sodium acetate buffer (10 mM, pH 4.3) and injected over the sensor chip surface at a flow rate of 5 μL min^{-1}. NaOH (25 mM) was injected to wash the surface, and capping of the unreacted sites was achieved by injection of ethanolamine (1 M, pH 8.0) for 7 min.

2.4. SPR immunoassay and indirect competitive ELISA (ic ELISA)

The SPR immunoassay was performed in the indirect inhibitive immunoassay format. MC-LR standards or samples (40 μL) were incubated with an equal volume of mAb for 30 min at room temperature. The equilibrated mixture was then injected over the functional surface at a flow rate of 5 μL min^{-1}; the remaining free mAb was captured by (MC-LR)–BSA on the surface. Real-time monitoring will be displayed in a sensorgram as the optical response (RU) versus time (in seconds). To convert the response back to baseline, the sensor chip was regenerated by injecting NaOH (40 mM) at a flow rate of 20 μL min^{-1}. The next sample was analyzed at random. A typical sensorgram for the real-time detection of MCs could be seen in Fig. 1.

To evaluate the reliability of the SPR immunoassay, MCs in the same samples were detected by the indirect competitive ELISA (ic ELISA) and the SPR immunoassay. The ic ELISA was performed according to our previous report [16].

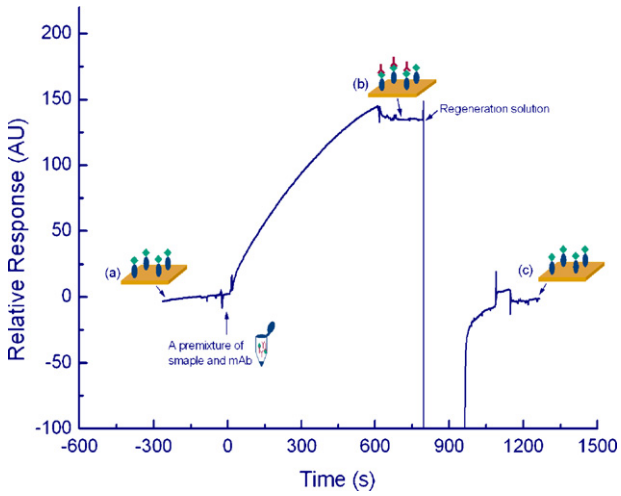

Fig. 1. The representative SPR response in real-time detection: PBS buffer was injected over the sensor chip surface immobilized with (MC-LR)–BSA, and a baseline of the SPR response was obtained (a); a premixture of samples and mAb was injected over the functional sensor chip for 10 min, and free mAb was captured by MC-LR on the sensor chip surface; the corresponding response was recorded (b); and the captured antibodies were removed using NaOH solution (40 mM) for the regeneration, the response returned to the baseline (c).

3. Results and discussion

3.1. The (MC-LR)–BSA bioconjugate immobilization

In the inhibitive SPR immunoassay, it is crucial to obtain a high bioconjugate immobilization level (amount), or rather a high hapten immobilization level because high amount of hapten generally means a potent capacity of antibody binding for the surface. The optimal immobilization level in this work was obtained through the preconcentration assay, as a result, a nearly saturated coverage level (approx. 9000 RU) was observed by using (MC-LR)–BSA solution (100 μg mL^{-1}) in 10 mM sodium acetate (pH 4.3). Subsequently, the capacity of mAb binding at the 9000 RU-immobilization level was further checked by injecting the mAb solution (15 μg mL^{-1}) over the functional surface, yielding a 218 RU-capacity of mAb binding, similar to the results in the other developed inhibitive immunoassays: 80 RU- and 300 RU-capacities of the antibody binding were generated at the same high bioconjugate immobilization level (10,000 RU) [17,18]. Actually, in a certain immunoassay, the capacity value of antibody binding on the surface should be evaluated rationally based on the used antibody affinity, working concentration, and especially, the effective hapten immobilization level. The surface with the high immobilization level did not necessarily yield a high capacity value of antibody binding. To be exact, only the high immobilization simultaneous with high molar ratio of hapten to carrier protein could contribute to the high surface antibody-binding capacity. Miura and co-workers previously reported the relative high capacity of antibody binding by using HBP–BSA bioconjugate with high molar ratio of HBP to BSA (n = approx. 54) [19], 22.5-fold more than that in this work (the molar ratio of MC-LR to BSA in this work, n = 2.4).

3.2. Detection of MCs using SPR biosensor and regeneration efficiency

According to the indirect inhibitive immunoassay format, MC-LR (0–100 μg L^{-1}) was incubated with mAb for 30 min; the mixture was then injected over the functional sensor chip. As observed in Fig. 2A, the binding response was inversely proportional to MC-LR concentration, which further supported the results obtained

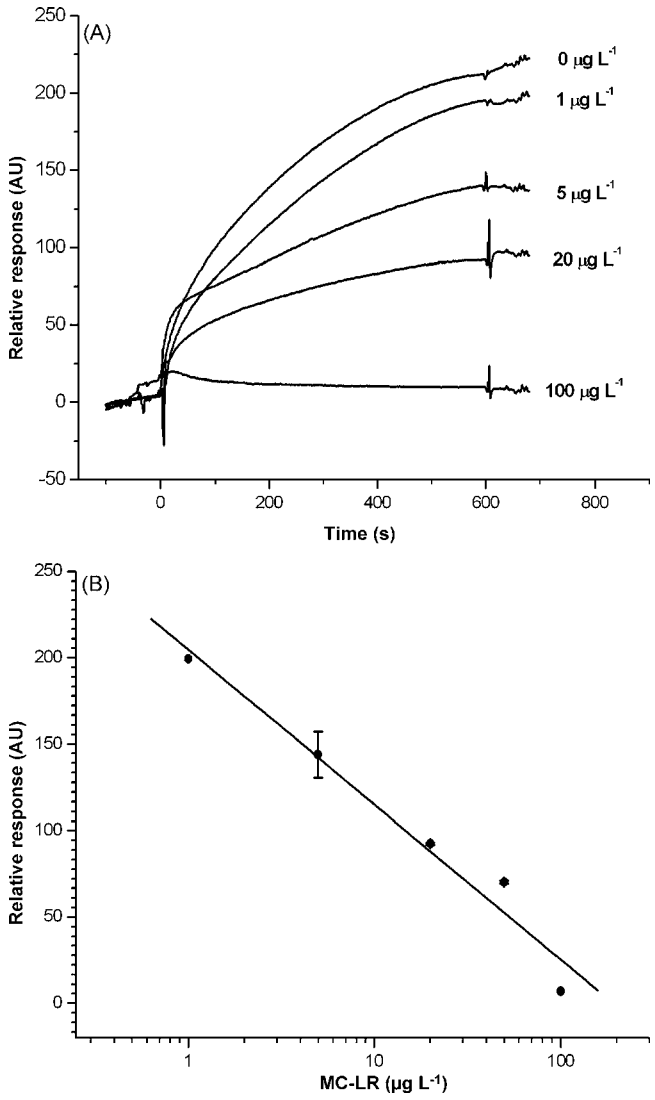

Fig. 2. (A) Sensorgram generated by injecting the solution mixture of monoclonal antibody and MC-LR at various concentrations (0, 1, 5, 20, and 100 μg L^{-1}) on the functional CM5 sensor chip and (B) standard curve for the detection of MCs by the SPR biosensor.

using the indirect inhibitive format. On the basis of these results, a dose–response curve was generated (Fig. 2B). The results indicated a good linearity (r^2 = 0.9667) in the wide quantitative range of 1–100 μg L^{-1}. And it has reached the permissive MCs concentration in drinking water (1 μg L^{-1}) by WHO [3]. In our previous work, sensitive time-resolved fluorescence (TRF) and chemiluminescence (CL) techniques were employed to improve the assay sensitivity, and exhibited the wide quantitative range of 0.01–10 and 0.05–10 μg L^{-1}, respectively [15,16], superior to the present SPR immunosensor sensitivity. However, the SPR immunosensor offered several important advantages over the above immunoassays: (1) compared to the ELISA, TRFIA, and CL immunoassays in our previous report, the SPR immunoassay could be rapidly accomplished in 50 min, whereas the immunoassays (ELISA, TRFIA, and CL immunoassays) required 2 h or more, (2) the entire SPR assay analysis is simple without any labeling and cumbersome washing that are indispensable for the above immunoassays, and (3) importantly the SPR sensor chip could be regenerated.

Furthermore, a comparison of the other biosensors for MCs detection is summarized in Table 1, in contrast to the other techniques such as the electrochemical and evanescent wave all-fiber biosensors for MCs detection [7,9,11–13], the present SPR immunosensor was not as highly sensitive as the biosensors above, which may be due to the different antibodies, assay strategies, and technique platforms. However, there is still further scope of the SPR immunoassay sensitivity improvement since antibody-amplification strategies have been successfully applied in other biochemical molecules analyses [21,22]. As an important parameter, the BIAcore analysis time could be 20 min, moreover, the whole analysis time including the preincubation and BIAcore analysis time was approximately 50 min, and could be also competitive with or better than other techniques in Table 1.

3.3. Regeneration efficiency

After one sample analysis, the antigen–antibody complex on the surface should be dissociated using a regeneration solution for the next analysis. In the present study, NaOH (40 mM) was found to be suitable for regeneration (Fig. 1). After 50 assay-regeneration cycles, the capacity of mAb binding for the functional chip was determined to be 179 RU compared with 218 RU-capacity of the original mAb binding, indicating that decrease in the binding capacity of the functional CM5 sensor chip was less than 20% of the initial binding capacity, which was an acceptable loss of binding capacity according to the validation parameters for the SPR biosensor [20].

3.4. Application of SPR immunoassay for environmental samples

In the present study, the reliability of the SPR immunoassay was evaluated by the conventional ELISA. The results are summarized in Table 2 [maximum relative standard deviation (RSD) for ELISA in the present study, 6.6%]. The results obtained by the biosensor and ELISA were in fairly good agreement, supporting the feasibility of the application of the SPR biosensor to detect

Table 2
Microcystins determined by SPR biosensor and ic ELISA in environmental samples.

Sample code[a]	SPR biosensor ($\mu g\,L^{-1}$), mean ± SD[b]	ic ELISA ($\mu g\,L^{-1}$)
1	<1	0.49
2	<1	1.12
3	1.8 ± 0.3	1.66
4	2.4 ± 0.2	2.70
5	2.8 ± 0.1	2.50
6	14.5 ± 1.2	10.17

[a] Samples 1–3 were water samples, the pretreatment of samples was seen in Section 2. Samples 4–6 were fish tissues; MCs extracted from the samples were dissolved in 1 mL aliquot of ultrapure water; SPE extracts were diluted to perform the MCs analysis (if necessary).

[b] Data were mean ± SD from triplicate analyses for each sample.

MCs in environmental samples. Therefore, the SPR biosensor could be reliable and practical for the MCs analysis in environmental samples.

4. Conclusion

We have developed an inhibitive SPR immunoassay for MCs detection in environmental samples. The immunosensor chip was functionalized with (MC-LR)–BSA by amine coupling. Using this chip, a wide linear range ($1–100\,\mu g\,L^{-1}$) was achieved, which reached the permissive MCs concentration in drinking water ($1\,\mu g\,L^{-1}$) by WHO, meanwhile, only $40\,\mu L$ of samples were required and the whole assay can be analyzed in 50 min. Additionally, the functional sensor chip was favorable as its binding ability was not significantly affected after 50 assay-regeneration cycles. The SPR biosensor was applied to environmental samples, the results compared well with those by the conventional ELISA. This work has demonstrated that SPR immunosensor is simple, rapid, and suitable for the detection of MCs in environmental samples. Meanwhile, since less expensive portable SPR devices become increasingly popular and useful, presently, our further effort may be made to miniaturize the SPR biosensor to monitor field samples *in situ* for MCs detection.

Metalloid

ABSTRACT

This review aims to provide an overview of homogeneous liquid–liquid extraction (HLLE) and dispersive liquid–liquid microextraction (DLLME) methods and their potential use in inorganic analysis. Relevant applications to the determination of metal ions, metalloids and organometals are included. The phase separation mechanisms of these unconventional solvent extraction techniques are discussed. The new trends in the field of miniaturization and automation are presented, while proposing future trends and potential new areas for their application.

1. Introduction

Transportation of materials from one phase to another is the most fundamental procedure for the separation of a chemical species from the matrix or from other coexisting components. Liquid–liquid or solvent extraction is based on the principle that a solute or analyte can distribute itself in a certain ratio between two immiscible solvents, one of which is usually water (aqueous phase) and the other an organic solvent (organic phase). In certain cases the analyte can be more or less completed moved into the organic phase.

Sample pre-treatment is often the bottleneck in a measurement process, as they tend to be slow and labor-intensive. In routine analysis, liquid–liquid extraction (LLE) is the most widely used sample preparation technique, whose goal is cleanup, enrichment and signal enhancement. However, some shortcomings like the use of extensive amounts of hazardous organic solvents and sample volumes, the generation of large amounts of pollutants make this procedure time consuming, expensive, environmentally unfriendly, tedious, laborious and hence potentially prone to sample contamination when ultra-trace determinations are required [1,2].

Modern trends in analytical chemistry are towards the simplification and miniaturization of sample preparation procedures as they lead inherently to a minimum solvent and reagent consumption and drastic reduction of laboratory wastes [3,4]. Under this context, unconventional LLE methodologies have been arisen like: single drop microextraction (SDME), wetting film extraction (WFE), cloud point extraction (CPE), homogeneous liquid–liquid extraction (HLLE), dispersive liquid–liquid microextraction (DLLME) and dispersive liquid–liquid microextraction based on solidification of a floating organic drop (DLLME-SFO).

SDME is based on a droplet of organic solvent, which is suspended at the tip of a microsyringe needle and immersed into the aqueous sample, which can be stagnant or moving. Recently, an automatic SDME method performing on-line metal preconcentration coupled with ETAAS has been presented [4]. A micro-drop of di-isobutyl ketone (DIBK) is generated and suspended at a glass capillary tip into the flow-through microextraction cell. As the fresh metal complex flows continuously around the micro-droplet, the analyte is extracted into the solvent. Subsequently, the micro-drop is retracted back into the holding coil for measuring. Xu et al. [5] overviewed the basic extraction principles of SDME as well as its latest developments and applications. WFE concept is based on the formation of a thin layer coating of organic phase on the inner walls of a PTFE extraction coil, as a result of the hydrophobic interactions between solvent and coil. The theoretical aspects as well as fundamental stages of the renewable phase WFE technique have been well presented by Miro et al. in a recent review [3]. Once the metal complex species have been preconcentrated a small plug of a suitable solvent or back-extraction solution is pumped into the coated reactor to strip out the isolated analyte, which thereafter is delivered to the detector for quantification. The CPE procedure is based on the phase separation, which occurs in aqueous solutions of non-ionic surfactants when heated above the so-called cloud point temperature. At this point the initial solution separates into a surfactant rich phase of small volume containing the metal trapped by organized structures and a bulk aqueous phase [6].

On the other hand, homogeneous liquid–liquid extraction (HLLE) utilizes the phase separation phenomenon from a homogeneous solution and simultaneously extracting the target solutes into the separated phase [7,8]. It can be considered, that the surface area of the interface between the two phases (aqueous and organic) initial is infinitely large. Consequently, vigorous shaking or mixing is not necessary. Generally, HLLE has been applied through binary [9,10] and ternary component miscible solvent systems [11,12]. In these cases, phase separation is based on salting-out phenomenon, on temperature, on pH of perfluorinated surfactant systems and on ion-pair formation. HLLE is a simple and powerful preconcentration method that reduces reagent consumption, extraction time, cost of analysis and the exposure to the organic solvents [11].

Recently, Assadi and co-workers [13] presented a microextraction technique, termed dispersive liquid–liquid microextraction (DLLME) based on ternary component solvent systems. An appropriate mixture of an extraction solvent and a disperser solvent, with high miscibility in both aqueous and organic phase (extraction solvent) is rapidly injected into the sample solution (aqueous phase). By this procedure a cloudy solution (high turbulence) is produced, which is consisted of fine droplets of the extraction solvent, dispersed throughout the aqueous solution. Consequently, the analyte is extracted into the fine droplets of extraction solvent usually through complex formation. After centrifugation, the fine droplets are settled down at the bottom of the conical test tube, removed by a syringe and analyzed by various analytical techniques like gas chromatography (GC) [14,15], gas chromatography–mass spectrometry (GC–MS) [16], high-performance liquid chromatography (HPLC) [17–19], electrothermal atomic absorption spectrometry (ETAAS) [20–22] and FAAS [23,24]. The applications of this new procedure have been reviewed recently by Bosch-Ojeda and Sanchez-Rojas [25] and Zang et al. [26]. DLLME has been performed in manually (batch) mode and only one study has been presented in on-line sequential injection mode up today. DLLME has been applied for determination of organic compounds [13,17–19] as well as for metals [14,15,20–24,27] and metalloids [14,28,29] in various types of samples but mainly in water samples. The principal advantage of HLLE and DLLME is that the initial surface area between extraction solvent and aqueous sample is very large, thus the equilibrium state is achieved quickly and the extraction time is very short.

An alternative DLLME procedure named DLLME-SFO has been presented by Leong and Huang for organic compounds determination. This method based on the solidification of floating organic droplet by cooling the glass tube in an ice bath for 5 min. The organic solvent was then transferred into a conical vial; melted quickly at room temperature and injected into gas chromatography [30,31] for analysis.

This review presents an update on progress in implementing the HLLE and DLLME for preconcentration of metal and metalloid species hyphenated with various detection systems such as atomic spectrometry, UV–vis spectophotometry, X-ray fluorescence spectrometry and polarography including the new trends and applications.

2. How do HLLE and DLLME work?

In LLE, certain solvents such as acetonitrile, acetone, 2-propanol, propylene carbonate, methanol, ethanol, and dimethylsulphoxide cannot be used as extracting solvents because they are miscible with water in all proportions. Also they are omitted from use as extractants from aqueous solution, although their high dielectric constants, donor numbers, and solubility parameters would make them helpful if they could be employed [28,32]. It is obvious that if some ways could be found to separate these solvents as organic phases from aqueous solutions, the versatility of solvent extraction would be greatly increased.

Murata et al. [33] proposed a method for the extraction of iron(III) in propylene carbonate from aqueous phase, based on the high solubility of organic solvent in water in higher temperature. At room temperature, the two phases are present heterogeneously, but at the elevated temperature they change into a homogeneous solution, which separates into the two phases again upon cooling. During these sequential procedures, the species in the aqueous phase transfers into the organic phase. The effectiveness of the homogeneous liquid–liquid extraction is attributed just to the higher reaction temperature.

Matkovich and Christian [34] have separated acetone as an organic phase by using the salting-out effect, and the organic phase thus obtained served not only to extract certain metal chelates but also to improve the performance characteristics of the flame-emission or atomic absorption spectrophotometry for metals determination. The best salting-out agents of the 79 studied, were calcium chloride, magnesium chloride and sucrose, but the metal impurities in the salts and the high viscosity in the aqueous phase produced by the sucrose caused problems in analysis.

Two relatively simple and similar theories have been used to explain salting-out phenomena, one postulating decreased mutual solubility of the solvents and the other postulating removal of one solvent via solvation processes [34]. The former assumes that compounds, not necessarily ionic in nature, are preferentially solvated by one of the solvents, making this solvent unavailable for dissolving the second. The latter theory, which applies only to ionic compounds, assumes that the more polar of the two solvents (e.g., water) preferentially congregates around the salt because of electrostatic attrac-

tion, leading to nonideal behaviour. A combination of these two processes is obviously possible, but the salt effect will probably predominate with ionic salting-out compounds. Three factors should be considered when evaluating a salt and its potential salting-out effect on acetone [34]. (1) The solubility of the salt in acetone must be negligible. Salts such as the lithium halides, which might be expected to cause phase separation based on the other parameters, showed no separation because they were soluble in acetone. (2) The solubility in water must be large in order to have maximum interaction with the water molecules. (3) The ability of ions to precipitate water loving substances (gels), according the lyotropic series ($Mg^{2+} > Ca^{2+} > Sr^{2+} > Ba^{2+} > Li^{+} > Na^{+} > K^{+} > Rb^{+} > Cs^{+}$). Various salts have been used for acetonitrile phase separation for metal determination, like: calcium chloride [35], sodium nitrate [36], ammonium sulphate [37], and sodium bromide [38].

In case of ternary solvent (water/methanol/chloroform) the phase separation of the extracting solvent (chloroform) from aqueous phase can also be accomplished by salt addition [39]. By this procedure, fine particles of the extraction phase were sedimented in the bottom of a conical test tube by centrifugation. In this case the volume of the sedimented phase is very small about 11 μL.

A similar HLLE method called "single phase" using ternary solvent system (water/ethanol/methylisobutylketone) [12], (acetonitrile/chloroform/HCl aqueous solution) [40] and (water/ethanol/chloroform) [41] has been proposed for metal extraction and determination. After preparing this single-phase solution, the homogeneous three component solvent system is "broken down" by the addition of an excess of water. By this procedure the homogeneous solution is separated into two liquid layers.

There is also the procedure of Fujinaga and Hori [32] that used, instead of the salting-out effect, the addition of a small volume of a third solvent to promote the separation of an immiscible ternary phase (water/acetonitrile/chloroform), made up almost entirely of the water-miscible solvent. Although such auxiliary solvents need to be found empirically, once a suitable one has been found and the phase diagrams for the ternary system have been constructed, the phases obtainable by use of various ternary solvent compositions can be used for solvent extraction as easily as the solvent pairs in conventional solvent extraction systems.

Igarashi and Yotsuyanagi [8] proposed an alternative homogeneous liquid–liquid extraction method based on pH-dependent phase separation. Neutralization of perfluorooctanoate ion ($PFOA^{-}$) in water-miscible organic solvent solution (such as acetone, 1,4-dioxane and tetrahydrofuran) induces phase separation, providing a small volume (down to 0.1 mL, depending on the amount of $PFOA^{-}$ which has been added) of an oily and transparent water-immiscible liquid phase, from a large volume of the aqueous solution. This phase separation was reversible with the pH change in the solution, corresponding to below and above the pK_{α}, value of perfluorooctanoic acid (HPFOA). The above method has been applied for organic and inorganic analytes [42–48].

The $PFOA^{-}$, pH dependent, method needs usually strongly acidic condition (pH < 1) and thus is difficult to be applied to the separation and concentration of biologically active substances, due to the fact that these substances easily hydrolyse the substituents and cause denaturation of the protein. In order to solve these problems, phase separation in the neutral pH region has been achieved using Zonyl FSA (the Du Pont trade name for $CF_3(CF_2)_n–CH_2CH_2–SCH_2CH_2–COOH$, $n = 6 \pm 8$), which induced the methylene group as a spacer of the fluorosurfactant [49]. The pH-dependent phase separation with Zonyl FSA has been applied as a preconcentration for the spectrofluorometric determination of chlorophyll-A [49] and recently for analysis of 14 elements with ICP-AES [50].

Table 1
Classification of the reported HLLE methods according the miscible solvent system and the phase separation mode.

Binary miscible solvent system
By temperature [33,55]
By salting-out with salt [11,39,56]
By salting-out with third solvent [32]
By pH with $PFOA^{-}$ [42–44,46–48]
By ion-pair formation [53,54,9]
Ternary miscible solvent system
By auxiliary solvent (excess of water) [12,41]
By pH-dependent ternary systems [51,52]

Moreover, a homogeneous liquid–liquid extraction method using the pH-dependent phase separation in the water/acetic acid/chloroform ternary solvent system was reported for copper(II) and palladium(II) determination [51,52]. It is postulated that the state of the homogeneous solution in water/acetic acid/chloroform dissolved in water is due to the solvation of the acetic acid molecule for small amounts of chloroform. When sodium hydroxide (4.5 mL, 10 mol L^{-1} NaOH) is added to this system, acetic acid converts to acetate ion due to the acid–base reaction of acetic acid, and consequently its function as a solvation molecule was absent. Hence, water-immiscible chloroform is formed in the aqueous solution by phase separation [51]. Extracting solvent selection in this case is an important factor and it has to meet the following characteristics: (a) it should be heavier than water, (b) it should form a ternary homogeneous system with water and acetic acid, (c) it should dissolve the analyte more than water and (d) it should be sedimented after adding a phase-separation agent (NaOH solution).

The ion-pair formation of tetrabutylammonium ion (TBA^{+}) and perfluorooctanoate ion ($PFOA^{-}$) in a homogeneous solution of water/sodium acetate has been used for extraction and spectrophotometric determination of uranium(VI) [53].

Recently, an ion-pair formation pH-independent phase separation method was established using a homogeneous ternary solvent system (water/TBA^{+}–ClO_4^{-}/chloroform) for iron(II), cobalt, copper and nickel determination, based on ion-pair formation of TBA^{+} and perchlorate ion (ClO_4^{-}) [54,9].

The classification of the reported HLLE separation modes from binary or ternary component solvent systems are summarized in Table 1.

Dispersive liquid–liquid microextraction (DLLME) is a miniaturized sample pre-treatment preconcentration technique based on ternary component solvent systems and salting-out phenomenon similar with as HLLE/Ternary miscible solvent system. The main difference between the above two techniques is that in HLLE, the mixture of solvents firstly produce a homogeneous form prior to the separation of the two phases by adding either a salt or an auxiliary solvent. In addition in HLLE much larger volumes of organic solvents are usually used. On the other hand, in DLLME the phase separation is accomplished instantly by adding rapidly the mixture of disperser and extraction solvent into the aqueous solution. No homogeneous form is appeared. Actually, it is a modified solvent extraction method and its acceptor-to-donor phase ratio is greatly reduced comparing with the other methods [20]. Thereby, cloudy solution is formed. In fact, the cloudy state results from the formation of fine droplets of the extraction solvent, which disperse in the sample solution. Then, this cloudy solution shall be centrifuged and the fine droplets will be sedimented at the bottom of the conical test tube as it is shown in Fig. 1. The determination of analytes in sedimented phase can be performed by various detection systems. By this procedure any component in the solution, directly or indirectly after previous (or simultaneous) derivatization reaction, interacts with the fine droplets of the extraction solvent and consequently get extracted from the initial aqueous

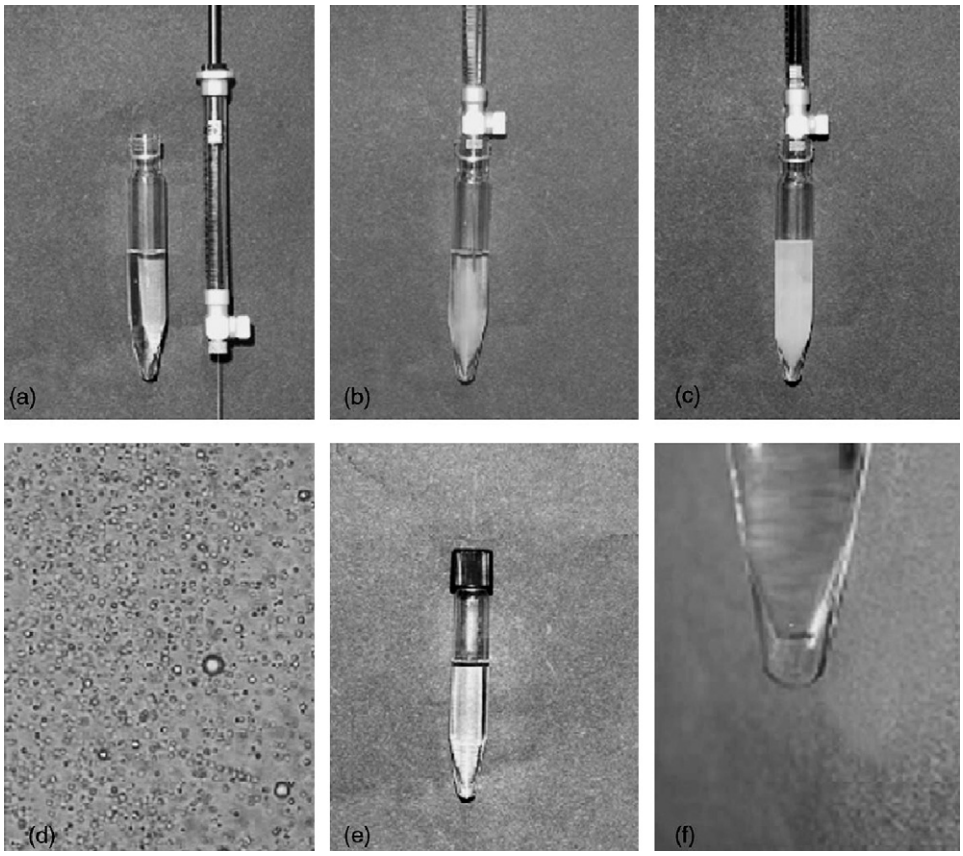

Fig. 1. Photography of different steps in DLLME: (a) before injection of mixture of disperser solvent (acetone) and extraction solvent (C_2Cl_4) into sample solution, (b) starting of injection, (c) end of injection, (d) optical microscopic photography, magnitude 1000 (that shows fine particles of C_2Cl_4 in cloudy state), (e) after centrifuging and (f) enlarged view of sedimented phase [13].

solution and concentrated in the small volume of the sedimented organic phase.

The miscibility of disperser solvent in aqueous and organic phase (extraction solvent) is an essential point for its selection. Acetone, acetonitrile, methanol and ethanol have been successfully used for this purpose. In addition, the volume of the disperser solvent plays an important role, due to the fact that variation of the amount causes changes in the sedimented phase volume, through the salting-out effect. At low volume of disperser solvent, the dispersion of the extraction solvent is not properly and the cloudy solution is not formed completely, while at high volume, the solubility of analytes in water increases, therefore, the extraction efficiency decreases [15].

The selection of a suitable organic solvent for DLLME is also a very important task. It should able to form a cloudy solution system with water and disperser solvent. Also it should have highly immiscibility with aqueous phase (sample solution), high extraction efficiency, selectivity and hydrophobicity [27]. Chloroform, chlorobenzene and carbon tetrachloride have been employed. In manual (batch) mode, organic solvents are selected on the basis of higher density rather than water, in order to facilitate the sedimentation with the centrifuging. In addition, they should have extraction capability of the interested compounds, and in some cases, good gas chromatography behaviour. Increasing the volume of the extraction solvent, the volume of the sedimented phase increases, resulting thus to a decreasing of the enrichment factor [15].

In contrast to manual DLLME systems, in the on-line procedure, organic solvent is not required to be heavier than water, due to the fact that the formation of the cloudy solution takes place in a moving stream and the retention of the fine droplets on the sorbent material is based on its hydrophobic nature. It means that the separation of the organic phase is based on the retention and not on the centrifuging [27].

3. Applications HLLE and DLLME for metal determination

The relevant applications of the two liquid–liquid extraction techniques, HLLE and DLLME, which have been discussed above in inorganic analysis including metals and metalloids, are summarized in Tables 2 and 3, respectively.

3.1. HLLE based on temperature separation

Murata and Ikeda used propylene carbonate ($PrCO_3$) with an aqueous phase at 80 °C for Mo(IV) and Fe(III) spectrophotometric determination [33,55]. This method is based on the high solubility of organic solvent in water at higher temperature and is characterized by immediate formation of the complex upon attaining a state of homogeneous solution consisting of water and the organic solvent during the procedure. At room temperature the two phases are present heterogeneously, but at the elevated temperature they change into a homogeneous solution, which separates into the two phases again upon cooling. However, no application data are given for real samples.

3.2. HLLE based on salting-out phenomenon with salt

By the use of the salting-out effect, Matkovich and Christian [34] were able to separate acetone from aqueous solutions with either saturated calcium chloride or 65% m/v sucrose. Several metals like Sc(III), Cr(III), Mn(II), Fe(II), Fe(III), Co(II), Ni(II), Cu(II) and Zn(II) as

Acronyms: FAAS: flame atomic absorption spectrometry; ETAAS: electrothermal atomic absorption spectrometry; HPLC: high-performance liquid chromatography; XRF: X-ray fluorescence; $PFOA^-$: perfluorooctanoate ion; TOPO: tri-*n*-octylphosphine oxide; ABO: α-benzoin oxime; DDTC: diethyldithicarbamate; 1,10-phen: 1,10-phenanthrolne; DFO: desfer-rioxamine B; DFB: desfer-rioxamine B; TBA^+: tetrabutylammonium ion; K-4-BPDC: 4-benzylpiperidinedithiocarbamate potassium salt; TPyP: 5,10,15,20-tetrakis(4N-pyridyl)porphine.

complexes with ammonium l-pyrrolidinecarbodithioate and dithizone were successfully extracted from calcium chloride solutions into the acetone phase while metal oxine chelates were extracted from sucrose solutions and analyzed by FAAS. Nagaosa and Fujinaga separated the acetonitrile phase, and applied for extraction and polarographic determination of some metal ions like Cu(II), In(III), Ni(II), Co(II) and Cd(II) [37,38,56,57], without any application in real samples.

3.3. HLLE based on salting-out with auxiliary solvent

This technique was first applied by da Silva and Martins [12] for the extraction and spectrophotometric determination of Fe(III), Cu(II), Co(II), Ni(II) and Pb(II). More recently, it has been used as an analytical tool by de Andrade et al. [41] for single-phase extraction of Mo(VI) with α-benzoin oxime in a mixture of water–ethanol–chloroform homogeneous ternary solvent system. Then Mo(VI) is spectrophotometrically determined with thiocyanate in the same solvent system. The calibration graph was linear up to 8.00 mg L^{-1}, according to the equation $A = 0.005 + 0.143$ [Mo(VI)] ($r^2 = 0.9999$). The accuracy of the proposed method was evaluated by comparing with standard samples determined by atomic absorption spectrometry and the applicability was tested by analyzing two commercial stainless steel samples with satisfactory results.

3.4. HLLE based on pH-dependent phase separation with $PFOA^-$

In a strongly acidic aqueous solution, desfer-rioxamine B (DFB) forms 1:1 complex with Ti(IV), Zr(IV), V(V), Nb(V), Ta(V), Mo(IV), and W(VI) at room temperature [42]. These metal chelates were preconcentrated by HLLE using perfluorooctanoic acid (HPFOA). Under the optimum conditions the volume of sedimented phase was 0.1 mL and the extraction procedure was varied in the range 83–98%. The metals were determined by X-ray fluorescence spectrometry the linear range of calibration curve for Ti(IV), Zr(IV), V(V), Nb(V), Ta(V) was up to 2.0×10^{-6} mol L^{-1} and the detection limits were at 10^{-8} mol L^{-1}. The proposed method was applied only in a synthetic sample for Ti(IV), Zr(IV) and V(V) determination.

Igarashi et al. reported two HLLE methods for 36 metal ions with diethyldithiocarbamate [43], 1-10-phenanthroline and desfer-rioxamine B [44] as complexing agents. Moreover, the proposed method was utilized as a preconcentration method for X-ray fluorescence analysis of these metals. The recovery of each metal was ca. 83–100%. The detection limits were at the 10^{-8} mol L^{-1} levels and the relative standard deviations were below 5%. The developed method was used for the determination of contaminants in a synthetic Al-based alloy sample and for the analysis of an Au–Pd alloy wire sample. The results were satisfactory.

In a weak acidic solution (pH ~ 2), acetone as a water-soluble organic solvent, 1,10-phenanthroline as chelate-forming agent and Zonyl FSA as a phase separating reagent 14 elements such as Al, Cu and Ti were determined with ICP-AES. The volume of the separated phase was 100 μL and the recovery of each element was at least 95% or more [50]. Although the proposed method could be applied in a wide range of practical fields, no application data are presented.

Ghiasvand et al. demonstrate the usefulness of HLLE combined with UV-spectrophotometer for determination of uranium(VI) [47] and molybdenum(VI) [46] using tri-*n*-octylphosphine oxide (TOPO) and α-benzoin oxime (ABO) as complexing agents, respectively, and perfluorooctanoate ion (PFOA) as a phase-separator agent under strongly acidic conditions. The maximum concentration factor was 5000-fold for Ur(VI) and 125-fold for Mo(VI). The methods were applied successfully in the analysis of natural water samples and also for spinach and lucerne samples.

Acronyms: FAAS: flame atomic absorption spectrometry; ETAAS: electrothermal atomic absorption spectrometry; ICP-AES: inductively coupled plasma atomic emission spectrometry; GC–ECD: gas chromatography–electron-capture detection; GC–FPD: gas chromatography-flame photometric detection; UV–vis: UV–vis spectrophotometry; FO-LADS: fiber optic-linear array detection spectrophotometry; DDTP: diethyldithiophosphoric acid; DDTC: diethyldithicarbamate; DDPA: ammonium diethyldithiophosphate; APDC: ammonium pyrrolidine dithiocarbamate; PAN: 1-(2-pyridylazo)-2-naphthol; PMBP: 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone; TMK: 4,4′-bis(dimethylamino)thiobenzophenone; [Hmim][Tf_2N]: 1-hexyl-3-methylimmidazolium bis(trifluormethylsulfonyl)imid; Salen: Salen(N,N′-bis(salicylidene) ethylenediamine).

Thirteen lanthanoids were extracted from a strong acid solution (pH ~ 1) by HLLE (water/HPFOA/acetone) and phosphoric acid di(2-ethlyhexyl)ester (D2EHPA) as extractant [48]. The concentration of lanthanoids(III) ion in the aqueous phase was determined by ICP atomic emission spectrometry and the recovery was varied in the range 85–95%. No application data were given for real samples.

3.5. HLLE based on pH-dependent ternary solvent systems

Igarashi et al. [51] and Farajzadeh et al. [52] applied the pH-dependent phase-separation process in a ternary solvent system (water/acetic acid/chloroform) for the preconcentration of copper and palladium by HPLC and for copper determination by FAAS, respectively. In order to obtain a water-immiscible phase of a small volume of chloroform, sodium hydroxide was added to a homogeneous aqueous solution which consisted of water, chloroform and acetic acid. The relative standard deviations for the central value of the calibration graph were 3.2% for Cu(II) and 3.7% for Pd(II) while the detection limits were 5×10^{-9} mol L^{-1} for Cu(II) and 8×10^{-9} mol L^{-1} for Pd(II) by HPLC. For FAAS determination the relative standard deviation was 7.6%, while the limit of detection and the limit of quantification of the method were 1.74 and 6 μg L^{-1}, respectively. The methods were applied in the analysis of natural water samples with satisfactory results.

3.6. HLLE based on ion-pair formation

Takahashi et al. [53] reported for the first time the ion-pair phase separation mode using $PFOA^-$ and tetrabutylammonium ion (TBA^+) for uranium(VI) extraction from weakly acidic acetate solution. The proposed method was applied as a preconcentration method for the spectrophotometric determination of uranium(VI) with arsenazo III, in sea-water samples. The uranium(VI) extraction was 96% and the maximum concentration factor was approximately 330-fold. The relative standard deviation was 1.4% and the detection limit was 6.0×10^{-10} mol L^{-1}. It was clearly shown that the volume of the sedimented phase depends on the concentration of $PFOA^-$. As it was proved, the phase separation phenomenon was observed at concentrations lower than the critical micelle concentration (CMC) of $PFOA^-$. Hence, this phenomenon could not be attributed to the micellar phase separation [53].

A HLLE method based on phase separation phenomenon which occurred by an ion-pair formation of TBA^+ and perchlorate ion was established using a water/chloroform solvent system for Fe(II) determination using 1,10-phenanthroline complex formation and ETAAS as detector [54]. A concentration factor of 260 was achieved in a linear range varied from 0.060 to 125 μg L^{-1} for Fe(II). However, no applications are reported for the proposed method.

Recently, a FAAS method presented for cobalt, copper and nickel determination after the formation of complex with 4-benzylpiperidinedithiocarbamate potassium salt (K-4-BPDC) using (water/tetrabutylammonium ion (TBA^+)/chloroform) as a ternary component system [9]. The phase separation phenomenon occurred by an ion-pair formation of TBA^+ and perchlorate ion. The detection limits were 10, 5, and 15 μg L^{-1} for Co(II), Cu(II), and Ni(II), respectively. The reliability of the developed method for Co, Cu and Ni determination was tested in natural water samples.

3.7. Dispersive liquid–liquid microextraction (DLLME)

Dispersive liquid–liquid microextraction (DLLME) as a simple and fast microextraction technique has been proved to be a suitable preconcentration procedure for gas chromatography (GC), liquid chromatography (LC), flame and electrothermal atomic absorption spectrometry (FAAS, ETAAS), as well as for inductively coupled plasma atomic emission spectrometry (ICP-AES) and UV–vis spectrophotometry. However, this technique is limited to a small number of extractants, which should efficiently extract the analytes of interest, since the required conditions, i.e., to have higher density rather than water, form a stable cloudy solution and be easily removed from the bottom of the conical vial after centrifugation, are met by a few organic solvents.

Firstly, DLLME has been demonstrated for cadmium determination in water samples by Jahromi et al. [20]. In this extraction method, 500 μL methanol (disperser solvent) containing 34 μL carbon tetrachloride (extraction solvent) and ammonium pyrrolidine dithiocarbamate (chelating agent) was rapidly injected by syringe into the water sample containing cadmium ions. Thereby, a cloudy solution is formed. After 2 min centrifugation at 5000 rpm, 20 μL of the sedimented phase was determined by ETAAS. The calibration graph was linear in the range of 2–20 ng L^{-1} with detection limit of 0.6 ng L^{-1}, requiring 5.00 mL volume of sample. The relative standard deviation (R.S.D.) was 3.5%. The analytical performance characteristics of the proposed method were compared with other reported preconcentration methods with adequate results and it was applied in the analysis of tap, sea and river water samples.

Shokoufi et al. [58] combined DLLME and fiber optic-linear array detection spectrophotometry (FO-LADS) using a cylindrical micro-cell for simultaneous preconcentration and determination of palladium and cobalt. Under the optimum conditions, the calibration graphs were linear in the range of 2–100 and 1–70 μg L^{-1} with detection limit of 0.25 and 0.2 μg L^{-1} and enhancement factors of 162 and 165 for palladium and cobalt, respectively. The method was applied to the analysis of several real and synthetic samples with satisfactory results.

Shamsipur and Ramezani [21] used DLLME–ETAAS ultra-trace amounts of Au(III) determination in tap water and silicate ore samples. The method is based on separation and preconcentration of gold by Victoria Blue R into fine droplets of chlorobenzene. A preconcentration factor of 388 and a detection limit of 0.005 μg L^{-1} were obtained for the system. The figures of merit of the proposed method were compared with other reported methods for Au(III) determination with sufficient results.

Farajzadeh and Jonsson [23] combined DLLME with FAAS for copper determination in natural water samples. 8-Hydroxy quinoline was used as a chelating agent and chloroform as extracting solvent. The effect of various experimental parameters was investigated using two optimization methods, one variable at a time and central composite design. The experimental design was performed at five levels of the operating parameters and the obtained results were almost similar using both methods. The calibration graph was linear over the range 0.050–2.0 mg L^{-1}. The relative standard deviation was 5.1% and the detection limit was 3 μg L^{-1}.

Preconcentration and spectrophotometric determination of Co(II) in tap and river water samples by DLLME was reported using 1-(2-pyridylazo)-2-naphthol (PAN) as complexing agent [59]. Enhancement factor of 125 was obtained from 50 mL of water sample, and the detection limit was 0.5 mg L^{-1}.

Mallah et al. [60] presented a DLLME method for simultaneous preconcentration of lanthanides such as samarium, europium, gadolinium and dysprosium based on the complex formation with the 1-(2-pyridylazo)-2-naphthol (PAN). After phase separation, the precipitate phase was dried (80 °C) and diluted to 0.5 mL by 1 mol L^{-1} HNO_3. Determination of the ions was accomplished using ICP-AES. However, no application of the method in real samples has been reported.

Naseri et al. [61] reported an application of DLLME to the determination of ultra-trace amounts of lead in tap, well, mineral and sea-water samples using diethyldithiophosphoric acid (DDTP) as chelating agent, with ETAAS. Enrichment factor of 150-fold was obtained from 5.00 mL water sample while the detection limit was 0.02 μg L^{-1}. In order to establish the validity of the

recommended procedure, the method was applied to the lead determination in a TM-23.3 certified reference water sample. The obtained result was in agreement with the certified value. The same group combined DLLME with FAAS by using microsample introduction system for the first time [24]. This novel introduction system was employed for the microvolume nebulization of the non-flammable chlorinated organic extracts. The calibration graph was linear in the range of 1–70 $\mu g\,L^{-1}$ with a detection limit of 0.5 $\mu g\,L^{-1}$. The relative recoveries of lead in tap, well, river and sea-water samples at the spiking level of 20 $\mu g\,L^{-1}$ ranged from 93.8 to 106.2%.

Liang et al. employed DLLME with ETAAS for lead [62] and palladium [22] determination using 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone (PMBP) and diethyldithiocarbamate (DDTC) as complexing agents, respectively. For lead the detection limit was 39 $ng\,L^{-1}$ and the enrichment factor was 78 while for palladium the detection limit was 2.4 $ng\,L^{-1}$ and the enrichment factor reached at 156. The methods were applied successfully for the determination of lead in human urine and natural water samples and for palladium determination in river, lake and tap waters.

A method combining DLLME and ETAAS for the determination of trace Co and Ni in environmental and food samples was proposed by Jiang et al. using 1-(2-pyridylazo) 2-naphthol (PAN) as chelating reagent [63]. The enrichment factors were 101 and 200 and the detection limits of the method were 21 and 33 $ng\,L^{-1}$ for Co and Ni, respectively. Two certified reference materials of Environment Water (GSBZ50009-88) and NIES No.10-b rice flour were analyzed for validation purposes. Also the method was applied to the determination of Co and Ni in lake and river samples with good recoveries.

Gharehbaghi et al. [64] combined DLLME with small amounts of a hydrophobic ionic liquid. Ionic liquid (IL) named 1-hexyl-3-methyl-immidazolium-bis(trifluormethylsulfonyl)imid ([Hmim][Tf_2N]), were used as an extraction solvent, which is dissolved in acetone (disperser solvent) and then dispersed into the sample solution (aqueous phase), which contains sodium dodecyl sulphate (SDS), an anti-sticking agent to prevent sticking of IL to the test tube wall. Thus, a cloudy solution of fine droplets of IL appeared and sedimented at the bottom of a conical test tube by centrifuging. The performance of DLLME technique based on IL was illustrated for mercury determination in water samples by using spectrophotometric detection.

Bidari and Assadi [28] demonstrate the application of DLLME combined with iridium-modified graphite tube atomizer atomic absorption spectroscopy for determination of selenium in water samples. Ammonium pyrrolidine dithiocarbamate (APDC) was elaborated as chelating agent and carbon tetrachloride as extraction solvent. Enrichment factor of 70 was obtained from 5.00 mL of water sample. The calibration graph was linear in the range of 0.1–3 $\mu g\,L^{-1}$ with detection limit of 0.05 $\mu g\,L^{-1}$. The relative recoveries of selenium in tap, river and sea-water samples at spiking level of 2.00 $\mu g\,L^{-1}$ were 106, 96 and 98%, respectively. The same authors used a derivatization reaction with Se(IV) and the application of the DLLME method for the microextraction of the formed piazselenol in environmental water samples by gas chromatography–electron-capture (GC–ECD) detection system [14]. The selenium derivative was extracted using a mixture of ethanol (disperser solvent) and chlorobenzene (extraction solvent). Enrichment factor of 122 and detection limit of 0.005 $\mu g\,L^{-1}$ was obtained from 5.00 mL water sample.

Birjandi et al. [15] was focused on the suitability of dispersive liquid–liquid microextraction and gas chromatography–flame photometry (DLLME–GC–FPD) for speciation and determination of butyl- and phenyl-tin compounds in water samples after derivatization with $NaBEt_4$. Some important parameters, such as pH, amount of $NaBEt_4$, derivatization time, kind and volume of extraction solvent and disperser solvent, extraction time and salt effect were investigated and optimized.

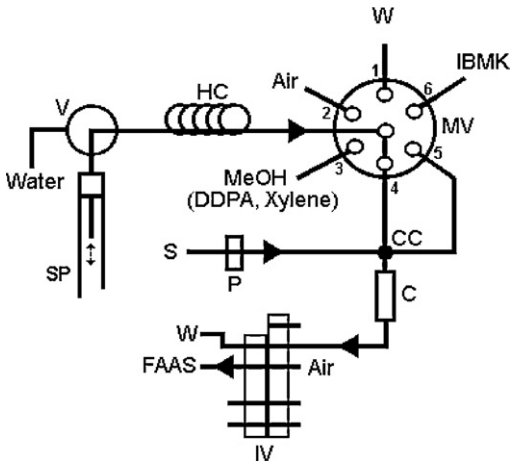

Fig. 2. Schematic manifold for SI-DLLME metal determination by FAAS. S, sample; MeOH, solution containing 2.0% (v/v) xylene and 0.3% (m/v) DDPA; W, waste; P, peristaltic pump; SP, syringe pump; MV, multiposition valve; IV, injection valve in "load" position; V, valve in "out" position; HC, holding coil; C, microcolumn; CC, confluence connector [27].

Recently, Rivas et al. [29] presented a DLLME method combined with ETAAS for the determination of inorganic arsenic (III, V) and antimony (III, V) in water samples using ammonium pyrrolidine dithiocarbamate (APDC). Total inorganic As and Sb are determined after the reduction of the pentavalent forms with sodium thiosulphate. The detection limits are 0.01 and 0.05 $\mu g\,L^{-1}$ for As(III) and Sb(III), respectively, with an enrichment factor of 115. The procedure has been applied to the speciation of inorganic As and Sb in bottled, tap and sea-water samples.

4. Automation of DLLME

Automatic on-line hydrodynamic analytical systems could be exploited with a view to enhancing the inherent properties of conventional measurement procedures. Up to date, the combination of the flow injection technique with DLLME or HLLE has appeared only in one publication [27], describing sequential injection dispersive liquid–liquid microextraction (SI-DLLME) system for metal preconcentration and determination using FAAS. The effectiveness and efficiency of the proposed SI-DLLME system has been demonstrated for copper and lead determination in environmental water samples. The method was evaluated by analysis of the certified reference material NIST CRM 1643e (National Institute of Standard and Technology, Trace elements in water). Ammonium diethyldithiophosphate (DDPA) was selected as chelating agent due to its good selectivity in strong acidic medium. The microcolumn for retention of the extraction solvent and the derivative chelate complex M–DDPA, was packed with a hydrophobic material, PTFE-turnings [65]. The manifold and its operation for on-line sequential injection dispersive liquid–liquid microextraction (SI-DLLME) metal determination by FAAS is presented schematically in Fig. 2. The xylene droplets, which contain the metal complexes, were retained on the PTFE-turnings into the microcolumn. In the next step, a segment of 300 μL isobutylmethylketone (IBMK) is pumped through C eluting the analyte. The eluent forwarded to the nebulizer for atomization and measuring.

Opposition to conventional (off-line) DLLME systems, extraction solvent is not necessary to have higher density than water, due to the fact that the formation of the cloudy solution takes place in a moving stream and the retention of the extraction fine droplets was based on the hydrophobicity of the sorbent material. It means

that the separation of the organic phase is based on the retention and not on the centrifugation. Chloroform, carbon tetrachloride, dichloromethane, hexane, benzene, xylene, toluene, IBMK, and diisobutyl ketone (DIBK) were compared as extraction solvent.

5. Conclusions

An overview of two unconventional liquid–liquid extraction procedures, HLLE and DLLME based on the mutually solubility of solvents and the separation of organic phase from a binary or ternary component solvent system is presented. Homogeneous liquid–liquid extraction is simple preconcentration method that reduces the extraction time and disposal costs. Although it seems to be promising for various determinations, the reported applications in real samples are limited. The miniaturization of solvent extraction procedures leads inherently to a minimum solvent, sample and reagent consumption and dramatic reduction of laboratory wastes. From commercial, economical and environmental point of view DLLME offers several important advantages over conventional solvent extraction methods: simplicity of operation, rapidity, low cost, high recovery and enrichment factor, low consumption of organic solvents, easier manipulation and less stringent requirements for separation. It shows increased wide applications in the field of trace analysis. The future trends of DLLME could be summarized in the following aspects: Applications in the analysis of samples with complex matrix, since, up to date, most of the analytes are detected in relatively simple samples matrices. Broadening of the range of used extraction solvents in order to increase the extraction capability of the method. Most of the extraction solvents, which have been reported, are halogenated hydrocarbons. Applications for determination of inorganic elements using the recent developed DLLME-SFO technique. New perspectives are to be certainly opened in the near future for trace-metal monitoring by hyphenation of miniaturized on-line DLLME systems with various detection systems especial with ICP-AES/ICP-MS for multielemental determinations.

ABSTRACT

Carbon dioxide (CO_2) is a greenhouse gas that makes by far the largest contribution to the global warming of the Earth's atmosphere. For the measurements of atmospheric CO_2 a non-dispersive infrared analyzer (NDIR) and gas chromatography are conventionally being used. We explored whether and to what degree argon content can influence the determination of atmospheric CO_2 using the comparison of CO_2 concentrations between the sample gas mixtures with varying Ar amounts at 0 and 18.6 mmol mol^{-1} and the calibration gas mixtures with Ar at 8.4, 9.1, and 9.3 mmol mol^{-1}. We newly discovered that variation of Ar content in calibration gas mixtures could undermine accuracy for precise and accurate determination of atmospheric CO_2 in background air. The differences in CO_2 concentration due to the variation of Ar content in the calibration gas mixtures were negligible ($<\pm 0.03$ μmol mol^{-1}) for NDIR systems whereas they noticeably increased ($<\pm 1.09$ μmol mol^{-1}) especially for the modified GC systems to enhance instrumental sensitivity. We found that the thermal mass flow controller is the main source of the differences although such differences appeared only in the presence of a flow restrictor in GC systems. For reliable monitoring of real atmospheric CO_2 samples, one should use calibration gas mixtures that contain Ar content close to the level (9.332 mmol mol^{-1}) in the ambient air as possible. Practical guidelines were highlighted relating to selection of appropriate analytical approaches for the accurate and precise measurements of atmospheric CO_2. In addition, theoretical implications from the findings were addressed.

1. Introduction

Carbon dioxide (CO_2) is a greenhouse gas that makes the key contribution to the global warming of the Earth's atmosphere. The atmospheric concentration of CO_2 remarkably increased from approximately 280 μmol mol^{-1} (ppmv) during the pre-industrial era to a global average of 379 μmol mol^{-1} in 2005. Atmospheric CO_2 monitoring started in 1958 to establish that the CO_2 concentration was rising and to document its rate of increase. During the past decade, increase in CO_2 is responsible for 84% of the increase in global radiative forcing. Such increase is due primarily to emissions from fossil fuel combustion [1].

Although CO_2 monitoring has been conducted in many parts of the world and on a voluntary basis, a number of strict criteria exist in order to establish and maintain the data quality for atmospheric CO_2 measurements. The Global Atmospheric Watch (GAW) under the World Meteorological Organization (WMO) has set the target precision of the atmospheric CO_2 measurement programme to 0.1 μmol mol^{-1} (parts per million as volumetric fraction) in the Northern Hemisphere and 0.05 μmol mol^{-1} in the Southern Hemisphere [2,3].

There are at least 3 major quality elements for guaranteeing CO_2 data reliability: (i) best available analytical method to ensure repeatability and reproducibility (precision, measurement uncertainty); (ii) the closeness of measured data to true values (accuracy); and (iii) establishment of a chain to be capable of tracing any sources of systematic errors from true values (traceability) [4].

Valid analytical approaches need to be well established prior to applications to real observations of atmospheric CO_2. Any valid method for the determination of CO_2 in gas mixtures requires basically not only calibration gas mixtures but also appropriate analytical equipment. Quantitative determination of CO_2 in gas mixtures is realized by comparison of instrumental response signals from calibration and sample gas mixtures using appropriate equipment [5].

The available analytical systems frequently used in practice to date for the measurement of atmospheric CO_2 are a non-dispersive infrared analyzer (NDIR) and a gas chromatograph (GC) equipped with a methanizer and a flame ionization

detector (FID) or with thermal conductivity detector (TCD) [6,7].

Potential sources of measurement uncertainties for CO_2 measurements come mostly from sample gas mixtures, calibration gas mixtures, instrumental drift, changes of environmental conditions, and matrix effects due to the interactions among these factors [8]. As far as CO_2 calibration gases are concerned, it is impossible in reality to prepare such calibration gases in which background composition is exactly identical to that of natural ambient air due to the presence of a number of minor constituents including Ne (18.2 μmol mol^{-1}), CH_4 (1.5 μmol mol^{-1}), and Xe (0.1 μmol mol^{-1}), and other trace elements. CO_2 calibration gases therefore must best simulate natural atmospheric composition as possible. In practice, simulated air is gravimetrically prepared with the mixture of N_2 and O_2 near to the levels found in dried ambient air (0.78083 mol mol^{-1} N_2 and 0.20944 mol mol^{-1} O_2). Depending on analytical goals, argon (Ar), an important noble gas found in ambient air, may need to be added (approximately 10 mmol mol^{-1}) to the mixture of N_2 and O_2. The best accurate value for Ar content in dried ambient air is reportedly 9.332 mmol mol^{-1} [9].

In order to guarantee high precision and accuracy of the measured data in gas analysis, it is of great importance to apply the identical amounts of sample and calibration gas mixtures to an analytical system for every run. For this goal, it is imperative to maintain flow rates of a sample gas as constant as possible. A mass flow meter and/or controller (MFC) are thus commonly used to minimize the variation of gas flow rates. Thermal mass flow controller (TMFC) is widely used to control due to merits that it is possible to directly measure relatively small mass flow rate of a gas with high precision and that no calibration needed against temperature and pressure. It is to be recognized that different gas species may result in different volumetric flow rates due to the nature of a thermal mass flow controller (TMFC) and that as a consequence, a gas species with different matrices are subject to different volumetric flow rates. In other words, if TMFC is used for different gas or different composition of a gas mixture from the initially calibration gas (e.g., N_2), the TMFC could lead to an important source of measurement uncertainty. In other words, depending on varying composition of gas mixtures, the gas flow rates are subject to change through the TMFC. The TMFCs should be calibrated prior to its usage for gas analysis [10]. As long as appropriate calibrations are conducted against the specific gas mixtures, the TMFC can maintain the mass flow rate of a gas unchanged throughout gas analysis. Without additional calibrations, the volumetric flow rate of an analyte through the TMFC may be altered by different matrices of gas mixtures depending upon the presence and the levels of other constituents. Best accuracy can ensure solely by conducting calibration processes appropriately under real operating conditions. However, it is not unusual to apply the TMFC to an analytical system without additional calibration because commercially available TMFCs in the market are initially one-point calibrated against high-purity inert gas (e.g., N_2). Moreover, it is practically impossible to calibrate the TMFC as to a number of different samples prior to analysis and to prepare all RMs with the identical matrices to those of the sample gas mixtures to be analyzed.

We report for the first time the initial findings from the investigation on whether and to which degree Ar as a matrix constituent (ranging from 0 to 18.6 mmol mol^{-1}) can influence CO_2 determination in gas mixtures using calibration gas mixtures prepared in different matrices through comparisons between analytical systems. This study explored a total of 5 different analytical systems after some modifications made to conventional systems, aiming at probing potential effects of Ar on instrumental sensitivity and precision of atmospheric CO_2 determination: (i) a conventional NDIR analyzer; (ii) a modified NDIR; (iii) a conventional GC-FID; and (iv) a modified GC-FID; and (iv) a modified GC-TCD. Based on these findings, practical implications and reliable analytical approach to the measurements of atmospheric CO_2 were suggested.

2. Experimental

2.1. Preparation of calibration and sample gas mixtures

The gravimetric method is officially a primary method that ensures international traceability for the preparation of calibration gas mixtures. A total of 5 gas mixtures (3 calibration gas mixtures and 2 sample gas mixtures) containing atmospheric-level CO_2 were prepared in the 30-L stainless-steel gas cylinders under ambient conditions (1.0 atm, 25 ± 2 °C) by a gravimetric technique [11]. Detailed description of the preparation procedures by this technique is found elsewhere [12]. A total of 4 source gases were used as the mother gases for each constituent. All source gases were of high purity grade: CO_2 (0.9999 mol mol^{-1} Matheson Co., USA), N_2 (0.9999 mol mol^{-1}, Deokyang Energen Co., South Korea); O_2 (0.99999 mol mol^{-1}, Prexair Co., Rep. South Korea), and Ar (0.99999 mol mol^{-1} Deokyang Energen Co., South Korea). The compositions and concentrations of gaseous impurities contained in the mother gases were determined as summarized in Supporting Information. A total of 6 calibration and sample gas cylinders were used in this study. The compositions and concentrations of the calibration and sample gas mixtures prepared by this technique are presented in Table 1. R and S stand for calibration and sample gas mixtures, respectively. The second calibration gas mixture ($R_{2,NDIR}$) was used exclusively for the NDIR whereas $R_{2,GC}$ for the GC systems only. $R_{2,GC}$ is a standard reference material (SRM) purchased from the Global Monitoring Division (GMD) under the National Oceanic & Atmospheric Administration (NOAA; Boulder, Colorado, USA) in September 2001. For of the SRM, the GMD/NOAA indicated that the SRM has CO_2 at 383.36 ± 0.04 μmol mol^{-1} as the World Meteorological Organization (WMO) mole fraction scale [4]. Information on the gravimetric concentrations for N_2 and O_2 (GMD/NOAA) were not available from the provider. The cylinders contain 4 major constituents in common: CO_2 (380–392 μmol mol^{-1}), N_2 (0.775–0.783 mol mol^{-1}), O_2 (0.205–0.216 mol mol^{-1}), and Ar (zero-18.6 mmol mol^{-1}). The sample gas mixtures were prepared in the different Ar matrices (0 and 18.6 mmol mol^{-1}). The amount of Ar in S_1 indicates only trace amount (<0.022 mmol mol^{-1}) estimated from the impurities analysis. For the calibration gas mixtures, the expanded uncertainty values ($U = ku_c$) at a coverage factor (k) of 2 for the preparation of 5 different CO_2 concentrations using a computer software (GUM Workbench Version 2.3) fall within 0.06 μmol mol^{-1} [13,14].

2.2. NDIR analytical systems

The modified NDIR analytical system is identical to the conventional one except a pressure control system (Fig. 1). The system compartments are comprised of an NDIR analyzer (Siemens Ultramat 6, Germany), two commercially available TMFCs (Brooks 5850E, Japan), and the pressure control system. The NDIR analyzer for measuring atmospheric CO_2 used in this study is of an open-path cell type. The NDIR analyzer determine the amount of CO_2 with a characteristic wavelength region of 2349 ± 50 cm^{-1} by measuring the difference in the intensities in the infrared radiation (2349 ± 50 cm^{-1}) passing through a sample cell relative to that through a reference cell. The TMFC has been initially calibrated against N_2 at a volumetric flow rate of 1000 mL min^{-1} by the manufacturer. The modified NDIR analyzer adopted a pressure control system which consists of a damping chamber and a pressure controller (a pressure sensor, an indicator, and a pressure relief valve). To make corrections for the drift of the instrumental signals during

NA = data not available; see Section 2.1 for details.

the analytical time, we applied an analytical order of (R_1-S_1-$R_{2,NDIR}$-S_2-R_3)-R_1. As a means to increase the instrumental sensitivity, the volumetric flow rates for sample and calibration gas mixtures were maintained at 800 mL min^{-1}. Instrumental sensitivity (S) can be defined as the ratio of increment in the magnitude of response signal in the instrument (ΔR) to a unit increment in CO_2 concentration ($\Delta[CO_2]$):

$$S = \frac{\Delta R}{\Delta[CO_2]} \quad (1)$$

The analytical conditions used for this NDIR system were 700 °C for IR source temperature. While CO_2 at 350 μmol mol^{-1} in N_2 balance from the zero gas cylinder passed through the reference cell, a calibration or a sample gas mixture passed through the sample cell. All analytical runs were conducted at least in triplicates under the laboratory environmental conditions at 23 °C and 1 atm.

2.3. GC analytical systems

The modified GC-methanizer-FID system is identical to the conventional one except a flow restrictor (Fig. 2). The system compartments are a gas chromatograph (GC, Agilent 6890N, USA), a methanizer (Agilent, USA) and a flame ionization detector (FID). The methanizer were installed between the column injection port and the FID. A FID is generally used for analyses of organic compounds containing carbon atoms (e.g., hydrocarbons).

Gas chromatography separates inorganic carbon gases (CH_4, CO, and CO_2) from other gases in the gas mixtures. Following the GC separation, CO_2 and CO were passed in a stream of carrier gas (He, 99.999%). In order to detect oxidized carbon gases (CO and CO_2) using FID, these molecules must first be reduced to CH_4. The CO an CO_2 undergo chemical transformation (methanization) from CO_2 and CO to CH_4 by catalytic reduction reactions in the flame generated by hydrogen-rich oxygenated carrier gas (e.g., a mixture of H_2 and air) in the presence of a hot nickel catalyst. The overall chemical reaction schemes for the methanization can be summarized [15,16]:

$$CO_2 + 4H_2 \overset{260^oC,\,Ni}{\longrightarrow} CH_4 + 2H_2O \quad (2)$$

$$CO + 3H_2 \overset{260^oC,\,Ni}{\longrightarrow} CH_4 + H_2O \quad (3)$$

Since the calibration coefficient for CO_2 determination using FID after methanization depends on the catalytic activity of the catalyst (Ni) and its temperature, recalibrations using calibration gases are needed prior to analysis. The catalytic conversion efficiency from CO_2 to CH_4 was virtually close to 1.0 as long as the system is stabilized, indicating that CH_4 and CO_2 molecules yield nearly identical sensitivity to the FID. Potential variation in this coefficient can be disregarded because atmospheric CO_2 in the sample gases was determined by comparison with the calibration gas mixtures.

A single TMFC (Brooks 5850E, Japan) of the same model as those used in the NDIR analyzers was installed before the sample loop for maintaining flow rates constant. The initial state of the TMFC available in the market has been calibrated against N_2 at a volumetric flow rate of 500 mL min^{-1}. While minimizing possibility of leaking and dead volume, the liner of the injection port was removed and the mixture of the carriers gas (He) and sample gas from the sample loop were directly introduced into the packed column. The electronic pressure controller in the inlet part of the column was installed before the 6-port valve in order to keep the flow rate of the carrier gas constant.

The sample loop is installed inside the valve box of which temperature remains nearly constant at 100 °C (constant T). The

identical volume (constant V) of the loop was applied for analyses of both calibration and sample gas mixtures.

The modified GC-methanizer-FID system adopted a flow restrictor (Valco Instruments Co. Inc., USA) as the additional pressure control device. The restrictor was installed at the end of the sample vent line in the modified GC-FID system in order to maximize instrumental sensitivity (e.g., response peak area) and to enhance stability of instrumental signals as well. To make corrections for any drift of response signals during the analytical time period, we applied an analytical order of (R_1-S_1-R_1-S_2-R_1-$R_{2,GC}$-R_1-R_3)-R_1. All analytical runs were conducted at least in triplicates under the laboratory environmental conditions at 23 °C and 1 atm.

In addition, a modified GC-TCD (thermal conductivity detector) system with a restrictor was examined as another GC technique. The analytical conditions for the GC-FID and GC-TCD systems are respectively listed in Tables 2 and 3.

3. Results and discussion

A total of 5 different analytical systems were explored in this study: (1) an NDIR analyzer with no sharing of the outlets without a pressure control system (conventional NDIR); (2) an NDIR analyzer in which the two outlets of the sample and the calibration cells are shared, and which is equipped with a pressure control system (modified NDIR); (3) a GC-methanizer-FID system without a flow restrictor (conventional GC-FID); (4) a GC-methanizer-FID system with the restrictor (modified GC-FID); and (5) a GC-TCD system with a restrictor (modified GC-TCD).

Fig. 3 shows whether and to which degree Ar, a matrix constituent, can influence the determination of CO_2 concentrations in the 2 sample gas mixtures prepared in the different Ar matrices (0 and 18.6 mmol mol^{-1}) from the calibration gas mixtures prepared in the simulated air containing 8.4, 9.1 or 9.3 mmol mol^{-1} of Ar by the 5 different analytical systems.

To evaluate the nearness of a measured value to the true value (accuracy), $\Delta[CO_2]$ were obtained from the difference in CO_2 concentration between the measured value and the gravimetrically prepared value (true value) using each analytical system:

$$\Delta[CO_2] = [CO_2]_{measured} - [CO_2]_{gravimetric} \quad (4)$$

Each data point represents an arithmetic mean from at least triplicate measurements for one sample gas mixture. The $\Delta[CO_2]$ from the NDIR systems were within ±0.03 μmol mol^{-1}, suggesting no noticeable matrix effect. To ensure accurate and precise measurements of CO_2, its amount (mol) should be under control. Volumetric flow rates of CO_2 are first controlled via the TMFCs before entering the reference and sample cells. A practical way is to maintain the pressure values inside the two different cells as equal as possible throughout measurements. For this purpose, the outlets of a sample cell and a reference cell were combined into a damping chamber within the modified NDIR system. The pressure values insides the reference and the sample cells can be equal due to the shared outlets of both the sample and the reference cells. Since the pressure control device was installed at the end to the outlet of the damping chamber, the overall pressure in the reference and the sample cells can be readily stabilized. Potential differences in the volumetric flow rates of CO_2 due to different matrices of calibration and sample gas mixtures can be thus prevented. As long as the pressures within the sample and the reference cells are equal in the NDIR systems, reliable determination of atmospheric CO_2 would not be hampered

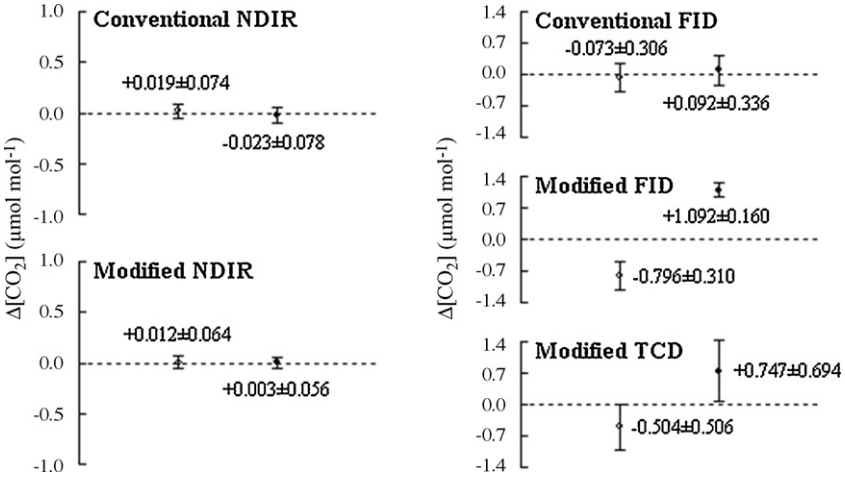

Fig. 3. Difference in CO_2 concentration between the measured and the gravimetric values of the calibration and sample gas mixtures with different mole fractions of Ar (open circle ○ from sample gases containing <0.022 mmol mol^{-1} Ar; filled circle ● from those containing 18.613 mmol mol^{-1} Ar).

significantly by the presence of Ar. The conventional NDIR analyzer is of the open path type capable of keeping the reference and sample cells at the ambient level, thereby little affected by varying flow rates. This characteristic is conducive to reliable monitoring of real atmospheric CO_2 by most GAW laboratories under WMO that use conventional NDIR analyzers.

GC modifications may be especially susceptible to variations in Ar content in calibration gases for determination of atmospheric CO_2. The value for the experimentally measured difference was the largest (1.09 μmol mol^{-1}) for the modified GC-FID system whereas the second largest value (0.75 μmol mol^{-1}) was observed for the modified GC-TCD system. Provided that there is no noticeable effect of system compartments other than the TMFC, the maximum limit of the predicted differences in CO_2 determination caused by variation in Ar content ($\Delta[CO_2]$) is ±1.16 μmol mol^{-1}. Comparison of the predicted differences with the measured ones indicates that the two values are at least comparable. These results support the first working hypothesis that the effect of variation in Ar content of calibration gases (i.e., matrix effect of Ar) on $\Delta[CO_2]$ can be directly caused by the role of TMFC. This hypothesis was tested by comparison of $\Delta[CO_2]$ between the observed values and predicted ones estimated by the principle of TMFC. However, such effect due to the TMFC appeared in the modified GC-FID system only, suggesting that this effect is closely associated with the presence of the flow restrictor. The second working hypothesis is that potential variations in the gas pressure inside the sample loop would be indicative of such effect because of the ideal gas law indicating that variations in gas amount (mol) are linearly proportional to those in gas pressure (atm) under constant volume and temperature. The second hypothesis was experimentally investigated further. Both the theoretical aspects and the experimental results demonstrated that these hypotheses are valid under the experimental conditions investigated in this study. Details are as described in Supporting Information.

In addition, to check the reproducibility (precision) of the measured concentrations of CO_2, uncertainty budgets were evaluated based on the international guides [13,14]. Each error bar indicates an expanded uncertainty ($U = ku_c$) at a coverage factor (k) of 2. Using the computer software (GUM Workbench, Version 2.3), standard combined uncertainties (u_c) were estimated for the NDIR systems and the GC systems, taking both the preparation of the calibration gas mixtures and the measurement by the three-point and the two-point calibration processes, respectively. Uncertainty sources were not only from measurement itself but also from the preparation of the CO_2 calibration gas mixtures. Results show that the measurement uncertainty values for the NDIR systems are much smaller than those for the GC systems. The U values for the NDIR systems fall <0.08 μmol mol^{-1} ($k = 2$), whereas those for the GC-FID systems were <0.31 μmol mol^{-1} ($k = 2$) and that for the modified GC-TCD system was <0.70 μmol mol^{-1} ($k = 2$). Details on the uncertainty estimates are presented in Supporting Information.

4. Conclusions

Based on our findings, we can draw some important implications. Under the explored experimental conditions, the NDIR systems were typically less susceptible to potential matrix effects due to the association of the TMFC as compared to the GC systems. Some practical implications and recommendations need to be addressed. In general, one should check whether an available analytical system with TMFCs can affect determination of the analyte due to different matrices between calibration and sample gas mixtures. In particular, for reliable monitoring of real atmospheric CO_2 samples and for the verification of gravimetrically prepared CO_2 calibration gas mixtures, one should use calibration gas mixtures that contain Ar content close to the level (9.332 mmol mol^{-1}) in the ambient air as possible.

One of the best options we recommend is to use the modified NDIR system without a trade-off between enhancing sensitivity and high accuracy and precision. The second best option would be the conventional NDIR. Unless NDIR analytical systems are available, the next option is the conventional GC-FID system. Since the sensitivity of TCD to CO_2 detection is generally low relative to that of the FID, the conventional GC-TCD system would not be the preferred choice for accurate and precise determination of atmospheric CO_2. The modified GC-TCD would be not be of desirable choice because the results showed the second largest difference from the true value (1.09 μmol mol^{-1}) and the largest measurement uncertainty (0.75 μmol mol^{-1}).

This research has just opened a great horizon for CO_2 determination by focusing the current research scope on fairly narrow concentrations of atmospheric CO_2 in background air. We will further investigate potential matrix effects on CO_2 concentrations far beyond atmospheric levels (up to emission or stack levels). It is anticipated that this extension would provide a deeper understanding and practical significance on reliable measurement of CO_2 in various applications.

ABSTRACT

An imaging mass spectrometric method using laser ablation inductively coupled plasma spectrometry (LA-ICP-MS) was developed to determine Cu, Zn, Cd, Hg and Pb and metal distribution in longitudinal tissue sections of the marine snail *Nassarius reticulatus* (Gastropoda, Prosobranchia). Snails were sampled in northern Brittany (France) at three stations with different contamination levels.

The quantification of metal distribution (imaging or mapping) in a thin slice of the snail tissue was carried out using different strategies: by one-point calibration and via matrix-matched laboratory standards using different biological materials (BCR 278, snail tissue, and rat brain). Together with the imaging of metals the distribution of two non-metals (carbon and sulfur) was analyzed. The imaging LA-ICP-MS analysis yielded an inhomogeneous distribution for all elements investigated. The detection limits for the distribution analysis of Cu, Zn, Cd, Hg and Pb measured by LA-ICP-MS were in the low $\mu g\,g^{-1}$ range.

1. Introduction

Laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) has been established as a promising powerful technique for the determination of elements in solid samples with high sensitivity and low detection limits [1–3]. The advantages of laser ablation ICP-MS include direct trace, bulk and isotope analysis of solids without any chemical procedures for the dissolution of samples. Therefore, the risk of contamination or analyte loss is reduced. Furthermore, the elemental and isotope analysis of very small samples including a spatially resolved analysis can be performed. The latter is of interest for the study of inhomogeneities of elements, e.g. in geological samples, metals, alloys or ceramics, layered systems or tissues. LA-ICP-MS allows a spatially resolved characterization of heterogeneities in solid materials or tissues with lateral and in-depth resolution in the μm range (from 200 μm down to 5 μm, e.g. micro-local analysis and in-depth profiling for single particle characterization and surface mapping) [1,3–5].

The determination of element concentrations, as well as their distribution in different kinds of biological tissues (e.g. brain, liver, plant section, etc.), is a challenging task in analytical chemistry and of great importance in different areas of biological research [6–11]. A deficit of essential elements within tissues (e.g. Fe, Cu, Se, Zn, Mn, Mo and Ni) results in different diseases. Some undesired metals can also catalyze cytotoxic reactions, which lead to DNA modification (such as the Fenton reaction), or toxic processes at high concentrations, which could be involved during tumor progression. Due to the fact that all essential and toxic elements tend to be inhomogeneously distributed in biological tissues, imaging studies require powerful analytical tools with good spatial resolution and low detection limits. Recently, imaging analysis has been used in studies to evaluate bioactivity, transport processes, distribution, and contamination, as well as to monitor environmental exposure using indicator organisms [2].

The distribution and quantity of elements involved in biological processes have been analyzed using different analytical techniques [11,12]. Not only are element concentrations in tissue of interest, but so are their precise spatial allocation (mapping or imaging) in organs, tissues and even single cells [6,11]. At the moment, a number of analytical techniques are available for imaging elements in biological tissues [13,14]. Some of these techniques offer exceptional spatial resolution, but poor detection limits and vice versa. However, for imaging studies on biological tissues, a powerful analytical technique with both good spatial resolution and high sensitivity

doi:10.1016/j.talanta.2009.06.080

is essential. Frequently used methods for element imaging in tissues are histochemical staining techniques [8], which, however, do not provide multi-element competence. Other surface analytical techniques, such as scanning electron microscopy with energy dispersive X-ray analysis (SEM-EDX) [13], proton-induced X-ray emission (PIXE) [14] or autoradiography [15], are generally less sensitive for trace analysis. Secondary ion mass spectrometry (SIMS) allows ion images of the distribution of chemical elements in tissue to be produced with a spatial resolution in the low μm to sub-μm range. However, a major problem in SIMS analysis is the strong matrix dependence of the ion yields, which makes the quantification of analytical data very difficult due to inherent matrix effects [16–18].

The application of LA-ICP-MS with its multi-elemental capability of imaging metals and non-metals in thin cross-sections of biological samples, is currently the most suitable approach for imaging metals, metalloids and non-metals, due to its high sensitivity, fewer matrix effects (compared to SIMS), low detection limits, and relatively simple quantification and sample preparation procedures [19,20].

For the quantification of analytical data in LA-ICP-MS, different strategies [1] can be applied (e.g. using certified reference materials (CRM) from the same or a similar matrix). If no suitable SRM is available, matrix-matched laboratory standards [21,22] can be prepared and analyzed together with the sample or an isotope dilution technique or solution-based calibration in LA-ICP-MS can be applied [23,24].

The netted whelk *Nassarius reticulatus* (L., 1758) is a marine prosobranch gastropod inhabiting most European coasts [25]. *N. reticulatus* is a well-established bioindicator for marine pollution, especially for organotin compounds [26–29]. Within the organotins, tributyltin (TBT) compounds are mainly used as antifouling biocides. They induce a masculinisation syndrome in prosobranch species, termed imposex [30]. Imposexed females develop male sex organs (penis and vas deferens) and may eventually be sterilized by a blockade of the vaginal opening or other malformations of the oviduct [31–33]. This phenomenon has been described for more than 150 species worldwide [34] and is used to monitor the TBT biological effects on a routine basis [35,36]. Due to the fact that *N. reticulatus* spends most of its life cycle burrowed in the sand and other soft sediments, it is suitable for the biomonitoring of marine sediments [37,38].

The aim of this work is to study the element distribution in *N. reticulatus* by imaging LA-ICP-MS in order to biomonitor the metal pollution in such species. Different calibration procedures were studied to quantify the analytical data.

2. Experimental

2.1. LA-ICP-MS instrumentation and measurement procedure

LA-ICP-MS measurements of elemental distribution in sections of snail tissues were performed using a quadrupole-based ICP mass spectrometer (ICP-QMS, Agilent 7500 ce) coupled to a laser ablation system (New Wave UP 266). The thin sections of biological tissues were ablated using a Nd:YAG laser (wavelength: 266 nm, repetition frequency: 20 Hz, spot size: 160 μm) and then transported by argon as the carrier gas into the inductively coupled plasma (ICP). The ions formed in the ICP were extracted in the quadrupole mass spectrometer and separated according to their mass-to-charge ratios. The experimental parameters of LA-ICP-MS were optimized with respect to the maximum ion intensity of $^{63}Cu^+$ using a well homogenized synthetic laboratory standard with known Cu concentration. Maximum ion intensity for $^{63}Cu^+$ was observed at an rf ICP power of 1500 W and a carrier gas flow rate of 1.2 L min^{-1} for the transport of ablated material to the ICP source. By means of two-dimensional (2D) imaging of biological tissues, a defined sample area (less than 1 cm^2) of a thin section of snail tissue (thickness: 20 μm) was ablated line by line with a focused laser beam. The distribution of metals in the sections of *N. reticulatus* was investigated by LA-ICP-MS under the optimized experimental parameters as summarized in Table 1.

Table 1
Optimized operating conditions for the developed imaging LA-ICP-MS procedure for the determination of the lateral distribution of Cu, Zn, Cd, Hg and Pb in thin cross-sections of snails.

ICP-MS	ICP-QMS, Agilent 7500 ce
Rf power (W)	1500
Carrier gas flow rate (mL min^{-1})	1.2
Sweeping/reading	1
Readings/replicate	Changeable
Laser ablation system	New Wave UP 266
Wavelength of Nd-YAG laser (nm)	266
Laser power density (W cm^{-2})	10^9
Ablation mode	Scanning (line per line)
Laser pulse duration (ns)	20
Repetition frequency (Hz)	20
Number of passes	1
Scan speed (μm s^{-1})	40
Laser spot size (μm)	160

Samples and calibration standards were arranged in a commercial laser ablation chamber (NewWave UP266, Fremont) in order to allow imaging LA-ICP-MS analysis be performed under the same experimental conditions. Thin sections of snail tissues were investigated to determine the elemental distribution of Cu, Zn, Cd, Hg and Pb. The background intensities of the analytes of interest were determined directly by LA-ICP-MS in a snail tissue ("blank") obtained from a reference site (C).

In all measurements $^{13}C^+$ ion intensity was used for internal standardization of mass spectrometric measurements. In addition, as internal standard element manganese (with the certified value of 7.3 ppm) was used for semi-quantitative analysis of metals in tissue when one-point calibration was used [1]. A multi-element analysis by LA-ICP-MS was carried out directly on standard discs fixed on the glass slides with special target-holder tape together with the snail tissue.

2.2. Samples and sample preparation

2.2.1. Certified reference materials

Reference mussel tissue from the Community Bureau of Reference (BCR CRM 278) with certified metal concentration for the selected analytes was employed to evaluate the analytical data using one-point calibration in the semi-quantitative modus.

This powder biological certified reference material (mussel tissue BCR CRM 278) was pressed into discs with a diameter of 3 mm at 8 atm. The LA-ICP-MS method was used to determine essential and toxic metals by measuring $^{63}Cu^+$, $^{66}Zn^+$, $^{111}Cd^+$, $^{202}Hg^+$ and $^{208}Pb^+$ in mussel tissue and snail sample that had been dried, ground and pressed into discs.

2.2.2. Field samples and sample preparation

Adult specimens of *N. reticulatus* (shell height of 2.2–3.9 cm) were collected in spring 2007 at different locations in northern Brittany, near Roscoff (France). One sampling site (site A) represents a heavily polluted area (harbor: 48°43′33.2″N 3°58′39.2″W). A second site (site B, 2.2 km west of the harbor: 48°43′51.0″N 4°0′22.0″W) is contaminated to a lesser extent due to the tidal transport of pollutants from the harbor. The third sampling site (site C, Beg en Fry: 48°42′4.2″N 3°43′1.2″W) is more remote from anthropogenic influence and therefore serves as reference site. The vas

deferens sequence index (VDSI), as a measure for imposex intensities (maximum value: 4.0 in *N. reticulatus*) and thus for the degree of TBT exposure [26] in the sampled snails, was 3.94, 0.78 and 0 at the sites A, B and C, respectively. These values demonstrate the different contamination levels of the sampling stations [39].

The snails were transported to the Frankfurt laboratory and housed in glass aquaria (60 L) with reconstituted sea water [40]. Prior to further analysis, they were kept under starvation for at least 2 weeks to remove remaining food particles from the alimentary tract. After this time, the snails were narcotized in 7.5% $MgCl_2$ solution for 2 h. Shell and aperture height were measured. The shell was broken with a vice and carefully removed. Morphological parameters were analyzed as reported previously [39]. The imposex stage was determined according to Stroben et al. [26,27]. Immediately after morphometrical analysis, the single specimen were embedded in Tissue-Tek (Sakura Finetek Europe B.V., Zoeterwoude, The Netherlands), frozen in liquid nitrogen and stored at −80 °C.

Female snails from site A with pronounced imposex (VDSI stage 3) and snails from the less contaminated site B (no imposex) were dissected in 50 μm frozen sections using a cryostat (Microtom HM 50 O, Walldorf, Germany). Serial section slices were thaw-mounted on microscope slides, air-dried and measured at Forschungszentrum Jülich by developed imaging LA-ICP-MS method. Furthermore, whole snail tissue from site C (reference site) was used as "Blank" to prepare matrix-matched laboratory standards to quantify the analytical data (via standard addition strategy) and calculate the background.

2.3. Semi-quantitative analysis via one-point calibration using certified reference material

Strategy 1: Certified reference materials (CRMs) are mainly applied to validate the analytical procedure developed for routine analysis in order to determine the accuracy of analytical data, the recovery of selected elements, the uncertainty of element determination and the detection limits [1]. In LA-ICP-MS, the one-point calibration has been employed as a possible calibration strategy using CRMs to obtain semi-quantitative data. In our work, the relative sensitivity coefficients (RSCs) of elements, defined as the ratio of the experimentally measured concentration to the certified (true) concentration of an element in a given matrix [41,42], are determined using the reference material of mussel tissue (BRC CRM 278). Manganese with a known concentration (certified value) present in a matrix was used as an internal standard element. In LA-ICP-MS, the RSCs correction of measured values is a quantification method that uses only one reference material.

2.4. Quantitative trace metal analysis

The distribution profiles of the essential and toxic trace metals of interest in snail tissues using LA-ICP-MS were quantified using synthetic laboratory standards:

Strategy 2: Synthetic laboratory standards were prepared from mussel tissue BRC 278 doped with trace elements with defined concentrations. Milli-Q water or standard solutions with known concentrations of analytes (Cu, Zn, Cd, Hg and Pb) were added to the mussel tissue. After absorption for 48 h, the materials were dried, ground into a fine powder and pressed under 8 atm. The final metal concentrations in these laboratory standards were determined by ICP-MS (Elan 6100) after digestion with HNO_3 and H_2O_2 in a microwave oven (range of concentration between 0.5 and 25 $\mu g\,g^{-1}$ for all elements).

Strategy 3: Matrix-matched synthetic laboratory standards were prepared from the reference snail tissue (C) spiked with standard solutions containing the elements of interest (Cu, Zn, Cd, Hg and Pb). A laboratory standard without spike was used as the "blank". Each standard was homogenized and centrifuged for 5 min. After this, the samples were frozen, cut and placed onto the glass slides as described in Ref. [8]. The final concentrations in these standards measured by ICP-MS were in the range of 0.5–30 $\mu g\,g^{-1}$ for all the analytes.

Strategy 4: Another series of synthetic laboratory standards were prepared from a rat brain tissue doped with standard solutions with well-defined analyte concentrations. The procedures were the same as described above. The final metal concentrations in the brain tissue standards were in the range of 0.5–10 $\mu g\,g^{-1}$ for all elements.

Calibration curves were produced by measuring the ion intensities of analytes in several lab standards by LA-ICP-MS.

All calibration strategies were applied to quantify the interested elements (Cu, Zn, Cd, Hg and Pb) in the snail samples. The accuracy of the strategies was evaluated with a corresponding analysis of the same samples digested by ICP-MS.

2.5. Measurement procedure for imaging Cu, Zn, Cd, Hg and Pb by LA-ICP-MS

Thin biological tissue sections of *N. reticulatus* were analyzed using developed imaging LA-ICP-MS method together with the synthetic laboratory standards under the same experimental conditions. To obtain two-dimensional images of element distribution, the region of interest in the sample was scanned line by line by a focused laser beam. LA-ICP-MS data files for each element analyzed were converted into .txt files and used to create 2D images of element distribution. The images were plotted using in-house computing software.

3. Results and discussion

3.1. Comparison of different calibration strategies

The quantification of the analytes in the solid sample is a fundamental aspect of acquiring the best possible results from mass spectrometric measurements [1]. In accordance with this fact, in this work we investigated different methods for the quantification of the potentially toxic elements in the tissues from field samples of the marine prosobranch *N. reticulatus*.

A semi-quantitative measurement is often used for a quick analysis of a sample in respect to a rough determination of matrix, major and trace element concentrations, and can be performed as the first step before the quantitative analysis. Firstly, a semi-quantitative multi-element analysis was performed by LA-ICP-MS using Mn as an internal standard element with a known concentration (certified value: 7.3 $\mu g\,g^{-1}$) whereby the concentrations of analytes in the sample were calculated from the ion intensities measured with respect to the known concentration of internal standard element using the following analysis equation (1):

$$c(x) = \frac{c(v) \cdot I(x) \cdot A(v)}{I(v) \cdot A(x)} \quad (1)$$

where x is the element to be determined, v is the internal standard element, c is the element concentration, I is the ion intensity measured, and A is the isotopic abundance [1].

The element concentration in the mussel tissue (BCR 278) measured by LA-ICP-MS was corrected using experimentally determined relative sensitivity coefficient (RSC) of a chemical element. The RSC [defined as the ratio of measured (experimental) to certified (true) element concentrations in a given matrix] of chemical elements depend on the analytical procedure applied. The same matrix or a similar matrix composition should therefore be compared to the sample (under identical experimental conditions) [1,41]. In this case, RSCs were measured on pressed discs of

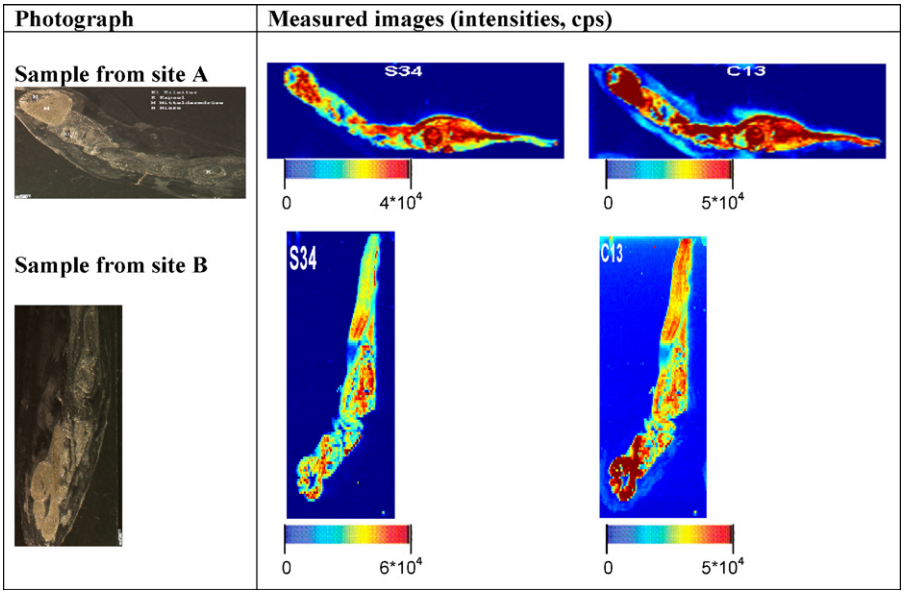

Fig. 1. Photograph and ion images of analyzed thin section of snail samples from site A and site B.

Table 2
Relative sensitivity coefficients in LA-ICP-MS determined using pressed discs of the certified reference material (CRM) of mussel tissue (BRC 278) and the certified concentrations [$\mu g\,g^{-1}$].

Element	Isotope measured	RSC	Certified values [$\mu g\,g^{-1}$]
Cu	63	2.7	9.6 ± 0.16
Zn	66	0.4	76 ± 2
Cd	111	1.8	0.34 ± 0.02
Hg	202	1.6	0.188 ± 0.007
Pb	208	1.9	1.91 ± 0.04

reference mussel tissue (BCR CRM 278), the values of RSCs together with the certified values are presented in Table 2.

The RSCs for the investigated elements varied from 0.4 to 2.7, therefore a semi-quantitative determination of these metals by LA-ICP-MS is possible with an error factor in this range. Using the RSC as correction factors of measured data of real samples in the semi-quantitative mode is often sufficient for a first survey analysis on the sample analyzed. The pressed disc of mussel tissue sample (BCR 278) was used for the calibration in order to study the performance in this mode of one-point calibration for the snail sample and mussel tissue by LA-ICP-MS. The results of analytical data in a snail sample and mussel tissue using different calibration strategies: one point calibration compared to the use of synthetic laboratory standards for calibration are summarized in Table 3 and were compared with ICP-MS solutions analysis ($n = 3$). A semi-quantitative multi-element analysis is limited in accuracy and precision. Semi-quantitative trace metal analysis by LA-ICP-MS via one-point calibration was compared with ICP-MS analysis and the values for Hg, Cd and Pb were found to be in agreement. However, LA-ICP-MS values for Cu and Zn are on average 65% and 26% higher than ICP-MS analysis, respectively. Reliable data were obtained for the determination of Hg, Cd and Pb in snail sample and mussel tissue using BCR 278 in the semi-quantitative approach.

In the next step the quantitative analyses of Cu, Zn, Cd, Hg and Pb were performed using three types of synthetic laboratory standards with three types of biological matrix. The quantification in LA-ICP-MS using all calibration strategies with synthetic laboratory standards yielded a good linearity in the calibration graphs, with linear correlation coefficients (R^2) better than 0.99 for all three calibration strategies in Table 3.

Table 3
Results of trace metal analysis in snail-sample and mussel-tissue using different strategies for calibration: (A) one-point calibration (semi-quantitative); (B) synthetic matrix-matched solid standard (mussel tissue SRM 278); (C) matrix-matched laboratory synthetic standard (snail blank); (D) matrix-matched laboratory synthetic standard (rat brain).

		Calibration strategy

n.d.: not determined; $n = 3$.

[a] The correlation coefficients for calibration curves (R^2) varied for all analytes investigated in the different calibration strategies between 0.997 (for Cd) and 0.999 (for Pb).

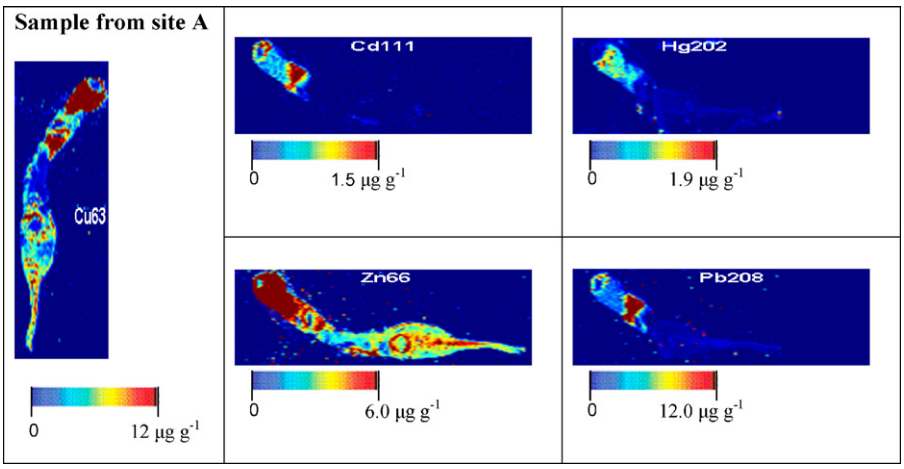

Fig. 2. Cu, Cd, Hg, Zn, and Pb images in a cross-section of snail tissue from site A. The analyzed area was 34 mm × 9 mm; the measured isotopes are given in the images.

The accuracy of the investigated methods was verified by comparing the results obtained with the values from ICP-MS analysis using the Student's *t*-test. We concluded that there was no significant difference at a confidence level of 95% between the values determined by LA-ICP-MS (all quantitative strategies) and those determined by ICP-MS analysis for all elements investigated. However, the best strategy was found to be the use of matrix-matched synthetic laboratory standards of snail tissue (strategy 2).

The analytical results obtained in the semi-quantitative and quantitative calibration modes are compared in Table 3. Generally good agreement of the data sets was obtained by quantitative calibration via calibration curves and one-point calibration by LA-ICP-MS, when compared to ICP-MS analysis. The analysis of the snail sample and mussel tissue using calibration curves for quantification (for three cases) yielded a better accuracy overall compared to the semi-quantification using RSCs. However, this technique was more time-consuming and required matrix-matched certified standard reference materials.

The concordant results obtained using the investigated calibration technique (strategy 2) and ICP-MS analysis indicates that the use of matrix-matched laboratory standards is the method of choice for the bio-imaging of metals.

With respect to calibration strategies, synthetic pressed-powder pellets (strategy 1) and another kind of artificial matrix were not sufficiently similar in either physical structure or chemistry to be ablated in the same way as the real field samples.

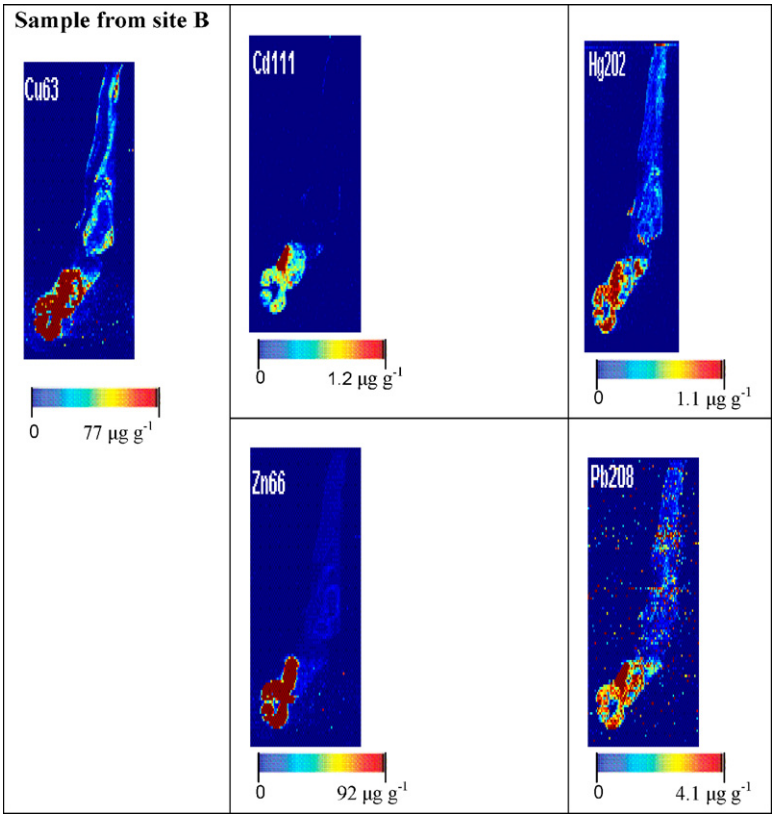

Fig. 3. Images of Cu, Cd, Hg, Zn, and Pb in a cross-section of snail tissue from site B. The analyzed area was 34 mm × 12 mm; the measured isotopes are given in the images.

3.2. Quantitative two-dimensional mapping of Cu, Zn, Cd, Hg and Pb in analyzed thin sections of snail tissue

Laser ablation ICP-MS was applied to produce images of element distribution in sections of *N. reticulatus* collected at sampling sites with a different degree of pollution. Fig. 1 shows the distribution of two essential non-metals (S and C). For anatomical orientation, photomicrographs of the sections (posterior part of the snail on the left side, anterior on the right) are shown together with LA-ICP-MS images of S and C. Sulfur and carbon are distributed uniformly across the snail's body. The elemental images obtained by LA-ICP-MS correlated very well with the anatomical structure of snail tissue shown in the photographs.

The quantification of the distribution of metals in snail samples was performed by measuring matrix-matched synthetic laboratory standards with well-defined element concentrations (under the same experimental conditions as the tissue sections) using LA-ICP-MS according to the developed method (strategy 2). Two-dimensional distributions of Cu, Cd, Hg, Pb and Zn were determined in the cross-sections of three snail tissues (Figs. 2 and 3).

Figs. 2 and 3 show a heterogeneous distribution of all elements analyzed by LA-ICP-MS. There are no pronounced differences between animals collected at the different sampling sites, indicating that *N. reticulatus* collected at site B are still contaminated with the toxic elements. High concentrations of copper (77 $\mu g\,g^{-1}$) and zinc (92 $\mu g\,g^{-1}$) were found in the female *N. reticulatus* from site B. In snails collected at the contaminated site A, much lower levels of Cu and Zn were measured. This gave rise to the assumption that the harbor (site A) may not be the only source of pollution for Cu and Zn. Cadmium, mercury and lead were detected in low $\mu g\,g^{-1}$ range with one exception: lead concentration in the female collected at site A (26 $\mu g\,g^{-1}$) is much higher compared to the lead concentrations in the male from the same site and the female from site B. Metal concentrations are frequently determined in marine clams mainly for reasons of food safety [43,44]. It is difficult to compare these total concentrations with the data presented here, since whole tissue is conventionally analyzed by ICP-MS [45,46]. In our work, metal concentrations were presented with a lateral resolution at the 160 μm range of the tissue section within the snail body using the developed bio-imaging LA-ICP-MS technique.

In general, the highest metal concentrations were found in the visceral mass of the snails, where the digestive and reproductive organs were located. All elements seemed to accumulate mainly in the digestive gland. Copper and zinc were distributed most broadly and were also found in the reproductive tract in parts of the testis (male) and oviduct (female) but not in the ovary. Cadmium and mercury accumulation was restricted to the digestive gland, whereas lower levels of lead were also found in the testis and ovary. Furthermore, copper, cadmium and lead were detected in the kidney, the gland and the mantle epithelium. The anterior part of the mantle epithelium (high concentrations of Cu, Cd and Pb) contained ectodermic cells secreting the shell material. The accumulation of metals in this body region may be a first step for their storage and thus detoxification in the gastropod shell.

4. Conclusions

An imaging mass spectrometric technique was developed for the quantitative determination of essential and toxic metals in biological tissues using LA-ICP-QMS. Several quantification procedures, e.g. using certified reference materials or synthetic matrix-matched laboratory standards, were established for selected metals in LA-ICP-MS. With the ability to analyze thin sections of biological tissues with sufficient sensitivity, as well as a relatively short analysis time, LA-ICP-MS is a very powerful technique for the quantitative multi-elemental imaging analysis of tissues sections to study the uptake and transport of metals. The technique presented here is promising for a wide applications ranging from environmental research and toxicology to drug development and the basic life sciences.

Sample treatment

ABSTRACT

The 3051 USEPA method (or alternatively, the 3051A) can be considered nowadays as a reference method to extract metals from sediments. However, after microwave heating, the sample must be allowed to cool down, which results in a considerable lengthening of the whole analytical process. Microwave ovens and their maintenance are, in addition, expensive, and its use is relatively dangerous. The use of ultrasound focused energy to assist the extraction of chemicals from solid samples is a safe and relatively cheap technique. In this work we propose a new method to extract simultaneously several elements from sediments using ultrasound energy focused in a glass probe to accelerate the process, and check its possibilities to become an alternative to the EPA3051(A) approach. The optimised procedure allows extracting 13 elements in only 6 min, with similar recoveries and, in general, better repetitivities than the EPA3051. In addition, the suspension is only slightly heated during the leaching process.

1. Introduction

Metals, specifically arsenic, and their compounds are included in the indicative list of main pollutants of the EU water framework directive [1]. They are present in natural aquatic systems at trace and ultratrace levels [2]. There is a continuous exchange of trace elements between sediments and water in oceans, estuaries, rivers and lakes [3]. This exchange plays an important role in the biogeochemical cycle of these pollutants and usually determines their availability to living organisms [4,5]. In addition, sediments serve as reservoir of trace elements and, due to the long residence times involved, they can be used to investigate historical pollution in selected areas [4,6]. In this context, the need of measuring the concentration of trace metals in sediments becomes evident.

The analysis of trace and ultratrace elements in sediments is a long process which involves several steps. Nowadays, extraction of the analytes from the matrix constitutes the bottleneck of the analysis in terms of time, reproducibility and accuracy [7]. A quantitative extraction requires the total dissolution of the sample, which is only attained using hydrofluoric acid or any of its derivatives (usually combined with other strong acids and/or oxidants) as extractant. In many cases, however, the determination of total concentrations is not mandatory, and the result obtained after the extraction of the analytes using strong mineral acids such as nitric and hydrochloric acids (or mixtures of them, e.g., *aqua regia*) is enough for toxicological purposes. The so-called "pseudo-total" metal content (or acid leachable fraction) is usually well up the bioavailable fraction and has been frequently used, for instance, in environmental monitoring programs [8] and toxicological risk assessment [9].

Solid–liquid acid leaching has become, consequently, the most popular technique to extract trace elements from sediments. The conventional hot-plate procedure [10] is long and tedious. The methods recommended by the International Organization for Standardisation (ISO 11466 [11]) and the U.S. Environmental Protection Agency (EPA 3050B [12]) use a reflux condenser, mixtures of mineral acids and oxidants, and still take several hours. Different approaches, such as pressure-bombs [13], ultrasound baths [14] and both focused [15] or pressurised [16] microwave ovens, have been investigated to accelerate the process. By far, the last option has been the most popular one over the last 10 years. The EPA method (EPA 3051) describes the microwave assisted HNO_3 extraction of sediments for metal analysis [17]. Its alternative, the EPA 3051A [18] allows using HNO_3–HCl mixtures to improve the performance for several elements. Microwave assisted leaching, however, is affected by several and serious limitations, such as relatively long extraction time and low reproducibility. The sample is subjected to high temperature and pressure and must be allowed to cool down before going on with the general procedure. Last generation microwave ovens and their maintenance, in addition, are relatively expensive, and must be manipulated by well trained personal.

Ultrasound energy has been used to accelerate the extraction of organics, metals and also organometals from environmental solid samples [19,20]. Ultrasound baths provide a simple and cheap way to deliver ultrasound energy. They allow using a large variety of

doi:10.1016/j.talanta.2009.07.002

solvents as extractants. However, the irradiation power is poor, the reproducibility is low and the ultrasonic efficiency is not homogeneously distributed in the bath [21]. Focused ultrasound systems overcome those problems. The ultrasound energy is focused in the tip of a probe, typically made in titanium, which is immersed in the solution to be irradiated. The irradiation power is up to 100 times higher than that provided by a bath. Only long irradiation times result in a constant but modest increase in temperature of the irradiated system. Use of focused ultrasound produces relatively short, quantitative and reproducible extractions of pollutants from solid samples of different origin [19,22,23]. The use of concentrated strong mineral acids as extractant, however, is not recommended by manufacturers, because the half-life of the titanium probe is considerably reduced. Consequently only a few works, all of them appeared before 2000, have been published on the extraction of metals from sediments using an ultrasonic probe [24–26]. In all the cases, short extraction times (less than 5 min) and diluted HNO_3 (up to 10%, v/v) were used, and recoveries of 60%, 54–69%, 15% and 75–95% were obtained, respectively, for Cu, Pb, Cr and Cd. From these results it becomes evident that the impossibility of using concentrated acids seriously limits the applicability of the technique.

The commercialisation of a glass probe as an alternative to the classical titanium one is recent. Glass is chemically resistant to strong concentrated acids and becomes an excellent candidate to be used in the extraction of metals from solid samples. There is no restriction regarding irradiation time and acid concentration. In addition, potential contamination of the samples with impurities contained in the titanium probe is eliminated [21]. As a drawback, the ultrasound power and amplitude delivered by a glass probe are limited, due to the low mechanical resistance of glass compared to titanium. There is only one work dealing with the extraction of eight metals from solid samples (sewage sludge) for using industrial ultrasound focused on a glass sonotrode to accelerate the process [27]. To our knowledge, this technique has not been yet used in the analysis of sediments.

In this work we check the possibilities of the ultrasound energy focused in a glass probe as an alternative to the microwave assisted leaching of trace elements from sediments. The results obtained have allowed us proposing a very fast procedure (6 min of irradiation time) for the simultaneous extraction of several elements (Al, As, Co, Cr, Cu, Fe, Mg, Mn, Ni, Pb, Sn, V and Zn) from sediments and their simultaneous detection and quantification by ICP/MS.

2. Experimental

2.1. Materials and reagents

Calibrant solutions of the analytes all together were prepared by weight in 1% HNO_3 from individual commercial stock solutions of Al, As, Co, Cr, Cu, Fe, Mg, Mn, Ni, Pb, Sn, V and Zn (1000 mg L^{-1} in 5% HNO_3, Specpure, Alfa Aesar, Ward Hill, MA, USA). Be^9, Sc^{45}, In^{115} and Bi^{209} stock standard solutions (1000 mg L^{-1} in 5% HNO_3, Specpure, Alfa Aesar) were added to blank, standard and sample solutions to yield at 10 μg L^{-1} in concentration as internal standard. Preparation of calibrants and analysis of samples were performed in a "class 100" clean room.

Efficiency of the extraction method was checked using the certified reference materials NIST 1646a (estuarine sediment, National Institute of Standards and Technology, Gaithersburg, USA).

Hydrochloric acid (37%, Tracepur), acetic acid (100%, Pro analysis) and nitric acid (69%, Tracepur) were purchased from Merck (Darmstadt, Germany). Milli-Q quality water ($\kappa < 0.05$ μS cm^{-1}, Millipore, Billerica, MA, USA) was used throughout.

All plastic and crystal materials in contact with calibrants or samples were first cleaned with water and soap, rinsed with deionised water and finally left in a 10% nitric acid bath for 24 h. Afterwards, it was thoroughly rinsed with deionised and MilliQ water before use.

Chemometric analysis of data was carried out with The Unscrambler 9.2 (Camo Process, Oslo, Norway) and Multisimplex 1.0 (Grabitech, Sundsvall, Sweden).

2.2. Instrumentation

Weighing solid samples and preparation of calibrants were carried out by means of an analytical balance AE200 (Mettler Toledo, Columbus, OH, USA) with a precision of ±0.00001 g.

An HD 2070 Sonopuls Ultrasonic Homogenizer (Bandelin, Germany) equipped with a GM 2070 generator (70 W, 20 kHz), an UW 2070 ultrasonic converter and either a SH 70G horn and MS 73 titanium probe (3 mm) or, alternatively, a SH 70 GQ horn and GS 6 glass probe (6 mm) was used in the extraction step. A variable power setting (0–100%) allows controlling amplitude of the delivered ultrasound. A maximum power of 35% is recommended by the manufacturer when using the glass probe. In some experiments, the sample was continuously stirred during extraction by means of an Asincro magnetic stirrer (Selecta, Barcelona, EU).

Trace element analysis was carried out with an Elan 9000 ICP/MS (PerkinElmer, Ontario, Canada), provided with Ryton cross-flow nebulizer, Scott-type double pass spray chamber and standard nickel cones. Preparation of calibrants and analysis of samples were done inside a clean room (class 100). Argon (99.999%, Praxair, Spain) was used as carrier gas in the ICP/MS measurements.

2.3. Experimental procedure

2.3.1. Ultrasound assisted extraction of sediments

Previously freeze-dried and sieved (<75 μm) sediment collected in December 2005 in the estuary of the Nerbioi-Ibaizabal River (Bilbao, Bay of Biscay, Basque Country, N 43°19′04.5″; W 02°59′35.1″), *NI0512*, was used in all the experiments. Design of experiments (DoE) was used to study the influence of several variables on the extraction efficiency and to optimise the extraction process. DoE addresses several advantages when compared to the classical "one-experiment-at-a-time" approach: (i) it is possible to investigate simultaneously the effect of several factors as well as interactions among them, (ii) the ratio between obtained information and experimental effort is optimised, and (iii) DoE allows modelling mathematically the system under study.

An exact amount of dry sediment (0.2–0.5 g) was transferred to a polyethylene cylindrical extraction vessel together with an appropriate volume of extractant (10–20 mL). In some experiments a stir bar was added to the vessel. The probe (titanium or silica–glass) was placed inside the suspension (0.5–2 cm), the magnetic stirrer was switched on (when applicable) and sonication was applied at a fixed power (10–100%) and cycles (1–9 or continuous) during a fixed time (5–3540 s). To avoid cross-contamination the probe was rinsed several times with MilliQ water and then air dried between sample runs. After sonication, the suspensions were filtered through PVDF 0.45 μm filters using plastic syringes. In some experiments, the extract was separated from the residual solid by centrifugation at 2500 rpm during 10 min (2×) and the supernatant was filtered through PVDF 0.45 μm filters before analysis. Two different dilutions of the extract were prepared in water to measure, respectively, minor and major elements. In both of them HNO_3 and HCl concentrations were adjusted to 1% and 0.45% respectively by adding the appropriate amounts of concentrated HNO_3 and HCl. All dilutions were made by weight. In both dilutions, Be^9, Sc^{45}, In^{115} and Bi^{209} were added (10 μg L^{-1} each) as internal standard before analysis. Blanks were processed in a similar way.

Table 1
Experimental conditions used in the ICP/MS analysis.

Nebulization flow	0.94 L min^{-1}
Plasma flow	15 L min^{-1}
Auxiliary flow	1.2 L min^{-1}
Sample flow	1 L min^{-1}
Measured isotopes	^{27}Al, ^{75}As, ^{59}Co, ^{52}Cr, ^{63}Cu, ^{57}Fe, ^{24}Mg, ^{55}Mn, ^{60}Ni, ^{208}Pb, ^{120}Sn, ^{51}V, ^{66}Zn
Radiofrequency power	1000 W
Integration time	1000 ms
Replicates	3–4

2.3.2. Analysis of extracts and calibrants

The concentrations of Al, As, Co, Cr, Cu, Fe, Mg, Mn, Ni, Pb, Sn, V and Zn in the dilutions of the extracts and calibrant solutions were simultaneously measured by ICP/MS using the external calibration method with internal standard correction [28]. The experimental conditions are summarised in Table 1. All measurements were run in triplicate. The accuracy of the analysis was checked using the NIST 1640 standard reference material (Natural water, National Institute of Standards and Technology, Gaithersburg, USA) with satisfactory results.

3. Results and discussion

3.1. Influence of several variables on extraction efficiency

In a first approach, the influence of several variables, e.g., sonication time (t), amplitude of the ultrasound (A), length of probe immersed in the suspension (l), and cycle (cy; cy indicates a pulsed mode; for instance, $cy = 4$ means a 0.4 s active period followed by a 0.6 s passive period) was studied using different solutions as extractants. In each case, experiments were organised according to a full factorial design with variables at two different levels and four replicates of the central point. Experiments were always run in a random order. About 0.2 g of sediment was weighted in a conical (flat) bottom extraction vessel and extraction was performed as described in Section 2, without stirring, under the experimental conditions defined in the design. The suspension was filtered before dilution and ICP/MS analysis. Analysis of variance (ANOVA) of the results was carried out by means of Unscrambler to decide if the variables considered or any combination among them significantly influenced the extraction of each element at a 95% confidence level.

First, acetic acid was checked as extractant using the titanium probe to focus the ultrasound energy. In this case, t (5–600 s), A (10–100%), l (0.5–2 cm), cy (1–9 or continuous) and concentration of acetic acid (c_{HAc}, 0.1–3 mol dm^{-3}) were studied. A total of 36 experiments were run as suggested by a full factorial design $2^5 + 4$. ANOVA showed that only the influence of c_{HAc} was significant (and positive) for all the elements considered. Irradiation time, t, only affected significantly in a positive way the extraction of As, Cu and Mn. The rest of variables and combination of variables did not influence the extraction efficiency.

In a next step, t (5–600 s), A (10–35%), cy (1–9 or continuous) and concentration of nitric acid (c_{HNO_3}, 0.01–15 mol dm^{-3}) were considered ($2^4 + 4$, 20 experiments) using HNO_3 aqueous solutions as extractant and the silica–glass probe. The probe was immersed 1.5 cm in the suspension. It was concluded that only c_{HNO_3} influenced positively the extraction of all the elements, being the influence highly significant. Like in the case of HAc, irradiation time also affected positively the extraction of several elements, As, Fe, Mg and Mn. The rest of variables and combinations were not significant.

Finally, a $2^4 + 4$ full factorial design with 20 extraction experiments was used to study how t (5–600 s), A (10–35%), cy (1–9 or continuous) and proportion of HNO_3 in the extractant (%HNO_3, 0–100%) affected the extraction of metals when aqueous mixtures of HNO_3 and HCl are used as extractants and the silica–glass probe to focus the ultrasound energy. The probe was immersed 1.5 cm in the suspension, and 69% HNO_3 and 36% HCl were used to prepare the extractant solution at the proportion defined in the design, in a way that %HNO_3 = 0, 50 and 100 results, respectively, in an aqueous solution of HCl 13.2 mol dm^{-3}, an aqueous mixture of HNO_3 7.1 mol dm^{-3} and HCl 6.6 mol dm^{-3}, and an aqueous solution of HNO_3 14.2 mol dm^{-3}. ANOVA showed that it is possible to define two groups of elements: those which are better extracted with HNO_3 rich solutions (Al, Co, Cu, Mg, Pb and Zn), and those which prefer HCl rich solutions (As, Fe, Mn, Ni, Sn and V). Extraction of Cr is not clearly influenced by this variable. In addition, extractions of Al, As, Co, Cu, Fe, Mg, Mn and Ni are positively affected by irradiation time, t. The rest of variables and combination showed no clear trend.

For each design, the concentration of each element in the leachate was estimated under the best possible experimental conditions using the mathematical models provided by Unscrambler after ANOVA of the results. Concentrations were compared with those obtained after analysis of the sediment according to the EPA 3051 method [17] with a Mars Xpress microwave oven from CEM Corporation, Matthews, NC, USA. The extraction efficiencies calculated in this way are shown in Fig. 1a. The best recoveries were always obtained with a mixture of HNO_3–HCl as extractant, except for Fe and Mg. In those cases, extraction with HAc offered better results, probably due to the fact that the use of the titanium probe allowed delivering ultrasound energy of higher amplitude.

To check the effect of agitation on extraction efficiency, analysis of the *NI0512* sediment was repeated with ($n = 4$) and without ($n = 4$) magnetic stirring. About 0.4 g of sample was weighed in a flat bottom extraction vessel, a magnetic bar was added (in experiments with agitation) and it was processed as described before using 20 mL of HNO_3 2.8 mol dm^{-3}–HCl 3.1 mol dm^{-3} as extractant and the silica–glass probe. The leachate was separated from the solid residue by filtration. The rest of variables was fixed as follows: $t = 1800$ s, $A = 35\%$, $l = 1.5$ cm and $cy = 5$. As it can be observed in Fig. 1b, extraction efficiency was systematically higher in experiments with agitation. Similar experiments showed that separating the leachate from the solid residue by filtration or centrifugation did not significantly affect the result of the analysis. Consequently, in all the next experiments the suspension was magnetically stirred during extraction and the leachate was separated by filtration.

3.2. Optimisation of the extraction step

After the preliminary experiments described in the previous section it was concluded that the variables with higher influence on the extraction of the elements considered from sediments using ultrasound energy focused in a silica–glass probe were irradiation time, t, as well as proportion, %HNO_3, and concentration, c_{acid}, of acids in the HNO_3–HCl aqueous mixture used as extractant. A central composite design (CCD) with three variables at five different levels and four repetitions of the central point (18 experiments run in a random order) was used to find the optimal experimental conditions for the extraction of each element considered. t, %HNO_3 and c_{acid} were varied from 0.5 to 59 min, 8–92% and 0.01–11.8 mol L^{-1}, respectively ($-\alpha$ to $+\alpha$ levels). In all the experiments, about 0.4 g of the *NI0512* sediment was suspended in about 20 mL of extractant, the suspension was magnetically stirred along the extraction process, the glass probe was immersed 1.5 cm in the solution and ultrasound amplitude of 35% was applied with a cycle of 5. The extract was separated from the solid residue by filtration. Regression analysis of the obtained results allowed defining the response surface for each element, and observation of these surfaces led to the best experimental conditions summarised in Table 2.

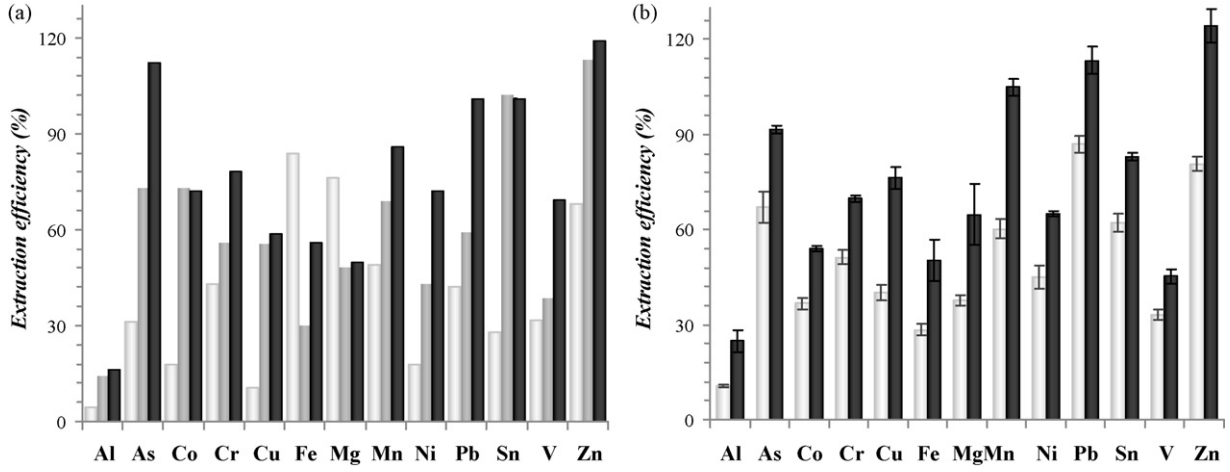

Fig. 1. Extraction efficiencies (as percentage referred to the EPA 3051 method) found for each element considered: (a) using the combination HAc/titanium (white), HNO_3/silica–glass (dark grey) and HNO_3–HCl/silica–glass (black) as extractant/probe. The sediment used in the experiments was the *NI0512* collected in the estuary of the Nerbioi-Ibaizabal River in December 2005; (b) after analysis of the same sediment with ($n = 4$, black) or without ($n = 4$, white) stirring the suspension during ultrasound assisted extraction with a silica–glass probe and HNO_3–HCl as extractant.

The extraction efficiencies calculated at those conditions are shown in the last row of Table 2, using as reference the EPA 3051 method (Mars Xpress unit from CEM was used).

3.3. Best conditions for a simultaneous extraction of the elements considered

The experimental conditions that provide the best extraction efficiency substantially differs from element to element, as observed in Table 2. One of the goals of this work was to propose a method for the simultaneous analysis of trace elements in sediments so, the next step consisted on looking for a combination of t, $\%HNO_3$, and c_{acid} able to provide an equilibrated, and as high as possible, extraction efficiency for all the elements considered. MultiSimplex helped us in this task. MultiSimplex is a modification of the Simplex algorithm [29] that allows optimizing simultaneously more than one response (extraction efficiency of each element) by changing the values of multiple variables (t, $\%HNO_3$, and c_{acid}). In this case, the optimisation process was simulated using the mathematical models provided by The Unscrambler (after regression analysis of the results obtained in the CCD, previous section) to calculate the extraction efficiency obtained at each combination of variables proposed by MultiSimplex. The same statistical weight was assigned to all the elements. The best set of variables found was as follows: $t = 6$ min, $\%HNO_3 = 45\%$ and $c_{acid} = 6.8$ mol L^{-1}. The extraction efficiencies estimated at these conditions are shown in the first column of Table 3. As observed, they are only slightly lower than those provided in Table 2. For many elements the recoveries are close (As, Mn and Sn) or even over (Pb and Zn) those obtained by the EPA 3051 method. Other ones (Co, Cr, Cu, Mg, and Ni) show acceptable recoveries (55%–75%) and only for Al, Fe and V the recovery is below 50%.

Table 3
Extraction efficiency (%, compared with the EPA 3051 method) estimated for the elements considered at different experimental conditions. t: irradiation time; $\%HNO_3$: proportion of HNO_3 in the HNO_3–HCl used as extractant; c_{acid}: concentration of the HNO_3 and HCl aqueous solution used to prepare the solution used as extractant.

	$t = 6$ min; $\%HNO_3 = 45\%$; $c_{acid} = 6.8$ mol L^{-1}	$t = 0.5$ min; $\%HNO_3 = 8\%$; $c_{acid} = 8.2$ mol L^{-1}	$t = 0.5$ min; $\%HNO_3 = 55\%$; $c_{acid} = 6.3$ mol L^{-1}
Al	22 ± 2	17 ± 2	21 ± 2
As	95 ± 9	100 ± 10	96 ± 9
Co	56 ± 6	61 ± 6	57 ± 6
Cr	72 ± 5	71 ± 5	72 ± 5
Cu	67 ± 3	56 ± 2	66 ± 3
Fe	45 ± 5	39 ± 5	43 ± 5
Mg	56 ± 5	46 ± 4	54 ± 5
Mn	98 ± 10	83 ± 9	94 ± 9
Ni	68 ± 5	70 ± 5	69 ± 5
Pb	107 ± 6	90 ± 5	105 ± 6
Sn	88 ± 5	98 ± 6	90 ± 6
V	48 ± 5	54 ± 3	49 ± 2
Zn	119 ± 7	106 ± 6	117 ± 7

An USF based extraction strategy will be a valid alternative to the microwave classical approach only if the method is effective and comparatively fast. The second and third columns of Table 3 show the extraction efficiencies estimated using an irradiation time as short as 0.5 min and two different acid mixtures as extractant (HNO_3 poor mixture (8%) and HNO_3 rich mixture (55%)). In general, the extraction efficiencies obtained in each case are very similar to those reported in the first column of the Table, especially in the case of the HNO_3 rich mixture. This result suggests that the influence of irradiation time on the extraction efficiency is important only at the very beginning of the extraction process (first 0.5–1 min), reaching a plateau very fast.

Table 2
Best experimental conditions found for the ultrasound assisted extraction of each element considered. t: irradiation time (min); $\%HNO_3$: proportion of HNO_3 in the HNO_3–HCl used as extractant; c_{acid}: concentration (mol L^{-1}) of the HNO_3 and HCl aqueous solutions used to prepare the extractant. EE: extraction efficiency (compared with the EPA 3051 method).

	Al	As	Co	Cr	Cu	Fe	Mg	Mn	Ni	Pb	Sn	V	Zn
t	31	2	59	58	30	29	30	29	1	30	59	21	29

3.4. Validation of the proposed method

3.4.1. Accuracy

The extraction efficiencies provided in Tables 2 and 3 are result of an estimation using mathematical models. In order to compare experimentally the efficiencies of the methods, the *NI0512* sediment and certified reference material (*NIST 1646a*) sediment were analysed using the ultrasound based method (n = 8) proposed here (t = 6 min, %HNO_3 = 45%, c_{acid} = 6.8 mol L^{-1}) and the EPA 3051 method (n = 8). This time the MW extractions were carried out using an Multiwave 3000 microwave oven from Anton Paar. Previous experiments demonstrated that the results obtained with the Anton Paar oven did not differ significantly (95% confidence level) from those obtained with the CEM unit. The results obtained are compared in Fig. 2. The recoveries (related to certified total concentrations) obtained after the analysis of the NIST 1646a with the EPA 3051 are also provided in Table 4. No significant difference between both methods (MW *vs* USF) was observed, except in the case of tin. It is worth noting that only a non-certified value is provided for tin in the certificate of the NIST 1646a material.

3.4.2. Uncertainty

The uncertainty of the optimised ultrasound based method (t = 6 min, %HNO_3 = 45%, c_{acid} = 6.8 mol L^{-1}) was checked by analysis of the *NI0512* sediment in 4 consecutive days. In addition, in the first day four replicates of the analysis were carried out. For comparability, analysis of the same sediment was repeated eight times the same day by the EPA 3051 method (Anton Paar unit). The results, expressed as relative standard deviations are shown in Table 5. As it can be observed, the precision obtained by the USF method was considerably better in most of the cases, with RSDs always below 5%.

3.4.3. Detection limit

The detection limit of the method was estimated after replicate analysis (n = 8) of a blank. The results obtained for each element, expressed as concentration of element in the sediment in mg kg^{-1} (for 0.5 g of sediment processed), are shown in Table 5. It is worth noting that the detection limit is higher when the measurement by ICP/MS is done in the second dilution rather than in the first one (this is the case when the concentration of the element in the extract is higher than about 100 mg L^{-1}).

Table 5
Uncertainty (calculated after replicate analysis of the *NI0512* sediment) of the USF based proposed method and the MW assisted EPA 3051, together with the detection limits for the USF proposed method (calculated after analysis of 8 blanks).

	Uncertainty (RSD, %)			Detection limit (mg kg^{-1})
	USF		MW	USF
	Within day (n = 4)	Between days (n = 4)	Within day (n = 8)	
Al	2.0	2.9	11.2	18
As	1.2	3.7	5.1	0.9
Co	2.2	4.0	3.0	0.2
Cr	2.3	2.5	12.8	0.5
Cu	0.7	1.7	3.1	23
Fe	3.3	4.2	3.2	12
Mg	2.1	3.3	7.9	6.0
Mn	3.2	4.7	3.0	0.9
Ni	1.5	2.6	5.4	4.0
Pb	0.9	1.1	4.9	1.0
Sn	1.2	2.2	13.6	1.9
V	1.8	3.5	10.1	0.3
Zn	2.0	2.0	4.7	4.0

4. Conclusions

Ultrasound energy focused in a glass probe is a good alternative to accelerate the simultaneous extraction of elements from sediments. The process is highly repetitive and extremely fast. The recoveries obtained are comparable to those of the microwave assisted EPA 3051 method. In addition, the suspension of the sediment in the extractant is only slightly heated during the process. As a consequence: (i) possible losses of analytes by evaporation are minimised and (ii) the extract must not be allowed to cool down before going on with the general analysis procedure. The equipment involved and its maintenance is cheap, and operation safe and extremely simple. As a drawback of the technique, it should be mentioned that samples must be treated one by one but, since the analyst can go on with the general procedure as soon as the extraction process is finished, sample throughput is similar to that of a standard microwave oven. The method proposed here is appropriate for monitoring purposes, ecotoxicological studies and risk assessment.

ABSTRACT

Determination of amino acids by mass spectrometry (MS) is an important technique to investigate soil nitrogen transformation and cycling as amino acids being the major nitrogen-containing compounds in soil organic matter. However, researchers have long faced a critical problem in coupling an efficient separation technique to a sensitive MS detection system simultaneously. In this context, we established a new method of liquid chromatography coupled to mass spectrometry based on the 6-aminoquinolyl-N-hydroxysuccinimidyl carbamate (AQC) derivatization method for convenient and accurate quantification of amino acids in soil samples. Baseline separation of 17 amino acid AQC-derivatives was achieved on an XTerra^R MS C_{18} column using ammonium formate as a mobile phase modifier. The concentration of ammonium formate and the pH of the mobile phase were optimized in order to obtain sensitive MS signals. The response curves were linear over the range of 50–800 $\mu mol\,L^{-1}$ amino acids. The detection limits were 0.20–0.60 $pmol\,\mu L^{-1}$ on column and 0.07–0.24 $\mu g\,g^{-1}$ soil under the optimized conditions. The method has been applied successfully for the first time to determine amino acids in 4 types of soil samples, in which 15 amino acids were quantified by MS detector but methionine and cystine were below the detection limits. Both the recovery and the precision were satisfactory. Hence, this proposed technique shows a potential for the identification of amino acids in soil as well as tracing the transformation of soil amino acids with isotope dilution technique in nitrogen cycling investigation.

1. Introduction

Amino acids are the main component in soil organic matter and play important roles in soil nitrogen (N) biogeochemical cycling in terrestrial ecosystems [1]. Quantitatively speaking, around 20–50% of total N in soil organic matter was found in the form of amino acids, which are mainly present in peptide or protein and can be released by acid hydrolysis [2–5]. Hence, the determination of amino acids in soil and tracing the transformation process of amino acids became a powerful tool in characterizing N turnover in soil.

Although various methods have been applied to quantify amino acids in soil samples, mass spectrometry (MS) is still a promising technique especially for the selective measurement of the compounds at low concentrations in complex matrix and has a great potential for the application to the compound-specific isotope enrichment investigation [6,7]. Theoretically, it is unnecessary to separate the target compounds in MS detection; however, there are still some limitations mainly occurred in the following three cases: (1) the isomass compounds cannot be separated by mass; (2) the "chemical suppression" phenomenon in ion trap is brought when several molecules are co-eluted and ionized together; and (3) in a lesser extent, the presence of isotopes can interfere with other molecules, especially when the mass difference is 1 or 2 only [8]. Therefore, the good chromatography separation is still essential for sensitive MS analysis.

Gas chromatography–mass spectrometry (GC–MS) has been used to identify amino acids and trace isotope enrichment in target compounds [9–13]. However, a complex and laborious derivatization procedure has to be conducted before GC determination. For example, two steps of reactions at 110 and 150 °C are required to form pentafluoropropionyl isopropyl ester derivatives of amino acids. Even though, it is still difficult to ensure complete derivatization of arginine and histidine. As a result, the reproducibility of the

doi:10.1016/j.talanta.2009.07.013

derivatization is not always satisfied under such rigorous reaction conditions [13].

Compared with GC–MS, liquid chromatography–mass spectrometry (LC–MS) is more convenient for both amino acid separation and isotope enrichment measurement due to easier sample preparation. Traditionally, amino acid isolation can be achieved by ion-exchange liquid chromatography [14–16], but the high salt concentration in modifier is not suitable for MS detection. Hence, amino acid analyses without derivatization have been re-updated for MS detector [16] and the separation under this condition is usually achieved by ion-pair reversed-phase liquid chromatography [8,17–22]. Although the procedure without derivatization can reduce the errors introduced by side reactions and reagent interferences, there are still some notable disadvantages that cannot be overcome at present. Firstly, because the molecular weight of most amino acids is below 200, the interference from the mobile phase and sample matrix are obvious for the fragmentation acquirement of individual amino acids [8,17,19,23]. Hence the specific MS/MS detection has to be adopted for a satisfactory quantification of amino acids in the complex matrix, for instance soil samples [17,23]. Secondly, the detection limits of most amino acids are bigger than 1 pmol, much higher than that of UV or fluorescence detection [23]. Thirdly, some widely used ion-pair reagents, such as perfluoroheptanoic acid (PFHA) [19] can be accumulated in the column slowly. PFHA would change the surface of the stationary phase of the column, and furthermore, influence the reproducibility and separation significantly. As a result, the column has to be flushed frequently with pure organic solvent during analysis process, and this prolongs the analysis time and makes the process more complicated.

In this context, the pre-column derivatization method is more promising for amino acid analysis by liquid chromatography. The commonly used derivatization reagents include *ortho*-phthalaldehyde (OPA) [24,25], phenyl isothiocyanate (PITC) [26–29], 2-(9-fluorenyl)-ethyl chloroformate (FMOC-Cl) [30–33], 2-(9-carbazole)-ethyl chloroformate (CEOC) [34] and 6-aminoquinolyl-N-hydroxysuccinimidyl carbamate (AQC) [35]. The AQC derivatization technique for the analysis of amino acids was established by Cohen and Michard [35] and was commercialized by the Waters Co. Ltd. Notable advantages of this method included rapid, sensitive, quantitative and linear reactions [36]. In the past 15 years, AQC derivatization has been used in a wide variety of samples including amino acid nutrients in feed grain hydrolyzates [37,38], non-amino acid analytes such as polyamines [39] and incompletely hydrolyzed peptides [40,41] as well as nicotianamine and amino acids in some metal-hyperaccumulating plants [42]. Compared with other derivatization reagents, the compatibility of derivatization in the presence of salts makes the AQC reagent as the preferred choice for the amino acid analysis in complex samples. However, the identification and quantification of AQC–amino acid derivatives with mass spectrometer has not been reported until today, especially in soil samples. The reason, to our knowledge, is just due to the use of the non-volatile modifier in the mobile phase for obtaining good separation [35–37]. The non-volatile components will bring noisy background, and consequently, decrease the sensitivity of the MS system and affect the accuracy of quantification seriously [43]. In practice, the non-volatile modifiers in mobile phase are either removed by using on-line membrane suppressor or replaced by volatile modifier in order to be compatible with MS, but unfortunately, this attempt does not always give identical resolution for the analyzed compounds.

In a word, there is still a need to optimize the mobile phase for achieving both good resolution and high sensitivity of amino acid identification and quantification if AQC-derivatization technique is applied. Our objective is, therefore, to develop a new LC–MS method for the determination of amino acids in soil samples, providing a new choice for tracing the dynamics of amino acids in soil.

2. Experimental

2.1. Soils and reagents

2.1.1. Soils

Four types of surface soil samples (0–20 cm) were collected in 2006 across four provinces in China for amino acid determination. The physical and chemical characteristics of the tested soils are significantly different and main properties were listed in Table 1.

2.1.2. Reagents

AccQ. Fluor reagent kit (consisting of AQC reagent, acetonitrile and 0.2 mmol L^{-1} sodium borate buffer, pH 8.8) as well as glass reaction tubes (6 × 50 mm) were provided by Waters Co. Ltd. (Milford, MA, USA). Amino acid standard solution was purchased from Pierce (Rockford, IL, USA) and it contains 17 amino acids including alanine (Ala), arginine (Arg), aspartic acid (Asp), cystine (Cys–Cys), glutamic acid (Glu), glycine (Gly), histidine (His), isoleucine (Ile), leucine (Leu), lysine (Lys), methionine (Met), phenylalanine (Phe), proline (Pro), serine (Ser), threonine (Thr), tyrosine (Tyr), and valine (Val). The concentration of each amino acid is 2.5 mmol L^{-1}. Ultra-pure water was generated using a Milli-Q water purification system (Millipore, Milford, MA, USA). HPLC-grade acetonitrile (ACN) and formic acid (>96.0%) were purchased from DIKMA Tech. Inc. (Richmond Hill, ON, USA). L-2-aminobutyric acid (AABA) (>99.0%) and Dowex 50WX8 cation exchange resin (100–200 mesh) was bought from Sigma–Aldrich Inc. (St. Louis, MO, USA). Parafilm® was the product of Alcan Packaging Co. Ltd. (Neenah, WI, Canada). Ammonium formate was purchased from Yili fine chemical Co. Ltd. (China). HCl, $NH_3{\cdot}H_2O$ and oxalic acid were also purchased in China and are all analytical-grade (Shenyang, LN, China).

2.2. Pre-column derivatization with AQC

A set of amino acid standard mixture solutions containing 200 μmol L^{-1} of internal standard was prepared at a concentration range of 50–800 μmol L^{-1}. A portion of 10 μL of each standard mixture solution was pipetted into the bottom of a glass tube, and then 110 μL sodium borate buffer (0.2 mmol L^{-1} at pH 8.8) was added. After 15 μL of AQC (10 mmol L^{-1} in acetonitrile) was added, the glass tube was closed with Parafilm^R and heated for 20 min at 55 °C to form AQC–amino acid. Thereafter, the solution was cooled down to room temperature and 10 μL portion of each solution was injected into the HPLC-ESI-MS system for amino acid analysis without further purification. It was reported that di-AQC substituted derivatives were dominantly formed for lysine and cystine, while the other tested amino acids reacted with AQC at 1:1 ratio [42].

2.3. Samples hydrolysis and purification

Soil amino acids in bound forms were liberated by acid hydrolysis and the hydrolyte was purified before derivatization to remove the interfering organic components and metal ions in soil matrix. The hydrolysis and purification process was conducted according to the method of Amelung and Zhang [13]. Briefly, 200–250 mg of the air-dried and sieved (< 0.25 mm) soil samples was weighted accurately, and then hydrolyzed with 20 mL of 6 mol L^{-1} HCl for 12 h (105 °C). After 80 μL of 2.5 mmol L^{-1} L-2-aminobutyric acid addition, the hydrolyte was filtered. The filtrate was dried using a rotary evaporator (<45 °C) and the residue was re-dissolved in 4 mL of 0.05 mol L^{-1} HCl. The solution was then transferred into a polypropylene column of 25 mL (BioRad Laboratories, Munich, Germany), which was filled with 3 g Dowex 50WX8 cation exchange

Table 1
Some properties of the soil samples studied.

Soil types (based on FAO classification)	Sampling site (city, province)	Location	Content of total organic carbon (g kg^{-1})	Content of total nitrogen (g kg^{-1})	pH (water:soil = 2.5:1)
Ultisol	Yingtan, Jiangxi	115°50′E 28°46′N	7.68	1.07	5.5
Alfisol	Shenyang, Liaoning	123°24′E 41°31′N	11.34	1.21	6.0
Inceptisol	Gongzhuling, Jilin	124°40′E 43°36′N	12.51	1.52	7.1
Mollisol-1	Hailun, Heilongjiang	126°38′E 47°26′N	29.32	2.42	6.3
Mollisol-2 (fertilized)	Hailun, Heilongjiang	126°38′E 47°26′N	35.50	3.14	6.0

resin for sample purification. After being rinsed with 5 × 5 mL of 0.1 mol L^{-1} oxalic acid (pH 1.6–1.8, adjusted with $NH_3{\cdot}H_2O$), 5 × 5 mL of 0.01 mol L^{-1} HCl and 5 mL of de-ionized water in turn, the amino acids were eluted with 5 × 5 mL of 2.5 mol L^{-1} $NH_3{\cdot}H_2O$. The eluted solution was also dried by rotary evaporator (<45 °C), and re-dissolved in 4 mL 0.1 mol L^{-1} HCl. After being centrifuged, the supernatant was freeze-dried and then was dissolved with 700 μL of 0.02 mol L^{-1} HCl. Finally, a portion of 10 μL solution was used for derivatization as described in Section 2.2.

2.4. LC–MS system

The Waters 2695 LC–MS systems (USA) was used and it is equipped with four pumps, Waters 996 photodiode array detector for ultraviolet detection and ion trap mass spectrometer with electrospray ionization (ESI) source (Waters micromass ZQ4000, USA). Waters MassLynx 3.5 software was used for data analysis. The separation of amino acid derivatives was carried out on an XTerra^R MS C_{18} column (3.5 μm, 150 mm × 2.1 mm I.D.) maintained at 35 °C. L-2-aminobutyric acid was used as internal standard and the injection volume of sample solution was 10 μL. The mobile phase consisted of three solvents: 1.5 mmol L^{-1} ammonium formate in water (solvent A, pH 3.0, adjusted with formic acid), acetonitrile (solvent B), and water (solvent C). The gradient profile was listed in Table 2. The wavelength λ = 248 nm was used for ultraviolet detection and the analysis time was 50 min.

The operation conditions of MS detector were optimized using a 17 AQC–amino acid standard at 50 μmol L^{-1} and the derivatives were infused into the ESI-MS system with the flow rate of mobile phase at 0.2 mL min^{-1}. The MS detection conditions were set as: capillary voltage, 3000 V; cone voltage, 25 V; extractor and RF lens voltage, 4 and 0.4 V, respectively; ion source temperature, 105 °C; desolvation temperature, 120 °C; desolvation gas flow (N_2), 2.5 L min^{-1}; and cone gas flow (N_2), 1.7 L min^{-1}. Under the full scan mode (the mass range was 220–900), the signal intensity of m/z $[M+H]^+$ on the positive ion mode was maximal for most amino acids, but for lysine and cystine derivatives, m/z 244 and 291 was the most abundant, respectively.

2.5. Quantification technique and method validation

The internal standard method was applied for amino acid quantification and it was done by calculating the ratio between the integration of the most abundance peak (i.e., m/z $[M+H]^+$) of the target amino acid and that of AABA, but m/z 244 for lysine and 291 for cystine were better than m/z $[M+H]^+$. The same procedure was employed to plot calibration curves and six standard mixtures at concentrations of 50, 100, 200, 400, 600 and 800 μmol L^{-1} were prepared for the linearity calculation of the MS detector. The detection limits (LOD) were determined by the direct injection of the amino acids standard solution at 5 μmol L^{-1} and then calculated based on the signal to noise ratio of 3. Ten μL of 2.5 mmol L^{-1} amino acid standard mixture solution was spiked to a Mollisol-1 sample to evaluate the recovery of individual amino acids. The determination procedure of amino acids in the spiked soil was the same as described above.

In addition, the amino acids in soil samples was determined by a amino acid auto analyzer (Hitachi L-8800, Japan), an independent technique, to test the accuracy of the proposed MS method. The operation conditions of the instrument were set as follows: column type: 4.6 mm × 60 mm (#2622 resin); analysis column temperature: 50 °C; reaction column temperature: 135 °C; flow rate of the buffer: 0.4 mL min^{-1}; flow rate of chromogenic agent (Ninhydrin): 0.35 mL min^{-1}; injection volume: 20 μL; detection wavelength: 570 nm (440 nm for proline).

Table 2
Gradient profiles for the optimized separations of AQC–amino acids.

Time (min)	Mobile phase A (%)	Mobile phase B (%)	Mobile phase C (%)	Curve[a]
0	100	0	0	1
0.5	99	1	0	11
21	91	9	0	6
25	85	15	0	6

37	0	60	40	11
40	100	0	0	11

[a] Curve 6 is a linear segment; curve 1 and 11 are two of the step functions.

3. Results and discussion

3.1. Preliminary modification of the AQC derivatization method

As developed by the Waters Co. Ltd., sodium acetate (CH_3COONa) used in the traditional AQC method [35] has been replaced by ammonium acetate (CH_3COONH_4) for coupling to MS detector and the mobile phase contained 140 mmol L^{-1} CH_3COONH_4 (pH 4.95–5.05, titrated with acetic acid), acetonitrile and water, respectively. Unfortunately, under such conditions, no intensive MS response was acquired at the scan mode although the separation was excellent (Fig. 1). If CH_3COONH_4 was no longer used, while other conditions were kept unchanged, the intensity of MS response was enhanced significantly. However, the separation of 17 AQC–amino acids became poor (see Fig. 2). The findings indicated that 140 mmol L^{-1} CH_3COONH_4 at pH 4.95–5.05 was essential for good resolution of AQC–amino acids, but the MS response of the derivatives was restrained significantly due to high concentration CH_3COONH_4 addition. Therefore, more work should be conducted to optimize the pH and volatile modifier of the mobile phase in order to improve both the sensitivity of MS response and the resolution of AQC–amino acids.

3.2. Effect of the mobile phase pH on MS response and separation of AQC–amino acid derivatives

Mass spectrometry is a universal detection mode, and the ionization of a compound is the precondition for determination. Among different ionization modes, ESI is especially appropriate for the ionization of polar or ionic compounds such as amino acids [44]. Unlike most of other ionization processes occurring in the gas phase,

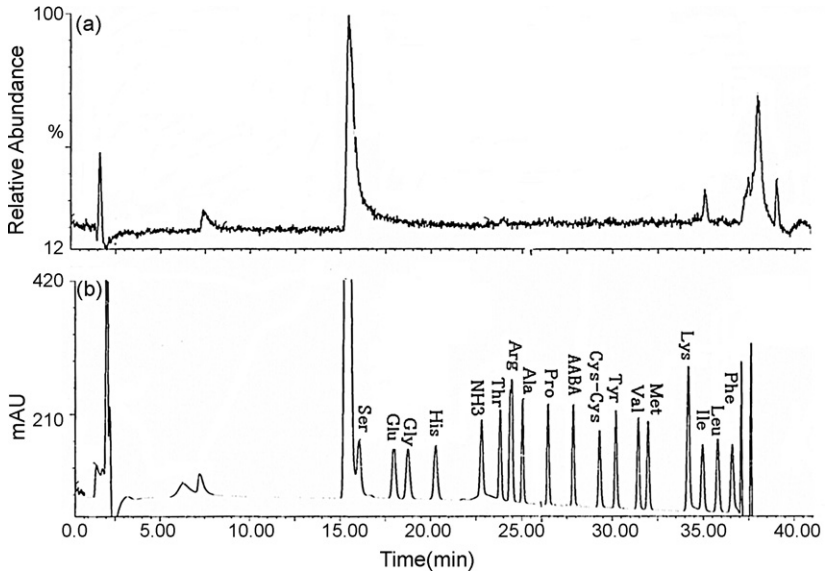

Fig. 1. LC-UV-MS analysis of AQC–amino acids (a) MS detection and (b) ultraviolet detection. Mobile phase: (A) 140 mmol L^{-1} of ammonium acetate in water (pH 4.95–5.00, titrated with acetic acid); (B) acetonitrile; and (C) water. Gradient: Initial = 100% A, 0.5 min = 99% A and 1% B, 18 min = 95% A and 5% B, 19 min = 91% A and 9% B, 29.5 min = 83% A and 17% B, hold for 4.5 min, washed with 60% acetonitrile in water for 3 min, and equilibrate with 100% A for 9 min before subsequent injection (step gradient at 0.5 min, wash and equilibration steps, liner steps for all other elution).

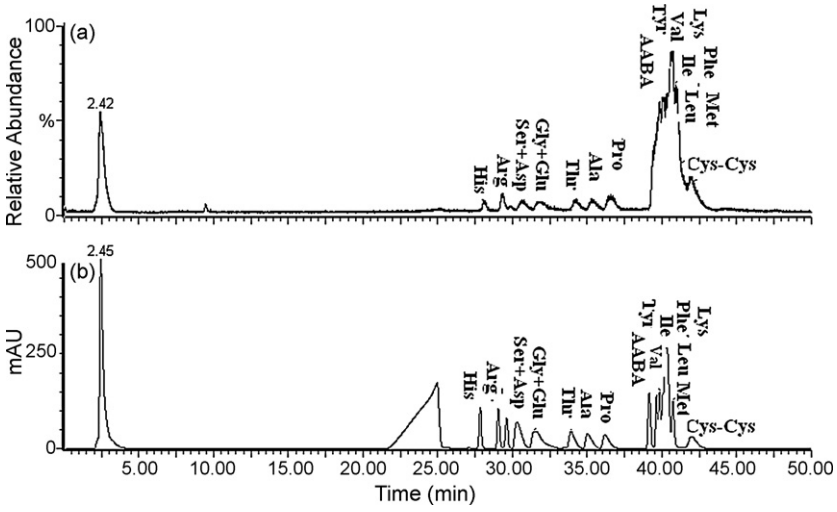

Fig. 2. Primarily modified LC-UV-MS analysis of AQC–amino acids (a) MS detection and (b) ultraviolet detection. Mobile phase: A, water solution (pH 4.95–5.00, adjusted with acetic acid); B, acetonitrile; and C, water. Gradient: Initial = 100% A, 0.5 min = 99% A and 1% B, 18 min = 95% A and 5% B, 19 min = 91% A and 9% B, 29.5 min = 83% A and 17% B, hold for 4.5 min, washed with 60% acetonitrile in water for 3 min, and equilibrate with 100% A for 9 min before subsequent injection (step gradient at 0.5 min, wash and equilibration steps, liner steps for all other elution).

electrospray ionization is the transfer of the ions present in a liquid phase into their gas phase [44]. Therefore, a prerequisite for the ionization with ESI is that the analyte exist in ion form in the solution, i.e., the AQC–amino acids in the mobile phase should be ionized intensively in order to obtain the sensitive MS response. On the basis of the reaction principle, the AQC–amino acid derivatives contain both NH and COOH groups (Fig. 3) and the ionization of the compounds was highly depended on solution pH [42]. When the pH of mobile phase A (water in this case) was adjusted by formic acid or $NH_3 \cdot H_2O$ and other conditions were kept the same as shown in Fig. 1, the ionization degree of AQC–amino acids was affected by the pH of the mobile phase A. As shown in Fig. 4, when the pH value was increased from 2.5 to 9.9, the intensity of MS signal changed greatly and the highest response was obtained between

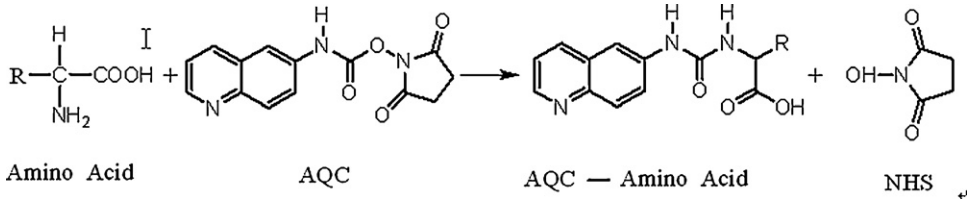

Fig. 3. The derivatization reaction model of AQC and amino acids.

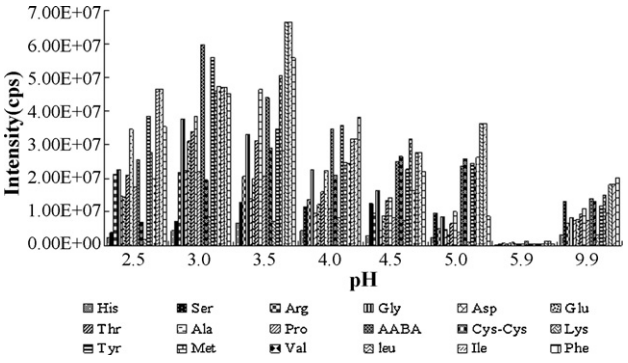

Fig. 4. The effect of mobile phase pH on MS detection of AQC–amino acid derivatives. Mobile phase: (A) water solution with pH from 2.5 to 9.9, adjusted with formic acid or $NH_3{\cdot}H_2O$; (B) acetonitrile; and (C) water.

pH 3 and 3.5, while the lowest was found at pH 5.9, suggesting that pH was a key factor to influence the sensitivity of MS response due to the occurrence of isoelectric point in amino acids. Hence lower pH of the mobile phase enhanced the ionization of the AQC–amino acids to produce positive ions in the solution [35,36]. According to the results in Fig. 4, the pH of the mobile phase was optimal between 3 and 3.5 for the MS detection of AQC–amino acid derivatives.

Not only ionization but also the retention behavior of AQC–amino acids on the column was highly related to the mobile phase pH. The separation of amino acids was improved significantly when the pH of the mobile phase was decreased from 5.0 to 3.5 even without any modifier addition. Ten of the 17 amino acids in the standard mixture were fully separated under the same gradient condition, while Arg, Ser, Ile, Leu, and Phe were partly separated and the other two pairs were co-eluted (Cys–Cys with Lys and Val with Met) (Fig. 5a). It is known that Leu and Ile should be separated absolutely for accurate quantification because they cannot be distinguished by their mass in MS detector. When the pH of the mobile phase was decreased to 3.0, only Met and Val were still co-eluted, while Leu, Ile and the other AQC–amino acids were all in the baseline separation (Fig. 5b). The results showed that pH 3.0 of mobile phase A is optimal, but the overall separation is still unacceptable, hence further optimization should be done.

3.3. Effect of ammonium formate in mobile phase on the resolution and MS response

In principle, it is unnecessary for the target compound to be totally separated from the co-eluted components when identified by MS due to different m/z acquirement, but the co-eluted ions may severely disturb the ionization process of the analyte to be measured due to so called chemical suppression effect, and consequently, it might influence the accuracy of quantification. Therefore, the baseline separation was preferred by adjusting the modifier in mobile phase. Considering excess inorganic ion can deteriorate the MS response severely even if it was volatile and beneficial to the resolution of amino acid derivatives, we attempted to add low concentration gradients of volatile modifier such as ammonium formate (the concentration is 1.0–2.5 mmol L^{-1}) to solvent A to improve the resolution of the AQC–amino acids. It was found that the separation of Cys–Cys-, Lys-, Tyr-, Met-, and Val-AQC derivatives was improved significantly with the modifier addition at 1.5–2.0 mmol L^{-1} and the sensitive MS response was also acquired at the same time (data not shown). Therefore, the concentration of 1.5 mmol L^{-1} of ammonium formate was preferred for the derivative resolution and MS detection. The determination of AQC–amino acids in both standard and soil hydrolysate under the optimized conditions was shown in Fig. 6. The separation of individual amino acids was improved due to the enhanced hydrophobic character of AQC–amino acids which results in increased retention on a C_{18} column [42]. Consequently, the interference of mobile phase on the ionization of AQC–amino acids was reduced because of the significant increase in the derivative mass (246–581) [8,17,19,23].

3.4. Validation and applicability of the method

The validation of our method was conducted at the optimized condition, i.e., the pH of mobile phase A was 3.0 by using 1.5 mmol L^{-1} ammonium formate as the modifier. In the concentration range of 50–800 μmol L^{-1}, the MS response of the AQC-amino acids showed excellent linearity (r^2 = 0.988–0.999, as listed in Table 3). The detection limits were determined by using a 5 μmol L^{-1} of a standard mixture of 17 AQC–amino acids and calculated based on the signal to noise ratio of 3. The detection limits for all amino acids were in the range of 0.20–0.60 pmol μ L^{-1} (Table 3).

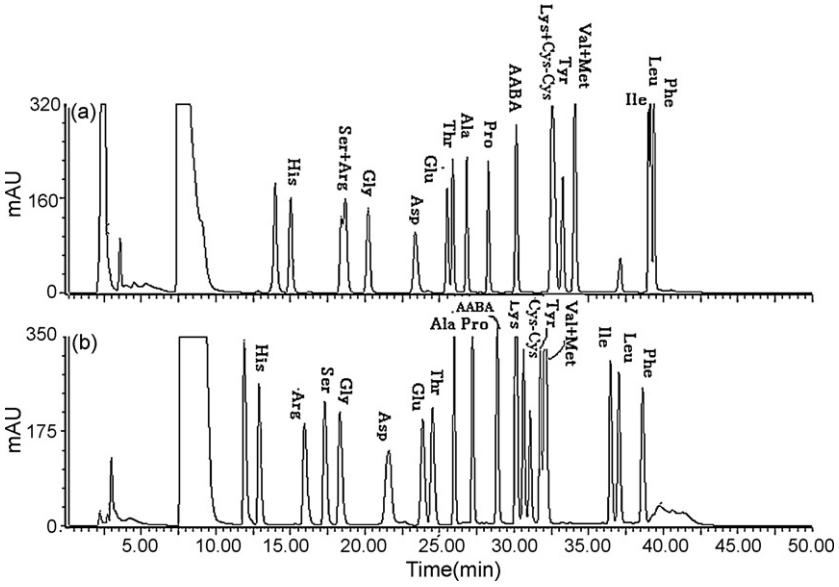

Fig. 5. Effect of mobile phase pH on the separation of AQC–amino acid derivatives at (a) pH 3.5 and (b) pH 3.0 by ultraviolet detection. Mobile phase: (A) water solution (pH 3.0 or pH 3.5, adjusted with formic acid); (B) acetonitrile; and (C) water.

Table 3
Calibration linearity, precision and detection limits of the MS method for the determination of AQC–amino acids.

Amino acid	[M + H] + ion of AQC–amino acid derivative (m/z)[a]	Calibration linearity (r^2)	Detection limit (pmol μL^{-1})	Precision (RSD%)

Phe	336	0.999	0.27	1.2	5.9

[a] The molecule weight of AQC combined with amino acid is 171.

Furthermore, we spiked a mixture of amino acid standard (10 μL of 2.5 mmol L^{-1} amino acid) to Mollisol-1 sample and the mean recovery of all amino acids ranged from 82.8% to 111.0% (Table 4). On the basis of the LOD on column, recovery and aliquot of hydrolyte solution for derivatization, the calculated detection limits of amino acids in the soil samples were in the range of 0.07–0.24 μg g^{-1} soil (Table 4), suggesting that the proposed MS method is sensitive and quantitative. The precision of the method was firstly tested using a mixed standard of 17 AQC–amino acids at the concentration of 100 μmol L^{-1}. The mixture was analyzed for six consecutive times in 1 day (intraday, $n = 6$) and 6 times in three different days (interday, $n = 6$). The relative standard deviation (RSD%) for the intraday and interday analyses ranged from 1.1% to 4.0% and from 2.3% to 8.7%, respectively (Table 3). The RSD of the LC–MS determination of the soil samples ($n = 4$) among different assays was below 10% (except tyrosine) for the very heterogeneous and complex matrix, indicating that this method was highly precise (Table 4).

AABA was recommended for the quantification of amino acids by LC analysis, while the application in MS detection should be further validated due to the possible chemical suppression in complex samples which may affect the reliability of quantification. When AABA concentration was kept as 200 μmol L^{-1} and amino acid standard in the range of 50–800 μmol L^{-1}, the intensity ratio between the selected ion of the target amino acid and AABA was strictly proportional to the corresponding concentration. And furthermore, the purification of soil amino acids was effective and the baseline AQC–AA separation was obtained in our method, which enables the quantitative determination of amino acids in soil samples. Thereby, we recommend using AABA as an internal standard without isotope labeling for routine analysis. Nevertheless, the correction of chemical suppression by stable isotope labeled amino acids is still preferred; especially when the target compounds were not well separated from their complex matrix.

Table 4
Recovery, precision and detection limit of amino acids in soil samples and concentrations of amino acids detected by MS and UV in Mollisol-1.

Amino acid	Precision (RSD%)	Recovery (%)	Detection limit (μg g^{-1} soil)	Concentrations of amino acids (μg g^{-1} soil)		
				MS detection	UV detection	MS/UV

[a] The recovery evaluation was conducted by adding a amino acid standard with known concentration to the soil samples and then to determine total amount of the amino acids in the spiked samples and the same soil samples without spiking were also determined in the same manner. The recovery was calculated by the following formula: recovery% = the amount of AAs in the spiked soils/(the amount of AAs in the original soil plus that of added AA) × 100%.

[b] The detection limits of amino acids in soil samples were calculated based on the detection limit on column and the recovery of amino acids in soil samples as well as the aliquot of hydrolyte solution for derivatization.

[c] The soil samples were determined in four replicates (n = 4) and the confidence level was 95%.

[d] Concentrations were below detection limits.

Table 5
Concentrations of amino acids in four different soils determined by the proposed method (data 1) and amino acid automatic analyzer (data 2).

[a] The soil samples were determined in three replicates ($n = 3$) and the confidence level was 95%.
[b] Concentrations were below the detection limits (not reliable enough).

To test the applicability of the method for a broad range of soils, we analyzed amino acids in five samples representing different types of soil with significantly different properties, especially soil organic matter (SOM) and total nitrogen (TN) contents. The soil samples are classified as Ultisol, Alfisol, Inceptisol, and Mollisols (Mollisol-1 and 2), respectively. The amino acid contents in the soil samples were determined firstly by our MS method (Table 5) and it was found that the concentration of all amino acids was in different range, which is accordant with that from other studies [5]. In order to test the reliability of the method, the amino acids in Mollisol-1 sample was also analyzed by the UV detector online with the MS detector on the same condition (see Table 4). Both total and individual amino acid concentrations determined by the two detectors were very close, suggesting that the quantitative results by the MS detector are reliable. In addition, the contents of amino acids in soil samples were determined independently by using a widely accepted method, the amino acid automatic analyzer. We found that the concentrations of most amino acids are identical between the two independent methods, though significant difference was observed for lysine, isoleucine and tyrosine (Table 5). The reason, to our opinion, is mainly derived from the different principles for amino acid determination. Each amino acid was quantified by the selective ion ($[M+H]^+$ or the fragment with the most abundance) in our method, while it was evaluated by the total area of its chromatogram peak in the amino acid automatic analyzer technique. The separation of isoleucine was excellent in both standard and soil samples under the two detection techniques, but its concentrations in the Inceptisol was significantly higher detected by amino acid automatic analyzer. This might have been attributed to the interference from the co-elution of soil impurities because not all the impurities in soil hydrolysis can be removed during purification. If this happens, it is known for sure that the quantification from amino acid automatic analyzer detection should be influenced more significantly than those from our MS detection. In this context, the amino acid automatic analyzer method could result in overestimation of isoleucine. On the other hand, chemical suppression may influence the accuracy of MS quantification for the co-eluted amino acids (lysine and tyrosine in our case), especially for those with low concentrations, so the concentration of tyrosine might be erratically determined by our MS method. However, tyrosine is a minor amino in soils and its quantification result does not influence the interpretation of the whole picture of soil amino acids. The concentrations of cystine and methionine in the tested soils were below detection limits from both methods, but the recoveries and sensitivity of the two amino acids were quite high, inferring that it is still possible to quantify the two amino acids while increasing soil sample amounts.

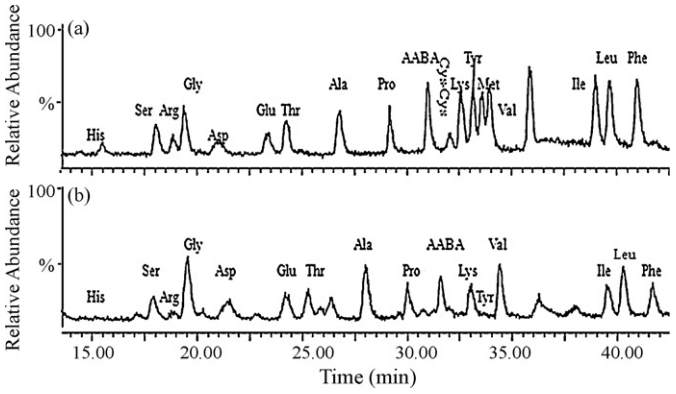

Fig. 6. The total ion current chromatogram of amino acids in standard (a) and soil samples (b) under the optimized mobile phase conditions. Mobile phase: (A) 1.5 mmol L^{-1} of ammonium formate in water (pH 3.0, titrated with formic acid); (B) Acetonitrile; and (C) water. Gradient conditions: Initial = 100% A, 0.5 min = 99% A and 1% B, 21 min = 91% A and 9% B, 25 min = 85% A and 15% B, 35 min = 83% A and 17% B, hold for 2 min, washed with 60% acetonitrile in water for 3 min, and equilibrate with 100% C for 10 min before subsequent injection (step gradient at 0.5 min, wash and equilibration steps, liner steps for all other elution). The flow rate of mobile phase was set at 0.2 mL min^{-1} and the analysis time was 50 min.

4. Conclusion

A new method of liquid chromatography coupled to mass spectrometry was established for convenient and accurate quantification of amino acids in soil samples. The method is based on the use of pre-column AQC derivatization as well as the optimization of mobile phase conditions, especially of pH and ammonium formate concentration. In addition, the sensitivity, linearity and detection limits of amino acids by using MS detector were assessed strictly. Finally, the method is validated by the calculation of the recoveries of the amino acids in the spiked soil and the comparison of the results quantified by the MS detector and UV detector as well as by the two independent methods. All findings indicate that the

proposed MS method can be practically applied for the determination of amino acids in a wide range of soil samples. It is the first time that 15 amino acids in soil have been quantified by HPLC-MS and thus, the technique shows a potential for tracing the transformation of soil amino acids with isotope technique for N transformation and cycling investigation.

ABSTRACT

CE/Ru(bpy)$_3^{2+}$ electrochemiluminescence (ECL) system with the assistance of ionic liquids (ILs) was successfully established for sensitive determination of verticine and verticinone in *Bulbus Fritillariae* for the first time. Migration behavior of alkaloid largely relies on the hydrogen bonding interactions between alkyl imidazolium cations in ILs and the alkaloids. Running buffer containing 40 mmol/L 1-butyl-3-methylimidazolium tetrafluoroborate ($BMImBF_4$) IL–8 mmol/L phosphate resulted in significant changes in separation selectivity for alkaloids with similar structures. The highest sensitivity of the detection was obtained by maintaining the detection potential at 1.2 V. Under the optimized conditions, relative standard derivations of the ECL intensity and the migration time were 3.27 and 2.84% for verticine and 4.42 and 1.69% for verticinone, respectively. The standard curves were linear between 1×10^{-8} and 1×10^{-6} mol/L for verticine and between 5×10^{-8} and 1×10^{-6} mol/L for verticinone, respectively. Detection limits of 1.25×10^{-10} mol/L for verticine and 1×10^{-10} mol/L for verticinone were obtained (S/N = 3). Developed method was successfully applied to determine the amounts of alkaloids in *Bulbus Fritillariae*.

1. Introduction

In the last few decades, the research and development of bioactive ingredients of traditional medicines has attracted international scientific attention [1,2]. *Bulbus Fritillariae* is a famous Chinese crude herb, which has been used as one of the most important antitussive and expectorant drugs thousands of years ago. Pharmacological studies demonstrate that verticine and verticinone in *Bulbus Fritillariae* are the primary active ingredients responsible for the antitussive activity [3,4]. Then, work on the quality control and quantitative analysis of verticine and verticinone in *Bulbus Fritillariae* is very necessary.

Verticine and verticinone are non-chromophoric, which makes the use of direct UV detection without pre- or post-column derivatization impossible. Molecular structures of verticine and verticinone are shown in Fig. 1. Ding et al. [5] and Li et al. [6] analyzed major pharmacologically active alkaloids of *Fritillaria* species by a HPLC method with prederivatization. Also, a method of pre-column derivatization GC was developed for the determination of major steroidal alkaloids in *Bulbus Fritillariae* [7]. Liu et al. [4] and Jin et al. [8] described high-speed counter-current chromatography coupled with evaporative light scattering approach used for the separation and purification of verticine and verticinone from *Bulbus Fritillariae thunbergii*. However, no detection limits for verticine and verticinone were given in their methods. By using HPLC-evaporative light scattering detection in combination with a low-temperature adapter, Li et al. determined the major biologically active isosteroidal alkaloids in *Bulbus Fritillariae* [9]. In addition, HPLC–MS [10] and direct GC method [11] were used for the analysis of *Fritillaria* alkaloids. However, a major drawback of the methods mentioned above appears to be low sensitivity and time-consuming due to necessary derivatization although the several alkaloids could be detected simultaneously in such procedures. Therefore, it is necessary to establish sensitive, rapid and effective methods for the quantization of verticine and verticinone in *Bulbus Fritillariae*.

Electrochemiluminescence is a means of converting electrical energy into radiative energy [12]. Among a wide range of ECL reagents, Ru(bpy)$_3^{2+}$ ECL has received considerable attention as a sensitive detection technique in chemical analysis because of its excellent stability and high efficiency in the aqueous phase. ECL based on Ru(bpy)$_3^{2+}$ has found many applications such as in immunoassays and for detection of a number of biologically important species without derivatization [13–15].

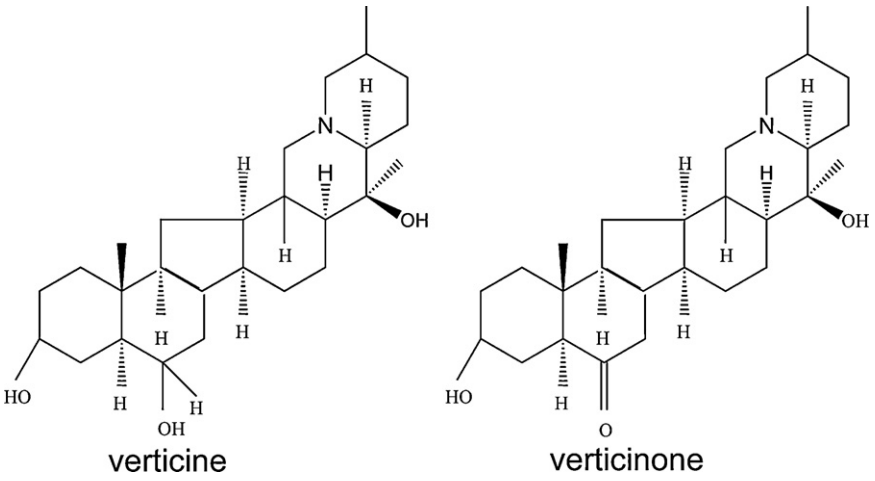

Fig. 1. Molecular structures of verticine and verticinone.

Capillary electrophoresis–Ru(bpy)$_3^{2+}$ electrochemiluminescence method (CE–ECL) has been proved as a highly efficient and sensitive analytical technique for the determination of medicines and biomaterials containing no strong chromophores. The technique has been applied to the measurement of active ingredients in Chinese traditional medicine [16–20].

IL is a new advanced material with potential use in various fields of modern chemistry because of its special chemical and physical properties [21–23]. ILs are frequently used as electrolyte since it shows reasonable ionic conductivity, hydrophobicity, polarity and selectivity. Due to higher conductivity and lower viscosity of 1-ethyl-3-methylimidazolium tetrafluoroborate (EMImBF$_4$) among ILs, it was once chosen as a representative to investigate the effect of ILs on ECL behavior of alkaloids in Chinese traditional medicine [17]. However, the influences of chain lengths and anions of ILs on CE separation and ECL behavior of alkaloids were seldom investigated.

In this paper, the coupling of CE–ECL method was employed to detect verticine and verticinone in *Bulbus Fritillariae*. Several ILs with different chain lengths and different anions were studied. BMImBF$_4$ was finally selected as the optimum running buffer for the separation of analytes. It was demonstrated to be an efficient separation system for alkaloids determination in Chinese traditional medicine. All separation and detection parameters were optimized in order to achieve good resolution and high sensitivity.

2. Experimental

2.1. Chemicals and materials

Verticine and verticinone standard samples were purchased from National Institute for the Control of Pharamaceutical and Biological Products, Ministry of Health (Beijing, China). The purity of the verticine and verticinone standards is over 99%, and they can be used directly in the experiment without further purification. Tris(2,2′-bipyridyl) ruthenium (II) chloride hexahydrate was purchased from Aldrich Chemical Co. (Milwaukee, WI, USA). Chinese herb *Bulbus Fritillariae* was obtained from various areas of China and from National Institute for the Control of Pharmaceutical and Biological Products, Ministry of Health (Beijing, China). EMImBF$_4$, BMImBF$_4$, 1-octyl -3-methylimidazolium tetrafluoroborate (OMImBF$_4$), 1-hexadecyl-3-methylimidazolium tetrafluoroborate (HMImBF$_4$) and 1-butyl-3-methylimidazolium hexafluorophosphate (BMImPF$_6$) used in this work were synthesized by Centre for Green Chemistry and catalysis, Lanzhou Institute of Chemical Physics, Chinese Academy of Sciences following the procedure described elsewhere [24], and the starting materials were obtained from Sigma–Aldrich (Steinheim, Germany). Borax, phosphate, sodium hydroxide, acetonitrile, ethanol, methanol, chloroform and ammonia were from Beijing Chemical Reagent Factory (Beijing, China). All reagents used in the analysis were of analytical purity and used without further purification.

2.2. Preparation of standard solutions

The stock solutions of verticine and verticinone were prepared by dissolving the standard samples in methanol and stored at 4 °C in a refrigerator. A series of standard solutions with suitable concentrations were prepared by diluting the solution with methanol. Other various running buffers with different concentrations were prepared with double-distilled water.

2.3. Extraction of verticine and verticinone from Bulbus Fritillariae

The crude alkaloid extracts were from seven *Fritillaria* species: *Fritillaria hupehensis*, *Fritillaria walujewii*, *Fritillaria cirrhosa*, *F. thunbergii*, *Fritillaria ussuriensis*, *Fritillaria pallidiflora and Fritillaria przewalskii.* About 0.2 g herbal medicine powdered was weighted accurately, alkalinized with 0.2 ml ammonia, extracted for 30 min with 3 ml of chloroform as the extraction in an ultrasonic bath. The extraction was repeated two times. The extracts were combined and evaporated at room temperature. The dry residue was resolved in 1 mL methanol and filtered through a 0.45 μm membrane before use.

2.4. Apparatus and analysis conditions

The detection of analytes was employed by an ECL system (Xi'an Remax Electronics Co. Ltd, Xi'an, China). Electrophoresis was driven by a high-voltage power supply (Spellman Electronics Corp., Plainview, NY). A three-electrode configuration was used in the detection system consisting of a 500 μm Pt disk as a working electrode, Ag/AgCl as a reference electrode and Pt wire as a counter electrode. The end-column ECL detection was employed by using a wall-jet configuration. Detection voltage was set at 1.2 V. The distance 150 μm between working electrode and separation capillary was aligned setting with the aid of an optical microscope. The voltage of photomultiplier tube for collecting the ECL signal was set at 800 V. ECL detection reservoir used herein is the same as that reported previously [25]. In the reservoir, a solution of 5 mmol/L Ru(bpy)$_3^{2+}$ and 50 mmol/L phosphate buffer was replaced once for 2 h.

Separations were performed in a 58 cm long fused-sillica capillary (Yongnian Optical Fabric Factory Hebei, China) with a 50 μm internal diameter and 360 μm outer diameter. Methanol was used as solvent for verticine and verticinone. Electrokinetic injections were performed at 16 kV for 3 s. Separation voltage was set at 16 kV. A new capillary was filled with 0.1 mol/L NaOH overnight. At the beginning of experiment each day, the capillary was activated with 0.1 mol/L NaOH for 5 min, followed by double-distilled water for 5 min and running buffer for 5 min so as to maintain an active and reproducible inner surface. 40 mmol/L $BMImBF_4$–8 mmol/L phosphate (pH 8.00) was used as a running buffer. Every run was repeated at least three times under the same conditions.

3. Results and discussion

3.1. Method optimization

3.1.1. Selection of detection potential

Preliminary static experiments are necessary to acquire useful information about verticine and verticinone. Cyclic voltammetries under the static conditions were performed. As is shown in Fig. 2 inset, the oxidation current of $Ru(bpy)_3^{2+}$ (solid line) increased to a peak at about 1.18 V. In the presence of verticine (dash line), rise in the anodic current and fall in the cathodal current, a marker of catalytic effect of $Ru(bpy)_3^{2+}$, were observed as the potentials were scanned to +1.19 and −1.10 V, respectively. In addition, similar catalytic effect produced by verticinone (dash line) was observed. Fig. 2 shows the corresponding ECL responses. It can be seen that the enhancement to $Ru(bpy)_3^{2+}$ ECL by verticine and verticinone is quite similar. The possible reason is two alkaloids have the similar structures. The $Ru(bpy)_3^{2+}$ ECL intensity increased by about 5 times for verticine and verticine, respectively. The results showed that the ECL method was sensitive for verticine and verticinone detection.

In CE–ECL system, the intensity of light depends on the rate of light-emitting reaction and the reaction rate is decided by the applied potential. Therefore, the influence of applied potential on ECL intensity was studied in the range from 0.9 to 1.4 V, and the results were illustrated in Fig. 3. No evident ECL signal was observed below 1.0 V. The ECL intensities of two alkaloids enhanced with the increasing of potential from 1.0 to 1.2 V and then decreased after 1.2 V. The most sensitive detection potential for verticine and verticinone should be maintained at 1.2 V.

3.1.2. Effects of injection condition

Electrokinetic injection volume is directly proportional to the injection voltage and the injection time, respectively. Effect of injection time and injection voltage was studied by increasing the injection time ranging from 2 to 8 s and by adjusting injection voltage from 10 to 18 kV, respectively. Long injection time and excessive injection voltage led to strong ECL signal and low resolution between verticine and verticinone due to the introduction of more analytes. However, when shorter injection time and lower injection voltage were used, it was difficult to obtain favorable ECL intensity of analytes though high column efficiency could be achieved. Then, electrokinetic injection for 3 s at 16 kV was used as a compromise in this experiment.

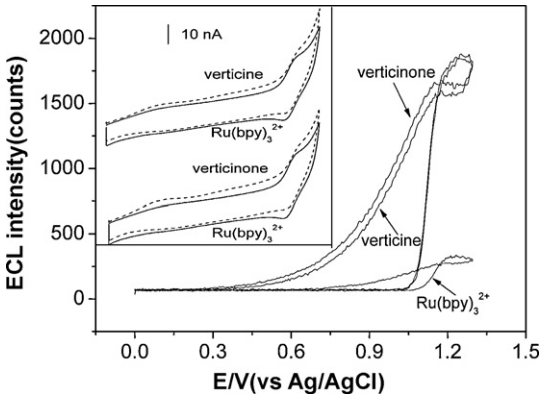

Fig. 2. Electrochemical and ECL responses of $Ru(bpy)_3^{2+}$ and alkaloids on cyclic scanning. BGE, 3 mmol/L $Ru(bpy)_3^{2+}$ in 25 mmol/L phosphate buffer at pH 8.0; analytes concentration: verticine, 1×10^{-7} mmol/L; verticinone, 1×10^{-7} mmol/L; Scan rate, 0.1 V/s.

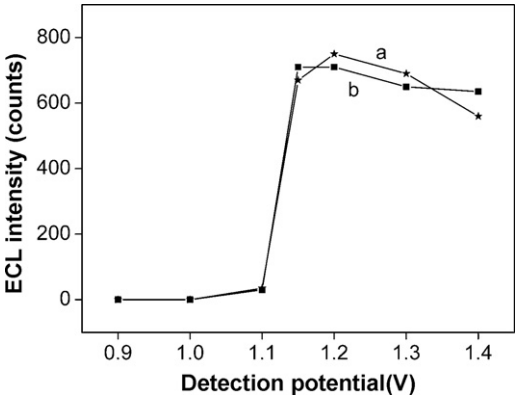

Fig. 3. Selection of detection potential: (a) ECL intensity of 1×10^{-6} mol/L verticine and (b) ECL intensity of 1×10^{-6} mol/L verticinone. 5 mmol/L $Ru(bpy)_3^{2+}$ and 50 mmol/L phosphate buffer in the detection cell; electrokinetic injection, 3 s at 16 kV; separation voltage, 16 kV.

3.1.3. Selection of solvent

At first, water was used as sample solvent, but the experimental results showed that the sensitivities of verticine and verticinone in water were not satisfactory. Verticine and verticinone are poorly soluble in water. However, they have good solubility in alcohols. To obtain the high sensitivity and good separation efficiency, the solvent was chosen from ethanol and methanol. It can be seen that the sensitivity and resolution can be improved markedly by use of alcohols. Lee et al. studied the effect of organic solvents on the chemiluminescence intensity between $Ru(bpy)_3^{3+}$ and carbamazepine [26]. The results show the chemiluminescence signal was enhanced in the presence of alcohols, and the chemiluminescence signal in methanol system was higher than that in ethanol system. Similar to their results, methanol was found to give high ECL intensities of verticine and verticinone in our experiment. The reason is that the alcohols may improve the solubility of verticine and verticinone and result in field-amplified sample stacking in CE. Therefore, methanol was used as solvent for verticine and verticinone.

3.2. Choice of running buffer and the use of ILs

Separation in CE is generally based on differences of the charge/size ratio of the analytes in running buffer. Initial separation investigation of analytes was carried out using various buffer systems such as phosphate, borate, phosphate–borate and acetonitrile–phosphate buffers in order to study resolution and sensitivity of analytes. But only one overlapped peak was found in the electropherograms.

As the resolution of analytes in these buffer systems was not sufficient for the determination of verticine and verticinone, several ILs with different anions and different alkyl chain lengths were used for investigating the effects of ILs on CE separation.

$BMImPF_6$ and $BMImBF_4$ were elected representatives to investigate the effects of ILs with different anions on CE separation. Due

to the high viscosity and low ionic conductivity of hydrophobic $BMImPF_6$, addition of even a small quantity of $BMImPF_6$ to the electrolyte leads to increases both in the migration times and overlapped peaks. However, by employing hydrophilic $BMImBF_4$, there was significant change in separation selectivity.

ILs with different alkyl chain lengths such as $EMImBF_4$ containing ethyl alkyl chain, $BMImBF_4$ with butyl alkyl chain, $OMImBF_4$ with octyl alkyl chain and $HMImBF_4$ with hexadecyl alkyl chain were used to study the effect on the separation of verticine and verticinone. As the alkyl chain length of ILs increases, the solubility in aqueous media decreases [27]. Because of poor solubility of $HMImBF_4$ in aqueous media, it cannot be used for separation of analytes. By using $EMImBF_4$, the peaks of verticine and verticinone overlapped completely, only one peak was observed on the electrophoregram. But employing $BMImBF_4$ or $OMImBF_4$, the two peaks separated and similar ECL intensity of analytes was achieved. Compared with ILs with short alkyl chain, $OMImBF_4$ with longer alkyl chain provided better resolution between analytes. However, the improved resolution was obtained at the expense of longer analyses time.

Analogous to previously reported polyphenols separations using ILs [28], the separation mechanism largely relies on the hydrogen bonding interactions between alkyl imidazolium cations and the alkaloids. Cation in ILs is a little larger than anion in ILs and its electrostatic attraction with negative charged capillary surface would change the net charge in capillary channel. Accordingly, it would reduce EOF in electrophoresis and lead to too long migration time of verticine and verticinone, thereby affording more opportunity for the analytes to associate with the alkyl imidazolium cation. Despite the very similar structures of verticine and verticinone, favorable interactions between the alkaloids and the imidazolium cations result in different migration times for analytes and caused significant changes in separation selectivity. To maintain high resolution with a suitable analysis time, $BMImBF_4$ was finally selected for further experiments. While using $BMImBF_4$ in the running buffer, not only baseline separation of verticine and verticinone was guaranteed, but also shorter separation time than that of using $OMImBF_4$ was achieved.

The effect of $BMImBF_4$ concentration on the separation and ECL intensity of the alkaloids was studied in a concentration range from 10 to 60 in 10 mmol/L units. With increasing $BMImBF_4$ concentration, the resolution between analytes was improved gradually. When $BMImBF_4$ concentration was higher than 40 mmol/L, resolution of alkaloids changed no longer sequentially, while ECL intensity of analytes decreased. Thus phosphate with different concentrations was added into $BMImBF_4$ buffer in order to shorten analyte migration time. Effect of phosphate concentration on resolution and migration time of verticine and verticinone is shown in Fig. 4. With increasing phosphate concentration, the migration time of analytes reduced gradually and resolution between analytes increased remarkably. Finally, buffer containing 40 mmol/L $BMImBF_4$ and 8 mmol/L phosphate at pH 8.00 was found to be optimum condition for the separation of these analytes in CE–ECL system.

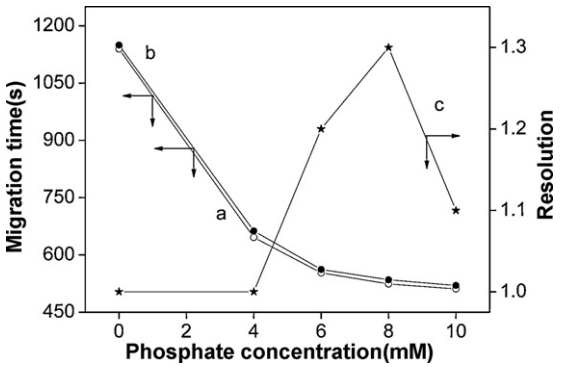

Fig. 4. Effect of phosphate concentration on resolution and migration time. (a) Migration time of verticinone, (b) migration time of verticine and (c) resolution between verticine and verticinone. Condition: detection voltage, 1.2 V; electrokinetic injection, 3 s at 16 kV; 40 mmol/L $BMImBF_4$; separation voltage, 16 kV.

3.3. Repeatability, linearity, detection limit of verticine and verticinone

Under the optimized conditions: ECL detection at 1.2 V, electrokinetic injection for 3 s at 16 kV, separation voltage at 16 kV, 5 mmol/L $Ru(bpy)_3^{2+}$ and 50 mmol/L phosphate buffer at pH 7.48 in the detection cell, 40 mmol/L $BMImBF_4$–8 mmol/L phosphate (pH 8.00) as running buffer, the reproducibility of this method was tested by six identical injections of 1×10^{-6} mol/L verticine and verticinone standard solution. Relative standard derivations of the ECL intensity and the migration time were 3.27 and 2.84% for verticine and 4.42 and 1.69% for verticinone, respectively. To investigate the detection linearity of verticine and verticinone, a series of standard mixture solutions containing verticine and verticinone were tested using CE–ECL system. The standard curves were linear between 1×10^{-8} and 1×10^{-6} mol/L for verticine and between 5×10^{-8} and 1×10^{-6} mol/L for verticinone, respectively. The calibration equations and regression coefficients were $y = 1.29 \times 10^9 x + 93.08$ and $R = 0.998$ for verticine, $y = 9.15 \times 10^8 x + 272.50$ and $R = 0.997$ for verticinone in terms of peak height response as a function of analyte concentration. Detection limits of 1.25×10^{-10} mol/L for verticine and 1×10^{-10} mol/L for verticinone were obtained (S/N = 3). Comparison of the proposed method with other methods is listed in Table 1. The developed method significantly improved limits of detection for two alkaloids between 10^2- and 10^4-fold more sensitive than those existing analytical methods and provided an appropriate linear range. The high sensitivity analysis method is better suited than existing methodology for the target analytes and sample type with sensitive, precise and reproducible performance. Further studies on the quantitative determinations of related alka-

loid in *Fritillariae* species by using the presently developed CE–ECL method are currently in progress in our research laboratories.

3.4. Applications

The proposed CE–ECL method was applied to the determination of verticine and verticinone in the extract of *Bulbus Fritillariae* under the optimized conditions. Identification of the analytes in herbal extracts was confirmed by comparing the electropherograms of diluted extracts with that of diluted extracts spiked with verticine and verticinone, where the increase of peak height at certain migration time was directly proportional to the amount spiked with verticine and verticinone. We collected seven plant samples such as *F. hupehensis*, *F. walujewii*, *F. cirrhosa*, *F. thunbergii*, *F. ussuriensis*, *F. pallidiflora and F. przewalskii.* All plant samples were detected by using standard addition method, the contents and recovery of the individual constituents in seven herbs were summarized in Table 2. The typical electropherograms including *F. hupehensis and F. walujewii* are shown in Figs. 5 and 6, respectively. The results showed the presently developed CE–ECL in combination with ILs is sensitive and efficient on the quantitative analysis of verticine and verticinone in *Bulbus Fritillariae.* Investigations into the fingerprinting

application of the proposed approach are currently in progress in our research laboratories and the results will be reported separately.

4. Concluding remarks

In this work, it was observed that the presently developed CE–ECL in combination with ILs is more sensitive and efficient than conventional HPLC and GC methods on the quantitative analysis of verticine and verticinone in *Bulbus Fritillariae.* It significantly improved limits of detection for two alkaloids between 10^2- and 10^4-fold more sensitive than those existing analytical methods. The excellent sensitivity allows quantification of low levels of alkaloids in complex *Fritillariae* species extracts. The hydrogen bonding interactions between alkyl imidazolium cations in ILs and the alkaloids caused significant changes in separation selectivity for alkaloids with similar structures. The assay is proved sensitive, simple and practicable, which is valuable addition to existing analytical tools and may be used for the determination of verticine and verticinone in *Bulbus Fritillariae*.

Fluorescence enhancement
One-step competitive assay

ABSTRACT

A novel method to significantly enhance fluorescence resonance energy transfer (FRET) signal which occurred from fluoresceine isothiocyanate (FITC) to Dylight 549 was studied in this paper. Streptavidin was labeled with the donor fluorophore FITC and biotinamide was conjugated to the acceptor Dylight 549. When biotinamide bound to streptavidin, FRET would occur from FITC to Dylight 549 while a remarkable fluorescence enhancement of streptavidin–FITC was observed. The fluorescence enhancement of streptavidin–FITC in the presence of biotin was utilized in the FRET system to obtain higher fluorescence signal. Increase of fluorescence intensity of FITC and decrease of Dylight 549 depended on the concentration of competitive biotin. A homogeneous analysis method was established based on the fluorescence recovery of FITC in the FRET system with fluorescence enhancement. This method is highly sensitive and simple to determine the concentration of biotin. The detection limit for biotin was 0.5 nM and the linear range of the assay was 0.8–9.8 nM. The response time is no more than 15 min during the one-step assay due to the high affinity between streptavidin and biotin.

1. Introduction

Fluorescence resonance energy transfer (FRET) is a non-radioactive process without the appearance of a photon. It occurs between a donor molecule in the excited state and an acceptor molecule in the ground state. The donor molecules typically emit at shorter wavelength that overlap with the absorption spectrum of the acceptor. The rate of energy transfer depends on the extent of spectral overlap of the emission spectrum of the donor with the absorption spectrum of the acceptor, the quantum yield of the donor, the relative orientation of the donor and acceptor transition dipoles, and the distance between the donor and acceptor molecules [1].

As FRET efficiency is sensitive to the distance between the donor and the acceptor, typically no more than 10 nm, it can be used as a 'spectroscopic ruler' to calculate the nanoscale distance [2]. The classic application of FRET is to study the structure of biomacromolecules and their interaction, like proteins [3] and nucleic acid [4,5]. One example of this application is to determine the conformation of an apolipoprotein when bound to lipids [6]. Krull et al. have demonstrated the potential for a simultaneous two-color diagnostic scheme for nucleic acids operating on the basis of FRET [5]. Organic dyes, fluorescent proteins (e.g. green fluorescent protein) and quantum dots [7–11] are commonly used as energy donors or acceptors with the linker such as immunocomplex [9,12,13], maltose binding protein [7,8] and streptavidin–biotin complex [14]. Streptavidin–biotin is a perfect linker in FRET owing to the strong interaction between streptavidin and biotin (Kd$\sim 10^{-15}$ mol/L) [14]. It is also a useful technique that is commonly utilized in the area of quantitative assay. FRET combined with immunoassay has been developed to detect antigens, such as β-estradiol [15,16], thyronine [17], biotin [14], urinary albumin [18] and immunoglobulin G. Su et al. have studied FRET between two quantum dots with immunocomplex of antigen and antibody as a linker and applied for the determination of the concentration of immunoglobulin G with a linear range of 0.1–20.0 mg/L [9]. A novel method combining FRET and flow-injection analysis has been proposed for the determination of vitamin B_{12} by Tang and his co-workers, with a detection limit of 1.65 μM [2]. Compared with conventional chemical analytical methods, FRET-based analysis has higher sensitivity and convenience in detection of ligand–receptor binding [19].

As a traditional fluorescent dye, fluoresceine isothiocyanate (FITC) is widely used in fluorescence analysis. It has many good properties such as high fluorescent efficiency and easy to label to proteins. Therefore, FITC can be applied as an energy donor in FRET assays. It is seldom used as an energy acceptor due to its relative short emission wavelength. Zhao et al. have investigated FRET between FITC (donor) [20] and quantum dots (acceptor) and provided a new trail of the thought for FRET research based on quantum dots. FITC served as an energy donor for quantitative analysis, for gastric cancer cell imaging [21] with tetramethyl rhodamine isothiocyanate (TRITC) as an acceptor or for DNA hybridization study [22]

with Light Cycler-Red 640 as an acceptor. FITC has also been used in assays based on fluorescence enhancement. Al-Hakiem et al. have discovered that fluorescence of FITC labeled to avidin enhanced in the presence of biotin and developed simple fluorimetric assays for avidin and biotin [23]. Smith-Palmer et al. have utilized the fluorescence enhancement of avidin–FITC by biotin to develop a flow-injection method for biotin assay [24]. However, to our knowledge, few studies have been focused on the combination of FRET and fluorescence enhancement. Dylight 549 NHS ester is a product of Pierce Biotechnology. It fluoresces over a broad pH range, matches the output wavelengths of common fluorescence instrumentation and can be excited by the emission of FITC so as to be an efficient energy acceptor with FITC donor. Additionally, the water solubility of the reagent allows a high fluor-to-protein ratio without precipitation during conjugation [25].

Herein, our overall objective of this study is to establish a simple feasible quantitative assay based of FRET as a model for the determination of biotin. Streptavidin–biotin conjugate was used as a linker in the FRET assay. FITC and Dylight 549 were selected as energy donor and acceptor, respectively. The specific binding of streptavidin–FITC and biotinamide–Dylight 549 brought the two fluorophores close enough to induce energy transfer from FITC to Dylight 549. Therefore, the fluorescence intensity of Dylight 549 enhanced while that of FITC reduced. In the presence of competitive biotin, the fluorescence intensity of Dylight 549 would reduce while that of FITC would recover. The change of fluorescence intensity could be applied for quantitative analysis of biotin. The fluorescence enhancement of streptavidin–FITC with biotin was first applied in FRET assay in our research and proved to improve the sensitivity of the method.

2. Experimental

2.1. Reagents

FITC was purchased from Amresco. Dylight 549-NHS Ester, a novel high quantum yield water soluble fluorophore, was purchased form Piece Biotechnology. Streptavidin was obtained from Promega and N-(2-aminoethyl)biotinamide from Invitrogen Corporation. D-biotin was purchased from Kangjie Biotechnology Limited Company (Shanghai, China). Sephadex G25 was the product of GE Healthcare.

2.2. Apparatus

Fluorescence experiments were recorded by a Hitachi F-4500 fluorescence spectrophotometer. Fluoroimmunoassays were carried out by a PerkinElmer 1420 multilabel counter.

2.3. Methods

2.3.1. Conjugation of fluorophores to streptavidin and biotinamide

FITC and Dylight 549, which composed the FRET fluorophore pair, were conjugated to streptavidin and biotinamide, respectively.

FITC labeled streptavidin was prepared by mixing 37.5 μL of 1 mg/mL solution of FITC in DMSO with 150 μL of 2 mg/mL solution of streptavidin in carbonate buffer (0.1 M, pH 9.10). After 2-h reaction at room temperature, the product was separated from unconjugated FITC by gel filtration on a column (1.2 cm × 10 cm) of Sephadex G25 that was equilibrated and eluted with carbonate buffer.

Dylight 549 labeled biotin was prepared by mixing 50 μL of 1 mg/mL solution of Dylight 549 in DMF with 200 μL of 1 mg/mL solution of biotinamide in carbonate buffer (0.1 M, pH 9.10). After 2-h reaction at room temperature, the reaction was terminated by adding 10 μL 1 M β-mercaptoethanol.

The fluor-to-protein ratio of streptavidin–FITC was calculated by the following formula:

$$\text{Moles dye per mole protein} = \frac{A_{\max} \text{ of the labeled protein}}{\varepsilon_{\text{flour}}} \times \text{protein concentration}\,(M)$$

Calculate protein concentrations as follows:

$$\text{Protein concentration}\ (M) = \frac{A_{280} - A_{\max} \times \text{CF}}{\varepsilon_{\text{protein}}} \times \text{dilution factor}$$

$\varepsilon_{\text{protein}}$ = protein molar extinction coefficient; CF = correction factor = $A_{280}/A_{\max}$

The fluor-to-protein ratio of streptavidin–FITC was 2.0 and the concentration of streptavidin was 7.52 μM.

The conjugate biotinamide–Dylight 549 was not purified by gel filtration because of the low molecular weight of biotinamide. The fluor-to-biotin ratio of biotinamide–Dylight 549 was assumed as 1, which was the reactive ratio of biotinamide to Dylight 549.

2.3.2. Biotin induced fluorescence enhancement of streptavidin–FITC

D-biotin solutions of various concentrations were dispensed (50 μL) into a microtitration plate. To each well 50 μL of streptavidin–FITC (0.7 μM streptavidin) was added. The final molar ratio of D-biotin to streptavidin ranged from 0.1 to 8. After 15-min reaction at room temperature, the fluorescence was measured by a PerkinElmer 1420 multilabel counter at excitation wavelength of 485 nm and emission wavelength of 535 nm.

FITC solution of 1 mg/mL was prepared in DMSO and placed overnight at room temperature so that FITC could not be labeled to proteins (–SCN of FITC was inactivated and could not react with $-NH_2$ of proteins). 1.4 μM FITC solution was obtained by diluting the 1 mg/mL FITC using carbonate buffer (0.1 M, pH 9.10). D-biotin solutions of various concentrations were dispensed (50 μL) into a microtitration plate. To each well 25 μL of streptavidin (0.7 μM) and 25 μL of FITC (1.4 μM) was added. The final molar ratio of D-biotin to streptavidin ranged from 0.1 to 8. After 15-min reaction at room temperature, the fluorescence was measured by a PerkinElmer 1420 multilabel counter at excitation wavelength of 485 nm and emission wavelength of 535 nm.

2.3.3. FRET and one-step competitive assay for determining biotin

Biotinamide–Dylight 549 solutions of various concentrations were dispensed (50 μL) into centrifuge tubes, ranging from 0 to 4.5 μM. To each tube 50 μL of streptavidin–FITC solution (0.7 μM) was added. After 15-min reaction at room temperature, 10 μL of D-biotin solution (14.1 μM) was added. Then the fluorescence was measured by a Hitachi F-4500 fluorescence spectrophotometer at excitation wavelength of 480 nm and emission wavelength ranging from 490 to 650 nm.

D-biotin solutions of various concentrations were dispensed (10 μL) into centrifuge tubes, ranging from 0 to 20.5 μM. To each tube 50 μL of biotinamide–Dylight 549 solution (biotinamide 2.8 μM) was added, followed by 50 μL of streptavidin–FITC solution (0.7 μM). After 15-min reaction at room temperature, the fluorescence was measured by a Hitachi F-4500 fluorescence spectrophotometer at excitation wavelength of 480 nm and emission wavelength ranging from 490 to 650 nm.

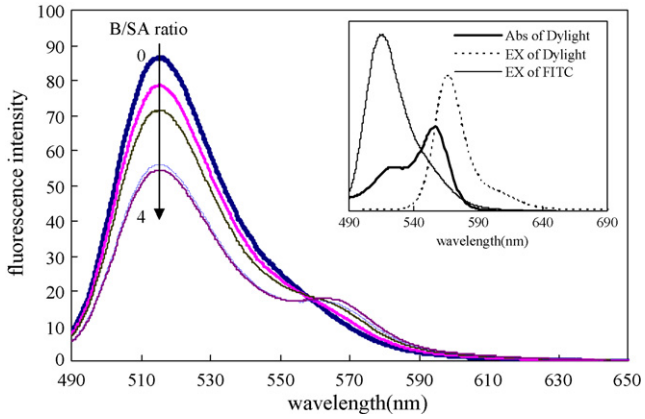

Fig. 1. The process of fluorescence resonance energy transfer between streptavdin–FTIC and biotinamide–Dylight 549. Ratios of biotinamide to streptavidin were 0, 1, 2, 3 and 4, respectively. The insert displays spectral properties of the donor FITC and the acceptor Dylight 549. The emission spectrum of FITC (excited at 480 nm), the emission spectrum of Dylight 549 (excited at 520 nm) and the absorbance spectrum of Dylight 549.

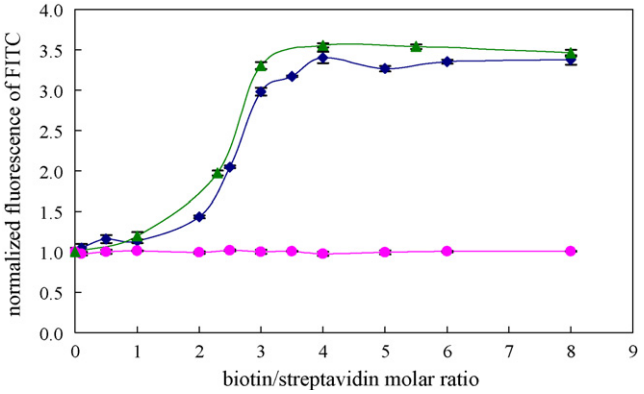

Fig. 2. The enhanced effect of biotin to the fluorescence of streptavidin–FITC. The relationship between the fluorescence of FITC and ratios of biotin to streptavidin when FITC was labeled to streptavidin (♦) and when FITC was free (●). The normalized fluorescence intensity of FITC conjugated to streptavidin in the presence of biotinamide (▲).

3. Result and discussion

3.1. Spectra characteristics of FRET system

The absorbance spectrum of Dylight 549 is from about 520 to 550 nm (Fig. 1), which mostly overlaps with the emission spectrum of FITC. So Dylight 549 can be excited effectively by the emission of FITC. Besides, Dylight 549 is emitting maximum from about 560–580 nm as shown in Fig. 1, separating from the emission spectrum of FITC. Therefore, FITC can be used as an energy donor and Dylight 549 as an acceptor in a FRET system.

FRET occurred between streptavidin–FITC and biotinamide–Dylight 549 when biotinamide specifically bound to streptavidin with FITC as an energy donor and Dylight 549 as an acceptor. The fluorescence intensity of FITC reduced while that of Dylight 549 increased as shown in Fig. 1. In order to enhance the fluorescence intensity of streptavidin–FITC to the same extent, D-biotin was added after mixing streptavidin–FITC and biotinamide–Dylight 549 for 15 min. Interaction between biotin and streptavidin was strong ($Kd \sim 10^{-15}$ mol L^{-1}), so D-biotin would not compete with biotinamide–Dylight 549 to bind to streptavidin.

3.2. The enhanced effect of biotin to the fluorescence of streptavidin–FITC

The specific binding of streptavidin and biotin enhanced the fluorescence intensity of FITC that was labeled to streptavidin. Fig. 2 showed that the enhancement of fluorescence intensity of FITC increased with the addition of molar ratio ($1 \leq$ molar ratio ≤ 4) of biotin to streptavidin. When the molar ratio of biotin to streptavidin was below 1, the fluorescence intensity of FITC was not affected. When the molar ratio increased to 4 and more, FITC reached a maximal intensity and remained the same despite a further increase in molar ratio. This phenomenon could be related to the quadrovalent nature of streptavidin (one molecule of streptavidin could bind to maximum four molecules of biotin). The fluorescence of streptavidin–FITC was enhanced by biotin to a maximum extent of about 3 to 4 fold. The fluorescence intensity of free FITC would not enhance when streptavidin and biotin mixed with it. So only the fluorescence intensity of labeled FITC can be enhanced. This can be utilized to improve the sensitivity of fluorescent quantitative analysis based on FRET.

Biotinamide would also enhance the fluorescence of streptavidin–FITC as shown in Fig. 2. The fluorescence intensity of streptavidin–FITC was enhanced by biotinamide to a maximum extent of about 3.5 fold. The trend of the curve of enhancement was similar to that of biotin on streptavidin–FITC. Thus, the enhancement by biotinamide had the same effect as by biotin. It was expected that biotinamide in the conjugate biotinamide–Dylight 549 would enhance the fluorescence of streptavidin–FITC. In the one-step competitive assay below, the molar ratio of biotinamide to streptavidin (B/SA) in all competition assays was 4:1, which would saturate the fluorescence enhancement of streptavidin–FITC. Therefore, the change of fluorescence signal was only caused by FRET between streptavidin–FITC and biotinamide–Dylight 549.

3.3. One-step competitive assay based on FRET for biotin determination

Competitive assay was carried out by mixing D-biotin and biotinamide–Dylight 549 first and then adding streptavidin–FITC. When streptavidin–FITC was added to the mixture of D-biotin and biotinamide–Dylight 549, D-biotin competed with biotinamide–Dylight 549 to bind to streptavidin–FITC. So the number of the complex FITC–streptavidin–biotinamide–Dylight 549 reduced and the probability of FRET reduced accordingly. Compared with the normal process of FRET (Fig. 1), the fluorescence intensity of FITC recovered and that of Dylight 549 reduced. The fluorescent enhancement of FITC and decrease of Dylight 549 were related to the concentration of competitive D-biotin. It was shown in Fig. 3a that the fluorescence intensity of FITC increased with the increase of the concentration of competitive D-biotin. The area under fluorescence peak of Dylight 549 was inversely proportional to the concentration of competitive biotin. It was not as expected that the fluorescence intensity of Dylight 549 reduced with the increase of the concentration of competitive D-biotin, because the fluorescence intensity of Dylight 549 was not as strong as that of FITC. So the area under fluorescence peak of Dylight 549 was used instead of fluorescence intensity.

Competitive curve for D-biotin assay was obtained by measuring the area under the fluorescence peak of Dylight 549 for different D-biotin concentrations. The fluorescence intensity of Dylight 549 was not as strong as that of FITC, so the fluorescence of FITC would influence that of Dylight 549 slightly. The concentration of D-biotin was inversely proportional to the fluorescence of Dylight 549 that was

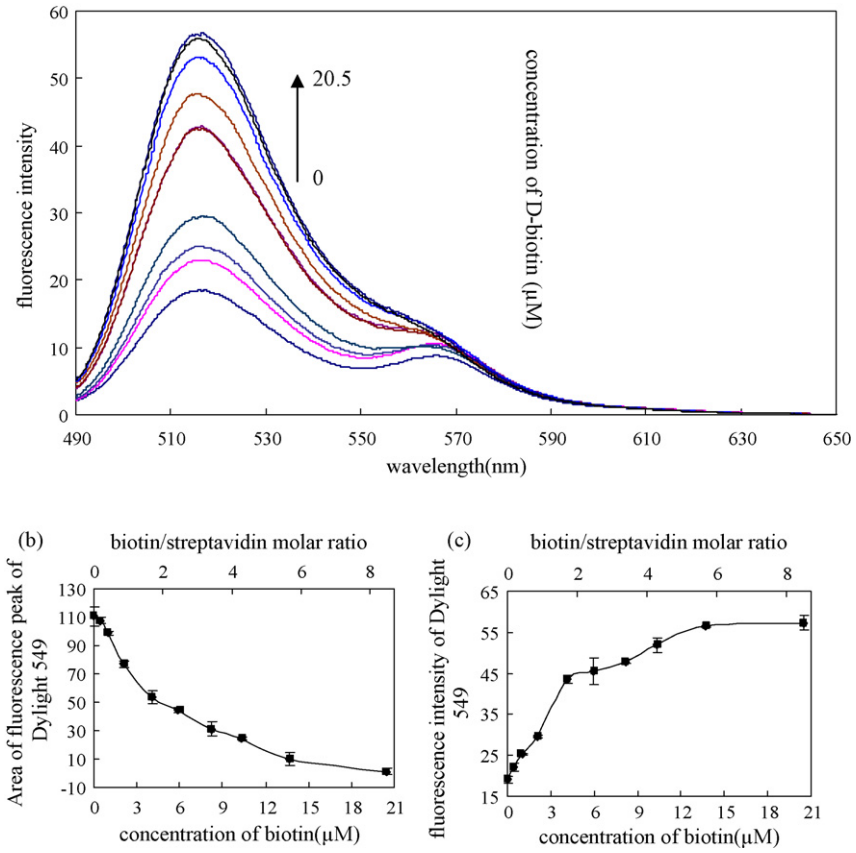

Fig. 3. (a) The relationship between fluorescence intensity of streptavidin–FITC mixed with biotinamide–Dylight 549 and different amounts of D-biotin. Concentrations of D-biotin in the samples were 0, 0.4, 1.0, 2.1, 4.1, 5.9, 8.2, 10.3, 13.7, 20.5 μM, respectively. (b) The competitive curve of D-biotin in the FRET system of streptavidin–FITC and biotinamide–Dylight 549. (c) Relationship between competitive D-biotin and the fluorescence intensity of FITC. Data were presented as average ± SD from four repeated measurements.

labeled with biotinamide as presented in Fig. 3b. The fluorescence intensity of FITC was strong enough to be used as detection signals. The concentration of D-biotin was proportional to the fluorescence intensity of FITC labeled to streptavidin as shown in Fig. 3c. Therefore, both fluorescence signals of energy donor (FITC) and acceptor (Dylight 549) can be utilized for quantitative analysis of D-biotin.

3.4. Sensitivity of the one-step homogeneous assay and analysis of real samples

The detected signals were low and the operation was complex in Hitachi F-4500 fluorescence spectrophotometer, so PerkinElmer 1420 multilabel counter was used to simplify the operation and improve the detected signals. Therefore, the sensitivity of the assay was improved.

In this experiment, the capability of quantitative analysis of D-biotin based on the streptavidin–FITC/biotinamide–Dylight 549 FRET system was investigated. Standard curve (Fig. 4) for D-biotin was obtained by measuring the fluorescence intensity of FITC while the amount of streptavidin–FITC was 7.5 nM and biotinamide–Dylight 549 was 30 nM. The reduced concentration of streptavidin–FITC and biotinamide–Dylight 549 led to low detection limits of biotin. However, streptavidin–FITC and biotinamide–Dylight 549 could not be diluted infinitely owing to detection limit of the instrument. The lowest concentrations of streptavidin–FITC and biotinamide–Dylight 549 were 7.5 and 30 nM, respectively. The lineal regression equation is $Y = 0.0451X + 1.1309$, with the regression coefficient $R = 0.9959$. In this equation, X and Y represent D-biotin contents and the normalized fluorescence intensity of FITC (in conjugate streptavidin–FITC). The linear range of D-biotin concentration is from 0.8 to 9.8 nM. For the blank test, the mixture of streptavidin–FITC and biotinamide–Dylight 549 was used as the sample and the detection limit for the proposed method is 0.5 nM based on the 3δ criterion ($n = 19$). R.S.D. of intra-assay ($n = 4$) and inter-assay ($n = 3$) of various D-biotin concentrations were less than 3.51% and 9.87%, respectively.

Pure milk purchased from native market was detected with this system. 1 mL milk was treated with 3 mL H_2SO_4 (1 M) and centrifuged at 12,000 g. The upper clear solution was adjusted to pH 9.1

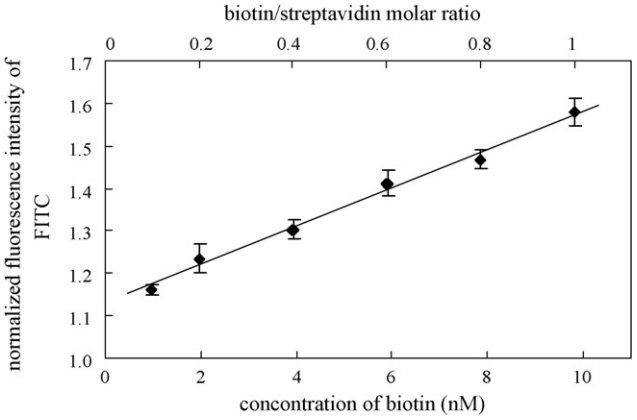

Fig. 4. Standard curve for biotin assay by measuring the fluorescence intensity of FITC based on the FRET system of streptavidin–FITC and biotinamide–Dylight 549. Data were presented as average ± SD from four repeated measurements.

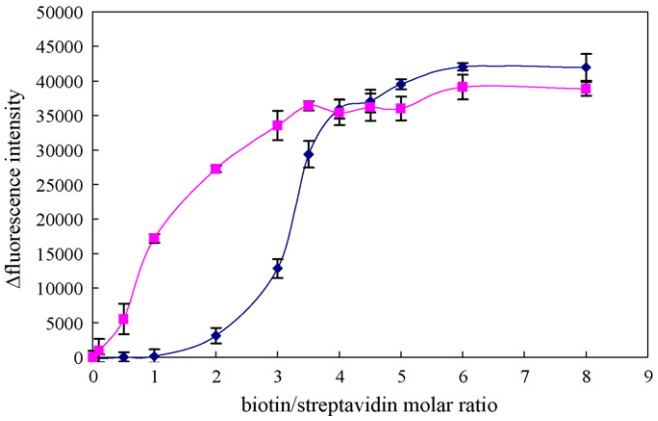

Fig. 5. The relationship between fluorescence intensity of FITC and ratios of biotin to streptavidin by the method of fluorescence enhancement (♦) and FRET based on fluorescence enhancement (■). Data were presented as average ±SD from four repeated measurements.

by NaOH (4 M). The milk was diluted about 5 times during the disposal procedure. The results showed that D-biotin contained in pure milk was about 36.5 nM (n = 4, R.S.D. = 4.19%). The results demonstrated that the proposed method can provide precise data when real life samples are analyzed.

3.5. Comparison of methods of fluorescence enhancement and FRET with fluorescence enhancement

The sensitivity of the assay could be improved due to the fluorescence enhancement by biotin to streptavidin–FITC. B/SA in all competitive assays was higher than 4, which would saturate the fluorescence enhancement of streptavidin–FITC. Thus, the fluorescence change of streptavidin–FITC was only related to FRET effect other than fluorescence enhancement by competitive D-biotin.

The method of FRET with fluorescence enhancement has the potential of lower detection limit, broader measurable range and higher sensitivity than that of the method of fluorescence enhancement to determine D-biotin. As shown in Fig. 5, there was no fluorescence change in the method of fluorescence enhancement when the B/SA is less than 1. However, obvious change emerged in the same range by the method of FRET competition assay with fluorescence enhancement. This indicated that the method of FRET with fluorescence enhancement is more sensitive to detect D-biotin and has lower detection limit.

4. Conclusion

We have demonstrated a novel competitive homogeneous analysis method based on fluorescence resonance energy transfer between FITC and Dylight 549 with fluorescence enhancement. The method is a fast, simple method and reaches a high sensitivity with the detection limit of 0.5 nM for biotin. The assay has the advantage of double-labeled detection, which means the fluorescence recovery of donor and decrease of acceptor can both be utilized for quantitative assays. The fluorescence enhancement introduced into the assay significantly improves the sensitivity. The results also demonstrate that FRET is a powerful tool for sensitive, precise and prompt quantitative analysis of some important biomolecules when it combines with fluorescence enhancement and homogeneous immunoassay. As a homogeneous assay, the procedure is more simple with only one step than that of Enzyme Linked Immunosorbent Assay which includes many washing steps. Such FRET system can be applied as immunosensor with antigen–antibody as linkers to detect more antigen or antibody. The FRET system can also be carried out by utilizing other fluorescent materials, such as quantum dots or lanthanide, which have anti-photobleaching fluorescent characteristics or long stock shift and long fluorescent life.

ABSTRACT

The peroxidase activities of the complexes of hemin and intermolecular four-stranded G-quadruplexes formed by short-stranded $X_nG_mX_p$ sequences (X = A, T or C), especially $T_nG_mT_p$ sequences, were compared. The results, combining with those of circular dichroism (CD) spectra and acid–base transition study for DNA–hemin complexes, provide some important information about DNAzymes based on G-quadruplex–hemin complexes, such as the formation of a G-quadruplex structure is an important factor for determining whether a DNA sequence can enhance the catalytic activity of hemin; both intramolecular parallel G-quadruplexes and intermolecular four-stranded parallel G-quadruplexes can enhance the catalytic activity of hemin; the addition of T nucleotides to the 5′-end of a G-tract confers corresponding G-quadruplex greatly enhanced catalytic activity, whereas the addition of T nucleotides to the 3′-end of the G-tract has little effect; the high catalytic activity of hemin in the presence of some short-stranded G-rich sequences may be a result of the reduction of the acidity of the bound hemin cofactor. These studies provide more information for the DNA–hemin peroxidase model system, may help to elucidate the structure–function relationship of peroxidase enzymes and to develop novel, highly efficient peroxidase-liking DNAzymes. As a sequence of such an investigation, a new Hg^{2+} detection method was developed.

1. Introduction

DNAzymes are catalytically active DNA molecules that could show different enzymatic activities. With all else being equal, DNAzymes should be superior to many protein-based enzymes because DNAzymes are relatively less expensive to produce and more readily to mutate and self-replicate. [1,2]. Therefore, the development of DNAzymes with interesting activities attracted increasing interest [3,4].

An important development in the field of DNAzymes has been the discovery of the peroxidase-like activity of some DNA–hemin complexes. It has been reported that the complexes formed by hemin and some G-quadruplexes can reveal enhanced peroxidase activity [5,6]. This class of DNAzymes has been used in the detection of telomerase activity [7,8], hemin [9] and cofactor units of DNAzymes (e.g. Pb^{2+} ions, L-histidine and AMP) [10,11], the screening of G-quadruplex ligands [12] and the development of DNA sensors [13–15]. Compared with application studies, the basic studies (e.g. structure–function relationship study) on this class of DNAzymes are relatively backward. In DNA–hemin peroxidase model system studies, the most widely used catalytic DNA apatmer is PS2.M. PS2.M originally resulted from an in vitro selection for a reaction (porphyrin metallation) very different from peroxidation [16–19]. Travascio et al. reported that PS2.M–hemin can show peroxidase activity two orders of magnitude higher than that of hemin [6]. The ability of PS2.M to enhance the catalytic activity of hemin is attributed to the formation of a specific DNA structure, that is, a G-quadruplex. G-quadruplexes are unique higher-order structures formed by G-rich nucleic acid sequences based on stacked arrays of G-quartets connected by Hoogsteen-type base pairing. These structures are stabilized by monovalent cations (especially K^+) and can have different types dependent on the number of associated DNA strands, such as intermolecular four-stranded quadruplex formed by the association of four nucleic acid strands possessing a single poly(dG) domain, intermolecular dual-stranded quadruplex formed by two nucleic acid strands possessing two poly(dG) domains, and intramolecular single-stranded quadruplex formed by a nucleic acid strand possessing four or more than four poly(dG) domains [20]. Even with the same number of associated molecules, G-quadruplexes can reveal many topological structures differing by mutual strand orientation (Scheme 1) [21].

Scheme 1. Schematic representation of different types of G-quadruplex. (a) intermolecular four-stranded parallel quadruplex; (b) intermolecular two-stranded parallel quadruplex; (c and d) intermolecular two-stranded antiparallel quadruplex; (e) unimolecular parallel quadruplex; (f and g) unimolecular antiparallel quadruplex; (h) unimolecular mixed-parallel quadruplex. arrows indicate 5′–3′ polarity.

It is generally accepted that PS2.M can fold to a G-quadruplex, but the details of the folded and catalytically active structure of PS2.M have not been adequately elucidated to date. In most cases, such G-quadruplexes are described as a unimolecular quadruplex with antiparallel structure [10,11,13,14], but no evidence for this structure was presented yet. Lee et al. constructed two closely related structural models for the folded PS2.M, which both contained two guanine quartets [22]. But it seems that these two models cannot be supported by results of circular dichroism (CD) spectroscopy. Majhi and Shafer concluded the catalytically active form of PS2.M may be the multistranded parallel quadruplex rather than the unimolecular antiparallel structure [23]. This conclusion issues a challenge to the most applications of these DNAzymes because of the slow formation kinetics of multistranded quadruplexes. Recently, we demonstrated that the catalytically active form of CatG4 (5′-$TG_3TAG_3CG_3TTG_3AAA$), a 21-nucleotide oligonucleotide that has similar sequence to PS2.M and has been demonstrated to be able to enhance the peroxidase activity of hemin [13], is a unimolecular parallel quadruplex rather than a multistranded parallel quadruplex [24]. In summary, the basic knowledge of DNA–hemin peroxidase model system is relatively inadequate, which may seriously hinder the development of new DNA aptamers with higher catalytic activities and the discovery of new analytical applications for this kind of DNAzyme.

Herein, the peroxidase activities of the complexes formed by hemin and different four-stranded G-quadruplexes were compared to provide more information for the DNA–hemin peroxidase model system. The four-stranded G-quadruplexes are formed by different short-stranded DNAs that have a single G-tract with different numbers of T residues attached at the 5′ or/and 3′-ends. The results demonstrated that some four-stranded G-quadruplexes can increase the peroxidase activity of hemin to some extent, and the position of T residues in the sequence has a great influence on the level of activity.

2. Experimental

2.1. Materials

All Oligonucleotides that were used in this study were purchased from Jinsite Co., Ltd. (China). The concentrations of these oligonucleotides were represented as single-stranded concentrations. Single-stranded concentrations were determined by measuring the absorbance at 260 nm. Molar extinction coefficients were determined using a nearest neighbor approximation (http://www.idtdna.com/analyzer/Applications/OligoAnalyzer). H_2O_2, 2,2′-azinobis(3-ethylbenzothiozoline)-6-sulfonic acid (ABTS), Triton X-100 and hemin were obtained from Sigma. All chemical reagents were of reagent grade and used without further purification.

2.2. Peroxidase activity measurements

DNA solutions (0.86, 1.72 and 3.44 μM for one-stranded, two-stranded and four-stranded G-quadruplexes, respectively) were prepared in buffer A (10 mM Tris–HCl, pH 8.0, 16 mM KCl, 0.8 mM $MgCl_2$, 0.0017% (v/v) Triton X-100). In order to ensure the formation of G-quadruplex structures, the mixtures were heated to 90 °C for 5 min, cooled slowly to room temperature, and then incubated at room temperature for 30 min. 1.72 μM of hemin was added to the mixtures. The reaction mixtures were held for another 1 h at room temperature, then 1.28 mM of ABTS and 1.28 mM of H_2O_2 were added. The color of the reaction mixtures was recorded by a digital camera, and the absorption intensity at λ = 414 nm was followed using a TU-1901 UV–vis spectrophotometer.

2.3. Circular dichroism (CD) study

CD spectra were measured on a Jasco J-820 spectropolarimeter at room temperature. DNA solutions (0.86, 1.72 and 3.44 μM for one-stranded, two-stranded and four-stranded G-quadruplexes, respectively) were prepared in buffer A. To ensure the formation of quadruplex structures, the solutions were heated to 90 °C for 5 min, cooled slowly to room temperature, and then incubated at room temperature overnight. Spectra were recorded between 200 and 320 nm in 1 mm pathlength cuvettes. Spectra were averaged from three scans, which were recorded at 50 nm/min with a response time of 1 s and a bandwidth of 0.2 nm.

2.4. Acid–base transition study for DNA–hemin complexes

The mixtures of 1.72 μM hemin and individual DNAs (0.86, 1.72 and 3.44 μM for one-stranded, two-stranded and four-stranded G-quadruplexes, respectively) were prepared in different buffers: glycine–HNO_3 (pH 2.0–4.0), MES–Tris (pH 4.6–7.0), HPO_4^{2-}–$H_2PO_4^-$ (pH 5.8–6.8), Tris–HNO_3 (pH 7.0–8.9), and glycine–OH^- (pH 8.5–10.5). The electronic absorption spectra of various DNA–hemin complexes were recorded between 300 and 600 nm. The ratio of A_{360}/A_{404} was plotted as a function of pH value, and corresponding p*K*a value was determined from the position of the maximum of the first derivative of the plot.

2.5. Detection of Hg^{2+} ion

Aliquots of 3.44 μM T_4G_3 (5′-TTTTGGG) solutions containing 10 mM Tris–HCl (pH 8.0), 16 mM KCl, 0.8 mM $MgCl_2$, 0.0017% (v/v) Triton X-100 were heated to 90 °C for 5 min, cooled slowly to room temperature. Then, different concentration of Hg^{2+} ion was added and the mixtures were incubated at room temperature for 30 min. 1.72 μM of hemin was added to the mixtures and the reaction mixtures were held for another 1 h at room temperature. Then 1.28 mM of ABTS and 1.28 mM of H_2O_2 were added. 10 min later, the absorption spectra of the reaction product $ABTS^+$ were recorded. The absorbance at 414 nm (the maximal absorption of $ABTS^+$) was used for quantitative analysis.

Table 1

3. Results and discussion

3.1. Catalytic activity and structural studies of various DNAs

Although the structure of the DNA aptamers that can provide hemin with enhanced peroxidase activity is unclear, it is generally acknowledged that they may form a G-quadruplex structure. The peroxidase activity of hemin in the presence of seven different G-quadruplexes (Table 1) was compared to investigate the abilities of these G-quadruplexes to enhance the peroxidase activity of hemin. The results are shown in Fig. 1, where it can be seen that PS2.M and T_4G_4 have markedly enhanced peroxidase activity compared with hemin alone. They catalyze the oxidation of 2,2′-azinobis(3-ethylbenzothiozoline)-6-sulfonic acid (ABTS) by H_2O_2, and the absorption intensity of reaction mixtures at $\lambda = 414$ nm are greatly increased. TG_4T enhances the peroxidase activity of hemin much less than PS2.M and T_4G_4. The other four G-quadruplexes induce very little enhancement of peroxidase activity.

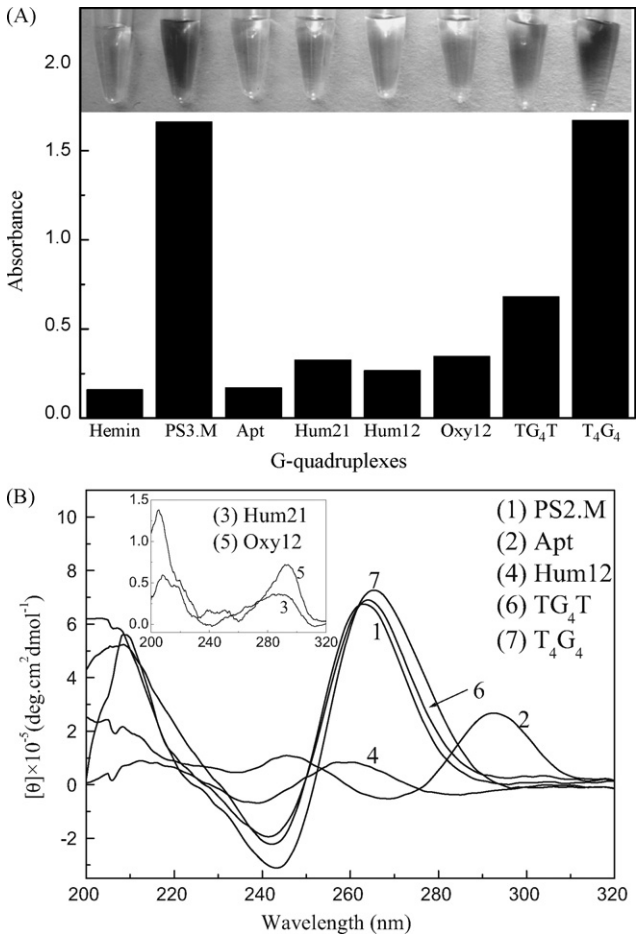

Fig. 1. (A) Oxidation of ABTS by H_2O_2 in the presence of hemin and the DNAs listed in Table 1, and (B) the CD spectra of corresponding DNAs. For clarity, the CD spectra of Hum21 and Oxy12 were given in the inset figure. Corresponding color figures can be found in supporting information.

The CD spectra of the seven G-quadruplexes were recorded in order to investigate whether there is any relationship between the peroxidase activity of a G-quadruplex and its conformation. Earlier studies showed that the CD spectra of quadruplexes can be used to indicate whether they fold in a parallel or an antiparallel conformation. The CD spectrum of a parallel G-quadruplex has a positive peak near 265 nm and a negative peak near 240 nm, whereas an antiparallel G-quadruplex has a positive peak near 295 nm and a negative peak near 265 nm [25]. The results shown in Fig. 1B suggest that Apt and Oxy12 can form antiparallel quadruplexes, whereas PS2.M, T_4G_4, TG_4T and Hum12 can form parallel quadruplexes. The CD spectrum of Hum21 has a positive peak at around 295 nm and a negative peak at around 240 nm, suggesting the co-existence of parallel and antiparallel conformations in solution, or the presence of a hybrid structure containing both *syn* and *anti* bonds as in Scheme 1h [26–29]. It is interesting that the three G-quadruplexes (PS2.M, T_4G_4 and TG_4T) that can enhance the peroxidase activity of hemin adopt the parallel G-quadruplex conformation and have a strong positive peak at around 265 nm in CD spectra. This result suggests that the conformation of G-quadruplexes may be an important factor in determining their effect on peroxidase activity.

3.2. Catalytic activity and structural studies of $T_nG_mT_p$ sequences

The results described above indicate that both unimolecular parallel G-quadruplexes and intermolecular four-stranded parallel G-quadruplexes can enhance the catalytic activity of hemin. A detailed study of the catalytic activity of four-stranded quadruplexes formed by $T_nG_mT_p$ sequence is reported here for the first time.

3.2.1. G_4T_n and T_nG_4

G_4 has little effect, and G_4T_n and T_nG_4 ($n = 0$–5) enhance the catalytic activity of hemin to different extents (Fig. 2). The increase is much greater in the presence of T_nG_4 sequences than that in the presence of G_4T_n sequences; i.e. the addition of T residues to G_4 increases the catalytic activity of hemin, and the greatest effect is obtained when the T residues are added to the 5′-end. However, the number of T nucleotides added to the same side of G_4 has little effect on the catalytic activity.

The CD spectra of the oligonucleotides with sequences of G_4T_n and T_nG_4 are shown in Fig. 2. The CD spectra of both T_nG_4 and G_4T_n sequences have a major positive peak around 265 nm and a minimum around 240 nm, which is typical of a parallel arrangement of the strands. These results suggest that the ability of the intermolecular G-quadruplexes to enhance the catalytic activity of hemin is correspond not only to G-quadruplex structure, but also to the position of added T nucleotides.

3.2.2. $T_4G_4T_n$ and $T_nG_4T_n$

The results described above show that the position of T nucleotides in the sequence has a marked influence on the catalytic activity. Two experiments were done to further investigate the effect of the location of the T nucleotides. In the first experiment, different numbers of T nucleotides were added to the 3′-end of T_4G_4, and the catalytic activity of the resulting $T_4G_4T_n$ sequences ($n = 0$–5) was determined (Fig. 3). The addition of T nucleotides at the 3′-end dramatically decreases the catalytic activity of T_4G_4, but there was little difference in the effect when different numbers of T nucleotides were added. In the second experiment, the catalytic activity of the $T_nG_4T_n$ sequences ($n = 0$–4) was investigated. As shown in Fig. 3, the $T_nG_4T_n$ sequences have a level of catalytic activity comparable to that of the $T_4G_4T_n$ sequences. That is to say,

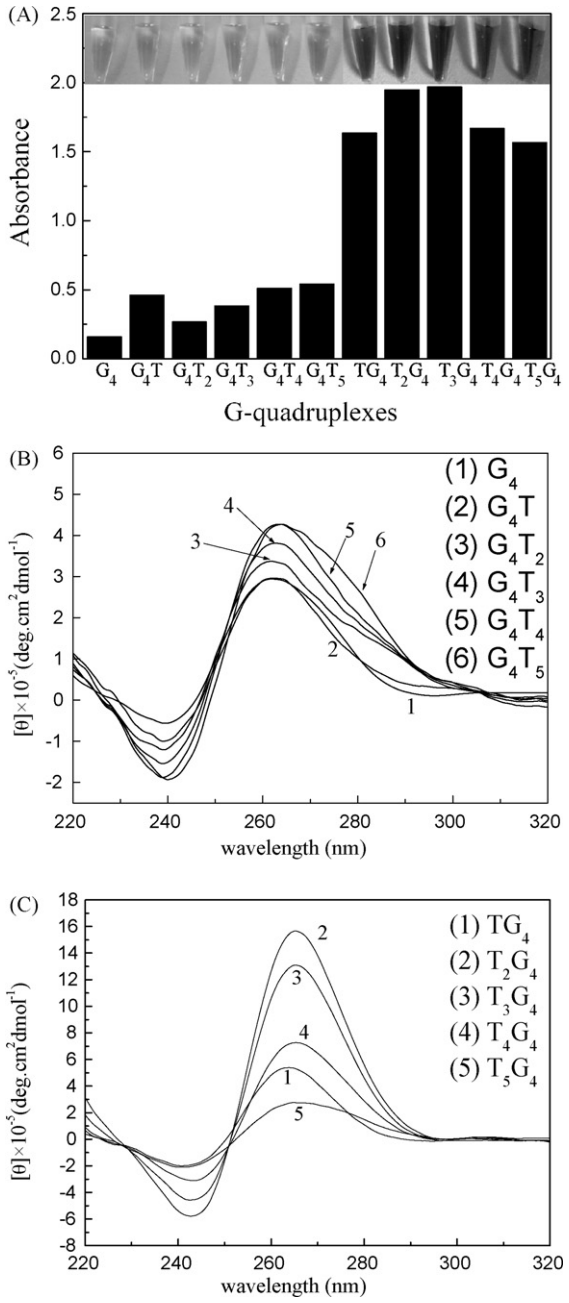

Fig. 2. Oxidation of ABTS by H_2O_2 in the presence of hemin and G_4T_n or T_nG_4 (A), and the CD spectra of G_4T_n (B) and T_nG_4 (C). Corresponding color figures can be found in supporting information.

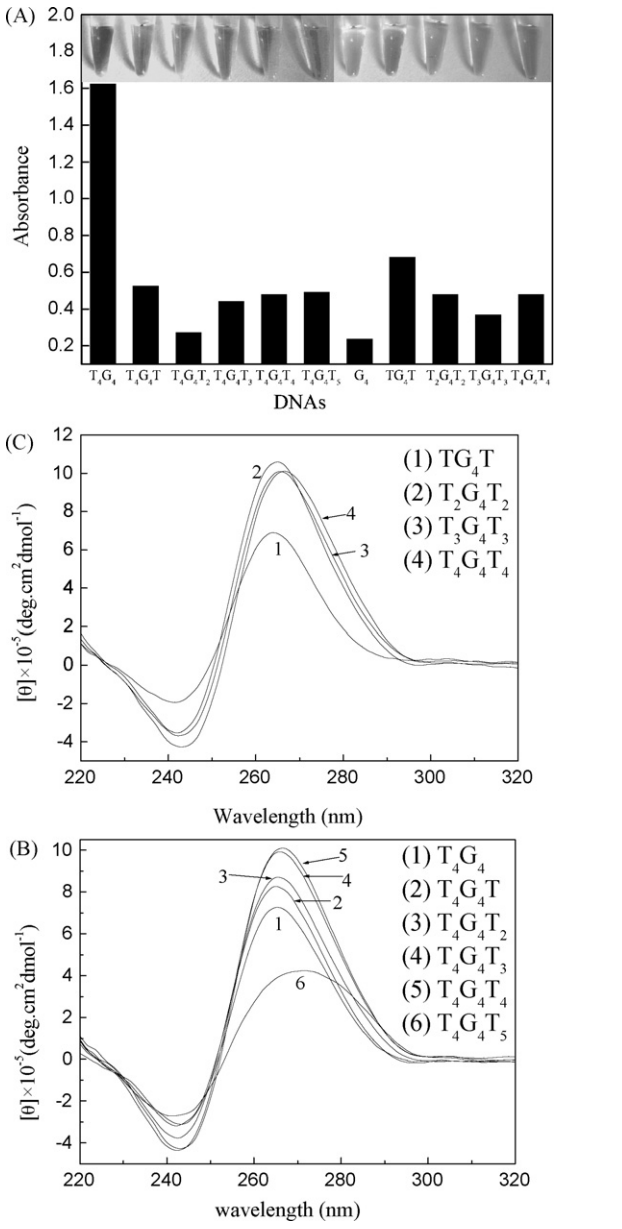

Fig. 3. Oxidation of ABTS by H_2O_2 in the presence of hemin and $T_4G_4T_n$ or $T_nG_4T_n$ (A), and the CD spectra of $T_4G_4T_n$ (B) and $T_nG_4T_n$ (C). Corresponding color figures can be found in supporting information.

although the $T_nG_4T_n$ sequences have slightly higher catalytic activity than G_4, it is much weaker than those of the T_nG_4 sequences ($n = 1$–4).

The CD spectra of both $T_4G_4T_n$ and $T_nG_4T_n$ sequences have a major positive peak around 265 nm with a minimum around 240 nm, indicating that all of the G-quadruplexes formed by these sequences adopt the parallel quadruplex conformation.

On the basis of the results described above, the catalytic activity of the $T_nG_4T_m$ sequences is ranked in the order: $T_nG_4 > G_4T_n \approx T_nG_4T_m$ ($m > 0$) $> G_4$

3.2.3. T_4G_n

The number of quarterts in a G-quadruplex is an important factor in determining the stability of the G-quadruplex. From the results described above, it can be seen that the addition of T nucleotides to the 5′-end of a G tract can provide corresponding G-quadruplexes with strong catalytic activity. So, in this experiment, the position of the T nucleotides was fixed at the 5′-end of the G tract, the number of T nucleotides was fixed at 4, and the number of G nucleotides in the G tract was changed from 3 to 9, and the catalytic activity and CD spectra of the resulting T_4G_n sequences ($n = 3$–9) were compared. As shown in Fig. 4, T_4G_3 has no catalytic activity, whereas each of the other T_4G_n sequences has very strong catalytic activity, which increases as the number of G nucleotides increases from 4 to 6; after that, the catalytic activity reaches a plateau and there is no change as the number of G nucleotides increases.

T_4G_3 did not show any CD signal in the range of wavelengths studied here, implying that it cannot form a G-quadruplex structure. Under the same conditions, as the CD spectra display a positive peak around 265 nm with a minimum around 240 nm, the T_4G_4–T_4G_9 sequences can form a typical parallel G-quadruplex structure.

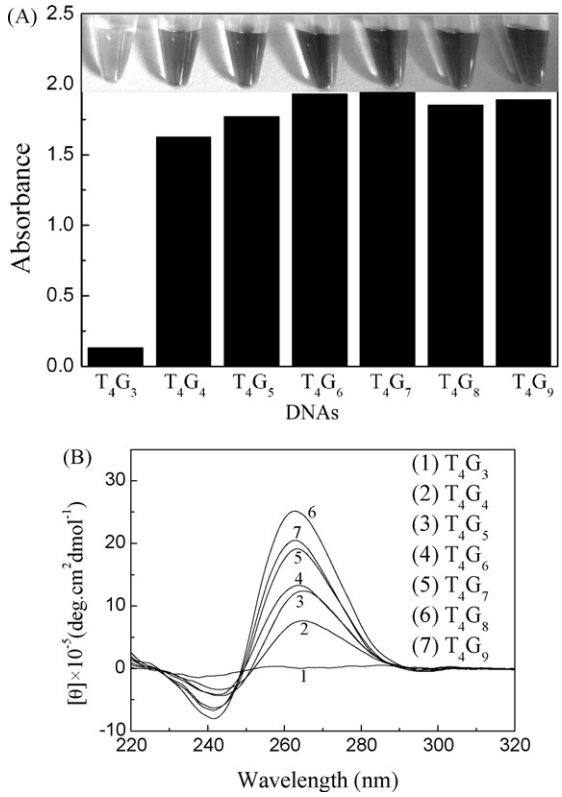

Fig. 4. Oxidation of ABTS by H_2O_2 in the presence of hemin and the T_4G_n (A), and the CD spectra of T_4G_n (B). Corresponding color figures can be found in supporting information.

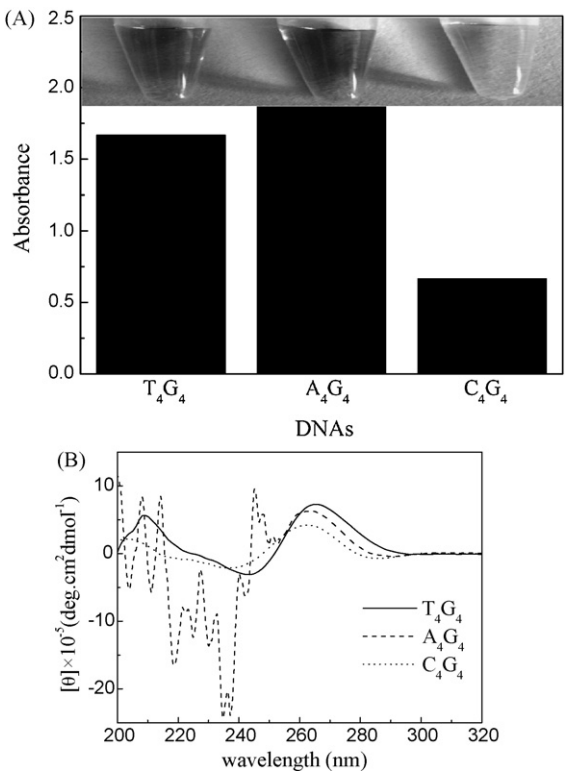

Fig. 5. Oxidation of ABTS by H_2O_2 in the presence of hemin and the X_4G_4 (A), and the CD spectra of X_4G_4 (B). Corresponding color figures can be found in supporting information.

From these results, it can be concluded that: (1) the formation of a stable G-quadruplex structure is an important factor for determining whether T_4G_n sequences can enhance the catalytic activity of hemin; (2) stable intermolecular four-stranded G-quadruplexes cannot be formed when the number of G nucleotides in the G tract is less than 4; (3) in the range of $n = 4$–6, the catalytic activity of the T_4G_n sequences gradually increased as n increased. Any further increase of n has very little effect on the catalytic activity.

3.3. Catalytic activity and structural studies of X_4G_4 (X = T, A or C) sequences

The catalytic activity of the X_4G_4 sequences (X = A, T or G) were compared to investigate the effect of the identity of the nucleotide that was added to the 5′-end of the G tract. As shown in Fig. 5, both T_4G_4 and A_4G_4 have strong catalytic activity, and the activity of A_4G_4 is a little higher than that of T_4G_4. The catalytic activity of C_4G_4 is much lower than that of either T_4G_4 or A_4G_4.

The CD spectrum of T_4G_4 has a positive peak around 265 nm with a minimum around 240 nm, indicating that T_4G_4 adopts a parallel G-quadruplex structure. The CD spectrum of C_4G_4 shows a positive peak at 263 nm, and a negative peak is at 235 nm. The secondary structure of C_4G_4 cannot be determined directly from the CD spectrum. It is well known that the presence of divalent cations (e.g., Mg^{2+}) will aid the formation of duplex DNAs, and the presence of monovalent cations (especially K^+) will aid the formation of G-quadruplex structures. Under the buffer conditions used here (0.8 mM Mg^{2+}; 16 mM K^+), both duplex and G-quadruplex structures may be formed, but only the G-quadruplex DNA can enhance the catalytic activity of hemin. Therefore, the catalytic effect of the C_4G_4 sequence is smaller than that of either T_4G_4 or A_4G_4. The CD spectrum of the A_4G_4 sequence has a positive peak at 263 nm, but fluctuates sharply at short wavelengths, so it is difficult to identify the presence of the G-quadruplex structure. Considering that no base-pair can be formed between A and G, it is very possible that the A_4G_4 sequence will adopt the intermolecular parallel G-quadruplex structure. Considering that two hydrogen bonds may be formed between T and G, and the stability of the T:G mismatch is the highest of all base mismatches, the possibility of the formation of the G-quadruplex structure for A_4G_4 is even higher than that for T_4G_4. That is to say, the possibility of the formation of G-quadruplex structures for the three sequences follows the order: $A_4G_4 > T_4G_4 \gg C_4G_4$, which is quite consistent with the results of catalytic activity studies.

3.4. The "acid–base transition" of the DNA–hemin complexes

Recently, Travascio et al. demonstrated that the high catalytic activity of PS2.M may be a result of the reduction of the acidity of the bound hemin cofactor (e.g., a water molecule coordinated to the iron atom of the hemin that is bound to the DNAzyme scaffolds) [16]. Here, the acid–base titrations for hemin and DNA–hemin complexes were also followed by monitoring the absorption curve at various pH values, and corresponding pK_a values could be derived from A_{360}/A_{404}–pH plots. As shown in Fig. 6 (and see supporting information Fig. S6), regardless of hemin or the DNA–hemin complexes, the absorbance ratio of A_{360}/A_{404} increases greatly with increasing pH, and pK_a can be determined from the position of the maximum of the first derivative of the transition curves. According to the relationship between catalytic activities and pK_a values (Table 2), hemin and the DNA–hemin complexes that were studied can be clearly divided into two groups (Fig. 7). Hemin has a pK_a value of 4.36 ± 0.15, which is very similar to those of the DNA–hemin complexes (pK_a < 6.50) whose catalytic activities are comparable to hemin itself, but is much lower than those of the DNA–hemin complexes (pK_a > 7.20) that have much higher catalytic activities. Our results are gen-

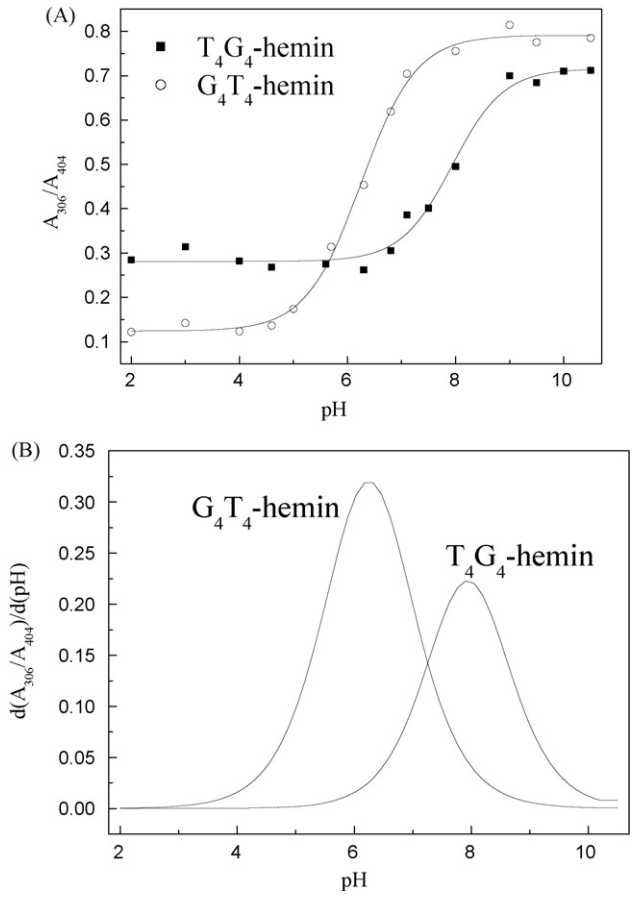

Fig. 6. Spectrophotometric titration to determine the p*K*a of the water molecule ligated to T_4G_4–hemin and G_4T_4–hemin complexes from the ratio of absorptions at 360 and 404 nm. (A) Titration plots; (B) first derivative of the titration plots.

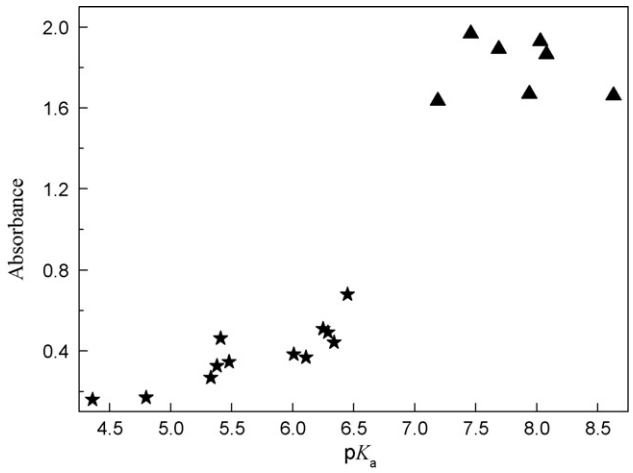
erally consistent with the conclusion drawn by Travascio et al. It is noteworthy that the pK_a values of T_nG_m–hemin complexes are much higher than those of G_4T_n–hemin and $T_nG_4T_m$–hemin complexes, suggesting that the acidicity of the bound hemin cofactor may be an important factor in determining the abilities of $T_nG_mT_p$ sequences to enhance the catalytic activity of hemin. More experiments are needed to elucidate why the addition of T residues to different sides of the G_4 sequence results in very different pK_a values for the corresponding DNA–hemin complexes.

Table 2
Derived pK_a values for the acid-base transitions of various hemin complexes.

Enzyme (hemin complex)	pK_a	Catalytic activity
Hemin	4.36 ± 0.15	Very low
PS2.M–hemin	8.63 ± 0.08	High
Apt–hemin	4.80 ± 0.12	Very low
Hum21–hemin	5.38 ± 0.12	Low
Oxy12–hemin	5.48 ± 0.12	Low
Hum12–hemin	5.33 ± 0.25	Low
TG_4–hemin	7.19 ± 0.06	High
T_3G_4–hemin	7.46 ± 0.05	High
T_4G_4–hemin	7.94 ± 0.12	High
T_4G_6–hemin	8.03 ± 0.12	High
T_4G_9–hemin	7.69 ± 0.11	High
G_4T–hemin	5.41 ± 0.37	Low
G_4T_3–hemin	6.01 ± 0.05	Low
G_4T_4–hemin	6.25 ± 0.05	Low
TG_4T–hemin	6.45 ± 0.06	Low
$T_3G_4T_3$–hemin	6.11 ± 0.08	Low
$T_4G_4T_3$–hemin	6.34 ± 0.09	Low
$T_4G_4T_5$–hemin	6.29 ± 0.08	Low
A_4G_4–hemin	8.08 ± 0.10	High



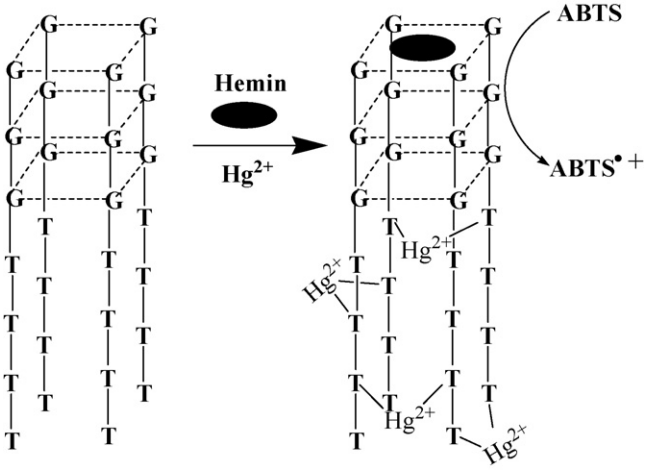


Fig. 7. The relationship between catalytic activities versus pK_a values. The catalytic activities of hemin and the DNA–hemin complexes were represent as the absorption intensities for the reaction solutions of ABTS oxidation by H_2O_2.

3.5. Application in Hg^{2+} ion detection

Mercury is an important toxic pollutant in the environment, and it is attractive to develop a reliable sensing system for mercury detection. To date, numerous studies concerning Hg^{2+} ion assays have been reported [30]. Many of them are based on the fact that Hg^{2+} ion can bind to two thymine (T) and stabilize T–T mismatches in a DNA duplex. Recently, Li et al. reported a new Hg^{2+} ion detection method utilizing the Hg^{2+}-mediated T–T base pair to destroy the G-quadruplex structure and to inhibit corresponding catalytic activity [31]. Although this method gave a good detection result, from the sensing point of view, this is not a "turn-on" sensor. The results mentioned above indicate that the addition of T nucleotides to the 5′-end of the G-tract can confer enhanced catalytic activity, but the prerequisite is that a stable G-quadruplex can be formed. In the intermolecular G-quadruplex formed by T_nG_m sequences, four T_n tails locate at the 5′-terminals of the G-quadruplex. The addition of Hg^{2+} ion can promote the formation of T–Hg^{2+}–T base pairs. The formation of T–Hg^{2+}–T base pairs may strength the intermolecular G-quadruplexes, resulting in the increase of catalytic

Scheme 2. Intermolecular G-quadruplex-based DNAzyme as sensing platform for colorimetric detection of Hg^{2+} ion.

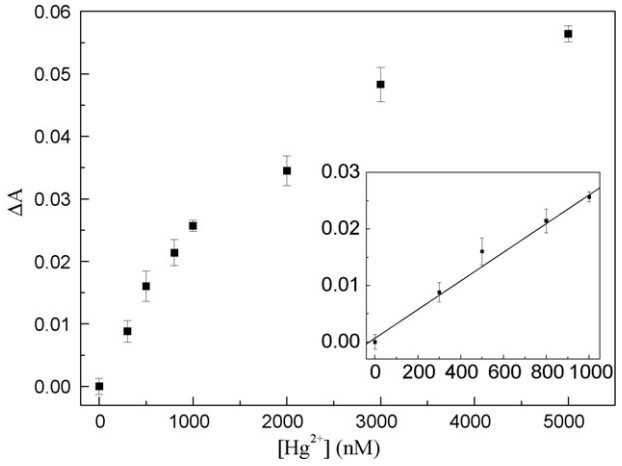

Fig. 8. Hg^{2+} ion concentration-dependent increase in the absorbance at $\lambda = 414$ nm. ΔA represents the difference between A_{414} and the background absorption imparted by hemin catalysis. The insert shows the change of ΔA value as a function of Hg^{2+} ion concentration in the n range of 0–1000 nM. The solid line represents linear fit to the data.

activity (Scheme 2). To test this idea, the catalytic activity of the T_4G_3–hemin complex as a function of Hg^{2+} ion concentration was investigated. As shown in Fig. 8, upon increasing addition of Hg^{2+} ion, the catalytic activity gradually enhanced. After subtracting the background absorption due to the intrinsic catalytic activity of hemin, the ΔA values at 414 nm increased linearly with Hg^{2+} ion concentration up to 1 μM with a detection limit of 52 nM based on 3α/slope.

4. Conclusions

The catalytic activity and the secondary structure of short-stranded $X_nG_mX_p$ sequences (X = A, T or C), especially $T_nG_mT_p$ sequences, were investigated. The results of these experiments suggest that: (1) both intramolecular parallel G-quadruplexes and intermolecular four-stranded parallel G-quadruplexes can enhance the catalytic activity of hemin. (2) When the number of G nucleotides in the G-tract is fixed at 4, the catalytic activity of the $T_nG_4T_m$ sequence follows the order:

$$T_nG_4 > G_4T_n \approx T_nG_4T(m > 0) > G_4$$

That is to say, the addition of T nucleotides to the 5′-end of the G-tract confers greatly enhanced catalytic activity, whereas the addition of T nucleotides to the 3′-end of the G-tract has little effect on the catalytic activity. (3) As for T_4G_n, when the number of G nucleotides in the G-tract is 3, no stable G-quadruplex structure can be formed and the sequence is unable to enhance the catalytic activity of hemin. When the number of G nucleotides exceeds 4, stable intermolecular parallel G-quadruplexes can be formed, and greatly enhanced catalytic activity can be observed. (4) The catalytic activity of X_4G_4 follows the order $A_4G_4 > T_4G_4 \gg C_4G_4$, which may be correlated with the competitive formation of G-quadruplex and duplex structures. (5) The high catalytic activity of hemin in the presence of some short-stranded G-rich sequences may be a result of the reduction of the acidity of the bound hemin cofactor. These studies may help to elucidate the structure–function relationship of peroxidase enzymes and the ways in which a DNAzyme might work to enhance the intrinsic activity of hemin. Also, these studies may be helpful for the development of novel, highly efficient DNAzymes with peroxidase activity. Based on these studies, a "turn-on" Hg^{2+} ion detection method with a detection limit of 52 nM was developed.

ABSTRACT

The sensitivity of surface plasmon resonance (SPR) transducers depends on the thickness and spatial organization of interfacial structures at their surfaces. This is because the response of the SPR sensor is determined by integrating the distance-dependent refractive index (spatial interfacial architectures), weighted by the square of the electromagnetic field, from zero to infinite distance. The effect of SPR transducer sensitivity variation on the accuracy of SPR analysis is considered. Our quantitative estimation (based on the results of refractometric studies) gave a value for sensitivity variation of about 3% for the formation of a self-assembled thiocyanate layer or a trypsin-soybean trypsin inhibitor surface complex. The estimated accuracy in measured variation (*i.e.*, by 0.01) for the refractive index of the external medium was 3×10^{-4}. This restriction, which follows immediately from the physical mechanism of the SPR phenomenon, should be taken into account when analyzing data obtained with the above technique.

1. Introduction

The surface plasmon resonance (SPR) phenomenon is a basis of many optical nondestructive analytical techniques [1–5]. Typically, the technique involves the excitation of surface plasmon–polariton waves by a polarized laser beam on a gold film employing the Kretschmann configuration for achieving an attenuated total reflection [6,7]. This effect (that manifests itself as an abrupt drop of reflected light intensity at certain angles or wavelengths in conventional setups) can be easily measured with high precision. The parameters of the SPR plot (*e.g.*, the dependence of reflectivity R *versus* the incidence angle, θ) are modified in the presence of the adsorbed particles, molecules, *etc*. In particular, the binding of an analyte to the sensor surface may be monitored in real time if the analyte has a different refractive index than the bulk solution. This is the basis for SPR sensor applications [6,8]. This method is widely used for the registration of protein adsorption on the surface, protein–protein interactions, reactions of proteins with small molecules, DNA, *etc*. [9–11] using many available commercial single- and multi-channel SPR systems [4].

The main advantage of the SPR technique is possibility of direct registration of surface interactions without any additional procedures or labels [12]. Real time response registration enables the investigation of interaction kinetics and, thereby, tracking of a system's evolution on a nanometer scale [12,13]. This is the result of the fact that the dielectric-metal interface is being probed with high sensitivity because the effective path length is increased as the plasmons, being guided waves, propagate along the surface [14]. The plasmon–polariton wave, which decays exponentially with moving off the surface, has penetration depth approximately equal to half of the incident wavelength, so the SPR excitation angle depends on environmental optical parameters adjacent to the metal layer. Therefore, the response of the SPR sensor is determined by integrating the distance-dependent refractive index (interfacial particles architectures), weighted by the square of the electromagnetic field, from zero to infinite distance [15,16]. The physical phenomena of surface plasmon resonance is relatively well understood and widely discussed in the literature [6,13,17,18].

In general, an optoelectronic technique measuring parameters depend on interfacial structure in nonlinear manner since evanescent wave distribution at the interface depends strongly on variations in the permittivity within interfacial architectures on a nanometer scale and, consequently, on the presence of different spatial organizations of analyte or other molecules that are introduced [19,20]. Thus, both the interface conditions and the characteristics of the metal film may affect functionality of optoelectronic transducers based on surface effects. In particular, for SPR transducers, parameters of the metal film that support propagation of a guided optical plasmon–polariton mode may influence the sensor's response through variations in the performance characteristics of the instrument [21]. However, in fact, the details of these processes are not fully understood at the present time. Although

the SPR facilities are widely used, there is relatively little information concerning the accuracy of the technique and conditions for its adequate application in routine researches. Most of the latest publications are related to the theoretical estimations [14] and determination of the limit of detection of SPR for specific systems. Several papers have previously addressed some aspects of the quantitative interpretation of SPR signals in terms of structural parameters of adlayers in the so-called linear-response regime [22]. This approach can be efficiently used for the adsorbed films that are thinner than the decay length of the evanescent field [23]. A few papers have addressed the response to thicker films, beyond the linear regime [24,25], but generally theoretically. Also, careful analysis of nonlinearity of SPR calibration plots presented in Ref. [20] cannot be implemented in convential analytical practice because of the necessary estimation a characteristic decay length of the evanescent electromagnetic field at the interface. At the same time, various publications during the last few years have addressed SPR research of bacteria and virus particles, high-molecular weight proteins nanoparticles and so on without any comments regarding accuracy of the measurements, *i.e.*, "closeness of the agreement between the result of measurement and a true value of the measured" [26]. In particular, no experiments have been reported to date in which the role of biofilms has been investigated from the point of measurement uncertainty (the width of a confidence interval for the relative measurements as used here) in SPR analysis. In line with that, the purpose of this paper is to examine critically the accuracy of the SPR measurements in the presence of different interfacial layers, and, in particular, to quantify the uncertainty in the measurement of the refractive index of several binary solutions of glycerol/water with a range of concentration in contact with different sensor surfaces.

First we consider a simple analytical model for surface-type physical transducers with the idealized linear calibration plot. Relative variations (changes of SPR angle and analyte concentration) of the measurement process serve as informative parameters of the model. Then we analyze the methods of determination of the minimum of SPR resonance curve, as well as the procedure for obtaining the calibration equation. After this, we present experimental data on variation of SPR sensor sensitivity in the case of treatment of the gold film surface with a strong oxidizing agent and adsorption of low- and high-molecular compounds onto the film surface. At the end of this work, we give a generalized analysis of the results obtained, as well as estimation of the uncertainty in the SPR measurements that depends on the surface condition and formation of interfacial architectures at it.

2. Experimental

Spectra were acquired on a scanning SPR spectrometer "Plasmon" [1,7,10,27] developed at the V. Lashkaryov Institute of Semiconductor Physics of the National Academy of Sciences of Ukraine (Kyiv). A GaAs laser, $\lambda = 670$ nm, was used as excitation source. Glass plates (refractive index $n = 1.61$) with a 50 nm gold layer evaporated on a 1.5 nm chromium interlayer were fixed at a supporting glass prism ($n = 1.61$) using immersion liquid (polyphenyl ether, $n = 1.6$) [1,10,28]. "Piranha" solution ($1H_2O_2$ (30%):$3H_2SO_4$ (37%), v/v) was used to clean the surface. A solution of sodium thiocyanate, NaSCN (40 μM, Sigma, USA) was prepared, using distilled water, immediately before application [29]. Soybean trypsin inhibitor (STI) (Radomed, Hungary) and trypsin (Radomed, Hungary) were dissolved in distilled water (100 μg/ml) [30]. The refraction coefficients of glycerol solutions in water (2.5–10 vol.%) were determined with a commercial refractometer IRF-23 [31].

Winspall 2.0 software (Max-Planck-Institute for Polymer Research, Mainz, Germany) was used to calculate the SPR curves and approximate the experimental dependences with an optical model within the framework of Maxwell macroscopic approach [6]. To approximate the curves and linear dependences, we applied the standard procedures of OriginPro 7.5 (OriginLab Corporation).

3. A simple model of an SPR transducer with linear calibration equation

A rapid proliferation and diversity of SPR systems has led to a lack of understanding in defining some of their performance criteria. General characteristics of SPR sensors are common to different types of transducers [32,33]. However just the efficiency of SPR sensors for detection the process over the extended interfacial architectures like dextran films or multilayer structures is determined by sensitivity variations in the sensor in the course of measurements. Indeed, for SPR sensors, when a linear calibration is applied it is usually assumed that this calibration does not vary in the course of analysis [34]. However, taking into account the features of evanescent wave distribution at interface (exponential decay of intensity from the surface [35]), it seems reasonable to expect variation of SPR sensors' sensitivity if the interface architecture is changed.

Owing to some discussion regarding the meaning of the analytical sensitivity S [36–38], we note that use IUPAC defines S as the slope of the calibration curve, *i.e.*, $(y–y_0)$ *versus* x, where x refers to the analyte amount, and responses y corrected for a background signal y_0 [26]. The following simple phenomenological model demonstrates how the uncertainty in the measured analyte amount on the surface depends on variation of sensitivity S.

A measurement system is assumed to give an output response, y, for a given value of the input variable of interest, x. Fig. 1 includes two hypothetical calibration plots, depicted by square ("Q") and circle ("C") symbols, with different sensitivities and similar measurement errors (y) for two hypothetical situations on the transducer surface. A fixed measurement error was used in the example for sake of simplicity. The combined effects of the sensitivities and measurement errors can be quantified by projections of the error bars onto the analyte concentration axis (x axis). These projections show that the measurement uncertainty (confidence interval for direct measurements) for the absolute value of x for "C"

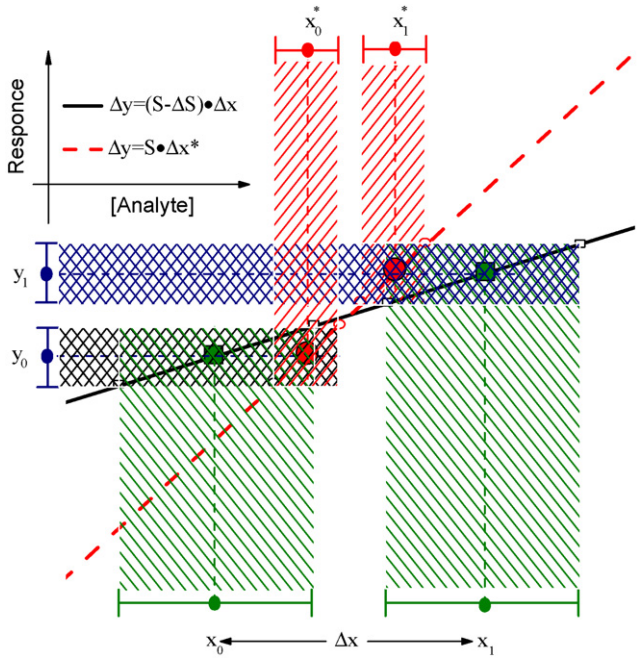

Fig. 1. Effects of sensitivity and measured error on the measurement accuracy.

case is smaller than for "Q" one, the reason being that "C" is more sensitive than "Q". Thus, the increasing of a quantitative resolution in relative measurements for more sensitive sensors is the reason to improve the sensitivity of SPR transducers [39].

Consider the case where the initial sensitivity, S ("C") changes by ΔS ("Q") due to some modification of the surface or formation an interfacial layer (Fig. 1). In this case for the same value of SPR response $\Delta y = y_1 - y_0$, we would determine two different values for the change in refractive index for the same solution in contact with the sensor surface, Δx and Δx^*:

$$\Delta y = S(x_1 - x_0) = S\Delta x, \quad (1)$$

$$\Delta y = (S - \Delta S)(x_1^* - x_0^*) = (S - \Delta S)\Delta x^*. \quad (2)$$

The difference between the determined Δx and Δx^* values is

$$\delta x = \Delta x^* - \Delta x = \left(\frac{\Delta y}{S}\right)\left(\frac{\Delta S}{(S - \Delta S)}\right) = \left(\frac{\Delta y}{S}\right)\left(\frac{\Delta S/S}{(1 - \Delta S/S)}\right). \quad (3)$$

Taking into account Eq. (1), we get

$$\delta x = \Delta x \frac{(\Delta S/S)}{(1 - \Delta S/S)} \quad (4)$$

Eq. (4) makes it possible to estimate directly the absolute (δx) or relative ($\delta x/\Delta x$) error that arises due to variation of transducer sensitivity ΔS. One can see from Fig. 2 that $\delta x/\Delta x$ is rapid-growing function of $\Delta S/S$ because of the asymptote that is approached as $\Delta S \to S$. This fact has to be accounted for when solving the problems of analysis related to estimation of the true value of analyte amount on the surface from the sensor response. To obtain quantitative estimation of the absolute (δx) or relative ($\delta x/\Delta x$) errors one must determine the $\Delta S/S$ value experimentally. To do this, we used the results of analysis of variations of SPR transducer sensitivity under different conditions at the gold film surface obtained from the refractometric measurements.

4. Results and discussion

To apply SPR sensing for the monitoring of interfacial processes, some method must be available to extract from raw SPR data a quantitative measurement of the surface concentration [9,38] of the adsorbed layer or refractive index of the "infinitely thick" medium in contact with the sensor surface. For example, the analyte surface concentration Γ (surface coverage, in units of mass/area, *i.e.*, ng/mm^2) can be calculated from experimental data (the change in the thickness d and the refractive index Δn near the surface) *via* a linear approach for homogeneous or inhomogeneous surface-adsorbed layers or for low-concentration solutions [38,39]. However, despite the wide application of SPR, no simple yet general method has been proposed for transformation the SPR response in some variation of refractive index. The reason for that lies in the complex procedure for SPR calibration plot measurement that generates compounding errors and use some assumptions regarding the form of fitting functions. Indeed, the measurement accuracy of the analyte surface concentration, *etc*. depends on:

1) *the instrumental errors* related to the determination of the value of
   a) incident angle, and
   b) reflection intensity;
2) *the data processing errors* related to
   a) the effectiveness of the asymmetric SPR curve-fitting procedure for determination the curve minimum, and
   b) the standard errors indicating the deviation from linearity of the calibration plot obtained using the values of SPR curve minima, and
3) *the truncation errors* related to
   a) the assumption of linear calibration plot for SPR sensor, and
   b) the values of the refractive index increment [38] or other constants used for conversion procedure.

It is necessary to stress that the errors arising from modern instrumental facilities (1a and 1b) are at least an order of magnitude less than one related to (2). The value of constants (3b) results in systematic errors in surface concentration of analyte. Thus, the main sources of uncertainly in SPR measurements arising from both data processing and, possibly, assumption of linearity for the calibration plot.

4.1. Selection curve-fitting equation for the accurate determination of SPR resonance angle

In real time SPR measurements various procedures based on analytical functions for finding the resonance angle in the SPR curve are applied, for example, polynomial approximation, centroid algorithms, Lorentzian approximation, *etc*. [40]. Most used methods are just within "minima hunt" techniques in the SPR curve. Procedures based on multilayer Fresnel equations are much more time-consuming and are unacceptable in real time measurements. To determine the position of minimum in the SPR curve $R(\theta)$ (Fig. 3) we used the following approaches that are applied most often:

I. direct determination of the absolute minimum in the curve $R(\theta)$,
II. calculation of the minimum by approximating the curve as a parabola $(\theta - \theta_{SPR})^2$ (ii) or third-order polynomial $(a_1\theta^3 + a_2\theta^2 + a_3\theta + a_4)$ (iii) in the vicinity of the minimum of angular dependence $(\theta_{SPR} \pm \Delta\theta)$,
III. numerical simulation of $R(\theta)$ using an optical model using multilayer Fresnel equations.

One should note that accuracy of determination of the minimum increases with the number of the experimental points used for calculation (N) because stochastic noise decreases as $\sqrt{N}$ if approximating function has been chosen adequately. Therefore, choosing the widest possible approximation range enables one to obtain the most valid estimates for θ_{SPR}.

The effectiveness of the approximation methods for θ_{SPR} determination was examined using the curve-fitting routine of OriginPro 7.5. Origin's nonlinear regression method is based on the Levenberg–Marquardt algorithm and is the most widely used algorithm in nonlinear least squares fitting. Shown in Fig. 3b are typical examples of approximation of angular dependence of the SPR

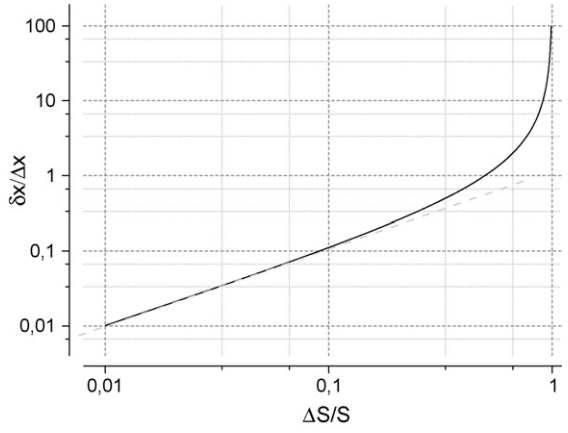

Fig. 2. Relative error of Δx determination, $\delta x/\Delta x$, as function of relative variation of transducer sensitivity, $\Delta S/S$. Dashed line indicates the semilinear region of the curve.

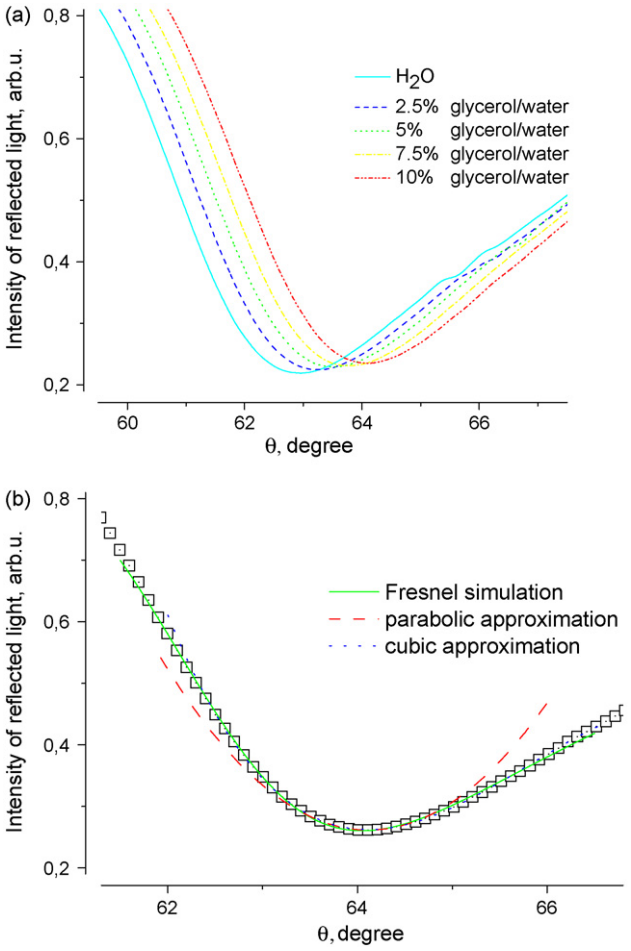

Fig. 3. Measured SPR response for an untreated gold surface (a) and an example of approximation by different functions for sample with 10 vol.% of glycerol in water (b).

reflection curve for a sample of glycerol solution in water (volume concentration of 10.0%). The parabolic approximation of angular dependence is adequate only in a narrow angle range (no wider than $\theta_{SPR} \pm 0.5^\circ$) near the minimum, owing to asymmetry of $R(\theta)$ about θ_{SPR}. As the range is increased up to $\theta_{SPR} \pm 2.0^\circ$, approximation with a third-order polynomial is adequate. The best results are given by numerical simulation of the response curve based on an optical model for interface structure within the framework of the Maxwell macroscopic approach.

The numerical characteristics of the approximation procedure are given in Table 1. The data presented in Fig. 3b and Table 1 enable one to conclude that, to determine θ_{SPR} in the range no more than $\theta_{SPR} \pm 2.0^\circ$, it is reasonable to approximate the minimum with third-order polynomials. Thus, this procedure was used for the analysis that follows. It is necessary to stress that the presented results are relatively common for many different situations including both measurements of solutions and thin interfacial films owing to the ubiquity of SPR curve form for various situations.

4.2. SPR response to bulk solutions: experimental technique of refractometric analysis

For bulk solutions the SPR response is the shift of SPR angle associated with changes in the index of refraction of the medium in contact with the surface of SPR device. Sufficiently accurate refractometric measurements require the absence of the processes of solution components (in our case, binary solutions glycerol/water with a range of concentrations) adsorbing on the surface. In an optimal situation, this usually assumes that the change in SPR angle due to difference in adsorption between different solutions is small compared to the measured shift, which is dominated by changes in the bulk index of refraction of these solutions. To elucidate this problem, we performed a number of methodological experiments (see Fig. 4). In the first set of measurements, the solutions were replaced in series one after another, while in the second set, the surface was washed in distilled water after each sample.

In both series of experiments, the gold film surface was untreated. As expected, the response in both cases was fairly linear over narrow range of refractive index of used solutions (up to 10% of glycerol). Thus, over a narrow range, the response to changes in bulk index of refraction, in the absence of adsorption from the solution, can be approximated as linear. Similar results have been reported repeatedly previously [19,41]. As can be seen from Fig. 4c, the distinction between the results of measurements is within the experimental error (1×10^{-4} for the refractometer and 2×10^{-4} for SPR spectrometer). At the same time, the above results confirm that the adsorption of glycerol on the gold surface is reversible for concentrations of 2.5–10 vol.%. However, to exclude a possible shift of the instrument's baseline, all following experiments were performed with sensor surface washing after each solution.

It should be noted that difference in sensitivity might not be related only to the problems concerning approximation accuracy. To avoid inaccuracies resulting from gold surface nonuniformity and variations of its optical parameters within a chip, the measurements were made at the same place.

4.3. Measured calibration plot for bulk solutions: effect of SPR curve-fitting equation

To check how the type of approximation of the SPR curves affects the parameters of calibration plot, we compared sensitivities S for different approximation techniques. The data presented in Table 1 enable one to conclude that the biggest deviation from linearity (largest standard error and smallest r^2 value) appeared in the calibration plot based on the values determined from the curves' absolute minima (method i). Curves based on the parabolic approximation (method ii) introduced a systematic bias, overestimating the sensitivity compared to other approaches (apparently

Table 1
Comparison of methods used for determination of position of angular dependence minimum when studying linearity of the SPR transducer calibration plot.

Approximation function	r^2 (approximation of angular dependences $R(\theta)$)	Sensitivity (tangent of angle of slope of calibration plot)	r^2 (linearity of calibration curve)
Absolute minimum of angular dependence	–	94.9 ± 7.1	0.994
Parabolic approximation $\theta_{SPR} \pm 0.5^\circ$	0.985–0.994	98.6 ± 2.7	>0.999
Third-order polynomial approximation $\theta_{SPR} \pm 0.5^\circ$	>0.998	93.7 ± 3.6	>0.998
Third-order polynomial approximation $\theta_{SPR} \pm 1.0^\circ$	>0.999	93.0 ± 2.1	>0.999
Third-order polynomial approximation $\theta_{SPR} \pm 2.0^\circ$	>0.998	92.8 ± 1.2	>0.999
Model curve (Fresnel) $\theta_{SPR} \pm 0.5^\circ$	>0.999	92.4 ± 2.4	>0.999
Model curve (Fresnel) $\theta_{SPR} \pm 1.0^\circ$	>0.999	92.9 ± 2.7	>0.999
Model curve (Fresnel) $\theta_{SPR} \pm 2.0^\circ$	>0.999	92.6 ± 3.5	>0.999

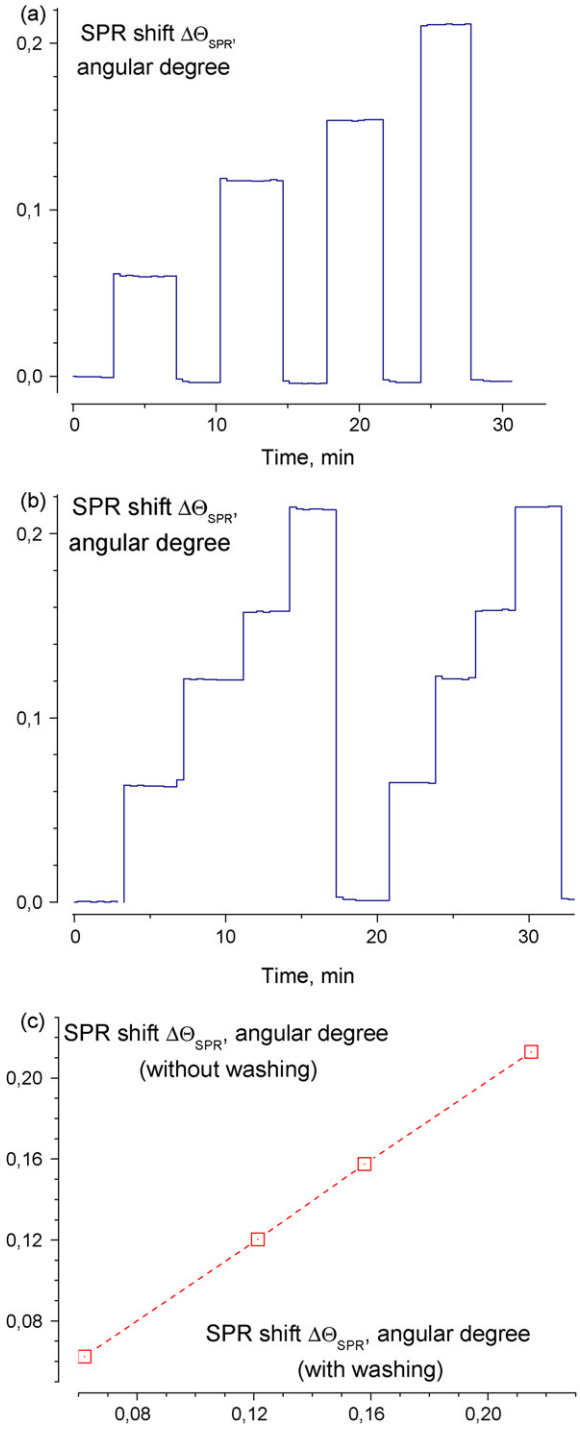

Fig. 4. Variation of SPR minimum position with concentration of glycerol solution for an untreated sensor surface for experiments with (a) and without (b) washing by water before use of each new glycerol solution (with increased concentration: 2.5, 5.0, 7.5 and 10.0 vol.%) and their cross correlation (c). The symbol size indicates the measurement uncertainty.

due to $R(\theta)$ asymmetry). The calibration based on approximating the experimental SPR curves with third-order polynomials (method iii) demonstrate that, in the $\theta_{SPR} \pm 2.0^\circ$ angle range, the sensitivity and linearity of this method are comparable to those obtained with numerical simulation in accordance with the optical model of the system. The last method is the most accurate one in the widest-angle range but requires numerically solving Maxwell's equations for the optical model of the system with known layer parameters.

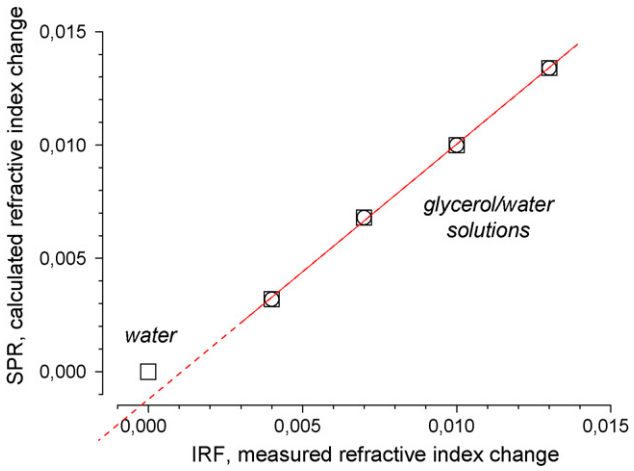

Fig. 5. Comparison of the refraction coefficient values for (different) samples: measured (with refractometer IRF-23) and calculated from SPR data (Winspall 2.0). Numerical simulation of the SPR curves was performed in the region $\theta_{SPR} \pm 2.0^\circ$ using a single-layer optical model: a semi-infinite prism ($1.61 + 0i$), a gold film (with effective thickness of 280 nm and refractive index $0.229 + 4.208i$) and a semi-infinite sample ($n_r + 0i$). The symbol size indicates the measurement uncertainty.

These results show that application of third-order polynomials is the most convenient and adequate procedure for construction of calibration equation for SPR transducers in the case of conventional measurements. Some additional information regarding the procedures for the determination of SPR resonance angle can be found in Ref. [40].

4.4. Calculating the refraction coefficient for external medium from SPR data

Shown in Fig. 5 are the calculated values of indices of refraction for the binary glycerol–water samples. They were obtained using numerical simulation (Winspall 2.0) of the SPR response curves near the minimum ($\theta_{SPR} \pm 2.0^\circ$), within the framework of a single-layer optical model of the system: a semi-infinite prism ($n = 1.61 + 0i$), a gold film with effective thickness of 280 nm ($n_{eff} = 0.23 + 4.21i$) and a semi-infinite sample ($n_r + 0i$)). One can see that the results of calculation (based on SPR curves) agree well with those measured using a standard refractometer. These observations enable us to stress that the application of angular dependence measurements in the analysis of SPR data makes it possible to take into account the features of the spatial distribution of the evanescent wave at the interface. At the same time, one should note that variation of instrument's baseline for different chips mounting in an immersion layer on the supporting prism surface can change the values of calculated parameters. One of the simplest and admissible ways to take into account such variations in the instrument parameters is the use of effective parameters of a thin gold film for numerical calculations.

It should be noted that the refractive indices for water and aqueous solutions of glycerol, measured by the SPR technique or by refractometry, also do not demonstrate linear dependence. The SPR technique overestimates the refractive index for water if we compare one with the linear calibration curve constructed from four values for glycerol solutions (2.5–10 vol.%, $r^2 > 0.999$).

The observed effect seems to be related to a process of nonspecific adsorption of glycerol on the surfaces. This process is reversible but it leads to formation of a dynamic Langmuir adsorption layer on the surface. This is the reason for effective overestimation of the calculated refractive index of the external medium by the SPR.

The above observation shows that one should be careful when choosing calibration solutions. It is desirable to take systems of

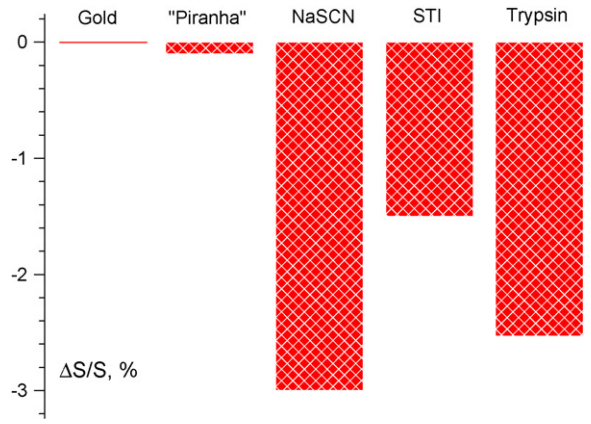

Fig. 6. Variation of SPR transducer sensitivity determined from the refractometric measurements data (5–10 vol.% glycerol in water) for different conditions at the interface: after treatment in "piranha" solution for 5 s. ("Piranha"), modification in NaSCN (4×10^{-5} M) solution for 5 min. ("NaSCN"), after adsorption of STI from 100 μg/ml solution ("STI"), and after interaction with 100 μg/ml trypsin ("Trypsin").

similar composition, with minimal amounts of surface-active components and narrow concentration range.

4.5. Dependence of SPR sensor sensitivity on surface structure formation

To study how the modification of SPR transducer with low-molecular weight compounds and subsequent interfacial biospecific reactions affect the sensitivity, we considered the results of refractometric analysis made with glycerol solutions made with increasing concentrations (5, 7.5 and 10 vol.%), washing the sensor after each measurement. For all the approximation methods, r^2 was over 0.998 and the standard error was less than 3%.

The results were obtained for the following surfaces: (1) an untreated gold surface without any additional molecular layers; (2) a gold film treated with an oxidizing etchant ("piranha" solution); (3) surface 1 modified with a NaSCN (4×10^{-5} M) solution; (4) surface 1 after STI (100 μg/ml) immobilization; and (5) surface 4 after interaction of immobilized STI with trypsin of the same concentration. It was shown (Fig. 6) that, in all cases, sensitivity variation depended on surface pretreatment.

It is necessary to stress that the variations of analysis sensitivity are of the same order as the standard error of S determination (2–3%). At the same time, the following two features are observed in the data set presented in Fig. 6. First is that formation of a thiocyanate layer on the gold film results in considerable sensitivity variations. This seems reasonable because the properties of gold film – the carrier of plasmon oscillations – change near the maximum of the electric field at the surface. Second is the reduction of analytical sensitivity as the thickness of a protein layer on the surface grows (such as in the case of the formation of an initial STI layer and then its complex with trypsin). This effect results from a decrease in the overlap area of the evanescent wave field and the sample (in this case, the external medium) owing to formation of a dielectric layer at the interface as discussed above [42]. The absence of any effect of treatment in "piranha" solution (a few seconds' exposure to minimize gold etching) on refractometric sensitivity seems to be because we used freshly prepared gold samples for analysis that should have only minimal organic surface contamination.

5. Some concluding remarks

The experimental variation of SPR transducer sensitivity (about 3%) at formation of interfacial biospecific architecture based on two proteins (molecular mass of about 20–25 kDa, diameter of several nanometers) enables one to estimate the measurement uncertainty of refractive index variation at the interface when performing analytical studies. The value obtained is, of course, the lower limit for the SPR transducer sensitivity variation because it does not take into account the accuracy in the refractive index based on refractometric measurements (2–3%). Therefore, the total error of sensitivity determination will be bigger owing to convolution of these factors. This fact is of particular importance when comparing the results of a series of experiments obtained with different SPR transducers as well for multilayer measurements.

Eq. (4) enables one to estimate the absolute measurement uncertainty arising at Δx measurements with the SPR technique. For instance, if the sample's refractive index is changed by 0.1 (Δx) and the sensitivity changes by 3% (say, due to formation of an interfacial protein structure), then the absolute error δn (δx) will be about 3×10^{-3}, and at $\Delta x = 0.01$, it will be $\delta x = 3 \times 10^{-4}$. One should take into account that sizes of both STI and trypsin are considerably below those of different specific immunoglobulins most often used for analysis. Therefore, the above values are lower limits for the error in determination of the refraction coefficient of external medium with the SPR technique. It is of interest that the estimated error we calculate is larger than the traditionally used value (about 10^{-4}) for variation of the refraction coefficient of water at temperature change by 1 K [43].

All these restrictions enable one to conclude that parameters of most of the present-day commercial SPR spectrometers are better than the above estimates. Therefore, we believe that further development of the SPR technique should involve not only increasing the sensitivity of optoelectronic transducers (which facilitates only better quantitative resolution of the method) but also developing the simple procedures for unification and standardization of the SPR chips. Moreover, it seems reasonable to apply various methods for initial signal amplification using selective agents (of biological [44] as well as inorganic [45] nature), analytical procedures [46], biochemical reactions [47] or even fluorescent labels [15,16] or light scattering techniques [2,20].

ABSTRACT

Near Infrared Chemical Imaging (NIR-CI) is demonstrating an increasing interest in pharmaceutical research since it meets the challenging analytical needs of pharmaceutical quality and may serve as a versatile adjunct to conventional NIR spectroscopy in many fields.

The direct analysis of samples by using hyperspectral imaging techniques, which provide a NIR spectrum in each pixel of the image, generates a big amount of information from one sample. Focusing the interest in pharmaceutical research, several chemometric algorithms are demonstrating their usefulness extracting the relevant information (i.e. quantitative determination of the component in one sample) in tablets with only one sample and without damaging it.

In this work, a quantitative method to analyze different commercial Acetylsalicylic acid tablets is proposed by using Multivariate Curve Resolution-Alternating Least Squares (MCR-ALS) method to the hyperspectral image and without any previous calibration model. For this purpose, a large concentration range of active pharmaceutical ingredient (ASA, Acetylsalicylic acid in this work), between 82% and 12%, was covered depending on the manufacturer. MCR-ALS allowed obtaining a concentration maps for acetylsalicylic acid and therefore, consequent analysis of the ASA distribution in the tablet was developed by using the histograms of the distribution of concentration.

Results certified the good distribution of ASA despite the different origins of the tablets. Moreover, the obtained values of concentration showed a very good concordance with the nominal value of ASA. As a matter of fact, the quality of the results demonstrated the useful of encompassing NIR-CI techniques with MCR-ALS and, consequently, the well development on the production of Acetylsalicylic acid tablets.

1. Introduction

Once conventional spectroscopy techniques have been demonstrated to be a useful tool in pharmaceutical technology providing a high number of publications praising this technique [1–4], hyperspectral imaging techniques have appeared with the aim not only to cover weak points in conventional spectroscopic techniques but also to extend the knowledge in this field [5–8]. Hyperspectral imaging techniques result especially attractive because of the possibility of providing huge spectral and spatial information of one sample (up to 82,000 spectra per sample) in a short time analysis.

Among all Imaging techniques, Near Infrared-Chemical Imaging (NIR-CI) has been confirmed to be an excellent tool to extract information of high quality of the sample surfaces, being applied in very diverse fields [9–14].

The greatest capacity of NIR-CI technique has drawn attention within the pharmaceutical field where robust methods are continuously demanded to obtain information of the quality of products in all the stages of the manufacturing process. Concerning this aspect, the final assessment of the quality in the final tablet (i.e. obtaining both quantitative and information about the spatial distribution of the components) is becoming a key-point in where NIR-CI is starting to gain importance [15].

Despite the benefits of NIR-CI in pharmaceutical research, there exists still a gap between the acquisition of the hyperspectral image and the treatment of such amount of information. In this sense some multivariate models have been previously used and tested, as Principal Component Analysis (PCA) [5,16,17], providing valuable initial information that helps to focus the further quantitative analysis.

On the other hand, quantitative analysis of pharmaceutical samples using NIR-CI has been performed using techniques as Partial Least Squares Regression (PLS) or PLS-Discriminant Analysis (PLS-DA) [18–21]. However, these techniques require a complete calibration set of samples with the corresponding time consuming until the calibration model is performed and adequately tested.

Concerning the quantification purposes without needing a previous calibration model, Classical Least Squares (CLS) may be presented as an alternative, since CLS only requires the pure spectra

of all the components of the tablet. This is not a problem in tablets manufacturing, in where the pure spectra of the components are commonly available. Nevertheless, typical phenomena as interaction between analytes, illumination noise or moisture contributions are important drawbacks that may CLS not to be as robust as it can be expected since the pure analytes do not recover the experimental variation [20].

One alternative that does not require a specific calibration set of samples has been recently proposed. Multivariate Curve Resolution-Alternating Least Squares (MCR-ALS) and its augmented version have been successfully applied to extract quantitative information of NIR Chemical Images in pharmaceutical samples [20,22,23]. This augmented version consists in providing information to the initial sample, helping the method to solve the inherent drawbacks of the Chemical Imaging measurement. Therefore, this technique presents a welcome alternative to quantify different components in tablets without needing a specific calibration model.

The objective of this paper is demonstrating the capability of the NIR-CI to extract information of different samples without the application of chemical quantitative information studying the distribution of Acetylsalicylic acid in commercial tablets. For this purpose, commercial tablets of Aspirin from 10 different manufacturers and different content of Acetylsalicylic acid were selected and studied by means of Multivariate Curve resolution-Alternating Least Squares. The consequent distribution of ASA content in each different commercial tablet surface was also studied and compared by using histograms.

2. Experimental

2.1. Reagents and instrumentation

2.1.1. Samples

10 commercial tablets of Aspirin were used in this study and purchased at the pharmacies. The ASA concentration for all the tablets was obtained by dividing the nominal content by the weight for each tablet. The nominal concentrations of ASA in the different tablets covered a wide range of concentration, from 82% to 12%.

The composition of the formulations is unknown and only the information, indicated in the brochure accompanying the different pills each box or in the Vademecum guide [24], has been used in this study. Table 1 shows the main features of each tablet.

Microcrystalline Celullose (MCC) is the main excipient in 6 of the preparations; whereas manitol is the main excipient in the other 2 tablets. *Dolmen* and *Aspirina C* are effervescent tablets and also content ascorbic acid as active component and other known excipients used in the formulation as citric acid, sodium carbonate and sodium bicarbonate anhydrous.

2.1.2. Instrumentation

All tablets were measured obtaining a hyperspectral image of the surface for each sample by using a "Think Spectrally Roda-25" NIR Hyperspectral Imaging Spectrophotometer (*Think Spectrally*, Valencia, Spain). This instrument is a Focal Plane array (FPA) and it is composed by a Liquid Crystal Tunable Filter (LCTF) monochromator

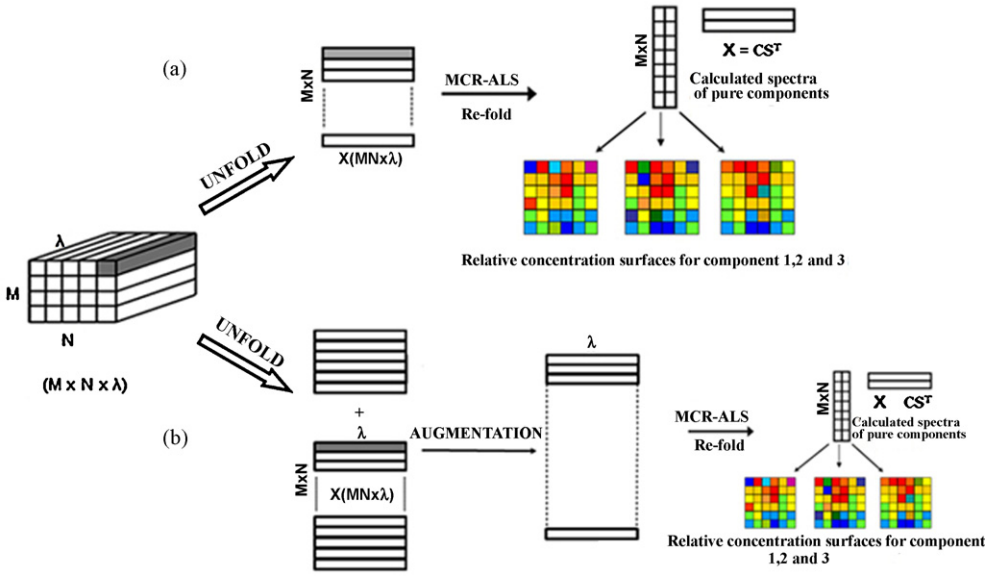

Fig. 1. Scheme of MCR-ALS analysis (a) and augmented MCR-ALS (b) application to the hyperspectral cube.

and a Mercury Cadmium Telluride (MCT) detector which provides a spectral range between 1000 and 2400 nm with 7 nm of spectral resolution and a spatial resolution of 100 μm × 100 μm each pixel.

Three different areas of image were used depending on the size of the tablets: 15 × 15, 8 × 8 and 5 × 5 mm^2. The total time of image acquisition was about 2 min. The lighting to the sample is a very relevant parameter in order to obtain quality images avoiding noise related to a bad illumination. Therefore, 4 halogen lamps were focused to the sample place with a 45° orientation. Prior to the registration of the images the calibration of the instrument was performed by using 6 standards (FOSS *AP-0200 NIR*) covering reflectance values from 99% to 0.2%.

2.1.3. Software

All the spectral pretreatments were applied by using home-made routines programmed in MATLAB code (MATLAB v 7.0, *The MatWorks*, Massachussetts) [18] and they are available via web [25]. MCR-ALS software from the reference [26] working under MATLAB was used.

2.2. Hyperspectral images pretreatment

When a sample is registered with a Hyperspectral image device a three-dimensional array, X ($M \times N \times \lambda$) is obtained being the M and N axis the spatial information and the λ axis represents the spectral information. The three-dimensional structure of the hyperspectral data cube requires a previous unfolding step to a bi-dimensional matrix, adapting the image for further pretreatments or any other method.

Once the images were unfolded several spectral pretreatments were applied to avoid the influence of undesirable phenomena commonly found in NIR measurements. Thus, Standard Normal Variation (SNV), 1st and 2nd Savitzky–Golay Derivatives and also smoothing were applied.

2.3. MCR-ALS in imaging data

Multivariate Curve Resolution-Alternating Least Squares (MCR-ALS) [17,27] decomposes the unfolded matrix X ($MN \times \lambda$) into the product of two matrices, C ($MN \times A$), containing the concentration profiles and S^T ($A \times \lambda$), containing the spectral profiles for each A component (Fig. 1a) (Eq. (1)):

$$X = CS^T + E \quad (1)$$

where E ($MN \times \lambda$) corresponds to the experimental error matrix. The ALS optimization stops when the relative difference in lack of fit (%LOF) values between consecutive iterations is below than a threshold value where e is each mnth element of the residual matrix E, and x is each mnth element of the X matrix. The threshold value

Bioplak 250	71.84	71.34	−0.5	0.993	0.997	–
Bioplak 125	72.09	67.84	−4.25	0.986	0.994	–

* Effervescent tablets.

of LOF should be selected according to the noise in the spectra (Eq. (2)):

$$\%\mathrm{LOF} = 100 \times \sqrt{\frac{\sum_m^M \sum_n^N e_{mn\lambda}^2}{\sum_m^M \sum_n^N x_{mn\lambda}^2}} \quad (2)$$

where $e_{mn\lambda}$ and $x_{mn\lambda}$ represent each point of the residuals and original three way array, respectively. A very used criterion is to stop the iterations when the difference between two consecutive %LOF values is below 0.1%.

Before starting the iterations, initial estimates are required to help the algorithm to converge to the absolute minimum error. Using the pure spectra of the components (if they are available) as initial estimations becomes one of the most attractive ways of including information about the sample. Other constraints can be used to correctly decompose the matrix when chemical images are analyzed: (1) non-negativity in concentration and/or spectral profiles, which imposes that concentration profiles of the components are supposed to be always positive; and (2) closure, where each pixel can be supposed to accomplish a constant mass balance of 1, representing the totality of the concentration.

However, the quality of the images, which depends on the spatial and also spectral resolution, could be a disadvantage when MCR-ALS is applied since there could be lack of selectivity in the surface of the image. To overcome this problem an alternative has already been formulated: The augmentation of the original sample with

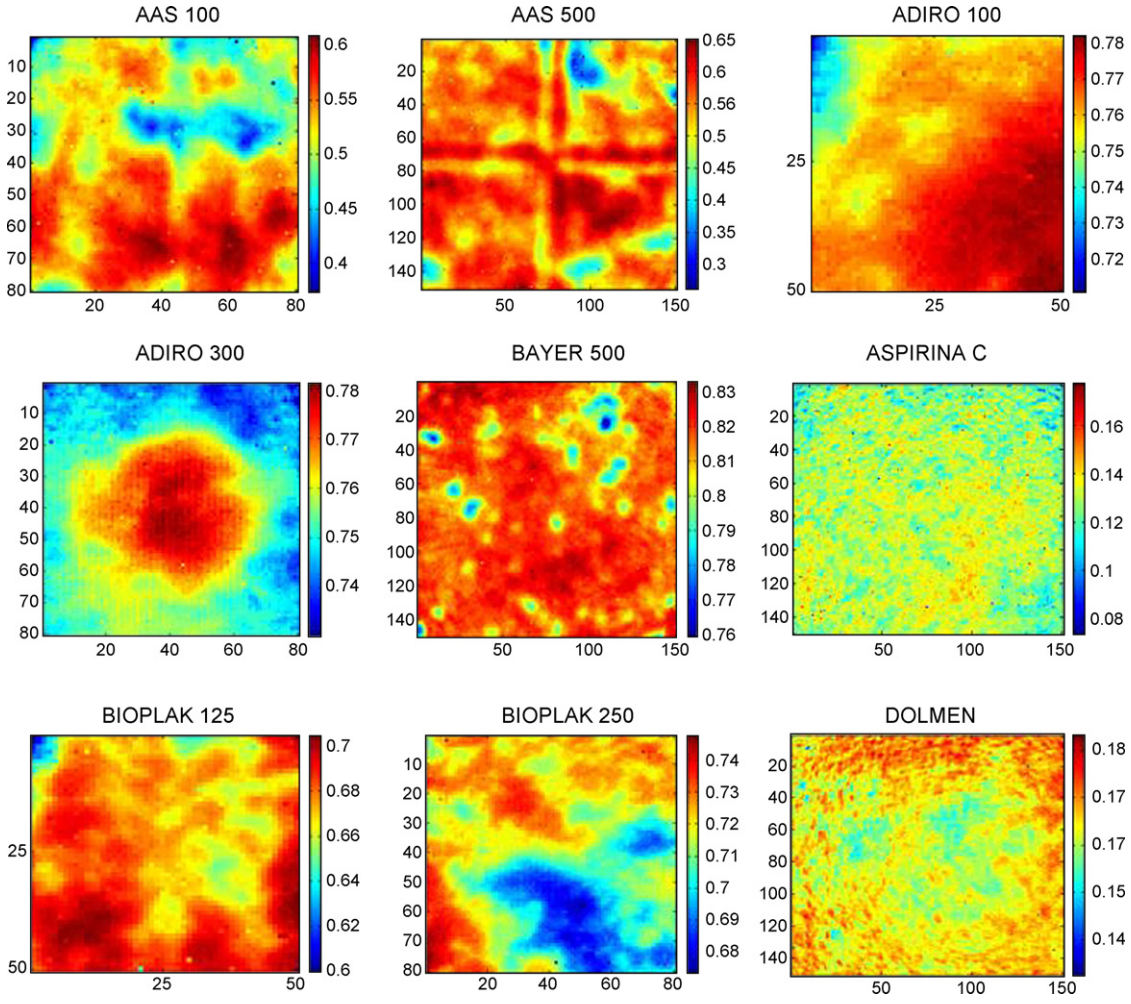

Fig. 4. Concentration maps for ASA obtained by using Augmented MCR-ALS.

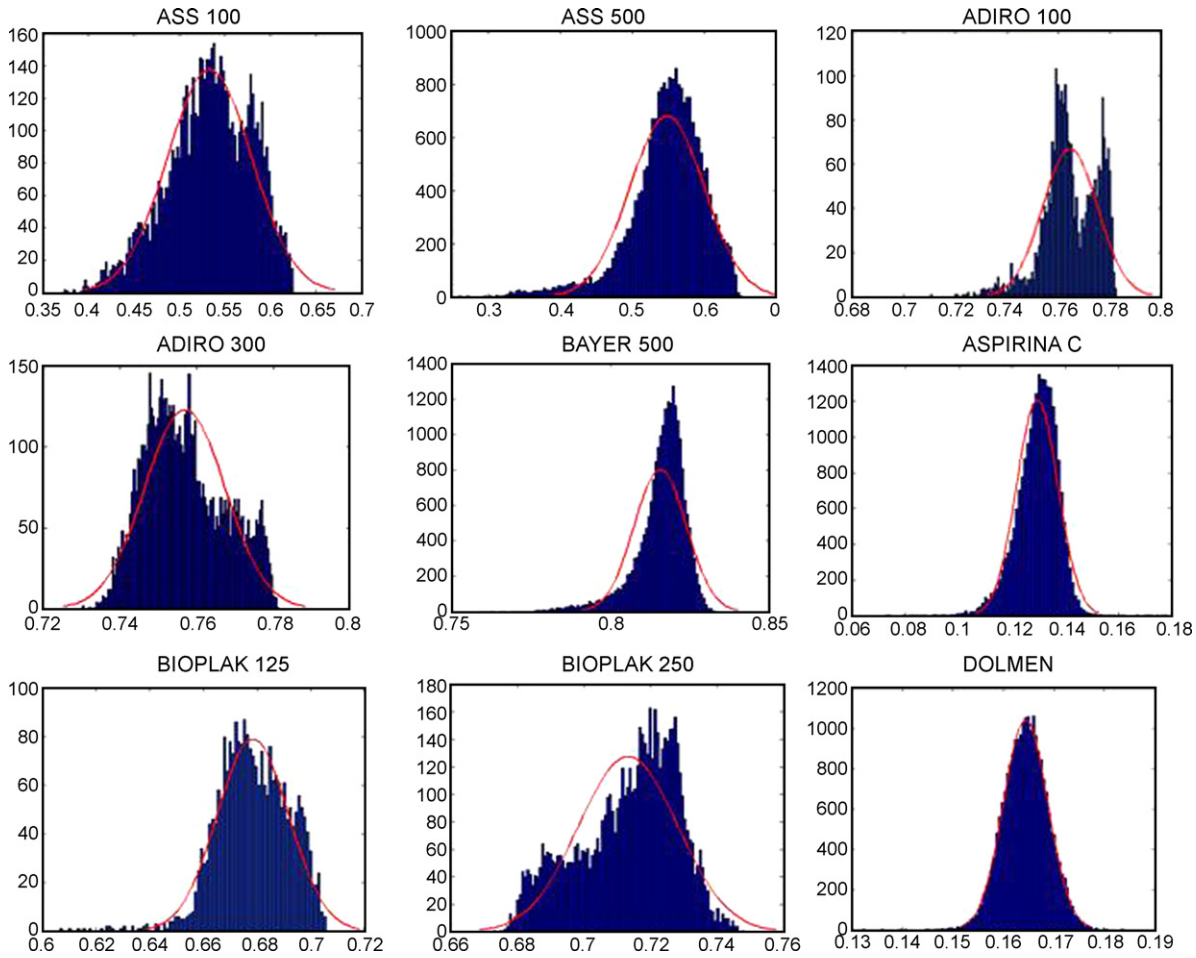

Fig. 5. Histograms for the ASA distribution on the surface tablets.

images of the pure analytes (Fig. 1b). The original idea consisted analyzing several samples simultaneously by augmenting all the images [17]. In the present work, the augmentation is performed by inserting images of pure components as it is shown in Amigo and Ravn [20]. These images of pure components can be easily measured in the same way as the commercial tablet. This approach helps to minimize the problem and offers valuable information to the algorithm.

3. Results and discussion

3.1. MCR-ALS and augmented MCR-ALS analysis

Fig. 2 offers a first impression of the main differences between tablets; these differences are expected since the composition of each tablet depends on the different excipients; however, the spectral band of ASA (around 1680 nm) can be observed in all spectra. Moreover, the tablets *AAS*, *Adiro* and *Bioplak* can be distinguished in depending on the different origins, because they present very similar spectra between them and can be clearly distinguished from other formulations. On the other hand, *Dolmen* and *Aspirina C* mean spectral profiles are very similar despite the fact that they come from different manufacturers.

Several pretreatments were tested with the images, and the combination of SNV and smoothing average with a window size of 7 points provided the best results. Prior to apply MCR-ALS, non-negativity of concentration profiles and closure constraint were applied as constraints. Despite the fact that the tablets were comprised by a different number of components, closure constraint was applied taking into consideration the Active Pharmaceutical Ingredient (ASA) and the main excipients for each of the tablet (MCC or Manitol for 8 tablets and the whole formulation for *Dolmen* and *Aspirina C*). Therefore, the spectral profiles obtained by MCR-ALS will provide information about the goodness of the decomposition of images. Moreover, ASA and the excipients used in this study provided the highest spectral information and were used to perform the MCR-ALS analysis, while the minor excipients may be related with the residual matrix. The pure spectra of the main components were included as initial estimations to start the iterations. The same methodology has been followed when the augmented version of MCR-ALS was applied, including 10 spectra for both analytes (ASA and major excipient) to the unfolded matrix in order to improve the decomposition. To test the MCR-ALS decomposition, %LOF and correlation coefficient between pure spectra and obtained spectral profile were used.

As an example, the %LOF of the MCR-ALS model applied to *Aspirine Nicholas 500* was 2.79%, explaining 99% of variance, indicating the goodness of the model. Moreover, quantitative results from this tablet were accurate compared to the formulation percentage (77.5% for ASA while theoretical value is 80.1%). Nevertheless, the correlation coefficient between the obtained spectral profile for ASA and MMC with the pure spectrum was lower than 1 (0.76 and 0.51 respectively).

To overcome this problem, the augmented version of MCR-ALS was applied. The augmentation was developed by including selective information (10 pure spectra) for each component in the image. The same pretreatments for the image and restrictions were applied. The model obtained with Augmented-MCR

ALS showed quite similar values for %LOF (3.55) and explained variance (99.87%), providing also quite good results in the quantitative analysis. As it can be seen in Fig. 3a and b, the spectral profiles obtained with the augmented version of MCR-ALS perfectly matched with the pure spectra of each compound. Correlations coefficients between these spectra, shown in Table 2, are closed to 1.

The concentration map calculated for ASA using this model showed the distribution on the surface of the tablet and some regions with different concentrations of ASA. At first sight, ASA could be thought not to be well distributed in the tablet. However, the colour scale of this image showed a narrow range, between 0.70 and 0.78. Therefore, the ASA content in each pixel was similar as showed the histogram of the concentration map with a distribution close to a Gaussian distribution (Fig. 3d).

3.2. Results for all the commercial tablets

Table 2 shows the quantitative results for the 10 tablets obtained by using augmented MCR-ALS. The concentration for ASA in the surface of the tablets was similar to the calculated value confirming the goodness of the quantitative analysis. Good results were obtained for almost all of the samples (the spectral correlation between pure ASA spectrum and the spectral profile for ASA in all samples was close to 1 confirming the goodness of the application of augmented MCR-ALS). Tablets with Manitol as the main significant excipient showed not so good results for the determination of ASA content. Looking at their correlation coefficients with Manitol, they were not so close to 1. It might be caused by the influence of another excipient with a high spectral relevance providing information to the image, but avoiding the correct decomposition of the data matrix.

On the other hand, samples where the ASA content was lower could be waited to show bad predictive results. However, the use of all pure spectra allowed obtaining quite good results. Taking into account the fact that closure constraint was applied and in these samples, ASA is not the most relevant spectral compound, the decomposition of the image could have been less successful.

Despite of using all the compounds in the analysis of *Dolmen* and *Aspirina C*, the correlation coefficients obtained were not of high quality. For *Aspirina C* the correlation coefficients obtained were 0.851 for Citric Acid, 0.957 for Ascorbic Acid and 0.995 for Carbonate whereas for *Dolmen* the coefficients obtained were 0.856 and 0.823 for Ascorbic Acid and Carbonate respectively. However, ASA concentration obtained in both tablets was truly similar with real values.

All the concentration maps for ASA are depicted in Fig. 4, where different distributions of the ASA were observed. As already described for the *Aspirine Nicholas 500*, the first impression might be misleading, because of the scale of the colour maps. Therefore, the histogram for each ASA concentration map was depicted in Fig. 5 for better interpretation. Ideally, one would expect a histogram whose values were around the prediction values, and with a narrow variation, implying that the whole surface of the tablet contained the same amount of ASA.

Looking at the histograms of the local concentration it was possible to correctly visualize tablets with best ASA distributions. Thus, the tablets with narrowest ASA distribution were: *Aspirine C*, *Dolmen*, *Bayer 500* (according to the prior conclusion). Although the range for ASA 100 tablet was not as narrow as for the other 3 samples, the distribution of concentration values remained close to a normal distribution. For the other samples, the visual inspection of the concentration maps and the representation of histograms confirmed a less regular distribution for the ASA in the surface.

4. Conclusions

Intact commercial tablets were analyzed by NIR-Chemical Imaging in order to determine de distribution of ASA and its ASA concentrations for each tablet using the MCR-ALS decomposition. The quantification results in combination with the spectral profiles obtained provided information about of the 10 commercial tablets quality.

MCR-ALS decomposition de applied to images to obtain accurate information of the surface demonstrated to be an appropriate tool to obtain quantitative information of ASA content on the surface of the tablets. In addition, the augmented version of MCR-ALS demonstrated to be an outstanding methodology to overcome the problems of MCR-ALS decomposition itself.

The distribution of ASA in the surface and the mean concentration were correctly calculated without needing a calibration model with reference values. The quantitative results obtained were of quality, especially for the tablets whose major ingredient was ASA.

The low time of analysis without altering the sample and the good results obtained, make the combination of NIR-Imaging and MCR-ALS a very interesting approach in the pharmaceutical field for the quality control assessment of final preparations.

One-step single-metal nanoparticles deposition
Latent fingermarks

ABSTRACT

A simple and environment friendly chemical route for detecting latent fingermarks by one-step single-metal nanoparticles deposition method (SND) was achieved successfully on several non-porous items. Gold nanoparticles (AuNPs) synthesized using sodium borohydride as reducing agent in the presence of glucose, were used as working solution for latent fingermarks detection. The SND technique just needs one step to obtain clear ridge details in a wide pH range (2.5–5.0), whereas the standard multi-metal deposition (MMD) technique requires six baths in a narrow pH range (2.5–2.8). The SND is very convenient to detect latent fingermarks in forensic scene or laboratory for forensic operators. The SND technique provided sharp and clear development of latent fingermarks, without background staining, dramatically diminished the bath steps.

1. Introduction

Hitherto, fingermarks constitute one of the most important categories of physical evidence in the forensic science. In past decades, methods of visualization of fingermarks have been developed significantly, such as iodine fuming, ninhydrin, silver nitrate [1], and cyanoacrylate fuming [2–4]. Recently, nanoparticles were widely used in this filed, e.g. CdS [5–8], CdTe [9], SiO_2 [10], and AuNPs. Multi-metal deposition method (MMD), as a useful mean to detect latent fingermarks on porous and non-porous items, was first proposed by Saunders in 1989 [11,12]. It is a two-step wet chemical process for latent fingermarks detection, combining the principles of small particles reagent with AuNPs and following a silver physical developer (AgPD). It is an equivalent, and usually superior to the well-known methods of cyanoacrylate fuming [2–4] and vacuum metal deposition [13] on various kinds of items. Schnetz and Margot used smaller AuNPs to take further studies on MMD procedure, yielding better results [14]. They explored the influence of particle size, pH value, concentration of the colloidal gold solution and the concentration of Tween 20 on detecting latent fingermarks. Mandler and Almog [15] proposed AuNPs stabilized by n-alkanethiols according to Brust et al. [16] to detect latent fingermarks on porous items in petroleum ether. Meanwhile, they probed the relationship among the thiol chain length, concentration of AuNPs, and fingermark enhancement. Becue et al. developed a new MMD technique of modifying AuNPs with mercaptocyclodextrin as a host for organic dye. This technique reduced the bath numbers and enhanced the latent fingermarks through utilizing organic dye instead of AgPD [17]. Stauffer et al. presented a single-metal deposition (SMD) to visualize latent fingermarks [18]. In the second step, they replaced the AgPD with tetrachloroauric acid and hydroxylamine hydrochloride to enhance the fingermark detection. Actually the SMD technique is quite similar to the standard MMD technique. Latent fingermarks detection techniques, as described above, suffer from restrictive experimental conditions, such as bothersome processes to prepare precursors (AuNPs), many baths, high cost preparation, and even some harmful solvents involved. So far, latent fingermarks detection only with AuNPs through one-step has not been reported yet.

AuNPs have received considerable attention for potential applications in the fields of physics, chemistry, optics, biology, electronics, and materials science [19]. A variety of methods have been reported and reviewed for preparation of AuNPs [10,20–23]. The most commonly used method is chemical reduction of gold salts by various reductants, such as sodium citrate [22], thiocyanate [20], and sodium borohydride [10]. Several forensic science laboratories [12,14–16,20] have also concluded that colloidal gold is a particularly effective reagent on detecting latent fingerprints.

In this work, glucose stabilized AuNPs were synthesized and utilized as working solution to detect latent fingermarks. Two methodologies, the SND and MMD, were applied in fingermarks detection under the same condition. The influence of pH values

on detecting latent fingermarks was also explored. It was found that the SND technique provided sharp and clear development of latent fingermarks, without background staining, dramatically diminished the bath steps in a wide pH range.

2. Experimental

2.1. Chemicals

Chloroauric acid tetrahydrate, sodium borohydride, and sodium hydroxide were purchased from Sinopharm Chemical Reagent Co. (Shanghai, China). Citric acid was purchased from Beijing Chemicals (Beijing, China). Glucose was purchased from Aldrich (USA). All of the chemical reagents were used without any further purification. All glassware used in the following procedures was cleaned in a bath of freshly prepared 3:1 HCl/HNO_3 (v/v), and rinsed thoroughly with double distilled water prior to use. All the experiments were carried out at room temperature.

2.2. Preparation of AuNPs

Glucose stabilized AuNPs were prepared according to the following procedures: 2×10^{-5} mol chloroauric acid tetrahydrate and 2×10^{-4} mol glucose were dissolved in 18 ml deioned water in a flask with stirring. 30 min later, a freshly prepared 2 ml ice-water solution of sodium borohydride (1×10^{-4} mol) was added dropwise into the above solution under vigorous stirring. Color of the solution changed immediately from straw yellow to wine red, indicating the formation of AuNPs. After stirring for 1 h, the prepared AuNPs were used for detecting latent fingermarks.

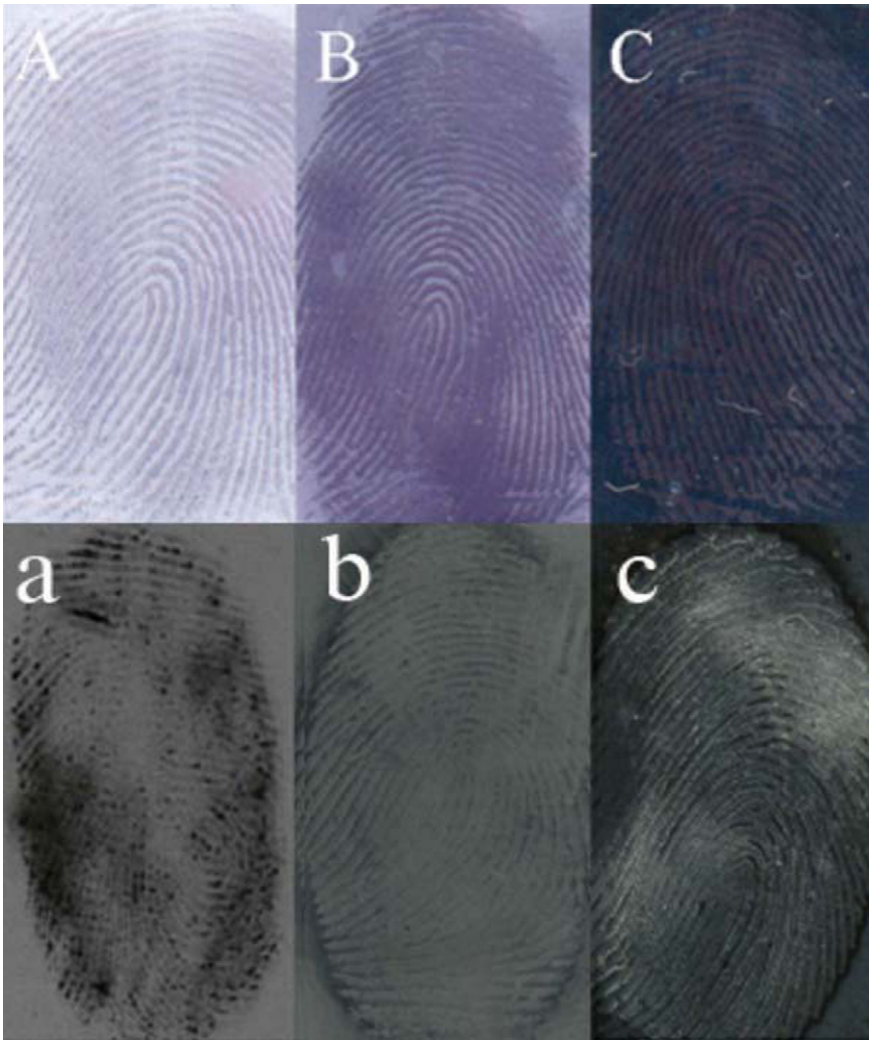

Fig. 2. Latent fingermarks were developed with the SND technique using glucose stabilized AuNPs on (A) glass slide, (B) plastic, and (C) tin foil; and with the standard MMD technique on (a) glass slide, (b) plastic, and (c) tin foil.

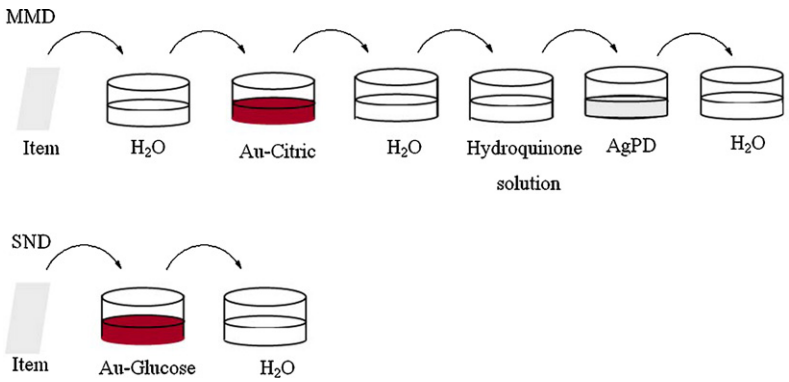

Fig. 3. Schematics of the standard MMD and the SND technique.

2.3. Detection of latent fingermarks

Latent fingermarks were obtained all from one volunteer by rubbing fingers against the forehead and stamping them onto glass slides, plastic and tinfoil at the same condition, respectively. The obtained latent fingermarks are similar to real samples on the same items.

Citric acid (1 M) and sodium hydroxide (1 M) solution were used to adjust the pH value of the prepared AuNPs. Then, the items bearing latent fingermarks were immersed into the working solution, removed from the solution 40 min later, rinsed with deioned water, and dried with nitrogen steam. Clear ridges of prints were obtained.

Control experiments were carried out at pH 2.8, using the SND and the standard MMD [14].

The influence of the pH on detecting latent fingermarks was further investigated. Different pH was adjusted with citric acid (1 M) and sodium hydroxide (1 M) (2.0, 2.5, 3.0, 3.5, 4.0, 5.0, 5.5, 6.0, and 7.0) to detect latent fingermarks at room temperature.

2.4. Instrumentations

UV–vis measurement was carried out on a Cary 50 UV–vis spectrophotometer (Varian, USA). TEM measurement was performed on a JEOL 2010 transmission microscopy operated at an accelerating

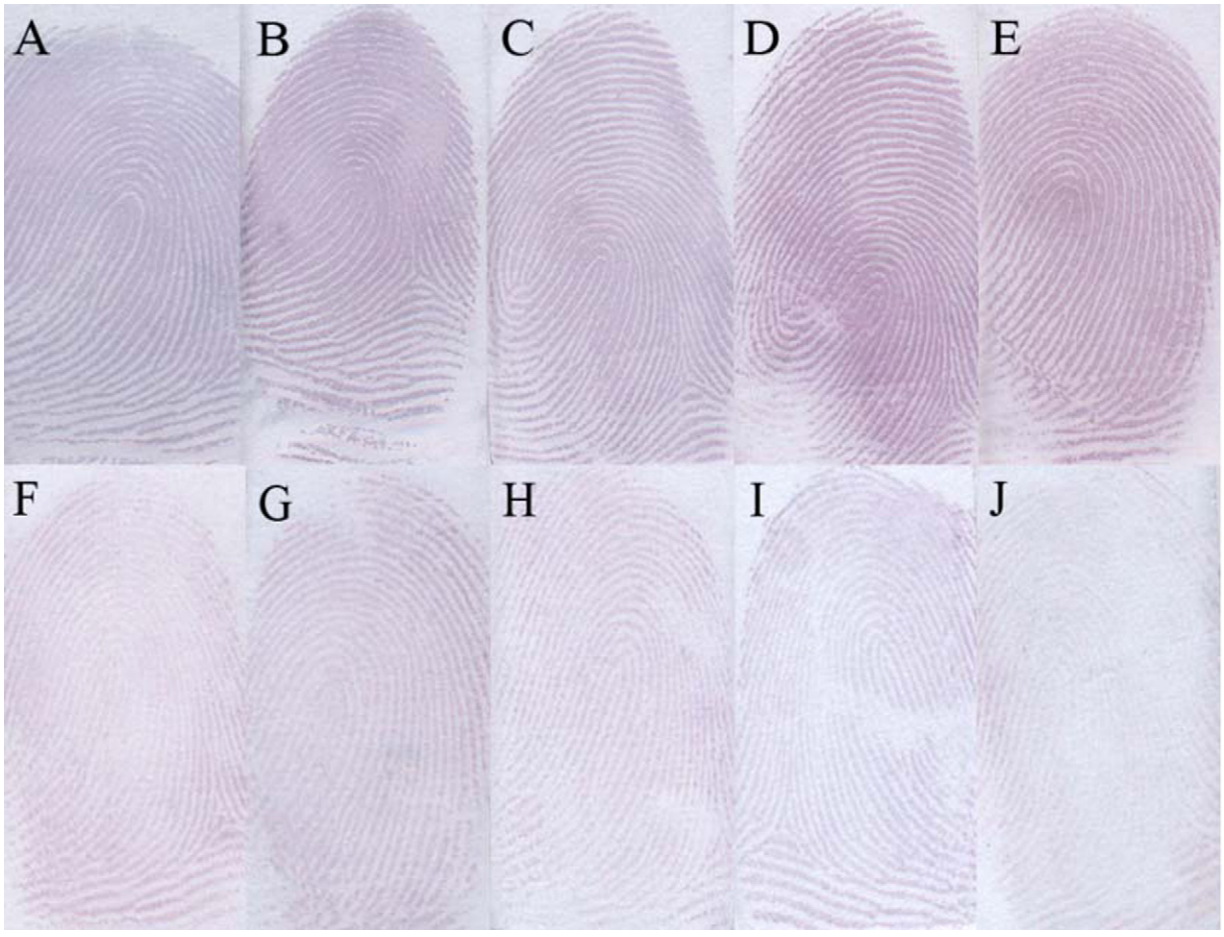

Fig. 4. The pH influence of colloidal gold solution on the fingermarks detection on glass slides: (A) 2.0, (B) 2.5, (C) 3.0, (D) 3.5, (E) 4.0, (F) 4.5, (G) 5.0, (H) 5.5, (I) 6.0, and (J) 7.0, respectively.

voltage of 200 kV. The sample for TEM measurement was prepared by placing a drop of as-prepared AuNPs solution onto a carbon-coated copper grid and dried at room temperature. SEM and EDAX measurement was taken on a FE-SEM, S-4800, Hitachi Scanning Electron Microscopy. Photos were taken with Nikon D100 made by Nikon Corporation.

3. Results and discussion

AuNPs were prepared using sodium borohydride as the reducing agent in the presence of glucose. The UV–vis spectrum and TEM image were used to confirm the formation of AuNPs (Fig. 1). The UV–vis spectrum of the AuNPs shows an absorption peak at 511 nm, assigned to the characteristic surface plasmon resonance [19]. TEM image was applied to further confirm the AuNPs formation. Inset of Fig. 1 displays the AuNPs are generally well-separated from each other. The size distribution histogram shown in the inset reveals an average diameter of 2.5 nm, as judged from more than 200 individual particles, which is much smaller than particles in Schnetz and Margot's work (14 nm).

Control experiments were carried out between the SND and the standard MMD technique. The items bearing latent fingermarks were immersed into the glucose stabilized AuNPs at pH 2.8 for 40 min, and washed with deioned water to remove redundant AuNPs, natural drying. On glass slide, plastic and tinfoil, high quality prints were developed and shown in Fig. 2A–C. Meanwhile, control experiments were carried out according to the MMD procedure [14]. Correspondingly, Fig. 2a, b, and c were the results developed on glass slide, plastic, and tin foil, at the same condition as above. Comparatively, both of the two methods can obtain quasi-identical ridge details of fingermarks. Nevertheless, the SND procedure has no background interference and shows much clearer ridge details than the MMD procedure (Fig. 2). The color of fingermarks detected by the SND is reddish while the other is black with MMD procedure.

The standard MMD and the SND technique procedures were schematically depicted in Fig. 3. The standard MMD is seldom used in forensic laboratories, due to its labor intensive, time consuming, and only producing dark grey or black fingermarks. The MMD laboratory procedures are consisted of six consecutive baths into which the items were immersed for different time (upper in Fig. 3). The first three baths assure the deposition of gold colloids, while the other three baths were the reduction of silver on the gold colloids to enhance the detected latent fingermarks to be grey or black. The SND technique was carried out in two baths, with no reinforcing reagent (as AgPD or organic dye) just glucose stabilized AuNPs (lower in Fig. 3). The SND has significantly diminished the number of laboratory operations, and cut the cost for detecting latent fingermarks. So the procedure might be an attractive alternative to the MMD procedure.

The influence of pH on detecting fingermarks was further explored. Latent fingermarks were immersed in different pH solutions of glucose stabilized AuNPs (2.0, 2.5, 3.0, 3.5, 4.0, 5.0, 5.5, 6.0, and 7.0) for 40 min, washed with deioned water, and dried with nitrogen steam (as shown in Fig. 4). In a wide pH range, marks on glass surfaces could be visualized well. At a low pH value, the synthesized AuNPs are unstable and aggregated easily, so the fingermarks are light blue (Fig. 4A and B). At high pH value, there are not enough protons to activate the protein or peptide included in the latent fingermarks. So the obtained results are not as good as those in lower pH solution. In the neutral condition (pH 7.0), there were almost no ridge details obtained. From these points we conclude that the favorable pH range for latent fingermarks detection is around 2.5–5.0, which is obviously wider than traditional MMD (only working for pH 2.5–2.8). It is much convenient for workers to detect latent fingermarks in forensic science or laboratory.

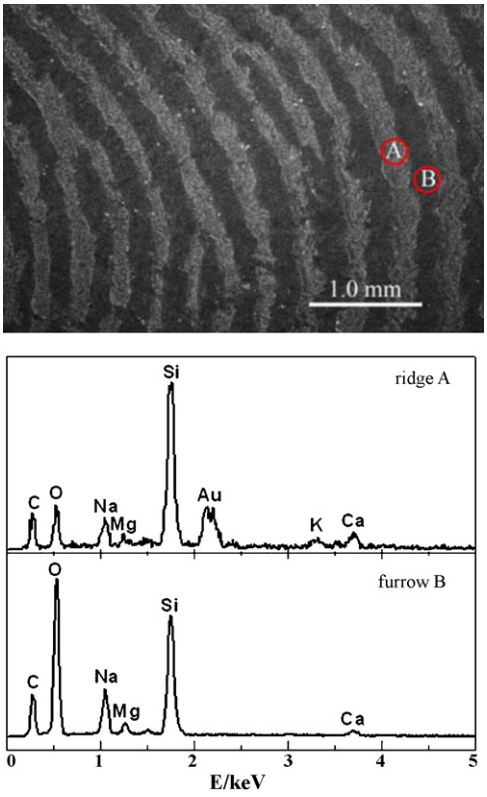

Fig. 5. SEM image of detected fingermarks with glucose stabilized AuNPs on silicon wafer and EDAX analysis for the ridges (region A in SEM image) and furrows (region B).

The binding mode of the AuNPs to the fingermark residues remains misunderstood, even if the electrostatic attraction is the most widely accepted one. The theory is that proteins or amino acid containing components within a fingermark can be protonated under acidic conditions and thus charged positively. Negatively charged AuNPs are deposited preferentially onto the fingermark ridges through electrostatic interactions or non-covalent interaction [6]. There are more components, like oil, protein and salt, on the ridges of the fingermarks than on the furrows [7]. So there are more AuNPs attracted on the ridges. Hence, latent fingermarks can be revealed. Fingermarks detected by glucose stabilized AuNPs on silicon wafer was characterized by SEM and EDAX (Fig. 5). Au element appeared on the ridges of the developed latent fingermarks (Fig. 5 ridge A), while no Au element on the furrows (Fig. 5 furrow B).

4. Conclusion

In this report, a one-step single-metal nanoparticles deposition method (SND) has been proposed for detecting latent fingermarks on non-porous items. AuNPs stabilized by glucose have been successfully synthesized and suggested to be utilized as the working solution to detect latent fingermarks. The SND technique could obtain even better results in a wide pH range compared with the standard MMD. It is a simple method to detect latent fingermarks only with AuNPs and just in one step rather than tow or more. This technique has dramatically diminished the baths, operated simply and expediently, and enlarged the pH range for detecting latent fingermarks. These may establish a new possibility for the detection of latent fingermarks in forensic science.

ABSTRACT

A novel and simple electrochemical method for determination of melamine is developed based on oligonucleotides film modified gold electrodes. The electrochemical probe of ferricyanide was used to investigate the interactions between oligonucleotides and melamine. Results of cyclic voltammetries, differential pulse stripping voltammetries, electrochemical impedance spectrometry and atomic force microscope, proved that melamine might interact with oligonucleotides mainly through electrostatic and hydrogen-bonding interactions. The interactions between oligonucleotides and melamine lead to the increase in the peak currents of ferricyanide, which could be used for electrochemical sensing of melamine. The redox peak currents of ferricyanide were linear with the concentration of melamine in the range from 3.9×10^{-8} to 3.3×10^{-6} M with a linear coefficiency of 0.990. The detection limit was 9.6×10^{-9} M. The proposed electrochemical biosensor is rapid, convenient and low-cost for effective sensing of melamine. Particularly, the proposed method was applied successfully to the determination of melamine in milk products, and the recovery was 95%.

1. Introduction

Melamine, a kind of triazine analogue with three amino groups (Fig. 1), is widely used as an industrial chemical in the production of melamine resins, which are used in laminates, glues, adhesives, and plastics. Melamine can be found as a contaminant in a variety of foods from food-contact materials. When added to milk powder, melamine increases the nitrogen concentration, which suggests a false increase in protein concentration. When meeting strong acids or alkali, melamine yields ammeline, ammelide and cyanuric acid by hydrolysis. Melamine could form insoluble complexes with cyanuric acid, depending on urine pH, which could lead to crystallization and subsequent tissue injury [1], such as urolithiasis and bladder cancer. Recently many young children have suffered from renal stone caused by melamine in the milk powder, so significant efforts have been made on the fast and effective detection of melamine.

Up to now, some methods, such as gas chromatography (GC) [2], high performance liquid chromatography (HPLC) [3], high performance liquid chromatography/mass spectrum (HPLC/MS) [4], surface enhanced raman spectroscopy [5] and capillary zone electrophoresis/mass spectrum (CE/MS) [6] have been employed for the determination of melamine. However, complicated preconcentration, time-consuming steps and high-cost instruments limit the application of the existing methods. Hence, there have been increasing demands for new, fast, simple, convenient and sensitive methods for the determination of melamine. Compared to those existing methods, much importance has been attached to the electrochemical sensors due to their simplicity, low-cost, accurateness, sensitivity and high stability. Unfortunately, so far few of papers have been reported concerned about electrochemical methods to determine melamine at solid electrodes.

In this paper, surface electrochemical method based on an oligonucleotide ($d(T)_{20}$) film modified electrode is developed for the determination of melamine (Fig. 2). Due to complementary triamino triazine unit, melamine can be immobilized onto the oligonucleotides modified electrode via electrostatic interaction and hydrogen-bonding [7]. The morphologic differences between melamine and melamine interacted with oligonucleotides were observed by AFM. The electrochemical probe of $[Fe(CN)_6]^{3-/4-}$ was used to investigate the interaction between melamine and oligonucleotides since melamine is non-electroactive over the potential range studied. The peak currents of the electrochemical probe evaluated by differential pulse stripping voltammetry (DPSV) were linear with the concentrations of melamine in the range from 3.9×10^{-8} to 3.3×10^{-6} M with a linear coefficiency of 0.990. The detection limit was 9.6×10^{-9} M. On the other hand, electrochemical impedance spectrometry is a useful

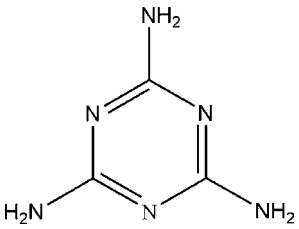

Fig. 1. The structure of melamine.

method to study the interfacial properties of modified electrode [8–12]. The immobilization of materials on the electrode surface might probably alter the interfacial electron transfer features at the electrode surface. Therefore, in this study, electrochemical impedance spectrometry was further used to study the interaction between oligonucleotides and melamine. The proposed method was applied successfully to the determination of melamine in milk products, and the recovery was 95%. To the best of our knowledge, the proposed method has not been reported, which will have great implications in the determination of melamine in food.

2. Experimental

2.1. Chemicals and materials

Melamine, analytical grade, was purchased from Sigma (USA). Oligonucleotides ($d(T)_{20}$) containing a 6-mercaptohexyl linker at the 5′ end was obtained from Shanghai Invitrogen Corporation (China). The $d(T)_{20}$ stock solution (20 μM) was prepared by dissolving the $d(T)_{20}$ powder in 0.01 M phosphate buffer solution (pH 7.0) containing 0.5 M NaCl and stored at 4 °C. Other chemicals were of analytical reagent grade and used as received. All aqueous solutions were prepared with distilled water.

2.2. Apparatus and equipments

Electrochemical measurements were carried out by a CHI 760C electrochemical workstation (CHI Instrument Company, Shanghai, China). A three-electrode system was used in the measurements, composed of a bare gold electrode (d = 2 mm) or $d(T)_{20}$/Au as the working electrode, a saturated calomel electrode (SCE) as the reference electrode and the Pt wire as the counter electrode. All the pH measurements were performed with PB-10 pH meter (Sartorius, Germany). The images of atomic force microscope (AFM) were obtained by Veeco Dimension 3100 (Digital Instrument, USA) in the tapping mode in air.

2.3. Preparation of $d(T)_{20}$ modified electrodes

Gold electrode was cleaned by exposure to warm piranha solution (70% concentrated sulfuric acid, 30% peroxide solution (30%)) for 10 min, and rinsed ultrasonically with ethanol and water. Then the electrode was cycled between 0.2 and 1.5 V in 0.1 M H_2SO_4 at 100 mV/s until reproducible voltammograms were obtained.

Self-assembled monolayer was prepared by transferring 15 μL $d(T)_{20}$ solution onto the gold electrode's surface. After the 16 h immobilization period, the electrode was soaked in sterilized water for 2 h to remove any un-adsorbed $d(T)_{20}$, and dried with a nitrogen stream. Thus, the $d(T)_{20}$ modified gold electrode($d(T)_{20}$/Au) was obtained.

2.4. Atomic force microscopy

Cleaned mica substrates were dried under a stream of N_2, and a drop of melamine phosphate buffer solution (pH = 7.0) was deposited on the freshly mica surface. Half an hour later the excess solution was gently cleaned with a jet of distilled water, and the mica with adsorbed melamine molecules was then dried in a sterile atmosphere. Afterwards a drop of $d(T)_{20}$ phosphate buffer solution (pH = 7.0) was deposited on the positively charged melamine-modified substrates for 1–4 h as incubation time, and the excess solution was gently cleaned with a jet of distilled water. After the mica substrate was completely dried, the morphology of the resulting surfaces was characterized using atomic force microscopy.

3. Results and discussion

3.1. Atomic force microscopy evaluation of melamine–$d(T)_{20}$ interaction

Atomic force microscopy is another common method to study the interaction between small molecules and oligonucleotides [13–15]. Therefore, it is used to further investigate the interaction between melamine and $d(T)_{20}$. Mica was chosen as substrate because of its atomically flat surface over a large area. A drop of melamine solution spreads rapidly across the mica surface in a thin layer because of the high hydrophilicity of the mica surface when it is deposited on a freshly cleaved mica surface. Cationic melamine can be easily adsorbed on the negatively charged mica surface by electrostatic attractive force (Fig. 3A). Firstly we changed the incubation time to evaluate the effect of incubation time on $d(T)_{20}$ immobilization. Fig. 3B and C show the AFM images of $d(T)_{20}$ molecules absorbed on the melamine-modified mica surface for 1–2 h incubation time, respectively. The $d(T)_{20}$ molecules which carry negatively charged phosphate groups were immobilized onto positively charged melamine-modified mica surface via electrostatic attractions, while the negatively charged $d(T)_{20}$ molecules can hardly absorb onto the mica surface. The thickness of the $d(T)_{20}$ layer on the positively charged melamine-modified surfaces was 8.2 nm during the first 1 h, and increased to around 32.8 nm in 2 h. Obviously, the $d(T)_{20}$ molecules formed much more clusters to form a higher surface coverage with the increasing incubation time. The effect of concentration on the thick-

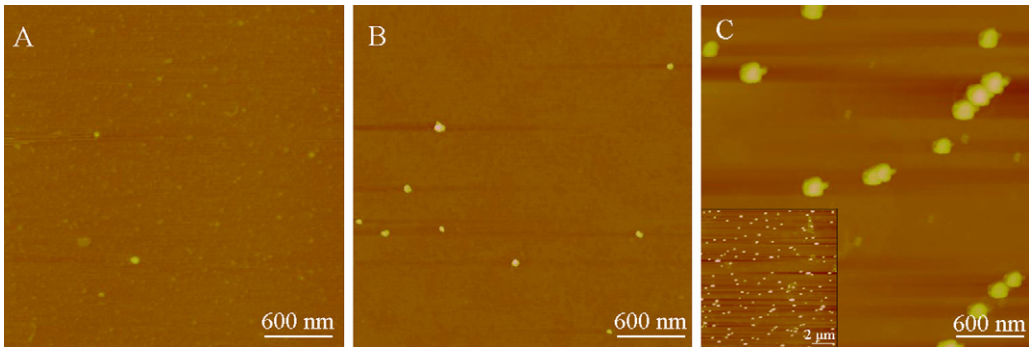

Fig. 3. AFM images (3 μm × 3 μm) of melamine-modified mica surface for different incubation time with $d(T)_{20}$: (A) 0 h, (B) 1 h, (C) 2 h. ($d(T)_{20}$ concentration: 2.2×10^{-5} M). Inset in Fig. 3C shows AFM image (10 μm × 10 μm) of melamine-modified mica surface incubated with 2.2×10^{-5} M $d(T)_{20}$ for 2 h.

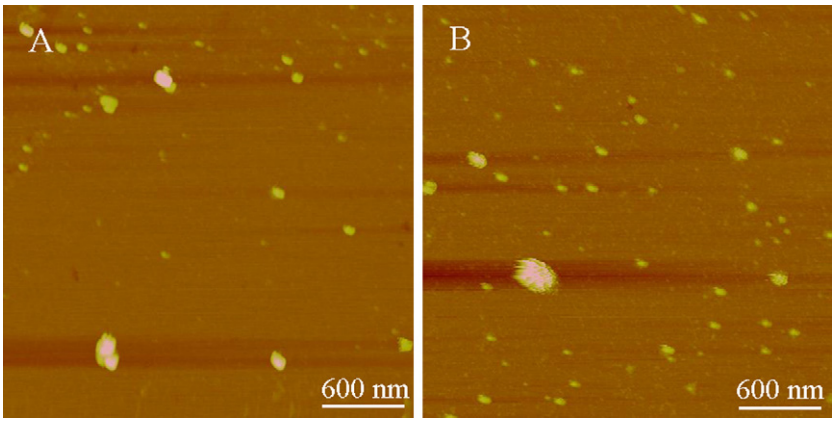

Fig. 4. AFM images (3 μm × 3 μm) of two different surfaces for different concentration of $d(T)_{20}$: (A) 5.4×10^{-6} M, (B) 1.1×10^{-5} M (Incubation time: 4 h).

nesses of the $d(T)_{20}$ overlayers formed on the positively charged melamine-modified surfaces was investigated by applying different concentration of $d(T)_{20}$ solutions (5.4×10^{-6} and 1.1×10^{-5} M, in pH 7.0 phosphate buffer solution) at room temperature. As seen from Fig. 4, more clusters formed on the melamine-modified mica surface with the increasing $d(T)_{20}$ solution concentration since the assembly becomes more convenient at higher concentration of $d(T)_{20}$.

3.2. Optimum conditions for melamine determination

3.2.1. Effect of the amount of $d(T)_{20}$

The electrochemical impedance spectroscopy was used to select a suitable $d(T)_{20}$ concentration for the electrochemical measurements. With increasing $d(T)_{20}$ concentration from 1 to 40 μM, the semicircle diameter in EIS initially increased and then became a plateau at 20 μM or higher. And the large semicircle diameter confirms the high surface density of $d(T)_{20}$ on the gold electrode when the concentration of $d(T)_{20}$ is selected as 20 μM. Therefore, 20 μM of $d(T)_{20}$ was employed for further assay.

3.2.2. Effect of accumulation potential and time

The electrochemical probe of $[Fe(CN)_6]^{3-/4-}$ was used in PBS buffer solution (pH7.0) containing 1.6 μM melamine by DPSV, varying the accumulation potential from 0.2 to 1.0 V, with 30 s accumulation time. The peak current increased with increasing accumulation potential and reached the highest at 0.8 V. Therefore, we select 0.8 V as the optimum accumulation potential.

In the same solution as above, the accumulation time changed from 0 to 300 s when the accumulation potential went to 0.8 V. The peak current value increased slowly with the time, so we selected 30 s as accumulation time to realize the rapid detection.

3.2.3. The pH effect on the melamine–$d(T)_{20}$ interaction

Fig. 5 displays the pH effect on the interaction between $d(T)_{20}$ and melamine. The strength of the interaction between melamine and $d(T)_{20}$/Au electrode is pH dependent. At pH 8.0, melamine is electrically neutral so its electrostatic interaction with the $d(T)_{20}$ is weakened (likely to be due to deprotonation of the amino groups

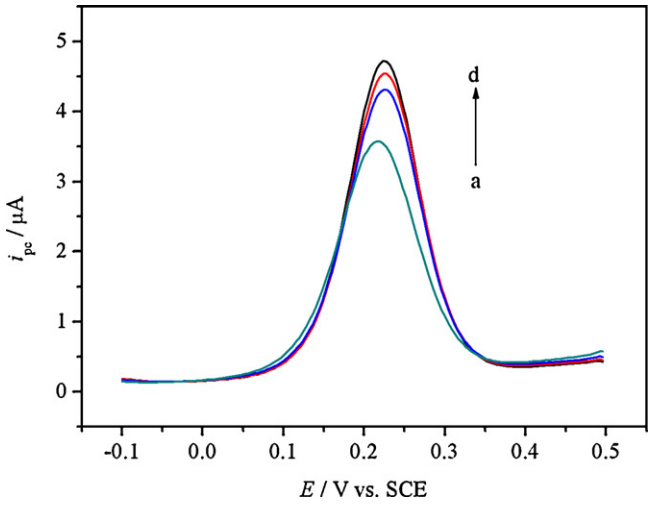

Fig. 5. Differential pulse stripping voltammograms of 1.0 mM $K_3Fe(CN)_6$ mixed with 7.6×10^{-8} M melamine in PBS buffer of different pH values (a–d: the pH values are 8.0, 7.0, 6.0, 5.0) at $d(T)_{20}$/Au.

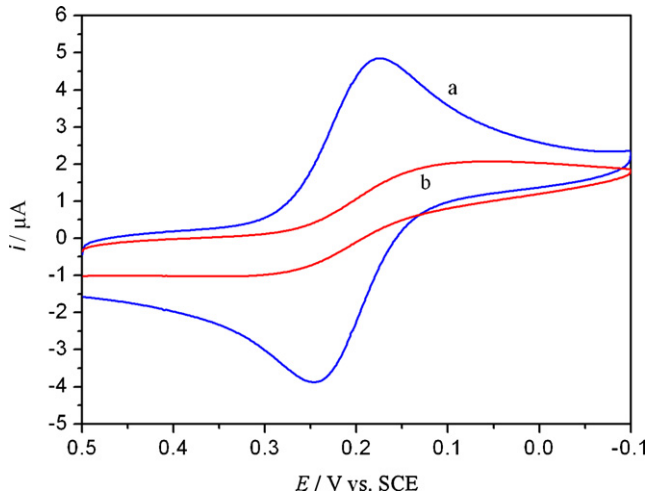

Fig. 6. Cyclic voltammograms of 1.0 mM $K_3Fe(CN)_6$ in pH 7.0 PBS buffer at the bare gold (a) and $d(T)_{20}$/Au (b) with a scan rate of 0.05 V/s.

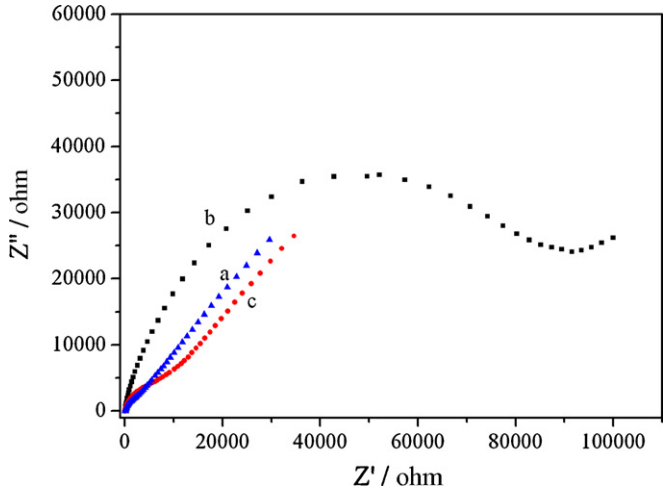

Fig. 7. AC impedance plots of 1.0 mM $K_3Fe(CN)_6$ in pH 7.0 PBS buffer at the bare gold (a), $d(T)_{20}$/Au (b) and $d(T)_{20}$/Au dealed with 6.7×10^{-7} M melamine by DPSV(c).

in melamine). With the decreasing of pH value the peak currents increased, especially from pH 8.0 to pH 7.0. Thus, it is indicated that the interaction becomes stronger in low pH condition, and we presume that the electrostatic interaction between $d(T)_{20}$ and melamine is predominate. To be close to the physiological condition (pH 7.4), we selected pH 7.0 for experiments.

3.3. Electrochemical characteristics of the $d(T)_{20}$/Au

3.3.1. Cyclic voltammograms

The electrochemical behavior of the modified electrode was characterized by cyclic voltammetry using $[Fe(CN)_6]^{3-/4-}$ as an electroactive probe. As shown in Fig. 6, a pair of reversible redox peaks was observed on the bare gold electrode. Compared with the bare gold electrode, the anodic peak potential (E_{pa}) on the $d(T)_{20}$ modified gold electrode shifted from 0.25 to 0.32 V, and the cathodic peak potential (E_{pc}) from 0.17 to 0.06 V, demonstrating that the potential separation between anodic and cathodic peaks ($\Delta E_p = E_{pa} - E_{pc}$) was larger than that of on the bare gold electrode. And the amperometric response of the modified electrode decreased. These results showed that the electron transfer kinetics of $[Fe(CN)_6]^{3-/4-}$ redox reactions was perturbed when the bare gold electrode was modified with the $d(T)_{20}$, confirming that the $d(T)_{20}$ was successfully assembled on gold surface through the Au-S bond.

3.3.2. Impedance analysis

Fig. 7 shows the electrochemical impedance spectroscopy (EIS) at the bare gold electrode and the electrode modified with $d(T)_{20}$. The impedance change of the electrode surface can characterize the stepwise-assemble process of the surface-modified electrode. The typical impedance spectrum (presented in the form of the Nyquist plot) includes a semicircle portion at higher frequencies corresponding to the electron-transfer-limited process and a linear part at lower frequency range representing the diffusion-limited process. The semicircle diameter in the impedance spectrum equals the electron-transfer resistance, R_{et}, which is related to the electron-transfer kinetics of the redox probe at the electrode surface. The response of electrochemical impedance spectroscopy at the bare gold electrode is a straight line (Fig. 7a), revealing there is almost no heterogeneous charge-transfer resistance on bare gold electrode surface, while the impedance response at the modified electrode (Fig. 7b) is much larger, illustrating the immobilization of $d(T)_{20}$ on the electrode. Due to the non-conductivity of $d(T)_{20}$, the introduction of $d(T)_{20}$ layer forms a barrier for electron transfer between the redox probe in the electrolyte solution and the electrode. On the other hand, the negatively charged phosphate groups on $d(T)_{20}$ can also resist the access of the $[Fe(CN)_6]^{3-/4-}$ redox couple to the electrode surface. These results are in good agreement with the results of cyclic voltammetry in Fig. 6.

3.4. The electrochemical determination of melamine

The electrochemical probe of $[Fe(CN)_6]^{3-/4-}$ was used to investigate the interaction between $d(T)_{20}$ and melamine by DPSV. Fig. 8A shows the reductive peak current value of $[Fe(CN)_6]^{3-/4-}$ at $d(T)_{20}$/Au increased with the increasing concentration of melamine in the range from 3.9×10^{-8} to 3.3×10^{-6} M. Fig. 8B shows the linear relationship between the reductive peak current and the concentration of melamine from 3.9×10^{-8} to 3.3×10^{-6} M with a coefficiency of 0.990. The detection limit is up to 9.6×10^{-9} M. These results are attributed to the interaction between melamine and $d(T)_{20}$ on the electrode surface. As we know, the pK_a of melamine is 8.0 [16], hence, the amino groups of melamine could be protonated in pH7.0 PBS solution. Thus, protonated melamine interacted with the negatively charged phosphates of the $d(T)_{20}$ through electrostatic attraction. This suggests that the presence of melamine gives rise to partial charge screening (neutralization) of the negative charges of the phosphate groups of $d(T)_{20}$, which facilitates the electrochemical reaction of $[Fe(CN)_6]^{3-/4-}$ at the $d(T)_{20}$/Au electrode. Meanwhile, melamine can bind to the thymine base through its complementary triamino triazine unit by hydrogen-bonding [17] and specifically combine to the $d(T)_{20}$. Therefore, we presume that the interactions between melamine and $d(T)_{20}$ including electrostatic interaction and hydrogen-bonding. The results of electrochemical impedance spectroscopy can further prove the interaction of $d(T)_{20}$ and melamine (Fig. 7). The radius of the semicircle of $d(T)_{20}$/Au after the interaction with melamine became smaller obviously than that of before the interaction, but it was still lager than that of bare Au. The EIS results indicated that melamine can absorb on the electrode modified with $d(T)_{20}$ and reduce the electron-transfer resistance.

3.5. The selectivity for melamine detection

The influences of some foreign substances on the determination of 9.6×10^{-7} M melamine were investigated. The proposed method showed a good selectivity for melamine detection. For example, 100 fold K^+, Na^+, NH_4^+, Cl^-, PO_4^{3-}, SO_4^{2-}, Ac^-, glucose, alanine, arginine, tyrosine, and monosodium glutamate barely interfere in the determination of melamine.

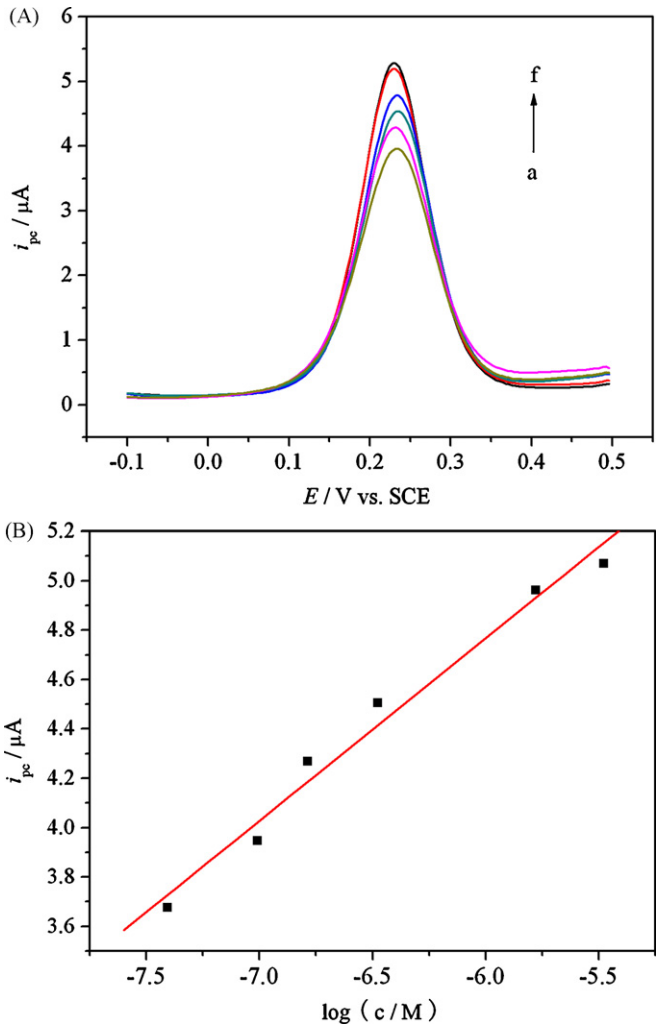

Fig. 8. (A) Differential pulse stripping voltammograms of 1.0 mM $K_3Fe(CN)_6$ in the mixture of melamine in pH 7.0 PBS buffer at $d(T)_{20}$/Au (a–f: the concentration of melamine is 3.9×10^{-8} M, 9.8×10^{-8} M, 1.6×10^{-7} M, 3.3×10^{-7} M, 1.7×10^{-6} M, 3.3×10^{-6} M). (B) Linear relationship between the reductive peak current and the concentration of melamine.

3.6. Stability and reproducibility of $d(T)_{20}$/Au

The stability of the $d(T)_{20}$/Au was examined. After keeping it in refrigerator for two weeks, the current response of the electrode did not remarkably change, showing that the $d(T)_{20}$/Au has good stability.

The reproducibility of the current response for the $d(T)_{20}$/Au was examined in 1.0 mM $K_3Fe(CN)_6$ solution containing 4.8×10^{-7} M melamine. The relative standard deviation was 1.9% for 10 independent determinations.

3.7. Analytical application in milk

To assess its applicability, the proposed method was applied to the analysis of melamine in liquid milk bought from supermarket. The liquid milk was pretreated according to the general procedure. Briefly, 5 g milk was first mixed with 5 mL of 61 mM trichloroacetic acid and 35 mL of 4.9 M methanol solution. After 15 min sonication and 10 min shaking, the mixture was centrifuged at 10000 rpm/min for 10 min, and then the supernatant was filtrated. Next, the filtrate was condensed to give a total volume of 5 mL and filtered through a 0.45 μm filter membrane to obtain the samples for detection. Because the existing milk in the market is free of melamine, the sample was spiked with certain amounts of melamine standard solution directly. The concentration of melamine was calculated to be 3.8×10^{-7} M by standard addition method. The recovery rate was calculated to be 95%, demonstrating the accuracy of the proposed method.

4. Conclusions

In conclusion, we have developed a rapid, simple and reliable method to study the interaction between $d(T)_{20}$ and melamine by using $K_3Fe(CN)_6$ as an electrochemical indicator. Melamine might interact with $d(T)_{20}$ in two modes, electrostatic attraction and hydrogen-bonding. The proposed electrochemical sensor has a good sensitivity for the detection of melamine, and the peak current of $K_3Fe(CN)_6$ linearly increased with the increasing concentration of melamine over a range from 3.9×10^{-8} to 3.3×10^{-6} M. The detection limit of the proposed sensor is lower than that of traditional methods. The proposed method was applied successfully to the determination of melamine in milk products, and the recovery was 95%. Thus this sensor is expected to have a potential application in food inspection.

Infrared spectroscopy

ABSTRACT

A method for the determination of oleic acid in sunflower seeds is proposed. One hundred samples of sunflower seeds were analyzed by near-infrared diffuse reflectance spectroscopy (NIRDRS). The direct measures were realized in ground and sifted seeds. The PLS multivariate calibration model was obtained using first derivate absorbance values as response matrix, while the oleic acid concentration matrix was obtained analyzing the seed samples by gas chromatography with a flame ionization detector (GC-FID). The NIRDRS-PLS model was validated externally using unknown samples of sunflower seeds. The accuracy and precision of the method was evaluated using GC as reference method. The following figures of merit (FOM) were obtained: LOD = 3.4% (w/w); LOQ = 11.3% (w/w); SEN = 8×10^{-5}; SEL = 0.15; analytical sensibility (γ) = 1.5 and linear range (LR) = 18.1–89.2% (w/w). This method is useful for the fast determination of oleic acid in sunflower seeds and for quality control of raw materials.

1. Introduction

In Argentina, sunflower crops represent an important agricultural, industrial and commercial activity due to the high production of this grain. In the year 2007, the total world production of sunflower grains was 2.7×10^7 ton; Argentina occupied the 3rd place in the production of sunflower seeds, with 3.5×10^6 ton, after Russia and Ukraine, with a sunflower cultivated area for the first country of 2.44×10^6 ha [1].

Since 1975, when the crop was introduced in Argentina, varieties of sunflower have been cultivated, with high content of oleic acid, higher than 77% of the total content of fatty acids, higher than the traditional sunflower whose range of oleic acid is 15–25%. Due to its high content of oleic acid, the high oleic sunflower varieties are very much requested by edible oil factories to obtain oils with high oleic acid concentration, which have a higher commercial price in comparison with the rest of the common edible oils. For this reason, the oleic acid analysis is crucial to define the final price of the raw material.

On the other hand, the production of biodiesel around the world involves the use of vegetable and animal oils, including traditional and high oleic sunflower varieties [2]. In previous works, the use of sunflower oil in biodiesel production was reported, including the production of biodiesel at room temperature [3], optimization of biodiesel production from vegetable oils [4] and the study of blended vegetable oils for production of biodiesel [5]. Sunflower oil is frequently used for biodiesel production and, as in the case of edible oil factories, the cost of sunflower raw material depends on the content of oleic acid in the seed.

The percentage of oleic acid in seeds is determined by gas chromatography, which is the more classical method for this determination [6]. The technique requires an important time of analysis, including the sample preparation and chromatographic times, which result in a critical aspect in the commercialization of seeds for biodiesel production and edible oil factories. Since the percentage of oleic acid determines the final price of the raw material, it is an important fact to find a single and fast method that may allow analyzing the content of oleic acid by direct measure on seeds, without chemical pretreatment of samples, reducing considerably the analysis time.

Oleic and fatty acids analysis were widely studied in previous works. In this way, a physiological study of the stearic synthesis and oleic acids in developing high-oleic sunflower seeds has been reported by use of TLC and radio-isotope scanning in biological assays [7]. Nevertheless, spectroscopic methods have been the preferred ones for analysis of fatty and organic acids in different kinds of samples. On the other hand, near-infrared diffuse reflectance

spectroscopy (NIRDRS) has been proved to be a convenient and fast quantitative method for complex samples and its properties have been improved by means of the multivariate calibration methods [8]. Near-infrared reflectance hyperspectral imaging and multivariate calibration methods were used to determine the concentration of oleic acid in corn kernel [9]. An automated method for the determination of total fatty acids and peroxide value by FTIR with spectral reconstitution was reported [10]. In a previous work, the determination of total fatty acids in poultry feed by FTIR and attenuated total reflectance was reported [11]. Also, fatty acids composition in intact seed of perilla was studied using NIRS and PLS [12]. The profile of fatty acids was determined in cotyledon soybean seeds by reflectance NIR and PLS [13]. A study of acidity and peroxide index in edible oil was carried out by near-infrared spectrometry and PLS [14]. The determination of trans isomers of fatty acids was carried out for edible oil by FTIR and spectral reconstitution procedure [15]. The monitoring of oleic, linoleic, un-saturated, mono-unsaturated and poly-unsaturated fatty acids in virgin olive oil and FTIR and PLS was proposed [16]. The determination of oleic, linoleic, total saturated and unsaturated fatty acids was carried out in edible oils samples by IR spectroscopy, second derivate data and multivariate calibration analysis [17]. Also, a work has been reported that uses the second derivate spectra of NIRS and PLS to estimate the content of total free fatty acids in high oleic sunflower seeds, using a titrimetric method as reference [18] and there is a preliminary technical report that uses NIRS and PLS for the estimation of oleic and linoleic acids in sunflower seed using a special device for seeds analysis and absorbance measures without preprocessing [19]. On the other hand, previous works have been reported related to the classification of edible oils by use of multivariate calibration methods to evaluate quality/authenticity [6,20], designation of origin [21] and a study of oxidative index for determination of aging of edible oils by NIRS and chemometric methods [22].

This paper discusses a fast and complete method to quantify a wide range of oleic acid concentrations in all varieties of sunflower seeds, by near-infrared reflectance diffuse spectroscopy (NIRDRS) and data evaluation using the partial least square regression (PLS) multivariate calibration method. In comparison with previous works, the proposed method was of easy application, because it requires a very simple treatment of sunflower seed samples and simple modeling, and also because it uses only 100 variables (first derivate absorbance spectra) and 2 PLS components. Another important contribution of this method is the report of the complete study of analytical properties: accuracy, precision and figures of merit (FOM) of the NIRDRS-PLS method. FOM have not been reported previously for the determination of oleic acid in sunflower seeds by infrared spectroscopy. The reported FOM include limit of detection (LOD), limit of quantification (LOQ), sensibility (SEN), selectivity (SEL) and analytical sensibility (γ) and linear range (LR) [23–24].

2. Experimental

2.1. Instrumental

The chromatographic analysis was carried out with a Varian Gas Chromatograph model GC 3900 (CA, USA) with a Varian flame ionization detector (FID). A capillary column Varian factor FOUR VF-23 (cyanopropyl stationary phase, 30 m, 0.25 mm ID) was used.

Diffuse reflectance infrared measures were taken by a Brimrose NIRS model Luminar (MA, USA) with acoustic–optic tuning filter (AOTF) and a rotator cup as sample cell.

The Unscrambler 6.11 by CAMO-AS (Trondheim, Norway) software was used for the PLS-1 modeling and the figures of merit were calculated using the MVC1 software [25].

2.2. Reagents

A 1000 $\mu g\,mL^{-1}$ of fatty acid Supelco 31 mix FAME (MO, USA) standard solution was used for the chromatographic analysis. Heptane and methanol were provided by Merck (Darmstad, Germany) and potassium hydroxide was provided by Sigma (MO, USA). The N_2 gas carrier and H_2 and air (chromatographic quality) were provided by Air Liquid (Buenos Aires, Argentina).

2.3. Sampling and sample treatment

The varieties of sunflower seeds (from low to high oleic acid content) were obtained from different places of Argentina and harvested from 2007 to 2008. Validation was carried out with 20 samples, different from those used to obtain the model. The criteria for selection of samples for the calibration step covered a wide range of oleic acid concentrations, from low to high oleic sunflower varieties, to improve the predictive ability of the model. For the validation step all samples were selected randomly.

The chromatographic analysis was carried out following the ISO 5590 method for the determination of fatty acids methyl esters by gas chromatography. A portion of 20.00 g of whole seeds was weighted in an OHaus analytical balance (NJ, USA) and pressed in a hydraulic press (Jack, Argentina). A weight of 0.50 g of obtained oil was transferred to a 10 mL volumetric flask, dissolved with 5 mL of n-heptane, added with 0.2 mL of 2 mol L^{-1} potassium hydroxide in methanol, stirred for 20 s and diluted with n-heptane to mark. After phase separation, the supernatant was collected for gas chromatography analysis [26]. This esterification method is recommended due to its low reagent toxicity and cost [27].

For the NIRDRS analysis, whole sunflower seeds, free from dust, samples were ground in a Dalvo grinder, model MCI. The fraction $\leq$2 mm was obtained by passing through a 2 mm sieve and placed in the sample rotator cup.

3. Results and discussion

3.1. Chromatographic analysis

Calibration solutions of oleic acid were prepared by adequate dilutions of 1000 $\mu g\,mL^{-1}$ standard of fatty acids. Five triplicates concentration levels were analyzed, obtaining a calibration fit with an r^2 coefficient of 0.995. Then, the analysis of 100 sunflower samples was carried out to obtain the necessary concentration matrix to build the PLS model for the calibration step. Chromatographic parameters were the following: injection volume: 1 μL; temperature program: 150 °C during 4 min, 3 °C/min to 190 °C, 1 °C/min to 200 °C; final temperature 200 °C during 3 min; detector temperature: 225 °C; injector temperature: 275 °C; gas carrier flow: N_2, 1 mL min^{-1}; split: 1:20; total run time: 30 min and oleic acid time: 12 min.

3.2. Near-infrared diffuse reflectance spectroscopy (NIRDRS)

A portion of the same samples used for chromatographic analysis was analyzed by infrared spectroscopy. A weight of 20 g of whole ground and sifted sample seeds were placed in the rotator cup and the NIRDRS spectra were obtained. The total spectral range went from 1100 to 2200 nm every 2 nm. The sample rotator cup with the samples was irradiated with NIR radiation, and detected by acousto-optic tunable filter (AOTF). The instrumental system is based on the measurement of the relative beam intensities produced when a 45° plane polarized beam of radiation passes through a sample cell and is directed to the entrance window of the AOTF. The AOTF filter uses an anisotropic crystal of TeO_2, producing two planar and orthogonally polarized beams. The presence of an optically active sample

causes the polarization plane to rotate and a consequent difference in the intensities of the AOTF diffracted beams is registered as a function of the optical activity of the sample. Thirty scans were obtained for every standard and sample seeds and the total number of scans collected from every sample was averaged by Brimrose software into a single spectrum, which was used in the response matrix. Measurements were carried out at room temperature.

3.3. PLS model: calibration step

The concentration of oleic acid obtained by the GC method was used as the concentration matrix for the NIRDRS-PLS model. The response matrix was obtained using the first derivate absorbance values from the NIRDRS spectrum (a single averaged spectrum for every sample was used). The first derivate absorbance signal was preferred due to the fact it had yielded better results in the previous multivariate models in comparison with the second derivate and conventional absorbance signal. The range from 1596 to 1794 nm was selected by analysis of the correlation coefficient and important variables as function of wavelength [28]. This selected range produced a response matrix with 100 variables (wavelength) and 100 objects (calibration samples). Fig. 1 shows the first derivate spectral data of 100 calibration samples. With the selected range of wavelength, the final model was built using internal validation (cross-validation method), where the model leaves out one standard of the calibration set every time. Then, the calibration and validation model error was calculated through root mean square of calibration (RMSEC) and root mean square of prediction (RMSEP), finding a minimum value for both cases in the second PLS component: for this component, RMSEC and RMSEP showed a value of 4.65 and 4.72 respectively. The explained variance, obtained in the calibration and validation processes for the NIRDRS-PLS model, were 99.46 and 99.45% respectively, using 2 PLS components, which are in agreement with the minimum value found for the RMSEC and RMSEP. With this 2 PLS components for the NIRDRS-PLS model, the observed-predicted concentrations plot for oleic acid was obtained, showing an r^2 coefficient = 0.995, abscise and slope (mean ± standard deviation): 0.63 ± 1.10 and 0.99 ± 0.02 respectively, which suggest a good fit of the model (ideal values of $r^2 = 1$, abscise = 0 and slope = 1).

3.4. External validation set: accuracy and precision

In order to corroborate the predictive ability of the model, 20 triplicates of the unknown samples were predicted by the NIRDRS-PLS method and the obtained concentrations were compared with gas chromatography analysis. Table 1 shows the mean values with standard deviation of 20 validation samples. The accuracy of the method was evaluated by the elliptical joint confidence region (EJCR) test, which is frequently used to evaluate accuracy of new analytical methods [29,30]. This ellipse must contain values of abscise = 0 and slope = 1, which indicate the absence of systematic errors [31,32]. The ellipse for oleic acid includes these theoretical values (1, 0) at a level of confidence of 95%, which indicates absence of systematic errors of the IR-PLS method in comparison with gas chromatography.

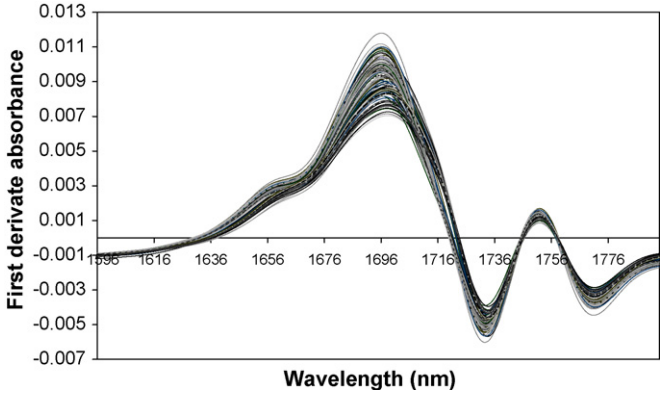

Fig. 1. Spectra data plot. First derivate absorbance – from 1596 to 1794 nm – for 100 calibration samples of sunflower seeds.

Table 1
Results of validation test set.

Sample	GC[a]	NIRDRS-PLS[a]	Sample	GC[a]	NIRDRS-PLS[a]
1	20.5 ± 0.1	21.2 ± 0.3	11	69.7 ± 0.2	69.0 ± 0.7
2	27.2 ± 0.1	27.0 ± 0.4	12	27.5 ± 0.1	28.4 ± 0.3
3	30.2 ± 0.2	29.0 ± 0.5	13	42.3 ± 0.1	44.1 ± 0.4
4	26.9 ± 0.1	25.4 ± 0.4	14	81.9 ± 0.3	82.2 ± 0.9
5	59.8 ± 0.2	55.7 ± 0.6	15	51.3 ± 0.2	49.2 ± 0.5
6	85.5 ± 0.3	86.0 ± 1.0	16	89.2 ± 0.3	90.1 ± 1.1

8	65.8 ± 0.2	63.5 ± 0.7	18	79.6 ± 0.2	75.9 ± 0.7
9	27.5 ± 0.1	28.4 ± 0.3	19	75.7 ± 0.2	78.4 ± 0.6
10	72.9 ± 0.3	76.2 ± 1.0	20	48.5 ± 0.1	46.4 ± 0.4

[a] Concentration of oleic acid (%, w/w) ± standard deviation ($n = 3$).

Precision of the NIRDRS-PLS model was evaluated using the F test, through the analysis of 10 replicates of the same sample, analyzed by both, gas chromatography and the NIRDRS-PLS methods. The critical value is $F = 4.026$ ($n_1 - 1 = 9$ and $n_2 - 1 = 9$). The calculated F value was 3.810, lower than the F critical value, which indicates that the proposed method was precise in comparison to the classical chromatographic method. The percentage of precision obtained for a same day (intra-day precision) was 1.2%, while the precision found for a week (inter-day precision) was 2.0%.

3.5. Figures of merit (FOM)

The method's calculated figures of merit (FOM) were: limit of detection (LOD), limit of quantification (LOQ), sensibility (SEN_k), selectivity (SEL_k) and analytical sensibility (γ_k). SEN_k is described as:

$$SEN_k = \frac{1}{\|\mathbf{b}_k\|}$$

where $\mathbf{b}_k$ is the vector of regression coefficient for the k analytes. LOD is defined as:

$$LOD = 3.3 \|\delta_r\| \|\mathbf{b}_k\|$$

where $\|\delta_r\|$ is a measure of instrumental noise. LOQ is defined as:

$$LOQ = 3LOD$$

SEL_k is defined as:

$$SEL_k = \frac{\|\mathbf{s}_k^*\|}{\|\mathbf{s}_k\|}$$

Table 2
Figures of merit (FOM) calculated for the NIRDRS-PLS method.

Figures of merit	Value
Limit of detection (LOD)	3.4% (w/w)
Limit of quantification (LOQ)	11.3% (w/w)
Sensibility (SEN)	0.00008
Selectivity (SEL)	0.15
Analytical sensibility (γ)	1.5
Linear range	18.1–89.2% (w/w)

Table 3
Comparative table for the determination of oleic acid and other analytes by infrared spectroscopy reported in previous works.

IR method	Sample	Analyte	Reported FOM
NIR-reflact–multiv. cal [9]	Corn kernel	Oleic acid	Non-reported
FTIR–spect. reconst. [10]	Edible oils	Total fatty acids and peroxide value	Non-reported
FTIR-ATR [11]	Poultry feed	Total fatty acids	Non-reported
NIR and mult. cal. [12]	Perilla seed	Palmitic, stearic, oleic, linoleic, linolenic acids	Non-reported
NIR reflectance–multiv cal. [13]	Soybean cotyledons	Palmitic, stearic, oleic, linoleic, linolenic acids	Non-reported
NIR-PLS [14]	Edible oil	Peroxide and acidity index	LOD
FTIR-ATR [15]	Edible oil	Trans fatty acids	Non-reported
FTIR-PLS [16]	Virgin olive oil	Oleic, linoleic, unsaturated, mono-unsaturated, poly-unsaturated fatty acids	LOD, LOQ, SEN, γ and SEL
FTIR-PLS [17]	Edible oil	Oleic, linoleic, unsaturated and saturated fatty acids	Non-reported
NIRS-PLS [18]	Sunflower seed	Total free fatty acids	Non-reported
NIRS-PLS [19]	Sunflower seed	Oleic and linoleic acids	Non-reported

where $\mathbf{s}_k$ is the vector of spectral sensitivities of k components in the pure form, while $\mathbf{s}_k^*$ is the projection onto the net analyte signal space [24]. Finally, analytical sensibility is defined as:

$$\gamma_k = \frac{\mathrm{SEN}_k}{\left\|\delta_r\right\|}$$

The figures of merit for determination of oleic acid in sunflower seeds by the proposed NIDRS-PLS method are shown in Table 2. Table 3 shows a summary of the determination of oleic acid and other analytes using infrared spectroscopy, reported in previous works for edible oil and seed samples.

4. Conclusions

This paper shows the result of a complete research for the determination of oleic acid by direct analysis in sunflower seeds, using near-infrared diffuse reflectance spectroscopy and data evaluation by partial least square multivariate calibration. The proposed method is fast, accurate and precise in comparison to the gas chromatography classical method and figures of merit were presented. Due to the fact that pretreatment of solid samples was minimal, this method can be useful for the fast analysis of oleic acid in sunflower seeds, and also for quality control of raw material in edible and biodiesel oil factories.

Phenylurea herbicides (PUHs)
Polar organic compounds

ABSTRACT

Partitioned dispersive liquid–liquid microextraction (PDLLME), using THF as the dispersive solvent and dichloromethane as the extraction solvent, was utilized to isolate and concentrate phenylurea herbicides (PUHs) from aqueous samples. In PDLLME, a dispersive solvent should be able to partition in the organic extractant droplets to effectively extract the polar organic compounds from aqueous samples. The mixture of the water-immiscible extractant and the partitioned dispersive solvent was obtained by centrifugation, dried under low pressure, reconstituted in methanol–water mixture (1:1), and injected into a HPLC system for the determination of PUHs. The enrichment factors of the PUHs ranged from 68 to 126 under the optimal conditions. The linear range was 0.5–100 ng ml^{-1} for each analyte, the relative standard deviations of PUHs were in the range of 1.5–5.9% (n = 5), and the detection limits (signal-to-noise ratio of 3) ranged from 0.10 to 0.28 ng ml^{-1} for the herbicides. The range of intraday precision (n = 5) for PUHs at the levels of 0.5, 5, and 50 ng ml^{-1} were 3.0–5.9%, 1.8–3.3%, and 2.2–3.6%, respectively. The range of interday precision (n = 5) at 0.5, 5, and 50 ng ml^{-1} were 0.4–1.8%, 1.2–2.4%, and 0.9–2.3%, respectively. The recoveries of PUHs from three spiked river water samples, at a level of 10 ng ml^{-1}, were 91.2–104.1%. Due to its rapidity, ease of operation, and high recovery, PDLLME can be utilized to isolate and concentrate organic environmental contaminants such as PUHs from aqueous samples.

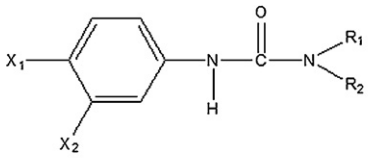
1. Introduction



Phenylurea herbicides (PUHs) are commonly used in agriculture for weed control by inhibiting their photosynthesis pathways. There are quite a few of PUHs reported to be potential carcinogens [1–3]. Herbicides including PUHs can enter environment through various pathways such as washing and leaching into surface and ground waters, which may be slowly accumulated and lead to toxic levels. These concerns urge the need of monitoring herbicides in environment as well as establishing an admissible limit for any individual herbicide. The European Union regulates the use of PUHs and allows a permissible limit of 0.1 μg l^{-1} of any single herbicides in drinking water [4].

A number of publications have reported the determination of PUHs in water and crops by various analytical techniques. Gas chromatography (GC) can achieve efficient separation and quantitative determination for many small organic molecules. However, derivatization is necessary for thermally unstable PUHs to be determined by GC [5,6]. High performance liquid chromatography (HPLC) provides the advantage of direct analysis of PUHs without derivatization prior to chromatographic separation. A variety of publications utilized HPLC for determining the amount of PUHs in water samples [4,7–9], crops [10,11], and soil [12,13]. Several detection methods have been coupled to HPLC for the determination of PUHs, including post-column derivatization with fluorescence detection [8,9,11], mass spectrometry (MS) [10,14], and UV detection [4,7,12]. Although UV detection does not provide superior sensitivity for quantitative analysis, the absence of labeling process and the relatively low cost for equipment setup make UV detection an attractive detection method compared to fluorescence and MS.

A sample preparation technique, which can isolate and concentrate target analytes prior to separation, becomes desirable in order to allow UV detection for determining trace analytes. Most commonly used sample preparation techniques include solid phase extraction (SPE) [8,15], solid phase microextraction (SPME) [7,9,16], liquid–liquid extraction (LLE) [10,17], liquid phase microextraction (LPME) [18–20], and dispersive liquid–liquid microextraction (DLLME) [21–25]. Conventional LLE requires a large amount of organic solvent and is a time-consuming process. Although SPE greatly reduces the use of organic solvent for extracting analytes, the cost of purchasing solid phase particles can be expensive. SPME is a solvent-free extraction technique, which utilizes a section of polymer-coated fiber as the stationary phase to allow analytes partitioning between the sample matrix and the stationary phase.

Fig. 1. Structures of phenylurea herbicides.

However, the polymer-coated fiber is usually fragile, limited types of polymer coatings are commercially available, and SPME fibers are fairly expensive. Same as SPME, LPME generally requires a longer extraction time. DLLME, a relatively new sample preparation technique, provides the advantages of ease of operation, rapid extraction, and use of small volume of organic solvent. In DLLME, a water-immiscible organic extractant and a water-miscible dispersive solvent are two key factors to form fine droplets of the extractant, which disperse entirely in the aqueous solution, for extracting analytes. The cloudy sample solution is then subjected to centrifuge to obtain sedimented organic extractant containing target analytes. However, the partitioning of analytes in organic extractant may be decreased due to the increased solubility of analytes in aqueous phase as larger volumes of dispersive solvent are used [26]. This phenomenon becomes more critical for isolating polar organic compounds using DLLME. A recently developed sample preparation technique, partitioned dispersive liquid–liquid microextraction (PDLLME) [27], improves the extraction efficiency by choosing a dispersive solvent that can be partitioned in the extractant droplets. The polar nature of the dispersive solvent allows the partitioning of the polar analytes into the disperser, which increases the amount of analytes transferred into the extractant droplets, and leads to the increase in extraction efficiency by PDLLME.

In this study, we utilized PDLLME for the determination of PUHs in aqueous samples using HPLC coupled with UV detection. The type and volume of both extractant and dispersive solvent, salt addition, and pH adjustment were investigated as well as optimized to achieve efficient extraction of PUHs by PDLLME. Application of PDLLME was also demonstrated by determining PUHs in three river water samples.

2. Experimental

2.1. Materials and reagents

Analytical standards of phenylurea herbicides (metoxuron, monuron, metobromuron, isoproturon, monolinuron, buturon, linuron, and chlorbromuron), as shown in Fig. 1 and Table 1, were purchased from Riedel-de Haen (Seelze, Germany). Sodium chloride (NaCl) and hydrochloric acid (HCl) were also obtained from Riedel-de Haen. HPLC-grade organic solvents including acetone, isopropyl alcohol (IPA), acetonitrile (ACN), methanol, tetrahydrofuran (THF) and dichloromethane (DCM) were purchased from Mallinckrodt Baker, Inc. (Phillipsburg, NJ, USA). Chlorobenzene (CB; 99.5+%) was from Aldrich (Milwaukee, WI, USA). Tetrachloroethylene (C_2Cl_4; 99.9+%) was obtained from Sigma–Aldrich (Steinhelm, Germany). Deionized water was from a Milli-Q Plus water purification system (Millipore, Bedford, MA, USA). All herbicide stock solutions were prepared individually in methanol at a concentration of 1000 mg l^{-1} and stored at −20 °C. Working standard solution was prepared by spiking a stock solution into river water. Three river water samples were collected from Wai-Shuanghsi, Shuanghsi, and Keelung River in Taipei, Taiwan to serve as real environmental samples. All aqueous samples were filtered through a 0.45 μm Durapore membrane filters (Millipore, County Cork, Ireland) prior to extraction. Solvents and reagents used in this study were all HPLC or analytical grade.

2.2. Instrumentation and LC conditions

A HP-1100 HPLC system (Hewlett-Packard Co., Palo Alto, CA, USA) equipped with a quaternary pump, an online degasser, an autosampler, a photodiode array detector, and a reversed phase SymmetryShield™ RP18 column (2.1 mm × 50 mm, 3.5 μm; Waters, Ireland) was employed for determining the herbicides. ChemStation for LC3D (Rev. A. 10.02[1757], Agilent, USA) was used for controlling the HPLC system and data analysis. The solvent used for isocratic separation was 40% ACN in deionized water at a flow rate of 0.2 ml min^{-1}. Full scan UV spectra of herbicide standards were performed to develop proper LC separation and confirm the appearance of PUHs in real samples. The detection was then set at 243 nm for optimizing the extraction parameters. Fig. 2 shows the representative chromatograms of blank (bottom trace) and the spiked (1 ng ml^{-1}, top trace) sample solutions.

A Kubota centrifuge (Model 2420, Tokyo, Japan), a miVac DUO concentrator (Genevac Ltd., Ipswich, UK) operated under low pressure, and Hamilton syringes (100 μl and 2.5 ml; Reno, NV, USA) were utilized for the study. The screw-capped test tubes with conical bottom were used for extraction. The 2 ml sample vials with PTFE/red silicon rubber septa and 300 μl vial inserts with polymeric feet were purchased from Agilent and used to hold sample solutions for auto-injection.

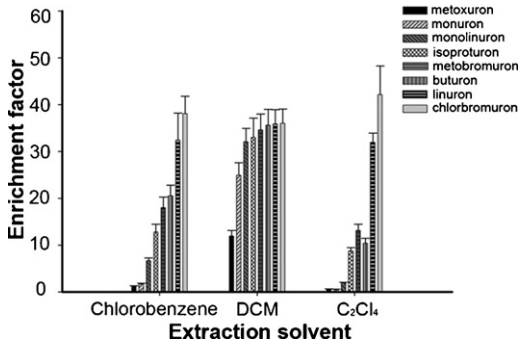

Fig. 3. Selection of organic extractant. Three measurements were performed for each set of experiments. Conditions: spiked sample solution (50 ng ml^{-1} each); organic extractant: 10 μl chlorobenzene, 70 μl DCM, 10 μl C_2Cl_4; dispersive solvent: 500 μl acetone. Refer to Section 3.1 for experimental details.

2.3. Extraction procedures

A 5 ml aqueous sample containing the target herbicides (in 0.5% NaCl, without adjusting pH) was placed in a conical-bottomed test tube. A 1 ml of DCM/THF (60/1000, v/v) mixture was rapidly injected into the sample using a 2.5 ml syringe and gently mixed the cloudy solution. The extracted herbicides in the mixed phase of DCM droplets and DCM-partitioned THF were collected by centrifugation (4000 rpm, 5 min) and the sedimented organic phase (~75 μl) was transferred into a 300 μl insert using a 100-μl syringe. The organic phase was dried under low pressure in a concentrator and reconstituted in a 30 μl methanol–water (1:1) mixture. Then 20 μl of the sample solution was auto-injected into the HPLC system for analysis.

2.4. Validation process

The following experiments were performed to validate the method used for quantifying the amount of PUHs remaining in river water samples for this study. Linearity was obtained by generating a calibration curve of individual herbicide concentration vs. peak area. Seven different concentrations (0.5, 1, 5, 10, 30, 50, and 100 ng ml^{-1}) of individual herbicide were spiked in river water collected from Wai-Shuanghsi to mimic the matrix effect in river water and five runs of each sample were performed. The limit of detection (LOD) was defined as the signal-to-noise ratio of 3. The precision and accuracy, including intra-day and inter-day experiments, were obtained at three different concentrations (0.5, 5, and 50 ng ml^{-1}) by calculating the relative standard deviations and the relative recoveries of individual herbicide, respectively. Five runs of each sample were performed. The relative recovery was determined by comparing the measured extracted concentration with the initially spiked concentration of each analyte.

3. Results and discussion

3.1. Selection of organic extractant and dispersive solvent

Selecting an appropriate organic extractant (also called as extraction solvent) is an important issue for performing PDLLME. A suitable extractant needs to meet the following criteria: (1) immiscible in water, (2) with higher density than that of water, (3) having high extraction capability for target analytes. For the selection of dispersive solvent, a suitable candidate has to be miscible with both organic extractant and water as well as to form a cloudy phase when injected with a selected extractant into an aqueous solution. Based on these criteria, chlorobenzene, DCM, and C_2Cl_4 were chosen to be the candidates of organic extractant when acetone was used as

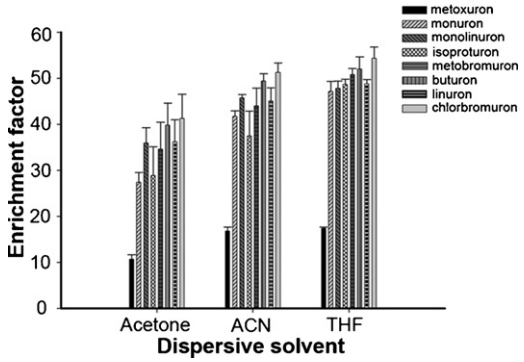

Fig. 4. Selection of disperser solvent. Three measurements were performed for each set of experiments. Conditions: spiked sample solution (50 ng ml^{-1} each); organic extractant: 70 μl DCM; dispersive solvent: acetone, ACN, and THF (500 μl each). Refer to Section 3.1 for experimental details.

dispersive solvent for the study. In the cases of chlorobenzene and C_2Cl_4, 10 μl of the organic extractant was mixed with 500 μl acetone and 500 μl of the organic mixture was rapidly injected into a 5 ml spiked aqueous solution (50 ng ml^{-1} each) for extraction. However, in the case of DCM, no phase separation was observed when the volume of DCM was lower than 70 μl. This phenomenon might be due to the relatively high solubility of DCM in water. Therefore, 70 μl of DCM was used to investigate the extraction efficiency of individual herbicide. The extraction efficiency was determined by calculating the enrichment factor (EF) of each analyte, where $EF = C_{ex}/C_0$ (C_{ex} and C_0 are the concentration of an extracted analyte and the initial concentration of the target analyte, respectively). According to the experimental results shown in Fig. 3, DCM was cho-

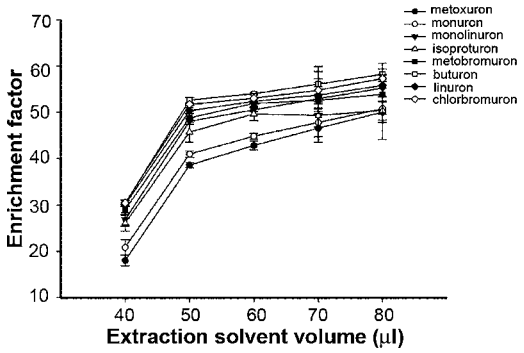

Fig. 5. Effect of extraction solvent volume. Three measurements were performed for each set of experiments. Conditions: spiked sample solution (50 ng ml^{-1} each); dispersive solvent: 500 μl THF. Refer to Section 3.2 for experimental details.

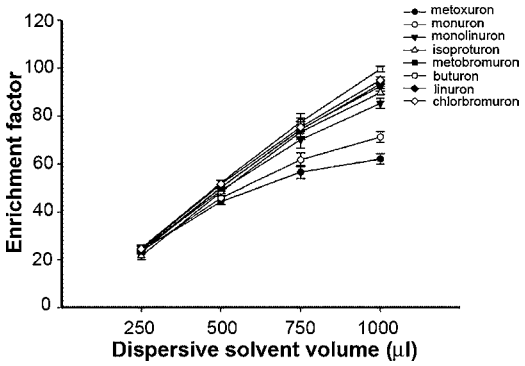

Fig. 6. Effect of disperser solvent volume. Three measurements were performed for each set of experiments. Conditions: spiked sample solution (50 ng ml^{-1} each); organic extractant: 70 μl DCM. Refer to Section 3.2 for experimental details.

sen as the extraction solvent due to the high EF value obtained for most target herbicides.

In addition, methanol, IPA, acetone, ACN, and THF (500 μl each) were utilized as the dispersive solvents while DCM (70 μl) served as the extraction solvent. Same as the procedures mentioned above, the DCM–dispersive solvent mixture was rapidly injected into a spiked sample to form a cloudy phase. However, no phase separation after centrifugation was observed in both cases of methanol and IPA. An increase in the volume of the settled phase (compared with the volume of DCM applied) was observed when THF was used as the dispersive solvent. This volume increase may be due to the partition of THF in the organic extractant droplets, which can effectively extract the polar organic compounds from aqueous samples [27]. Due to the increase in the volume of the settled phase, the EFs calculated based on the volume of the settled phase will decrease proportionally [22]. To improve EF, the settled phase was dried and the residue was reconstituted in LC compatible solvent with a fixed volume. Therefore, the influence of the settled phase volume in EF became negligible. For the selection of dispersive solvent, results shown in Fig. 4, highest EFs were found for all selected PUHs using THF as the dispersive solvent compared to the EFs obtained using acetone or ACN. Similar to the trend with THF, the EFs attained using ACN increased with the increasing volume of ACN (data not shown). However, the EFs (5–32) obtained using ACN were lower than the EFs (22–100) obtained using THF. In the case of acetone, no phase separation was observed when the volume of acetone reached 750 μl or higher. Therefore, THF was chosen as the dispersive solvent for further investigations. The variation in the volume of the extract, using 60 μl DCM and increased volumes of THF (250–1000 μl), ranged from 5 to 10%.

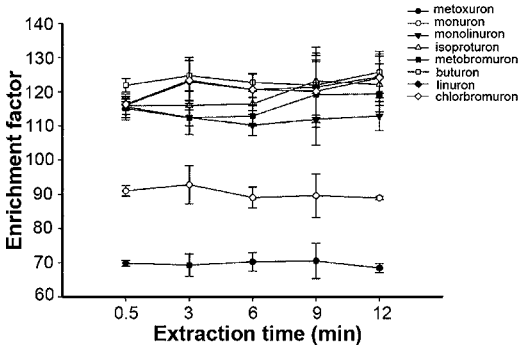

Fig. 7. Effect of extraction time on PDLLME efficiency. Three measurements were performed for each set of experiments. Experimental conditions: spiked sample solution (50 ng ml^{-1} each); organic extractant: 60 μl DCM; dispersive solvent: 500 μl THF. Refer to Section 3.3 for experimental details.

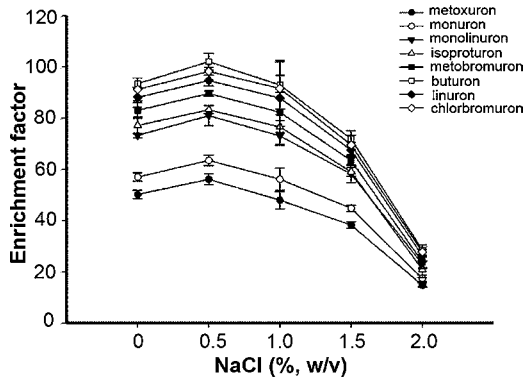

Fig. 8. Effect of ionic strength on PDLLME efficiency. Three measurements were performed for each set of experiments. Conditions: spiked sample solution (50 ng ml^{-1} each); organic extractant: 60 μl DCM; dispersive solvent: 1000 μl THF. Refer to Section 3.4 for experimental details.

3.2. Volume effect of organic extractant and dispersive solvent

To investigate the volume effect of organic extractant on extraction efficiency, several different volumes of DCM (40, 50, 60, 70, and 80 μl; no phase separation after centrifugation was observed as DCM volume was smaller than 40 μl) were applied to perform PDLLME. As shown in Fig. 5, a dramatic increase of EFs was observed on all target analytes as the extraction solvent volume was increased from 40 to 50 μl. For most analytes, except for isoproturon, the EFs were slightly increased with increasing DCM volume (from 50 to 80 μl). However, in the case of isoproturon, a small decrease in EF was found when DCM volume was increased from 60 to 70 μl. According to these observations, a volume of 60 μl DCM was applied for the subsequent experiments.

The dispersive solvent volume is another important factor that affects extraction efficiency in PDLLME. At low disperser volume, the organic extractant droplets cannot form properly which leads to low EFs. At high disperser volume, the solubility of polar organic analytes in aqueous phase will increase due to the increasing partitioning of THF in water. In order to optimize the THF volume, a fixed DCM volume (60 μl) was mixed with a series of THF in different volumes, 250–1000 μl at a 250 μl interval, was utilized to perform PDLLME. The settled phase became unstable at 1250 μl and no phase separation was observed when THF volume reached 1500 μl. Fig. 6 shows that the EFs were increased for all analytes as the THF volume increased from 250 to 1000 μl. Therefore, 1000 μl THF was mixed with 60 μl DCM and 1 ml of the mixture was rapidly injected into an aqueous sample to perform PDLLME for further experiments.

3.3. Effect of extraction time

The importance of extraction time on EF was also investigated to optimize the experimental conditions of PDLLME. After injecting

Table 2
Numerical results of the calibration of PUHs by PDLLME from aqueous samples.

Herbicides	Calibration equation	Regression (R^2)	RSD (%)	LOD (ng ml^{-1})
Metoxuron	$y = 20.45x - 0.11$	0.9998	2.7–4.8	0.18

	50	2.6	98.8	2.1	99.8

the extractant–disperser mixture, the extraction was carried out for five different time intervals (0.5, 3, 6, 9, and 12 min) prior to centrifugation. No significant differences in EFs were observed for all target analytes by increasing extraction time. The experimental results are presented in Fig. 7. This observation implied that the mass transfer of analytes from a sample solution was fast to quickly reach extraction equilibrium due to the considerably large surface area between extractant droplets and sample solution. Similar observations were also reported by other researchers [23,24]. This short extraction time provides a remarkable advantage to perform PDLLME for sample preparation.

3.4. Effect of ionic strength and pH

To assess the influence of ionic strength on extraction efficiency of PDLLME, a series of experiments were performed by increasing NaCl concentration in the range of 0–2% (w/v) at an interval of 0.5% in sample solution. The experimental results (Fig. 8) showed that EFs were increased as 0.5% NaCl was applied and started being decreased for all analytes when NaCl concentration was higher than 0.5%. In all cases, it was also observed that the organic phase became less dense (occupied the upper layer after centrifugation) when 2.5% or more NaCl was added into the system. Therefore a salt concentration of 0.5% was utilized for the subsequent studies.

The pH value of each original sample solution was measured prior to PDLLME. The pH of all sample solutions ranged from 5 to 6. The evaluation of pH effect on PDLLME efficiency was therefore performed within pH 4–pH 9 at an interval of pH 1. The pH value was adjusted by adding 0.1 M HCl or 0.1 M NaOH in spiked river water. No obvious EF changes in the pH range of 4–9 (data not shown) for all target herbicides. Similar pH effect on the determination of PUHs was also reported by Huang's group [7]. As a result, no pH adjustment was done for extracting PUHs from river water.

3.5. Quantitative features

Linearity, LOD, precision, and accuracy were investigated to validate PDLLME for the quantitative analysis of PUHs in river water samples under optimal conditions (60 μl DCM as extraction solvent, 1 ml THF as dispersive solvent, containing 0.5% NaCl, without pH adjustment). The validation procedures were described in Section 2.4. A fairly linear relationship in the concentration range of 0.5–100 ng ml^{-1} was observed with a linear regression coefficient higher than 0.9995 for each target herbicide. The numerical results of the calibration are summarized in Table 2. The precision and accuracy (including intra-day and inter-day experiments) of PDLLME were also examined under optimal conditions. The experimental results are presented in Table 3. The intraday and interday precisions of PUHs were in the range of 1.8–5.9% and 0.4–2.4%, respectively. The method accuracy defined as relative recovery was observed in the range of 97.3–102.5%. In addition, the extraction efficiency of PDLLME for each analyte was investigated and found the enrichment factors of the PUHs ranged from 68 to 126 under the optimal conditions.

3.6. Application of PDLLME

Three aqueous environmental samples collected from Wai-Shuanghsi, Shuanghsi, and Keelung River (close to Soochow University, Taipei, Taiwan) were utilized to demonstrate the capability of PDLLME under optimized conditions. According to our preliminary results, the properties of these 3 matrices, such as pH and ionic strength, were quite similar. They also showed similar chromatographic patterns after extraction. The experimental results (data not shown) showed that the residual PUHs were under their detection limits (see Table 2) in all three samples. In order to examine the matrix effect in real samples, river waters were spiked with PUHs at a level of 10 ng ml^{-1}. Table 4 shows high recoveries of PUHs (91.2–104.1%) from the spiked river waters. The high recoveries indicated a negligible matrix effect on PDLLME efficiency in different aqueous samples from environment.

In addition, two aqueous samples collected from rice fields, one in northern Taiwan (before harvest) and the other in central Taiwan (after harvest), were also examined (data not shown). In brief,

Table 4
Standard deviations and recoveries of PUHs from spiked river water samples.

both samples showed negligible matrix effect. However, both contained an unknown component overlapped with metobromuron in HPLC chromatogram without spiking. The full UV spectrum of the unknown was performed to exclude the possibility of the appearance of metobromuron in the two samples from rice fields. Therefore, no further experiments were done with spiked PUHs.

4. Conclusions

In this study, we demonstrated the capability of PDLLME for determining phenylurea herbicides in aqueous environmental samples. The comparison of PDLLME with SPE [15] and SPME [7] techniques for determining PUHs in aqueous samples is also summarized in Table 5. This PDLLME method showed acceptable linear range (0.5–100 ng ml^{-1}), low detection limits (0.10–0.28 ng ml^{-1}), good intraday/interday precision (1.8–5.9% and 0.4–2.4%, respectively), high recovery (97.3–102.5%), and short extraction time for quantifying PUHs in aqueous solutions. Due to its rapidity, ease of operation, and high recovery, PDLLME can be an alternative to isolate and concentrate organic environmental contaminants such as PUHs from aqueous samples.

ABSTRACT

Etching of silicon with mixtures of hydrofluoric acid and nitric acid is a widely used process in silicon solar cell fabrication. One precondition for an optimized usage of the acidic etching baths is the exact knowledge of the chemical bath composition. In this paper, we investigated a fast and online-capable method for the total analysis of all bath constituents by ion chromatography. The chromatographical system consists of a low-volume injection valve, which injects the concentrated samples directly into the KOH-based eluent. After separation and detection of nitrate and fluoride, a post-column derivatization with sodium molybdate is applied to detect the hexafluorosilicic acid, which enriches in the texturisation bath during the etching process. The results of the presented approach are discussed and compared with already published chromatographical and titration methods found in literature.

1. Introduction

Acidic texturisation of multicrystalline silicon wafers is a widely used process step in solar cell fabrication [1,2]. The dissolution of silicon in a solution of hydrofluoric acid (HF) and nitric acid (HNO_3) removes the saw damage from the wafer surface and creates a surface structure which improves the light coupling into the solar cell and therefore the cell efficiency. The dissolution of silicon is commonly described by the following equation [3]:

$$3Si + 4HNO_3 + 18HF \rightarrow 3H_2SiF_6 + 8H_2O + 4NO \quad (1)$$

The etching rate as well as the surface morphology mainly depends on the chemical composition of the texturisation bath [3–5]. Hence, maintaining a constant process requires a fast and reliable online-capable analysis method for determination of the main components.

Recently, several analysis techniques for the measurement of HF, HNO_3 and H_2SiF_6 have been published. Two titrimetric methods were proposed, in which the total analysis is achieved in two steps [6]. In a first pH-titration, the total acid amount and the concentration of dissolved silicon are determined. In method 1, this step is followed by a non-aqueous acid–base titration using a methanolic solution of cyclohexylamine as titrant to determine the amount of nitric acid, the concentration of HF is then calculated as difference between the total acid amount and the concentrations of H_2SiF_6 and HNO_3. Method 2 uses a fluoride sensitive electrode (F-ISE) for the determination of the total fluoride concentration. The HF concentration is then calculated as difference between the total fluoride content and the fluoride originating from the H_2SiF_6, the nitric acid content is calculated as difference between the total acid amount and the concentrations of H_2SiF_6 and HF. Method 1 delivers a higher reliability with respect to the recovery rate, but it includes a precipitation step which needs approximately 2 h for the separation of dissolved silicon which prevents an application as industrial process control. Method 2 is fast enough for industrial purposes, but the uncertainty of the measured HF content increases with increasing silicon contents.

Adjacent to the titrimetric analysis, a method for the analysis of acidic texturisation baths by ion chromatography was presented [7]. The nitric acid amount is directly measured as nitrate in the ion chromatography, the concentrations of HF and H_2SiF_6 are both calculated from the measured fluoride concentration. Therefore, a precipitation step, where the SiF_6^{2-} is removed from the solution is needed. The HF concentration can be determined in the filtrate, the H_2SiF_6 concentration is calculated from the fluoride concentration of the re-dissolved and hydrolyzed precipitate.

All three presented approaches stick out due to their high accuracy, but the high expenditure of time avoids an implementation as online process control method. A much faster approach is the ion chromatographical determination of fluoride and nitrate with a post-column derivatization (PCD) of the present silicate with sodium molybdate [8]. This method enables the simultaneous measurement of all components in acidic texturisation baths. In this paper, we describe a fully automated online-method for total analysis of acidic texturisation baths with ion chromatography, where a measurement cycle of 8 min is reached.

2. Experimental

2.1. Ion chromatography system

All experiments were performed with an ICS-2000 System with an integrated eluent generation, an ASRS 300 self-regenerating suppressor and conductivity measurement cell (Dionex, Sunnyvale, USA). Separation was achieved with a 4 mm × 50 mm IonPac AG11-HC guard column and a 4 mm × 250 mm AS11-HC separation column (Dionex, Sunnyvale, USA). The conductivity measurement outlet was connected via a mixing tee (Dionex, Sunnyvale, USA), wherein the post-column derivatization reagent is added to a reaction coil (self-made from PTFE tube 1.06 mm × 10 m), and then to an ICS-3000 VWD UV/VIS detector (Dionex, Sunnyvale, USA). Post-column reagent delivery was performed with an AXP-pump with a high pressure pulse damper DXP-DX 100 (Dionex, Sunnyvale, USA). The offline samples and validation samples were injected with an ICS-3000 AS autosampler (Dionex, Sunnyvale, USA) with variable injection volume.

2.2. Post-column derivatization

The post-column reagent is an acidified sodium molybdate solution, which was prepared by dissolving 19.36 g sodium molybdate (p.a., Sigma–Aldrich, Taufkirchen, Germany) in a graduated beaker in approximately 2 l of deionized water, 50 ml concentrated nitric acid (>69%, puranal, Honeywell, Seelze, Germany) and 6.00 g sodium laurylsulfate are added, after stirring, the solution is filled up to a volume of 4.00 l.

2.3. Measurement conditions

All measurements were performed with an eluent flow rate of 1.3 ml/min; the eluent concentration was 30 mM KOH. Suppressor current was adjusted to 100 mA. Post-column reagent was added with a flow rate of 0.5 ml/min, the resulting silicomolybdate was detected in the UV–vis channel at 390 nm.

2.4. Calibration

A sodium nitrate solution with a concentration of 1.00 g/l (Sigma–Aldrich, Taufkirchen, Germany) was used for the calibration of nitrate. The fluoride and hexafluorosilicate calibration was performed with a 1:10 dilution of an ammonium hexafluorosilicate solution with a silicon concentration of 1.000 g/l Si, which is equivalent to a fluoride concentration of 4.058 g/l F^- (Merck, Darmstadt, Germany). The calibration was performed by varying the injection volume of the standard solution. The volumes for the calibration can be calculated from the concentration range in the texturisation bath, the concentrations of the standard solutions and the injection volume of the online injection valve by Eq. (2):

$$V_{\text{standard}} = \frac{c_{\text{texturization}}}{c_{\text{standard}}} V_{\text{inline injection loop}} \quad (2)$$

The acidic texturisation bath, used in the investigation, contains up to 120 g/l HF and 500 g/l HNO_3. In our laboratory environment, the silicon amount enriches up to 40 g/l, texturisation baths in industrial applications reach concentrations up to 60 g/l. Regarding these concentration ranges and the injection volume of 0.1 μl, the calibration was carried out with the following volumes:

Fluoride/silicate (SiF_6^{2-}): 1, 2, 4, 8, 16, 32 μl

Nitrate (NO_3^-): 25, 30, 35, 40, 45 μl

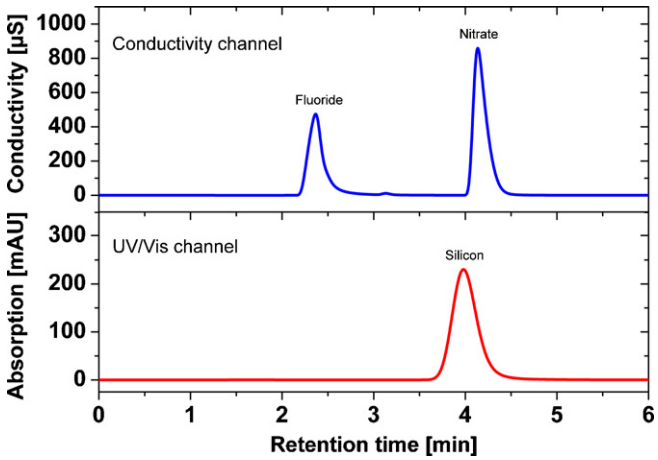

Fig. 1. Online-measured chromatogram of an acidic texturisation bath. Fluoride and nitrate are detected in the conductivity channel, molybdosilicic acid, generated in the post-column derivatization from the hexafluorosilicic acid, is observed in the UV–vis channel at 390 nm.

2.5. Reference samples

Certified reference samples are not commercially available for acidic texturisation baths, hence, we prepared reference samples from pure hydrofluoric acid, nitric acid (puranal, Honeywell GmbH, Seelze, Germany) and hexafluorosilicic acid (20–25%, Sigma–Aldrich, Taufkirchen, Germany). The concentrations of the concentrated acids were exactly determined by titration against sodium hydroxide, whose concentration was adjusted by titration of potassium hydrogen phthalate (primary standard material, traceable to NIST reference material, Merck, Darmstadt, Germany). The reference samples were prepared as 1:100 dilutions by pipetting the respective amounts of each acid into a 50 ml volumetric flask and filling up with deionized water. An error propagation calculation, including the errors of weighting, pipetting and titration gave an estimation of the relative error of $1\sigma = 1.0\%$ for the concentrations in the prepared reference samples. An amount of 8 μl was injected for each sample.

2.6. Online-measurement

Texturisation experiments were carried out with an inline saw damage etching tool (Gebr. Schmid, Freudenstadt, Germany) with a production capacity of 1000 wafers per hour and a process bath volume of 175 l. Silicon enrichment was achieved by etching multicrystalline silicon wafers.

The delivery of the process medium in online-measurement mode was carried out by a Reglo Digital MS-2/12 peristaltic pump (ISMATEC, Wertheim-Mondfeld, Germany), for the sample injection, a separate injection valve with an injection volume of 0.1 μl (Valco Instruments, Houston, USA) was used.

3. Results and discussion

3.1. Calibration

Fig. 1 shows an online-measured chromatogram of an acidic texturisation solution. Fluoride and nitrate are detected in the conductivity channel, the molybdosilicate is registrated in the UV–vis channel. Due to the column overloading, a more or less pronounced deviation from the linear relation between peak area and calibration volume is observed, hence a quadratic function was selected as calibration curve for each species. Using these calibration

Table 1
Correlation coefficients and relative standard deviations for the calibration curves of fluoride, nitrate and silicon from hexafluorosilicate.

No.	Peak name	Calibration curve type	Number of samples	Relative standard deviation	Correlation coefficient
1	Fluoride	Quadratic with offset	10	0.66%	99.98%
2	Nitrate	Quadratic with offset	10	0.21%	99.99%
3	Silicate	Quadratic with offset	10	0.52%	99.99%

The relative standard deviation is calculated from the residuals with respect to the measured peak area.

Table 2
Recovery rate for the nitric acid concentration, calculated from the nitrate amount, and the common hydrofluoric acid concentration, calculated from the fluoride amount.

Sample ID	HNO_3			HF common

functions, good correlation coefficients and relative standard deviations are reached (see Table 1).

3.2. Reference samples

Nine 1:100 diluted reference samples, which cover the range of possible bath compositions, were prepared from the pure acids. The initial and analysed concentrations as well as the recovery rates are listed in Tables 2 and 3. Nitric acid concentration as well as the total hydrofluoric acid amount are found with a mean recovery rate of 99.6 ± 0.7% and 100.3 ± 1.2%, respectively. The silicon recovery rate, analyzed with post-column derivatization, was 98.7 ± 2.9%. The high deviation is due to the low concentrations of samples *Reference* 5 and *Reference* 6, where the low silicon content is associated with a relatively high uncertainty during the sample preparation.

The most challenging concentration is the one of free hydrofluoric acid. This concentration is calculated as difference from the total fluoride amount and the silicon concentration (Eq. (3)):

$$c_{\mathrm{HF_{free}}} = c_{\mathrm{HF_{total}}} - 6\frac{M_{\mathrm{HF}}}{M_{\mathrm{Si}}}c_{\mathrm{Si}} \tag{3}$$

Assuming constant relative uncertainties for the total HF concentration as well as for the silicon concentration, the relative

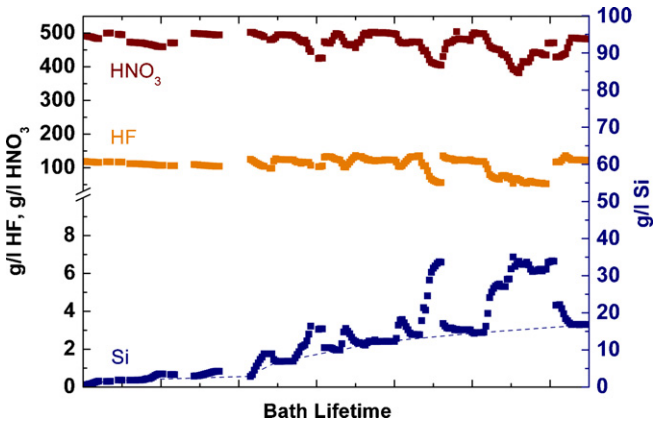

Fig. 2. Enrichment of silicon during the lifetime of a texturisation bath in the PV-Tec laboratory of Fraunhofer ISE.

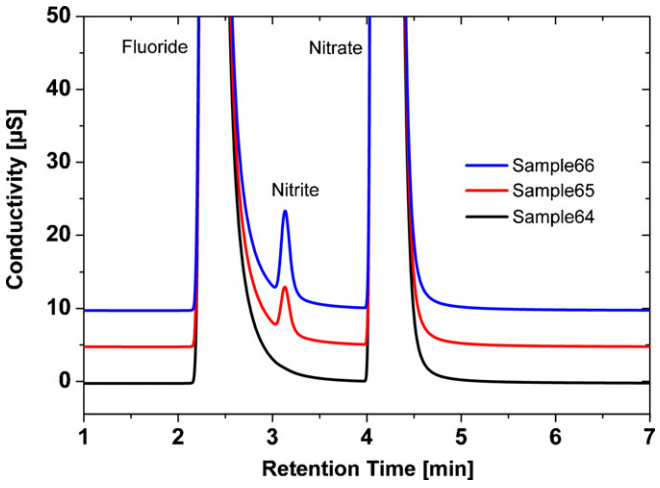

Fig. 3. Online-measured chromatograms of an acidic texturisation bath before (sample 64) and after (samples 65 and 66) addition of silicon. The rising nitrite peak summarizes the total amount of N(III) species in the etching bath.

uncertainty of the free HF concentration increases with increasing silicon and decreasing free HF content. This manifests itself in a higher variation of the recovery rate on the one hand and in a high relative standard deviation for the free HF concentration in sample *Reference* 8 on the other hand. Despite this, the reached recovery rates of $100.6 \pm 2.2\%$ are comparable to the existing ion chromatographic and titration methods and suitable for the industrial process control.

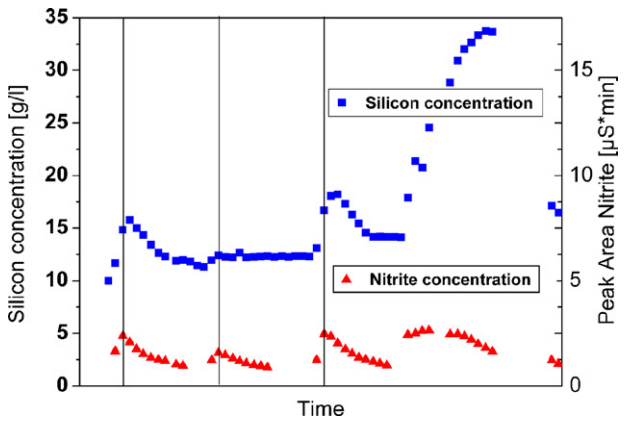

Fig. 4. Peak area of nitrate plotted together with the silicon amount in the texturisation bath. A high etching activity, corresponding to a high slope in the silicon concentration, correlates with an increasing nitrite peak area.

3.3. Online-measurement

In a first step, the exact volume of the 0.1 µl injection loop was determined. Therefore, a sample, consisting 1 g/l fluoride and 1 g/l nitrate was measured five times with the 0.1 µl injection loop. Thereafter, 8 µl of a 1:100 dilution of this sample was injected five times via the autosampler. The exact volume was calculated from the ratio between the peak areas to 0.0792 ± 0.0008 µl.

Industrial application for process control requires a stable calibration during at least one shift. Therefore, the stability of the system was tested with a solution of HF, HNO_3 and H_2SiF_6, which was measured continuously with the online-mode. Over a period of 8 h, the concentrations were stable in a range of 1% relatively for total HF, HNO_3 and silicon; the free HF concentration had a relative standard deviation of 2%.

To validate the accuracy of the online-measurement, six samples were taken during a texturisation process and – after a 1:100 dilution – measured via the autosampler. The assignment to the online-samples was made using the timestamps of the online- and offline-measurements. The comparison of the online- and offline-measurements is shown in Table 4, no significant differences are observed.

The new method was used to observe the silicon enrichment in an acidic texturisation bath in the Photovoltaic Technology Evaluation Center (PV-Tec) at Fraunhofer ISE. During the experiment, broken silicon wafers were dissolved in a texturisation bath, while the concentrations of HF and HNO_3 were kept constant by dosing the pure acids. At certain silicon concentrations, multicrystalline silicon wafers were textured to study the influence of hexafluorosilicic acid on the surface structure. The development of the bath concentrations is shown in Fig. 2.

During the etching of silicon, an additional peak raised at a retention time of 3.1 min (Fig. 3). This peak was identified as nitrite.

Table 5
Comparison of the presented method with existing methods regarding accuracy, measurement cycle time and online capability.

	Titration method 1 [6]	Titration method 2 [6]	IC [7]	IC with PCD [this paper]

Measurement time	>2 h	~10 min	>2 h	8 min
Online capability	–	+	–	+

[a] Calculated from the presented data; only sample series S1 (dissolving of SiO_2 in HF/HNO_3) was considered.
[b] Data from *route a* was taken for the calculation.

Nitrogen oxides are produced as intermediate reaction products in the etching process. In the alkaline environment of the ion chromatography, they decompose into nitrite ions. These nitrogen oxides have a very strong influence on the etching rate and hence on the texturisation results [9] on the one hand, and on the other hand, they are a very sensitive parameter to monitor the etching activity of the texturisation bath. This can be seen in a time dependent plot of the silicon concentration and the peak area of the nitrate peak (Fig. 4). In those regions, where the silicon concentration is increasing, the areas of the nitrite peaks show a maximum. Regions with a constant silicon concentration and no etching reaction show a slight decreasing of the peak area. This is due to the destruction of nitrogen(III) oxides by oxidation and disproportionation, according to Eq. (4):

$$N_2O_3 + O_2 \rightarrow 2NO_2 \quad (4)$$

$$2NO_2 + H_2O \rightarrow HNO_2 + HNO_3$$

4. Conclusions

The described method enables an online determination of the acidic texturisation bath components. Table 5 shows a comparison of the presented method with the cited titration and chromatographic methods. Precision and accuracy of the two ion chromatographical methods are in the same range and seems to be more accurate than titration. Considering the online capability, only titration method 2 [6] seems to be suitable for a fully automated process control in solar cell fabrication. Compared to this method, inline ion chromatography with silicon detection by means of post-column derivatization enables a very fast measurement cycle of only 8 min with enhanced precision and accuracy. Due to the high flexibility of ion chromatography, a further measurement of additives for advanced texturisation solutions like sulfuric or phosphoric acid is possible. In addition to the concentrations of hydrofluoric acid, nitric acid and hexafluorosilicic acid, the total amount of N(III)-species like NO_2^- can be monitored as nitrite peak. These species are expected to be an indicator for the bath activity.

Gas chromatography–mass spectrometry
Multivariate optimization

ABSTRACT

A method for the extraction of triethyl lead (TEL^+), trimethyl lead (TML^+), and Pb^{2+} from sand was developed using supercritical modified CO_2–CH_3OH extraction and *in situ* complexation with sodium diethyldithiocarbamate (NaDDTC) using a 2^5 factorial exploratory design is described. The screened variables were (i) pressure (69–193 bar), (ii) temperature (40–150 °C), (iii) ligand amount (0–100 mg), (iv) methanol volume (0.0–0.5 mL) and (v) static time (0–45 min). The optimum extraction conditions found were as follow: pressure, 193 bar; temperature, 40 °C; amount of NaDDTC, 100 mg; methanol volume, 0.5 mL; static time 45 min; and CO_2 flow rate, 1 mL min^{-1}. Under these conditions the following recoveries were obtained (TML^+ 97 ± 2%, TEL^+ 70 ± 5%, and Pb^{2+} 100 ± 4%). The presence of NaDDTC is not necessary for the extraction of TML^+ and TEL^+, but it is a very significative parameter for Pb^{2+}. A second experimental design 2^2 + star for temperature and pressure was realized, but the results were not better than those of the first model. SFE extract derivatization was achieved with pentylmagnesium bromide, and target analyte determination was carried out by gas chromatography–mass spectrometry. Detection limits in the full-scan mode were 4, 10, and 39 pg as lead for TMPeL, TEPeL and $PbPe_4$, respectively. The method was validated with urban dust containing TML^+ (CRM 605. Pb 7.9 ±1.2 μg kg^{-1}) and river sediment containing inorganic lead (GBW08301. Pb 79.0 ± 12.0 mg kg^{-1}) as reference materials. The proposed method was applied to lead analysis in sand collected from an oil-polluted beach in Chile.

1. Introduction

Inorganic lead is introduced into the natural environment from several sources, but organolead compounds are mainly exhausted into the air from the petroleum industry and automobiles, and then they contaminate soil and water sources. Organolead compounds such as tetramethyl lead and tetraethyl lead have been widely used as antiknocking agents in fuels [1]. In 1990, leaded gasoline (latter a.k.a. gas) represented over 57% of the global world gasoline market. Consumption decreased to 40% in 1996, 20% in 2000, and 8% by the end of 2005. A 2007 report from the International Fuel Quality Center [2] stated that approximately 25 countries worldwide were still using leaded gasoline: Bosnia, Kazakhstan, Macedonia, Serbia, Tajikistan, Turkmenistan, Uzbekistan, Korea, Algeria, Morocco, Tunisia, Western Sahara, Afghanistan, Iraq, Jordan, Palestine, and Yemen. In America, Cuba and Venezuela are the only countries still using leaded gasoline [2]. In Chile leaded car gasoline was eliminated toward the end of 2000, but aviation gasoline (100/130 n-octane) still contains 1.06 mL of tetraethyl lead per liter [3].

Aviation gasoline is currently the fuel with the highest alkyl lead content, ranging from 5.4×10^{-4} to 1.07 g of lead per liter [4,5]. Only TEL is used in aviation gasoline and very recently the US EPA has filed a claim requesting to limit lead emissions from aircraft [6]. Alkyl lead (tetraethyl lead and tetramethyl lead) is one of 12 chemicals identified as Level 1 priority called *Persistent*, *Bioaccumulative*, and *Toxic* (PBT) pollutants. Nowadays sources of alkyl lead emissions include airport fuel terminals, bulk aviation gasoline plants, bulk leaded racing and other non-road vehicle gasoline plants, spills from fuel loading, transfer storage, and fuelling. Once released into the environment, progressive dealkylation takes place leading to the formation of inorganic lead [7].

Tetraalkyl lead is a fat-soluble compound and consequently it is easily absorbed by living organisms (through the skin, lungs, or intestinal tract). Alkyl lead absorption depends on the nature of the compound, exposure time, and type of organism. It has been

confirmed that chronic exposure of alkyl lead compounds is more toxic than inorganic lead compounds to human beings. Once in the body, organolead compounds are degraded by the liver to ionic alkyl lead or Pb^{2+}, and these metabolites are excreted in urine [8–12].

In the soil it has been reported that TML^+ degrades rapidly in the forest floor with a half-life of 33.5 days, while in wetland soil it is 421 days, and in mineral soil it is 612 days [13,14]. Toxicity decreases with decreasing number of ethyl or methyl moieties or with decreasing number of carbon atoms (e.g., from ethyl lead to methyl lead). The toxicity of alkyl lead compounds decreases according to the following sequence: $R_4Pb > R_3Pb^+ > R_2Pb^{2+}$, with R = $-CH_3$ or $-C_2H_5$ [15,16]. Therefore, urban dust, sediments, and rainwater are still currently monitored to assess the levels of alkyl lead.

Lead speciation of various matrices has traditionally been carried out by several techniques, including a combination of complexation–extraction–derivatization, and separation–quantitation by gas chromatography (GC) coupled with selective detectors (e.g., atomic absorption, atomic emission, mass spectrometry) [17].

Supercritical fluid extraction (SFE) with modified CO_2 could be a feasible method for the simultaneous extraction of inorganic and organometallic lead compounds from solid samples [18–21]. A method for the supercritical fluid extraction of TML^+, TEL^+ and DEL^{2+} from solid samples in the absence of ligand has been reported [22]. The sediment samples analyzed contained about 45 $\mu g\,g^{-1}$ as Pb^{2+}, however the extraction of inorganic lead was avoided adding EDTA in the extractor cell. The objective of our work was the simultaneous extraction of inorganic and organolead compounds.

SFE of ionic compounds cannot be carried out with neat supercritical CO_2 or CO_2 modified with methanol due to the charge neutralization requirement and weak solute–solvent interaction. However, when ionic compounds are bound to ligands like NaDDTC with *in situ* complexation, their solubility in supercritical fluids is increased significantly. Extraction of inorganic compounds with *in situ* complexation (β-diketonates, diethyldithiocarbamates, fluorinated derivatives) has been successfully carried out with methanol-modified CO_2. For example, the extraction of Cu^{2+}, Co^{2+}, Cd^{2+}, and Zn^{2+} from filter paper, sand, and silica gel, and heavy metals including As, Cd, Cu, Mn, Pb, Se, and Zn in environmental or biological samples have been extracted prior *in situ* complexation with ligands such as tetrabutylammonium diethyldithiocarbamate, dibutyldithiocarbamate, or diethyldithiophosphate [23–30].

Before the determination, the chromatographic behavior of alkyl lead can be improved by its derivatization using a Grignard reagent [11,35–39]. For instance, ionic alkyl lead has been extracted as neutral complexes into organic solvents and propylated [31–34]. The organolead determination has been carried out with GC combined with different detectors including microwave-excited-helium-plasma detection (MWPD) [40,41], microwave induced plasma atomic emission spectrometry (MIP-AES), inductively coupled plasma time-of-flight mass spectrometry (ICP-TOFMS) [42], atomic emission spectrometry (AES) [43], mass spectrometry (MS) [44]. GC–MS with electron impact source, despite its widespread availability as a commercial GC detector and its usefulness in confirming the structure of derivatized compounds, has seldom been used in lead speciation [8].

The aim of this work was to develop and optimize an extraction method based on SFE with simultaneous *in situ* complexation of TEL^+, TML^+ and Pb^{2+} using NaDDTC as complexing agent and methanol as CO_2 modifier. Speciation of organolead compounds has been investigated, but the benefits of including Pb^{2+} in the determination have not been studied thoroughly. On the other hand, this method may be potentially used for other organic and inorganic trace elements like Hg and As.

Separation and detection of the target analytes have been carried out with GC–MS after penthylation using a Grignard reagent. Some publications on organolead compounds indicate that inorganic lead, usually present in much higher concentration than organolead compounds, interferes with the derivatization reaction with NaDDTC, and for that reason the validation was carried out with reference material with low organolead content and high inorganic lead content. The materials chosen were urban dust containing TML^+ with $7.9 \pm 1.2\ \mu g\,kg^{-1}$ of lead (CRM 605) and river sediment containing $79.0 \pm 12.0\ mg\,kg^{-1}$ of lead (GBW08301). The method was applied to the analysis of these compounds in sand samples from a Chilean beach located near a petroleum refinery that includes an automobile gasoline plant, storage tanks for crude and refined oil, asphalt plants, etc., that has been in operation for 80 years.

2. Experimental

2.1. Reagents and solutions

All aqueous solutions were prepared with Milli-Q water (18.2 MΩ). Trimethyl lead and triethyl lead chloride stock solutions (≈5 $mg\,L^{-1}$ as Pb) were prepared by dissolving appropriate amounts of the corresponding alkyl lead salts in methanol (CRM, Karlsruhe, Germany). A standard solution of triphenylamine (200 $\mu g\,L^{-1}$) was prepared in hexane. These working solutions were prepared when needed and kept at −20 °C in the dark Standard stock solutions with different Pb^{2+} concentrations were prepared from standard Pb^{2+} 1000 $mg\,L^{-1}$ solution (Merck, Darmstadt, Germany). All solvents used were obtained from Merck. NaDDTC, hydrochloric acid, and anhydrous sodium sulfate were analytical-reagent grade (Merck). White sand quartz (50–70 mesh) used for the optimization of the methodology was obtained form Sigma–Aldrich. SFE grade liquid carbon dioxide was obtained from Praxair (Barcelona, Spain). Urban dust reference material (CRM 605) was obtained from the Community Bureau of Reference (Brussels, Belgium) and river sediment (GBW08301) from the China National Analysis Center for Iron & Steel.

2.2. Instrumentation

All the experiments were carried out in an SFE-400 extractor (Supelco, Bellefonte, PA, USA). The extraction cell (6.94 mL, Keystone Scientific, Bellefonte, PA, USA) was filled with raw sand samples (5.0 g). The flow rate of liquid was adjusted with a micro mite forged metering valve to approximately 1.0 $mL\,min^{-1}$, holding the temperature at 50 °C.

A trace GC–MS from Thermo Finnigan (Austin, TX, USA) fitted with a splitless injector and a ZB-5ms fused silica capillary column (5% phenyl, 95% methyl-polysiloxane, 30 m, 0.25 mm i.d.; 0.25 μm film thickness) was used for the separation of the organolead compounds (Phenomenex, Torrance, CA. USA).

2.3. Procedures

2.3.1. Sand sampling and treatment

The sand samples were obtained from an Chilean beach (center zone). It has a length of 800 m, with sampling points every 120 m from which samples were obtained at three different depths (0–27, 50–80, and 100–140 cm), since the pipeline transporting crude and refined oil from the beach to the storage area is deeper than 1.5 m. Sand samples were collected with metallic collectors, returned to the laboratory in polyethylene bags, and stored at 4 °C. Before analysis the sand samples (about 10 kg) were spread and dried at ambient temperature. The dried samples were homogenized and sifted through a 2-mm stainless steel sieve.

2.3.2. Supercritical fluid extraction optimization

To carry out the extraction optimization, white sand quartz was spiked with a mixture of TELCl, TMLCl and $PbCl_2$ (ca. 100 ng g^{-1}). In a first step triphenyl lead was used as surrogate, but a large number of signals of phenyl lead compounds were seen in the chromatograms, because during the derivatization step the triphenyl lead degrades, since it is an exothermic reaction and the phenyl groups form other organolead compounds. The spiked samples were equilibrated during 24 h in a refrigerator at 4 °C before extraction. *In situ* complexation was performed with NaDDTC. The extracts containing complexed inorganic and organolead compounds were depressurized in a vial containing 6 mL of hexane. Volatilization of the target analytes was avoided using a cryogenic trap (acetone–dry ice). The selected parameters to be optimized were pressure, temperature, ligand amount, methanol volume, and static extraction time. The first optimization step was a 2^5 factorial design, and 35 experiments were carried out choosing two levels (high and low), with the central point repeated three times (Table 1). This design was used as an exploratory experimental design using STATGRAPHICS Centurion XV program. Statistical validation was performed by an ANOVA test with 95% confidence level. Then, a central 2^2 + star composite design was carried out optimizing pressure and temperature. Experiments were performed using a star experimental design for which 11 extractions were made, including the central point three times in triplicate (Table 2).

2.3.3. Derivatization reaction

For the preparation of penthylated standards, 100 μL of TMPbCl (5.26 μg mL^{-1} as lead), 100 μL of TEPbCl (4.97 μg mL^{-1} as lead), and 100 μL of $PbCl_2$ (5.26 μg mL^{-1} as lead) in the presence of NaDDTC were added to a dry 100 mL round-bottom flask placed in a vortex mixer. The Grignard reagent was added slowly (3.0 mL of 2.0 mol L^{-1} PeMgBr). Once addition was completed, the mixture was stirred for 1 min and allowed to stand for 20 min for complete reaction. Excess Grignard reagent was destroyed by dropwise addition of deionized water, followed by the addition of concentrated HCl solution to solubilize the salts formed. The reaction mixture was transferred to a separatory funnel and the organic layer was separated, dried with kiln-fired anhydrous sodium sulfate, and extracted with aliquots of hexane. The extracts were concentrated down to 1 mL (≈500 ng mL^{-1}) in a gentle stream of nitrogen. The SFE extracts recovered from the samples were processed in a similar way.

2.3.4. Determination of lead compounds by GC–MS

Triphenylamine (TPA) in hexane (5 ng) was used as internal standard and added to ≈1 mL of extract. The oven temperature was programmed from 60 °C (1 min) to 90 °C at 5 °C min^{-1}, then from 90 to 220 °C (10 min) at 4 °C min^{-1} and finally from 220 to 280 °C (5 min) at 5 °C min^{-1}. Injections were made in the splitless mode keeping the injector, transfer line, and ion source tempera-

ture at 250, 280 and 200 °C, respectively. Helium was used as carrier gas at a constant flow rate of 1.2 mL min^{-1}. The injection volume was 2 μL and the solvent delay was of 5 min. The MS operating conditions were the following: positive electron ionization (EI^+) mode with an electron energy of 70 eV, and the scan range was m/z 50–550 with full scan acquisition type. Quantification was carried out using external calibration with $R^2 > 0.99$ for all the target analytes.

2.3.5. Method validation

The accuracy of the developed method was checked by analyzing two certified reference materials. For the validation of the methodology with respect to the extraction and analysis of TML^+, a certified urban dust sample reference material (CRM 605) was used (3.00 g). No reference material was found for TEL^+ determination. On the other hand, the inorganic lead content was validated with a certified river sediment reference material (100 mg) (GBW08301).

3. Results and discussion

3.1. Optimization of the SFE method

The effect of five main variables on supercritical methanol-modified CO_2 extraction was studied simultaneously using a five-factor exploratory design, with two levels for each factor (low (−1), and high (+1)) and middle point (0) in triplicate. The selected factors were extraction pressure (bar), temperature (°C), ligand amount (mg of NaDDTC), modifier (mL of methanol), and static extraction time (min). The ranges of the selected values were pressure from 69 to 193 bar, temperature from 40 to 150 °C, static extraction time from 0 to 45 min, methanol volume from 0.0 to 0.5 mL, and ligand amount from 0 to 100 mg. The responses considered for evaluation were extraction yields (in %) for three compounds (TML^+, TEL^+ and Pb^{2+}). Table 1 shows the parameters selected and the results obtained. For a better understanding of the importance of each variable, the relevant coefficients are plotted in Fig. 1.

Fig. 1C shows that for inorganic lead the most important factor was the amount of ligand, because to obtain good extraction recovery the charge of the metal ion must be neutralized. On the other hand, static time has a positive effect because it is necessary to form the complex. Chakrabarti and co-workers [45] and Nenenka and Branica [46] reported the stoichiometry and stability constants of the complexes between NaDDTC and organic or inorganic lead: $Pb(DDTC)_2$ ($\log K \approx 18$), TML(DDTC) ($\log K \approx 5$), and TEL(DDTC) ($\log K \approx 6$). However, the presence of ligand was not necessary for the quantitative extraction of TML^+ and TEL^+. The ligand has a small positive effect for TML^+ and a negative for TEL^+. This would indicate that these compounds are soluble in supercritical CO_2–CH_3OH and are extracted as ion pairs. The most important parameter for organolead compounds (Fig. 1A and B) was methanol volume, because the presence of modifier increases fluid polarity and can solubilize these ionic compounds neutralized with an anion present in synthetic or real samples. Considering the individual results shown in Table 1 and the average extraction percentages of the three analytes, the best conditions were the following:

	Pressure (bar)	Temperature (°C)	Ligand mass (mg)	MeOH volume (mL)	Static time (min)	% Ex TML^+	% Ex TEL^+	% Ex Pb^{2+}
13	69	40	100	0.5	0	92	72	101
25	193	40	100	0.5	45	97	70	100

On the other hand, good recoveries of TML^+ and TEL^+ were obtained in the absence of ligand, but its presence did not interfere with the extraction.

	Pressure (bar)	Temperature (°C)	Ligand mass (mg)	MeOH volume (ml)	Static time (min)	% Ex TML^+	% Ex TEL^+	% Ex Pb^{2+}
23	69	40	0	0.5	0	57	77	22
30	193	40	0	0.5	0	100	93	55

Pressure had a small positive effect for TML^+ and TEL^+ because it increases fluid density and solvating power. Static extraction time and temperature had a negative effect because these organolead compounds can be degraded during extraction. Therefore, higher temperature and long extraction times can contribute to degradation of the compounds.

The results of the first design showed that the amount of NaDDTC and the volume of methanol were the most significant factors. However, for these two parameters a compromise was found, because at higher levels of NaDDTC as ligand the SFE restrictor was clogged and it was necessary to repeat some extractions. The NaDDTC is not necessary for quantitative extraction of TML^+ and TEL^+, and therefore it was lowered from 100 to 70 mg. On the other hand, for greater

methanol volume the extraction is not carried out under supercritical conditions of temperature, and therefore it was increased only to 0.7 mL, which corresponds to about 10% in a 6.94-mL cell. Because extraction time has a negative effect on organolead compounds and good results were obtained to shorter times. The time was lowered from 45 to 25 min. After this exploratory design, the two main SFE parameters (pressure and temperature) were optimized more precisely.

Then, to find the optimum temperature and pressure values under these new conditions of NaDDTC amount (70 mg), methanol volume (0.7 mL), and static extraction time (25 min), a central composite (2^2 + star) design was used. Pressure ranged from 69 to 207 bar and temperature from 50 to 150 °C. Table 2 shows the parameters selected and the results obtained. The response obtained for the different target analytes was fitted with a polynomial regression considering quadratic and first order interactions:

$$\%R^{+}_{TML} = 83.4(\pm6.7) + 12.2X_1(\pm4.1) - 4.9X_2(\pm4.1) + 0.5X_1X_2(\pm5.8) - 7.9X_1^2(\pm4.9) - 6.6X_2^2(\pm4.9)$$

$$\%R^{+}_{TEL} = 41.7(\pm7.5) + 12.3X_1(\pm4.6) - 4.9X_2(\pm4.6) - 2.7X_1X_2(\pm6.5) - 0.3X_1^2(\pm5.4) + 1.9X_2^2(\pm5.4)$$

$$\%R^{2+}_{Pb} = 108.9(\pm10.4) - 8.6X_1(\pm6.3) - 8.2X_2(\pm6.3) - 6.3X_1X_2(\pm8.9) - 8.7X_1^2(\pm7.6) - 7.6X_2^2(\pm7.6)$$

Considering the individual results shown in Table 2 and the average extraction percentage of analytes, the best conditions were:

	Pressure (bar)	Temperature (°C)	% Ex TML^+	% Ex TEL^+	% Ex Pb^{2+}
5	138	100	90	40	108
9	207	100	82	71	95
10	138	100	97	54	110

However, the results obtained in the second model (2^2 + star) were not better than those of the first model (2^5). Temperature and/or pressure affected the recovery of TML^+ and TEL^+, and Pb^{2+} extraction was better than 100% due to decomposition of organolead to inorganic lead.

The response surface for each analyte is shown in Fig. 2, where it is seen that the plots of TML^+, TEL^+ and Pb^{2+} are different. The extraction yield of TML^+ increases with increasing pressure up to 186 bar, but decreases with increasing temperature, reaching maximum values around 170 bar and 90 °C. In the same way, the extraction yield of TEL^+ increases with increasing pressure and decreases with increasing temperature, reaching a maximum extraction yield at 200 bar and 50 °C. For inorganic lead, the extraction yield increases with increasing pressure and temperature at low values, but decreases with increasing pressure and temperature at medium and high values, reaching maximum values at 120 bar and 85 °C. A different behavior was seen for inorganic lead compared to organolead compounds. For TML^+ and TEL^+ the effect of pressure was positive, an increase in pressure at constant temperature increasing the density of the fluid, and solvating power is higher as in the previous design. The effect of temperature was negative because these compounds have low thermal stability. On the other hand, for inorganic lead high pressure and temperature show a negative effect.

Briefly, the best parameters for the simultaneous extraction of TML^+, TEL^+, and Pb^{2+} were 200 bar pressure, 100 °C temperature, 70 mg of NaDDTC, 0.7 mL of methanol (6.94 mL cell), and 25 min of static extraction time. Dynamic extraction time was 10 min, sufficient for complete flushing of the methanol out of the extractor. Considering that TEL^+ has the lowest yields under all the experimental conditions, the chosen parameters were the best for this compound. Under these conditions, extraction yields were TML^+ 82 ± 3%, TEL^+ 71 ± 5%, and Pb^{2+} 94 ± 8%.

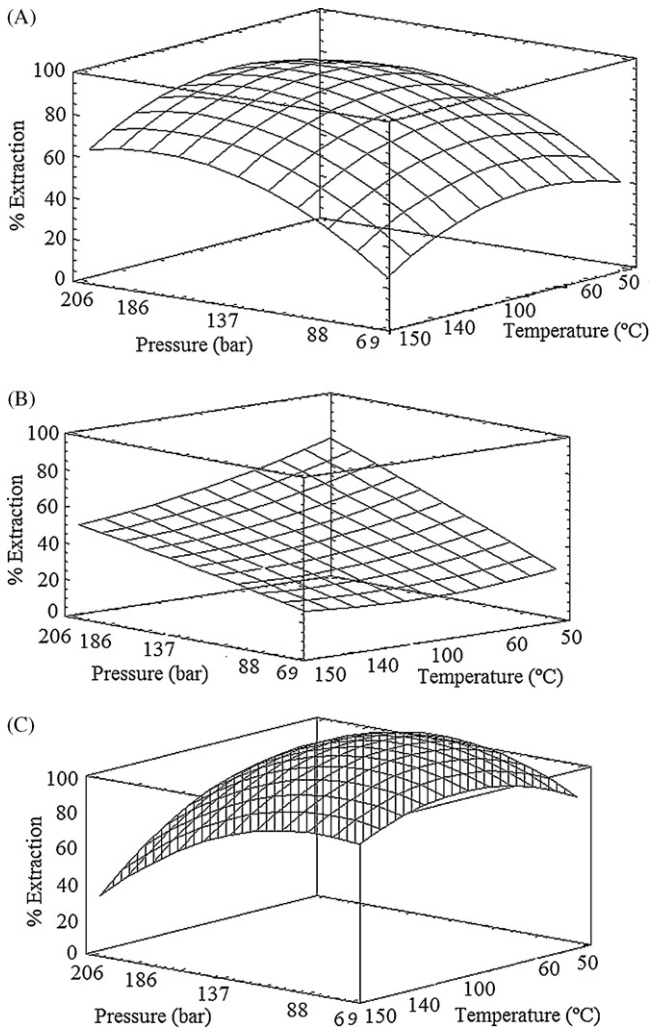

Fig. 2. Response surfaces for extraction in %. Plot as a function of pressure and temperature. (A) TML^+, (B) TEL^+, and (C) Pb^{2+}.

3.2. Determination of lead compounds by GC–MS

Organolead compounds were analyzed by GC–MS as penthylated derivatives and identified by combining the use of retention time data with mass spectral data. Retention times of TMPeL, TEPeL, Pe_4Pb, and TPA (internal standard) were 10.57, 17.03, 24.87, and 24.45 min, respectively, as shown in Fig. 3. The quantification ions for TMPeL, TEPeL, Pe_4Pb, and TPA were 253, 279, 279, and 245 m/z, respectively, as shown in Table 3. This method may be potentially used for other mono and dialkyl lead compounds.

Limits of detection and quantitation (LODs and LOQs) were 10 and 34 pg for TEPeL, 4 and 14 pg for TMPeL, 39, and 131 pg of Pe_4Pb for a 2 μL volume injection. These LODs are lower than those

reported previously using different techniques: GC-FAAS: 1.5 ng; GC-AF: 0.3 ng; GC-quartz-furnace-AAS: 0.1 ng; GC-quartz-furnace-suspended-flame: 0.09 ng, and GC-electrothermal-AAS: 0.03 ng for organolead compounds (1–5 μL injection volume) [47].

3.3. Validation of the developed method

The validation study was carried out by analyzing reference materials under the optimum conditions by triplicate. The value obtained with the certified urban dust (CRM 605) was $7.1 \pm 2.1\ \mu g\ kg^{-1}$ (certified value $7.9 \pm 1.2\ \mu g\ kg^{-1}$), while the result obtained for inorganic lead in river sediment (GBW08301) was $80.0 \pm 6.7\ mg\ kg^{-1}$ (certified value $79.0 \pm 12.0\ mg\ kg^{-1}$) calculated as Pb. The results obtained were satisfactory and not interference due to high concentration of inorganic lead was found.

3.4. Application to environmental samples

The method was applied to the determination of organolead and inorganic lead in sand samples collected from a Chilean beach (see Section 2.3.1). The vertical profiles obtained are given in Fig. 4, which shows that only inorganic lead was found in all the samples and that its concentration is usually higher on the surface. It could indicate that the lead pollution of this beach is attributable to recent industrial sources (i.e., oil refinery).

The surface sand analyzed was the most highly contaminated part. In fact, Moss and Constanzo [48] reported metal concentration values in sediments to establish baseline or reference values for heavy metals in the sediments of Queensland water. They considered $15\ mg\ kg^{-1}$ as allowed limits for Pb in this zone, and in our

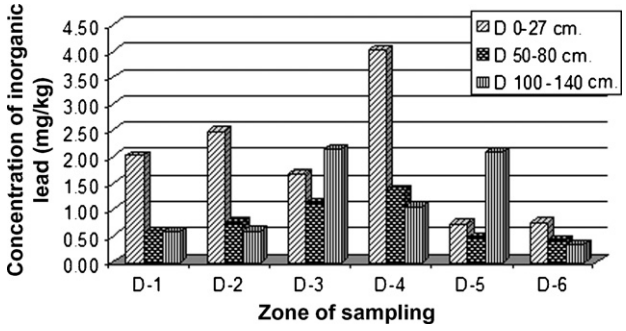

Fig. 4. Lead concentration in sand samples according to depth (0–27; 50–80, and 100–140 cm depths).

study the highest value was 4.0 mg kg^{-1}. Accordingly, the evaluation of contamination by organic or inorganic lead in this populated beach is not worrisome.

4. Conclusion

The suitability of SFE and GC–MS for the simultaneous determination of inorganic and organolead compounds in sand samples has been shown. The presence of inorganic lead does not interfere with the organolead analysis. With respect to supercritical fluid extraction, the amount of methanol was only relevant for organolead compounds, while the amount of ligand was the most important parameter for inorganic lead. This method is an alternative to GC-ICP-AS or GC-ICP-MS, frequently used for the separation and analysis of organolead compounds. This method may be potentially used for other mono and dialkyl lead compounds, and for organic and inorganic trace elements, e.g., Hg and As.

Accurate results were obtained in the validation with CRM 605 urban dust for TML^{+} and GBW08301 river sediment for inorganic lead certified materials. All the environmental samples analyzed contained only inorganic lead attributable to organolead degradation over time. Although tetraethyl lead in car gasoline was eliminated about 5 years ago in Chile but is still in use today in aviation fuel, the only occurrence of inorganic lead in the sand samples analyzed may indicate that aviation is a small input source, and the inorganic lead concentrations found can be attributable to an historical contamination.

ABSTRACT

A hybrid sol–gel material formed by acid hydrolysis of a mixture of tetraethylorthosilicate (TEOS) and phenyltriethylorthosilicate (PTEOS) as functional monomers was imprinted by tyramine and dopamine as template molecules for the purpose of molecular recognition. Imprinted materials were spin coated as thin films on the surface of glassy carbon electrodes and then were characterized using cyclic voltammetry (CV). After extraction of the encapsulated molecules, imprinted films were tested in solutions of their templates and other molecules. Rebinding experiments were followed by electrochemical characterization using square wave voltammetry (SWV). Imprinted films showed higher affinities toward their template molecules compared to other structurally similar molecules especially for tyramine imprinted film. With the exception of tyramine and norepinephrine, the interference level did not exceed 5% for all compounds studied for dopamine-imprinted films. Tyramine-imprinted films however showed high affinity to tyramine with dopamine 40% interference. Some factors related to the rebinding ability process like pH of solution, concentration of template were studied. The sensing surface lifetime extended to 2 weeks with decay in response signal that ranged from 22%, 40% to 60% for dopamine, tyramine and norepinephrine, respectively. The standard deviation from the mean of measurements for the repeated experiments is 7.4%. Electrochemical impedance spectroscopy (EIS) measurements confirmed the results obtained by electrochemical measurements. Morphological characteristics of the imprinted thin films and their thickness were investigated using scanning electron microscope (SEM).

1. Introduction

Molecular imprinting has been widely studied and applied in the last two decades as an innovative tool for various technological and scientific fields. The first approach to molecular imprinting was not well known until 1949 when Dicky succeeded to create complementary molecular cavities for certain dye molecules. Dickey's silicates could be considered as the first molecularly imprinted material [1].

In general, molecular imprinting process involves the formation of molecular cavities inside the polymer matrix being imprinted which are of complementary structural, functional group orientation and geometrical features with respect to the molecule being imprinted. Specifically, the molecular cavities are created by the incorporation of the template molecule during the polymerization process in such a way that a three-dimensional network is formed around the molecule being imprinted. Upon the extraction of the molecular moiety (template) from the polymer matrix, molecular cavities with specific shape, size and electrostatic features, remain in the cross-linked host material [2–4]. The imprinted material can be used to rebind the template molecules with very high degree of selectivity.

Because of its unique properties, molecularly imprinted materials have been widely utilized for a lot of applications and in various fields. They were applied in high performance liquid chromatography [5], food analysis [6], capillary chromatography, solid phase extraction [7] and drug delivery systems [8].

One of the most important applications of the imprinting technique is the molecular recognition. Biosensors prepared by imprinting methods could introduce good solution for the recognition of a variety of biologically active molecules. Recognition mechanism of the molecules is largely similar to what happens in living organisms. In our bodies, there are a large number of different molecules, and cells, without which we cannot survive. These molecules are able to work cooperatively and integrally in such a way that certain functions are carried out very precisely and accurately. For example, the receptors on the surface of cell membranes bind hormones specifically and selectively. When the receptor binds a hormone, its conformation is changed and a message of the hormone is transferred in terms of a conformational change in such away that the function is achieved. In molecular recognition, the molecules being imprinted can rebind to their

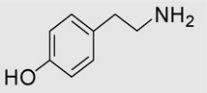
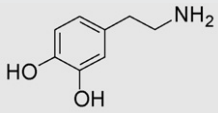
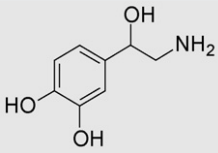
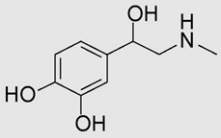
doi:10.1016/j.talanta.2009.07.014

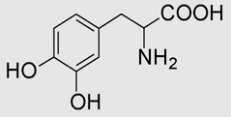
molecular cavities with very high degree of selectivity and specificity, so these materials may be named as artificial antibodies.

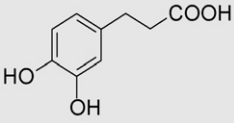


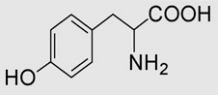












Sol–gel materials have been extensively used for the purposes of molecular imprinting. The imprinting of hybrid sol–gel materials has found great interest in the last few years [9–12] due to their unique properties. In this work, a hybrid sol–gel material synthesized by hydrolysis of a mixture of tetraethylorthosilicate (TEOS) and phenyltriethylorthosilicate (PTEOS) was molecularly imprinted with tyramine and dopamine for sensing applications in aqueous medium. Imprinted sol–gel materials were spin coated on the surfaces of glassy carbon electrodes at 2500 rpm for 45 s. The modified electrodes were electrochemically characterized using cyclic voltammetry for the imprinted molecules. Rebinding experiments were carried out by adsorption from solutions of the imprinted molecules and other test molecules followed by electrochemical characterization by SWV. Electrochemical impedance measurements were carried out to confirm the voltammetric results.

2. Experimental

2.1. Reagents

Tetraethylorthosilicate (TEOS) (>99%) and phenyltriethylorthosilicate (PTEOS) (>99%) were used as functional monomers for polymerization process. Dopamine (≥99%), tyramine (≥99%), dopa (≥99%), dopac (≥99.0%), tyrosine (≥99%), catechol (≥98%), epinephrine (≥99%), norepinephrine (≥99%), and catechol (≥98%) were used as template molecules in the imprinting process and as test molecules for rebinding experiments. Phosphate buffer solution (PBS) (pH 7.2 and 10 mmol L^{-1}) was prepared from sodium dihydrogen phosphate and disodium hydrogen phosphate. 2-Ethoxyethanol and absolute ethyl alcohol were used as solvents for dissolving template molecules and monomers for polymerization process. Hydrochloric acid and distilled water were used for hydrolysis of functional monomers in polymerization process. All chemicals were supplied by Aldrich Chem Co. (Milwaukee, WI, USA). Chemicals were used as received. Table 1 contains the chemical structures of template molecules and test molecules being studied.

Table 1
List of compounds studied in this work.

Molecule	Structure	Molecular volume (Å^3)
Tyramine		131.1
Dopamine		146.0
Norepinephrine		149.2
Epinephrine		166.1
Dopa		169.1
Dopac		157.4
Tyrosine		159.9

2.2. Equipments

Glassy carbon electrodes from BAS (USA) with 3 mm diameter were used as working electrodes. A platinum wire, 4 cm long with a diameter 0.5 mm, was used as counter electrode. All cell potentials were measured against saturated Ag/AgCl as a reference electrode. One compartment, three electrodes cell, made of glass (30 mL), fitted with gas bubbler was used for all electrochemical measurements. Electrochemical characterization including cyclic voltammetry (CV) and square wave voltammetry (SWV) were carried out using a BAS-100B electrochemical analyzer (Bioanalytical Systems, West Lafayette, USA). Electrochemical impedance spectroscopy (EIS) measurements were performed using a Gamry-750 system and a lock-in amplifier in conjunction with a personal computer used as data acquisition system and simulations. JEOL JSM-T330A scanning electron microscope (SEM) was used for all measurements.

2.3. Electrode preparation and procedures

2.3.1. Imprinted film preparation

The electrodes were polished well using 0.05 μL alumina slurry on Buehler felt pads and rinsed thoroughly with deionized water and ethanol. Electrodes were then electrochemically activated before spin coating. Glassy carbon electrode was activated by polarization at +1.6 V for 60 s and at −1.6 V for the same period. Electrodes were then cycled between +1.0 and −0.2 till a stable CV was obtained [13,14]. Then, 400 μL (1.791 mmol) tetraethylorthosilicate were mixed with 65 μL (0.351 mmol) phenyltriethylorthosilicate in 3.0 mL of 2-ethoxyethanol, and then solution was stirred till a homogeneous is obtained. This was followed by adding 100 μL of 0.1 mol L^{-1} HCl solution drop-wise with continuous stirring, and 90 μL H_2O were added in the same manner. The mixture was stirred gently for 2.5 h. A 1.0 mL portion of the prepared sol–gel mixture was mixed with 300 μL of 0.1 mol L^{-1} tyramine or 350 μL of 0.05 mol L^{-1} dopamine in order to prepare tyramine- or dopamine-imprinted surfaces, respectively. The resulting mixtures were stirred for another 2 h. The imprinted sol–gel materials were spin coated on the surfaces of glassy carbon electrodes at spinning rate 2500 rpm for 45 s. The electrodes were allowed to dry overnight, and then they were electrochemically characterized by cyclic voltammetry (CV) between −200 mV and +1000 mV at a scan rate 100 mV/s. Template molecules were extracted form the imprinted film by repeated CV and the decay in current response was followed as indicator for the extraction procedure. Electrodes were allowed to dry overnight before rebinding experiments were carried out.

2.3.2. Rebinding experiments

Modified electrodes were dipped for 15 min in rebinding solutions for different test molecules of concentration 50 μmol L^{-1} each, and then followed by electrochemical characterization with

square wave voltammetry. The incubation time for rebinding experiments was selected in such a way that high sensitivity and stability of the current response was obtained.

3. Results and discussion

3.1. Sol–gel synthesis and characterization

Tetraalkylorthosilicates monomers are hydrolyzed in the presence of either acid of base catalyst. Acid catalyst was the best to be used for a lot of applications especially for the design of sensing elements [15–18]. The hydrolysis step is followed by a condensation step of the hydrolyzed monomers. It was reported that strong concentrated acids produces highly cracked and slightly shrunken aerogels. On the other hand, very dilute acids results in monolithic and well shrunken aerogels [19]. In this work silica gel material was polymerized using dilute hydrochloric acid (0.1 mol L^{-1}). Condensation between completely hydrolyzed monomers occurs by the elimination of water while incompletely hydrolyzed monomers may condense by elimination of alcohol molecules.

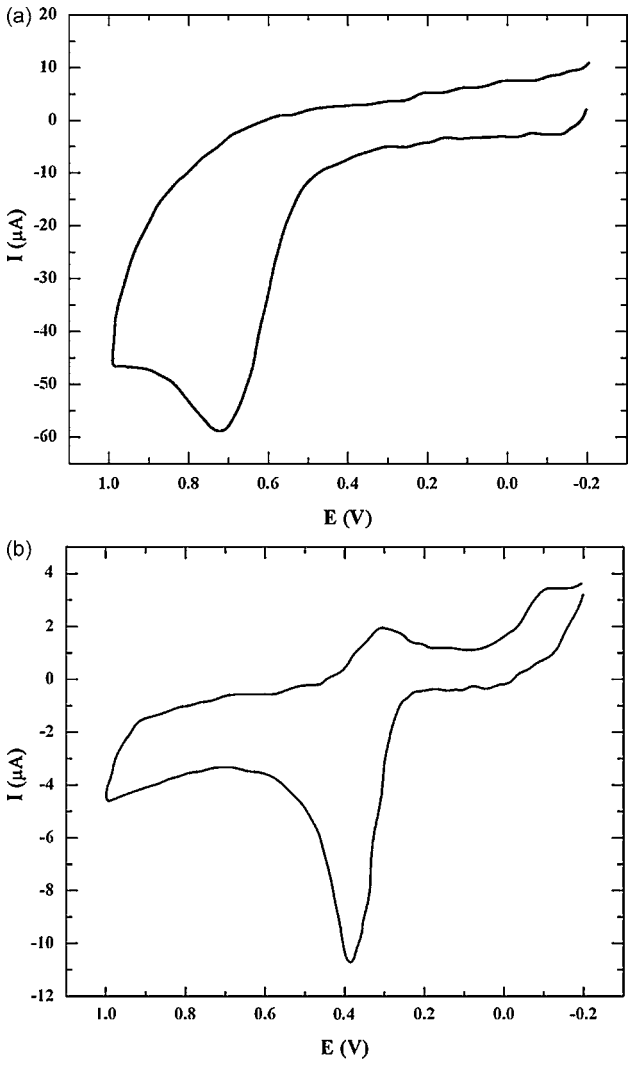
In order to obtain the best imprinted material with good physicochemical properties, water content has to be adjusted in the start mixture before synthesis step. The ratio of water and alkyl orthosilicates monomers was determined experimentally to be 4.5:1 (water:silane). This ratio was found to be sufficient for complete hydrolysis of all monomer units before the start of condensation step which was necessary to enhance the process of incorporation of template molecules into the sol–gel material before the growth of the polymeric networks around them.

The use of hybrid sol–gel matrix is very crucial factor for material design. A hybrid monomer solution composed of TEOS and PTEOS was hydrolyzed using 0.1 mol L^{-1} HCl solution. The phenyl group inserted in the sol–gel material is of great importance. This group allows for non-polar interaction with the imprinted molecules which all carry benzene rings so it could act as a Pi–Pi interaction center with the template molecules through further steps. Also, it was reported that a combination of functional monomers enhances and promotes the rebinding ability of template molecules to the imprinted films [20–22].

The modified electrodes coated with the imprinted sol–gel films were characterized electrochemically using CV. An applied potential window between −0.2 V and +1.0 V at scan rate of potential 100 mV/s, was sufficient to cover the oxidation potentials of all the template and test molecules rebinding to the imprinted film. Cyclic voltammetry characterization was carried out in PBS (10 mM and pH 7.2). Fig. 1(A and B) illustrates the CVs of sol–gel films imprinted with tyramine and dopamine, respectively.

The extraction process of template molecules was carried out through repeated CV in phosphate buffer solution followed by dipping in PBS only for a relatively short period of time (ca. 1.0 h) to confirm the complete extraction of the molecules from the imprinted films. Repeated cycling between −0.2 V and +1.0 V, at scan rate 100 mV/s, was applied to the surface till complete disappearance of the template current response was attained.

The mechanism of the extraction of template molecules by repeated cycling can be understood in terms of oxidation–reduction properties of the neurotransmitter molecules. For example;



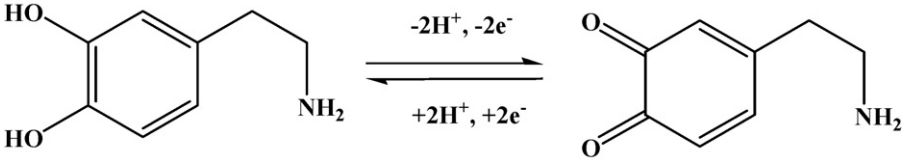


Fig. 1. Cyclic voltammograms of tyramine (A) and dopamine (B) molecularly imprinted sol–gel films spin coated on the surface of glassy carbon electrodes cycled in PBS (pH 7.2 and 10 mmol L^{-1}) versus Ag/AgCl reference electrode.

dopamine is electrochemically oxidized by losing two electrons and two protons. Oxidation reaction was found to be quasi-reversible process; as a result of this behavior, the structure of the molecules is changed during its oxidation process. The change in chemical structure makes the template molecule less bound to the molecular cavity (ca. the transformation of the two hydroxyl groups that affect the extent of hydrogen bonding) which in turn helps its extraction out of the molecular cavity inside the solution with repeated cycling.

3.2. Molecular recognition and selectivity of the imprinted films

3.2.1. Tyramine-imprinted film

Tyramine (p-hydroxy-phenylethylamine) is naturally occurring in animals and plants. In foods, it is produced via decarboxylation of amino acid tyrosine, so considerable amounts in food stuffs indicate potentially an expired product. The molecule increases the release

of neurotransmitters stored in the body. To the best of our knowledge, this is the first time that tyramine is molecularly imprinted. Rebinding experiments for tyramine-imprinted film were carried out from template solution of different molecules of concentration 50 μmol L^{-1} prepared in PBS. Rebinding experiments as mentioned in the above section were followed by electrochemical characterization using SWV. Tyramine molecularly imprinted films showed a preferential adsorption for their imprinted molecules compared to other molecules. The high affinity of the imprinted films toward its template was attributed to the fact that the molecular cavities created inside these films are correctly sized and shaped and appropriately functionalized in the way that they bind these molecules or allow the passage of any moiety which may be analogous in size or geometry into them [23–25]. It is also perceived that the recognition ability of molecularly imprinted materials comes from the functional group orientation inside the molecular cavities created during polymerization which enhances the ability of these template molecules to interact well with these molecular cavities. As shown in Fig. 2A tyramine-imprinted film showed relatively high current response for tyramine compared to other molecules. Although dopamine has larger molecular size than tyramine, it is found to be partially adsorbed into the surface imprinted with tyramine. The appreciable interference of dopamine into the tyramine cavities is largely attributed to the similarity of their functionality beside the fact that the molecular size of dopamine is not extremely larger than tyramine. On the other hand, norepinephrine showed relatively smaller interference to tyramine-imprinted film compared to dopamine. This is certainly due to larger molecular size of norepinephrine and the extra hydroxyl group which changed the average electron density around the molecule and in turn decreased the possibility of electrostatic interaction with the molecular cavity oriented functional groups. As illustrated in the same figure other molecules including epinephrine, dopa, dopac, tyrosine, and catechol showed almost no rebinding ability with respect to tyramine-imprinted film. All molecules except catechol are characterized by larger molecular size in addition to relatively different functionality. It is interesting to notice that although catechol is smaller in size compared to tyramine, it could not rebind to the imprinted film to any extent. This is attributed mainly to the fact that catechol is missing the amino group present in tyramine which inhibit its electrostatic interaction with the imprinted film. Therefore, we can conclude that the selectivity of imprinted films depends on the size of template molecule and its ability for electrostatic interaction with the functional groups oriented inside these cavities during polymerization. Moreover, it is important to mention that all measurements were carried out using three independent electrodes to ensure reproducibility of the results.

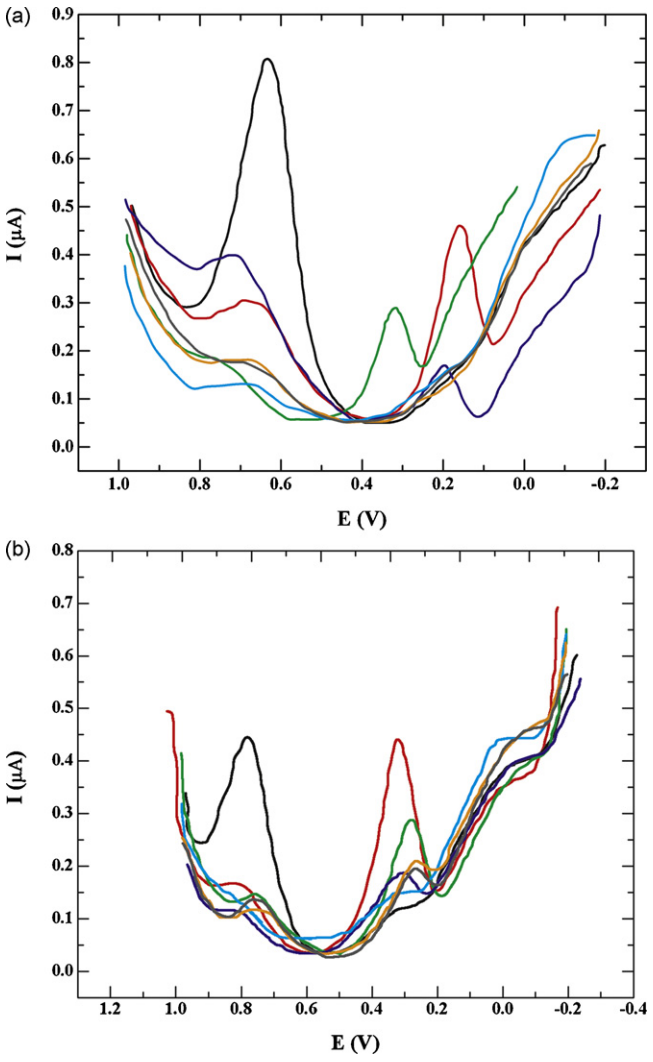

Fig. 2. (A) Square wave voltammograms of tyramine and other test molecules with respect to tyramine-imprinted film. Rebinding experiments are carried out by dipping electrodes in 50 μmol L^{-1} solutions of the tested molecules prepared in PBS: tyramine (—), dopamine (—), norepinephrine (—), epinephrine (—), tyrosine (—), dopa (—), dopac (—). (B) Square wave voltammograms of dopamine and other test molecules with respect to dopamine imprinted film. Rebinding experiments are carried out by dipping electrodes in 50 μmol L^{-1} solutions of the tested molecules prepared in PBS: tyramine (—), dopamine (—), norepinephrine (—), epinephrine (—), tyrosine (—), dopa (—), dopac (—).

3.2.2. Dopamine imprinted film

Dopamine is a neurotransmitter found in various animals whether vertebrates or invertebrates. It is produced in various areas in the brain and activates five types of receptors. As illustrated in Fig. 2B, current response after rebinding tyramine to dopamine-imprinted film is relatively high when compared to the current response after dopamine rebinding to its imprinted film. This is due to the smaller molecular size of tyramine which facilitates the diffusion of tyramine into the dopamine imprinted cavities. Although norepinephrine is larger in molecular size than dopamine, it gives relatively high rebinding current response. This is mainly due to the similarity of functional groups of both molecules which implies very similar electron density and as a result of this, strong electrostatic interactions arise between them and the molecular cavities oriented functional groups. Also, it is observed from the results that norepinephrine interferes with dopamine-imprinted film nearly to the same percentage of interference of dopamine to tyramine-imprinted film. Other molecules interfere to dopamine film with less than 5% as depicted in Fig. 2B.

It is to be mentioned here that non-imprinted sol–gel films were prepared following the same procedure as the imprinted films but without the addition of the template solution to the sol mixture during the polymerization process and were tested for rebinding of different test molecules. Percentage adsorption to non-imprinted films is negligible which confirms the fact that rebinding process mainly takes place into the imprinted surface sites.

3.3. Binary mixture analysis

One important challenge for the effective use of imprinted materials in molecular recognition processes is the ability of the imprinted film for selective recognition of imprinted template in the presence of other molecules. As an example dopamine molecularly imprinted film was tested for selective adsorption

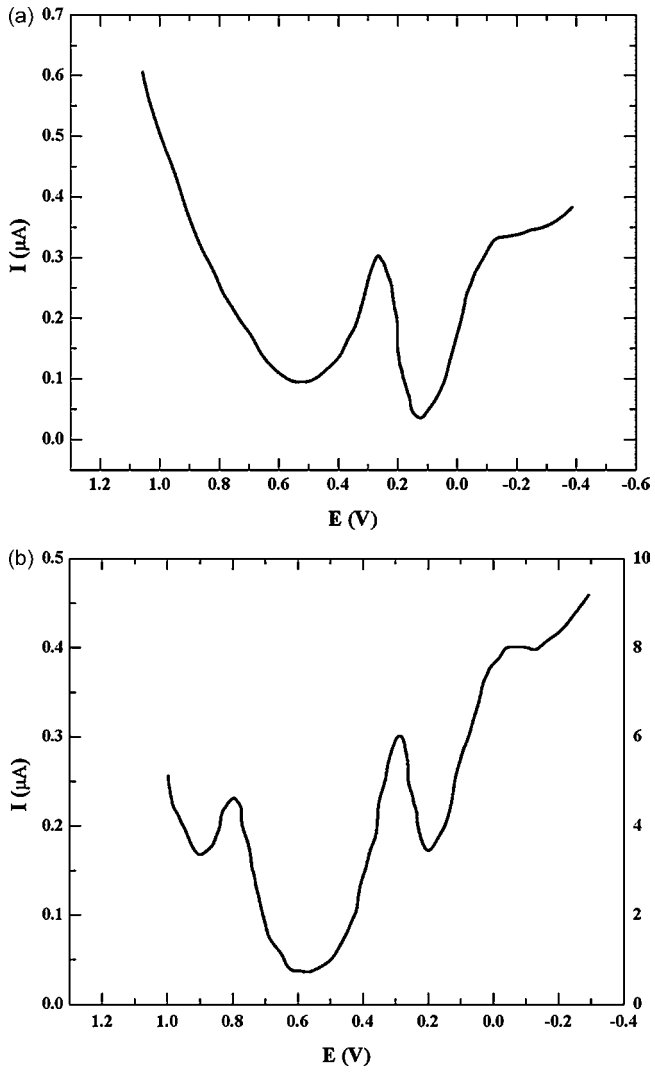

Fig. 3. SWV signal characteristic for dopamine imprinted film after dipping in (A) binary mixture of dopamine and tyrosine and (B) binary mixture of dopamine and tyramine. Rebinding binary solutions are 50 μmol L^{-1} with respect to template molecules.

(recognition) of a binary mixture of equal concentrations of tyrosine and dopamine (50 μmol L^{-1}). Dopamine-imprinted film showed high selectivity for dopamine in presence of tyrosine. As illustrated in Fig. 3A, dopamine showed relatively high current response at 250 mV while tyrosine showed almost no current response after the rebinding process. On the other hand, when the imprinted film was tested in a binary mixture of tyramine and dopamine, tyramine could rebind to the imprinted film and showed relatively appreciable current response at 780 mV with respect to dopamine imprinted film as shown in Fig. 3B. The results of rebinding experiments in binary mixture of dopamine and tyramine are similar to those obtained previously (cf. Section 3.2) in single rebinding runs. Thus, with the exception of tyramine that showed appreciable interference, dopamine imprinted film showed excellent selective recognition for dopamine in presence of other interfering molecules.

3.4. Effect of pH of the template solution on rebinding process

Virtually all drug-like molecules are weak acids or bases. This means that they contain at least one site that can reversibly disas-

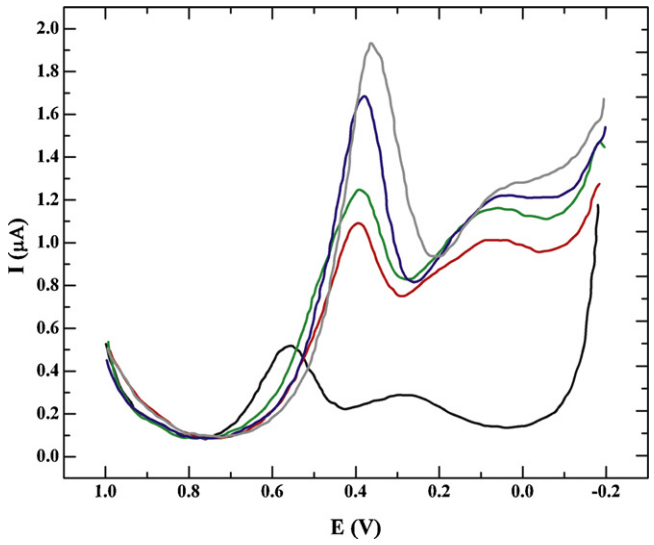

Fig. 4. SWVs of dopamine imprinted film after dipping in 100 μmol L^{-1} of dopamine solutions at different values of pH: 1.0 (—), 3.0 (—), 5.0 (—), 7.0 (—), 9.0 (—).

sociate or associate a proton (a hydrogen ion) to form a negatively charged anion or a positively charged cation. Molecules that disassociate protons are acids, and those that associate protons are bases. The reversibility means that a sample is always in equilibrium with some fraction protonated and the rest deprotonated.

$$HA \Leftrightarrow H^+ + A^- \text{ or } HB \Leftrightarrow H^+ + B^-$$

By varying the availability of protons, i.e. the acidity of the media, the balance of the equilibrium can be shifted. Alternatively, the p*K*a-values of a site can be thought of the pH at which the protonated and deprotonated fractions are equal. Experiments were carried out from different pH solutions on dopamine imprinted surface. All pH measurements were carried out from 100 μmol L^{-1} with respect to dopamine. As illustrated in Fig. 4, the current response increases with the increase in pH value. At pH-values lower than pKa_1 (8.57), the protonated form of dopamine predominates than the unprotonated zwitter ion form. On the other hand, at pH-values higher than pKa_2 (10.08) the deprotonated (phenoxide ion) form is higher than unprotonated zwitter ion. Between pKa_1 and pKa_2, the zwitter ion form predominates over the charged form [26]. This argument clarifies the fact that the protonated dopamine molecule is less interacting with the oriented functional groups in the molecular cavities while the neutral form is best fitted to the imprinted sites so by increasing the pH values current response enhances.

On the other hand, there was an increase in the oxidation potential value of the adsorbed species on the imprinted surface with the increase of pH value. This result could be explained from the fact that, positively charged molecules due to protonation of dopamine at lower pH values needs higher polarization potential (overvoltage) for oxidation. This is because the average electronic charge on the molecules is lowered, therefore it is more difficult to withdraw electrons at such a lower potential, while at higher pH values the molecule is either neutral or negatively charged which increases its electro-oxidation. This study was not extended to pH values higher than 9 because the glassy silicon film could decompose under the effect of strong alkaline medium.

3.5. Sensitivity versus electrode selectivity and lifetime

One important factor regarding the molecularly imprinted materials is the stability of the geometry of molecular cavities cre-

Table 2
Comparison of the rebinding results of dopamine imprinted film at the beginning and at the end of 2 weeks. Adsorption experiments were carried out from 50 μM solution with respect to dopamine prepared in PBS.

Molecule	I (10^{-7} A) Immediately after preparation	I (10^{-7} A) After 2 weeks	Percentage of decrease in current response signal (%)
Dopamine	3.35	2.59	22.3
Tyramine	3.01	1.82	40
Norepinephrine	1.93	0.71	63.5

ated inside the sol–gel material which in turn affects both the selectivity and the sensitivity of the imprinted material for template molecules on the long term. Dopamine imprinted films were tested in dopamine solution and in solutions of the other molecules being studied, then the electrodes were left in a dry place for relatively long period (ca. 2 weeks). The electrodes were tested again in dopamine solution and in solutions of other molecules at the end of the 2 weeks for rebinding process in order to test the selectivity and stability of the response. Measurements were carried out using three independent glassy carbon electrodes prepared in the same way to ensure repeatability of measurements. The standard deviation from the mean of measurements for the repeated experiments is 7.4%.

Current response for different test solutions was found to decrease after 2 weeks of drying with varying percentages. The most interesting point here is the incremental decrease in current response ascending from dopamine down to catechol. It was found that dopamine current response after 2 weeks, decreased by 22%. Tyramine signal decreased by 40% and norepinephrine by 63.5% of the original current response signal as indicated in Table 2. Rebinding current response disappeared completely for the remaining of the group of molecules being tested. It is concluded that the selectivity of the imprinted film increases appreciably for imprinted film if compared to other molecules, by increasing the time between drying and measurement.

Moreover, although the selectivity of the imprinted film toward its template compared to other structurally related molecules is enhanced, there is an appreciable decrease in the current response of the template itself. In other words meanwhile the selectivity of imprinted films toward its template molecule increases, the sensitivity of the imprinted films decreases. More extensive studies may help in the future to achieve a compromise between selectivity and sensitivity of molecularly imprinted materials.

3.6. The effect of concentration of the template molecule on the rebinding ability

In this part, we studied the relationship between the concentration of template molecule in the solution from which the template rebinds to the imprinted film, and the electrochemical current response after rebinding to the film. The imprinted films showed fairly linear rebinding response over the concentration range from 100 μmol L^{-1} down to 10 μmol L^{-1} as illustrated in Fig. 5. Beyond this concentration range; over the 100 μmol L^{-1} limit deviation from linearity was observed, while below 10 μmol L^{-1} the imprinted films are not sensitive for the template molecules. The linearity of the process confirms again that the rebinding process occurs specifically on selected sites created during the imprinted process in this concentration region.

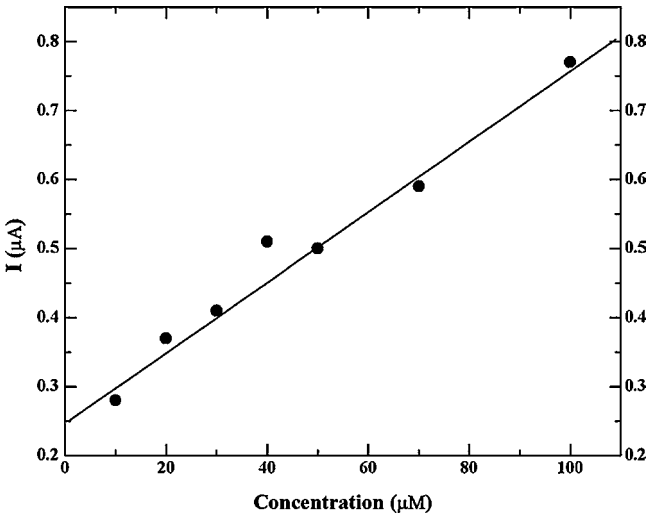

Fig. 5. Current response (SWV) of dopamine imprinted film as a function of the concentration of dopamine in the rebinding solution.

3.7. Electrochemical impedance characterization of the imprinted film

Impedance measurements were carried out over a frequency range from 0.5 Hz to 10^5 Hz with an applied AC voltage of 5 mV. Excitation DC voltages were predetermined using cyclic voltammetry for the molecules being tested against the imprinted films. Work was carried out at DC potentials 330 mV for dopamine, 720 mV for tyramine, and 550 mV for tyrosine. Previous studies showed that the imprinted film swells upon the association with their template molecules, which in turn enhances their electrical permittivity with respect to the electrolyte [27,28]. As a result of this, the electron transfer process is facilitated across the double layer. In case of dopamine-imprinted film that was incubated in dopamine solution the swelling effect of the imprinted film occurs due to rebinding of the template to its film. Fig. 6A illustrates Nyquist plots of dopamine films in case of incubation in dopamine solution and in PBS, respectively. Lines in Nyquist plot represent the calculated and fitted data for the equivalent circuit components while symbols represent the experimental data. Triangle symbols in the diagrams represent the signal after incubation of the imprinted film into its template solution while the square symbols represent the impedance signal of the imprinted film after incubation in buffer solution (buffer background).

Dopamine and tyramine-imprinted films were incubated in a solution containing a different molecule like tyrosine which showed no rebinding affinity to the imprinted film. The slope of Nyquist plots in both cases did not change appreciably for the incu-

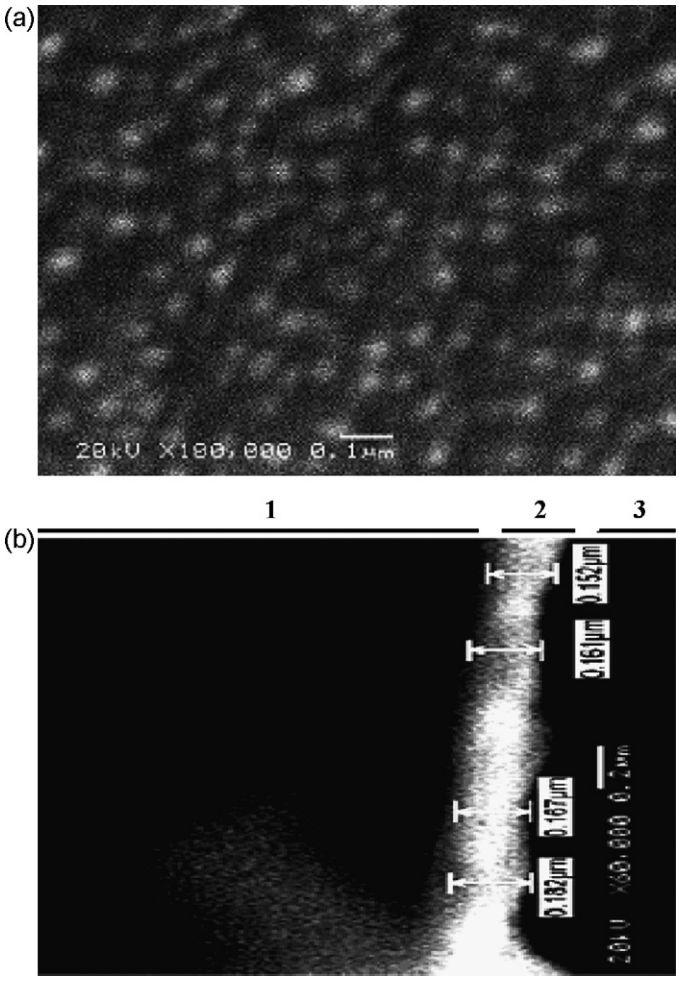

Fig. 8. Scanning electron microscope image of (A) sol–gel material used in the imprinting processes and (B) the side image of the sol–gel film coated on the surface of glassy carbon electrode. (1) Substrate edge, (2) sol–gel film and (3) air.

bation of the imprinted films in tyrosine solution compared to the incubation in PBS for the same period of time which is shown in Fig. 6B. This result indicated that tyrosine did not rebind into the molecular cavities of either tyramine or dopamine. From the foregoing results, it is confirmed again that imprinted sites are able to rebind their template molecules while molecules of largely different molecular structures and shape are unable to rebind.

The fitted electrochemical equivalent circuit is formed of five components connected in a specific way that they fit the impedance measurements carried out across the interface between the imprinted film coated on the electrode surface and the solution. Equivalent circuit designed for the molecularly imprinted film is indicated in Fig. 7. This circuit is formed of five components. R_u is the solution resistance, R_p is polarization resistance, C_f is capacitance component while CPE is another capacitance component called constant phase element. Constant phase element is more accurate component in describing the capacitance behavior of the double layer. W is Warburg component which describe the diffusion behavior of electro-active species with respect to the electrode surface.

Tables 3A and 3B lists the best fitting components calculated for the equivalent circuit for dopamine after testing in dopamine and in

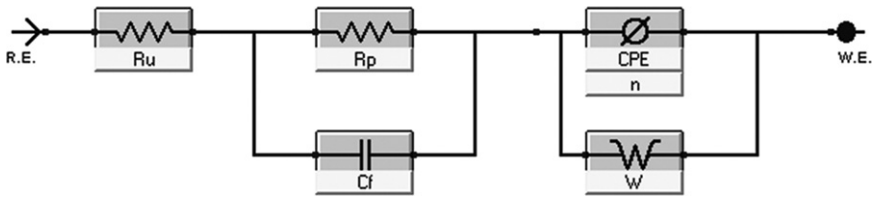

Fig. 7. Electrochemical equivalent circuit for EIS measurements.

tyrosine solutions, respectively. The circuit components decreased in case of incubation in dopamine solution compared to incubation in PBS. On the other hand these components did not change appreciably in case of incubation in tyrosine which confirms the experimental results described in Fig. 6(A and B).

3.8. Surface characterization

Sol–gel material synthesized for imprinting was characterized using scanning electron microscope at magnification power 100,000. The sol–gel particles were distributed very homogeneously and uniformly on the surface of substrate. The average particle size was found to be in the range of 38–45 nm as indicated in Fig. 8A. In this work, molecularly imprinted thin films were made using spin coating with spinning rate 2500 rpm as an optimized time in such away that it could allow the highest adsorption (recognition) capacity of the template molecules. The uniformity of the particles is mainly attributed to carrying spinning process at this high speed. Thin films were then allowed to dry to give a chance for complete polymerization of free hydroxyl groups on the film surface which may increase non-specific adsorption toward different molecular species by increasing the probability of H-bonding between the amino and hydroxyl groups of catecholamine compounds and these free hydroxyl groups.

We determined the average film thickness using side imaging of the coated electrode by scanning electron microscope [29] as illustrated in Fig. 8B. The film thickness ranged between 152 nm and 180 nm with an average value of 165 nm. The sensitivity as noticed in the high current responses of the modified electrode is highly affected by the film thickness. Thin films facilitate the diffusion of the template inside the molecular cavities compared to relatively thicker films [9].

4. Conclusions

Tyramine and dopamine molecules were imprinted successfully in a hybrid sol–gel material and then were spin coated as thin films on the surfaces of glassy carbon electrodes. The modified electrodes were used for sensing of the template molecules electrochemically. Selectivity of the electrodes for dopamine or tyramine was found to depend largely on the shape and size of the molecular cavity created during polymerization of sol–gel material in addition to the functional group orientation inside the cavities with respect to the template molecules.

Urine sample

ABSTRACT

The preparation and electrochemical characterization of a carbon paste electrode modified with layered birnessite-type manganese oxide for use as a sodium sensor is described. The effects of powder synthesis process (sol–gel and redox precipitation) for birnessite on the electrochemical activity of the sensor was investigated by cyclic voltammetry. The carbon paste electrode modified with birnessite-type manganese oxide that was synthesized by the sol–gel method showed a best electrochemical for sodium ions. The detection is based on the measurement of anodic current generated by oxidation of Mn(III) to Mn(IV) at the surface of the electrode and consequently the sodium ions extraction into the birnessite structure. The best voltammetric response was obtained for an electrode composition of 15% (w/w) birnessite oxide in the paste, a TRIS buffer solution of pH 8.0 and a scan rate of 50 mV s^{-1}. A sensitive linear voltammetric response for sodium ions was obtained in the concentration range of 7.89×10^{-5} to 3.49×10^{-4} mol L^{-1} with a slope of 37.5 μA L $mmol^{-1}$ and a detection limit (3σ/slope) of 3.43×10^{-5} mol L^{-1} using cyclic voltammetry. Under the working conditions, the proposed method was successfully applied to determination of sodium ions in urine samples.

1. Introduction

Porous manganese oxides are a class of materials that combine the high surface area/selectivity properties of zeolites with the redox capacity of manganese. Birnessite is a common manganese oxide mineral found in soils, ore deposits, and marine manganese nodules [1–5]. It has a two-dimensional layered structure that consists of edge-shared MnO_6 octahedra with cations and water molecules occupying the interlayer region, as indicated in Fig. 1. The interlayer distance in birnessite is typically 7 Å, but further hydration can increase this spacing to produce a closely related 10 Å birnessite variant known as buserite [6–9].

Manganese oxide forms various structures, including spinel (hausmannite), layered (birnessite, buserite), and one-dimensional tunnel (hollandite, todorokite). It also contains manganese atoms of different valencies, dependent on the molar ratio of manganese and oxygen, the defects in the crystals, or the content of other metal ions such as alkali metals [10]. Birnessite is an important ion-exchange material [11] and a precursor to todorokite (a class of octahedral molecular sieves containing 3×3 MnO_6 units) [12–14]. Birnessite can be used in rechargeable battery materials [15] and is also a promising catalytic material [16].

A lowering of the electrolytic concentration of sodium ions in the blood to a serum concentration below 136 mmol L^{-1} results in hyponatremia, an electrolytic disturbance in hospitalized patients. This reflects a water balance disturbance associated to hyposmolality [17,18]. The official method for analyzing sodium ion concentration is flame photometry [19]. Several reports demonstrate alternative procedures for the determination of sodium concentration that employ different analytical systems in various pharmaceutical, environmental and clinical samples [20–22]. However, the majority of the studies proposed in literature are based on spectrophotometric techniques [23–25].

In this paper, the construction of a carbon paste electrode modified with birnessite-type manganese oxide is proposed. The influence of various parameters such as electrode composition, pH, potential scan rate and interference in potential was studied by cyclic voltammetry.

2. Experimental

2.1. Apparatus

The cyclic voltammetric measurements were carried out with μAutolab III, controlled by a PC using GPES 4.9.7 software. The

doi:10.1016/j.talanta.2009.07.015

measurements were performed in a glass cell containing three electrodes: a modified carbon paste electrode (CPEM) as the working electrode, a saturated calomel electrode (SCE) as the reference electrode and a platinum wire as the auxiliary electrode. During the measurements, the solution in the cell (TRIS buffer solution at pH 8.0) was not stirred.

2.2. Reagents and solutions

All solutions were prepared using deionized water. Chemicals of analytical-reagent grade were used without further purification. The supporting electrolyte used for all experiments was a 0.1 mol L^{-1} tris(hydroxymethyl) aminomethane (TRIS) buffer solution at pH 8.0. A stock solution of 1.0×10^{-2} mol L^{-1} sodium ion was prepared daily by dissolving sodium chloride (Aldrich) in 100 mL of 0.1 mol L^{-1} TRIS buffer solution (pH 8.0). Graphite powder (1-2 μm particle size, Aldrich) and mineral oil (Aldrich), both of high purity, were used in the preparation of the carbon paste.

2.3. Synthesis of birnessite-type manganese oxide

The synthesis of birnessite-MnO_2 through a sol–gel method was realized by the procedure previously described [26], in the following way: 3.0 g of $NaMnO_4 \cdot H_2O$ dissolved in 50 mL of distilled water was added to 5.0 g of glucose dissolved in 20 mL of distilled water. The resulting mixture was swirled vigorously for 50 s and then allowed to stand without further agitation. The exothermic reaction produced a reddish sol that became a brown gel within 90 s of the initial mixing. The gel was allowed to cool at room temperature for 30 min before being dried at 110 °C overnight. Calcination of the resulting brown xerogel at 400 °C for 2 h produced an ash, which was ground into a fine brown/black powder. The crude product was stirred in water overnight before being isolated by filtration, washed with water and dried at 110 °C.

The synthesis of birnessite-MnO_2 though a redox precipitation method was realized by the procedure previously described [27], in the following way: a solution of 13.5 g of $MnSO_4 \cdot H_2O$ and 3.95 g of $MgSO_4 \cdot 7H_2O$ in 160 mL of deionized distilled water (DW) was added slowly to a solution of 40 g of sodium hydroxide in 180 mL of DW with vigorous agitation to form pink gels of $Mn(OH)_2$. A solution of 5.1 g of $KMnO_4$ in 160 mL of DW was then added slowly into the gel during vigorous agitation to produce a black suspension of MnO_x. This suspension was aged at room temperature and at atmospheric pressure. The resultant product was filtered and washed.

2.4. Structural characterization of birnessite-type manganese oxide

The powder of birnessite oxide was characterized by X-ray diffraction (XRD) using a D5000 X-ray diffractometer with Cu Kα radiation and monochromatic graphite. Samples were spread onto glass slides and scanned at 2° 2θ/min between 5° at 75°. The comparison with JCPDS card 23-1046 confirmed the peaks of greater intensity characteristic of the structure of birnessite-type manganese oxide.

2.5. Construction of the carbon paste electrode

The modified carbon paste electrode was prepared manually by carefully mixing the dispersed graphite powder with birnessite oxide at several mass ratios and subsequently adding a fixed quantity of 150 mg of mineral oil (15%, w/w). Those mixtures were mixed by magnetic agitation in a 50 mL beaker containing 10 mL of hexane. The final paste was obtained via evaporation of the solvent. The modified carbon paste was packed into an electrode body consisting of a plastic cylindrical tube (i.d. 3 mm) equipped with a stainless steel rod serving as an external electric contact.

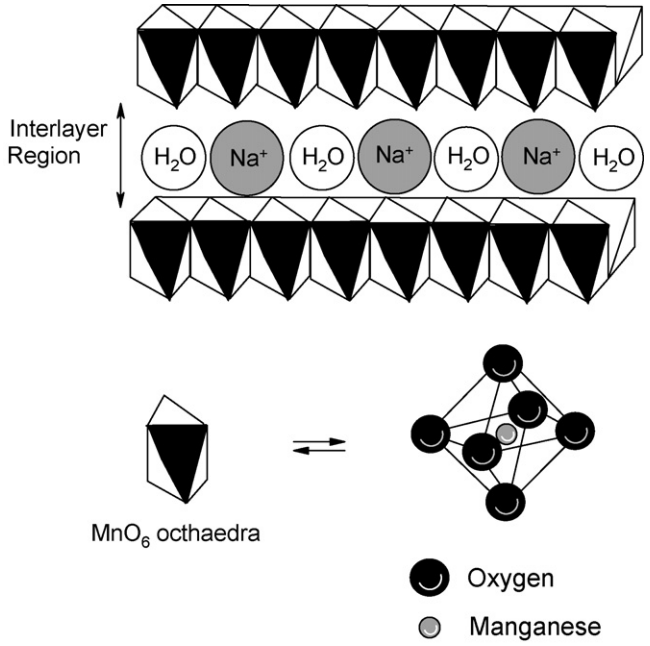

Fig. 1. Schematic representation of the birnessite-type manganese oxide.

3. Results and discussion

3.1. XRD characterization of birnessite-type manganese oxide

The birnessite-MnO_2 synthesized by the sol–gel and redox precipitation methods provided XRD spectra with many peaks. Among them were two structural phases of higher importance: one with an interlayer distance of 0.7 nm ($2\theta = 12°$) and another with a layer spacing of 0.55 nm ($2\theta = 25.0°$). The XRD patterns of the birnessite oxides synthesized by the sol–gel and redox precipitation methods are shown in Fig. 2, respectively. Prolonged stirring of this product mixture in water converts the 0.55 nm form into the 0.7 nm form [26]. Layered manganese oxides with spacing near 0.55 nm have previously been observed and characterized as dehydrated forms of 0.7 nm birnessite [28–31].

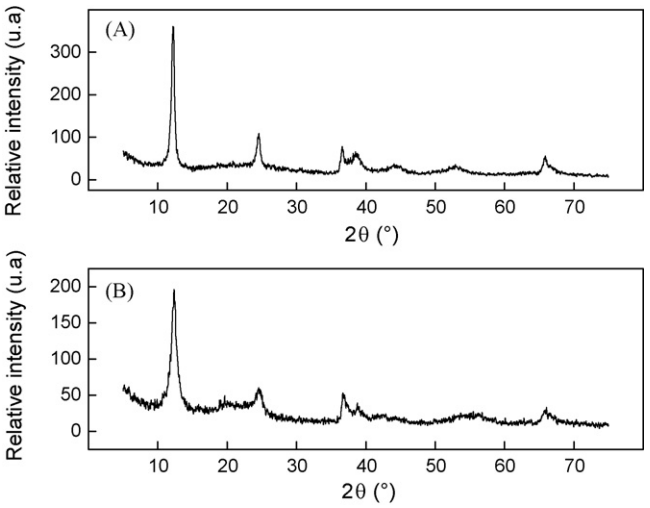

Fig. 2. The XRD patterns of birnessite synthesized by the sol–gel (A) and redox precipitation methods (B).

In terms of structural organization and crystallinity, some differences were observed between the oxides synthesized by the two methods. The sol–gel method yielded a diffractogram with narrower, more defined peaks, indicating good structural organization of the birnessite oxide. The redox precipitation method yielded a diffractogram with more phases, represented by characteristic signal located in the peaks of crystalline reflection: $2\theta = 12.43^\circ$; 19.86°; 24.75°; 55.45° and 65.97°. Although they have minor intensities, the presence of several allotropic phases of manganese oxide reduces the sensor's active region of electrochemical response, which is indicated by relative proportion Mn(III)/Mn(IV) of birnessite-MnO_2 contain in the interlayer region with distance of 0.7 nm. This space region is responsible for the intercalation/deintercalation reaction of sodium ions of layer conformation of birnessite manganese oxide, due to the higher negative charge density of MnO_6 octahedra.

However, the birnessite manganese oxide synthesized by the sol–gel method was the modifier utilized in the elaboration of this sensor. The carbon paste electrode modified with birnessite-type manganese oxide that was synthesized by the sol–gel method showed a best electrochemical for sodium ions. This performance is related to the degree of crystallinity, the homogeneity of the oxide and the ideal interlayer distance for the sodium ions.

3.2. Voltammetric behavior of the CPEM

The characteristics of the carbon paste electrode modified (CPEM) with birnessite-type manganese oxide were studied by cyclic voltammetry. Fig. 3 shows a typical cyclic voltammogram obtained for the CPEM with birnessite-type manganese oxide in 0.1 mol L^{-1} TRIS buffer (pH 8.0), both in the presence of 1.67×10^{-3} mol L^{-1} of sodium ions (indicated by curve **B**) and the absence of sodium ions (indicated by curve **A**). The potential was scanned between −0.50 and 1.0 V versus SCE; an anodic potential peak was observed at +0.57 V (peak **I**) and a cathodic potential peak was observed at +0.04 V (peak **II**). This electrochemical activity was due to the topotactic extraction process of the sodium ions from the birnessite structure, which occurs according to [32]:

$$NaMn^{3+}Mn^{4+}O_x + H_2O \rightarrow HMn_2{}^{4+}O_x(OH) + Na^+ + e^- \quad (\text{peak I}) \tag{1}$$

$$HMn_2{}^{4+}O_x(OH) + Na^+ + e^- \rightarrow NaMn^{3+}Mn^{4+}O_x + H_2O \quad (\text{peak II}) \tag{2}$$

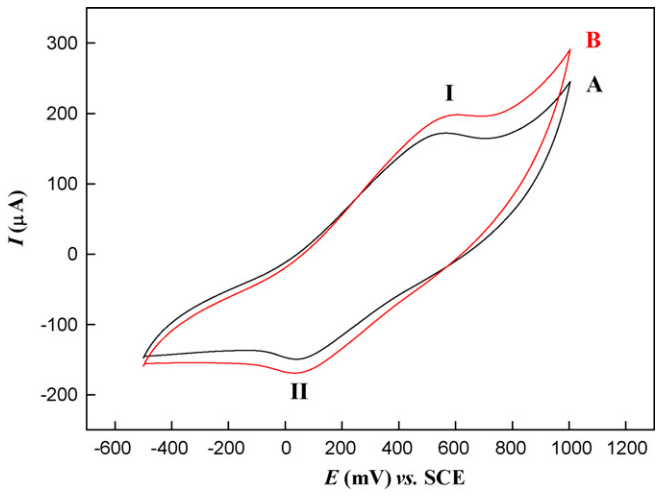

Fig. 3. Cyclic voltammogram at a scan rate of 15 mV s^{-1} for the CPEM with birnessite-type manganese oxide in TRIS buffer solution (pH 8.0) in the absence of sodium ions (A) and in the presence of 1.67×10^{-3} mol L^{-1} sodium ions (B).

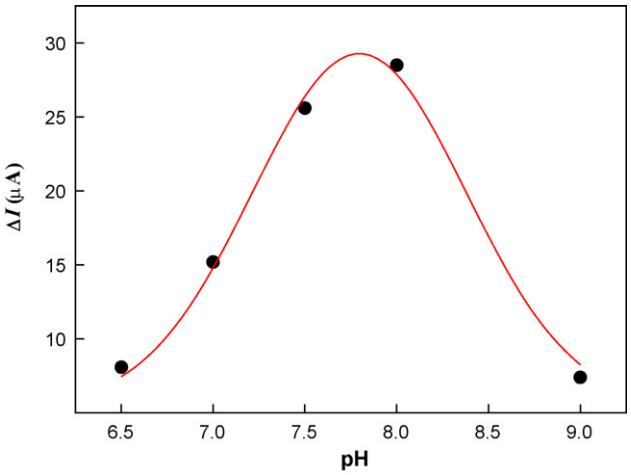
Reaction (1) represents the electrochemical response of the correspondent electrode, an oxidation reaction of Mn(III) to Mn(IV) with concomitant departure of the sodium ions from the birnessite structure. Reaction (2) represents the electrochemical response of the correspondent electrode, a reduction reaction of Mn(IV) to Mn(III) with intercalation of the sodium ions into the birnessite structure. The entrance and exit of water molecules in the birnessite-MnO_2 interlayer region is essential for oxidation and reduction of the manganese atom, respectively [33]. The electrochemical response is illustrated in Scheme 1. The enhanced response to sodium occurs because the cathodic polarization of the CPEM with birnessite-type manganese oxide is enough to reduce the manganese in the solid phase. Consequently, the sodium ions from the adjacent solution are able to diffuse through the birnessite structure to maintain the electroneutrality principle. In the absence of sodium ions (curve A—Fig. 3), the voltammetric profile of the modified electrode shows a redox peak. Supposedly, that behavior can be related with the vestige of sodium ions in the birnessite-type manganese oxide occurred during its preparation.

3.3. Electrode composition effect

The amount of manganese oxide in the carbon paste had a significant influence on the voltammetric response. The peak currents increased according the elevation on amount of birnessite-type manganese oxide up to 25% (w/w). For amounts of manganese oxide greater than 30% (w/w), the anodic peak current decreased significantly. This occurs because of a decrease of the graphite content in the paste and, consequently, a reduction of conductive area at the electrode surface. The best carbon paste composition was found to be an electrode composition of 15% (w/w) modified birnessite-type manganese oxide, 70% (w/w) graphite and 15% (w/w) mineral oil.

3.4. Effect of pH

The voltammetric response of the carbon paste electrode modified with birnessite-type manganese oxide was studied over a pH range between 5.0 and 10.0, controlled with TRIS buffer in the presence (1.67×10^{-3} mol L^{-1}) and absence of sodium ions. The results obtained indicated that the values difference current of anodic peaks are strongly influenced and reached a maximum value at pH values near 8.0, as shown in Fig. 4.



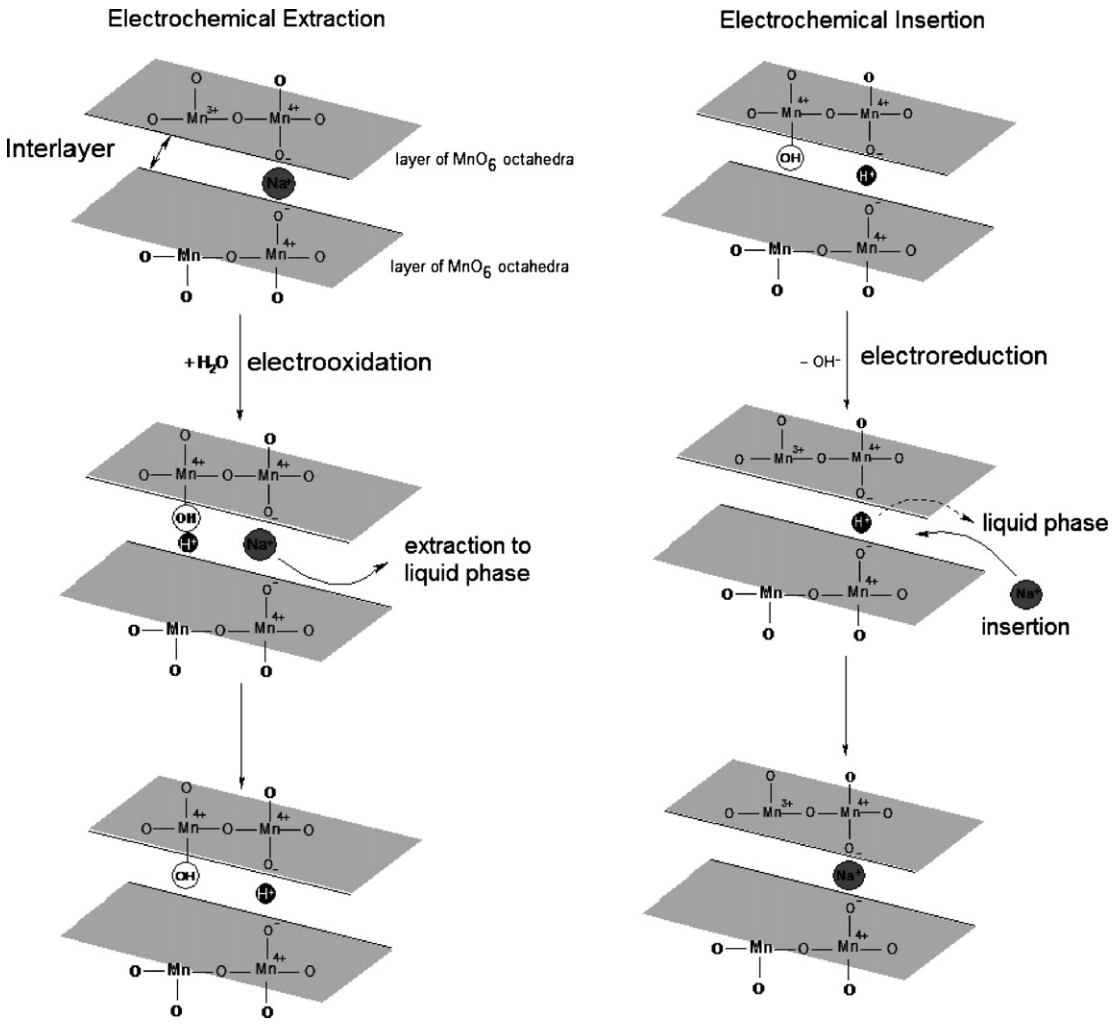


Fig. 4. pH dependence of the voltammetric response of the carbon paste electrode modified with 15% (w/w) birnessite at a scan rate of 50 mV s^{-1} in TRIS buffer solution containing 1.67×10^{-3} mol L^{-1} sodium ions. The anodic peak current (ΔI_{pa}) was obtained from the difference of the currents in the absence and presence of sodium ions.

Scheme 1. Schematic representation of the electrode modified with layered birnessite-type manganese oxide. Electrochemical extraction/insertion reactions of sodium ions from the birnessite structure. Adapted from Ref. [42].

At pH values under 8.0, the surface disproportion reaction proposed by Hunter [34] and Sato et al. [35] (represented in Eq. (3)) could explain the pH dependency of the peak current.

$$2Na[Mn^{3+}Mn^{4+}]O_{4(s)} + 4H_3O^+_{(aq)} \rightarrow 3HMn^{4+}O_2(OH)_{(s)} + 2Na^+_{(aq)} + Mn^{2+}_{(aq)} + 3H_2O_{(l)} \quad (3)$$

For pH values of 9.0 and 10.0, the values of the peak current decrease again, probably due to another surface formation of pyrochroite ($Mn(OH)_2$) and/or non-electroactive spinel-type oxide (Mn_3O_4-hausmannite) [36,37]. Therefore, only a TRIS buffer of pH 8.0 was used in further studies.

3.5. Studies on the ion extraction process

The time it takes to extract sodium ions from birnessite-type manganese oxide is an important parameter; with this parameter, one can obtain an oxide with a smaller proportion of sodium in the layered and two-dimensional structures of birnessite. Therefore, this parameter was studied in the hopes of obtaining an oxide with a better electrochemical performance. Oxide samples were agitated in 1 mol L^{-1} nitric acid over different cationic extraction periods (24, 48, 72 and 96 h) and evaluated in the CPEM in 0.1 mol L^{-1} TRIS buffer (pH 8.0) – both in the absence and presence of sodium ions ($[Na^+] = 1.67 \times 10^{-3}$ mol L^{-1}) – by cyclic voltammetry. A higher variation in the anodic peak current was obtained with the birnessite oxide sample that was subjected to 48 h of sodium ion extraction (Table 1). The cyclic voltammogram of the sample subjected to 72 h of cationic extraction, however, presented the best voltammetric profile, and this oxide was used in all further studies.

3.6. Effect of the scan rate

The effect of the scan rate on the voltammetric response of CPEM with birnessite-type manganese oxide in a solution containing 1.67×10^{-3} mol L^{-1} of sodium ions was investigated in the range of 5–100 mV s^{-1}. For scan rates higher than 50 mV s^{-1}, an increase in the values of the anodic peak currents was accompanied with a

Table 1
Effect of the extraction of sodium ions from birnessite-type manganese oxide in the anodic peak current (ΔI_{pa})[a] of the sensor in the presence of 1.67×10^{-3} mol L^{-1} sodium ions.

Cationic extraction periods (h)	ΔI_{pa} (μA)
24	22.4
48	70.8
72	54.2
96	40.0

[a] The values of anodic current were obtained by difference of the currents in the presence and absence of sodium ion in solution.

broadening and distortion of the peaks. When the values of the peak currents for both anodic peaks were plotted against the square root of the scan rate, a linear relationship was observed. These results show that the charge transfer reaction ($Mn^{3+} \rightarrow Mn^{4+} + e^-$) is controlled by diffusion of the sodium ions in the solid phase [38]. The linear relationship obtained was:

$$I_{pa}(\mu A) = 56.9 + 1322.6\,\nu^{1/2}(V^{1/2}s^{-1/2}) \quad r = 0.9993,\ n = 6 \qquad (4)$$

$$I_{pc}(\mu A) = -37.0 - 855.4\,\nu^{1/2}(V^{1/2}s^{-1/2}) \quad r = 0.9977,\ n = 6 \qquad (5)$$

The apparent electrochemical rate constant (k_e) and the electron-transfer coefficients (α_{anodic} and $\alpha_{cathodic}$) were calculated for the CPEM birnessite-MnO_2 according to the method described by Larivon [39]. It has been shown by Laviron that for a surface redox couple, α_a and α_c, k_e can be determined from the variation of E_{pa} and E_{pc} with scan rate. For large enough scan rates, the E_p versus $\log \nu$ plots gave two straight lines with slopes of $-2.303RT/\alpha_c nF$ for the cathodic branch and $2.303RT/(1-\alpha_a)nF$ for the anodic branch, where R is the gas constant, T is the absolute temperature, F is the Faraday constant, and n is the number of electrons involved in the redox process. Considering that the number of electrons involved in the redox process is 1, the calculated values for the coefficients α_a and α_c are 0.54 and 0.18, respectively. These results suggest that the redox process tends an almost irreversible system. The apparent electrochemical rate constant for anodic peak can then be determined applying the equation $k_e = 2.303\alpha_a nF\nu_o/RT$, in which the value of the scan rate (ν_o) is determined by extrapolation of the linear branch at higher scan rates to its intersection with the constant peak potential, represented by the peak of the voltammogram at the lower scan rate. From the equation, the observed value for k_e was $2.42 \times 10^{-1}\ s^{-1}$.

3.7. Effect of interference

For this study, cyclic voltammograms for the CPEM with birnessite-type manganese oxide were carried out in 0.10 mol L^{-1} TRIS buffer solution (pH 8.0) containing 1.67×10^{-3} mol L^{-1} of Li^+, K^+, Rb^+, Mg^{2+}, Ca^{2+}, Sr^{2+} and Ba^{2+}. Fig. 5 shows the effect of these different cations in the voltammetric response of the sensor. The relative current (%) was calculated by the difference in the peak currents in the presence and absence of the cations. The values of the anodic peak current decreased with the increase of the ionic radius of the cation. For ions with an ionic radius of less than 1.13 Å, current values were observed to be higher for bivalent ions than for monovalent ions. These results suggest that ions with a greater charge and smaller ionic radius easily insert into the birnessite-type manganese dioxide matrix. The magnesium ion was interference serious in the voltammetric response of CPEM. The magnitude of this interference was correlated with the high capacity of the magnesium ion to insert into the interlayer region of the birnessite oxide. This capacity is related to the high charge density (ion charge/ionic radius = 3.08) of the magnesium ion; for comparison, the charge density of a sodium ion is 1.05 [40].

3.8. Effect of the pre-concentration time

The dependence of the anodic peak currents on the pre-concentration time is presented in Fig. 6. The voltammetric responses of the CPEM with birnessite-type manganese oxide in a solution containing 1.63×10^{-3} mol L^{-1} sodium ions, after pre-concentration at −0.2 V, range 0 at 100 s was available. The values of the anodic peak currents increased linearly with the pre-concentration time (Fig. 6). This is because the birnessite-type manganese oxide structure enables accumulation of sodium ions through the oxide's larger superficial area, in comparison with respective areas for other manganese oxides (spinel-MnO_2) [41].

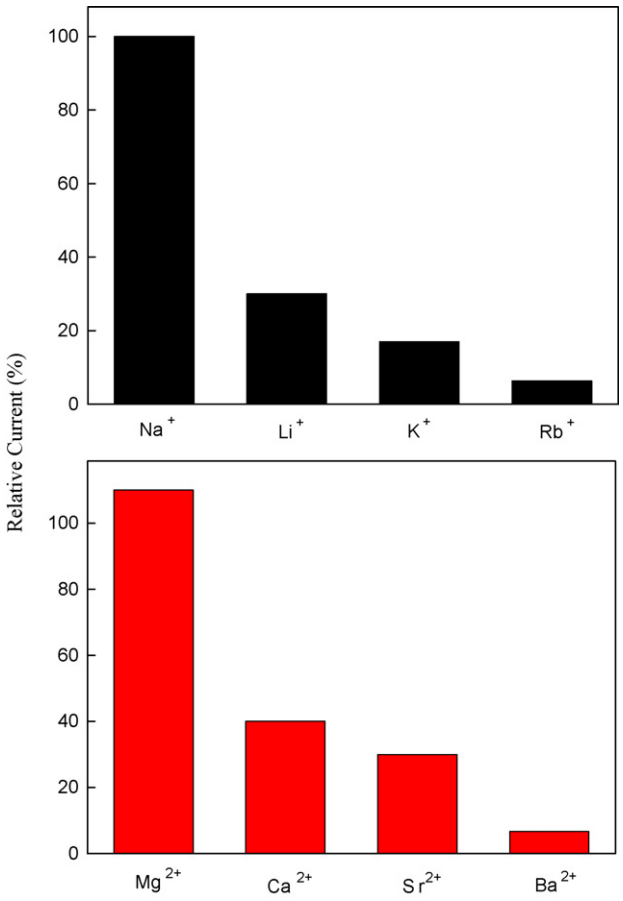

Fig. 5. Interference dependence of the voltammetric responses of the CPEM with birnessite-type manganese oxide in TRIS buffer solution (pH 8.0) containing 1.67×10^{-3} mol L^{-1} of Li^+, K^+, Rb^+, Mg^{2+}, Ca^{2+}, Sr^{2+} and Ba^{2+} ions. Scan rate = 50 mV s^{-1}.

Hence, for all subsequent measurements, a pre-concentration time of 100 s was employed.

3.9. Calibration graph and precision of the sensor

Under the optimized conditions previously studied–including composition of the electrode (15%, w/w), pH (8.0) and scan rate

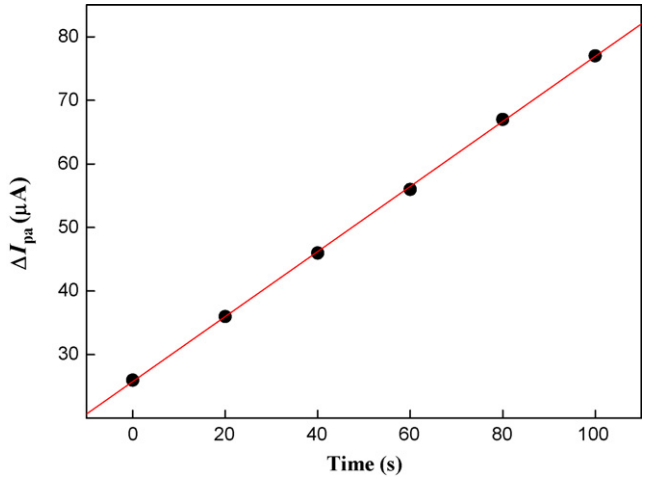

Fig. 6. Pre-concentration time dependence of the voltammetric responses of the CPEM with birnessite-type manganese oxide in TRIS buffer solution (pH 8.0) containing 1.67×10^{-3} mol L^{-1} of sodium ions after pre-concentration at −0.2 V vs. SCE. Scan rate = 50 mV s^{-1}.

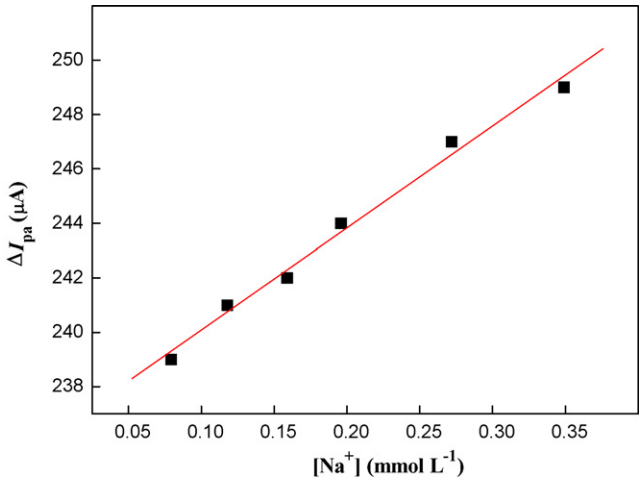

Fig. 7. Analytical curve for sodium ions in 0.1 mol L^{-1} TRIS buffer solution (pH 8.0) using the CPEM with 15% (w/w) birnessite-MnO_2, with a pre-concentration time at −0.2 V vs. SCE of 100 s. Scan rate = 50 mV s^{-1}.

(50 mV s^{-1})—cyclic voltammetrics were carried out in the buffered solution containing varying sodium ion concentrations in order to obtain the analytical curve of the CPEM. A linear relationship was obtained when the anodic peak current values were plotted against sodium ion concentrations in the range of 7.89×10^{-5} to 3.49×10^{-4} mol L^{-1} (I_{pa} (μA) = 236.3 + 37.5 [Na^+(mmol L^{-1})]; $r = 0.9948$; $n = 6$), as illustrated in Fig. 7. The sodium ion concentration detection limit (3σ/slope) was 3.43×10^{-5} mol L^{-1}.

The precision of the method was tested by analyzing six voltammograms of CPEM in 0.1 mol L^{-1} TRIS buffer solution at pH 8.0 containing 1.67×10^{-3} mol L^{-1} of sodium ions. A small increase in the peak current was observed with the increase of the number of cycles. This behavior can be related with the ionic capture capacity of oxides with bigger superficial areas.

3.10. Determination of sodium ions in urine samples

The sodium ions concentrations of three different human urine samples were determined by cyclic voltammetric using the CPEM with birnessite-type manganese oxide under the previously optimized experimental conditions. The urine samples were pre-treated with ammonium hydroxide to eliminate calcium and magnesium ions by precipitating them in the form of $Ca(OH)_2$ and $Mg(OH)_2$, respectively. The ammonia in the pre-treated samples was eliminated by heating. The sample solution was prepared in the TRIS buffer solution (pH 8.0) prior to analysis. The sodium ions concentration was determined by the standard addition method and compared with the values obtained by atomic absorption spectrophotometry at a wavelength of 589 nm. Relevant analyses are summarized in Table 2. The statistical calculations for the assay results show significant precision for the proposed method.

In the addition and recovery study, five different sodium concentrations (3.98, 7.94, 1.18, 15.7 and 19.6×10^{-4} mol L^{-1}) were added in triplicate in the urine sample. The results are showed in the Table 3. Recoveries between 92.7% and 107% of sodium ion were obtained using the sensor; it suggests the absence the interference of matrix effect in the procedure proposed.

Table 2
Comparative results for the determination of sodium ions content in urine samples using the voltammetric methodology and atomic absorption spectrophotometry.

Samples	Sodium ions (μg mL^{-1})		
	Spectrophotometry	Voltammetry	E_r (%)
1	4.783	4.702	5.7
2	4.836	4.734	7.2
3	4.812	4.725	6.1

E_r = relative error, voltammetric method vs. spectrophotometric method.

Table 3
Results of addition-recovery experiments using voltammetric procedure for three different standard concentrations of sodium ion.

Sodium ion* ($\times 10^{-4}$ mol L^{-1})		
Added	Found	Recovery (%)
3.98	3.69	92.7
7.94	8.20	103
11.8	12.6	107
15.7	15.6	99.4
7.94	8.70	97.4

* $n = 3$.

4. Conclusion

The present study demonstrates that the carbon paste electrode modified (CPEM) with birnessite-type manganese oxide can be used for the determination of sodium ion concentrations in the presence of several alkali metals. The electrochemical behavior of the CPEM with birnessite-type manganese oxide was well defined and stable. The best voltammetric response was obtained for an electrode composition of 15% (w/w) birnessite-type manganese oxide in the paste, a 0.1 mol L^{-1} tris(hydroxymethyl) aminomethane buffer solution at a pH of 8.0, a scan rate of 50 mV s^{-1}, an accumulation potential of −0.2 V versus SCE, and a pre-concentration time of 100 s. Under these experimental conditions, the proposed methodology responds to sodium ions in the concentration range of 7.89×10^{-5} to 3.49×10^{-4} mol L^{-1}, with a detection limit of 3.43×10^{-5} mol L^{-1}. The lifetime of the proposed sensor was at least six months (more than 100 determinations was performed using the same electrode surface and more than 600 determinations was done when the surface was renewed). The determination of sodium ions in urine using the proposed procedure is characterized by precision and selectivity. This makes the procedure applicable for the analysis and quality control of clinical samples.

ABSTRACT

A simple and rapid method has been reported for the determination of carbonyl compounds involving reaction with 2,4-dinitrophenylhydrazine and extraction of hydrazones with water-miscible organic solvent acetonitrile when the phase separation occurs by addition of ammonium sulphate, a process called salt-assisted liquid–liquid microextraction. The extract was analyzed by high-performance liquid chromatography with UV detection at 360 nm. The procedure has been optimized with respect to solvent suitable for extraction, salt for phase separation between water and organic solvent, reaction temperature and reaction time. The method has been validated when a linear dynamic range was obtained between the amount of analyte and peak area of hydrazones in the range 7 μg–15 mg L^{-1}, the correlation coefficient over 0.9964–0.9991, and the limit of detection in the range 0.58–3.2 μg L^{-1}. Spiked water samples have been analyzed with adequate accuracy, and application of the method has been demonstrated in the analysis of benzaldehyde formed as oxidation product in pharmaceutical preparation where benzyl alcohol is used as preservative, and for a keto drug dexketoprofen.

1. Introduction

Carbonyl compounds, aldehydes and ketones, are ubiquitous pollutants because of their toxicity and potential to react with other pollutants to form carcinogenic compounds [1–3]. In the troposphere, these compounds are formed mainly by photochemical oxidation of anthropogenic and biogenic hydrocarbons [4]. They are major contributors to urban photochemical smog, being significant source of free radicals in the atmosphere and acting as precursors to the formation of organic aerosols. Many carbonyl compounds are recognized irritants of skin and eyes, while formaldehyde even at concentration of 50 μg L^{-1} causes respiratory tract sickness and is a confirmed animal carcinogen and a suspected human carcinogen [5,6]. In Japan, formaldehyde is regulated below 80 μg L^{-1} in tap water [7]. Additionally, carbonyl compounds have been detected as drug metabolic products in urine, plasma, serum, amniotic fluid, etc. [8]. Many low molecular mass carbonyl compounds arise from the pyrolysis of cigarette and stimulate the sense organs and respiratory system of humans. Formaldehyde and acetaldehyde in cigarette smoke are deposited directly in the blood after inhalation and cause biological complication [9]. Aldehydes are considered as potential markers for enhanced oxidative stress and have been proposed to diagnose the status of cancer [10,11].

The high reactivity and volatility of low molecular mass carbonyl compounds impose the need for derivatization prior to their detection by a spectroscopic or chromatographic technique. The commonly used methods to determine aldehydes and ketones involve the reaction of carbonyl group with substituted amine, hydrazine or hydroxylamine, used as reagents, to form a Schiff base, hydrazone or oxime [12]. Hydrazines constitute the most popular group of derivatizing agents for formation of hydrazones of carbonyl compounds that are suitable for analysis by gas and liquid chromatography. Such reagents include 2,4-dinitrophenylhydrazine (DNPH) [13–15], 2,4,6-trichlorophenylhydrazine [16], 2,3,4,5,6-pentafluorophenylhydrazine [17], 5-dimethylaminonaphthalene-1-sulphohydrazide (dansylhydrazine) [18–20] and methylhydrazine [21]. Hydroxylamine derivatives, such as *O*-(2,3,4,5,6-pentafluorobenzyl)hydroxylammonium chloride (PFBHA) [22,23], where an oxime is formed, have also gained popularity due to its facile reaction chemistry and analysis by gas chromatography (GC). 2-Aminoethanethiol (cysteamine) [24,25], and Hantzsch reagents [26] have also been employed in GC for carbonyl compounds.

DNPH is the most extensively used reagent for hydrazone formation, and the precision obtained with it in high-performance liquid chromatography (HPLC) is better than that obtained with volatile oximes in GC. Carbonyl compounds in air were collected on DNPH coated cartridge and analyzed after elution by capillary

doi:10.1016/j.talanta.2009.07.021

electrochromatography-diode array detection [27]. The influence of sampling volume and concentration of atmospheric carbonyl compounds on collection by DNPH impregnated cartridge was investigated when the method was found to be affected more by the concentration levels of analytes [14]. DNPH treated filters were developed as convenient device for collection of carbonyl compounds in cigarette smoke [28]. A C_{18} precolumn was used in place of sample loop in the injector into which was introduced DNPH treated sample, any unreacted DNPH was removed by washing the precolumn and then the hydrazones were transferred to HPLC column for analysis [7].

The sample preparation step in an analytical process typically consists of an extraction procedure that results in the isolation, clean-up and enrichment of components of interest from the sample matrix. Extraction can vary in degree of selectivity, speed and convenience and depends not only on the approach and conditions used but also on the geometric configuration of the extraction phase [29]. The traditional extraction methods based on liquid–liquid extraction (LLE) are time-consuming and need a large amount of organic solvents, which are dangerous for human health and the environment. Impelled by the need to address these drawbacks, microextraction gradually evolved as a popular technique. Compared with LLE, solid-phase microextraction (SPME) is a solvent free process that includes simultaneous extraction and preconcentration of analytes by immersion of fibre into aqueous samples or by keeping it in the sample headspace. However, SPME is expensive, its fibres are fragile and have limited lifetime, and sample carry-over could be a problem [30]. As miniaturized LLE technique, single drop microextraction (SDME) has attracted great attention due to its merits of being simple, rapid and utilizing microlitre volumes of organic solvents [31–36]. However, attention is required to avoid drop instability due to evaporation or dislodgement under gravity or at higher stirring rate of sample [37]. SDME may be time-consuming due to slow attainment of equilibrium [36,38] and is less sensitive as the final extract is small (1–3 μL).

Salting-out is a process of addition of electrolytes to an aqueous phase in order to increase the distribution ratio of a particular solute. The term also connotes reduction of mutual miscibility of two liquids by addition of electrolytes. Weak intermolecular forces, *e.g.*, hydrogen bonds, between organic molecules or nonelectrolytes and water are easily disrupted by the hydration of electrolytes. The separation of acetone from aqueous solution for performing solvent extraction was first demonstrated by Matkovich and Christian [39] using salting-out of the acetone for phase separation. This method was later used for the extraction of several metal chelates with dithiocarbamate, dithionate and oxine using calcium chloride or sucrose for salting-out acetone [40]. Based on this phase separation phenomenon, a liquid–liquid extraction technique using acetonitrile as organic phase was developed [41]. Water and acetonitrile, which are miscible in all proportions, were made immiscible by the addition of an electrolyte such as tetrabutylammonium perchlorate [41], ammonium sulphate [42] or magnesium sulphate [43]. Acetonitrile was found promising extracting solvent owing to its compatibility with reversed-phase HPLC. However, there are a few methods available utilizing sample preparation by salting-out phase separation and HPLC. Secondly, all reported methods [41,42,44] used large volumes (typically 3–21 mL) of extracting solvent or diluted the extract with water before injection [43]. Injection of a part of extract decreased sensitivity, and to avoid this, the extract was evaporated and the residue dissolved in smaller volume (2 mL) of solvent and analyzed by HPLC [42]. The aim of the present work was to use microlitre volume (typically 500 μL) of water-miscible organic solvent and to optimize the experimental conditions of salt-assisted liquid–liquid microextraction (SALLME) of $\mu g\,L^{-1}$ level of carbonyl compounds after derivatization with DNPH, and analysis by HPLC. As an application of this method, determination of a keto drug dexketoprofen in pharmaceutical formulations, and benzaldehyde formed upon oxidation of benzyl alcohol, used as preservative, in drug formulations (injections) has been demonstrated.

2. Experimental

2.1. Instrumentation

The chromatographic system consisted of a Shimadzu (Tokyo, Japan) HPLC (LC-5A) isocratic pump and an SPD-2A spectrometric detector (8 μL flow-through cell). Detection was carried out at 360 nm. A Rheodyne Model 7010 valve (Alltech, Deerfield, IL, USA) equipped with a 10 μL sample loop was used for sample injection. Data processing was carried out with an HP 3395 integrator (Hewlett-Packard, Palo Alto, CA, USA). The analytical column, 25 cm × 4.6 mm i.d., packed with octadecylsilane (ODS, 5 μm particle size) (Princeton, Rankem, New Delhi, India) was used.

2.2. Reagents and solvents

Acetone (Rankem, New Delhi, India), benzaldehyde, furfural, ethylmethyl ketone, iso-propylmethyl ketone and cyclohexanone were obtained from Merck, Mumbai, India. The derivatizing agent DNPH was obtained from (BDH, Poole, England). HPLC grade or high purity solvents methanol, water, ethyl acetate and ethanol were obtained from Rankem, New Delhi, India. Ammonium sulphate, potassium chloride, sodium chloride, dipotassium hydrogenphosphate, potassium dihydrogenphosphate, ammonium chloride, sodium sulphate and sodium nitrate were from Merck, Mumbai, India.

2.3. Reagent and standards

The reagent solution was prepared by stirring together 10 mg of DNPH and about 0.5 mL of concentrated sulphuric acid to effect salt formation, dissolving the solid in methanol (carbonyl compounds free), filtering and diluting up to 10 mL in a standard flask. Less concentrated solution of reagent was made by sequential dilution with methanol and stored in a cool place.

Standard solutions, $1000\,mg\,L^{-1}$, of each carbonyl compound were prepared in methanol (carbonyl free) and stored in refrigerator when not in use. Working solutions were prepared by sequential dilution of the stock solution. Formaldehyde solution was standardized using Romijn hypoiodite method [45]. In this method a known volume of formaldehyde solution was treated with a measured excess of iodine solution in alkaline medium. Sodium hypoiodite formed *in situ* oxidized formaldehyde to formate ion. The surplus of hypoiodite after oxidation was determined iodimetrically by acidifying the solution and titrating the liberated iodine with standardized sodium thiosulphate solution using 1% starch as indicator near the end-point.

For the preparation of 2,4-dinitrophenylhydrazones of carbonyl compounds, about 200 mg of DNPH was treated with 0.2–0.3 mL of concentrated sulphuric acid, stirred to effect formation, cooled in crushed ice bath, and the solid was dissolved in about 4 mL of carbonyl free methanol. About 150 mg (or 0.2 mL) of the carbonyl compound was added, the reaction mixture heated in a boiling water bath for about 5 min and then cooled to the room temperature. If no precipitate appeared, distilled water was added dropwise until cloudiness appeared. The product was filtered, washed with 1% sulphuric acid and then with distilled water. The yield was quantitative and the product recrystallized from ethanol–water mixture was almost pure.

2.4. Chromatographic conditions

The flow rate of the mobile phase was set to 1 mL min^{-1} in all experiments. Initially all the compounds were eluted with methanol–water (containing 0.5% acetic acid), 60:40 (v/v), and their retention time were recorded to find the order of elution. The peaks were well separated but analysis time was long (about 22 min). The mobile phase of methanol–water (containing 0.5% acetic acid), 80:20 (v/v), resulted in adequate separation of peaks and the analysis was complete within 14 min. UV detector wavelength was set at 360 nm for the detection of hydrazones of carbonyl compounds. Peak area was used for quantitation.

2.5. Extraction and derivatization of carbonyl compounds

To 3 mL portion of aqueous sample solution containing 7 μg–15 mg L^{-1} of each carbonyl compound, 0.2 mL of 4% sulphuric acid and 100 μL of DNPH was added and the reaction mixture was heated in a water bath at 50–60 °C for 5 min. The mixture was cooled to room temperature and mixed with 500 μL of acetonitrile when a homogeneous phase was formed. The mixture was diluted to 5 mL with water and mixed with 0.5 g portions each of ammonium sulphate, shaking after addition, until the solution was saturated and a small amount of salt remained undissolved. Immediately, two phases separated out clearly, the top phase being about 150 μL of acetonitrile containing the derivatives. About 100 μL of extract was withdrawn with a Hamilton syringe and collected in the injection vial. A 10 μL portion of extract was injected on to the column.

2.6. Method for the determination of dexketoprofen in drugs

A known number of tablets of dexketoprofen were weighed, ground into a fine powder and a mass equivalent to a tablet was treated with 2–3 mL of 5% sodium hydrogencarbonate solution (to dissolve the carboxylic acid drug), stirred and filtered into a 100 mL standard flask. The residue on filter-paper was washed with water. The combined filtrate and washings were diluted to the mark with deionized water. A 1–2 mL portion of this solution was subjected to analysis as described in Section 2.5.

2.7. Method for the determination of benzaldehyde in drugs

The contents of a known number of ampoules for injection were combined and a volume equivalent to one injection was diluted to 10 mL with methanol in a standard flask. For analysis, 0.5 mL of this solution was taken through the procedure as described in Section 2.5.

3. Results and discussion

Fig. 1 shows the standard chromatogram of carbonyl compounds obtained by derivatization to their 2,4-dinitrophenylhydrazones and SALLME. Two peaks of unequal intensity were observed for 2,4-dinitrophenylhydrazones of unsymmetrical carbonyl compounds, viz., furfural, ethylmethyl ketone, benzaldehyde, iso-propylmethyl ketone and dexketoprofen corresponding to syn (*Z*) and anti (*E*) isomers [46]. The anti-isomer predominated owing to its higher thermodynamic stability and molar absorptivity.

3.1. Optimization of reaction conditions

Derivatization and extraction of hydrazones were two discrete steps that required optimization. For the first step, the amount of acid added and length of reaction time played critical role, while for the second step the nature and the volume/amount of water-miscible organic solvent and inorganic salt used for phase separation were important parameters. An aliquot of 200 μL of 4% sulphuric acid was found optimum for derivatization. The peak areas of hydrazones increased substantially with reaction temperature, but decreased with length of reaction time. The latter effect was apparently due to loss of carbonyl compounds formed by acid hydrolysis of hydrazones at longer reaction time. Reaction temperature in range 50–60 °C and heating for 5 min was optimum.

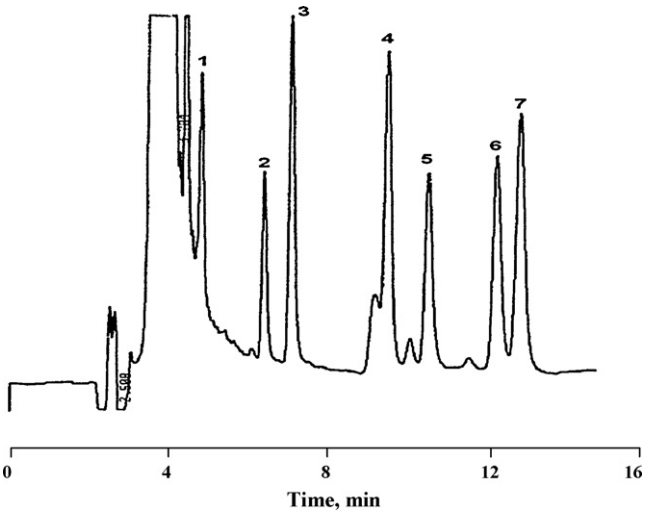

Fig. 1. Standard chromatogram of carbonyl compounds after derivatization with DNPH and SALLME. Experiment conditions, aqueous sample volume 4.5 mL, 500 μL of extracting solvent acetonitrile and 2.5 g of ammonium sulphate. Peaks identification (as their 2,4-dinitrophenylhydrazones; concentration of carbonyl compound), 1 = formaldehyde (0.5 mg L^{-1}), 2 = furfural (0.3 mg L^{-1}), 3 = acetone (0.5 mg L^{-1}), 4 = ethylmethyl ketone (1.0 mg L^{-1}), 5 = benzaldehyde (0.5 mg L^{-1}), 6 = iso-propylmethyl ketone (1.5 mg L^{-1}), and 7 = cyclohexanone (0.75 mg L^{-1}). AFS, 0.16.

3.2. Optimization of extraction system

Ammonium sulphate and dipotassium hydrogenphosphate gave better phase separation between water and water-miscible organic solvents in comparison to other salts used for this purpose, viz., potassium chloride, potassium dihydrogenphosphate, ammonium chloride, sodium sulphate and sodium nitrate. Methanol, ethanol, acetonitrile and ethyl acetate were examined for the extraction of hydrazone derivatives of carbonyl compounds when the best extraction and phase separation was found with acetonitrile (Fig. 2). Ethyl acetate was better for some hydrazones but the chromatographic performance (peak shape) was poor. Methanol–water mixtures did not show any phase separation. For clear phase separa-

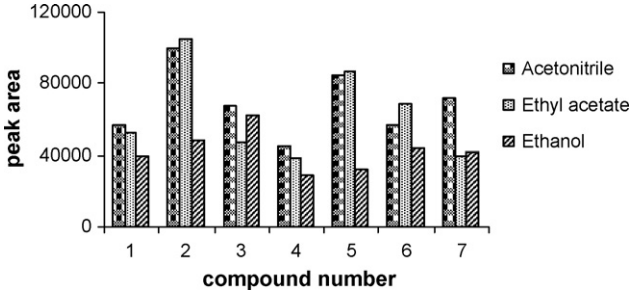

Fig. 2. Effect of organic solvents for SALLME of 2,4-dinitrophenylhydrazones of 2 mg L^{-1} of each carbonyl compounds. Experiment conditions, aqueous sample volume 4.5 mL, extracting solvent 500 μL and 2.5 g, 0.75 g and 3.2 g of ammonium sulphate used for extraction with acetonitrile, ethyl acetate and ethanol, respectively. The separated organic phase analyzed by HPLC. Peaks identification as in Fig. 1.

Table 1

[c] Six replicate analyses on 2 mg L^{-1} of carbonyl compounds.
[d] Limit of detection (S/N = 3).

tion of water–ethanol, water–acetonitrile and water–ethyl acetate mixtures containing 4.5 mL of water and 0.5 mL of water-miscible organic solvent, respectively 3.2, 2.5 and 0.75 g of ammonium sulphate were required to be added. The volume of organic solvent rich phase/water rich phase after separation were 0.6 mL/5.8 mL, 0.2 mL/5.2 mL and 0.4 mL/4.8 mL, respectively. In comparison to results obtained by direct injection of standards of equivalent concentration, the solvent extraction recovery of hydrazones ranged 92–99% when acetonitrile was used as solvent. A 1 mL aliquot of mixture containing 1 mg L^{-1} of each carbonyl compound was subjected to hydrazone formation, the total volume of reaction mixture being adjusted to 3.0, 3.5, 4.0 and 4.5 mL by addition of deionized water, cooled to room temperature and mixed respectively with 2.0, 1.5, 1.0 and 0.5 mL of acetonitrile and treated with 1.0–2.5 g of ammonium sulphate. Each experiment gave adequate phase separation. The recovered organic solvent, 1.8, 1.3, 0.8 and 0.2 mL, respectively, was analyzed by HPLC. As expected, smaller volume of organic solvent, 0.5 mL, led to higher preconcentration of analytes and better sensitivity (Fig. 3). An aliquot of 4.5 mL of sample containing 1 mg L^{-1} of each carbonyl compound was mixed with 500 μL of acetonitrile and 2.0–3.5 g of ammonium sulphate. The optimum recovery was obtained by 2.5 g of ammonium sulphate and remained practically unchanged with higher amounts (Fig. 4). The overall precision in extraction with 0.5 mL of acetonitrile was 1.5% (range 0.8–3.4%) when a test sample containing 1 mg L^{-1} of each carbonyl compound was analyzed by six separate derivatizations and extractions. Extracting solvent volume less than 0.5 mL was difficult to handle in the present method, and was not used. In subsequent experiments, acetonitrile as water-miscible organic solvent and ammonium sulphate as phase separating salt were used. Three standards containing each carbonyl compound at 50 μg L^{-1}, 1 mg L^{-1} and 10 mg L^{-1} were analyzed by the present method. The volume of sample was in range 5–50 mL, and of extracting solvent acetonitrile in range 0.5–5 mL. Ammonium sulphate required for separation of extracting phase was in range 2.5–14 g. The enrichment factor, as found relative to injection of standards without extraction, was in range 160–850. A 2 mL aliquot containing 1 mg L^{-1} of each carbonyl compound was diluted to 5–50 mL with deionized, derivatized and extracted as above. The extract obtained in each case was diluted to 0.5 mL with acetonitrile and analyzed by HPLC. Over the tested range of sample volume, the areas of carbonyl compounds were within 10% of the average value. The extraction time, range tested 5–20 min, did not have any effect on recovery. The recommended condition for analysis used 5 mL of sample, 0.5 mL of acetonitrile and 2.5 g of ammonium sulphate.

3.3. Calibration graph and detection limits

The dependence of the chromatographic signal on concentration of analytes was verified under optimum conditions of SALLME and LC-UV. The figures of merit in the analysis of diverse carbonyl compounds are summarized in Table 1. A linear dynamic range 7 μg–15 mg L^{-1} of analytes was obtained after derivatization to their 2,4-dinitrophenylhydrazones, overall the correlation coefficient, r^2, was 0.9975, relative standard deviation, 4.7%, and the limit of detection (S/N = 3), 1.69 μg L^{-1}.

Low molecular weight carbonyl compounds are volatile and require special attention in preparing their standard solutions. 2,4-Dinitrophenylhydrazones of carbonyl compounds, which are crystalline products, dissolved in methanol or acetonitrile, could be used as standards in the construction of calibration graph. Analysis of equimolar amounts of carbonyl compounds involving derivatization to hydrazones produced recoveries that ranged 94–102% with RSD in range 2–5% in comparison to when pre-prepared respective 2,4-dinitrophenylhydrazone was used.

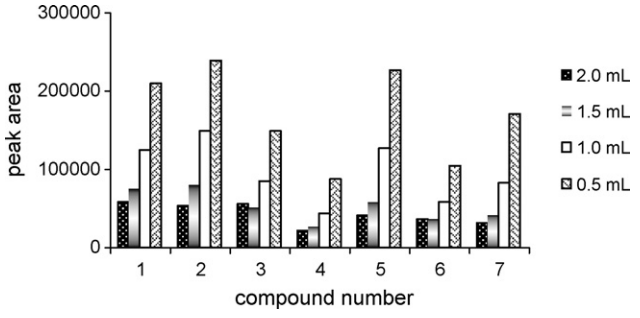

Fig. 3. Effect of volume of extracting organic solvent, 0.5–2.0 mL of acetonitrile, used in the SALLME of 2,4-dinitrophenylhydrazones of 1 mg L^{-1} of each carbonyl compound; sample volume 3.0–4.5 mL and ammonium sulphate 1.0–2.5 g. Peaks identification as in Fig. 1.

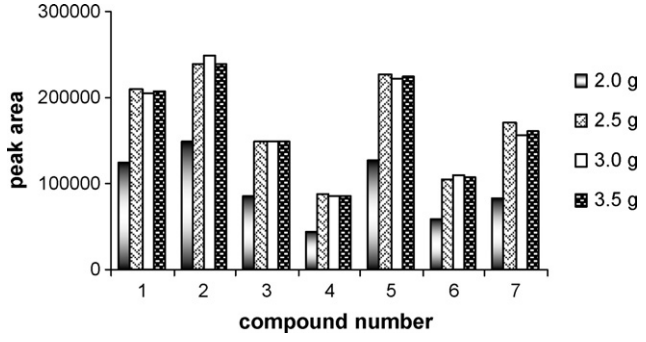

Fig. 4. Effect of amount of ammonium sulphate, 2.0–3.5 g, used in the SALLME of 2,4-dinitrophenylhydrazones of 1 mg L^{-1} of each carbonyl compound; aqueous sample volume 4.5 mL and extracting solvent acetonitrile 500 μL. Peaks identification as in Fig. 1.

Table 2
Recovery of carbonyl compounds spiked to river and tap water samples.

Compound	Recovery (%)					
	10 mg L^{-1} Narmada Water	Tap water	1 mg L^{-1} Narmada water	Tap water	30 μg L^{-1} Narmada water	Tap water
Formaldehyde	97.2	94.5	98.2	94.6	94.7	90.4

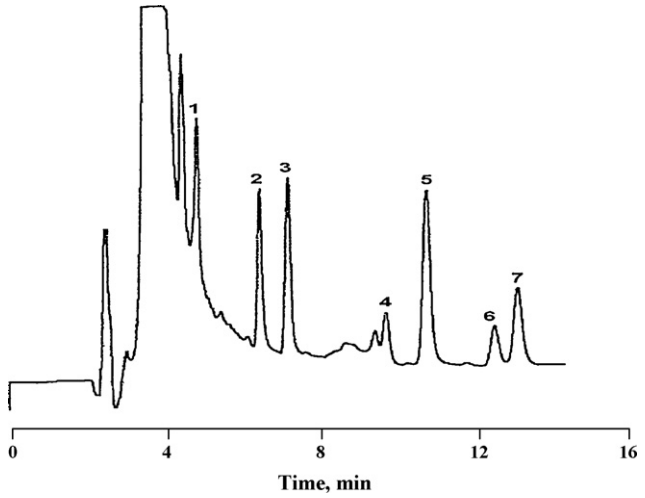

Fig. 5. Chromatogram for carbonyl compound spiked to the Narmada river water, Jabalpur, derivatization with DNPH and SALLME. Experiment conditions, sample volume 4.5 mL, 500 μL of extracting solvent acetonitrile and 2.5 g of ammonium sulphate. Peaks identification (as their 2,4-dinitrophenylhydrazones; concentration of carbonyl compound), 1 = formaldehyde (20 μg L^{-1}), 2 = furfural (10 μg L^{-1}), 3 = acetone (12 μg L^{-1}), 4 = ethylmethyl ketone (20 μg L^{-1}), 5 = benzaldehyde (40 μg L^{-1}), 6 = iso-propylmethyl ketone (60 μg L^{-1}), and 7 = cyclohexanone (30 μg L^{-1}). AFS, 0.04.

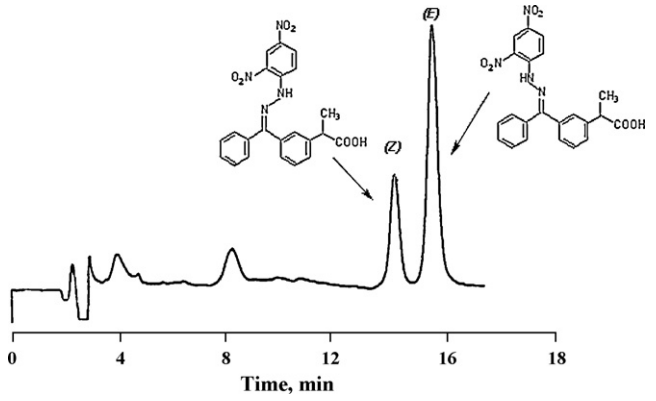

Fig. 6. Chromatogram of 0.5 mg L^{-1} of dexketoprofen, after derivatization to its 2,4-dinitrophenylhydrazone and SALLME. Experiment conditions, sample volume 4.5 mL, 500 μL of extracting solvent acetonitrile and 2.5 g of ammonium sulphate. AFS, 0.16.

4. Application to real samples

4.1. Environmental samples

The present method was validated by analyzing two water samples, viz., the Narmada river water, Jabalpur, and city tap water, Jabalpur, that were spiked with known amount of carbonyl compounds. Fig. 5 shows the chromatogram for Narmada river water spiked with 10–60 μg L^{-1} of carbonyl compound obtained after hydrazone formation, SALLME and HPLC. None of unspiked samples showed any peak for carbonyl compounds. Average recoveries of three replicate measurements on three concentration levels spiked to tap water and Narmada river water samples are given in Table 2. The results demonstrate that in samples matrices had practically no adverse effect on derivatization of carbonyl compounds and their SALLME.

4.2. Drug samples

Two pharmaceutical formulations were analyzed, dexketoprofen, a keto compound, in drug tablets and trace quantities of benzaldehyde in injectable formulations of Vitamin B-complex. Benzaldehyde is the oxidation product of widely used preservative and co-solvent benzyl alcohol in injectable formulations, and is toxic.

Dexketoprofen was determined under the recommended optimized conditions as its 2,4-dinitrophenylhydrazone. Though high level of drug in tablets does not require preconcentration, sample preparation was simplified by SALLME. The therapeutic dose of

Sample/pre-treatment method	Linear range	LOD (μg L^{-1})	Ref.
Water, drugs/SALLME of hydrazones with 500 μL of acetonitrile	0.007–15 mg L^{-1}	0.58–3.2	This work
Formaldehyde in presence of acetone/extraction with chloroform	1.5–40 mg L^{-1}	51	[48]
Air/collection on C_{18} cartridge loaded with DNPH	0.1–2 mg L^{-1}	0.08–0.1	[49]
Water/on-line C_{18} preconcentration column in HPLC	0–44 μg L^{-1}	0.13	[7]
Cigarette smoke/DNPH coated Cambridge filters	4–34 μg L^{-1}	0.027	[28]
Air, 2,4-dinitro-3,5,6-trideuterophenylhydrazine reagent/no pre-treatment	15 μg L^{-1}-?	3–12	[50]
Water/headspace in-drop derivatization and preconcentration	0.01–15 mg L^{-1}	1.7–24.1	[13]
Water/DNPH coated C_{18} cartridge in flow injection system	0.5–200 μg L^{-1}	0.1–1.0	[51]
Human saliva/polymer monolithic capillary microextraction	1.5–540 μg L^{-1}	0.43–1.4	[52]
Wine/no pre-treatment method	0.005–89.6 mg L^{-1}	1.3–7.5	[53]
Air/off-line DNPH coated C_{18} cartridge	0.05–10 mg L^{-1}	3	[54]
Fuel ethanol/no pre-treatment method	5–400 μg L^{-1}	1.7–2.0	[55]

The '?' refers to the upper limit in the linear range.

dexketoprofen is reported to be 1–5 μg mL^{-1} [47]. A linear dynamic range was obtained between the amount of dexketoprofen and peak area of hydrazone in the range 0.035–5.0 mg L^{-1}, the correlation coefficient was 0.9958 and the limit of detection was 15.5 μg L^{-1}. The average relative standard deviation for three concentration levels was found to be 6.4%. A standard chromatogram for hydrazone derivative of dexketoprofen is shown in Fig. 6, where cis (*Z*) and trans (*E*) isomers showed baseline separation.

For analysis of benzaldehyde in injectable formulation, appropriate known quantities of benzaldehyde was spiked to sample. Each spiked and unspiked samples were subjected to derivatization and extraction, and triplicate injections of each were made into the HPLC. Benzaldehyde found in a formulation was 8.5 μg L^{-1} with RSD of 3.2%.

5. Conclusions

In this study SALLME has been demonstrated as viable means of extracting trace level of carbonyl compounds in real samples after their conversion into 2,4-dinitrophenylhydrazones. SALLME integrates sampling, extraction and clean-up in a single step. Quick phase separation, rapid partition equilibrium, minimum amount and less toxicity of extracting solvent, and compatibility of extract with subsequent analysis by HPLC are advantages of SALLME. Furthermore, this method has benefit of its simplicity, high sensitivity, short preconcentration time and freedom from memory effects. A comparison of salient features of diverse HPLC methods [7,13,28,48–55] for the determination of carbonyl compounds as their 2,4-dinitrophenylhydrazones, as given in Table 3, suggests that SALLME is a simple sample preparation technique and can be used as an alternative to solid-phase extraction with DNPH loaded cartridge. In comparison to dispersive LLME [56], SALLME is more suitable for HPLC owing to the use of water-miscible extraction solvents.

ABSTRACT

An efficient colorimetric chemosensor with a thiourea binding site and 2-amino-6-nitrobenothiazole as a signaling unit has been synthesized by dithiocarbamate approach. The chemosensor has been utilized for selective recognition of fluoride and acetate anions in dry DMSO solution by UV–vis and ^{1}H NMR titration experiments. The chemosensor has shown naked-eye sensitivity for both the anions in solution.

1. Introduction

The selective recognition and sensing of anions via artificial organic chemosensor molecule/probe, containing a suitable receptor site, have attracted considerable attention for chemists in past decades [1]. Anions especially, fluoride and carboxylate play significant roles in chemical, environmental and biochemical processes [2–8], hence their recognition is important. The ionic recognition can be confirmed by different analytical methods like electrochemical methods – by variation in the redox potential, by change in chemical shifts in ^{1}H NMR signal or by change in fluorescence intensity signal – utilizing fluorescence spectroscopy [9]. The non-covalent ionic recognition generally, governs by the energy of the receptor–anion interaction, geometry, basicity of the employed anion and nature of the solvent systems. In fact, the strongest hydrogen-bond interactions are established with anions that contain the most electronegative atoms, such as, fluoride and carboxylate, and that display the most pronounced basic strength in a particular solvent. Recently, major impetus is given on strategies to develop colorimetric sensors for ionic species by utilizing binding site-signaling unit approach, in which an appropriate chromophore is attached to a specific anion receptor [10–18], to make sensitive recognition behaviors simple and convenient through naked-eye. The designing of such kind of chemosensor usually involves the covalent linking of a chromogenic fragment to a neutral receptor that should be capable in establishing selective interaction with the envisaged anion either by directional hydrogen bonding or by donation of one or more hydrogen of N–H fragment to the anions–deprotonation. In this sense several synthetic receptors (also referred as host) have been designed, to include, urea [19–23], thiourea [24–28], amides [29,30], macrocyclic ammonium/guanidinium [31], phenylhydrazone [32,33], indole [34], pyrrole [35–37] and phenol [38] units for interaction study with negatively charge ionic species (also referred as guest). The phenylhydrazone and indole type of receptors is neutral and the synthetic chemistry involved to synthesize these kinds of molecule is also simpler. Moreover, such kind of receptor molecule could recognize anions through color change, which is visible to naked-eye in aqueous medium.

In continuation of anion recognition by neutral receptors, urea and thiourea subunits, owing to their ability to act as hydrogen-bond donors have also been extensively utilized to produce chemosensors [39–41]. In fact, urea is capable for donating two hydrogen bonds to get an orientation complementary to Y-shaped oxoanions, parallel to carboxylates [42]. Further, by incorporating N–H unit into the chromogenic subunit, it is reasonable to have modification in the dipole and associated charge transfer transition in the influence of anions. Consequently, the ultimate negative charge being developed on the receptor will modulate UV–vis spectrum and thus, a prominent color change of medium that could be visible through naked-eye. To make chemosensor and recognition phenomenon more sensitive, presence of electron-withdrawing substituent on the chromophoric unit is useful. The presence of electron withdrawing group, like $-NO_2$, $-CF_3$, persuades for more acidity to the anion binding subunit—receptor site or more polarization in the N–H bond to facilitate more promising hydrogen-bond donating or interaction tendency, to support further an "incipient"

doi:10.1016/j.talanta.2009.07.020

and "frozen" proton-transfer phenomenon [43]. Although, both urea and thiourea-based neutral-receptor are efficient for bifurcate H-bond interaction with anions however, thiourea (pK_a = 21.1 in DMSO) specifically, due to more acidic nature generates stronger interaction with anions rather than urea (pK_a = 26.9) [44] and under typical circumstances both urea and thiourea-based receptor on interaction with very strong basic anions such as F^- increases the possibility of deprotonation at N–H fragment.

Keeping these perspective in mind, we have designed a new class of thiourea-based receptor **6**, [1-(naphthalen-2-yl)-3-(6-nitrobenzothiazol-2-yl)]-thiourea, to elucidate recognition for F^- and AcO^- anions through naked-eye visible color changes. The thiourea subunit, speculated to be a receptor-site and suitable to interact with the anions, has been appended in between naphthyl and 2-amino-6-nitrobenzothiazole units. The covalently linked benzothiazole moiety intends to act as a chromogenic signaling unit. The presence of electron withdrawing nitro substituent at benzothiazole moiety ensures low energy absorption bands for receptor as well as formation of anionic charged species due to more polarization at the N–H bond and hence associated prominent red-shift through extended conjugation in the system and consequent visible color change for naked-eye recognition.

2. Experimental

2.1. Reagents

All the anions in the form of tetrabutylammonium salts were purchased from Sigma–Aldrich Chemical Co. stored in a desiccator under vacuum containing self-indication silica, and used without further purification. Solvents like dimethylsulphoxide (DMSO) and tetrahydrofuran (THF) were purified prior to use. Spectroscopic grade solvents were used for titration studies. Commercial grade chemicals and solvents were used as such unless stated otherwise. Silica Gel G was used for thin layer chromatography (TLC).

2.2. Synthesis of

2.2.1. Isothiocyanates

1-Naphthylamine (0.28 g, 2 mmol) and triethylamine (0.9 ml, 6.2 mmol) were taken in anhydrous THF (5 ml) under nitrogen (N_2) atmosphere and cooled the reaction mixture on an ice-bath. To the well stirred cold reaction mixture, carbon disulfide (CS_2) (0.12 ml, 2 mmol) was added slowly (1 h). After complete addition reaction mixture was allowed to come at room temperature and stirred overnight and monitored (on TLC). ^{1}H NMR of an aliquot indicated incomplete conversion into the dithiocarbamate **2**. The reaction mixture was again cooled down and sodium hydride (0.048 g, 2 mmol) was added to the reaction and stirred for 1 h under atmosphere of N_2. CS_2 (0.12 ml, 0.2 mmol) was again added. The dithiocarbamate **2** was obtained in good yield after further stirring the reaction mixture at r.t. for 2–3 h as was evident on TLC with consumption of starting material.

Similarly, 2-amino-6-nitrobenzothiazole (0.39 g, 2 mmol) in *N*,*N*′-dimethylformamide (DMF) (4 ml) was reacted with CS_2 (0.12 ml, 2 mmol) in presence of sodium hydroxide (NaOH) (0.09 g, 2.2 mmol) under anhydrous condition. After completion of reaction (on TLC), chloroform ($CHCl_3$) was added to the reaction mixture. The orange color solid so obtained was filtered and washed again with $CHCl_3$ to get corresponding dithiocarbamate **5** in 97% yield.

The unpurified dithiocarbamic salts (**2** and **5**) were cooled on an ice-bath, tosyl chloride (0.42 g, 2.2 mmol) was added and reaction was allowed to warm at room temperature with continuous stirring for 1.5–2 h. 1N hydrochloric acid (HCl) (10 ml) was added to the reaction mixture and extracted with diethylether (4 times). The organic layer was pooled, kept over anhydrous sodium sulphate and concentrated in vacuum to obtain 1-naphthylisothiocyanate (**3**) as a brown color solid with in 65% yield (0.24 g, 1.3 mmol), m.p. 55 °C. The IR spectra have shown a strong band in 2095 cm^{-1} region corresponding to the cumulated double bond of isothiocyanate.

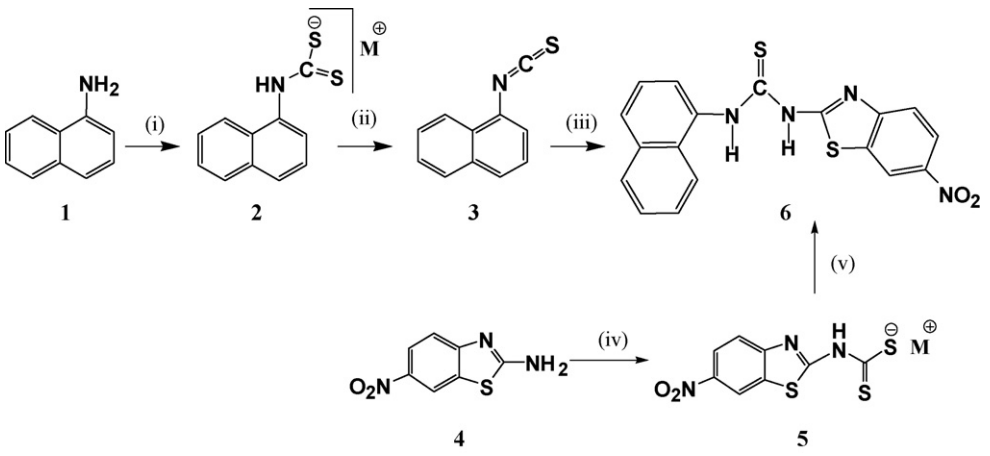
2.2.2. Synthesis of receptor [1-(naphthalen-2-yl)-3-(6-nitrobenzothiazol-2-yl)]thiourea **6**

2.2.2.1. Method 1. 2-Amino-6-nitrobenzothiozole (0.156 g, 0.8 mmol) and sodium hydride (NaH) (0.019 g, 0.8 mmol) in THF (3 ml) were stirred at room temperature for 2 h. 1-Naphthylisothiocyanate (0.148 g, 0.8 mmol), dissolved in THF (5 ml) was added drop-wise (0.5 h) and then refluxed the reaction mixture for 2–3 h. After completion of reaction (on TLC), reaction mixture was concentrated in vacuum to get orange color solid. The crude product was washed with water (10 ml, 4 times) and dried under vacuum to afford the pure thiourea compound in 55% yield (0.167 g, 0.44 mmol).

2.2.2.2. Method 2. Dithiocarbamate **5** (0.293 g, 1 mmol) and 1-naphthylamine (0.143 g, 1 mmol) were dissolved in DMF (3 ml) and stirred for 2 h at 60 °C. After completion of reaction (on TLC) excess amount of water was added to the reaction mixture, filtered and dried to get same compound in 65% yield (0.247 g, 0.65 mmol).

M.p. 137–140 °C. R_f 0.65 (EtOAc:hexane:: 4:6, v/v); IR (ν_{max}, KBr, cm^{-1}): 3325, 3166, 3056, 1568, 1511, 1445, 1329, 1228, 778; ^{1}H NMR (DMSO-d_6) δ (ppm): 10.40 (Br, 1H, NH), 9.72 (br, 1H, NH), 8.64 (s, 1H, benzothiazole), 8.01–7.98 (d, 1H, J = 8.1 Hz, benzothiazole), 7.96–7.93 (d, 1H, J = 7.8 Hz, naphthyl), 7.93 (t, 1H, J = 7.5 and 8.1 Hz, naphthyl), 7.79–7.76 (d, 1H, J = 7.5 Hz, naphthyl), 7.66–7.63 (d, 1H, J = 8.1 Hz, benzothiazole), 7.59–7.44 (m, 3H, naphthyl), 7.41–7.39 (d, 1H, J = 8.1 Hz); ^{13}C NMR ($CDCl_3$, 75.45 MHz.) δ (ppm): 156.2, 153.9, 142.7, 134.4, 131.8, 128.6, 127.3, 127.1, 126.7, 125.8, 125.6, 125.5, 122.1, 121.8, 121.6, 118.6, 117.3; Anal. Calc. for $C_{18}H_{12}N_4O_2S_2$; C, 56.83; H, 3.18; N, 14.73%. Found: C, 56.35; H, 3.41, N, 14.84%.

2.3. General methods



All the experiments were carried out at room temperature. The UV–vis spectra were recorded on a Shimadzu 1700 spectrophotometer using a quartz cuvette (path length = 1 cm). Infrared (IR) spectra in potassium bromide (KBr) were recorded on a Varian-3100 FTIR spectrophotometer. ^{1}H NMR spectra (chemical shifts in δ ppm) were recorded on a JEOL AL 300 FT-NMR (300 MHz) spectrometer, using tetramethylsilane (TMS) as internal standard. Elemental analysis was carried out on CE-440 CHN Analyser (Exeter Analytical Inc.). Melting points were recorded by open glass capillary method and are uncorrected.

2.4. Absorption titration studies

The binding stability of receptor or chemosensor for acetate and halide anions (as tetrabutylammonium salts) was investigated by UV–vis absorption spectroscopy in DMSO solution keeping a constant host concentration (2×10^{-5} mol l^{-1}) and increasing concentrations of anions by stepwise addition of different equivalents (10 μl for 1 equiv. of 6×10^{-3} M solution).

2.5. ^{1}H NMR titrations

Chemosensor **6** (1.02×10^{-2} mol l^{-1} in DMSo-d_6) was titrated with acetate and fluoride anions (as tetrabutylammonium salts) by addition of increasing equivalents of anion in DMSO-d_6.

Scheme 1. Synthesis of receptor molecule **6**. (i) CS_2/NaH/THF; (ii) TsCl/2h; (iii) **4**, NaH/THF/60 °C/2h; (iv) CS_2/NaOH/DMF; (v) **1**, DMF/60 °C/2h.

3. Results and discussion

The synthesis (Scheme 1) of receptor molecule was carried out by generating dithiocarbamic acid salt of 1-naphthylamine and 2-amino-6-nitrobenzothiazole in the presence of strong base followed by slow addition of carbon disulphide (2 h) under anhydrous condition for 2–3 h. To generate isothiocyanate active group, tosyl chloride (TsCl) was added to the well stirred suspension of derived unpurified salt under colder condition and then continued the stirring for further 0.5–1 h at room temperature. Naphthyl-1-isothiocyante **3** was isolated in 65% yield. The IR spectra have shown a strong band at 2095 cm^{-1} region corresponding to the cumulated double bond of isothiocyanate functional group. However, in case of 2-amino-6-nitrobenzothiazole **5** we were not able to convert dithiocarbamic acid salt to isothiocyanate derivative in good yield. Receptor **6**, was obtained by refluxing either dithiocarbamic acid salt, **5** with 1-naphthylamine or by refluxing 1-naphthyl isothiocyanate, **3** with 2-amino-6-nitrobenzothiazole in presence of sodium hydride in good yield.

3.1. UV–vis experiments

The anion binding affinity of present thiourea-base receptor was determined by UV–vis absorption spectra in the absence and presence of different anions such as Br^-, Cl^-, F^-, I^-, SCN^-, AcO^- (as tetrabutylammonium salts). The experiment was performed by preparing 2×10^{-5} mol l^{-1} solution of receptor in dimethylsulphoxide (DMSO) solution followed by addition of particular tetrabutylammonium anionic salts separately. In the absence of anions, the spectrum of chemosensor **6** showed two characteristic absorption peaks λ_{max} at 392 nm (ε = 26,100 mol^{-1} l cm^{-1}) and 325 nm. The low energy band (392 nm) was expected to intramolecular charge transfer (ICT) transition while the second high energy peak at 325 nm corresponds to $\pi \rightarrow \pi^*$ electronic transitions. Upon the addition of AcO^- or F^- to **6**, a prominent change was observed in UV–vis absorption spectra due to complexation between host–guest molecules. The ICT band at 392 nm as shown in Fig. 1, disappeared with the formation of a new peak in yellow region of spectra at 457 nm. The electronic excitation with considerable red-shift of 65 nm is attributed to the charge transfer from receptor site to acceptor substituent ($-NO_2$) of chromophoric moiety. On addition of other anionic species as their tetrabutylammonium salts no significant modulation in the UV–vis absorption spectra was observed thus, showing the specificity of the chemosensor for selective binding interaction with AcO^- and F^- anions.

In order to estimate the specific concentration for selective anions and its associated colorimetric changes, chemosensor **6** was titrated by successive increment of number of equivalents for acetate and fluoride ion separately and monitored the UV–vis absorption spectra. From UV–vis titration spectra (Fig. 2) it can be seen that as the number of equivalents of AcO^-, as $[Bu_4N]AcO$ salt increases, the absorption bands, appeared at 392 and 325 nm wavelengths gradually reduced and new bands appeared at 457 and 330 nm with concomitant development of two isosbestic points at 424 and 347 nm wavelengths. The formation of isosbestic points shows the presence of two ionic species in the medium. In titration experiment the observed change at high energy band, 325 nm was less peculiar with a small red-shift of 5 nm. This is attributed to intramolecular charge transfer (ICT) towards electron deficient $-NO_2$ group of benzothiazole moiety from anionic –NH fragment of receptor in the influence of AcO^- anion. Further, from Fig. 2 it is also evident that on addition of 5.5 equiv. of AcO^- anion, a saturation point reached with a marked visible color change of the sensor solution from light yellow-green to red. To know the stoichiometry between the guest (AcO^-) and host (receptor) molecule in DMSO solution Job's plot (Fig. 2, inset) has been drawn that shows the maxima at 0.5 molar fraction, for 1:1 stoichiometry between the two interacting species for which association constant (K_{ass}), determined by non-linear fitting of spectroscopic titration curve [45] was found $K_{ass} = 5.27 \pm 0.45$ log unit.

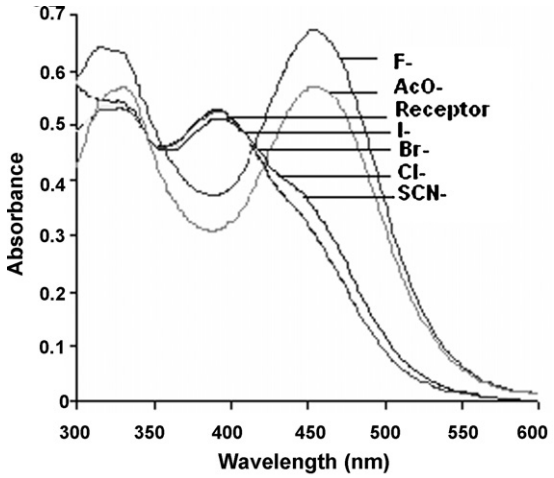


Fig. 1. Change in UV–vis spectra for the receptor **6** (2×10^{-5} mol l^{-1}) in DMSO solution with addition of different anions as their tetrabutylammonium salt.

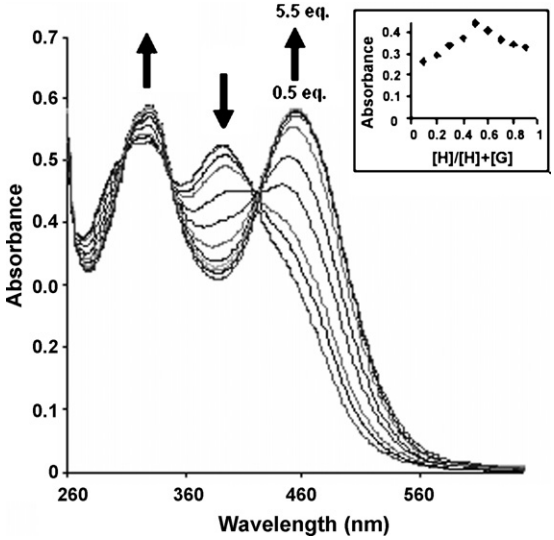

Fig. 2. Change in UV–vis spectra for the receptor **6** (2×10^{-5} mol l^{-1}) in DMSO solution with sequential addition of [Bu_4N]AcO from 0 to 5.5 equiv. Inset: Job's plot for receptor 1 with AcO^-.

Similarly, spectrophotometric behavior of receptor molecule with fluoride was monitored by titrating solution of chemosensor **6** with [Bu_4N]F. The change in spectral pattern (Fig. 3) was almost same as observed in case of AcO^- anion. The only difference being that the change in absorption bands appeared at 392 and 325 nm wavelengths gets modulated to new bands at 457 and 330 nm, rapidly with concomitant development of prominent isosbestic points at 424 and 347 nm wavelengths, respectively. The new lower energy band at 457 nm, representing the deprotonated form of chemosensor, reaches to a saturation point on addition of 2 equiv. of F^- anion. The isosbestic points observed with F^- was more prominent than AcO^- anion on addition of less number of equiv. of anions along with higher absorption intensity. This shows the presence of two ionic species in the medium with pronounce affinity for F^- compare to AcO^- anion, as is evident from Job's plot (Fig. 3, inset) and association constant determined to have $K_{ass} = 6.73 \pm 0.33$ log unit value.

The above discussed results indicate the occurrence of equilibrium between the host and guest molecule in which a proton is abstracted from one of the N–H fragments of the thiourea-based chemosensor and bridges two fluoride ions, to result the

3.2. ^1H NMR titrations

On the basis of spectrophotometric investigations it is difficult to predict whether the prominent changes involve formation of complex between host and guest through hydrogen bonding or deprotonation of host by sufficient basic strength of guest molecules. To affirm the real phenomenon we have carried out ^1H NMR titration experiment with receptor molecule in DMSO-d_6 ($c = 1.05 \times 10^{-2}$ mol l^{-1}) by stepwise addition of equivalents of AcO^- and F^- as their [Bu_4N]AcO and [Bu_4N]F salts. The ^1H NMR spectrum of chemosensor **6**, shows two characteristic broaden peaks at 10.40 and 9.72 ppm corresponding to thiourea fragment protons designated as NH1 and NH2 protons. The assigned positions of respective protons have been demonstrated in the model picture for receptor molecule (Fig. 4). On addition of 0.5 equiv. of AcO^- both singlet signals for N–H protons are shifted towards downfield with broadening in signals (Figs. 5 and 6). On addition of 0.5 equiv. of AcO^- the signal for N-H2 proton shifted downfield from 9.72 to 9.73 ppm which on further successive addition of AcO^- significantly shifted towards more downfield (10.1 ppm) region. Additionally, at 2.5 equiv. of acetate ion, N-H1 proton attached to benzothiazole moiety disappeared. The H1 (8.64 ppm) and H2 (8.01 ppm, $J = 8.1$ Hz) peaks of benzothiazole moiety appeared as singlet and doublet, respectively, are due to an increase as well as decrease in electron density on benzothiazole and naphthyl units, respectively. The H1 proton shifted towards upfield while the H2 proton towards the downfield with broadening at 4.0 equiv. of AcO^- ion. This attributes the shielding and de-shielding electronic environments by through-bond propagation mechanism on respective protons. The H3 proton of benzothiazole moiety appeared at 7.66–7.63 ppm ($J = 8.1$ Hz) as a doublet and Hm proton of naphthyl unit appeared at 7.93 ppm as a triplet ($J = 9.3$ Hz, $J = 8.1$ Hz), remain unaffected after addition of AcO^-. The two characteristic peaks of H′ and H2 protons initially, were partially overlapped, and by the addition of AcO^- anion (1.5 equiv.) gets separated to appear at 7.96 ppm ($J = 7.8$ Hz) as a doublet. All the signals corresponding to aromatic protons get broadened and shifted toward downfield could be due to the deshielding affect caused by a polarization of C–H bonds or induced by through-space effect on interaction with AcO^- ion. The second triplet for Hp′ proton at 7.81–7.76 ppm of naphthyl unit on addition of salt reappears as doublet at 7.79–7.76 ppm ($J = 7.5$ Hz) and finally merged with other aromatic protons of naphthyl unit at 4 equiv. of AcO^-. A multiplet resonance signal for Hm′, Hp and Ho′ protons was appeared at 7.59–7.47 ppm along with merged Ho proton signal at 7.4 ppm. The Ho proton reappeared as a doublet

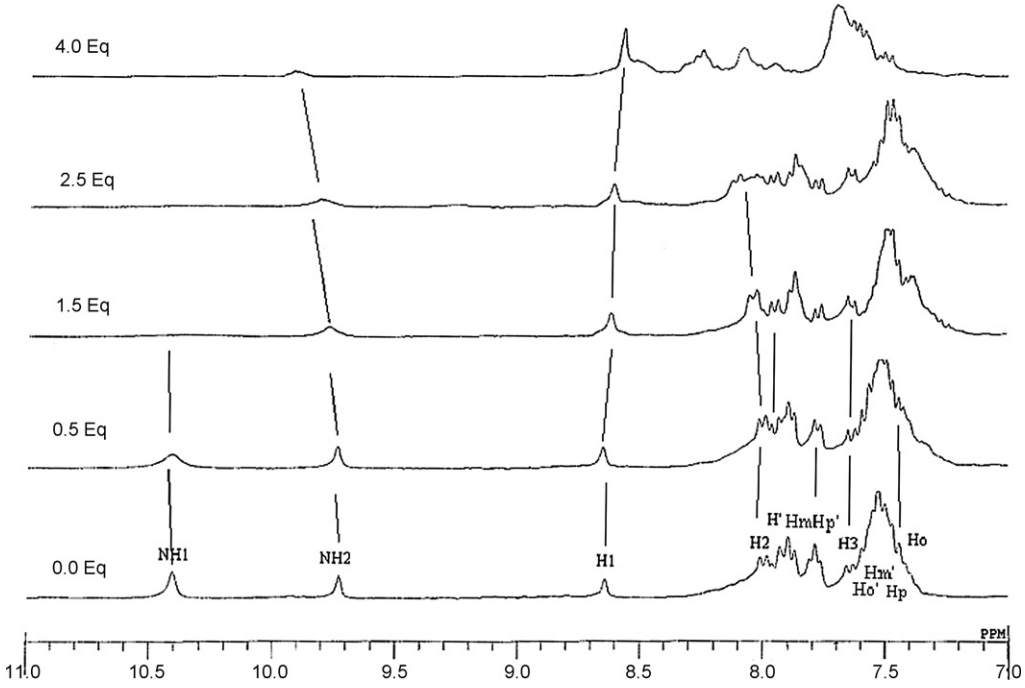

Fig. 5. Changes in ^{1}H NMR titration spectra for chemosensor **6** (1.05×10^{-2} M) in DMSO-d_6 solution with gradual addition of equiv. of [Bu_4N]AcO.

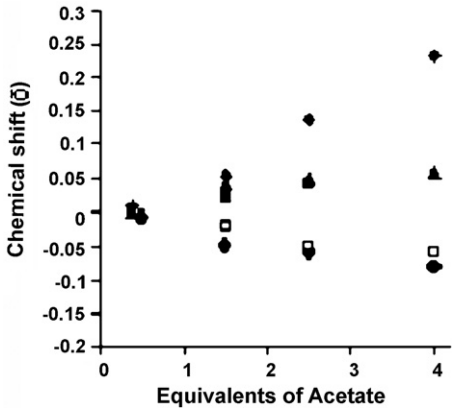
by the addition of 0.5 equiv. of AcO^- and initially shifted upfield at 7.38 ppm and disappeared after the addition of 2.5 equiv. of AcO^-.

These results clearly indicate that chemical shifts are varying in narrow range with pronounced broadening and all the aromatic protons close to anionic receptor site are moving towards the upfield via a through-bond propagation mechanism. Such features can be deduced for complexation between guest and host through H-bond formation as indicated in Scheme 2. The peculiar broadening in resonance signal obtained as a result of complex formation is due to restricted relative rotation of naphthyl and benzothiazole rings. Since, in ^{1}H NMR most of the broadening occurs in the benzothiazole ring's proton hence, is more closure to the nitrogen atoms of thiourea fragment and in turn closure to H-bound acetate. However, whatever the case, on H-bond complexation between chemosensor and AcO^-, the electron density is transferred more on the receptor site, causing more shielding effect and hence accounting the distinct chemical shifts in the proton signals. Moreover, as speculated, with the transfer of more electron on receptor site, modulation in dipole moment occurs in such a fashion that the extent of optical transition becomes equivalent to the state of deprotonation and we observed the respective changes in ^{1}H NMR titration spectra. On the other hand, by considering H-bonding interaction as an incipient proton transfer from donor to acceptor, these results are supporting the proton transfer from an early transition state with strongly basic AcO^-, and hence the electronic properties of receptor molecule in complexation state become close to those of deprotonation form. These facts has been observed in Fig. 3 (inset) that on addition of 2.5 equiv. of AcO^- there is case of H-bond complexation between the receptor and anion which on further addition of AcO^- disappeared showing the deprotonation state (Scheme 2).

Similarly, significant variations in chemical shifts were observed on performing ^{1}H NMR titration experiment in case of fluoride-induced deprotonation of chemosensor, **6** (Figs. 7 and 8). The



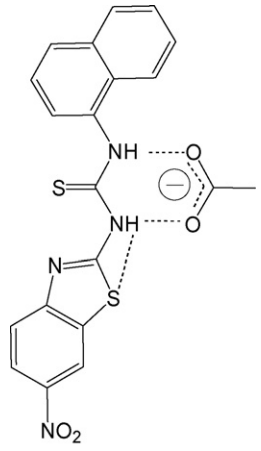


Fig. 6. Changes in chemical shifts in ^{1}H NMR titration with equiv. of [Bu_4N]AcO (diamond, NH2; square, NH1; triangle, H2; circle, H1 and hollow square, Ho).

Scheme 2. Proposed deprotonation mechanism for thiourea-based chemosensor, **6** with AcO^- ion.

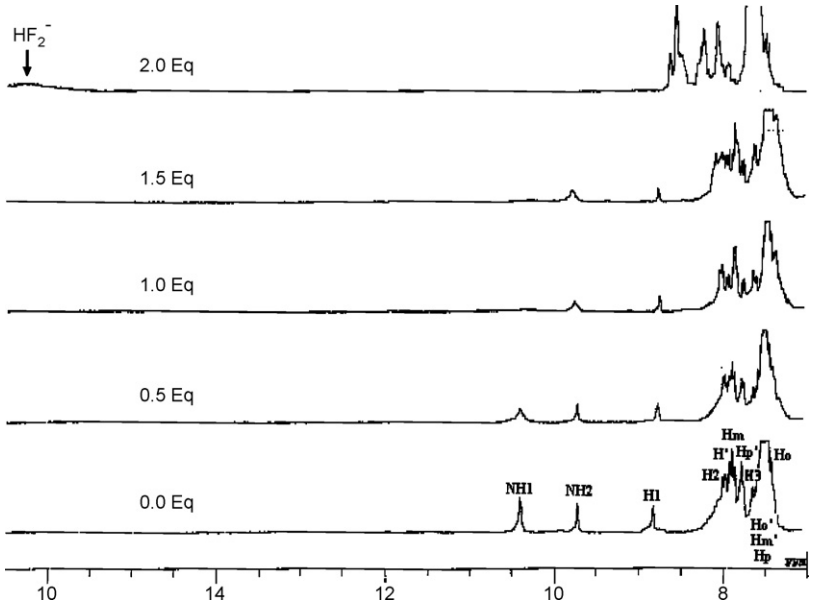

Fig. 7. Changes in ^{1}H NMR titration spectra for chemosensor **6** (1.05×10^{-2} M) in DMSO-d_6 solution with gradual addition of equiv. of [Bu_4N]F.

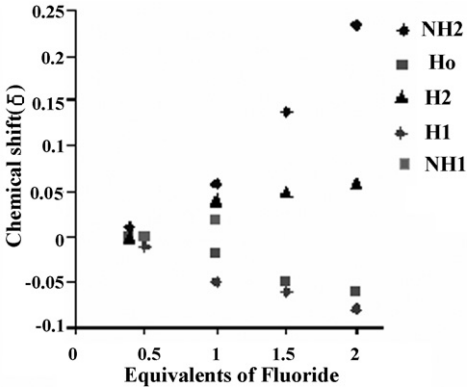
spectral pattern obtained over the course of titration in DMSO-d_6 solution of receptor **6** with [Bu_4N]F was very much similar to that of AcO^-. The difference being that the chemical shifts corresponding to NH1 (10.40 ppm) and NH2 (9.72 ppm) protons get affected by addition of less equivalents of F^- anion. The association constant, was determined from UV–vis titration spectra, of 6.73 ± 0.33 log unit value and frequent chemical shifts corroborate greater affinity of chemosensor for F^-, compare to AcO^-. In case of fluoride the NH1 proton of receptor **6** on addition of 1 equiv. of F^- disappeared while the resonance signal for NH2 proton become broaden and shifted toward lowfield due to more shielded electronic environment effect. On successive addition of 1.5 equiv. of F^- NH2 proton further shifted toward downfield and disappeared on addition of 2 equiv. F^-. Thus, the initial broadening in the ^{1}H NMR signal of the amino peaks of the receptor molecule attributes interaction between guest and host molecules through the hydrogen bonding which on increasing the amount of F^- (1 equiv.) deprotonated first, more acidic proton (N-H1), close to the benzothiazole unit, thereby generating HL^- species in the reaction medium. On addition of more amount of F^- broadening in the N-H2 proton signal of receptor occured and at 2.0 equiv. of F^-, resonance signal corresponding to N-H2 proton almost become flattened or disappeared.



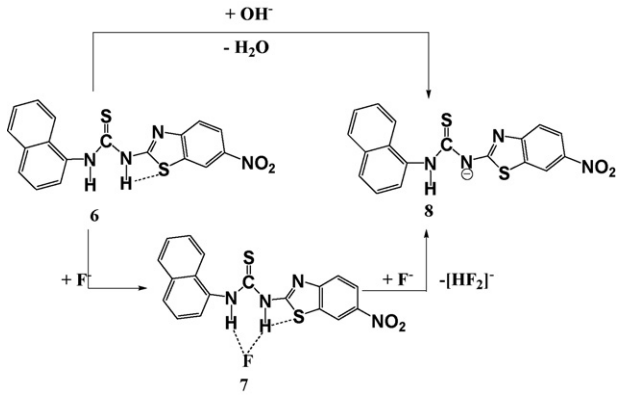


Fig. 8. Changes in chemical shifts in ^{1}H NMR titration with equiv. of [Bu_4N]F; (diamond, NH2; square, NH1; triangle, H2; circle, H1 and hollow square, Ho).

Scheme 3. Proposed deprotonation mechanism for thiourea-based chemosensor, **6** with F^- ion.

This indicates that the receptor molecule is in deprotonated dianionic (L^{2-}) state (Scheme 3). The resonance signal for formation of HF_2^- complex has been started after the addition of 1.5 equiv. of F^- and appeared prominently at 16.32 ppm chemical shift after addition of 2.0 equiv. of F^- and subsequent color change of chemosensor solution, that was visible to naked-eye from light yellow-green to red (Fig. 9).

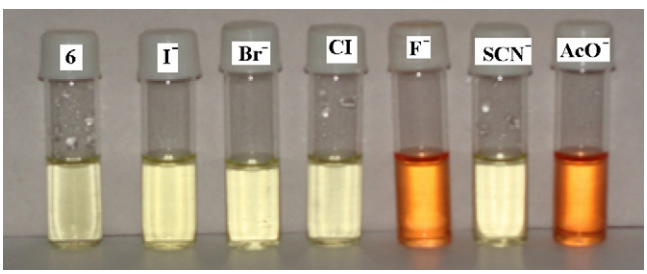

Fig. 9. Color changes of chemosensor **6**, in DMSO solution (2×10^{-5} M) after addition of 5 equiv. of different anions.

4. Conclusion

To sum up, a new colorimetric chemosensor has been synthesized via dithiocarbamate synthetic strategy and by keeping in mind binding site-signaling unit approach in which an appropriate chromophore was attached to a specific anion receptor to make sensitive recognition behaviors simple and convenient through naked-eye. The sensor has demonstrated successfully, recognition for fluoride and acetate and expected to have other opportunities for detection of anions.

ABSTRACT

Nickel hexacyanoferrate film modified gold electrode was prepared by a simple chemical deposition procedure from a fresh prepared solution containing ferricyanide, Ni^{2+}, and sodium nitrate. The resultant films have solo composition and are significantly stable as compared to the electrochemically deposited NiHCF films. For different concentrations of Na^+ in the solution, the formal potential values of NiHCF shift according to the Nernstian behavior with a slope of 48 mV in the range of 10^{-4} to 1.0 M. The NiHCF film was also used for the electrocatalytic oxidation of ascorbic acid. The anodic peak current observed in cyclic voltammetry increased with the ascorbic acid concentration. At a fixed potential under hydrodynamic conditions, the calibration plot was linear over the ascorbic acid concentration range 0.1–12 mM.

1. Introduction

Prussian blue (PB) and its related transition metal hexacyanoferrates (MHCFs), an important class of inorganic polymeric compounds, recently have attracted intense interests because of their attractive properties such as electrocatalysis, electrochromicity, ion sensing and magnetism [1–7]. Moreover, metal hexacyanoferrates have been widely studied as environmentally benign ion exchangers for the selective removal of radioactive ^{137}Cs from nuclear waste solutions containing high concentration of alkali metals because of their zeolitic structure and strong affinity for Cs^+ [8,9].

Nickel hexacyanoferrate (NiHCF) is an important analogue of PB. Among the cyanometallate systems, NiHCF can be considered as a material for certain fundamental and applied studies since NiHCF films show well-defined and reproducible voltammetric responses not only in K^+ containing electrolytes, but also in other alkali metal cations such as Li^+, Na^+, Rb^+ or Cs^+. Unlike Prussian blue and many of its metal-substituted analogues, both the oxidized and reduced forms of NiHCF seem to be fairly open and allow an easy transport of alkali metal cations of different sizes while providing charge balance during the redox processes [10–12].

Although the electrochemical behaviors of MHCFs might be similar, it is still necessary to investigate such kinds of electroactive materials, since under different conditions the formation of MHCFs on electrode surface as well as the electrochemical behaviors may be different. NiHCF films can be easily formed on many conductive substrates by electrodeposited through potential cycling [10,11]. However, NiHCF films formed by potential cycling contain two different composites [11,13]. It is important to note that, for an ideal sensor or separation matrix, one would design the processing conditions that produce the NiHCF with predominantly one type of intercalation site or the other, rather than a mixture of both [14]. In this paper, we propose a novel method for the fabrication of NiHCF films on electrode substrates. The NiHCF was deposited by immersing conductive substrate in a fresh prepared solution containing ferricyanide, Ni^{2+}, and sodium nitrate. This approach is simple and effective for establishing electroactive NiHCF interface. The resultant NiHCF has solo composition and is significantly stable as compared to the electrochemically deposited NiHCF films. Compared with the electrochemical method, the present approach can modify many electrodes at the same time by just immersing them in the reaction solution. To verify the applicability of the proposed NiHCF interface, two important properties and potential applications of metal hexacyanoferrate, ion sensing and electrocatalysis, were then studied. Based on the established voltammetry and amperometry, sodium ion in blood and ascorbic acid in pharmaceuticals were successfully determined, respectively.

2. Experimental

2.1. Electrode fabrication

NiHCF films were deposited on polished gold electrodes. Before deposition, the electrode surfaces were electrochemically cleaned in the potential region for oxygen and hydrogen evolution in 0.5 M H_2SO_4 by cyclic voltammetry. In chemical deposition, the gold electrodes were immersed in a freshly mixed solution of 1 mM $K_3Fe(CN)_6$, 1 mM $NiSO_4$ and 0.5 M $NaNO_3$ for 30 min. Then, the NiHCF-modified electrode was rinsed thoroughly by distilled water. The electrochemically deposited NiHCF films were fabricated in the same solution by cycling the potential from 0 to 850 mV for 20 cycles.

2.2. Electrochemistry

Cyclic voltammograms of the NiHCF modified electrodes were performed with a CHI model 1140 analyzer. A platinum wire was used as the counter electrode and all reported potentials are referenced to an Ag/AgCl reference electrode.

2.3. Sodium sensing

The formal potential of NiHCF modified electrode was measured by cyclic voltammetry at a scan rate of 1 mV/s. Serum and plasma from healthy volunteers were determined without any pretreatment.

2.4. Ascorbic acid detection

Quantitative determination of ascorbic acid was carried out amperometrically in a stirred PBS solution (pH 7.0, containing 1.0 M $NaNO_3$). The potential of the electrode was kept constant at +0.40 V, which corresponds to the peak potential for oxidation. The response was recorded by adding a series of standards of the analyte to the measuring solution.

3. Results and discussion

3.1. Electrochemical characterization

As an analogue of Prussian blue, NiHCF also contains electrochemically reversible iron centers that switch between the ferrous reducing and the ferric oxidizing states depending on applied potential. To maintain charge neutrality, reversible intercalation and deintercalation of charge-compensating alkali cations take place in the NiHCF electrochemical redox reaction. Fig. 1 indicates the voltammetric response of NiHCF films fabricated by chemically or electrochemically deposited in a 1.0 M KNO_3 or $NaNO_3$ aqueous solution. The observation of reproducible and well-behaved cyclic voltammetric peaks provides evidence for the attachment of the NiHCF film on the electrode surfaces. Since the Ni^{2+} cations in the modifying film are not expected to be electroactive in the potential range examined, the redox peaks present a single electron process of hexacyanoferrate (III/II) in the film. Positive currents correspond to the oxidation of NiHCF with the release of alkali cations from the matrix and negative currents denote the reduction with the uptake of alkali cations. The cyclic voltammograms show that the redox processes of both the electrodes are electrochemically reversible and the cations loading and unloading can be controlled by modulating the potential. However, it is noteworthy that different preparation procedures of the electrodes lead to different CV shapes. In electrolytes containing sodium or potassium, particularly in the presence of K^+ ions, voltammetric peaks of the electrodeposited NiHCF tend to undergo splitting, implying the coexistence of two stable forms of NiHCF and two overlapping redox reactions [11]. Fig. 1A, curve b shows the cyclic voltammogram of the electrodeposited NiHCF film modified Au electrode in a solution of 1.0 M KNO_3 at a scan rate of 25 mV/s. There are two pairs of well-defined redox peaks, namely redox couple I and redox couple II, appearing in the curve. The anodic (E_{pa}) and cathodic (E_{pc}) peak potentials are +492 and +482 mV, respectively, and the formal potential $E^{0'}$, which was defined as the mid-point potential of the anodic and cathodic peak potentials, is +487 mV for the redox couple I. The separation of the anodic and cathodic peak potentials, ΔE_p, is 10 mV. For the redox couple II, the values of E_{pa}, E_{pc}, $E^{0'}$ and ΔE_p are +618, +612, +615 and 6 mV, respectively. The respective redox reactions can be represented by Eqs (1) and (2) [11,13].

$$ANi[Fe^{III}(CN)_6] + A^+ + e^- = A_2Ni[Fe^{II}(CN)_6] \quad (1)$$

$$Ni_{1.5}[Fe^{III}(CN)_6] + A^+ + e^- = ANi_{1.5}[Fe^{II}(CN)_6] \quad (2)$$

where A is the intercalated alkaline cation, and A^+ is the corresponding alkaline cation in solution.

As compared to the electrodeposited hybrid NiHCF, the chemically deposited NiHCF films have the solo formation, which shows only one pair of redox peaks in potassium electrolytes (Fig. 1B).

Fig. 2A shows that the chemically deposited NiHCF on gold electrode has a chemically reversible redox couple in a 1.0 M $NaNO_3$ solution when cyclic voltammetry is performed at various scan rates over a range of 5–500 mV/s. It is observed that as the scan rate increases the peak current as well as the peak-to-peak separation increase. The peak-to-peak separation, ΔE_p, varies from 5 to 30 mV upon varying the scan rate from 5 to 500 mV/s. Fig. 2B shows the plot of I_p vs. scan rate. Both the anodic and cathodic peak currents are directly proportional to the scan rate up to 500 mV/s. The ratio of the anodic to cathodic peak current, I_{pa}/I_{pc}, is almost equal to unity. This behavior is as expected for diffusionless, surface-confined redox

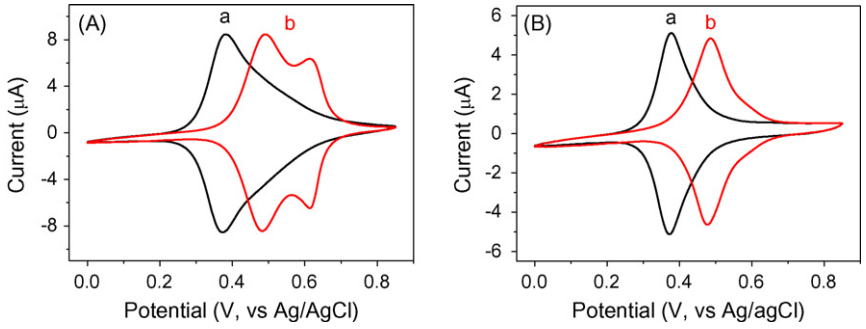

Fig. 1. Cyclic voltammograms of (A) an electrodeposited NiHCF film and (B) a chemically deposited NiHCF film on Au electrode in a 1.0 M (a) $NaNO_3$ and (b) KNO_3 solution at a scan rate of 25 mV/s.

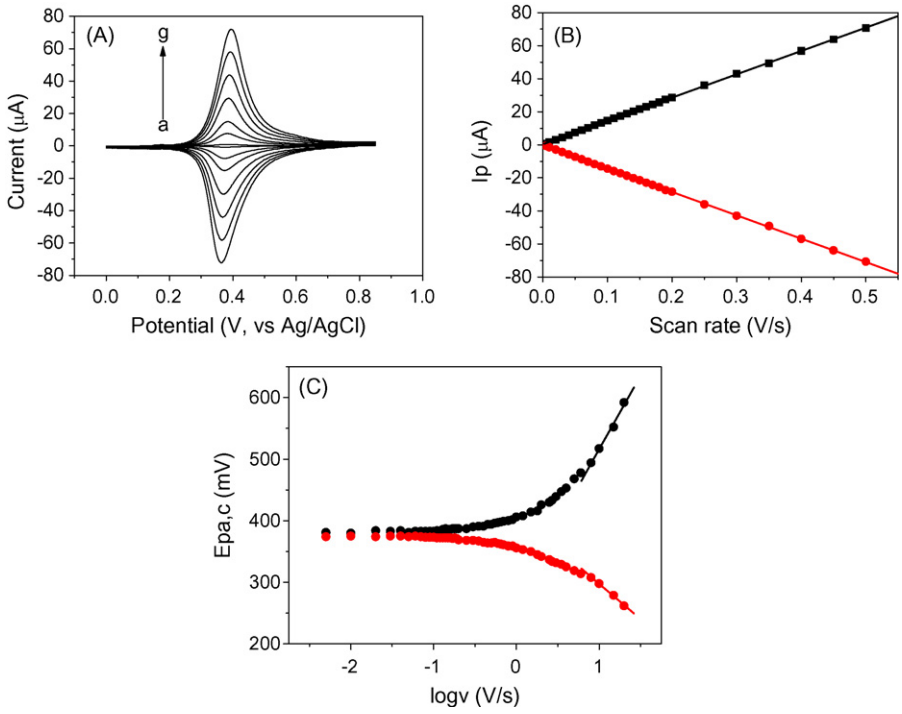

Fig. 2. (A) Cyclic voltammograms of the chemically deposited NiHCF on gold electrode in 1.0 M $NaNO_3$ at different scan rates: (a)–(g) 5, 50, 100, 200, 300, 400, 500 mV/s. (B) Plot of the anodic and cathodic peak currents vs. scan rate. (C) Plot of anodic and cathodic peak potentials as function of log ν.

systems. The peak current and scan rate are related as

$$I_p = \frac{n^2F^2\nu AG_0}{4RT} \quad (3)$$

where G_0, ν, A and I_p represent the surface coverage concentration, the scan rate, the electrode area, and the peak current, respectively. This result indicates that the redox process is confined to the surface of the NiHCF/Au electrode, confirming the immobilized state of the NiHCF.

As shown in Fig. 2C, the peak separation begins to increase at higher scan rates, indicating the limitation arising from charge transfer kinetics. The anodic and cathodic peak potentials are proportional to the logarithm of the scan rate for $\nu > 8000$ mV/s. Based on the Laviron theory [15], the electron transfer rate constant (k_s) as well as the transfer coefficient (α) can be calculated. For the anodic and cathodic peaks, the slope of E_p (E_{pa} and E_{pc}) vs. log ν is 239.3 and −114.6, respectively. The calculated value of α is 0.68. According to the following equation:

$$\log k_s = \alpha\log(1-\alpha)+(1-\alpha)\log\alpha-\log\left(\frac{RT}{nF\nu}\right)-\frac{\alpha(1-\alpha)nF\Delta E_p}{2.3RT} \quad (4)$$

From this Eq. (4), the electron transfer rate constant (k_s) was also calculated to be 19.3 s^{-1}.

3.2. Morphological characterization

Fig. 3 shows the morphology of the NiHCF fabricated by chemical and electrochemical methods on gold-CD electrode. In the case of electrochemical deposition, the resultant NiHCF film consists of irregular nanoparticles, which are equally distributed over the whole surface (Fig. 3A). In contrast, NiHCF nucleated sparsely on the gold substrate and quasi cubic structures formed in the chemical deposition process (Fig. 3B). This phenomenon could be ascribed to the different nucleation and crystal growth rates in these two methods.

3.3. Stability of the NiHCF modified electrodes

It has been described that the main drawback for hexacyanometallates-based chemically modified electrodes is the gradual dissolution during continuous potential scan, which is an important factor hindering their practical performances [16]. Therefore, the major concern regarding the use of PB and its

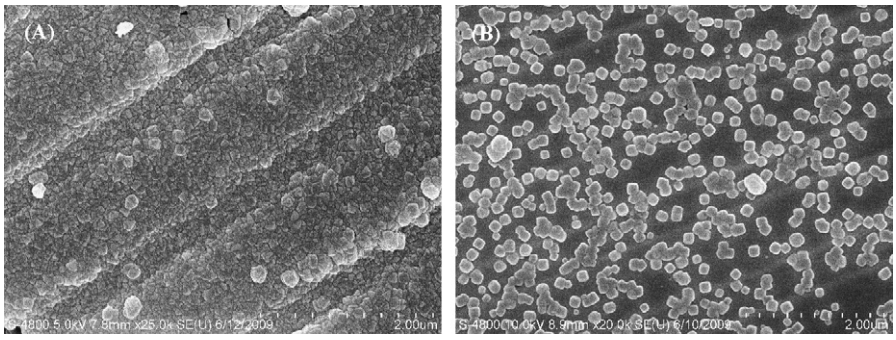

Fig. 3. Scanning electron micrographs of the NiHCF modified gold-CD electrode fabricated by (A) electrochemical and (B) chemical methods.

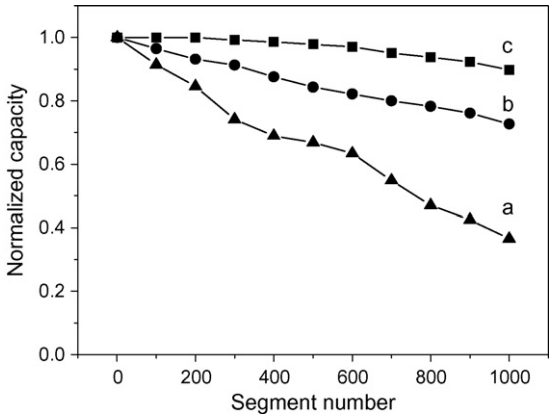

Fig. 4. Normalized capacity as a function of the potential scan cycles showing the electrochemical stability of NiHCF film on gold electrodes fabricated by (a) electrochemical deposition, (b) chemical deposition for 30 min, and (c) chemical deposition for 60 min. Data were obtained from the cyclic voltammograms of these modified electrodes in a 1.0 M $NaNO_3$ solution at a scan rate of 100 mV/s.

analogues for sensor and biosensor design is the enhancement of their stability. For this reason, some works have been carried out for improving the stability of NiHCF [17,18]. The stability of the as-prepared films was characterized using cyclic voltammetry in a 1.0 M $NaNO_3$ solution starting from 0 to 0.85 V at a scan rate 100 mV/s. The ion exchange capacities were estimated by the charge passed under the redox peaks [19], and the capacity values are normalized by their corresponding initial capacity. To shed light on the significance of the stability of the chemically deposited NiHCF film, results were also compared with a NiHCF film modified electrode prepared by a common electrochemically deposition method. As shown in Fig. 4, the fabrication process considerably influences the redox cycling stability of the NiHCF modified electrode. For the electrochemically deposited NiHCF, the ion exchange capacity decreases very quickly upon repeated potential cycling (Fig. 4, curve a). About 60% decrease in the ion exchange capacity is observed after 500 cycles of potential scan. On the contrast, the chemically deposited NiHCF films have a significant stability during potential cycling. The NiHCF films chemically deposited for 30 and 60 min remained 72.7% and 89.8% of the exchange capacity of their initial values after 500 cycles of potential scan, respectively (Fig. 4, curves b and c). This relative high stability could be attributed to the chemical composition of the NiHCF fabricated.

3.4. Na^+ sensing

Sodium ion is the most essential extracellular cation for maintaining osmotic pressure and electrodynamic cellular properties in living organism. Electrolyte disorders are frequently observed in clinical practice, and quantitative detection of sodium ion is routinely performed in biochemistry laboratories. Since the formal potential changes linearly with log[Na^+], the NiHCF films modified gold electrode were employed as sodium sensor by voltammetric determination of the formal potential of the nickel hexacyanoferrate film modified electrode.

Cyclic voltammograms of the chemically deposited NiHCF film on gold electrode in different concentrations of $NaNO_3$ are shown in Fig. 5A. When the concentration of $NaNO_3$ decreases from 1.0 to 0.0001 M, the redox peaks shifts towards less positive potential from 0.38 to 0.19 V with a simultaneous decrease in peak current. The gradual decrease in peak current can be explained by the Fick's first diffusion law [20]. Fig. 5B shows the plot of Na^+ ion concentration vs. formal potential. A linear graph with a slope of 48 mV is obtained in the range of 10^{-4} to 1.0 M.

The application of the NiHCF-modified electrode in the determination of sodium ion in blood was also examined. Table 1 compares the results obtained using the electrochemical method with that using flame emission spectrophotometry. Both methods show good reproducibility, low standard deviations and good agreement with each other. However, the electrochemical method has the significant advantages of ease of operation and low cost.

Table 1
Concentration of sodium ion (mM) in blood obtained by different analytical methods ($n = 5$).

Method	Sample	
	Serum	Plasma
Voltammetry	134.9 ± 0.3	140.1 ± 0.3
Flame emission spectrophotometry	135.1 ± 0.5	139.8 ± 0.4

3.5. Electrocatalytic oxidation of ascorbic acid

To validate the electrocatalytic property of the resultant NiHCF film, the electrooxidation of ascorbic acid on the modified electrode was studied. Fig. 6A shows the cyclic voltammograms of the chemically deposited NiHCF film modified Au electrodes in the absence and presence of ascorbic acid. As seen in Fig. 6A, the NiHCF film modified Au electrode in the blank solution (20 mM phosphate buffer, pH 7.0, 1.0 M $NaNO_3$) exhibits a well-behaved redox reaction at 430 mV (curve a). Upon the addition of ascorbic acid, an enhancement in the anodic peak current was observed and the cathodic peak current tends to disappear (curve b). This behavior is typical of that expected for mediated oxidation. The anodic peak current increases with increasing the ascorbic acid concentration in solution (curves b–d). A typical calibration curve based on the hydrodynamic amperometric measurement (Fig. 6B and C) shows a linear range in the concentration range 0.1–12 mM

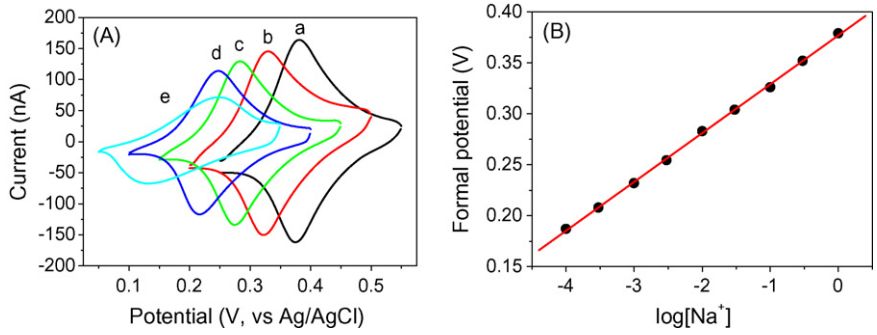

Fig. 5. (A) Cyclic voltammograms of the chemically deposited NiHCF film on gold electrode in (a) 1.0 M, (b) 0.1 M, (c) 0.01 M, (d) 0.001 M, and (e) 0.0001 M $NaNO_3$ solutions. Scan rate: 1 mV/s. (B) The plot of formal potential vs. log[Na^+].

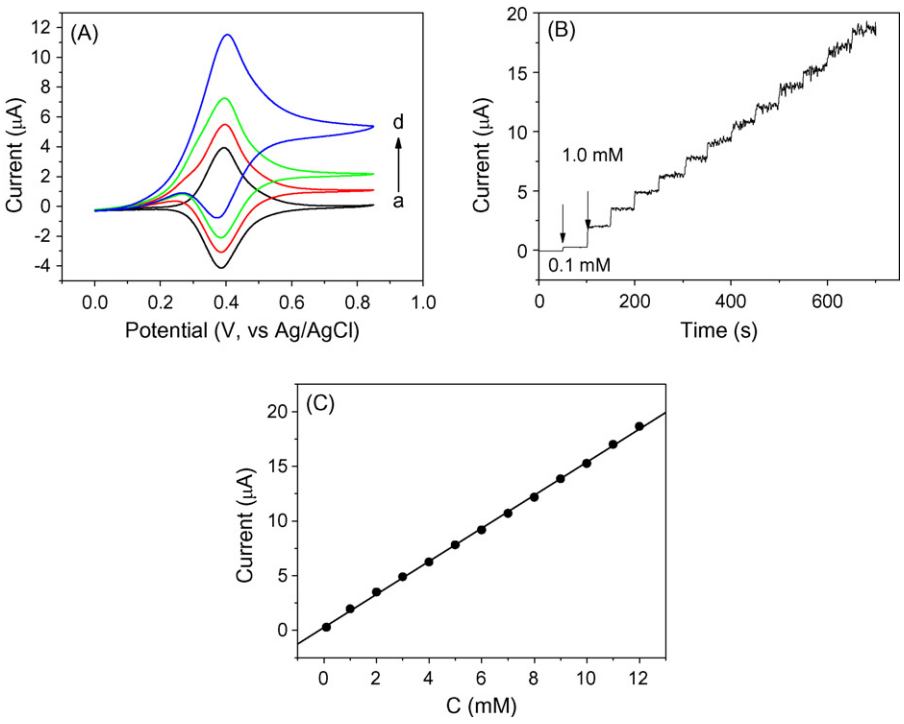

Fig. 6. (A) Cyclic voltammograms of a chemically deposited NiHCF film on Au electrode in the absence (a) and in the presence of ascorbic acid (b) 2.0, (c) 4.0, (d) 10.0 mM, respectively. Supporting electrolyte: 1.0 M $NaNO_3$ with 20 mM phosphate buffer (pH 7.0); potential scan rate: 25 mV/s. (B) Typical amperometric response of a chemically deposited NiHCF film on Au electrode to successive injection of ascorbic acid into a stirring PBS solution (pH 7.0, containing 1.0 M $NaNO_3$). The working potential was 0.4 V. (C) The calibration curve of ascorbic acid concentration at the modified electrode.

Table 2
Results for the determination of ascorbic acid in pharmaceuticals.

Sample	Amount of ascorbic acid[a]	
	Proposed method	Iodine titration method
Tablet (mg/tablet)	986.5 ± 16.3	994.7 ± 10.2
Injection (mg/ml)	255.1 ± 2.6	249.8 ± 3.3

[a] Average of five replicate determinations.

with a correlation coefficient over 0.9996. The detection limit is 0.025 mM.

To verify the present catalytic method, pharmaceutical dosage forms containing ascorbic acid including tablets and injections purchased from local sources were analyzed. The evaluation of the ascorbic acid concentration is carried out with the aid of a standard addition method. The results for the analysis of these preparations with the amperometric method compared favorably with those obtained by the iodine titration method (Table 2).

4. Conclusion

A novel chemical deposition method has been established for construction of NiHCF film on conductive substrates. The resultant NiHCF films have single chemical composition. Both alkaline ions response and electrocatalytic activity are favorable for these films. The ease of preparation and the relatively high stability of the film represent important factors for use in routine quantitative analysis.

ABSTRACT

A new on-line preconcentration technique called borate complexation-assisted field-enhanced sample injection (BCA-FESI) was proposed for preconcentrating *cis*-diol-containing compounds (CDCCs) in capillary electrophoresis (CE). The principle relies on amplification of the difference in the electrophoretic mobilities of CDCC in sample matrix and background electrolyte (BGE) through complexation of CDCC with borate in a sample matrix of basic pH and dissociation of the complex in a BGE of acidic pH. Meanwhile, CDCC and borate ions electro-injected into the capillary are finally in neutral state, which maintains the pre-filled low conductivity zone and thus allows for longer injection time. With catechol as a test compound, the principle and effectiveness of BCA-FESI was verified. As compared to conventional sample injection, BCA-FESI allowed for sensitivity enhancement of 1850-fold. The established method was further evaluated with three catechins, including (−)-epicatechin gallate (ECG), (−)-gallocatechin gallate (GCG), and (−)-epigallocatechin (EGC), in a standard mixture of trace content. The limit of detection (LOD) was found to be 1.4, 3.8, 17.5 nM (S/N = 3) for ECG, GCG, EGC, respectively. Finally, the BCA-FESI method was applied to a real sample of diluted tea beverage, in which the three catechins were detected.

1. Introduction

CE has become an important separation and analytical tool because of its significant advantages of high efficiency, short analysis time, low sample consumption and multiple modes. However, the major limitation of CE lies in insufficient concentration sensitivity with UV absorption detection due to its limited optical path and small sample volume. Many attempts have been focused on how to overcome this drawback. In addition to alteration of the hardware configuration, including the use of bubble-cell [1], Z-shaped capillary [2], mass spectrometry [3] and laser-induced fluorescence detection [4], on-line sample preconcentration [5] is a practical, simple and effective strategy to improve the detection sensitivity of CE. According to the focusing mechanism, the on-line sample preconcentration techniques can be grouped into four major principles: (1) sample stacking [6–8], (2) sweeping [9,10], (3) pH junction [11,12], and (4) transient isotachophoresis [13].

Sample stacking is in common use, on the basis of which several other modes have been developed, such as large-volume sample stacking (LVSS) and field-enhanced sample injection (FESI). The basic principle of sample stacking relies on conductivity-induced difference in the velocities of analytes in two distinct zones in the capillary: the sample zone, which is of low conductivity, and the remaining zone of BGE, which is of high conductivity. The analytes migrate at higher velocities in the sample zone but slow down when migrating into the BGE zone. Thus a relatively large sample plug can be introduced hydrodynamically into the capillary, and under an electric field applied to the capillary, the analytes are focused at the boundary between the sample zone and BGE. From this principle, the higher the difference in the conductivity between the two zones, the higher the concentration efficiency is. In practice, however, BGE of too high conductivity should be avoided in order to prevent excess Joule-heating. Moreover, generally the maximum sample volume allowed is not very large (usually 10% or so). Further increase in injected sample volume failed to focus the sample zone effectively, because the electric field enhancement gained across the sample zone becomes lower and ions migrating into this zone from BGE apparently increase the conductivity of the sample zone. A strategy for injecting a larger sample volume and keeping effective sample stacking is to remove the sample matrix during the process of sample stacking. Burgi and Chien [14] and other groups [15–17] proposed the technique LVSS, in which a reversed electroosmotic flow (EOF) is used to pump the sample matrix out of the capillary. However, the disadvantage of this method is the difficulty to exactly monitor the current change during the stacking process, which leads to irreproducible results. In regular sample stacking and LVSS, the sensitivity enhancement is limited by the sample volume injected. As the maximum sample volume allowed

is usually about 30–50% of the total capillary length, the sensitivity improvement is not very high, only 1–2 orders of magnitude. As a comparison, FESI is a more effective solution to reach higher sensitivity improvement. In FESI, the velocity difference of analytes between the low-conductivity zone and the high-conductivity zone is dramatically increased by amplifying the electric field at the capillary inlet. A short plug of low conductivity solution (usually water) is introduced hydrodynamically into the capillary inlet and the sample prepared in dilute buffer is injected electrokinetically. The electric field strength established across the low-conductivity zone is enhanced by a factor of up to several hundred times relative to that in normal CE [18]. FESI allows for pumping a large amount of analytes into a very narrow zone, obviating the limit on the sample volume injected. By FESI, the sensitivity can be improved by 2–3 orders of magnitude without degradation of separation efficiency. According to the principle of sample stacking, if difference in the velocity of analytes between the low-conductivity zone and the high-conductivity zone can be effectively enlarged by any means, then the detection sensitivity can be further improved [11].

It has been known that borate and boronate can form stable complexes with *cis*-diol-containing compounds (CDCCs) [19–22]. Boric acid and boronic acids form covalent bonds with 1,2- or 1,3-*cis*-diols to generate five- or six-membered cyclic esters in non-aqueous or basic aqueous media. When the pH of the environment is changed to an acidic condition, the complexation reversibly releases boronic acids and CDCC. This reversible specific chemical reaction leads to the successful applications in chemical sensing [23–26] and boronate affinity chromatography [27–32]. Boronate complexation-based new chromatographic techniques have been developed [33–36]. In CE, borate complexation has been a useful strategy for the separation of carbohydrates [22,37–39]. Also, it has been used as a carrier for preconcentrating of CDCC in sweeping [40,41] and sweeping-pH junction [42], where borate is present only in the BGE.

In this study, we propose a new on-line preconcentration technique, borate complexation-assisted FESI (BCA-FESI), for preconcentrating CDCC, by taking advantage of the pH-dependent reversible feature of the borate complexation as an additional means to increase the difference in the velocity of analytes in the low-conductivity zone and the high-conductivity zone. The principle is schematically illustrated in Fig. 1. CDCC are dissolved in borate buffer of low conductivity and high pH, while the BGE is of high conductivity and low pH. In the high pH sample matrix, CDCC associate with borate and become negatively charged, and thereby gain faster electrophoretic velocities as compared with the case without borate in the matrix; when the complexes migrate into the low-pH BGE, CDCC dissociate from the complexes and become completely neutral and therefore gain a zero velocity. Thus, the concentration efficiency of FESI can be effectively improved by the borate complexation. On the other hand, borate ions migrating to the water plug-BGE boundary from the sample matrix become boric acid due to the low local pH. The final neutral state of borate and CCDC, especially the former as it is plentiful in the sample matrix, helps maintain the water plug of low conductivity during the electro-injection process and thereby allows for injection of a larger amount of analytes. Due to the neural state feature of the preconcentrated analytes in BCA-FESI, separation mode for neutral analytes, such as micellar electrokinetic chromatography (MEKC) or capillary electrochromatography (CEC), is required for consequent separation of the preconcentrated analytes. In this study, we demonstrate the principle of BCA-FESI through combining it with MEKC (in which sweeping is involved, but is not the essential preconcentration effect). Due to the presence of BCA-FESI, the MEKC separation was performed under an acidic pH, which is different from general MEKC where a basic pH BGE is used.

Catechol, a 1,2-*cis*-diol-comtaining compound, was first selected as the test analyte to demonstrate the principle and to investigate the experimental factors that influenced the preconcentration efficiency, such as the water plug length and the sample injection time. The results indicate that the presence of borate complexation can apparently improve the sensitivity enhancement of FESI. Finally, the established method was applied to the preconcentration of three catechins in standard mixture solution of trace content and in diluted tea beverage.

2. Materials and methods

2.1. Instrumentation

CE experiments were performed on a PACE/MDQ system (Beckman Coulter, Fullerton, CA, USA) equipped with a DAD detector. The detection wavelength was set at 214 nm, and the temperature was kept constant at 25 °C. A bare fused-silica capillary (Yongnian Optical Fiber Factory, Hebei, China) of 30 cm (20 cm to detector) × 50 μm i.d. was used for the separations. The length of pre-filled water plug was calculated with the software CE expert from Beckman Coulter according to the experimental parameters used, with calibration using the measured travel time of a neutral marker (methanol or other organic solvent) from the capillary inlet to the detection window at the pressure under use. Dimethyl sulfoxide (DMSO) was used as EOF marker.

2.2. Chemicals

Catechol was purchased from Alfa-Aesar (Tianjin, China), while (−)-epicatechin gallate (ECG), (−)-epigallocatechin (EGC) and (−)-gallocatechin gallate (GCG) were from Sigma-Aldrich (St. Louis, MO, USA). Chemical structures for the three catechins are given in Fig. 2. Sodium dodecylsulfate (SDS) was bought from Bio-Rad (California, USA). Other chemicals were from Sinopharm Chemical Reagent Co. Ltd (Shanghai, China). All chemicals used were of analytical grade or higher. Ultrapure water produced by a Milli-Q advantage A10 system (Millipore, Milford, MA, USA) was used to prepare all solutions. Suntory Wulong Tea beverage (non-sugar containing) was bought from local supermarket in Nanjing.

2.3. Electrolyte and sample preparation

When measuring the effective mobility of catechol under different pH and sample matrix-BGE systems, two kinds of buffer were used: (1) 0.2 M boric acid containing 1 mM sodium dihydrogen phosphate and 6 mM sodium metabisulfite; (2) 5 mM sodium dihydrogen phosphate buffer containing 6 mM sodium metabisulfite. Borate buffers of 5, 12.5, 25, 50, 100, and 200 mM at pH 9.5 containing 6 mM sodium metabisulfite were used to investigate the effect of borate concentration on the effective mobility of catechol.

The non-micellar BGE was 50 mM phosphate buffer containing 100 mM sodium chloride, pH 2.0. The micellar BGE, contained 50 mM phosphate, 50 mM sodium chloride and 100 mM SDS, pH 2.0, the conductivity of which was measured to be the same as that of non-micellar BGE. For the separation of catechins, the non-micellar BGE and micellar BGE were prepared in a similar way with slight modification, where the concentrations of phosphate buffer and SDS were adjusted. All buffers were adjusted to the desired pH by sodium hydroxide or hydrochloric acid, and sonicated for 15 min in a water bath before use.

The stock solutions of catechol (5 mg/mL), ECG (1 mg/mL), EGC (1 mg/mL), and GCG (1 mg/mL) were prepared with ultrapure water. Then they were diluted by different sample matrix under various conditions. Sodium metabisulfite was added to the sample matrices

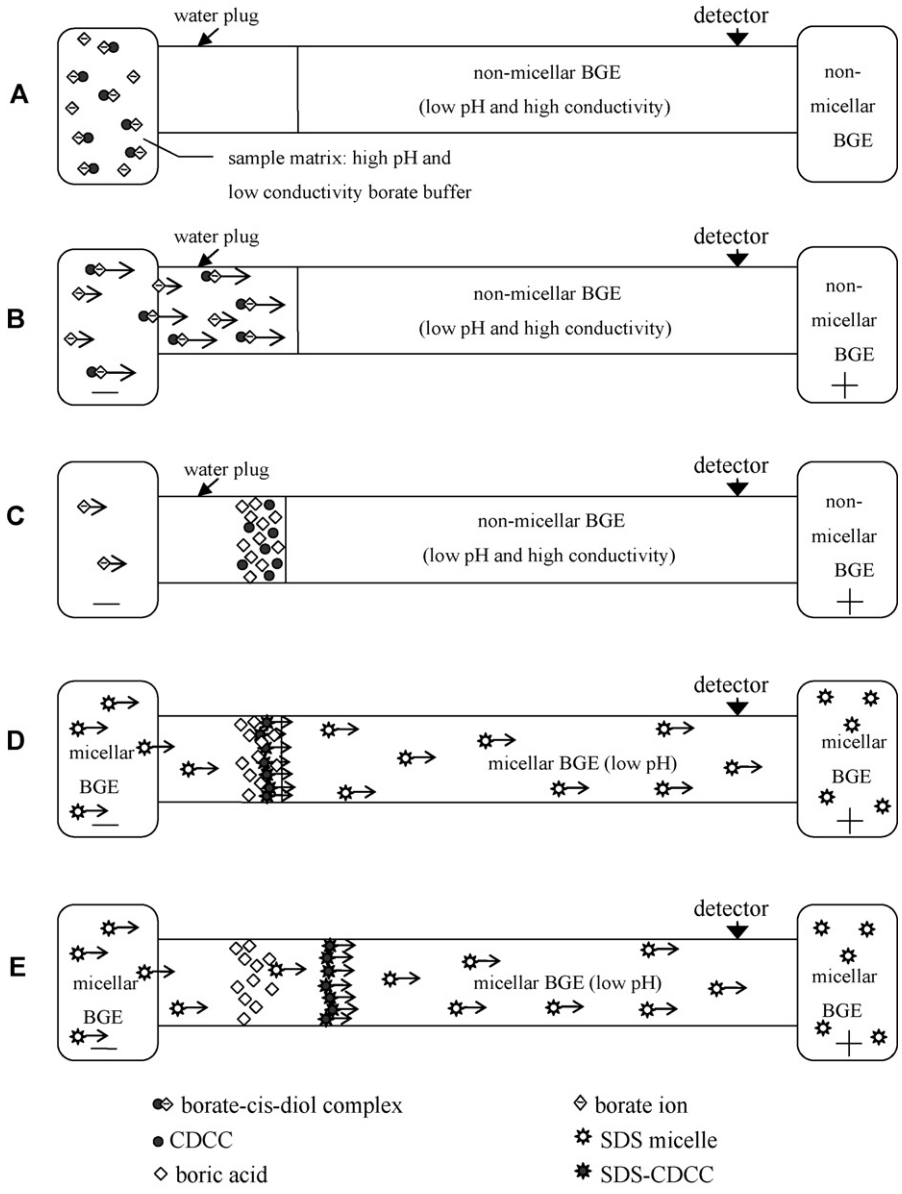

Fig. 1. Schematic of the principles of BCA-FESI (A–C) and its combination with MEKC (D and E): (A) a certain length of water plug is hydrodynamically injected into the capillary which is pre-filled with non-micellar BGE of low conductivity and high pH; the sample is prepared with borate buffer of high conductivity and low pH, and therefore contains the CDCC–borate complexes; (B) the complexes and excessive borate ions are electrokinetically injected into the capillary by applying a negative voltage, which migrate forward quickly within the water plug due to the enhanced electric field; (C) when they reach the boundary between the water plug and the non-micellar BGE, the complexes dissociate into free borate and free CDCC, and both borate and CDCC are neutralized and consequently stack into a narrow zone at the boundary; (D) the solutions at both capillary ends are replaced by micellar BGE, and a negative voltage is applied to the capillary for MEKC separation; the anionic SDS micelles sweep through the stacked sample zone and further preconcentrate the analytes; (E) the stacked analytes are separated in MEKC mode.

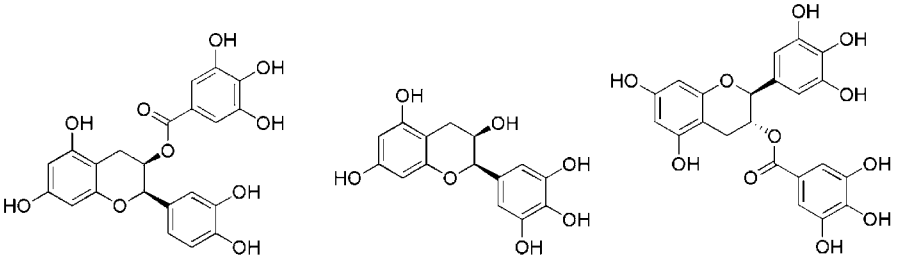

Fig. 2. Chemical structures of the three catechins used in this study.

and the BGE of basic pH as an antioxidant to avoid oxidation of CDCC in alkaline conditions.

2.4. CE conditions

At the beginning of each day, the capillary was preconditioned sequentially with 1.0 M sodium hydroxide, 0.1 M sodium hydroxide, water, and the separation buffer for 5 min each. Between runs the capillary was rinsed with 0.1 M sodium hydroxide, water, and the separation buffer, for 2 min each.

The BCA-FESI-MEKC process included three steps: (1) a certain length of water plug was first hydrodynamically introduced into the capillary, which was pre-filled with non-micellar BGE; (2) a constant negative voltage (−3.5 kV) was applied for the electrokinetic injection; (3) finally, a negative voltage (−12 kV) was applied to the capillary for separation, with the micellar BGE at both ends of capillary. Samples once used were replaced with fresh ones after each electro-injection, in order to avoid sample exhaustion.

3. Results and discussion

3.1. Effect of borate complexation on the electrophoretic mobility

Since the principle of BCA-FESI is based on the enhancement of the electrophoretic mobility of the analyte through borate complexation, the effect of borate complexation was first investigated. Fig. 3 illustrated the electrophoretic mobility of catechol in different sample matrix-BGE systems under different pH in the range of 8.5–11.0. When the sample matrix-BGE system was a borate–borate combination, the electrophoretic mobility of catechol kept nearly constant within the pH range investigated (trace A). When the BGE was changed to a phosphate buffer, the electrophoretic mobility of catechol was apparently reduced, which increased as the pH was increased (trace B). When sample matrix-BGE system was switched to a phosphate–phosphate combination, the electrophoretic mobility of catechol was further reduced, which also increased as elevating the pH (trace C). Clearly, as compared with

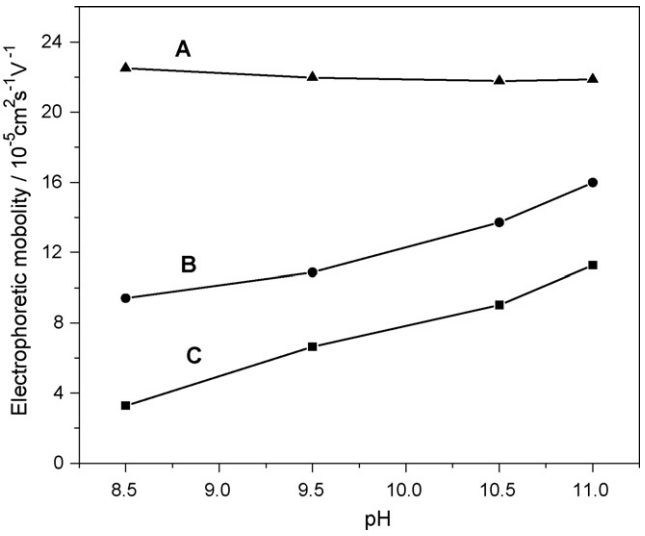

Fig. 3. Dependence of effective electrophoretic mobility of catechol on the pH in different sample matrix-BGE systems. Sample, 0.25 mg/mL catechol; sample matrix: (A) and (B) 0.2 M borate buffer containing 1 mM sodium dihydrogenphosphate and 6 mM sodium metabisulfite, (C) 5 mM phosphate buffer containing 6 mM sodium metabisulfite; BGE: (A) 0.2 M borate buffer containing 1 mM sodium dihydrogenphosphate and 6 mM sodium metabisulfite, (B) and (C) 5 mM phosphate buffer containing 6 mM sodium metabisulfite. Both sample matrix and BGE are at the same pH values ranging from 8.5 to 11.0. Sample injection, 0.3 psi × 3 s from the outlet end of the capillary; applied voltage, −20 kV.

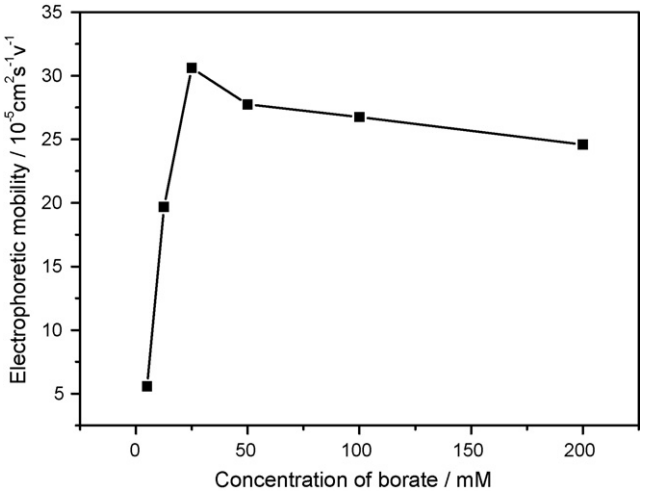

Fig. 4. Effect of borate concentration on effective electrophoretic mobility of catechol. Sample, 0.25 mg/mL catechol; sample matrix is the same as BGE; BGE, borate buffer (pH 9.5) with concentration ranging from 5, 12.5, 25, 50, 100, to 200 mM. Other conditions are the same as in Fig. 3.

that in the borate-free matrix-BGE system, the electrophoretic mobility of catechol can be apparently enhanced by addition of borate into the sample matrix. Although a higher pH favors the absolute electrophoretic mobility, pH 9.5 was chosen for further investigation because borate buffer has a highest buffer capacity among the pH values examined, at which the electrophoretic mobility of catechol was amplified by a factor of 1.6 by borate complexation.

3.2. Effect of borate concentration on the electrophoretic mobility

The influence of borate concentration on the electrophoretic mobility of catechol was investigated through changing the borate concentration in both the sample matrix and the BGE. As shown in Fig. 4, the electrophoretic mobility catechol increased as elevating the borate concentration from 5 to 25 mM, and then gradually slightly decreased as further increasing the borate concentration. Thus, 25 mM was chosen as the sample matrix for further investigate to ensure the maximum enhancement of the electrophoretic mobility.

3.3. Dissociation of borate complex in low-pH buffer

A prerequisite of BCA-FESI is that when the CDCC–borate complexes migrate to the BGE of acidic pH, they can dissociate quickly; otherwise, the preconcentration efficiency is poor. To confirm such a precondition, normal MEKC experiments were carried out with low pH BGE and high pH borate and phosphate matrices. The phosphate matrix was used as a comparison. If CDCC–borate complexes formed at high pH can dissociate into free CDCC and free borate ions when they encounter a low pH BGE, the peaks observed should have the same peak width as that in the control experiment. This is verified experimentally, as shown in Fig. 5.

3.4. Effect of water plug length

The water plug pre-injected plays a key role in FESI, which provides an enhanced electric field for the electro-injection. A general equation has been proposed to describe the relationship between the analyte amount injected and the experimental parameters in FESI [8]. According to this equation, the water plug length should as short as possible for the largest injection amount. However, if the water plug is too short, the introduced ionic analyte will increase

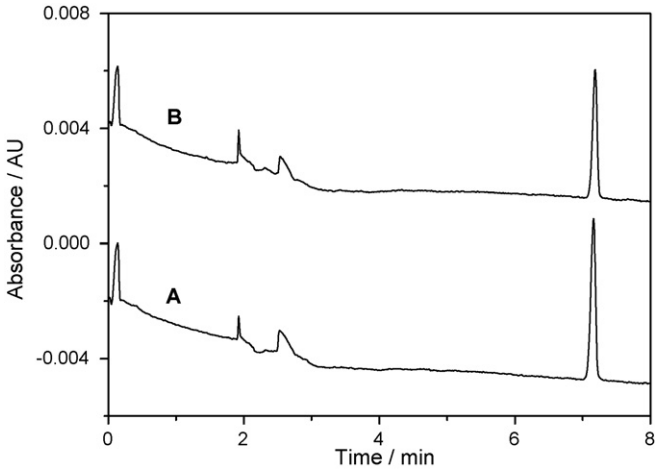

Fig. 5. Electrophoretograms of catechol dissolved in different sample matrix in MEKC mode under an acidic condition. Sample, 0.25 mg/mL catechol; sample matrix: (A) 25 mM borate and 6 mM sodium metabisulfite, pH 9.5, (B) 25 mM phosphate and 6 mM sodium metabisulfite, pH 9.5; sample injection, 0.3 psi × 3 s; the capillary is filled with non-micellar BGE-containing 50 mM phosphate buffer and 100 mM NaCl, pH 2.0. After injection, the vials at both ends are changed into micellar BGE-containing 50 mM sodium dihydrogenphosphate, 50 mM NaCl, and 100 mM SDS, pH 2.0. Separation voltage is −12 kV.

the conductivity of the water plug quickly, and as a result the stacking process will become feeble or even stop soon. Therefore, an optimal water plug length, which is usually millimeters in length, can be found experimentally. The effect of the water plug length was investigated. As illustrated in Fig. 6, there was an optimal water plug length under the conditions used, 2.4 mm (the corresponding injection pressure and time were 0.5 psi and 5 s), in terms of the dependence of the corrected peak area (peak area/migration time) and corrected peak height (peak height/migration time) for the preconcentrated analyte. This trend is in agreement with that reported previously [8].

3.5. *Effect of sample injection time and maintaining low conductivity*

The amount of analyte injected in FESI is dependent on the sample injection time if other experimental parameters, such as water plug length and injection voltage, are fixed. As mentioned above, in regular FESI, the water plug must be short enough, usually millimeters long. As stated in earlier context, the final neutral states of borate ion and analyte in BCA-FESI allow them serve as low conductivity maintainers, thus BCA-FESI permits longer sample injection time as compared with regular FESI. To demonstrate such a phenomenon, two water plugs of different length, 2.4 and 12.0 mm, were used for investigation on the effect of sample injection time. As shown in Fig. 7, at both water plugs, there was an optimal injection time, in terms of dependences of the corrected peak areas and the corrected peak heights of catechol on the injection duration. This means that beyond the optimal value, one cannot further improve the sensitivity by extending the injection time. However, BCA-FESI significantly extended the optimal injection time through using a longer water plug, from 15 min at 2.4 mm to 35 min at 12.0 mm, as can be seen in Fig. 7. Accordingly, the sensitivity enhancement was improved by use of the longer water plug. Under the optimal injection time at the water plug of 2.4 mm, the sensitivity enhancement factor was calculated to be 1080 according to the following equation:

$$\alpha = \frac{C_1 H_2}{C_2 H_1} \quad (1)$$

where α is the sensitivity enhancement factor; C_1 and C_2 are the analyte concentration used for conventional injection and on-line sample preconcentration, respectively; H_1 and H_2 are corresponding corrected peak height (peak height/migration time). On contrast, the value obtained at the water plug of 12.0 mm was 1850, which was nearly doubled.

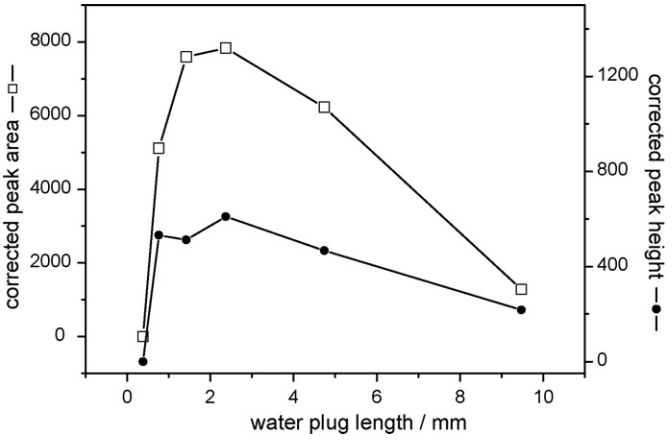

Fig. 6. Effect of water plug length on BCA-FESI-MEKC. Sample, 0.25 μg/mL catechol dissolved in 25 mM borate and 6 μM sodium metabisulfite, pH 9.5; injection, −3.5 kV × 90 s; the length of water plug, 0.4, 0.8, 1.4, 2.4, 4.7 and 9.5 mm. Other conditions are the same as in Fig. 5.

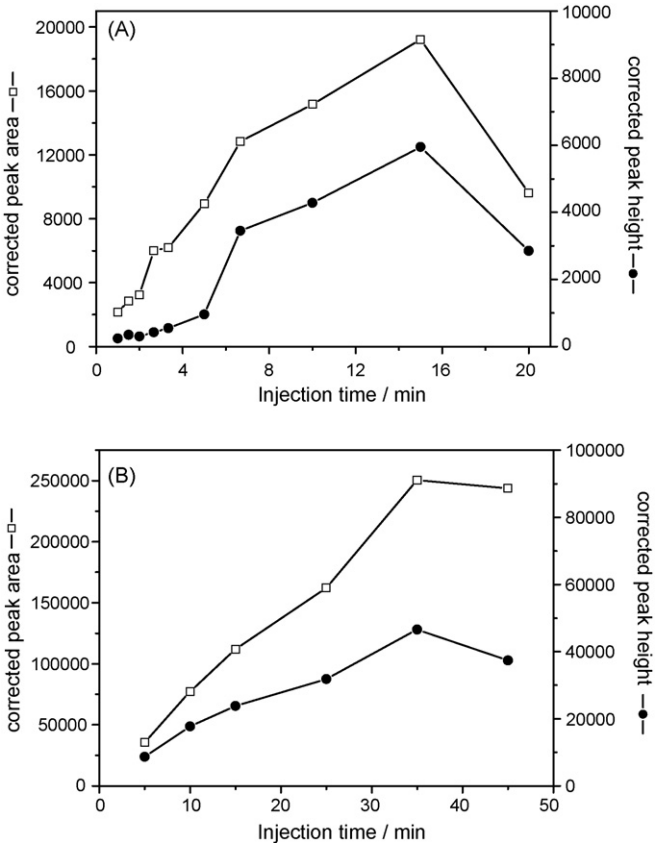

Fig. 7. Dependence of corrected peak area or peak on electrokinetic injection time with different length of water plug in BCA-FESI-MEKC. Sample, 0.25 μg/mL catechol dissolved in 25 mM borate and 6 μM sodium metabisulfite, pH 9.5; water plug length: (A) 2.4 mm; (B) 12.0 mm; injection voltage, −3.5 kV; injection time: (A) 1–20 min; (B) 5–45 min. Other conditions are the same as in Fig. 5.

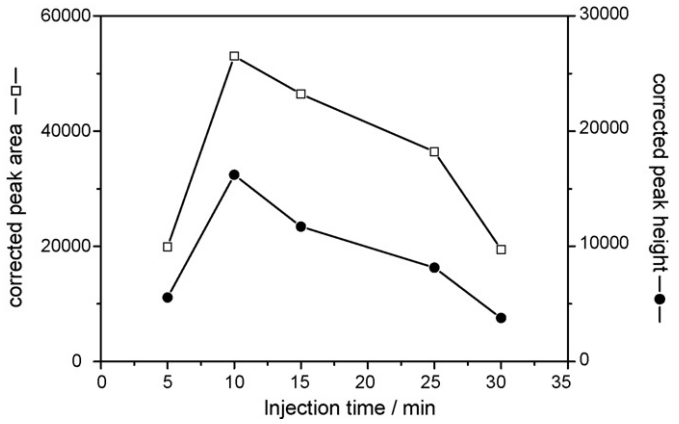

Fig. 8. Dependence of corrected peak area or peak on electrokinetic injection time in regular FESI-MEKC. Sample, 0.25 μg/mL catechol; water plug length, 12.0 mm; injection voltage, −3.5 kV; injection time, 5–45 min; sample matrix, 8 mM sodium metabisulfite and 6 μM sodium metabisulfite, pH 9.5. Other conditions are the same as in Fig. 5.

3.6. Comparison of BCA-FESI with regular FESI

The effectiveness of borate complexation assistance was investigated by comparison of the optimal sample injection time and the sensitivity enhancement factor calculated according to corrected peak height in BCA-FESI and regular FESI under otherwise identical conditions. In regular FESI, the optimal sample injected time was only 10 min, as can be seen from Fig. 8, and the sensitivity enhancement factor was 400. As a comparison, in BCA-FESI, the optimal sample injected time was 35 min and the sensitivity enhancement factor was 1850. The sensitivity in BCA-FESI was further improved by 4.6-fold on the basis of the best results of regular FESI. Clearly, the presence of borate complexation assistance allows for longer sample injection duration and therefore provides higher preconcentration efficiency, which can be supported by the electropherograms shown in Fig. 9.

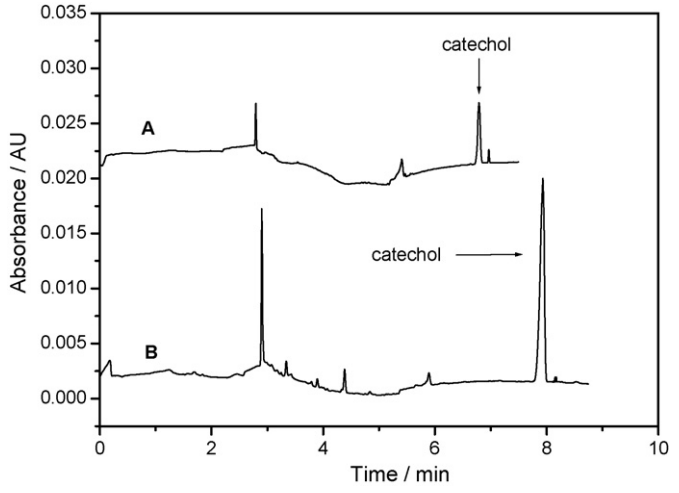

Fig. 9. Comparison of the preconcentration of catechol by regular FESI-MEKC (A) and BCA-FESI-MEKC (B). Sample: (A) 0.25 μg/mL catechol dissolved in 8 mM phosphate and 6 μM sodium metabisulfite, pH 9.5, (B) 0.25 μg/mL catechol dissolved in 25 mM borate and 6 μM sodium metabisulfite, pH 9.5; sample injection: electro-injection at −3.5 kV for 10 min (A) and 35 min (B), with a pre-filled water plug of 12.0 mm. Other conditions are the same as in Fig. 5.

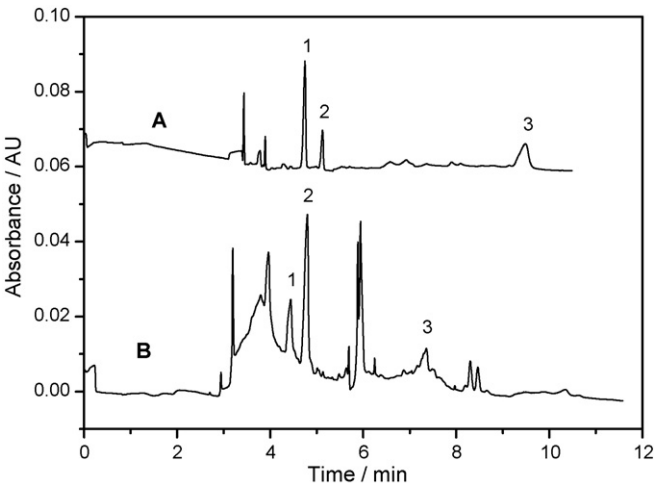

Fig. 10. BCA-FESI-MEKC of catechin standards (A) and real sample (B). Sample (A) a standard mixture containing 0.2 μg/mL ECG, 0.2 μg/mL GCG, and 0.4 μg/mL EGC; (B) 50-fold diluted tea beverage; sample matrices are both 25 mM borate and 0.24 mM sodium metabisulfite, pH 9.5; water plug length, 12.0 mm; injection, −3.5 kV × 35 min; the capillary is filled with non-micellar BGE-containing 37.5 mM phosphate buffer and 75 mM NaCl, pH 2.0. After injection, the vials at both ends are changed into micellar BGE-containing 50 mM sodium dihydrogenphosphate, 75 mM NaCl, and 50 mM SDS, pH 2.0. Other conditions are the same as in Fig. 4. Peak identities: 1, ECG; 2, GCG; 3, EGC.

3.7. Application to catechins and real sample

Catechins, polyphenolic compounds that contain *cis*-diol groups, are main components of tea leaves. More interestingly, catechins are found to be able to reduce or delay the risk of some major health problems such as stroke, aging, cancer and diabetes [43–47]. So it is important to determine the catechins level in tea products for quality control. Three catechins, including ECG, GCG, ECG, were used as test compounds to investigate the feasibility of the established methods for more complicated samples and real samples. Catechin standards in diluted sample that contains borate matrix at high pH were first examined. As shown in Fig. 10A, the three catechins were baseline separated with sharp peak shape and detectable at trace content level. The LOD was found to be 1.4, 3.8, 17.5 nM (S/N = 3) for ECG, GCG, EGC, respectively. Finally, this method was applied to a 50-fold diluted Wulong tea beverage, and the three catechins were clearly found in this real sample.

4. Concluding remarks

In this paper, a new on-line preconcentration method, BCA-FESI, has been developed and validated for preconcentrating CDCC in CE. By virtue of the assistance of borate complexation, the preconcentration efficiency of CDCC can be effectively improved on the basis of regular FESI. As compared with conventional FESI under optimized conditions, the sensitivity improvement is 4.6-fold higher. Although such an enhancement is not outstanding, it is of significance since it is on the basis of the best result of conventional FESI. The overall sensitivity improvement by BCA-FESI relative to conventional injection is usually of 3 orders of magnitude. The distinct features of BCA-FESI are its longer pre-filled water plug and longer sample injection time. As a great number of biologically active compounds contain one or more vicinal diol groups, such as carbohydrates, nucleotides, theaflavins, some vitamins and some flavonoids, BCA-FESI can be a promising on-line sample preconcentration technique for these compounds.

ABSTRACT

This study integrated dielectrophoresis (DEP) with non-flow through biochips to enhance the immuno-capture and detection of foodborne pathogenic bacteria. It demonstrated two major functions provided by DEP to improve the chip performance: (i) concentrating bacterial cells from the suspension to different locations on the chip surface by positive and negative DEP; (ii) making the cells in close contact with the immobilized antibodies on the chip surface so that immuno-capture efficiency can be dramatically enhanced.

The microchip achieved the immuno-capture efficiencies of ~56.0% and ~64.0% to *Salmonella* cells with 15 and 30 min DEP, respectively, which were considerably higher than those of ~10.4% and ~17.6% for 15 and 30 min immuno-capture without DEP. The immuno-captured bacterial cells were detected by the sandwich format ELISA on the chips. The final absorbance signals were enhanced by DEP assisted immuno-capture by 64.7–105.2% for the samples containing 10^3–10^6 cells/20 μl. The integration of DEP with the biochips has the potential to advance the chip-based immunoassay methods for microbial detection.

1. Introduction

Foodborne pathogens have been a serious threat to the public health and food safety for decades and remain one of the major concerns of our society. In the United States of America, foodborne pathogens cause an estimated 76 million cases of foodborne diseases, resulting in 325,000 hospitalizations and more than 5000 deaths each year [1]. Today, there are more than 250 known diseases caused by different foodborne pathogenic microorganisms. Pathogenic bacteria are the most common foodborne pathogens, accounting for 91% of the total outbreaks of foodborne diseases in the USA [2,3].

Effective detection of pathogens in food products is the first control point for the prevention of fooodborne diseases. Although traditional microbiological methods have been a gold standard practice for the detection and identification of pathogens in food for nearly one century and continue to be a reliable standard for ensuring food safety, these methods are time-consuming and labor intensive, and are therefore not suitable for modern food quality assurance to make a timely response to possible risks. As a result, over the past 25 years, numerous rapid methods have been studied with the main purpose of reducing the assay time. Various biosensors and biochips have gained popularity in this field due to their rapid detection speed, high sensitivity, and reliability. Many biosensors and biochips are based on derived sandwich immunoassay formats, in which the immuno-capture of the target cells by the immobilized antibodies on the sensor surface is the critical step. This step determines the amount of the target cells bound to the sensor surface, and thus determine the sensitivity of the method. The detection limits of these biosensors/biochips typically range from 10^2 to 10^7 cells/ml with detection times ranging from tens of minutes to several hours [4–7].

It is becoming increasingly difficult to continue improving the detection limit of such biosensors and biochips for the detection of bacterial pathogens. There are two main reasons that can account for this difficulty: (i) the limited physical sensitivities of the transducers; and (ii) the low immuno-capture efficiency of the immobilized antibodies on the solid sensor/chip surfaces. Fortunately, the advances in microfabrication technology have made it possible to fabricate sensors with scales and dimensions similar to target cells, which can improve the physical sensitivity of the transducer to be able to sense a few cells or even a single cell binding to the sensor/chip surface [8]. However, the issue of the low capture efficiency of immobilized antibodies on sensor surfaces has not been well addressed. Since bacterial cells in suspensions do not diffuse as easy as small molecules, it is particularly difficult for the cells to access and interact with immobilized antibodies on the sensor surfaces. Researchers have attempted various approaches to make the immuno-capture on the sensor surface more efficient, mainly

doi:10.1016/j.talanta.2009.07.024

including different antibody immobilization methods [9] and different immuno-reaction conditions [10]. For example, orientated immobilized antibody on a sensor surface can generally achieve a better capture efficiency than non-orientated antibody layer [9]. Although these efforts have achieved moderate improvement, the immuno-capture efficiencies of *Salmonella* and other foodborne bacteria cells are still limited, ranging from 0.01% to less than 20% [10,11]. Further improvement in the immuno-capture efficiency in biosensor and biochip settings required the integration of available technologies to develop new concepts and devices that can address the challenges.

Dielectrophoresis (DEP) is the electrokinetic motion of dielectrically polarized particles in non-uniform electric fields [12]. As most biological cells behave as dielectrically polarized particles in external electric field, DEP has been recognized as a powerful tool in manipulation of biological cells. Its typical applications are the separations of different types of mammalian cells based on the differences in their dielectric polarizabilities [13–19]. DEP has also been employed for the separation of viable and nonviable yeast cells [20,21], the trapping of viruses from fluid [22], and the separation of bacterial cells [23–28].

In addition to the typical separation function, DEP can also provide other attractive functions that can be integrated with biosensor and biochip platforms to improve the sensor performance. Gomez et al. [29] demonstrated DEP concentration of *Listeria* cells in a lab-on-a-chip impedance microbiology, achieving a concentration factor of 10^4–10^5. This DEP concentration step eliminated the long time growth-based enrichment steps that are usually used in traditional microbial methods. In our previous study [30], we used DEP in a flow through microchip to concentrate *Listeria monocytogenes* cells from the flow and used immobilized antibody to capture the cells in the microfluidic channel. This microfluidic chip achieved an improved immuno-capture efficiency of ~27% to *Listeria* cells. A latest study reported that the capture efficiency of *L. monocytogenes* by heat shock protein 60 (Hsp60) immobilized on silicon dioxide was increased by 60% when a DEP force was applied for 5 min at the beginning of the 1 h incubation step [31]. These studies have demonstrated that DEP can concentrate bacterial cells from the flow and help to increase the capture efficiency to bacterial cells in microfluidic chips.

In this study, we integrated DEP with non-flow through biochips to assist the immuno-capture of one of the major foodborne pathogenic bacteria—*Salmonella* Typhimurium, and coupled with absorbance measurement. We demonstrated two significant functions of DEP in the biochip platforms to improve the detection of *Salmonella*: (i) DEP can concentrate bacterial cells from the suspension to different locations on the chip surface, which make it very useful in manipulating bacterial cells in biosensors and biochips; (ii) DEP can make bacterial cells in close contact with the immobilized antibodies on the chip surface, which can effectively improve the immuno-capture efficiency. The immuno-captured cells were detected by absorbance measurements. The enhancement in the final absorbance signals resulted from the DEP assistance to the immuno-capture was investigated.

2. Materials and methods

2.1. Chemicals

Biotinylated bovine serum albumin (BSA) and streptavidin were purchased from Pierce (Rockford, IL). Biotinylated anti-*Salmonella* antibody and horse radish peroxidase (HRP) labeled anti-*Salmonella* antibody were purchased from Biodesign International (Saco, ME). Hydrogen peroxide (30%) and ammonium hydroxide (30%) were obtained from VWR (West Chester, PA). Phosphate buffered saline (PBS) solution (pH 7.0), containing 0.1 M sodium phosphate and 0.15 M sodium chloride, was prepared by dissolving one pack of PBS powder (JAW PBS pack from G Bioscience, St Louis, MO) into 1 L of deionized (DI) water according to the instruction. Millipore water (Milli-Q-System, 18.2 MΩ cm, Molsheim, France) was used throughout the experiments.

2.2. Preparation of bacterial samples

Salmonella Typhimurium culture was purchased from Carolina Biological Supply Company (Burlington, NC). The culture was grown in brain heart infusion (BHI) broth (TEKnova, Hollister, CA) at 37 °C for 16–18 h. When harvested, 1 ml of the culture was centrifuged (Eppendorf, Westbury, NY) at 6000 × *g* for 2 min, then the supernatant was removed in order to get rid of ionic residues from the growth medium. The cells were washed with DI water 3 times and resuspended in 1 ml sterilized DI water. The cell concentration in the suspension was determined by surface plating 0.1 ml of appropriate dilutions onto XLT4 agar plates (Difco, Sparks, MD). Colonies were counted after incubation of the plates at 37 °C for 24 h. The average cell concentration in a culture was at ~10^9 colony forming units per milliliter (cfu/ml). The cell suspension was serially (1:10) diluted with DI water to desired concentrations for further experiments.

2.3. Microchips

The non-flow through biochip was assembled by two parts: a gold interdigitated microelectrode (IME) on a glass substrate (ABtech Scientific, Inc., Richarmond, VA) and a micro-chamber right above the electrode area formed by poly dimethylsiloxane (PDMS) (Sylgard 184 Silicone Elastomer kit, Dow Corning Co., Midland, MI) (Fig. 1A). The insert in Fig. 1A shows the image of the IME chip with the rectangle (red line) showing the IME area. The IME contained 50 pairs of opposing gold finger electrodes with 15 μm of electrode width and space, and 5 mm of electrode length. The chips were cleaned with a solution of 1:1:5 (v/v) H_2O_2(30%)/NH_4OH(30%)/H_2O for 5 s, rinsed with DI water, and dried with air, before they were assembled with the PDMS chamber. The PDMS layer (approxi-

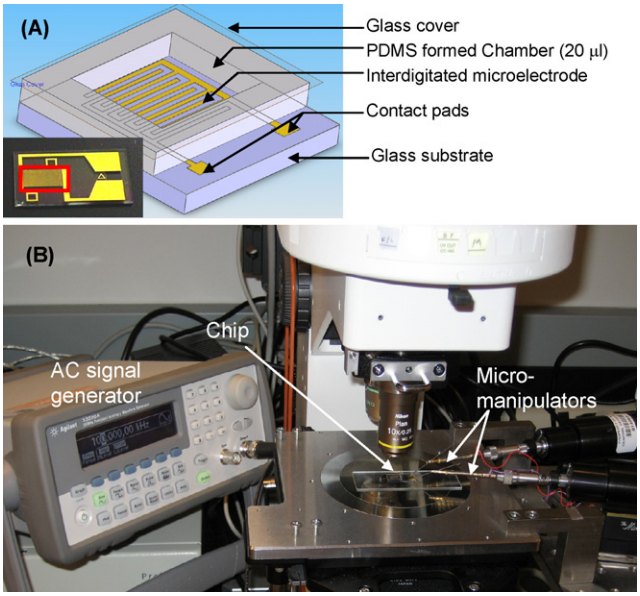

Fig. 1. (A) The non-flow through chip used in this study for DEP enhanced immuno-capture of *Salmonella* cells, which consists of a chamber formed by PDMS and a set of interdigitated microelectrodes (IMEs) on a glass substrate and (B) the experiment setup. The chip was placed on the stage of a microscope. An Agilent waveform generator was used to apply DEP voltage to the IME through a pair of micromanipulators.

mately 2 mm thick) was made by mixing the elastomer monomer: the curing agent at the ratio of 15:1 (w/w) and was cured at 70 °C overnight in a petri dish. The PDMS layer was then cut into 1 cm × 1 cm pieces. A rectangle shaped chamber (~3 mm × 5 mm, equivalent to the IME electrode area) was made in the center of each PDMS piece. The PDMS piece was then aligned with the IME chip and attached to the chip by gentle pressing to form a chamber right above the electrode area.

2.4. Antibody immobilization on the chips

Anti-*Salmonella* antibody was immobilized onto the chip surface through a sandwich structure consisting of biotinylated BSA – streptavidin – biotinylated anti-*Salmonella* antibody as previously reported [30]. In detail, an aliquot of 10 μl of 0.5 mg/ml biotinylated BSA in 0.1 M PBS was introduced into the chamber, and the chip was placed in a moisture chamber and kept at 4 °C overnight, allowing physical absorption of biotinylated BSA onto the chip surface. The chip was then rinsed with PBS for 2 min to remove unbound biotinylated BSA from the surface. Then, an aliquot of 10 μl of 0.25 mg/ml streptavidin in 0.1 M PBS was placed into the chamber and allowed to react at 4 °C for 2 h. The excess streptavidin was washed away with PBS. Finally, an aliquot of 10 μl of 0.25 mg/ml of biotinylated anti-*Salmonella* antibody in 0.1 M PBS was introduced into the chamber to react with streptavidin at 4 °C for 2 h. The chip was washed with PBS for 2 min and rinsed with DI water for 2 min before further use in the experiments.

2.5. DEP assisted immuno-capture of bacterial cells on the chip.

Fig. 1B shows the image of the experimental setup. The chip was mounted on a glass slide and was placed on the stage of the microscope. An Agilent 33120A arbitrary waveform generator (Agilent Technologies, Inc., Palo Alto, CA) was used to apply sinusoidal voltages (3 Vpp with different frequencies ranging from 1 Hz to 1 MHz) to the IME electrodes through a pair of micromanipulators (Micromanipulator, Carson city, NV).

The mechanism of DEP assisted immuno-capture of *Salmonella* cells on the chip in comparison with non-DEP assisted immuno-capture is shown in Fig. 2A and B. When *Salmonella* cell samples are placed in the chamber, if without DEP (Fig. 2A), the cells suspended in the solution generally move around in the solution and do not have sufficient opportunities to reach the surface of the chip and interact with the immobilized antibodies. Only a small population of cells can reach the chip surface by sediment, as a result, the capture efficiency of immobilized antibody is generally very low, especially when a small sensor is used in a large volume of sample. When a DEP voltage is applied, *Salmonella* cells can be pulled down to the chip surface from the suspension by the DEP forces, which results in much more cells reaching the chip surface, and the cells can make well contact with the immobilized antibodies on the chip surface (Fig. 2B). With such DEP assistance, an increased immuno-capture efficiency of the immobilized antibody to bacterial cells can be realized.

2.6. Determination of the immuno-capture efficiencies with and without DEP assistance by traditional plating method

Two sets of tests were performed in order to compare the immuno-capture efficiencies with and without DEP assistance: the control tests and the DEP assisted immuno-capture tests. In DEP-assisted immuno-capture, an aliquot of 20 μl of *Salmonella* cell suspension was introduced into the chamber. The chamber was covered with a glass cover (VWR, West Chester, PA) to prevent evaporation. A DEP voltage was applied to the IMEs with desired periods of time (15 or 30 min). The control tests were preformed in the same way but no DEP voltage was applied to the electrodes.

To examine the immuno-capture efficiencies, 10 μl of the sample in the chamber was taken after the immuno-capture with or without DEP and diluted with 90 μl sterilized DI water. Further serial 1:10 dilutions (100 μl sample + 900 μl DI water) of these samples were made. Appropriate dilutions were plated on XLT4 agar. Colonies were counted after the plates were incubated at 37 °C for 24 h, and the cell number was determined by the calculated cfu/ml. The immuno-capture efficiencies were estimated using the following equation:

$$\text{immuno-capture efficiency} = \frac{\text{cell number in original suspension} - \text{cell number in suspension after immuno} - \text{reaction}}{\text{cell number in original suspension}} \times 100 \quad (1)$$

2.7. Enzyme-linked immuno absorbance detection of the captured bacterial cells on chip

After the immuno-capture of cells on the chips either with or without DEP, non-specifically bound cells were washed out, the captured cells were further detected by using the derived sandwich ELISA on the chip (Fig. 2C). To produce a quantitative absorbance signal, HRP labeled secondary anti-*Salmonella* antibody was added to react with these captured cells. After washing out the excess secondary antibody, the substrate 3,3′,5,5′-tetramethylbenzidine (TMB) (VWR, West Chester, PA) was added to produce a color product which can be read by absorbance at 450 nm (Fig. 2C). In detail, the following steps were performed to detect the cells using absorbance: (1) the chips were washed with PBS, and HRP labeled secondary anti-*Salmonella* antibody (10 μl, 0.01 mg/ml) was added into the chamber and reacted with the captured cells for 30 min. (2) After washing with PBS, TMB (20 μl) was added and allowed to react for 5 min. The product (15 μl) was taken from the chamber and transferred into a microcentrifuge tube which already contained 15 μl of 1 M HCl in order to stop the enzymatic reaction. Twenty microliter of the yellow product was transferred into a 384-well ELISA plate (Corning, Lowell, MA), and the absorbance at 450 nm was read using Spectramax Plus^{384} plate reader (Molecular

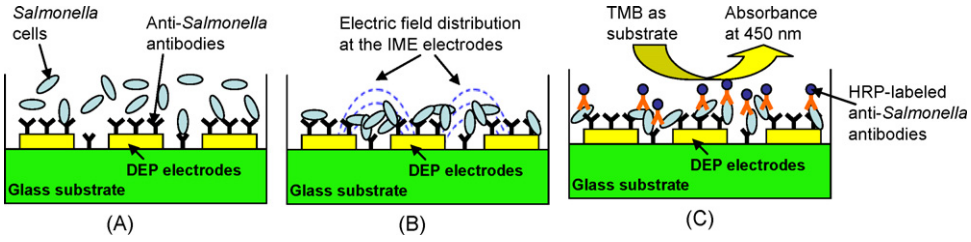

Fig. 2. The mechanisms of immuno-capture of *Salmonella* cells (A) without DEP and (B) with DEP assistance, and (C) the further sandwich ELISA detection of captured cells on the chip.

Devices, Sunnyvale, CA). The plate reader has a photometric range of 0–4000 OD (optical density), with photometric error for microplate <±1.0% and ±0.006 OD within 190–1000 nm (from manufacturer user guide).

2.8. Imaging

The fluorescent images were taken on a Nikon ECLIPSE E600FN fluorescence microscope (Japan) with a Coolsnap HQ camera (Roper Scientific, Inc.—Photometric, Tucson, AZ) using a FITC (Fluorescin isothiocyanate) filter. For visualization purposes, *S.* Typhimurium cells were stained with 3,3′-dihexyloxacarbocyanine iodide ($DiOC_6(3)$) dye (green) (Molecular Probes, Eugene, OR). To stain the cells, 3 μl of 1 μM $DiOC_6(3)$) dye was added to 1 ml of the cell sample and incubated at 37 °C for 10 min. The stained cells were centrifuged and washed with sterilized DI water 3–4 times to remove excess dye. Appropriate dilutions were made for further experiments.

Field emission scanning electron microscopic (FESEM) images were taken on a Hitachi S 4800 FESEM microscope (Tokyo, Japan). The acceleration voltage was at 2.0 kV. Images were acquired digitally using Quartz PCI v. software (Hitachi High-technologies Canada, Inc., Resdale, Ontario, Canada).

3. Results and discussion

3.1. Manipulating Salmonella cells on the chip by positive and negative DEP

When a particle experience DEP in a non-uniform electrical field, the time-averaged dielectrophoretic force acting on a spherical particle can be approximated as Eq. (2) [32]:

$$F_{DEP} = 2\pi r^3 \varepsilon_m \,\mathrm{Re}[f_{CM}(\omega)]\nabla E_{rms}^2 \quad (2)$$

where r is the particle radius; ε_m, the permittivity of the suspending medium; E_{rms}, the root mean square value of the electric field; and $\mathrm{Re}[f_{CM}(\omega)]$, the real part of the Clausius–Mossotti factor (f_{CM}), which is given by

$$f_{CM}(\omega) = \frac{\varepsilon_p^* - \varepsilon_m^*}{\varepsilon_p^* + 2\varepsilon_m^*} \quad (3)$$

where $\varepsilon_p^* = (\varepsilon_p - j\sigma_p)/\omega$ and $\varepsilon_m^* = (\varepsilon_m - j\sigma_m)/\omega$ are the complex permittivities of the particle and the medium, respectively, with σ the conductivity, ε the permittivity, ω the angular frequency of the applied electric field, and $j = \sqrt{-1}$.

The frequency dependence of $\mathrm{Re}[f_{CM}(\omega)]$ indicates that the force acting on the particle varies with the frequency. Depending on the relative polarizability of the particle with respect to the surrounding medium, the particle can experience positive DEP or negative DEP. When $\mathrm{Re}[f_{CM}] > 0$, the particle will experience positive DEP which will move the particle towards the region where the electrical field is the strongest. While $\mathrm{Re}[f_{CM}] < 0$, the particle will experience negative DEP which will move the particle towards the region where the electrical field is weak.

In this study, we used the designed IME to generate a non-uniform electrical field and to serve as DEP electrodes for capturing bacterial cells to the electrode surface. Fig. 3A shows the non-uniform electrical field generated by the IME. It has the strongest electrical field zones at the edges of the finger electrodes and the weakest electrical field zones at the centers of the finger electrodes and the gaps between the finger electrodes. Depending on the relative dielectric constant between the bacterial cells and the medium as well as the frequency of the applied voltage, *Salmonella* cells can either experience negative DEP which moves them towards the regions where the electric fields are the weakest, i.e. the centers of the finger electrodes or the gaps between the finger electrodes, or experience positive DEP which moves them to the regions where

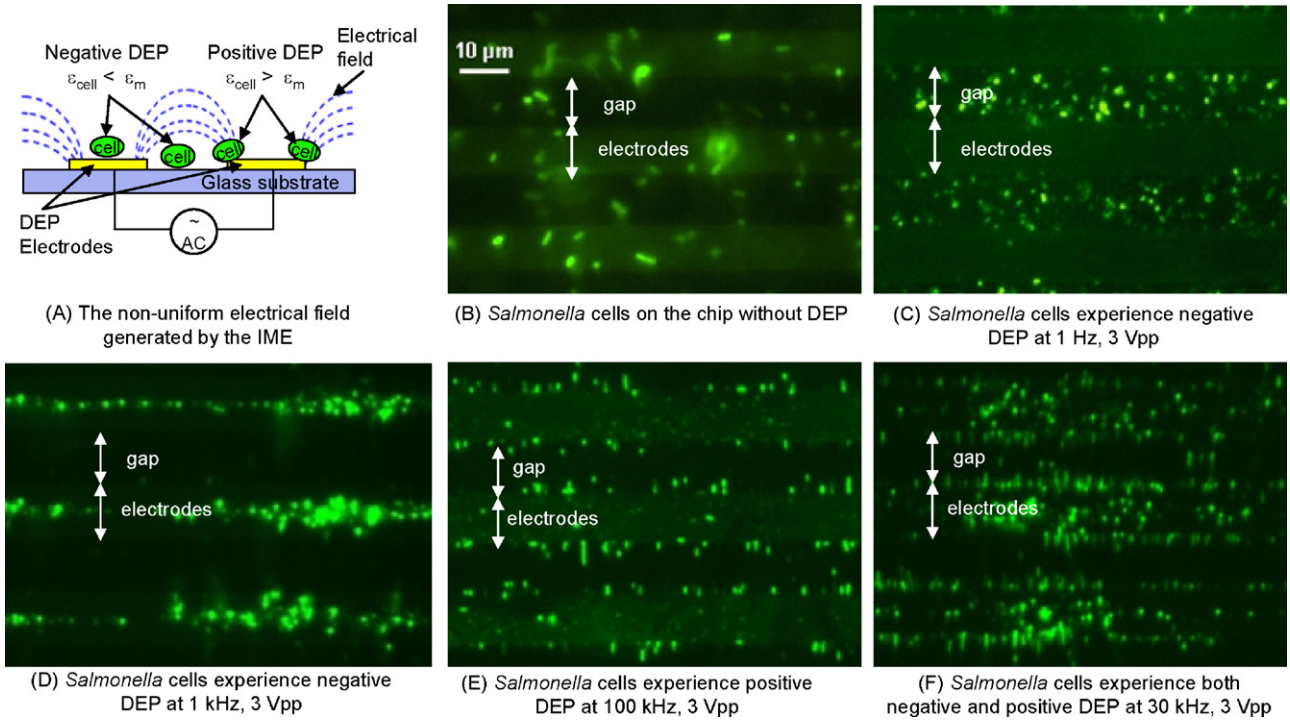

Fig. 3. (A) Schematic of the non-uniform electrical field generated by the interdigitated microelectrodes, and the positive and negative DEP for bacterial cells in this electrical field; and the fluorescence images of (B) *Salmonella* cells on the non-flow through chip without DEP; (C) cells collected in the gap between the finger electrodes by negative DEP at 1 Hz and 3 Vpp; (D) cells collected at the centers of the finger electrodes by negative DEP at 1 kHz and 3 Vpp; (E) cells collected at the edges of the finger electrodes by positive DEP at 100 kHz and 3 Vpp; and (F) cells exhibited positive or negative DEP at 30 kHz and 3 Vpp. The IMEs were with anti-*Salmonella* antibody immobilized on their surfaces. Green dots are *Salmonella* cells stained with $DiOC_6(3)$.

the electrical fields are the strongest, i.e. the edges of the finger electrodes.

Fig. 3B–E present the fluorescence microscopic images of *Salmonella* cells on the IMEs with anti-*Salmonella* antibody immobilized on their surfaces, when there was (B) no DEP, (C) negative DEP at 1 Hz and 3 Vpp, (D) negative DEP at 1 kHz and 3 Vpp, (E) positive DEP at 100 kHz and 3 Vpp (green dots are *Salmonella* cells stained with $DiOC_6(3)$. As shown in Fig. 3B, when there was no DEP voltage applied, *Salmonella* cells distributed randomly in the suspension. When DEP voltage was applied to the IME, cells were trapped at different locations depending on the applied frequency. Fig. 3C and D shows the fluorescence images of bacterial cells captured in the gaps between the finger electrodes and at the centers of the finger electrodes by negative DEP at 1 Hz, 3 Vpp, and 1 kHz, 3 Vpp, respectively. The results indicated that at frequencies no more than 1 kHz, *Salmonella* cells exhibited negative DEP, and depending on the applied frequency, cells could be captured at the two different locations where the electrical fields were the weakest. The trapped rod-shaped *Salmonella* cells looked like small round dots, suggesting that the cells were aligned upwards on the electrodes at these frequencies. When the applied frequency was increased to 100 kHz or higher, *Salmonella* cells exhibited positive DEP, and they were trapped at the edges of the finger electrodes (Fig. 3E). In between these frequencies, in the same sample, some cells exhibited negative DEP while other cells exhibited positive DEP due to the slight variations among these individual cells. Fig. 3F shows a representative image of *Salmonella* cells on the IME with some cells exhibiting positive DEP and some exhibiting negative DEP, when the applied DEP frequency was at 30 kHz. Our previous study indicated that DEP treatments (1 h or less) at all these frequencies would not affect the viability of bacterial cells [33].

This frequency-dependent positive and negative DEP of *Salmonella* cells is due to the relative dielectric properties of the cells with respect to that of the medium at different frequencies. Bacterial cells consist of adjacent structures of materials that have very different electrical properties. The cell membrane consists of a lipid bilayer containing many proteins, thus is highly insulating, while the inside of a cell, the cytoplasm, is complex and contains many dissolved charged molecules, and is therefore highly conductive. The conductivity of the cell membrane is around 10^{-7} S/m, whereas the conductivity of the interior of a cell can be as high as 1 S/m [13]. The medium, DI water, has its conductivity in a range from 1–2 μS/cm to about 10–15 μS/cm. In DEP manipulation, most likely, at low frequencies, the electrical field is mainly dropped across the outermost membranes of the cells. The cells behave as poorly conductive spheres having the permittivity of the cell membrane [26,34], hence negative DEP is expected. As the frequency increases, the applied field gradually penetrates into the cells. The cells then behave as more conductive spheres with the permittivity of the cell interior [26], and positive DEP is expected. In practice, the actual frequency at which *Salmonella* cells exhibit positive or negative DEP may vary case by case, because it is related to many factors including the medium, the physiological stages of the cells, the dimensions and the design of the electrodes.

This frequency-dependent positive and negative DEP manipulation of *Salmonella* cells allows us to trap cells at different regions on the chip. This would be particularly useful to address one of the technical challenges for detecting a few cells or a single cell in a sensor/chip setting, i.e. how to bring the cells to the sensor site. This problem has not been well addressed in most of the studies related to single cell detection. Gray et al. [35] demonstrated that DEP could register thousands of single mammalian cells on each of thousands of 3 μm diameter planar microelectrodes. However, trapping of single bacterial cells onto microelectrodes for detection has not been reported yet. The results here suggested that DEP could be a possible tool to drive a single bacterial cell to the desired locations on a sensor/chip, but the realization of single cell detection is also related to other factors such as the dimension, the effective area, and the physical sensitivity of the sensor.

Of particular interest in this study is the ability of DEP to pull cells from the suspension to the chip surface. As we can see in Fig. 3B, when there is no DEP, it is obvious that most cells did not have opportunities to reach the chip surface and to interact with the immobilized antibodies on the chip surface. All other images in Fig. 3 indicate that, with DEP, *Salmonella* cells were pulled to the chip surface by DEP forces, so that much more cells had the opportunities to react with the immobilized antibodies, thus an enhanced immuno-capture efficiency could be expected.

Fig. 4A shows the FESEM image of *Salmonella* cells captured by DEP on the chip surface at the high cell density region, clearly showing that the captured cells are in close contacts with the chip surface, which confirms that DEP can effectively make these cells in close contact with the immobilized antibodies on the chip surface, so that the antibodies can react to the cells more effectively, and thus the immuno-capture efficiency can be improved. Fig. 4B presents a FESEM image of captured *Salmonella* cells on the chip by positive DEP at the low cell density region. It can be seen that the cells trapped by positive DEP at the edges of the electrodes has the maximum value of the polarization at the two ends of the rod-shaped cells, and they tended to align as a 'pearl chain' parallel to the electrical field.

It should be noted that the planar interdigitated microelectrodes have a limited effective DEP region above its surface. Several research groups have developed mathematical models for calculation of the DEP forces on IMEs, and have found that the DEP forces decrease exponentially with the height from the electrode surface

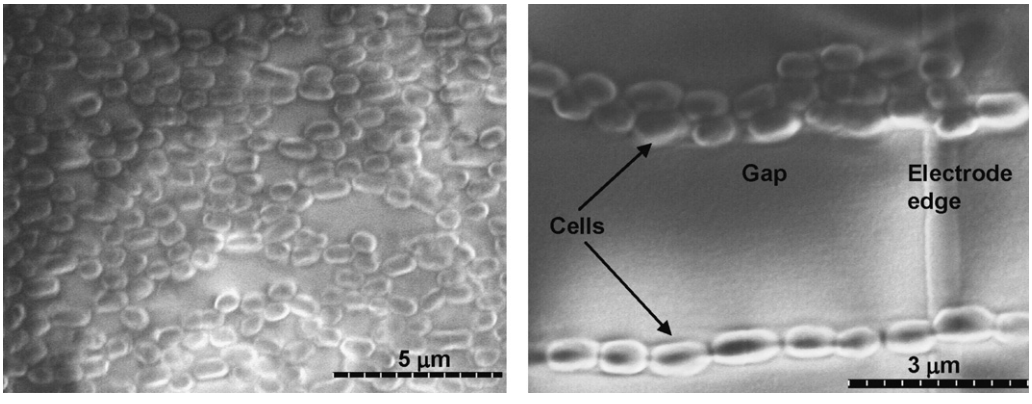

Fig. 4. The FESEM image of *Salmonella* cells captured by positive DEP at 100 kHz and 3 Vpp on the chip surface (A) in the high cell density region and (B) captured cells forming "pearl chains" at the edge of the finger electrode in the low cell density region.

[36–38]. Roughly, the effective DEP region for an IME is within the height equivalent to the electrode width from the electrode surface [36] (~15 μm in this study), therefore, a thin layer of cell sample right above the electrode surface is required for effective capture of the cells in the sample. As long as the cells move or settle down into the effective DEP region, they can be captured by DEP to the sensor surface.

3.2. DEP assisted immuno-capture of Salmonella cells in the chips

Fig. 5 presents the representative fluorescence images of *Salmonella* cells that were captured by immobilized antibodies on the chip with DEP treatment at 100 kHz and 3 Vpp for 5 min and without DEP. Images on the left side show the immuno-captured cells on the chips when 20 μl of the samples with concentrations at 1.2×10^8, 1.2×10^7, and 1.2×10^6 cfu/ml were placed on the chip with DEP treatment, while images on the right side show the immuno-captured cells without DEP treatment. It can be seen that almost all the cells being captured with positive DEP distributed at the edges of the finger electrodes, while without DEP treatment the cells distributed randomly on the chips. At each concentration, much more cells were captured by the immobilized antibodies with DEP treatment than without DEP. As evidenced by these fluorescence images, the immuno-capture efficiency of the immobilized antibody on the chips can be increased dramatically with DEP assistance. The enhanced immuno-capture are resulted from the two functions of DEP: one is that DEP pulls more cells down to the chip surface such that more cells have the opportunities to react with the immobilized antibodies, acting as a concentration step; and the other is that DEP helps these captured cells to make well contacts with the immobilized antibodies, so that the reaction between the cells and the antibodies are more efficient.

Table 1 shows the immuno-capture efficiency of the immobilized antibodies to *Salmonella* cells with DEP assistance in comparison with those without DEP, determined by the traditional surface plating method. As shown in Table 1, when 20 μl of a sample containing $\sim 1.93 \times 10^6$ cfu/ml was introduced into the chamber, after the 15 min DEP treatment at 100 kHz and 3 Vpp, the cell concentration in the suspension was found to be $\sim 8.50 \times 10^5$ cfu/ml. The reduced cell concentration in the suspen-

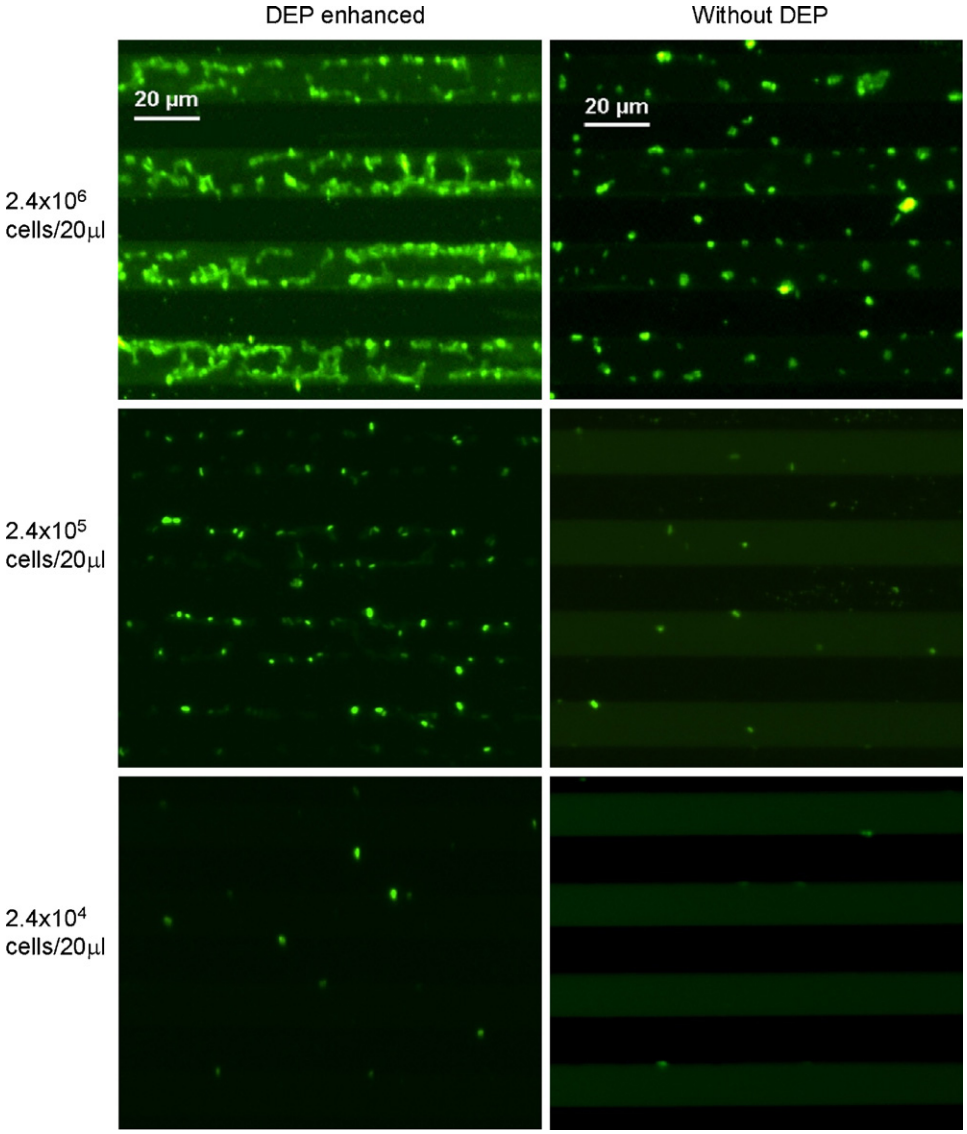

Fig. 5. The representative fluorescence images of *Salmonella* cells captured by immobilized antibodies on the chip with DEP treatment at 100 kHz and 3 Vpp for 5 min in comparison with those without DEP. Images on the left side are immuno-captured cells with DEP assistance, and the images on the right side are immuno-captured cells without DEP assistance. The three samples contained different cell concentrations at 2.4×10^6, 2.4×10^5, and 2.4×10^4 cells/20 μl.

Table 1
The immuno-capture efficiency of the immobilized antibody on the non-flow through chip to *Salmonella* cells with 15 and 30 min DEP assistance in comparison with those without DEP assistance.

Reaction time (min)	Cell concentration in suspension			
	Original sample (cfu/ml)	After immuno-reaction with DEP (cfu/ml)	After immuno-reaction without DEP (cfu/ml)	Immuno-capture efficiency (%)
15 min	$(1.93 \pm 0.21) \times 10^6$	$(8.5 \pm 0.48) \times 10^5$	–	~56.0%
	$(1.93 \pm 0.21) \times 10^6$	–	$(1.73 \pm 0.15) \times 10^6$	~10.4%
30 min	$(4.03 \pm 0.43) \times 10^6$	$(1.45 \pm 0.13) \times 10^6$	–	~64.0%
	$(1.42 \pm 0.46) \times 10^6$	–	$(1.17 \pm 0.33) \times 10^6$	~17.6%

DEP: 100 kHz and 3 Vpp.

sion was a result of the immuno-capture of cells by the immobilized antibodies on the chip. So the capture efficiency of the antibodies to the cells with DEP enhancement was approximately 56.0%. Whereas the 15 min immuno-reaction without DEP reduced the cell concentration to ~1.73×10^6 cfu/ml, and the capture efficiency was calculated to be approximately ~10.4%. The results demonstrated that the 15 min DEP assisted immuno-capture increased the immuno-capture efficiency by approximately 5-folds. We further investigated the immuno-capture efficiency with prolonged DEP treatment. The immuno-capture efficiency with a 30 min DEP treatment (100 kHz and 3 Vpp) was about 64.0% for the sample with cell concentration of ~4.03×10^6 cfu/ml, while the immuno-capture efficiency without DEP was ~17.6% for the control sample with similar cell concentration (1.42×10^6 cfu/ml) with 30 min immuno-reaction time. The data indicated that the prolonged reaction time could increase the capture efficiency of the immobilized antibodies on the chip regardless of with or without DEP. This is mostly due to the increased number of cells reaching the chip surface either because of DEP or sediment during the prolonged time. But it is still true that the immuno-capture efficiency with DEP assistance is much higher (>3-folds) than that without DEP.

In general, the immuno-capture efficiencies of antibodies immobilized on solid surfaces to bacterial cells are very low. For example, Brewster et al. [10] reported that the binding efficiency of anti-*Salmonella* antibodies immobilized on a roughened glassy carbon electrode surface was less than 0.01% by immersing the electrode into 1 ml solution containing 10^7 cells; it increased to ~0.5% by placing a droplet (containing ~10^5 cells) directly on the electrode surface. Ruan et al. [11] achieved a capture efficiency of ~16% of anti-*E. coli* antibody immobilized on an indium tin oxide (ITO) electrode surface to *E. coli* cells, when 50 μl of 6.0×10^6 cfu/ml sample was dropped on the sensor surface twice and incubated for 1 h at 37 °C. We achieved the capture efficiencies of 18–27% for *Listeria* cells with concentrations ranging from 10^1 to 10^3 cells in a flow through microchip with DEP at 1 MHz, 20 Vpp [30]. The results in this study demonstrated that DEP can effectively improve the immuno-capture efficiency to 56–64% with a considerable short reaction time (15–30 min) in the designed non-flow through microchip device.

When bacterial cells get into the electrical field, they get polarized and be captured very rapidly (within about microsecond) [39]. Generally, cells close to the electrodes are captured onto the electrodes' surface by DEP immediately (less than 1 s). Cells further from the electrodes can be captured by DEP when they move or settle down by gravity closer to the electrode surface into the effective DEP region. Therefore, with DEP, most bacterial cells in the suspension can be captured onto the sensor surface within a very short time, while without DEP, cells take much longer time to settle down onto the sensor surface. In this respect, DEP can effectively shorten the time required for bacterial cells to reach the antibodies immobilized on the chip surface, thus save the total assay time while still achieve high immuno-capture efficiency.

3.3. On chip ELISA detection of immuno-captured Salmonella cells

Fig. 6 shows the absorbance detection results of *Salmonella* cells on the chip captured with and without DEP. For samples with 5.0×10^3, 5.0×10^4, 4.7×10^5, and 5.0×10^6 cells/20 μl, the absorbance signals produced by the cells immuno-captured with DEP were 0.39 ± 0.084, 0.84 ± 0.11, 1.66 ± 0.20, and 2.66 ± 0.071, while the absorbance signals produced by the cells immuno-captured without DEP were 0.19 ± 0.071, 0.42 ± 0.049, 0.91 ± 0.066, and 1.65 ± 0.13. The absorbance signals with DEP assistance increased by 105.2%, 101.2%, 82.4%, and 64.7% compared with those without DEP. The enhancement in the absorbance decreased with the increasing cell concentrations in the samples. This is possibly due to the aggregation of cells on the chip surface during the DEP capture process for samples containing higher cell concentrations, and not all the cells can access to the antibodies on the chip surface, resulting in less effective capture enhancement (less increase in the final absorbance signal). While for samples with low cell concentrations, cells captured by DEP on the chip surface only form a monolayer, and all the captured cells can access to the immobilized antibodies, therefore resulting in a more effective DEP enhanced immuno-capture (larger increase in the final absorbance signal). Based on the data in Fig. 6, using the sample containing no bacteria as control, the detection limit of the on chip ELISA detection with DEP assistance was 5.0×10^3 cells/20 μl (2.5×10^5 cfu/ml), one order of magnitude better than that of without DEP (5.0×10^4 cells/20 μl or 2.5×10^6 cfu/ml). The results here demonstrated that DEP assisted immuno-capture of bacterial cells can provide a substantial enhancement in the finial detection signal and thus improve the detection limit of immuno-based detection of bacterial cells.

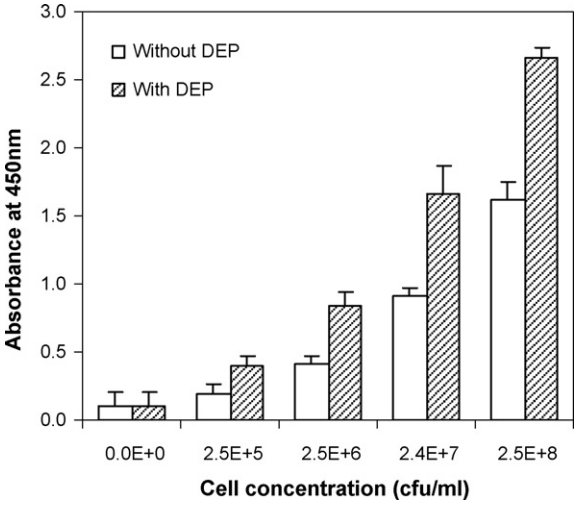

Fig. 6. The absorbance signals of the on-chip ELISA detection of the captured *Salmonella* cells with and without DEP assistance in the non-flow through chips.

DEP as the concentration step is very useful in both flow through and non-flow through microchip platforms for bacterial cell detection. Flow through microchips allow continuous injection/perfusion of bacterial samples and accumulation of the cells inside the fluidic chip even without additional concentration steps [40]. However, different concentration methods can be integrated with the flow through microchip to further help the accumulation/concentration of bacterial cells in the chips. For example, Varshney et al. [41] reported a microfluidic chip method that coupled antibody-coated magnetic nanoparticles as separation and concentration steps with an impedance sensor for detection of *E. coli* cells. The integration of DEP into flow through microchips can concentrate/accumulate bacterial cells in the chip for detection, and at the same time DEP also helps to improve the immuno-capture inside the fluidic chips [30]. The sample volume for fluidic chips can vary from several microliter to hundreds microliter, however, the larger the sample volume, the longer time it takes to inject the sample into the chips. The non-flow through microchip platforms usually use only one time addition of the sample. The sample volume is generally from several microliter to tens microliter. Therefore, it would be particularly useful to concentrate bacterial cells from the suspension to the chip surface to enhance the detection. This study demonstrated that the integration of DEP with non-flow through microchips could effectively concentrate bacterial cells from the suspension to the chip surface, and enhanced the immuno-capture efficiency by 3–5-folds in comparison with non-DEP assisted immuno-capture.

4. Conclusions

This study has demonstrated the successful integration of DEP with non-flow through biochips for immuno-capture and detection of foodborne pathogenic bacterial cells. DEP could serve two major functions in the biochips to significantly improve the chip performance: (i) concentrating bacterial cells from the suspension to different locations on the chip surface by positive and negative DEP; (ii) making the cells in close contact with the immobilized antibodies on the chip surface so that immuno-capture efficiency can be dramatically enhanced.

We have achieved the immuno-capture efficiencies of ~56.0% with 15 min DEP and ~64.0% with 30 min DEP to *Salmonella* cells in the non-flow through chip, which were 3–5-folds higher than ~10.4% and ~17.6% for 15 and 30 min immuno-capture without DEP, respectively. The captured bacterial cells were detected by the sandwich format ELISA on the chip. The final absorbance signals were enhanced by DEP assisted immuno-capture by 64.7–105.2% for the samples containing 10^3–10^6 cells/20 μl. The detection limit of the on chip ELISA detection with DEP assistance (5.0×10^3 cells/20 μl) was one order of magnitude better than that of without DEP (5.0×10^4 cells/20 μl).

This non-flow through microchip-based method integrated DEP, immuno-capture, and absorbance measurement, to detect foodborne pathogenic bacteria, and achieved enhanced detection signals. Microchips usually use very small sample volume, therefore capture of the cells from suspension to chip surface to enhance immuno-capture are particularly useful to improve the detection. Theoretically, the DEP assisted immuno-capture could be integrated with any other measurements to enhance final detection signals. This suggests that the integration of DEP with biochips has the potential to advance the state-of-the-art in chip-based immunoassay methods for microbial detections.

ABSTRACT

The quantitative determination of chemical elements in organic or biological samples is an important analytical problem. Normally the elements to be determined in the organic matrix must be transformed into a simple inorganic form. A digestion method by heating on a block digestor has been developed for the determination of Al, As, Ba, Ca, Cd, Co, Cu, Fe, Mg, Mn, V and Zn in Oyster tissue by ICP OES. A simplex centroid statistical mixture design has been used to study the effects of changing HNO_3, HCl and H_2O_2 reagent proportions on the digestion of these samples. Response surface and principal component analyses show that the species Ca, Cd, Cu, Fe, Mg, Mn and Zn have very similar analytical tendencies under this experiment. By means of mixture modeling maximum recoveries for these ions were predicted using 19%, 18% and 63% of the HCl, HNO_3 and H_2O_2 pseudocomponent mixtures, respectively. This corresponds to 21.4%, 30.8% and 47.8% of the HCl, HNO_3 and H_2O_2 commercial solutions. Furthermore the As, Co and V ions present large recoveries for these mixtures as well. The Al and Ba ion recoveries are seen to be independent of the mixture proportions. The analysis of Oyster tissue reference material (SRM 1566b – NIST) under optimized conditions at the selected wavelengths resulted in ion recoveries between 90% and 100%.

1. Introduction

Decomposition methods of biological samples are generally executed using two or more reagents because their different chemical properties can be exploited for the complete destruction of the organic material. Nitric and sulfuric acids, used individually or together with hydrogen peroxide are common digestion mediums. A reliable decomposition method that results in the complete solubilization of the biological sample while retaining the volatile components, reducing the contaminants, having low blank readings as well as an acceptable analytical frequency is one of the most critical steps of a spectrochemical analytical technique [1–4].

Biological materials rich in proteins and fats require high decomposition temperatures or the use of concentrated oxidizing mineral acid or a mixture of an oxidizing acid with hydrogen peroxide in open or closed systems with conventional or microwave heating [3].

Microwave (MW) radiation has become an analytical tool for sample decomposition. The use of high pressure flasks and oxidizing acids results in faster digestion permitting the processing of a larger number of samples while eliminating losses of volatile species. This technique, however, is sensitive to several factors such as sample mass, acid type, reagent proportions, temperature, pressure and heating time. Different researchers have employed MW ovens or steel bombs for the digestion of biological materials although sample mass and acid volumes were as small as possible to avoid a very acidic final solution as well as for safety reasons.

In these solutions trace elements are preferably determined using mass spectrometry with inductively coupled plasma (ICP-MS) [5] or atomic absorption spectrometry with electrothermal atomization (ET AAS) [6–8] but atomic emission spectrometry [9,10] can also be used.

Some researchers describe the use of acidic or alkaline solubilization [11,12] in open systems [13–16], with larger sample masses and reagent volumes than those used in closed systems, for the determination of trace elements in addition to major elements, although these processes are slow and inadequate to determine volatile elements.

Based on the above considerations the objective of this study is to optimize mixtures of an oxidizing (HNO_3) and non-oxidizing (HCl) acids and an auxiliary oxidizing agent (H_2O_2) to determine macro- and micro-constituents in Oyster tissue using block digestor heating under reflux (cold finger).

Unfortunately the optimum mixture of these components cannot be determined from chemical principles or existing information. For this reason statistical mixture designs are employed in this work to determine the mixture proportions that result in maximum percentage recoveries of the 12 metals from the organic material by inductively coupled argon plasma optical emission spectrometry (ICP OES) [17–20]. These designs are especially appropriate for this study since they not only permit a determination of the linear blending properties of each solution but also the second and third order synergic and antagonistic interaction effects among the mixture components for each of the metallic elements investigated.

2. Experimental

2.1. Reagents and solutions

All the solutions were prepared with analytical reagent grade and ultra pure water, obtained by a Milli-Q system (Millipore, USA, with a conductivity of 0.054 μS cm^{-1}). All the glassware and plastic flasks used were cleaned with a neutral detergent (5%, v/v), dilute nitric acid (10%, v/v for 24 h) and then with deionised water.

Multielement standards of Al, As, Ba, Ca, Cd, Co, Cu, Fe, Mg, Mn, V and Zn were prepared by dilution of 1000 μg L^{-1} standard solutions (Merck) of the elements. Analytical curves were made using the following concentrations of the analytes: (i) 0.5; 1.0; 2.0; 4.0; 6.0 μg mL^{-1} for Al, Cu and Fe; (ii) 0.02; 0.04; 0.10; 0.20; 0.40 μg mL^{-1} for As, Ba, Cd, Co, Mn, and V; (iii) 5.0; 10; 15; 20; 40 μg mL^{-1} for Ca, Mg and Zn.

2.2. Sample digestion

The solutions for each point of the mixture design were prepared weighing approximately 0.5000 ± 0.0001 g of reference material (SRM 1566b – NIST) in a digestion tube and adding volumes of 37% (v/v) HCl and 65% (v/v) HNO_3, as listed in Table 1. The tubes were put in a TECNAL model TE 040/25 block digestor. Cold finger condensors with water refrigeration were attached to the tubes. The system remained in operation overnight, at a temperature of 50 °C. After this step 30% (w/v) H_2O_2 was added and the temperature gradually raised until about 140 °C, with digestion occurring for 4 h at this temperature. After digestion the tubes were taken off the block digester and cooled to room temperature. The solutions were then transferred to a 25.0 mL volumetric flask with the volume being completed with ultra pure water [21]. The Al, As, Ba, Ca, Cd, Co, Cu, Fe, Mn, Mg, V and Zn concentrations were determined at the selected wavelengths shown in Table 2.

2.3. Statistical mixture design

Mixture properties are governed by reagent proportions and not by the total quantity of each reagent. The mixture proportions are not independent of one another since

$$f_{HCl} + f_{HNO_3} + f_{H_2O_2} = 1$$

where the f values are the volume fractions of the commercial grade acids. Since digestion is not recommended using pure acid or peroxide solutions only ternary mixtures of these solvents were investigated. To facilitate the statistical interpretation of the mixture models the component proportions were converted to pseudocomponents using the usual equation:

$$x_i = \frac{f_i - L_i}{1 - \sum L_i}$$

where L_i are the lower limits of the proportions of the components used in the mixture design, and f_i are the volume proportions. The subscript i represents HCl, HNO_3 and H_2O_2. The volumes of HCl, HNO_3 and H_2O_2 solutions used to make the mixtures and the corresponding pseudocomponent values are included in Table 1. Fig. 1 shows the compositions of the 10 mixtures investigated here. The vertices correspond to the pseudocomponent mixtures of the commercial solutions: (1) 10% HCl, 20% HNO_3 and 70% H_2O_2, (2) 70% HCl, 10% H_2O_2 and 20% HNO_3 and (3) 10% HCl, 10% H_2O_2 and 80% HNO_3. Since the pseudocomponents are linearly related to the volume proportions, model interpretation in terms of pseudocomponents is easily converted into laboratory values.

Mixture models are determined for each of the metallic ions being analyzed. The recovery value for each ion, y, is expressed as a function of the mixture pseudocomponents by linear, quadratic and special cubic models incorporated in the equation:

$$y = b_{HCl}x_{HCl} + b_{HNO_3}x_{HNO_3} + b_{H_2O_2}x_{H_2O_2} + b_{HCl-HNO_3}x_{HCl}x_{HNO_3} + b_{HCl-H_2O_2}x_{HCl}x_{H_2O_2} + b_{HNO_3-H_2O_2}x_{HNO_3}x_{H_2O_2} + b_{HCl-HNO_3-H_2O_2}x_{HCl}x_{HNO_3}x_{H_2O_2} + e$$

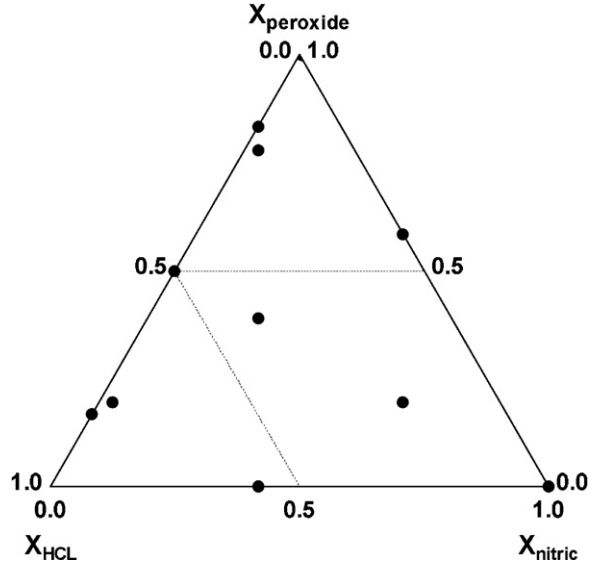

Fig. 1. Mixture design points, 1–10, of Table 1. The pseudocomponents correspond to the vertices of the inner triangle.

For additive mixture behavior a linear model including only the first three terms is adequate to describe percentage recovery. The b_{HCl}, b_{HNO_3} and $b_{H_2O_2}$ are linear blending terms reflecting the importance of each pure pseudocomponent on the percentage recovery. Synergic and antagonistic interactions between pairs of mixture pseudocomponents are given by the next three terms in the equation. Quadratic models contain all the terms in the above equation except the ternary mixture term that describes the interaction involving all three mixture components. The special cubic model includes all the terms in the above equation.

Linear, quadratic and special cubic models were determined for each of the metallic ions analyzed here, Al, As, Ba, Ca, Cd, Co, Cu, Fe, Mg, Mn, V and Zn. Attempts to obtain the best recovery percentage for all these ions involved determining individual linear, quadratic and special cubic models for each ion. These models were compared using ANOVA (ANalysis Of VAriance) and by calculating standard errors for each model coefficient. Models can be validated if they do not have statistically significant lack of fit at the 95% confidence level but have statistically significant regression results at this level. For those ions for which more than one model meets these criteria, the preferred model can be chosen based on the statistical significance of individual model coefficients.

The mixture that is optimum for the recovery of one element may not be optimum for the other ones. For this reason the validated models for all 12 ions must be examined to determine the most appropriate mixture for recovery of all the elements studied. In this case principal component analysis (PCA) and hierarchical cluster analysis (HCA) were used to treat all the experimental data simultaneously rather than individually. These methods allow the user to extract the maximum amount of useful information from multivariate data sets.

2.4. Instrumentation

The analytical measurements were made with a Perkin-Elmer Inductively Coupled Optical Emission Spectrometer, model Optima 3000DV (Norwalk, CT, USA), equipped with a peristaltic pump, a cross-flow nebulizer coupled to a Ryton double pass spray chamber (Scott type) and a ceramic central torch tube injector with an internal diameter of 2.0 mm. This instrument has a solid-state segmented array charge coupled device (SCD) detector and operates in radial and axial torch configurations. For the axial viewing mode a shear gas interface was used to strip off the cool plasma recombination area. The entire system is controlled with PE Winlab software. The spectrometer conditions [22] of operation are presented in Table 2.

3. Results and discussion

3.1. Statistical mixture design

Table 3 contains the recoveries percentage for Al, As, Ba, Ca, Cd, Co, Cu, Fe, Mg, Mn, V and Zn ions determined by digestion of the NIST 1556b reference material using the 10 mixtures of the statistical design. All determinations were performed in duplicate in order to validate the mixture models. Decompositions performed with the 2.8 mL HCl, 1.1 mL HNO_3 and 1.1 mL H_2O_2 solutions were not successful because the Oyster tissue was carbonized.

Linear, quadratic and special cubic models were determined for all the metallic ions. The coefficients and their standard errors for the preferred models for each ion are given in Table 4 for all ions except Al and Ba. The linear and quadratic models for Al suffered from statistical lack of fit at 95% confidence level whereas the special cubic model was not significant at that level. For the Ba ion all models showed insignificant regression results. As such the recoveries of the Al and Ba ions are predicted to be independent of the component proportions of the digestion mixture. Significant mixture models with no statistical lack of fit were found for all the other ions. Quadratic models were most adequate for describing the As, Ca, Cd, Cu, Fe, Mg, Mn and Zn ion recoveries. For all these models at least one binary interaction model coefficient was significant at the 95% confidence level. Furthermore none of the special cubic models for these ions had significant ternary interaction model coefficients. Linear models were validated for the Co and V ions. Their quadratic models did not contain any significant binary interaction model coefficients.

For each of these models the *F* distribution statistical for lack of fit was calculated using ANOVA. All the values given in Table 4 are much smaller than the 95% confidence critical *F* value demonstrating that the models accurately predict the recovery values within experimental error. Furthermore the *F* statistical values calculated for regression significance, also given in Table 4, are con-

Fig. 2. Principal component loading plot of the ion recoveries for the experiments of the mixture design. The cluster of points represents the Ca, Cd, Cu, Fe, Mg, Mn and Zn ions.

siderably higher than their corresponding critical values showing that recovery values indeed depend on the HCl, HNO_3 and H_2O_2 proportions.

The quadratic models in Table 4 contain some striking similarities. First, for all the ions except for As and Cu, $b_{H_2O_2} > b_{HCl} > b_{HNO_3}$. For the As model $b_{H_2O_2} > b_{HCl} = b_{HNO_3}$ and for Cu $b_{HCl} = b_{H_2O_2} > b_{HNO_3}$ within experimental error. Second, the HNO_3–H_2O_2 interaction coefficients are two to four times larger than the corresponding standard errors in each model with all these coefficients being significant at the 95% confidence level. The linear models for Co and V have some similarities to the quadratic models. Both models have $b_{H_2O_2} > b_{HCl} > b_{HNO_3}$ although no binary interaction terms were found to be significant.

The above similarities show that the percentage recoveries of these ions have similar dependencies on the HCl, HNO_3 and H_2O_2 proportions. The linear terms indicate that recoveries for these ions are highest for the H_2O_2 pseudocomponent (10% HCl, 20% HNO_3 and 70% H_2O_2 solution) followed by the HCl pseudocomponent (70% HCl, 10% H_2O_2 and 20% HNO_3) with the HNO_3 pseudocomponent (10% HCl, 10% H_2O_2 and 80% HNO_3) promoting the smallest recovery. The synergistic HNO_3–H_2O_2 interaction term provides significant contributions to the recoveries of As, Ca, Cd, Cu, Fe, Mg, Mn and Zn ions. The HCl–H_2O_2 binary interaction terms are positive for all these ion recoveries and usually are larger than their corresponding standard errors. However they are not significant at the 95% confidence level for any of these ions.

Principal component (PC) graphs are useful for illustrating the correlations between the analytical results of the different ions. Fig. 2 shows the loading graph for the first two principal components that represent 80% of the total variance of the data set in Table 4. The ion recoveries more adequately described by the quadratic models have almost identical loadings and their points form a tight cluster in the PC plot except for As point that is closer to this cluster than any of the other ion points. This indicates that ion recoveries for the experiments of the mixture design are highly correlated. Indeed correlation coefficients for all the ions in the tight cluster are 0.95 or more and between 0.72 and 0.78 for all these ions with the As ion. The V and Co ion points are close to each other and farther from the cluster. Their ion recoveries follow a linear model with $b_{H_2O_2} > b_{HCl} > b_{HNO_3}$ the same numerical ordering in the linear terms as have most of the quadratic models, but without any significant binary interaction. The Al and Ba ion recoveries with models indicating no dependence on the type of mixture used for

Table 5
Equivalent background concentration (BEC), limits of detection (LOD) and limits of quantification (LOQ) for the elements studied.

Element	Wavelength (nm)	Instrumental BEC ($\mu g\,mL^{-1}$)	BEC ($\mu g\,mL^{-1}$)	LOD ($\mu g\,mL^{-1}$)	LOQ ($\mu g\,mL^{-1}$)
Al	396.153	0.95	0.076	0.0025	0.0082
As	188.979	4.55	0.0028	0.012	0.04

Zn	213.856	0.06	0.0083	0.00001	0.000033

digestion have loading points at the bottom right far removed from the other points.

The contour lines for the response surface for Cd recovery are shown in Fig. 3. It is representative of all the elements that are described by quadratic models for ions with points in the tight cluster. The vertex for the H_2O_2 pseudocomponent is predicted to have higher recoveries than those for HCl pseudocomponent. The HNO_3 pseudocomponent is predicted to have the smallest recovery value. However does exist a high plateau region in the upper portion of the triangle with ion recoveries expected to be 95% or more. The plateau represents mixtures for which the synergic binary interactions have important contributions that increase ion recovery. A maximum recovery is predicted for 19%, 18% and 63% of the HCl, HNO_3 and H_2O_2 pseudocomponents, respectively. This corresponds to 21.4%, 30.8% and 47.8% of the HCl, HNO_3 and H_2O_2 commercial solutions used here.

3.2. Figures of merits

BEC, SBR and LOD were calculated according to the literature [23], relating to the analyte concentration and SBR (analytical signal and signal background ratio). Limit of quantification was calculated as 3.3 LOD [24].

Table 5 presents the values of BEC, LOD and LOQ. Comparing the values of BEC from the manufacturer with those obtained experimentally it is possible to conclude that the instrumental conditions of this work were robust ones as can be seen by the MgII/MgI ratio of 9.2 and by the low background signal.

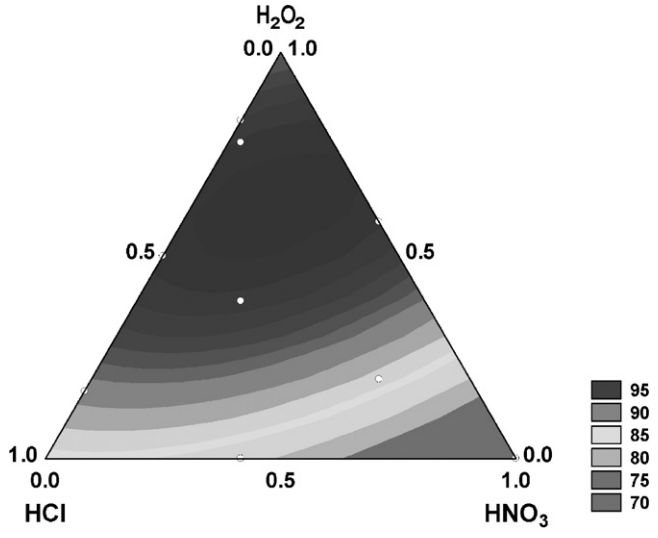

Fig. 3. Contour curves for the response surface of the Cd ion determined from the results of the mixture design.

Table 6
Concentration and recovery values for the analytes in the certified reference material (CRM 1566b).

Element	Concentration of CRM		Recovery (%)
	Declared value ($\mu g\,g^{-1}$)	Obtained value ($\mu g\,g^{-1}$)	
Al	197.2 ± 6.0	94 ± 8	47.9 ± 4.2
As	7.65 ± 0.65	7.52 ± 0.17	98.4 ± 2.2
Ba	8.6 ± 0.3	7.11 ± 0.39	92.9 ± 5.1
Ca	838 ± 20	877 ± 12	104.7 ± 1.4
Cd	2.48 ± 0.08	2.677 ± 0.56	108.0 ± 2.2
Co	0.371 ± 0.009	0.311 ± 0.017	83.8 ± 4.5
Cu	71.6 ± 1.6	72.8 ± 1.4	101.7 ± 1.9
Fe	205.8 ± 6.8	205.3 ± 2.7	99.8 ± 1.3
Mg	1085 ± 23	1106 ± 15	101.9 ± 1.4
Mn	18.5 ± 0.2	20.22 ± 0.47	109.3 ± 2.5
V	0.577 ± 0.023	0.393 ± 0.037	68.0 ± 6.4
Zn	1424 ± 46	1415 ± 61	99.3 ± 4.3

3.3. Validation of method

An evaluation of the accuracy of the digestion method using a digestion block was carried out under the optimized instrumental conditions. Table 6 shows good efficiency of digestion procedure with recoveries between 84% and 110%. Concentrations for Co and V in the certified reference material are lower than their LOQ values resulting in low recoveries. Aluminum also showed problems and this can be understood considering the need to add fluoridric acid in the sample for the recovery of aluminum since fluoride ion reacts with refractory oxides and forms a complex in order to increase the solubility [1].

Statistical tests using one-way ANOVA as well as the multiple Student and Newman–Keuls comparison methods were carried out to verify the existence of significant differences between results from the decomposition method with those of the reference material for the analyzed ions [25]. The null hypothesis indicating no significant difference at the 95% confidence level between the results of the proposed digestion method and the certified values was obtained for the As, Ba, Ca, Cd, Cu, Fe, Mg, Mn and Zn ions.

4. Conclusion

An optimum 21.4%, 30.8% and 47.8% mixture of HCl, HNO_3 and H_2O_2 commercial solutions was determined using a statistical simplex centroid design for the digestion of a biological sample and the subsequent determination of the Al, As, Ba, Ca, Cd, Co, Cu, Fe, Mn, Mg, V and Zn concentrations by ICP OES.

Humidity sensor

ABSTRACT

A novel humidity sensor made up of nano-crystalline zinc oxide (ZnO) film, coated onto the U-shaped typical glass substrate as a wave guide, conjugated with an optical fiber and He–Ne un-polarized laser source. The nano-crystalline zinc oxide (ZnO) was synthesized using single molecular precursor method. The resulting material was characterized with Fourier transform infrared spectroscopy (FTIR), X-ray diffractometry (XRD), thermogravimetric-differential thermal analysis (TG-DTA) and scanning electron microscopy (SEM). In the thin film, ZnO particles exhibited the wurtzite phase structure with the particle size in a diameter range of 70–80 nm. The humidity sensing characteristic has been estimated by measuring the optical permeability (OP) as a function of percentage relative humidity (%RH) in the ranging from 5 to 90 inside a closed chamber. The OP decreases linearly with increase in %RH with a respond time of about 30 and recovery time of 35 s. The sensor exhibits the sensitivity of 0.45 in the %RH range 5–50 and 0.30 from 50 to 90.

1. Introduction

In the recent years, humidity sensors have been gained much attention of scientists because of their demand for the monitoring of humidity in the environment and also in various industrial processes including food, electronics, textile, and pharmaceuticals [1–4]. It is found that most of the existing humidity sensors are based on the modulation of range of materials in their electrical parameters like resistance, capacitance or conductance [5–7]; however, they are expensive, large in size, and sometimes cannot operate at room temperature. Thus, much attention has been paid lately to the development of compact, low-priced sensors that can detect humidity in real time at room temperature.

Particularly, with the advent of optical fiber technology, a considerable level of research has been focused on fiber optic based techniques especially for humidity sensing. The fiber optic based humidity sensors show additional features such as small size, immunity to electromagnetic interference, multiplexing, remote sensing capabilities and offer specificity and efficiency for the detection of wide range of analytes [8–12]. A fiber optic detection system, comprises: (1) a light source; (2) an optical sensitive layer; (3) an optical detector with optical connection. The optical fiber has a plurality of bends which follow a circuitous path and establishes a detection zone of the optical sensor [13–16].

In this context, the use of nano-materials to fabricate sensors is one of the most exciting approaches because nano-materials have a unique structure and high surface-to-volume ratio. The surfaces of nano-materials can also be tailored in the molecular scale in order to achieve various desirable properties [17]. Many attempts have been made to fabricate nano-crystalline ZnO of unique properties for versatile applications in the area of transparent electronics, light emitting diodes, piezo-electric devices, spin electronics and chemical sensors [17–20]. Further, nano-crystalline ZnO has stable structure with good chemical stability and favorable properties that are suitable for device fabrications [21–25]. In the past few years, many reports have been published on the fabrication of ZnO films of different surface morphologies such as single and multi-dimensional nano-structural shapes like nano-wire, nano-tube, nano-ring and nano-tetrapods using various film deposition techniques for example chemical vapor deposition, thermal evaporation, electro-deposition [26–30]. Although physical processes are prevailing for the synthesis of the nano-structured ZnO but the chemical methods such as electro-deposition, polymer assisted growth and sol–gel have been developed simultaneously. Among them, sol–gel methods have proven the easiest ways to form ZnO

nano-structures at relatively lower temperature and less rigorous synthesis conditions [31–33].

Recent development of nano-materials, with every imaginable combination of physical and chemical characteristics, has led to the fabrication of efficient humidity sensors that can be used for a wide range of applications. Zhou et al. reported fiber optics based humidity sensors using etched borosilicate optical fiber segment doped with $CoCl_2$ that sense humidity by in-line absorption technique [34]. Otsuki et al. have prepared rhodamine-B doped HPC film and they observed humidity sensing measurements with U-bent fiber [35]. Gupta et al. fabricated phenol red doped polymethyl methacrylate film based humidity sensor having limited detection range from 30 to 80%RH [36,37]. Also, the doped and undoped nano-structured ZnO were used to detect humidity using various transducers as listed in Table 1. Most of the reported humidity sensors are not widely adaptable due to their limited operational range, cost effectiveness and risky temperament. Therefore, it will be interested to prepare an efficient humidity sensor of a wider operational range using eco-friendly nano-materials such as nano-crystalline ZnO at room temperature.

This study investigates the feasibility of nano-crystalline ZnO film for a potential humidity sensor. A typical U-shaped nano-crystalline zinc oxide coated Pyrex glass rod has been used as sensing element, conjugated with an optical fiber, and He–Ne unpolarized laser source. The advantageous features of the present sensor include low price tag, ease of fabricated, sufficiently larger operational range, good stability and sensitivity.

2. Experimental

2.1. Materials

Zinc acetate dihydrate ($Zn(OAc)_2{\cdot}2H_2O$, 99%, Sigma–Aldrich), ethanol (99.5%, E. Merck), methanol (99.8%, E. Merck) and benzene (99.8%, Sigma–Aldrich) were used without further purifications.

2.2. Synthesis of precursor

To prepare the precursor solution, 50 mM of $Zn(OAc)_2{\cdot}2H_2O$ was dissolved in a 25 mL of anhydrous ethanol. Next, the resulting mixture was stirred for 2 h at room temperature until the $Zn(OAc)_2{\cdot}2H_2O$ flakes were completely dissolved. In the obtained homogeneous solution, added 5 mL of anhydrous benzene and again stirred at 60 °C for 24 h. The solution is then kept at standing for 72 h to ensure hydrolytic stability against any sort of precipitation, coagulation or suspension. The prepared precursor solution was used further for the fabrication of nano-crystalline ZnO films.

2.3. Preparation of precursor film

In our already ongoing laboratory programme for developing metal oxide thin film or coatings on variedly shaped complex substrate, we have preferred relatively convenient 'spin casting' or dip coating methodology. To facilitate prior physico-chemical and spectroscopic characterizations, we have also casted the precursor film on the glass substrate and then subjected it to thermal treatment through gradual heating up to ~500 °C. The thickness of representative nano-crystalline ZnO films was measured using profile-meter (SPN Technology).

2.4. Characterization

The produced film has been characterized using FTIR, TGA-DTA, XRD, and SEM techniques. FTIR spectra are recorded by a PerkinElmer (RK-1310) FTIR spectrometer by making pellet with dehydrated KBr at 10 ton pressure. The thermal analysis was carried out with a Rigaku Thermoflex PTC-10A thermal analyzer at 10 °C min^{-1} heating rate. The nano-sized crystalline structure of the ZnO film was studied by Rigaku Rotaflex (RAD/Max-200B) XRD spectrometer, Rigaku Corporation Japan at 1° min^{-1} scanning speed and JEOL-840 scanning electron microscope, JEOL Corporation Japan operated at 15 kV. The films were sputter-coated with a thin layer of gold (~20 nm) prior to the morphological examination.

2.5. Fabrication of film on U-shaped glass rod

The glass rod with the diameter of 1 mm has bent in U-shaped and dipped in the above prepared precursor solution, dried and then gradually heated again up to ~500 °C to obtain nano-crystalline ZnO cladding.

2.6. Device fabrication, assembly and sensing measurements

The nano-sized ZnO coated U-shaped Pyrex glass was fixed on the wall of a glass chamber (4 cm × 7 cm) via two holes. The resulting both arms of U-shaped glass were projected outside and coupled with optical fiber. The optical fiber was a standard single mode optical fiber at 1300 nm with core and cladding diameters of 8.3 and

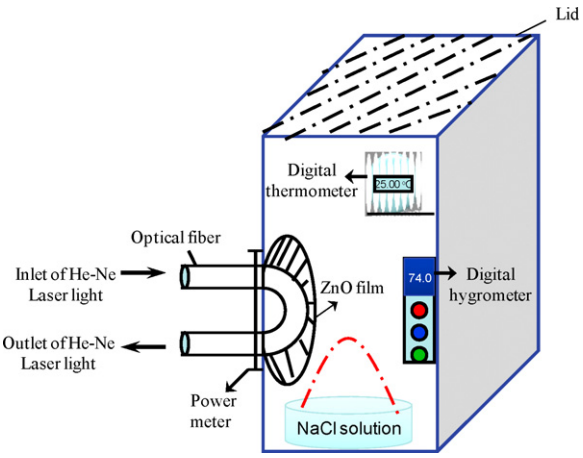

Fig. 1. Schematic illustration of optical fiber based humidity sensor using nano-crystalline ZnO film as a sensing element in a complex device assembly.

125 μm, respectively (cable type OFNR from Optical Cable). The unpolarized laser light from He–Ne laser source (2 mW) was passed from one end of the fiber and the output intensity was measured at the other end of the optical fiber. The photo-detector-II (Epitaxx InGaAs Photodetector, type ETX) was used to provide a reference for the optical power incident at the nano-crystalline ZnO film coating. The photo-detector-I (Anritsu Optical Power Meter ML93B) measured the reflected optical power. The saturated solution of KOH was used to control %HR of the glass chamber and also monitored by a reference hygrometer. During our experimental observations setup, the relative humidity inside the sensing chamber was variably controlled up to 90%. A thermometer with least count of 0.1 °C was also positioned together for monitoring the temperature inside the chamber. The complete experimental setup is shown in Fig. 1. All experiments were conducted at room temperature (~25 °C), with the same sensor used for each set of measurements. Prior to each measurement the sensor was heated in vacuum at 100 °C for 2 h to completely remove the adsorbed moisture. All measurements were carried out at 25 °C.

3. Results

The deposition of film specifically on a complex shaped substrate has been found relatively a difficult task often as the challenging ones, apart from being expensive as experienced by us in our previous studies. In the present study, U-shaped Pyrex glass rod was employed as a candidate to act as a prospective wave guide when carefully clad with nano-crystalline ZnO film with a desired as homogenous cast as possible. We prepared the nano-crystalline ZnO film as described in the literature [38]. To modify or if possible to work out in parallel methodology, where procuring nano-crystalline ZnO film on the above mentioned target could be made simple and cost effective. Thus, we happened to devise–design–develop and arrive at a method to prepare a precursor solution desirable for casting of ZnO thin film, coatable onto any complex shape of glass substrate, i.e., just by dipping substrate into the precursor solution, drying and then firing at a desired temperature to an optimum duration.

3.1. FTIR spectra

The soluble form of the precursor, coated on the glass substrate as a film at room temperature and subjected to a scratched portion of the film for the FTIR investigation in the region from 500 cm^{-1} to 4000 cm^{-1}. The spectrum given in Fig. 2A, clearly shows a broad

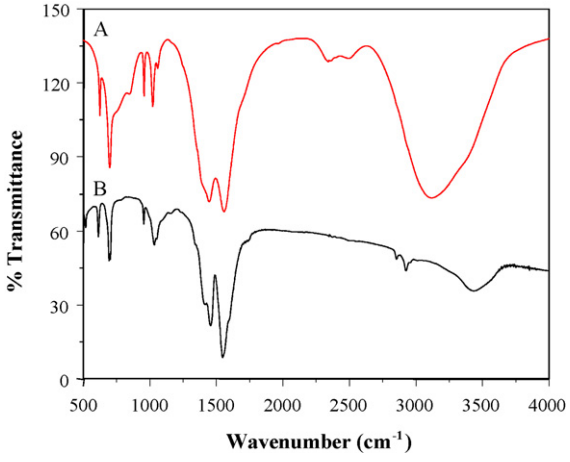

Fig. 2. FTIR spectra of the ZnO film prepared at: (A) room temperature and (B) after heat treatment at 500 °C.

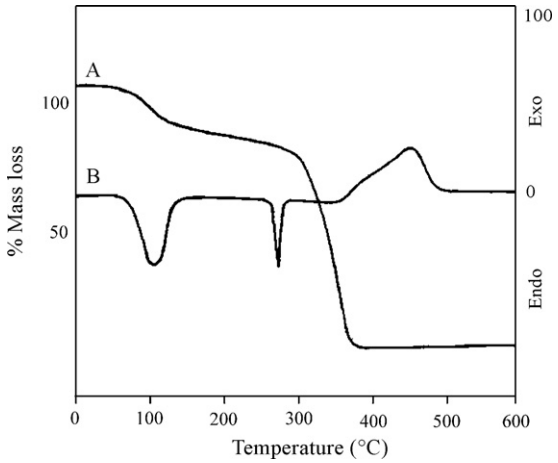

Fig. 3. (A) TGA and (B) DSC profiles of the prepared ZnO film.

strong band centered around 3130 cm^{-1} possibly due to the presence of –OH stretching vibrations contributed by the surrounding solvent molecules. The two bands appearing at 1554 cm^{-1} and 1440 cm^{-1} may attribute to the presence of anti-symmetric and symmetric C–O stretching vibrations, respectively, which confirm the presence of acetate group in the precursor. Though further investigations are required while ascertaining various modes of coordination involved in carboxylate bonding with the metal ions, the current individual positions and particularly the separation between the asymmetrical C–O (~1554 cm^{-1}) and symmetrical C–O (~1440 cm^{-1}) stretching vibrations probably indicate rather bridging modes of coordination involving in the acetate group surrounding the zinc metal ions.

In another supporting exercise, the above precursor film was subjected to gradual heating and maintained for some time at ~500 °C, cooled to room temperature and then subjected to FTIR investigations. The spectrum is given in Fig. 2B. It was observed that after treatment, the broad band at ~3130 cm^{-1} in Fig. 2A was found somehow completely missing in Fig. 2B. But appear a new band centered on ~3444 cm^{-1}. The individual position and separation between anti-symmetric and symmetric carboxylate stretching vibrations were again observed with a considerable shift at ~1546 cm^{-1} and 1458 cm^{-1}, respectively. It indicates that the surroundings of zinc metal ion including the modes with the carboxylate binding and resulted a positive change evolving through metal oxygen bonds. It suggests that after the gradual heating precursor film produces anhydrous zinc oxide film. Hence, heat treatment is a basic requirement for anhydrous fabrication of zinc oxide film.

3.2. Thermogravimetric analysis

Thermal behavior of a scratched portion of the ZnO precursor film has been recorded and is shown in Fig. 3. The TGA curve shows two-step mass losses, first at ~125 °C due to desolvation and second at ~320 °C due to decomposition of intermediate to form zinc oxide. The observed and calculated weight change of the precursor film at different steps is corresponding to the zinc acetate. The data is given in Table 2.

The DTA curve as in Fig. 3 is showing three peaks at temperatures 100.4 °C (endothermic), 256.7 °C (endothermic) and 452.3 °C (exothermic). The first endothermic peak is due to desolvation and second is because of the melting of precursor, while the third exothermic peak is associated for the decomposition of zinc acetate [39]. The thermogram indicates that decomposition of zinc acetate completed at ~400 °C. Therefore, in order to prepare a ZnO film, it

Table 2

Sl. no.	Temperature (°C)	Nature	Inference
1	100.4	Endothermic	Desolvation
2	256.7	Endothermic	Melting
3	425.3	Exothermic	Decomposition

is necessary to anneal the precursor film above 400 °C. The heating at 500 °C is done in the present study in order to ensure complete decomposition of zinc acetate precursor into ZnO. The transition temperatures, nature and inference about precursor film concluded from DTA curve is also tabulated Table 3.

3.3. XRD spectra

The ZnO precursor film, after heating at 500 °C has been examined by XRD and the diffraction pattern shown in Fig. 4. The observed peaks in XRD are matching with the reported diffraction peaks for ZnO for wurtzite hexagonal structure [39]. In the XRD pattern ZnO film shows the sharp X-ray reflection at $2\theta = 31^\circ$ (1 0 0), 34 (0 0 2), 36 (1 0 1), 47 (1 0 2), 56 (1 1 0), 62 (1 0 3), 66 (2 0 0), 67 (1 1 2), 69 (2 0 1), 72 (0 0 4), and 76° (2 0 2). These peaks correspond to nano-crystalline ZnO. The crystallite size of ZnO nano-particles was calculated using the Scherrer's equation [40] and was found to be in the range of 70–80 nm.

3.4. SEM study

SEM image of the ZnO film (after heat treatment at 500 °C) is shows as in Fig. 5. The microstructure of ZnO film illustrates a homogeneous distribution of globular particles in a porous film surface. The estimated value of ZnO particles in the film was measured in a range of ~70–80 nm. It appeared that some of the ZnO particles visualized bigger. It may happen due to the agglomeration of neighboring ZnO particles. In this context, the dip coated precursor of ZnO film can be converted into nano-crystalline ZnO film. The obtained film has a unique surface structure and can provide a high surface-to-volume ratio for the adsorption of humidity over the film.

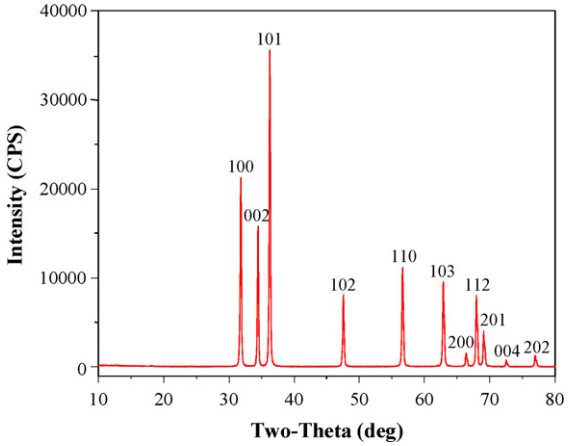

Fig. 4. XRD of the ZnO film after heat treatment at 500 °C.

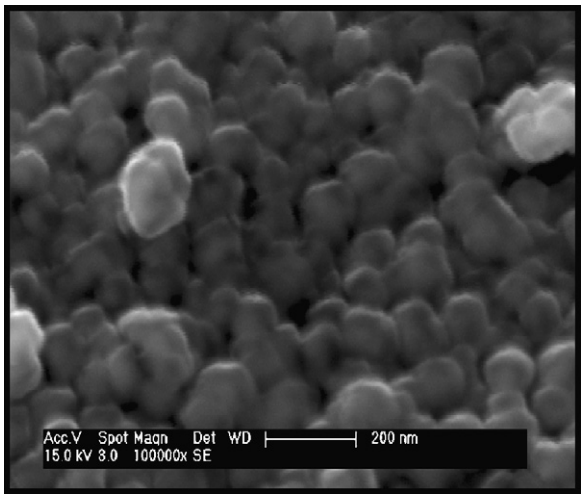

Fig. 5. SEM micrograph of the nano-crystalline ZnO film after heat treatment at 500 °C.

3.5. Humidity sensing behavior

The humidity sensing behaviors of nano-crystalline ZnO film (thickness of film = ~600 nm) were evaluated by the reported method [34]. The change in the optical permeability of the sensing probe, i.e., U-shaped nano-crystalline ZnO film as a function of %HR and time was recorded in a closed chamber at room temperature. Fig. 6 shows the variation of output Ir/Ii versus %RH profile of U-shaped nano-crystalline ZnO film with varying %RH in the presence and absence of interferences such as methanol and ethanol. The output Ir/Ii decreases with an increase in %RH ranging from 5 to 90. In general, the optical permeability of probe decreases

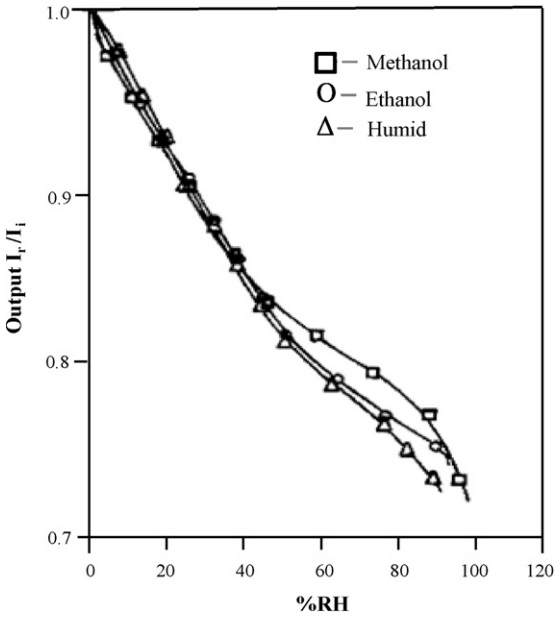

Fig. 6. Linear relationship between optical output and relative humidity content up to 90% at 25 °C.

Table 4
Effect of interference on the nano-crystalline ZnO humidity sensor at 25 °C.

Sl. no.	Analyte/interference	Output Ir/Ii
1.	75%HR	0.76
2.	75%HR + ethanol (80 mM)	0.77
3.	75%HR + methanol (80 mM)	0.80

linearly with increase in %RH and exhibits the sensitivity of 0.45 (%RH range 5–50) and 0.3 (%RH range 50–90). The effect of interferents (methanol and ethanol) was studied on the output Ir/Ii responses of the probe (Table 4). The volatile methanol (80 mM) and ethanol (80 mM) were added into the sensing chamber. It was found that the presence of interferents had a negligible effect at %RH ranging from 5 to 45 but after that optical response was obtained about 2–6% higher than those obtained from the standard method; therefore, using this probe, %HR can be detected negligible interference.

The sensitivity of the sensor was estimated from the measured value of output Ir/Ii (i.e., optical permeability) in the evacuated chamber or/and at a fixed %RH. The graph of changes in output Ir/Ii of the probe as a function of time is shown in Fig. 7. With exposure of humidity (%HR 80) to probes, the sudden decrease in output Ir/Ii was observed at 25 °C. The U-shaped nano-crystalline ZnO film was obtained a response time of ~30 s and a recovery time of about 35 s. Table 1 compares the characteristics of nano-sized ZnO based humidity sensors as reported in the literature. From this table it is clearly observed that most of the reported humidity sensors are not widely adaptable due to their limited operational range, cost effectiveness and risky temperament. Thus, present nano-crystalline ZnO probe exhibited as an efficient humidity sensor of a wider operational range with higher selectivity, sensitivity at room temperature. The lifetime of the nano-crystalline ZnO probe was determined by measuring the current up to ~6 months at an interval of 7 days. It was observed that the optical permeability decreased slowly with the increase in time period. After 6 months, the decrease in optical permeability was found to be about 18%.

The lowest detection limit of the %HR was found to be about ~0.45. The reproducibility of the response of the probe was investigated at a 45%RH. No significant decrease in optical response was observed after at least 10 uses in testing; thus, the sensing probe displayed good reproducibility. The relative standard deviation was found to be about ±4% determined by five successive measurements of a 45%RH standard using a single probe. In a series of 10 sensors using 10 different U-shaped nano-crystalline ZnO film sensing probes, a relative standard deviation of about ±5% was obtained for the individual optical response at constant 45%RH. Thus, a good reproducibility was observed with the sensor.

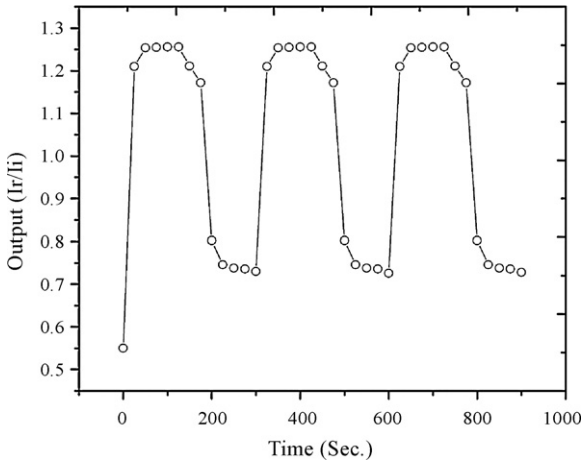

Fig. 7. Effect of time on the output power of the nano-crystalline ZnO film with 80% RH at 25 °C.

4. Discussion

During past few years, a great advancement has been ended in the field of optical fiber based humidity sensors [41,42]. In these devices, external perturbation involving physical forces such as temperature, pressure, composition of liquid and gas phase induces the change in intensity phase or polarization of magnetic wave propagating through the sensing element like optical fiber, glass plate or prism, etc. The magnitude of emerging light is related to changes in refractive index of optical fiber [43]. The change in refractive index depends on the cladding materials and adsorbed chemical species. It is known that, while entering the cross-section of the optical fiber, laser light obeys the Snell's law:

$$n_1 \sin\theta_1 = n_2 \ \sin\theta_2 \tag{1}$$

where, n_1 and n_2 are the refractive index (RI) of the first medium, i.e., air and the optical fiber respectively. θ_1 is the angle of incidence at the axis of the optical fiber where as θ_2 is the angle of emergence in the optical fiber. By using the basic optical geometry, one can show that:

$$\text{Numerical aperture (NA)} \ = \sin\theta_1 = \sqrt{n_c^2 - n_l^2} \tag{2}$$

Eq. (2) shows that NA is directly proportional to θ_1 which depends on n_c and n_l, i.e., RI of core of the optical fiber and that of cladding around the fiber which is nano-crystalline ZnO film in the present experimental setup. n_c is constant and n_l value is being changed in the experimental setup by varying the humidity around the nano-crystalline ZnO film on the optical fiber. Thus the net value of RI of the cladding and the humid medium is being denoted by n_{net} and Eq. (2) can be written as

$$\sin\theta_1 = \sqrt{n_c^2 - n_{net}^2} \tag{3}$$

Eq. (3) can also be interpreted using the elementary geometrical optics, that higher is the value of NA, more the cone of laser light will be able to enter the optical fiber and hence more intensity of light will be able to pass through the optical fiber.

The refractive index of glass is 1.5 and ZnO is ~2.0, therefore, the net refractive index or composite refractive index n_{net} of sensing element (U-shaped nano-crystalline ZnO film) is increased. It further decreases after adsorption of H_2O molecules with refractive index 1.33. In any medium, when water vapor content increases, the amount of oxygen and nitrogen decreases per unit volume and the density will decrease because the mass decreases as dry air is denser than the humid. It is also a common fact that in all transparent medium the optical density is in direct proportion to its mechanical density and also the RI of the medium. Since the optical density of the humid medium is inversely proportional to magnitude of its humidity. In other words, as the humidity of the medium increases, its rarity increases. This in turn causes n_{net} change as result of which NA will decrease (cf. Eq. (3)). Thus, on the other side of the optical fiber, less light will be able to pass through.

This expected result is in quite good agreement with our experimental results as shown in Fig. 6. The optical output power (OP) decreases linearly with increase in humidity content up to 90%. It may be because adsorption of water vapor on the surface of nano-crystalline ZnO film causes the change in refractive index and successively numerical aperture of used optical fiber. This also changes light output power emerging out from optical fibers. The ZnO films prepared by sol–gel technique are offered the fine particle on glass rod. The nano-sized ZnO particles on the surface of the glass rod enhances the surface activity of the film, and useful

for adsorbing polar molecules including water vapor. The sensitivity of the film was calculated from Fig. 6 and found to be 0.45 to the range of 5–50% and 0.3 for the range of 50–90%. It indicates better sensitivity in the lower range. The best linear fitting is observed in all the three cases: (1) with varying %RH, (2) with varying %RH in the presence of 80 mM ethanol and (3) with varying %RH in the presence of 80 mM methanol. It was found that the presence of interferents had a relative error of less than 4% in the optical method; therefore, this humidity sensor can detect %RH with negligible interference.

Fig. 7 shows the change output power with the time at 80% RH. The maximum change in output power was observed at ~30 s and this will be response time of sensor [44]. After then the graph shows a flat region up to 35 s and then increases to approximately original value which proves the good reversibility, recovery and reproducibility of the nano-crystalline ZnO coated optical fiber as a humidity sensing element, and the device as a humidity sensor after due calibration. The recovery of adsorbed moisture took place at 80% HR at 25 °C, while complete recovery of adsorbed moisture was observed after evacuating at 45 °C. Therefore, one can conclude that co-efficient of adsorption is proportional to the amount of humidity around the nano-crystalline ZnO film, which can be a versatile principle of fabricating a humidity monitoring device. This is because the adsorption of water molecules on cladding changes the effective refractive index of the wave guide, this change would shift the coupling angle and would be detected as an apparent absorbance [15].

There are various forces responsible for adsorption namely the physical and chemical forces [45]. The reversibility in R_f value is related to types of surface binding. If the H_2O is weakly bonded, i.e., physical adsorption, reversal of nano-crystalline ZnO surface is possible along with the change in R_f value after the change in vapor pressure in the surrounding. Further, if H_2O is strongly adsorbed on the nano-crystalline ZnO surface, it does not recover nano-crystalline ZnO surface because of change in water vapor pressure in surrounding of optical fiber. This may depend on the particle size, surface area, and the adsorption binding energy. In the present case, an isothermal TGA–DTA at 45 °C and 30 °C was recorded and observed the weight loss of moisture without any significant DTA peaks. It confirms the formation of very weak type of interaction appeared in between H_2O and nano-crystalline ZnO surface in the study.

Moreover, not all light, which is coupled or allowed into the fiber, will emerge from the fiber. Several attenuations take place during the course of transmission of light through the core for example light striking the core cladding interface at an angle larger than the critical angle (θ_c) is no longer completely transmitted. This microscopic non-uniformity of the RI partially scatters the light into much direction, known as Rayleigh loss. Here, in explaining the experimental results of our experiment, we are not concerned with any of the above mentioned losses, as they remain constant for any optical fiber in use. We are mainly concerned with the loss of intensity of light because of variation of numerical aperture due to variation in the value of RI of the humid medium around the cladding.

5. Conclusion

The sol–gel deposited ZnO film has been prepared with ZnO particles size 70–80 nm size, becoming sensitive for humidity adsorption application. It would be utilized for monitoring the change in humidity in the environment and can be employed safely in many possible applications. Also, nano-crystalline ZnO film was deposited on the U-shaped glass rod, where the change in optical output power corresponds to change in humidity. This can be calibrated as a humidity sensor element and are more convenient than the conventional humidity sensors. In conclusion, as the humidity around the cladding is increasing, output power is decreasing because the change in refractive index. This, perfectly, is in agreement with our experimental results and can be an underlying principle for humidity detecting devices.

Metabolite identification

ABSTRACT

Metabolite identification for the compounds that undergo multiple and sequential metabolism is still a great challenge. Echinacoside (ECH), a typical phenylethanoid glycoside, contains multiple unstable chemical bonds and high reactive functional groups which are susceptible to multiple pathways of degradation and metabolism, leading great difficulties for its metabolite identification. This study proposed a novel approach for rapidly identifying the complicated and unpredictable metabolites of ECH, based on the powerful liquid chromatography hybrid ion trap and time of flight mass spectrometry (LC/MS-IT-TOF) analysis. Four degradation products were rapidly identified via the "fragmentation–degradation" comparisons. Five phase I and phase II metabolites of the degradation products were rapidly characterized via the crossover mass differences comparisons of their quasi-molecular ions with the potential precursors. Four direct phase I and phase II metabolites of the parent compound were identified by the mass differences analysis of the molecular ions between metabolites and the parent compound. Multiple stages of fragmentation patterns were used to confirm the metabolites characterizations. This study provides a novel approach to characterizing the complicated metabolites, and would be widely applicable for the metabolite identification of natural products.

1. Introduction

Phenylethanoid glycoside is a class of polyphenolic compound distributed in many plants. They are reported to posses cytostatic [1], cardioactive [2], hepatocyte protective [3], antibacterial, antioxidative [4], neuroprotective [5] effects and so on. In particular, echinacoside (ECH), a representative phenylethanoid glycoside contained in Herb Cistanchis [6], *Echinacea angustifolia* and *E. pallida* roots have been the best-selling herbal medicine in the United States and Europe as the immunostimulant [7]. It has been also observed to have various kinds of other pharmacological activities including antioxidant [8–10], neuroprotective [11] and anti-inflammatory [12].

In spite of the well defined pharmacological activities of phenylethanoid glycoside, very less is known about its pharmacokinetic and metabolic characteristics. Previous studies showed that no phenylethanoid glycoside was detected in human plasma after echinacea tablets ingestion [13] and the bioavailability of echinacoside in rat was only about 0.83% [14], suggesting poor membrane permeability and/or extensive presystemic metabolism.

The chemical structure of ECH is composed of three chemical moieties including cafffeic acid (CA), phenylethanoid aglycone (PhA, 3,4-dihydroxyphenethyl alcohol, hydroxytyrosol), and sugar. The chemical bonds linking these moieties and the multiple hydroxyl groups in ECH structure are susceptible to multiple and sequential routes of hydrolysis, phase I (oxidation and reduction) and/or phase II (glucuronic acid, sulfate, and methyl conjugation) metabolism. Thus, we hypothesized that ECH may be susceptible to extensive and multiple metabolism. In a recent study [15], eight phase II metabolites (methyl and glucuronic acid conjugations) of ECH were identified from the rat bile samples. Although this study resulted in an unambiguous identification of eight metabolites of ECH by using NMR, we hypothesized that there should have much other metabolites failed to be identified, in view of the characteristics of ECH chemical structure. The present study was thus aimed to characterize ECH metabolites from rat urine and feces as many as possible.

Despite the recent advancement of various analytical tools, the metabolite identification for the compounds undergoing multiple and unpredictable metabolism from the biological matrix remains still a great challenge. In the past few years, mass spectrometry (MS) coupled with chromatographic separation has become a powerful and frequently used technique for metabolite identification. For their low sensitivity in full scan mode, LC/MS or LC/MS/MS are challenged for complex biological samples containing many compounds [16]. In contrast, LC–TOF/MS characterized with a wide mass range, sensitivity in full scan mode, the high resolving power, and accurate mass measurement, enables to the powerful identification of non-target compounds at trace level [17,18]. In addition, LC–IT/MS is also a useful tool for identifying unknown compounds because of its ability to gain abundant fragment ions [19]. The LC/MS-IT-TOF and LC–QTOF/MS, a combination of these two techniques can provide structural information from fragmentation as well as elemental compositions from accurate mass measurement, which represents a powerful tool to analyze unknown compounds of trace levels in complex matrices [20–27].

The present study was thus designed to detect and identify the metabolites of ECH in urine and feces based on the powerful LC/MS-IT-TOF analysis. A generally applicable approach to identifying the complicated metabolites including the degradation products, the phase I/phase II metabolites of the parent compound and its degradation products has been proposed in this study.

2. Experimental

2.1. Chemicals and reagents

Echinacoside (powder, purity 96.4%) was separated and purified from an ethanol extract of Cistanche tubulosa (Schenk) R. Wight [14]. Verbascoside (powder, purity 98.8%) was purchased from Chengdu Push Bio-Technology Co., Ltd. (Chengdu, Sichuan, China). 3,4-Dihydroxyphenethyl alcohol (oil, purity 98.5%) was from Chengdu Biopurify Phytochemicals Ltd. (Chendu, Sichuan, China). Caffeic acid (CA, powder, purity >98%) was from National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China). HPLC grade acetonitrile and methanol was obtained from sigma company, USA. Solid-phase cartridge was from Waters Chromatography (HLB 6cc, OasisTM, Waters, USA). Deionized water was purified using a mili-Q system (Milipore, Milford, MA, USA). Acetic acid and other chemicals and solvents used were all of analytical grade.

2.2. Drug administration and sample collection

Sprague–Dawley rats (230–250 g) were obtained from academy of military medical sciences (Beijing, China) and housed with unlimited access to food and water except for fasting 12 h before experiment. The rats were maintained on a 12 h light–dark cycle (light on from 8:00 to 20:00 h) at ambient temperature (22–24 °C) and ca. 60% relative humidity. After an oral administration of echinacoside 1.5 g/kg, urine was collected at 6, 12, 24, and 36 h in ice-bath. Feces were also collected at 24 and 36 h. All samples were stored at −80 °C immediately after collection.

2.3. Separation and extraction procedures

Solid phase extraction (SPE) was used to extract the metabolites from the biological samples. All samples were thawed in a water-bath at 37 °C. The 1:2 dilution of urine samples and the 1:10 dilution of feces homogenate samples were added onto the SPE cartridge, which had been previously activated with 4 mL methanol and equilibrated with 4 mL water. After the sample had been absorbed by the cartridge, the cartridge was washed with 2 mL water, and then eluted with 3 mL methanol. The elution was then evaporated under an air stream at 25 °C in a water-bath. The residue was reconstituted in 200 μL of methanol with vortex. After centrifugation at 20,000 × *g* for 10 min, 100 μL of supernatant was drawn and 5 μL was injected into the LC/MS-IT-TOF.

2.4. Instruments and analytical condition

LC experiments were conducted using a Shimadzu (Kyoto, Japan) HPLC system consisting of an LC-20AB binary pump, an SIL-20AC autosampler, a CTO-20AC column oven and an SPD-M20A PDA. Chromatographic separation of analytes was achieved using a 100 mm × 2.0 mm capcell pak C18 MG analytical column (Shiseido, Tokyo, Japan) protected by a Security guard (Phenomenex, USA). The column and autosampler tray temperatures were set at 25 and 4 °C, respectively. The mass detection was carried out using a hybrid Shimadzu ion trap/time-of-flight mass spectrometry (IT-TOF/MS) (Shimadzu, Kyoto, Japan), equipped with an electrospray ionization source. In automatic mode, all ions were firstly accumulated in octopole and then rapidly pulsed into IT for MS^n analysis according to the criteria settings. All ions produced were finally introduced into the TOF instrument for accurate mass determination. Data acquisition and analysis were performed with LC solution 3.0 software (Shimadzu, Kyoto, Japan).

A mobile phase composed of eluent A (0.1% acetic acid in water, v/v) and B (acetonitrile) with a gradient elution was employed for the separation. The mobile phase was programmed as follows: an isocratic elution of 5% B for the first 10 min, followed by a linear gradient elution of 5–10% B from 10 to 20 min, 10% B from 20 to 30 min, 10–30% B from 30 to 50 min and 30–70% B from 50 to 60 min. After holding the solvent composition of 70% B for the next 10 min, the gradient was returned to its starting conditions.

The optimized MS conditions were as follows: negative ion mode; electrospray voltage, −3.5 kV; CDL temperature, 200 °C;

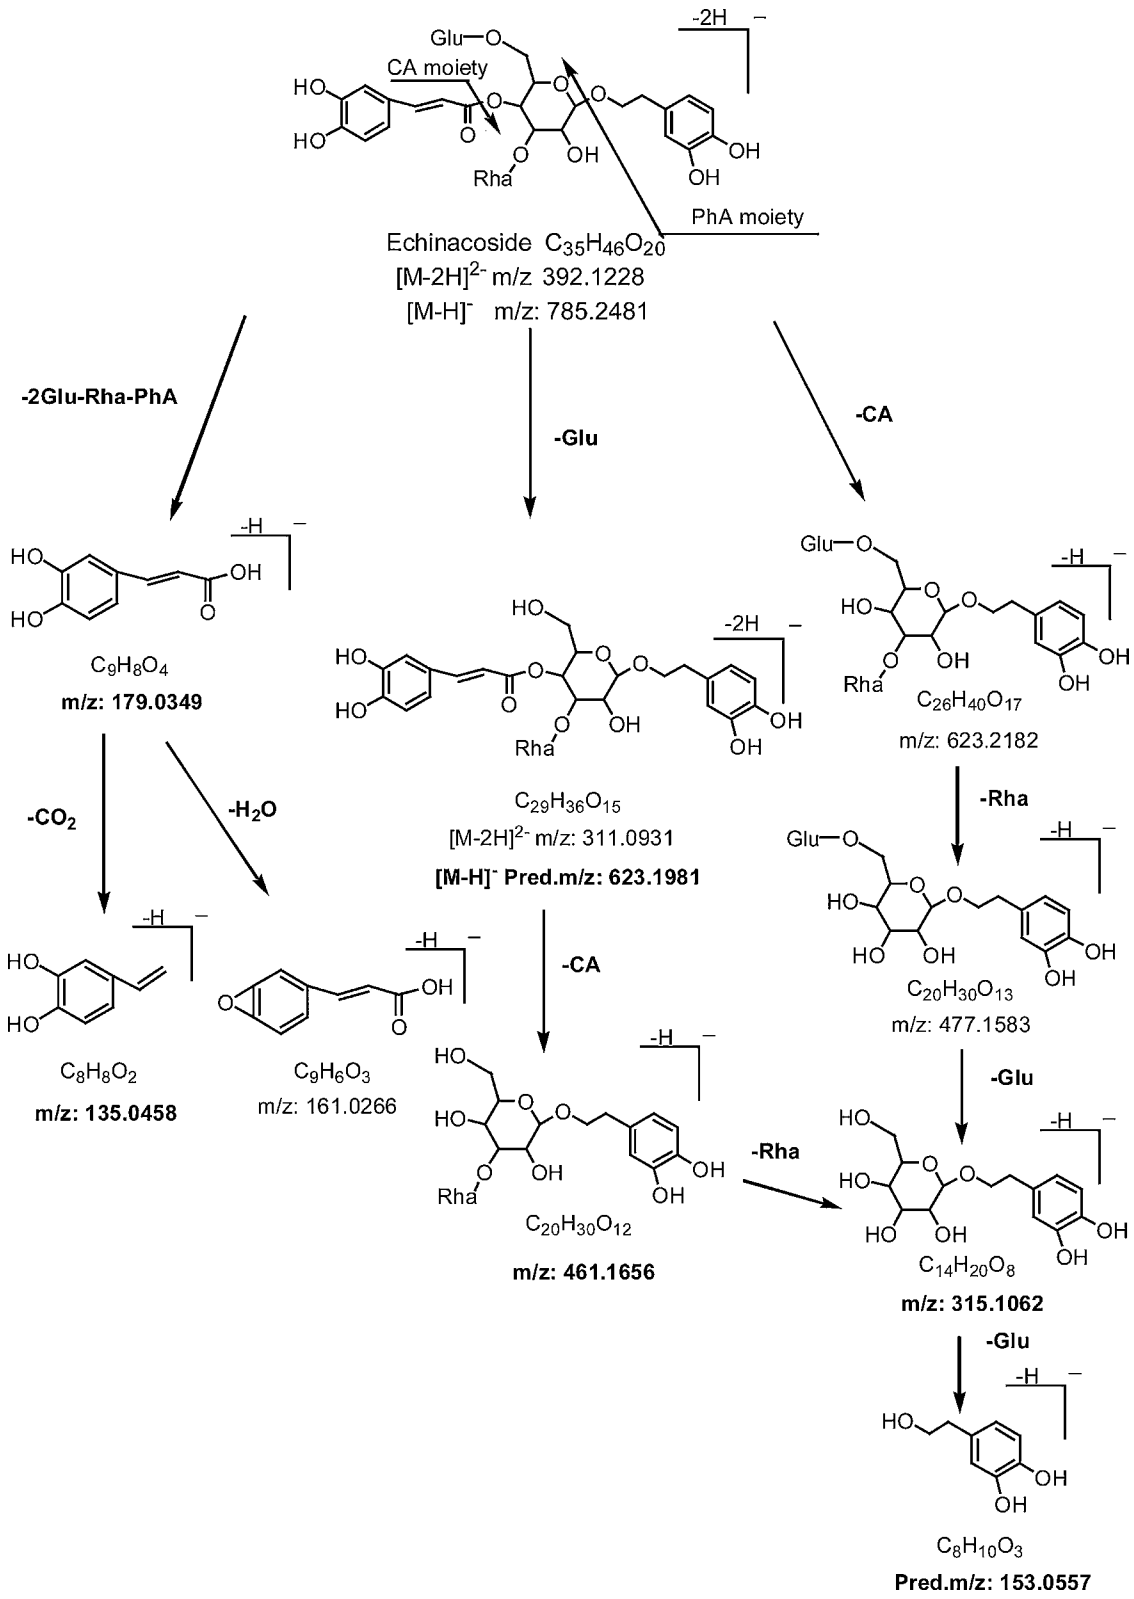

Fig. 1. Proposed fragmentation pathways of echinacoside.

Block Heater temperature, 200 °C; nebulizing gas (N_2), 1.5 L/min; drying gas (N_2) pressure, 0.1 MPa. Mass spectra were acquired in the range of *m/z* 100–1000 for MS^1, 100–1000 for MS^2. The MS^n data were collected in an automatic mode and the software could automatically select precursor ions for MS^n analysis according to criteria settings. Argon was used as the collision gas and the collision energy was set at 150% for MS^2. Prior to data acquisition, the instrument was calibrated with sodium TFA clusters against the entire mass range (*m/z* 50–5000) specified for the instrument.

3. Results and discussion

3.1. Fragmentations of echinacoside

Since it has been well proven that the mass fragmentation patterns of metabolites are always similar to the parent compounds, and thus the fragmentation patterns analysis of parent compound is very helpful for the metabolite characterizations, we firstly conducted a detailed fragmentation study of the ECH authentic standard in LC/MS-IT-TOF. To ensure sufficient fragments production, 5 μg/mL of ECH authentic samples prepared in methanol was used for the fragmentation pattern study. Accurate mass measurements of pseudo-molecular and fragment ions of ECH are listed in Table 1. The $[M-2H]^{2-}$ ion at *m/z* 392.1228 ($C_{35}H_{46}O_{20}$) was observed as the predominant pseudo-molecular ion. The product ion at *m/z* 179.0349 ($C_9H_8O_4$) corresponding to CA moiety is one of the major fragments. The fragment at *m/z* 135.0458 ($C_8H_8O_2$) and *m/z* 161.0266 ($C_9H_6O_3$) was formed from the CO_2 and H_2O loss from CA moiety, respectively. The loss of a glucose (Glu) from the double deprotonated pseudo-molecular ion forms a fragment at *m/z* 311.0931 ($[M-2H]^{2-}$, $C_{29}H_{36}O_{15}$), which further losses a CA moiety and produces a fragment at *m/z* 461.1656 ($C_{20}H_{30}O_{12}$). The fragments at *m/z* 623.2182 ($C_{26}H_{40}O_{17}$), *m/z* 477.1583 ($C_{20}H_{30}O_{13}$), and *m/z* 315.1062 ($C_{14}H_{20}O_8$) are produced from the sequential CA, rhamnose (Rha) and Glu moiety loss from the molecular ion, respectively. The proposed fragmentation pattern of ECH is illustrated in Fig. 1.

3.2. Identification of metabolites in rat urine and feces

To ensure the detecting sensitivity of this method, the limit of detection (LOD) and the limit of quantification (LOQ) of quantifying ECH in the rat urine and feces had been validated. The determined LOD (defined as the concentration producing signal to noise ratio over 3) and LOQ (defined as the concentration producing signal to noise ratio over 10 and with the precision variations less than 20%) for quantifying ECH in both biological matrixes was 10 and 25 ng/mL, respectively, indicating that the present LC/MS-IT-TOF based method was sensitive enough to detect and identify the metabolites of ECH at trace level. The representative mass chromatograms for profiling the rat urine and feces samples after intragastric administration of ECH are shown in Fig. 2. The peaks corresponding to potential metabolites were determined from the

automated mass chromatogram comparisons between the blank samples and the drug treated samples. The retention time, accurate mass data of the parent and fragment ions for the parent compound and all metabolites are collected in Table 2. A total of 13 metabolites were found from the rat urine and feces samples. The metabolites identification strategy and results were elucidated in detail as follows.

3.2.1. Identification of degradation products via direct fragment comparisons

The chemical structure of ECH is composed of three chemical moieties including CA, phenylethanoid aglycone (PhA, 3,4-dihydroxyphenethyl alcohol, hydroxytyrosol), and sugar. According to the current knowledge of drug metabolism, ECH are readily subject to hydrolysis under the biological conditions, especially cat-

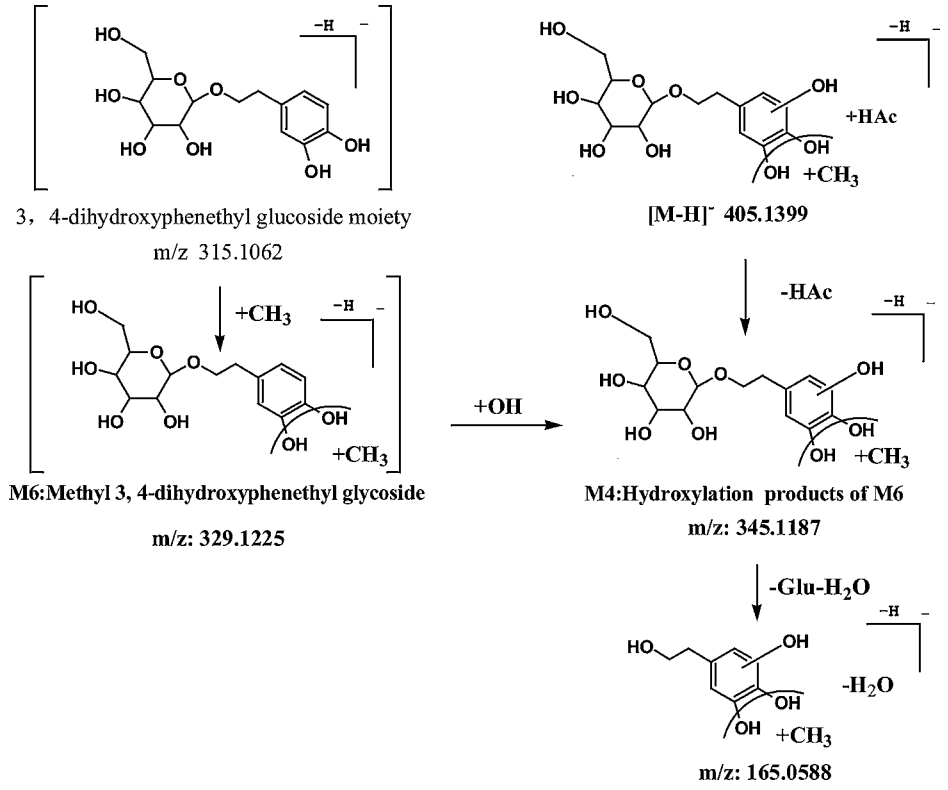

Fig. 4. Proposed fragmentation mechanism of M4.

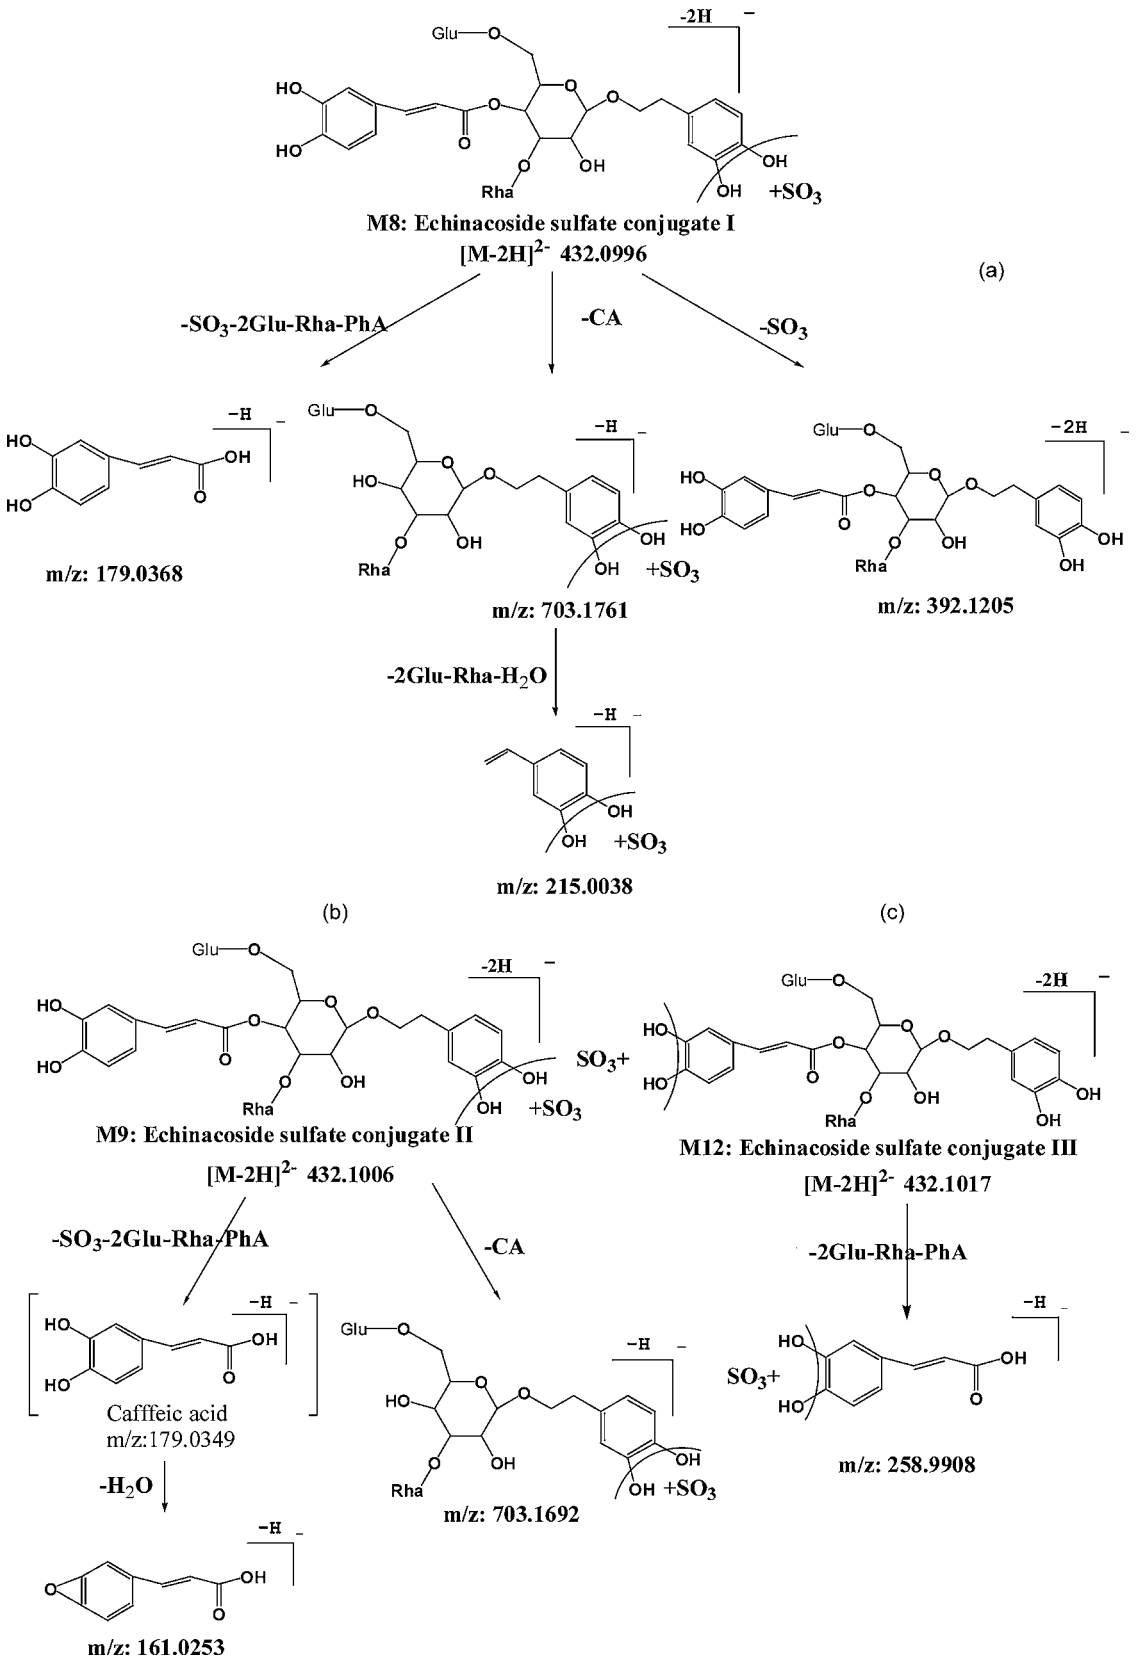

Fig. 5. Proposed fragmentation mechanism of M8 (a), M9 (b), M12 (c).

alyzed by the intestinal microflora. Therefore, we proposed that ECH may produce several degradation products in the rat gastrointestinal tract. Recently, García-Reyes et al. [28] proposed a "fragmentation–degradation" correlation strategy to identify the degradation products based on the fact that the compounds degradation pathways are always similar to the fragmentation patterns in the mass CID conditions. For this consideration, we applied such a strategy to search for the potential degradation prod-

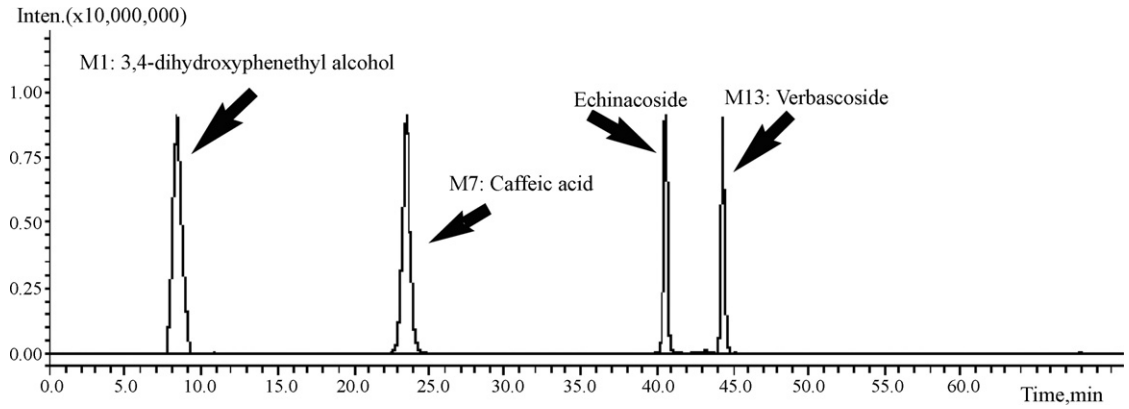

Fig. 6. Extracted ion chromatogram of 3,4-dihydroxyphenethyl alcohol, caffeic acid and verbascoside standards.

ucts of ECH using the determined fragments of ECH authentic standard.

The determined and predicted fragment ions of ECH were searched against the mass chromatograms of rat urine and feces samples. A total of four metabolites have been found to characterize the pseudo-molecular ions with same *m*/*z* and calculated elemental compositions to that of the ECH fragments. M7, eluted at 23.0 min, is characterized with the pseudo-molecular ion at *m*/*z* 179.0359 ($C_9H_8O_4$), which is actually identical to the ECH fragment ion at *m*/*z* 179.0349 ($C_9H_8O_4$, caffeic acid moiety). The major fragment ion determined at *m*/*z* 135.0474 ($C_8H_8O_2$) for M7 is also same to that of the caffeic acid moiety. Therefore, M7 is identified as a degradation product of echinacoside, caffeic acid. M13, eluted at 44.2 min, characterized with the deprotonated molecule ion at *m*/*z* 623.2024 ($C_{29}H_{36}O_{15}$) which is really close to the de-glucose fragment ion (*m*/*z* 623.1981) of ECH, is proposed to be the de-glucose product of ECH named as verbascoside. The major fragment ions of M13 (*m*/*z* 461.1688, *m*/*z* 315.1116) are also same to that from the verbascoside moiety. Based on this rule, M3 (Rt, 12.0 min; *m*/*z* 461.1668) and M1 (Rt, 8.0 min; *m*/*z* 153.0561) is identified as the decaffeoyl product of verbascoside and 3,4-dihydroxyphenethyl alcohol, respectively.

3.2.2. Phase I and phase II metabolites of degradation products

The degradation products can further undergo phase I and/or phase II metabolism. Since such metabolites are always produced from multiple metabolic reactions from the parent compound, it is relatively difficult to characterize their structures. In this study, we proposed a strategy for rapidly characterizing the phase I and phase II metabolites of the degradation products. Firstly, the pseudo-molecular ions of such metabolites were compared with those of the determined degradation products. With the benefit of accurate mass measurements by TOF, it is feasible to obtain the elemental composition differences between the target metabolites and their precursors (degradation products). Subsequently, the reasonable elemental composition difference could be determined based on the current understanding of the metabolic routes. Finally, the fragmentation patterns comparisons would help to confirm the characterizations. The observed quasi-molecular ion for M5, eluted at 16.0 min, was at *m*/*z* 258.9923, which was 80 Da over that of the degradation product M7, caffeic acid. The major fragment ion of M5 at *m*/*z* 179.0381 ($C_9H_8O_4$) confirms that M5 is caffeic acid sulfate conjugate. Similarly, M2 (Rt, 10.0 min) characterized with the quasi-molecular ion at *m*/*z* 233.0119 was readily identified as the sulfate conjugate of M1, 3,4-dihydroxyphenethyl alcohol.

However, some degradation products of the parent compound might be immediately and completely metabolized and thus could not be detected. The identification of such kind of metabolites when their precursors were not detected would be more difficult. In view that the degradation modes are always similar to the mass fragmentation patterns, we proposed here that the multiple crossover comparisons of the quasi-molecular ions with the fragments of the parent compound would help for characterizing such metabolites. As is in this study, M6 has been rapidly characterized following such a strategy. As shown in Fig. 3, M6 eluted at 18.0 min produced a predominant quasi-molecular ion at *m*/*z* 389.1457 ($C_{17}H_{26}O_{10}$), which was presumed to be an acetic adductive ion as evidenced from its elemental composition difference ($C_2H_4O_2$) from the deprotonated ion at *m*/*z* 329.1225 ($C_{15}H_{22}O_8$). Comparing the deprotonated molecular ion of M6 with that of the defined degradation products leaded to none of reasonable results, suggesting that M6 was not a subsequent metabolite of the detected degradation products. When matching the quasi-molecular ion of M6 with the fragments of parent compound, a 14 Da difference corresponding to a methyl group has been observed from a fragment at *m*/*z* 315.1062 ($C_{14}H_{20}O_8$), which was the 3,4-dihydroxyphenethyl glucoside moiety. Therefore, M6 was proposed to be a methyl 3,4-dihydroxyphenethyl glycoside. The fragmentation pattern of M6 supported such a characterization. The loss of a Glu from the deprotonated molecular ion produced a fragment ion at *m*/*z* 167.0740 ($C_9H_{12}O_3$), which further produced a fragment ion at *m*/*z* 123.0472 ($C_7H_8O_2$) by the CH_3 and CH_2O dissociation.

M4, eluted at 12.7 min, showed a major quasi-molecule ion at *m*/*z* 405.1399 ($C_{17}H_{26}O_{11}$) which was also presumed to be an acetic acid adduct ion since it also produced a deprotonated molecular ion at *m*/*z* 345.1187. The predicted elemental composition of $C_{15}H_{22}O_9$ for M4 is an oxygen atom more than that of the M6 and a CH_2O more than the fragment at *m*/*z* 315.1062 ($C_{14}H_{20}O_8$). Therefore, the M4 was tentatively presumed to be the subsequent hydroxylation products of M6. As shown in Fig. 4 the major fragment ion at *m*/*z* 165.0588 ($C_9H_{10}O_3$) presumed to be produced via losing a Glu moiety and a H_2O group from the deprotonated molecular ion of M4 supported such a characterization.

3.2.3. Phase I and phase II metabolites of echinacoside

The direct phase I and phase II metabolites of a compound are relatively easy to be characterized based on the fragmentation comparisons with the parent compound. M8, M9 and M12, characterized with similar quasi-molecular ion ($[M-2H]^{2-}$) mass at *m*/*z* 432.0996, *m*/*z* 432.1006 and *m*/*z* 432.1017 and same predicted elemental composition of $C_{35}H_{46}O_{23}S$, suggested that they were the sulfate conjugation products at different hydroxyl groups. The further fragmentation patterns and retention behavior analysis helped us to determine the sulfate conjugating positions for M8, M9 and M12. The fragment ion at *m*/*z* 703.1769 ($C_{26}H_{40}O_{20}S$) was a CA moiety loss from the molecular ion, which suggested that the sulfate conjugation position was not at the CA moiety for M8. In addition,

Table 3
Comparison of retention time (t_R) and accurate mass data for the metabolites proposed and their respective authentic standards.

Peak No.	Compound name	Metabolites			Standards		
		t_R (min)	Pseudo-molecular ion m/z (ppm)	Fragment ion m/z (ppm)	t_R (min)	Pseudo-molecular ion m/z (ppm)	Fragment ion m/z (ppm)
1	3,4-Dihydroxyphenethyl alcohol	8.0	153.0561 (2.61)	123.0473 (17.07)	8.3	153.0563 (3.92)	123.0462 (8.13)
7	Caffeic acid	23.0	179.0359 (5.03)	135.0474 (16.29)	23.4	179.0349 (−0.56)	135.0458 (4.44)
13	Verbascoside	44.2	623.2024 (6.90)	461.1688 (5.64), 315.1116 (9.48)	44.4	623.1999 (2.89)	461.1643 (−4.77), 315.1044 (5.40)

the fragment ion at m/z 215.0038 ($C_8H_8O_5S$) presumed to be a H_2O loss from 3,4-dihydroxyphenethyl alcohol sulfate conjugate (m/z 233.0119, $C_8H_{10}O_6S$), confirmed that the site of sulfate conjugant of M8 was at PhA moiety. For M9, the major fragment ion at m/z 703.1692 ($C_{26}H_{40}O_{20}S$) was formed through a CA moiety loss from the quasi-molecular ion, suggesting that the sulfate was conjugated with the hydroxyl group at PhA moiety. The sole fragment ion at m/z 258.9908 ($C_9H_8O_7S$) for M12 which was proposed to be the caffeic acid sulfate conjugate (m/z 258.9923, $C_9H_8O_7S$) supported that the sulfate conjugation was formed at the CA moiety. The fragmentation patterns of M8, M9 and M12 are illustrated in Fig. 5 separately.

M10, eluted at 36.3 min, showed the predominant quasi-molecular ion $[M-2H]^{2-}$ at m/z 400.1192 ($C_{35}H_{46}O_{21}$) that is an oxygen atom more than the parent compound ECH, suggesting that it was a hydroxylation product of ECH. The major fragment ion at m/z 391.1129 ($C_{35}H_{44}O_{20}$) was a H_2O loss from the quasi-molecular ion. The fragment ions found at m/z 179.0363 ($C_9H_8O_4$) and m/z 135.0479 ($C_8H_8O_2$) were same to that of the parent compound ECH, suggested that the hydroxylation position was not on the caffeic acid moiety. In addition, in view that the H_2O loss fragmentation for M10 has not been observed from the parent compound, we proposed that the hydroxylation was more likely to occur on the PhA moiety to form a benzenetriol structure.

M11, eluted at 38.8 min, was characterized with the major qausi-molecular ion $[M-2H]^{2-}$ at m/z 480.1386 ($C_{41}H_{54}O_{26}$). The double and mono-deprotonated fragment at m/z 392.1218 ($C_{35}H_{46}O_{20}$) and m/z 785.2481 ($C_{35}H_{46}O_{20}$) that was formed through a glucuronic acid (176 Da, $C_6H_8O_6$) loss from the parent ion of M11, supporting that M11 was a glucuronic conjugate of ECH. Due to the insufficient fragmentation information, we failed to determine the conjugation position.

3.2.4. *Metabolites identification verified by authentic standards*

To further confirm the metabolite identifications, three major metabolites M1, M7 and M13 that were proposed as 3,4-dihydroxyphenethyl alcohol, caffeic acid and verbascoside, respectively, were verified by using authentic standards. The three compounds were prepared in methanol at 5 μg/mL of each as a mixture and injected into the instrument which was run under same conditions as that used for the metabolites identification. The obtained extracted ion chromatogram is shown in Fig. 6 and the retention time and mass spectra data are summarized in Table 3. The retention times and accurate mass data comparisons showed that the metabolites proposed from the real world biological samples (rat urine and feces) matched well with their respective authentic standards, further supporting the original structure characterizations.

4. Conclusion

This study proposed a systematic approach for rapid metabolites identification of such compounds as ECH undergoing multiple and unpredictable metabolism from biological matrix, based on the LC/MS-IT-TOF analysis. Firstly, the degradation products of ECH were characterized via degradation and fragmentation relationship analysis. Based on the fragmentation patterns analysis of ECH, four degradation products were rapidly identified. Secondly, the further metabolites of the degradation products were characterized by the elemental composition differences analysis of the quasi-molecular ions between the metabolites and their precursors. Finally, the direct phase I and phase II metabolites of the parent compound were readily characterized by the quasi-molecular ion mass difference analysis. With the benefit from the sufficient fragments information, the metabolic positions can be determined in most cases. Using this approach, a total of 13 metabolites of ECH has

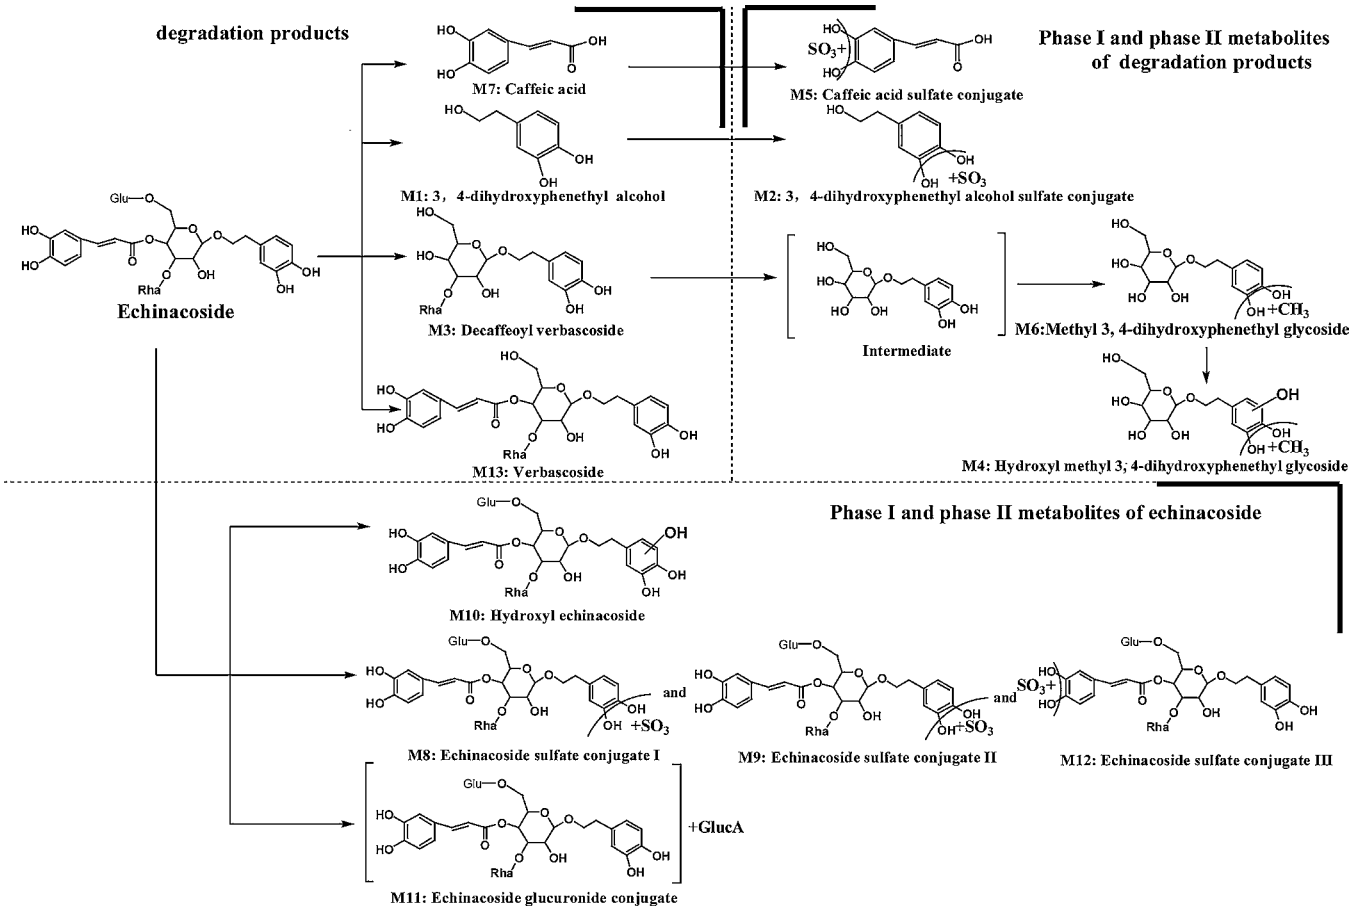

Fig. 7. Proposed metabolic pathways of echinacoside.

been identified from the rat urine and feces after an intragastric dosage. Fig. 7 depicts the identified metabolic pathways for ECH, including degradation products, and glucuronic acid, sulfate, and methyl conjugation of both parent compound and the degradation products.

In summary, the present study provides a more comprehensive map of ECH metabolism than that from the previously published results [15], where only eight phase II metabolites of the parent compound ECH had been identified. In addition, this study presents a feasible and generally applicable strategy for the complicated metabolites identification of natural products.

ABSTRACT

A novel approach was developed for nitrate analysis in a FIA configuration with amperometric detection ($E = -0.48$ V). Sensitive and reproducible current measurements were achieved by using a copper electrode activated with a controlled potential protocol. The response of the FIA amperometric method was linear over the range from 0.1 to 2.5 mmol L^{-1} nitrate with a detection limit of 4.2 μmol L^{-1} (S/N = 3). The repeatability of measurements was determined as 4.7% ($n = 9$) at the best conditions (flow rate: 3.0 mL min^{-1}, sample volume: 150 μL and nitrate concentration: 0.5 mmol L^{-1}) with a sampling rate of 60 samples h^{-1}. The method was employed for the determination of nitrate in mineral water and soft drink samples and the results were in agreement with those obtained by using a recommended procedure. Studies towards a selective monitoring of nitrite were also performed in samples containing nitrate by carrying out measurements at a less negative potential (−0.20 V).

1. Introduction

Nitrate can be found naturally in soil, water, vegetables and foods. In soil, the presence of nitrate is essential for the conversion of nitrogen unused by plants and its concentration is controlled by some processes like reduction by bacteria (denitrification), uptake by plants and decay of organic matter [1–3]. Anthropogenic sources of nitrate in soil are correlated to the intensive cultivation of lands and application of nitrogen fertilizers [1–3]. As a result of the high solubility of nitrate in water, this chemical species is easily leached down into groundwater, leading to a contamination of water supplies.

In the last years, concern has been expressed about the increasing levels of nitrate ion in drinking water, due to the toxicological problems associated with the formation of *N*-nitrous compounds [1–4]. Accordingly, these compounds are classified as carcinogenic hazard to humans and animals. Moreover, high levels of nitrate in water could result in disequilibrium of the freshwater ecosystem, due to a fast eutrophication process. The intake of large amounts of nitrate for infants could result in the "blue-baby syndrome", as a consequence of nitrate reduction in the organism to nitrite and further reaction of this metabolite with haemoglobin. Hence, the absorption and transfer of oxygen to cells is compromised. For this reason, nitrate levels (as N-NO_3^-) in potable water should not exceed 11 mg L^{-1} (or 0.8 mmol L^{-1}) and 10 mg L^{-1} (or 0.7 mmol L^{-1}), according to recommendations of the World Health Organization (WHO) [5] and the US Environmental Protection Agency (EPA) [6], respectively. Taking into account these aspects, it is clear that the development of fast and sensitive methods for quantification of nitrate in natural water samples is a pertinent topic in Analytical Chemistry.

Several procedures have been reported in the literature to quantify nitrate in different matrices and they were reviewed by Compton et al. [7]. Different techniques have been used such as UV/vis, chemiluminescence, fluorimetry, infrared, Raman and molecular cavity emission, chromatography, capillary electrophoresis and electrochemistry. In the case of electrochemical methods, copper [8–15], nickel [16], copper–nickel alloys [17], copper–cadmium alloys [18], copper–palladium alloys [1], platinum [19,20], lead [21], silver [22], rhodium [23], boron-doped diamond [24], gold [25] and polypyrrole nanowires [26] have been employed as substrate materials. The use of bare unmodified electrodes for the direct determination of nitrate is difficult owing to the slow kinetics of the charge transfer step. Hence, methods based on the direct reduction of nitrate are characterised by low sensitivity and irreproducibility and associated with surface passivation effects [27]. Nonetheless, procedures to increase the sensitivity in direct electroanalytical determinations of nitrate are generally associated with activation of the electrodic surface, especially when copper cathodes [13] are used. The indirect determination of nitrate

doi:10.1016/j.talanta.2009.07.028

has been proposed after a derivatisation procedure [28], as also reported in a method for nitrite analysis [29].

The use of a copper surface as amperometric detector in a flow-through configuration has been already explored by our group in the determination of sulphite in alkaline conditions [30]. As fresh copper surfaces are more effective for cathodic reactions, we have also proposed the development of a renewable process for the activation of copper electrodes without the necessity to introduce copper ions into the sample [13]. However, as the majority of other published works involving the electroanalytical determination of nitrate, measurements were obtained in a batch mode with low analytical frequency. In the present work, we describe our efforts to associate the renewable copper surface with a mechanised process (flow injection analysis). The analytical applicability of this high-throughput proposed method was examined by measuring the nitrate content in mineral water and soft drink samples.

2. Experimental

2.1. Chemicals, materials and samples

All solid reagents were of analytical grade and were used without further purification. Sulphuric acid, sodium sulphate, potassium nitrite and potassium nitrate were obtained from Merck (Darmstadt, Germany). The supporting electrolyte for flow injection experiments was a 0.1 mol L^{-1} Na_2SO_4 solution, pH 2.0 (adjusted with H_2SO_4). In almost all cases the solutions were prepared by dissolving the reagents in deionised water processed through a water purification system (Nanopure Infinity, Barnstead). Samples of mineral water and soft drink were acquired from a local market. Carbon dioxide was removed from soft drink samples by thorough bubbling with argon. Nitrite solutions were standardised as reported in the literature [31].

2.2. Electrodes and instrumentation

An Autolab PGSTAT 30 (Eco Chemie) bipotentiostat with data acquisition software made available by the manufacturer (GPES 4.8 version) was used for electrochemical measurements. Experiments were done in a conventional electrochemical cell, a Ag/AgCl (saturated KCl) electrode and a stainless-steel tube being used as reference and counter electrodes, respectively. A copper sheet (Pertech® of Brazil) fabricated by copper electroplating in a substrate composed of paper and phenolic resin was used as working electrode (area = 56 mm^2). This copper sheet is used for fabrication of printed circuit boards. The flow injection apparatus consisted of an aquarium air pump (to propel the solution by pressurization), a homemade rotatory injection valve and an acrylic cell mounted in a thin layer configuration [32,33].

2.3. Activation of the electrode surface in FIA experiments

The working electrode surface is activated by two potential steps prior current measurements, Fig. 1. To drive copper dissolution, the working electrode is polarised at +0.50 V (step a). Then, the redeposition is carried out at −0.25 V (step b). Both steps are performed in absence of flow, otherwise, copper ions would escape from the diffusion layer after the anodic dissolution. These two steps (copper dissolution and redeposition) are required to produce a fresh copper layer with an active role concerning the cathodic reduction of nitrate, as previously demonstrated [13]. The optimisation of both time parameters involved in the pre-treatment potential program (steps a and b) was investigated as an attempt of enhancing the sensitivity of nitrate determinations. After the activation process, the electrode was polarised at the potential required for nitrate reduction. Three samples were injected after each activation step.

2.4. Spectrophotometric analysis

An evaluation of the accuracy of the proposed method for quantitative determinations of nitrate in mineral water samples was performed by UV-spectrophotometry without derivatisation at 220 nm in a Hitachi U-3000 spectrophotometer using a 1.00 cm optical pathlength quartz cuvette. As soft drink samples are more complex and contain large amounts of organic compounds (glucose), comparative measurements were obtained with the UV-spectrophotometry Griess assay. The reduction of nitrate to nitrite was accomplished by using a copperised cadmium reactor column prior to spectrophotometric measurements with the Griess method at 543 nm.

3. Results and discussion

Previous reports on the literature [8,12,13] have demonstrated that the reduction of nitrate can be promoted on a fresh copper surface, in accordance with Eq. (1):

$$NO_3^- + 10H^+ + 8e^- \rightleftharpoons 3H_2O + NH_4^+ \quad (1)$$

Taking into account the necessity of a fresh copper layer, a protocol involving the dissolution of the outer copper layer for further redeposition of copper ions is required. A schematic representation of the pre-treatment procedure used in the FIA system is shown in Fig. 1. At the activated detector surface, FIA experiments were carried out to investigate the best applied potential for nitrate reduction. From the results obtained in hydrodynamic voltammetric experiments (not shown), the working potential value −0.48 V was selected as the most appropriate to ensure complete analyte reduction at the copper sensor.

The optimisation of both parameters (dissolution and redeposition time) was also investigated. Data in Fig. 2, curve A, shows that no faradaic signal is obtained at a non pre-treated surface (i.e. bare copper electrode), a different situation being observed as the amount of copper ions redeposited during the cathodic process increases (for a constant dissolution time). In a similar way, the signal for nitrate reduction increases with the increase in the dissolution time (for a constant redeposition time) (Fig. 2, curve B). Optimal conditions were achieved by using 30 s, respectively, for the dissolution and redeposition steps, and this procedure was employed for all analytical determinations.

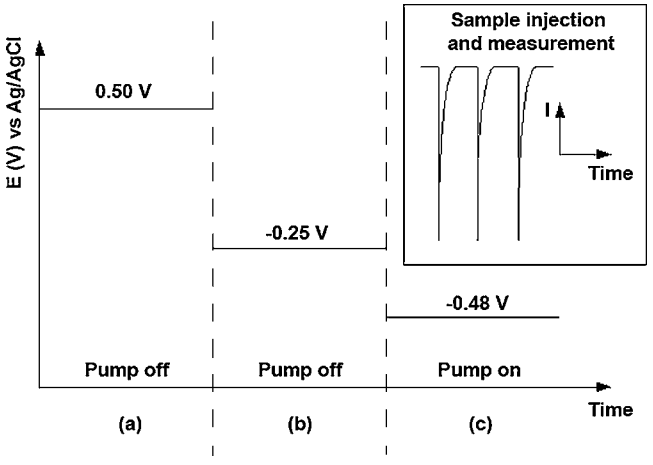

Fig. 1. Schematic representation of the copper surface activation protocol in the FIA system: copper dissolution (a); copper redeposition (b) and nitrate electroreduction (c). The inset shows the amperometric signal recorder after 3 injections of a nitrate solution in the FIA apparatus.

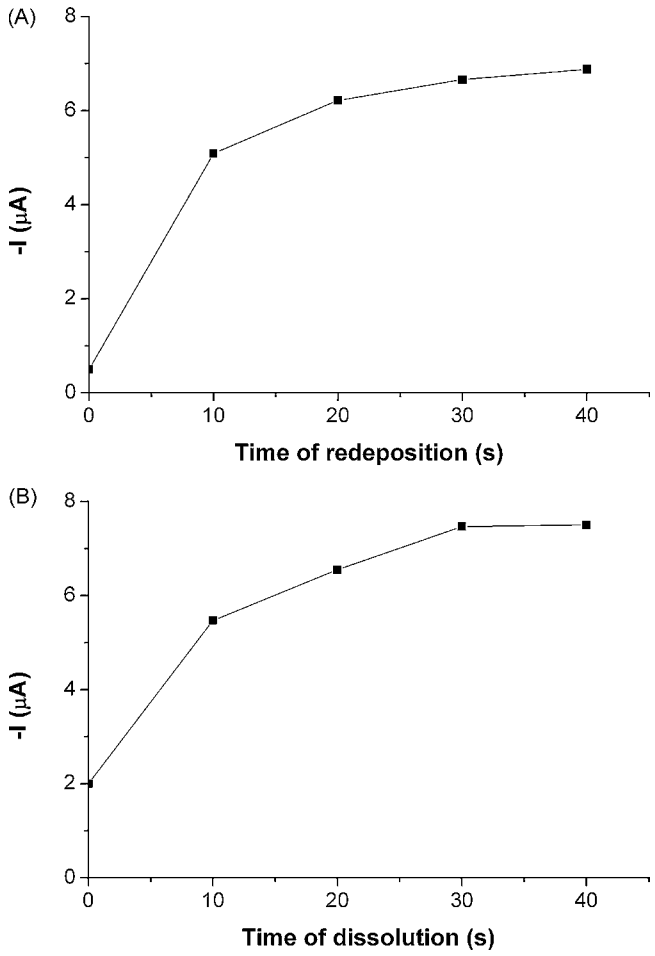

Fig. 2. Dependence of cathodic peak current values on the redeposition (A) and dissolution (B) time for injections of a 0.1 mol L^{-1} Na_2SO_4 + 1.0 mmol L^{-1} NO_3^- solution (pH 2.0). The dissolution time was 30 s for experiments represented by curve (A) and the redeposition time was 30 s for experiments represented by curve (B). Carrier solution: 0.1 mol L^{-1} Na_2SO_4 (pH 2.0), E = −0.48 V, number of measurements: 3, flow rate: 3.0 mL min^{-1}, sample volume: 150 μL.

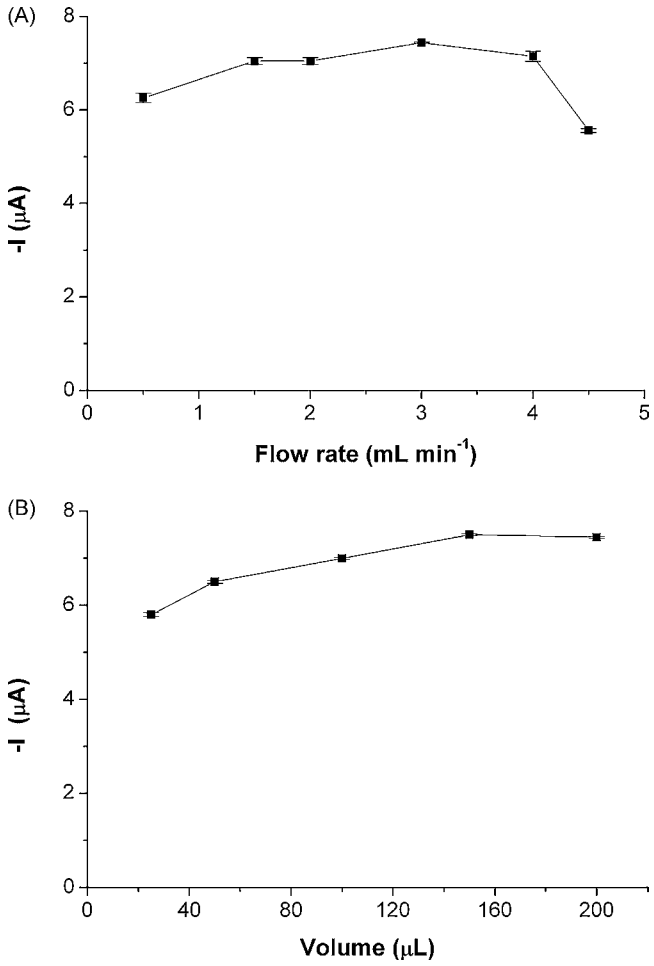

Fig. 3. Average current peak values (n = 3) recorded for a 1.0 mmol L^{-1} nitrate + 0.1 mmol L^{-1} de Na_2SO_4 solution (pH 2.0) at various flow rates (A) (sample volume 150 μL) and various sample volumes (B) (flow rate 2.0 mL min^{-1}). Carrier solution: 0.1 mol L^{-1} Na_2SO_4 (pH 2.0), E = −0.48 V.

To investigate the optimal conditions for the flow injection system performance, parameters such as sample volume and flow rate were varied using a 1.0 mmol L^{-1} nitrate solution. The effect of flow rate (studied from 0.5 to 4.5 mL min^{-1}) on the analytical signal was evaluated (Fig. 3A) and the current increased with flow rate up to 3.0 mL min^{-1}. This indicates that a kinetic limitation is prevalent at more efficient mass-transport conditions. Taking into account these aspects, a flow rate of 3.0 mL min^{-1} was selected as the most favourable. The effect of sample volume was evaluated using injection loops from 25 up to 200 μL, Fig. 3B. The amperometric signal increased almost linearly up to 150 μL, and then a slight decrease was noticed. Hence, a 150 μL sample volume was selected as the most appropriate, based on the best compromise between reproducibility and sampling rate.

In order to confirm the importance of surface activation on the repeatability of the measurements, two independent studies were performed. Firstly, nitrate solutions were injected in the FIA system after one activation procedure (30 s of dissolution and 30 s of redeposition, Fig. 4, curve B) at the beginning of experiment. A continuous current decrease was noticed, indicating the sensor activity loss during the experiment. On the other hand, by using the protocol described in Section 2 a completely different result was obtained (Fig. 4, curve A). In this case, 3 samples were injected after each activation step and the standard deviation (SD) for 9 injections was found to be 4.7% (60 samples per hour). No significant improve-

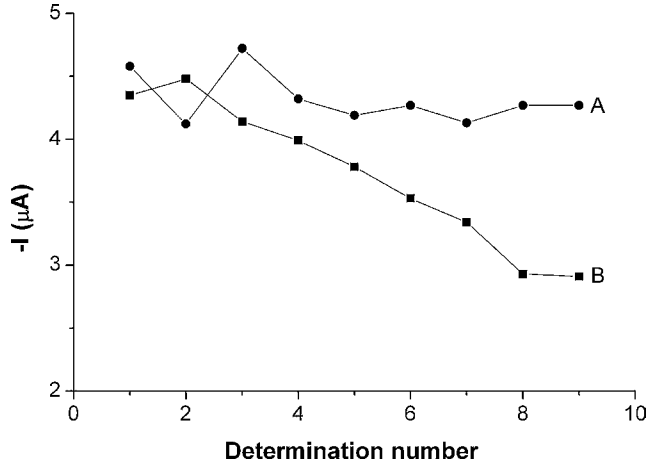

Fig. 4. Current peak values as a function of time for injections of a 0.1 mol L^{-1} Na_2SO_4 + 0.5 mmol L^{-1} NO_3^- solution (pH 2.0). Data were obtained by using the proposed protocol (pre-treatment of the copper electrode after each set of 3 injections) (A) and by pre-treating the electrode only in the beginning of the experiment (B). Carrier solution: 0.1 mol L^{-1} Na_2SO_4 (pH 2.0), E = −0.48 V, flow rate: 3.0 mL min^{-1}, sample volume: 150 μL.

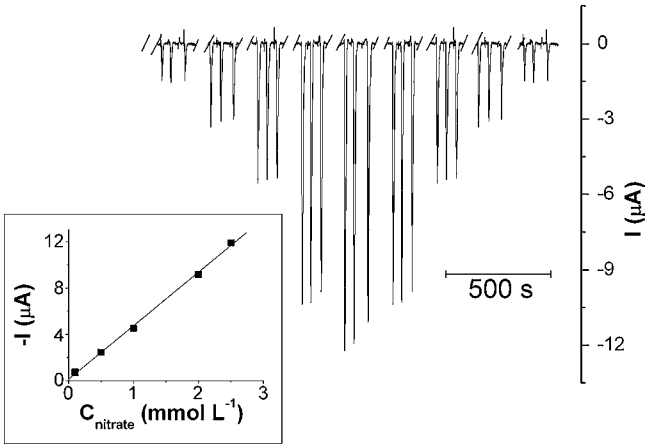

Fig. 5. Peaks recorded for injections of nitrate standard solutions at the optimised FIA conditions (0.1–2.5 mmol L^{-1}). The breaks (//) in the figure represent the pre-treatment gap (60 s). The inset shows the calibration curve. Carrier solution: 0.1 mol L^{-1} Na_2SO_4 (pH 2.0), E = −0.48 V, flow rate: 3.0 mL min^{-1}, sample volume: 150 μL.

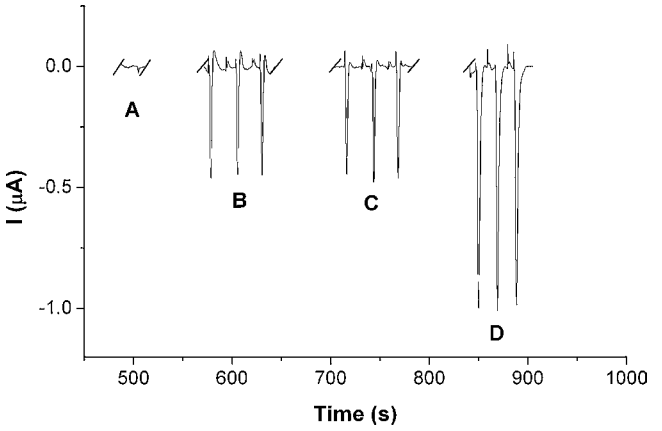

Fig. 6. Peaks recorded at the optimised FIA conditions for injections of 1.0 mmol L^{-1} nitrate (A), 0.05 mmol L^{-1} nitrite (B), a mixture of 1.0 mmol L^{-1} nitrate + 0.05 mmol L^{-1} nitrite (C) and a mixture of 1.0 mmol L^{-1} nitrate + 0.10 mmol L^{-1} nitrite. Carrier solution: 0.1 mol L^{-1} Na_2SO_4 (pH 2.0), E = −0.20 V, flow rate: 3.0 mL min^{-1}, sample volume: 150 μL.

Table 1
Analytical parameters for nitrate determination.

Analytical parameters	Batch mode [13]	Proposed method
Analytical frequency (h^{-1})	25	60
Detection limit (μmol L^{-1})	11.6	4.2
Quantification limit (μmol L^{-1})	38.7	14.0
Linear range (mmol L^{-1})	0.1–2.5	0.1–2.5
Sample volume (mL)	10	0.15

ment in the precision was noticed by injecting each nitrate sample after the activation step. Hence, in order to increase the analytical frequency without lose in precision, the second protocol (one activation step prior to 3 sample injections) was elected as the most convenient for all subsequent FIA experiments.

The relationship between the amperometric peak current and the concentration of nitrate was investigated in the range 0.1–2.5 mmol L^{-1} (Fig. 5). Using the optimised conditions previously reported, a linear response ($(-Ip/\mu A) = 0.13 + 4.6 (C_{nitrate}/mmol\ L^{-1})$, $R^2 = 0.9991$) was obtained. No memory effect was observed during the experiment, demonstrating that the adopted procedure is convenient. The detection (3 SD) and quantification (10 SD) limits were estimated as 4.2 and 14 μmol L^{-1}, respectively. In order to compare the results obtained by using the batch method [13] with those proposed in this work, figures of merit of both methods are summarised in Table 1. It is clearly seen that the limit of detection, sample volume and analytical frequency of the FIA proposed method are better, indicating its potentiality as an alternative method for routine analysis of nitrate.

The applicability of the renewable copper electrode as detector in a FIA configuration for the determination of nitrate in real samples was also performed. Table 2 shows the nitrate content in 3 mineral water and 3 soft drink samples. The results were in good agreement with those obtained by using standard methods [31] (for a 95% confidence level according to the Student's t-test). As an additional accuracy test of the proposed method, a set of recovery experiments in which nitrate was added directly to water samples was carried out. Recovery results were satisfactory and ranged from 90 to 97%. Accordingly, we can conclude that the proposed method is reliable for nitrate measurements in the investigated samples.

Table 2
Nitrate content (as $N\text{-}NO_3^-$) in mineral water and soft drink samples.

Sample	Standard method [31] (mg L^{-1})	Proposed method (mg L^{-1})
Aquana[1]	11.03 ± 0.04	11.3 ± 0.1
Schincariol[1]	10.49 ± 0.07	10.6 ± 0.1
Lindoya[1]	5.16 ± 0.02	5.7 ± 0.2
Soda Antártica[2]	6.30 ± 0.01	6.1 ± 0.1
Tônica Antártica[2]	17.60 ± 0.01	18.0 ± 0.2
Sprite[2]	15.27 ± 0.09	14.7 ± 0.6

Number of replicates = 3, 1 = mineral water, 2 = soft drink.

Previous experiments with the activated copper electrode [13] have shown the good resolution between nitrate and nitrite reduction current peaks in differential pulse voltammograms, respectively −0.48 and −0.20 V. In order to investigate the possibility of analysing nitrite in the presence of nitrate using the proposed FIA method, a standard solution of nitrite was injected under the optimised conditions for nitrate determination. However, experiments were carried out at −0.20 V, instead of −0.48 V. A transient signal for nitrite is observed (Fig. 6, injection B), no response being obtained for nitrate at the same experimental conditions (injection A). By injecting solutions containing both nitrate and nitrite, the current response (injection C) is similar to the one observed after injection of nitrite (injection B). The FIA response for nitrite is proportional to the analyte concentration, as can be observed by comparing peaks C and D. Data shown in this figure also demonstrate that the detector sensitivity for nitrite is good, as a suitable discrimination between signal and noise is observed for 0.05 mmol L^{-1} nitrite solutions (around 0.7 ppm N-nitrite). Accordingly, an interesting option for the simultaneous determination of both analytes in mixtures is envisaged by performing experiments using dual-detection. We are currently undertaking experiments on this subject, and determining low levels of nitrite in water samples with the proposed copper sensor is an expected challenge.

4. Conclusions

A renewable copper electrode was successfully used as an amperometric detector in a flow injection apparatus for nitrate determination. The system provides high throughput with good reproducibility and sensitivity, hence the analytical parameters are significantly improved in comparison with determinations performed using the batch method. Moreover, taking into account the principles of Green Chemistry, the proposed method is favoured as no carcinogenic compounds are required to convert the analyte. Finally, the possibility to differentiate nitrate and nitrite may consti-

tute a valuable tool in examining samples containing both analytes in a rapid, simple, inexpensive and safe way.

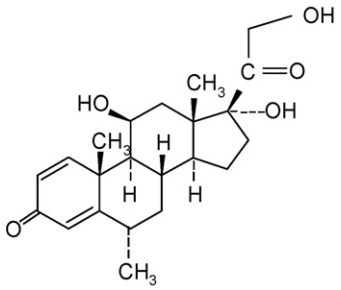
Blood plasma

ABSTRACT



An electrochemical protocol based on reduction is developed to determine methylprednisolone using single-wall carbon nanotubes (SWNTs) modified edge plane pyrolytic graphite electrode (EPPGE). To obtain a good sensitivity, instrumental variables were studied using Square Wave Voltammetry (SWV). The voltammetric results indicate that SWNTs modified EPPGE remarkably enhances the reduction of methylprednisolone which leads to considerable improvement of peak current with shift of peak potential to less negative values. The voltammetric current showed a linear response for methylprednisolone concentration in the range 5–500 nM with a sensitivity of 98 nA nM^{-1}. The limit of detection was estimated to be 4.5×10^{-9} M. The developed method is used for the determination of methylprednisolone in pharmaceutical dosages and human blood plasma samples of patients undergoing treatment with methylprednisolone. The major metabolites present in blood plasma did not interfere with the present investigation as they did not exhibit reduction peak in the experimental range used. A comparison of results with high performance liquid chromatography (HPLC) indicates a good agreement.

1. Introduction

The last few years have signaled a remarkable evolution of the approach followed, at an international level, to control the abuse of drugs in competitive sports. A series of preventive actions and educational campaigns have been put in place by the World Anti-Doping Agency (WADA), to discourage the illicit use of performance-enhancing agents, thus complementing the traditional activities of the anti-doping laboratories. Glucocorticosteroids, anabolic steroids, beta-2 agonists are all included in the prohibited list of WADA [1]. Neale Greaves had his license suspended in the year 2009 racing season as his horse Double Agent was tested positive for methylprednisolone [2]. Brass Hat was disqualified for having trace amounts of methylprednisolone in the year 2006 [3]. The triple jumper Kenta Bell, who placed third at United States Championship in June 2007, accepted a first-offence suspension of three months as he tested positive for the banned substance methylprednisolone [4]. It is therefore mandatory for the accredited laboratories to develop an effective method which aims at the determination of methylprednisolone, a drug abused for doping.

Methylprednisolone **(I)** is a synthetic glucocorticosteroid which is readily absorbed from the gastrointestinal tract and is sold under the brand names Medrol, Depo-Medrol, Solu-Medrol, Phocenta and Cadista. It is primarily used in the therapeutic treatment, particularly for its anti-inflammatory and immunosuppressive actions [5,6]. It is used for the treatment of various conditions like allergic rhinitis, arthritis, blood diseases, respiratory problems, certain cancers, eye diseases, intestinal disorders, collagen and skin diseases [7–16]. It is used to achieve prompt suppression of inflammatory conditions like systemic lupus erythematosus, ulcerative colitis and Crohn's disease [17–20]. Systemic administration of methylprednisolone can reduce neurological deficits after acute spinal cord injury [21] and it is also used for the treatment of patients with multiple sclerosis [22] and proliferative lupus nephritis [23]. Thus, keeping in consideration the efficacy of the drug in pharmaceutical industry and its abuse for doping, a need was felt to develop a sensitive and rapid assay for the determination of methylprednisolone.

doi:10.1016/j.talanta.2009.07.029

Literature survey revealed that the analysis of methylprednisolone in the past years have been mostly based on the chromatographic methods. Liquid chromatography–tandem mass spectrometry [24], high performance liquid chromatography [25], high performance liquid chromatography–mass spectrometry [26], atmospheric pressure chemical ionization–liquid chromatography mass spectrometry [27], GC-ion-trap MS/MS [28] and ultra performance liquid chromatography [29] are some of the chromatographic techniques used for the determination of methylprednisolone. In spite of being sensitive, the chromatographic methods encounter problems like the low volatility of compounds, need for derivatisation, expensive instrumentation and time-consuming extraction procedures. Voltammetric oxidation of methylprednisolone has also been investigated using differential pulse voltammetry [30] and linear sweep voltammetry [31] but the drawback in these studies was the interference caused by the major metabolites present in biological fluids like uric acid, ascorbic acid, dopamine, etc. Therefore, the aim of the present work is to determine the electrochemical reduction of methylprednisolone using SWV which is a simple, rapid and sensitive technique. The studies have been performed at SWNTs modified EPPGE as edge plane pyrolytic graphite has been found to be a better substrate for modification in comparison to other conventional electrodes like glassy carbon electrode [32] due to its strong adsorption property and wide potential window. Methylprednisolone has been determined in pharmaceutical samples and human blood plasma following administration of therapeutic doses of the drug. The results obtained by the proposed method have also been compared with HPLC.

2. Experimental

2.1. Apparatus

The voltammetric experiments were performed using a three electrode single compartment cell equipped with SWNTs modified edge plane pyrolytic graphite electrode (~6 mm^2) as the working electrode, platinum wire as the counter electrode and an Ag/AgCl (3 M NaCl) reference electrode (BAS Model MF-2052 RB-5B). The edge plane pyrolytic graphite piece was obtained from Pfizer Inc., New York, USA and the electrode was prepared as reported in literature [32]. Experiments were carried out using a BAS CV-50 W voltammetric analyzer (Bioanalytical Systems, West Lafayette, IN, USA). All the potentials quoted are versus Ag/AgCl electrode at an ambient temperature of 25 ± 2 °C. The surface morphology of modified electrode was characterized by recording FE-SEM using Quanta 200 FE-SEM instrument. HPLC studies were performed on Agilent 1100 series system with RP-18e (5 μm) column. The method involved the systematic use of isocratic mobile phase of water and methanol in the ratio 40:60 at a flow rate of 1.4 mL min^{-1} and detection was carried out at 254 nm.

2.2. Chemicals

Methylprednisolone acetate injectable suspension USP was obtained from Pfizer Products India Private Limited, Mumbai, India and was used as received. SWNTs of purity > 95% was purchased from Bucky USA, Houston, TX, USA. Methylprednisolone containing tablets and injection marketed by different medical companies were purchased from the local market. Phosphate buffers (1 M) of different pH were prepared from analytical grade chemicals according to the reported method [33]. All other solvents and reagents used were of analytical grade. Double distilled water was used to prepare the solutions.

2.3. Procedure

Stock solution (1 μM) of methylprednisolone acetate was prepared by diluting the injection content (40 mg in 1 mL) with double distilled water. The solution was ultra sonicated for 30 min. Required amount of the stock solution was added to 3 mL of phosphate buffer solution (1.0 M, pH 7.2) and the total volume was made to 6.0 mL with double distilled water. Since oxygen is a major interference at negative measurement potential, high-purity nitrogen was bubbled for 12–15 min to deoxygenate the solutions before recording each voltammogram. The electrode surface was cleaned after each run by applying a potential of 200 mV for 60 s in the blank solution (3 mL of phosphate buffer solution and 3 mL of double distilled water). Instrumental conditions for square wave voltammetry were: Initial E: −800 mV, Final E: −1600 mV, Square wave amplitude (E_{sw}): 25 mV, Potential Step (E): 4 mV, Square wave frequency (f): 15 Hz.

Human blood plasma samples of normal person (control) were obtained from the Indian Institute of Technology hospital and used as control. The plasma samples of patients undergoing treatment with methylprednisolone were obtained from Matrichaya Nursing Home, Roorkee after centrifuging the whole blood with EDTA as anticoagulant for 15 min. The samples were obtained after 10 h of administration of 16 mg tablet of methylprednisolone. The biological samples did not exhibit any reduction peak on scanning from −0.8 to −1.6 V indicating thereby the absence of other reducible compounds in this potential window. The samples were therefore used for analysis without any dilution.

2.4. Preparation of SWNTs modified electrode

Prior to modification, the surface of bare EPPGE was rubbed on an emery paper and then rinsed with double distilled water and dried. A 0.5 mg/mL suspension was prepared by dispersing 0.5 mg SWNTs in 1.0 mL N,N-dimethylformamide (DMF) using ultrasonic bath. A known volume (40 μL) of this suspension was coated onto the surface of the bare EPPGE and the solvent was allowed to evaporate at room temperature. The working electrode surface with a well coated layer of SWNT was then ready for use after 4–6 h. A comparison of the surface morphology of bare and modified electrodes was studied by recording FE-SEM images as shown in Fig. 1. The image in Fig. 1(B) clearly indicates the deposition of SWNTs at the surface of the EPPGE.

3. Results and discussion

3.1. Determination of surface area

To determine the efficacy of surface modification procedure, the surface area of bare and SWNTs modified EPPGE was calculated. For this purpose, cyclic voltammograms were recorded for 1 mM $K_3Fe(CN)_6$ at different scan rates using 0.1 M KCl as the supporting electrolyte. Due to the presence of Fe^{+3}/Fe^{+2}, well defined redox couple was observed at both the electrodes. There was an enhancement in the peak current values at SWNTs modified electrode in comparison to the bare EPPGE. For a reversible process, the following equation applies:

$$i_p = 2.69 \times 10^5 A n^{3/2} D_R^{1/2} c_o \nu^{1/2}$$

where i_p refers to the peak current in Ampere and A is the electrode surface area in cm^2. For 1 mM $K_3Fe(CN)_6$, $n = 1$, $D_R = 7.6 \times 10^{-6}$ cm^2 s^{-1}, c_o is the concentration of $K_3Fe(CN)_6$ in M and ν is the scan rate in V s^{-1}. The slope of i_p versus $\nu^{1/2}$ plot was then used to calculate the surface area of bare and SWNTs modified EPPGE which were found as 0.08239 cm^2 and 0.22479 cm^2 respec-

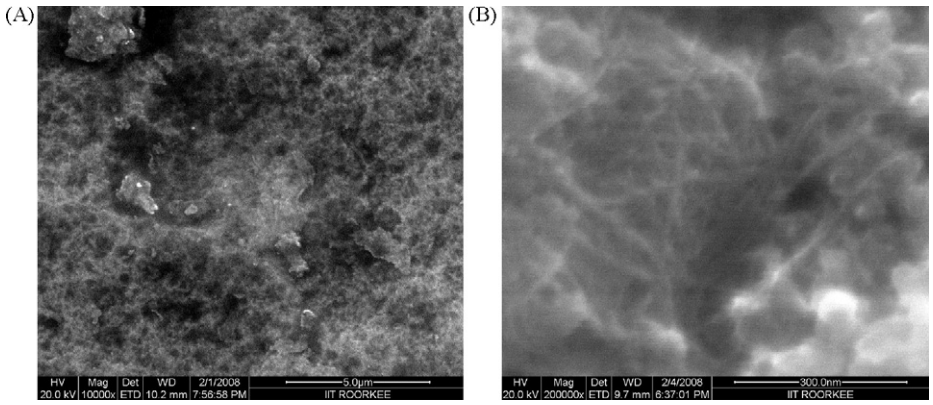

Fig. 1. A comparison of typical FE-SEM images of (A) bare and (B) SWNTs modified edge plane pyrolytic graphite electrode.

tively. The effective working area of the modified electrode is ~2.7 times larger than that of the bare EPPGE thereby indicating that the bare electrode has been modified efficiently by SWNT film. In recent studies, the increased dc current signals in cyclic voltammetry seen for the ferri/ferro cyanide at SWNTs modified glassy carbon electrode have been assigned to effect of diffusion within a porous thin layer [34]. Thus, apart from semi-infinite planar diffusion of ferri/ferro cyanide at the SWNTs modified electrode thin layer diffusion effects are also likely to operate.

3.2. Voltammetric behavior of methylprednisolone

3.2.1. Cyclic voltammetry

The cyclic voltammograms recorded for 0.3 μM methylprednisolone at the bare and SWNTs modified EPPGE in 1 M phosphate buffer solution at pH 7.2 are illustrated in Fig. 2. A well defined single reduction peak at ~−1312 mV was obtained at SWNTs modified EPPGE which shifted to more negative potentials (~−1458 mV) with a marked decrease in peak current at the bare EPPGE. These results clearly reveal that SWNTs acts as a very efficient promoter to enhance the kinetics of the electrochemical reduction of methylprednisolone. The absence of anodic peaks in the reverse scan clearly indicated that the reduction of methylprednisolone at this particular voltammetric sensor is irreversible in nature. To ascertain the nature of electrode reaction, sweep rate studies were performed in the range 10–1000 mV s^{-1}. The peak current was found to increase with increasing sweep rates and the plot of $i_p/v^{1/2}$ versus log v clearly indicated that the electrode process is adsorption controlled [35,36]. The peak potentials shifted to more negative potentials with increasing scan rate. The change in peak potential at different pH values was also studied and a linear plot was obtained between E_p and pH which obeyed the following equation:

$$-E_p(\text{pH } 2.4\text{–}11.0) = [889 + 60.50\,\text{pH}]\ \text{mV versus Ag/AgCl}$$

with a correlation coefficient of 0.9950. The slope clearly indicated that the total number of electrons and protons taking part in the charge transfer was the same. As SWV is considered to be a more sensitive technique in comparison to cyclic voltammetry, hence it is used for the determination of methylprednisolone.

3.2.2. Square wave voltammetry

Initially, square wave voltammograms were recorded for 100 nM methylprednisolone at pH 7.2 at the bare basal plane pyrolytic graphite electrode (BPPGE), bare EPPGE and SWNTs modified EPPGE. The working electrodes had almost the same surface area exposed to solution. Fig. 3 represents a comparison of square wave voltammograms observed for the drug at different working electrodes. In the case of bare BPPGE, a small peak is observed at ~−1395 mV which shifts to ~−1336 mV at bare EPPGE, thus indicating that the exposed edge plane sites in bare EPPGE contribute in making it a better substrate for modification than bare BPPGE. At SWNTs modified EPPGE, methylprednisolone gets reduced at ~−1285 mV with a significant increase in the peak current (Fig. 3). The increase in peak current confirms that the adsorption is much stronger on SWNTs modified EPPGE than bare EPPGE as reported

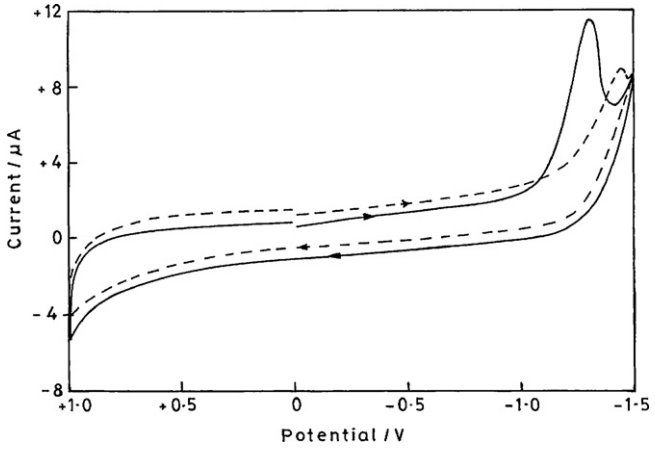

Fig. 2. Cyclic voltammograms obtained for 0.3 μM methylprednisolone at pH 7.2 at bare (- - - -) and SWNTs modified EPPGE (—) at 50 mV s^{-1}.

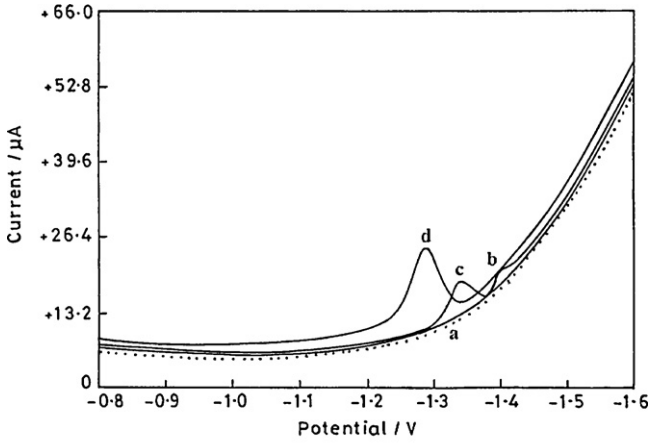

Fig. 3. A comparison of square-wave voltammograms of 100 nM methylprednisolone at pH 7.2 at bare BPPGE (b), bare EPPGE (c) and SWNTs modified EPPGE (d). (a) is the background phosphate buffer solution (pH 7.2) at SWNTs modified EPPGE.

earlier for other compounds [37–39]. Thus, the increase in current response along with the lowering of peak potential is a clear evidence of the electrocatalytic activity of SWNTs modified EPPGE towards the reduction of methylprednisolone. It has been reported that the electrocatalytic activity of SWNTs is due to the metallic impurities present in it [40,41]. Hence, further investigations were carried out at SWNTs modified EPPGE.

3.3. Influence of pH and square wave frequency

The electrochemical behaviour of methylprednisolone at different pH and square wave frequency were then studied at SWNTs modified EPPGE. The voltammetric reduction of 100 nM methylprednisolone was studied in the range 2.4–11.0 in phosphate buffer solution. The pH value strongly affects the peak potential of methylprednisolone, with the E_p shifting linearly towards more negative potential values with increase in pH. The relationship between $-E_p$ and pH is represented by the following equation:

$$-E_p(\text{pH } 2.4\text{–}11.0) = [842 + 62.85\ \text{pH}]\ \text{mV versus Ag/AgCl}$$

having correlation coefficient of 0.9969. The slope of 62 mV/pH indicates that the number of protons and electrons involved in the reduction process is equal. The results were thus found to be consistent with the previous studies performed using cyclic voltammetry.

The effect of square wave frequency on peak potential was examined in the range 5–200 Hz at pH 7.2 at SWNTs modified EPPGE. The plot of $-E_p$ versus log f was linear and is found to shift towards more negative potentials with increase in square wave frequency. The variation of $-E_p$ with log f can be expressed by the equation:

$$-E_p(\text{mV}) = 74.98\ \log f + 1197$$

with a correlation coefficient of 0.9937.

The peak current (i_p) for the reduction of methylprednisolone was found to increase linearly with the increase in square wave frequency in the range 5–200 Hz and the relation between i_p and f can be expressed by the relation:

$$i_p(10^{-5}\ \text{A}) = 0.139f - 0.329$$

having a correlation coefficient of 0.9933. These observations are in agreement with the properties of irreversible electrochemical process which is adsorption controlled [42–44]. The results supported the inferences obtained from cyclic voltammetry studies.

3.4. Concentration study

The quantitative analysis of the drug was based on the dependence of the peak current on the concentration of methylprednisolone. Typical square wave voltammograms depicting the systematic increase in the peak current values with an increase in the concentration in the range 5–500 nM is presented in Fig. 4 along with the linear calibration plot as the inset. The peak current is found to increase linearly with increasing concentration of methylprednisolone and the linear regression equation is expressed as:

$$i_p(10^{-5}\ \text{A}) = 0.0098C\,(\text{nM}) + 0.373$$

where C is the concentration of methylprednisolone. The correlation coefficient for the expression was 0.993. The current values are obtained by subtracting the background current and are reported as an average of at least three replicate determinations. The detection limit of the proposed method was calculated by using the formula $3\sigma/b$, where σ is the standard deviation of the blank and b is the slope of the calibration curve and it was found as 4.5×10^{-9} M. The sensitivity was estimated to be 98 nA nM^{-1}.

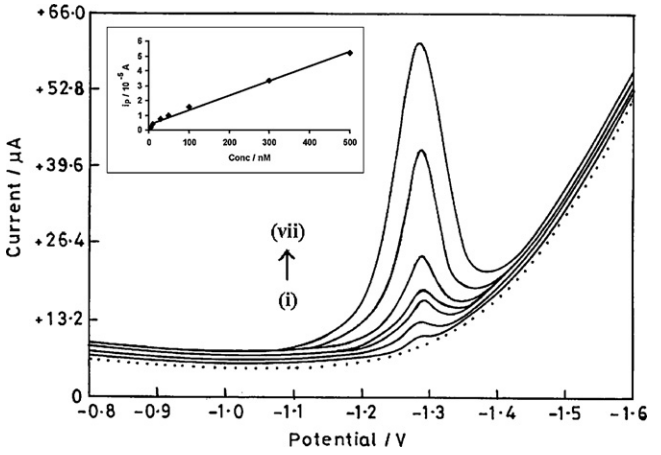

Fig. 4. Square wave voltammograms recorded for (a) phosphate buffer solution (background) at the modified electrode (...) and (b) increasing concentration of methylprednisolone at the modified electrode (—) [curves were recorded at (i) = 5; (ii) = 10; (iii) = 30; (iv) = 50; (v) = 100; (vi) = 300; (vii) = 500 nM concentration in phosphate buffer solution of pH 7.2] and observed calibration curve of peak current on methylprednisolone concentration (inset) measured at pH 7.2 at SWNTs modified EPPGE.

3.5. Effect of the amount of SWNTs

The effect of different quantity of SWNTs on the peak current response of methylprednisolone was examined. For this purpose, different volumes of the suspension prepared by dispersing SWNTs in N,N-dimethylformamide were casted on the bare electrode surface. It was observed that up to 40 μL there was an increase in the peak current response of 100 nM methylprednisolone at pH 7.2. At SWNTs volume more than 40 μL, the peak current response became almost constant. Therefore, it can be stated that the optimum amount of SWNTs required to catalyze the reduction of methylprednisolone is 40 μL and is used in the present investigation.

3.6. Reproducibility and stability of the SWNTs modified electrode

The reproducibility of the modified electrode has been evaluated by repetitive determinations of 100 nM methylprednisolone at pH 7.2. The results of six replicate measurements showed a relative standard deviation (R.S.D.) of 2.13% indicating that the results are reproducible. Further, inter-day precision was examined by measuring the current response of the modified electrode for six consecutive days for the same 100 nM concentration of methylprednisolone and the R.S.D. was found to be 3.02%. To confirm the reproducibility of the results further, four different modified electrodes with approximately the same exposed surface area were independently constructed. They showed an acceptable reproducibility with a R.S.D. of 1.67% for 100 nM methylprednisolone.

To characterize the stability of the SWNTs modified EPPGE, the voltammetric current response of fixed concentration of 100 nM methylprednisolone was measured after the modified electrode was stored over a period of 10 days. The electrode was used daily and stored in air. Only a minimal decrease of current sensitivity with a R.S.D. of about 3.62% was observed which can be attributed to the excellent stability of the modified electrode. Thus, the SWNTs modified EPPGE exhibits good stability and reproducibility for the determination of methylprednisolone.

Table 1
Determination of methylprednisolone in pharmaceutical formulations using SWNTs modified EPPGE.

Sample	Stated content	Determined content	Error (%)
Medrol	16 mg	15.65 mg	−2.2
Sterio-16	16 mg	15.78 mg	−1.4
Depo-Medrol (injection)	40 mg/mL	38.74 mg/mL	−3.1

The R.S.D. value for determination was less than 4.1% for $n = 3$.

3.7. Pharmaceutical formulations

The method was successfully implemented for the analysis of three commercial medicinal samples containing methylprednisolone, viz. Medrol (Pharmacia, Pfizer products India private limited, Jogeshwari, Mumbai), Sterio–16 (Welcure drugs and pharmaceutical limited, Ranipur, Haridwar) and Depo-Medrol (Pfizer products India private limited, Jogeshwari, Mumbai). Solutions obtained by dissolution of methylprednisolone tablets and injection were subsequently diluted so that methylprednisolone concentration lies in the range of calibration plot. Square wave voltammograms were then recorded and the concentration of methylprednisolone in the pharmaceutical preparations was determined. Results summarized in Table 1 show that the content for all assayed tablets and injection falls within the claimed amount indicating the good agreement with the proposed voltammetric method.

3.8. Quantification in real samples

The effectiveness of the proposed approach was evaluated on human blood plasma samples obtained from patients undergoing treatment with methylprednisolone. The samples were used for analysis without any dilution as the major metabolites present in human plasma such as ascorbic acid, uric acid and dopamine did not exhibit reduction peak in the range −0.8 to −1.6 V. Curve a in Fig. 5 represents a typical voltammogram which depicts human blood plasma of normal person used as control. The human blood plasma of patient obtained after 10 h of administration of Medrol tablet and the blood plasma of patient spiked with methylprednisolone are shown by curves b and c. A well-defined peak of methylprednisolone was observed at ∼−1285 mV and the results obtained are tabulated in Table 2.

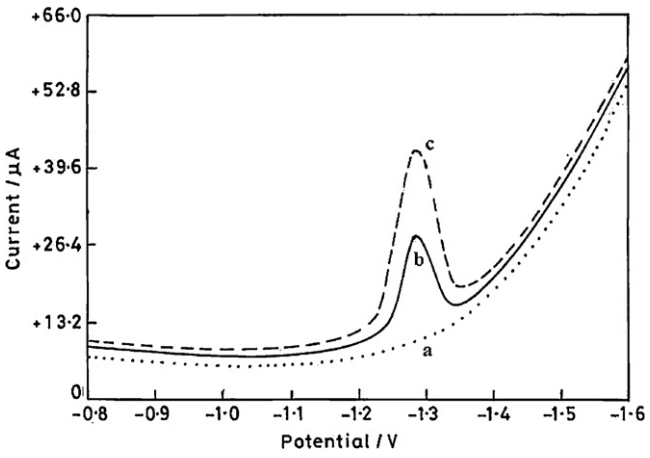

Fig. 5. Voltammograms observed for (a) normal blood plasma sample (. . .), (b) plasma sample of patient being treated with methylprednisolone (—) and (c) the patient sample spiked with methylprednisolone (- - - -) at pH 7.2 at SWNTs modified EPPGE.

Table 2
A comparison of observed concentration of methylprednisolone in human plasma after 10 h of methylprednisolone administration at SWNTs modified edge plane pyrolytic graphite electrode and by using HPLC.

Added (μM)	Found (μM)	Actual concentration (μM) by	
		Modified EPPGE	HPLC
Sample 1			
0.00	0.15	0.15	0.14
0.10	0.24	0.14	0.15
0.20	0.35	0.15	0.13
Sample 2			
0.00	0.16	0.16	0.15
0.10	0.25	0.15	0.14
0.20	0.35	0.15	0.15
Sample 3			
0.00	0.14	0.14	0.14
0.10	0.25	0.15	0.16
0.20	0.36	0.16	0.15

The R.S.D. value for determination was less than 2.3% for $n = 3$.

3.9. Comparison by HPLC

The results obtained by the voltammetric method were compared with HPLC analysis to prove the reliability of data obtained. For this purpose, various concentrations of methylprednisolone were analyzed using HPLC and the peak area was calculated. A well-defined peak is obtained at $R_t \sim 9.176$ min in the standard sample of methylprednisolone as shown in Fig. 6(A). Blood plasma sample of normal person used as control was then injected in HPLC and the peak of methylprednisolone was found to be absent as depicted in Fig. 6(B). Finally, the concentration of the drug was determined in the human blood plasma of patients undergoing treatment with methylprednisolone. Fig. 6(C) shows a typical HPLC chromatogram of Sample 1 of patient plasma. The peak at $R_t \sim 9.176$ min is due to methylprednisolone. However, no attempt was made to identify the

Scheme 1. Tentative mechanism for the reduction of methylprednisolone.

rest of the peaks which are likely to be due to uric acid, ascorbic acid etc. The plasma sample of the patient was then spiked with methylprednisolone which is presented in Fig. 6(D). The chromatogram clearly indicates the increase in peak at $R_t \sim 9.176$ min. A calibration curve was obtained by plotting the peak area of the analyte peaks against the analyte concentration. The resulting calibration plot was linear. A comparison of the values obtained by HPLC and the proposed voltammetric method (as listed in Table 2) clearly indicated that the results obtained by two methods are in good agreement.

4. Conclusions

The purpose of the present investigation was to develop a specific and robust method for the determination of methylprednisolone in pharmaceutical formulations and real samples. The electrochemical reduction of the drug had an advantage over the voltammetric oxidation of methylprednisolone because the major metabolites like uric acid, ascorbic acid, dopamine etc. present in real samples did not interfere with the studies. These metabolites did not exhibit any reduction peak in the potential window of −0.8 V to −1.6 V. The voltammetric reduction of related corticosteroids was also investigated on the SWNTs modified EPPGE. It was found that prednisolone, triamcinolone and betamethasone showed reduction peaks at ∼−1332, ∼−1232 and ∼−1102 mV indicating that SWNTs modified EPPGE is specific for the reduction of methylprednisolone at ∼−1285 mV. The significant increase in current response for the ferri/ferro cyanide oxidation at SWNTs modified EPPGE cannot account for by the semi-infinite diffusion model alone and can also be attributed to the thin layer diffusion as reported earlier at SWNTs modified glassy carbon electrode by Streeter et al. [34]. The improvement of methylprednisolone voltammetric signal at the modified electrode also suggests the diffusion within porous layer in addition to semi-infinite diffusion. Also in addition to the increased surface area of the electrode, the improved adsorption efficiency of the electrode surface due to the presence of SWNTs plays a vital role as reported earlier [37–39]. Thus, the SWNTs modified EPPGE shows electrocatalytic activity towards the reduction of methylprednisolone leading to an increase in the current response and a shift of the reduction potential to lower values in comparison to bare BPPGE and bare EPPGE. The developed protocol has lower detection limit (4.5×10^{-9} M) as compared to the previously reported at gold nanoparticles modified indium tin oxide (2.68×10^{-7} M) [30] using differential pulse voltammetry.

The available sites for reduction in methylprednisolone are the keto groups present at positions 3 and 20. It is clearly stated in literature that in ketosteroids the carbonyl group conjugated with a double bond undergoes reduction preferably in comparison to the isolated keto group [45]. Thus, the most probable site for reduction in methylprednisolone is at position 3 where the keto group undergoes reduction in $2e^-$, $2H^+$ process to give a hydroxyl group as shown in Scheme 1.

Thus, the present method has been satisfactorily applied to the voltammetric determination of methylprednisolone in pharmaceuticals and human blood plasma samples obtained from patients being treated with the drug. A comparison of the results with HPLC indicates that the method is sensitive and the results are comparable. The developed protocol is simple, rapid, specific, reproducible and sensitive for the determination of methylprednisolone at SWNTs modified edge plane pyrolytic graphite electrode at the site of competitive games to detect the cases of doping.

ABSTRACT

Prion proteins that have transformed from their normal cellular counterparts (PrP^c) into infectious form (PrP^{res}) are responsible for causing progressive neurodegenerative diseases in numerous species, such as bovine spongiform encephalopathy (BSE) in cattle (also known as mad cow disease), scrapie in sheep, and Creutzfeldt–Jakob disease (CJD) in humans. Due to a possible link between BSE and CJD it is highly desirable to develop non-invasive and *ante mortem* tests for the detection of prion proteins in bovine samples. Such *ante mortem* tests of all cows prior to slaughter will help to prevent the introduction of PrP^{res} into the human food supply. Furthermore, detection of PrP^{res} in donated blood will also help to prevent the transmission of CJD among humans through blood transfusion. In this study, we have continued development of a micromechanical resonator array that is capable of detecting PrP^c in bovine blood serum. The sensitivity of the resonators for the detection of PrP^c is further enhanced by the use of secondary mass labels. A pair of antibodies is used in a sandwich immunoassay format to immobilize PrP^c on the surface of resonators and attach nanoparticles as secondary mass labels to PrP^c. Secondary mass labeling is optimized in terms of incubation time to maximize the frequency shifts that correspond to the presence of PrP^c on the surface of resonators. Our results show that a minimum of 200 pg mL^{-1} of PrP^c in blood serum can be detected using micromechanical resonator arrays.

1. Introduction

Prions, discovered by Stanley Prusiner in 1982 [1], are proteins, which in mis-folded form are believed to be responsible for causing progressive neurodegenerative diseases in numerous species, such as bovine spongiform encephalopathy (BSE) in cattle (also known as mad cow disease), scrapie in sheep, and Creutzfeldt–Jakob disease (CJD) in humans. These are fatal diseases and currently untreatable. It is believed that these diseases are caused by the conversion of normal cellular prion proteins (PrP^c) into a mis-folded infectious form (PrP^{res}). Although the infectious form has the same amino acid sequence as the normal form, it is rich in beta-sheet structures as compared to the normal form which is rich in alpha helical structures [2].

The current state of technology to detect BSE relies upon the *post-mortem* detection of prions in homogenates of brain tissue removed from slaughtered cows. The numerous methods used to detect PrP^{res} in the brain homogenate are described below. Such *post-mortem* testing therefore is not suitable for routine screening of all animals, regardless of initial symptoms of BSE when animals cannot stand or walk. But, it has been shown that the animals not showing any symptoms of the disease could potentially be carrying the disease [3,4]. If these animals are not tested for PrP^{res}, they could conceivably make their way into the human food supply. Thus in order to improve the safety of human food, new technologies must be developed to allow *ante mortem* tests for PrP^{res} proteins in the body fluids of the cows. Blood is considered as the most appropriate body fluids, and is known to contain infectivity even before the onset of the clinical symptoms [5–7]. An important aspect of these *ante mortem* tests is the short detection time, so that all animals can be routinely screened prior to slaughter. Contraction of CJD in humans is not only attributed to the consumption of contaminated meat, but also to blood transfusions from an infected donor [5,8]. This is a serious problem, especially if an asymptomatic infected individual was not prevented from donating blood because of the lack of sufficiently sensitive screening tests [9–11]. Such presumed healthy humans could trigger the transmission of the disease to other humans through blood transfusion. Therefore the lack of routine testing of cattle is compounded by the lack of routine testing of human blood for transfusion, establishing a dangerous scenario whereby transmission of infectious prions from cattle to humans could lead to additional transmission of those infectious prions from one human to another via blood transmission.

There are several methods available for the detection of prion proteins in animals, namely, protein misfolding cyclic amplification,

doi:10.1016/j.talanta.2009.07.032

conformation-dependent immunoassay, dissociation enhanced lanthanide fluorescent immunoassay, capillary gel electrophoresis, fluorescence correlation spectroscopy, flow microbead immunoassay, etc. [12]. Most of these techniques are intended to detect PrP^{res} in the brain homogenate and thus will not be suitable for routine blood screening based tests. Saa et al. [13] developed a method to detect PrP^{res} proteins in the blood of presymptomatic animals. The number of PrP^{res} proteins in the blood of infected hamsters was amplified by mixing them with normal brain homogenate and running protein misfolding cyclic amplification (PMCA) to convert PrP^{c} (in the normal brain homogenate) into PrP^{res}. Seven rounds of 144 PMCA cycles were performed in order to sufficiently amplify the initial low numbers of PrP^{res} to the detection level. The technique was sensitive to detect as low as 20–50 molecules of monomeric hamster PrP, however, the time of cyclic amplification alone was 525 h (7× 75 h). Another study based on cytometric methods demonstrated analytical sensitivity in the range of 10 aM or 0.24 fg mL^{-1} of PrP^{res} for serum samples [14]. The cytometric test, however, requires at least a 20 h incubation time, followed by flow cytometry. Both of these methods are highly sensitive to detect extremely small amounts of infectious prions in blood, but until either of these methods can be automated and performed in a faster manner, they will prove to be too complicated and time consuming to be practical for routine rapid screening of all cattles prior to slaughter.

Micromechanical resonators are considered as suitable candidate to develop sensitive and rapid blood based tests to detect prion proteins. Resonators have been used to detect attograms of masses [15]. They are suitable to detect variety of biomolecules, as the resonators can be functionalized with a number of different biorecognition molecules (antibody, nucleic acid, and other protein). Resonators can be fabricated with a variety of materials or coated with a particular material as suitable for the functionalization chemistry. These devices resonate at a frequency which decreases as mass is added to the surface. This frequency shift is measured to detect the presence of mass on the surface. The sensitivity of these resonators to mass detection depends on size, shape, thickness and the fabrication material [16–22]. In order to detect biomolecules of smaller masses, mass amplification techniques are used. Amplification is achieved by using secondary mass labeling with massive particles binding to the target analyte already present on the surface of resonators [23]. These amplification techniques are not time consuming as compared to PMCA or cytometry used for prion protein detection, although the amplification is limited by the background noise due to non-specific binding. In addition to this, the array format of the resonators makes it possible to run multiple tests on the same sample to improve the statistics of detection as well as to reduce false positives and negatives.

In the current work, we demonstrate the potential of these devices for the direct detection of prion proteins in blood serum. We have fabricated an array of paddlever shaped resonators for the detection PrP^{c} in blood samples. Secondary antibodies and nanoparticles were used for the mass amplification to detect the presence of small amounts of PrP^{c}. A sandwich immunoassay was used to immobilize PrP to the surface of resonators and subsequently add nanoparticles. Kinetic studies of secondary mass labeling have also been performed to improve the sensitivity of the resonators for detection of PrP^{c}. Due to the limitation of biosafety level of our research lab, we were able to work on non-infectious full length prion protein (PrP^{c}) and not infectious prion protein (PrP^{res}). We project this work to be successfully used with PrP^{res} in real world based on the affinity of the antibodies used, which have been claimed to be equally sensitive for the detection of both PrP^{c} and PrP^{res} (based on the information provided by the antibodies supplier).

2. Materials and methods

2.1. Reagents

Two antibodies were used for the sandwich assay. One is conjugated to the surface of the resonators (capture antibodies) while another is used to attach nanoparticles as additional mass labels (detection antibodies). Both antibodies are monoclonal and are produced in mice against different epitopes of bovine prion protein. Prion proteins used in this work are histidine tagged recombinant proteins and are full-length mature part of bovine PrP (25–244) expressed in *E. coli* BL21 (Millipore Inc.). Capture antibodies are against amino acids 23–237 of bovine prion protein (Millipore Inc.) and detection antibodies are against amino acids 123–136 and 140–160 of bovine prion protein (Abcam Inc.). Bovine serum albumin was used to block the surface of the resonators and was purchased from Sigma. Streptavidin conjugated nanoparticles (R&D Systems, Minneapolis, MN) of diameter 150 nm were used as secondary mass labels. These particles were irregularly shaped particles with diameters ranging from 80 nm to 200 nm (as analyzed with SEM). Deprionized fetal bovine serum was obtained from BioRad Laboratories. BioRad obtained fetal bovine serum from Biowest, Rau. Della Caille, Nuaille, France and origination of the product is from Canada. Deprionization was performed by BioRad Laboratories. Aliquots were made from the stock and were stored frozen until used. Before use the aliquots were thawed and vortexed. 3-Aminopropyl triethoxysilane (APTES, Sigma) was used to functionalize the surface of resonators with primary amine groups. Glutaraldehyde was used as a homo-bifunctional cross-linker to attach antibodies on the silanized surfaces. Glycine solution prepared in deionized (DI) water was used for quenching. Both of these chemicals were purchased from Sigma. Detection antibodies were modified with biotin to attach 5–7 biotin molecules per antibody molecule by using NHS-PEO_4-biotin (Pierce Chemicals). The biotin per antibody was determined by using EZ biotin quantification kit (Pierce Chemicals).

2.2. Resonator fabrication and functionalization

Resonators were fabricated as described in our previous work [24]. Briefly, a 150 nm thick layer of low-stress nitride was deposited on a thermally oxidized silicon wafer. The silicon nitride device layer was then patterned using an anisotropic reactive ion etch. Chips were then dipped in hydrofluoric acid in order to remove the 1.5 μm thick sacrificial silicon dioxide layer under the resonators and release them from the substrate. Release allows them to move freely and resonate. Resonators in this work were cantilevered structures with a 3 μm × 10 μm paddle at the free end, also called paddlevers, with typical resonant frequencies of approximately 4.6 MHz and quality factors of about 7000 for bare devices.

In this study, APTES (10% solution in dry toluene) was used to silanize the surface of the resonators. Glutaraldehyde (5% solution in 10 mM borate buffer pH 8.0) was used as a cross-linker between amine groups on capture antibodies (50 μg mL^{-1} in PBS buffer) and the surface of the resonators. The conjugation chemistry to modify the surface of resonator with capture antibodies is shown in Fig. 1. After a wash with DI water (95 rpm for 4 min, two times), the devices were quenched with glycine (50 mM solution in DI water, 30 min) to block unreacted amine group binding sites on the surface of the resonators followed by a blocking with 1% BSA (w/v) in PBS buffer (30 min). Blood serum obtained from BioRad laboratories was spiked with different concentrations of prion protein. Excess of prion protein was removed by washing with DI water (95 rpm for 4 min, two times). This was followed by a 10 min blocking step. Detection antibodies (50 μg mL^{-1} in PBS buffer) were used to label prion protein on the surface of resonators (80 min

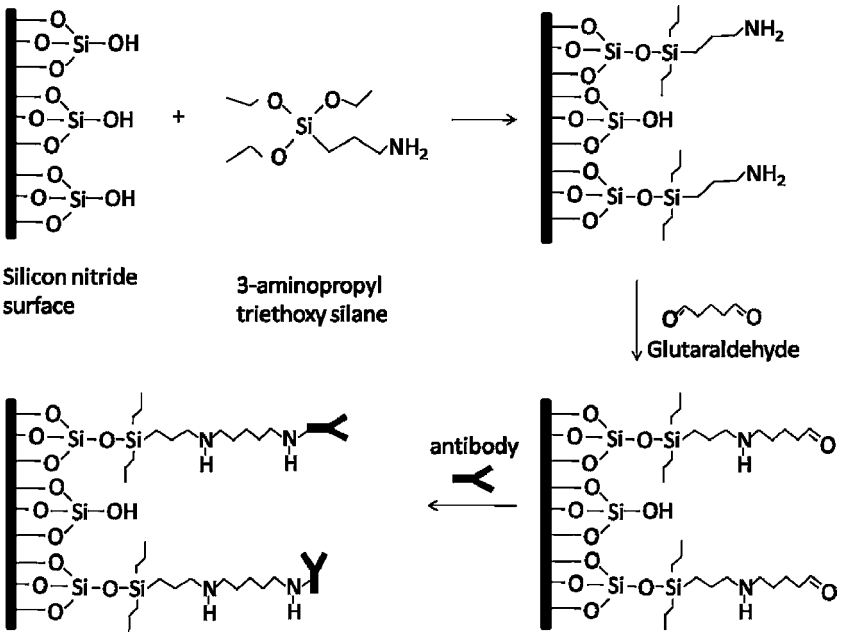

Fig. 1. Schematic diagram of the capture of antibodies on the surface of resonators. Amine groups were formed on the resonator surface by covalent reaction between 3-aminopropyl-triethoxy silane and silanol groups on silicon nitride surface. Glutaraldehyde was used as a cross linker between amine groups on the resonator surface and antibodies.

incubation time). After the removal of excess of detection antibodies (DI water wash, 95 rpm for 4 min, two times), the streptavidin conjugated nanoparticles were attached to biotin on the detection antibodies. Finally, excess nanoparticles were washed (DI water wash, 95 rpm for 4 min, two times). An orbital shaker was used for washing.

2.3. Frequency measurement

Resonators were both excited and sensed in vacuum using optical techniques as shown in Fig. 2a [18]. A 405 nm diode laser was modulated in intensity and used to excite the resonators by focusing the beam near its clamped end. Due to the higher thermal conductivity of the silicon nitride layer as compared to the underlying silicon dioxide layer, a temperature gradient is induced that is responsible for the inhomogenous thermal expansion of the device. Thermal expansion mismatch between the silicon nitride and oxide is ultimately responsible for actuation of the sensor. Resonant frequencies were determined interferometrically by measuring the reflectance variation from an incident HeNe red laser focused at the free end of the resonator. As the sensor moves in and out of the plane, the gap between the wafer and device layers changes in thickness. This dynamic film stack changes the degree of optical interference and modulates the intensity of reflected light at the mechanical resonant frequency of the device. The reflected signal was collected by a photodetector, and the resonant spectrum of the device extracted using a spectrum analyzer.

Resonators chips were dried under the stream of nitrogen gas before frequency measurements. They were loaded into a small vacuum chamber that was mounted to a motorized stepper stage and the resonant frequencies were measured. Computer control of the stage and spectrum analyzer allowed easy measurement of large arrays of resonators in a short amount of time. The chip consisted of blocks of arrays of the resonators, each containing 20 devices. All devices on the chip were alike and they gave similar response in terms of the resonant frequency and quality factor. For each concentration of PrP^c and control experiments (without PrP^c), 2 arrays of resonators (40 devices) per chip were chosen randomly on the chip and they were used for frequency measurement in a single test. The average values and errors were calculated based on frequency measurements from 40 resonators. These experiments were repeated on other day as well.

The paddlever shaped cantilevers were used for mass detection because the tip of the cantilever is sensitive to bound mass [22]. Paddlever design increases the area for binding in the tip region and in turn improves its sensitivity. Fig. 2b and c shows the conjugation of prion proteins and nanoparticles mass labels on the surface of resonators. The addition of mass decreases the resonant frequencies of resonators (Fig. 2d).

3. Results and discussion

3.1. Reaction kinetics of secondary mass labeling

Secondary mass labeling was optimized by varying the incubation time during the antibody and nanoparticles conjugation step. Separate experiments were performed for antibodies and nanoparticles to see the effect of each mass label on frequency shifts. The concentrations of PrP^c used for this purpose for antibodies and nanoparticles were 2 $\mu g\,mL^{-1}$ and 20 $ng\,mL^{-1}$, respectively. The incubation times for antibodies and nanoparticles were varied from 20 to 120 min and 10 to 60 min, respectively. The results showed that the frequency shifts (measured before and after secondary mass labeling) for control and sample increased with the increase in incubation time (data not shown). The optimum incubation time was determined based on the normalized frequency shift calculated by subtracting the frequency shift of the control sample from the frequency shift of the specimen being tested. The control devices had no PrP^c added to the blood serum. The results indicated that the incubation times of 80 min and 30 min were sufficient to maximize the effect (normalized frequency shifts) of secondary mass labeling for the detection of PrP^c in blood serum.

The first order Langmuir model is used to study adsorption kinetics of secondary antibodies and nanoparticles labeling. This model is based on the following assumptions—adsorption occurs only at specific localized sites on the surface and coverage of the surface takes place in the form of a monolayer of adsorbate. Our experimental conditions will sufficiently satisfy these conditions.

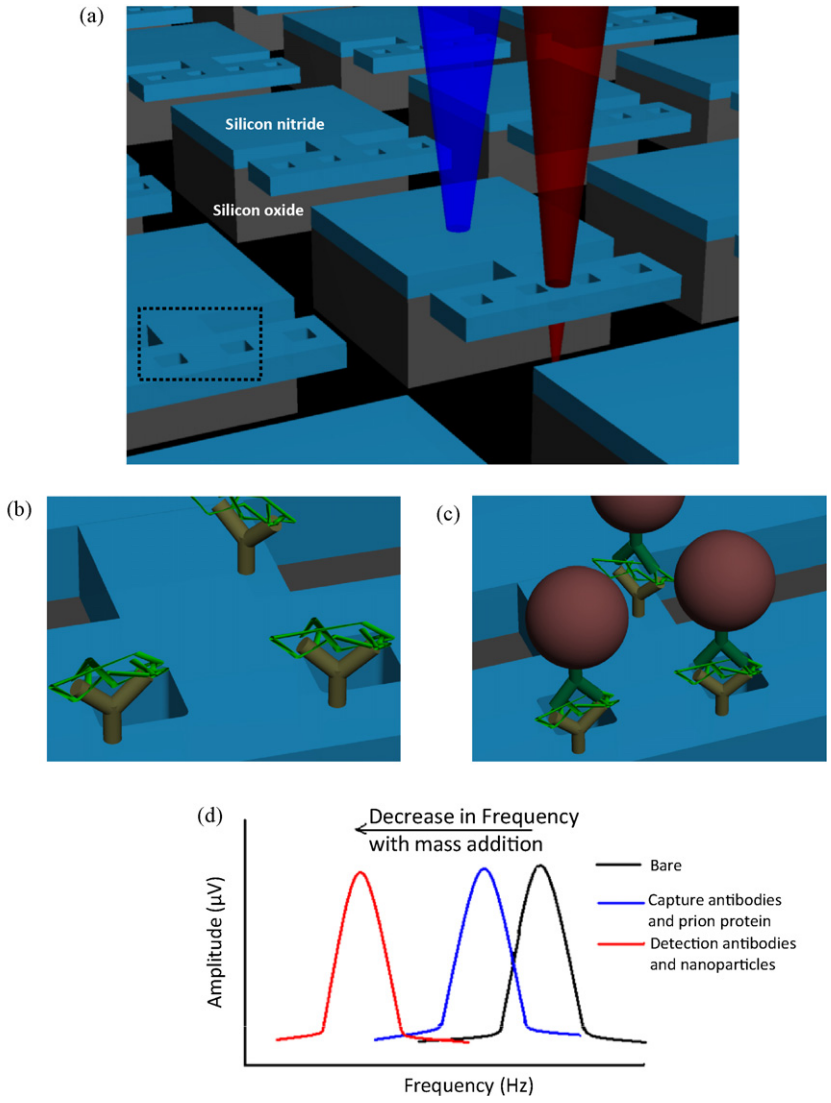

Fig. 2. Schematic diagrams of mechanism of actuation and detection of resonant frequencies and secondary mass labeling. (a) shows an array of bare resonators actuated and detected by blue and red laser, respectively. Dotted rectangle shows the area of the resonator shown in figures b and c; (b) shows the conjugation of prion protein on the surface using capture antibodies; (c) shows the secondary mass labeling with nanoparticles. Detection antibodies were used in between nanoparticles and prion protein; and (d) shows the change in resonant frequencies with mass addition. Antibodies, prion proteins and nanoaprticles are represented by Y-shape, intertwined ribbon, and spheres, respectively. Diagram is not drawn to scale.

As far as the localization of binding sites is concerned, secondary antibodies are developed against PrP and they will bind only to the location where PrP^c are present. Self-binding and non-specific binding of antibodies were minimum as shown by the presence of very small number of nanoparticles in the SEM image of the control (Fig. 3). The possibility of multiple layer formation during the addition of nanoparticles is also avoided by sequential addition of secondary antibodies and nanoparticles. Keeping in mind that there are multiple biotin molecules per antibody and streptavidin molecules per nanoparticles, cluster formation is minimized by the addition of nanoparticles after conjugation of secondary antibodies on the surface of the resonator. Assuming an irreversible adsorption of antibodies and nanoparticles on the surface of the resonator, the first order Langmuir model can be written as:

$$\theta = 1 - \exp^{-k_{obs}\tau} \tag{1}$$

where θ is the fraction of sites occupied by antibodies or nanoparticles at time τ, k_{obs} is the absolute rate constant observed for the molecules adsorbed on the surface. θ can also be represented in terms of n, the number of binding sites at time τ, and N, the maximum number of sites required to form a monolayer:

$$\theta = \frac{n}{N} \tag{2}$$

Since the frequency shift can be related to the mass change on the surface of the resonator by:

$$\frac{\Delta f}{f} = -\frac{1}{2}\frac{\Delta m}{m} \tag{3}$$

We can write

$$\Delta f \alpha\, n \quad \text{and} \quad \Delta f_\infty \alpha\, n \tag{4}$$

where Δf and Δf_∞ are the frequency shifts when surface is partially (with n number) and completely (with N number) covered with molecules. Rearranging Eq. (3) and putting the ratio of above two equations into n/N, we get:

$$\ln\left(\frac{\Delta f_\infty - \Delta f}{\Delta f_\infty}\right) = -k_{obs}\tau \tag{5}$$

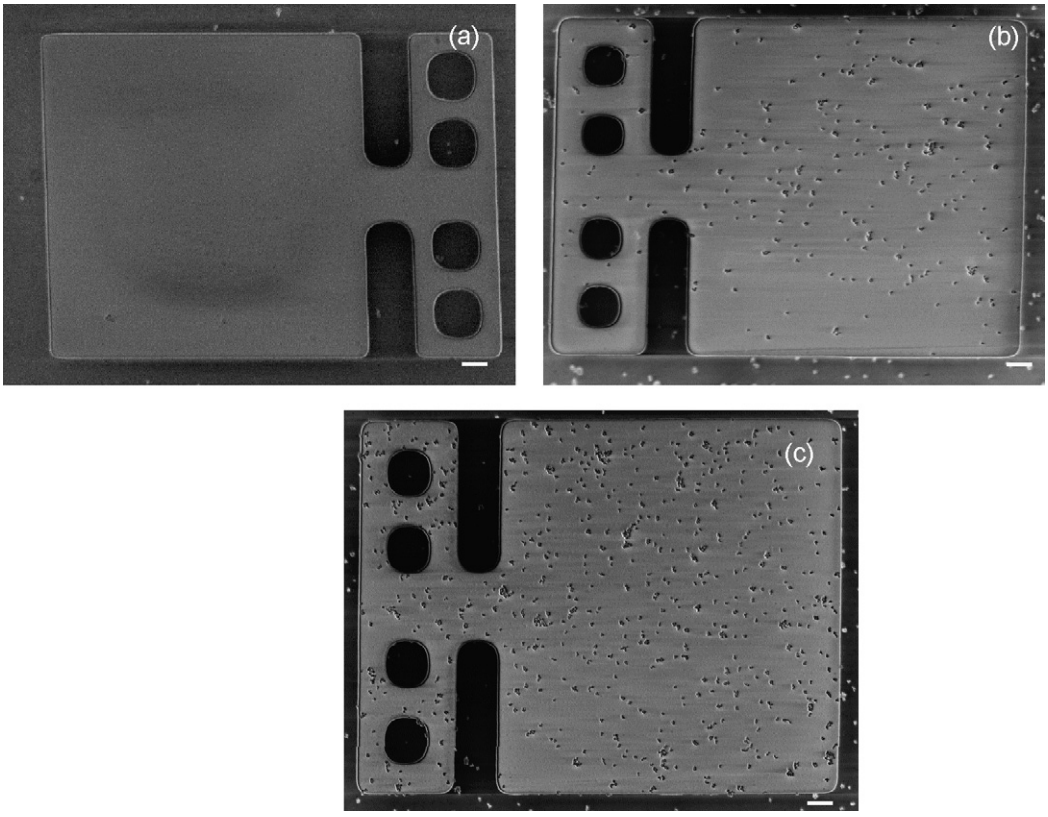

Fig. 3. Scanning electron micrographs of resonators with nanoparticle mass labeling for (a) control, and (b) 200 pg mL^{-1}, (c) 20 ng mL^{-1} of prion proteins in blood serum. Scale bar is 1 μm in length.

The plot of this equation with left hand side of the equation on y-axis and time (τ) on x-axis will determine the rate constant for the adsorption of antibodies and nanoparticles. Fig. 4 shows the plot of Eq. (5) for binding of secondary antibodies and nanoparticles. A linear curve fit results in a straight line with the equation $y = -mx$ where m represents the rate constant of adsorption. Based on the curve fit, we observed that the rate constant of adsorption of nanoparticles is twice as large as that of antibodies, which reveals that nanoparticles bind faster as compared to antibodies.

The total time of secondary mass labeling could have been reduced by preparing detection antibody–nanoparticle-conjugates before adding to the surface of the resonators. However, previous studies have shown that these conjugates form clusters and they are not uniform in size [25]. There are several biotin molecules per antibody and hundreds of streptavidin molecules per nanoparticle. As a result, several bonds are formed between antibodies and nanoparticles that give rise to the formation of clusters. The size of the cluster will depend on the relative concentrations of antibodies and nanoparticles and incubation time. Therefore, cluster formation will give non-uniform mass labeling and could also result in a higher variation in frequency shifts from one resonator to the other. Additionally, antibodies would not be available for binding with antigen due to physical entrapment into the clusters. Keeping these possibilities in mind, in the current study, we have added antibodies and nanoparticles in separate steps and have compromised on the total time for secondary mass labeling.

3.2. Prion protein detection in blood serum

The optimized conditions determined in the previous section were used to maximize the effect of secondary mass labeling to detect of PrP^c in blood serum. PrP^c was spiked in blood serum in a range of concentrations from 20 pg mL^{-1} to 200 ng mL^{-1}.

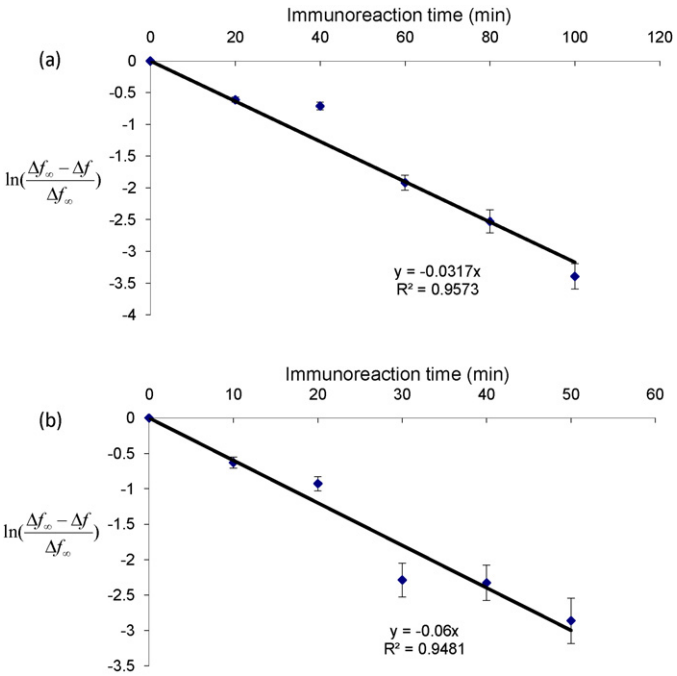

Fig. 4. Fitting of the Langmuir model to the change in the values of frequency shifts for the (a) secondary antibodies and (b) nanoparticles mass labeling with respect to immunoreaction time. Y-axis shows the left hand side of the equation $\ln\left(\frac{\Delta f_\infty - \Delta f}{\Delta f_\infty}\right) = -k_{obs}\tau$

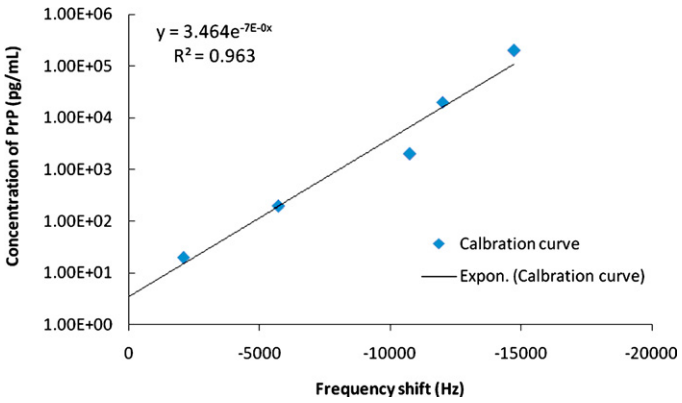

Fig. 5. Calibration curve for detection of unknown concentrations of prion proteins in blood serum by measuring the frequency shifts.

The frequency shift due to non-specific binding of non-targeted proteins in the blood serum was measured by using a control experiment with no PrP^c. This control experiment will also provide information about the presence of normal prion protein present in the fetal bovine serum. The frequency shift of the control experiments were -5519 ± 1201 Hz which matches clearly with the control experiments that were performed with buffers not with fetal bovine serum (shown in our previous work). It seems that the deprionization performed by BioRad Laboratories removed all prion proteins from fetal bovine serum. No information was made available to us about the deprionization protocol to make some specific comments about removal of PrP^c or PrP^{res} or both. The frequency shift for each concentration of PrP^c was determined by subtracting frequencies measured after PrP^c addition from that measured after nanoparticle addition. Such frequency shifts were measured for 40 resonators per chip and an average of these values was used to calculate the mean frequency shift for a concentration of PrP^c. Based on the comparison of mean values of frequency shifts for different concentrations of PrP^c and control sample, the minimum detection limit of PrP^c in blood serum was shown to be 200 pg mL^{-1}. Fig. 5 shows the calibration curve suitable for the measurement of an unknown concentration of PrP^c. The calibration curve is plotted with the frequency shifts on the x-axis and concentrations on a logarithmic scale on y-axis. It is observed that the frequency shifts and concentrations follow an exponential linear relationship with a function of $y = 3.464 \exp^{-7E-0x}$ and a coefficient of relationship (R^2) value of 0.963. In an application where we have a sample with unknown concentration of the PrP, we will experimentally determine two frequency shifts—control and sample. The normalized frequency shifts for the sample will be located on (x-axis) the calibration curve and tracked (on y-axis) for the unknown concentration of the PrP in the sample.

In order to show the conjugation chemistry of secondary mass labeling, SEM pictures are shown for two concentrations (20 pg mL^{-1} and 2 ng mL^{-1}) of PrP and the control sample (Fig. 3). It has been shown in our previous work that the number of nanoparticles increases with the increase in concentration of the PrP^c. The mass calculated from the number of particles counted on each resonator was not significantly different ($P > 0.05$) from the mass calculated using experimentally observed frequency shifts. Fig. 3 also shows that the numbers of nanoparticles increase with the increase in the concentrations of the PrP and the non-specific binding of antibodies and nanoparticles on the control is negligible as compared to samples. The number of nanoparticles on control represents the non-specific binding of antibodies and nanoparticles.

The current detection limit of PrP in blood is an order of magnitude lower than our previous work of detecting PrP in PBS buffer [24]. This can be attributed to the optimized protocol, thinner resonators and the blood serum proteins acting as blocking agents. Thinner resonators with smaller mass show large frequency shifts for the same change in mass on the surface, thus are more sensitive for the detection of small masses [16]. The albumin present in the bovine serum is most commonly used as blocking agent in immunoassays. Other blood serum proteins also act as blocking agent which may have reduced the non-specific binding of nanoparticles on the surface of resonators. The average frequency shift of the control sample in the current study was reduced by 25% as compared to the average frequency shift for the control in our previous work. Though these frequency shift values were not significantly different ($P > 0.05$).

The concentration of PrP^{res} in the buffy coat (a component of the blood) extracted from animals in their symptomatic and presymtomatic phase of the disease is expected to be 1 pg mL^{-1} and 0.1 pg mL^{-1}, respectively [6,11]. The resonators used in the present study could be used for the detection of such low concentrations of the PrP^{res} in the blood samples. Our current detection limit is not the fundamental limit of the system, rather is dependent on the capture efficiency of antibodies and uniform coating of antibodies on the surface. In one of our unpublished work, we have used cantilever array technology for the detection of fg/ml of similar mass of protein (prostate specific antigen). Thus antibodies and other reagents also play critical role in the detection low amounts of protein with this detection system. Moreover, thickness and shapes of the device can also play role in improving the detection limits. Concentration of PrP^{res} prior to detection could also be performed to detect low levels of PrP^{res} in the buffy coat of presymptomatic animals. Thus combining all these possibilities we are very confident that in the future current detection system could be used for the detection PrP in preclinical animals. The specificity of the system is a function of the antibodies. Although, our current system was developed for the detection of PrP^c, the same antibodies are also claimed to be sensitive for the detection of PrP^{res} (Product specification sheet, Chemicon Inc. and Abcam Inc.), and thus the current system could also be optimized for the detection of PrP^{res}. The combination of a concentration step, use of high density nanoparticles, thinner devices and different shapes of resonators could be instrumental in the detection of extremely low levels of infectious prion proteins in the blood of animals in the early stages of the disease. If so, resonators based system could serve as an industry standard to screen all animals going into the human food supply.

4. Conclusions

A detection system based on arrayed resonant sensors was successfully used to detect a minimum of 200 pg mL^{-1} of PrP^c in blood serum, and the response of the system was a linear exponential for a range of concentration from 20 pg mL^{-1} to 200 pg mL^{-1}. Additional effort will be required to improve the current detection limit and run appropriate field trials to detect infectious prions in the blood of animals at an early stage of the disease.

ABSTRACT

The prospect of using single bounce attenuated total reflectance (SB-ATR)-Fourier transform infrared (FTIR) spectroscopy as a rapid quantitative tool to determine the main fatty acid groups present in different edible oils was investigated. Partial least squares (PLS) calibrations were developed using SB-ATR-FTIR spectra which were associated with fatty acid groups (saturated, *trans*, mono- and polyunsaturated) using quantitative data obtained by gas chromatography (GC). Good calibrations were obtained for all main four fat groups (saturated, mono, *trans* and polyunsaturated) with excellent precision. The coefficient of determination (R^2), root mean square error of prediction (RMSEP) and bias for validation set were obtained as 0.999, 2.43 and 0.998 for saturated; 0.999, 1.850 and 0.003 for mono; 0.999, 0.625 and −0.001 for *trans* while for poly the values were 0.999, 1.170 and 0.003, respectively. The results of 13 validation samples for total saturated, mono, *trans* and polyunsaturated fats by FI-IR were found in the range of 8.16–55.16, 37.62–74.75, 0.20–18.16 and 1.36–62.35%, respectively. The present study shows that it may well be possible to expand the utility of SB-ATR-FTIR spectroscopy not only to provide isolated *trans* data, but also serve as a simple, rapid and quantitative means of categorizing the main groups present in the edible oils. The information obtained would be useful for meeting the new lipid nutritional labeling requirements.

1. Introduction

The rapid determination of fatty acid groups i.e. saturated, monoene, *trans*, and polyunsaturated is an essential obligation to assess food material due to the consumers demand to get better quality of fat in the foods. The more concern in dietary fat has developed in the last few years with reference to *trans* fatty acids (TFAs), which are formed artificially by the industrial hydrogenation process [1]. The consumption of *trans* fat has been related with the increase in serum cholesterol levels and the risk of cardiovascular diseases [2,3]. Additionally, TFAs are linked with higher circulating markers of systemic inflammation and increased tumor necrosis factor (TNF) system activity among healthy women [4,5]. These vital concerns have strengthened the consideration of nutritionists and food manufacturers to manage the FA composition of food products. Therefore, a rapid, cheap and reliable method for the determination of fatty acid profile of edible oils is the increasing importance for manufacturers, consumers and standard control laboratories.

Concern in the development of a more versatile method was largely motivated by the intention of the FDA to mandate *trans* labeling of highly lipid containing foods. Traditionally, this issue starts from the legislation originally propagated in 1993, when the FDA issued a final rule entitled "Food Labeling: Mandatory Status of Nutrition Labeling and Nutrient Content Revision, Format or Nutrition Label" that prescribed how nutrition labeling was to be provided on foods that were regulated by the agency [6]. FDA also anticipated descriptions for claims and a proposed footnote statement [6–9]. Therefore consumers are also compelling to affirm fatty acid profile labeling so that they could know the fatty acid composition including TFA content of foods to make the right purchase decision. The regulations required the declaration of total fat, saturated fat, monounsaturated and polyunsaturated fat when claims are made about quality of oils. Since that time evidence has accumulated that *trans* fatty acids behave more like saturated acids and monounsaturated fatty acids have also become more prominent from a nutritional perspective. Hence the new legislation will mandate the inclusion of the *trans* content and its declaration. From a practical standpoint, processors will need to provide a quantitative breakdown of lipid composition with regard to four main categories; (a) saturated fatty acids, (b) monounsaturated fatty acids, (c) isolated *trans* fatty acids and (d) polyunsaturated fatty acids.

Information of this nature is usually obtained by gas chromatography (GC), which provides a complete fatty acid profile from which the respective amounts of each lipid component category can be calculated. Although a standardized methodology, GC is a cumbersome, time consuming and an expensive analytical methodology to implement, maintain and support, and it would be useful to have a simpler and more straightforward method by which to obtain the relative amounts of saturates, mono- and polyunsaturates including *trans* content in food lipids.

Fourier transform infrared (FTIR) spectroscopy is an excellent analytical tool, as it has already been shown to be a means of rapid determination of important quality parameters of vegetable oils [10–13]. Attenuated total reflectance (ATR) is widely used sample handling technique in mid-FTIR spectroscopy. ATR technique provides a simple approach that control many sample handling problems and explored the mid-IR spectroscopy as an analytical technique in a number of areas, including food samples [14]. ATR sample handling devices are based on the phenomenon of the total internal reflection of light [15]. When light passing in a medium of high refractive index hits an interface with a medium of lower refractive index at an angle equal to or greater than critical angle the light will totally internally reflect in the medium of higher refractive index. This results to an evanescent wave in the medium of lower refractive index whose amplitude decays exponentially with distance from interface. The attenuation of the evanescent wave is due to the absorption of energy of the totally internally reflected light beam. Thus, measurement of the energy of the totally internally reflected light as a function of frequency yields the absorption of these species. In single bounce (SB) ATR sampling devices, the sample is placed in contact with an "internal reflection element" (IRE) which is a crystal of an IR-transmitting material of high refractive index, such as zinc solenoid or germanium. Light from the infrared source impinges on the IRE and reaches the interface between the IRE and the sample at such an angle that the beam totally reflects in the IRE, thus, an evanescent wave emerges in the sample, the material of lower refractive index. The depth of penetration is very short: in the mid-IR region, it lies between 1 and 4 μm. When higher sensitivity is needed, the effective path length can be extended by using multiple-bounce ATR device, in which light is made to bounce through the IRE so that it undergoes multiple internal reflections. One of the most common ATR sampling accessories is the horizontal ATR (HATR, usually 1 cm × 8 cm), which can hold the sample volume between 0.2 and 0.5 ml. It is also possible to use temperature controlled HATR, which is particularly advantageous in the analysis of oil and fats [16–18]. This paper presents evidence that SB-ATR-FTIR spectroscopy has the prospective to quantitatively classify lipids into the broad categories and offer the information required for the revised nutritional labeling regulations proposed by the FDA.

2. Materials and methods

2.1. Samples and reagents

Twenty-one samples representing a broad range of saturation and unsaturation, including *trans* fat, such as palm, sunflower, soybean, canola, cotton seed, rice bran and partially hydrogenated oils were obtained from different edible oil industries, Karachi, Pakistan. All reagents, chemicals and solvents used were procured from E. Merck (Darmstadt, Germany). *Trans* and fatty acids methyl ester (FAME) standards (GLC 481-B and 607) were purchased from Nu-Check-Prep, Inc. (Elysian, MN).

2.2. GC–FID analysis

Fatty acid methyl esters (FAMEs) were prepared using standard (IUPAC method 2.301, 1979) and analyzed on a PerkinElmer gas chromatograph (8700) fitted with a RT-2560 biscyanopropylsiloxane capillary column (100 m × 0.25 mm i.d × 0.25 μm film thickness) and a flame ionization detector. Oxygen-free nitrogen gas was used as mobile phase. Oven temperature was programmed as follows: the column held initially at 130 °C for 2 min after injection increased to final temperature 220 °C with 4 °C/min heating holding for 5 min; injector temperature, 260 °C; detector (FID) temperature, 270 °C; column flow rate, 4 ml/min; split ratio, 40:1; injected volume, 1 μL. Elaidine methyl ester was identified by comparing the retention time of the authentic standard obtained from Nu-Check-Prep, Inc. (Elysian, MN). The integration was done by a built-in data-handling program provided by the manufacturer of the gas chromatography(PerkinElmer). Fatty acids were reported as relative percentage of the total peak area. Standards FAMEs for calibration, and samples were run on GC under the same conditions and parameters. The fatty acid composition was expressed as a percentage of the total fatty acid composition, which included minor fatty acids not accounted for by the standards.

2.3. FTIR spectral measurements

All infrared spectra were obtained using a ThermoNicolet Avatar 330 FTIR spectrometer equipped with a removable ZnSe crystal, deuterated triglycine sulfate (DTGS) detector and KBr optics, controlled by OMNIC software (Thermo Nicolet Analytical Instruments, Madison, WI). An SB-ATR accessory with heated demountable cell and time proportional temperature controller (Spectra-Tech, Shelton, CT) was used to control the temperature at constant value. All spectra were collected by co-addition of 32 scans at a resolution of 4 cm^{-1} in the range of 4000–650 cm^{-1}. The spectrum of each standard or sample was ratioed against a fresh background spectrum recorded from the bare ATR crystal; prior to collection of each background spectrum, the ATR crystal was carefully cleaned with propanol to remove any residual contribution of the previous sample, and remaining solvent was then evaporated using a stream of nitrogen gas.

2.4. FTIR calibrations/validations

The FTIR calibration set consisted of 21 oil samples spectra, which had been analyzed for their fatty acid composition by GC. These spectra, along with their respective reference fatty acid compositional data were input into the TQ Analyst program to develop partial least squares (PLS) calibrations. A set of PLS calibrations were developed for the determination of saturated, *trans*, mono, and polyunsaturated fatty acids by selecting their specific spectral regions from the mid-FTIR spectra. Correlation and variance spectra were generated to identify spectral regions that contained information related to the grouped and ungrouped data and these regions were subsequently explored for calibration development and refinement. The performance of the calibrations was assessed by linear regression, and evaluated by running the samples of known fatty acid profile. Therefore, in the calibration step, cross-validation and partial least square regression (PLSR) [19–21] were applied for developing the calibration models for the determination of saturated, mono, *trans* and polyunsaturated fatty acids. The number of calibration models and maximum number of PLS factors were set at 4 and 6, respectively. The latter is commonly depends on the following rule: one PLS factor per 10 samples of the training set plus 2. Statistic parameters as residual mean standard error of calibration (RMSEC) and the determination coefficient (R^2) were also employed. While in the validation, the validation set was introduced in the model, thus statistic parameters such as standard error prediction (SEP) and R^2 were obtained. Table 1 presents some statistical performance characteristics of each calibration/validation model obtained from mid-ATR-FTIR

Table 1

spectroscopy versus GC to assess the methodology for accuracy and reproducibility.

3. Results and discussion

3.1. Gas chromatography

The fatty acid composition of 21 vegetable oil samples was determined by capillary GC. As reported in Fig. 2 the sum of SFA (C14:0, C16:0, C18:0, C20:0, C22:0 and C24:0), MUFA (C16:1, C17:1, C18:1 and C20:1), *trans* (C18:1t) and PUFA (C18:2 and C18:3) were accounted for 28–55.49, 11.00–69.69, 1.00–18.31 and 5.00–64.27%, respectively. Usually in vegetable oils, palmitic (C16:0) and stearic acids (C18:0) are predominant among saturated fatty acids. In

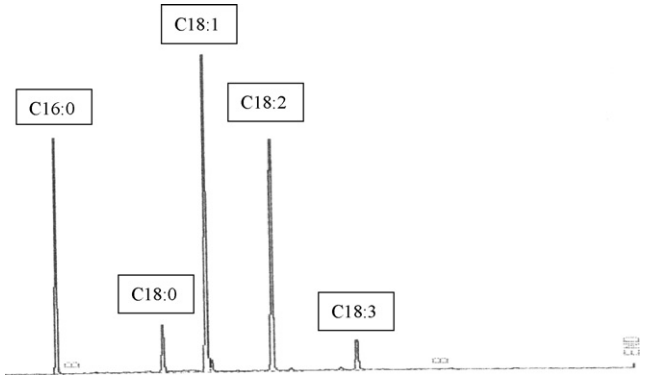

Fig. 2. A representative gas chromatogram of canola oil.

monounsaturated fatty acids (MUFA), oleic (C18:1c) acid and elaidic acid (C18:1t), while among the polyunsaturated fatty acids, linoleic (C18:2) and linolenic (C18:3) fatty acids were found in significant amount. Although technically elaidic acid is also a monounsaturated fatty acid, but for nutritional labeling purposes, only cis monounsaturated fatty acids are categorized as such, the same being true for any *trans* double bonds present in polyunsaturated fatty acids.

Gas chromatography provided the amount of all individual fatty acids for each analyzed oil sample. The information about fatty acids was grouped into saturated, mono, *trans* and polyunsaturated constituents by summation of the areas contributed by specific concerned peak. Representative gas chromatogram of the methyl esters of pure canola oil sample is shown as Fig. 2. The resultant fatty acid methyl ester peaks were identified by comparing the chromatogram of the samples with standards. From Fig. 2 it is evident that all the fatty acids methyl esters were well separated with good peak shapes under the adopted gas chromatographic conditions.

3.2. FTIR spectroscopy and general considerations

The infrared spectrum of an organic molecule is known to provide detailed information about its molecular structure, in effect providing a unique spectral fingerprinting. This unique fingerprint becomes unclear as more molecules with similar structural features are mixed together as is the case of fats and oils, which are complex mixtures of triacylglycerols. Besides, when fats are hydrogenated, new *trans* fatty acids can also be produced, these, however, are readily discerned by their unique and strong *trans* absorption at 966 cm^{-1}. Hence in the case of triacylglycerols, as glycerol is a constant molecular feature, the spectral variations observed in oils are largely the result of differences in overall fatty acid composition. In theory this spectral variation should be something which can be modelled and quantified through the use of advanced chemometric techniques such as partial least squares (PLS) regression techniques.

In Fig. 3 the spectra A–D illustrate the spectra of palm oil (containing high amount of saturated fatty acids), hydrogenated palm oil blended with canola oil (containing high amount of *trans* fatty acids), pure sunflower cooking oil (containing higher amount of polyunsaturated fatty acids) and canola oil (containing higher amount of monounsaturated fatty acids). These spectra have been collected on a heated SB-ATR accessory at 60 °C. These spectra, which are on-scale over the whole mid-IR range, appear very similar with some spectral differences, mainly in the CH, C=O and fingerprint regions. One of the main benefits of using a SB-HATR accessory is its simplicity in terms of sample handling, only requiring that a sample be placed on the crystal and the spectrum taken against the fresh background of the clean crystal.

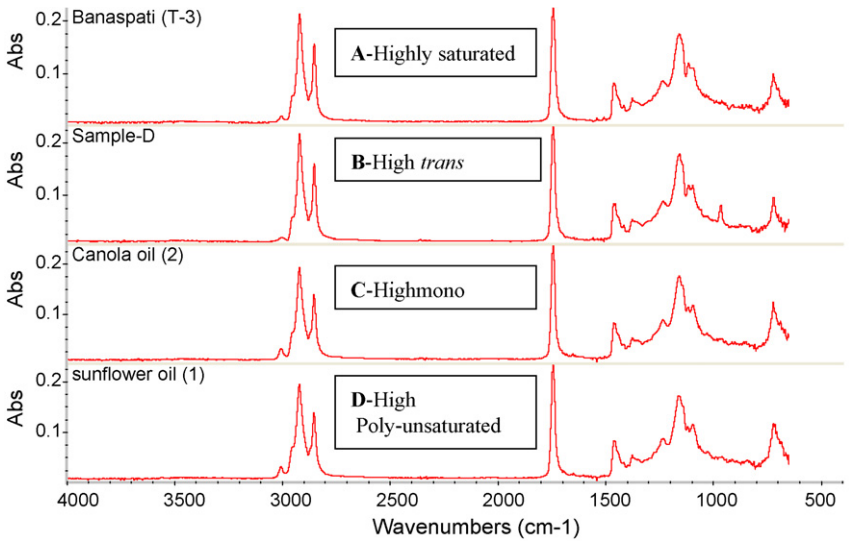

Fig. 3. Full Fourier transform mid-infrared spectra (4000–650 cm^{-1}) of high saturated-palm oil (A), high *trans*-partially hydrogenated palm oil (B), high monounsaturated-pure canola oil (C) and high polyunsaturated-sunflower oil (D).

It can be seen in Fig. 3A, that the highly saturated constituents do not show any significant cis unsaturated features around 2900 cm^{-1} as compared to the *trans* and saturated spectra. Which in turn differ in intensities in the regions of 964 and 700 cm^{-1}, respectively.

In order to obtain information, PLS calibrations were developed on full mid-FTIR spectral range of different type of vegetable oils, based on the main fatty acid classes of the 21 vegetable oil samples, determined by capillary GC analysis which are summarized in Fig. 1.

3.3. PLS calibration development

3.3.1. Saturated, monounsaturated, trans and polyunsaturated groupings

One of the advantages of working advanced chemometric techniques such as PLS is that as long as there is some relationship between the spectral information and a measurable property which could attribute the possibility of establishing a calibration. PLS is a sophisticated statistical practice in which complete or partial spectral region rather than single peak can be used. The algorithm is stand on the capability to precisely compare the spectral information to a property matrix while concurrently accounting for all other important spectral factors that perturb the spectrum.

In developing a PLS model, the group percent values for saturated, mono, *trans* and polyunsaturated fatty acid of different type of oils obtained from GC were put along with the spectra in the TQ Analyst program. The calibrations were developed for the determination of saturated, monoene, *trans* and polyunsaturated fatty acids using three different regions individually and in combination in a structured fashion, initially using cross-validation to assess the general predictive performance of each calibration, followed

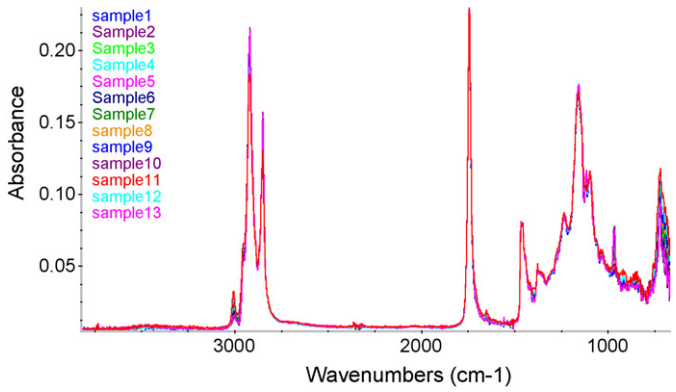

Fig. 5. Full mid-FTIR spectra (4000–650 cm^{-1}) blended with 13 different ratios of partially hydrogenated palm oil blended, canola and soybean oil.

by validation using a separate validation set. On this basis, the full mid IR region encompassing 4000–650 cm^{-1} combined with the 1000–900 and 827–665 cm^{-1} were used to produce good calibrations for all four groupings as shown in Fig. 4A–D.

In order to obtain the reproducibility of proposed developed method, 13 validation samples were run twice. The validation samples were obtained as a result of the mixing of canola, soybean and hydrogenated palm oil with known values of saturated, monoene, *trans* and polyunsaturated by GC. The amount saturated, mono, *trans* and polyunsaturated fatty acids of the freshly prepared mixtures were quantitatively calculated from the known values of their base oils. The GC values of 13 validation samples are presented in Table 1.

Fig. 5 presents 13 FTIR spectra of 13 validation samples with known values of saturated, monoene, *trans* and polyunsaturated. The pure component spectra reproduce the spectral uniqueness and such grouped constituents would have as a result of their numerical assignments, derived from the GC data. The FTIR spec-

tra of the prediction samples were subjected to the same spectral data pre-processing and before fitting in the calibration model the concentration of saturated, monoene, *trans* and polyunsaturated contents in the oil samples were determined by gas chromatography (Fig. 6).

From the calibration, the assessment of the errors was carried out by calculating the residual mean standard error of calibration (RMSEC) after comparing the actual concentration with the computed one for each component, the residual mean standard error of prediction (RMSEP) and bias according to reported method [19–21].

Table 2 lists the parameters that were used to assess statistically the results of calibration and prediction for the models to determine saturated, monoene, *trans* and polyunsaturated fatty acid by using normal mid-ATR-FTIR spectra. As observed, all four models performed properly for calibration, yielding very good correlation coefficients and low RMSEC values; predictions were also very satisfactory, in terms of RMSEP and bias values. These parameters were applied for evaluating the analytical quality of the proposed FTIR method with reference to GC.

The values of R^2 and bias were useful parameters for distinguishing the accuracy and studying the correlation between the GC values and the FTIR method. Table 2 clearly indicates that the cross-validated models could predict total saturated, monoene, *trans* and polyunsaturated fatty acids with residual mean standard error of prediction (RMSEP) of 2.430, 1.850, 0.625 and 1.170, respectively which proves that all calibrations developed were robust. The coefficient of determination (R^2), root mean and bias for validation set were 0.999, and 0.998 for saturated; 0.999, and 0.003 for mono; 0.999, and −0.001 for *trans* while for poly the values were 0.999, and 0.003, respectively. These parameters were evaluated for testing whether statistically they are close to 1 and 0, correspondingly. For all four models, the values for R^2 and bias were within the acceptable range.

The results of saturates, monoene, *trans* and polyunsaturated fatty acids obtained by single bounce ATR-FTIR using are shown in Table 3. The comparable results of FTIR and GC were revealed that SB-ATR-FTIR could be used as an alternate technique to GC for determination of main fatty acid classes in vegetable oils (Tables 1 and 3).

4. Conclusion

The results indicated that ATR-FTIR method can clearly track the total amount of saturated, mono, *trans* and polyunsaturated contents present in the oils and fats. Furthermore, no costly standards were used for the calibration and validation of saturated, monoene, *trans* and polyunsaturated fatty acids for FTIR calibration. Also sample preparation and use of organic solvents were totally avoided just to take the results quickly and not only to reduce the cost of toxic chemicals but also to save the natural environment. The use single bounce-heated ATR facilitated the both liquid and solid vegetable oil samples. For food labeling point of view the proposed method could be easily applied on oils and fats for the determination of total saturates, monoene, *trans* and polyunsaturated fatty acids as an alternative technique to GC.

Acknowledgments

The authors would like to thank the management of Shujabad Agro Industries (Pvt.) Limited, Karachi, Pakistan for providing the oil samples and the National Centre of Excellence in Analytical Chemistry, University of Sindh, Jamshoro, Pakistan for the financial support to carry out this research work.

Single-stranded DNA

ABSTRACT

Triphenylmethane (TPM) dyes normally render rather weak fluorescence due to easy vibrational deexcitation. However, when they stack onto the two external G-quartets of a G-quadruplex (especially intramolecular G-quadruplex), such vibrations will be restricted, resulting in greatly enhanced fluorescence intensities. Thus, TPM dyes may be developed as sensitive G-quadruplex fluorescent probes. Here, fluorescence spectra and energy transfer spectra of five TPM dyes in the presence of G-quadruplexes, single- or double-stranded DNAs were compared. The results show that the fluorescence spectra of four TPM dyes can be used to discriminate intramolecular G-quadruplexes from intermolecular G-quadruplexes, single- and double-stranded DNAs. The energy transfer fluorescence spectra and energy transfer fluorescence titration can be used to distinguish G-quadruplexes (including intramolecular and intermolecular G-quadruplexes) from single- and double-stranded DNAs. Positive charges and substituent size in TPM dyes may be two important factors in influencing the binding stability of the dyes and G-quadruplexes.

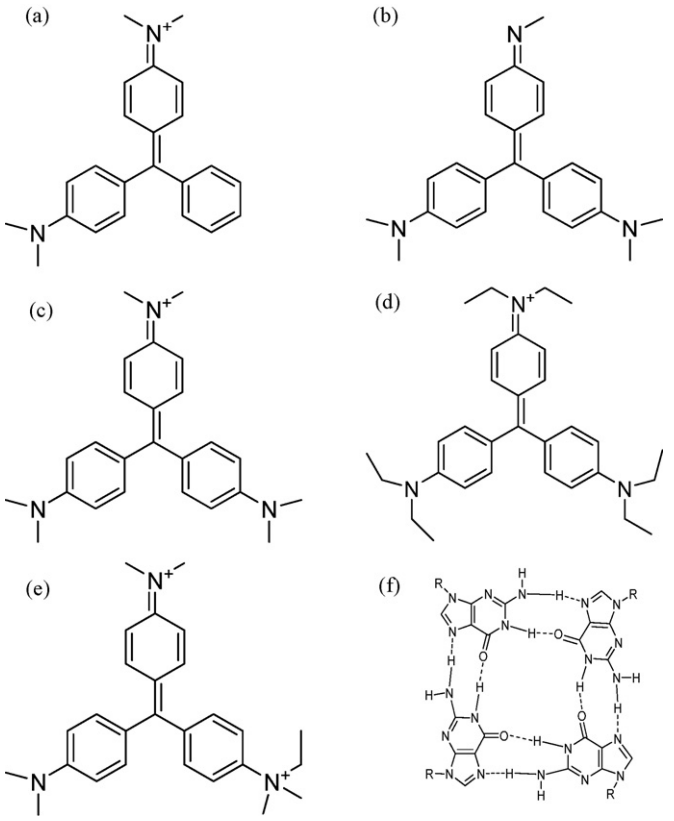
1. Introduction

As we know, genomic DNAs usually adopt a double-stranded helical form in living organisms, but they can also exist in other conformations. Particularly, guanine-rich nucleic acid sequences are capable of folding into four-stranded structures called G-quadruplexes [1–5]. G-quadruplexes are unique higher-order structures formed by G-rich nucleic acid sequences based on stacked arrays of G-quartets connected by Hoogsteen-type base pairs (Scheme 1). These structures are stabilized by monovalent cations, especially by potassium ion. G-quadruplex-forming sequences are prevalent in pivotal genomic regions, such as telomeres, promoters of oncogenes, and most growth control genes [6–8]. In addition, G-quadruplexes have been proposed to play a functional role in a variety of biological processes. For example, such structures are not only involved in the regulation of the telomerase activity but also associated with mechanisms of cancer, HIV, and other diseases [9–11]. Therefore, substantial research efforts have been devoted to develop a specific probe for distinguishing the quadruplex from other DNA conformations, especially the predominant double-stranded conformation [12–15].

Triphenylmethane (TPM) dyes such as malachite green (MG) normally render rather weak fluorescence due to easy vibrational deexcitation, but viscous, cold environments or MG aptamer have been demonstrated to enhance the fluorescence by restricting such vibrations [16,17]. Moreover, it is reported that MG becomes highly fluorescent upon mixing with intramolecular G-quadruplexes [18]. In our previous work, we studied the interactions between crystal violet (CV), another TPM dye, and G-quadruplexes, single- and double-stranded DNAs, and therefore concluded that CV could be developed as a specific probe for G-quadruplex recognition based on fluorescence spectra or energy transfer fluorescence spectra [19]. These exciting results promoted us to assume that other members of the TPM family may be applicable in G-quadruplex recognition. With this idea in mind, here the abilities of other three known TPM dyes—methyl violet (MV), ethyl violet (EV) and methyl green (MEG), to distinguish G-quadruplexes from single- and double-stranded DNAs were investigated and compared with those of MG and CV.



2. Experimental

2.1. Materials

All TPM dyes in this work were obtained from Sigma–Aldrich (St. Louis, MO) and were used as received without further purification. CtDNA was purchsed from Sangon Biotech. Co. Ltd. (Shanghai, China). The oligonucleotides were purchased from Etiwu Biotech. Co. Ltd. (Tianjin, China). The concentrations of these oligonu-

cleotides were represented as single-stranded concentrations unless otherwise noted, which were determined by measuring the absorbance at 260 nm in a quartz cuvette. Molar extinction coefficients were determined using a nearest neighbor approximation (http://www.idtdna.com/analyzer/Applications/OigoAnalyzer). The DNAs we studied are listed in Table 1. The water was purified using a Millipore filtration system.

2.2. Fluorescence spectroscopy and energy transfer fluorescence spectroscopy

Fluorescence measurements were made using a Hitachi RF-4500 spectrofluorimeter. Oligonucleotide solutions were prepared in Tris–HCl buffer (25 mM, pH 7.0) containing KCl (100 mM). To ensure the formation of quadruplex structures, the solutions were heated to 95 °C for 5 min and then cooled slowly to room temperature. After incubation at room temperature overnight, the TPM dye (10 μM) was added. The mixtures were kept at 30 °C for 1 h before spectrometric detection. In fluorescence spectroscopy determination, the spectra were excited at 605 nm and monitored from 630 to 800 nm for MG, excited at 635 nm and monitored from 660 to 800 nm for MEG. When the other three TPM dyes were used, the excited wavelengths were, respectively, 570 nm for EV, 580 nm for MV and 580 nm for CV, and their spectra were monitored from 600 to 800 nm. In energy transfer fluorescence spectroscopy determination, the spectra were excited at 280 nm for MV, CV, MG and MEG and 270 nm for EV and monitored from 600 to 800 nm.

Table 1
Sequences of oligonucleotides used in this work.

Name	Oligonucleotide sequence
Hum21	5′-$G_3(T_2AG_3)_3$
Oxy28	5′-$G_4(T_4G_4)_3$
Hum12	5′-$(T_2AG_3)_2$
Oxy12	5′-$G_4T_4G_4$
CtDNA	
AT	5′-$(AT)_6$
LD	5′-$GCGCA_2T_2GCGC$
GC	5′-$(GC)_6$
ssDNA1	5′-GAGCTCTCGAAAGAGCTCCGATTA
ssDNA2	5′-TAGAGCACAGCCTGTCCGTG

2.3. The fluorescence titration and energy transfer fluorescence titration

The measurements were performed by keeping the concentration of the TPM dye at 10 μM while varying the DNA concentrations (from 1 μM to 18 μM for Hum21 and Oxy28, strand concentration; from 16 μM to 2.72 mM for CtDNA, base concentration; from 2 μM to 30 μM for other DNAs, strand concentration). The emission at 635 nm for MV, 640 nm for CV, 645 nm for EV, 680 nm for MG and MEG was monitored as a function of DNA concentration on a Hitachi RF-4500 spectrophotometer.

3. Results and discussion

3.1. Fluorescence spectra

In order to evaluate suitability of the 5 TPM dyes for the sensitive recognition of G-quadruplexes, the fluorescence spectra of these TPM dyes were measured in the presence of 10 different DNAs (Table 1). Hum21 and Oxy28 can fold into intramolecular G-quadruplex structures; Hum12 and Oxy12 can exist as intermolecular G-quadruplex conformations (Hum21 and Hum12 mimic the human telomeric sequence, Oxy28 and Oxy12 have the repeated subunits of Oxytricha telomeres); AT, GC and LD can form short double-stranded structures; CtDNA belongs to long double-stranded duplex DNA; ssDNA1 and ssDNA2 are single-stranded DNAs with a random DNA sequence. As shown in Fig. 1, all of the five dyes displayed rather faint intrinsic fluorescence, the addition of intramolecular G-quadruplexes (Hum21 and Oxy28) could greatly enhance the fluorescence of the dyes (except that the addition of Hum21 to EV only gave a very small fluorescence enhancement). When 10 μM of each dye was mixed with 5 μM Hum21 or Oxy28, the Hum21/MV mixture showed the maximal fluorescence enhancement compared with corresponding free dye, and the fluorescence enhancement could reach 80-fold. The Oxy28/CV mixture gave the minimal fluorescence enhancement, but the fluorescence enhancement could also reach 12-fold. These results indicate that all of the five triphenylmethane dyes can be used as sensitive intramolecular G-quadruplex fluorescence probes. The addition of intermolecular G-quadruplexes, single- or double-stranded DNAs could also increase the fluorescence of the dyes, but the fluorescence enhancements were much weaker. Except that the fluorescence intensities of MV and CV in the presence of intermolecular G-quadruplexes were always higher than those in the presence of single- or double-stranded DNAs, other three TPM dyes did not show any selectivity for intermolecular G-quadruplex DNAs over single- or double-stranded DNAs. For example, the addition of CtDNA to MG caused higher fluorescence enhancement than that of Hum12, and the addition of AT and LD to MG caused similar fluorescence enhancement to that of Oxy12. The fluorescence intensity of EV induced by ssDNA2 was similar to that by Oxy12. CtDNA, LD and AT had more effects on fluorescence of MEG than Oxy12 and Hum12. The results mentioned above suggest that MG, MV, CV and MEG may be developed as good

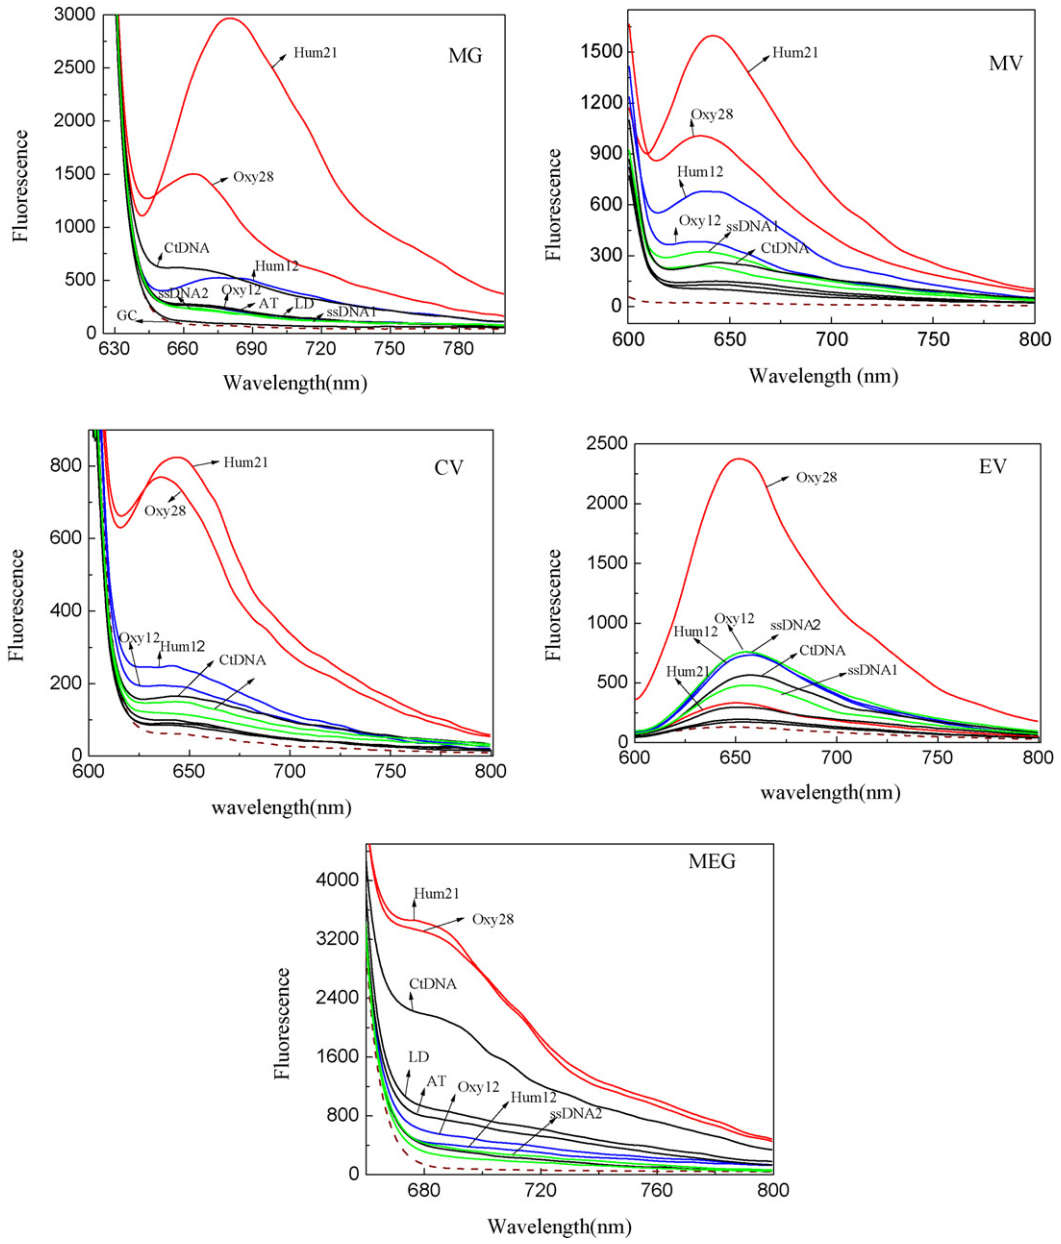

Fig. 1. Fluorescence spectra of the five TPM dyes in the presence of different DNAs. Free dye (purple, dotted lines), intramolecular G-quadruplexes (red), intermolecular G-quadruplexes (blue), duplex DNAs (black), single-stranded DNAs (green). [Hum21] = [Oxy28] = 5 μM; [Hum12] = [Oxy12] = [AT] = [LD] = [GC] = [ssDNA1] = [ssDNA2] = 10 μM; [CtDNA] = 240 μM (base concentration), [MG] = [MV] = [CV] = [EV] = [MEG] = 10 μM. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

fluorescent probes to discriminate intramolecular G-quadruplexes from intermolecular G-quadruplexes and to discriminate intramolecular G-quadruplexes from single- and double-stranded DNAs, but cannot give satisfactory results in discriminating intermolecular G-quadruplexes from single- and double-stranded DNAs. EV is not a good G-quadruplex probe because not all intramolecular G-quadruplexes we studied can increase the fluorescence of EV to a high level.

3.2. Energy transfer fluorescence spectra

The energy transfer fluorescence spectra of the 5 TPM dyes in the presence of the 10 DNAs were also studied in order to further investigate the ability of these 5 dyes to discriminate G-quadruplex DNAs from single- and double-stranded DNAs. As can be seen from Fig. 2, when excited at 270 or 280 nm, which is in the DNA absorption region [20], free dyes can only emit very weak fluorescence. However, the addition of intramolecular G-quadruplexes can greatly enhance the fluorescence of the dyes (except the addition of Hum21 to EV), indicating that efficient energy transfer occurs between the dyes and the intramolecular G-quadruplexes. Though the fluorescence emission intensities of the dyes were also enhanced in the presence of intermolecular G-quadruplexes, the enhancements were far lower compared with those in the presence of intramolecular G-quadruplexes, suggesting that energy transfer can also occur between intermolecular G-quadruplexes and the dyes, but the efficiencies of energy transfer are much weaker than those between the intramolecular G-quadruplexes and the dyes. It was previously demonstrated that energy transfer between DNA bases and a bound fluorescent ligand is only possible if the ligand is in close contact with the DNA bases [21]. This happens only when a fluorescent ligand is intercalated between stacked base pairs in duplex

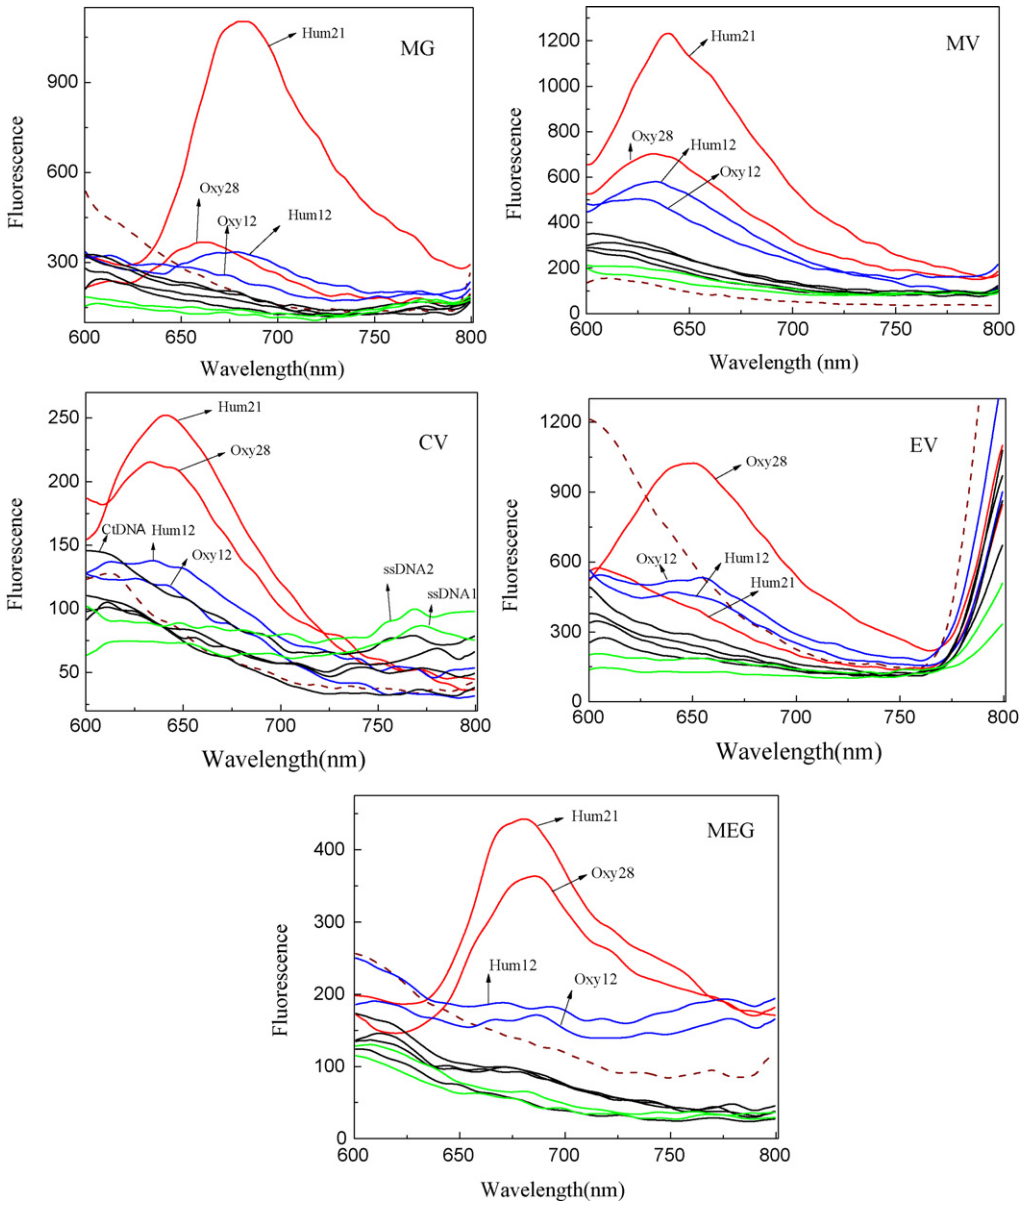

Fig. 2. Energy transfer fluorescence spectra of the five TPM dyes in the presence of different DNAs. Free dye (purple, dotted lines), intramolecular G-quadruplexes (red), intermolecular G-quadruplexes (blue), duplex DNAs (black), single-stranded DNAs (green). [Hum21] = [Oxy28] = 5 μM; [Hum12] = [Oxy12] = [AT] = [LD] = [GC] = [ssDNA1] = [ssDNA2] = 10 μM; [CtDNA] = 240 μM (base concentration), [MG] = [MV] = [CV] = [EV] = [MEG] = 10 μM. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

DNAs and G-quartets in G-quadruplex DNAs or stacked onto the two external G-quartets of quadruplexes. The above results surely indicated that the binding modes between the TMP dyes and the G-quadruplex DNAs were intercalation or external stacking but not outside binding. To the contrary, the fluorescence intensities of MG, CV, EV and MEG decreased upon addition of single- or double-stranded DNAs, indicating that no energy transfer occurs between the dyes and single- or double-stranded DNAs. It is not surprise because the added single- and double-stranded DNAs can compete with the dyes to absorb the energy of excitation light, causing the fluorescence of the dyes to decrease. Though all DNAs studied in this work could cause a large fluorescence enhancement for MV, the extents of fluorescence enhancement in the presence of G-quadruplexes (including intramolecular and intermolecular G-quadruplexes) were much higher than those in the presence of single- or double-stranded DNAs. The results mentioned above indicate that energy transfer fluorescence spectra are better than fluorescence spectra in differentiating DNAs with different conformations. According to the fluorescence change trends caused by the addition of DNAs, energy transfer fluorescence spectra can be used to distinguish G-quadruplexes (including intramolecular and intermolecular G-quadruplexes) from single- and double-stranded DNAs. According to the fluorescence change extents caused by the addition of DNAs, energy transfer fluorescence spectra can be used to discriminate intramolecular G-quadruplexes from intermolecular G-quadruplexes.

3.3. *Fluorescence titrations and energy transfer fluorescence titrations by different DNAs*

To gain further insight into the interactions between DNAs and the TPM dyes, the fluorescence titration and energy transfer fluorescence titration experiments were conducted. The fluorescence titration results are shown in Fig. 3, from which one can find that the fluorescence of each TPM dye initially increased greatly with increased concentrations of added intramolecular G-quadruplexes,

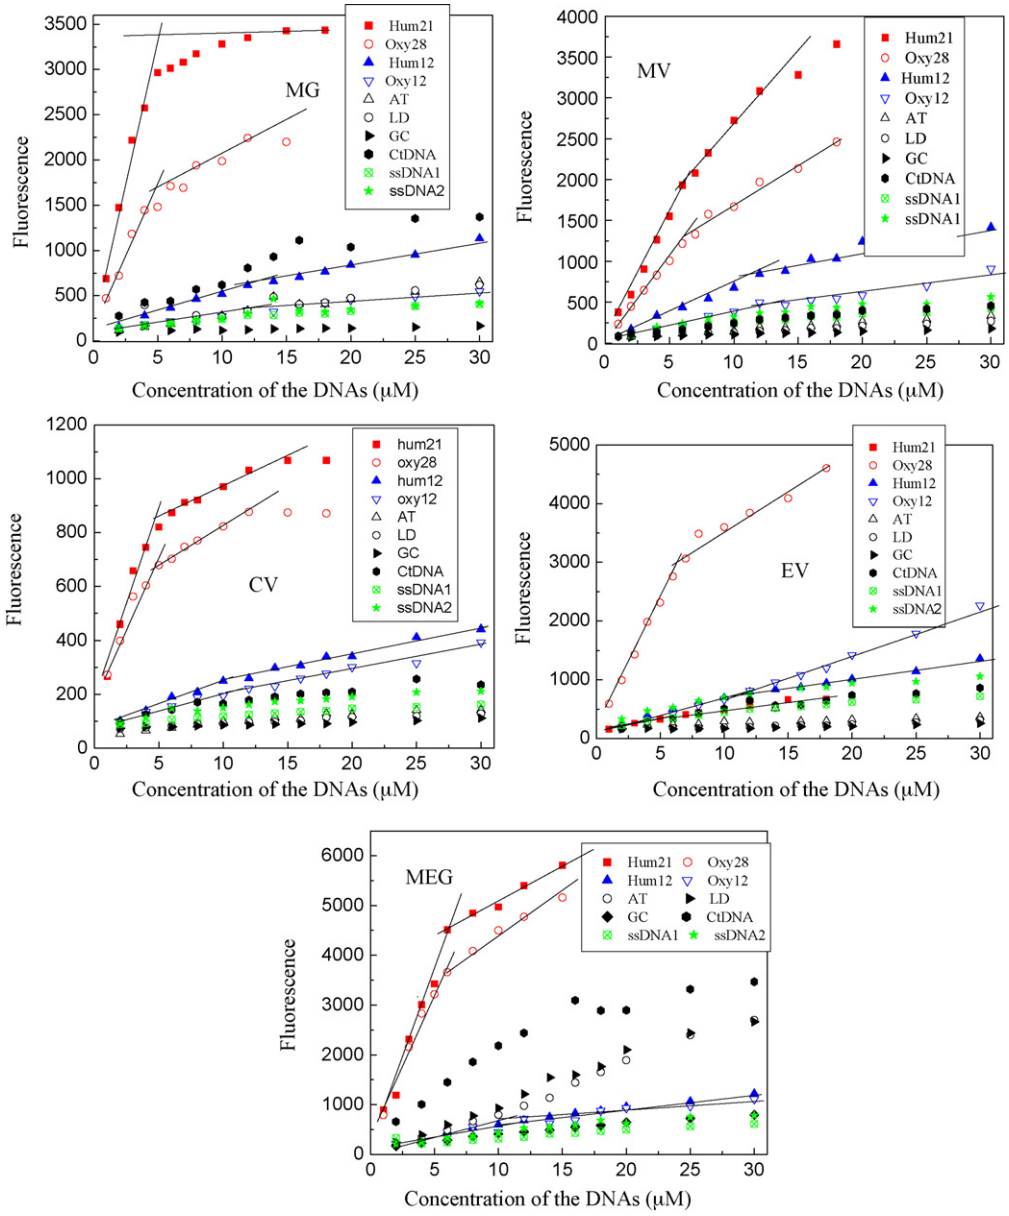

Fig. 3. Fluorescence titrations of the five TPM dyes by different DNAs. [MG] = [MV] = [CV] = [EV] = [MEG] = 10 μM. DNA concentration is expressed as strand concentration. The concentration of CtDNA is converted to the strand concentration of an oligonucleotide with 12-nucleotide.

and then leveled off or slowed down. A close examination of the fluorescence data indicated that the DNA concentrations (strand concentration) at the intersection points in the titration curves were about 5.0 μM for Hum21 and Oxy28 when the concentration of each dye was fixed at 10.0 μM, indicating that the binding stoichiometric ratios of the TPM dyes to the two intramolecular G-quadruplexes were all 2:1. This 2:1 stoichiometry is consistent with a binding mode based on stacking of the dye onto the two external G-quartets of the intramolecular quadruplexes [21–23]. Titration of the TPM dyes with intermolecular G-quadruplexes could result in similar fluorescence change trends (except that the fluorescence of EV continuously increased with the increase of Oxy12 concentration), but the fluorescence changes were much smaller and the intersection points in the titration curves were also not so clear. However, after a close examination of the fluorescence data, one can also find that 10.0 μM of each TPM dye can interact with 10.0 μM Hum12 or Oxy12. Considering that two strands of Hum12 (or Oxy12) can form a quadruplex, the binding stoichiometric ratios of the TPM dyes to the two intermolecular G-quadruplexes were also 2:1, indicating that the interaction of the TPM dyes with intermolecular G-quadruplexes also follows an external stacking mode. To the contrary, the fluorescence intensities of the dyes were continuously enhanced with increased concentrations of added single- or double-stranded DNAs, and no obvious inflexions were observed in the titration curves over the studied concentration range. The exceptional phenomenon appeared when MEG was mixed with CtDNA, whose fluorescence seemed to reach a platform with an increase in the concentration of CtDNA.

Fig. 4 shows the energy transfer fluorescence titration results. From this figure, one can find that the energy transfer fluorescence of the dyes firstly increased dramatically with increased concentrations of added intramolecular G-quadruplexes, then reached a maximum, and at last decreased abruptly. Such phenomenon could be well explained by the competition between the dyes and intramolecular G-quadruplexes for the absorption of excitation light. In the low DNA concentration range, the TPM dye was in excess. The addition of intramolecular G-quadruplexes was helpful in the formation of G-quadruplex–TPM complexes

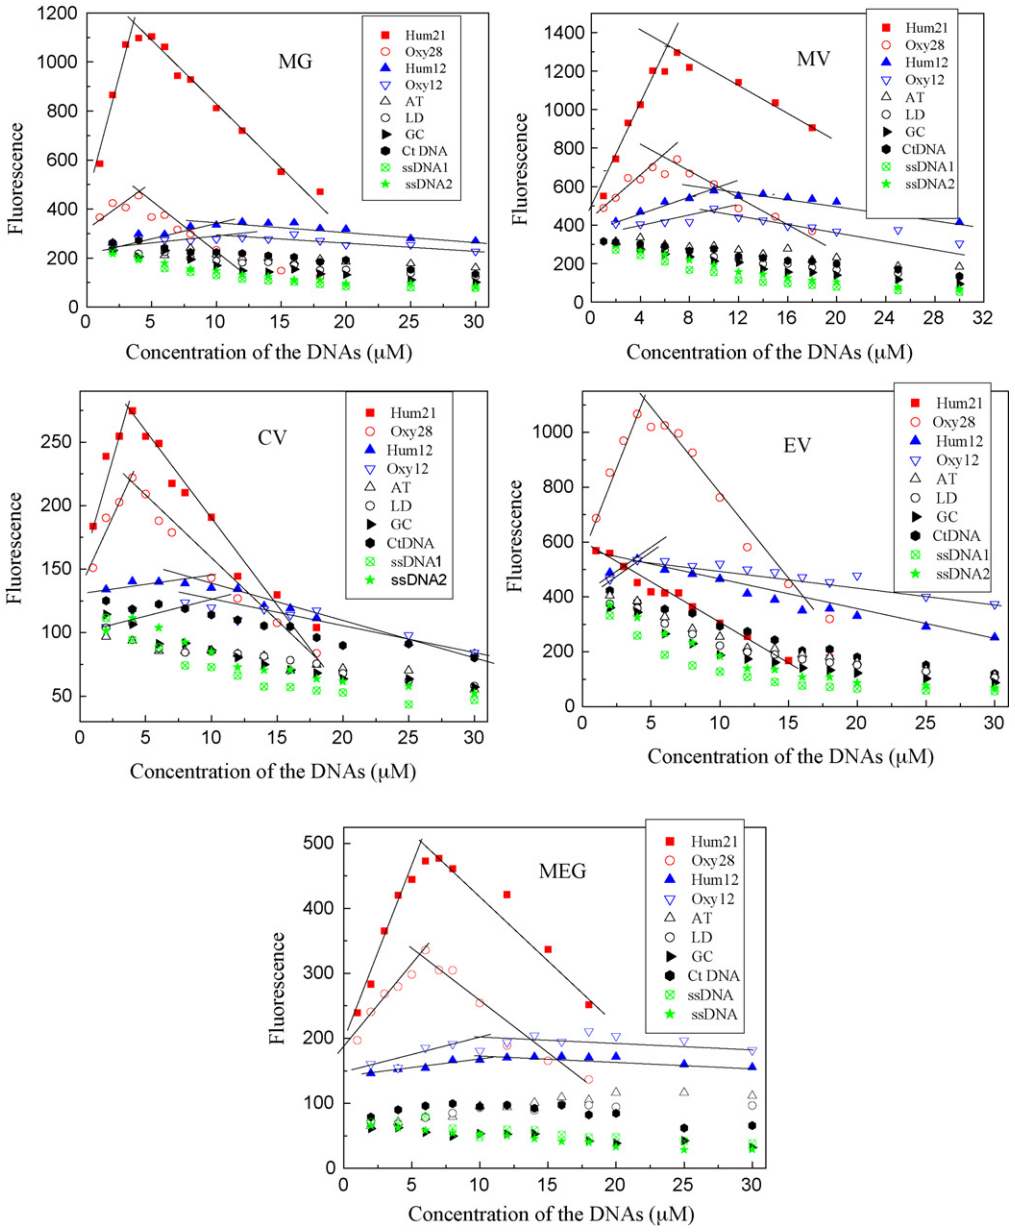

Fig. 4. Energy transfer fluorescence titrations of the five TPM dyes by different DNAs. [MG] = [MV] = [CV] = [EV] = [MEG] = 10 μM. DNA concentration is expressed as strand concentration. The concentration of Ct DNA is converted to the strand concentration of an oligonucleotide with 12-nucleotide.

as more and more energy was transferred from DNA to TPM, thus the fluorescence of TPM increased continuously. In the high DNA concentration range, the intramolecular G-quadruplexes were in excess. Free intramolecular G-quadruplexes competed with G-quadruplex–TPM complexes to absorb the energy of excitation light and, therefore, the fluorescence of the TPM dyes decreased sharply. Noting that the maxima occurred around 5.0 μM for the intramolecular G-quadruplexes, we could easily conclude that the binding stoichiometric ratios of the TMP dyes to intramolecular G-quadruplexes were all 2:1. Again, titration of the TPM dyes with intermolecular G-quadruplexes can result in similar energy transfer fluorescence change trends, and maximal points in the titration curves can also be observed clearly. According to the maximal points, the binding stoichiometric ratio of 2:1 can also be obtained for the interaction between TMP dyes and intermolecular G-quadruplexes. Unusually, the fluorescence emission of EV continuously went down as a consequence of addition of Hum21, and the binding stoichimetric ratios of EV to the two intermolecular G-quadruplexes seemed to be 4:1. Under the same conditions, mixing with single- or double-stranded DNAs resulted in a steady decrease in the fluorescence of the dyes, which also could be interpreted by the competitive absorbance of DNAs and dyes for excitation energy. The results mentioned above indicate that energy transfer fluorescence titration data are more suitable in studying the binding stoichiometric ratios of dyes to G-quadruplexes than fluorescence titration data due to the more obvious inflexions observed in the energy transfer fluorescence titration curves. In addition, they can also be used to distinguish G-quadruplexes from single- and double-stranded DNAs according to the trend in fluorescence change of dyes with the increase of DNA concentration.

3.4. Binding stability between dyes and G-quadruplexes

Based on the stoichiometric ratio of 2:1, the association constants (K_a) between the five dyes and the two intramolecular G-quadruplexes can be obtained by fitting the data in fluorescence

Table 2
The K_a (μM^{-1}) values of the intramolecular G-quadruplex–TPM complexes.

	Hum21	Oxy28
MV	0.0026(5)	0.0019(3)
EV	0.00078(26)	0.0064(15)
MG	0.45(18)	0.029(17)
CV	0.049(14)	0.025(5)
MEG	0.026(8)	0.019(6)

titration experiments using the equation we deduced [19]:

$$[G\text{-quadruplex}]_T = \frac{F - F_{\min}}{F_{\max} - F_{\min}} \times \frac{[\text{Dye}]_T}{n} + \frac{(F - F_{\min})(F_{\max} - F_{\min})^{n-1}}{nK_a(F_{\max} - F)^n[\text{Dye}]_T^{n-1}}$$

In which, $F_{\min}$, $F_{\max}$ and F represent the fluorescence of free dye, fully bound dye and partially bound dye, respectively. n is the number of the dye that one G-quadruplex can bind. Here, the value of [Dye] is 10 μM. The value of n is fixed at 2.

The fitting results are listed in Table 2. As for the interaction between Hum21 and the dyes, the K_a value follows the order of MG > CV > MEG > MV> EV; as for the interaction between Oxy28 and the dyes, the K_a value follows the order of MG > CV > MEG> EV > MV. In these five dyes, each MG, CV and EV carries one positive charge. The main difference among them is the number and the size of substituent moieties. MG has two dimethylamino substituents, CV has three dimethylamino substituents, and EV has three diethylamino substituents. That is, the size of substituents in triphenylmethane backbone as follows: MG < CV < EV, which is justly contrary to the order of the K_a values. When the dyes bind to G-quadruplexes, it is likely that the three phenyl rings of the dyes stack onto the two external G-quaterts of the G-quadruplex, and the pendent substituents intercalate into the grooves of the G-quadruplex [24]. Such opposite orders of the binding stability and the substituent size suggested that the increase of size could hinder the intercalation of substituents into the grooves, resulting in the decrease of binding stability. MV has two dimethylamino substituents and one methylamino substituent, the size of the substituents in MV is even smaller than that of CV, but the binding stability between MV and G-quadruplexes is lower than that between CV and G-quadruplexes, which may be attributed to the difference of positive charges the two dyes carry. CV carries one positive charge, but MV has none. The protonation of the methylamino substituent may provide MV a positive charge, but protonation needs acidic condition. Based on the results mentioned above, we conclude that positive charge and substituent size are two important factors in determining the binding stability of the intramolecular G-quadruplexes–TPM complexes. As for which one is more predominant, it is very possible that the presence of one positive charge is very important for improving the binding stability (this can be proved by the difference between CV and MV), but the presence of the second positive charge seems to have less influence than the size of the substituent, which can be deduced from the difference between CV and MEG. MEG has two positive charges and a larger substituent size, but its binding stability is weaker than CV.

4. Conclusions

In order to evaluate the suitability of the five TPM dyes to discriminate G-quadruplex DNAs from single- and double-stranded DNAs, the fluorescence and energy transfer fluorescence of the five TPM dyes in the presence of G-quadruplexes, single- or double-stranded DNAs were investigated in the present paper. The results indicate the fluorescence spectra of the TPM dyes except EV can be used to discriminate intramolecular G-quadruplexes from intermolecular G-quadruplexes as well as single- and double-stranded DNAs, but cannot be used to discriminate intermolecular G-quadruplexes from single- and double-stranded DNAs. The energy transfer fluorescence spectra (especially MG, CV and MEG) not only can be used to discriminate intramolecular G-quadruplexes from intermolecular G-quadruplexes but also can be used to discriminate G-quadruplexes (including intramolecular G-quadruplexes and intermolecular G-quadruplexes) from single- and double-stranded DNAs. The energy transfer fluorescence titration experiments can be used to distinguish G-quadruplex DNAs from single- and double-stranded DNAs according to the fluorescence change trend of dyes with the increase of DNA concentration. The interaction of the five TPM dyes with G-quadruplexes may follow an external stacking mode, and the binding stoichiometric ratios are all 2:1. Positive charges and substituent size in TPM dyes may be two important factors in influencing the binding stability of the dyes and G-quadruplexes. This study may provide some important information for the development of sensitive and specific G-quadruplex fluorescent probes.

SPE
Breakthrough volume
Polymeric sorbents

ABSTRACT

Solid-phase extraction is one of the most popular sample preparation methods. The selection of the appropriate extraction system is an important stage in the elaboration of analytical procedure. In this case, the knowledge of the interactions between isolated compounds, sorbent and elution solvents seems to be important. The extraction ability of sorbents in the SPE bed depends also on: (i) the bed capacity; (ii) the volume of sample loaded, (iii) the nature and volumes of conditioning solvents and eluents. One of the important parameters is the breakthrough volume, which determines the maximum volume of water sample which can be introduced into the sorbent. In this work two methods of determination of the breakthrough volumes are presented: experimental method with frontal analysis, and theoretical method with computational applications. Both procedures were used for the characterization of nine polymeric sorbents based on divinylbenzene copolymers. Comparison of results allows to choose the computational procedure of breakthrough volume determination as the easier one and less time consuming.

1. Introduction

Solid-phase extraction (SPE) technique was invented in the 1970s. It is an alternative method to liquid–liquid extraction. This technique has spread very fast and found interest in different domains of research. The analytical procedures using SPE are applied very often in both science and industry. This technique is used in the analysis of different samples, e.g. environmental, biological, medical and many others. The use of SPE allows the isolation of different compounds, sample pre-concentration, change of the sample matrix and sample clean-up. Wide interest results from numerous advantages of this extraction method:

- it is fast and easy;
- small volumes of solvents are used;
- capability of automation of this technique;
- there are no problems related to emulsion formation during the extraction process;
- it is selective and effective;
- relatively inexpensive.

In the selection of the extraction system very important is the knowledge of the relations/interactions between isolated compounds, sorbent and elution solvents. Physicochemical properties: polarity, acidity, basicity and hydrophobicity of sorbents, isolated compounds and the solvents used in the extraction process affect mutual interactions and finally extraction efficiency.

The selection of the appropriate sorbent is an important stage in the elaboration of the analytical method. There are many sorbents used in this technique. This can be divided into three main groups: silica sorbents, polymeric sorbents and activated carbon or graphitized carbon black. All kinds of sorbents can be modified in different ways, to change their extraction properties. The series of papers were published in this field [1–9].

The SPE method development very often relies on trial-and-error procedures. As it is time consuming and arduous way, so the optimization methods are investigated. These are based on physicochemical and thermodynamical dependencies between sorbents, analytes and solvents. One of them is the solublility parameter system, used in the description of the interactions in the extraction systems, especially between analyte and sorbent and the selection of the appropriate eluent [10,11].

The physical characteristics of the sorbents: its surface area, particle size, pore size or pore volume are crucial sorbent properties. However, the extraction ability of sorbents in the SPE bed depends also on the bed capacity; the volume of sample loaded on the bed, the nature and volumes of conditioning solvents and eluents. These are some critical SPE parameters: breakthrough volume, volume of rinsing solvent, elution volume, which depends on the kinetic properties of the SPE bed, its hold-up volume and retention factor. The aim of this paper is the description and discussion of the theoretical background and methods of breakthrough volume determination.

2. Theory

The breakthrough volume (V_B) is one of the parameters characterizing the SPE sorbent bed. This parameter is defined in literature in different ways:

- the sample volume which can be loaded on the sorbent bed without the loss of the analytes;
- the sample volume over which the analytes are eluted by the sample matrix;
- the sample volume that can be loaded onto the a SPE bed providing a given ratio of outlet to inlet analyte concentration at a given temperature [12,13];
- maximum sample volume which can be applied with a theoretical 100% recovery [14];
- the volume of sample which has to flow through the sorbent in order to obtain a percent of retention of 99–95% [15];
- V_B expressed the capacity of a sampling column (sorbent bed) [16–18].

V_B depends on the concentration of analytes in the solution loaded to the sorbent, the temperature, the flow rate, the number of theoretical plates [12]. In the on-line method, the breakthrough depends on the flow rate, so it must be constant [19]. The breakthrough volume determines the amount of analyte that can be isolated, it depends on the kinetic properties of the extraction device [20].

The breakthrough volume can be described or presented by the breakthrough curve. It is the relationship between the sample concentration and the sample volume passed through the sorbent. Plotting the observed concentration of the analyte, against the corresponding aliquot volumes generates the breakthrough curve [19]. The breakthrough volume depends on kinetic parameters of sorbent and on the retention parameters as well as on the flow rate of the sample. The experiments with SPE disks [21] show that there is an optimum flow rate at which the breakthrough volume reach the maximum value. The breakthrough volume is reduced at very low and very high flow rates [21].

Another important parameter, which is connected with the breakthrough volume is the breakthrough level. This parameter is defined as the fraction of the total mass of analyte which has passed out of the sorbent and has been lost [13].

To treat the SPE as chromatographic process, one have to define the breakthrough level as the function of retention volume or retention time. Breakthrough volume can be than defined as the volume giving an assumed breakthrough level (the ratio of outlet to inlet concentration). More useful is the definition based on mass instead of the concentration, then the breakthrough level is defined as the fraction of total mass of analyte which has passed out of the column without adsorption. When the relationship is converted from time scale to volume scale, one can define the breakthrough volume as the function of the plate number of the column. Eq. (1) was proposed by Lövkvist and Jönsson [18] and cited many times [12,19,22–24].

$$V_B = V_R\left(a_0 + \frac{a_1}{N} + \frac{a_2}{N^2}\right)^{-1/2} \quad (1)$$

where V_R is the retention volume, $a_0 = (1-b)^2$ and give the correct asymptotic limit for large values of N, a_1, a_2 are complicated function of b and numerical values, a_1 was adjusted to provide a good fit for intermediate values of N, a_2 was found from equation for b when N tends toward zero, b is the breakthrough level [%], N is the number of theoretical plates.

The numerical value of a_0, a_1 and a_2 coefficients, determined for various values of "b", can be found in the literature [18].

Another relationship between breakthrough volume and number of theoretical plates was proposed by Werkhoven-Goëwie at al. [21,24,25].

$$V_B = V_R\left[\frac{\sqrt{N}-2}{\sqrt{N}}\right] \quad (2)$$

3. Experimental determination of the breakthrough volume

Breakthrough volume can be determined experimentally in several ways using on-line or off-line methods including frontal or elution chromatography.

3.1. Frontal chromatography [14,16,17,26,27]

It is the process where a solute (sample) is continually applied to the column (sorbent) until some of the analytes begins to appear in the effluent of the column (sorbent), breakthrough occurs when the capacity of the sorbent has been reached. The concentration of the analyte in the effluent can be measured by UV detector. The dependence between the concentration of the analyte in the effluent and volume of the sample passed through the sorbent gives the breakthrough curve on the diagram (Fig. 1) [15]. Under ideal conditions, the breakthrough curve has a bilogarithmic shape and the chromatographic parameters can be determined from the curve as follows:

- the inflection point of the curve corresponds to the retention volume V_R of the analyte;
- V_B is defined as the volume of the mobile phase, that corresponds (on the breakthrough curve) to 1% of max concentration of the analyte in the effluent;
- V_M – hold-up volume – is defined as the volume of the mobile phase, that corresponds (on the breakthrough curve) to 99% of max concentration of the analyte in the effluent.

Under real conditions the retention parameters can be determined from the diagram as seen in [26,27]:

Breakthrough volume V_B is defined as:

$$V_B = V_R - 2\sigma_V \quad (3)$$

where V_R is the retention volume, can be determined graphically from the diagram, it corresponds to 0.5 of the average value of maximum analyte concentration in the effluent (C_E); it can be expressed

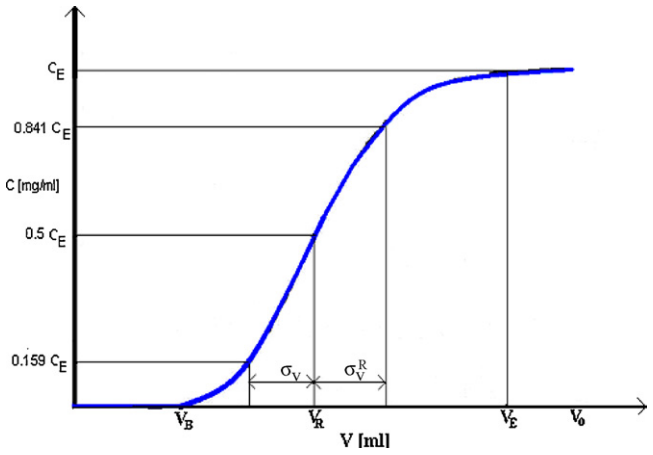

Fig. 1. Breakthrough curve.

analytically by the well known equation:

$$V_R = V_M(1+k) \tag{4}$$

where k is the retention (capacity) factor of the solute (for the analyte in the sample) [21,24], σ_V, σ_V^* are the standard deviations of the derivative curve determined graphically from the breakthrough curve; due to its asymmetry these are given suitably as values corresponding to 0.159 and 0.841 of the average value of max concentration of analyte in the effluent (C_E), respectively.

It can be given as follows [14,19,28]:

$$\sigma_V = V_M \frac{1+k}{\sqrt{N}} \tag{5}$$

V_E is the equilibrium volume defined as:

$$V_E = V_R + 2\sigma_V^* \tag{6}$$

The breakthrough volume depends on plate number (N) of the sorbent. For small plate number ($4 < N < 9$) the V_B can be described by Eq. (1) or (2). For plate number $N > 9$ the breakthrough volume is described by the following functions:

$$V_B = V_R - 3\sigma_V \tag{7}$$

or

$$V_B = \left[1 - \left(\frac{3}{\sqrt{N}}\right)\right] V_R \tag{8}$$

For the sorbent beds with large plate number, the breakthrough volume can be given as in Eq. (9) at the 1% breakthrough level [12–14]:

$$V_B = V_R \left(1 - \frac{2.3}{\sqrt{N}}\right) \tag{9}$$

3.2. Off-line methods [19,27,29–32]

In this kind of experimental method, the sample is introduced into the sorbent in aliquots. The sorbent should be conditioned earlier. The volume of the individual aliquot (fraction) varies from 5 to 10 ml. Each sample aliquot is collected in separate vial, and analyzed with spectroscopic or chromatographic techniques [29,30] to measure the concentration of the analyte in each aliquot of the sample. If liquid chromatography is used as analytical technique, the water sample can be analyzed directly. However, when the gas chromatography is used, the additional extraction of the effluents is necessary to change the sample matrix [30].

3.3. On-line methods

One of the on-line methods is elution chromatography, where SPE cartridge is treated as chromatographic column, water is the mobile phase, and the analyte is injected into the column in a microliter volume. The concentration of the analyte in the effluent can be measured by UV detector [14,17,26].

Another method is when the SPE sorbent is applied as a precolumn in SPE–HPLC system. A solution containing a constant concentration of analyte is pumped at a constant flow rate through the sorbent (column). The effluent from the sorbent goes directly to the detector. The appearance of the analyte is recorded [19]. The relationship between the peak area against the sample volume is linear. When the breakthrough of analyte begins, this relationship starts to deviate from linearity [33].

Another on-line method of determining the breakthrough volume is the connection of the sorbent packed tube with GC/FID or GC/MS system. In this method, the breakthrough volume can be determined in the whole temperature range (from −10 to 170 °C) by using microtrap technology [12,34]. The measurement of breakthrough volume can be carried out in the appropriate system [35]. The sorbent tube is placed in the GC oven or in a separate unit – in the thermal desorber. In this method the specific breakthrough volume (in given temperature) is determined. The dimension of the specific breakthrough volume is ml/g, it is the volume of gas per gram of adsorbent.

3.4. Plate number

The plate number depends on column parameters (diameter, length) and on the physicochemical properties of the sorbent.

The plate number (N) is related to mobile and stationary phase properties [18] or can be calculated from the breakthrough curve [13,19,25,27,36].

The number of theoretical plates corresponds to the efficiency of the SPE column.

Approximate plate number can be calculated using reduced values of mobile phase velocity (ν) and plate height (h) [18,37,38].

3.5. Retention factor

Retention factor is an essential parameter describing the sorption properties of the SPE bed. It is determined for each solute, extracted with the SPE system. The retention factor influences extraction process, it can describe the minimum amount of sorbed analyte, the elution volume or sample volume. It is related to the most important extraction parameter – recovery [19].

The value of retention factor can be determined from the breakthrough curve or by using the method based on the equilibration of the solutes between the SPE sorbent and the model solution [19,27,28].

Generally, the retention factor can be defined as ratio of amount of moles of analyte adsorbed in the stationary phase (n_s) and amount of moles present in the mobile phase (n_E):

$$k = \frac{n_s}{n_E} \tag{10}$$

$$n_E = c_E V_M \tag{11}$$

C_E is defined as:

$$c_E = \frac{n_0 - n_s}{V_0 + V_M} \tag{12}$$

Then retention factor is given as:

$$k = \frac{n_s(V_0 + V_M)}{V_M(n_0 - n_s)} \tag{13}$$

If one defines n_0 as number of moles in aqueous solution V_0, than retention factor is given as:

$$k = \frac{n_0 - c_E(V_0 + V_M)}{c_E V_M} \tag{14}$$

V_0 – is defined as the sample volume – volume of the solute used to determine breakthrough curve.

Recovery can be expressed by the following relationship when using the retention factor [27,28]:

$$r = \frac{V_M k}{V_0} 100\% \tag{15}$$

It is for the solutes when the value of sample volume is:

$$V_0 > V_R + 2\sigma_V \tag{16}$$

3.6. Estimation of the breakthrough volume with short experiment

Experimental determination of breakthrough volume, particularly by using off-line methods, is time consuming. The theory of frontal chromatography allows to deduce a relationship between

the breakthrough volume and the properties of the SPE device: plates number, hold-up volume of the sorbent bed and retention factor of the analyte.

Combining the relationships described above, one can try to approximate the breakthrough volume with only short experiment necessary to determine the recovery.

In this work the relationships described above were used for the characterization of several polymeric sorbents – nine divinylbenzene copolymers. The breakthrough volume was determined experimentally by using frontal analysis and theoretical relationship described by equations given above. The aim of this work was to compare theoretical and experimental methods for the determination of breakthrough volume for some polymeric sorbents, to compare the values of plates number and breakthrough volume obtained in these two different ways. The final effect of this work should be the procedure of the estimation of breakthrough volume after a short experiment. Three aromatic compounds were use as analytes: phenol, hydroquinone and benzoquinone. These compounds can be found in water solutions after phenol oxidation process. The development of analytical procedures for phenol and its degradation products determination allow to describe phenol degradation pathway and degree.

4. Experimental

4.1. Chemicals

Methanol p.a., acetonitryle p.a. and dichloromethane were obtained from POCh (Gliwice, Poland). Phenol (99%), hydroquinone (99%), benzoquinone (98%) were obtained from Sigma–Aldrich, Chimie GmbH (Steinheim, Germany).

4.2. Sorbents

Nine divinylbenzene copolymers were used as SPE sorbents. There were five commercial sorbents:

- SDB-1 – styrene-divinylbenzene copolymer, J.T. Baker (Deventer, Holland, supplied by Witko, Łódź, Poland);
- Strata-X – styrene-divinylbenzene copolymer modified with butyrlactame, interaction: reversed phase;
- Strata-X-C – styrene-divinylbenzene copolymer modified with sulphonic groups, interaction: strong cation exchange and reversed phase;
- Strata-X-CW – styrene-divinylbenzene copolymer modified with carboxylic groups, interaction: weak cation exchange and reversed phase;
- Strata-X-AW – styrene-divinylbenzene copolymer modified with diamine, interaction: weak anion exchange and reversed phase.

All Strata-X sorbents were from Phenomenex® (USA, supplied by Shim-Pol "A.M. Borzymowski", Poland).

All commercial sorbents mass were of 200 mg weight. They were placed into polypropylene cartridges of 6 ml (SDB-1) and 3 ml volume.

Four non-standard polymeric sorbents were also examined:

- BM-DVB (sorbent mass: 193 mg);
- DMN-DVB (sorbent mass: 133 mg);
- MEDDE-DVB (sorbent mass: 191 mg);
- MEMDE-DVB (sorbent mass: 170 mg).

The non-standard polymeric materials were synthesized by the suspension copolymerization of 4,4′-bis(maleimido)diphenylmethane (BM) and divinylbenzene (DVB) and by combined suspension–emulsion copolymerization of divinylbenzene (DVB) with di(methacryloxymethyl)naphthalene (DMN), p,p′-dihydroxydiphenylmethane diglycidyl methacrylic ester (MEMDE), p,p′-dihydroxydiphenylpropane diglycidyl methacrylic ester (MEDDE). Synthesis of monomers (BM, DMN, MEMDE and MEDDE) and the extraction properties of divinylbenzene copolymers were described earlier in literature [39–41].

New synthesized polymeric resins were placed into 6 ml polypropylene cartridges, produced by J.T. Baker (Deventer, Holland, supplied by Witko, Łódź, Poland).

Physical characteristic of sorbents is given in Table 1.

4.3. SPE experiments

SPE experiment was carried out as follows: 25 ml of solution (concentration 0.08 mg/ml) was introduced into SPE sorbent conditioned with methanol (10 ml) and water (10 ml), then the sorbent was dried with air and then analytes were eluted using 5 ml of dichloromethane. Eluate was analyzed by GC–FID.

For each compound (phenol, hydroquinone and benzoquinone) frontal analysis was carried out as follows.

4 mg of analyte were diluted in 500 ml of ultra pure water (Maxima, Ultra Pure Water) then the solute was given to the sorbent in aliquots of 5 ml. From each aliquot the 1 ml sample of effluent was analyzed with HPLC. Breakthrough curves were determined as the relationship between concentration in the water sample after extraction and the total volume of water sample passed through the sorbent. For each sorbent/analyte system the retention parameters were determined from the appropriate curve.

Retention factor k (Eq. (15)) and retention volume V_R (Eq. (4)) were determined.

The plate number was determinated from breakthrough curve using following equation:

$$N = \frac{V_R(V_R - \sigma_V)}{\sigma_V^2} \tag{17}$$

Number of theoretical plates in calculating way was determined as follows:

Table 1
Physical characteristic of sorbents.

Sorbent	Sorbent mass (mg)	Surface area (m^2/g)	Pore diameter (Å)	Pore volume (cm^3/g)	Particle size (μm)
DMN-DVB	157.9	105.5	85	0.26	20–30
BM-DVB	187.2	35.0	155	0.12	30–50
MEDDE-DVB	193.7	21.5	–	0.33	20–40
MEMDE-DVB	186.3	68.3	–	0.36	20–30
SDB-1	200	299.0	90	0.77	43–123
Strata-X	200	800	85	1.2	30
Strata-X-C	200	800	85	1.2	30
Strata-X-CW	200	800	85	1.2	30
Strata-X-AW	200	800	85	1.2	30

First the mobile phase reduced velocity was calculated as:

$$\nu = \frac{ud_p}{D_M} \quad (18)$$

where d_p is the particle diameter and D_M is the diffusion coefficient in mobile phase.

The reduced plate height (h) was determined from the Knox equation [18,37,38]:

$$h = A\nu^{1/3} + \frac{B}{\nu} + C\nu \quad (19)$$

where A, B, C are the constants; for sorbents with particle size near 20 μm $A = 1$; $B = 2$; $C = 0.1$, and ν is the mobile phase reduced velocity.

The relation between plate height and reduced plate height is described as:

$$H = hd_p \quad (20)$$

Then the plate number was calculated from equation:

$$N = \frac{L}{H} \quad (21)$$

where L is the column length and H is the plate height.

Finally the breakthrough volume was calculated from Eqs. (1), (2) or (9) depending on plate number.

The breakthrough level (b) was determined as the fraction of total mass of analyte which has passed out of the column without adsorption, parameters a_0, a_1, a_2 were taken from literature [18]. The number of theoretical plates was calculated using Eq. (17) (for frontal analysis), and using equations given above. Retention parameters (k, V_R, V_M) were determined in frontal analysis and without experiment using Eqs. (15) and (4). The hold-up volume V_M value was determined using the value to multiply pore volume and sorbent mass. Recovery was determined as the ratio of mass of analyte introduced to the sorbent bed and mass of analyte indicated in the eluent, multiplied by 100%.

4.4. Chromatographic analysis

4.4.1. HPLC

Qualitative and quantitative analysis of effluent samples was carried out with the use of liquid chromatograph HPLC HP 1100. Conditions of HPLC experiment were as follows: Ultra Aqueous C18 5 μm column, 250 mm × 4.6 mm i.d. (Restek), acetonitrile as mobile phase at a flow rate of 1 ml/min; UV-DAD detector. The column was thermostated during analysis at 45 °C. For quantitative analysis the calibration curves were determined for each compound in the range from 0.0005 to 5 mg/ml.

4.4.2. GC

Gas chromatograph HP 5890II was used with capillary column RTX-1701 (Restek) 0.25 μm, 30 m × 0.32 mm, helium was used as carrier gas at flow rate 1.5 ml/min, and a head pressure of 150 kPa. Flame-ionization detector (FID) and split/splitless injector were used. Analyses were carried out in a programmed temperature: the column temperature was held at initial temperature of 60 °C for 2 min, then ramped at 10 °C/min to 125 °C, then at 70 °C/min to 250 °C where it was held for 5 min total analysis time was 15.30 min.

5. Results and discussion

Extraction process of phenol, hydroquinone and benzoquinone from water samples by means of SPE with the use of series of polymeric sorbents might be characterized by the parameters collected in Tables 2–4. Significant similarities were found when these data were analyzed. For all analytes better efficiency of SPE columns (cartridges) given by the number of theoretical plates corresponded to the highest breakthrough volume. Strata-X-AW sorbent was found to be the most efficient sorbent for phenol: the number of theoretical plates is higher than 100 and breakthrough volume is equal to 243.1 ml. The most efficient sorbent for hydroquinone is Strata-X where the number of theoretical plates is very high and equal to 188 and the breakthrough volume equal to 159.1 ml. Strata-X-CW was the most efficient sorbent for benzoquinone ($N = 31$ and $V_B = 121.6$ ml). The highest efficiency and the highest breakthrough volume corresponds to a large surface area of the sorbent. All sorbents from the Strata-X group have large surface areas (800 m^2/g), and these sorbents are efficient in the extraction of phenol, hydroquinone and benzoquinone. The information on sorption properties of the sorbent may be deduced from the maximum concentration of analyte in the effluent (C_E). High C_E values indicate weak sorption properties for given analyte and it results in

low breakthrough volume. When C_E is low then sorption properties are better and the breakthrough volume is higher. These relationships are illustrated in Fig. 2 for phenol, in Fig. 3 for hydroquinone and in Fig. 4 for benzoquinone.

The plate number determined for some sorbents are too high (these values are impossible for SPE columns), it is connected with imprecise determination of retention volume (V_M) from the breakthrough curve.

The aim of this work was to find simple and fast method to approximate the breakthrough volume using only short experiment. V_B values might be calculated from Eq. (1) [18] and Eq. (2) [21,24,25]. The values of breakthrough volume given in Tables 5–7 were obtained using V_R and N calculated from linear velocity and reduced plate height, using Eqs. (20), (18) and (19). These values are compared with V_B determined in the frontal analysis (V_B exp.). For phenol and hydroquinone these values are determined for all sorbents and for hydroquinone the data are given only for three sorbents: Strata-X with very good extraction properties and MEMDE-DVB and MEDDE-DVB being rather weak sorbents.

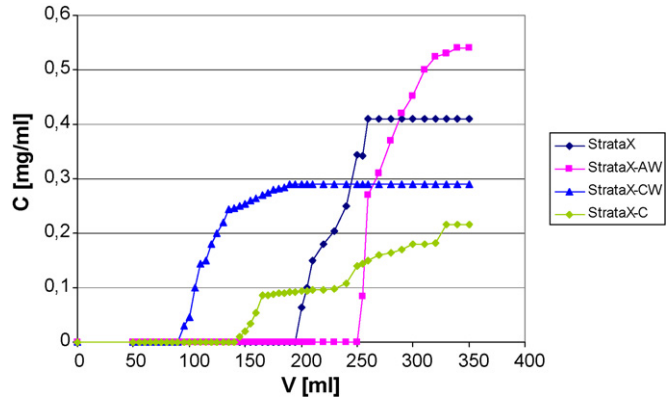

Fig. 2. Comparison of breakthrough curves determined for phenol on polymeric sorbents.

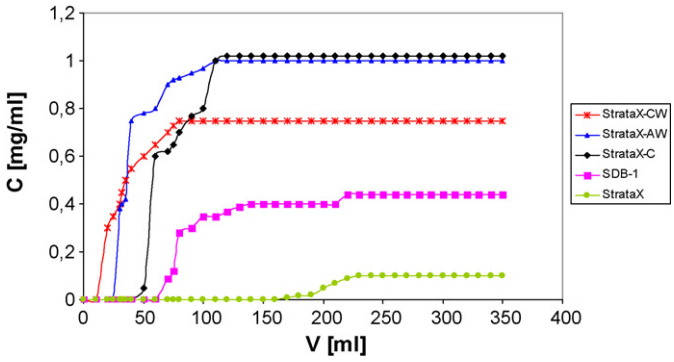

Fig. 3. Comparison of breakthrough curves determined for hydroquinone on polymeric sorbents.

Comparison of the breakthrough volume values determined using Eq. (1) or (2) with those found experimentally show that for all analytes V_B determined from Eq. (2) do not differ significantly from experimental data. The differences are much lower than those obtained when Lövkvist equation was applied. The existence of such large differences can be connected with the use of a_0, a_1, a_2 factors taken from literature. These factors depend only on breakthrough level (b), and they are the same for all sorbents. The determination of V_B by using equations proposed by Werkhoven-Goëwie is therefore easier and more precise and it was used in further calculations.

The breakthrough values determined using Eqs. (1) and (2) (or (9)) are similar to V_B values determined experimentally especially for sorbents from Strata-X group. However, differences between both the theoretical and experimental values of discussed parameters for other sorbents are higher. It can be connected with different values of V_R and N determined experimentally (from breakthrough curve) and determined theoretically using recovery and retention factor k.

When the absolute and relative errors are analyzed (Tables 5–7) it can be found that differences between the values of breakthrough volume determined in computational and experimental methods for some sorbents are in error range, e.g. for Strata-X-AW sorbent in phenol separation. The precision of computational method is determined with the precision of recovery determination.

The efficiency of SPE sorbents (expressed by N) determined for phenol, hydroquinone and benzoquinone to a large extent depends on their specific surface area. The large surface area of the sorbent is "accompanied" by high N values while small surface area corresponds to lower efficiency (N value). It means that the sorbent efficiency is not identical with its extraction properties given by recovery.

Comparison of two methods used for the determination of the breakthrough volume is presented in Fig. 5. It is clear that calculating way is shorter and more precise. The required experiment

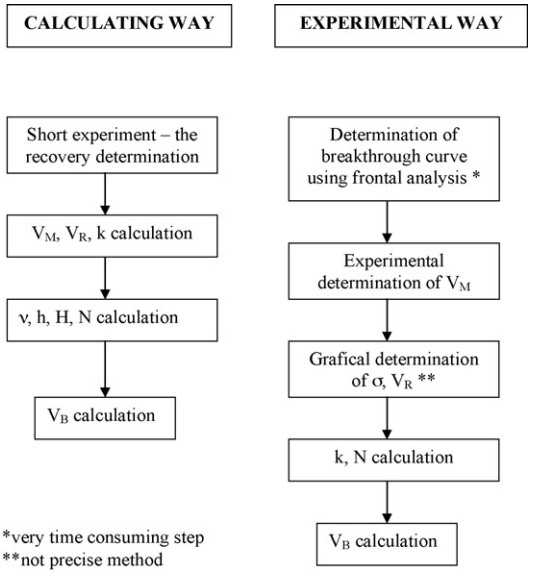

Fig. 5. Two ways of breakthrough volume determination.

is limited by the recovery determination only, the other steps are computational. In experimental way the first step is very time consuming as breakthrough curve determination in frontal chromatography is rather long. Some parameters must be determined graphically from breakthrough curve, and it can cause relatively large error.

Both methods – experimental and calculating – gave satisfactory results during the estimation of breakthrough volume and the efficiency of SPE sorbents but calculating way is somewhat quicker and more precise.

6. Conclusion

The method proposed in this work allows to determine the breakthrough volume with short experiments. The compared experimentally and computationally achieved values are close. It shows that these two ways of determining the breakthrough volume of SPE sorbents are equivalent. The computational way is more suitable as it is non-time consuming and easy. The method allows to estimate the sorbents' properties in a sufficient way.

Computational methods seem to be useful. However, one should take into account other, e.g. kinetic factors, influencing the SPE

process. The success of calculating procedure depends on the precise and reproducibility determination of recovery.

Gas chromatography–quadrupole mass spectrometry

ABSTRACT

A stir bar sorptive extraction with liquid desorption followed by large volume injection coupled to gas chromatography–quadrupole mass spectrometry (SBSE-LD/LVI-GC–qMS) was evaluated for the simultaneous determination of higher alcohol acetates (HAA), isoamyl esters (IsoE) and ethyl esters (EE) of fatty acids. The method performance was assessed and compared with other solventless technique, the solid-phase microextraction (SPME) in headspace mode (HS). For both techniques, influential experimental parameters were optimised to provide sensitive and robust methods. The SBSE-LD/LVI methodology was previously optimised in terms of extraction time, influence of ethanol in the matrix, liquid desorption (LD) conditions and instrumental settings. Higher extraction efficiency was obtained using 60 min of extraction time, 10% ethanol content, *n*-pentane as desorption solvent, 15 min for the back-extraction period, 10 mL min^{-1} for the solvent vent flow rate and 10 °C for the inlet temperature. For HS-SPME, the fibre coated with 50/30 μm divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS) afforded highest extraction efficiency, providing the best sensitivity for the target volatiles, particularly when the samples were extracted at 25 °C for 60 min under continuous stirring in the presence of sodium chloride (10% (w/v)). Both methodologies showed good linearity over the concentration range tested, with correlation coefficients higher than 0.984 for HS-SPME and 0.982 for SBES-LD approach, for all analytes. A good reproducibility was attained and low detection limits were achieved using both SBSE-LD (0.03–28.96 μg L^{-1}) and HS-SPME (0.02–20.29 μg L^{-1}) methodologies. The quantification limits for SBSE-LD approach ranging from 0.11 to 96.56 μg $L^{-}$and from 0.06 to 67.63 μg L^{-1} for HS-SPME. Using the HS-SPME approach an average recovery of about 70% was obtained whilst by using SBSE-LD obtained average recovery were close to 80%. The analytical and procedural advantages and disadvantages of these two methods have been compared.

Both analytical methods were used to determine the HAA, IsoE and EE fatty acids content in "Terras Madeirenses" table wines. A total of 16 esters were identified and quantified from the wine extracts by HS-SPME whereas by SBSE-LD technique were found 25 esters which include 2 higher alcohol acetates, 4 isoamyl esters and 19 ethyl esters of fatty acids. Generally SBSE-LD provided higher sensitivity with decreased analysis time.

1. Introduction

Aroma compounds are important in wine as they contribute to the quality of the final product, hence to the consumer acceptance [1]. The wine volatile fraction can be composed by over 800 different compounds [1,2], but only several tens of which can be odour active [3] and must be considered for differentiation purposes. These compounds belong to different chemical families, including *higher alcohols*, *ethyl esters*, *fatty acids*, *acetates*, *isoamyl esters*, *carbonyls*, *sulphurs*, *furanics*, *monoterpenols*, C_{13}-*norisoprenoids* and *volatile phenols*, presenting different polarities, volatilities and moreover, are found in a wide range of concentrations from ng L^{-1} to mg L^{-1} [4,5]. They proceed from four major sources, like (i) grapes; (ii) processing of the grapes (namely crushing, pressing, *etc.*) by chemical, enzymatic-chemical and thermal reaction in grape must; (iii) fermentation process, and (iv) chemical reactions during maturation of wine (wood, commonly oak). An important part of wine aroma arises during the alcoholic fermentation of grape sugars by the wine yeast, which produces ethanol, carbon dioxide and a number of by-products including

doi:10.1016/j.talanta.2009.07.038

higher alcohols and esters [6], whose formation is closely related to the particular yeast species involved. Acetates, such as ethyl acetate, hexyl acetate, isoamyl acetate and 2-phenylethyl acetate are recognised as very important flavour compounds in wine and other grape-derived alcoholic beverages. In general, these volatile compounds have a pleasant odour and a low perception threshold, which allows the assumption that they contributed to the wine aroma even present in small concentrations. The main esters in commercial wines used to be ethyl and 3-methylbuthyl esters of short-chain fatty acids [7].

The analysis of volatile and semi-volatile organic compounds that contribute to wine aroma has been carried out following different methodologies, such as liquid–liquid extraction [4,8,9], purge and cold trapping extraction [10], simultaneous distillation–extraction [11], supercritical fluid extraction [12], solid-phase extraction [13] and ultrasound extraction [14]. However, most of these approaches present several disadvantages, including expensive equipment requirements, significant amounts of environmentally unfriendly solvents, multiple handling steps that increase error, and the need for a concentration step to achieve detectable levels. Nowadays, there are available solventless alternatives to these classical methodologies, which may overcome all those disadvantages such as the well-known solid-phase microextraction (SPME), developed by Pawliszyn et al. [15,16] and more recently, stir bar sorptive extraction (SBSE) proposed by Baltussen et al. [17]. The latter methodology uses the Twister™, a glass stir bar onto which is bonded a polydimethylsiloxane (PDMS) phase, in quantities far in excess of those found on SPME fibres [18]. The SBSE extraction takes place when the aqueous sample begins to be stirred by the bar during a period of time until the volatile or semi-volatile compounds reach the equilibrium and after enrichment, are thermally desorbed (TD) followed by gas chromatography analysis usually coupled to mass spectrometry (GC–MS) [19–21]. These sorptive extraction approaches showed great advantages when compared with other conventional enrichment methodologies, since eliminate the use of toxic organic solvents, allow the determination of a large number of analytes with low limits of detection and good linear dynamic ranges, combine extraction, concentration and instrumental analysis into a single step, require no or little manipulation/sample preparation, reduce substantially the analysis time, are simple and faster methods, cover a wide range of sampling techniques, including field, *in situ* and air matrices and can be performed by immersing the polymeric coatings into sample medium or in the headspace (HS). In general, the accepted disadvantages are relatively lot-to-lot variations, sensitivity against organic solvents and the limited range of commercially available specific stationary phases [22,23].

In the last years, SBSE have becoming more accepted since present remarkable sensitivity and accuracy than SPME in particular, during trace analysis of complex matrices such as wine samples [18,24,25]. For instance, it was already demonstrated that SBSE-TD is an analytical technique much more powerful than HS-SPME, which allowed higher ability for profiling trace and ultra-trace compounds for Madeira wine characterisation [18]. Nevertheless, the TD systems are expensive devices and many times, are not the best option to analyse particular thermolabile constituents, due to the very high desorption temperature requirements with possible occurrence of artefacts. Moreover, the TD mode does not offer the opportunity of multiple injections, which is an important issue in many studies during validation purposes. More recently, we proved that SBSE-LD is a remarkable alternative presenting interesting features to overcome these limitations [20,21,26]. In this approach, the analytes are trapped followed by removal through back-extraction with a small volume (typically microliters) of a convenient organic solvent prior to GC–MS analysis. Furthermore, if we combine large volume injection (LVI) to enhance sensitivity with suitable desorption solvents under optimised conditions [19], volatile compounds can be easily analysed in wine matrices, as was reported lately [27]. Although HS-SPME [28,29] and SBSE-LD methodologies can be easily applied in any laboratory since they do not need special instrumental requirements, both procedures were never compared in terms of analytical advantages, selectivity and sensitivity.

The purpose of the present work is to compare the performance of two solventless sorptive extraction approaches: HS-SPME/GC–MS versus SBSE-LD/LVI-GC–MS, for the determination of volatile compounds in wines, using HAA, IsoAE and EE as model compounds. The optimisation, validation and application of both methodologies, as well as the advantages observed are fully discussed using commercial wines from different grape varieties produced in Madeira Island.

2. Experimental

2.1. Reagents and standards

Methanol (MeOH), acetonitrile (ACN) and acetone purchased from Fluka (Buchs, Switzerland) were of HPLC grade. 2-Phenylethyl acetate, ethanol, diethyl ether and *n*-pentane were supplied from Riedel-de Haën (Barcelona, Spain). Isoamyl acetate, 2-propanol, ethyl hexanoate, octanoate and ethyl salicylate and clear glass vials were purchased from Sigma-Aldrich Química S.A. (Madrid, Spain). Ethyl decanoate, dodecanoate, cinnamate, benzoate, lactate, 2-furoate and ethyl butyrate were supplied from Acros (Geel, Belgium). Isoamyl hexanoate and isoamyl octanoate were obtained from SAFC (Steinheim, Germany). Pure water was obtained from a Milli-Q purification system (Millipore, Bedfords, MA, USA). Sodium hydroxide (NaOH, 98%) and sodium chloride (NaCl, 98.5%) were purchased from Panreac (Barcelone, Spain). The SPME fibres, the manual SPME holder and the PTFE coated-silicone caps, were purchased from Supelco (Bellefonte, PA, USA). The glass vials (30 ml) were obtained from Macherey-Nagel, (Düren, Germany). The manual crimper was obtained from Agilent Technologies (Little Falls, DE, USA) and the Variomag Multipoint komet agitation plate from Thermo Fisher Scientific Inc. (Waltham, MA, USA). The stir bars (Twister; Gerstel, Müllheim a/d Ruhr; Germany) containing PDMS (0.5 mm film thickness, 10 mm in length) with a volume of 24 μL were used. Ultrasonic equipment, Branson 3510, was purchased from Branson Ultrasonic Corporation (Danbury, CT, USA).

Individual stock standard solutions of each target compound were prepared by weight in ethanol. A global stock standard solution, containing all the analytes under study, was prepared in a synthetic wine matrix (120 ml L^{-1} of ethanol, 5 g L^{-1} of tartaric acid and pH 3.3 adjusted with NaOH). Working solutions were prepared by diluting different amounts of the global standard solution in a synthetic wine. All solutions were stored at 4 °C. For calibration purposes five different levels of concentration, covered the concentration ranges expected in wines, were prepared. Three replicates of each level were analysed. The average and the relative standard deviation (R.S.D.) were calculated.

2.2. Wine samples

All varieties used were *Vitis vinifera* L. species. The most important and most representative commercial "Terras Madeirenses" wines from Madeira Island (Portugal), produced according to standard procedures, were selected. The grapes were crushed, de-stemmed, racked and pressed. The musts were fermented in stainless-steel containers at 22 °C with spontaneous yeast. The white wines, Enxurros (ENX) and Palmeira (PAL) of 2005 vintage and Quinta do Moledo Reserva (QMR) of 2004 vintage, were produced using Verdelho & Arnsburguer, Verdelho & Bual & Arns-

R^2: determination coefficient; (–) not determined by SBSE (solvent delay higher than its retention time).

burguer and Verdelho grapes, respectively. Therefore, Verdelho grapes were the main composition of white wines studied. The Colombo (COL) red wine of 2004 vintage was produced using Tinta Negra Mole grape variety. The grapes were harvested at optimum maturity evaluated by indices of sugar and acid content. All samples were taken from bottled wines (750 ml) and stored at −28 °C until analysis. In all cases, analysis was performed in triplicate and the values were averaged. For the optimisation of HS-SPME extraction methods, Enxurros (ENX) young white wine from 2005 harvest was used.

2.3. Extraction procedure

2.3.1. SPME assays

Six different coating fibres: 75 μm carboxen-poly(dimethylsiloxane) (CAR/PDMS), 65 μm carbowax-divinylbenzene (CW/DVB), 50/30 μm divinylbenzene-carboxen-poly(dimethylsiloxane) (DVB/CAR/PDMS), 100 μm poly(dimethylsiloxane) (PDMS), 85 μm polyacrylate (PA) and 65 μm poly(dimethylsiloxane)-divinylbenzene (PDMS/DVB) were assessed to evaluate their performance for the study of HAA, IsoAE and EE in wines. The fibres were conditioned following the manufacturer instructions by inserting them into the GC injector port. Before the first daily analysis the fibres were conditioned for 6 min at 240 °C in the GC injector. A blank test was performed to check possible carry-over. Besides the fibre type, some other SPME parameters that influence the extraction process were optimised, namely extraction time (5, 15, 30, 60 and 75 min), temperature (25, 30, 40 and 60 °C), ionic strength (0, 10, 20 and 30% NaCl (w/v)) and matrix effects (12, 15, 17 and 19% (v/v) of ethanol). For each HS-SPME assay, aliquots of 10 mL of wines were placed into a 20 mL clear glass vial, to which 10% (w/v) of NaCl was added, and hermetically sealed with a PTFE coated-silicone cap, after addition of a small stirring bar. The extractions were carried out at wine pH (3.3). The vial was placed in a thermostat block on a stirrer. The SPME fibre was inserted into the HS at the sampling time during the sampling extraction time. All solutions were stirred at constant speed (800 rpm). After sampling, the fibre was retracted, removed from the sample vial and manually introduced into the GC injection port. Each assay was performed in triplicate.

2.3.2. SBSE assays

Each wine sample was introduced into a glass vial (30 mL); a stir bar with PDMS coating film (0.5 mm thick; 10 mm long, 24 μL) was immersed, and the vial was closed with a seal (aluminium seals with PTFE septa) using a manual crimper. Assays were performed in a 15th agitation point plate at room temperature (25 °C), using an extraction time of 60 min and a rotation speed of 800 rpm. For back-extraction purposes, the stir bars were placed into 250 μL glass flat-bottom inserts filled with 200 μL of *n*-pentane inside a glass vial. The back-extraction was performed by using ultrasonic treatment and desorption time of 15 min at constant temperature (25 °C). After back-extraction, the stir bars were removed by means of a magnetic rod and the vials were closed with seals, using a manual crimper, and placed into the automatic liquid sample (ALS) tray for LVI-GC–MS analysis. After each extraction, the stir bars were cleaned to dryness under a stream of purified nitrogen followed by a cleaning with ACN. All the experiments were performed in triplicate.

2.4. GC–MS analysis

After sampling the SPME fibre containing the volatile compounds were introduced into the GC injection port at 260 °C and kept for 6 min for thermal desorption. Desorbed volatile compounds were separated in an Agilent Technologies 6890 gas chromatograph equipped with a 30 m × 0.25 mm (i.d.) × 0.25 μm film thickness TRB-5MS fused silica capillary column (95% dimethyl, 5% diphenylpolysiloxane; Teknokroma, Spain), connected to an Agilent 5973N quadrupole mass selective detector (Agilent 7683, Agilent Technologies, Little Falls, DE, USA). The carrier gas used was helium N60 (Air Liquid, Portugal) at 3.5 mL min^{-1} with a column-head pressure of 21 psi and splitless injections were used (6 min). The GC oven temperature was programmed as follows: initial oven temperature 40 °C, then increased in two steps: 40–175 °C at 2 °C min^{-1} and 175–220 °C at 10 °C min^{-1} (5 min) in a 77 min running time. The quadrupole operating in electronic ionisation (70 eV) and the acquisition was made in full scan mode (35–550 *m*/*z*) using the selected ions illustrated in Table 1. The quadrupole detector was set as follows: transfer line temperature 280 °C; ion source temperature 230 °C and quadrupole analyzer temperature 150 °C. The analysis from the SBSE-LD assays were performed using the GC–MS conditions as above with the exception of the inlet port for which an Agilent 7683 ALS and a programme temperature vapourizing (PTV) injector having a baffled liner and a septumless head (SLH; Gerstel, Mülheim a/d Ruhr, Germany) were used. LVI using the solvent vent mode and liquid nitro-

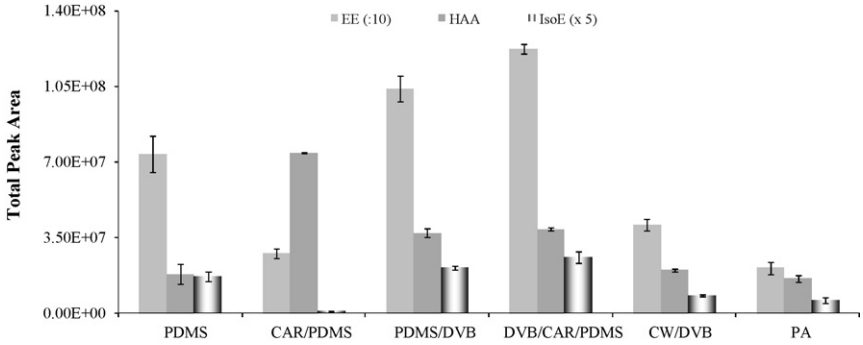

Fig. 1. Influence of the polymeric fibre coating on the HS-SPME yields of higher alcohol acetates (HAA), isoamyl esters (IsoE) and ethyl esters (EE) in wines (other extraction conditions: 60 min and 25 °C).

gen as inlet cooling was operating according to previous work [19]. The solvent vent injection mode was performed (vent time: 0.30 min; flows: 10 mL min^{-1}; pressure: 0 psi; purge: 60 mL min^{-1} at 2 min), for which the inlet temperature was ramped from 10 °C (0.35 min) to 300 °C at a rate of 600 °C min^{-1} and subsequently decreased to 200 °C (held until end) at a rate of 50 °C min^{-1}. The injection volume and speed were 20 μL and 100 mL min^{-1}, respectively.

The mass spectra data were compared with the Wiley library reference spectral bank (G1035B; Rev D.02.00; Agilent Technologies, USA) and confirmed with the retention indices (RI) of standards when they were available. Data recording and instrument control were performed by the MSD ChemStation software (G1701CA; version C.00.00; Agilent Technologies, USA). For the determination of the retention indices (RI) a C8–C20 *n*-alkanes series was used.

2.5. Method validation

Calibration plots constructed using suitable dilution of the global solutions were obtained by the least-square linear regressions of ratio of the peak area of each compound versus the added amount of the targets.

The proposed analytical methods were evaluated in relation to linearity, repeatability (precision, expressed as relative standard deviation (R.S.D.)), evaluation of the recovery of known quantities of substance (accuracy) and detection and quantification limits. The detection (LOD) and quantification (LOQ) limits were calculated as the concentration of the analyte that produce a signal-to-noise ratio of 3 and 10 times, that is $3S_{y/x}/b$ and $10S_{y/x}/b$, respectively, where $S_{y/x}/b$ is the blank standard deviation and b is the slope of the regression plot. The linear range experiments provide the essential information to determine the detections and quantifications limits, from lowest concentration point on the linear calibration curve. For recovery studies, ENX wine was spiked with target volatiles and six replicates of the original and spiked wines were assayed (HS-SPME and SBSE-LD) and analysed by GC–MS. The area increments between spiked and original wines were interpolated in the calibration graphs and the experimental concentration calculated. The recovery was determined according to the following relation:

$$\text{Recovery } (\%) = \frac{C_1 - C_0}{C_2} \times 100$$

where C_0 is the concentration in the ENX wine, C_1 is the concentration found in spiked wine and C_2 is the concentration added. The repeatability of the method was calculated by six consecutive extractions of the spiked synthetic wines. For each assay the average values and R.S.D. were determined.

3. Results and discussion

To compare the performance of both HS-SPME and SBSE-LD analytical methodologies, 15 volatile components were selected as model compounds, *i.e.* 3 HAA, 2 IsoE and 10 EE in order to optimise the experimental conditions.

3.1. HS-SPME optimisation

In the beginning we investigated for the best fibre coating for HS-SPME, followed by optimisation of the extraction time and temperature, ionic strength and matrix effects, using a constant magnetic stirring (800 rpm). Six types of SPME fibres, differing in the polarity and thickness of the stationary phase, were tested in order to compare their extraction yields towards higher alcohol acetates and esters. The data presented in Fig. 1 showed that the DVB/CAR/PDMS fibre performed the best extraction efficiency for all EE and IsoE. The CAR/PDMS fibre achieved almost two times higher efficiency for acetates than PDMS/DVB and DVB/CAR/PDMS ones, but did not show better extraction efficiency for the ester compounds. On the other hand, the lowest extraction efficiency was obtained by PA. Therefore, the PDMS/CAR/PDMS fibre was selected as the most convenient polymeric phase for HS-SPME analysis of EE and HAA in commercial wines.

Subsequently, the extraction time profile for the 15 compounds was also performed and the data obtained are depicted in Fig. 2a. Since HS-SPME is a distribution process of the analytes between the wine matrix, vapour phase and polymeric phase (three-phase system), it is very important to establish the most convenient time to reach the equilibrium [30]. In order to investigate the sorption behaviour of wine HAA, IsoE and EE using a DVB/CAR/PDMS fibre, assays were performed at five different extraction times, *i.e.* 5, 15, 30, 60 and 75 min (25 °C). For almost all compounds, the extraction yields increased with time until 60 min. However, after this period, the extraction efficiency decreases slightly due probably to the phenomena competition as this type of fibres present capacity limitations. On the basis of the results obtained, 60 min of extraction time were selected for further assays.

During HS-SPME analysis, the distribution constant of an analyte between the sample and the fibre coating is influenced very much by the extraction temperature, which depends on the matrix composition and the polymeric phase selected. Since SPME is an exothermic process, when temperature arises the sorption process reduces enhancing HS concentrations but, on the other hand, decreases the partition coefficients due to the thermodynamic effect. According to Carvalho et al. [30], excessive increment of temperature can cause premature desorption of the analytes. Therefore, the effect of temperature on the extraction efficiency was also evaluated by sampling an ENX wine at 25, 30, 40 and 60 °C, with the

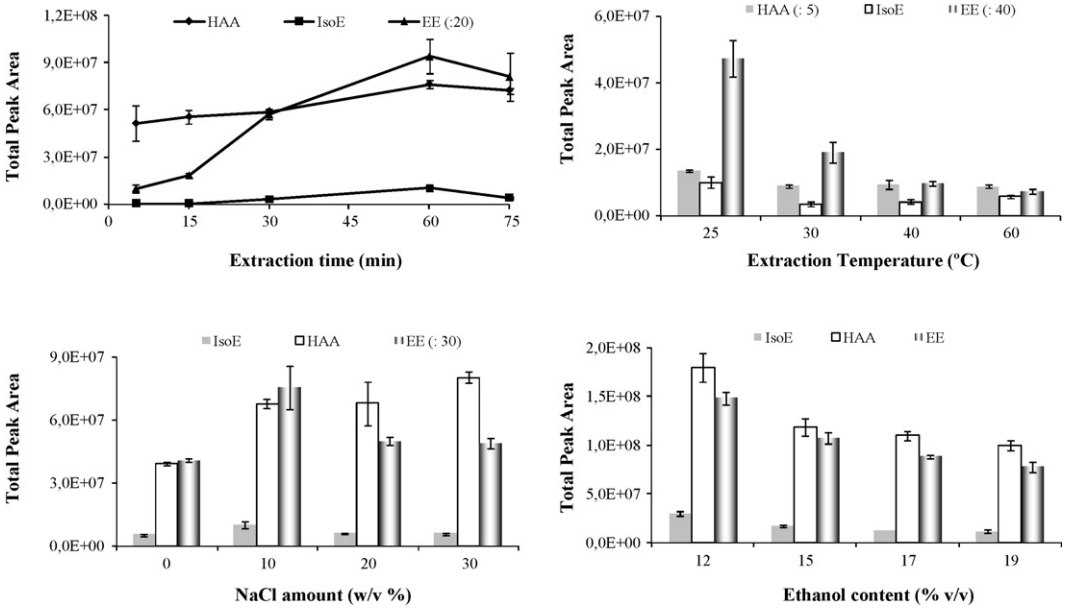

Fig. 2. Influence of the extraction time (a), temperature (b), ionic strength (c) and ethanol content (d) on the extraction efficiency of HAA, IsoE and EE in wines by HS-SPME using a DVB/CAR/PDMS fibre.

DVB/CAR/PDMS fibre incubated for 60 min (extraction of salt saturated sample: 10% NaCl (w/v)). As can be observed in Fig. 2b, the temperature increment leads to a decrease in the extraction yield for the IsoE and EE, although the HAA content increased. As a consequence, 25 °C was selected for further optimisation. Another parameter that must be taken into consideration is the ionic strength once this greatly influences the partitioning coefficient of the solutes between the liquid and vapour phases. An increment of salt concentration increases the extraction efficiency due to the decrease of analytes solubility, which improves sensitivity by promoting higher enrichment into the stationary phase [31]. Thus, the ionic strength was tested at 0, 10, 20 and 30% of NaCl (w/v) using the DVB/CAR/PDMS fibre (60 min at 25 °C) and the results obtained are depicted in Fig. 2c. With the exception of EE for which better yields were obtained with 10% of salt, for the remaining chemical families (HAA and IsoE), the analytical response increased with higher salt levels. In general, the addition of 10% NaCl promotes the best results and therefore, this amount was chosen to all wine samples prior to analysis. The distribution constant between the polymeric coating and the sample are

LOD: limit of detection; LOQ: limit of quantification; R.S.D.: relative standard deviation; (–) not determined by SBSE (solvent delay higher than their retention time).

strongly dependent on the matrix effects. For instance, the ethanol content in wines appears to interfere very much during the HS-SPME analytical procedure [23]. Thereby, to check the effect of ethanol content on the HS-SPME extraction yields, four solutions having different contents (12, 15, 17 and 19% (v/v)) and spiked with the same amounts of volatile compounds were assayed using DVB/CAR/PDMS fibre (extraction of salt sample: 10% NaCl (w/v) during 60 min at 25 °C). Fig. 2d compares the data obtained for HAA, IsoE and EE on that media, where the peak area decreases as the ethanol content increases for all of the studied chemical families. As a consequence no advantages were observed by increasing the ethanolic content.

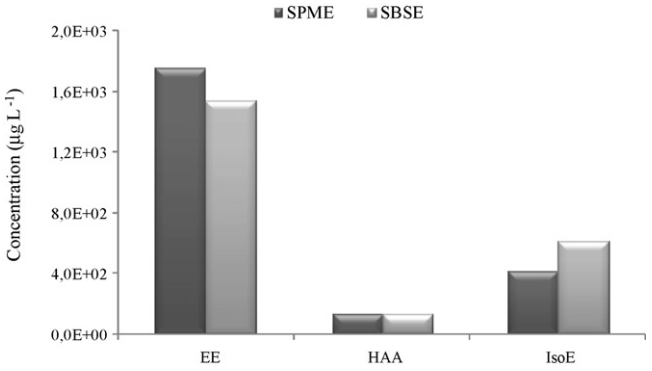

Fig. 4. Comparison of extraction efficiency performance of SBSE and SPME for the analysis of HAA, IsoE and EE.

3.2. SBSE-LD/LVI optimisation

By using the SBSE-LD/LVI approach the extraction time, ethanol content, LD conditions and instrumental settings were established, according to a methodology previously optimised [19]. Therefore 10 volatile compounds, representative of the main chemical families of wine, were used, *i.e.* guaiazulene, (*E*, *E*)-farnesol, β-ionone, geranylacetone, ethyl decanoate, β-citronellol, 2-phenylethanol, linalool, hexyl acetate and *n*-hexanol were selected for SBSE-LD optimisation. During our assays, stir bars coated with 24 μL of PDMS were chosen, once this polymer is the only one commercially available, more effective to non-polar compounds, and needs a low amount of back-extraction solvent (<200 μL) inside an insert, which is a key role during the liquid desorption step. The use of a minimum amount of solvent for LD is very convenient since avoid the undesirable solvent evaporation step usually performed for sensitivity enhancement and minimizes possible losses of volatiles. The best solvents used for LD should be the ones that must desorbs the analytes from the PDMS phase and simultaneously present low boiling points for LVI under solvent vent mode avoiding losses of volatiles. For this purposes, several solvents were already tested, namely, ACN, MeOH, *n*-pentane, acetone, diethyl ether, propan-2-ol and azeotropic mixtures. According to the data obtained, *n*-pentane was chosen as the best back-extraction solvent during the LD process, because all standards were detected and the peaks did not present fronting, consequently, more reproducibility was obtained. The time for the back-extraction used was 15 min, since higher period of time did not bring any advantages. For LVI purposes, the chromatographic performance is also very dependent of the He flow rate against solvent used, due to the dependence of the inlet purge flow rate and temperature in the solvent vent mode. Better performance was observed with flow rate of 10 mL min^{-1} and therefore, was selected as the purge vent. Different inlet purge temperatures were also tested because solvent vent mode is also a critical parameter. According to previous data [19], the recovery of the volatile compounds seems to present higher reproducibility and recovery when the analysis carried out at 10 °C. Since SBSE was used in a two-phase system (liquid sample-stir bar) and is time dependent, we have decided to use 60 min at 800 rpm.

(–) Not determined by SBSE (solvent delay higher than their retention time).

Fig. 3 compares total ion chromatograms of wine samples obtained by HS-SPME$_{DVB/CAR/PDMS}$/GC–MS (a) and SBSE-LD/LVI-GC–MS (b) methodologies, under optimised experimental conditions. As it can be observed, both methods present good performance besides the latter approach showed much better overall sensitivity in particular to detect minor constituents.

3.3. Validation and comparison of SPME and SBSE methodologies

In a first approach, both methodologies are very easy to work-up without special instrumental needs, which make them potential analytical tools to analyse wines in any conventional laboratory. Although SBSE-LD presents a much higher capacity and therefore better sensitivity than HS-SPME, the selectivity concerning the polar characteristics of the analytes under study, seems to be better performed by the latter since we have the possibility to choose the more suitable polymeric phase and in the former case, only PDMS is available. In the experimental point of view, SBSE-LD is a technique much more robust than HS-SPME, without any polymeric damage during analytical manipulation, do not need salt addition to increase the vapour tension or suitable temperature control and if the right desorption solvent is combined with LVI, present a remarkable performance as it was successfully demonstrated to the particular case of acetates and esters in wines.

In Tables 1 and 2, the calibration parameters (linearity, repeatability (precision, expressed as R.S.D.), recovery of known quantities of substance (accuracy), LODs and LOQs, are given for both methodologies. Calibration plots constructed using suitable dilutions of the global solutions were obtained by the least-square linear regressions of ratio of the peak area of each compound versus the added amount of the targets. Both methodologies showed good linearity over the concentration ranges tested with all determination coefficients (r^2) higher than 0.982. Regarding the detection purposes, some differences were observed between both analytical approaches since ethyl lactate and ethyl butanoate were not found by SBSE-LD. Detection and quantification limits (Table 2) were achieved by extrapolation of the lowest concentrations points from the standard plots (3 and 10 times the R.S.D. of blanks, respectively). Therefore, LODs ranged between 0.02 $\mu g\,L^{-1}$ (isoamyl hexanoate) and 20.29 $\mu g\,L^{-1}$ (isoamyl acetate) were found for HS-SPME methodology, whereas for SBSE-LD ranged from 0.03 $\mu g\,L^{-1}$ (ethyl cinnamate) to 28.96 $\mu g\,L^{-1}$ (ethyl salicylate). In average the LOD's values obtained by SBSE-LD were lower than those obtained by HS-SPME. LOQs ranged from 0.06 $\mu g\,L^{-1}$ (isoamyl hexanoate) to 67.63 $\mu g\,L^{-1}$ (isoamyl acetate) and 0.11 $\mu g\,L^{-1}$ (ethyl cinnamate) to 96.56 $\mu g\,L^{-1}$ (ethyl salicylate) for HS-SPME and SBSE-LD, respectively. The repeatability has been evaluated by means of a series of six extractions from the same wine. The results indicated that the methods had good repeatability. For HS-SPME good within-day precision was noticed with R.S.D. values between 4.10% (isoamyl hexanoate) and 15.87% (isoamyl acetate). For SBSE-LD methodology the R.S.D. values ranges between 8.21% (isoamyl acetate) and 17.88% (ethyl cinamate). In order to check the accuracy of the proposed methods, a recovery study was carried out by fortifying an ENX wine sample. For HS-SPME approach, the recoveries of the higher alcohol acetates, isoamyl esters and ethyl esters from spiked samples varied from 21.78% (isoamyl octanoate) to 117.27% (ethyl 2-furoate) with an average recovery of 69 ± 8%, while by using SBSE-LD approach the recoveries ranging between 32.49% (ethyl hexanoate) to 108.04% (isoamyl hexanoate) with an average of 81 ± 8%. These results corroborate the higher accuracy of SBSE.

3.4. SBSE and SPME application to wines

Six samples of each wine (one red and three white wine) were analysed by SBSE and SPME methodologies under optimised conditions. As expected, the recovery of EE depends on the enrichment methodology used. Qualitative and quantitative differences were definitely observed in the chromatographic profiles obtained by both approaches (Fig. 3). A higher number of HAA, IsoE and EE were detected in the sample studied by means of SBSE. A total of 25 target compounds were identified and quantified from the analysed wines by SBSE-LD/LVI-GC–qMS, while by HS-SPME/GC–qMS only 16 compounds were identified. The compounds included 20 EE, 2 HAA and 4 IsoE. The results obtained for these samples are shown in Table 3. SBSE-LD/LVI-GC–MS provided higher efficiency in the extraction of HAA (31.1%) and IsoE (1.2%) than HS-SPME/GC–MS (21.6% and 0.3%, respectively). The latter methodology showed a better efficiency extraction of EE (78.2%) than the former (67.7%). This analysis allows the conclusion that the SBSE-LD approach is generally a more sensitive methodology than HS-SPME in extracting these chemical classes of volatile compounds (Fig. 4). However, these methodologies can be complementary because some volatile compounds with low log $K_{O/W}$ values (ethyl butanoate) are not detected by SBSE-LD.

Among HAA, isoamyl acetate highlighted with their higher concentrations. Hexyl acetate and 2-phenylethyl acetate were found as well, but at lower amounts. As can be seen (Table 3), SBSE-LD exhibits better sensitivities than HS-SPME for IsoE and 2-phenylethyl acetate. However, hexyl acetate shows better extraction efficiency by HS-SPME than that SBSE-LD. According to their mean contents (Fig. 5), the ENX, PAL and COL wines had higher concentrations (559.40–816.40 $\mu g\,L^{-1}$ (HS-SPME) and 636.62–1050.03 $\mu g\,L^{-1}$ (SBSE-LD) than QMR wines (239.84 $\mu g\,L^{-1}$ (HS-SPME) and 328.23 $\mu g\,L^{-1}$ (SBSE-LD)). In general, these compounds are responsible for the "fruity" and "floral" characteristics of young wines.

The fatty acids EE are produced enzymatically during yeast fermentation from ethanolysis of acylCoA which is formed from fatty acids synthesis or degradation. Their concentration is dependent on several factors mainly: yeast strain, fermentation temperature, aeration degree and sugar contents. Among the EE identified, the major compounds were, ethyl octanoate, ethyl hexanoate and ethyl decanoate. HS-SPME showed higher sensitivities for this chemical group than SBSE-LD approach.

As can be seen in Table 3, SBSE-LD exhibits better sensitivities than HS-SPME for IsoE. It has been observed that their mean values were very similar and they did not present significant differences between ENX, PAL and QMR wines using HS-SPME and SBSE-LD approaches. The COL wine presents the lowest concentration of IsoE, namely 2.26 and 3.74 $\mu g\,L^{-1}$ for HS-SPME and SBSE-LD methods, respectively. Among the identified IsoE, the isoamyl octanoate were at higher concentrations in the four types of wines.

4. Conclusions

HAA, IsoE and EE of red and white commercial wines extracted using the two analytical methods headspace solid-phase microextraction and stir bar sorptive extraction–liquid desorption, were determined by GC–MS. These methodologies are sensitive, fast, easy, reliable, solventless techniques and an alternative to the traditional methods to characterize volatiles in wines.

The SBSE-LD method showed higher sensitivity than HS-SPME for the selected volatile compounds. Twenty-five esters were identified by SBSE-LD using *n*-pentane as solvent back-extraction whereas only 16 esters were identified by the HS-SPME method.

Both analytical methods showed good linearity, precision, detection and quantification limits that allow their application in real samples. Quantitatively, EE of fatty acids, namely ethyl hexanoate, octanoate and decanoate were the major volatile compounds found in studied wines. Their concentration, higher than LPO, enables their contribution to wine sensory proprieties with

"fruit" and "cheese/fatty" odours. Both approaches are highly sensitive and can be applied to a wide variety of food matrices.

ABSTRACT

A simple procedure for the chemical synthesis of bismuth nanoparticles and subsequent adsorption on commercial screen-printed carbon electrodes offer reliable quantitation of trace zinc, cadmium and lead by anodic stripping square-wave voltammetry in nondeareated water samples. The influence of two hydrodynamic configurations (convective cell and flow cell) and the effect of various experimental variables upon the stripping signals at the bismuth-coated sensor are explored. The square-wave peak current signal is linear over the low ng mL^{-1} range (120 s deposition), with detections limits ranging from 0.9 to 4.9 ng mL^{-1} and good precision. Applicability to waste water certified reference material and drinking water samples is demonstrated. The attractive behaviour of the new disposable Bi nanoparticles modified carbon strip electrodes, coupled with the negligible toxicity of bismuth, hold great promise for decentralized heavy metal testing in environmental and industrial effluents waters.

1. Introduction

The development of "green", "sustainable" or "environmentally friendly" analytical procedures is an active and growing research field [1]. Increasing concern about the side impact of chemical waste derived from analytical methodologies have promoted new method design strategies, based on reduction or suppression of toxic reagents used for sample pretreatment and analytical signal measurement. Green analytical chemistry is especially relevant when the methodologies are intended for use in the field or in decentralized laboratories, where dangerous waste processing is less available, or directly absent. This is usually the case in field environmental monitoring. Electrochemical methods of analysis have been especially sensitive to this trend in recent years, so they have moved greener in different ways. A wide set of electrochemical sensor that fulfils the environmental friendly requirements are available [2–4], and several of them are commercially available or in advanced prototype stages for water monitoring [5,6].

Replacement of conventional electrochemical cells by screen-printed electrodes (SPEs) connected to miniaturized potentiostats is a main trend in the shift of lab electrochemical equipments to hand-held field analyzers. SPEs produced by printing different inks on plastic or ceramic supports are gaining widespread applicability for electrochemical monitoring, especially in the environmental, biomedical and industrial fields. An increasing number of SPE types are commercially available, but they are also amenable for lab production since screen-printed technology is cheap and easily accessible. Unmodified and modified carbon and metallic working electrode surfaces have been explored [7,8]. The specific applicability of SPE to the determination of heavy metals has been reviewed [9].

From the original work of Wang et al. [10], modification of carbon electrodes, especially glassy carbon supports, with metallic bismuth for anodic stripping of heavy metals has been widely explored as an environmentally friendly alternative to the well-known mercury film electrode [11,12]. Applicability of other supporting materials has been described, including carbon fibres [13], carbon films [14], edge plane pyrolytic graphite [15], and a variety of modified carbon pastes [16,17]. Screen-printed carbon working electrodes (SPCEs) have been also explored as supports for Bi modification, including Bi codeposition (so called "in situ" Bi film) and preplated Bi (so called "ex situ" Bi film) approaches. Wang et al. [18] described anodic stripping procedures for lead on home-made Bi preplated disposable SPCEs for the quantification of trace Pb(II) in drinking water by anodic stripping with a detection limit of 0.3 ng mL^{-1}. Kadara and Tothill [19,20] fabricated single use Bi preplated SPCEs for the voltammetric stripping analysis of Pb(II) and Cd(II), obtaining detection limits of 8 and 10 ng mL^{-1} in soil extracts and waste waters for Cd(II) and Pb(II) respectively,

with a deposition time of 120 s. Zaouak et al. [21] have modified screen-printed carbon microband electrodes by preplating a Bi film and demonstrated application to the detection of labile cadmium in river water. Microelectronic Bi-film electrode preparation have been also described [22,23]. About "in situ" Bi films for heavy metals determination on SPCE, Chuanuwatanakul et al. [24] have described a stopped flow system for Zn(II), Cd(II) and Pb(II) in water samples. Our group has recently described the simultaneous determination of the same elements at a novel cell design with improved convective accumulation by "in situ" bismuth codeposition on commercial SPCE strips [25].

Some authors have attempted the modification of SPEs with metallic nanoparticles before stripping analysis of heavy metals, in order to benefit from unique advantages over macroelectrodes: enhancement of mass transport, catalysis, high effective surface area and control over electrode microenvironment [26]. Two groups have reported electrode modification with Bi nanoparticles before voltammetric stripping of heavy metals, based on electrochemical synthesis of the metallic particles on thick film printed electrodes [27], electrode modification with Bi nanopowder synthesized by a levitational gas condensation (LGC) method [28] and sono-melting of Bi powder in octane [29]. We propose here a simpler and easier way to modify commercial SPCEs with metallic Bi nanoparticles, consisting on chemical synthesis on the particles by a procedure based on a method previously reported by Zhao et al. [30], and passive adsorption of the modifying material onto the carbon working electrode surface. We have tested the procedure for the determination of Zn(II), Cd(II) and Pb(II) in water samples.

2. Experimental

2.1. Materials

All chemicals used for the preparation of stock and standard solutions were of analytical grade. 1000 mg L^{-1} stock solutions of Zn(II), Cd(II), Pb(II) and Bi(III) were supplied by Scharlab (Spain). Working solutions were prepared by dilution with ultrapure water obtained from a MilliQ (Millipore) system. Dilute standards were adjusted to pH 2 with subboiled HNO_3. 0.1 M buffer solutions were prepared with HPLC grade acetic acid and sodium acetate (Merck). Multielement test solutions and real samples were adjusted to pH 4.5 with acetate buffer. 10^{-2} M potassium chloride (Merck) was added for better performance of the Ag strip reference electrode. Bismuth granules (99.99%, 100 mesh, Sigma), paraffin oil (Panreac, Spain) and chloroform (Merck) were used as for the preparation of bismuth nanoparticles.

Samples of the SPS-WW2 waste water certified reference material obtained from Spectrapure Standards A.S. (Norway) were used as received for accuracy evaluation. The drinking water samples were collected from a running water tap in our lab at the Department of Analytical Chemistry, University of Extremadura.

2.2. Instrumentation

Square-wave voltammetric measurements were taken by a computerized hand-held, battery-powered PalmSens potentiostat/galvanostat (Palm Instruments BV, The Netherlands) interfaced with a laptop. The whole analytical procedure is controlled by the Palm Sens PC software, including stirring of the samples by a standard stirrer and magnetic bar. Screen-printed three electrode strips were purchased from Drop Sens (Spain). They include a three electrode configuration printed on the same strip. The strips present a 4 mm diameter disk screen-printed carbon working electrode (SPCE) and a counter electrode, both printed on alumina substrate using heat curing carbon composite inks, and a silver pseudo-reference electrode. An insulating layer serves to delimit the working area and electric contacts. Ink formulation and production characteristics of commercial SPCEs are regarded by the manufacturers as proprietary information. A specific connector allows the connection of the electrochemical strip to the potentiostat.

The Bi modified electrochemical strips were mounted on two different supporting systems for accumulation and stripping measurements:

(a) *Accumulation by conventional stirring*: a novel cell configuration recently described by our group was used [25]. The cell allows fast and highly efficient convective accumulation by conventional stirring. Briefly, the Bi modified screen-printed strip is inserted face down through a partially cut 16 mm diameter (10 mL volume) plastic tube, leaving the electrical connection pads out of the tube. The stirring bar is placed in the bottom of the tube, close and parallel to the working electrode surface for highly effective convection. The planar screen-printed surface is parallel to the plane described by the stirring bar movement, so a very significant increasing of the accumulation efficiency is obtained at the proposed convective cell compared with the sample drop approach commonly used for voltammetric measurements on SPEs.
(b) *Flow cell*: Analyte accumulation was also performed by inserting the Bi modified screen-printed strips in a commercial (Drop Sens, Spain) wall jet (90° jet angle) electrochemical flow cell. The flow cell consists of two pieces of methacrylate fixed together by magnets; the upper part has the inlet and outlet flow channels, and the lower part has an insert for the screen-printed strip, the electrochemical cell volume being defined by an o-ring. A peristaltic pump (Perimax Spetec, Germany) was used in connection with the flow cell.

A PerkinElmer ELAN 9000 ICP-MS was used for accuracy check of the electrochemical results.

The morphology of bismuth particles adsorbed on the modified electrodes was observed by scanning electron microscopy (SEM) on a FE-SEM Hitachi S-4700 microscope.

2.3. Procedures

2.3.1. Chemical synthesis of the Bi nanoparticles

Bismuth nanoparticles were prepared by a modification of an extremely simple one-step solution dispersion method starting from bulk metal described by Zhao et al. [30]. Briefly, 50 mg bismuth granules were dispersed in 30 mL paraffin oil. The vessel was a sealed and the mix then was heated for 10 h at 230 °C for bismuth melting under vigorous stirring. After cooling, the supernatant was transferred to a tube and centrifuged for 30 min. The bismuth particles residue was washed several times with chloroform to eliminate any paraffin, and finally dried under N_2 stream. The dark grey powder obtained was stored in a sealed vial at room temperature.

2.3.2. Electrode modification with Bi nanoparticles

Electrode modification was performed according to an experimental procedure previously described by Lee et al. [28]. 2.5 mg of the synthesized Bi nanopowder was dispersed in 50 mL ultrapure water under ultrasonic radiation for 1 h. 10 μL of the dispersion was placed onto the carbon working electrode of a screen-printed strip. After solvent evaporation at room temperature, the electrode was stored for future use.

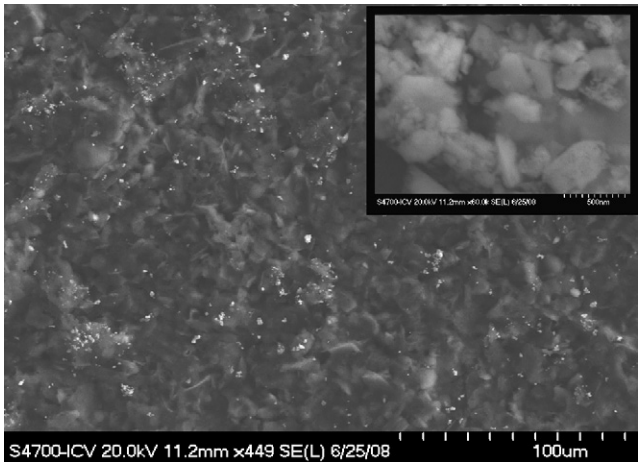

Fig. 1. Scanning electron microscopy (SEM) image of the Bi nanoparticles modified screen-printed carbon working electrode surface.

2.3.3. Voltammetric measurements

Convective (at stirred or flowing sample solutions) accumulation of Zn, Cd and Pb on the SPCE was carried out at a deposition potential of −1.4 V at variable rotation speed or flowing rates. After the accumulation time and 10 s equilibration, the anodic voltammetric curves were registered in the quiescent solution by square-wave voltammetry with frequency of 20 Hz, step potential of 5 mV and amplitude of 25 mV. The potential sweep was ended at −0.6 V (vs Ag/AgCl). The rest potential between experiments was set at −0.6 V to avoid damage of the Bi nanoparticles modification.

3. Results and discussion

3.1. SEM characterization of the modified electrodes

The simple and fast adsorption procedure employed in this work produces ready to use Bi modified electrodes without the need of special instrumentation used in previously described methodologies [22,23,28]. Fig. 1 shows a SEM image of a modified screen-printed carbon electrode. A nearly homogeneous dispersion of irregularly shaped adsorbed Bi particles was observed on the carbonaceous surface, with a size range within 0.25 and 5 μm. The large particle size distribution is probably caused by the broad size distribution of bismuth droplets formed in solvent by stirring effect [30]. Quantitative microanalysis of bismuth by scanning electronic microscopy with energy dispersion X ray (Fig. 2), confirmed the presence and purity of bismuth nanoparticles. Carbon and oxygen signals are also observed due to the nature of the electrode supporting material. A similar EDX spectrum has been reported for a similar Bi nanoparticles synthesis procedure based on reducing bismuth chloride with hydrazine hydrate in the presence of sodium oleate [31].

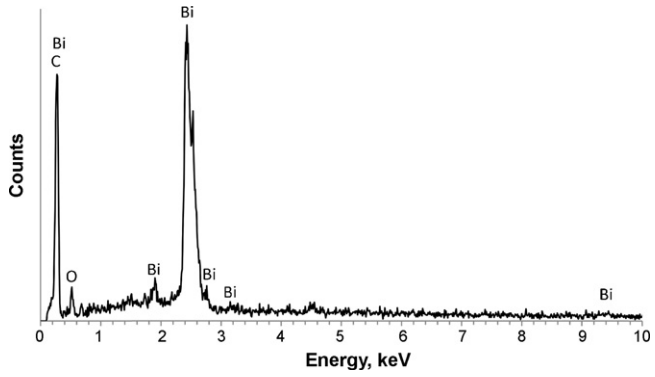

Fig. 2. Energy dispersion X ray (EDX) pattern of the Bi nanoparticles modified screen-printed working electrode surface.

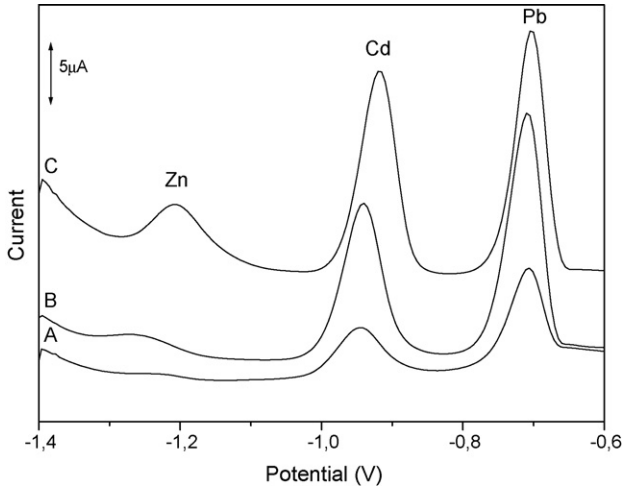

Fig. 3. Stripping voltammograms for 80 ng mL^{-1} Zn(II), Cd(II) and Pb(II) at the Bi nanoparticles modified screen-printed electrode. pH 4.5 0.1 M acetate buffer. Square-wave voltammetric stripping scan with a frequency of 20 Hz, step potential 5 mV, and amplitude 25 mV. (A) Unmodified electrode. (B) Convective cell with 500 r.p.m. stirring speed and 120 s deposition time. (C) Flow cell with 2,3 mL min^{-1} flow rate and 120 s deposition time.

3.2. General voltammetric behaviour and signal stability

The voltammetric stripping behaviour and signal stability of the ready to use Bi modified nanoparticles SPCEs for the detection of Zn(II), Cd(II) and Pb(II) was first inspected. Two hydrodynamic configurations as described in 2.2 were used to enhance analyte deposition during the accumulation step, based on convection by stirring (convective cell) and by flow (flow cell). Consecutive runs were carried out on the same Bi nanoparticles modified electrode on a pH 4.5 0.1 M acetate buffer solution containing 80 ng mL^{-1} Zn(II), Cd(II) and Pb(II). Fig. 3 shows the typical response obtained at both hydrodynamic configurations. Intense, well-resolved and clearly defined peaks were obtained, with enhanced signals with respect to the electroanalytical response on unmodified electrodes. The overall response is comparable with previously reported voltammetric stripping results at in situ [24,25] and preplated [18,19] Bi-film SPCEs. No significant differences in terms of peak height or potential were observed between the convective cell (Fig. 3, solid line) and the flow cell (Fig. 3, dashed line), apart from a slightly higher Zn(II) signal at the flow cell.

Signal stability was first inspected as a key parameter to test the practical usability of the proposed beforehand prepared Bi modified SPCE electrodes. Since electrode modification is based on passive adsorption of Bi sumicroparticles on the carbon screen-printed surface, erosion of the modified layer by repeated cycles of stirring or flowing accumulation could be expected, with the consequent lose of electrode activity. As seen in Fig. 4, analytical signals are stable for some measuring cycles, so a single modified electrode can be used for a complete set of blank measurement, sample run and standard additions if necessary. Electrode stability was found to be dependent on experimental conditions, especially the deposition potential. A somewhat better stability was found for the Pb signal. Signal stability is similar for both the convective cell and the flow cell hydrodynamic configurations. An experiment was conducted to test the repeatability of the modification procedure by assaying a set of 8 electrodes modified in parallel. The rela-

tive standard deviations were 6% for Zn, 7.5% for Cd, and 10.5% for Pb.

3.3. Instrumental variables

Stirring speed and flow rate were studied as hydrodynamic instrumental variables for the Bi modified SPCE placed in the convective cell and the flow cell, respectively, using a model solution containing 80 ng mL^{-1} Zn(II), Cd(II) and Pb(II). The influence of stirring speed on the analytical signals was inspected in the range from 0 to 900 r.p.m. Increased sensitivity was observed up to a point where turbulent conditions caused an unstable response, so an optimal value of 500 r.p.m. was selected. Increasing flow rates from 0.7 to 4.5 mL min^{-1} produced increasing peak currents at the flow cell. The effect of deposition time was studied in the range from 30 to 480 s, for Bi modified SPCE placed both at the convective and in the flow cell. Sample voltammograms are shown in Fig. 5 for the convective cell configuration. Linear correlations between peak currents and deposition times were obtained for Zn, Cd and Pb.

3.4. Calibration data

Calibration data for Zn, Cd and Pb by using the proposed Bi nanoparticles modified screen-printed electrodes were estimated by analyzing multistandars solutions of increasing concentrations, both at the convective cell and at the flow cell, the results being summarized at Table 1. Detection limits were calculated according to Long and Winefordner [32]. Somewhat better values were obtained for Zn(II) Cd(II) and Pb(II) at the flow cell with respect to the convective cell. The results were better than those previously described for stripping analysis on "in situ" Bi modified screen-printed electrochemical strips with convective accumulation on sample drops [25]. SWASV on modified thick film electrodes, prepared by electrochemical synthesis of Bi nanoparticles on thick film printed electrodes [27] gave somewhat lower detection limits: 0.52 ng mL^{-1} for Zn (II), 0.45 ng mL^{-11} for Cd (II) and 0.41 ng mL^{-1} for Pb (II), but the modification procedure is more complicated than our approach. Lee et al. [28] have reported the lowest to date voltammetric stripping detection limits for Cd (0.15 ng mL^{-1}) and Pb (0.07 ng mL^{-1}) on Bi nanoparticles modified electrodes, by using SWASV on a glassy carbon electrode modified with Bi nanopowder synthesized by a complex levitational gas condensation (LGC) method, using 10 min accumulation time. Five aliquots of a synthetic standard solution containing 12 ng mL^{-1} Zn(II) and 8 ng mL^{-1} Cd(II) and Pb(II), were assayed by the proposed methods. The recoveries obtained at the convective cell were in the range 101.3–118.3%, with RSD between 2.7 and 7.4%. The recoveries obtained at the flow cell were in the range 101.7–105.5%, with RSD between 2.1 and 7.5%.

3.5. Certified reference materials and real samples

The SPS-WW2 waste water certified reference material was assayed to test the applicability of the proposed Bi modified elec-

Table 1

Cd(II)	$y = 0.238x - 0.144$	0.986	94	0.6	1.3
Pb(II)	$y = 0.172x + 0.050$	0.993	96	0.5	0.9

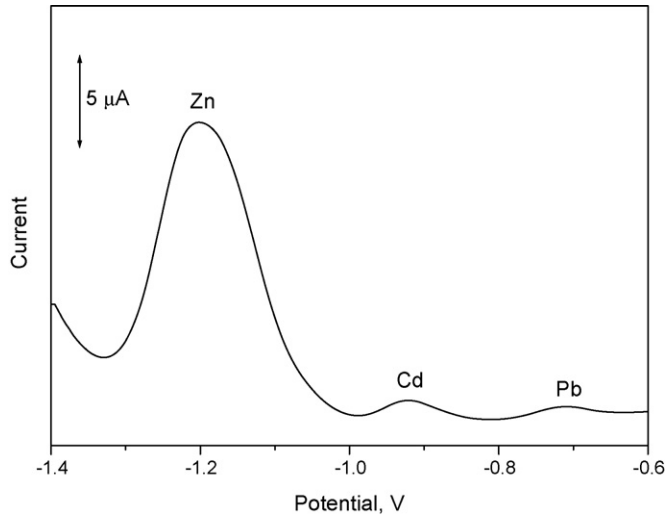

Fig. 6. Stripping voltammogram for a tap water sample at the Bi nanoparticles modified screen-printed electrodes. pH 4.5 0.1 M acetate buffer. Square-wave voltammetric stripping scan with a frequency of 20 Hz, step potential 5 mV, and amplitude 25 mV. Convective cell with 500 r.p.m. stirring speed. 120 s deposition time.

Table 2
Determination of Zn(II), Cd(II) and Pb(II) on screen-printed carbon electrodes modified by Bi nanoparticles in drinking water. Square-wave voltammetric stripping scans with a frequency of 20 Hz, step potential 5 mV, and amplitude 25 mV. Convective cell with 500 r.p.m. stirring speed and 120 s deposition time. Flow cell with 2.3 mL min^{-1} flow rate and 120 s deposition time.

Metal ion	SWASV convective cell (ng mL^{-1})	SWASV flow cell (ng mL^{-1})	ICP-MS (ng mL^{-1})
Zn(II)	212.3 ± 11.0	212.3 ± 29.7	216.1 ± 2.6
Cd(II)	11.6 ± 2.8	7.3 ± 0.9	11.1 ± 0.5
Pb(II)	3.7 ± 0.6	3.2 ± 0.1	3.3 ± 0.2

trodes and voltammetric methods. Five replicates were analyzed after 1/10 dilution and pH adjustment with acetate buffer. It was only possible to quantify Pb in the samples by the standard additions method; Zn and Cd were not measurable, probably due to high level of interfering ions like Cu(II) (2 mg/L), as previously described [12,19,33]. A concentration of 497 ± 24 ng mL^{-1} Pb(II) was measured by using the convective cell with the optimized experimental conditions (see Table 1); 461 ± 103 ng mL^{-1} Pb(II) was found by using the flow cell. The certified value is 500 ng mL^{-1}.

Tap water samples obtained at the lab were also assayed to test the proposed methodologies, using ICP-MS as the reference technique. The only treatment was pH adjustment with acetate buffer and Cd(II) addition to obtain a measurable level. Fig. 6 shows a typical voltammetric response obtained for the real sample at the convective cell. Table 2 presents the metal concentrations measured by the SWASV methods at the convective and flow cell, and the corresponding ICP-MS results. An overall acceptable agreement was found between both methodologies, showing potential applicability of the proposed methods for real sample analysis.

4. Conclusions

Passive adsorption of metallic bismuth chemically synthesized nanometric particles is a simple and useful protocol to modify screen-printed carbon electrodes for the voltammetric stripping detection of Zn(II), Cd(II) and Pb(II) in liquid samples. The placement of microlitre amounts of an aqueous Bi dispersion onto the working electrode followed by solvent evaporation to dryness resulted in stable adsorption of Bi nanoparticles, without the need of sophisticated instrumentation. This procedure allows easy and fast modification of multiple electrodes beforehand analysis, without the need of Bi preplating or addition of Bi(III) to the sample solution. Optimization of chemical and instrumental variables, including accumulation under convective and flow configurations using disposable three electrode screen-printed electrochemical strips gave detection limits in the low ng mL^{-1} with a good recovery and reproducibility. The performance of the proposed method was tested with a certified reference sample (waste water) and tap water, with overall acceptable results but affected by interferences when high Cu(II) concentrations were present, suggesting potential applicability for decentralized electrochemical sensing of heavy metals in water samples.

ABSTRACT

Patulin (PAT) is a mycotoxin produced in fruits, mainly in apples, by several fungal species that can be carried into industrial apple juice by-products during factory processing. An analytical method for determination of PAT in apple juice and another one for determination of this compound in apple purees and apple compotes by liquid chromatography are proposed in the present paper. These methods have better precision and sensitivity than previously reported methods and focus mainly on extraction and clean-up. To accomplish analytical methods with higher accuracy, lower limits of detection and simpler procedures for application in quality control of the goods, different extraction and clean-up procedures for PAT were comparatively studied. PAT recoveries in apple juice spiked with 1.0 mg PAT/kg varied between 52.3% and 81.0%. The highest PAT recovery in apple puree spiked with 0.1 mg PAT/kg was 82.9%. Addition of NaH_2PO_4 during the extraction phase here reported for the first time has the advantage of keeping the pH slightly acidic, thus avoiding PAT degradation.

1. Introduction

Patulin {4-hydroxy-4H-furo[3,2-c]pyran-2(6H)-one} (PAT) is a polyketide lactone produced by certain *Penicillium*, *Aspergillus*, and *Byssochlamys* species, principally by *Penicillium expansum*, on fruits, such as apples, and apple products [1–3]. It has also been determined in oranges, peaches, apricots and tomatoes and its by-products [4,5]. It is considered immunotoxic, genotoxic, embryotoxic, and neurotoxic [6], but no adequate evidence exists for carcinogenicity in experimental animals. Recent studies have demonstrated that micromolar concentrations of PAT induce a rapid and dramatic decrease of transepithelial resistance of human epithelial intestinal cell lines without major signs of toxicity as assessed by the lactate dehydrogenase release assay [7].

PAT carryover during factory processing into industrial apple juice concentrates and subsequently into commercial apple juices as well as in a variety of apple products is a cause of food safety concern [8]. Based on a no-observed-effect level (NOEL) of 43 μg/kg body weight (bw)/day and a safety factor of 100, a provisional maximum tolerable daily intake (PMTDI) of 400 ng/kg bw was established by the JECFA and recently endorsed by the Scientific Committee for Food (SCF) [9,10].

PAT is considered a marker of the quality of apples entering the processing factory, and levels in the final product are subjected to legislative regulatory control. Maximum levels for this mycotoxin in fruity foodstuffs have been established by the European Commission. They are 50 μg/kg, for apple fruit juice and apple juice ingredients in other beverages, 50 μg/kg in spirit drinks, ciders and other fermented drinks, 25 μg/kg for solid apple products, such as apple puree, and 10 μg/kg for apple products intended for infants and young children [11]. The new regulation shows a separate limit for baby food to protect infants and young children who have a higher fruity foodstuffs consumption compared to adults [12].

Some methods have been developed to quantify PAT in apple juice concentrate [8,13–18]. They are based on TLC, GC and LC [19,20]. Among them, LC, coupled with UV detection, is particularly well suited to the determination of PAT. GC/MS and LC/MS are also used [21–24]. There are no commercial enzyme-linked immunosorbent assay kits available for testing PAT. For sample pretreatment, conventional methods such as multistep liquid–liquid extraction with ethyl acetate, the most common extraction solvent, and purification by $NaHCO_3$ solution have been widely used [8,11,19,25]. Liquid–liquid extraction (LLE) is time-consuming owing to the use of large amounts of organic solvents that imply environmental disposal problems [4]. Clean-up procedures using Na_2CO_3 deactivate PAT because this compound (a lactone) is more stable in acidic medium. In recent years, new methods of extraction and clean-up using SPE cartridges have been validated and

doi:10.1016/j.talanta.2009.07.040

published [19,20,25–29]. These methods are reportedly more reliable, repeatable with increased throughput, better recoveries, and increased sensitivity, enabling the determination of much lower levels of toxin [30]. In 2006, a simplified LLE procedure prior to LC separation and UV detection was reported [31]. This procedure is even simpler than those that use SPE columns [22]. However, more suitable analytical methods with high accuracy, low limits of detection and simple procedures are needed for application in quality control of the goods.

The method adopted by the European Committee for Standardization as European Standard for PAT determination in clear and cloudy apple juice and in apple puree is a LC method that has been validated by a collaborative trial at levels equal or higher than 25 μg PAT/kg [32,33]. This method has been recently modified to permit the determination of PAT at a level of 10 μg/kg or lower, and has been validated by a collaborative study [34].

The aim of this study was to develop an optimized analytical method for the determination of PAT in apple products (apple juice and apple puree) using LC-UV. A goal was to improve precision and sensitivity over previously reported methods. Comparison of the better existing methods and changes in some of them were performed to get the optimized one.

2. Experimental

2.1. Chemicals and reagents

The following standards were purchased for the analysis: PAT, 5-hydroxymethyl furfural (HMF), dihydrated monosodium phosphate and sodium hydrogencarbonate (Sigma–Aldrich, Alcobendas, Spain), sodium carbonate, anhydrous sodium sulfate, sodium acetate and acetone (Panreac, Barcelona, Spain), acetonitrile, methanol, hexane, ethyl acetate, acetic acid, SPE–C_{18} cartridges, and SPE–silica cartridges (J.T. Baker, Deventer, The Netherlands). All solvents were LC grade. Whatman No. 4 filter paper (Whatman, Maidstone, UK) were as well used. Milli-Q water (Milli-Q, Millipore, Milford, MA, USA) was generated in situ. Acetic acid/acetate buffer solution (AABS) was prepared by addition of 0.45 ml of acetic acid and 0.15 g of sodium acetate to 40 ml of water, the pH was adjusted to 4.0 with acetic acid. The volume was finally brought to 50 ml and the solution was stored in the dark.

2.2. Samples

Fifty-four samples of juices, solid products, including compotes and puree, and products for infants and young children containing apple and/or pear as the main component were studied. Samples were acquired in different supermarkets and stores located in Spain. Twenty-eight of them belonged to juices, 5 to compotes, nectars and jams made of apple, and the remaining samples to foods for young children. These samples were stored in their original packages at 4 °C until the moment of analysis. The samples were thoroughly homogenized and opened the same day of the analysis.

2.3. Preparation of standards

A 10-ml solution of PAT (1.0 mg/ml) in ethyl acetate was prepare and stored at −20 °C. A 0.2-ml aliquot of this PAT solution was poured into a 10-ml volumetric flask and evaporated to dryness under a stream of N_2. Immediately absolute ethanol was added to dissolve the residue, and after dilution to volume, the absorption of this standard stock solution was measured at 276 nm. The concentration of the mycotoxin was calculated according to the AOAC Official Method 974.18C [35].

Working standards were prepared by evaporation of the appropriate volume of the stock solution under a stream of N_2 at room temperature. Furthermore, they were solved in the corresponding volume of AABS. Calibration curves were made by LC analysis of these standard solutions.

2.4. Extraction and clean-up

The extraction and clean-up procedures described below have been applied to apple product samples that had been previously analyzed by official methods to check that they had no detectable PAT levels. Suitable volumes of PAT standard solution were added to blank matrices using a precision syringe to obtain concentrations of 0.02, 0.05, 0.1, and 1.0 mg of PAT/kg. The spiked samples were allowed to stand overnight and extracted as described below (Sections 2.4.1–2.4.7).

2.4.1. LLE–$NaHCO_3$ procedure

The method is based on the procedure reported by Iha and Sabino [31]. Apple juice was homogenized and 5 g was placed in a 50-ml centrifuge tube, together with 0.5 g of $NaHCO_3$ and 5 ml of ethyl acetate–hexane (96:4, v/v). The sample was shaken for 10 min in an orbital shaker at 250 rpm, and then centrifuged for 3 min at 3000 rpm. A 3-ml volume of the organic phase was transferred to a glass tube, together with 30 μl of acetic acid, and then the solvent was evaporated just to dryness under a gentle N_2 stream at room temperature. Immediately, 1 ml of AABS was added and the mixture was vigorously vortexed for 1 min. Finally, 50 μl was injected into the chromatographic system.

2.4.2. C_{18}–SPE procedure

It is based on the procedure reported by Li et al. [27]. C_{18} SPE cartridges were preconditioned with: (i) 10 ml of methanol, (ii) 3 ml of 10% methanol in aqueous solution, and (iii) 10 ml of water. The columns were not allowed to be dry. One gram of apple juice sample with 0.5 ml of AABS solution was transferred to a C_{18} SPE cartridge and the solution was pushed at 2–3 ml/min with a plunger. Next, 5 ml of hexane was added and then the column was dried with air stream for 15 min. Eluates were discarded and the cartridge was successively eluted (three times) with 5 ml of different mixtures of hexane–ethyl acetate–acetone where the proportion changed in the order 1:5:4, 1:4:5, and 1:3:6. The flow of each portion was stopped for 1 min to allow enough contact time with the packing material of the cartridge. The eluates were combined. Then, 30 μl of acetic acid was added to the solution and the solvent was evaporated just to dryness under a gentle N_2 stream at 30 °C. The extract was immediately dissolved with 1 ml of AABS and 50 μl was injected into the LC system.

2.4.3. Modified Arranz procedure

The method is based on the collaborative study performed by Arranz et al. [34] with some modifications: (i) sea sand was not added where LLE was accomplished because it was not necessary; (ii) purified sample was dissolved with AABS instead of water (pH 4). Briefly, 15 g of Na_2SO_4 and 2 g of $NaHCO_3$ were added to a 50-ml screw cap conical flask and homogenized. Then, 10 ml of ethyl acetate–hexane (60:40, v/v) was added and shaken softly. Ten grams of apple product sample was transferred to the conic tube, which was vortexed for 30 s and then shook in an orbital shaker at 250 rpm for 5 min. Then, the sample was centrifuged at 3000 rpm for 3 min to separate phases. A 2.5-ml aliquot of the organic phase was transferred to a SPE–silica cartridge without preconditioning. The eluate was collected at a flow of a drop per second in a glass vial containing 50 μl of acetic acid. Immediately, the cartridge was washed with 3 ml of ethyl acetate–hexane (60:40, v/v) to elute PAT in the same vial. The solvent was evaporated just to dryness in a gentle N_2 stream at 30 °C. After drying, 1 ml of AABS was quickly

added, the extract was vortexed for at least 1 min, and 50 μl was injected into the LC system.

2.4.4. MacDonald procedure

This is the AOAC Official Method 2000.02 for PAT in clear and cloudy apple juices and apple puree [32]. Ten grams of cleaned juice sample and 20 ml of ethyl acetate were put in a 250-ml separatory funnel and the mixture was shaken for 1 min. The extraction was repeated two more times and the organic phases were mixed in the separatory funnel. The tube that contained the organic phase extract was rinsed with 5 ml of ethyl acetate, which were also added to the separatory funnel. Four milliters of an aqueous solution of Na_2CO_3 (1.5%) was added and the mixture was shaken for 30 s. The aqueous phase was left in a conical flask and the organic phase was filtered through a filter paper that contained 15 g of anhydrous sodium sulfate into a balloon flask. The aqueous phase was transferred to the separatory funnel again, the conical tube was rinsed with 10 ml of ethyl acetate and this liquid was added to the separatory funnel. Then, it was shaken, let stand and once the two phases were separated, the aqueous phase was discarded and the organic phase was filtered through filter paper containing anhydrous sodium sulfate into a balloon flask. Finally, the separatory funnel was washed twice with 10 ml of ethyl acetate and the rinsing solvent was added to the flask. The obtained solution was evaporated just to dryness under a gentle N_2 stream at room temperature. The remaining solid was quickly solved in 1 ml of AABS solution, and a 50-μl aliquot was injected into the LC system.

2.4.5. LLE–NaH_2PO_4 procedure

This procedure is similar to the LLE–$NaHCO_3$ procedure (Section 2.4.1), but $NaHCO_3$ was substituted by the same amount of NaH_2PO_4.

2.4.6. LLE–NaH_2PO_4–silica procedure

It is applied to apple juice. The first part of the extraction until the collection of 3 ml of organic phase coincides with the LLE–NaH_2PO_4 procedure (Section 2.4.5). The difference is that the 3-ml aliquot (without acetic acid addition) was transferred to a non-preconditioned silica SPE cartridge and the eluate was collected at a drop per second in a glass vial with 50 μl of acetic acid. Immediately, the cartridge was washed with 3 ml of ethyl acetate–hexane solution (60:40, v/v) to quantitatively elute PAT of the column in the same vial. The solvent was evaporated just to dryness under a gentle N_2 stream at 30 °C. Then, 1 ml of AABS was immediately added, the extract was vortexed during at least 1 min and 50 μl was injected into the LC system.

2.4.7. LLE–NaH_2PO_4–C_{18} procedure

The apple product sample was homogenized and 5 g was placed in a 50-ml centrifuge tube containing 1 g of NaH_2PO_4, 5 g of anhydrous Na_2SO_4 and 5 ml of ethyl acetate–hexane (96:4, v/v). The tube was shaken in an orbital shaker (250 rpm, 10 min) and later centrifuged (3000 rpm, 3 min). Three milliliters of the organic phase was transferred to a glass tube containing 30 μl of acetic acid, and the solvent was evaporated just to dryness under a gentle N_2 stream at room temperature. Immediately, 2× 1 ml of AABS was added and the mixture was transferred to a C_{18} SPE cartridge, previously conditioned with 5 ml of ethyl acetate–hexane (80:20, v/v) and then with 5 ml of water. The redissolved extract was passed through the cartridge at a speed of 2–3 ml/min with the help of a plunger. Immediately, the cartridge was washed with 5 ml of hexane and then dried with a flow of air during about 15 min. These eluates were discarded and the column was washed with 4 ml of ethyl acetate–hexane (80:20, v/v). The eluate was collected in a 10-ml screw cap tube. Thirty microliters of acetic acid was added to the eluate and the solvent was evaporated just to dryness under a gentle N_2 stream at 30 °C. The solid was quickly dissolved with 0.5 ml of AABS and 50 μl was injected into the LC system.

2.5. Patulin determination

The obtained aliquots were analyzed by liquid chromatography. The LC system was a Waters 600 quaternary pump, with a Waters 717 autosampler and a Waters 996 UV–visible diode array detector. Millennium 32 (version 3.05.01) software was used to control the system and to process the obtained signals (Waters, Milford, MA, USA). The separation was performed at 30 °C in a C18 Agilent Zorbax XDB-C18® reversed-phase column (150 mm × 4.6 mm, 5 μm particle size) connected to an Agilent Zorbax® guard column (4 mm × 3 mm, 5 μm particle size) filled with the same stationary phase.

To optimize the separation column, 50 μl of AABS containing 2 μg of HMF/ml and 50 ng of PAT/ml was injected. HMF and PAT should elute as two completely separated peaks. The content of acetonitrile in the LC mobile phase is generally increased to achieve this objective. The two peaks can be separated satisfactorily using acetonitrile–water as a mobile phase. The elution was carried out at a flow of 1 ml/min with a mixture of acetonitrile (solvent A) and water (solvent B) applying the following gradient program: (i) initial solvent: 99% B, maintained for 2 min, (ii) lineal variation of B from 99% to 90% for 11 min, (iii) lineal variation of B from 90% to 1% for 3 min, (iv) 1% of B for 1 min, and (v) return to the initial conditions in 1 min. Detection wavelength was 276 nm.

2.6. Validation of analytical methods

The analytical methods used for PAT were assessed for selectivity, linearity, and precision from the regulated minimum of 0.010–5.0 μg/ml. Selectivity was checked by injecting three times 50 μl of PAT standard solution before injecting extracted samples and comparing the peak retention times and the UV spectra of the substances that produce these peaks. Linearity was assessed by performing triplicate injections of standard solutions whose concentrations were 0.01, 0.02, 0.05, 0.1, 0.25, 0.5, 1.0, 5.0, 10.0 and 15.0 μg PAT/ml. Standard curves were generated by linear regression of peak areas against concentrations.

Precision and recovery were established for each method by determination of PAT in apple juice and apple puree, covering the range of the method (0.02, 0.05, 0.1, and 1.0 mg/kg). Recovery was determined by comparing the absolute responses of PAT obtained from the apple juice samples with the absolute responses of calibration standards. Recovery ratios between 70% and 105% and RSD < 15% for precision were considered as acceptable.

The limit of detection (LOD) was considered as the PAT concentration that provides a signal equal to $b + 3S_b$, where b is the intercept of the calibration curve and S_b is the standard error of the estimate assuming to be the blank, and the limit of quantification (LOQ) was considered equal to 3× LOD [36].

3. Results and discussion

3.1. Comparison of procedures for apple juice

The analytical methods chosen for this comparative study are the most common at present. Comparison involve two official methods [32,34] and two other more recent and simple methods (developed by Li et al. [27] and Iha and Sabino [31]). In addition, variations of some of the previous methods were included in this study. For comparative purposes the study has been centered mainly on the following aspects: recovery, limit of detection (LOD),

Table 1
Average recoveries, relative standard deviations ($N = 3$) and limits of detection of PAT by different procedures in apple juices contaminated with 0.02, 0.05, 0.1 and 1.0 mg of mycotoxin/kg.

Procedure	Spiking level (mg/kg)	Recovery (%)	RSD (%)	LOD (μg/kg)
LLE–$NaHCO_3$	0.02	69.3	7.3	2.1
	0.05	72.3	4.2	
	0.1	74.3	1.7	
	1.0	72.1	3.1

	0.05	65.5	7.3	
	0.1	68.3	9.9	
	1.0	72.5	11.0	
Modified Arranz	0.02	70.1	10.3	2.5
	0.05	68.3	7.1	
	0.1	64.2	4.5	
	1.0	68.9	5.3	
MacDonald	0.02	72.4	6.2	1.8
	0.05	78.4	9.4	
	0.1	73.2	8.5	
	1.0	81.0	12.3	
LLE–NaH_2PO_4	0.02	71.6	6.8	2.0
	0.05	73.6	5.6	
	0.1	82.9	3.1	
	1.0	77.0	1.7	
LLE–NaH_2PO_4–silica	0.02	62.4	9.3	2.1
	0.05	63.9	5.8	
	0.1	67.8	4.0	
	1.0	69.2	4.9	
LLE–NaH_2PO_4–C_{18}	0.02	65.4	8.2	1.3
	0.05	62.3	6.4	
	0.1	55.1	6.2	
	1.0	52.3	8.0	

and selectivity (possible interferences that can appear in the analyzed samples). As shown in Table 1, it can be found that recoveries in apple juice spiked with 0.1 mg PAT/kg varied between 55.1% for the LLE–NaH_2PO_4–C_{18} procedure and 82.9% for the LLE–NaH_2PO_4 procedure. Although PAT recovery is below the required minimum value (60%) for the LLE–NaH_2PO_4–C_{18} procedure, its LOD is the lowest (1.3 μg/kg) of all the procedures. This is due to the higher sample pre-concentration ratio (6:1), which is generally superior to the one for the other methods.

The best recoveries in apple juices spiked with 0.05 mg PAT/kg were obtained using the methods of MacDonald (78.4%) and LLE–NaH_2PO_4 (73.6%) (Table 1). Although the MacDonald method provided good recoveries, the obtained RSD is relatively high (9.4%) and the LOD (1.8 μg/kg) is not significantly lower than those attained by the other methods. The sample is concentrated in a 10:1 ratio by the MacDonald method, whereas this ratio is 3:1 by the LLE–$NaHCO_3$ method, whose LOD is 2.1 μg/kg. This is because, although the sample is very concentrated, many impurities may be co-eluted due to the more complex liquid–liquid extraction step. Other disadvantages of the MacDonald method are the time-consuming extraction step and the cost of solvents, since it uses more volume of organic solvent than other methods (see Section 2.4.4), which also involves environmental problems. The LLE–NaH_2PO_4 method is fast, simple, has a low LOD (2.0 μg/kg) and a low RSD that provides good repeatability and is accurate enough. This method provided the best results among all the studied methods. According to what has been indicated, extraction in basic medium is used to eliminate acidic compounds. Nevertheless, any interference originating a peak near PAT, or any increase of the background noise that could influence the result of PAT determination was not observed following the LLE–NaH_2PO_4 method. In addition, PAT is more stable in slightly acidic medium than in basic medium. For this reason, it is reasonable to think that this procedure must have a higher PAT recovery.

Table 2
Average recoveries and relative standard deviations for PAT in apple juice spiked at 0.02 and 0.1 mg/kg obtained by change in the proportions of the extraction solvent mixture used in the LLE–$NaHCO_3$ procedure ($N = 3$).

	Spiking level 0.02 mg PAT/kg		Spiking level 0.1 mg PAT/kg	
	Recovery (%)	RSD (%)	Recovery (%)	RSD (%)
98:2	61.9	9.0	63.1	5.3
96:4	75.2	7.3	73.4	2.3
90:10	59.8	8.2	67.0	6.4
80:20	60.1	11.2	63.8	6.1
60:40	28.4	8.3	39.2	6.7

With the purpose of improving the LLE–$NaHCO_3$ method, different ethyl acetate–hexane ratios were assayed to improve the LLE step (Table 2). The best toxin recoveries were 75.2% and 73.4%, for spiking levels of 0.02 and 0.1 mg PAT/kg, respectively, when the original ethyl acetate–hexane ratio (96:4) was used.

At a spiking level of 0.1 mg PAT/kg the recoveries obtained by the C_{18}–SPE method were lower than those obtained by the LLE–$NaHCO_3$ method (68.3% and 74.3%, respectively) (Table 1). In addition, the RSD of the C18–SPE method is higher (9.9%), thus being less precise. The LOD of the C_{18}–SPE method (6.6 μg/kg) is the highest, because sample concentration ratio is 1:1. Moreover, the chromatograms obtained by this method were the noisiest. Some changes in the elution solvent were assayed to improve the procedure for PAT elution out of the C_{18} cartridge (Table 3). A series of three mixtures hexane–ethyl acetate–acetone of different composition used by Li [27], was substituted by a unique mixture of two solvents (ethyl acetate–hexane) which implies an easier and fast procedure. When ethyl acetate–hexane (96:4) (the mixture used in the Iha extraction procedure) was used, PAT was not recovered (Table 3). However, when the polarity was lowered (ethyl acetate–hexane, 80:20), the recovery obtained was not significantly different ($p < 0.05$) from that obtained by the original C_{18}–SPE method. This modification led to less solvent consumption and lower run time, but it was unable to improve recovery and LOD.

Finally, the modified Arranz method and the LLE–NaH_2PO_4–silica method gave recovery ratios of 68.3% and 63.9%, respectively, for apple juices spiked with 0.05 mg PAT/g. These values are not significantly different between them ($p < 0.05$). For this reason, the modification carried out in the LLE–NaH_2PO_4–silica procedure did not produce any significant improvement.

Fig. 1 shows the chromatograms obtained for an apple juice sample spiked with PAT (0.1 mg/kg) by the methods of LLE with NaH_2PO_4 (Fig. 1A), modified Arranz (Fig. 1B), and LLE–NaH_2PO_4–C_{18} (Fig. 1C). The peak of PAT eluted at about 13.3 min. Moreover, in all except the LLE–NaH_2PO_4–C_{18} method, another peak that can interfere with the analyte, usually appeared

Table 3
Average recoveries and relative standard deviations ($N = 3$) for PAT in apple juice spiked with 0.05 and 1.0 mg of mycotoxin/kg, obtained by change in the SPE solvent mixture using the C_{18}–SPE procedure.

	Spiking level 0.05 mg/kg		Spiking level 1.0 mg/kg	
	Recovery (%)	RSD (%)	Recovery (%)	RSD (%)

at 12.8 min. The LLE–NaH_2PO_4–C_{18} procedure eliminates this interfering peak, although the recoveries were below 70%.

3.2. Comparison of procedures for solid apple products

Comparison of procedures was limited to the Modified Arranz and LLE–NaH_2PO_4–C_{18} methods that can be applied to semisolid samples, such as purees. The other procedures are only applicable to juices and when they are used for apple purees and compotes the chromatograms show several interfering peaks. The recovery ratios and LOD obtained by these two procedures are listed in Table 4, which shows that PAT recoveries were always slightly higher when the LLE–NaH_2PO_4–C_{18} procedure was performed. Nevertheless, the LOD of the LLE–NaH_2PO_4–C_{18} procedure (1.4 μg/kg) was lower than the LOD of the Modified Arranz one (2.4 μg/kg). This may be due to the different pre-concentration ratio of the sample before being injected in the chromatograph, as commented for apple juice (Section 3.1). It is worth taking into account that, when the LLE–NaH_2PO_4–C_{18} procedure is used, the peak that can interfere with PAT detection does not appear (Fig. 2) and, hence, the determination is free from this error. The chromatogram for the sample of puree of apple and banana for infant consumption spiked with

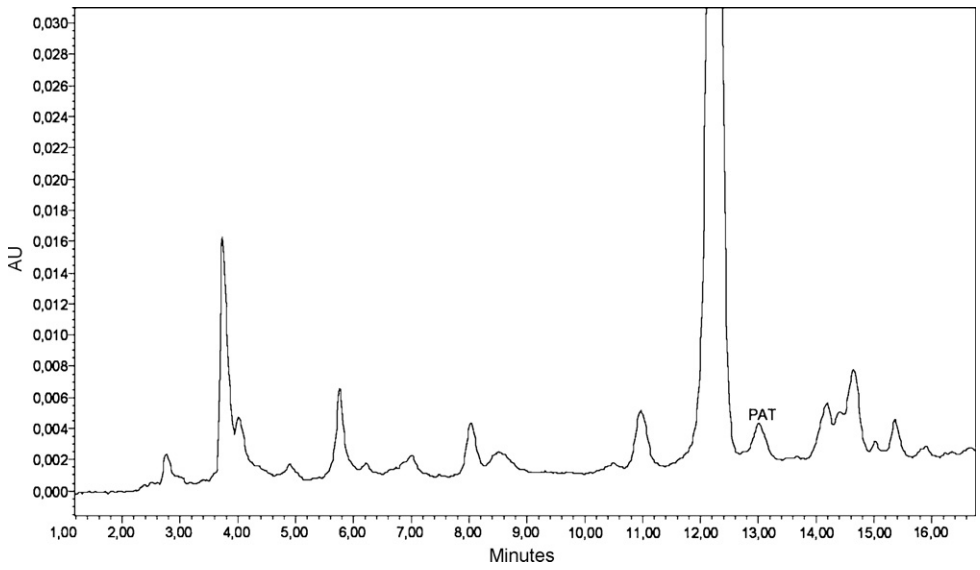

Fig. 2. Chromatogram of an apple/banana puree sample destined to infant consumption contaminated with 0.02 mg PAT/kg using the LLE–NaH_2PO_4–C_{18} procedure for sample preparation.

0.02 mg PAT/kg using the LLE–NaH_2PO_4–C_{18} procedure is observed in Fig. 2. Moreover, addition of NaH_2PO_4 in the LLE–NaH_2PO_4–C_{18} procedure makes slightly acidic the sample pH, which hinders the lactone ring opening.

This method is valid for compotes and apple puree products but its application to dried solid apple products, as performed by Katerere et al. [29], has not been assayed.

3.3. Occurrence of patulin in apple samples

The PAT levels in the apple samples determined by applying the Iha–NaH_2PO_4 method for juices, and the Iha–C_{18} method for apple puree and fruity products for young children were always below the LOQ. However, there were two juice samples that contained PAT concentrations over the LOD (between 2 and 6 μg/kg). Therefore, none of the analyzed samples appears to contain PAT concentrations surpassing the maximum levels fixed by the European Union. Although the risk of PAT intake by the Spanish population is apparently small, it cannot be ruled out. These results should be confirmed by a broader study and, if PAT seemed to be a problem, the apple product manufacturing industries should implant strict control systems to avoid the contamination with this mycotoxin.

In another survey concerning apple juices and apple products performed in Spain [37], PAT was detected in 2 out of 13 samples. The maximum concentration was 7.5 ng/g, which is slightly higher than the levels determined in our analyses, where the highest toxin level was only slightly above the LOD. In that survey [37], PAT was not detected in purees and apple compotes although one out of 59 infant food samples was found to contain 5 ng/g. In all the samples, PAT concentrations were below the limits permitted in the European Union. However, other authors [38] found PAT in 66 out of 100 apple juice samples with an average of 19.4 ng/ml and a maximum value of 118.70 ng/ml. Similar values were obtained in other surveys in Spain [39–41]. Prieta et al. [39] carried out a survey of PAT in 100 samples of commercial apple juice and 12 samples of apple food for children. In apple juice, PAT was detected in 82% of samples, and the maximum concentration found was 170 μg/l with a mean level of 13.8 μg/l, and 7 samples had PAT levels above 50 μg/l. However, children's apple food samples were free of PAT. Rovira et al. [40] found this mycotoxin in only one of the 18 apple juices analyzed with a level higher than 50 μg/l, and 15 samples of them were positives to PAT with a mean value of 20.2 μg/l. González-Osnaya et al. [41] analyzed 53 apple-containing products and detected PAT in 26.4% of the samples in the 1.5–50.9 μg/l range, and 6 samples surpassed the maximum permitted level in the European Union.

Although the results from different authors do not agree, it can be observed that contamination with PAT of apple products has occurred during the past years in Spain. Control of products intended for infant consumption is being stricter but in any case, a greater effort to reduce the incidence of PAT in apple-based food is needed to minimize the toxicological risk.

Table 4
Average recoveries, relative standard deviations ($N = 3$) and limits of detection for PAT in fruity foods for young children containing mainly apple puree at spiking levels of 0.02, 0.05, 0.1 and 1.0 mg of mycotoxin/kg by two procedures.

Procedure	Spiking level (mg/kg)	Recovery (%)	RSD (%)	LOD (μg/kg)
Modified Arranz	0.02	69.0	7.4	2.4
	0.05	72.8	8.1	
	0.1	68.3	7.3	
	1.0	65.3	6.5	
LLE–NaH_2PO_4–C_{18}	0.02	70.1	8.7	1.4
	0.05	74.3	6.2	
	0.1	71.6	8.9	
	1.0	69.3	5.7	

4. Conclusions

An easy and fast sample preparation procedure for the determination of PAT in apple juices has been proposed. It uses NaH_2PO_4 [30] instead of $NaHCO_3$ and involves a simple liquid–liquid extraction and has a low LOD (2.0 μg/kg) to be applied in the frame of the European Union regulation. This procedure is carried out at acidic pH thus avoiding PAT degradation during manipulation. Another procedure for the determination of PAT in apple purees and apple compotes is suggested. It is similar to that applied to apple juices, but there is an additional clean-up step with C_{18} SPE cartridge to eliminate impurities that were not removed during the liquid–liquid extraction step.

Food

ABSTRACT

This paper presents the optimisation of a programmed temperature vaporization solvent vent (PTV-SV) injection gas chromatographic mass spectrometric (GC–MS) method for the analysis of the 15 + 1 EU-priority PAHs in food extracts. Three operation parameters (vent time, vent flow and vent pressure) were optimised by applying a D-optimal experimental design. Among these variables, vent time showed the highest effect on the analytical response (signal intensity) of the target PAHs.

The 15 + 1 EU-priority PAHs were analysed in solvent solutions and in extracts of fortified sausage. In addition, blank lamb meat extracts were prepared and spiked with the target PAHs prior to GC–MS analysis. The performance of the optimised PTV-SV injection GC–MS method was scrutinised for linearity, precision, matrix effects and robustness. All parameters were found satisfactorily. Compared to PTV injection in splitless mode, the PTV-SV injection method provided an enhancement of sensitivity for all target PAHs. Especially significant was the improvement of the S/N ratios of the compounds with the highest molecular mass.

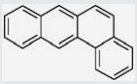
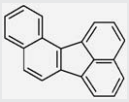
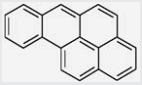
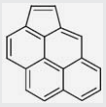
1. Introduction

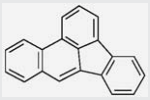
Polycyclic aromatic hydrocarbons (PAHs) are a large group of organic compounds containing two or more fused aromatic rings constituted of carbon and hydrogen atoms. PAHs constitute a large class of environmental contaminants. They are emitted from diesel engines, but also stationary sources, e.g. different kinds of industries [1]. The main source of exposure to PAHs for non-smoking humans is food. Food might be contaminated by PAHs through the environment or via formation during processing. The dietary intake of PAHs is of concern because some of them can cause cancer in humans [2]. The Scientific Committee on Food (SCF) assessed in 2002 the toxicity of 33 PAHs and concluded that 15 of them are potentially genotoxic and carcinogenic to humans [3]. In 2005, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) identified an additional PAH (benzo[*c*]fluorene) as probably carcinogenic [4]. The joint set of PAHs is recognized as the 15 + 1 EU-priority PAHs (Table 1). This terminology serves to distinguish them from the 16 PAHs highlighted in the 1970s by the US Environmental Protection Agency (EPA) [5]. Though eight of the 15 + 1 EU-priority PAHs are identical with PAHs of the US-EPA list they are challenging from the analytical point of view. Difficulties are related to both separation efficiency and sensitivity.

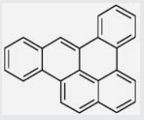


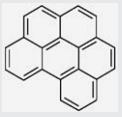


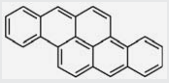


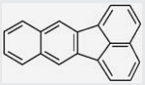


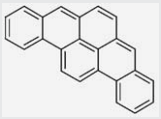


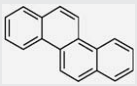


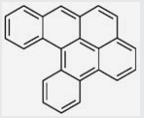


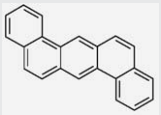


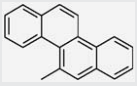


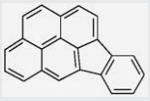


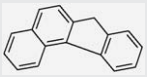












High discrimination of the signal intensities of low and high molecular weight compounds is a common problem in the analysis of PAHs by gas chromatography [6,7]. The lower abundance of the heavier compounds causes also smaller signal-to-noise (S/N) ratios which result in the increase of the limits of detections (LOD). Among the 15 + 1 EU-priority PAHs are four dibenzopyrenes (Table 1), which are especially susceptible to discrimination of signal intensities due to their high molecular mass.

Large-volume injection (LVI) techniques such as programmed-temperature-vaporization (PTV) and cool-on-column (COC) injection can be used to increase method sensitivity through the injection of larger volumes of the final extract. PTV injection has also been used to reduce discrimination of certain analytes compared to classical split–splitless injection [8]. In addition, PTV injection is preferred to on-column injection when the analyses involve complex samples [9]. Several studies have been recently reported using PTV methods for the determination of trace pollutants, such as phenols [10], pesticides [11] and polychlorinated biphenyls [12]. Likewise, PAHs have been also determined in environmental samples [12–17] and foodstuff [18,19] using PTV injection. However, it

8	Indeno[1,2,3-*cd*]pyrene (IcP) (Mw 276)		+1	**Benzo[*c*]fluorene (BcL)** (Mw 216)	

must be stressed that none of the cited studies covered the whole set of 15 + 1 EU-priority PAHs.

PTV injection offers more operating parameters than split/splitless injection. Hence the optimum combination of parameter settings needs to be identified for each analysis task individually. Some authors [11,13] tackled the optimisation of the PTV injection by univariate procedures, whereas others applied multivariate statistical experimental designs for that purpose [12,14,16,20]. From the latter, only Yusà et al. [14] and León et al. [20] focused in their studies on the determination of PAHs, which however covered only a part of the analytes dealt with in this paper.

The use of statistically based experimental designs (two-level full factorial designs, fractional factorials, central composite or Plackett-Burman designs) can simplify the optimisation of PTV injection through the use of a selected number of experiments that randomly combines the desired variables. This approach provides a method for the simultaneous investigation of multiple variables, estimating any interaction among them, and requires fewer experiments to complete the optimisation [14].

Only a few papers have been published on the optimisation of PTV injection for the determination of PAHs by GC–MS. They reported a significant increase in sensitivity by the use of PTV injection if compared to splitless injection [13,14,16]. These studies however have focused only on few selected PAHs [14] or on the 16 EPA PAHs [13,16]. A study has been published recently concerning the determination of high molecular mass PAHs by application of PTV injection GC–MS [21]. This paper reported on the measurement of 15 out of the 15 + 1 EU-priority PAHs in solvent solution and edible oil extracts by using PTV injection (1 μL) in splitless mode [21]. However PTV injection in splitless mode has the same limitations with regard to tolerated solvent volume as conventional splitless injection. If the solvent volume exceeds a certain level peak distortions have to be taken into account. PTV injection in solvent vent mode (PTV-SV) in contrary offers the possibility to perform large volume injection and gain thereby extra sensitivity. The limitation of this injection technique is provided by the larger amount of matrix that is injected into the instrument, which might interfere with the analyte signal. However, no studies are currently available that focus on the employment of PTV-SV injection for the GC–MS analysis of the 15 + 1 EU-priority PAHs in food samples.

The aim of the present study was the optimisation of a PTV-SV injection method for the GC–MS analysis of the 15 + 1 EU-priority PAHs in foodstuff. The optimisation of different operating parameters of the PTV injection was carried out by application of a statistically based experimental design. Sausage samples prepared with oil fortified with the 15 + 1 EU-priority PAHs and non-contaminated lamb meat samples were used throughout the study. Different performance parameters such as linearity, precision, and matrix effects were evaluated for the optimised PTV-SV injection GC–MS analysis method. Sensitivity and discrimination of signal

intensities were compared to standard PTV injection in pulsed splitless injection mode (PTV-PSL).

2. Materials and methods

2.1. Reagents and reference materials

All solvents were purchased in chromatographic grade from VWR International (Leuven, Belgium). The drying material poly(acrylic acid), partial sodium salt-graft-poly(ethylene oxide) was obtained from Aldrich (Milwaukee, USA) and Ottawa sand from Acros Organics N.V. (Geel, Belgium).

The analytes benz[*a*]anthracene (BaA) CAS#56-55-3, chrysene (CHR) CAS#218-01-9, 5-methylchrysene (5-MC) CAS#3697-24-3, benzo[*b*]fluoranthene (BbF) CAS#205-99-2, benzo[*j*]fluoranthene (BjF) CAS#205-82-3, benzo[*k*]fluoranthene (BkF) CAS#207-08-9, benzo[*a*]pyrene (BaP) CAS#50-32-8, indeno[1,2,3-*cd*]pyrene (IcP) CAS#193-39-5, dibenz[*a,h*]anthracene (DhA) CAS#53-70-3, benzo[*ghi*]perylene (BgP) CAS#191-24-2, dibenzo[*a,l*]pyrene (DlP) CAS#191-30-0, dibenzo[*a,e*]pyrene (DeP) CAS#192-65-4, dibenzo[*a,i*]pyrene (DiP) CAS#189-55-9, dibenzo[*a,h*]pyrene (DhP) CAS#189-64-0, were commercially available BCR certified reference materials (IRMM, Geel, Belgium). Cyclopenta[*cd*]pyrene (CPP) CAS#27208-37-3, purity >99.0% by GC, was manufactured on request (Biochemisches Institut für Umweltkarzinogene, Großhansdorf, Germany). Benzo[*c*]fluorene (BcL) CAS#205-12-9, purity 99.99%, was purchased from Dr. Ehrenstorfer GmbH (Augsburg, Germany). The isotopically labelled compounds benz[*a*]anthracene (^{13}C6, 99%), benzo[*a*]pyrene (^{13}C6, 99%), benzo[*b*]fluoranthene (^{13}C6, 99%), benzo[*ghi*]perylene (^{13}C12, 99%), benzo[*k*]fluoranthene (^{13}C6, 99%), chrysene (^{13}C6, 99%), dibenz[*a,h*]anthracene (^{13}C6, 99%), dibenzo[*a,e*]pyrene (^{13}C6, 99%), dibenzo[*a,i*]pyrene (^{13}C12, 99%), indeno[1,2,3-*cd*]pyrene (^{13}C16, 99%) and pyrene (^{13}C3, 99%), which was used as internal standard for BcL, were obtained from LGC Promochem GmbH (Wesel, Germany). 9-Fluorobenzo[*k*]fluoranthene, used as injection standard, was purchased from Chiron AS (Trondheim, Norway). Stock solutions of the individual PAHs were gravimetrically prepared in toluene. The different working solutions containing the 15 + 1 EU-priority PAHs were prepared by mixing appropriate volumes from the individual stock solution and adding toluene to achieve the desired concentrations (6 different levels between 15 ng/mL and 80 ng/mL).

2.2. Sample preparation

Contaminated sausage samples were prepared at the Max-Rubner-Institut (MRI), Bundesforschungsinstitut für Ernährung und Lebensmittel, Institut für Sicherheit und Qualität bei Fleisch (Kulmbach, Germany) by applying spiked olive oil for the production of sausages. The sausage samples were split into portions of 50 g each and packed into aluminium cans. The final analyte contents ranged from 3.9 $\mu g\,kg^{-1}$ to 9.9 $\mu g\,kg^{-1}$. Benzo[*a*]pyrene, the only PAH regulated by current EU legislation, was present at a level of 5.3 $\mu g\,kg^{-1}$, a value slightly above the maximum level specified in Commission Regulation (EC) No 1881/2006 (5 $\mu g\,kg^{-1}$) [22].

Blank meat extracts were prepared from commercial minced lamb meat. They were fortified with the 15 + 1 EU-priority PAHs prior to the GC–MS analysis in order to evaluate matrix effects of the optimised PTV-SV method. The blank extracts were fortified to a concentration of 50 ng mL^{-1} for each PAH, a concentration similar to that expected in the final extract of the sausage sample considering sample intake and analyte enrichment.

2.2.1. Pressurised liquid extraction (PLE)

Extraction was carried out in accordance with the method described by Jira et al. [23]. Briefly, 5 g of homogenised sausage was mixed with the same amount of poly(acrylic acid), partial sodium salt-graft-poly(ethylene oxide) and 15 g of Ottawa sand. After adding 200 μL of the ^{13}C-labelled standard solution, the mix was placed into 33 mL extraction cells with cellulose filters at the bottom. The extraction was performed with *n*-hexane (at 100 °C and 100 bars at a static time of 10 min) in an ASE 300 pressurised liquid extraction system (Dionex, Amsterdam, The Netherlands). The flush volume was 60% and the purge time 120 s. Two static extraction cycles were performed per sample. Afterwards, the extractant was evaporated in a Turbo Vap® workstation (Zymark, Hopkinton, USA) at 40 °C using a stream of nitrogen.

2.2.2. Gel permeation chromatography (GPC)

The evaporated PLE-extract was dissolved in approximately 5 mL of cyclohexane:ethyl acetate (1:1 v/v) and filtered through PTFE filters of 5 μm pore size (Millipore, Bedford, USA). GPC clean up was carried out on a GPC column (25 mm internal diameter and 320 mm length) filled with 50 g Bio-Beads S-X3 (Bio-Rad Laboratories, Nazareth-Eke, Belgium) applying a GPC Ultra instrument (LCTech, Dorfen, Germany) connected to a FW-20 detector (LCTech) that was operated at 254 nm. Chromatographic separation was achieved with cyclohexane:ethyl acetate (1:1 v/v) at a flow rate of 4 mL min^{-1}. The PAHs containing fraction eluted between 35 min and 80 min. The volume of this fraction was reduced to 4.5 mL by using an automated concentrator (CPC 2000-II Vacuubrand, Wertheim, Germany) that was integrated in the GPC system. The sensitivity of the UV detector was not sufficient to detect the elution of the PAHs. As an alternative the elution of toluene, which got into the extract as a residue of the spiking with internal standards dissolved in toluene, and the elution of the fat fraction were monitored for quality control purposes. Toluene eluted shortly after the fat fraction and directly in front of the first target analyte, benzo[*c*]fluorene.

2.2.3. Solid phase extraction (SPE)

The GPC eluate was further reduced with a stream of nitrogen to 200 μL. Then 800 μL of cyclohexane were added and the mix was quantitatively loaded onto a preconditioned silica SPE cartridge (500 mg/4 mL, Alltech, Deinze, Belgium). The PAHs were eluted with 10 mL of cyclohexane.

2.2.4. Preparation for GC–MS analysis

Toluene (200 μL) was added as a keeper to the SPE eluate, which was then concentrated to a volume of about 200 μL. Afterwards, 300 μL of toluene containing 9-fluorobenzo[*k*]fluoranthene was added, which served for monitoring the variability of injection.

2.3. Instrumentation and analytical conditions

A gas chromatograph HP 6890N from Agilent Technologies (Waldbronn, Germany) with a programmable-temperature vaporization (PTV) injection port (septumless head) was used for the analysis of the target PAHs. The GC was coupled to an Agilent 5975B single quadrupole mass spectrometer (Agilent Technologies) operated in electron ionization (EI) mode at 70 eV. The analyses were performed in selected ion monitoring (SIM) mode recording the molecular ion of each compound (Table 1). Transfer line temperature and ion source temperature were maintained at 325 °C and 300 °C, respectively. The mass spectrometer was equipped with a 6 mm ultra large aperture draw out lens (Agilent Technologies). Injection was carried out using an automated GC PAL injection system (CTC Analytics, Zwingen, Switzerland).

PTV-PSL injection was performed to set reference values on which basis the performance characteristics of the PTV-SV injection method were evaluated. The parameters of the PTV-PSL injection method were: injection volume 1 μL, injection pulse pressure 30 psi

for 0.3 min, and injection port temperature 300 °C. The purge valve was opened after 1 min (purge flow 30.5 mL min^{-1}).

The parameters of the PTV-SV injection were subject of the optimisation process and are discussed later in this paper.

All analyses were carried out on a DB-17MS column 60 m × 0.25 mm internal diameter, 0.25 μm film thickness (Agilent Technologies, Diegem, Belgium). The oven temperature programme was 80 °C (hold 1 min), to 250 °C at 40 °C min^{-1}, to 305 °C at 25 °C min^{-1}, to 315 °C at 2 °C min^{-1}, to 330 °C at 40 °C min^{-1} and hold for 35 min. Helium was used as carrier gas at 1.5 mL min^{-1} flow rate.

2.4. Statistical software

Dedicated software for the design of experiments and optimisation, MODDE version 8.0 (Umetrics, Umeå, Sweden), was used for building up the parameter matrix and further evaluation of the results.

3. Results and discussion

3.1. Optimisation of PTV-SV injection

All standards and sample extracts were prepared in toluene. Although toluene is not the preferred solvent for large volume injection due to its rather high boiling point, it is the most suitable solvent to dissolve PAHs with high molecular mass (i.e. dibenzopyrenes). Its application was also recommended to prevent the adsorption of micro-contaminants to glassware [24].

Large volume injection into a PTV injector can be done in different modes: *at-once* (i), or using *multiple injection* (ii) [25]. In mode (i), the sample is introduced at relatively high speed, whereas in mode (ii) the sample is introduced at a rate that is theoretically equal to that of evaporation.

At-once injection was applied for this study. Different speeds were tested and the best results were obtained by injecting the sample at a speed of 5 μL s^{-1}.

3.1.1. Selection of the inlet liner

The most appropriate PTV inlet liner has to be identified prior to the optimisation of operating parameters, as this device has a crucial role in the trapping and transfer of the analytes. The optimisation was carried out using a step-wise approach. Four different PTV inlet liners were tested in this study: the single-baffle, the single-baffle packed with glass wool, the multi-baffle, and the sintered glass inlet liner. Another type of liner, which is filled with Tenax was not considered in this study since it has been reported that their use can provoke problems during the transfer of high boiling compounds to the column, leading to peak distortion and losses among other negative effects [9].

Standard solutions containing 100 ng mL^{-1} of each target analyte were injected ten times into each liner applying PTV-SV injection, and repeatability of injection was evaluated. An injection volume of only 1 μL was selected to avoid chromatographic problems stemming from the, at that point of time, non-optimised PTV-SV injection.

The sintered glass inlet liner showed the worst performance in terms of mass transfer and was therefore excluded from further studies. Fig. 1 shows the respective chromatograms for the baffle inlet liner (A) and the sintered glass inlet liner (B). As can be seen strong discrimination in terms of peak height occurred especially for the compounds with the highest molecular weight, the dibenzopyrenes.

Table 2 shows the relative standard deviations (RSDs) obtained under repeatability conditions for the other three inlet liners. The

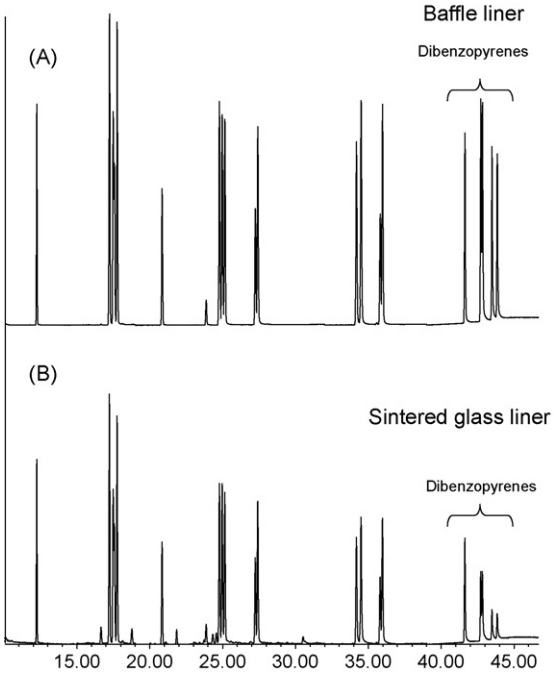

Fig. 1. Chromatograms of the 15 + 1 EU-priority PAHs on a DB-17MS column 60 m × 0.25 mm internal diameter, 0.25 μm film thickness applying a PTV baffle liner (A) and a PTV sintered glass liner (B).

multi-baffle inlet liner provided the best results in terms of precision for all compounds, although a similar level of precision was obtained with the single-baffle inlet liner for the compounds with low and medium molecular mass (from BcL to BaP). However the performance of the multi-baffle liner was superior for analytes with high molecular mass.

The results obtained with the single-baffle inlet liner packed with glass wool were generally worse than those obtained with the other two baffle inserts. Noticeably high RSDs were found for BcL and for high molecular weight compound like DiP and DhP. This might be caused by losses of BcL during the solvent evaporation phase, and irreversible adsorption of the heavy PAHs on active sites of the glass wool.

When increasing the injection volume from 1 μL up to 5 μL, peak symmetry was maintained only with the multi-baffle inlet liner.

Therefore, the multi-baffle inlet liner was applied for further optimisation of the PTV-SV injection.

3.1.2. Injection volume

The maximum tolerable injection volume of toluene was determined for the multi-baffle inlet liner by injecting different volumes of toluene into the PTV injector without connecting the column. The carrier gas flow was turned on in that experiment. According to Godula et al. [26] the injection volume can be increased until a solvent drop is observed at the exit of the inlet liner. A volume of 10 μL of toluene was injected into the multi-baffle inlet liner without visible overflow of the liquid and hence further-on used in this study.

3.1.3. Initial inlet temperature

The initial injector temperature plays an important role in large volume injection in solvent vent mode. It has to be set to allow fast removal of the solvent without losses of the analytes. The temperature of the injection port was set in the described experiments to 55 °C because higher temperatures caused losses of the most volatile target analyte, benzo[*c*]fluorene. This temperature reflects also the minimum temperature that can be reached in a

Table 2
Repeatability expressed as RSD % obtained for the injection of 1 μL of a standard solution containing the 15 + 1 EU-priority PAHs in toluene in a DB-17MS column 60 m × 0.25 mm internal diameter, 0.25 μm film thickness (100 ng/mL, $n = 10$). The RSD (%) of three different liners is shown.

	Single-baffle liner	Single-baffle packed with glass wool liner	Multi-baffle liner
			
	RSD (%)		
Benzo[*c*]fluorene	1.32	37.84	3.13

Dibenzo[*a,e*]pyrene	6.01	2.40	1.19
Dibenzo[*a,i*]pyrene	6.61	24.19	1.96
Dibenzo[*a,h*]pyrene	6.20	26.18	2.33

reasonable period of time without applying cryogenic inlet cooling. Compressed air was used as replacement of cryogenic gases for facilitating the cooling process of the PTV injector. Consequently less than 5 min were necessary after each run to reach the initial inlet temperature.

3.1.4. Optimisation of PTV operating parameters

The PTV-SV injection can be divided into four different phases: the injection, the solvent vaporization, the transfer of analytes and the cleaning phase. During the injection the split valve is open (solvent vent mode) and the sample is introduced into the injection port set at a temperature below the boiling point of the carrier solvent. The following step, the solvent vaporization, is critical with regard to the analyte transfer onto the column and its effect on the quality of separation. The aim of the solvent vaporization is to eliminate the excess of solvent without loosing the analytes. If the residual solvent volume is too high a long flooded zone is formed in the front part of the column leading to peak distortion (a phenomenon known as "peak band broadening in space") [27]. Too excessive elimination of solvent will lead to losses of the most volatile compounds. Hence a small quantity of remaining solvent that is later-on transferred onto the column is desirable, not only to prevent analyte losses, but also to form a film at the front part of the column that traps and thereby focuses early eluting compounds [26].

The solvent elimination is influenced by different parameters that were considered in the optimisation process. They were in particular vent flow, vent time, vent pressure, and initial inlet temperature. The initial inlet temperature was set to 55 °C, as detailed before. Hence the focus was put onto the other three variables. Previous reported studies [28] and own investigations revealed that a high final temperature of the injection port enhanced the transfer of the analytes with high molecular mass onto the column, while the slope of the temperature increase in the PTV injection port did not have any significant influence. Accordingly, the final temperature of the injection port was maintained throughout the study at 400 °C and the temperature ramp at the maximum value of 600 °C min^{-1}. Regardless the conditions selected during optimisation, the split valve was opened after 3 min (purge time) and kept in this position for 15 min at 400 °C (cleaning step).

Vent time, vent flow and vent pressure were the variables that had to be optimised in order to maximise the analytical response (peak area) of the different PAHs.

The type of experimental design was selected taking into consideration the number of experiments to be performed and hence the time needed for measurements and the information level gained, which is expressed by the efficiency of the design. A full factorial experimental design including the three variables at two levels would consist of eight analyses, but would only allow the set up of linear models. Any non-linear relationships cannot be identified at two levels. A full factorial experimental design at three levels would consist without replication of 27 (3^3), and at four levels even of 64 (4^3) experiments. The advantage of full factorial designs is that all main effects and all multi-factor interactions can be described. However, if higher order factor interactions are not considered important fractional factorial experimental designs such as the D-optimal design may be applied. This is a computer generated design which consists of N runs out of all runs of the full factorial design, select in a way that maximum information can be gained with a minimum number of analyses [29]. The D-optimal design applied in the current work comprised 21 randomized chromatographic runs (10 corner experiments to which 11 axial points were added) out of 64 possible runs that span maximally the experimental region.

Table 3 shows the parameter settings employed for each variable in the D-optimal experimental design.

The correlation matrix obtained from the experimental data indicated an extremely high correlation between the responses obtained for all PAHs, which justifies the application of one single model for all the 15 + 1 EU-priority PAHs. The data was fitted by means of partial least square regression (PLS-R) providing an independent multivariate regression curve (model) for each PAH. No significant lack-of-fit was identified for any of the responses. Among the selected factors, vent time showed the highest influence on the analytical responses (negatively correlated with all the 15 + 1 EU-priority PAHs) followed by vent pressure and vent flow. Contour surface plots were used to visualise the modelled region and to assist in finding the optimal experimental conditions. Fig. 2 shows the contour plots of the response variable for the most volatile compound within the set of target analytes (BcL),

Table 3
Experimental conditions employed for the optimisation of the programmed temperature vaporization (PTV) injection in solvent vent mode by applying a D-optimal experimental design.

Parameter	Level		
	Minimum	Intermediate	Maximum
Vent time (min)	0.5	1 and 1.5	2
Vent flow (mL min^{-1})	25	50 and 75	100
Vent pressure (bar)	0.25	0.5 and 1	1.5

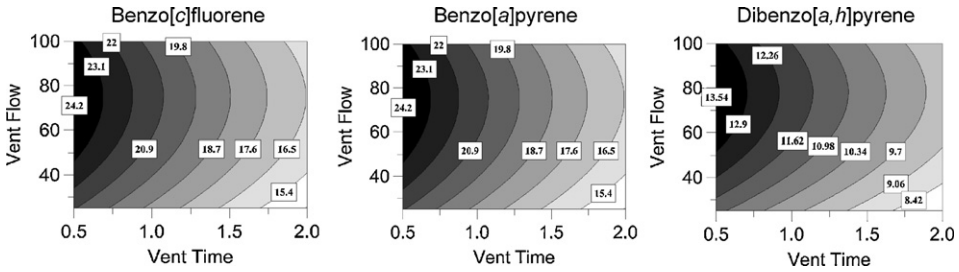

Fig. 2. Contour surface plots of BcL, BaP and DhP for two independent variables (vent time and vent flow) at a constant value of the other independent variable (vent pressure = 0.5 bar). Values inside the plots represent analytical responses in arbitrary units.

for BaP, for which maximum levels in food are specified in EU legislation, and for the last eluting PAH (DhP) for the two independent variables vent time and vent flow at a constant value of the vent pressure (0.5 bar). The contour plots show that small variations in vent time provoke significant changes in the analytical response of the PAHs (the response decreases as the vent time increases). A minimum value of the vent time (0.5 min) combined with vent flow values ranging between 60 mL min^{-1} and 100 mL min^{-1} maximised the analytical response of all compounds. Long vent times showed a negative effect on the response even though the vent flow was kept low.

The optimisation of the response for the individual analytes is not the way to success if the target is performance at the best for the whole set of analytes, because parameter settings to maximise performance for the volatile target analytes might be improper for the six-ring PAHs, which show low volatility. Therefore, the optimiser and the prediction list (two features provided by MODDE software) were used to predict the best experimental conditions considering that the response variables for all 15 + 1 EU-priority PAHs have the same importance. This is done by optimising an overall desirability function that is combining the individual desirability for each response. However, a finding that is not reflected in the models was that broad and fronting chromatographic peaks were obtained when short vent times were combined with low vent flows. Similar responses were gained for vent flows in the range of 60 mL min^{-1} to 100 mL min^{-1} when combined with low vent time (0.5 min) (Fig. 2). Therefore it was decided to set for the optimisation of the model the vent flow to the highest value to ensure adequate solvent elimination. Hence the following parameter settings were found most appropriate for the PTV-SV injection of PAH solutions: vent time 0.5 min, vent flow 100 mL min^{-1} and vent pressure 0.5 bar.

3.2. Method validation

The optimised PTV-SV method was validated to assess its applicability for the analysis of the 15 + 1 EU-priority PAHs in different samples. Different parameters such as linearity, precision (repeatability and intermediate precision), influence of matrix effects, and robustness of the PTV-SV injection method were evaluated.

3.2.1. Linearity

The linearity of the optimised PTV-SV injection GC–MS method was evaluated in the range of 15 ng mL^{-1} to 80 ng mL^{-1} from calibration standards applying Mandel's fitting test. All calibration functions were found linear. Table 4 presents performance characteristics of the method that were determined from replicate injections of six PAH standard solutions, respectively sausage extracts. The coefficients of determination of the calibration functions were for all 15 + 1 EU-priority PAHs higher than 0.99.

3.2.2. Precision and matrix effects

The precision of the PTV-SV method was evaluated both under repeatability and intermediate precision conditions. Standard solutions in solvent (toluene) and sausage extracts containing the 15 + 1

[a] 50 ng mL^{-1} standard mix of the 15 + 1 EU-priority PAHs.

[b] Sausage meat extract (3.9 μg kg^{-1} to 9.9 μg kg^{-1} for the 15 + 1 EU-priority PAHs).

[c] Average recovery (%) plus standard deviation calculated from triplicate analysis of blank lamb meat extracts (n = 3) fortified with the 15 + 1 EU-priority PAHs (50 ng mL^{-1}) prior to their analysis by GC–MS.

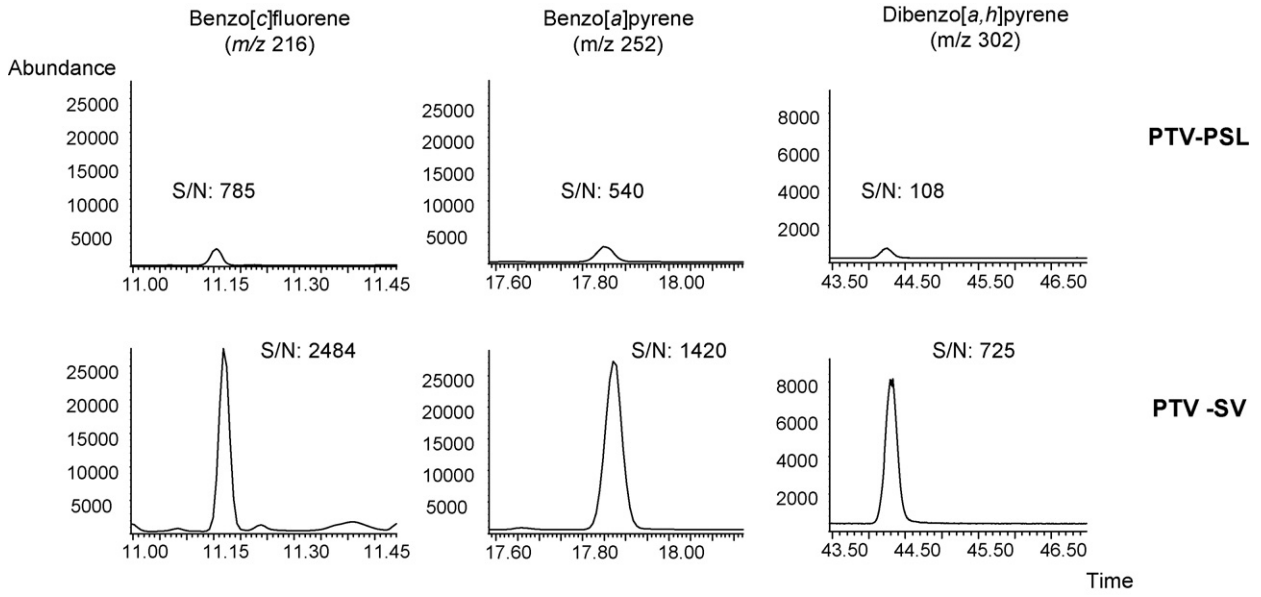

Fig. 3. SIM chromatograms of BcL (*m*/*z* 216), BaP (*m*/*z* 252) and DhP (*m*/*z* 302) obtained with PTV-SV and PTV-PSL injection of an extract of sausage fortified with the 15 + 1 EU-priority PAHs (concentration ranging from 3.9 μg kg^{-1} to 9.9 μg kg^{-1}). Concentration of the presented compounds were 3.9 μg kg^{-1}, 5.3 μg kg^{-1} and 9.9 μg kg^{-1} for BcL, BaP and DhP, respectively.

EU-priority PAHs were analysed. Repeatability was calculated from analysis results of three consecutive injections on the same day of either one PAH standard solution in toluene (50 ng mL^{-1} of each analyte), or one sausage extract sample (3.9 μg kg^{-1} to 9.9 μg kg^{-1} of the different PAHs), while intermediate precision was evaluated performing one-way ANOVA of three consecutive injections of both samples on three different days. Hence the calculated precision estimates reflect only the contribution of the GC–MS measurements on the overall precision of the analysis method.

The relative repeatability standard deviations (RSD_r) of the PTV-SV injection GC–MS measurements were satisfactory for the PAH solution in toluene, ranging between 0.77% for CHR and 3.54% for DhP. The respective relative intermediate precision standard deviation (RSD_i) ranged between 1.79% for DlP and 5.56% for IcP (Table 4).

The influence of matrix effects on the GC–MS measurement can be deduced from the precision estimates of the sausage sample. For most analytes the intermediate precision was of the same order of magnitude as the repeatability, which indicates that the gradual accumulation of co-extractives in the injection liner did not negatively impact precision. They were significantly different only for BcL and DhP (Table 4). The precision estimates for the sausage samples were somewhat higher than the respective estimates for the solvent solution, which was to be expected. However the vaporization of the analytes from food extracts was not significantly different to that from solvent solutions. This was confirmed by the replicate injection of blank lamb meat extract samples that were spiked with the target analytes to a level of 50 ng mL^{-1} just before injection and comparison of the results to those for solvent solutions. The ratio of the results for the meat sample and of the solvent solution would indicate matrix effects, if it was significantly different from one. The last column of Table 4 contains this information, expressed as percent recovery. Most of the results were close to 100%, which reveals the absence of matrix interferences in the analysis of meat samples applying this particular combination of sample preparation and PTV-SV-injection-GC–MS analysis.

3.2.3. Robustness

The robustness of the optimised PTV-SV method was evaluated using a screening fractional factorial design. Robustness measures the capacity of the method to remain unaffected by small but deliberate variations in the method parameters [30]. Assuming that the precision of the temperature control and of the control of pneumatics of the PTV injector is better than 5%, this value was selected for testing of the robustness of the PTV-SV injection. Therefore, values between 0.475 min and 0.525 min were selected for vent time, between 95 mL min^{-1} and 105 mL min^{-1} for vent flow and between 0.475 bar and 0.525 bar for vent pressure. A *t*-test was used to estimate the significance of each effect relative to the random variability (expressed as the observed standard deviation obtained under repeatability conditions at the centre of the experimental region). The PTV-SV method was considered robust since none of the three investigated factors had a statistically significant effect at the 95% confidence level on the analytical response of the different PAHs.

3.3. PTV in solvent vent mode and PTV splitless injection. Sensitivity of the optimised method

The performance of the optimised PTV-SV injection method was compared to the PTV-PSL injection (injection volume 1 μL) in terms of the signal-to-noise (S/N) ratios of two different samples: a standard solution containing the 15 + 1 EU-priority PAHs (15 ng mL^{-1}) and a sausage sample fortified with the 15 + 1 EU-priority PAHs (concentration ranging from 3.9 μg kg^{-1} to 9.9 μg kg^{-1}). A PTV-PSL injection method was already published by Bordajandi et al. [21]. The aim of the current experiments was to identify potential improvements of sensitivity of the PTV-SV injection method (10 μL) compared to the pulsed splitless injection method (1 μL). Fig. 3 shows selected SIM chromatograms of both PTV-SV injection and PTV-PSL injection of the meat extract for the ions with *m*/*z* 216, 252 and 302 corresponding to the base peak ions of BcL, BaP and DhP, respectively. The S/N ratios were for all analytes much higher in the chromatograms recorded after injection of the meat extract with the optimised PTV-SV method. Significantly increased was the sensitivity obtained for DhP, with an almost seven-fold higher S/N ratio after PTV-SV injection compared to PTV-PSL injection.

The gain of sensitivity with the PTV-SV injection was noticeable also for the other six-ring PAHs (Table 5). An increase in S/N ratios

Table 5
Signal-to-noise (S/N) ratio of GC–MS analysis applying the optimised PTV injection in solvent vent mode (PTV-SV) and PTV injection in pulsed splitless mode (PTV-PSL) for the analysis of both a solution of the 15 + 1 EU-priority PAHs in solvent (15 ng mL^{-1} in toluene) and an extract of a sausage samples fortified with the15 + 1 EU-priority PAHs (content ranging from 3.9 μg kg^{-1} to 9.9 μg kg^{-1}).

Dibenz[*a,h*]anthracene	4597	118	1794	368	1.26	0.68
Benzo[*ghi*]perylene	585	127	1202	221	0.85	0.41
Dibenzo[*a,l*]pyrene	779	43	608	119	0.43	0.22
Dibenzo[*a,e*]pyrene	811	46	643	105	0.45	0.19
Dibenzo[*a,i*]pyrene	483	37	380	62	0.27	0.11
Dibenzo[*a,h*]pyrene	442	33	725	108	0.51	0.20

ranging between 5.1 and 6.7 times was observed. This is particularly important with regard to the typical discrimination of signal intensities that is observed in the analysis of PAHs by GC–MS [6,7]. However the effect of the injection technique on the discrimination of the signal intensities was visualised by determining relative signal-to-nose ratios in order to demonstrate that the enhancement of signal-to-noise ratios in PTV injection in solvent vent mode was not only the consequence of the higher amount of analyte introduced into the instrument. For that purpose the S/N ratio of the analytes were normalised to the S/N ratio of BaP (Table 5). For the last eluting PAHs (DiP and DhP) a 2.5-fold increase of the normalised S/N ratios was observed when applying PTV-SV injection compared to PTV-PSL injection. Likewise, the normalised S/N values of the other two dibenzopyrenes (DlP, DeP) as well as the rest of PAHs (except for BaA and CPP that showed similar values) were improved when the PTV-SV injection was used. Therefore, the PTV-SV injection does not only improve the sensitivity of the 15 + 1 EU-priority PAHs, it is moreover also able to reduce the discrimination of signal intensities between the low- and the high-molecular weight compounds.

4. Conclusions

A PTV method in solvent mode (PTV-SV) for the analysis of the 15 + 1 EU-priority PAHs has been optimised and validated. The use of statistical experimental design simplified the optimisation of the most important parameters governing the PTV injection. As compared to PTV injection in splitless mode, the optimised PTV-SV method provided higher sensitivity for all studied analytes, irrespective of the type of injected sample being it a solvent solution of the target analytes or an extract of a fortified sausage sample. Especially significant was the improvement in the S/N ratio of the compounds with the highest molecular weight (more than six-fold increase for DeP, DiP and DhP). The optimised PTV-SV injection showed very good performance in terms of linearity, precision, and robustness. Matrix effects were not experienced in the analysis of meat extract samples.

ABSTRACT

An analytical protocol for the isolation and quantification of indole-3-acetic acid (IAA) and its amino acid conjugates was developed. IAA is an important phytohormone and formation of its conjugates plays a crucial role in regulating IAA levels in plants. The developed protocol combines a highly specific immunoaffinity extraction with a sensitive and selective LC–MS/MS analysis. By using internal standards for each of the studied compounds, IAA and seven amino acid conjugates were analyzed in quantities of fresh plant material as low as 30 mg. In seeds of *Helleborus niger*, physiological levels of these compounds were found to range from 7.5 nmol g^{-1} fresh weight (IAA) to 0.44 pmol g^{-1} fresh weight (conjugate with Ala). To our knowledge, the identification of IAA conjugates with Gly, Phe and Val from higher plants is reported here for the first time.

1. Introduction

Indole-3-acetic acid (IAA), referred to as auxin, is an important phytohormone. It plays crucial roles in many aspects of the regulation of plant growth and development, including cell elongation [1], tropisms [2] and the establishment of apical-basal polarity in both individual cells and the whole plant [3]. Such wide-ranging regulation of developmental processes by IAA requires that its concentration in cells and tissues is rapidly and sensitively regulated in both space and time. One of the mechanisms by which IAA level in plants is regulated is by conjugation of free IAA with amino acids, giving rise to either biologically inactive, but hydrolyzable, conjugates with alanine (IAAla) and leucine (IALeu) or to unhydrolyzable conjugates with aspartic acid (IAAsp) and glutamic acid (IAGlu). These two groups of conjugates are believed to have a storage function or to precede degradation of excessive IAA, respectively [4].

Although plant materials consist of a very complex matrix containing large amounts of ballast compounds, quantification of IAA – the quantities of which per gram of fresh weight (FW) vary typically between tens and hundreds of pmol – is not too difficult to perform. In current practice, raw extract is usually purified by solid-phase extraction [5] and analyzed by GC–MS [6] following methylation [7], trimethylsilylation [6] or other kind of derivatization [8,9]. Analysis by HPLC coupled to tandem mass detection is also an option, both with [10] or without [11] prior derivatization.

Compared with free IAA analysis, the quantification of IAA amino acid conjugates is much more elaborate due to the significantly lower levels of the analytes present in plant material. Thus in *Arabidopsis thaliana*, a model organism often used in plant biology, Kowalczyk and Sandberg [12] have described, together with free IAA (the amounts of which ranged between 40 and 130 pmol per gram of fresh material) conjugates with the following four amino acids: Asp, Glu (both present at picomolar level), Leu (hundreds fmol g^{-1} FW) and Ala, with quantities as low as 20 fmol g^{-1} FW. The extracts from *A. thaliana* were subjected to solid-phase (SPE) extraction and after methylation analyzed by HPLC linked to tandem mass detection. The protocol appeared to be notably simpler than that of Tam and coworkers [13] who used preparative HPLC before quantification of IAAsp and IAGlu by GC–MS.

Recently, an analytical protocol for the quantification of IAA and its conjugates in rice (*Oryza sativa*) has been described [14], which consists of SPE and subsequent HPLC–MS/MS analysis without prior derivatization. The protocol allows quantification of IAA conjugates with these amino acids: Ala, Asp, Glu, Leu, Phe and Val. It was applied to rice samples of 20–100 mg in fresh weight.

Table 1
Selected parameters of HPLC–MS/MS analysis of methyl esters of IAA and seven IAA amino acid conjugates. In parentheses, transitions of ^{15}N- and/or $^{2}H_5$-labeled standards are described.

RT (min)	Analyte	Transition	CV (V)	CE (eV)	LOD (fmol)	Dynamic range (pmol)	Calibration curve	R^2
8.60	IAGly-Me	247.2 > 130.1 (253.2 > 134.1)	19	22	0.2	0.004–2.5	$y = 0.9744x + 0.3592$	0.9998
11.41	IAAla-Me	261.2 > 130.1 (267.2 > 134.1)	21	19	0.7	0.004–2.5	$y = 0.9853x + 0.4162$	0.9995
12.53	IAAsp-Me_2	319.2 > 130.1 (325.2 > 134.1)	21	25	0.7	0.2–125	$y = 0.9829x + 0.3599$	0.9993
14.19	IAGlu-Me_2	333.2 > 130.1 (339.2 > 134.1)	21	35	0.6	0.04–25	$y = 1.0132x + 0.2683$	0.9998
16.19	IAA-Me	190.2 > 130.1 (195.2 > 134.1)	21	13	1.2	0.2–125	$y = 0.9693x + 0.1860$	0.9996
17.42	IAVal-Me	289.2 > 130.0 (295.2 > 134.1)	23	22	0.3	0.004–2.5	$y = 0.9962x + 0.4024$	0.9998
19.86	IALeu-Me	303.2 > 130.1 (309.2 > 134.0)	25	24	1.0	0.004–2.5	$y = 0.9888x + 0.3500$	0.9992
20.36	IAPhe-Me	337.2 > 130.0 (343.1 > 134.1)	16	27	0.6	0.004–2.5	$y = 0.9680x + 0.3064$	0.9998

However, only conjugates with Ala, Asp and Glu were detected in the selected plant material.

In this paper we introduce a complex analytical protocol suitable for isolation and quantification of IAA and a broad range of its amino acid conjugates. Based on a polyspecific anti-IAA immunoaffinity purification, it may be used to study novel (previously undescribed) naturally occurring IAA conjugates. Since we used internal standards for each of the analyzed compounds, we were able to quantify four known and three novel derivatives over a wide range of concentrations in which they are present in plant material.

2. Experimental

2.1. Reagents and materials

Indole-3-acetic acid and other indole compounds were obtained from OlChemIm (Olomouc, Czech Republic). ^{15}N- and/or $^{2}H_5$-labeled internal standards were prepared according to Ilić et al. [15]. Affi-Gel 10 was ordered from Bio-Rad (Hercules, CA, USA). Other reagents and solvents were provided by Sigma–Aldrich (St. Louis, MO, USA). Water was purified by the Simplicity 185 water purification system (Millipore, Bedford, MA, USA).

2.2. Preparation of antibodies and their use in immunoaffinity extraction

Polyspecific polyclonal antibodies against IAA and its conjugates were obtained by immunizing rabbits with an IAA–protein conjugate. To couple IAA to bovine serum albumin (BSA) through its carboxyl group, the procedure described by Weiler [16] was used, resulting in a hapten:protein molar ratio of 23. Purification of the antibodies and the preparation of immunoaffinity columns and their use were essentially as described earlier [17]. Capacity and recovery of the columns estimated by application of various amounts of indole-3-acetamide was about 3 nmol and 95–100%, respectively.

2.3. Sample processing and LC–MS/MS analysis

The extraction and subsequent SPE were similar to those used by Karin Ljung (personal communication). Approximately 30 mg (fresh weight) of plant material frozen in liquid nitrogen was ground with pestle and mortar and extracted for 5 min with 1 ml of cold phosphate buffer (50 mM; pH 7.0) containing 0.02% sodium diethyldithiocarbamate and the following ^{15}N- and/or $^{2}H_5$-labeled internal standards: [$^{2}H_5$]IAA, [^{15}N,$^{2}H_5$]IAAla, [^{15}N,$^{2}H_5$]IAAsp, [^{15}N,$^{2}H_5$]IAGlu, [^{15}N,$^{2}H_5$]IAGly, [^{15}N,$^{2}H_5$]IALeu, [^{15}N,$^{2}H_5$]IAPhe, and [^{15}N,$^{2}H_5$]IAVal.

After centrifugation (36,000 × *g*; 10 min; +4 °C), each sample was transferred into an eppendorf tube, acidified with 1 M HCl to pH 2.7 and applied on a C8 column (Bond Elut, 500 mg, 3 ml; Varian) pre-washed with 2 ml of methanol and equilibrated with 2 ml of formic acid (1%; v/v). The column was washed with 2 ml of methanol (10%; v/v) acidified with formic acid (1%; v/v) and retained analyte was eluted with 2 ml of methanol (70%; v/v) acidified with formic acid (1%; v/v). The eluate was evaporated to dryness *in vacuo*.

Samples were reconstituted in 100 μl of methanol acidified with concentrated hydrochloric acid (1 μl per ml of methanol) and methylated with 300 μl of ethereal solution of diazomethane. After 10 min the reaction mixture was evaporated under a stream of gaseous nitrogen (40 °C).

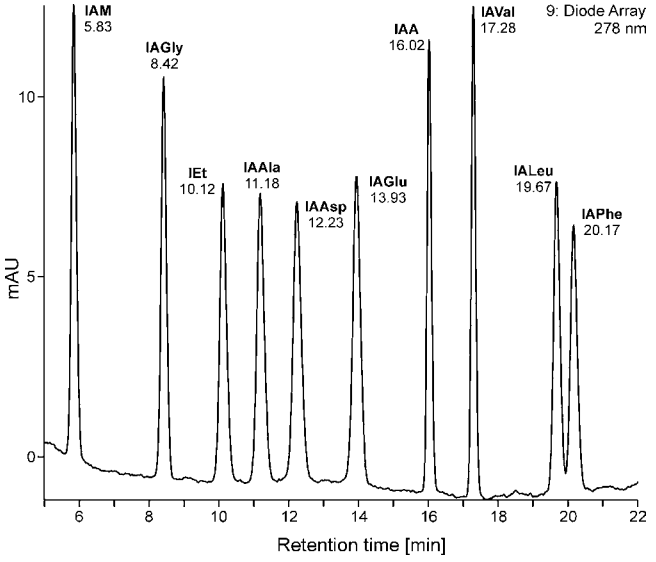

Fig. 1. HPLC–UV chromatogram (278 nm) of methyl esters of IAA, seven IAA conjugates and two other indole compounds retainable by a polyspecific anti-IAA immunoaffinity extraction: Indole-3-acetamide (IAM) and indole-3-ethanol (IEt).

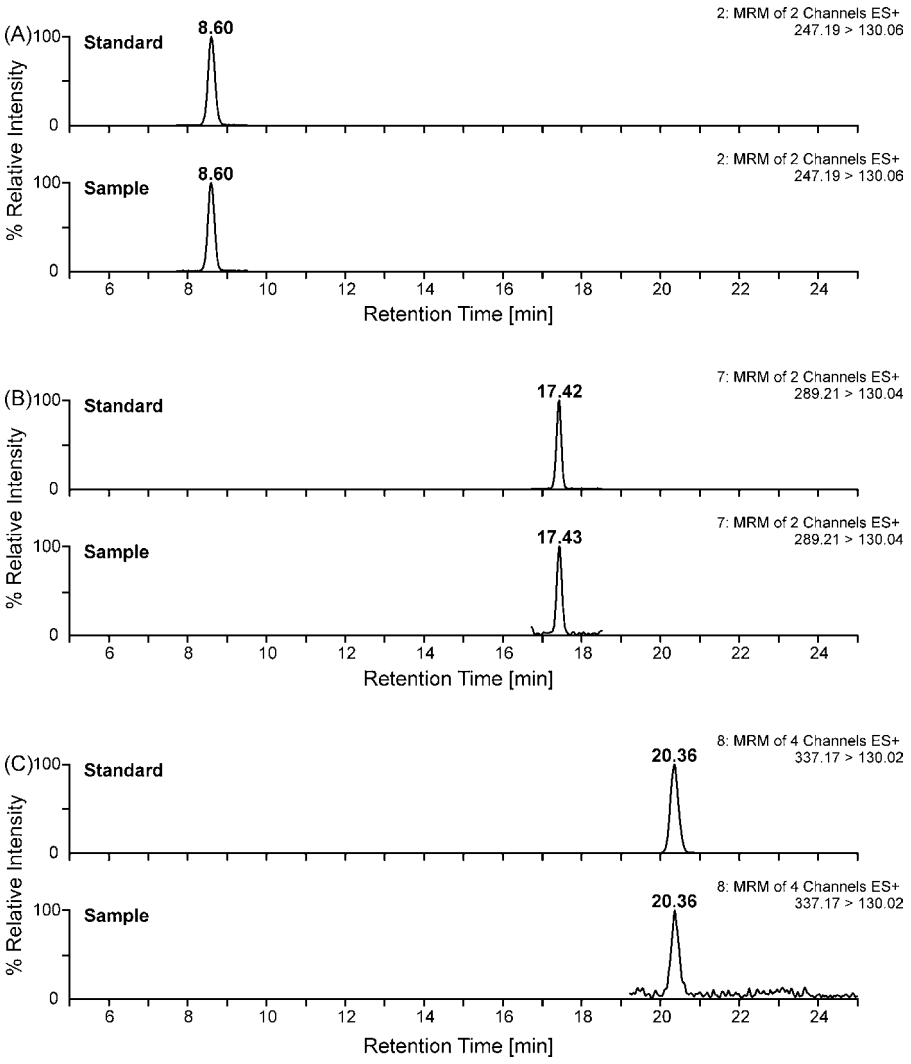

Fig. 2. Chromatograms of the newly discovered IAA amino acid conjugates compared with chromatograms of the corresponding authentic compounds: IAGly (A), IAVal (B) and IAPhe (C).

Prior to immunoaffinity purification, the sample was dissolved in 50 μl of ethanol (70%; v/v) and 450 μl of phosphate buffer (20 mM NaH_2PO_4; 15 mM NaCl; pH 7.2) and passed through a pre-column containing gel with immobilized BSA. The pre-column was then washed with 0.5 ml phosphate buffer and pooled effluent was applied on an immunoaffinity column with immobilized polyspecific rabbit polyclonal antibody against IAA. The application of the solution was repeated five-times. The immunoaffinity column was then washed three-times with 3 ml of H_2O and the analyte was subsequently eluted with 3 ml of methanol (−20 °C). The eluate was evaporated to dryness under nitrogen (40 °C).

Final analysis was done by HPLC coupled to tandem MS/MS detection with the use of a triple-quadrupole mass spectrometer. Separation was performed on an Acquity UPLC System (Waters) equipped with a Symmetry C18 column (5 μm, 2.1 mm × 150 mm; Waters) at 30 °C by gradient elution with a flow-rate of 250 μl min^{-1}. The mobile phase consisted of 10 mM aqueous formic acid and methanol containing 10 mM formic acid. The content of methanol kept at 25% during the first minute was then increased linearly to 38% (at 7 min), 40% (12 min), 58% (15 min), and 60% (26 min). The effluent was introduced into the ion source of a Quatro micro API tandem quadrupole mass spectrometer (Waters). The capillary voltage was set to +500 V, desolvation gas flow was 500 l h^{-1}, desolvation temperature was 350 °C and source block temperature was 100 °C. Other settings of the instruments, together with multiple reaction monitoring (MRM) transitions of individual compounds, are listed in Table 1.

3. Results and discussion

3.1. Anti-auxin polyspecific immunoaffinity purification

Immuno-based sample preparation techniques have extraordinary potential for trace analysis [18] and have been successfully utilized in analytical protocols used for quantification of various phytohormones including IAA [19,20], cytokinins [10,21–25] and abscisic acid [20,26,27].

In our study of IAA and its conjugates, we exploited the polyspecificity of anti-IAA antibodies. These were obtained by immunizing rabbits with a BSA conjugate in which IAA was linked to the protein through its carboxyl group (IAA-C1′-BSA). Such antibodies are capable of interacting specifically not only with IAA itself but also with other indole compounds substituted in position 3, such as indole-3-acetamide and indole-3-acetonitrile [28]. Furthermore, such antibodies have been reported [16] to cross-react in radioimmunoassays with the IAA homologues indole-3-propionic and indole-3-butyric acid and with IAA conjugated with aspartic

acid. However, this relatively high cross-reactivity is contingent on the free acids being transformed into their methyl esters. Hence, it is necessary to treat samples with diazomethane prior to analysis by an immunomethod [16,29].

An extensive study of our rabbit anti-IAA antibodies, performed by ELISA, has corroborated their polyspecificity. Compared to methylated IAA, cross-reactivities of 3-substituted indoles, including indole-3-acetamide, indole-3-acetonitrile, indole-3-ethanol and methyl esters of IAA conjugates, range typically between 85% and 210%. This allows the antibodies to be used in specific immunoaffinity purification of diverse IAA derivatives. We successfully used immunoaffinity extraction based on these antibodies to isolate and subsequently quantify IAA conjugates with Ala, Asp, Glu and Leu. Furthermore, we succeeded in isolating from a vascular plant and identifying novel naturally occurring IAA conjugates with the three amino acids: Gly, Val and Phe.

3.2. HPLC–MS/MS analysis

Using a linear methanol gradient acidified with formic acid, we achieved base-line separation (see Fig. 1) of a mixture containing methyl esters of IAA and seven IAA conjugates and also two other indole derivatives retainable by the developed immunoaffinity extraction: indole-3-acetamide and indole-3-ethanol (data not shown). In Table 1 the methyl esters are listed in order of their retention time.

Positive ESI tandem mass detection was run in multiple reaction monitoring (MRM) mode. Diagnostic transitions were similar to those used by Kowalczyk and Sandberg [12]: The parent ion of the protonated molecule $[M+H]^+$ fragments to a quinolinium ion of m/z 130.

To cover various recoveries of individual analytes, which may vary depending on the plant material being analyzed, we used internal standards corresponding to each of the studied compounds. All the standards comprised the indole skeleton labeled with five deuterium atoms; additionally, in standards of the conjugates the amino acid was ^{15}N-labeled. Thus values of m/z of internal standard parent ion differed by six units (or by five in the case of IAA) from those of the corresponding unlabeled compounds. Collision-induced dissociation yielded fragments of m/z = 135, 134 and 133. We used the fragment of m/z 134, the most intensive one, to perform MRM detection of labeled IAA and its conjugates. We achieved limits of detection (for signal-to-noise ratio of 3) around 1 fmol per injection. Detailed parameters together with other MS settings are listed in Table 1.

3.3. Identification of novel IAA conjugates

A recent study by Staswick et al. [30] has revealed the capability of *Arabidopsis* GH3 enzymes to catalyze synthesis of IAA conjugates with a wide range of amino acids, thus raising the question of whether IAA conjugates other than those with Ala, Asp, Glu and Leu exist. The question gains significance as Ludwig-Müller et al. [31] have very recently identified IAA conjugate with Val in non-vascular plant (moss *Physcomitrella patens*) grown on medium supplemented with IAA.

In our screening for putative IAA conjugates we concentrated on immature seeds of the Christmas rose (*Helleborus niger* L.), in which we had previously detected very high levels of free IAA (around 10 nmol g^{-1} FW). Alongside IAA and the conjugates described earlier [12] we identified novel IAA conjugates with Gly, Phe and Val.

In Fig. 2, chromatograms of newly discovered IAA conjugates are compared with chromatograms of the corresponding authentic compounds. Each pair of chromatograms is characterized by practically identical retention times of peaks for the standard and for the putative compound isolated from plant material. Each pair of chromatograms was obtained in MRM mode where the m/z of the parent ion corresponds to the m/z of the pseudomolecular ion $[M+H]^+$ of the respective IAA conjugate, while an m/z equal to 130 for the daughter ion corresponds to an m/z of the quinolinium ion, which is typical of fragmentation of IAA and its conjugates.

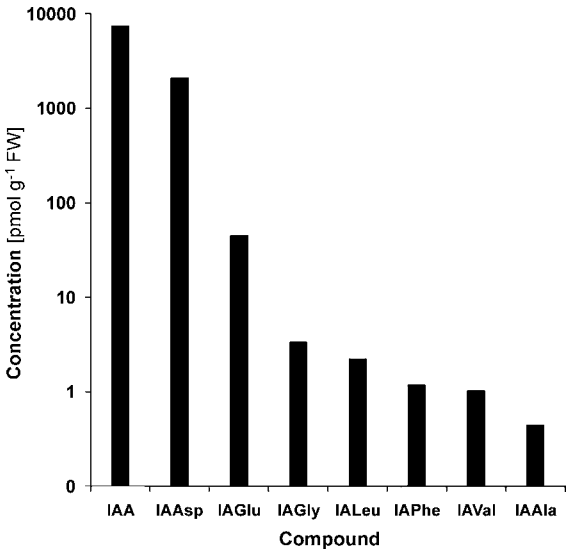

Fig. 3. Semi-logarithmic overview of IAA and seven IAA amino acid conjugates quantified in immature seeds of the Christmas rose (*Helleborus niger* L.).

The identity of the conjugates analyzed in *H. niger* seeds seems to be further verified by the fact that they passed through a preceding immunoaffinity purification designed to interact specifically with (3-substituted) indole skeleton. Thus, to our knowledge, for the first time naturally occurring IAA conjugates with Gly, Phe and Val have been identified in vascular plant.

3.4. Quantification of IAA and its conjugates in milligram amounts of plant material

Combination of the highly specific immunoaffinity extraction described above and a sensitive and selective LC–MS/MS – together with the application of internal standards for each of the studied compounds at the initial phase of sample processing – allowed us to reliably quantify IAA and a wide spectrum of its amino acid conjugates. Amounts of fresh plant material required for such an analysis typically lie between 25 mg and 40 mg.

On the basis of our previous experience, we supply the analyzed samples with amounts of internal standards corresponding to expected levels of respective native compounds. In a parallel manner we construct calibration curves which cover typical physiological levels of individual analytes in plant material. The curves

Table 2
Indole-3-acetic acid and its amino acid conjugates as quantified by HPLC–MS/MS in immature seeds and pericarp of *Helleborus niger*.

Analyte	Content in plant tissue (pmol g^{-1} FW)[a]	
	Immature seeds	Pericarp
IAA	7378 ± 17	313 ± 16
IAAsp	2089 ± 79	62.5 ± 3.7
IAGlu	44.9 ± 1.2	2.86 ± 0.05
IAGly	3.35 ± 0.19	n.d.[b]
IALeu	2.24 ± 0.11	1.60 ± 0.14
IAPhe	1.17 ± 0.17	n.d.
IAVal	1.02 ± 0.13	n.d.
IAAla	0.44 ± 0.02	n.d.

[a] Mean value of three independent analyses ± standard deviation.
[b] n.d.: not detected.

extend to a little under three orders of magnitude, with good linearity and correlation coefficients (R^2) between 0.9992 and 0.9998 (see Table 1).

Fig. 3 shows the results of an analysis of IAA and its conjugates performed on immature seeds of *H. niger*. The semi-logarithmic plot of the results demonstrates clearly the vast difference (of about four orders of magnitude) between the contents of free IAA (7.5 nmol g^{-1} fresh weight) and IAAla, the least abundant of quantified conjugates (0.44 pmol g^{-1} fresh weight). The value found for IAA itself is comparable to that estimated by Matsuda et al. [14], who analyzed auxins in seeds of rice (*O. sativa*).

Detailed results of our quantification are listed in Table 2 together with the results obtained by analysis of *H. niger* pericarp (husk). Levels of IAA and its conjugates with Asp, Glu and Leu in the pericarp were remarkably lower than those found in seeds, while conjugates with Ala, Gly, Phe and Val were below their limits of detection.

4. Conclusion

We developed a highly specific protocol for analysis of IAA and its amino acid conjugates in small quantities (about 30 mg) of fresh plant material. The protocol is based on a combination of polyspecific anti-IAA immunoaffinity extraction and a sensitive LC–MS/MS method. We successfully used the protocol for quantification of IAA and its conjugates in immature seeds and in the pericarp of *H. niger*. Furthermore, we isolated three novel naturally occurring conjugates of IAA with Gly, Phe and Val and confirmed their identity by analysis of corresponding synthesized standards.

Differential pulse voltammetry
Biosensor
Hematoxylin

ABSTRACT

A highly efficient noradrenalin (NA) biosensor was fabricated on the basis of hematoxylin electrodeposited on a glassy carbon electrode, GCE. The cyclic voltammetric responses of the hematoxylin biosensor at various scan rates, which were obtained in a 0.25 mmol L^{-1} NA solution, showed the characteristic shape typical of an EC_{cat} process. The kinetic parameters such as electron transfer coefficient, α, the catalytic electron transfer rate constant, k', and the standard catalytic electron transfer rate constant, k^0, for oxidation of NA at the hematoxylin biosensor surface were estimated using cyclic and RDE voltammetry. The peaks of differential pulse voltammetric (DPV) for NA and acetaminophen (AC) oxidation at the hematoxylin biosensor surface were clearly separated from each other when they co-exited in the physiological pH (pH 7.0). It was, therefore, possible to simultaneously determine NA and AC in the samples at a hematoxylin biosensor. Linear calibration curves were obtained for 5.0×10^{-1} to 65.40 μmol L^{-1} and 65.40–274.20 μmol L^{-1} of NA, and for 12.00–59.10 μmol L^{-1} and 59.10–261.70 μmol L^{-1} of AC. The sensitivities of the biosensor to NA in the absence and presence of AC were found virtually the same, which indicates the fact that the electrocatalytic oxidation processes of NA are independent of AC and, therefore, simultaneous or independent measurements of the two analytes (NA and AC) are possible without any interference. The results of 16 successive measurements show an average voltammetric peak current of 1.13 ± 0.03 μA for an electrolyte solution containing 5.00 μmol L^{-1} NA. The hematoxylin biosensor has been satisfactorily used for the determination of NA and AC in pharmaceutical formulations. The results obtained, using the biosensor, are in very good agreement with those declared in the label of pharmaceutical inhalation products.

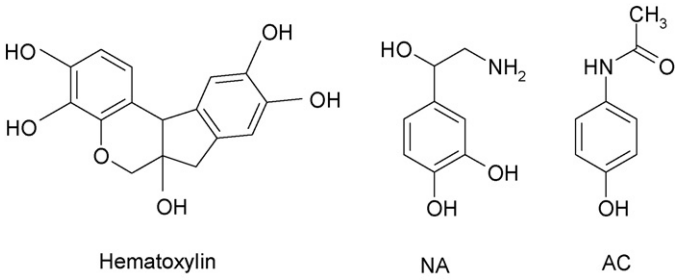
1. Introduction



The chemical modifications of bare electrodes with a thin film of a suitable electroactive species offer significant advantages in the design and development of electrochemical sensors and biosensors. In practice, electrode surface modification has been tried as a means of reducing the overvoltage and overcoming the slow kinetics of many electrode processes [1–4]. A further advantage of chemically modified electrodes is that they are usually less exposed to surface fouling than bare electrodes are. Also, modified electrodes can sometimes separate the electroanalytical signals of solution components whereas, at bare electrode surfaces, the signals appear at potentials close to each other [5–11].

The electrochemical determination of biomolecules has been intensively studied over the past two decades. Noradrenalin (NA) is a very important catecholamine neurotransmitter in the mammalian central nervous system. Many diseases are related to the changes of NA concentration. Thus, the determination of its concentrations in biological systems provides useful information. The determination of NA is usually executed by high-performance liquid chromatography [12–14], gas chromatography [15], ion chromatography [16], capillary electrophoresis [17], and spectrophotometry [18]. NA is also an electroactive compound that can be detected by electrochemical oxidation on various electrodes. The electrochemical oxidation of NA has led to the development of useful methods for measuring NA concentrations [7,19–21].

In addition, acetaminophen (AC) is a widely used analgesic antipyretic drug with actions similar to aspirin. It is a suitable alternative for the patients who are sensitive to aspirin and is safe up to therapeutic doses. Unfortunately, easy availability has resulted in its increased use in attempted suicides. Hence, the need has arisen for the development of rapid and reliable methods for the determination of AC concentration. Many methods have been used for the determination of AC in pharmaceutical formulations and biological fluids including titrimetry [22], UV–vis spectrophotometry [23,24], spectrofluorimetry [25], near infrared transmittance spectroscopy [26], and chromatography [27,28]. Also, electrochemical methods

Scheme 1. Structures of hematoxylin, noradrenalin (NA) and acetaminophen (AC).

have attracted much attention because of their quick response, high sensitivity, as well as ability to miniaturize [29–33].

It is known that on a bare electrode, the oxidation peaks of NA and AC are nearly at the same potential, which results in overlapped voltammetric responses making their discrimination highly difficult. Therefore, the establishment of a simple, economical, and accurate analytical method for the simultaneous determination of NA and AC would be useful to medical manufacturers.

Although there are some studies on NA [7,19–21] or AC [29–33] electrochemical oxidation alone, to the best of our knowledge there are no reports about the simultaneous determination of NA and AC using electrochemical or other techniques in the literature. A published paper has reported that AC administrated in high doses results in increased serotonin (5-HT) levels in rat forebrains [34]; 5-HT is known to play a role in NA release in the brain [35]. Also, researchers have investigated the effect of AC and aspirin on the brain [36] and the posterior cortex [37]. The results show that AC administration alone significantly increase NA levels in the forebrain [36] and the posterior cortex [37]. Since so many over-the-counter analgesic preparations contain AC, we decided to investigate the simultaneous determination of NA and AC by electrocatalytic oxidation. Also, there are a few reports concerning the electrocatalytic activity or electrochemical properties of hematoxylin [38–40]. As a follow-up of our studies to prepare modified electrodes for the simultaneous determination of important biological compounds [41–43], we employed a hematoxylin biosensor for NA electrocatalytic oxidation and the simultaneous determination of NA and AC in the physiological pH (pH 7.0). Our findings indicate that a hematoxylin biosensor offers several distinct advantages including extraordinary stability, high surface charge transfer rate constant, and good limit of detection for NA. Differential pulse voltammetry (DPV) was also used to evaluate the analytical performance of the biosensor in quantification of NA in the presence of AC. Finally, to evaluate the utility of the hematoxylin biosensor for analytical applications, it was used for the simultaneous voltammetric determination of NA and AC in real samples.

2. Experimental

2.1. Reagents and apparatus

NA, 4-(2-amino-1-hydroxyethyl)benzene-1,2-diol hydrochloride (see Scheme 1 for structure) was purchased from Aldrich and used without purification. Hematoxylin and AC, 4′-hydroxyacetanilide (see Scheme 1 for their structures) and other reagents were of analytical grade from Merck and used as received. NA injection solution (from Bio&Pharma Companies, Brussels, Belgium), AC oral solution and AC tablet (from Pharma Chemi, Iran) were purchased in a local drugstore. All the solutions were prepared with doubly distilled water. NA and AC solutions were prepared just prior to use.

All the electrochemical experiments were carried out using a potentiostat PGSTAT 30 model from Autolab (Ecochemie, Netherlands), interfaced with a personal computer. The geometrical area of the bare glassy carbon working electrode (Metrohm, Switzerland) was 0.031 cm^2. All the electrochemical experiments were carried out in a conventional three-electrode cell at room temperature. A platinum electrode and a saturated calomel electrode (SCE) were used as the counter and reference electrodes respectively. All the potentials were reported with respect to this reference electrode. pH was measured with a Metrohm model 691 pH/mV meter. Also, the experiments were carried out inside a Faraday cage at room temperature (ca. 25 °C).

2.2. Preparation of the hematoxylin biosensor

The glassy carbon electrode, GCE, was first polished mechanically with 0.05 μm alumina in water slurry using a polishing cloth and then rinsed with doubly distilled water. The electrochemical activation of the electrode was performed by a continuous potential cycling from −1.4 to 1.6 V at a sweep rate of 100 mV s^{-1} in a sodium bicarbonate (0.1 mol L^{-1}) solution until a stable voltammogram was obtained. For modification, the activated electrode was placed in a 0.10 mmol L^{-1} solution of hematoxylin in a 0.15 mol L^{-1} phosphate buffer (pH 7.0), and it was modified by eight cycles of potential sweep between −0.4 and 0.5 V at 50 mV s^{-1}.

3. Results and discussion

3.1. Electrochemical behavior of the hematoxylin biosensor

The mechanism of electrodeposition of *o*- or *p*-hydroquinone derivatives, such as hematoxylin, as modifiers on the surface of an activated GCE has already been discussed [44,45]. Indeed, electrochemical treatment of an electrode surface leads to the formation of some reactive functional groups which can react as nucleophiles with the *o*-quinone produced during the electro-oxidation of the modifier. Fig. 1A shows the cyclic voltammograms of a hematoxylin biosensor in a 0.15 mol L^{-1} phosphate buffer solution (pH 7.0) as the supporting electrolyte at various scan rates. When the potential was scanned between −30 and 300 mV, a surface immobilized redox couple with a formal potential ($E^{0'}$) value of 104 mV was observed. In addition, the formal potential, $E^{0'}$, was almost independent of the potential scan rate for sweep rates ranging from 10 mV to 2000 mV s^{-1}, suggesting facile charge transfer kinetics over this range of sweep rate. The peak-to-peak potential separation ($\Delta E_p = E_{pa} - E_{pc}$) was small, and about 70 mV for the sweep rates below 1000 mV s^{-1}. Also, the electrochemical responses of the biosensor were those anticipated for a surface-confined redox couple because the anodic and cathodic peak currents were directly proportional to the scan rate (not shown), as predicted for the deposited chemical species at the electrode surface. The ratio of cathodic to anodic peak currents at various scan rates was almost constant. The electron transfer coefficient, α, between the electrode and the surface-confined redox couple can be evaluated in cyclic voltammetry from the variation of the anodic and cathodic peak potentials with the logarithm of scan rates, according to the method described by Laviron [46]. For high scan rates, this theory predicts a linear dependence of E_p upon $\log \nu$, which can be used to extract the kinetic parameter of α from the slope of such plots. We found that for the scan rates above 3 V s^{-1} the value of E_{pa} and E_{pc} were proportional to the $\log \nu$ (Fig. 1B). Using these plots at pH = 7.0, the value of $\alpha = 0.59$ was obtained.

3.2. Electrocatalytic oxidation of NA at the hematoxylin biosensor

The cyclic voltammetric responses of the bare GCE in a 0.15 mol L^{-1} phosphate buffer (pH 7.0), without and with NA in solution, are shown in Fig. 2 (curves c and d respectively). If a

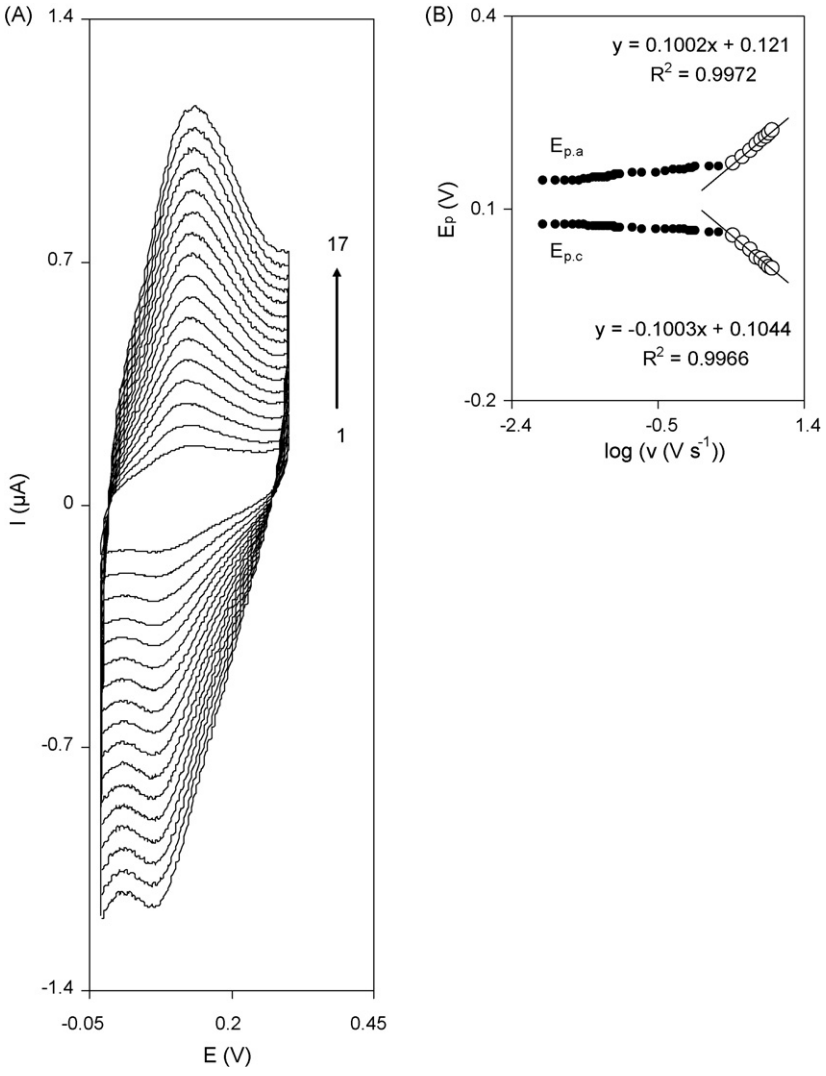

Fig. 1. (A) Cyclic voltammograms of the hematoxylin biosensor in a 0.15 mol L^{-1} phosphate buffer (pH 7.0) at various scan rates. The numbers 1–17 correspond to 10, 15, 20, 25, 30, 35, 40, 45, 50, 55, 60, 65, 70, 75, 80, 85 and 90 mV s^{-1}, respectively. (B) Variation of E_p versus the logarithm of the scan rate.

hematoxylin biosensor is placed into the same NA containing an electrochemical cell, a large anodic peak is observed without a cathodic counterpart (Fig. 2, curve b). That the current observed is associated with the NA oxidation and not only with the oxidation of surface-attached hematoxylin is demonstrated by comparing the current in curve b with that in curve a. Fig. 2, curve a, shows the cyclic voltammetric behavior of the hematoxylin biosensor in a NA-free electrolyte (0.15 mol L^{-1} phosphate buffer with pH 7.0). It is apparent that the anodic current associated with the surface-attached materials is significantly lower than that obtained in the solution containing NA. The anodic peak potential for the oxidation of NA at the hematoxylin biosensor is about 150 mV (Fig. 2, curve b), while NA starts to oxidize at about 570 mV (Fig. 2, curve d) at the bare GCE under identical conditions. So, a decrease in an overpotential of about 420 mV is observed.

The cyclic voltammograms of the hematoxylin biosensor at various scan rates obtained in a 0.15 mol L^{-1} phosphate buffer solution (pH 7.0) containing 0.25 mmol L^{-1} NA are shown in Fig. 3A. As shown in Fig. 3A inset, curve a, the oxidation currents increase linearly with the square root of the scan rate, suggesting that at a sufficient overpotential the reaction is mass transport controlled. From the slope of the I_P versus $v^{1/2}$ plot can be obtained the number of electrons in the overall reaction. According to the following equation for a totally irreversible diffusion controlled processes [47]:

$$I_p = 3.01 \times 10^5 n[(1-\alpha)n_\alpha]^{1/2} A C_b D^{1/2} v^{1/2} \quad (1)$$

and considering $(1-\alpha)n_\alpha = 0.69$ (see below), $D = 5.8 \times 10^{-6}$ cm^2 s^{-1} (D was determined by chronoamperometry), and $A = 0.0314$ cm^2, it is estimated that the total number of electrons involved in the anodic oxidation of NA is $n = 2.1 \cong 2$. Also, the plot of the scan rate-normalized current ($I_p/v^{1/2}$) versus the scan rate (Fig. 3A inset, curve b) exhibits a characteristic shape typical of an EC_{cat} process. These results show that the overall electrochemical oxidation of NA at the biosensor might be controlled by the cross exchange process between the redox site of the hematoxylin and the diffusion of NA. Under these conditions for EC catalytic mechanism, Andrieux and Saveant theoretical model [48] can be used to calculate the catalytic rate constant between NA and hematoxylin, k'. According to the approach of Andrieux and Saveant and using Fig. 1 in their theoretical paper [48], the average value of k' was calculated to be $(3.64 \pm 0.49) \times 10^{-3}$ cm s^{-1}.

The inset of Fig. 3B shows a Tafel plot that was drawn from the data of the rising part of the current–voltage curve recorded at a scan rate of 30 mV s^{-1} (Fig. 3B). This part of voltammogram, known as Tafel region, is affected by the electron transfer kinetics between the substrate (NA) and the surface-confined hematoxylin,

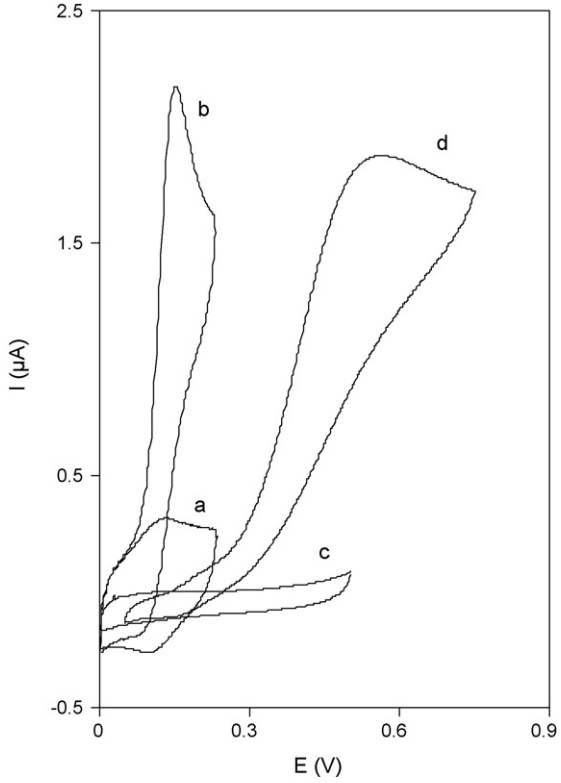

Fig. 2. Cyclic voltammograms of the hematoxylin biosensor in a 0.15 mol L^{-1} phosphate buffer (pH 7.0) solution in the absence (a) and presence (b) of 0.15 mmol L^{-1} NA. (c) As (a) and (d) as (b) for a bare GCE. In all cases the scan rate was 20 mV s^{-1}.

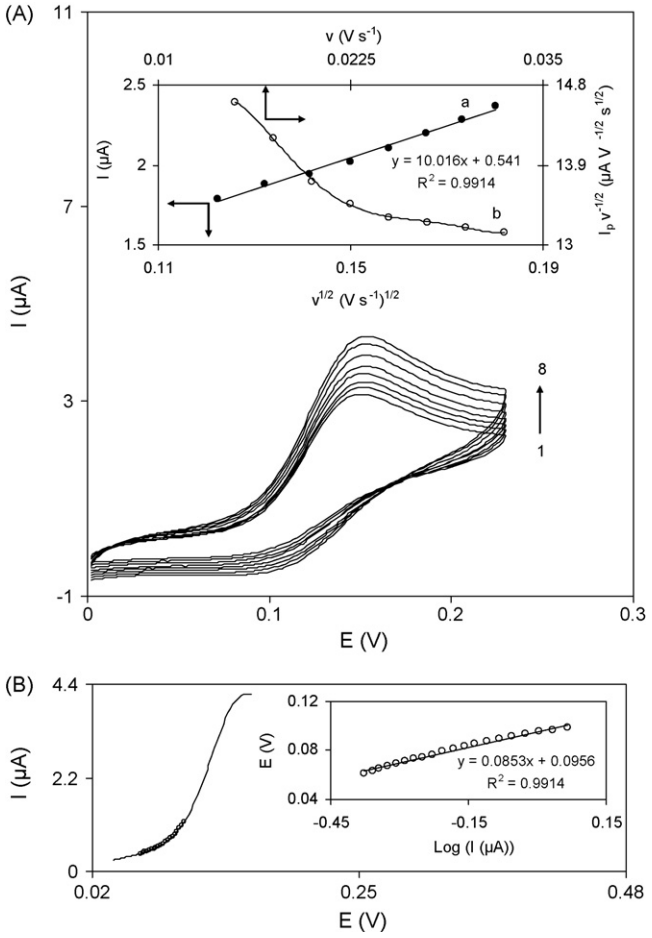

Fig. 3. (A) Cyclic voltammograms of the hematoxylin biosensor in a 0.15 mol L^{-1} phosphate buffer (pH 7.0) containing 0.25 mmol L^{-1} NA at different scan rates. The numbers of 1–8 correspond to 15, 17.5, 20, 22.5, 25, 27.5, 30 and 32.5 mV s^{-1}, respectively. Inset shows the plot (a) variation of the electrocatalytic peak current (I_p) with the square root of sweep rate and (b) variation of the sweep rate-normalized current ($I_p/v^{-1/2}$) with the sweep rate. (B) Linear sweep voltammogram recorded at 30 mV s^{-1}. Inset shows the Tafel plot derived from the linear sweep voltammogram.

assuming the deprotonation of the substrate as a sufficiently fast step. In this condition, the number of electrons involved in the rate-determining step can be estimated from the slope of Tafel plot. A slope 0.0853 V decade^{-1} is obtained indicating a one-electron transfer in the rate-determining step of the electron transfer process, assuming a charge transfer coefficient of $\alpha = 0.31$ [49].

The catalytic oxidation of NA with a hematoxylin biosensor was also studied by chronoamperometry. The chronoamperometric measurements of different concentrations of NA at a biosensor were done by setting the working electrode potential at 200 mV. In chronoamperometric studies, based on Cottrell equation [49], we have determined the diffusion coefficient of NA. Fig. 4A shows the experimental plots of I verses $t^{-1/2}$ with the best fit for different concentrations of NA employed. The slopes of the resulting straight line were then plotted versus the NA concentration (Fig. 4B), from whose slope we calculated a diffusion coefficient of 5.8×10^{-6} cm^2 s^{-1} for NA.

In order to elucidate the kinetics of NA oxidation at a hematoxylin biosensor, RDE measurements were performed at different rotation speeds in a 0.15 M phosphate buffer (pH 7.0) containing various concentrations of NA. Fig. 5 represents a typical example of RDE voltammograms of a 0.50 mmol L^{-1} NA at the biosensor as a function of the electrode rotation rates. Levich plots obtained at 220 mV for different concentrations of NA are shown in Fig. 5, inset A. According to Levich plots, the current increases with increasing electrode rotation speed but was found to be nonlinear. The clear lack of linearity immediately suggests that the reaction is limited by kinetics and not by transport [49]. In addition, we again conclude that the reaction between NA and the electrodeposited hematoxylin is the sole rate-limiting step [50]. In such cases, the currents are conveniently analyzed by plots of I^{-1} versus $\omega^{-1/2}$ [49]. Fig. 5, inset B, presents such plots (so-called Koutecky–Levich plots) and, in this case, well behaved linear responses are obtained. The value of catalytic reaction rate constant, k', between the oxidized form of the deposited hematoxylin and NA can be calculated from the intercepts of Koutecky–Levich plots [49]. From the values of the intercept of various plots, the mean values of k' dependent on potentials of 140, 160, 180, 200, and 220 mV are calculated and the results are shown in Table 1. As it can be seen in Fig. 5, inset C, and Table 1, the rate constant, k', is strongly potential dependent and k' increases with the increase of the potential which is considered for obtaining Koutecky–Levich plots. The kinetic parameters of the standard heterogeneous rate constant, k^0, and transfer coefficient, α, can be evaluated from the intercept and the slope of the plot of $\ln k'$ versus $E - E^{0'}$ (Fig. 5, inset C), according to the following equation described in [49]:

$$k'(E) = k' = k^0 \exp\left[\frac{n_\alpha(1-\alpha)F(E-E^{0'})}{RT}\right] \quad (2)$$

where E and $E^{0'}$ are the potentials which are considered for the obtained Koutecky–Levich plot and the formal potential of

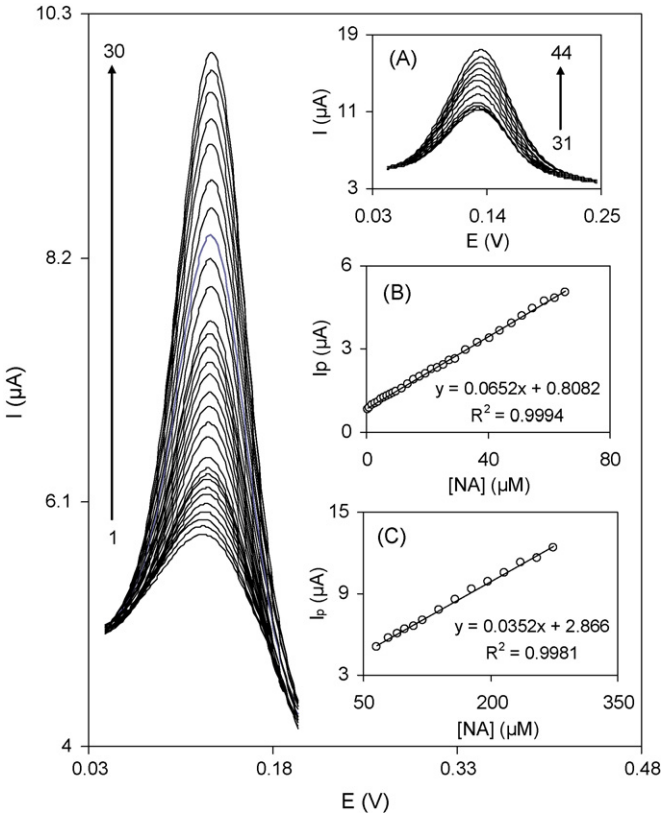

Fig. 6. Differential pulse voltammograms of the hematoxylin biosensor in a 0.15 mol L^{-1} phosphate buffer solution (pH 7.0) containing different concentrations of NA. The numbers of 1–30 correspond to 5.0×10^{-1} to 65.40 μmol L^{-1} of NA. Insets: (A) DPVs of the hematoxylin biosensor in solution containing 65.40–274.20 μmol L^{-1} of NA. (B) and (C) shows the plots of the electrocatalytic peak current as a function of NA concentration in the range of 5.0×10^{-1} to 65.40 and 65.40–274.20 μmol L^{-1} of NA, respectively.

hematoxylin respectively. The slope of 0.0271 mV^{-1} was obtained, indicating that a one-electron process is involved in the rate-determining step, $n_\alpha = 1$, assuming a charge transfer coefficient of $\alpha = 0.30$. This value of α is very close to that obtained from Tafel plot previously discussed. Also, the value of k^0 is found to be 1.02×10^{-3} cm s^{-1} from the intercept of Fig. 5, inset C. The value obtained for k^0 indicates that the electron transfer between the electrodeposited hematoxylin and NA is fast enough. Thus, hematoxylin can be used as a good electron transfer mediator for NA electrocatalytic oxidation.

3.3. Differential pulse voltammetric detection of NA and AC at the hematoxylin biosensor

The main objective in this study was the development of a biosensor capable of the electrocatalytic oxidation of NA and simultaneous detection of NA and AC. Since differential pulse voltammetry (DPV) has a much higher current sensitivity than cyclic voltammetry, it was used to estimate the lower limit of detection and the linear range of NA. In addition, the charging current contribution to the background current, which is a limiting factor in the analytical determination, is lower in DPV mode. The effects of increasing the concentration of NA on the voltammograms are presented in Fig. 6 (in range of 5.0×10^{-1} to 65.40 μmol L^{-1}) and its inset A (in range of 65.40–274.20 μmol L^{-1}). Also, insets B and C of Fig. 6 clearly show that the plot of the peak current versus the NA concentration is constituted of two linear segments (5.0×10^{-1} to 65.40 μmol L^{-1} and 65.40–274.20 μmol L^{-1}) with different slopes.

Table 2

[a] DPV: differential pulse voltammetry, CV: cyclic voltammetry.

The plot of the average peak current of three replicates of DPVs versus NA concentration in the range of 5.0×10^{-1} to 4.00 μmol L^{-1} (not shown) was used to estimate the lower limit of NA detection at the biosensor. For these low concentrations, a linear correlation with a slope of 0.0673 μA μmol^{-1} L and a correlation coefficient 0.9943 are observed between the measured average current and the NA concentration. From the analysis of these data, we estimate that the lower limit of detection ($X_{\text{l.o.d.}}$) of NA is 0.14 μmol L^{-1} according to the definition $X_{\text{l.o.d.}} = (Y_{\text{l.o.d.}} - Y_{\text{bl.}})/m$ [51]. The lower detection limit of NA obtained in this method is lower than those previously reported for other biosensors [17,52–54]. The average voltammetric peak current and the precision estimated in terms of the coefficient of variation for 16 repeated measurements ($n = 16$) of 5.00 μmol L^{-1} NA at the hematoxylin biosensor were 1.13 ± 0.03 μA and 2.6% respectively. The coefficient of variation value indicates that the biosensor is stable and does not undergo surface fouling during the voltammetric measurements. This also demonstrates the fact that the results obtained at the biosensor are reproducible in analytical applications. In Table 2, some of the response characteristics obtained in this work are compared with those previously reported by others [7,20,21,52,53]. These data show that the responses of the proposed biosensor are superior in most cases to those of the previously reported biosensors.

The next attempt was made to detect NA and AC simultaneously by using a hematoxylin biosensor. Fig. 7 shows the differential pulse voltammetric responses which were gained by varying either the NA (Fig. 7A) or AC (Fig. 7B) concentration while the concentration of the other compound was kept constant. As shown in Fig. 7A, the electrochemical response of NA in the presence of a constant concentration of 5.0×10^{-1} mmol L^{-1} AC increased linearly with the increase of the NA concentration, while the response of AC remaining almost constant. Similarly, Fig. 7B shows DPVs obtained by increasing the concentrations of AC in the presence of 2.0×10^{-1} mmol L^{-1} NA. As it can be seen, an increase in the peak current of AC is observed with increasing AC concentration, while the voltammetric peak of NA is almost unchanged during the oxidation of AC. It can also be noted from these results that the responses to NA and AC at the biosensor are relatively independent. On the other hand, Fig. 7C shows the DPV of a mixture of 1.0×10^{-1} mmol L^{-1} NA and 4.0×10^{-1} mmol L^{-1} AC at the bare GCE. As shown, the bare GCE could not separate the voltammetric signals of NA–AC, and only one broad voltammetric signal at around 304 mV was obtained.

The utilization of the hematoxylin biosensor for the simultaneous determination of NA and AC was demonstrated by simultaneously changing the concentrations of NA and AC. The DP voltammetric results show that the simultaneous determination of NA and AC with two well distinguished anodic peaks at potentials of 127 and 300 mV, corresponding to the oxidation of NA and AC, is possible at the biosensor (Fig. 8). Fig. 8, inset A, shows that the linear range of NA concentration is 7.5×10^{-1} to 65.40 μmol L^{-1}. Also insets B and C of Fig. 8 clearly show that the plot of the peak current versus the AC concentration is constituted of two linear segments of 12.00–59.10 μmol L^{-1} and 59.10–261.70 μmol L^{-1} with different slopes, corresponding to two different ranges of substrate concentration. The decrease of sensitivity (slope) in the second linear range (Fig. 8, inset C) is likely to be due to kinetic limitation. Comparing Fig. 6, inset B, to Fig. 8, inset A, the sensitivities to NA in the absence and presence of AC were found to be 0.0652 (absence of AC) and 0.0697 (presence of AC) μA μmol^{-1} L. It is very interesting to note that the sensitivities of the biosensor to NA in the absence and presence of AC are virtually the same, which indicates the fact that the oxidation processes of NA at the hematoxylin biosensor are independent and, therefore, simultaneous or independent measurements of the two analytes are possible without any interference. If the NA signal was affected by AC, the above-mentioned slopes would be different.

3.4. Application of the hematoxylin biosensor for determination of NA and AC in real samples

The utility of the present hematoxylin biosensor for determination of NA and AC in pharmaceutical formulations was tested by measuring the NA concentration in an injection solution and the AC concentration in an oral solution and tablet samples. The NA injection solution and the AC oral solution were diluted 10^3 and 10^4 times respectively. Also one tablet of AC (0.4356 g), after dissolving in 1 L doubly distilled water was diluted 100 times with a phosphate buffer solution before the measurements. The differential pulse voltammograms of various real samples solutions are shown in curve (a) Fig. 9A–C. The measurements were performed using the calibration plots which are shown in Fig. 8, insets, and the results obtained are listed in Table 3. To authenticate the validity of the results, the samples were spiked with certain amounts of NA and AC at levels similar to those found in the samples themselves. The results in Table 3 show that the relative standard deviations (RSD%) and the recovery rates of the spiked samples were acceptable. Thus, the proposed biosensor can be efficiently used for the simultaneous determination of NA and AC in pharmaceutical samples. The reliability of the proposed biosensor was also evaluated by comparing the obtained results with those declared in the label of the pharmaceutical inhalation products. The data in Table 4 demonstrate that the results obtained by a differential pulse voltammetric method (utilizing the biosensor) are in very good agreement with the values declared in the label of the analytes.

Table 4
Comparison of the total values of NA and AC of various formulations obtained using the hematoxylin biosensor with those declared in the label of the pharmaceutical inhalation products[a].

Samples	Declared value	Found value	RSD (%)
Injection solution of NA (mg mL^{-1})	1.0	0.98	3.1
Oral solution of AC (mg mL^{-1})	24.0	23.37	3.0
Tablet of AC (mg g^{-1})	725.3	724.62	2.9

[a] The total values (average of three measurements) were obtained by multiplying the measured values by the appropriate dilution factor and number of sample assayed was three.

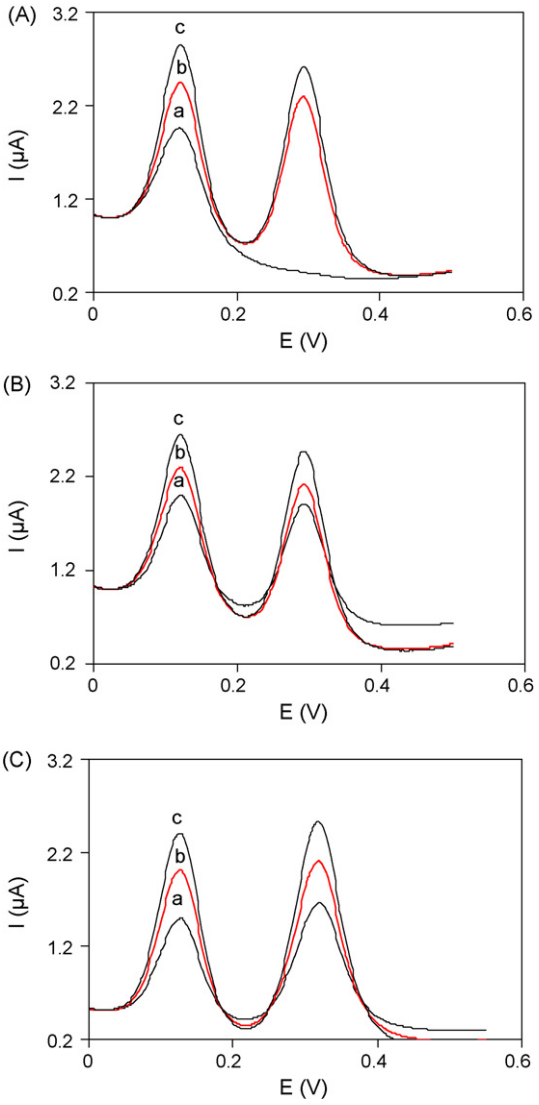

Fig. 9. Voltammograms of (a) are shown the differential pulse voltammograms of the hematoxylin biosensor in a 0.15 mol L^{-1} phosphate buffer solution (pH 7.0) containing a concentration of the real samples which indicated in Table 3 for (A) an NA injection solution, (B) AC oral solution and (C) AC tablet. In all cases, for voltammograms of (b) and (c), different concentrations of NA and AC added to the real samples according to the data which reported in Table 3.

4. Conclusions

In this study, a simple and fast procedure was used for the electrodeposition of hematoxylin on a GCE. The electrodeposited hematoxylin layers on the GCE exhibited excellent electrocatalytic activity toward the electro-oxidation of NA, which appeared as a reduced overpotential and an increase in the peak current. The transfer coefficient, α, the catalytic rate constant, k', the standard catalytic rate constant, k^0, and the overall number of electrons involved in the electrocatalytic oxidation of NA at a hematoxylin biosensor surface were determined using voltammetric methods. The diffusion coefficient of NA was calculated as 5.8×10^{-6} cm^2 s^{-1} for experimental conditions, using chronoamperometric results. The hematoxylin biosensor could successfully separate the voltammetric peaks of NA and AC, which are indistinguishable on a bare GCE. The precision of the differential pulse voltammetry (DPV) method was found to be 2.6% for the replicate determination of a 5.00 μmol L^{-1} solution of NA ($n = 16$). Also, in DPV measurements, two linear calibration ranges were obtained for NA and AC. The sensitivities of NA and AC determination at the biosensor surface were obtained 0.0697 and 0.0255 μA μmol^{-1} L respectively. The proposed hematoxylin biosensor has been applied to the simultaneous determination of NA and AC in an injection solution of NA, an oral solution of AC, and a tablet of AC with satisfactory results. Thus, the reliability and stability of the biosensor offers a good possibility for applying the technique to a routine analysis of NA and AC in pharmaceutical formulations.

Magnetic iron oxide nanoparticles
Fluoride
Solid phase extraction
Spectrophotometric determination

ABSTRACT

A new, sensitive, fast and simple method using magnetic iron oxide nanoparticles (MIONs), as an adsorbent has been developed for extraction, preconcentration and determination of traces of fluoride ions. The determination method is based on the discoloration of Fe(III)–SCN complex with extracted fluoride ions which was subsequently monitored spectrophotometrically at λ_{max} = 458 nm. Various parameters affecting the adsorption of fluoride by the MIONs have been investigated, such as pH of the solution, type, volume and concentration of desorbing reagent, amount of adsorbent and interference effects. A linear response for the determination of fluoride was achieved in the concentration range of 0.040–1.250 μg mL^{-1}. The limit of detection (LOD) and limit of quantification (LOQ) for fluoride based on 3 times and 10 times the standard deviation of the blank ($3S_b$, $10S_b$) were 0.015 and 0.042 μg mL^{-1} (n = 20) for fluoride ion, respectively. A preconcentration factor of 50 was achieved in this method. The proposed procedure has been applied for determination of fluoride concentration in various water samples. The results obtained from this method were successfully compared with those provided by standard SPADNS method.

1. Introduction

Fluoride is widely distributed in natural water at low concentrations. In unpolluted fresh and sea waters, it generally exists in the range of 0.01–0.30 and 1.2–1.5 μg mL^{-1}, respectively. A fluoride concentration of approximately 1.0 μg mL^{-1}, in drinking water effectively reduces dental caries without harmful effects on health. Some fluorosis may occur when the fluoride level exceeds the recommended limits [1]. Acute toxicity, generally due to ingestion of fluoride-containing rat poisons, includes gastrointestinal symptoms and neurological signs of hypocalcemia presumably related to the calcium-binding properties of fluoride. Due to the adverse effects of fluoride, the World Health Organization (WHO) has limited the maximum fluoride concentration acceptable in drinking water to 1.5 mg L^{-1} [2]. Therefore continuous monitoring of the fluoride levels in water samples is important to ensure good water quality.

Several analytical methods have been developed and described for fluoride determination in water including potentiometry [3–6], spectrophotometry [7–12], ion chromatography [13,14], fluorometry [15,16], capillary electrophoresis [17] and polarography [18]. Methods based on flow injection analysis have also been reported, using different detection techniques [19–21].

Among all the techniques mentioned above, for both potentiometric methods with fluoride ion selective electrode and standard colorimetric methods proved to be the most popular. Spectrophotometric methods for instance are widely used due to their simplicity, low cost and reliability. In most of these methods, fluoride ions displace organic ligands from colored complexes of metal ions such as zirconium and thorium. However both methods (potentiometric and colorimetric) do suffer from drawback, e.g. interfering effects from ions like sulphate, phosphate, chloride, iron and aluminum and it may be necessary to distill the sample. Thus lengthy distillation process (up to 80 min) is required prior to sample analysis. Additionally, this step is considered hazardous due to the strong acids required throughout the process [1]. Chromatographic methods are also time consuming and expensive to run.

Nanoscale materials have recently utilized in methods development and validation. The unique properties of nanoscale materials offer excellent prospects for designing new methods and instrumentation for chemical analysis [22,23]. Their small particle size will increase the surface area-to-volume ratio thus generating new electrical, magnetic, and optical properties among others [24–26].

Among many nanomaterials investigated, systems made from magnetic iron oxide nanoparticles (MIONs), proved to be useful in variety applications such as biomedicine, bioseparation and waste water treatment [27–31]. Moreover, these nanoparticles are known to be capable of sorption of some ligands, dyes, metal ions, anions, cations and use of them is thus becoming very attractive in a

doi:10.1016/j.talanta.2009.07.045

new area of adsorption, recovery or removal of some ions [32–37]. A major advantage of using MIONs is the possibility of recovering the particles through the application of a magnetic field. This makes magnetic nanoparticles, excellent candidates for combining adsorption properties with ease of phase separation.

In this work, a new method has been proposed for solid phase extraction (SPE) and determination of fluoride, without particular interference, using MIONs as solid phase extractor. Extraction of fluoride ion is based on adsorption of analyte as Fe(III)–fluoride complex on MIONs and desorption by NaOH solution. After neutralization of the alkalinity, the extracted fluoride ions react with colored Fe–SCN complex and form FeF_6^{3-} colorless anionic complex which causes discoloration of Fe–SCN complex. As the amounts of fluoride ions increase, the color of the reaction mixture becomes progressively lighter. The optimum conditions for quantitative recoveries of fluoride were investigated and application of this method for analysis of water samples was established.

This analytical approach provides a selective, sensitive, simple, rapid and low cost colorimetric method for the determination of fluoride in water samples. The results of analysis by the proposed method compared favorably with results by standard SPADNS method [20].

2. Experimental

2.1. Instrumentation

The spectrophotometric measurements were carried out with a Cintra 101 spectrophotometer (GBC SCIENTIFIC EQUIPMENT, Australia). A transmission electron microscope (906E, LEO, Germany), pH-meter (632 Metrohm, Herisau, Switzerland) and a magnet (1.2 T, 10 cm × 5 cm × 2 cm) were used.

2.2. Reagents

All reagents and standards were of analytical grade unless otherwise stated, and all dilutions have been carried out with doubly distilled water. A 1000 μg mL^{-1} stock solution of fluoride was prepared from NaF (Merck, Darmstadt, Germany). Ammonium thiocyanate, ammonia solution (25%, m/m), hydrochloric acid (37%, m/m), acetic acid (99.9%, m/m), $FeCl_3$ (96%, m/m), $FeCl_2{\cdot}4H_2O$ (99.9%, m/m) were purchased from Merck (Darmstadt, Germany). pH adjustments were performed with 0.01–1.0 mol L^{-1} HCl and NaOH solutions. A formate buffer (pH = 2.5) was prepared by mixing formic acid (1.0 mol L^{-1}) and NaOH (1.0 mol L^{-1}) solutions.

2.3. Preparation of MIONs

The magnetite iron oxide nanoparticles, Fe_3O_4, (MIONs) were synthesized by coprecipitation of a stoichiometric mixture of ferrous and ferric chlorides (molar ratio 1:2) in an ammonium hydroxide solution with constant stirring [38]. The nanoparticles were collected by the magnet and thoroughly washed with distilled water to remove excess amounts of ammonium hydroxide. Experimental conditions such as temperature, addition rate of ammonia and stirring rate are of critical parameters that can affect the size of nanoparticles. The average size of the nanoparticles obtained was about 80 nm as shown in the transmission electron micrograph (TEM) image (Fig. 1).

2.4. Extraction and determination procedure

The extraction procedure was carried out in a batch process. A 250 mL solution containing 0.040–1.250 μg mL^{-1} of fluoride ion, 0.75 mL of 0.1 mol L^{-1} $FeCl_3$ and 5 mL of formate buffer solutions was stirred with 0.25 g damped MIONs for 2 min in a beaker.

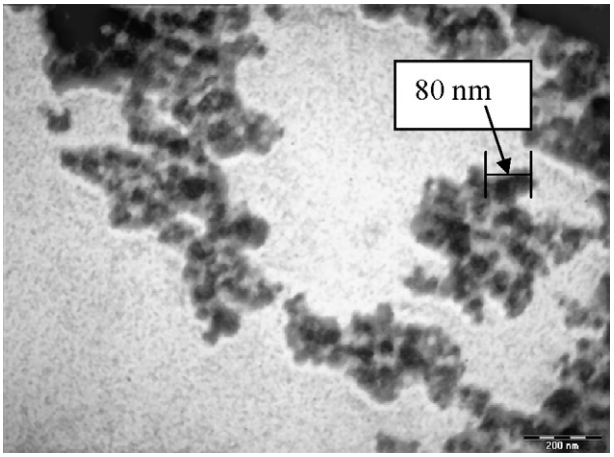

Fig. 1. TEM image of magnetic iron oxide nanoparticles (MIONs).

The beaker was placed on the magnet and nanoparticles were collected. After decanting the supernatant solution the collected MIONs have been washed with 2 mL of 1.0 mol L^{-1} NaOH solution in order to desorb the adsorbed fluoride ions by stirring for 3 min. The alkalinity of the extracted solution was neutralized with 1.1 mL of 2.0 mol L^{-1} of HNO_3 solution and transferred into the 5 mL volumetric flask containing 0.6 mL of reagent mixture (0.3 mL of 0.01 mol L^{-1} $FeCl_3$ solution and 0.3 mL of 0.1 mol L^{-1} NH_4SCN solution) and diluted to the mark with distilled water. Finally the absorption of the Fe–SCN complex solution containing the preconcentrated fluoride ion was measured spectrophotometrically at λ_{max} = 458 nm. A blank solution was also run under the optimized conditions without adding the analyte.

2.5. Method validation

The method was validated for linearity, precision, accuracy, extract recovery and selectivity according to the FDA guideline for validation of bioanalytical methods [39]. Validation runs were conducted on six consecutive days. The absorbance measurements of desorbing solution containing the preconcentrated fluoride amounts of quality control (QC) samples were interpolated from the calibration curve on the same day to give concentrations of the analyte. The results from QC samples in three runs were used to evaluate the precision and accuracy of the method developed.

The calibration curve of F^- ions was constructed using standard desorbing sample solutions at eight concentrations in the range of 0.040–1.250 μg mL^{-1} with least squares linear regression method. The limit of quantification (LOQ) is defined as the lowest concentration on the calibration curve at which an acceptable accuracy (R.E.) within ±20% and a precision (R.S.D.) below 20% can be obtained.

In order to test the reproducibility and repeatability of the proposed method, the intra-day precision and accuracy were evaluated by determining a replicate analysis of QC samples of fluoride ions on the same day. The run consisted of a calibration curve and five replicates of each low, mid, and high concentration quality control samples. For determining the inter-day accuracy and precision, analysis of three batches of QC samples was performed on different days.

The solid phase extraction efficiency of F^- was determined by analyzing five replicates of water sample solutions at three QC concentration levels of F^-. The recovery was calculated by comparing the absorbance of the preconcentrated F^- (spiked into blank water, extracted and 50-fold preconcentrated) in the desorbing solution (1.0 mol L^{-1} NaOH solution) with those obtained from F^- standard solutions in 1.0 mol L^{-1} NaOH solution.

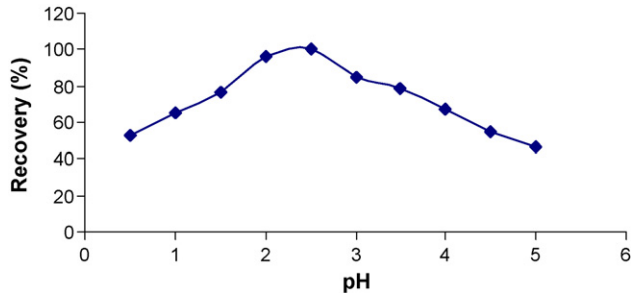

Fig. 2. The effect of pH on the recovery percentage of 0.2 μg mL^{-1} of fluoride ion (conditions—volume of 0.1 mol L^{-1} of $FeCl_3$ solution: 0.75 mL; sample volume: 250 mL; amount of adsorbent: 0.25 g).

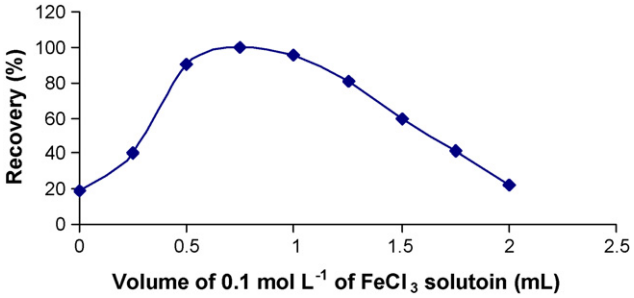

Fig. 3. The effect of Fe(III) concentration in Fe–fluoride complex formation and its sorption on MIONs (conditions—pH = 2.5; sample volume: 250 mL; amount of adsorbent: 0.25 g).

3. Results and discussion

Fe(III)–SCN complex has been known for a long time and used for spectrophotometric determination of Fe(III) ions [40]. On the other hand, primary experiments showed that adsorption of fluoride ions complex (FeF_6^{3-}) on the surface of MIONs took place in acidic solutions. Therefore, the uptake of this complex by MIONs, can take place via the surface complex formation mechanism due to adsorption affinity of surface hydrated ferric oxide at low pHs [36]. The optimum conditions for extraction and determination of traces of fluoride on magnetite nanoparticles were investigated. Preliminary experiments carried out with two levels full factorial designs showed that there is no significant interaction between significant parameters such as pH and adsorbent amount; pH and Fe(III) concentration; adsorbent amount and Fe(III) concentration. Therefore, these parameters were optimized by the one-factor at a time method.

3.1. Effect of pH

The influence of pH on the adsorption of fluoride ion on MIONs was investigated. The pH of each solution was adjusted to values ranging from 1 to 5 with HCl solutions. According to the results (Fig. 2), maximum recovery for the analyte was obtained at pH = 2.5. Additional experiments on type and volume of suitable buffer showed that 5 mL of formate buffer solution (pH = 2.5) gives the best result. However, at pH values higher than 2.5, adsorption of fluoride ion was diminished due to decrease of active surface area of hydrated ferric oxides. At lower pH values, the amount of MIONs was decreased because of high solubility of nanoparticles in stronger acidic solutions and also lower stability of FeF_6^{3-} complex.

3.2. Effect of Fe(III) concentration on the adsorption of F^- on MIONs

Early experiments showed that the adsorption of fluoride ion is very low without the presence of free Fe^{3+} ion in the test solution. It seems that the adsorption of fluoride on nanoparticles occurs via Fe(III)–fluoride complex (FeF_6^{3-}). Therefore, in order to determine the optimum concentration of Fe(III) for quantitative adsorption and recovery of fluoride, the proposed method was applied using different volumes of $FeCl_3$ (0.1 mol L^{-1}) solution. According to Fig. 3, 0.75 mL of 0.1 mol L^{-1} solution of $FeCl_3$ was recommended as optimum reagent volume for quantitative recovery of fluoride ion.

3.3. Effect of the type, concentration and volume of the desorbing solution

In order to choose the best solvent for desorption of the adsorbed fluoride ion on MIONs many reagent solutions were investigated. Among these reagents, NaOH solution provided the maximum recovery. The concentration of the NaOH solution was optimized and the results indicated that highest recovery was obtained by using 1 mol L^{-1} of NaOH solution. Since the desorbing NaOH solution contains high concentration of hydroxyl ions, we propose that OH^- ions can exchange and desorb the analyte (fluoride) from the surface of iron nanoparticles via the formation of highly stable iron hydroxide particles. Subsequent experiments showed that 2 mL of 1 mol L^{-1} solution of NaOH was the optimum volume for desorbing the fluoride from MIONs (Fig. 4). It must be mentioned that higher amounts of NaOH solution cause lower desorption and recovery of fluoride which may be due to formation of colloidal particles of iron oxides (decreasing the active surface area of the nanoparticles) and also entrapment of fluoride between the particles.

3.4. Effect of the adsorbent amount

In order to choose the optimum amount of adsorbent (MIONs) required for quantitative recoveries for fluoride ions, different quantities of pretreated MIONs (damped) were used in this testing ranging between 0.125 and 1.000 g. The maximum recovery percentage (recovery %) was obtained at 0.250 g of MIONs as shown in Fig. 5. Above this point the recovery percentage started to decrease due to high surface area of nanoparticles and the small volume of desorbing solvent. The repeatability of the preparation procedure of MIONs was evaluated by repeating the synthesis of magnetic nanoparticles for 8 times and each time 0.250 g of freshly prepared adsorbent was used for adsorption of fluoride ion. The validity of preparation procedure of magnetic adsorbent was checked by recovery tests carried out for adsorption and desorption of 0.2 and 1.0 μg mL^{-1} of F^-. Mean recovery percent values for 0.2 and 1.0 μg mL^{-1} of F^- test solutions were estimated to be 97.5 and 98.1, respectively. The R.S.D. values for eight adsorp-

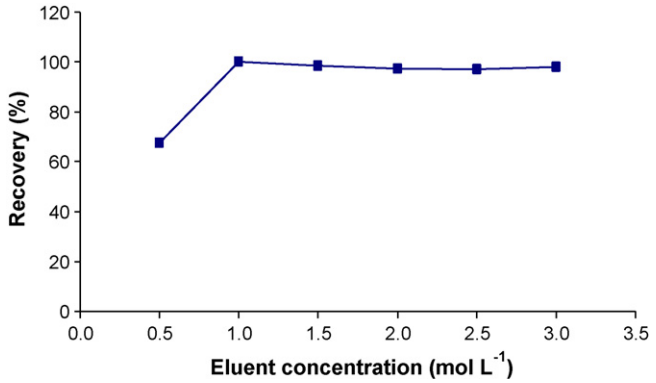

Fig. 4. The effect of NaOH concentration as desorbing eluent on the recovery percentage of 0.2 μg mL^{-1} of fluoride ion (conditions—pH = 2.5; volume of 0.1 mol L^{-1} of $FeCl_3$ solution: 0.75 mL; sample volume: 250 mL; amount of adsorbent: 0.25 g).

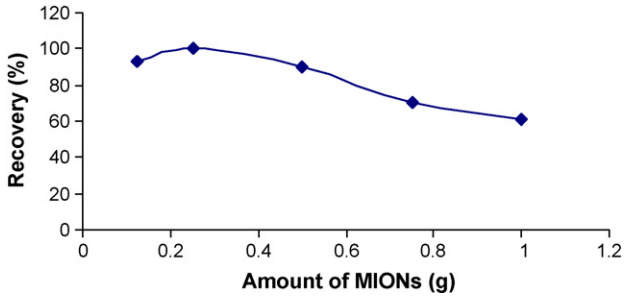

Fig. 5. The effect of the magnetic iron oxide nanoparticles (MIONs) adsorbent amount on the recovery percentage of 0.2 μg mL^{-1} of fluoride ion (conditions—pH = 2.5; volume of 0.1 mol L^{-1} of $FeCl_3$ solution: 0.75 mL; sample volume: 250 mL).

tion and desorption processes with freshly prepared MIONs for two mentioned concentrations are 3.50 and 2.74, respectively.

3.5. The effect of sample volume on the recovery percent and preconcentration factor

In order to carry out solid phase extraction procedure on natural water samples leading to high preconcentration factor, the sample volume need to be optimized. In this case the effect of sample volume on the adsorption of fluoride ions on MIONs was investigated. By using different feed volumes of water samples ranging between 50 and 300 mL, each of which containing fixed amounts of MIONs (0.250 g) and fluoride ions (50 μg), the maximum sample volume with high recovery percentage for the process was determined. As can be seen in Fig. 6, the recoveries of fluoride were quantitative up to 250 mL of sample volume. By applying of 250 mL sample volume under optimum conditions and as stated previously, desorbing of fluoride ions with 2 mL of 1.0 mol L^{-1} NaOH solution and dilution to 5 mL (the final volume of desorbed solution is 5 mL as mentioned in Section 2.4), the preconcentration factor of 50 was obtained.

3.6. Effect of interfering ions

Prior to the application of proposed method on real samples it was vital to investigate the effect of some of the interfering ions on the recovery percentage of fluoride. The adsorption–desorption of fluoride ion was tested in the presence of spiked known amounts of interfering ions. The tolerance limit was defined as the amount of the foreign ion causing a change of ±5% in the absorbance reading. The tolerable limits of interfering ions are given in Table 1. The results showed that most of the investigated ions do not interfere in the adsorption–desorption and determination of traces of fluoride in water samples.

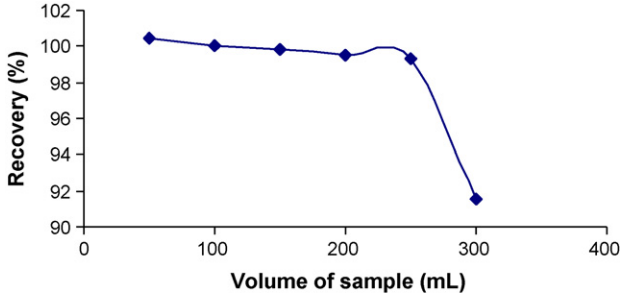

Fig. 6. The effect of sample volume on the recovery percentage of 0.2 μg mL^{-1} of fluoride ion (conditions—pH = 2.5; volume of 0.1 mol L^{-1} of $FeCl_3$ solution: 0.75 mL; desorbent volume: 2 mL of 1 mol L^{-1} of NaOH solution; amount of adsorbent: 0.25 g).

Table 1
The effect of foreign ions on adsorption–desorption and recovery percentage of fluoride ion (0.20 μg mL^{-1}) on MIONs.

Ion	Tolerance limit (mg L^{-1})
Na^+, K^+, Cl^-	5000
NO_3^-, SO_4^{2-}	250
Ca^{2+}, Mg^{2+}, CO_3^{2-}, HPO_4^{2-}	150
Cr^{3+}	20
Al^{3+}	1

Conditions—pH = 2.5; volume of 0.1 mol L^{-1} of $FeCl_3$ solution: 0.75 mL; sample volume: 100 mL; desorbent volume: 2 mL of 1 mol L^{-1} of NaOH solution; amount of adsorbent: 0.25 g.

Table 2
Precision and accuracy data for SPE of F^- from water solution by using MIONs (intra-day: $n = 5$; inter-day: $n = 5$ runs per day, 6 days).

F^- concentration (μg mL^{-1})		R.S.D. (%)		R.E. (%)
Added	Found (mean ± S.D.)	Intra-day	Inter-day	
0.200	0.191 ± 0.007	3.5	7.9	−3.6
0.400	0.415 ± 0.014	3.7	7.6	+3.0
0.800	0.781 ± 0.042	2.2	8.8	−2.6

3.7. Loading capacity

The loading capacity of MIONs was determined by batch method. The adsorbent (0.250 g) was mixed with 250 mL solution containing 5 μg mL^{-1} of fluoride using a stirrer for 1 h period under optimal experimental conditions. After removing the supernatant, the MIONs nanoparticles were collected and washed by 8 mL of 1 mol L^{-1} NaOH solution in four steps prior to the determination of the fluoride concentration. The loading capacity calculated from the measurement process was found to be 0.204 mg g^{-1}.

3.8. Analytical performance and method validation

In order to show the validation of the proposed method, the analytical features of the method such as linear range of the calibration curve, limit of detection (LOD), limit of quantification (LOQ), accuracy and precision were examined. Two calibration curves were obtained for determination of fluoride ion. The calibration graphs were linear in the ranges of

Table 3
Determination of fluoride content and recovery test of fluoride ion in tap (100 mL), river (100 mL) and sea (25 mL) water samples with the proposed method ($n = 5$).

Sample	Added F^- (μg mL^{-1})	Found F^-[a] (μg mL^{-1})	Recovery (%)
Tap water[b]	–	0.141 ± 0.002	–
Tap water	0.1	0.243 ± 0.003	99.7
Tap water	0.2	0.342 ± 0.003	100.1
River water[c]	–	0.139 ± 0.002	–
River water	0.1	0.236 ± 0.002	97.0
River water	0.2	0.343 ± 0.003	99.9
Sea water[d]	–	0.217 ± 0.002	–
Sea water	0.1	0.309 ± 0.003	96.0
Sea water	0.2	0.423 ± 0.003	100.1

Conditions—pH = 2.5; volume of 0.1 mol L^{-1} of $FeCl_3$ solution: 0.75 mL; sample volume: 100 mL; desorbent volume: 2 mL of 1 mol L^{-1} of NaOH solution; amount of adsorbent: 0.25 g.

[a] $x \pm s$ ($n = 5$).

[b] Tap water components: $Ca^{2+} = 52$; $Mg^{2+} = 29$; $Na^+ = 37$; $CO_3^{2-} = 61$; $Cl^- = 24$; $SO_4^{2-} = 25$; $NO_3^- = 9$ μg mL^{-1}; pH = 7.3; EC = 853.

[c] River water main components: $Ca^{2+} = 82$; $Mg^{2+} = 49$; $Na^+ = 68$; $CO_3^{2-} = 91$; $Cl^- = 44$; $SO_4^{2-} = 35$; $NO_3^- = 9$ μg mL^{-1}; pH = 7.1; TDS = 387; EC = 1340.

[d] Sea water main components: $Ca^{2+} = 400$; $Mg^{2+} = 900$; $Na^+ = 11{,}058$; $CO_3^{2-} = 150$; $Br^- = 68$; $Cl^- = 17{,}000$; $SO_4^{2-} = 2400$; $K^+ = 400$ μg mL^{-1}; pH = 7.6; EC > 4500 (25 mL of sea water was diluted to the final volume of 100 mL).

Table 4
Determination of fluoride ion in water samples with the proposed and standard SPADNS methods ($n = 5$).

Water sample	Proposed method ($\mu g\,mL^{-1}$)	Standard SPADNS method ($\mu g\,mL^{-1}$)
Tap water	0.141 ± 0.002	0.143 ± 0.002
River water	0.138 ± 0.003	0.136 ± 0.002
Sea water	0.217 ± 0.002	0.205 ± 0.001

Conditions—pH = 2.5; volume of 0.1 mol L^{-1} of $FeCl_3$ solution: 0.75 mL; sample volume: 100 mL; desorbent volume: 2 mL of 1 mol L^{-1} of NaOH solution; amount of adsorbent: 0.25 g.

0.04–0.20 and 0.20–1.25 $\mu g\,mL^{-1}$ of fluoride ion. The equations for these calibration graphs were $\Delta A = 0.971C_F - 0.0122$ ($R^2 = 0.9967$) and $\Delta A = 0.337C_F + 0.1051$ ($R^2 = 0.9971$), respectively (ΔA is the absorbance difference between blank and sample solution and C_F is the concentration of fluoride in $\mu g\,mL^{-1}$). The limit of detection (LOD) and limit of quantification (LOQ) based on 3 times and 10 times the standard deviation of the blank ($3S_b$, $10S_b$) [41], under optimum experimental conditions were 0.015 and 0.042 $\mu g\,mL^{-1}$ for fluoride ($n = 20$), respectively. The relative standard deviations (R.S.D.) for 0.2 and 0.8 $\mu g\,mL^{-1}$ of fluoride ($n = 10$) were 3.1 and 2.0%, respectively.

Intra- and inter-day precision and accuracy data (showing reproducibility and repeatability terms) for SPE of fluoride by MIONs from quality control (QC) samples are summarized in Table 2. The precision and accuracy of the present method conform to the criteria for the analysis of biological samples according to the guidance of FDA where the R.S.D. determined at each concentration level is required not exceeding 15% (20% for LOQ) and R.E. within ±15% (±20% for LOQ) of the actual value [39].

The extraction recoveries from QC samples of plasma solutions containing low, middle and high concentrations of F^- (0.20, 0.40 and 0.80 $\mu g\,mL^{-1}$) were 96.4 ± 3.6, 97.0 ± 3.0, and 97.4 ± 2.6%, respectively. No significant matrix effect for SPE of F^- by MIONs was observed indicating that no co-adsorbing substance could influence the separation and determination of the analyte.

Table 5
The comparison of the proposed method (magnetic solid phase extraction–spectrophotometric, MSPES) with other reported methods of F^- determination.

Detection method[a]	Detection limit ($\mu g\,mL^{-1}$)	Time of analysis (min)	Recovery (%)	Ref.

3.9. Application on real sample

In order to test the validity of the method, the proposed procedure was applied to determination of fluoride ion in water samples. Recovery tests were used to examine the reliability and accuracy of the method, different amounts of fluoride were spiked into the tap (100 mL), river (100 mL) and sea (25 mL) water samples and fluoride content of each sample was determined at optimum conditions. The fluoride content of different samples and recoveries of added analyte were evaluated and the results showed that it is possible to determine the fluoride concentration in real sample solutions using the proposed method outlined in this investigation (Table 3). The results achieved were comparable with those obtained by the SPADNS method [20] (Table 4).

4. Conclusion

The proposed methodology was simple, sensitive and cheap, especially if more sophisticated techniques such as spectrofluorometry or ion chromatography are not available. In addition, it is notable that both the adsorption and desorption of fluoride are fast and could be completed within 5 min. LOD and linear dynamic range of the method are comparable or better than some of the previously reported methods [3–5,7,8,10–13,15,17–21]. The proposed method was successfully applied for determination of fluoride in water samples and concentration values obtained are in agreement with those of standard SPADNS method (CRM was not available). No use of toxic compounds, short time of the procedure (total time of a single determination is about 8 min) and low LOD are the main advantages of the proposed methods. Table 5 shows a comparison of the proposed method with other reported methods. Some reported values for LOD [6,9,14,18,19] are better than that of the proposed method, but total time of analysis of this method is short. The proposed method shows good and comparable recovery values with respect to other reported methods.

Environmental analysis

ABSTRACT

A centrifugal microanalysis system using spectrophotometric detection has been developed for the determination of nitrite and chromium VI. The system was designed to illustrate the potential of centrifugal microfluidic systems for on-site (field) analysis of waters. The performance was significantly better than manual/visual field test systems and approaches that of bench top systems with detection limits of 0.008 mg L^{-1} NO_2^--N and 0.03 mg L^{-1} Cr^{6+}. The system used pre-loaded solid reagents on the disc, providing ease of use, and could process up to 24 samples simultaneously. Precision was enhanced by the use of a multiwavelength ratiometric blank estimation technique.

1. Introduction

In environmental studies there may be considerable advantage to be had if the analysis can be done on-site. Bulk transport problems are eliminated as well as concerns over changes in chemical form (*e.g.* nitrite to nitrate), degradation, or concentration (*e.g.* VOCs). Additionally, in some cases, contamination risks may be minimized by on-site analysis. There may also be an additional logistic advantage if the analysis can provide immediate feedback to a process at hand, such as a site remediation. Thus there appear to be considerable advantages to the development of analytical techniques which can be used on-site to provide accurate results in a timely manner and at low cost.

Recently, there has been an increase in the development of methods for analyzing samples in the field including: a portable GC for analyzing VOC's [1], a mass spectrometer for field gases [2], and an electrochemical instrument for heavy metal mapping [3]. Field-portable instruments can often be very specialized, require a large financial investment and entail extensive operator training. To address these limitations, user-friendly, rugged systems have been developed that can analyze multiple analytes on-site [4,5]. This is especially important for water and wastewater contaminants as supplying unadulterated, potable, recreational and economic water supplies becomes an ever increasing issue.

For several years, the advantages of small size, minimal reagent consumption, and the low power requirements of microfluidics have been seen as a gateway to meeting the needs for developing field-portable systems. Several review papers discuss the use of microfluidic manifolds for environmental analysis [1,6,7]. The majority of methods available, however, have several drawbacks including the requirement for external sample preparation (*e.g.* pre-concentration, filtering, separation), high power demand, complex procedures or high cost.

In the present work, we demonstrate microanalysis instrumentation that is applicable to a variety of environmentally significant analyses. The technique is demonstrated with two different model analytes, nitrite and hexavalent chromium.

Contamination of natural waters from anthropogenic sources of nitrogen is a widespread problem. Nitrite is often found in industrial effluent as a byproduct of corrosion inhibitors in boiler systems, as a curing agent for meat, and in the production of explosives. It is also used extensively in agriculture for crop fertilization. Excess nitrite nutrients can cause eutrophication of lakes, rivers and estuaries leading to an imbalance in the natural food and life cycles of organisms. Nitrite can also fuel algal blooms that result in high levels of cyanobacteria and other toxic microorganisms leading to dead zones, unusable recreational waterways, and commercial fish kills.

Chromium(VI) is a compound with demonstrated carcinogenic effects for both humans and animals [8]. Natural and drink-

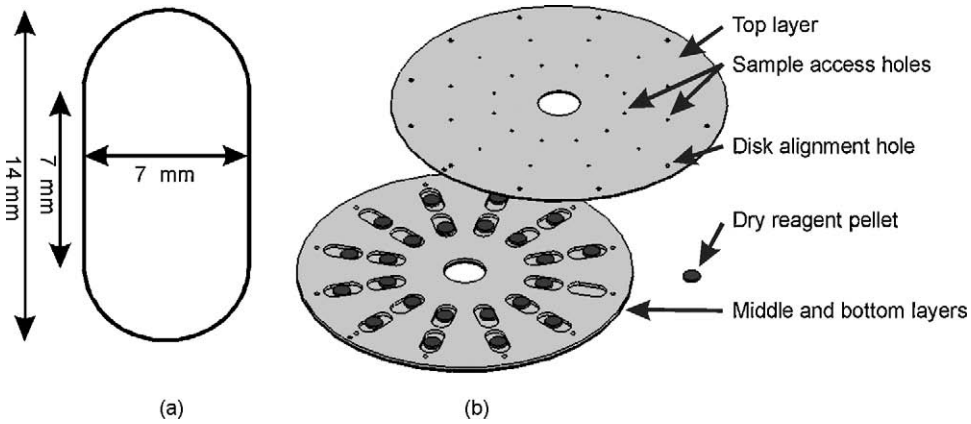

Fig. 1. Disc used for the derivatization and detection of nitrite and/or hexavalent chromium using pressed powder reagent pellets; (a) illustrates the size and dimensions of cells made by machining the center layer of the composite disc, and (b) shows a partially assembled disc. All of the cells, except for one, have the dry reagent pellet in place.

ing waters can become contaminated with Cr(VI) as a result of untreated, or under treated, industrial effluent discharged into waterways. The US EPA has imposed a limit of 0.05 mg L^{-1} for Cr(VI) in drinking water.

This paper demonstrates the detection of both NO_2^- and Cr(VI) on a simple microfluidic/microanalysis centrifugal disc system. Incorporation of measured amounts of dry reagents on the disc allows storage of the disc for long periods of time and facile, quantitative analyte derivatization and measurement. Centrifugal force is used to rapidly mix the dry reagents and sample followed by spectrophotometric detection on the device. The discs can be fabricated inexpensively and provide analytical results that approach those of bench top instruments.

2. Experimental

2.1. Reagents

The modified Griess reaction was used for the detection of nitrite. The reaction consisted of a coupling reaction between chromatropic acid and the diazonium ion formed in acidic solution after a stoichiometric reaction with the nitrite in the sample [9,10]. Chromium(VI) was detected using the classic 1,5-diphenylcarbazide reaction [11,12].

All standards were prepared with deionized water by mass in appropriately cleaned containers. Nitrite solutions were diluted from a 100 mg L^{-1} NO_2^--N (nitrite as nitrogen) stock solution (SPEX, Metuchen, NJ, USA) to appropriate concentrations. Chromium standards were made daily from a 100 mg L^{-1} $K_2Cr_2O_7$ solution (SCP Science, Baie D'Urfé, QC, Canada) in clean, 30 mL plastic bottles. The reagents for both derivatization reactions were purchased from Hach Corporation (Loveland, OH, USA) in the form of sealed foil/plastic "pillow packets". According to the manufacturer, the nitrite reagent (Nitriver3®) consisted of chromatropic acid disodium salt, sodium sulfanilate, potassium pyrosulfate, monobasic potassium phosphate, 1,2-cyclohexanediaminetetraacetic acid trisodium salt. The chromium reagent (Chromaver3®) consisted of potassium pyrosulfate magnesium sulfate and 1,5-diphenylcarbohydrazide.

2.2. Microfluidic/microanalysis disc design

The microfluidic discs were fabricated using a combination of computer numerically controlled (CNC) micro-milling machining and xurography as previously described by Bartholomeusz et al. [13]. The body of the 120 mm diameter microfluidic disc was made using commercially available uncoated polycarbonate discs of two thicknesses: a 1200 μm thick disc used in the manufacture of compact discs (CD) and a 600 μm thick disc normally used in the manufacture of digital video discs (DVD) (U-Tech Media Corporation, Taiwan). These relatively simple microfluidic discs consisted of a 1200 μm thick disc as an internal layer that provided the depth, and hence volume, for the solution reservoirs. The top and bottom layers/covers were made using the 600 μm thick discs to reduce the overall thickness and weight of the system and minimized the optical window thickness. The disc was assembled using 2 alignment holes and sealed using 101.6 μm thick pressure sensitive acrylic adhesive layers (FLEXcon, Spencer, MA, USA) by cold pressing with a Sidewinder Roller Laminator (Desert Laminator, Palm Springs, CA, USA). Considerable additional detail on aspects of the design and experiments is available elsewhere [14].

The disc comprised 24 individual cells with injection holes (Fig. 1a). The reaction/detection cell consisted of two 7 mm diameter half-circles connected by a 7 mm × 7 mm square. The nominal sample pathlength for spectroscopic measurements was 1400 μm (a 1200 μm thick disc plus two 101.6 μm thick adhesive layers) but variances in disc construction and sealing, may introduce a few percent error in the pathlength and necessitates calibration with standard solutions on each disc.

A pellet containing all the reagents needed for analysis was inserted into the disc prior to sealing (Fig. 1b). The metal surfaces of the pellet press were either covered with Parafilm or replaced with

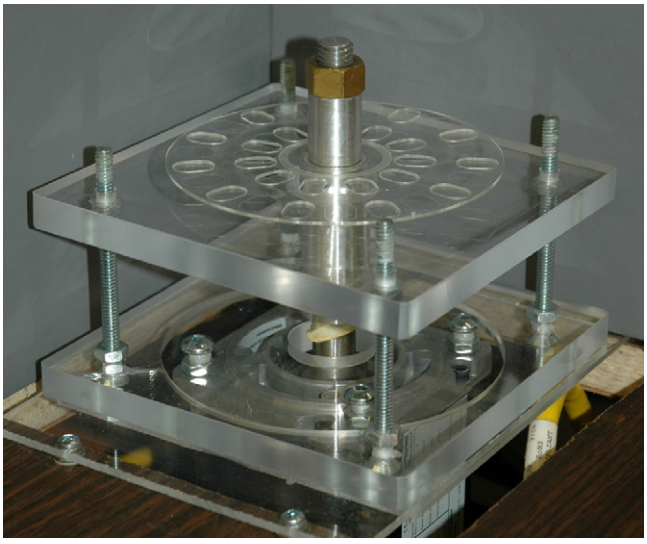

Fig. 2. An image of the servo motor system, and spindle used to spin the disc.

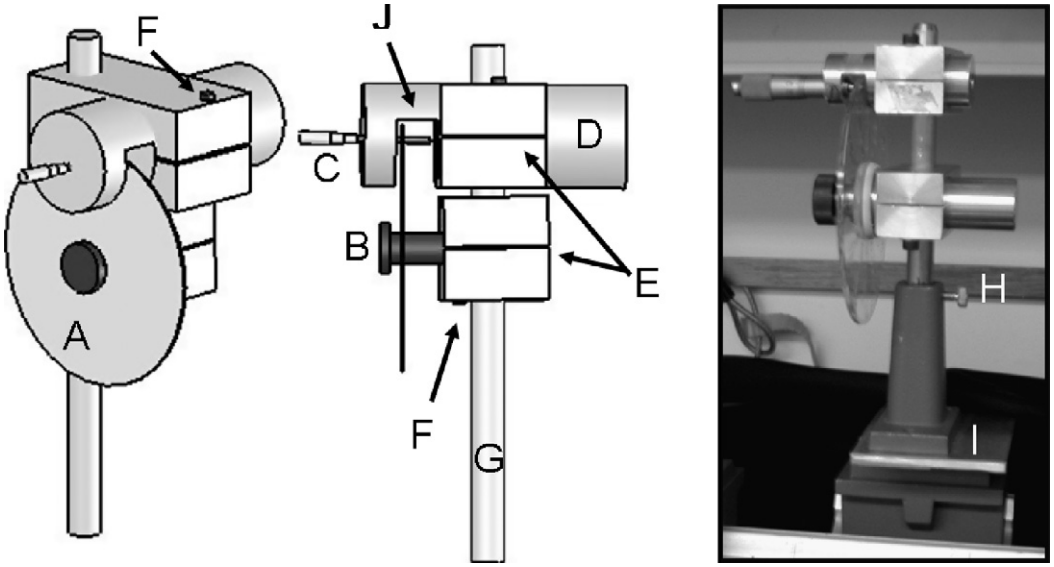

Fig. 3. The disc (A) fits onto a cylinder fitted with a tightening screw (B) and is locked into position with a micrometer (C). D and B provide the *X*-axis adjustment by sliding through two blocks (E) that are fitted with tension screws (F). The blocks (E) also individually slide along G, which provides movement along the *Z*-axis for different sizes of discs. *Z*-axis adjustment is also provided by adjusting H, which allows the whole assembly to slide along the *Z* (up/down) axis. The entire apparatus is mounted on I, which provides adjustment in the *X*-axis, using a typical optical rail mount. A portion of D has been cut-away (J) to allow proper positioning.

Teflon to avoid metal contamination of the pellets. After sealing the disc, vinyl adhesive was used to seal the access ports/openings to the cell and the entire disc was placed in a desiccator until use.

2.3. Instrumentation configuration

The disc was mounted on a servo motor (Parker Automation Servo Motor with Aries Servo Drive, Parker Hannifin Corp., Rohnert Park, CA) using a lab constructed spindle designed to accept the disc. The speed, direction and duration of the motor were all controlled via a National Instruments Motion Controller (Model# UMI-7764) and software written in LabView (National Instruments, Quebec, Canada). An image of the system is shown in Fig. 2. The system is also described in detail by Duford et al. [15].

For spectral measurements the disc was removed from the spindle and installed in the optical path of the spectrometer system using the disc holder, shown in Fig. 3, which was designed for maximum flexibility and is adjustable in three axes allowing for multiple thicknesses, sizes and disc designs. The open design of the holder allowed for easy placement of the entire sample cell area in the optical path and minimized reflective materials, reducing the amount of light scatter (see Fig. 4). Evenly spaced stabilization/alignment holes on the periphery of the disc provided reproducible disc placement and aligned the cells in the optical path (not shown but approximately at the 4 o'clock position on the disc). New cells were positioned in the path by loosening the micrometer and rotating the disc to the next alignment hole.

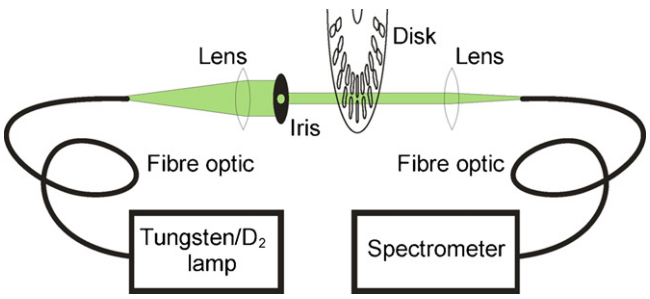

Fig. 4. Overall schematic of the optical detection system showing the relative positioning of the source and receiving fiber optics and the lenses. The adjustable iris limited illumination to the central area of the reaction/detection cell while preventing scatter from the milled cell walls.

The detection apparatus shown in Fig. 4, consisted of a Tungsten-Halogen/Deuterium light source (DT-MINI-2-GS, Ocean Optics, Dunedin, FL) that provided radiation in both the visible and ultraviolet region. The light was transferred to the disc using a 300 μm × 1 m, solarization resistant fiber optic (QP300-1-SR, Ocean Optics, Dunedin, FL). The light was collimated using a 4 cm focal length quartz lens, truncated to a 6 mm diameter beam with an iris, directed through the sample cell on the disc in the holder apparatus and focused by a matching lens onto the detection fiber optic. This fiber optic was connected to a USB compatible asymmetric crossed Czerny-Turner type miniature spectrometer with a linear charged coupled device (CCD) photodiode array detection system (USB4000-UV-VIS, Ocean Optics, Dunedin, FL).

2.4. Procedure and measurement

Standard or sample (100 μL) was pipetted into the disc and the seal over the injection hole was replaced. The reagent pellet was dissolved by mounting the disc on the spindle and programming the motor to rotate the disc by alternating direction every half turn for 180 s at 150 rpm. After mixing was complete the disc was held at rest for the 20 min reaction period and placed in the disc holder for absorbance measurements.

The "reference (large scale) experiment" consisted of preparing standards and reagents according to the manufacturer's suggested protocol with 10 mL volumes and measuring the resulting spectra with a bench top spectrometer using the same calculation technique as spectra taken using the disc. These absorbance measurements were made using a 1 cm optical grade, plastic cell from Ocean Optics (Dundin, FL, USA) and an Agilent 8453 spectrometer.

To establish the length of time the reagent pellet was stable and whether pellet size affected the absorbance a single disc was constructed using normal procedures, sealed and placed in a desiccator until use. Several cells with known pellet mass were tested over a 31-day period using a fresh solution of approximately 0.5 mg L^{-1} $NO_2{}^{-1}$-N. The final absorbance was adjusted for any difference in standard concentration.

In order to overcome the path length and absorbance imprecision associated with using plastic discs as both reaction chamber and detection cell window, a ratiometric method was used to estimate the blank. The blank absorbance signal can be estimated directly from a sample spectrum provided that the sample does not absorb over the entire available spectral range. First, several sample spectra were taken and the wavelength(s) at which the analyte absorbs (λ_1) and at which the analyte does not absorb (λ_2) were found. Second, a blank spectrum was taken. The ratio of the blank signal (I) at the analyte absorbing wavelength (λ_1) to the blank signal at the sample's non-absorbing wavelength (λ_2) was found from the blank spectrum using the following equation.

$$\text{Ratio} = \frac{I_{\lambda_{1\text{blank}}} - I_{\lambda_{1\text{dark}}}}{I_{\lambda_{2\text{blank}}} - I_{\lambda_{2\text{dark}}}} \quad (1)$$

When a sample was run, the measured signal at the non-absorbing wavelength (λ_2) was multiplied by the ratio to give an estimated signal of the blank at the absorbing wavelength (λ_1). The modified transmittance equation is:

$$T = \frac{I_{\lambda_{1\text{sample}}} - I_{\lambda_{1\text{dark}}}}{\text{Ratio}(I_{\lambda_{2\text{sample}}} - I_{\lambda_{2\text{dark}}})} \quad (2)$$

A single blank spectrum per disc was taken during each set of measurements and used to provide the ratio. For the nitrite calculations, the average absorbance from 499 to 540 nm was used for the absorbing wavelength and 603 to 624 nm for the non-absorbing wavelength. For chromium, the ratio was calculated using 530–560 nm for the absorbing wavelengths and 758–786 nm for the non-absorbing wavelengths.

3. Results and discussion

3.1. Centrifugal microfluidics

Centrifugal microfluidics is a relatively unexplored research avenue in the pantheon of analytical methodologies and offers many appealing features to the analytical chemist developing new instrumentation, especially if field portability is the ultimate goal. Some of the key aspects of a field-portable instrument that centrifugal microfluidics have are: simplicity, robust and reliable mechanisms, minimal sample, and reagent handling, low power consumption and versatility. Although closely related to microfluidics, centrifugal microfluidics has the advantage for portable instrumentation due to its operational simplicity, freedom in choice of fabrication materials and operating conditions. Centrifugal microfluidics excels when multiplexed analyses are implemented on the same disc. Scaling an analysis up into a multiplexed assay is easy, because the driving and mixing forces on a rotating disc are a function of radial position. This provides uniform conditions for all positions/devices on the disk that are located at the same radial position.

In the present implementation, we have made the simplest of multiplexed discs: an array of reaction/detection cells, but more complicated manifolds have been presented in the literature [16]. The motor system that we used allowed the disc to be oscillated by 1/2 turns for 180 s under programmed control and ensured rapid dissolution of the dry reagent pellet in the sample solution and initiation of the reaction.

It became apparent early in testing that there were disc to disc variations which resulted in spectral differences that would introduce appreciable variance into any analysis. We attributed these differences to small pathlength and disc transparency changes that an appropriate blank measurement would largely eliminate. Analytically, the best blank measurement utilizes the sample cell filled with a blank solution; however, in centrifugal systems this is impractical so estimation of the blank signal (at the analyte wavelength) using non-analyte wavelengths was the next best alternative.

By using the ratio method, only one blank spectrum per disc was needed to establish the appropriate ratios to apply to all samples on that disc. This reduced the analysis time significantly and improved precision and accuracy by taking a simultaneous measurement for both wavelengths through the same optical window. During the Cr(VI) experiments, there was poor performance due to inconsistencies caused by fiber optic movement. In this prototype instrument, the fiber optics were not permanently secured and the transmittance of different wavelengths of light through the fiber varied based on the position of the fiber optic. Blank spectra were taken throughout the experiments to insure that the ratio was correct. Results were similar to the classical method, but suffered from higher detection limits and a lower replicate precision. In this case, superior results were calculated by using the classic manner using the averaged blank signal taken before and after each sample.

3.2. Stability study

The stability study was performed to determine how long a disc, with reagent pellets included, could be stored and still provide reliable results. In this experiment we chose to use the nitrite assay because the reagents are known to be sensitive to water vapor [9] and should prove to be the most sensitive to storage effects. The disc sampling holes were sealed using a plastic adhesive and stored in a desiccator for the 31-day test period. There was a 7.91% relative standard deviation for the concentration adjusted absorbance (*i.e.* the absorbance was adjusted for the small changes in the concentration of the standard nitrite solution that was made fresh daily). It is important to note that both the nitrite and Cr(VI) methods are designed to use excess reagents and that all of the pellets used were of sufficient mass to ensure that this excess was obtained [14]. The precision might be further improved with more consistent pellet mass and by better sealing of the injection holes or construction of the disc in a low humidity environment. Importantly, this data shows that on-disc dry reagent pellets can provide a stable long term solution for a portable device.

3.3. Nitrite

The visual color comparison method is a widely used field method for detecting nitrite, and Cr(VI), in water because it is simple, cost effective, and very portable. The human eye is a log-normal detector and can discriminate a large range of colors and intensities; however, depending on the person, the color and intensity is

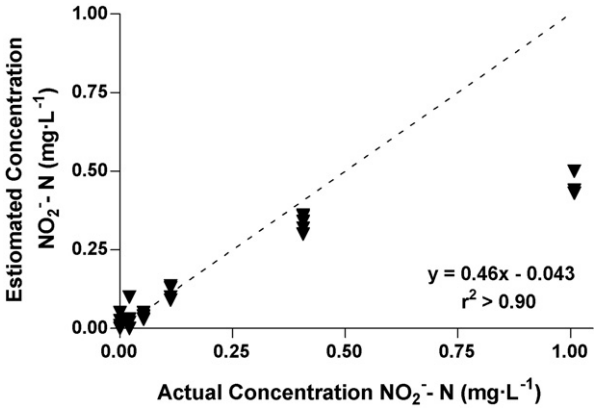

Fig. 5. Comparison of standard nitrite concentrations to visually estimated concentrations using a Hach conventional field analysis test kit, $n = 5$.

Table 1
Summary of calibration parameters for the detection of nitrite (NO_2^--N) using the disc-based microanalysis and the reference procedures.

Analysis method	Pathlength (cm)	Slope (AU/mg L^{-1})	DL (mg L^{-1})	Upper calibration limit (mg L^{-1})
Visual field test	1.2	N/A	0.1	0.5
Bench top	1.0	2	0.006	1
Disc	0.14	0.27	0.008	5

open to subjective assessment [17]. The results of visual tests using a Hach NI-12 color wheel based system for nitrite are illustrated in Fig. 5. The non-linear response is evident and, of course, detection limits are much higher than those obtained with bench top instruments. The manufacturer states "accurate to ±10% or ± the smallest increment, subject to individual color perception".

It is generally accepted that analyses performed in the controlled laboratory environment provide the maximum in precision, accuracy and dynamic range for most analytical methods. To compare our method to the US EPA Standard Method 4500, we used an Agilent HP8542 bench top spectrometer and the Hach reagents to obtain a linear calibration (Table 1) with a precision of 1% at the 0.5 mg L^{-1} level ($n = 6$). These results are of course superior to those of the visual field test but the real question is: how do the disc-based measurements compare to these two measurement strategies?

The analytical figures of merit for the linear calibration ($r^2 > 0.99$) of the microanalysis disc are presented in Table 1. Recall that the bench top instrument uses a 1 cm pathlength cell which should make the measurement more sensitive than the disc. We verified that the slope was proportional to pathlength. Of greater significance than the method sensitivity, the precision ranged from 0.2 to 3% RSD ($n = 3$–9 cells/disc) at the 0.5 mg L^{-1} level, a performance that is comparable to a bench top instrument. After some investigation, we found that small bubbles sometimes formed in some of the cells during reaction and these bubbles affect the apparent transmittance. Most bubbles could be removed by gently tapping the disc to dislodge them; however, some remained causing slightly degraded precision.

These results suggest several possible improvements to the disc design with the goals of increasing the sensitivity, to further lower the detection limit, and elimination of bubbles from the optical path to improve precision. Increasing the method sensitivity, with this reagent system, will require longer pathlengths. This can be easily achieved by making the middle disc layer thicker than the currently used 1.4 mm or by modifying the light path using internal reflection methods previously described [18,19]. In this analysis, sample consumption is not a limitation so both the sample and disc volume could easily be scaled-up by an order of magnitude. However, minimizing reagent and sample consumption is beneficial for some analyses, so a using a smaller diameter sample cell is a viable alternative with a thicker disc or a folded optical path of the type shown by Steigert et al. [20].

Loss of analytical performance within microfluidic systems due to bubbles is an established problem [21,22] but modifying the disc surface to be more hydrophilic or including surface tension reducing surfactants in the reaction mixture may be sufficient to eliminate some of the precision damaging bubble problems.

Environmental field testing is often used to guide and evaluate contamination remediation efforts. In these cases, the accuracy, precision, ability to measure many samples simultaneously, and speed of analysis is a clear advantage of the disc-based system over the visual field and laboratory-based strategies. When measuring nitrite, the promptness with which samples can be measured is especially important since nitrite is easily converted to other nitrogen species, mainly by oxidation to nitrate, so the delays introduced by transporting samples to a lab facility may significantly bias results and should be avoided.

3.4. Chromium(VI) results

To simplify the hexavalent chromium experiments and result comparisons, only the Ocean Optics spectrometer was used for measurements (*i.e.* the fiber optics were connected to either an Ocean Optics 1 cm cell holder or the disc holder). Using the Hach recommended procedure with a 5 mL sample and a 1 cm cell, a linear calibration curve from 0.01 to 1.5 mg L^{-1} Cr(VI) was calculated (Table 2). Measurement of Cr(VI) using the disc-based approach, with 1.5–2.2 mg pellets of Chromaver3, yielded an extinction coefficient (approximately 40,000 L g^{-1} cm^{-1} Cr(VI)) and spectral shape that are in close agreement with the literature [12,23]. The calculated slope was the expected one order of magnitude smaller than that of the 1 cm path cell. Despite this loss of sensitivity, the detection limit only increased by a factor of 2 to 0.03 mg L^{-1}. The decreased sensitivity of the disc-based measurement was accompanied by a corresponding increase in the linear dynamic range to 5 mg L^{-1} Cr(VI) suggesting that further improvements in detection limit can be achieved by increasing the pathlength as discussed above.

The current disc-based detection limit is considered acceptable for industrial point-of-source monitoring. However, the limit of quantification (0.1 mg L^{-1} Cr(VI)) is not adequate to meet the 0.05 mg L^{-1} US EPA/Health Canada drinking water limits [24] and would need to be improved by at least a factor of two. Incorporation of a longer pathlength, or reduction of blank noise, on the disc would be beneficial and should address this issue.

To demonstrate the potential for analysis of realistic samples several spiked waste water samples, collected from a waste water management company, were analyzed. As before, samples were injected onto a disc containing reagent pellets and calibrated using simple aqueous standards. The results produced approximately 130% recovery from the spiked recovery measurements. The high recovery may be due to the organic matrix in the samples and suggests that standard additions may be needed. The high time and labor costs associated with standard additions make a very powerful argument for parallel sample analysis that is easily achieved with the present disc-based approach. With 24 reactions operating in parallel already demonstrated, it is easy to conceive of a disc that apportions a single sample into an array of reaction cells

Table 2
Summary of calibration parameters for hexavalent chromium (Cr^{6+}) using the developed system, a common field instrument and the reference procedure.

Analysis method	Pathlength (cm)	Slope (AU/mg L^{-1})	DL (mg L^{-1})	Upper calibration limit (mg L^{-1})
Visual field test	1.2	N/A	N/A	1.5
Bench top	1.0	0.7	0.01	1.5
Disc	0.14	0.07	0.03	5

[25] with increasing amounts of analyte and fixed amounts of the derivatization reagents. Reading the results from the array would provide a standard additions calibration while mitigating the negative aspects of this calibration strategy.

4. Conclusions

It is possible to quantify nitrite-nitrogen and hexavalent chromium using a centrifugal microfluidic platform suitable for on-site analysis. The procedure requires 100 μL of sample or standard. By incorporating the dry reagents on disc, derivatization and detection can be performed in one step and directly on disc. In the current design, 24 individual cells are available on one disc and would permit calibration and multiple sample measurements on a single disc. Both reactions showed molecular extinction coefficients similar to those reported in the literature with detection limits of 0.008 mg L^{-1} NO_2^--N and 0.03 mg L^{-1} Cr(VI). Reproducibilities of 0.2–3% ($n = 3$) and 7% ($n = 3$) RSD respectively for mid-range samples, are within the range required for industrial and environmental applications for both analytes. The analytical performance is also adequate for detection of both analytes in drinking water as the detection limits are below the maximum permissible drinking water limits (Section 1); however, the quantification limit for Cr(VI) is above the permissible limit. Increasing the pathlength of the disc should provide the required increase in sensitivity and allow performance nearly equivalent to bench top instrumentation.

Multiwavelength measurements allowed the use of the ratio technique for the blank estimation that produced improved precision and a decreased analysis time, as only one blank measurement was needed. In a portable system designed for a single species, this could be inexpensively done with two appropriate wavelength light emitting diode sources and one detector. However, the multiwavelength source and detection system provides an extremely flexible system capable of measuring multiple reactions on a single disc.

Other single step reaction kits for environmentally important species such as orthophosphate, sulfate and molybdenum are commercially available and may be good candidates for single step centrifugal microfluidic discs.

ICP-MS determination of zinc isotope ratios

ABSTRACT

This study evaluates the potential use of stable zinc isotopes in toxicity studies measuring zinc uptake by the gills of brown trout (*Salmo trutta*) and rainbow trout (*Oncorhynchus mykiss*). The use of stable isotopes in such studies has several advantages over the use of radioisotopes, including cost, ease of handling, elimination of permit requirements, and waste disposal. A pilot study using brown trout was performed to evaluate sample preparation methods and the ability of a quadrupole inductively coupled plasma mass spectrometer (ICP-MS) system to successfully measure changes in the $^{67}Zn/^{66}Zn$ ratios for planned exposure levels and duration. After completion of the pilot study, a full-scale zinc exposure study using rainbow trout was performed. The results of these studies indicate that there are several factors that affect the precision of the measured $^{67}Zn/^{66}Zn$ ratios in the sample digests, including variations in sample size, endogenous zinc levels, and zinc uptake rates by individual fish. However, since these factors were incorporated in the calculation of the total zinc accumulated by the gills during the exposures, the data obtained were adequate for their intended use in calculating zinc binding and evaluating the influences of differences in water quality parameters.

Published by Elsevier B.V.

1. Introduction

The level and mechanism of aqueous zinc uptake in fish is a topic of recent research efforts. As a micronutrient, zinc is found at naturally high levels in fish tissues. Although zinc uptake primarily occurs through the diet, at elevated zinc levels in water uptake can also occur via the gills causing morphological alterations and toxicity [1–4]. Zinc is thought to competitively disrupt calcium uptake across the gills that can lead to acute hypocalcemia and eventual death, depending on the zinc concentrations [2,5]. Rainbow trout (*Oncoryhnchus mykiss*), and to a lesser extent brown trout (*Salmo trutta*), are susceptible to increased concentrations of waterborne zinc, for example, in streams impacted by acid rock drainage [5–7]. In some cases, zinc toxicity is sufficient that popular recreational fishing streams must be routinely restocked to compensate for fish losses due to exposure to waters with high zinc concentrations [5].

Previous toxicological studies on the uptake of zinc in fish have utilized radio-labeled ^{65}Zn to differentiate the comparatively low levels of zinc accumulated via waterborne exposure versus the larger pool of endogenous zinc [1–4]. Although an effective means of studying zinc uptake, the use of radioactive isotopic spikes has several disadvantages, including: cost, handling requirements, and disposal of radioactive waters from fish exposure studies. These earlier radioisotope studies utilized atomic absorption spectrometry for total zinc determinations and gamma spectrometry to determine uptake of the radioactive zinc isotopes. With current inductively coupled plasma mass spectrometer (ICP-MS) instrumentation, it is possible to use enriched stable (i.e., non-radioactive) zinc isotopes to perform these types of studies, eliminating the concerns and costs involved in employing methods that utilize radioactive isotopic methods. A recent review article by Stürup et al. [8] discusses the use of a variety of enriched stable isotopes, including zinc, as tracers in biological systems. Since the main goal in such studies is to measure an enriched isotopic ratio and not to perform quantitative isotopic measurements, these

types of measurements can generally be performed as long as precisions of 1% RSD or better can reasonably be achieved. Another review by Cloquet et al. [9] specifically discusses the use of stable zinc isotopic tracers in biological systems. Croteau et al. have reported the use of Cu, Cd, and Cr stable isotopes to examine biological uptake rates in freshwater bivalves and gastropods [10,11]. With the advent of multi-collector ICP-MS systems, the precision of zinc isotope ratios has improved dramatically to better than 0.01% RSD [8,9], allowing many more biochemical and geochemical applications to be realized. In the geochemical realm, multi-collector ICP-MS measurements are often utilized to examine the fractionation of Zn isotopes by geochemical processes because the shifts in isotopic abundances can be very small [12–14]. However, most of these applications require the Zn isotopes to be chemically separated from other elements in the sample matrix prior to analysis, and these methods require tedious sample clean-up procedures. Balcaen et al. [15] used a high-resolution sector-field ICP-MS to perform a double-spiking study on water fleas (*Daphnia magna*) using ^{67}Zn and ^{68}Zn isotopic spikes and reported precisions for ^{67}Zn/^{66}Zn of 1.3% RSD and 0.7% RSD for high-resolution ICP-MS and quadrupole ICP-MS, respectively.

In this study, we examine the use of a quadrupole ICP-MS system to determine changes in ^{67}Zn/^{66}Zn ratios in gills extracted from brown trout and rainbow trout exposed to various Zn concentration levels and exposure times in ^{67}Zn-enriched exposure media. Due to its low natural abundance (4.1%) and availability, ^{67}Zn was selected as the spiking isotope in order to maximize the ability to detect a change in the measured ratio as a result of the exposure. The data will ultimately be used to evaluate the influence of water chemistry parameters on acute fish toxicity and will be used to determine physical constants that can be incorporated into the Biotic Ligand Model (BLM), which can be used to estimate the acute toxicity of metal exposure to fish populations [16].

2. Materials and methods

2.1. Reagents

Unless otherwise noted, all reagent and stock solutions were prepared in 20% (v/v) nitric acid made from de-ionized water (Millipore, Billerica, MA, USA, 18 MΩ) and double-distilled HNO_3 (prepared via sub-boiling distillation, Milestone subPUR, Shelton, CT, USA), in order to match the acid matrix resulting from the sample preparation procedure. Zinc metal enriched in ^{67}Zn (^{67}Zn (89.6%), ^{64}Zn (1.56%), ^{66}Zn (3.88%), ^{68}Zn (4.91%), ^{70}Zn (0.05%)) was obtained (Isoflex, San Francisco, CA, USA) and was dissolved in double-distilled HCl and diluted with de-ionized water to prepare a ^{67}Zn-enriched spiking solution of 995 mg/L in 5% HCl. This spiking solution was used to prepare the exposure solutions for both the pilot study and the rainbow trout study.

2.2. Fish care

Two groups of fish were used in our study. The first was a group of approximately 50 juvenile brown trout (*S. trutta*) included in a pilot study performed in order to test the various laboratory methods employed in the full-scale exposure study. Brown trout were selected for the pilot study due to their availability, similarity to the planned test species, and because they are known to be less susceptible to metal toxicity than rainbow trout; so, if differences were observed in the brown trout, they should also be observed in the planned test species. The second group of approximately 300 juvenile rainbow trout (*O. mykiss*) was used in the primary zinc exposure study. Fish for both groups were obtained from the Colorado Division of Wildlife Research Hatchery (Bellevue, CO) and were transported to the Colorado Division of Wildlife Aquatic Toxicology Laboratory in Fort Collins, CO, USA. Dim fluorescent lighting provided a 16-h:8-h light:dark photoperiod. Trout were fed twice daily using appropriately sized trout food (Rangen Inc., Buhl, ID, USA) at an estimated rate of 2% body weight per day. Feeding was ended 48 h prior to test exposures, a common practice in acute toxicity testing, to avoid problems caused by feeding, such as possible alteration of toxicant concentration, build-up of metabolic wastes, and possible increased oxygen demand. Water temperature was maintained at $12 \pm 0.7\,^{\circ}C$ during holding and all experiments using a recirculating chiller.

For the pilot study, the brown trout were maintained in Fort Collins municipal tap water (~44 mg/L $CaCO_3$ total hardness) until the test exposure. Fish weights ranged from 2.5 g to 4.5 g with an overall average weight of 3.15 g.

For the rainbow trout exposure, fish were maintained in water matching the hardness of the hatchery water (201 mg/L $CaCO_3$). Prior to testing, the trout were divided equally into two aerated acclimation tanks and the water hardness adjusted gradually (~10 mg/L per day) to the test hardness of ~30 mg/L $CaCO_3$ for soft water and ~140 mg/L $CaCO_3$ for hard water testing, respectively. Trout were maintained at the test hardness for 14 days prior to testing. The average mass of hard water acclimated trout was 8.3 ± 2.7 g while the soft water trout were slightly larger at an average weight of 9.9 ± 3.3 g.

2.3. Isotopic exposures

The primary objective of the pilot study was to determine if the changes in the ^{67}Zn/^{66}Zn ratios in the gill material would be large enough to be measured at the exposure times planned. Additional objectives included determining the optimum parameters for ICP-MS detection, evaluating the efficacy of the digestion method, and determining any necessary sample pretreatment (e.g., rinsing) of the dissected gill material prior to digestion.

For the pilot scale study, the brown trout were allowed to acclimate for several weeks in water of the same hardness and chemical composition as the exposure water. A control group of fish ($n = 8$) was harvested before the exposure. The remaining fish were exposed to water spiked with ~600 μg/L of the enriched ^{67}Zn solution. Ten fish were harvested after 3 h and 24 h of exposure. At the end of each exposure time sequence, the selected number of fish were randomly netted and placed into a bucket containing a lethal dose, 1 g/L, of an anesthetic solution MS-222 (Tricaine Methanesulfonate, Argent Chemical Laboratories, Redmond, WA). Post mortem, the gills from five fish in each exposure group were "rinsed" with a stream of de-ionized water applied through the mouth over the gills for approximately 5–10 s, while the gills from another set of five fish in the same exposure group remained "unrinsed".

An additional 20 fish were harvested after 3 h of exposure and their gills excised, rinsed, and composited. Composited samples were used to estimate the size fish that would be necessary in the event that the differences in zinc isotope ratios were undetectable in the gills from individual fish. One half of the composite sample was used to approximate a 30 g fish, one quarter was used to approximate a 15 g fish and one-eighth was used to approximate a 7.5 g fish. Fish were refrigerated until dissection. Fish gills were removed and separated from gill rakers within 24 h after fish death using high-quality corrosion-resistant stainless steel instruments. The gills were subsequently frozen ($-80\,^{\circ}C$) until sample digestion.

For the rainbow trout exposure study, calculated amounts of the enriched ^{67}Zn stock solution discussed previously were added to fully aerated 30-L static exposure tanks to achieve nominal concentrations in hard water (75 μg/L, 150 μg/L, 250 μg/L, 500 μg/L, and 1000 μg/L) and soft water (25 μg/L, 50 μg/L, 75 μg/L, 150 μg/L,

Table 1
Measured water quality parameters for rainbow trout exposure study experiments in hard and soft waters. Measured values are expressed as means (standard deviation). Additional information on measurement of water quality values can be found in Todd et al. [18].

Parameter	Hard water	Soft water
Hardness (as mg/L $CaCO_3$)	144 (1.2)	31.7 (1.3)
Alkalinity (as mg/L $CaCO_3$)	88 (5.1)	29.2 (1.6
Temperature (°C)	12.4 (0.2)	12.1 (0.2)
pH	7.7 (0.3)	7.2 (0.2)
Dissolved oxygen (mg/L)	8.5 (0.5)	8.5 (0.9)
Ca^{2+} (mg/L)	35.6 (1.2)	7.9 (0.4)
Mg^{2+} (mg/L)	10.3 (0.4)	1.7 (0.1)
Na^{+} (mg/L)	12.7 (3.2)	5.5 (0.1)
K^{+} (mg/L)	1.0 (0.16)	0.4 (0.12)
SO_4^{2-} (mg/L)	42.3 (0.8)	10.1 (0.3)
Cl^{-} (mg/L)	21.3[a] (7.4)	4.8 (0.2)
Dissolved organic carbon (DOC) (mg/L)	3.1[b] (0.9)	2.3[b] (0.8)

[a] Chloride values varied significantly as a result of the HCl in the metal stock solution.
[b] Average DOC concentration calculated from measurements in accumulation tanks at all time intervals. DOC started low and was observed to increase over the course of the exposure.

250 μg/L, and 500 μg/L). Prior to the addition of the zinc spikes, the pH value of each solution was adjusted back to that of the dilution water with NaOH. Average water quality parameters for the soft and hard waters used can be found in Table 1. Thirty rainbow trout were transferred from the acclimation tanks to each static exposure tank. Ten rainbow trout were harvested from each acclimation tank as controls. At sampling times of 0.75 h, 1.5 h, 3 h, 24 h, 48 h, and 72 h, five fish from each aquarium were randomly netted and placed into buckets containing a lethal dose of the anesthetic solution, MS 222. The rationale for the exposure times and concentrations selected was, in part, to allow for comparison with the radioisotope study by Alsop and Wood [3] and is discussed in Todd et al. [18]. At each sampling time, a water sample was also taken from each aquarium for total zinc and zinc isotope analysis. Post mortem, the gills of each fish were rinsed for approximately 10 s with a stream of de-ionized water through the mouth, as discussed previously, to remove Zn present in the gill mucus. After rinsing, the gills were dissected and frozen (−80 °C) in polypropylene sample vials until sample digestion.

Additionally, the gills of a wild-caught adult lake trout (*Salvelinus namaycush*) not used in the Zn exposure study were rinsed, removed, and composited for use as an analytical quality control (QC) sample. A large adult fish was used in order to obtain enough gill material (approximately 3.5 g) so the same material could be analyzed periodically with the exposed rainbow trout gill tissues to estimate the long-term analytical precision of the method. The lake trout was selected due to its size and availability. A portion of this composited gill QC sample (approximately 0.150 g) was weighed out and prepared with each sample preparation batch.

2.4. Sample preparation

The frozen gill tissue samples were weighed to the nearest 0.0001 g and transferred to acid-washed 50 mL perfluoroalkoxy polymer (PFA) microwave digestion vessels. The samples were digested using 4 mL of double-distilled HNO_3 and 2 mL of ultrapure H_2O_2 (Seastar, Inc., Vancouver, BC, Canada) in a microwave digestion system equipped to handle 48 samples (Multiwave 3000 with Rotor 48MF50, Anton Paar, Graz, Austria). The microwave temperature/pressure sensor was located in vessel number 1. The microwave digestion program consisted of a heating step at 1400 W power at the lowest fan speed with a ramp time of 10 min followed by a hold time of 10 min. After the heating program completed, the power was reduced to zero and the fan speed increased to the medium setting for 10 min, followed by an additional 30-min cooling step at the highest fan speed. After this program completed, the samples were allowed to sit in the digestion vessels until they cooled to room temperature. This procedure resulted in a complete digestion (no residue) for all samples, except three samples from the pilot study where small portions of gill raker remained attached to the gill and were not digested. The resulting clear sample solutions were quantitatively transferred to 50 mL polypropylene centrifuge tubes (Becton Dickenson Labware, Franklin Labs, NJ, USA) and diluted to 20 mL, using the scribed volume marks on the tubes, with de-ionized water. Prior to dilution, the accuracy of the scribed volumetric markings on a series of tubes ($n = 10$) were checked by weight and were found to be accurate to within 2% of the marked volume. The final sample solutions contained approximately 20% (v/v) nitric acid and were directly analyzed by ICP-MS for both total elemental content as well as zinc isotopic ratios.

2.5. Instrumentation

It was desirable that the final analysis protocol not require any complicated sample pretreatments, such as those described by Borrok et al. [14], for multi-collector ICP-MS analysis of zinc isotopes due to the large number of samples (>600) that would eventually require isotopic analysis. For this reason, the use of quadrupole ICP-MS was investigated for determination of the zinc isotope ratios and total zinc concentrations, although the laboratory also has at its disposal both multi-collector ICP-MS and high-resolution sector-field ICP-MS instruments. The instrument used was an ELAN DRC II ICP-MS system (PerkinElmer LAS, Inc., Waltham, MA, USA) equipped with a quartz cyclonic spray chamber and 2 mm quartz injector. Due to the limited sample volume available, the system was equipped with a glass concentric nebulizer (Type TR-50-C1, Meinhard Glass Products, Golden, CO) and was operated at a sample uptake rate of approximately 0.35 mL/min. A detector deadtime correction value of 60 ns was determined using the procedure recommended by the instrument manufacturer. Other instrument operating parameters are given in Table 2.

Considerations in using quadrupole ICP-MS for the analysis of Zn include the impacts of both isobaric and polyatomic interferences on particular zinc isotopes. As illustrated by Table 3, ^{64}Zn can be

Table 2
General ICP-MS instrument operating conditions (ELAN DRC II).

RF power	1100 W
Lens (total Zn)	Autolens
Lens (Zn isotopes)	Static, 7.5 V
Nebulizer flow (total Zn)	0.74 mL/min, optimized for $CeO^{+}/Ce^{+} < 3\%$
Nebulizer flow (Zn isotopes)	0.78 mL/min, optimized for maximum ^{67}Zn
Nebulizer type	Glass type TR-50-C1
Peristaltic pump (total Zn)	0.889 mm i.d. tubing for sample and internal standard, total flow rate ~ 0.7 mL/min
Peristaltic pump (Zn isotopes)	0.889 mm i.d. tubing for sample, total flow rate ~ 0.35 mL/min
Spray chamber	Quartz cyclonic
Injector	Quartz 2 mm i.d.
Data acquisition (total Zn)	Dwell times 10–100 ms/isotope, 15 sweeps, 3 replicates, 80 masses monitored, total time 2:10 min
Isotopes monitored (Zn isotopes)	^{64}Zn, ^{66}Zn, ^{67}Zn, ^{68}Zn, ^{70}Zn, ^{60}Ni
Detector mode (Zn isotopes)	Pulse only (short settling time not used)
Deadtime correction	60 ns
Data acquisition (Zn isotopes)	Dwell 20 ms/isotope, 500 sweeps, 10 replicates, total acquisition time/isotope = 10 s, total time 11:30 min

Table 3
Common interferences affecting Zn isotope measurements. Interferences with high abundance will have greater impact on Zn isotopes than those with lower interference abundance, given equal concentrations.

Mass affected	Exact mass	Zn isotope abundance (%)	Interference	Exact mass[a]	Interference abundance (%)	Estimated resolving resolution[b]
$^{64}Zn^+$	63.92915	48.63	$^{64}Ni^+$	63.92797	0.93	54,200

impacted by several major interferences, particularly in biological matrices which may contain high levels of sulfur or phosphorus. Preliminary studies on the use of dynamic reaction cell (DRC) technology available on the quadrupole ICP-MS used in our laboratory to eliminate the various interferences on the Zn isotopes, using ammonia as the reaction gas, resulted in attenuation of the Zn signal. Since lower signal levels would require longer analysis times for the isotope ratio analysis and the total volume of sample available for both the total Zn analysis and the Zn isotopic analysis was limited to 20 mL, standard (non-DRC) conditions were utilized for this study. Preliminary estimates based on counting statistics indicated that precisions of 0.5% RSD or less could be achieved if the zinc concentrations were 10 μg/L or greater.

Although in most geochemical studies the $^{67}Zn/^{64}Zn$ ratio is reported, due to the potential interferences on ^{64}Zn from nickel, sulfur, and phosphorus, there could be significant error in measured ^{64}Zn values. For this study, the $^{67}Zn/^{66}Zn$ ratio was determined since ^{67}Zn and ^{66}Zn measurements are not affected by nickel and phosphorus interferences (see Table 3) and the potential impact of any sulfur present in the sample is greatly reduced. As is illustrated in Table 3, the abundances of the $^{34}S^{16}O_2^+$ and $^{34}S^{16}O_2H^+$ species that interfere with ^{66}Zn and ^{67}Zn measurements, respectively, are approximately only 4% as compared to the 94% abundance of the $^{32}S^{16}O_2^+$ species that interferes with ^{64}Zn measurement. Therefore, by using the $^{67}Zn/^{66}Zn$ ratio the impact of any sulfur interferences on the measurements should be reduced. In order to verify this, the contributions on the ^{64}Zn, ^{66}Zn, ^{67}Zn, ^{68}Zn, and ^{70}Zn signals were measured using separate solutions containing 10 mg/L of phosphorus and sulfur and 10 μg/L nickel. In Table 4, these signals are compared to the signals obtained from 10 μg/L solutions of zinc (JMC 30749 and HP 403518). As Table 4 indicates, the contributions at masses 66 and 67 from the 10 mg/L sulfur solution are 116 cps and 21 cps (counts per second), respectively. This contribution is within the observed average standard deviations at masses 66 and 67 of 150 cps and 27 cps, respectively, from measurement of the 10 μg/L zinc solutions. Likewise, the contributions at masses 66 and 67 from the 10 mg/L phosphorus solution are 64 cps and 17 cps, respectively. This contribution is also within the observed average standard deviations at masses 66 and 67 from measurement of the 10 μg/L zinc solutions. Since the digested fish gill samples yielded solutions containing less than 10 mg/L phosphorus or sulfur (see Table 6 for average concentration information) with a total Zn concentration of approximately 20 μg/L or more, the impact of the sulfur and phosphorus interferences on the signals for ^{66}Zn and ^{67}Zn would be indistinguishable as compared to the short-term reproducibility of the zinc measurements. Furthermore, the data in Table 4 also illustrate that the contributions from the sulfur interferences on the measurement of ^{64}Zn and ^{68}Zn and of the phosphorus interference on ^{68}Zn are significantly larger than the standard deviation of the measurement of the 10 μg/L zinc standards and would be of significant concern, if these isotopes were used for monitoring the change in the zinc isotopic ratios in the fish gills. It was therefore concluded that the quadrupole ICP-MS instrument could be used for the zinc isotopic measurements in our study, if the $^{67}Zn/^{66}Zn$ ratios were used, instead of the more traditional $^{67}Zn/^{64}Zn$ ratio.

2.6. Elemental and total zinc analysis

In order to verify that the total zinc concentrations were sufficient (>10 μg/L) for isotope ratio analysis using established measurement conditions, each gill digestate was analyzed for total Zn content and for the concentrations of approximately 40 other elements for informational purposes prior to the zinc isotopic analyses. Multi-element calibration standards were prepared by appropriate dilution of single and multi-element stock solutions purchased commercially (High Purity Standards, Charleston, SC, USA) and the matrix stock solution in 20% HNO_3 (v/v) as detailed in Table 5. The matrix stock solution containing the major cations typically found in a wide variety of sample matrices was added to the multi-element stock solutions to bring the concentrations up to acceptable levels for multi-point calibration of these elements and to minimize any ionization effects that the presence of these elements might have on other elements in the calibration. The matrix stock solution was also used to provide high-level calibration standards for the matrix elements, which were monitored for possible use in performing ratios of selected trace elements, such as Zn, to biological matrix elements, such as Mg, K, and Ca to identify any

Table 4
Measured effects of potential interferences from sulfur, phosphorus, and nickel on measured zinc isotope intensities. Int is the measured intensity of the solution at the mass or isotope listed using the developed isotope ratio method. The standard deviations of the 10 individual replicates in each analysis are given in parentheses.

Test solution	$Int^{64}Zn$ (SD)	$Int^{66}Zn$ (SD)	$Int^{67}Zn$ (SD)	$Int^{68}Zn$ (SD)	$Int^{70}Zn$ (SD)
20% HNO_3 blank ($n = 3$)	172 (117)	102 (76)	22 (12)	795 (42)	243 (9)

10 mg/L S	762 (46)	116 (6)	21 (1)	739 (22)	230 (6)
10 mg/L P	155 (22)	64 (3)	17 (2)	717 (32)	220 (3)
10 μg/L Ni	240 (13)	58 (3)	14 (1)	754 (28)	235 (6)

Table 5
Stock solution concentrations and working standard concentrations for elemental and total Zn analysis.

Solution ID	Element(s)–concentration (units)
Matrix stock	Na, Mg, K, Ca, Fe–30 mg/L, Al–100 mg/L, Si, Ti, Mn–5 mg/L, P–1 mg/L
Stock A	Li, Be, Na, Mg, Al, P, K, Ca, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Ga, As, Se, Rb, Sr, Cd, Cs, Ba, La, Ce, Pr, Nd, Sm, Eu, Tb, Gd, Dy, Ho, Er, Tm, Yb, Lu, Tl, Pb, Bi, Th, U–10 mg/L
Stock B	Si, Ti, Ge, Zr, Nb, Mo, Ag, Sb, Ta, W, Hf, Sn, Te–10 mg/L
Calibration Standard 1	All elements from calibration Stocks A and B–5 μg/L, no matrix stock
Calibration Standard 2	Stock A elements–20 μg/L, Stock B elements–10 μg/L, 1:1000 dilution of matrix stock
Calibration Standard 3	Stock A elements–100 μg/L, Stock B elements–50 μg/L, 1:5 dilution of matrix stock
Calibration Standard 4	Matrix stock solution, undiluted
Calibration Standard 5	1:2 dilution of matrix stock solution
Calibration Standard 6	SO_4^{2-}–141.2 mg/L, Na–50 mg/L, Ca–25 mg/L

possible trends based on changes in sample weight. Finally, sulfur, a possible interference, was monitored after calibration with Standard 6 in Table 5. An internal standard solution containing 500 μg/L ^{6}Li, 20 μg/L Rh, and 20 μg/L Ir was prepared in 20% HNO_3 (v/v). The internal standard solution was mixed on-line with the sample solution using the peristaltic pump on the ICP-MS instrument and a polypropylene barbed T-connector (Cole-Parmer Instrument Company, Part. No. WU-30506-15, Vernon Hills, IL, USA) with 0.889 mm i.d. pump tubing (Meinhard Glass Products, Golden, CO). Sample usage for the total Zn analysis was approximately 2 mL, including sample uptake and stabilization times.

In order to obtain accurate total Zn concentrations, the ^{64}Zn, ^{66}Zn, ^{67}Zn, and ^{68}Zn isotopes were added together using the elemental equations portion of the instrument software to compensate for the increasing amount of ^{67}Zn present in the samples as exposure times increased. The calibration curve for zinc was based on the total intensity (Int) of the four major zinc isotopes summed together: $Int^{total}Zn = Int^{64}Zn + Int^{66}Zn + Int^{67}Zn + Int^{68}Zn$. The ^{70}Zn isotope was not used in the determination of total Zn due to its low abundance (0.6%) and the presence of Ge, which has an isotope of major abundance (21.2%) at mass 70, in the multi-element calibration standards. The accuracy of the total zinc measurements using the summed zinc isotopes by ICP-MS was verified by a separate analysis of a subset of the samples ($n = 52$) by inductively coupled plasma atomic emission spectrometry (ICP-AES). A comparison of the ratio of the ICP-OES results to the ICP-MS results gave an average ratio of 0.99 ± 0.06, indicating the results were within acceptable agreement. A summary of the results for the total Zn measurements and for other elements of interest in the gill digests is given in Table 6. All other elements that were monitored were not detected at concentrations above 1 μg/L in the sample digests, including Ba, which is also identified in Table 3 as a potential interference on ^{68}Zn measurements. As illustrated by Table 6, the average concentrations sulfur and phosphorus, key elements that could potentially cause interferences affecting the measurement of the ^{67}Zn/^{66}Zn ratios, are both less than 10 mg/L in the digested solutions that were analyzed directly without dilution. In addition, the concentration of Mg, which could potentially cause an interference on ^{66}Zn was less than 0.5 mg/L in all solutions. Since the calculated abundance of the potential interference from Mg is very low, 0.11, as illustrated in Table 3, the potential for this molecular species causing significant impact on the measured ^{67}Zn/^{66}Zn ratios was considered to be quite low.

2.7. Isotopic Zn analysis

Since no certified natural abundance zinc isotope reference material was available, mass-bias corrections were performed using a natural abundance Zn standard, JMC Zinc (Johnsen Matthey batch 3-0749-L), which has previously been characterized by several laboratories [12–14]. Due to the limited availability of this particular standard, a secondary zinc standard, HP 403518, (1000 mg/L Zn, High Purity Standards, Lot 403518) of "natural" abundance was cross-correlated to the JMC Zinc values for use as a secondary isotopic standard. The HP 403518 standard was then run approximately every 15–20 samples during the isotopic analysis run and appropriate mass-bias corrections were applied to the sample data between bracketing standards. Although the standard-sample bracketing technique is traditionally run for each sample, i.e., the isotopic standard is run before and after every sample, the large number of sample analyses required (over 600 individual samples) us to modify this procedure in order to maintain suitable sample throughput. The JMC Zinc solution was also analyzed as a check periodically throughout the rainbow trout study sample run. It should be noted that the measured isotopic ratios are relative to the standards, JMC Zinc and HP 403518, used for mass-bias correction and are not absolute isotopic ratios, since there is no internationally agreed upon isotopic standard for zinc at the current time. However, since we are only interested in measuring observed changes in the zinc ratios due to exposure of our test organisms to enriched ^{67}Zn waters, this matter is of no consequence to the results of our study.

In order to obtain suitable precision for the zinc isotope analysis, a total integration time of 10 s was used per isotope. All five zinc isotopes, ^{64}Zn, ^{66}Zn, ^{67}Zn, ^{68}Zn, and ^{70}Zn were measured as well as ^{60}Ni, as indicated in Table 2 along with other operational parameters. Although we decided to use the ^{67}Zn/^{66}Zn ratios for this study, the ^{67}Zn/^{64}Zn ratios were also monitored. All isotope ratios were automatically calculated using the instrument software. The relative internal precision (% RSD) of the 10 replicate ^{67}Zn/^{66}Zn or ^{67}Zn/^{64}Zn measurements for each individual sample was of the order of 0.2–0.4%. Due to the long total analysis time of 15 min (including sample uptake and stabilization times) for the isotope ratio measurements, a low sample uptake rate was necessary in order to have enough solution to perform both the total Zn analysis and the Zn isotope analysis. The sample introduction system (nebulizer and peristaltic pump) was adjusted to obtain a sample flow rate of ~0.35 mL/min, requiring approximately 6 mL of sample solution per isotopic analysis.

Table 7 gives a summary of the figures of merit for the method. The expected ^{67}Zn/^{64}Zn ratio of 0.0822 and the calculated

$^{67}Zn/^{66}Zn$ ratio of 0.1455 for the JMC Zinc standard were obtained from the values last reported by Bermin et al. [13]. The expected values for the HP 403518 standard (0.0804 for $^{67}Zn/^{64}Zn$ and 0.1442 for $^{67}Zn/^{66}Zn$) were obtained by running this sample immediately after mass-bias calibration with the JMC Zinc standard. The precisions obtained over the shorter 15-h runs for the HP 403518 standard were of the order of 0.5–1.5% RSD for the $^{67}Zn/^{64}Zn$ ratio and 0.1–0.2% RSD for the $^{67}Zn/^{66}Zn$ ratio. For the 96-h long analysis of the rainbow trout gill tissue samples, the precisions obtained for both the JMC Zinc and the HP 403518 standards were of the order of 4% RSD for the $^{67}Zn/^{64}Zn$ ratio and 1% RSD for the $^{67}Zn/^{66}Zn$ ratio. It is possible that the higher RSDs for the $^{67}Zn/^{64}Zn$ ratios could be the result of the effects of the various interferences impacting the measurement of ^{64}Zn, including the correction for ^{60}Ni, as was discussed previously. The better precisions obtained for the $^{67}Zn/^{66}Zn$ ratios supported our decision to use this ratio for the study instead of the more traditional $^{67}Zn/^{64}Zn$ measurement.

As illustrated in Table 7, the short-term analytical precision of the isotope ratio method for both the zinc standards and the rainbow trout gills from the two sets of 10 exposure control samples (for hard and soft water exposures) is of the order of 0.2% RSD during the 2 h time period it took to analyze these groups of samples. In order to estimate long-term analytical precision over the course of the 96 h of total analysis time, the ratios for the zinc standards analyzed every 15–20 samples for mass-bias correction and for the composited gill QC samples in each sample preparation batch were averaged and the standard deviations calculated. As shown in Table 7, the long-term analytical precision for the mass-bias correction standards and the composited gill QC samples were 1.0% RSD and 0.7% RSD, respectively. The use of the composited gill QC sample allows the long-term analytical precision of the method to be calculated without any effects due to differences between individual fish, such as amount of endogenous zinc present, zinc uptake rate, amount of gill mucus, and gill weights. The error of the measured $^{67}Zn/^{66}Zn$ ratio over the entire 96-h period was 0.3% for the JMC Zinc standard.

3. Results and discussion

3.1. Pilot study–Brown trout

3.1.1. Determination of total Zn by ICP-MS

A summary of the results for the total Zn analysis on a gill wet-weight basis (in μg Zn/g gill), for the pilot study gill samples is given in Fig. 1. Initial studies and calculations based on counting statistics indicated that in order to obtain usable isotope ratio analyses using 10-s integration times, the zinc concentrations in the digestates needed to be 10 μg/L or greater. Total Zn concentrations in the pilot study ranged from 18 μg/L to 110 μg/L in the gill digests for individual fish and from 115 μg/L to 475 μg/L in the composited samples.

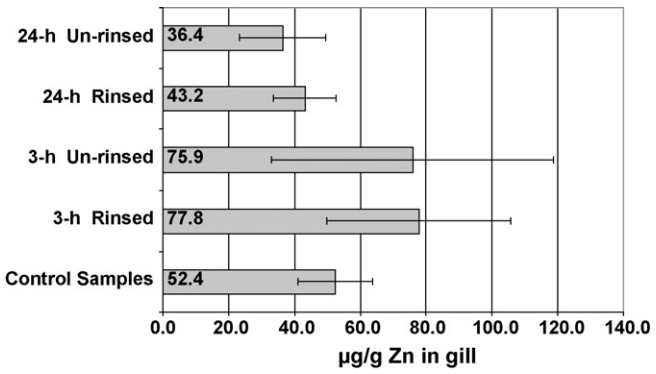

Fig. 1. Summary of total Zn content in gills (μg/g) from the brown trout pilot study, mean values are given at the base of each bar. Error bars are ±1standard deviation of measured values for each exposure group ($n = 8$ for control samples, $n = 5$ for all 3-h and 24-h exposures).

One of the considerations in the experimental design was to evaluate whether rinsing the dissected gill tissues would be necessary to remove Zn that was contained in the gill mucus and not actually bound to the gill. Earlier studies [17] had used physical means, e.g., wiping the gill material with a laboratory tissue, to remove mucus from the gill. This was identified as a possible source of contamination since leaching studies performed on laboratory wipes indicated a significant amount of Zn present (~0.9 μg/g). As the data in Fig. 1 indicate, the values of zinc found in the rinsed gills appear to have slightly less variation (based on smaller standard deviation values) than did the un-rinsed samples, presumably because any additional Zn present in the mucus or from residual exposure water was being rinsed off. However, the mean values for the rinsed and un-rinsed samples are not statistically different. From this study, it was concluded that rinsing was not a detrimental practice and could reduce the variability in the total zinc values and should be used in the rainbow trout exposure study.

In addition, as shown in Fig. 1, the error (plotted as ±1standard deviation of the mean value) on the total Zn measurement for each exposure group is quite large. It is believed this is due to the significant amount of endogenous zinc present in the gill tissues, which can vary widely from fish to fish. In fact they are so large that no significant differences can be discerned between each exposure group, confirming that the use of total Zn measurements to estimate Zn uptake in the gills would lead to inconclusive results.

3.1.2. Determination of Zn isotopes by ICP-MS

The results for the isotope ratio analyses for the pilot study are summarized in Fig. 2. Fig. 2 shows the mean $^{67}Zn/^{66}Zn$ ratio along with the error (plotted as ±1standard deviation) for each exposure group. Preliminary analysis of the ratios in Fig. 2 indicate that there is an increase in $^{67}Zn/^{66}Zn$ ratios in fish exposed to the ^{67}Zn-enriched water after just 3 h time and an even more significant increase after 24 h of exposure. However, in order to determine if the differences in the ratios were significant, a statistical analysis was performed using a two-tailed *t*-test for samples with unequal variances (MINITAB Release 14.13, State College, PA, USA). Compared to the control group that was not exposed to the ^{67}Zn-enriched water, both the 3-h rinsed and un-rinsed groups resulted

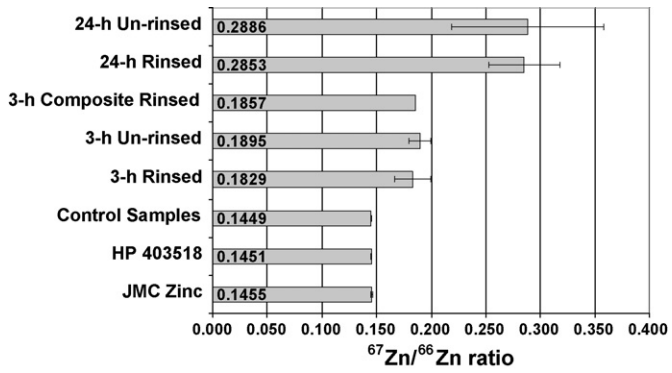

Fig. 2. Summary $^{67}Zn/^{66}Zn$ ratios for brown trout pilot exposure test results. Mean values for each exposure group are given at the base of the bar. Error bars are ±1standard deviation of measured values for each exposure group ($n = 8$ for control samples, $n = 3$ for 3-h composite group, $n = 5$ for all other 3-h and 24-h exposures).

in increases in the $^{67}Zn/^{66}Zn$ ratio that were statistically different ($p < 0.05$). Likewise, the 24-h rinsed and un-rinsed groups showed $^{67}Zn/^{66}Zn$ ratios that were significantly different than those from the 3-h rinsed and un-rinsed groups, respectively. However, comparisons of the rinsed and un-rinsed sample ratios from both the 3-h and 24-h exposures were not significantly different from one another ($p > 0.05$), although errors did vary somewhat, but not conclusively. Based on the Zn ratio data in Fig. 2, it would seem that rinsing would be unnecessary. However, as discussed in the section above, rinsing did make a difference in the variation of the total zinc values, which are also necessary for the calculations that will be ultimately be performed on the data to estimate gill Zn uptake.

For the brown trout control samples ($n = 10$) in Fig. 2, it should be noted that the mean value does not vary significantly (within the standard error) from the values obtained for the zinc standards (JMC Zinc and HP 403518) used for mass-bias correction. For the control samples, the precision obtained was 0.3% RSD. This indicates that the differences, if any, that might be occurring due to the various interferences possible in the digested gill matrix, including those from phosphorous and sulfur, are small.

It is believed that the errors observed for the measured zinc ratios in the different exposure groups are due to a number of factors, including the amount of endogenous Zn present, the small sample sizes (~20 mg of gill tissue was harvested from each fish), variation in sample size, variability in individual fish zinc uptake rates, and the relatively low number of fish ($n = 5$) in each exposure. The observed precision of 0.2% RSD for the three 3-h Composite samples in Fig. 2 is significantly smaller than the 9% RSD and 6% RSD that were obtained for the 3-h Rinsed and 3-h Unrinsed groups, respectively. This is an indication that many factors affecting overall precision are due to differences between individual fish, as discussed above. In the composited sample, these variations from individual fish have been removed by homogenization of the samples. The 3-h Rinsed and 3-h Unrinsed groups each contain five fish, averaging 3.5 g in total weight, with individual gill weights that ranged from 0.008 to 0.030 g each and an average gill weight of 0.018 g. This high variation in individual gill weights could lead to significant errors in the measured zinc isotopic ratios depending on the amount of endogenous zinc present on the gills, which would also vary on a per fish basis. The data in Fig. 2 illustrate that improved precision in the isotope ratios might be obtained if either larger fish or composited samples could be used. However, both these options have limitations, including availability of suitable numbers of stock of the same age and size, cost, space available, and predation issues (particularly with larger fish).

3.2. Rainbow trout exposure study

3.2.1. Determination of total Zn

As in the pilot study discussed previously, all gill digests were analyzed for total Zn content prior to isotopic analysis. Zinc concentrations in the gills ranged from 22.42 ± 6.43 μg/g to 80.82 ± 37.48 μg/g for the soft water exposures and from 23.47 ± 6.78 μg/g to 77.21 ± 56.22 μg/g for the hard water exposures (see Table S1 in the electronic supplement for details). All sample digests were above the minimum concentration of 10 μg/L required for the zinc isotopic analysis.

3.2.2. Determination of Zn isotope ratios

Summary data for the determination of the isotopic ratios for $^{67}Zn/^{66}Zn$ are given in Fig. 3a and b for soft water and hard water exposures, respectively. In general, a trend can be seen where the mean $^{67}Zn/^{66}Zn$ ratios increase with increased exposure concentration and time for both soft and hard water exposures. However, statistical analysis (see Table S2 in the electronic supplement for detailed data and statistics) indicates that while all exposure means differ significantly from the control means, only a few exposures in each exposure concentration group differ significantly from the exposure time immediately preceding it. Specifically, for the soft water exposures (Fig. 3a), a significant difference is only observed between the ratio means for the 3-h and 24-h exposures for the

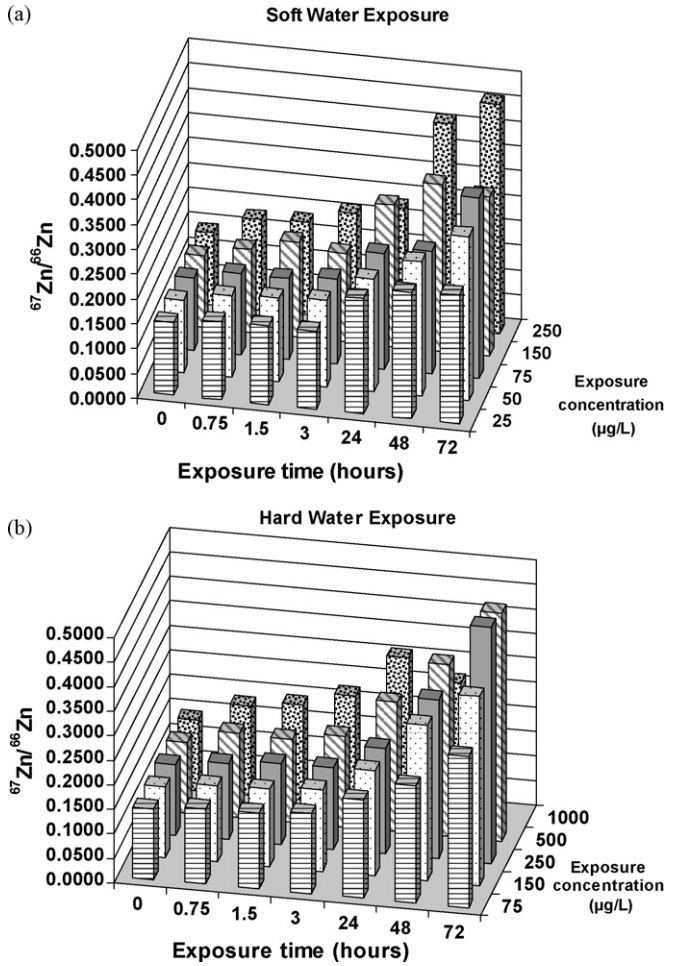

Fig. 3. (a) Summary data for $^{67/66}Zn$ ratio (mass-bias corrected) for rainbow trout exposure study using soft water. Detailed data, including statistics are available in Table S2(a). (b) Summary data for $^{67/66}Zn$ ratio (mass-bias corrected) for rainbow trout exposure study using hard water. Detailed data, including statistics are available in Table S2(b).

25 μg/L, 75 μg/L, and 150 μg/L exposure concentrations. For the hard water exposures (Fig. 3b), there is a statistical difference between the means for the 3-h and 24-h exposures at all concentrations, except for the highest exposure at 1000 μg/L. In addition, there are differences between the 3-h and 1.5-h exposures at the lowest zinc concentration, 75 μg/L, and between the 48-h and 24-h exposures at the 150 μg/L and 250 μg/L exposure concentrations. Although a general upward trend in the measured ratios was observed, as expected, the close proximity of the time intervals and concentrations could be a factor in the lack of statistically significant differences between adjacent time and concentration groupings. In addition, after 24 h, there may be complicating factors such as non-specific sorption of Zn onto the gills that result in a leveling off of the observed increase in the $^{67}Zn/^{66}Zn$ ratio, particularly in the soft waters.

Although the precision obtained for the control samples in both hard and soft waters was 0.2% RSD, for subsequent exposure times and zinc concentrations the precision of the measured values increased from 2% RSD to as much as 50% RSD (see Table S2 for detailed data). A generalized trend of increasing uncertainty with increased exposure concentrations and times was observed. Uncertainties greater than 10% RSD were observed for soft water exposure groups greater then 75 μg/L Zn and for hard water exposure groups greater than 500 μg/L Zn. Because long-term reproducibility of the measured ratios in the composited gill QC samples was very good (0.7% RSD over 96 h) the increasing relative standard deviations in the exposure groupings must be related to differences between individual fish. As stated previously, the reproducibility of the measured zinc isotope ratios is influenced by the low sample number ($n = 5$ in most cases), the high degree of variability in the total Zn concentration in each fish based on sample weight (see Table S1 in the electronic supplement for details), and the different zinc uptake rates for individual fish. These three factors result in a relatively high variance in the measured zinc ratios in each individual fish because the observed change in the $^{67}Zn/^{66}Zn$ ratios is greatly affected by the variability in the amount of total endogenous zinc on the gills as compared to the sample weight. The levels of endogenous zinc present may have greater effect on longer exposure times as zinc is ultimately exchanged between various tissues in the fish or if other effects such as increased mucus production (a stress response) occur. Nevertheless, these uncertainties should be an important consideration in any inferences made based on the calculated amount of bound zinc, particularly for longer exposure times at higher exposure concentrations.

3.2.3. Determination of accumulated zinc

The ultimate goal of the total zinc and zinc isotopic analysis was to use the measured values to determine the total zinc accumulated or bound onto the gills of each individual fish during the various exposures. The amount of bound zinc was calculated for each fish using the equation

$$Zn_{accum} = \frac{Zn_{total}(f_{67-nat} - (R_{final} \times f_{66-nat}))}{R_{final}(f_{66-enr} - f_{66-nat}) + f_{67-nat} - f_{67-enr}}$$

where Zn_{total} = total zinc post exposure in gill tissue; Zn_{accum} = total accumulated zinc in gill tissue; R_{final} = final $^{67}Zn/^{66}Zn$ ratio in gill tissue; f_{x-enr} = fraction of given isotope in exposure media; f_{x-nat} = fraction of given isotope in control gill tissue.

Calculation of total estimated analytical error on the determination of accumulated zinc using the equation above, based on measurement error propagation, results in an estimated analytical error of 2.4% on the calculated accumulated zinc values. Summarized results for calculated accumulated zinc in each exposure grouping are given in Fig. 4a and b. The mean values for accumulated zinc in all exposures for both soft and hard waters were statistically different (see Table S3 in the electronic supplement for details and statistics) from the control group. In the soft waters, all exposure concentrations show a significant difference between amount of zinc accumulated between the 3-h and 24-h exposures and the 24-h and 48-h exposures. In addition at the lowest exposure concentration, 25 μg/L, the amount of accumulated zinc is significantly different for all exposures longer than 0.75 h.

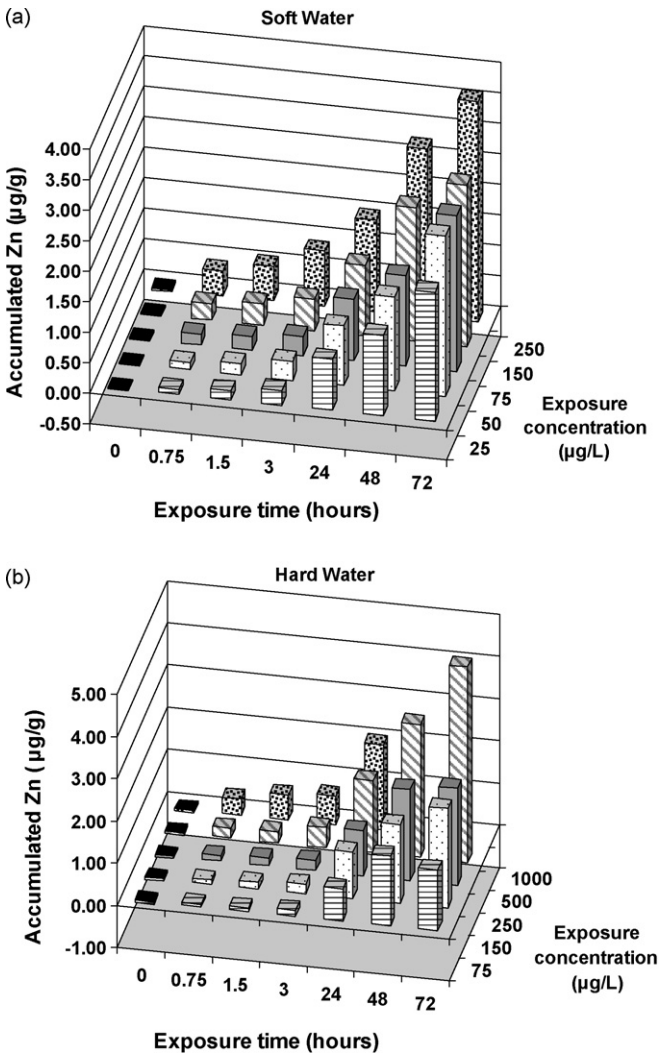

Fig. 4. (a) Summary data for accumulated zinc (μg/g) in soft water rainbow trout exposures. Detailed data, including statistics, are available in Table S3(a). (b) Summary data for accumulated zinc (μg/g) in hard water rainbow trout exposures. Detailed data, including statistics, are available in Table S3(b).

For the hard waters illustrated in Fig. 4b, all exposure concentrations show significantly different amounts of accumulated zinc between the 3-h and 24-h exposure times. In addition, the amounts of accumulated zinc also differ significantly between the 24-h and 48-h exposure times at the lower exposure concentrations (75 μg/L, 150 μg/L, and 250 μg/L).

However, the most significant result is that the amounts of accumulated zinc in the 75 μg/L, 150 μg/L, and 250 μg/L exposure concentrations differ significantly between the soft and hard exposures, as is indicated in Fig. 5. It should be noted that the error bars in Fig. 5 are the standard deviations of the average value of calculated accumulated zinc for each exposure group which were obtained from individually calculated accumulated zinc values for each fish in the study. These observed differences between exposure concentrations as a function of water hardness are important in evaluating the potential effects of water chemistry parameters, such as hardness, on fish toxicity. The use of these data is further discussed in

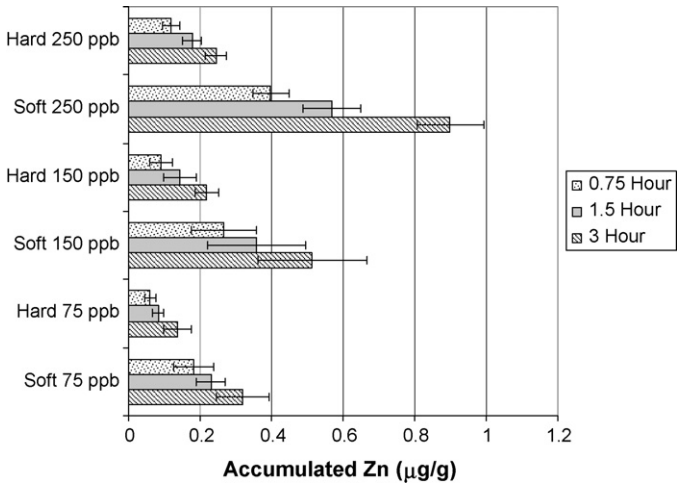

Fig. 5. Comparison of accumulated zinc in rainbow trout gills for exposures ≤3 h for both soft and hard waters. Error bars are ±1standard deviation of mean values of individually calculated values of accumulated zinc.

Todd et al. [18] for evaluating the impact of water chemistry on toxicity models, such as the Biotic Ligand Model (BLM).

4. Conclusion

The results from the pilot study indicate that the sample preparation and methods of analysis for both total Zn and Zn isotopic analysis described were suitable for use on the rainbow trout exposure study. The $^{67}Zn/^{66}Zn$ ratio was found to be less susceptible to interferences and demonstrated better precision than the more traditionally used $^{67}Zn/^{64}Zn$ ratio. As a result, the $^{67}Zn/^{66}Zn$ ratio was used in the subsequent rainbow trout exposure study. The measured $^{67}Zn/^{66}Zn$ ratios for the fish control samples did not vary significantly from those obtained for the zinc standards, indicating that any possible effects due to the presence of phosphorus and sulfur in the sample digests on the $^{67}Zn/^{66}Zn$ ratio was minimal. A key finding of the pilot study is that statistically significant differences in the $^{67}Zn/^{66}Zn$ ratios can be seen in individual fish in exposures times as short as 3 h. Another finding was that the use of composited samples could possibly improve the precision of the measured isotope ratios significantly, by eliminating differences between individual fish in each exposure group due to variables such as zinc uptake rate and endogenous since levels, if required for future studies.

The methods discussed in the pilot study were successfully used in the rainbow trout exposure study. The isotope ratio method was found to have a long-term analytical precision of 0.7% RSD for the composited gill QC samples. However, it was found that the high variability of factors such as levels of endogenous zinc, zinc uptake rate, and gill weight among individual fish in each exposure grouping resulted in widely varying total zinc concentrations and isotope ratios in the individual gill digests. This led to higher standard deviations and more uncertainty in the measured $^{67}Zn/^{66}Zn$ ratio than anticipated for each exposure grouping, particularly at longer exposure times and higher exposure concentrations. However, the calculations to determine the amount of zinc accumulated by individual fish incorporated these variances and the resulting values for accumulated zinc showed significant differences between 3-h and 24-h exposures as well as between 24-h and 48-h exposures for most exposure concentrations in both soft and hard waters. Most significant was the difference in accumulated zinc in exposure media of the same concentration in soft and hard waters. This supports other findings [1–6] that water chemistry parameters such as hardness have an important effect on aquatic toxicity results. The data obtained in this study are further discussed in relationship to the biotic ligand model and in comparison to earlier studies performed using radioactive ^{65}Zn in a companion paper by Todd et al. [18].

ABSTRACT

Poly(vinylchloride) (PVC) based membranes of macrocycles 2,3,4:9,10,11-dipyridine-1,3,5,8,10,12-hexaazacyclotetradeca-2,9-diene (L_1) and 2,3,4:9,10,11-dipyridine-1,5,8,12-tetramethylacrylate-1,3,5,8,10,12-hexaazacyclotetradeca-2,9-diene (L_2) with NaTPB and KTpClPB as anion excluders and dibutylphthalate (DBP), benzyl acetate (BA), dioctylphthalate (DOP), *o*-nitrophenyloctyl ether (o-NPOE) and tri-n-butylphosphate (TBP) as plasticizing solvent mediators were prepared and investigated as Co^{2+} selective electrodes. The best performance was observed with the membranes having the composition L_2:PVC:TBP:NaTPB in the ratio of 6:39:53:2 (w/w; mg). The performance of the membrane based on L_2 was compared with polymeric membrane electrode (PME) and coated graphite electrode (CGE). The PME exhibits detection limit of 4.7×10^{-8} M with a Nernstian slope of 29.7 mV decade^{-1} of activity between pH 2.5 and 8.5 whereas CGE exhibits the detection limit of 6.8×10^{-9} M with a Nernstian slope of 29.5 mV decade^{-1} of activity between pH 2.0 and 9.0. The response time for PME and CGE was found to be 11 and 8 s, respectively. The CGE has been found to work satisfactorily in partially non-aqueous media up to 35% (v/v) content of methanol, ethanol and 25% (v/v) content of acetonitrile and could be used for a period of 4 months. The CGE was successfully applied for the determination of Co^{2+} in real and pharmaceutical samples and as an indicator electrode in potentiometric titration of cobalt ion.

1. Introduction

The increasing use of ion sensors in the fields of environmental, agricultural and medicinal analysis is putting more and more pressure on analytical chemists to develop new sensors for the fast, accurate, reproducible and selective determination of various species. During the past few decades, many intensive studies on the design and synthesis of highly selective ionophores as sensory molecules for ion-selective electrodes have been reported and much interest has been focused on macrocyclic compounds. The design and function of synthesized macrocyclic carriers for cation selective membrane sensors are usually based on such diverse parameters as the structure and cavity size of ion carrier, the stability and its ability to extract the target ion into the membrane phase. Currently, a great deal of attention is being focused on macrocyclic ligands because they play an important role in many aspects of chemistry, medicine and the chemical industry.

The need of selective determination of heavy metal ions has increased immensely during the last few decades due to the growing environmental problems. Among heavy metals, the pollution caused by cobalt is of considerable concern. Determination of cobalt assumes importance because of its widespread occurrence in sea as well as in fresh water, earth crust, meteorites, animals and plants. It is a vital trace element in animal nutrition and widely distributed in the body with high concentration in liver, bone and kidney. Cobalt is used in high-temperature alloys, in permanent magnets and its salts are useful in paint dryers as catalysts, abrasion resistant glasses, ceramics, batteries and in production of numerous pigments like cobalt blue and cobalt green, in ground coats for porcelain enamels and in electroplating industry. Cobalt, in the form of cobalamin, is an essential component of Vit. B_{12} required for the production of red blood cells and prevention of pernicious anaemia [1]. Deficiency of cobalt may cause anaemia, retarted growth and loss of apetite. On the other hand, if consumed in large doses, cobalt may be toxic and cause diarrhea, irritation of gastrointestinal tract and vomiting. Exposure to cobalt may cause lung effects, which include respiratory irritation, coughing, asthma, pulmonary edema and pneumonia. The maximum dietary tolerable level of cobalt for common livestock species is 10 ppm [2].

A number of sophisticated methods such as flame atomic absorption [3], electrochemiluminescence [4], thin film sequential injection [5], graphite furnace-atomic absorption spectrometry (GF-AAS) [6], electrothermal-atomic absorption spectrometry [7], differential pulse anodic stripping voltammetry [8] have been reported for the determination of cobalt. However, these methods are disadvantageous as they are time consuming, involves sample

doi:10.1016/j.talanta.2009.07.049

manipulation, relatively expensive and require large infrastructure back up. Selective analytical methodologies, which are easily operated and involve harmless reagents, cost effective equipment, have therefore been proposed as alternative to standard methods. Potentiometric sensors based on ion-selective electrodes are especially suited for such determination because they offer advantages such as selectivity, sensitivity, good precision, simplicity and low cost [9,10].

A literature survey revealed that the sensors developed for cobalt make use of chelates [11], macrocycles [12–17], extractants [18], organic resins [19,20], mercapto compounds [21], OXCDD (diamide) [22], Schiff base [23,24], isothiazole [25], calixarenes [26,27] and variety of other ligands [28,29]. However, most of these sensors suffer from disadvantages such as narrow working concentration range. With a near or non-Nernstian response, exhibit high response time, poor reproducibility.

The purpose of the present work is to explore the polymeric membrane electrode (PME) and coated graphite electrode (CGE) as Co^{2+} selective sensors based on two newly synthesized macrocyclic ligands (L_1 and L_2).

2. Experimental

2.1. Reagents

Reagent grade sodium tetraphenylborate (NaTPB), potassium tetrakis *p*-(chloro phenyl)borate (KTpClPB), dibutylphthalate (DBP), tri-n-butylphosphate (TBP), benzyl acetate (BA), dioctylphthalate (DOP), *o*-nitrophenyloctyl ether (*o*-NPOE), tetrahydrofuran (THF) and high molecular weight poly(vinylchloride) were purchased from E. Merck (Germany) and used as received. Ethylenediamine and 2,6-dichloropyridine were procured from Aldrich (USA). The nitrate salts of all the cations used were of analytical grade and used without any further purification. The solutions of metal salts were prepared in doubly distilled water and standardized whenever necessary.

2.2. Synthesis of macrocyclic ligand 2,3,4:9,10,11-dipyridine-1,3,5,8,10,12-hexaaza-cyclotetradeca-2,9-diene (L_1)

The macrocyclic ionophore L_1 (Fig. 1) was synthesized by dissolving equimolar amounts of ethylenediamine (0.01 M) and 2,6-dichloropyridine (0.01 M). Ethylenediamine was dissolved in minimum quantity of methanol and to this solution 2,6-dichloropyridine dissolved in methanol was added dropwise with stirring. The resulting mixture was refluxed for 10 h and then was concentrated to half of its original volume on a water bath, followed by cooling and keeping aside for 1 day. A white crystalline product was obtained. Yield: 72%. M.pt.: 138 °C. Anal. calcd. for [$C_{14}H_{18}N_6$] (%): C, 62.19; H, 6.69; N, 31.12; Observed (%): C, 62.20; H, 6.71; N, 31.09, ^{1}H NMR (MeOH, 500 MHz) δ_{ppm}: 7.02–7.64 (m, H–Ar, 6H), 2.64–2.67 (m, –C–NH–C–, 4H), 2.32 (s, –N–CH_2–C, 8H). FT-IR (KBr, cm^{-1}): 3268 (–NH str.).

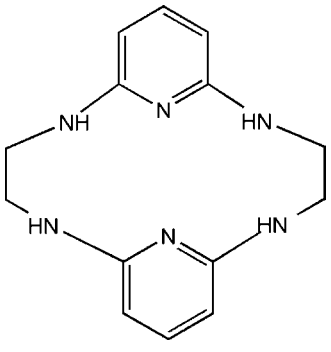

Fig. 1. Structure of macrocyclic ligand 2,3,4:9,10,11-dipyridine-1,3,5,8,10,12-hexaazacyclotetradeca-2,10-diene (L_1).

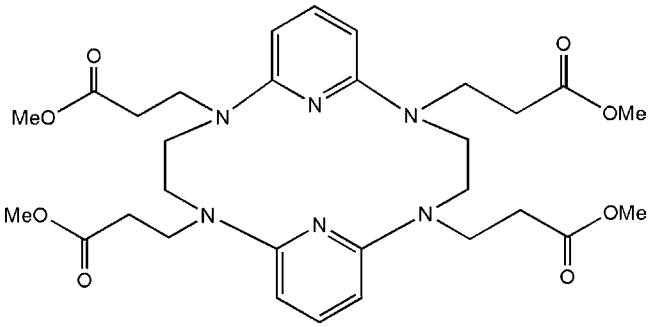

Fig. 2. Structure of macrocyclic pendant ligand 2,3,4:9,10,11-dipyridine-1,5,8,12-tetramethylacrylate-1,3,5,8,10,12-hexaazacyclotetradeca-2,10-diene (L_2).

2.2.1. Synthesis of macrocyclic ligand 2,3,4:9,10,11-dipyridine-1,5,8,12-tetramethylacrylate-1,3,5,8,10,12-hexaazacyclotetradeca-2,9-diene (L_2)

The macrocyclic pendant ligand L_2 (Fig. 2) was synthesized from macrocycle L_1. To a stirred solution of the macrocycle L_1 (1 mmol) in 10 mL saturated solution of anh. K_2CO_3 in anhydrous MeOH, 5 mL methylacrylate (excess amount) was added drop by drop and then it was stirred overnight and refluxed for 24 h. Then the volume was reduced half of its initial amount and was kept in a refrigerator overnight. A creamish coloured oily product was obtained. Yield: 43%. Anal. calcd. for [$C_{30}H_{42}N_6O_8$] (%): C, 58.60; H, 6.88; N, 13.67; O, 20.85; Observed (%): C, 58.62; H, 6.89; N, 13.67; O, 20.82. ^{1}H NMR (MeOH, 500 MHz) δ_{ppm}: 6.90–7.22 (m, H–Ar, 8H), 2.97–3.25 (m, –N–CH_2–C–, 8H), 2.52 (s, N–CH_2–CH_2–N, 8H), 2.38–2.42 (m, –C–CH_2–COOMe, 8H), 1.36 (s, –OCH_3, 12H), FT-IR (KBr, cm^{-1}): 2930 (asymmetric –CH_2– str.), 2848 (symmetric –CH_2– str.), 1747 (ester C=O str.), 1570–1382 (aromatic C=C and C=N str.), 1163 (OC–OCH_3 str.), 1109 (–OCH_3 str.).

2.3. Electrode preparation

The nature and amount of ionophore, nature of plasticizers, plasticizer/PVC ratio and especially the nature of lipophilic additives used, are known to significantly influence the sensitivity and selectivity. Varying amount of the ion-active phase and anion excluder KTpClPB and NaTPB were dissolved with an appropriate amount of PVC in 3 mL THF. To these, solvent mediators, *viz*. DBP, TBP, BA, DBS and *o*-NPOE were added to get membranes of different compositions. The mixture was shaken vigorously with a glass rod. When the solution became viscous it was poured in acrylic ring placed on smooth glass plate. The solution was then allowed to evaporate for 24 h at room temperature. Transparent membranes of about 0.1 mm thickness were obtained, which were then cut to size and glued to one end of a pyrex glass tube with araldite. The ratio of membrane ingredients, time of contact and concentration of equilibrating solution were optimized so that the potential recorded were reproducible and stable within the standard deviation. Membrane to membrane reproducibility was assured by carefully following the optimum condition of fabrication. The membrane that gave reproducible results and showed best performance was selected for further studies.

To prepare the coated graphite electrodes, spectroscopic grade graphite rods 10 mm long and 3 mm in diameter were used. A

* Mean value ± standard deviation (three measurements).

shielded copper wire was glued to one end of the graphite rod, and the electrode was sealed into the end of a PVC tube of about the same diameter with epoxy resin. The working surface of the electrode was polished with fine alumina slurries on a polishing cloth, sonicated in distilled water and dried in air. The polished graphite electrode was dipped into the membrane solution mentioned above, and the solvent was evaporated. A membrane was formed on the graphite surface, and the electrode was allowed to stabilize overnight.

2.4. Equilibration of membranes and potential measurements

The time of contact and concentration of equilibrated solutions were optimized so that the sensors generated stable and reproducible potentials at relatively short response times. The polymeric membrane electrodes and coated graphite electrodes were equilibrated for 4 days and 2 days, respectively in a 1.0×10^{-1} M $Co(NO_3)_2$ solution. The potentials were measured by varying the concentration of $Co(NO_3)_2$ in test solution in the range 1.0×10^{-9} to 1.0×10^{-1} M. Standard $Co(NO_3)_2$ solution was obtained by gradual dilution of 0.1 M $Co(NO_3)_2$ solution. The emf measurements with the polymeric membrane electrode and the coated graphite electrode were carried out on a Orion 4 pH meter at 25 ± 0.1 °C using saturated calomel electrode (SCE) as reference electrode with the following cell assemblies:

$Hg/Hg_2Cl_2|KCl$ (satd.)|internal solution (0.1 M $Co(NO_3)_2$)||PVC membrane||sample solution|$Hg\text{-}Hg_2Cl_2$, KCl (satd.) (PME).

CGE||test solution||$Hg\text{-}Hg_2Cl_2|KCl$ (satd.)

Activity coefficients were calculated according to the Debye–Huckel procedure, using the following equation [30].

$$\log \gamma = -0.511 z^2 \left[\frac{\mu^{1/2}}{(1 + 1.5\mu^{1/2}) - 0.2\mu} \right] \quad (1)$$

where μ is the ionic strength and z the valency.

2.5. Determination of formation constant

Formation constant of the ion–ionophore complex within the membrane phase is a very important parameter that indicates the practical selectivity of the sensor. In this method, two membrane segments are fused together, with only one containing the ionophore, to give a concentration-polarized sandwich membrane. A membrane potential measurement of this transient condition reveals the ion activity ratio at both interfaces, which translates into the apparent binding constants of the ion–ionophore complex [31]. In this method complex formation constants were obtained by neglecting ion pairing. As reported, the membrane potential E_M was determined by subtracting the cell potential for a membrane without ionophore from that for the sandwich membrane. The formation constant was then calculated from the following equation:

$$\beta_{IL_n} = \left(L_T - \frac{nR_T}{Z_I} \right)^{-n} \exp\left(\frac{E_M z_I F}{RT} \right) \quad (2)$$

where L_T is the total concentration of ionophore in the membrane segment, R_T is the concentration of lipophilic ionic site additives, n is the ion–ionophore complex stoichiometry, and R, T and F are the gas constant, the absolute temperature, and the Faraday constant. The ion I carries a charge of z_I. The determined formation constants ($\log \beta_{IL_n}$) for the examined different complexes are recorded in Table 1. The elapsed time between sandwich fusion and exposure to electrolyte was typically <1 min. The potential was recorded as the mean of the last minute of a 5 min measurement period in the appropriate salt solution. The potential of such sandwich membranes remained free of diffusion-induced potential drifts for about 20 min. Standard deviations were obtained based on the measurements of sets of at least three replicate membrane disks that were made from the same parent membrane. A careful analysis of the data in Table 1 reveals that cobalt ion has significant cation-binding characteristics.

3. Results and discussion

3.1. Optimization of membrane composition

The selectivity, linearity and sensitivity obtained for a given ionophore depend significantly on the membrane composition, nature of plasticizers and additive used [32–34]. The potentials of membranes of two macrocyclic ligands L_1 and L_2 were investigated as a function of cobalt ion concentration and the results are summarized in Tables 2 and 3, respectively. The optimization of membrane sensor is known to be highly dependent on the incorporation of additional membrane components. In order to guarantee a good membrane performance, an adequate plasticizer must show sufficient lipophilicity, no crystallization and exudation in the membrane phase. It is now well established that the plasticizer plays a vital role in the sensor performance as it is responsible for ionophore salvation and distribution in the membrane matrix, thus controlling the detection limit affecting the selectivity and sensitivity and giving the plastic membrane its proper elasticity and strength. It can be seen from Fig. 3 that the sensor no. 1 having membrane of L_1 without plasticizer exhibits linear response over a working concentration range of 3.4×10^{-5} to 1.0×10^{-1} M with a slope of 28.2 mV decade^{-1} of activity. Similarly, sensor no. 13 (Fig. 4) having the membrane of L_2 without plasticizer exhibits working concentration range of 3.6×10^{-5} to 1.0×10^{-1} M with a slope of 27.8 mV decade^{-1} of activity. The slopes of the membranes are near Nernstian and the working concentration ranges narrow.

Several membranes of varying composition were fabricated to improve the performance characteristics of the electrode by adding different plasticizers such as DBP, BA, DOP, o-NPOE and TBP as shown in Fig. 3 (for L_1) and Fig. 4 (for L_2) and the results are compiled in Tables 2 and 3, respectively. The electrodes based on L_1 and L_2 exhibited good Nernstian behaviour with DOP and TBP, respectively.

It is well known that the incorporation of lipophilic additive can significantly improve the selectivity of an ion sensor by decreasing the membrane resistance and co-ion interference [35]. In our experiments, we examined the effect of NaTPB and KTpClPB as suitable lipophilic additives in conjugation with ionophores L_1 and L_2 on the potentiometric response of Co(II) selective electrode. As is obvious from Tables 2 and 3, the use of 3 mg KTpClPB (for L_1) and 2 mg NaTPB (for L_2) significantly improves the performance characteristics of the membrane sensors.

The variation in potential with different amounts of ionophores was also examined as shown in Table 2 (sensor nos. 8–10) and Table 3 (sensor nos. 19, 21, 22). In this case of carrier type ion-selective electrodes, the extraction equilibrium in the vicinity of the interface between the membrane and aqueous layer affects the potentiometric response of membrane. Inspite of these considerations, a carrier content of 7 mg for L_1 and 6 mg for L_2 was chosen as the optimum ionophore amount, because the surface conditions of the PVC membrane deteriorated on decreasing and

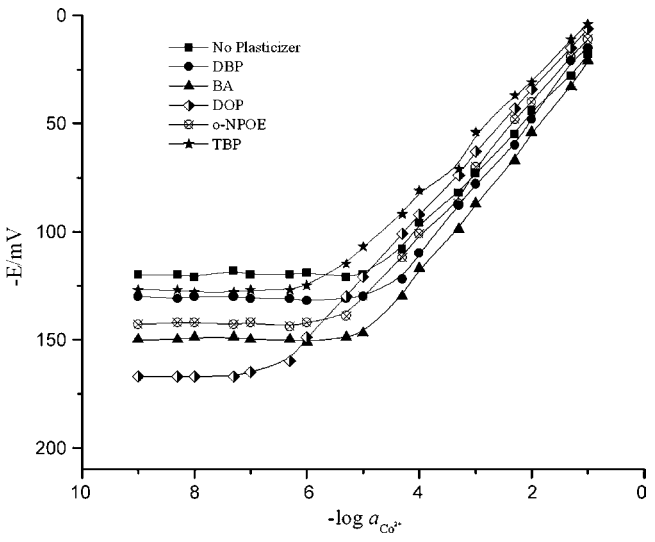

Fig. 3. Plots showing variation of membrane potential with the concentration of Co^{2+} ions based on L_1 with different plasticizers.

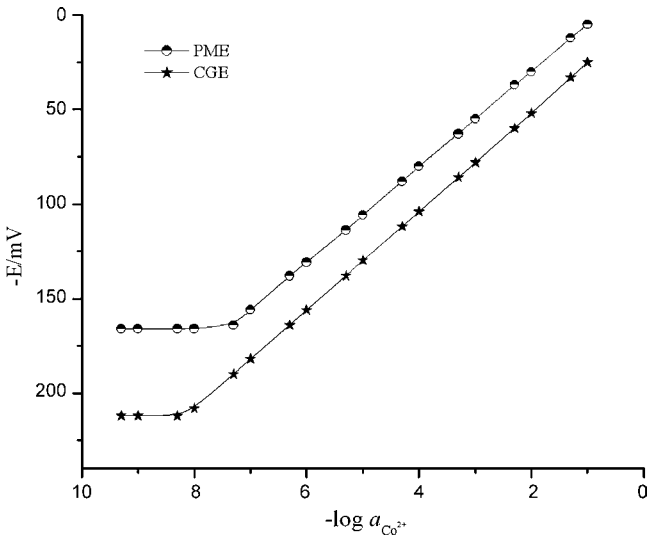

Fig. 5. Calibration characteristics of Co^{2+} selective electrodes (PME and CGE) based on L_2.

increasing the carrier content. Hence the membrane obtained with L_1:PVC:DOP:KTpClPB in the ratio of 7:32:58:3 (w/w; mg) (sensor no. 8) and L_2:PVC:TBP:NaTPB ratio as 6:39:53:2 (w/w: mg) (sensor no. 19) showed Nernstian slope over wide Co^{2+} concentration range.

3.2. Potentiometric response characteristics of the best electrode

The result thus obtained indicate that the best electrode (no. 8) (Table 2) based on L_1 exhibits a Nernstian slope (29.9 ± 0.2 mV decade^{-1} of activity) and a concentration range of 4.6×10^{-7} to 1.0×10^{-1} M with a limit of detection 2.2×10^{-7} M while the best results are shown by the electrode (no. 19) (Table 3) based on L_2 which exhibits a good Nernstian slope (29.7 ± 0.2 mV decade^{-1} of activity) over a wide concentration range of 6.0×10^{-8} to 1.0×10^{-1} M with a limit of detection 4.7×10^{-8} M.

3.3. Effect of internal solution

The proposed electrodes were also examined at different concentration of inner reference solution (1.0×10^{-1} to 1.0×10^{-3} M) and potential response of the electrodes based on L_1 and L_2 membrane have been observed. It was found that the best results in terms of slope and working concentration range has been obtained with internal solution of activity 1.0×10^{-1} M. Thus, 1.0×10^{-1} M concentration of the reference solution was quite appropriate for the smooth functioning of the proposed electrodes.

3.4. Response characteristics of polymeric membrane electrode (PME) and coated graphite electrode (CGE)

The investigations on PVC based membrane of two macrocyclic ligands, *viz.* L_1 and L_2 have shown that they act as Co^{2+} selective sensors. However, of the two ligands, the sensor no. 19 based on (L_2) containing TBP as solvent mediator with the composition L_2:PVC:TBP:NaTPB in the ratio of 6:39:53:2 (w/w; mg) exhibit widest working concentration range (6.0×10^{-8} to 1.0×10^{-1} M), Nernstian compliance (29.7 ± 0.2 mV decade^{-1} of activity), low detection limit (4.7×10^{-8} M) and high selectivity for Co^{2+} ions. The performance of this membrane based on L_2 was compared with polymeric as well as coated graphite electrode. Thus, sensor no. 19, *i.e.* membrane containing TBP as plasticizer was selected to prepare both the PME and CGE for the Co^{2+} ion.

The EMF response of the PME and CGE (Fig. 5) indicates their Nernstian behaviour over a wide concentration range. A comparison of data given in Table 4 revealed the superiority of CGE with respect to concentration range (1.3×10^{-8} to 1.0×10^{-1} M), detection limit (6.8×10^{-9} M) and Nernstian slope (29.5 mV decade^{-1} of activity) over PME. The improved performance characteristics of the CGE over those of PME presumably originate from the coated graphite technology, where an internal 1.0×10^{-1} M $Co(NO_3)_2$ solution, in case of PME, has been replaced by a copper wire of much higher electrical conductivity, in case of CGE. It is well known that the higher limit of detection of PME than that of CGE is mainly due to some leakage of the internal solution into the test solution via. polymeric membrane [36].

3.5. Effect of soaking time and lifetime

The lifetime of the electrodes were determined by soaking both PME and CGE in 0.1 M $Co(NO_3)_2$ solution for interval ranging from 2 to 120 days till the electrode lost its Nernstian behaviour. This behaviour attributed to the decomposition of the ionophore and loss of other components in the membrane phase that was in contact with aqueous test solution containing cobalt ion. The response of both electrodes has been measured by recording the calibration graph at 25 °C at different intervals. The results listed in Table 5 show the effect of soaking time on slope, detection limit and concentration range. It can be seen that the lifetime measured in this way was found to be 3 months for PME and 4 months for CGE during which the slope of electrode, showed only a slight change from 29.7 ± 0.2 to 23.1 ± 0.2 mV decade^{-1} of activity for PME and 29.5 ± 0.1 to 24.5 ± 0.1 mV decade^{-1} of activity for CGE.

3.6. Dynamic response time behaviour of the proposed sensors

Dynamic response time is an important factor for any ion-selective electrodes. To measure the dynamic response time of the proposed electrode the concentration of the test solution was

Response time (s)	11	8
Life span	3 months	4 months
pH range	2.5–8.5	2.0–9.0

Table 5
Effect of soaking time on the potential response of the cobalt selective electrode.

Soaking time	Slope (mV decade^{-1} of activity)	Working concentration range (M)	Detection limit (M)
PME			
2 days	29.7	6.0×10^{-8} to 1.0×10^{-1}	4.7×10^{-8}
10 days	29.7	6.5×10^{-8} to 1.0×10^{-1}	4.9×10^{-8}
25 days	29.4	7.0×10^{-8} to 1.0×10^{-1}	5.3×10^{-8}
45 days	29.2	7.9×10^{-8} to 1.0×10^{-1}	6.0×10^{-8}
70 days	28.9	8.4×10^{-8} to 1.0×10^{-1}	7.1×10^{-8}
90 days	28.5	9.7×10^{-8} to 1.0×10^{-1}	7.9×10^{-8}
95 days	23.1	4.2×10^{-7} to 1.0×10^{-1}	2.3×10^{-7}
CGE			
2 days	29.5	1.3×10^{-8} to 1.0×10^{-1}	6.8×10^{-9}
10 days	29.4	1.8×10^{-8} to 1.0×10^{-1}	7.0×10^{-9}
25 days	29.2	2.6×10^{-8} to 1.0×10^{-1}	7.3×10^{-9}
45 days	29.0	3.1×10^{-8} to 1.0×10^{-1}	7.9×10^{-9}
70 days	28.9	4.8×10^{-8} to 1.0×10^{-1}	8.4×10^{-9}
90 days	28.6	6.1×10^{-8} to 1.0×10^{-1}	8.8×10^{-9}
105 days	28.4	7.4×10^{-8} to 1.0×10^{-1}	9.0×10^{-9}
120 days	28.2	9.1×10^{-8} to 1.0×10^{-1}	9.8×10^{-9}
125 days	24.5	1.5×10^{-7} to 1.0×10^{-1}	9.4×10^{-8}

successively changed from 1.0×10^{-6} to 1.0×10^{-1} M. The average time required for the electrodes to reach a potential response within ±1 mV of the final equilibrium value after successive immersion in a series of Co^{2+} ion solution, each having a 10-fold difference in concentration was 11 s for PME (Fig. 6) and 8 s for CGE (Fig. 7). Potentials generated by the developed sensors remained stable for more than ~5 min after which a slow divergence was recorded. The much higher electrical conductivity of the copper wire (in CGE) than that of the internal solution (in PME) is expected to result in lower response time of the CGE in comparison with the PME.

3.7. Influence of pH on sensor performance

The pH dependence of both PME and CGE has been tested over the pH range 1.0–10.0 for 1.0×10^{-3} and 1.0×10^{-4} M for the Co^{2+} ion. The pH was adjusted by using 0.1 M solution of either HCl or NaOH and the results are shown in Fig. 8. It can be seen that potential response for PME remains constant over pH range 2.5–8.5 and 2.0–9.0 for CGE. Therefore, the same was taken as the working pH range of the electrodes. The significant change in potential response observed at lower pH can be reasonably related to the response of the sensor to the hydrogen ions. On the other hand, the observed potential drift at higher pH values could be due to the formation of some hydroxyl complexes of Co^{2+} in solution.

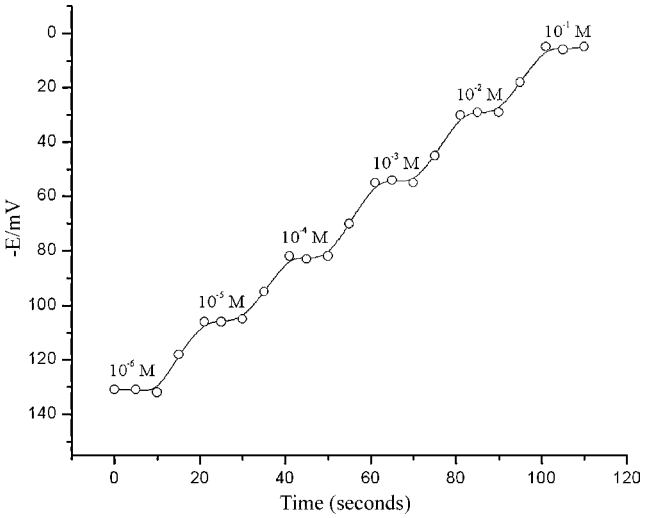

Fig. 6. Dynamic response of polymeric membrane electrode based on L_2.

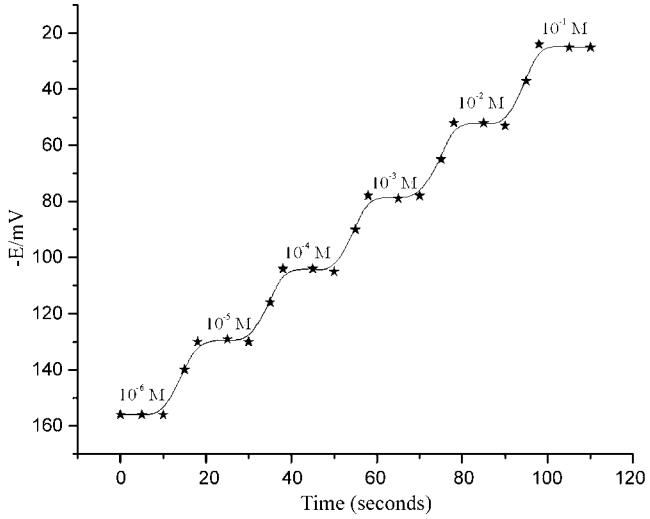

Fig. 7. Dynamic response of coated graphite electrode based on L_2.

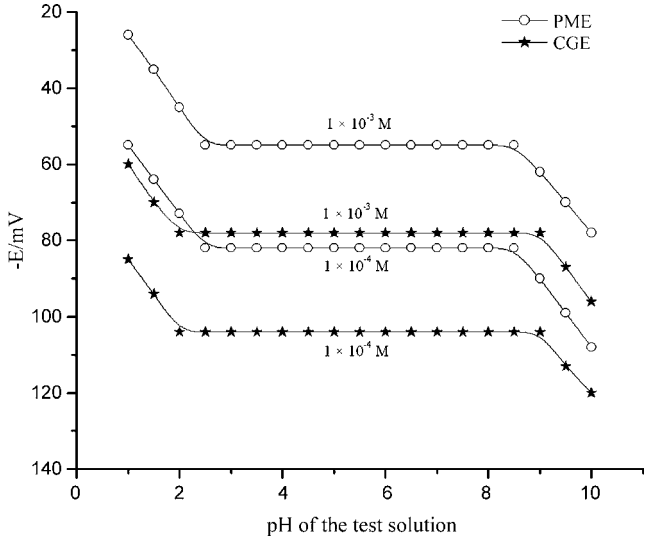

Fig. 8. Effect of pH of the test solutions on the potential responses of the PME and CGE.

3.8. Effect of interfering ions on sensor performance

Selectivity is an important characteristic of an electrode that delineates the extent to which the device may be used in the estimation of analyte ion in the presence of other ions and extent of utility of any electrode in real sample measurement. In this work, the selectivity coefficients of the electrode towards different cationic species were evaluated by using the fixed interference method (FIM) [37] and matched potential method (MPM) [38]. In the matched potential method, the selectivity coefficient was determined by measuring the change in potential upon increasing the primary ion activity from an initial value of a_A to a'_A and a_B represents the activity of interfering ion added to the reference solution of primary ion of activity a_A which also brings about same potential change. It is given by expression:

$$K^{pot}_{A,B} = \frac{\Delta a_A}{a_B} = \frac{a'_A - a_A}{a_B}$$

In the present studies a_A and a'_A were kept at 1.0×10^{-3} and 3.0×10^{-3} M Co^{2+} and a_B was experimentally determined.

However, in the FIM, the selectivity coefficient was evaluated from potential measurement on solutions containing a fixed concentration of interfering ion (1.0×10^{-2} M) and varying amount of Co^{2+} ions. The selectivity coefficient was calculated from the following equation:

$$K^{pot}_{A,B} = \frac{a_A}{(a_B)^{z_A/z_B}}$$

where a_A is the activity of primary ion A (Co^{2+}) at the lower detection limit in the presence of interfering ion B, a_B, the activity of interfering ion B and z_A and z_B are their respective charges.

The values of selectivity coefficient so determined for PME and CGE are compiled in Table 6. It is quite obvious from the corresponding table that Co (II) ion-selective electrodes are highly selective w.r.t. other common cations. The data in Table 6 revealed that, in all cases, the selectivity coefficients obtained for CGE are lower than those for the PME, emphasizing the superiority of CGE in this respect as well and hence further studies were carried out with it only.

Table 6
Selectivity coefficient of various interfering ions for Co^{2+} selective electrodes.

Metal ions	Selectivity coefficient ($K^{MPM}_{A,B}$)

30	1.0×10^{-7} to 1.0×10^{-1}	24.7

3.9. Effect of non-aqueous content

The real samples may also contain non-aqueous component, and the performance of the sensor was also investigated in partially non-aqueous media using 10%, 20%, 30%, 35% and 40% (v/v) methanol–water, ethanol–water and acetonitrile–water mixtures (Table 7). It was found that the membranes did not show any appreciable change in working concentration range and slope in methanol–water and ethanol–water mixtures up to 35% (v/v) non-aqueous contents, whereas in acetonitrile–water mixture, membrane could tolerate up to 25% (v/v) non-aqueous content. However, above these mentioned non-aqueous contents, the slope and working concentration range decreased appreciably, consequently reliable measurements could not be obtained. The drift in potentials in the organic phase may probably be due to swelling in membrane and made it mechanically weak and leaching of ionophore from membrane to non-aqueous solution took place.

3.10. Effect of ionic and nonionic surfactants

It is commonly known that both ionic and nonionic surfactants interact with the polymer membrane being divided between the aqueous phase and the membrane phase and result in increased background potential and lower binding ability for the ionophore [39]. Such effects should result in deteriorated detection limits, reduced response slopes and lower selectivity for the primary ions.

In the present paper, we examined the effect of cationic (tetrabutylammonium chloride, TBC), anionic (sodium dodecyl sulfate, SDS) and nonionic (Triton X-100) surfactants on the potentiometric properties of proposed CGE based on the macrocyclic pendant ligand L_2 and the results obtained are compiled in Table 8. It was observed that the content of surfactants up to 1.0×10^{-4} M does not cause any significant change in the response characteristics of the proposed electrode. However, concentration of the surfactants above 1.0×10^{-4} M adversely affected the performance of the electrode as the selectivity, slope and working concentration range were observed to decrease.

4. Analytical application

The analytical applicability of the electrode was evaluated by carrying out potentiometric titration of 20 mL of 5.0×10^{-3} M Co(II) ions against 1.0×10^{-2} M EDTA at pH 6 using CGE as an indicator

Table 8
Effect of different surfactants on the performance of Co(II) selective electrode.

Interfering ions	−log (selectivity coefficients)

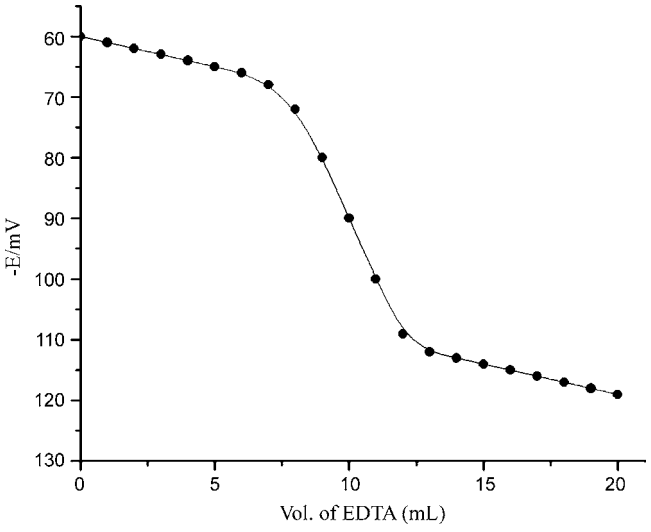

Fig. 9. Potentiometric titration curve of 20 mL of 5.0×10^{-3} M solution of Co^{2+} ion with 1.0×10^{-2} M EDTA at pH 6.0 using CGE as indicator electrode.

electrode. The titration plot shown in Fig. 9 is of sigmoid shape that is also an indication of selectivity of electrode. The inflexion point of the plot corresponds to 1:1 stoichiometry of Co-EDTA complex.

The proposed coated graphite electrode (CGE) was successfully applied for the direct determination of cobalt in different water samples. The results are given in Table 9. It was found that the cobalt contents obtained from triplicate measurements were in satisfactory agreement with those obtained by using AAS method.

Table 9
Potentiometric determination of Co^{2+} ions in different water samples by CGE.

Samples	ISE[a] (mg/mL)	AAS[a] (mg/mL)
Fresh water	0.58 ± 0.01	0.61 ± 0.03
River water	6.47 ± 0.02	6.46 ± 0.02
Sea water	13.26 ± 0.01	13.22 ± 0.02

[a] Results of triplicate measurements.

The cobalt selectivity exhibited by the membrane electrode makes it potentially useful for monitoring the concentration of Co^{2+} in real samples. In this regard, experiments were performed to measure Co^{2+} in beer samples. Cobalt is present in trace amounts in virtually all-living tissues and thus the raw materials used for brewing barley, corn, rice and hops, are no exception. As a consequence, commercial beer normally contains a minute concentration of cobalt, usually a few hundredths of a part per million. So there is need to develop a method to check whether a beer sample contains added cobalt or not. An amount of 1 mL of 18N H_2SO_4 was added to 50 mL of degassed beer, evaporated to dryness and 10 mL of distilled water was added. The pH was adjusted to 6.0 using either 0.1N HCl or 0.1N NaOH. The solution was filtered and finally diluted to 50 mL with water. A beer containing known amount of cobalt was chosen. Aliquots of the working solution were added to 50 mL samples of this beer, to give known concentration of added cobalt ranging from about 0.6–1.5 ppm. The concentration of added cobalt was then determined for each sample by CGE that is presented in Table 10.

The accuracy and applicability of the proposed CGE was also evaluated by its application for the determination of cobalt in various pharmaceutical samples. A sample each of injectable Neurobion (Merck, India) and Sioneuron (Albert David Ltd., India) was digested with nitric acid in a covered beaker. The residue of the sample was leached with dil. H_2SO_4 and diluted to the mark in a calibrated flask. Working solutions were prepared by taking an appropriate amount of the sample and its cobalt content was determined by the proposed electrode. The results obtained are compiled in Table 11 and were found to be in good agreement with those obtained by AAS, thereby reflecting the utility of this sensor for determination of cobalt in real samples.

5. Conclusion

The investigations on PVC based membrane of two macrocyclic ligands *viz.* (L_1) and (L_2) shows that they are Co^{2+} selective sensors. However, of the two ligands, the sensor no. 19 based on L_2 with membrane composition L_2:PVC:TBP:NaTPB in the ratio of 6:39:53:2 (w/w; mg) exhibited widest working concentration range (6.0×10^{-8} to 1.0×10^{-1} M), Nernstian compliance (29.7 mV decade^{-1} of activity) and high selectivity for cobalt ions. The performance of the membrane based on L_2 was compared with PME as well as with CGE. Comparison of data (Table 4) revealed that CGE was superior to PME with regard to detection limit (6.8×10^{-9} M), response time (8 s) and selectivity. The proposed sensor is superior to the reported sensors (Table 12). Thus, the CGE was used as indicator electrode in the potentiometric titration of Co^{2+} ions with EDTA and in determination of cobalt ions in real and pharmaceutical samples.

ABSTRACT

Molecular imprinted polymers (MIPs) were prepared through thermal polymerization by using quercetin as the template molecule, acrylamide (AA) as the functional monomer and ethylene glycol dimethacrylate (EDMA) as the cross-linker in the porogen of tetrahydrofuran (THF). The synthesized MIPs were identified by both Fourier transform infrared (FTIR) and scanning electron microscope (SEM). Systematic investigations of the influences of key synthetic conditions, including functional monomers, porogens and cross-linkers, on the recognition properties of the MIPs were conducted. Scatchard analysis revealed that the homogeneous binding sites were formed in the polymers. Besides quercetin, two structurally similar compounds of rutin and catechol were employed for molecular recognition specificity tests of MIPs. It was observed that the MIPs exhibited the highest selective rebinding to quercetin. Accordingly, the MIPs were used as a solid-phase extraction (SPE) sorbent for the extraction and enrichment of quercetin in cacumen platycladi samples, followed by HPLC-UV analysis. The application of MIPs with high affinity and excellent stereo-selectivity toward quercetin in SPE might offer a novel method for the enrichment and determination of flavonoid compounds in the natural products.

1. Introduction

Molecular imprinting technique (MIT) is an attractive synthetic approach to mimic natural molecular recognition [1–4], which exhibits a high affinity and selectivity toward a particular target compound (template molecule). The MIT utilizes template molecules to assemble their own recognition sites by interacting with complementary functional groups of appropriate monomers. The technique is schematically depicted in Fig. 1. In the process, the selected template molecules (quercetin) are first allowed to establish binding interactions with functional monomers (acrylamide, AA), in which the polymerizable functional monomers are pre-arranged around a template molecule in porogenic solvent. The resulting complexes are then copolymerized with an excess of cross-linkers (ethylene glycol dimethacrylate, EDMA) in the presence of a free radical initiator (2,2′-Azobisisobutyronitrile, AIBN) by thermal polymerization. Subsequent removal of the template molecules creates specific binding sites with the precise spatial arrangement of the functional groups in the polymer network together with the shape [5]. Thus, reversible re-binding and high selective recognition of the target molecules are realized. Since it was invented by Wuff and Sarhan [6], MIT has been exploited extensively in many fields including chiral resolution [7], biosensor [8], biochemical separation [9–11], antibody simulation [12], enzyme catalysis simulation [13], etc. So, molecularly imprinted polymers (MIPs) display excellent application prospects. In particular, MIPs used as adsorbents of solid-phase extraction (SPE) are being widely involved in the concentration and determination of drug molecules, and the extraction of active components from natural products [2,14–16].

Quercetin (3,3′,4,5,7-penta-hydroxy flavone) is the most active compound in flavone family, widely occurring in leaves, fruits, and flowers of many plants [17]. Quercetin has now become the topic of increasing interest based on its various bioactivities such as inoxidability, antiviral property, antitumor and adjusting the immune function [18], as well as its chemical applications, e.g., quercetin is immobilized on silica gel and used as a solid-phase reagent for tin (IV) determination [19]. The determination of quercetin is typically performed with HPLC-UV [15,20,21], besides electrogenerated chemiluminescence (ECL) [22] and capillary electrophoresis (CE) [23]. Because of the existence of quercetins in nature at low concentrations, the complexity of the sample matrices and the structural similarity to other flavonols, selective sample preparation methods are necessary

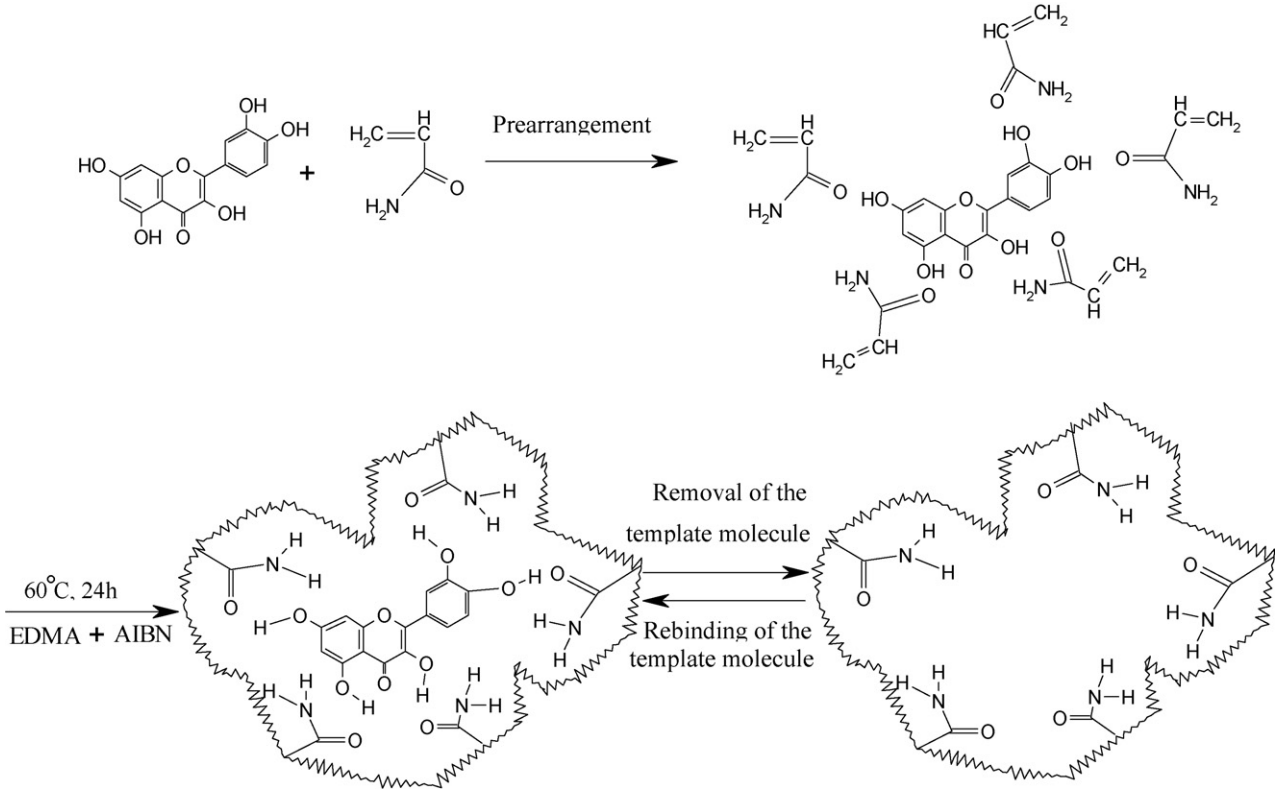

Fig. 1. Schematic representation of MIPs for quercetin.

prior to chromatographic analysis. Preconcentration and/or separation of the compounds are frequently conducted by using SPE [20,21], in which new selective materials employing molecular recognition mechanisms might guarantee selective analyte separation from complex real world matrices. This mechanism can improve significantly the method specificity and sensitivity. Related works on quercetin determination and separation by using MIT have been reported [5,24,25]. Weiss et al. reported that MIPs for quercetin was prepared by using quecertin as template molecule, 4-vinylpyridine as functional monomer and EDMA as cross-linker [5]. The prepared MIP showed excellent performance on quercetin separation. Yan et al. also prepared effective MIPs for quercetin by using AA as a functional monomer [24]. He and Deng reported the effectiveness of MIPs prepared by using different functional monomers including methacrylic acid (MAA), AA and 2-vinylpridine, and found the properties of MIPs for quercetin were varying in different functional monomers [25].

In this work, the feasibility of preparing quercetin imprinted polymers and the utilization of the selective membranes as sorbent for SPE were demonstrated. The influences of porogenic solvents, functional monomers and cross-linkers on the adsorption specificity for quercetin of the MIPs were investigated and the stabilization energy calculated by computational quantum chemical analysis (CQCA) was adopted to support the analysis. The synthesized MIPs were characterized by Fourier transform infrared (FTIR) and scanning electron microscope (SEM). HPLC-UV and Scatchard method were used to evaluate the adsorption properties and recognition mechanism of the MIPs. Structurally similar compounds including rutin and catechol were utilized for verifying the molecular selectivity and characterizing the recognition capability of the MIPs. The MIP–SPE was testified to be applicable for the preconcentration and determination of cacumen platycladi samples.

2. Experimental

2.1. Chemicals

Quercetin, rutin and catechol were purchased from Shanghai Sinopharm Chemical Reagent Co., Ltd. Fig. 2 shows their chem-

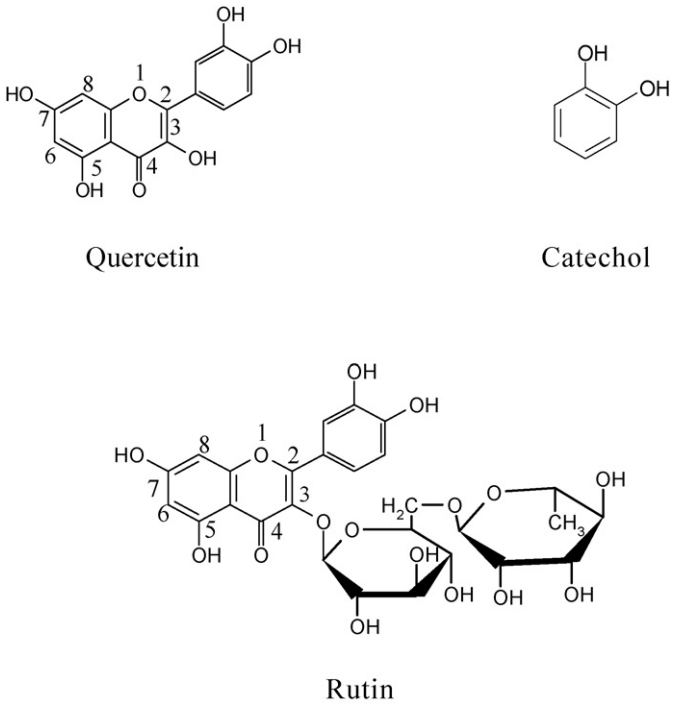

Fig. 2. Chemical structures of quercetin, catechol and rutin.

ical structures. AA was supplied from Tianjin Chemical Research Institute. EDMA, divinylbenzene (DVB), pentaerythritol triacrylate (PTA) and N,N′-methylenebisacrylamide (BisAA) were purchased from Sigma–Aldrich (Taufkirchen, Germany). AIBN was obtained from Shanghai Chemical Reagent Company. HPLC-grade tetrahydrofura (THF), acetone, acetonitrile (ACN), 1,4-dioxane, methanol (MeOH) and anhydrous acetic acid were all from Merck (Darmstadt, Germany).

2.2. Preparation of the MIPs and NIPs

The MIPs were prepared with a slight modification according to the published procedures [24]. Briefly, 0.13 g (0.40 mmol) of template molecules (quercetins) and 0.20 g (2.8 mmol) of functional monomers (AA) were dissolved in 5 mL different porogenic solvents including 1,4-dioxane, THF, acetone and ACN in four corked test tubes, respectively. After oscillating for 30 min, 3.5 mL (18.5 mmol) of cross-linkers (EDMA) and 0.01 g initiators (AIBN) were added. The solutions were degassed in a sonicating bath for 15 min and filled with nitrogen for 15 min and sealed. The test tubes were immersed into isothermal water bath and the mixtures were thermally polymerized at 60 °C for 24 h. The resultant polymers were then grinded and sieved through a 105 μm sieve. The polymer particles were extracted with a mixture of MeOH/acetic acid (9:1, v/v) in Soxhlex extractor for 24 h to remove the template molecules (quercetins) and then were rinsed with MeOH. After removing acetic acid, the MIPs were dried at 60 °C under vacuum for 24 h and stored in a desiccator for further use. As references, the non-imprinted polymers (NIPs) in the absence of template molecules were prepared and treated by using the above same method. The compositions of MIPs (M1–M4) and NIPs (N1–N4) are shown in Table 1.

2.3. FTIR measurements

FTIR spectroscopic measurements were performed on model Avatar 370 FTIR Spectrometer (Thermo Nicolet Corporation, USA) with KBr pellet method. The wave numbers of FTIR measurement range were controlled from 500 to 4000 cm^{-1}, and collected at one data point per 2 cm^{-1} with sample scanning for 32 times.

2.4. Adsorption determination of MIPs and NIPs for quercetins

The adsorption experiments were carried out to confirm the rebinding performance and the subsequent Scatchard analysis of the polymers as follows.

The MIPs and NIPs (Table 1) of 100 mg were added into eight 50 mL conical flasks, respectively, and were mixed with 25 mL of solution containing a known concentration of 20 μg mL^{-1} quercetins in MeOH. Then, these mixtures were shaken at 20 °C by using SHA-B Water Bath Isothermal Shaker (Jiangsu Jintan Medical Instrument Factory) and centrifuged using a high-speed centrifuge. 20 μL of the supernatant was taken out for HPLC analysis to measure the free concentration of quercetin and determine the adsorption quantity of quercetin in different time intervals.

In the other hand, the M2 and N2 (Table 1) of 100 mg, respectively, were added into 50 mL conical flasks, and were mixed with 25 mL of a known initial concentration of quercetin (0.01–0.1 μmol mL^{-1}) in MeOH solution. The mixtures were oscillated by using a SHA-B Water Bath Isothermal Shaker at 20 °C for 24 h, and then were centrifugated for 10 min. The concentration of quercetin in the solution was analyzed using HPLC-UV. And thus, the saturated extents of adsorption of MIPs and NIPs for quercetins were obtained. The selectivity of MIPs was investigated by using quercetin adsorption on the MIPs and NIPs.

Table 1
Compositions of MIPs and NIPs.

Polymers	Quercetin (g)	AA (g)	EDMA (mL)	AIBN (g)	Porogenic solvents
M1	0.13	0.2	3.5	0.01	1,4-Dioxane
M2	0.13	0.2	3.5	0.01	THF
M3	0.13	0.2	3.5	0.01	Acetone
M4	0.13	0.2	3.5	0.01	ACN
N1	–	0.2	3.5	0.01	1,4-Dioxane
N2	–	0.2	3.5	0.01	THF
N3	–	0.2	3.5	0.01	Acetone
N4	–	0.2	3.5	0.01	ACN

2.5. Computational quantum chemical analysis (CQCA)

Molecular simulation as a promising technology of computational chemistry is also a useful tool in the studies of molecular imprinting technology, so the stabilization energy by solvent was often used to evaluate the interaction strength of molecular template with solvent, monomer or cross-linker with solvent. In this study according to calculation method of Gaussian 98, B3LYP/6-31+G**, the stabilization energy of quercetin and AA with different solvents was obtained through calculating the interaction energy between gas and solvent. The simulation of solvent effect is based on the Onsager self-consistent reaction field (SCRF) technique [26], which supposes that the solute molecule is embedded into a spherical cavity with radius a_0 surrounded, and the solvent is characterized by a given dielectric constant. The gas-phase geometry of quercetin and functional monomer or cross-linker is used as its initial guess to start the full optimizations at the same level of B3LYP/6-31+G** with different dielectric constants of porogenic solvents. The radius a_0 automatically resorted from quantum mechanical procedures. After stationary points were located, vibrational frequencies were calculated in order to ascertain that each structure was characterized to be the stable structure (no imaginary frequencies). All calculations were carried out with the Gaussian 98 program on a Pentium IV computer using the default convergence criteria. The stabilization energy of solvents is calculated as $E_{solvation} = E_{in\ solvent} - E_{in\ gas}$. The $E_{solvation}$ is the energy stabilized by a solvent, namely the relative energy difference of a complex in the solvent and that in a gas phase.

2.6. MIP–SPE procedures

A PTFE frit (10 μm in porosity size) was placed on the bottom of an empty polypropylene SPE cartridge (5 mL in total volume and 8 mm in diameter) purchased from Agilent Technologies (USA), which was employed as the MIP–SPE column, packed with 500 mg of quercetin-MIPs in 5 mL MeOH solution using a wet packing method. Then another frit was placed on the top of the cartridge. Prior to loading the sample, the cartridge was washed with a mixture of MeOH/acetic acid (9:1, v/v) until quercetin could not be detected by the HPLC analysis in the filtrate. Then the cartridge was conditioned with 10 mL of MeOH.

Considering the solubility of quercetin and its structurally similar compounds (rutin or catechol), a mixture containing quercetin and its analogues in MeOH was prepared. Then, 2–4 mL of the different concentration mixtures were loaded onto the SPE cartridge at 1 mL min^{-1}. Subsequently, the cartridge was consecutively rinsed with 3 mL of MeOH and 3 mL of the mixed solution of MeOH/acetic acid (v/v, 9:1). The collected column-solution, rinsed solution and eluates were evaporated to dryness under nitrogen and the residues were redissolved in 1 mL of MeOH, respectively, for HPLC-UV analysis.

In this work, the enrichment factor (EF) was introduced and it was defined as the ratio of the analyte concentration in the con-

centrated phase (C_{con}, μmol mL^{-1}) and the initial concentration of analyte within the sample (C_0, μmol mL^{-1}):

$$EF = \frac{C_{con}}{C_0}.$$

The C_{con} was obtained from the HPLC analysis for the analyte in eluates after being redissolved in 1 mL of MeOH.

2.7. Preparation of cacumen platycladi

The preparation of cacumen platycladi was consulted to previous work [27,28]. In brief, 1.0 g of cacumen platycladi was placed into a 100 mL of conical flask, followed by 50 mL of 50% MeOH, stewing for 6 h; subsequently the flask was marinated into a water bath at 80 °C for 6 h. The resultant leaching liquors were filtrated with a 0.45 μm membrane filter, and then evaporated to dryness under low fire. The extracts were dissolved in doubly distilled deionized (D.D.I.) water and extracted by 25 mL of saturated ethyl acetate for three times. The three aliquots of extraction solutions were pooled and dried with anhydrous sodium sulfate, and then they were transferred to a 250 mL of round flask for reduced pressure distillation. The residues were dissolved with anhydrous MeOH for use.

2.8. HPLC-UV analysis

The HPLC-UV analysis was performed using EasySepTM-1010 HPLC (Unimicro Technologies Co., Ltd., Shanghai, China) with a 1010 LC liquid delivery pump and a 1010 UV ultraviolet/visible variable wavelength detector with a spectral range from 190 to 700 nm. Column was C-18 column (2.1 mm × 250 mm). The analytical procedure was conducted according to reported work [29,30] with necessary modification. Briefly, the column was rinsed with a mobile phase until a stable baseline was obtained, which consisted of ACN and 0.1% (w/v) H_3PO_4 aqueous solution (36:64, v/v). The detection was carried out with wavelength at 365 nm. Column oven temperature was controlled at 25 °C. The flow-rate was maintained at 0.5 mL min^{-1} and 20 μL of sample was injected.

3. Results and discussion

3.1. Preparation and characterization of the quercetin-MIPs

Quercetin was dissolved in THF at the usual imprinting concentration, and AA was selected as the functional monomer because it was favorable for hydrogen-bonding interaction in the solvent [24]. Thus, a stable donor–receptor complex between template and functional monomer is formed in the imprinting process shown in Fig. 1. The existence of such a complex leads to the formation of well-defined specific binding sites in the MIPs. Then a thermal polymerization was followed, in which AIBN was used as free radical initiator and its half-life at 60 °C was around 10 h and proper for polymerization. The cross-linker, EDMA, formed a "frozen" spatial structure. The quercetin molecule contains five hydroxyl groups and one carbonyl group, which can form hydrogen bonds with functional groups such as hydroxyl, amino and carbonyl groups. From the structure of quercetin shown in Fig. 2, both the γ-OH (No. 3) and ε-OH (no. 5) of the quercetin molecule can form strong intramolecular hydrogen bonds with the δ-carbonyl group (no. 4), and therefore the inter-molecular interaction between the template and monomer is weakened. The remained three hydroxyl groups as main imprinting functional groups supply strong inter-molecular hydrogen bonds with the polymer and control the precise imprinting sites. So, there are less five apparent selective binding sites in the quercetin molecule. After removal of the template molecule, the specific imprinting sites will be maintained. These sites will selectively adsorb quercetin molecules.

To further ensure that the quercetin-MIPs had been made, we performed additional FTIR analysis (see Fig. 3). Fig. 3a shows the FTIR spectrum of quercetin. A strong and broad stretching vibration absorbance peak of hydroxyl groups was found at 3299 cm^{-1}, suggesting there are a few hydroxyl groups in the quercetin molecule, which might form the intra- and/or inter-molecular hydrogen bonds. A stretching vibration peak of carbonyl group was found at 1656 cm^{-1} [31], moving toward the low wave number region in the conjugated system. In addition, stretching vibration peaks of cyclobenzene skeleton in the quercetin molecule was found at 1615, 1512 and 1432 cm^{-1} [32]. Fig. 3b shows the FTIR spectrum of AA (monomer). The main absorption bands of AA situating around 3356 (and 3188), 1673, and 1613 cm^{-1} were assigned to the following vibrations: N–H stretching, being characteristic absorption peaks of primary acylamide, C=O stretching and C=C stretching, respectively.

For MIPs, shown in Fig. 3c, the peak at 1732 cm^{-1} was attributed to C=O stretching vibration absorbance, because the MIPs were synthesized by the polymerization of EDMA and AA, and the cross-linked polymers must carry the repeated cross-linking units of EDMA. At 1637 cm^{-1}, the weak absorbance peak of C=C suggests that most AA were cross-linked and only a few ones were remained. The broad peak at 3441 cm^{-1} was assigned to the asymmetric stretching vibration of N–H in acylamide. Moreover, the stretching vibration peak of methyl or methylene was found at 2990 cm^{-1}, and C–O stretching vibration of asymmetric ester was found at 1154.37 cm^{-1}. For NIPs shown in Fig. 3d, the characteristic signals of FTIR were almost the same, except for the intensity of the

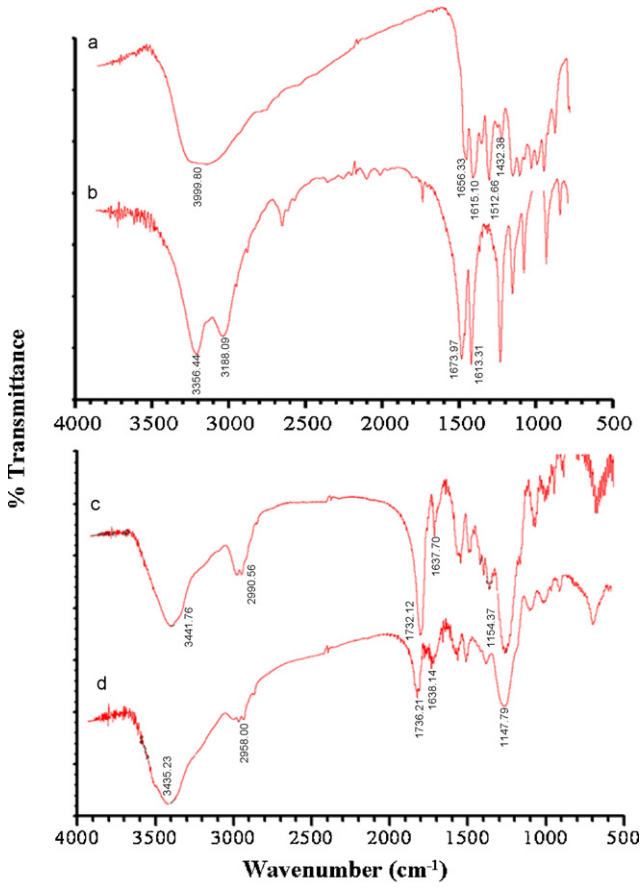

Fig. 3. FTIR spectra of quercetin (a), AA (b), MIPs removal of the template molecule (c), and NIPs (d).

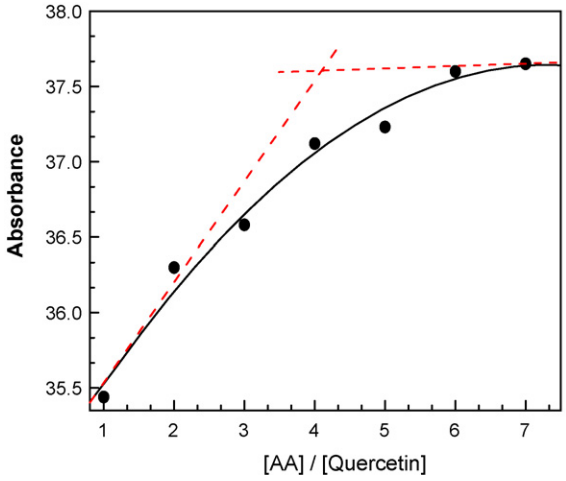

Fig. 4. Absorbance curve in different ratios of [AA]/[Quercetin].

stretching vibration peak of C=O (1736 cm^{-1}), distinctly lower than that for MIPs. The possible reason was that the template molecules which were assembled with monomer via the hydrogen-bonded interaction in preparing MIPs, helpful for the co-polymerization of monomer and cross-linker, and thus stable imprinting cavities was formed by ordered distribution of functional groups containing carbonyl group. The result of FTIR confirmed that obviously there were functional groups in the MIPs which would interact with the template molecule, namely acylamide group in the quercetin-MIPs.

3.2. Influence of polymerization conditions on adsorption properties of MIPs

3.2.1. Functional monomers

For non-covalent MIPs, the complementary inter-molecular reactions between the template and the functional monomer are crucial for the subsequent affinity and selectivity of the MIPs [33]. It is therefore important to search for a suitable functional monomer that can strongly interact with the template and form specific "donor–receptor" or "antibody–antigen" complexes prior to polymerization. Due to the higher specific binding but the lower non-specific adsorption of the resultant MIPs, AA was thus selected as the functional monomer for preparing the MIPs [24].

The molar ratio of functional monomer to template is important in terms of its interaction strength, which will have an effect on the number and property of MIP recognition sites [34]. The intensity and ratio range of the MIPs were estimated by absorption measurement. As shown in Fig. 4, the equilibrium absorbance of the complex increases with the ratio of AA to template (M/T) increasing, suggesting that the quercetin molecules form super-molecular structure with AA via non-covalent inter-cavity mode in the THF solution. At 7:1, the plot begins to level off, indicating that almost all the template molecules had been bound with the functional monomers. The coordination number was expected 4 (Fig. 4); from the quercetin structure (Fig. 2), it is clear that the number of the apparent selective binding sites was less 5. The molar ratio should be higher than 4:1. At lower content monomer, it is difficult to form stable imprinting sites. An excess of functional monomers can cause more non-selective adsorption sites with random distribution in the MIPs and result in self-association of the monomers, which will reduce the selective adsorption sites and increase the adsorption mass transfer resistance. So, the optimum ratio of M/T at 7:1 was chosen for preparing the maximum specific-selective MIPs in the following investigations.

3.2.2. Porogens

It is essential for the adsorption properties of MIPs that the functional monomer and imprinting molecules can form stable complexes. Strong interaction between imprinting molecules and functional monomers produces excellent stability of the resultant complex, which therefore results in high recognition specificity of the MIPs. On the other hand, weak interaction often causes inefficiency of MIPs. So, it is important to investigate the influence of porogens. The porogens generally act as dispersion media and pore forming agents in the polymerization process. The solvent is very important for providing the synthesis environment of MIPs. The polarity of solvents will affect the interaction between template molecule and functional monomer, and thereby the adsorption properties of MIPs.

As shown in Table 2, the interactions between solvent and quercetin or AA increased with increasing polarity of solvents, while the specific recognition capacity of the MIPs decreased. Higher polar solvents competed more efficiently with template molecules for binding the recognition sites of the functional monomers and thus weakened the interaction between the latter two compounds. This leads to forming fewer imprinting sites in MIPs and reduces its adsorption effectiveness for quercetin. In addition, quercetin was not easily dissolved and its floccule was easily observed in ACN, likely causing phase separation. This resulted in unfavorable MIPs with inhomogeneous pores and reduced internal surface area. For less polar solvent having less interaction with either template molecule or functional monomer, in which the interaction of template molecule and functional monomer is strong, however, the formed MIPs are easily precipitated due to less solubility in the less polar solvent. Only when the solvent has medium polarity, does it have proper interactions with quercetin or AA. And for the medium polar THF, it also offers better dissolving capacity for the quercetin-template and the initial polymers, which maintains the pore dimension, specific surface area and mass transfer rate, and therefore facilitates synthesizing the MIPs with homogeneous pores and high specific surface area. This assists to form uniform imprinting sites in MIPs. So, THF was selected as the porogenic solvent to produce better MIPs.

Meanwhile, the surface morphologies of MIPs prepared in different solvents were studied by using SEM (Fig. 5). Although all have rough surfaces, the MIPs from THF and acetone seemed more dense and homogenous with more and larger-dimension pores (Fig. 5a and b) than that from ACN and 1,4-dioxane (Fig. 5c and d). It can be evaluated that the surface of the MIPs in THF exhibits bigger dimension of the pore and bigger volume rough structure than that of the MIPs in acetone. The uniform and more open structure is obviously favorable for the embedding of the template molecules and mass transfer.

3.2.3. Cross-linkers

The basic structures of the polymers synthesized via cross-linkers and function monomers play a key role for preparing MIPs. Because the specificity of the template cavity is not controlled by the template molecules but is mainly dependent on the network spatial array of MIPs, the structural optimization is vital for the selectivity of MIPs. In the polymerization, cross-linkers are employed to control matrix stability and solid shapes of imprinting binding sites after removal of template molecules. The cross-linkers of DVB, EDMA, PTA and BisAA were introduced to investigate their influences on the adsorption properties of MIPs.

Fig. 6 shows the effects of solvation energy of cross-linkers on the imprinting factors of the four MIPs. DVB and EDMA are both better cross-linkers in the polymerization. The molecular chains of MIPs linked by EDMA are suitably feasible while the polymers containing DVB are of considerable rigidity but sometime they do not facilitate the rebinding of template molecules with MIPs.

Table 2
Specific adsorption properties of MIPs in different porogenic solvents.

Solvents	ε	$E_{solvation,\ AA}$ (kJ mol^{-1})	$E_{solvation,\ quercetin}$ (kJ mol^{-1})	Q_{MIP} (μg g^{-1})	$Q_{control}$ (μg g^{-1})	Imprinting factor (α)
1,4-Dioxane	2.25	3.23	4.78	372	354	1.05
THF	7.58	4.00	6.90	480	400	1.20
Acetone	20.7	7.25	9.78	409	381	1.07
ACN	37.5	9.18	11.2	309	300	1.03

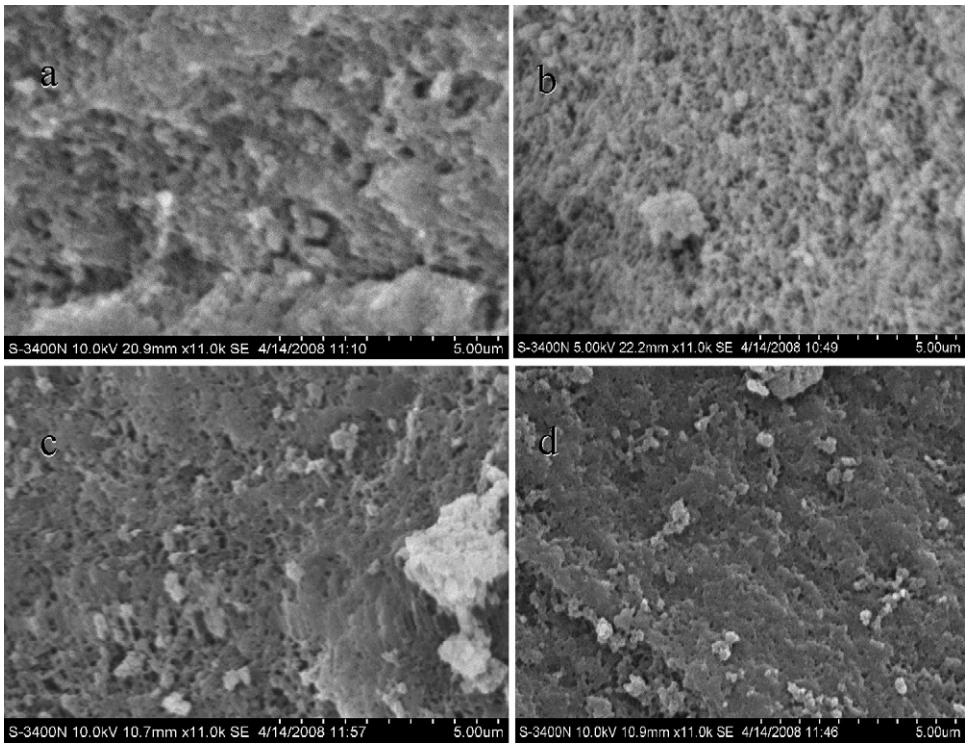

Fig. 5. SEM microphotographs of MIPs prepared in different porogens. (a) THF, (b) acetone, (c) ACN and (d) 1,4-dioxane.

Enhancement of the interaction between cross-linkers and template molecules will benefit the formation of selective template cavity. Increasing interaction between cross-linkers and solvents will increase the competition and therefore weaken the interaction between cross-linkers and template molecules. This is adverse to immobilize the binding sites and the mobility of sites will bring down the recognition specificity of MIPs.

In order to improve the recognition performance of the MIPs prepared by using EDMA, a series of polymers have been synthesized by increasing the molar percentage ratio of EDMA to quercetin (C/T) in the polymerization mixture. As shown in Fig. 7, the adsorption properties of MIPs are remarkably affected by the content change of cross-linkers, where Q_e (μg g^{-1}) is the equilibrium adsorption amount at each concentration. Increasing cross-linkers will increase the rigidity of MIPs and decrease the swelling in solvents, and thus will reduce the change of the spatial structure and the binding groups in the polymerization and recognition, which will facilitate forming stable binding sites and therefore improve the selectivity of MIPs. It is observed that for the MIPs, at the ratios of 10:1 to 25:1, the specific adsorption amounts were rapidly increased and the MIPs exhibited the better selectivity and

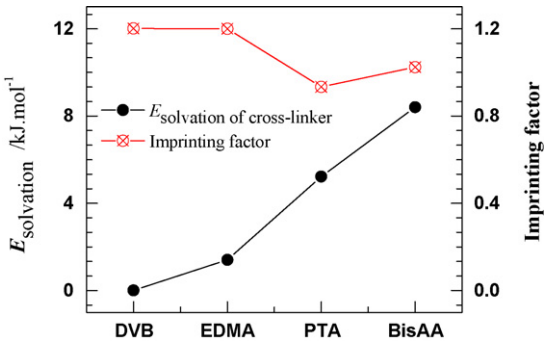

Fig. 6. Effects of the solvation energy of cross-linkers on the specific adsorption of MIPs.

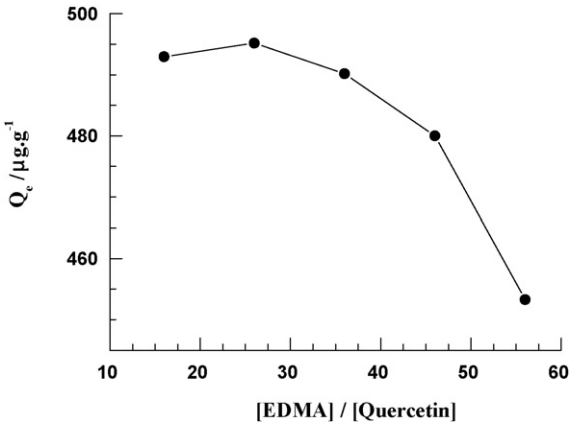

Fig. 7. Effects of the amounts of cross-linkers on the equilibrium adsorption amounts of MIPs.

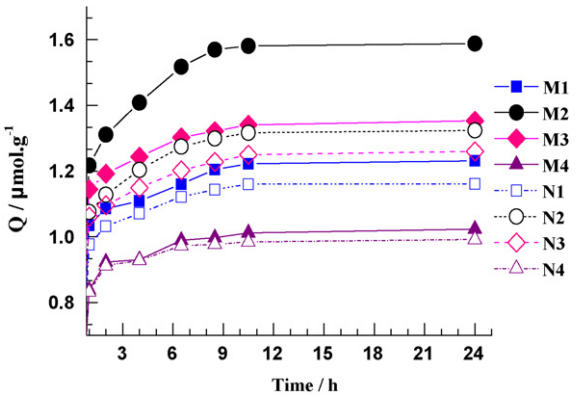

Fig. 8. Dynamic curves for the adsorption of quercetins onto MIPs and NIPs.

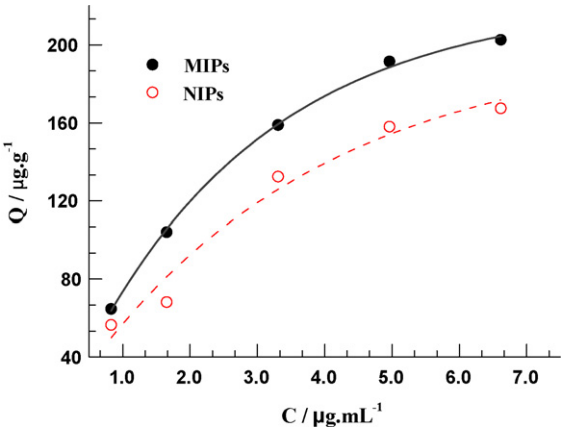

Fig. 9. Adsorption isotherms of polymers using THF as solvent.

recognition capacity. The high cross-linking degree will contribute to stabilize the recognition sites of MIPs. While the ratio of *C*/*T* is increased especially to 40:1, the specific adsorption and specific binding capacity of the resultant MIPs rapidly decay. At high concentrations of cross-linkers, the binding sites in MIPs are too mobile, which will reduce the orderliness of matrix arrangement of MIPs and increase non-specific cavity, resulting in high non-specific binding and low affinity.

3.3. Adsorption analysis and recognition mechanism

Fig. 8 shows the dynamic curves for the adsorption of quercetin onto the MIPs and NIPs in four different solvents, where *Q* is the amounts of quercetins adsorbed at any time. It is observed that the amounts of quercetins both adsorbed onto MIPs and bound to NIPs increased with time and nearly reached saturation state within 10 h. For the adsorption equilibrium, the adsorption time was set for 24 h in the following experiments. It is assumed that the high adsorption rate within 6 h might result from the preferential and rapid adsorption of template molecules onto the recognition sites in the surface of MIPs. When these imprinted sites in the surface were occupied, it became difficult for quercetin to implant into the MIPs. This would cause the adsorption to slow down. The various contributions of polymers on the template molecular recognition would be attributed to the hydrogen bonds between template and monomer, and the comprehensive functions of resultant microenvironment and complementary cavity to the template molecules [35]. It is also observed that both M2 and N2 have the largest adsorption amounts in THF among the MIPs and NIPs, respectively. Although NIPs show similar trend to MIPs on the quercetin adsorption (Fig. 8), their adsorption capacities are much lower. This might be likely because of the non-specific adsorption of NIPs caused by van der Waals force, due to the absence of imprinting procedure and thereafter lacking suitable recognition sites and imprinting cavities in the NIPs. However, there were numerous and precise imprinting sites in the MIPs, resulting in specific adsorption, and thus they produced higher adsorption capacity. So, the presence of complementary cavities to the template molecules in the MIPs is vital for the specific adsorption.

Fig. 9 shows the adsorption isotherms of quercetins onto the MIPs and NIPs using THF as recognition medium. The curves were obtained by plotting the saturated adsorption amounts with equilibrium concentrations of the quercetins in MeOH solution. In other words, the adsorption capacity (*Q*) of quercetin increased quickly with the increase of initial concentration. At higher equilibrium concentration than 6.0 μg mL^{-1}, adsorption of MIPs became stable and its recognition sites were almost saturated. NIPs had the same trend as MIPs with lower saturated adsorption amounts. Thus, adsorption isotherms are important for describing how adsorbates interact with adsorbent [36].

Scatchard analysis was employed to further analyze the binding isotherms, which is an approximate model commonly used to estimate the binding parameters of MIPs [2,26]. The Scatchard equation can be expressed as, $Q/C = (Q_{max} - Q)/K_d$, where K_d (μmol mL^{-1}) is defined as the equilibrium dissociation constant of the binding sites, Q (μmol g^{-1}) is the amount of quercetin bound to the polymer, Q_{max} (μmol g^{-1}) is the maximum adsorption amounts of quercetin on the polymer, and C (μmol mL^{-1}) is equilibrium concentration of quercetin in the solution. Fig. 10 shows the Scatchard plots of the binding of quercetin to MIPs and NIPs, respectively. It is clear that the Scatchard plot for MIPs is a single straight line. The linear regression equation was, $Q/C = -32.32Q + 98.30$ ($R^2 = 0.9903$), suggesting that the homogeneous recognition sites for quercetins were formed in the MIPs, namely the adsorption interaction was nearly equivalent for the four binding sites. From the slope (-32.32 ($1/K_d$)) and intercept (98.30 (Q_{max}/K_d)), K_d and Q_{max} for the affinity binding sites were calculated to be 0.03 μmol mL^{-1} and 3.04 μmol g^{-1}, respectively. For NIPs, the non-linearity indicated that there were not selective adsorption sites for quercetins on them. From the Scatchard analysis, it could be assumed that the rebinding sites in the MIPs are mainly dependent on hydrogen bonding, while the interaction between NIPs and quercetins was mainly from non-specific adsorption such as van der Waals.

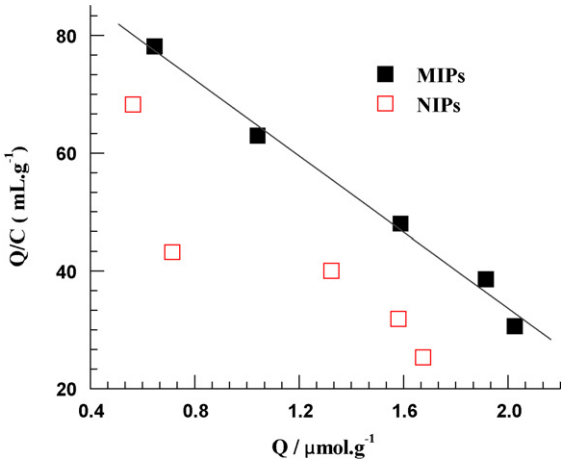

Fig. 10. Scatchard plots of MIPs and NIPs.

Table 3
Distribution coefficient (K_d) and ratio (β) of distribution coefficients between two tested substrates.

Sorbents	Initial conc. ($\mu g\,g^{-1}$)		Final conc. ($\mu g\,mL^{-1}$)		K_d ($mL\,g^{-1}$)		β
	Quercetin	Rutin	Quercetin	Rutin	Quercetin	Rutin	
MIPs	20	20	16.9	18.2	46.1	25.1	1.84
NIPs	20	20	19.0	19.1	13.2	12.5	1.06

3.4. Molecular selectivity of MIPs

The selective adsorption of MIPs was evaluated by using quercetin and its structurally similar compounds, rutin and catechol, as substrates in THF. Rutin and catechol were chosen as references for investigating the static adsorption specific selectivity and MIP–SPE specific selectivity, respectively. The static adsorption distribution coefficient K_d was utilized to evaluate the molecular selectivity of polymers [24]. K_d is defined as follows, $K_d = C_P/C_S$, where C_P ($\mu g\,g^{-1}$) is the concentration of the tested substrates adsorbed on the MIPs and C_S ($\mu g\,mL^{-1}$) is the equilibrium concentration of substrates in solution. Table 3 shows the K_d and the separation factor, β, namely the ratio of K_d of the two tested substrates. It is seen that the adsorption capacities of NIPs are very close for both rutin and quercetin because there are not selective recognition sites in the NIPs and the adsorption for substrates are non-selective. On the other hand, obviously, the MIPs offer better selectivity for quercetins since the MIPs present the β value about 1.7 times of that for the corresponding NIPs. The molecular recognition of MIPs mainly depends on two factors, molecular dimension of template and matching degree of the bonding sites [25]. For the rutin molecule, it has a large substitution group in γ-OH position of quercetin. Different molecular dimensions cause the rutin not complementary to the imprinting cavities of the quercetin-MIPs and therefore weak interactions. As a result, the MIPs gave a lower selectivity for rutin than that for quercetin.

Table 4 shows the comparisons of MIP–SPE properties between quercetin and catechol. As seen, the MIPs exhibit much stronger binding affinity for quercetin even if the concentration of catechol is 15 times of querectin, while both have the same adsorption trend in different solvents, namely strongest in THF and weakest in ACN. Since the molecular dimension of catechol is smaller than that of quercetin, the molecule maybe easily enters the MIP cavity. Also, because it contains two phenolic hydroxyl groups, the molecules could form two hydrogen bonds with the amino groups of AA in the MIPs. However, the smaller structure of catechol makes it poorly match the cavities induced by quercetin, resulting in weaker binding interaction and lower selectivity.

3.5. SPE specificity of the MIPs for quercetin

The prepared quercetin-polymer was employed as the sorbent of SPE column for the pretreatment of quercetin and structurally similar rutin. Fig. 11 shows the HPLC-UV chromatograms of the standard mixtures. Good baseline separation was obtained for them without SPE procedure and rutin was eluted first (Fig. 11a). Not any apparent peak is observed in Fig. 11b for determining

Table 4
Comparisons of two analogues before and after MIP–SPE.

Solvents	Before SPE ($\mu g\,mL^{-1}$)		After SPE ($\mu g\,mL^{-1}$)		K_d ($mL\,g^{-1}$)	
	Quercetin	Catechol	Quercetin	Catechol	Quercetin	Catechol
1,4-Dioxane	2	30	0.56	15.0	17.1	6.67
THF	2	30	0.28	12.3	41.0	9.59
Acetone	2	30	0.40	12.9	26.7	8.84
ACN	2	30	0.74	15.6	11.4	6.15

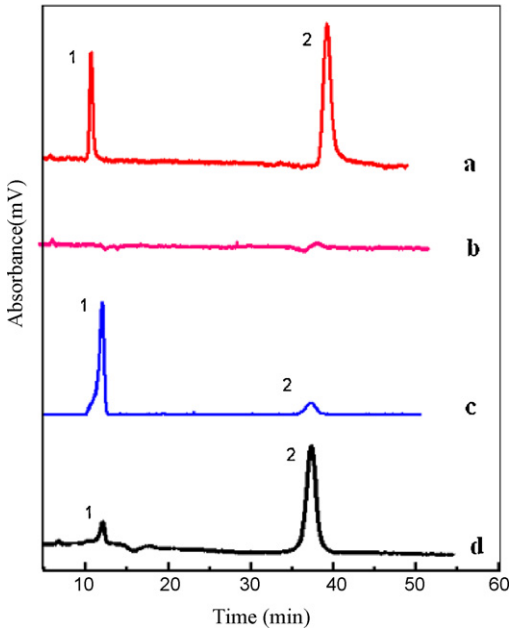

Fig. 11. Chromatograms of the standard mixture. (a) Initial solutions before MIP–SPE, (b) solutions after MIP–SPE, (c) solutions after rinsing with MeOH, and (d) eluates after washing with MeOH/acetic acid (9:1, v/v). (1) Rutin and (2) Quercetin.

the solutions after the MIP–SPE, which indicates quercetin and rutin were almost completely adsorbed onto the MIPs. Fig. 11c shows that almost all the rutins were eluted with only minor quercetins by rinsing the MIP–SPE column with MeOH; quercetin was not easily eluted with MeOH. Then using the more polar eluting solutions, namely MeOH/acetic acid (9:1, v/v), quercetins were nearly all eluted, shown in Fig. 11d. The linking of a rutinose group (α-L-mannopyranosyl-β-D-glucopyranosyl) in rutin causes a larger space volume than that of quercetin, and it is therefore most difficult for the rutin to be embedded into the cavity of the quercetin-MIPs, so it was easily eluted with MeOH. However, the quercetins adsorbed onto the MIPs through the specific recognition effects could be destroyed only by the strongly polar solvents containing acetic acid. Thus the MIPs are highly structural-selective toward quercetins.

In addition, quercetins in two eluates were analyzed after the above same MIP–SPE procedure for the standard mixture of quercetin and rutin of 2 mL at 20 $\mu g\,mL^{-1}$ and 5 mL at 4 $\mu g\,mL^{-1}$, respectively. The molar ratios of quercetin to rutin were both 2 to 1 before SPE, and then they became 8 to 1 and 143 to 1, respectively, for the two aliquots. The EF of quercetin compared to rutin was improved by at least 4–71.5 times. Therefore, under the suitable conditions of loading, rinsing and eluting, the MIPs with high selectivity can be employed not only to separate some structurally similar compounds, but also to excellently concentrate and clean up the trace analytes.

Fig. 12 shows the chromatograms of the solutions from cacumen platycladis. The peaks of quercetin and rutin were identified with the comparison of chromatographic retention times with those of the spiked standards shown in Fig. 11. It is supposed that querceins mainly exist in the cacumen platycladis. Also, a relatively large peak appeared between ca. 16–20 min shown in Fig. 12a, which is not surprising in the extracts before the MIP–SPE, and they were not identified. On the other hand, by the same MIP–SPE pretreatment as that for Fig. 11d, quercetin is predominantly present and there is only a minor of impurities and rutin is hardly observed (Fig. 12b). The MIP–SPE is not only high selective for quercetin but also offers cleanup and enrichment effects for the real samples. The obtained unique profile demonstrates

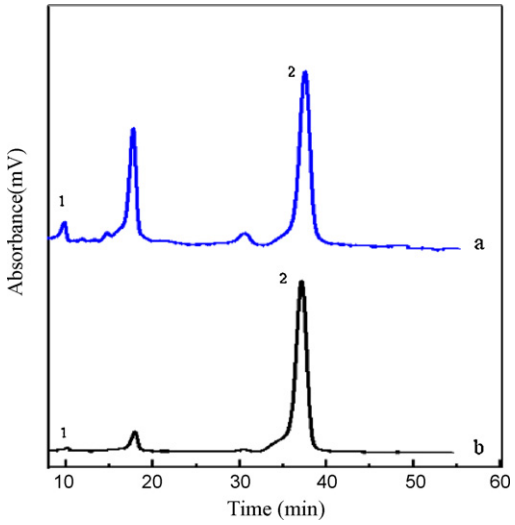

Fig. 12. Chromatograms of the solutions from cacumen platycladis. (a) Solutions before MIP-SPE and (b) eluates after MIP–SPE. (1) Rutin and (2) Quercetin.

the endogenous quercetins could be efficiently separated from the extracts of cacumen platycladis. It provides an effective method for the separation and determination of active ingredients from cacumen platycladis and further for flavonoid compounds in the traditional Chinese medicine. Besides for the SPE application, the quercetin-MIPs have been also employed in diverse fields. To take two examples, quercetin-MIPs immobilized silica gel could be used as a solid-phase reagent for the tin determination by using sorption-spectroscopic method [19] and quercetin-MIPs could be developed into sensors by self-assembling monolayer/mediator system for analyzing biomolecules and drug molecules [37]. Thus, further analysis and applications of quercetin-MIPs are under on the way.

4. Conclusions

The prepared quercetin-MIPs were confirmed by both FTIR and SEM, characterized by HPLC-UV, and applied for the SPE of a natural product (cacumen platycladi). Optimal imprinting parameters for enhanced recognition properties of MIPs toward quercetin were attained, which were very important for the successful preparation and application of the MIPs. The resultant MIPs displayed fast adsorption dynamics and high adsorption capacity. And they could contain single selective adsorption sites for quercetin. The molecular selectivity of the MIPs was also evaluated by using rutin and catechol as references. The high specific binding could be attributed to a large population of sites of high affinity for the templates. Selective recognition for the isolation of quercetin from cacumen platycladi samples was achieved, and thus the MIPs would powerfully be applied for the preconcentration of traditional Chinese medicines. Further research will focus on developing new imprinting materials for the separation and determination of quercetins from natural products, and extending to more flavonoid compounds, as well as using the promising quercetin-MIPs as an analytical tool for various potential applications.

ABSTRACT

Selective extraction of low molecular weight (LMW) proteins and peptides from complex biological samples plays an important role in the discovery of useful biomarkers and signaling molecules. Various methods, such as solid-phase extraction (SPE), ultrafiltration, and size-exclusion chromatography have been developed for such extraction purpose. In this study, we present, to our knowledge, the first demonstration of alkyl-diol@SiO_2 mesoporous material MCM-41 (alkyl-diol group on the external surface of mesoporous material) for selective extraction of LMW proteins and peptides from complex biological samples. The adsorption kinetics of LMW proteins, the influence of pH on adsorption and the desorption recovery by different elution solvents were investigated by using standard proteins as model samples. It was demonstrated that the modification of alkyl-diol group on the external surface could efficiently decrease the adsorption of HMW protein and increase the desorption recovery of LMW protein. Furthermore, the mesoporous materials were applied to selectively extract LMW proteins and peptides (<10 kDa) from crude human plasma. And the modified MCM-41 material had much better extraction selectivity and efficiency for LMW proteins and peptides than unmodified one.

1. Introduction

In the past decade, selective extraction of low molecular weight (LMW) proteins and peptides from complex biological samples, such as plasma and tissue extracts, drew more and more interest due to their important roles in elucidation of biological and pathological variations, as well as in the discovery of useful biomarkers and signaling molecules [1–4]. Various extraction methods, such as solid-phase extraction (SPE), ultrafiltration, acetonitrile precipitation, and size-exclusion chromatography have been developed [5–7]. Moreover, the combination of selective extraction with mass spectrometry (MS) analysis becomes a powerful tool to achieve high-throughout separations and identifications of LMW proteins and peptides from complex matrixes [5,8–10]. However, one of the major difficulties in extraction of LMW proteins and peptides is that their concentration is much lower compared with other proteins with high molecular weight (HMW). Therefore, the specific and efficient extraction of LMW proteins and peptides from complex sample solutions still presents challenges [11]. Orvisky et al. applied denaturing ultrafiltration to extract proteins and peptides smaller than 50 kDa from plasma and serum, followed by MALDI MS profiling and identifications of the peptides smaller than 5 kDa [6]. However, the selectivity of denaturing ultrafiltration was poor and Aristoteli et al. have demonstrated that SPE was another efficient approach among various extraction methods [5].

Various materials with different retention mechanisms had been developed to improve the efficiency and specificity of SPE method, such as chromatographic separation materials [7], magnetic beads [4], organic or inorganic polymers [12,13] and C60-fullerene silica [14] with reversed-phase or ion-exchange group. Yang and co-workers applied nanozeolite materials and $CaCO_3$–poly(methyl methacrylate) nanoparticles for adsorption and separation of low abundance peptides [10,15]. But these materials cannot be used to enrich LMW proteins and peptides exclusively from complex protein mixtures. MCM-41 material is a member of M41S family, and discovered by the scientists of Mobil Oil Corporation in 1992. These materials have high pore surface area, very ordered pore structure, narrow pore-size distribution, and relatively high chemical and mechanical stability [16,17]. The MCM-41 materials have been widely used to adsorb proteins and environment contaminations [18–24]. Tian et al. applied mesoporous silica MCM-41 particles with a pore size of 20.5 Å to selective

doi:10.1016/j.talanta.2009.07.050

enrichment peptides with a range from 1 to 12 kDa from plasma [9]. It was demonstrated that the unique pore structure of this material makes it efficient to enrich LMW proteins and peptides from complex matrixes. Though critical pore can repel most large proteins, the external surface of the material can also adsorb some HMW proteins, which greatly decreases the enrichment selectivity, and the adsorbed proteins on the external surface of the material can further prevent the LMW proteins and peptides from reaching the interior surface of the mesopores by steric exclusion. Katiyar and Ji investigated the adsorption of bovine serum albumin (BSA) on MCM-41 and Al-MCM-41 materials. They demonstrated that the characteristic of external surface can strongly influence the adsorption capacity, and the adsorption on the external surface may be misinterpreted as the adsorption on the interior surface of MCM-41 materials [18,19].

It is well known that the external surface of restricted access materials (RAM) is usually modified with electroneutral alkyl-diol group to eliminate the unspecific adsorption of protein matrixes, which makes it capable to extract small molecular objects directly from untreated biological fluid [25,26]. So in this study, we modified the external surface of mesoporous silica material with alkyl-diol group to improve the efficiency and specificity of the enrichment of LMW proteins and peptides. It was demonstrated that the alkyl-diol group modification on the external surface of mesoporous material could efficiently decrease the HMW protein adsorption and increase the desorption recovery in different elution solvents. The mesoporous material modified on external surface also showed much better extraction selectivity and efficiency for LMW proteins than the unmodified one when crude human plasma was applied. And the extraction efficiency increases about 1200 times for some LMW peptides and proteins by using the alkyl-diol@SiO_2 MCM-41 material.

2. Experimental

2.1. Materials

Tetraethoxysilane (TEOS) and [3-(2,3-epoxypropoxy)propyl] trimethoxysilane were from Meryer chemical technology Co. Ltd. (Shenzhen, China). Cetyltrimethyl ammonium bromide (CTAB) was from Aoboxing Biological Technology Co. Ltd. (Beijing, China). NH_4OH (25%), disodium hydrogen phosphate (Na_2HPO_4), sodium hydroxide (NaOH), and toluene were from Tianjing Kemael Chemical Reagents Center (Tianjing, China). Citric acid was from Shenyang Fourth Chemical Plant (Shenyang, China). Ovalbumin (from chicken egg white), insulin (from bovine pancreas) and a-cyano-4-hydroxycinnamic acid (CHCA) were obtained from Sigma (St. Louis, MO, USA). Human blood plasma was obtained from Beijing PLA 307 hospital. Trifluoroacetic acid (TFA) was purchased from Acros (Morris plains, NJ, USA). HPLC-grade acetonitrile (ACN) was obtained from Mallinckrodt Baker Inc. (Phillipsburg, NJ, USA). Deionized water (R > 18.2 MΩ) used for all experiments was purified by Millipore purification system (Billerica, MA, USA). Matrix CHCA (5 mg/mL) was dissolved in acetonitrile/water (50/50, v/v) solution containing 0.1% TFA.

2.2. Instrumentation

MALDI MS experiments were performed on an Applied Biosystems 4800 Proteomics Analyzer instrument (Framing, MA) in the positive reflector mode for low molecular weight peptides and proteins (m/z 700–3500) and in the linear mode for the proteins with m/z 3000–90 000 (linear middle mass range, m/z 3000–10 000, linear high mass range, m/z 10 000–90 000), respectively. Each mass spectrum was typically summed with 1000 laser shots after being calibrated using an internal calibration by using ion signal of peptide mixtures of myoglobin. All the MALDI MS experiments were performed in CHCA matrix.

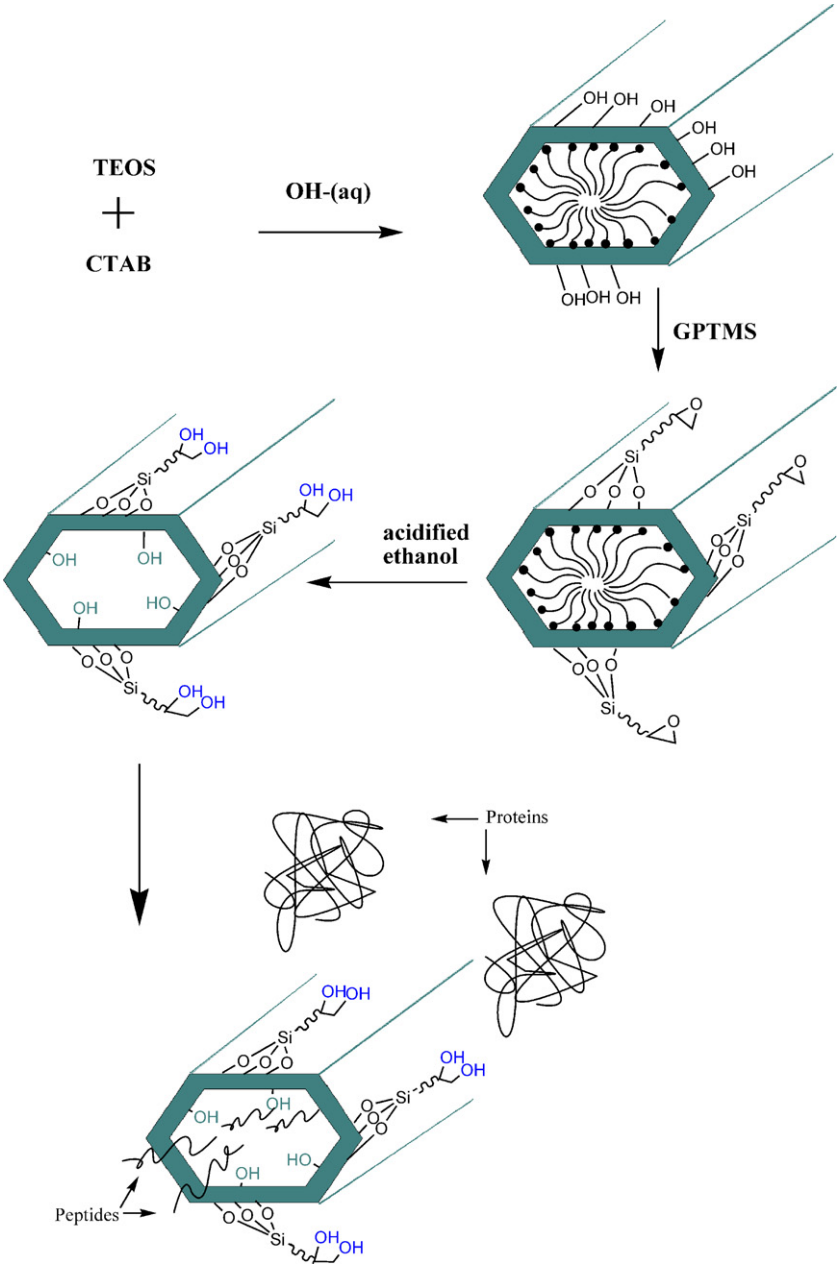
2.3. Synthesis and modification of the mesoporous materials

The reactant mixture for the synthesis of SiO_2 mesoporous material consisted of CTAB, TEOS, $NH_3{\cdot}H_2O$, NaOH and H_2O with molar ratio of 0.1:1:6:0.3:80. The synthesis was performed according to the previously published methods [16,17,27]. After the mixture reacting at room temperature for 3 h, the formed gel was transferred to a Teflon bottle and kept at 100 °C for 120 h. The resultant product was filtered, washed, and dried.

External surface modifications of the mesoporous particles were performed following the procedures as previously reported [28–31], which was carried out by two steps: the first is grafting of (2,3-epoxypropoxy)propyl group on the external surface of the mesoporous material containing the template species; the second is extraction of the template CTAB and conversion of the (2,3-epoxypropoxy)propyl group to alkyl-diol group by acidified ethanol (Scheme 1). Generally, 1 g of the as-synthesized MCM-41 silica sample was suspended in 30 mL toluene, then 3 mL of [3-(2,3-epoxypropoxy)propyl]trimethoxysilane was added under nitrogen protection. After refluxing for 24 h, the suspension was filtered, washed with toluene and ethanol, respectively, and dried at 100 °C under vacuum. The surfactant (CTAB) in the unmodified and modified materials was extracted by acidified ethanol according to the published methods [29,32]. Briefly, 100 mL ethanol including 1.5 mL aqueous HCl (37%) was added to per 1 g material and refluxed at 60 °C for 8 h, followed by drying at 100 °C under vacuum overnight. The resultant materials were designated as unmodified MCM-41 and alkyl-diol@SiO_2 MCM-41 material, respectively.

2.4. Characterizations of the mesoporous materials

X-ray diffraction (XRD) was used to identify the crystal phases of the materials. The data were recorded using a X′ Pert PRO (PANalytical, Holland) vertical goniometer with Cu Kα radiation (λ = 1.5406 Å), at 40 kV, 40 mA. XRD patterns were set as scan for 2θ ranging from 0.5° to 10° with a step size of 0.033° and a time step of 40 s.



Nitrogen adsorption and measurements were performed at 77 K on a NOVA 2200e surface area & pore size analyzer (Quantachrome, USA). The specific surface area was obtained by using the BET method, and the pore-size distribution was based on BJH methods [33,34].

Transmission electron microscope (TEM) was performed using a FEI Tecnai G^2 Spirit TEM instrument (Philips, Holland) operating at 120 kV. Samples were prepared on a copper grid by placing a small aliquot of a suspension of ground sample in ethanol on the grid, followed by drying at ambient conditions.

Fourier transform infrared (FT-IR) spectroscopy was performed on Spectrum 100/100N (PerkinElmer, USA) with the scan range of 4000–400 cm^{-1} at room temperature. Spectra were acquired at 4 cm^{-1} resolution and the scan rate was set as 0.20 cm/s. Spectrum ES software (version 6.1.0) was used in the manipulation of spectra data.

2.5. Protein adsorption on external surface of mesoporous materials

Ovalbumin (MW: 43 kDa, MD: 4.0 nm × 5.0 nm × 7.0 nm) [22] was selected as model HMW protein due to its relatively large dimension compared with the pore size of the adsorbents. To investigate the influence of pH on HMW proteins adsorption, 10 mg of mesoporous adsorbents were mixed with 1 mL of ovalbumin

Scheme 1. Synthesis of alkyl-diol@SiO_2 MCM-41 and its application of selectively adsorption of LMW proteins. TEOS: tetraethoxysilane, CTAB: cetyltrimethyl ammonium bromide, GPTMS: [3-(2,3-epoxypropoxy)propyl]trimethoxysilane.

solutions prepared in Na_2HPO_4–citric acid buffer with pH 2.8, 4.9 and 7.8, respectively. After 12 h incubation, the protein concentration of each supernatant was determined by UV–vis spectrometer (Lambda 35, PerkinElmer, USA) and the amounts of ovalbumin adsorbed were calculated by the difference of the concentration of the protein before and after adsorption [18–20]. Calibration experiment was done before ovalbumin adsorption process.

2.6. Determinations of adsorption kinetics and desorption recovery of LMW protein

Insulin was used as LMW protein to determine the adsorption kinetics and desorption recovery of the mesoporous materials. First, adsorption kinetics was investigated at pH 2.8. Briefly, the adsorption kinetics was investigated by mixing 5 mg of each mesoporous adsorbent with 8 mL of insulin solution (0.25 mg/mL). The resulting mixture was vigorously agitated in an Environmental Incubator Shaker at 180 rpm at room temperature. 500 μL supernatant was removed from mixture at the time point of 10, 30, 120, 300, 420, 600, 720 and 1440 min, respectively. The protein concentration of each supernatant was determined by UV adsorption [18–20] as described above. Then, the desorption recovery was also determined. Briefly, 3 mL of insulin solution (0.2 mg/mL, pH 2.8) was mixed with 5 mg of mesoporous adsorbents. The mixture was vigorously agitated at room temperature until equilibrium. Then the suspension was centrifugated, and the supernatant was collected. The mesoporous particles were washed with 1 mL deionized water for three times. Then, 500 μL 50% aqueous ACN (containing 0.1% TFA) was added to elute adsorbed insulin from the mesoporous particles. The protein concentration in supernatant and eluate were both determined by UV adsorption. Calibration experiment was done before insulin adsorption and desorption process. The recov-

ery (R) was calculated by the following formula:

$$R = \frac{C_e \times V_e}{(C_t - C_s) \times V_s}$$

C_e represents the protein concentration in eluate, V_e represents the volume of eluate, C_t represents the protein concentration before adsorption, C_s represents the protein concentration after adsorption, and V_s represents the volume of adsorption mixture.

In order to study the effect of eluents on the desorption recovery, different eluents: 50% ethanol solution, 1 M NaCl aqueous solution, and Na_2HPO_4–citric acid buffer with pH 7.8 were also investigated by the same way.

2.7. Extraction LMW proteins from human plasma

To extract LMW proteins and peptides from plasma, 10 mg of each mesoporous material was mixed with 0.5 mL deionized water and 0.5 mL plasma. The mixture was vigorously agitated at room temperature for 7 h. Then, the suspension was centrifugated and the supernatant was discarded. The mesoporous particles were washed with 1 mL deionized water for three times. Finally, 1 M NaCl was used to elute the adsorbed proteins. The NaCl eluates were exchanged to 50% ACN solution containing 0.1% TFA using C_{18} Ziptip and spiked with a double ^{18}O labelled standard peptide (FEDGVLDPDYPR, m/z = 1426.53). All the eluates were analyzed by MALDI MS [35,36], which were performed in CHCA matrix.

3. Results and discussion

3.1. Characterizations of the mesoporous materials

Fig. 1 shows three distinct diffraction peaks (d100, d110, d200) for both MCM-41 materials, which reflect the hexagonal pore structure of MCM-41 materials in X-ray diffraction (XRD) analysis [16]. Powder XRD patterns of alkyl-diol@SiO_2 MCM-41 mesoporous particles showed some a little less sharp peaks comparing with the unmodified ones, which can be well explained by the fact that the presence of the organic component can decrease the intensity of the XRD patterns [37], implying a successful external modification. The transmission electron microscope (TEM) images of unmodified and alkyl-diol@SiO_2 MCM-41 are shown in Fig. 2. It can be found that the mesopores of alkyl-diol@SiO_2 MCM-41 are well organized as those of unmodified MCM-41 material. The XRD analysis and TEM image implied that the external surface modification had little influence on the order of mesoporous structure, which is important for the high specific extraction of the LMW proteins from complex samples. The measurement of N_2 adsorption/desorption of alkyl-diol@SiO_2 MCM-41 shows a well-defined step associated with the filling of the mesopores due to capillary condensation, and the pore size is centered at 2.19 nm, and the corresponding surface area is 781 m^2/g (shown in Fig. 2b), which are a little smaller than those of unmodified MCM-41 (2.76 nm and 843 m^2/g, as shown in Fig. 2a). And it may be attribute to the modification on the external surface and inlet of mesopores. The FT-IR spectra of unmodified and modified materials were shown in Fig. 3. The bands near 1080 and 800 cm^{-1} are assigned to the Si–O–Si stretching mode of the mesoporous silica framework. 460, 960 and 3400 cm^{-1} correspond to Si–O–Si bending mode, Si–OH stretching mode, and O–H stretching mode, respectively. The FT-IR spectra of alkyl-diol@SiO_2 MCM-41 have some differences from the unmodified one, the bands near 1460 and 1380 cm^{-1} are assigned to the C–H bending mode, and the bands near 2960, 2930 and 2850 cm^{-1} become stronger due to the introduction of alkyl group.

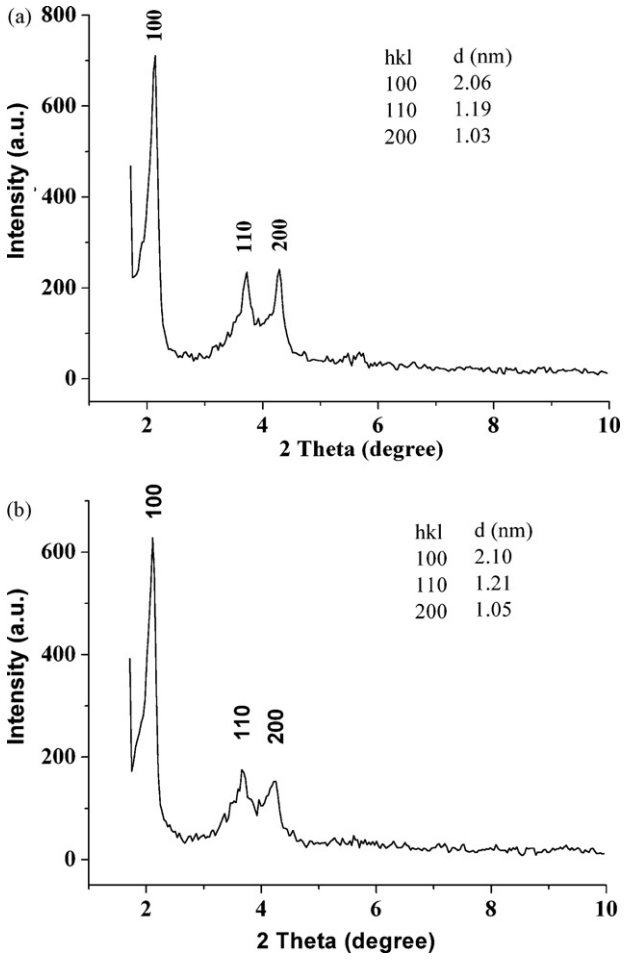


Fig. 1. Power XRD patterns of (a) unmodified and (b) alkyl-diol modified MCM-41 mesoporous materials.

3.2. Exclusion effectiveness on HMW proteins

Highly ordered mesoporous silica particles, especially MCM-41, have been demonstrated to be a useful adsorbent for selective enrichment of LMW proteins and peptides based on the effect of size-exclusion. However, the undesired adsorption of HMW proteins on the external surface was adverse to the selectivity of the enrichment. Therefore, we modified the external surface of MCM-41 material with alkyl-diol groups. To study the exclusion effectiveness of alkyl-diol group on HMW proteins, we used ovalbumin as a model HMW protein due to its larger dimension than the pore size of the adsorbents.

The HMW protein adsorptions were conducted into Na_2HPO_4–citric acid buffers at pH 2.8, 4.9 and 7.8 and the results are shown in Table 1. The adsorption amounts of HMW protein decreased at all of the pH after alkyl-diol group modification on external surface of material. Obviously, it is efficient to reduce the adsorption of HMW protein by introducing the electroneutral alkyl-diol group onto the external surface of mesoporous material. Compared with the adsorption amount by unmodified MCM-41 at pH 4.9, the adsorption amounts decrease 16.98% at pH 2.8, and 21.32% at pH 7.8, respectively. This result consisted with that, when the pH of the buffer is set as the pI of the protein, the highest adsorption capacity by unmodified mesoporous material can be obtained due to the hydrophobic interaction [19]. When the alkyl-diol@SiO_2 MCM-41 was applied, the adsorption amounts had little change when the pH was under the pI and decreased

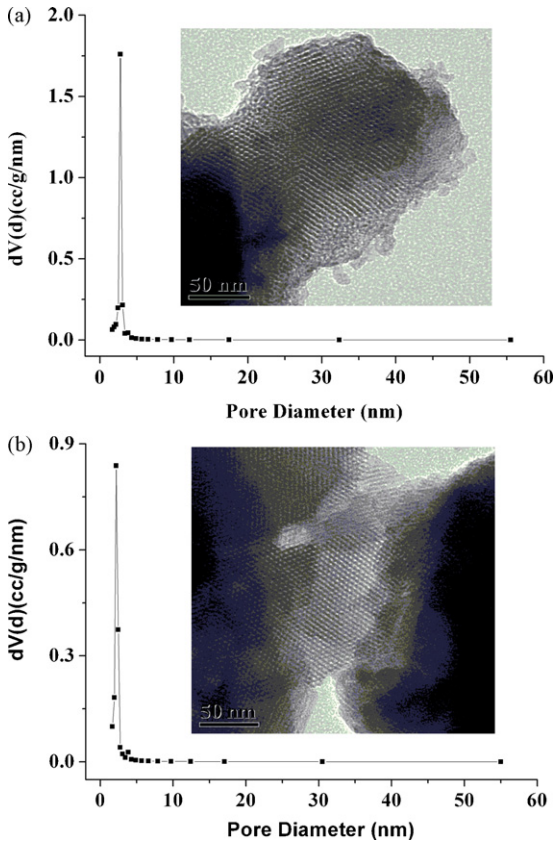

Fig. 2. Differential pore-size distributions calculated from nitrogen adsorption isotherms (inset: TEM image) of (a) unmodified and (b) alkyl-diol modified MCM-41 mesoporous materials.

greatly when the pH was above the pI. The highest adsorption capacity of modified MCM-41 materials was not obtained at the pI of protein, which might be attributed to that the introduction of alkyl-diol group would decrease the hydrophobicity of exterior of the material.

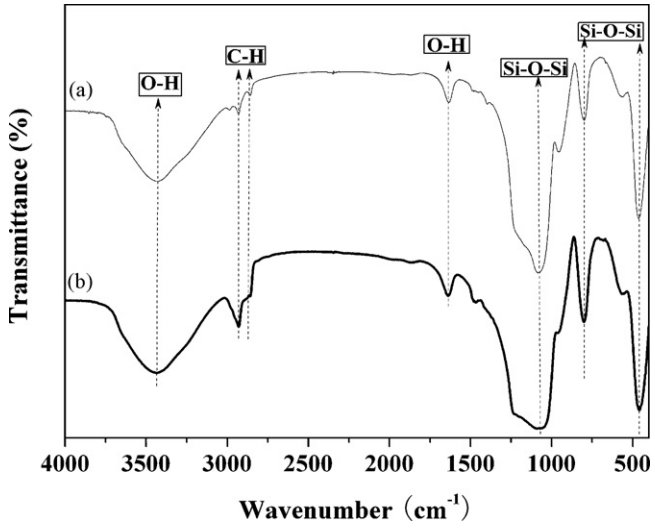

Fig. 3. FT-IR spectra of (a) unmodified and (b) alkyl-diol modified MCM-41 mesoporous materials.

Table 1
Comparison of adsorption efficiency for ovalbumin by unmodified and modified MCM-41 ($n = 3$)[a].

	Adsorption amounts (mg/g)[b]		(RSD (%))[c]
	pH 2.8	pH 4.9	pH 7.8
MCM-41	32.67 (0.8)	39.35 (2.8)	30.96 (0.3)
Modified MCM-41	25.63 (4.8)	24.61 (2.2)	13.63 (1.8)

[a] Protein/silica (wt/wt) = 0.1.
[b] The amounts of ovalbumin adsorbed on external surface (12 h) of the three mesoporous materials, which were obtained by subtracting the amounts in supernatant from the total amount, respectively.
[c] Each adsorption experiment was conducted three times, and the RSDs were given within the parentheses.

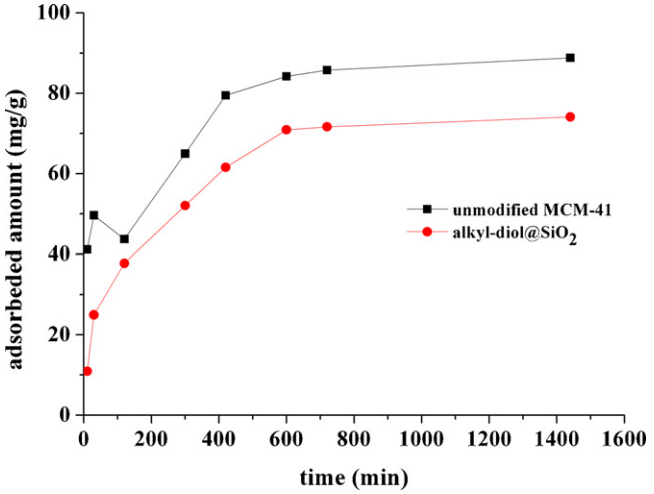

Fig. 4. Adsorption amounts of insulin as a function of time on the two mesoporous materials (protein/silica (wt/wt) = 0.4). The value of each spot was the average of three replicate measurements.

3.3. LMW protein adsorption kinetics and desorption recovery on different mesoporous materials

Desorption recovery is an important parameter for adsorbents in highly efficient extraction. Insulin (MW: 5.7 kDa) was used as a model LMW protein to investigate the adsorption kinetics and the desorption recovery of the mesoporous materials. The adsorption kinetics conducted in Na_2HPO_4–citric acid buffer at pH 2.8 is shown in Fig. 4. After equilibrium for 12 h, the unmodified MCM-41 had higher loading capacity than the modified material due to its stronger external surface adsorption. The desorption recovery of insulin by different elution conditions was also investigated and the results are shown in Table 2. It can be seen that most insulin could not be desorbed from the unmodified and alkyl-diol@SiO_2 MCM-41 materials by using organic solvents (50% ACN or ethanol). However, when 1 M NaCl solution was used, good desorption recovery (over 70%) was achieved for both the materials, and the better one was obtained for alkyl-diol@SiO_2 MCM-41 (91.77%). This might

Table 2
Recovery of insulin for unmodified and modified MCM-41 by using different eluents ($n = 3$).

	Recovery (%) (RSD (%))[a]			
	50% ACN	50% ethanol	1 M NaCl	Na_2HPO_4–citric acid (pH 7.8)
MCM-41	8.69 (9.7)	15.96 (7.9)	75.56 (3.9)	35.59 (12.8)
Modified MCM-41	40.78 (0.5)	44.57 (6.4)	91.77 (6.6)	56.05 (4.5)

[a] Each experiment was conducted three times, and the RSDs were given within the parentheses.

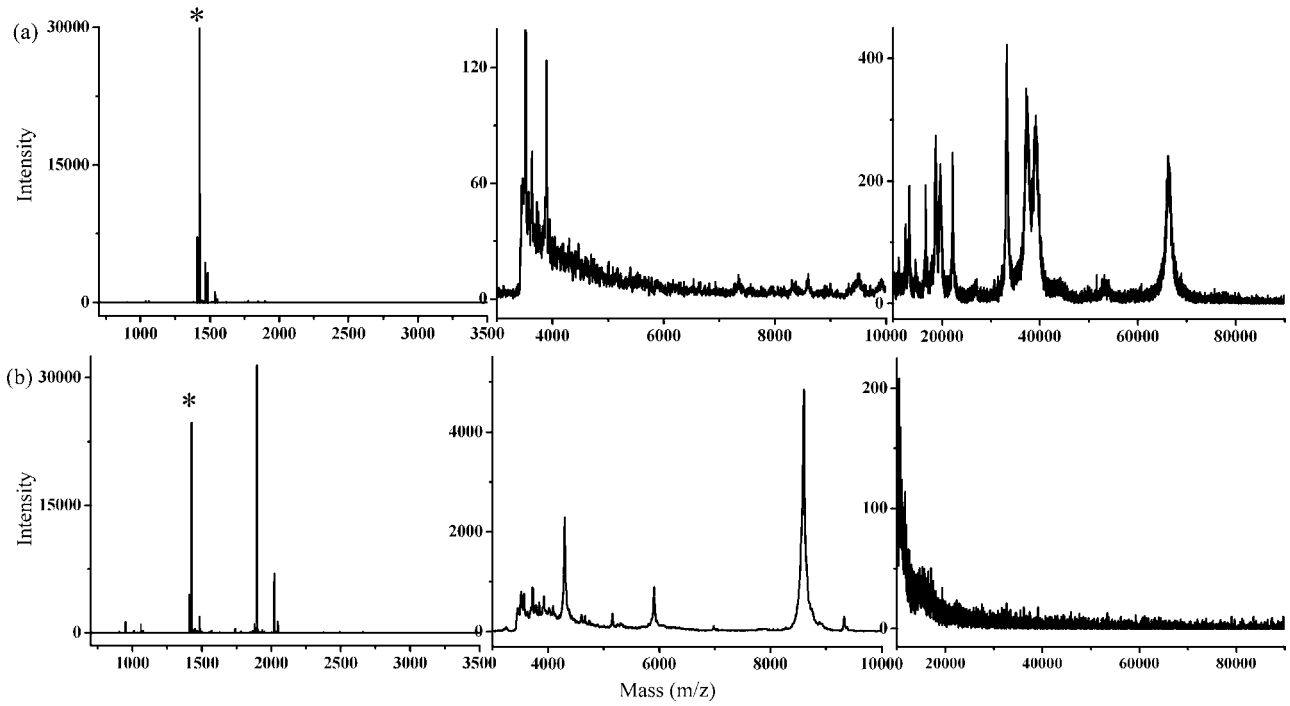

Fig. 5. MALDI MS spectra of human plasma extracts by using (a) unmodified and (b) alkyl-diol modified MCM-41 mesoporous materials. MALDI MS analysis was performed in the m/z range of 0.7–3.5, 3.0–10 and 10–90 kDa. CHCA was used as the matrix. The bound proteins and peptides on mesoporous materials were desorbed by 1 M NaCl. The peaks marked with * represent the internal standard (double ^{18}O labelled standard peptide FEDGVLDPDYPR, m/z = 1426.53).

be attributed to that the protein adsorbed onto the external surface could block the mesopores and influence the desorbing of proteins adsorbed onto the internal surface. Last, the elution by using Na_2HPO_4–citric acid buffer at pH 7.8 was also performed. The results were not better than that by 1 M NaCl (see Table 2). These results can be explained by the ion-exchange mechanism of Si–OH group. Therefore, it is obvious that alkyl-diol group modification on the external surface of mesoporous material can increase the desorption recovery due to eliminating of the adsorption on external surface.

3.4. LMW protein extraction efficiency and selectivity for human plasma

Human plasma is a complex biological sample comprised of tens of thousands of proteins and peptides, most of which is made up of high abundant species, such as albumin, immunoglobulins and so on [38]. However, some low abundant LMW proteins and peptides also play an important role in elucidation of biological and variation and discovery of useful biomarkers [1–4], and their identification is always interfered by high abundant species. Therefore, we applied the mesoporous material to repel high abundant proteins in plasma and selectively extract LMW proteins and peptides. The eluates by 1 M NaCl were desalted by C_{18} Ziptip and analyzed by MALDI MS. To measure the relative amounts of enriched LMW peptide, we added a double ^{18}O labelled standard peptide (FEDGVLDPDYPR, m/z = 1426.53) into the eluate as internal standard. When the unmodified MCM-41 material was applied, about 50 peaks were detected in the m/z range 800–10 000 (S/N > 10), and 8 peaks were observed in the m/z range 10 000–90 000 as shown in Fig. 5a, which indicates that the selectivity of LMW proteins extraction is poor due to the external surface adsorption. It could be also seen that extracted peptides have relative low intensity compared with the standard peptide and the relative area to standard peptide is 0.17 for extracted peptide with MW 1896.1 (assuming z = 1). When alkyl-diol@SiO_2 MCM-41 material was applied, about 100 peaks were detected in the m/z range 800–10 000 (S/N > 10), and few peaks were observed in the m/z range 10 000–90 000 as shown in Fig. 5b, which demonstrates the good selectivity of the external surface modified material for LMW proteins. Not only much more peaks are obtained in the m/z range 800–10 000, but the intensity is also much higher compared with that by unmodified MCM-41 material. As standard peptide was also added, the relative areas of peptides with MW 1896.1 and 2021.1 (assuming z = 1) to standard peptide are 209.45 and 42.55. Compared with the unmodified MCM-41, the extraction efficiency increases about 1200 times (209.45/0.17) for alkyl-diol@SiO_2 MCM-41 material. Obviously, alkyl-diol group modification on the external surface of MCM-41 materials is an efficient strategy to eliminate unspecific adsorption on external surface as well as increase the extraction selectivity and efficiency.

Mesoporous material is a new type of adsorbent for selectively extraction of LMW proteins and peptides from complex biological samples. However, the unspecific adsorption on external surface would decrease the extracting selectivity and desorbing recovery. Therefore, we selectively modified the external surface of the mesoporous MCM-41 particles with biocompatible alkyl-diol groups in this study. Compared with the unmodified MCM-41, the mesoporous material of alkyl-diol@SiO_2 has much higher extracting selectivity and efficiency for LMW proteins and peptides from crude plasma. It could be attributed to that the alkyl-diol group could eliminate the interference of HMW proteins, and the adsorbed HMW proteins would decrease the selectivity as well as block the mesopores and decrease the desorbing recovery of LMW proteins and peptides.

4. Conclusion

New mesoporous material (alkyl-diol@SiO_2) was synthesized and applied to extract LMW proteins and peptides from biological samples. It was demonstrated that the alkyl-diol group modification on the external surface could efficiently decrease the unspecific

HMW protein adsorption, and increase the extraction selectivity and efficiency for LMW proteins and peptides. The extraction efficiency of some LMW proteins and peptides increases about 1200 times by alkyl-diol@SiO_2 MCM-41 material compared with that by unmodified MCM-41 material. Therefore, alkyl-diol@SiO_2 MCM-41 material is suitable for selective extraction of LMW proteins and peptides from complex biological samples, making the approach promising for use in biological separation and the discovery of useful biomarkers.

ABSTRACT

Solid-phase microextraction in headspace mode coupled with gas chromatography–mass spectrometry was applied to the determination of volatile compounds in 30 commercially available coffee samples. In order to differentiate and characterize Arabica and Robusta coffee, six major volatile compounds (acetic acid, 2-methylpyrazine, furfural, 2-furfuryl alcohol, 2,6-dimethylpyrazine, 5-methylfurfural) were chosen as the most relevant markers. Cluster analysis and principal component analysis (PCA) were applied to the raw chromatographic data and data processed by centred logratio transformation.

1. Introduction

Standard multivariate statistical methods, like principal component analysis (PCA), are widely used to analyze results of chemical measurements. The main objective of PCA is to reduce high-dimensional data sets by preserving as much as possible of the variation, contained in the data. PCA is designed to transform the original variables into new, uncorrelated variables (axes), called the principal components, such that the new axes lie along the directions of maximum variance. PCA provides an objective way of finding indices of this type so that the variation in the data can be accounted as concisely as possible. The results of PCA, both loadings and scores, can be advantageously visualized using biplot [1] with the corresponding interpretation. On the other hand, too many variables in the original data set (often with only low concentrations) can cause a kind of 'pollution' of the PCA results because of the variability, presented in these variables. As a consequence, the results can be misleading or even completely useless. A standard way to overcome this undesirable effect is to omit such variables, which are not necessary for the further considerations, by using an expert knowledge before the analysis begins.

The most common way of expressing chemical data is to present them as percentages. That means the data contain only relative information (have relative scale) or, more precisely, contain only the relevant information among the ratios of the variables [2]. Unfortunately, this obvious and natural property of the data (called in the following compositional data, or shortly compositions) is in contradiction to the procedures of standard multivariate statistics, where the scale is absolute. This holds among others also for covariance structure of the data and leads to its undesirable behaviour. Concretely, leaving one or more compositional variables (parts), the covariance structure can completely change. Let us illustrate this situation on the example, arranged from [3].

Consider two scientists A and B interested in some chemical samples, which have been divided into aliquots. For each aliquot A records a 4-part composition, B works without recording the last element and arrives at a 3-part composition. Let us further assume for simplicity the ideal situation where the aliquots in each part are identical and where the two scientists are precise in their determination. Then clearly B's 3-part composition $[s_1, s_2, s_3]$ for an aliquot will be a subcomposition for A's 4-part composition $[x_1, x_2, x_3, x_4]$ for the corresponding aliquot related by

$$[s_1, s_2, s_3] = \frac{[x_1, x_2, x_3]}{(x_1 + x_2 + x_3)}.$$

This is then obvious that any statements that A and B make about the three common parts should agree. This is the nature of so-called subcompositional coherence [3]. Let us consider the simple data

set:

Full compositions$[x_1, x_2, x_3, x_4]$	Subcompositions$[s_1, s_2, s_3]$
[0.1, 0.2, 0.1, 0.6]	[0.25, 0.50, 0.25]
[0.2, 0.1, 0.1, 0.6]	[0.50, 0.25, 0.25]
[0.3, 0.3, 0.2, 0.2]	[0.375, 0.375, 0.25]

Scientist A would report the correlation between first two elements as $\mathrm{corr}(x_1, x_2) = 0.5$ whereas B would report $\mathrm{corr}(s1, s2) = -1$. There is thus incoherence of the correlation between raw components as a measure of dependence. Note, however, that the ratio of two components remains unchanged when we move from composition to subcomposition: $s_i/s_j = x_i/x_j$, so that, as long as we express all our statements about compositions in terms of ratios, we shall be subcompositional coherent.

Another serious requirement within compositions is that any statistical method, convenient for compositional data analysis, should respect their relative scale property. Its basic idea is to distinguish between the following two pairs of concentrations in a chosen compositional part, 0.50 and 0.51 together with 0.01 and 0.02. In the first one, the growth of an element's concentration is only negligible (the increase is by a factor 1.02) in contrary to the second case, when 0.02 is double of the previous size (i.e. increase by a factor 2). Thus, although the data pairs visually have the same distance (because we are thinking in terms of Euclidean distances), a distance between the second pair of compositions (with unaltered ratios of concentrations in the other parts) should be essentially greater than between the first one. Unfortunately again, standard methods, working with Euclidean distance, do not take this requirement into account. As a way out a new distance measure, or more generally, new geometry should be introduced, respecting this property as well as the necessity of the mentioned subcompositional coherence.

In the following section we give solutions for the above mentioned challenges like subcompositional coherence or relative scale preserving for compositional data introducing a family of so-called logratio transformations. Specially, we show how to use the logratio approach for cluster analysis and PCA of compositional data.

Consequently, the results will be applied to the analysis of coffee samples. As it is known, coffee aroma is composed of an extensive group of volatile compounds. Chemical composition of individual coffee products, accompanying coffee aroma, depends on several factors including species of green coffee beans (e.g. Arabica vs. Robusta variety) [4,5], geographical origin [6,7] and processing conditions [8–13], especially roasting, packaging and stocking of products. More than 800 significant volatile compounds have been identified, but the number of discovered aromatic compounds has been increasing. As a principal classes of aroma compounds [14–18], which are generated during a roasting process of green coffee beans, are presented aducts and derivatives of aldehydes, ketones, phenols, sulphur compounds, pyrazines, pyridines, pyrolles and furans as well. The aim of the study is to find out a relatively small group of compounds (major compounds, mainly formed during the roasting process), which could distinguish different coffee origins. Evidently, the perception of coffee aroma depends on both, the concentration of the compound and its odor threshold. So, the application of PCA and cluster analysis has been used to chromatographic results, obtained by headspace solid-phase microextraction (HS-SPME) in connection with gas chromatography–mass spectrometry (GC–MS). Simultaneously, the verification and the comparison between the standard statistical analysis and the introduced logratio approach were performed as well.

2. Theoretical considerations

As already mentioned in the previous section, D-part compositions are by their definition vectors $\boldsymbol{x} = [x_1, x_2, \ldots, x_D]$, rows of a data matrix $\boldsymbol{X}$, when all its components are strictly positive real numbers and they carry only relative information [2,19]. Indeed, the property that compositional information is relative is implicitly stated in the units, as they are always parts of a whole, like volume percent or molar fraction. It means that a composition and its positive real multiple convey essentially the same information. As a consequence, a way to simplify use of compositions is to represent them in closed form, i.e. as positive vector with constant sum k (usually 1 or 100 in case of percentages) of the parts. A set of all compositions with a constant sum k (also called closed data) forms a simplex, sample space of compositional data. An apparent problem is hidden in the requirement of nonzero values in the compositional parts. In compositional data we distinguish two kinds of zeros: essential zeros – or absolute of the part in the observation – and rounded zeros – or presence of a component, but below a detection limit [20]. Its different nature implies that the treatment of the two kinds of zeros should be different. When we consider that one component has a rounded zero, what represents apparently a more common problem in chemical data sets, i.e. when we consider that this value does not denote that the part is completely absent, but rather that no quantifiable proportion could be recorded to the accuracy of the measurement process, it seems reasonable, and is done traditionally, to replace them by a suitable small value. Possible problems of this approach (that do not occurs in the following) as well as proposed solutions are available in [20].

As mentioned above, the usual correlation analysis is not meaningful in the case of compositional data. For this reason, dispersion in compositional data sets can be described by *variations* [2], defined as

$$\tau_{ij} = \mathrm{var}\left(\ln \frac{x_i}{x_j}\right), \quad i, j = 1, \ldots, D.$$

It is possible to see that the problem of subcompositional incoherence does not occur more here as the ratio of two compositional parts x_i and x_j remains unchanged when taking only a subcomposition instead of the whole composition. However, the interpretation is different from the standard correlation measure. The values of τ_{ij} close to zero refers that the ratio x_i/x_j is nearly a constant and that the two parts, x_i and x_j, can be assumed to be redundant [21]. Generally, also a correlation analysis for compositional data in some cases is possible [22], but requires some more theoretical considerations.

In practice, regarding the above mentioned, standard statistical methods can lead to questionable results if they are directly applied to the original, closed data. The main reason is another geometry of compositional data on the simplex, called Aitchison geometry [19], in contrast to the standard multivariate data, represented by the well known Euclidean approach in real space. As a way out, the family of logratio one-to-one transformations from the simplex to the real space has been introduced [2,23]. For the purposes of the paper, we will consider so-called *centred logratio* (*clr*) *transformation* [2], where the compositions $\boldsymbol{x}$ are transformed to data $\boldsymbol{y}$, with

$$\boldsymbol{y} = [y_1, y_2, \ldots, y_D] = \left[\ln \frac{x_1}{\sqrt[D]{\prod_{i=1}^{D} x_i}}, \ldots, \ln \frac{x_D}{\sqrt[D]{\prod_{i=1}^{D} x_i}}\right].$$

The clr transformated data are already standard multivariate data, what enable us to use the mentioned PCA for data reduction. Moreover, clr transformation preserve distances among original compositions. Thus, the cluster analysis to reveal groups formed by the observations can be performed immediately when the data are transformed. Although this transformation has also some drawbacks like singularity of the data (the sum of the transformed variables y_i equals 0, see [2] for details), it treats all components symmetrically by dividing by the geometrical mean and the interpretation of the resulting values thus seems to be in some cases easier than by other members of the logratio transformations family (here for PCA of compositional data).

A way to perform PCA for compositional data is the following [19]. Consider the compositional data matrix $\boldsymbol{X}$ with n rows and D columns. Thus, D measurements have been obtained from each of n samples. Transform the rows of the matrix $\boldsymbol{X}$ with clr transformation to data matrix $\boldsymbol{Y}$. Then, for the purpose of better interpretation of the PCA results using biplot, centre the rows of matrix $\boldsymbol{Y}$, i.e. subtract the corresponding columns' means from each of elements of $\boldsymbol{Y}$. Note that $\boldsymbol{Y}$ is of the same order as $\boldsymbol{X}$, i.e. it has n rows and D columns and recall that clr transformation preserves distances. Thus, we can apply standard PCA procedure to $\boldsymbol{Y}$ in order to obtain resulting loadings and scores.

According to the relative scale of compositional data, the compositional parts with only small concentrations can contain a significant part of the total variability of the compositional data set and thus depreciate the results of PCA after clr transformation. For this reason, it is recommended, even more than in the case of standard multivariate data, to leave out such parts, not necessary for the further considerations, before the analysis is performed.

Anyhow when taking standard PCA, also in case of clr transformed compositions the loadings and scores can be visualized simultaneously using biplot, with interpretation of the loadings corresponding to the nature of compositional data [25]. Namely, the links (distances) between rays, representing the loading plot, approximate the variations. Thus, if the vertices of the rays coincide, or nearly so, this means that the ratio x_i/x_j is constant, or nearly so.

3. Experimental

3.1. Samples

Thirty commercially available roasted coffee samples of different origins, processed by different technologies were obtained in local supermarket. Different sort of coffee, including both, Arabica (16 samples) and Robusta coffee (3 samples), as well as various blends of them (11 samples), were examined in this study.

3.2. HS-SPME and GC/MS analyses

A commercially available carboxen/polydimethylsiloxane fiber (CAR/PDMS, 75 μm) was used for SPME analyses. At the first, the SPME fiber was reconditioned for 10 min in the GC injection port at 250 °C, and then was inserted into septum-sealed flask (40 mL) containing 2.00 g of ground coffee sample. The fiber was exposed for 60 min in the headspace at the laboratory temperature. All analyses were performed on a HP 6890 Series GC system with an Agilent 5973 N Mass Selective Detector (Agilent, Palo Alto, CA, USA), equipped with a Rtx-5Sil MS capillary column (30 m × 0.25 mm I.D. ×0.25 μm film thickness). SPME fibers were loaded in manual mode. The following conditions were used for the experiment: desorption temperature 250 °C, 4 min; splitless injection, temperature program 40 °C (2 min) – 5 °C/min – 200 °C (5 min), a carrier gas was helium (99.998%; velocity 0.9 mL/min; SIAD, Bergamo, Italy). MS scans were recorded within the range 29–370 m/z using electron ionization (energy 70 eV).

3.3. Data processing

Statistical analysis was accomplished by the statistical software R [24]. R is a free software environment that provides a wide variety of statistical (linear and nonlinear modelling, classical statistical tests, time-series analysis, classification, clustering, etc.) and graphical techniques, and is highly extensible.

4. Results and discussion

The HS-SPME analysis connected with GC–MS technique was used for the identification and quantification of the volatile compounds in commercially available coffee varieties (16 Arabica, 3 Robusta and 11 blends, denoted as A, R and AR, respectively). A multipurpose carboxen/polydimethylsiloxane SPME fiber has been applied to the determination of volatile compounds in coffee aroma. In qualitative analysis, 15 volatile flavor compounds were identified by the comparison with mass spectra in the NIST mass spectra library. These compounds could be essential for specification of coffee aroma in a particular coffee product. As promising descriptors of coffee aroma were selected following compounds: acetic acid, 1-hydroxy-2-propanone, pyrazine, pyridine, 2-methylpyrazine, furfural, furfuryl alcohol, 1,2-ethanediol diacetate, 2,6-dimethylpyrazine, 2-ethylpyrazine, 5-methylfurfural, furfuryl acetate, 2-ethyl-6-methylpyrazine, 3-ethyl-2,5-dimethylpyrazine, 1-furfuryl pyrrole. The representation of particular chemical components in each coffee sample is presented as relative contents in Table 1. An expertise mathematical consideration and examination of major volatile compounds made out to avoid the probable 'pollution' caused by compounds (compositional parts) with low concentrations, that cover, however, from the properties of Aitchison geometry, an extensive proportion of total variability of the data set. Only six flavor markers were selected from a number of alternative volatile compounds in coffee by the statistical approach: acetic acid (1), 2-methylpyrazine (2), furfural (3), 2-furfuryl alcohol (4), 2,6-dimethylpyrazine (5), 5-methylfurfural (6). These six compounds cover over 80% of the average relative amount of volatile compounds detected in the coffee samples. It could be stated that these flavor compounds observed in coffee samples are significant for distinguishing coffee variety or geographical origin, that was also reported by other authors [7,26].

The statistical evaluation of chromatographic data has been elaborated by the standard statistical analysis as well as the centred logratio transformation followed by both, cluster analysis and principal component analysis. Firstly, hierarchical clustering (using the complete agglomeration method) was applied to both raw and clr transformed data and the results were displayed using dendrogram (Fig. 1). As can be seen in Fig. 1, the standard cluster analysis causes that the data structure is not clearly visible. Arabica and blend samples are grouped together and only the group of Robusta coffees is quite well separated (Fig 1, upper plot). Performing clr transformation that turns out the compositions into the Euclidean geometry, the considered three groups (Arabica, Robusta and blends) are already distinguished. Now only few adjacent objects are assigned to wrong clusters (Fig. 1, lower plot), namely A1, A4 and A9 to blends and AR5, AR9 and AR11 to Arabica group. This effect can be explained by the unknown properties of the coffee samples, such as a composition of blended coffee (ratio of each coffee species in AR samples), coffee origin and quality. It is worth to mention, for example, that the manufacture process may affect on the part of coffee quality. For instance Arabica sample A16 and mixture AR11 were manufactured by the same producer and both samples were assigned to the same group in the dendrogram.

Table 1
Relative representation of volatile compounds in coffee ($\times 10^4$), nd—not detected.

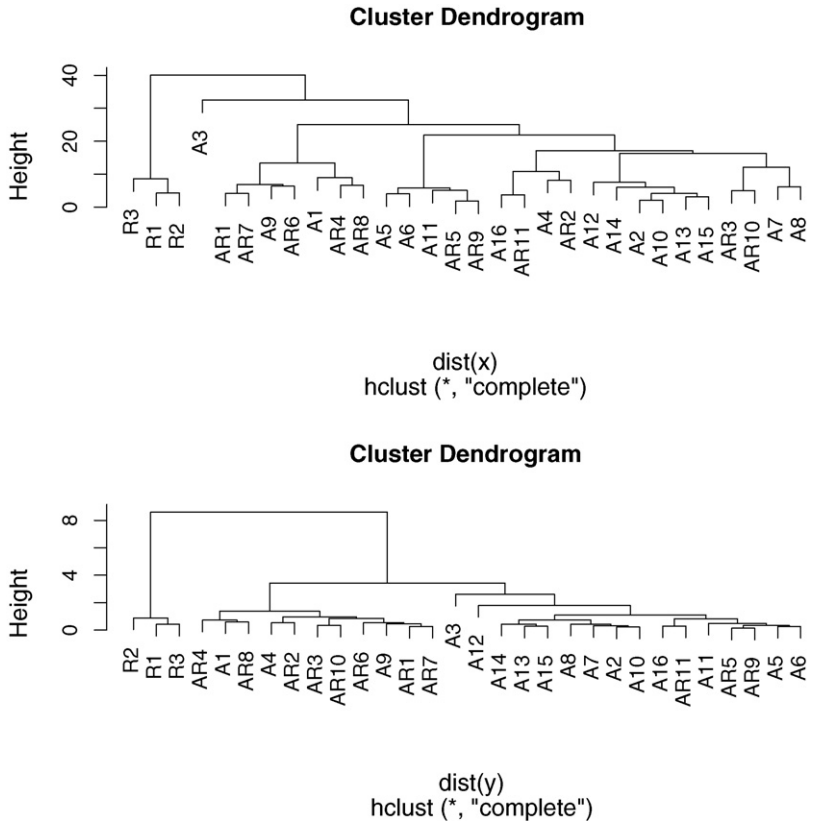

Fig. 1. Dendrograms for the raw coffee data (upper figure) and after clr transformation (lower figure).

Whereas the cluster analysis was able to distinguish particular groups of coffee, the PCA statistical analysis was performed to indicate similarities or differences within the complex odors, to establish the relation between varieties and particular volatile compounds. The results of PCA are presented in the widely used form of biplot [1] that displays both loadings and scores, with interpretation corresponding to compositional data [25] in the case of clr transformed compositions. Applying standard PCA to the data matrix consisting of the relative amounts of the 6 analytical variables (chosen major compounds) and 30 objects (coffee samples), the first two principal components were extracted. The total variance of initial data explain for 84.28%, where the first principal component (PC1) accounts 61.43% and the second principal component (PC2) accounts 22.85%, see Fig. 2. However, regarding the results of cluster analysis, the corresponding scores (representing objects) do not sufficiently meet the data structure (mixed A and AR samples). Thus the interpretation of this biplot could lead to misleading results.

On the other hand, the PCA for clr transformed data seems to produce much more interpretable results, presented again in the form of biplot (Fig. 3). The first two principal components account even for 96.01% of the total variance of the data; PC1 explains 88.79% of the variance in the clr transformed data set and PC2 explains 7.21%. Now, the scores illustrate very good resolution of groups of coffee and the reliability of the result is supported by high proportion of explained variability in the data set (96%) using the first two principal components. The loadings, represented by rays, refer to more or less constant ratio between the compounds (compositional parts). One can point out the role of acetic acid that forms the main source of differentiation of the Robusta variety by PC1. The groups of Arabica coffee and mixed coffee varieties are then measurably discriminated by PC2. If it is evident that the latter ones are divided into two groups, the second principal component might be interpreted as 'a factor of quality'. The resolution of these two coffee varieties is visualized through delimitated groups, however 'polluted' by objects, corresponding to the problematic samples revealed by the cluster analysis (A1, A4, A9 and AR5, AR9 and AR11, respectively, see Figs. 1 and 3).

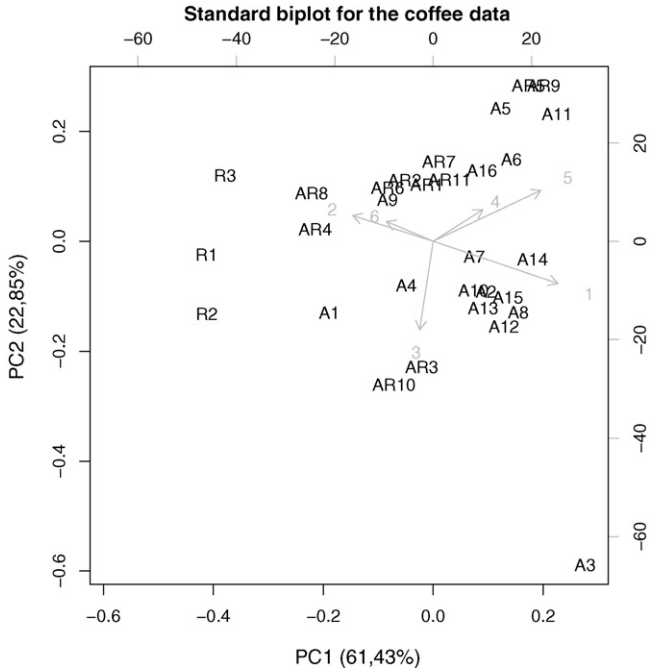

Fig. 2. Standard biplot for the coffee data.

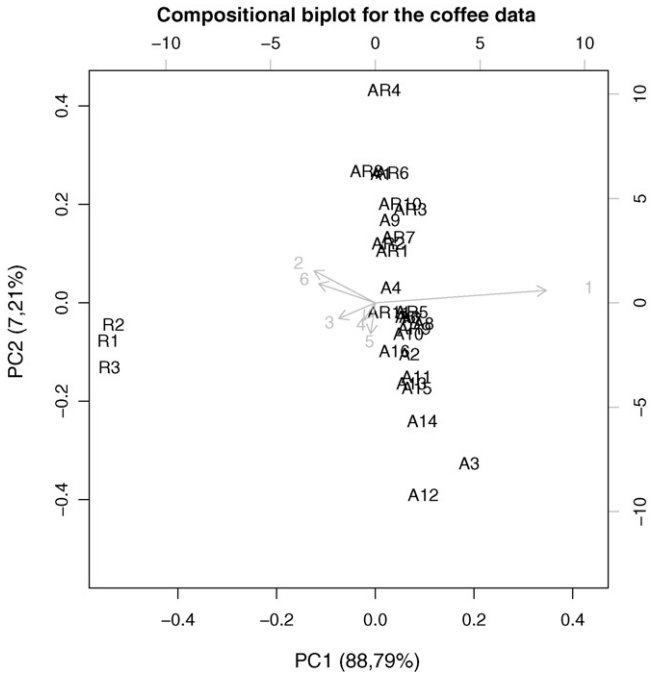

Fig. 3. Compositional biplot for the coffee data.

5. Conclusions

A comparison of the proposed centred logratio transformation and standard statistical approach of cluster analysis and principal component analysis has been applied on the data set concerning compounds of aroma profile of coffee samples. Two important conclusions have resulted from this study: (i) only 6 major volatile compounds (acetic acid, 2-methylpyrazine, furfural, 2-furfuryl alcohol, 2,6-dimethylpyrazine, 5-methylfurfural) provide sufficient differentiation of 30 roasted coffee samples under investigation. (ii) Application of centred logratio transformation provides better results in comparison to the standard statistical procedure (PC1 and PC2 explain 96% of total variability and provide better interpretation of the compositional data set).

ABSTRACT

The arsenic (As) spectral interference observed in the determination of cadmium (Cd) by inductively coupled plasma atomic emission spectrometry (ICP-AES) was studied in atomic absorption spectrometry (AAS) using flame (FAAS) and graphite furnace (GFAAS) as atomizers. The soils of 15 kitchen gardens located near two smelters in the North of France were selected according the ratio As/Cd. Four different extracting solutions usually used to evaluate the mobility of Cd were chosen to extract Cd from these soil samples: citric acid 0.11 M, acetic acid 0.11 M, calcium chloride 0.01 M and water. The quantitative determinations of Cd in the 15 soils for each solvent were investigated by ICP-AES at two lines (228.802 and 214.438 nm) and by FAAS or GFAAS with two-way background compensation. Compared to the Cd concentrations measured in the acid solutions and in the $CaCl_2$ solution after the addition of a chemical modifier, it was clearly demonstrated that the high-speed self-reversal background compensation (HSSR-method) was the method of choice to eliminate the spectral interference of As during Cd determination by FAAS and by GFAAS. In water, it was shown that the deuterium lamp used for the background compensation (D_2-method) was able to eliminate the most of the As interference. In comparison with Cd concentrations in water after adding a chemical modifier, those obtained with the HSSR-method were similar and a very good correlation was obtained between these two methods ($R^2 = 0.995$). It was therefore established that the HSSR-method would be able to replace the chemical modifiers to eliminate As interference in the determination of Cd-extractable from As contaminated soils.

1. Introduction

Since several metals are generally present in trace concentrations in complex matrix such as agricultural soils, urban soils, dust and plants, sensitive and selective methods are necessary to determine the metal concentrations [1–6]. FAAS and GFAAS are the most widely used general techniques for the analysis of metallic elements. This is attributed on the one hand, to the low initial and running costs of the instrument compared to the ICP-AES and on the other hand, to the high sensitivity of the GFAAS. However, as is the case with emission spectrometry, FAAS and GFAAS suffer from several types of interferences, which can be explained by the variability in the surface tension and the viscosity characteristics of samples, and which change the rate of the sample aspiration and affect the analyte atomization efficiency [7]. The latter changes according to the variability in ionization and chemical characteristics between samples too. Another class of interferences is the molecular and particular absorptions which overlap with the analytical line [8]. This phenomenon is explained by the scattering of the source beam due to incompletely atomized particles. Well known common types of spectral interferences in emission techniques are the mass interferences [9–12] and the atomic interferences which are due to the line overlap of the analyte and an element of the matrix [13–16]. For specific elements, some particular techniques have been developed. Based on the treatment of samples before analysis or using specific equipment [1,17–19], these techniques are used for the background compensation.

Atomic interference is a less common type of spectral interference in AAS. However some specific studies, concerning for example interferences between iron (Fe) and zinc (Zn), have recently been conducted. To eliminate spectral interferences between these two elements, some authors described a pretreatment of samples [20–23] while others developed an online elimination and/or preconcentration procedures before AAS determination [24–27] or used other techniques such as flow injection analysis (FIA), thermospray flame atomization or simultaneous electrothermal atomic absorption spectrometry (SIMAAS) [28–31]. However, the atomic interferences in AAS cannot always be fully resolved by the optical system of a spectrophotometer when spacing between the lines of the element and its interferent is less than the size of the slit width.

doi:10.1016/j.talanta.2009.07.053

Nowadays, analytical procedures require instruments obtaining reliable and reproducible quantification of the element with a minimum effort in time-consuming sample pre-treatment. For this, different background compensations are widely used to solve molecular and atomic interference problems generated by samples. In almost all cases, they concern the deuteriumlamp- and Zeeman-effect-based methods. The third is the Smith–Hieftje method (H–S method) which can operate in a single-beam mode and uses only a single source, the hallow cathode lamp in a double pulsed mode [32]. More recently, a new approach has been developed [33]. This one is based on the broadening, which occurs in the resonance lines when a hollow cathode lamp is operated in a pulsed mode with a high frequency (100 Hz) at high current, up to a maximum of 600 mA. This background compensation method is called high-speed self-reversal method (HSSR-method) and was described as a universal technique used in a flame and graphite furnace atomization covering the entire wavelength range from 190 to 900 nm [33].

The determination of trace amounts of Cd in the presence of large amounts of As by FAAS and GFAAS following the guidelines suggested by the manufacturers, which specify using a 1.0-nm slit width, is prone to overestimate or underestimate the Cd concentrations. The reason for this is that the more sensitive Cd atomic adsorption line at 228.802 nm is only 0.01 nm from the weakly absorbing arsenic line at 228.812 nm [34]. Moreover, in the extracting solutions from soils, interferences between Fe and Cd may occur because of two iron lines, which are closely positioned next to the Cd line at 228.802 nm with a difference of only 0.04 and 0.08 nm, respectively in FAAS using the deuterium technique [35] or using the Zeeman-effect background compensation system in ETAAS [36].

The purpose of the present work is to evaluate the HSSR-method as background compensation (BGC) developed by Shimadzu for its AAS to determine Cd-extractable of soils. Firstly, Cd concentration was measured in test solutions containing increasing As concentrations. Secondly, the objective was to validate the HSSR-method for the Cd determination in the soil of 15 kitchen gardens after single extractions with citric acid, acetic acid, calcium chloride and water using FAAS and ETAAS for which Fe interferences may exist.

2. Experiments

2.1. Reagents and solutions

All solutions were prepared from analytical grade reagents unless specified otherwise. Double distilled (Val de Reuil, France) water with a specific conductibility of 0.1 $\mu S\,cm^{-1}$ was used to prepare all aqueous solutions and dilutions.

2.1.1. Extractants

Calcium chloride 0.01 M was prepared by dissolving 1.47 g of calcium chloride dihydrate reagent for analysis (Acrōs Organics, Noisy-le-Grand, France) in 1000 ml of double distilled water. A solution of acetic acid 0.11 M was obtained by diluting of a glacial acetic acid (Acrōs Organics) used for trace metal analysis. Citric acid monohydrate for analysis (23.11 g) (Acrōs Organics) was dissolved in 1000 ml of double distilled water to obtain a solution of citric acid 0.11 M.

2.1.2. Metal ion stock solutions

The Cd metal stock solutions, 1, 2 and 5 $mg\,l^{-1}$ in 2% HNO_3 (C.P.A. groupe A.C.S.D., Voisins le Bretonneux, France) were used to prepare the other solutions. Test solutions containing As were prepared from 1000 $mg\,l^{-1}$ standard solution in 1 M HCl (Reagecon, Shannon, Ireland).

2.1.3. Test solutions of Cd + As

Test solutions containing Cd and As were prepared from the stock solutions described above. Samples were analysed in pairs to allow for machine drift, for example, Cd 1 $\mu g\,l^{-1}$; Cd 1 $\mu g\,l^{-1}$ + As 0 $mg\,l^{-1}$; Cd 1 $\mu g\,l^{-1}$; Cd 1 $\mu g\,l^{-1}$ + As 0 $mg\,l^{-1}$, etc.

2.2. Studied soils

Between 2003 and 2004, 15 kitchen gardens were chosen in an area contaminated by the past atmospheric emissions of two smelters in the North of France. The soils were sampled up to a depth of 25 cm with a hand auger. Depending on the site surface, a composite sample of the ploughed layer of the soils was made starting from about 10 sub-samples taken in a random fashion from the area of the kitchen garden. These sub-samples were then mixed and homogenized to constitute a representative sample of the site surface. Care was taken to avoid the proximity of pathways, vehicle tracks or roads. In these soils, agronomic parameters and the total concentration of 18 pollutants were determined following protocols detailed in the literature [37]. Data were detailed by Douay et al. [38]. The highest Cd and As contents in soils were 26.5 and 65.1 $mg\,kg^{-1}$, respectively, while the lowest Cd and As measured contents were 4.0 and 4.4 $mg\,kg^{-1}$. The maximum value of the ratio As/Cd was 3.6 and the minimum value was 0.5.

2.3. Soil extraction procedures

The preparation of the 15 topsoil samples was carried out according to standard NF ISO 11464. Samples were air-dried and crushed to pass through a 2-mm stainless steel sieve. After drying at a temperature less than 40 C, an automatically sieve was conducted with an ultra centrifugal mill <250 μm (Retsch type ZM 200, Hann, Germany) to obtain a representative sub-sample (100 g) for each of the 15 samples of soil. Sub-samples were then used for the determination of metals in extracting solutions.

2.3.1. Microwave-assisted digestion

The digestion of dry samples was conducted using a microwave oven (Berghof Speedwave™ MWS-2, Eningen, Germany) with a system to control the temperature inside the reactor pressure. This system, integrated into the microwave oven, is an infrared thermometer that permits the temperature radiation emitted by the digestion solution to be quickly determined and regulated. The analytical solutions were obtained by digesting of 300 mg of air-dry soil in a mixture of 1.5 ml nitric acid (70%) and 4.5 ml sulphuric acid (70%). Before beginning the digestion, the reactors were agitated to promote the formation of carbon dioxide and then closed with an aluminium rupture disc, a TFM lid and a coupling cap. The reactors were placed in the rotor and the system was inserted into the oven and connected in the centre to a vent PFA tube. Quality control was based on the use of a certified sample (BCR CRM 141R).

2.3.2. Single extractions of Cd and As from soils

Selective extractions with citric acid 0.11 M, acetic acid 0.11 M, calcium chloride 0.01 M and water were performed in three replicates. For this, 3 g of a representative soil sub-sample that had been crushed and sieved to pass through a 250 μm sieve were taken. The aliquots were shaken with a soil/extractant ratio of 1/10 (w/v). A circular agitation of the samples with the chemical extractants was carried out using a rotor disc (10 rpm) for 16 h in the case of acid extracts and for 2 h in the case of calcium chloride and water extracting solutions. The extract was separated from the solid residue by centrifugation (4 530 rpm) over 20 min at room temperature and the solution was filtered on an acetate Millipore membrane (Millipore, 0.45 μm porosity). The solution was put into

a polypropylene container, acidified with 92 μl of nitric acid solution (65%) and stored at 4 °C for analysis.

2.4. Apparatus

An ICP-AES (Varian, Mulgrave, Australia) was used to determine the pseudo-total Cd and As contents and the concentration of these elements in the single extractions from the soils. Characteristics and detection limits of this material were described by Abbasse et al. [39]. All samples analysed using ICP-AES were also analysed by FAAS or by GFAAS using the same set of standards for calibration. For atomic absorption determination, a Shimadzu AA-6800 (Tokyo, Japan) was operated under guidelines by the manufacturer using a 1.0 nm slit width, an ASC-6100 autosampler (Tokyo, Japan) and two techniques of background compensation. For graphite furnace investigations, the ASC-6100 autosampler (Tokyo, Japan) in combination with an ASK-6100 autodiluter (Tokyo, Japan) was used and the Shimadzu AA-6800 was fitted with a digital control technology graphite furnace atomizer (GFA-EX7, Tokyo, Japan) that had been fitted with a high-density graphite tube.

2.4.1. Background compensation used in AAS

The first BGC used is this study was based on the D_2-method which required a single element (Cd) hollow cathode lamp (Hamamatsu, Iwata, Japan) for the element specific absorption and a deuterium lamp (Hamamatsu, Iwata, Japan) for the background absorption. This method is one of the most popular and is available as a standard method in all Shimadzu atomic spectrometers. For this method, the hallow cathode lamp current was 8 mA.

The second BGC was based on the HSSR-method which is available on the Shimadzu AA-6800. To apply the technique of the self-reversal background compensation, the single Cd hollow cathode lamp current is modulated in two modes: a low current mode (8 mA) and a high current mode (100 mA). Because the high current mode measures only the background absorption, the difference between the absorption of both types of light provides accurate background compensation and measurement of the atomic absorption of the studied element.

2.4.2. Temperature programme for GFAAS

In absence of chemical modifier, the furnace programme was optimized for the determination of water or calcium chloride Cd-extractable from the studied soils (Table 1). The charring temperature was 300 °C [23,40] and the furnace temperature on atomization step was 1800 °C to obtain a maximum peak area absorbance value [23,41]. In presence of chemical modifier, the furnace temperature program was operated under guidelines by the manufacturer. The temperature applied for the atomization step was 2200 °C.

2.5. Statistical analysis

A Mann–Whitney *U* test was used to determine the influence of As on the determination of Cd concentrations in the test solutions. For each extractant and analytical techniques a Bonferroni, a Tuckey and a Fischer post hoc test were conducted to determine significant differences among Cd concentrations according to the analytical techniques and the background compensations. Moreover, a Dunnett-ANCOVA was carried out with datasets by choosing the data obtained by AAS with the HSSR-method as control. All statistical tests were performed using Statistica 6.0 for Windows.

3. Results and discussion

3.1. Analytical performance of the AAS

The measuring conditions used in FAAS were the same as those described by the manufacturers and in the literature [33,42]. For the graphite furnace, some modifications were made. The atomization conditions are summarized in Table 1. The limits of detection (LOD) and the limits of quantification (LOQ), respectively defined as the concentration equivalent to three times and to 10 times standard deviation of the reagent blank ($n = 10$) were determined for Cd using FAAS, GFAAS and the two methods of background compensation described above. Two methods of standard calibration were applied. In the case of FAAS, six standard solutions, in the 2–25 μg l^{-1} concentration range, were injected *via* the autosampler. For GFAAS, the same calibration procedure was applied injecting 20 μl of solutions, in the 0.025–4 μg l^{-1} concentration range. The results, expressed in molar concentration units, are shown in Table 2. Moreover, this one shows the characteristic mass, defined as $m_0 = (0.0044\ CV)/(A_1 - A_2)$ in which C is the analyte concentration, V is the introduced volume and A_1 and A_2 are the integrated absorbance of the sample and blank, respectively [43]. Values in Table 2 indicate clearly that the detection sensitivity using D_2-method was superior to that of the HSSR-method, making it ideal for analyses of Cd requiring high sensitivity in simple matrix. Nevertheless, the LOD, which were lower with the HSSR-

method, indicated that this background compensation method was more efficient than with the D_2-method.

3.2. Determination of Cd in test solutions

Initial investigations of ICP-AES showed that interference by As at 228.812 nm was significant. Its magnitude depended on the concentration of As and on the As/Cd ratio (Table 3). For the two other lines available for determination of Cd (226.502 and 214.438 nm) interference by As was not observed (Table 3). This result is in accordance with the strategy recommended by Lambkin and Alloway [34] for Cd determination in soils contaminated by As. Other investigations using the D_2-method and the HSSR-method in FAAS showed that arsenic interference was not significant when Cd >1 mg l^{-1} [44]. Moreover, from the summarized data given in Table 4, it was established that the lower was the Cd concentration, the higher the interference by As and it was shown that the interference was more significant when the D_2-method was used [44,45].

The graphite furnace atomization method is used to determine low Cd concentrations. It is a more sensitive technique than flame atomization and its detection limits are lower (Table 2). That is why interferences should be more prevalent with this device. The results obtained by measuring Cd with various amounts of As are summarized in Table 5. For each Cd concentration, the investigation showed that As spectral interference was minimized using the HSSR-method. Moreover, the Mann–Whitney *U* test showed that

As interferences were not significant when As <50 mg l^{-1} and the ratio As/Cd was inferior to 50,000.

3.3. Cadmium and arsenic in acid solutions

3.3.1. Cadmium measurements in citric and acetic acid solutions

Citric and acetic acid solutions are very used to evaluate the mobility of trace elements in contaminated soils. Some applications of the first acid were for the removal of metals from contaminated soils [46,47]. This acid was used on the other hand to simulate the condition of root environment of the plant [48] and to study the interaction of Cd with low molecular weight organic acids in soils [49,50]. Acetic acid is included in the SM&T Programme for metal fractionation in environmental solid samples. It is regularly used to evaluate the metal extractable in acidic conditions [51,52] and to estimate the metal bioavailability [53,54]. Therefore, it seems to be interesting to study in these extracting solutions the possible interference of As in the determination of Cd by ICP-AES and AAS.

Of the three lines available for the Cd determination by ICP-AES, only two lines were used. The 228.802 nm line coincides with the As line at 228.812 nm causing a spectral interference (Table 3) and the Cd line at 214.438 with Al line. The third line, at 226.502 nm, is less sensitive and it is subject to broad-interference by iron [34]. The same solutions were analyzed by FAAS at 228.802 nm using the D_2-method and the HSSR-method (see supplementary data). In almost all of the acid solutions, Cd concentrations were elevated when ICP-AES at 228.802 nm and AAS with D_2-method were used. This was mainly the case for the extractions with citric acid for which ANCOVA (Bonferroni, Fischer and Tuckey post hoc tests) statistical analysis showed that Cd concentrations obtained with these two analytical methods were not significant ($P < 0.05$). According to these tests, the statistical results showed significant differences between Cd concentrations measured after applying the D_2-method and this method with a chemical modifier in the solution. This result can be explained by the As interferences and the possible Fe interferences which can induce a underestimation of Cd concentrations [33]. On the other hand, differences between Cd concentration obtained with the D_2-method after adding a chemical modifier and those obtained with the self-reversal background compensation without modifier were not significant. This interesting result was confirmed considering the Cd concentrations obtained with a chemical modifier as control. In these conditions, the Dunett post hoc test indicated a non-significant difference between the control and concentrations obtained with the HSSR-method ($P < 0.05$). These results showed that the As spectral interferences were not significant for the Cd-extractable with citric acid using the HSSR-method. Moreover, as shown in a previous study [33], the HSSR-method is an efficiency

background compensation method to eliminate the possible Fe interferences. For some soil samples, the same remarks can be made about acetic acid used as extractant. Nevertheless, the differences between Cd concentrations obtained by ICP-AES and AAS were lower than those obtained using citric acid as extractant. This observation can be explained by the probable existence of molecular interferences between Cd and hydroxy groups or carboxy function [55–57] coming from the low molecular weight organic acids in soils during extractions with acids [58,59].

3.3.2. *Validation of aqua regia digest procedure for the Cd determination*

A certified reference material of soil (BCR CRM 141R), contaminated in particular with Cd and As, was systematically digested with the 15 studied kitchen garden soils by microwave-acid digestion followed by GFAAS measurements. The results are presented in Table 6.

For the certified reference material, the mean value and the standard deviation of replicates are indicated. Concerning reproducibility, the standard deviation values obtained with the application of *aqua regia* microwave digestions were lower than 5%. Compared to the average value obtained in a previous work, whose aim was to compare analytical techniques, the recovery was about 98.5% [60,61]. This result validates our procedure, *aqua regia* digests of soils, and the Cd determinations using GFAAS with the HSSR-method.

For the studied kitchen garden soils, Cd contents in *aqua regia* digests were compared to the total Cd determined by the INRA Laboratory of Soil Analysis (Table 6). The good values obtained in all *aqua regia* matrix indicate a complete dissolution of Cd contents of soil samples and the absence of interference problems by As and Fe during the Cd measurements using GFAAS with the HSSR-method.

3.4. *Cadmium and arsenic in aqueous solutions*

3.4.1. *Cadmium measurements in calcium chloride 0.01 M*

Many authors regularly use a solution calcium chloride 0.01 M to evaluate the phytoavailability of Cd in soils [62–64]. In fact, this procedure provides information concerning the phytoavailability of Cd without growing plants in greenhouses. However, this procedure can be perturbed by the presence of As in soils, such as those around smelters. It is so very important to obtain a good determination of Cd in a centimolar calcium chloride solution, which also probably contains As due to the multi-contamination of soils. In this extracting solution, systematic higher Cd values were observed using ICP-AES in comparison with those observed in GFAAS (see supplementary data). Regarding the latter technique, the Cd values were highest when deuterium lamp background compensation was applied. This point can be explained by the molecular interference of chloride ion with Cd [65]. The use of palladium as a chemical modifier to reduce the chloride interference was investigated using the D_2-method [66] and the results were compared with those measured after using the HSSR-method (Fig. 1). Based on the correlation between the obtained results ($R^2 = 0.933$), it has been established that the HSSR-method is an efficient technique to correct the As spectral interference for the Cd determination. Moreover, the HSSR-method seemed to correct the chloride interference observed using the D_2-method as background compensation.

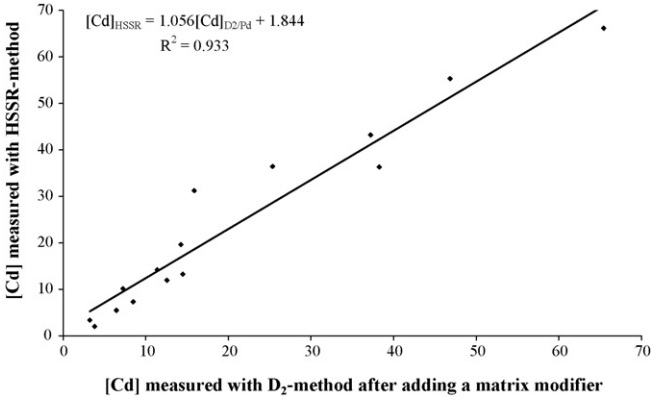

Fig. 1. Linear correlation between Cd concentrations (μg l^{-1}) in calcium chloride extract measured with GFAAS using the HSSR-method and those obtained after adding a chemical modifier and applying the D_2-method.

3.4.2. Cadmium measurements in water

In the last decades, a lot of work has been carried out in order to investigate the metal toxicity, such as that caused by Cd, collected near tailing mines, around metallurgical smelters and incinerators. Biotests have been also developed to assess the toxicity of metals and the results were then compared to the water-extractable metal concentrations of soils [67,68]. In many cases, Cd concentrations measured in water extracts of soil samples are very low. Thus, the determination of Cd requires analytical techniques exhibiting low detection limits for this element which has been designated a human carcinogen [69]. That is why new methods have recently been developed prior to the Cd measurements in water extracts by AAS [70,71]. The obtained results showed that the Cd concentrations measured using ICP-AES were systematically higher than those measured using GFAAS (see supplementary data). For some soils, the ratio between the two methods can even reach 80. For the line at 228.802 nm, this result can be explained firstly by the mean value of water-extractable As (2.72 mg kg^{-1}), which is approximately 250-fold higher than that of Cd.

For almost all of the samples, the Cd concentrations obtained using GFAAS with deuterium lamp for the background compensation were near those obtained with the HSSR-method. The statistical post hoc tests were not very clear because significant differences were found between these two methods using the Tukey test, and no difference was found using the Bonferroni and Fischer tests ($P < 0.05$) (see supplementary data). Then, the Cd measurements obtained using the HSSR-method were considered as control values and a Dunett post hoc test was conducted in order to compare the control values and those obtained after the background compensation with the D_2-method. Statistical results showed significant differences between the two background compensation methods ($P < 0.05$). These results may be explained by the As concentration in solution and probably by the high mean value of the water-extractable Fe (507 mg kg^{-1}), corresponding to an average concentration of 51 mg l^{-1}. According to the study led with the same scheme as the one described in this paper for As and Cd, a large overestimation (up to 55%) of the measured concentrations of Cd using the D_2-method can be obtained especially when the ratio Fe/Cd is 100,000. This result is explained by the closely positioned two lines to the Cd line at 228.802 nm (differences 0.04 and 0.08 nm). Using the HSSR-method for the background compensation, the overestimation corresponding to a ratio Fe/Cd = 100,000 calculated from [Cd] = 2 μg l^{-1} and [Fe] = 100 mg l^{-1} is lower than 25%. Taking into account of these data, the difference between Cd concentrations measured by AAS and ICP at 228.802 nm can be only explained by the As interference. On the other hand, differences between concentrations obtained using the HSSR- and D_2-methods can be explained by As and Fe interferences. But, according to the Dunett post hoc test, there was no significant difference between Cd concentrations found with the HSSR-method and those obtained with the D_2-method after adding a solution of palladium nitrate, used as a chemical modifier, into the water. As shown in Fig. 2, a very good linear correlation ($R^2 = 0.995$) was obtained between Cd concentrations obtained with these last two methods. These results confirm that the HSSR-method is an efficient background compensation of the spectral interferences caused by As during the Cd measurements using GFAAS. Moreover, it seems that the HSSR-method greatly reduces the Fe interferences during the Cd determination by ETAAS.

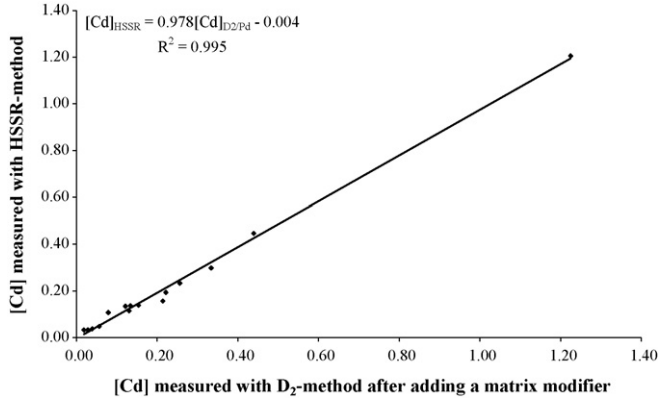

Fig. 2. Linear correlation between Cd concentrations in water (μg l^{-1}) measured with GFAAS using the HSSR-method and those obtained after adding a chemical modifier and applying the D_2-method.

4. Conclusion

Extractability of 15 kitchen garden soils contaminated by cadmium and arsenic were conducted using citric acid, acetic acid, calcium chloride and water as extractants. From our investigation, it has been observed that the HSSR-method is a versatile technique for quantitative determinations of Cd-extractable from As contaminated soils. The Cd concentration values in citric acid solutions depend on the method for the background compensation. Compared to the Cd concentrations measured using the D_2-method after adding a chemical modifier, those obtained using the HSSR-methods were not significantly different. The HSSR-method appears also as an accurate method for the background compensation in the studied case even if the differences between Cd concentrations measured using the HSSR-method and the D_2-method in acetic acid solutions are very low. In ETAAS, the obtained results are very clear and unambiguous. The high-speed self-reversal method appears so as an universal technique and using the Shimadzu atomic absorption spectrometer which is equipped with both D_2 and HSSR-methods as a standard configuration, As spectral interferences in the determination of Cd in complex matrix seem to be compensated in almost all studied cases.

ABSTRACT

The SIEFED ("Specific Immunological Extraction Followed by Enzymatic Detection") method already developed for the specific detection of the activity of equine myeloperoxidase (MPO) was adapted for the specific measurement of active human MPO in biological fluids or tissue extracts. The method consists of the extraction of MPO from aqueous solutions by immobilized anti-MPO antibodies followed by a washing (to eliminate the extraction medium and the biological fluid with their possible interfering molecules) and the measurement of the activity of MPO with a detection system containing a fluorogenic substrate, H_2O_2 and nitrite ions as reaction enhancer. The SIEFED was applied to study active MPO in human biological fluids (plasma, bronchoalveolar lavage fluid and supernatant from carotids extracts). The SIEFED for human MPO has a sensitivity limit of 0.080 mU/mL and showed good precision with intra- and inter-assay coefficients of variation below 10 and 20% respectively within a broad range of MPO activities establish from 0.156 to 473 mU/mL. The SIEFED for human MPO will be useful for the specific detection of active MPO in complex fluids and can be complementary to an ELISA to determine an active/total MPO ratio in healthy volunteers and patients especially in case of chronic or acute inflammatory diseases.

1. Introduction

Neutrophil myeloperoxidase (MPO) is involved in the intracellular bacterial destruction by producing potent oxidant molecules, mainly hypochlorous acid (HOCl) [1,2]. MPO is released in the extracellular milieu by dying or highly stimulated neutrophils in pathological conditions of acute and chronic inflammations [2–6]. In these conditions, MPO is able to exert a deleterious oxidant activity on neighbouring cells and tissues, and a therapeutic target should be to modulate its activity. Increased blood levels of MPO are now considered as markers of neutrophil activation and degranulation [7,8] and are measured by immunological methods (ELISA or RIA), which quantify the total concentration of the enzyme [9,10] without reflecting its true enzymatic activity. The activity of MPO is currently measured by the direct addition in the medium of H_2O_2 and a chromogenic or fluorogenic substrate as electron donors [11–13]. The oxidation of these electron donors is monitored by spectrophotometry or fluorimetry as a probe of the MPO activity [14,15]. Although these methods are suitable for measuring the activity of MPO *in vitro* in simple mixtures [13], they lack sensitivity, are cumbersome for cohort measurements and are not easily applicable to complex biological samples such as blood, plasma, or tissues, because of interferences with components endowed with peroxidasic activity (e.g. haemoglobin) [16,17], proteins (e.g. albumin, lipoproteins, ceruloplasmin) [18,19], reducing agents (e.g. ascorbic acid, glutathione) [16]. The physicochemical characteristics (pH, viscosity, etc.), the redox status or the colour of the biological fluids also interfere with the reading of the colorimetric or fluorescence response.

We designed a new technique, the SIEFED (for "Specific Immunological Extraction Followed by Enzymatic Detection") to measure the activity of an enzyme in biological fluids, and firstly developed it for equine MPO [20]. The major advantage of the SIEFED technique is its rapidity and an easy extraction of MPO out of the sample or reaction mixture by specific immobilized antibodies. The MPO binding to antibodies is followed by a washing

doi:10.1016/j.talanta.2009.07.052

step that eliminates the solution and its potential interfering capacity, before starting the detection of MPO enzymatic activity. In human, increasing evidence indicated that MPO plays important roles in the initiation and progression of arthritis, carcinogenesis, pulmonary, kidney, neurodegenerative, inflammatory bowel and especially cardiovascular diseases in which the enzyme is taken as an inflammatory marker and a prognostic agent [6]. In these diseases, an important clinical aspect is to know the active part of MPO, which is the real witness of the oxidant potential of the enzyme. We describe here the development and optimization of the SIEFED technique for the specific detection of the enzymatically active human MPO in complex media [plasma, bronchoalveolar fluids (BALs)] and tissue extracts (carotids). The SIEFED technique is based on the immunological capture of the antigen by antibodies. An interesting point of this study was to compare the active MPO content measured by SIEFED with the total MPO content measured by ELISA to determine an active/total MPO ratio for the tested samples.

2. Experimental

2.1. Reagents

Analytical grade phosphate salts, sodium and potassium chlorides, sodium hydroxide, sodium acetate, H_2O_2 (30%, w/v), ethanol and Tween 20 and human myeloperoxidase (Calbiochem) were purchased from Merck (VWR International, Leuven, Belgium). Bovine serum albumin (BSA) and sodium nitrite were purchased from Sigma–Aldrich (Bornem, Belgium). 96-Wells microtiter plates (Combiplate 8 EB) were from Thermo Scientific (Breda, The Netherlands). The fluorogenic substrate, Amplex Red (10-acetyl-3,7-dihydroxyphenoxazine), was purchased from Molecular Probes (Invitrogen) (Merelbeke, Belgium).

2.2. Purification of human MPO and rabbit anti-human MPO polyclonal antibodies

MPO was purified from human neutrophils by detergent enhanced extraction followed by two steps of chromatography, and antisera were obtained by rabbit immunization against the pure human MPO emulsified with complete Freud adjuvant as previously described [9,21]. Polyclonal antibody (IgG), purified from rabbit antisera by affinity chromatography on Protein A sepharose (GE Healthcare, The Netherlands), was characterized for its specificity and stability and firstly used to develop a radioimmunoassay for total MPO assay in human plasma [9].

2.3. Methodology of the SIEFED technique

Three buffers were used. The coating buffer was 20 mM K and Na phosphates (pH 7.4), 137 mM NaCl and 2.7 mM KCl. The blocking buffer was obtained by addition of 5 g/L BSA to the coating buffer. The diluting buffer was the blocking buffer added with 0.1% Tween 20. The washing solution was 154 mM NaCl with 0.1% Tween 20. Microtitration wells were coated overnight, at 4 °C with 100 μL/well of serial dilutions of a rabbit IgG solution (62.5–500 ng/well) diluted with the coating buffer to determine the optimal IgG concentration to be used in the SIEFED assay. After removing the coating solution, the blocking buffer was added, the plates were incubated for 150 min at room temperature and washed three times. Serial dilutions of a standard MPO solution (pure human MPO) or unknown samples were added (100 μL/well) and incubated for 1 or 2 h either at 22 °C or at 37 °C or for 20 h at 4 °C. After three washings, the peroxidasic activity of MPO was detected by adding 100 μL of a 40 μM Amplex Red solution freshly prepared in phosphate buffer (50 mM) at pH 7.5 and added with 10 μM H_2O_2 and 10 mM nitrite. After incubation in the darkness (30 min, 37 °C), the fluorescence was read with a Fluoroscan Ascent (Thermo Scientific) with excitation and emission wavelengths set at 544 and 590 nm, respectively. Controls (blank) were performed with the dilution buffer. The fluorescence value was directly proportional to the quantity of active MPO present in the sample.

2.4. Validation of the SIEFED technique

The stability of the reference human MPO (from Calbiochem) was tested after its dilution in phosphate buffer saline (PBS) or PBS added with 5 g/L BSA and 0.1% Tween 20 (dilution buffer) and either incubated for 2 h at 37 °C or submitted to several freezing–thawing cycles.

The cross-reactivity of the anti-MPO antibodies with albumin, haemoglobin, elastase or eosinophil peroxidase was measured as previously described [9]. The detection limit was defined as the lowest active MPO concentration (mean value ± SD) that was statistically different from the value obtained with buffer alone. The standard curve was calculated and plotted point to point by using the Ascent Software for Multiscan Ascent (Thermo Labsystems). The precision and reproducibility were estimated by the coefficients of variation (CV) within or between assays calculated for several determinations of the same sample in the same assay or in different assays performed on different days. Accuracy was estimated by the recovery of known amounts of purified MPO added to the samples (plasma, BALs and carotid extracts).

To assure that the SIEFED technique could be reproduced with other anti-MPO antibodies, the immunoreactivity of our antibody was compared with that of the primary MPO-antibody (polyclonal antibody from rabbit) used in the MPO-ELISA kit (ELIZEN MPO) purchased from the Zentech company (Belgium).

2.5. Sampling technique

To test the stability of the neutrophils in blood after sampling, blood was drawn from five healthy donors without anticoagulant and on three anticoagulants with centrifugation (10 min, 22 °C, 1000 × *g*) 1 or 3 h after sampling. The anticoagulants were EDTA (1.8 mg/mL blood, in 3.5 mL vacutainer tubes; Venosafe, Terumo, Belgium), lithium heparin (15 IU/mL blood), or citrate (3.2% Na-citrate solution). Blood in plain tubes was allowed to clot (3 h) at room temperature (22 °C) before serum collection. For all the other studies with healthy and pathological subjects, venous peripheral blood samples were obtained in vacutainer tubes on EDTA (1.8 mg/mL blood), and centrifuged within 30 min after drawing.

Bronchoalveolar lavages (BALs) were performed in intensive care patients for therapeutic purpose (bacterial agent determination) via the endotracheal tube, with four aliquots of 50 mL warm sterile 0.9% NaCl solution as previously described [22]. The first aliquot was discarded and the second used for bacterial studies. The aspirated liquids of the third and the fourth aliquots were strained through sterile gauze and centrifuged (10 min, 4 °C, 300 × *g*); the supernatant was used for SIEFED assay.

Carotid atherosclerotic plaques were collected during surgery for carotid thrombo-endatherectomy and rinsed with 0.9% NaCl solution before their freezing at −20 °C. After thawing, the carotid plaques were homogenised on ice in 20–25 mL of cold 10 mM Tris-buffer, pH 7.4. The extract was centrifuged (20 min, 4 °C, 17,000 × *g*) and the supernatant was used for SIEFED assay.

Plasma samples, supernatants from BALs and carotid extracts were freshly used or kept frozen in small aliquots at −20 °C. Immediately before the SIEFED assay, samples were thawed and diluted with the diluting buffer before loading into the wells.

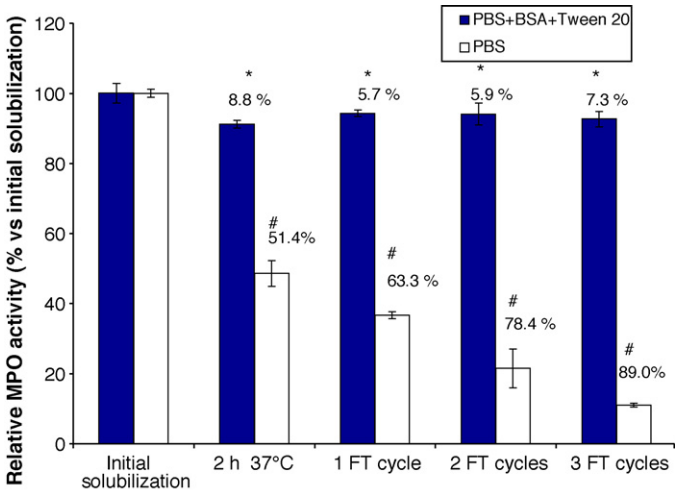

Fig. 1. Stability of human MPO activity in PBS buffer or PBS buffer + BSA + Tween 20 after an incubation period of 2 h at 37 °C or after several freezing–thawing (FT) cycles. The test performed directly after MPO dilution was taken as 100%. Mean ± SD, $n = 3$, ANOVA $^{*}p < 0.05$ versus initial solubilization in PBS + BSA + Tween 20; $^{\#}p < 0.05$ versus initial solubilization in PBS.

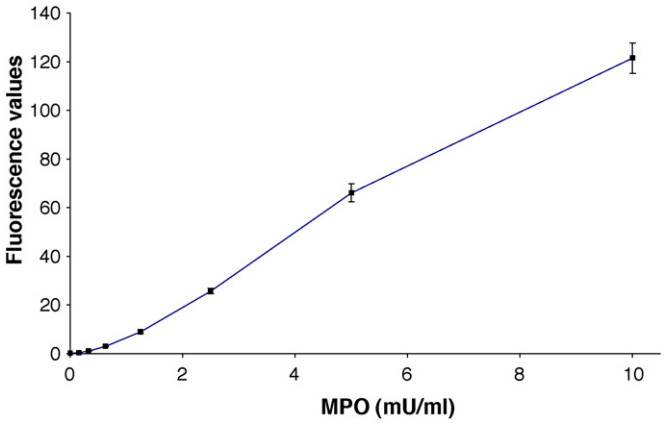

Fig. 2. Standard curve for the measurement of the activity of human MPO by the SIEFED technique (mean ± SD, $n = 5$).

Optimal dilution was determined by testing serial dilutions (1:1, 1:2.5, 1:5, 1:10, 1:20, 1:40, 1:80) of the samples in the dilution buffer.

2.6. Total MPO assay by a sandwich ELISA

To compare active MPO to the total content of the enzyme, total (active and non-active) MPO was measured with a sandwich human myeloperoxidase ELISA kit (ELIZEN MPO, Zentech SA, Belgium). Before the ELISA, plasma samples, and carotid extracts were diluted 20 times and BAL samples 50 times with the diluting buffer furnished by the ELISA kit.

2.7. Statistical analysis

SigmaStat 3.5 software (Systat, San Jose, CA) was used for the analysis. Data are presented as the mean ± SD and were evaluated by a one-way ANOVA.

3. Results

3.1. Stabilization of the reference human MPO

According to the supplier (Calbiochem), human MPO specific activity ranged from 180 to 220 U/mg proteins: we took the mean value, 200 U/mg proteins, as MPO specific activity. Fig. 1 shows that MPO diluted in PBS was not stable: the enzyme lost 51.4 ± 3.7% of its activity after 2 h at 37 °C and 89.0 ± 0.5% after three freezing thawing cycles. In PBS with 5 g/L BSA and 0.1% Tween 20, MPO remained stable, with only a slight loss of activity of 8.8 ± 1.1 and 7.3 ± 2.2% respectively after 2 h at 37 °C or three freezing thawing cycles.

3.2. Calibration curve and detection limit of the SIEFED technique

The standard curve was obtained by plotting the fluorescence values as a function of the known activity of the reference MPO, from 0.156 to 10 mU/mL (Fig. 2). Table 1 shows the fluorescence data measured for a typical active MPO reference curve (mU/mL) with the corresponding reference concentrations of the pure human MPO in ng/mL. The intra-assay CVs did not exceed 8%. The detection limit of the test (0.080 mU/mL) was determined as the lowest active MPO concentration (mean value ± SD) statistically different from the value obtained with buffer alone.

3.3. SIEFED method for MPO measurement in biological samples

Based on the detection limit and the slope of the standard curve, we chose 250 ng per well (or 2.5 μg/mL) as the optimal concentration of the coating antibody. After blocking and washing, the coated plates could be stored at 4 °C under dry conditions for up to 4 weeks. The binding of purified MPO to the coated antibodies increases with time and is similar at 37 °C and room temperature (RT) (Fig. 3). The activity of the samples measured after the incubation at RT are generally lower than after the incubation at 37 °C but, interestingly, the activity obtained after an overnight incubation at 4 °C or after 1 or 2 h incubation at 37 °C are similar (CV < 10%) (results not shown). The incubation at 4 °C does not disturb the activity of MPO and its binding to the antibody. The rapidity of the test being a priority factor, a 2 h incubation time at 37 °C was chosen for further studies.

As previously described [20], to reach a high sensitivity of the SIEFED technique for its application to biological samples, we used as peroxidase substrate, the Amplex Red molecule, which is transformed into the fluorescent resorufin upon its peroxidase-

Table 1
Standard curve values for the measurement of active human MPO by the SIEFED technique.

Human MPO (mU/mL)	Human MPO (ng/mL)	Mean fluorescence value ($n = 5$)	SD	CV (%)
0	0	0.149	0.002	1.3
0.156	0.78	0.441	0.025	5.7
0.3215	1.56	1.067	0.069	6.5
0.625	3.125	3.003	0.107	3.6
1.25	6.25	8.976	0.656	7.3
2.5	12.5	25.737	1.123	4.4
5	25	66.083	3.701	5.6
10	50	121.429	6.213	5.1

Mean ± SD, $n = 5$. The detection limit of the test was 0.080 mU/mL.

Table 2
Effect of the delay between blood collection and centrifugation on the activity of MPO measured by SIEFED in anticoagulated plasma and serum.

Collecting tube	Time between blood collection and centrifugation (h)	Mean MPO activity (mU/mL)	SD (mU/mL)	CV (%)
Citrate	1	1.4	0.3	23.2
	3	2.5	1.0	39.0
EDTA	1	1.9	0.2	11.7
	3	3.4	0.3	7.9
Li-heparin	1	2.9	0.7	23.4
	3	6.3	2.1	32.4
Dry (serum)	3	19.9	5.1	25.8

Mean ± SD of five healthy donors, $n = 5$.

catalyzed oxidation by H_2O_2 [23]. The optimal working conditions to measure the activity of MPO were reached with a freshly prepared 40 μM Amplex Red solution and 10 μM H_2O_2. The addition of 10 mM sodium nitrite ($NaNO_2$) in the reaction mixture increased 4–5-folds the sensitivity of the SIEFED [20].

3.4. Sampling conditions: effects of the anticoagulant and the delay in blood centrifugation

When centrifugation was done 1 h after blood sampling, the lowest mean MPO activity was observed for blood drawn on citrate and the highest one for blood drawn on Li-heparin (Table 2). After a delay of 3 h before centrifugation, the MPO activity values increased 1.8 times for EDTA and citrate and 2.1 times for Li-heparin. Interestingly, the lowest CVs, both after 1 and 3 h before blood centrifugation, were obtained for the EDTA plasmas what suggested that the neutrophils remained stable with time. For citrate and Li-heparin samples, the high CVs were unacceptable. A high mean value of MPO activity was observed for serum (Table 2). On the basis of these results, it was decided to use preferably EDTA anticoagulated blood for all the other studies; citrated samples obtained after blood centrifugation within 1 h can also be used, but we excluded the serum samples.

3.5. Application of the SIEFED technique to biological samples

The dilution of the sample improved the MPO activity till the dilution 1:10, undoubtedly by improving the binding between MPO and the primary antibody (Fig. 4). At higher dilutions, the measured values were stabilized and reached a plateau for most samples at the dilution 1:20 and for some samples at the dilution 1:40. But at this dilution, the limit of sensitivity is reached for samples with low content of active MPO. Linearity of the assay was determined by evaluating dilutional parallelism. Percentages of recovery calculated from observed-to-expected values for two plasmas, two BALs and two carotid extracts at two dilution factors (1:10 and 1:20) ranged from 94.1 to 130.0% (mean ± SD: 113.4 ± 12.2%; Table 3).

The accuracy of the assay was evaluated by determining the spiking recovery in two plasmas, two BALs and two carotid extracts. Percentages of recovery for seven spiking concentrations of active MPO added to the samples ranged from 72.6 to 113.1% (mean ± SD: 93.5 ± 9.2%; Table 4). A lack of recovery above 20% was observed for the highest active MPO concentrations (2.5 and 5 mU/mL) added to the plasma samples, but not to BALs and carotid extracts.

The intra-assay precision of the SIEFED technique estimated by repeated measurements within the same run on three different types of biological fluids with MPO activities ranging from 2.6 to 473.0 mU/mL showed CVs that did not exceed 10%. The mean CV value for all the samples ($n = 45$) was 3.8 ± 2.7% (Table 5).

Inter-assay precision was estimated by duplicate or triplicate assays of the biological fluids performed in different runs over a period of 4, 3 or 2 days. The MPO activities ranged from 1.8 to 118.1 mU/mL and the CVs did not exceed 20%. The mean CV value for all the samples ($n = 49$) was 10.2 ± 4.8% (Table 5).

In the plasma of 19 healthy donors, the total and active MPO contents were measured by ELISA (ELIZEN MPO, Zentech, Belgium) and by SIEFED respectively after checking that the primary antibody used in the kit had a similar response for the capture of active MPO than our antibody, and by diluting the samples in the same manner for the ELISA and the SIEFED. The mean total MPO value was 42.0 ± 15.0 ng/mL, while the mean active MPO value was 15.1 ± 5.2 ng/mL corresponding to 3.0 ± 1.0 mU/mL (Table 6). The active/total MPO ratio indicates that about 40 ± 9% of total plasmatic MPO was active in the healthy donors. The values of active and total MPO in five pathological plasmas, ranged from 80.5 to 210.7 ng/mL for active MPO and from 87.1 to 235.4 ng/mL for total MPO, were higher than the mean value obtained in healthy donors

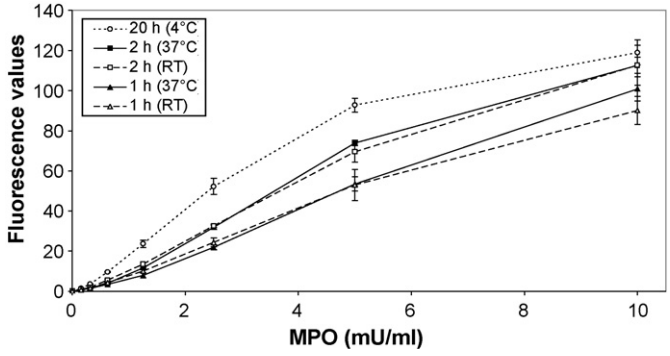

Fig. 3. Effects of incubation time and temperature on the MPO binding to its antibodies (mean ± SD, $n = 3$).

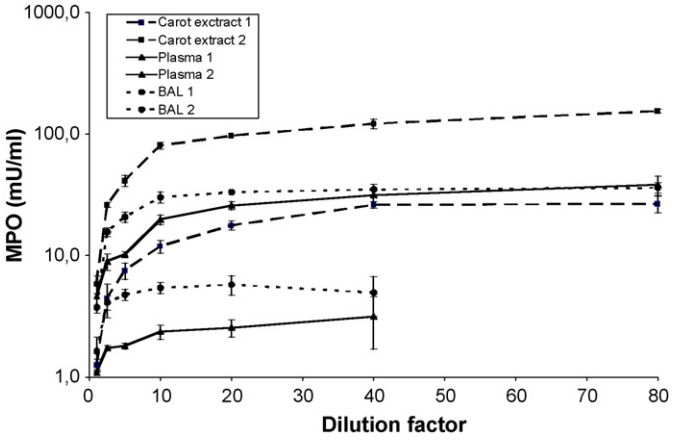

Fig. 4. Curves obtained with serial dilutions of plasma, carotid extracts and BALs (mean ± SD, $n = 5$).

(Table 6). The active/total MPO ratio was also higher than in healthy controls, with a range from 0.5 to 0.9 (Table 6). In the five carotid and three BAL samples, the ratio of active versus total MPO showed that the active part of the enzyme varied from 20 to 90% of total MPO amount (Table 6), but no comparison was possible with healthy carotid and BAL samples.

4. Discussion

Owing to our experience with equine MPO [20] and RIA assay of human MPO [21], we developed a SIEFED technique for the specific and rapid measurement of the enzymatically active form of human MPO in complex biological samples. This technique has five inter-

Table 5
Intra- and inter-assay reproducibility of the SIEFED technique for active MPO measurements in human plasma, carotid extracts and BALs.

Samples	n[a]	Mean MPO activity (mU/mL)	SD (mU/mL)	CV (%)
Intra-assay				
Plasma 1	4	16.0	0.2	1.3
Plasma 2	4	9.5	0.1	1.1
Plasma 3	3	6.3	0.0	0.6
Plasma 4	3	16.3	0.5	3.1
Plasma 5	2	5.9	0.3	5.1
Plasma 6	2	15.3	0.4	2.6
Carotid 1	4	119.5	11.9	10.0
Carotid 2	4	167.3	12.0	7.2
Carotid 3	3	4.2	0.1	2.4
Carotid 4	2	61.7	1.7	2.8
Carotid 5	2	473.0	26.0	5.5
BAL 1	4	4.3	0.1	2.3
BAL 2	4	30.9	2.2	7.1
BAL 3	2	17.6	0.4	2.3
BAL 4	2	2.6	0.1	3.8

BAL 7	3	29.0	2.9	3.4
BAL 8	2	50.8	5.6	11.0

CV = coefficient of variation, SD = standard deviation.
[a] Number of sample measurement during the same assay.
[b] Number of assays with the sample measured in duplicate or triplicate in each assay.

esting characteristics: (i) the easy immuno-capture of MPO out of a biological sample (or a reaction mixture containing MPO) without any preparation of the sample (no partial purification or precipitation of the enzyme), which is simply diluted, loaded into the antibody-coated wells and discarded after the incubation period during which MPO binding has occurred, (ii) the washing after the immuno-capture of MPO to eliminate the sample with its compounds potentially able to interfere with the enzymatic detection step, (iii) the specificity since the specific antibodies will only capture human MPO so that the detection system will disclose only the MPO activity, (iv) the high sensitivity of the test reached by the combined used of Amplex Red, a stable fluorogenic substrate for detection of peroxidases [12], and nitrite as an enhancer of the reaction, (v) the measurement of the activity by referring to a calibration curve made with pure human MPO.

As previously described, the success of the SIEFED technique depends on a good compromise between a strong binding of MPO and a low inhibition of its activity by the antibodies [20]. We obtained the best conditions to bind active MPO by coating the wells with 250 ng of rabbit anti-MPO IgG. The use of a polyclonal antibody increased the possibilities to capture MPO by different epitopes, but also the risk to inhibit the enzyme as observed in different models with MPO in solution [24,25]. We thus expected an inhibitory effect of immobilized antibodies on the MPO activity, but the MPO activities measured in the tested samples are calculated from a calibration curve, in which the reference human MPO is submitted to the same inhibitory effect of the antibody.

Good conditions for MPO incubation with the primary antibody were established at 37 °C for 2 h. Interestingly, the values obtained after an overnight incubation at 4 °C or a 2 h incubation at 37 °C were similar (CV < 10%): the overnight incubation at 4 °C can thus be used as an alternative condition for the SIEFED technique.

A good sensitivity of the test was obtained with the fluorogenic substrate Amplex Red, which is transformed during the peroxidasic cycle of MPO into the fluorescent resorufin in the presence of H_2O_2 [12,23]. We succeeded to greatly increase the sensitivity of the reaction by adding nitrite to the reaction mixture [20]. This increasing effect can be firstly explained by a cooperation of nitrite and Amplex Red for the turn over of the peroxidasic reaction of MPO. Burner et al. [26] showed that nitrite is a good substrate to reduce the compound I of MPO provided that a good electron donor is present to reduce the compound II. Amplex Red could play the role of the second electron donor for compound II. But, the oxidation of nitrite by the compound I mediates nitrogen dioxide, a reactive radical which can react with fluorescent probes [27]. Thus a second way to explain the amplification role of nitrite is the reduction of nitrogen dioxide by Amplex Red allowing both the formation of resorufin and the recycling of nitrite for the turnover of the peroxidasic cycle.

The study of the blood sampling conditions revealed that consistently higher MPO activity was measured in samples collected on heparin and in serum than in samples on EDTA or citrate. The delay between blood sampling and centrifugation increased the MPO activity values for all the anticoagulants, but the increase

Table 6
Concentration (ng/mL) of active and total MPO measured by SIEFED and ELISA and active/total MPO ratio in plasma of 19 healthy donors (mean ± SD) and in 5 plasmas, 5 carotid extracts and 3 BALs of pathological subjects.

	Active MPO (mU/mL)	Active MPO (ng/mL)	Total MPO (ng/mL)	Active MPO/total MPO
Mean plasmatic value for 19 healthy donors	3.0 ± 1.0	15.1 ± 5.2	42.0 ± 15.0	0.4 ± 0.1
Plasma 1	19.8	99.1	139.6	0.7
Plasma 2	26.1	130.6	235.4	0.6
Plasma 3	42.1	210.7	415.2	0.5
Plasma 4	23.1	115.3	170.1	0.7
Plasma 5	16.1	80.5	87.1	0.9
Carotid 1	4.6	22.8	26.0	0.9
Carotid 2	63.0	315.1	530.3	0.6
Carotid 3	5.3	26.5	97.1	0.3
Carotid 4	5.6	27.9	131.9	0.2
Carotid 5	18.6	93.0	442.8	0.2
BAL 1	3.4	16.8	61.2	0.3
BAL 2	21.9	109.5	251.2	0.4
BAL 3	2.6	13.2	71.4	0.2

was similar for citrate and EDTA and more pronounced for heparin. These results are in agreement with previous studies showing higher total MPO contents in heparin plasma and serum than in citrate and EDTA plasma [28,29].

The SIEFED method allows reliable quantification of MPO activity from 0.156 to 10 mU/mL, what corresponds to 0.78–50 ng/mL pure MPO. The dilution buffer stabilizes the enzyme during the incubation time and freezing–thawing cycles, because BSA and Tween 20 are known to prevent adhesion and aggregation of proteins [30]. The intra-assay coefficients of variation of the reference curve do not exceed 8%. The detection limit of the assay (0.080 mU/mL) allows an easy measurement of active MPO in diluted biological fluids. Like for ELISA, the dilution of the samples increases the sensitivity of the test by reducing the interactions between MPO and other biomolecules of the sample and by improving the binding of MPO to the primary antibody. The polyclonal antibody could also recognize the precursor of MPO, which is active in human [31]. The dilutions of 1:10 to 1:20 are adequate for most of the samples, but we cannot exclude that higher dilutions will be necessary for pathological samples.

We calculated the mean normal value of active MPO measured in EDTA plasmas as 15.1 ± 5.2 ng/mL or 3.0 ± 1.0 mU/mL, but the number of tested normal plasmas will be increased by further studies. In pathological samples, we measured MPO activities ranging from 2.9 to 42.1 mU/mL for plasmas, 1.8 to 473.0 mU/mL for carotid extracts and 2.6 to 50.8 mU/mL for BALs with good intra-assay CVs (below 10%) and acceptable inter-assay CVs (below 20%). These preliminary results indicate that the SIEFED technique will be useful to measure the active MPO in biological fluids or extracts from patients suffering from inflammatory pathologies with neutrophil activation and infiltration [6,22,32,33]. In theses pathologies, the measurement of total MPO by ELISA is often taken as a marker of neutrophil activation, but we compared the total and active MPO contents in samples and found in plasma an active/total MPO ratio of 0.4 ± 0.1 in healthy donors and a higher but variable ratio of 0.5–0.9 in pathological subjects. A still higher variability of this ratio (from 0.2 to 0.9) was observed for carotid extracts and BALs from pathological subjects. These original results suggest an important variability of active MPO contents in pathological samples probably linked to the activation status of neutrophils, the inhibitory capacity of the fluids towards the enzyme or other disease conditions. The results obtained with the SIEFED technique emphasized the importance of measuring the active part of MPO, which is the real witness of the oxidant potential of the enzyme that is not taken into consideration by a classical ELISA. Indeed, the presence of free active MPO increases the risk of cytotoxicity, as the enzyme is taken up by cells or binds on the cell surface with an *in situ* production of oxidant species [34,35], which are involved in chlorination and nitration of proteins [2,6], and surely contribute to the pathogenesis of the disease [2,6] or to the modulation of the inflammation reaction [36].

In conclusion, the SIEFED technique that we developed for human MPO opens news perspectives for the study of pathologies accompanied by the release of active MPO. The SIEFED is a method of choice to measure easily, reliably, quantitatively, and specifically the active part of MPO present in biological samples or tissue extracts. Moreover, SIEFED and ELISA can be used as complementary immunological techniques to determine with accuracy the active/total MPO ratio in biological samples, what constitutes a new prospect in clinical research.

ABSTRACT

The FLEC®-SPME sampler, described in a previous paper, consists of an emission cell coupled with solid phase microextraction (SPME) for passive sampling of VOCs emitted from building materials. It represents an interesting alternative to standard dynamic sampling protocol as it is easier to implement. If standard dynamic sampling determines emission rates, passive FLEC®-SPME aims to the determination of the concentration in air at the material surface. That could be assumed provided that material/air equilibrium is reached. Thus, VOCs emission kinetics were studied for 3 different materials (pine wood panel, carpet and PVC floor) to determine equilibrium times. Then, the relevance of the method has been assessed using new materials through a 3-day emission test. Qualitative results were compared to those obtained from the standard method to check the ability of FLEC®-SPME to detect the most toxic compounds, named "VOCs of interest" and listed in the French regulation. Minor differences were observed, so this methodology seems promising, especially for field studies aiming in the identification of VOCs sources in buildings. Moreover, the concentration at the material surface combined to emission modeling could be used to predict indoor VOCs concentrations helping in indoor air quality diagnostic.

1. Introduction

In order to reduce VOCs levels in indoor air, a major strategy relies on the control of emission from sources, especially building materials [1,2]. In France as in a few European countries, new products, such as floor coverings, can be evaluated through a time-consuming procedure involving a 28-day emission test in an environmental chamber or in an emission cell [3]. The test involves a dynamic sampling mode to transfer the VOCs emitted from the solid material to an adsorbent tube and is covered by ISO standards [4,5]. Thus, the sampling step of this procedure needs clean air supply, air flow meters and a long sampling duration (60 min) to concentrate the low quantity of VOCs emitted by the materials. To increase sampling frequency, microchambers, inspired from the emission cell described above, were developed for automated control of material emissions [6]. It requires specific and expensive equipment (Microchamber/Thermal Extractor) hyphenated to the chromatographic system and hence, is only suitable to laboratory samplings.

Several works [7–12] and national (or European) guides [2,3,13] use dynamic sampling to test single materials under laboratory conditions (fixed temperature, air flow-rate and relative humidity). These data are very useful to determine if the sample complies with labeling criteria or to compare it with other similar products. However, they may not be enough to predict the material behavior in the field because of the established effects of temperature, air exchange rate and relative humidity on the concentration–time profile of the VOCs specific emission rate (SER) [14]. For this purpose, on-site sampling must be developed by implementing simpler and faster sampling methods. Passive sampling, only based on VOCs diffusion, seems to be adapted as no pump or flow control is required. Recently, a sorption-based sampling technique, the Sorptive Tape Extraction (STE), was developed [15]: a polydimethylsiloxane (PDMS) tape is used to recover VOCs at the solid surface by direct contact. Although it is very simple and attractive, this method cannot be representative of emission in air because of the direct transfer of VOCs from the material to the PDMS which would favor low volatile compounds. Another device, the "Passive Flux sampler" (PFS) [16,17] seems to be more representative of material emissions. It consists of a glass Petri dish (inner diameter: 36 mm; depth: 10 mm) whose bottom is covered by an adsorbent layer. The PFS is simply placed on the surface to be studied and the VOCs diffuse to the adsorbent. The emission rate can be determined as described in the following Eq. (1) (from

doi:10.1016/j.talanta.2009.07.063

first Fick law under steady state conditions) [16]:

$$F = -D\frac{dC}{dx} = -D\frac{C_a - C_{as}}{L} \quad (1)$$

where F is the emission rate of the target VOC ($\mu g\,m^{-2}\,s^{-1}$), D, the diffusion coefficient ($m^2\,s^{-1}$), C_a the concentration in indoor air ($\mu g\,m^{-3}$), C_{as} the gas phase concentration at the material surface ($\mu g\,m^{-3}$), L the thickness of the gas phase boundary layer (m).

Studies with PFSs showed that the emission rates measured were proportional to those determined by the standard chamber method ($r^2 = 0.96$) [16]. These low cost and simple samplers are relevant for field measurements, especially for multipoint samplings. However, the sampling times are long (at least 4 h) to reach a sufficient sensitivity. Moreover, analysis requires collecting and introducing a part of the adsorbent in an empty tube for thermal desorption [17]. This supplementary step could be a source of experimental errors and complicates the protocol.

As an alternative, another passive sampling method has been developed in our laboratory [18]. It consists of coupling a standard FLEC® emission cell [19] with SPME [20] for rapid sampling and simple thermal desorption, directly performed in GC injector. As other passive samplings, this method could be more representative of the material in use than dynamic sampling procedures which require a fixed air flow-rate in the emission cell [21]. Moreover, during the standardized dynamic sampling, the air turbulences in the emission cell could lead to inhomogeneous surface emission and then to an inaccurate estimation of the VOC emission. So, the first part of this paper presents the modeling of the air flow turbulences in the emission cell under standard operating conditions to assess the relevance of the passive sampling considered in this study.

FLEC®-SPME sampling involves two steps: first, VOCs diffusion from the material to the gas phase (FLEC® headspace) and second, after introduction of SPME in the FLEC®, the VOCs transfer from the gas phase to the PDMS-Carboxen fiber. This latter step was already studied using standard gas and is detailed elsewhere [18]. In this paper, the first step (material to gas phase diffusion) will be studied on three different materials (pine wood panel, carpet and PVC floor). Assuming equilibrium is reached in the FLEC®, the headspace concentration could be assimilated to the gas phase concentration at the material surface, C_{as} (Eq. (1)). Unlike the standard evaluation procedure, all parameters (air velocity, relative humidity and temperature) could be adjusted according to field conditions to be as representative as possible of the studied building.

Then, the optimized method is applied to identify and quantify, respectively by gas chromatography–mass spectrometry (GC–MS) and gas chromatography-flame ionization detection (GC-FID), the VOCs emitted by the three studied materials. Qualitative results were compared to those obtained with the standard evaluation method to assess the ability of FLEC®-SPME to detect the VOCs of interest based on toxicological reference values and listed in the French AFSSET protocol [3].

2. Materials and methods

2.1. Modeling of fluid flow in the FLEC cell

Computational fluid dynamics (CFD) was used to study the fluid in the FLEC® cell using the Fluent 6.0 software (ANSYS, Canonsburg, USA), which solves mass and momentum conservation equations according to Navier–Stokes equation. The parameters used are summarized in the Table 1.

Table 1
Fluent simulation main parameters.

Cell structure	Tetrahedral
Cell size (m)	7×10^{-4}
Cell number	588886
Inlet pressure (Pa)	1.01×10^5
Temperature (°C)	20
Volumetric flow ($L\,min^{-1}$)	0.3
Model	k-epsilon standard
Turbulence intensity (%)	10
Hydraulic diameter (m)	4.67×10^{-3}
Wall roughness height (m)	0
Wall roughness constant	0.5

2.2. Material samples

The emission of VOCs from three material samples provided by CSTB (Scientific and technical Center for Building) was studied in this paper. A PVC floor tile (300 mm × 300 mm × 1 mm), a polyamide carpet (250 mm × 250 mm × 4 mm) and a natural raw pine wood panel (300 mm × 300 mm × 9 mm) with no varnish samples were studied for quantification.

Carpet and pine wood panel were also used to compare FLEC®-SPME procedure with the standard methodology. To avoid bias due to the variation of emission in time and the heterogeneity of material samples, dynamic and FLEC®-SPME samplings were performed successively the same day on the same material plate, at the CSTB laboratory. Thermal desorption, involved in the standard method, requires a specific analytical configuration (Automated Thermal Desorber on-line with GC). Hence, these analyses were carried out in the CSTB laboratory. Since this apparatus is dedicated to routine analysis, it was not possible to change its configuration for the SPME thermal desorption. Thus, SPME analyses were performed in our laboratory within 3 days after sampling ensuring a good preservation of the fibers [22].

2.3. Sampling methods

Both SPME and standard samplings were performed using the Field and Laboratory Emission Cell: *FL-0001* (FLEC®) (Fondis Electronic, Guyancourt, France).

2.3.1. Dynamic sampling (standard method)

The sampling was carried out according to ISO-16000-10 standard (Fig. 1A). Clean air was swept through the emission cell at a 300 mL min^{-1} flow rate, 50% RH (relative humidity) and 23 ± 2 °C. At the cell outlet, the air flow was divided in order to perform the preconcentration in duplicate with two adsorbent tubes filled with Tenax® TA. For each tube, the flow rate was fixed at 85 mL min^{-1} (FLEC Air pump 1001) (Chematek, Denmark) and the sampling time was 60 min.

2.3.2. Passive FLEC®-SPME sampling

The principle consists in sweeping clean and dry air, at 23 ± 2 °C and at 300 mL min^{-1}, through the emission cell, just a few seconds to replace the previous headspace (Fig. 1B). Then, the valves are closed to let the VOCs diffuse from the solid material to the gas phase (FLEC® headspace). Once the equilibrium is reached (see kinetics study in the following paragraphs), a 75 μm PDMS-Carboxen fiber (Supelco, Bellefonte, PA, USA) is introduced in the cell for passive sampling. Considering sensitivity [18], a 20 min sampling time was used. The comparative study between the standard and the SPME methods was performed in the CSTB laboratory under the same operating conditions that means that the cell was flushed in the two cases by clean air at 300 mL min^{-1} flow rate and 50% RH.

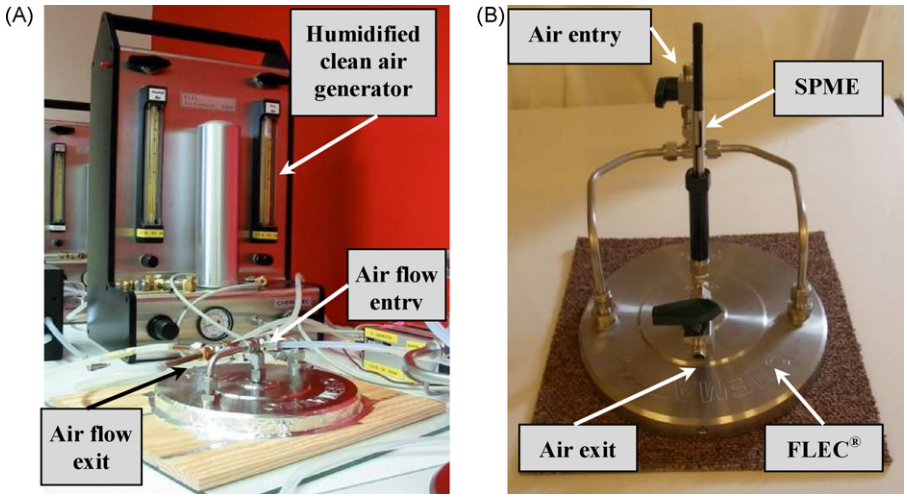

Fig. 1. (A) Dynamic sampling mode (standard protocol assembly) and (B) modified device for passive FLEC®-SPME sampling.

2.4. Chromatographic methods

Analyses were performed using GC-FID for quantification and GC–MS for identification of VOCs emitted from material surfaces. Parameters are grouped in Table 2.

GC-FID calibration was carried out using standard gas generated in laboratory. The FLEC® was placed on a glass plate and headspace was filled with the standard atmospheres before passive SPME sampling [18]. Calibration curves were plotted for fourteen VOCs and concentrations ranging from 2 to 10 mg m^{-3} according to a 20 min sampling time. These calibration curves were also used to calculate the concentrations of compounds belonging to the same chemical family as standard VOCs, according to the estimation method of the response factors [23]. The following relationship was applied (Eq. (2)):

$$EC_i = EC_{ref} \times MW_i \times \frac{c_{ref}}{c_i} \quad (2)$$

where EC_i is the concentration of the studied compound (μg m^{-3}), EC_{ref} is the emission concentration of the reference compound

	Cyclohexanone	16	48
Acids	Acetic acid	1.4	4
Esters and Lactones	Methyl metacrylate	0.6	2

($\mu g\,m^{-3}$), MW_i is the molecular weight of the studied compound, C_{ref} and C_i are the number of effective carbons, respectively in the compound of reference and in the studied compound.

For the different chemical families of VOCs, the model compounds used as references are described in Table 3. Limit of detection (LOD) and quantification (LOQ) in GC-FID for a 20 min sampling time are also presented. LOD and LOQ were determined according to Eqs. 3.

$$\mathrm{LOD} = \frac{3.3\delta_b}{a}, \quad \mathrm{LOQ} = \frac{10\delta_b}{a} \tag{3}$$

where δ_b is the standard deviation of the y-intercept for the calibration curve and a is the slope of the calibration curve.

3. Results and discussion

3.1. Dynamic or passive sampling

The fluid flow in the FLEC® under the dynamic conditions used in the standard method was characterized with CFD to assess its influence in the VOC mass transfer from the material to the gas phase. Main results of the simulation are shown in Fig. 2.

Turbulence intensity represents the relative deviation between local and mean velocities.

Contours of turbulence intensity show a relatively low turbulence level in the FLEC® cell (<21%), so the flow rate profile is quite uniform. However, central and peripheral areas of the material are exposed to a lower turbulence level which is unfavorable to an efficient mass transfer. In the future, it would be interesting to optimize the geometry of the cell to improve the contact between fluid and material.

Regarding these results, passive sampling seems to be an interesting alternative due to the homogeneous diffusion of VOCs to the gas phase. Moreover, this sampling mode corresponding to free convection could be easier to adapt to indoor conditions.

3.2. Kinetics of VOC emission from materials: determination of the equilibrium time

To optimize the sampling conditions, the passive diffusion of the VOCs from the solid sample to the headspace of the FLEC® was studied to determine the time required to reach equilibrium concentrations in the emission cell headspace (so-called "equilibrium time"). This study was performed on the 3 building materials (pine wood panel, carpet and PVC floor) which were left uncovered for 3 days according to the 3-day emission test. Before introduction of the SPME fiber, the FLEC® was placed on each material sample and flushed by clean air (see Section 2.3.2). Then, the valves are closed to let the VOCs diffuse from the solid material to the headspace for different times ranging from 5 to 60 min. Then, a 20 min SPME sampling was applied. This duration was chosen as a compromise between a short sampling time and a good reproducibility (relative standard deviation, RSD) ranging from 5% (α-pinene) to 16% (hexanal) for quantitative results. Under these conditions, LOD and LOQ are in the $\mu g\,m^{-3}$ range (Table 3). Relative standard deviations (RSD) were calculated from 3 replicates, applying 45 min material/gas phase diffusion in the FLEC® and 20 min SPME sampling. The RSD ranges from 9% (phenol) to 28% (acetic acid).

For readability, only results for four VOCs are shown in Fig. 3, considering, e.g. the two lower and the two higher emitted concentrations for each material.

For carpet, Fig. 3 shows that the material/FLEC® headspace equilibrium is reached after 25 min (5 min material/gas phase diffusion + 20 min SPME sampling) for all considered compounds and whatever the concentration level (from 20 to 200 $\mu g\,m^{-3}$).

For PVC floor, equilibrium is reached after 35 min (15 material/gas phase diffusion + 20 min SPME sampling) (Fig. 3). The longer equilibrium time is observed for pine wood panel: 65 min (45 material/gas phase diffusion + 20 min SPME sampling) (Fig. 3).

For all materials, the equilibrium time seems to only depend on the material and not on the compound. Actually, acetic acid equilibrium step was obtained for 25 min (carpet), 35 min (PVC) and 65 min (pine wood). This finding was also noted for 1-butanol comparing carpet (25 min) and pine wood (65 min) and for 2-ethyl-1-hexanol in the carpet (25 min) and PVC flooring (35 min).

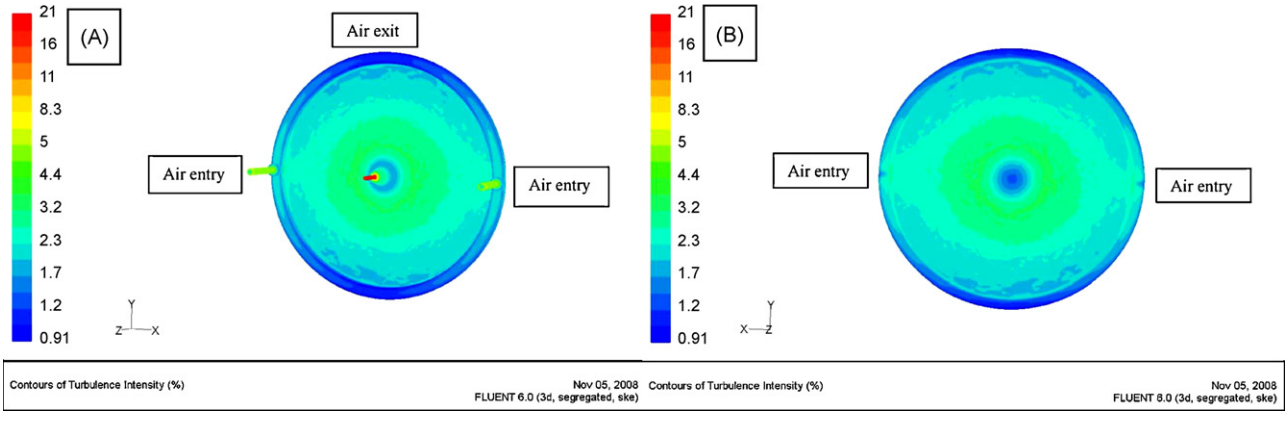

Fig. 2. Contours of turbulence intensity with a 0.3 L min^{-1} air flow: (A) top view; (B) underneath view.

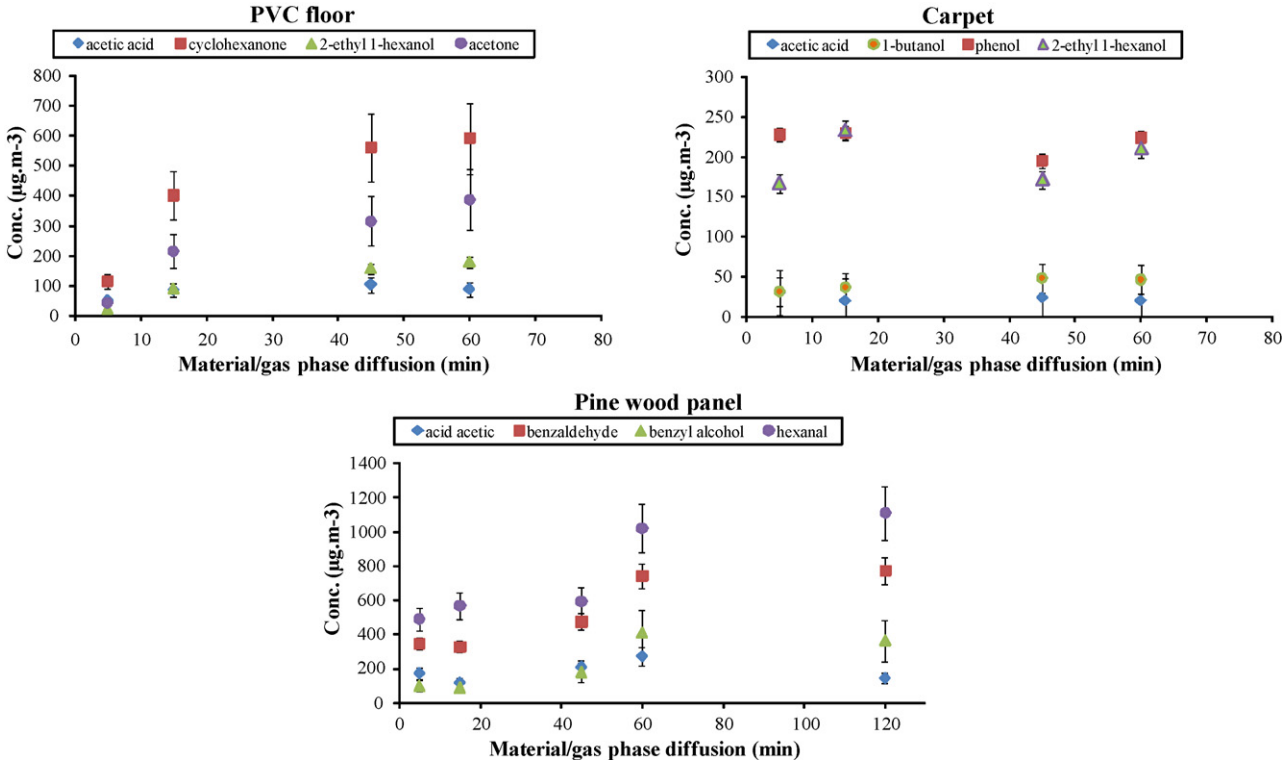

Fig. 3. Kinetic of VOCs emission from materials (PVC floor, carpet and pine wood panel).

Moreover, the equilibrium time does not seem to be related to the emission concentration. For example, equilibrium concentration of acetic acid reached 20 $\mu g\,m^{-3}$ for the carpet against 100 $\mu g\,m^{-3}$ for the PVC (Fig. 3). In the same way, the concentrations of 2-ethyl-1-hexanol determined for these two materials are similar (200 $\mu g\,m^{-3}$) (Fig. 3) but three more time is needed to reach equilibrium for PVC. These results also show that emission concentration at equilibrium does not depend on compound volatility. Thus, for PVC, the concentration of the most volatile VOC (acetone, 22 800 Pa at 20 °C) [24] is close to 200 $\mu g\,m^{-3}$ compared to 450 $\mu g\,m^{-3}$ for cyclohexanone (4700 Pa at 20 °C) [25]. From these results, it can be expected that the transfer of VOCs from the material to the gas phase is probably governed by diffusion in the material and not by surface evaporation.

A complementary study was performed to check that concentration equilibrium remains constant in the headspace even after SPME sampling. Hence, two successive SPME extractions were carried out for 45 min material/gas phase diffusion and 20 min SPME sampling on the pine wood panel. This material was chosen because of the longer associated equilibrium time, compared to carpet and PVC floor.

The average difference between concentrations at the material surface (C_{as}) obtained for the two successive SPME samplings is 4% and ranges from 0.5% (acetone) to 13% (α-pinene). So, these data suggest that the equilibrium between the building materials and the FLEC® headspace is sufficiently stable to perform quantitative analyses.

3.3. Application of the developed method to the three building materials

The three building materials (carpet, PVC and pine wood panel) were analyzed according to the longer equilibrium time determined in the previous paragraph. Results are summarized in Table 5.

Among the VOCs identified, a lot of them are shared by two or three of the materials studied. For example, acetone, acetic acid and 1-butanol were detected in the three materials. Pentanal, phenol and 2-ethyl-1-hexanol were found in pine wood panel and PVC. The other quantified compounds are specific of a material and often belong to the same families. Thus, the main families encountered in pine wood are aldehydes and terpenes. For the PVC floor studied, alcohol, ketone, glycol ester and glycol ether are the major substances. Finally, the carpet mainly emitted acids, alcohols and esters.

To conclude, this methodology allows the identification and quantification of VOCs in a wide range of physico-chemical properties and concentrations (Table 4). Hence, VOCs emission profiles could be drawn up. It could be an interesting tool to identify sources in indoor environments.

3.4. Evaluation of the SPME method for identification of VOCs of interest

The AFSSET protocol defines concentration limits for material labeling. Thus, a total VOCs concentration ([TVOC]) higher than 10 $mg\,m^{-3}$ for a 3 days test does not allow labeling. Then, a similar test is done after 28 days of conditioning. Compounds of interest are defined for observed concentrations higher than 5 $\mu g\,m^{-3}$. For each compounds of interest, a ratio (R) between the concentration after 28 days ([J28]) and the lowest concentration of interest (LCI) proposed in the protocol [3], is calculated. The health risks associated with the emission of VOCs from the material is considered to be low when both individual R ratios and their sum remain below 1.

As previously stated, the VOCs concentrations determined by passive and dynamic samplings cannot be directly compared, because of the different modes of mass transfer. So, the new FLEC®-SPME procedure was only evaluated for the identification of the VOCs of interest. It was applied to two materials (carpet

and pine wood panel) after 3 days. The VOCs of interest were defined according to the standard method. Results are presented in Tables 5 and 6. It can be noted that the sum of R ratios for the carpet is over 1 ($R = 3.05$), meaning that emissions of this flooring material could present health risks. If we look at individual R-values, it appears that the health impact would be mainly due to two compounds: caprolactam and phenol ($R = 1.64$ and 1.09, respectively). For pine wood panel, all the individual R ratios are below 1 and their sum just reaches 1, which suggests that the product does not present a significant health risk.

The comparison with the standard procedure shows that FLEC®-SPME did not detect all the VOCs identified by the standard protocol: thirteen compounds of seventeen for the carpet and twenty-one out of thirty two for the pine wood panel. This is mainly due to the lower sensitivity of the whole methodology compared to the standard evaluation method which is five to eight times better. This may be explained by several differences in the analytical protocols (Table 2), but the most influencing parameter is probably the difference between the adsorbent masses: around 200 μg for Carboxen® SPME fiber and 200 mg for Tenax® tubes. However, despite this lack of sensitivity, all the compounds of interest (Tables 5 and 6) are identified by the FLEC®-SPME method, except phenylundecane for the carpet. For this compound, adsorption affinity with Carboxen® is better than with Tenax®, leading to poor desorption efficiency [26]. Nevertheless, caprolactam was better detected with the SPME methodology: this can be explained by the higher desorption temperature applied (320 °C).

To summarize, the FLEC®-SPME methodology is able to determine 96% of the compounds of interest defined by the AFSSET protocol (concentration >5 $\mu g\,m^{-3}$), so it is relevant for the identification of the most toxic compounds emitted by materials.

4. Conclusion

A new FLEC®-SPME passive sampling method, firstly developed on standard gas in a previous study, was optimized to analyze VOCs emitted from solid building materials.

The fluid flow study in FLEC® emission cell puts in evidence low turbulences (central and peripheral areas of the material surface) when applying the standard dynamic sampling procedure. As this could lead to heterogeneous diffusion of VOCs from material to the gas phase, passive FLEC®-SPME was considered relevant because it better represents VOCs surface emissions and transfer to indoor air. To optimize the experimental procedure, VOCs diffusion from the solid material to the FLEC® cell headspace was studied and equilibrium conditions were determined for three materials. It was shown that equilibrium time only depends on the material type (25 min for carpet, 35 min for PVC floor and 65 min for pine wood panel). The longest sampling time is in the same order of the

standard dynamic sampling (60 min) and a factor four is gained compared to other passive sampling methods (several hours). Hence, this new method combined easy implementation and time-saving.

Comparison with the standard dynamic sampling protocol showed the potential of FLEC®-SPME in identifying the VOCs of interest defined by the AFSSET protocol. Quantification of VOCs is also possible by determining concentrations at the material/air interface. Therefore, this new method seems well adapted to field sampling and would be helpful for identification and rating of sources in indoor environments. Moreover, combined with emission modeling, it could become an interesting support tool to decision making in applications such as indoor air quality diagnostic and health advocacy.

Styrene-divinylbenzene copolymer (XAD)

ABSTRACT

Here, a simple new method is proposed to evaluate water for the presence of pesticides. Specifically, pesticides for golf link maintenance were used as the targets for this investigation. Water samples containing the pesticides were mixed with particulate adsorbent, after which the pesticides were extracted from the adsorbents using supercritical fluid carbon dioxide and then analyzed by gas chromatography–mass spectrometry. The recoveries of pesticides were examined with several types of adsorbents and found to be related to their octanol/water partition coefficients (K_{ow}) for most of the adsorbents. Good recoveries were obtained when the water samples were mixed with octadecylsilane (ODS) and stylene-divinylbenzene copolymer (XAD) resins for 15 and 30 min, respectively. In the supercritical fluid extraction, extraction pressure affected the efficiency of extraction from XAD while a little effect on extraction from ODS, probably due to the internal structure of the adsorbents. The limit of detection ranged from 0.002 to 2.3 $\mu g\,L^{-1}$ and the method is suitable for the measurement of golf link pesticides in $\mu g\,L^{-1}$ order to 100 $\mu g\,L^{-1}$. The procedure of the proposed method was simpler than the conventional solid-phase extraction method. Finally, the method presented here was used to identify pesticides present in actual wastewater from golf links.

1. Introduction

Although agricultural chemicals such as herbicides, germicides and insecticides (pesticides) are necessary to improve agricultural productivity, they can exert adverse effects on the ecosystem once they flow into natural or public water systems [1]. Therefore, the use of these chemicals is controlled by agricultural chemical regulation laws. In Japan, provisional guidelines for golf link pesticides that provide determination methods and acceptable limits of these concentrations were provided in May of 1990 in an attempt to prevent water pollution. The number of target chemicals covered by these guidelines was increased to 45 in December 2001 [2]. The provisional guidelines state that golf link chemicals should be determined by liquid–liquid extraction (LLE) [3] or solid-phase extraction (SPE), which both especially LLE require harmful organic solvents. Liquid–liquid microextraction is one of the new ways to reduce the use of organic solvent [4]. Conventional LLE and SPE require a great deal of time and special skills to conduct the extraction and refining processes. Furthermore, the results obtained using these methods can be affected by the sample and experimental conditions. In most modern water contaminant analyses, the compounds are trapped by solid-phase cartridges [5,6] or solid-phase disks [7,8] and then extracted using organic solvents to enable their subsequent analysis by gas chromatography (GC). Guardia-Rubio et al. applied the SPE–GC method to the multi-residue analysis of three groups of pesticides in wash waters [9]. Supercritical fluid chromatography is also a powerful tool for analysis after SPE [10]. However, in real water analyses, suspended materials such as algae sometimes clog the SPE cartridge, which can make it difficult to push water through the cartridge at a high flow rate during the extraction.

Residual pesticides in agricultural products can be screened using simple whole analyses [11]. Recently, solid-phase microextraction (SPME) was coupled with GC analysis [12–14] or HPLC analysis [15] to measure the levels of pesticides in water and juice samples, and stir-bar-sorptive extraction–thermal desorption was also applied to water analysis [16]. However, due to the limited surface area and adsorbing capacity of these micro-solid devices, the recoveries are generally not very good. As a result, the SPME devices are primarily used to identify specific species.

Supercritical fluid extraction (SFE) is known to be a useful method of pretreating samples for subsequent screening [17–19] and analysis for the presence of specific pesticides such as rotenone [20]. Ong and Hites developed a low solvent method comprising solid extraction disks and subsequent SFE [21]. SFE provides an advantageous extraction because the extraction medium is highly

doi:10.1016/j.talanta.2009.07.061

soluble as a liquid and has a high diffusion rate as a gas. Generally, CO_2 is a good medium for SFE because it goes to supercritical state at relatively low temperatures (32 °C and 7.4 MPa), inert and will not affect chromatographic analyses. Therefore, SFE with CO_2 is preferable for the analysis of thermally unstable compounds such as pesticides.

Glazkov et al. developed a method for the direct extraction of organic compounds from water by SFE [22]. In their method, the water sample was placed in a SFE cell, after which high-pressure CO_2 fluid was introduced and the extracts were trapped with glass wool. Although this direct extraction for analytical purpose is very simple, small number of papers on this subject has been published [23] while its usefulness for the remediation of polluted water is currently being evaluated [24]. Unstable compounds such as pesticides tend to decompose in response to exposure to water in the supercritical fluid, and SFE is often used to induce the degradation of water contaminants [25]. Indeed, it is well known that water adsorbent is placed in the SFE cell to prevent water catalyzed decomposition. Therefore, a strategy comprising the collection of pesticides by solid adsorbents and subsequent extraction from the adsorbents would be better for the analysis of pesticides than the direct SFE from water samples. Previous studies have utilized SPME devices [26] and disks [21] as pre-collection devices prior to SFE. In this study, adsorbent resin powders were placed directly in the water samples to enable quantitative adsorption.

Here, we present a simple method to evaluate the pesticides contained in water samples. We investigated the use of simple and solvent free pretreatment for the determination of golf link pesticides based on batch-wise adsorption and SFE. In the batch-wise adsorption, solid adsorbents were simply added to the water samples; therefore, special equipment such as syringe pumping systems was not required. Then we optimized the adsorbents and adsorption conditions, after which we applied the system to real water analyses.

2. Experimental

2.1. Chemicals

A standard solution of golf link pesticides (10 mg mL^{-1}) was obtained from Kanto Kagaku (Tokyo). The standard solution contained 27 kinds of pesticide which were measurable by gas chromatography. Adsorbents were used as purchased or after pretreatment as follows. One gram of octadecylsilane adsorbent (ODS, Bondesil-C18, 40 μm) obtained from Varian (Palo Alto, CA) or Tenax GR obtained from GL Science (Tokyo) was placed in a 100-mL beaker, after which 5 mL of acetonitrile and 5 mL of acetone were added. The adsorbents were then allowed to dry at room temperature for 15 min. Activated carbon powder (acid treated) and silica gel 60 for column chromatography, which were both obtained from Nacalai Tesque (Kyoto), were heated at 200 °C for 2 h and then cooled in a desiccator. A styrene-divinylbenzene copolymer adsorbent (XAD, Amberlite XAD-4, Φ 0.49–0.69 mm, 750 m^2 g^{-1} dry, pore 12 nm) obtained from Sigma–Aldrich (St. Louis, MO) was washed with acetone with a help of ultrasonication just before use. Activated alumina 200 and diatomaceous earth both from Nacalai Tesque were used without any treatment. For comparison, two SPME devices coated with 100 μm polydimethylsiloxane (PDMS) or 75 μm polyacrylate (PA) both obtained from Supelco (Bellefonte, PA) were utilized for collection of the pesticides in water.

2.2. Analytical procedure

One gram of adsorbent (2.0 g in case of XAD) and a Teflon stir-bar (4 cm in length) were placed in a 100-mL glass beaker, after which 50 mL of water standard (containing each pesticide at a concentration of 20 μg L^{-1}) or of water sample were added. The samples were then stirred on a six-stage-multi-stirrer for 15 or 30 min. Next, the absorbents were collected on a cellulose membrane filter (1.0 μm, Φ 47 mm, Advantec, Tokyo) and then dried in a vacuum desiccator with silica gels overnight. All of the adsorbent was then transferred to a 50-mL beaker and mixed with 2.0 g of diatomaceous earth as wet support. Round sand, the adsorbent/wet support mixture, and the wet support were then placed in an extraction cell in this order, after which 1 mL of methanol was added as a modifier. The cell was then placed in the SFE instrument (SE-30; Isco). The typical SFE conditions were a temperature of 50 °C, a pressure of 3000 psi, static 15 min and dynamic 15 min, and a restrictor temperature of 60 °C. The extracts were then collected by bubbling through 5 mL of acetone in a test tube. Next, the solution volume was adjusted to 1 mL by vaporization induced by blowing of nitrogen, after which 2 μL of the solution was injected in split-less mode (injector temperature: 250 °C) into a gas chromatograph equipped with a mass spectrometer (GC–MS, Agilent 6890N/5973 or Thermo Electron GC ultra DSQ). An InertCap 5MS/sil separation column (0.25 mm i.d. × 30 m, 0.25 μm thick) obtained from GL Science was used and helium was applied at 1.0 mL min^{-1} as a carrier gas. The column oven temperature was initially 50 °C for 2 min, after which it was ramped to 120 °C at 20 °C min^{-1} and then to 270 °C at 5 °C min^{-1}. Each compound was measured using selected ion monitoring in accordance to the library PEST provided from Agilent. For calibration, from 0.5 to 5 mL of acetone solution containing 1-mg L^{-1} standards were added to 50 mL water, and treated in the same way as sample waters.

2.3. Recovery test and sample water analysis

Water samples were collected from golf link wastes and rivers and then stored in a refrigerator until analysis, which was conducted within one week. The pesticides contained in the 50-mL samples were then determined as described in Section 2.2. The pesticides were also concurrently evaluated using the conventional SPE–GC–MS method [2,27] for comparison. To accomplish this, a 200–500 mL of sample water was allowed to flow through a SPE cartridge (Sep-PaK VAC 500 mg, Waters) at a rate of 10 mL min^{-1} with the aid of a syringe pump (Sep-Pak concentrator N10003, Waters). The inside of the cartridge was then dried by allowing nitrogen to flow through the cartridge, after which the analytes were extracted with 10 mL of acetone and 5 mL of acetonitrile. Next, 0.5 mL of 2% diethylene glycol acetate was added to the extract and the sample was concentrated to a volume of 1 mL using a rotary evaporator. The volume of the sample was then adjusted to 2 mL by the addition of acetone to prepare it for GC–MS analysis. For recovery tests, 1 mL of standard solution (each concentration was 1 mg L^{-1}) was added to the water samples to give final concentrations of 20 μg L^{-1}.

3. Results and discussion

3.1. Investigation of adsorbents

Several types of adsorbents were tested for use with batch-wise adsorption/SFE. Fig. 1 shows the results obtained using a 15-min adsorption time plotted against the octanol–water partition coefficient (K_{ow}). Interestingly, the recoveries were related to K_{ow} for most of the adsorbents, which suggests that the adsorption onto these materials was based on the hydrophobic interaction between the pesticides and materials. Even for the silica gel and alumina, the recovery increased as K_{ow} increased. For the relatively hydrophilic materials, it is reasonable to assume that the molecular–matrix interaction between these two materials increases as the molec-

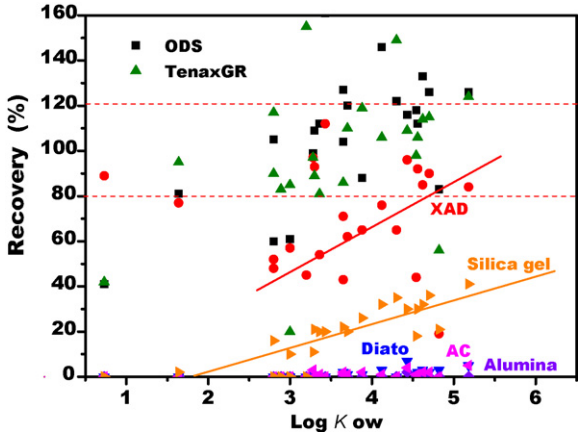

Fig. 1. Recoveries of the pesticides obtained using the batch-wise adsorption plotted against log K_{ow}. The following seven materials were tested: (■) ODS, (●) XAD, (▲) Tenax GR, (▲) silica gel, (▼) diatomaceous, (▲) activated carbon and (▲) activated alumina.

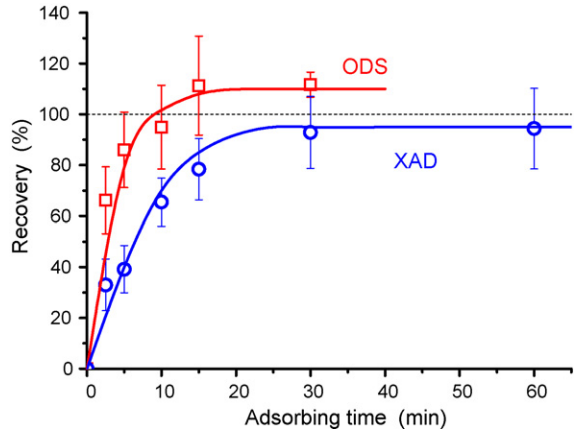

Fig. 2. Recoveries of pesticides as a function of adsorbing time for ODS and XAD.

ular size increases which subsequently affects K_{ow}. In the case of ODS, the recoveries were around 100%, which indicates a good adsorption of pesticides. These findings are similar to the results previously obtained using ODS in a study conducted by Junk and Richard [28]. Conversely, recovery was found to be a function of K_{ow} for XAD when the same adsorption time was used. In addition, a partial adsorbing equilibrium was observed after 15 min when the XAD resins were used, whereas complete equilibrium could be achieved after 30 min of treatment (Fig. 2). Based on the results shown in Fig. 1, ODS, Tenax GR and XAD were considered to be good adsorbing materials. However, Tenax GR is an expensive material and was therefore not used in the subsequent experiments. This was because the cost of the material is an important factor since the adsorbents can only be used once. As a result, ODS and XAD were chosen as optimal adsorbents for this study.

Fig. 2 shows the change in recovery with the adsorbing time. For both ODS and XAD, the recoveries initially increased as the adsorbing time increased and then reached the constant values after 15 or 30 min. The time required to reach the steady equilibrium was shorter for the ODS than the XAD. The typical diameters of ODS and XAD were 0.04 and 0.6 mm, respectively. Therefore, the apparent spherical surface area to volume ratio of ODS is 15 times greater than that of XAD. This high apparent surface area ratio was advantageous for the short-time collection. In addition, adsorptions only occur on the surface of ODS particles, whereas molecules are adsorbed inside the micropores of the XAD resins. As a result, the actual adsorbing area per mass of XAD was 3000 times greater than that of ODS, and more time was required to enable the molecules to enter the pores of the XAD resins. Accordingly, the optimal adsorbing times were determined to be 15 and 30 min for ODS and XAD, respectively.

We also evaluated the use of SPME for pesticide analysis in the same stirring condition to compare the adsorbing performance. SPME is a well-known tool for the analysis of organic compounds contained in water and has been successfully applied to a variety of compounds [12,15,26]. The recoveries after 60 min of SPME collection ranged from 10 to 30% for the eight compounds (diazinon, tolclofosmethyl, dithiopyr, chlorpyrifos, pendimethalin, butamifos, trichlopyr butoxyethyl, and isoxathion) evaluated in this study. In addition, for most of the pesticides, the recoveries were lower than 1% with the same stirring conditions. Taken together, these results indicate that ODS and XAD particulates are superior than the thin PDMS film on the SPME device based on the interactions with the organic compounds, adsorbing capacity and adsorbing area. As a result, it can be said that the conventional SPE and the present batch-wise collection are more suitable for multi-compound analysis of aqueous pesticides.

3.2. Conditions of supercritical fluid extraction

The conditions of SFE were examined to determine their effects on the extraction of pesticides from ODS and XAD resins. First, the effects of each modifier that was added to the SFE cell were examined to determine if it improved the extraction efficiency. Methanol and acetone were tested and methanol was found to be a better modifier than acetone. Some of the pesticides, such as trichlopyr-2-butoxyethyl ether, were extracted well even without the modifier.

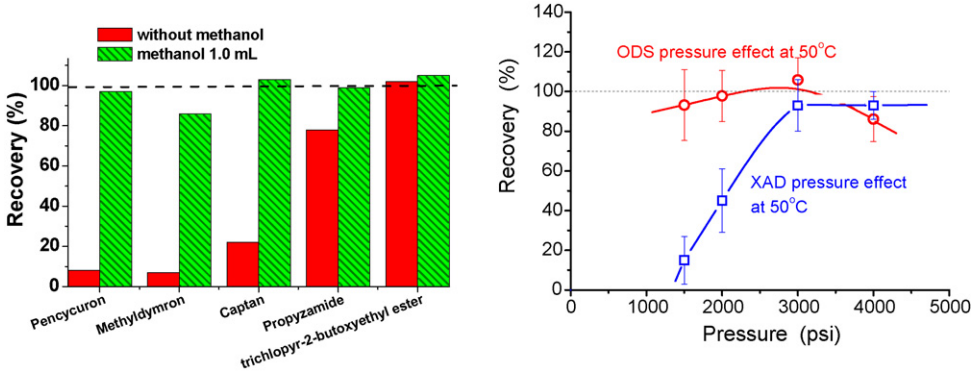

Fig. 3. Examination of extraction conditions. Effect of methanol as a modifier (left) and effect of extraction pressure (right). In the right panel, 19 pesticides were selected whose recoveries were 100 ± 20% at 3000 psi and average of recoveries are plotted with deviation against the extraction pressure at extraction temperature of 50 °C for XAD and ODS.

[a] Guidelines and LODs are shown in $\mu g\,L^{-1}$.

However, the extraction performance was dramatically improved in response to the addition of the modifier for most of the pesticides, especially pencycuron and methyldymron (Fig. 3, left).

Next, the effects of temperature and pressure on the extractions were examined. The recovery was almost constant as the extraction temperature changed from 30 to 50 °C at a constant pressure of 3000 psi for both ODS and XAD. Conversely, different effects on the recovery were observed in response to changes in pressure. Specifically, pressure exerted a small effect on the extraction conducted using ODS, whereas the recoveries were very poor at pressures lower than 2000 psi in the case of XAD as shown in Fig. 3, right. Furthermore, the recovery obtained using the XAD resins increased in proportion to the pressure up to 3000 psi. These findings reveal an interesting behavior in the SFE process. occurs independently of the extraction pressure. Conversely, higher pressure is required for extraction from materials with complicated structures. Because adsorption occurs on the surface of ODS, but inside the XAD particles, XAD requires a higher pressure for the extraction. Based on these data, the optimum conditions were determined to be 50 °C at 3000 psi with the modifier methanol.

3.3. Performance of the method

After optimization, the method was tested with standard solutions which containing 0, 1, 5, 10, 20, 40 (or 50) and 100 μg L^{-1} pesticides. The series of measurements were repeated 3 times for the each concentration sample. In both ODS and XAD adsorption methods, the calibration curves were straight up to 100 μg L^{-1} for all pesticides investigated except pencycuron with XAD (sigmoid). Some chromatogram peaks were small below 5 μg L^{-1} for such as pencycuron, simazine, chlorothalonil, methyldymron, isofenfos, isoprothiolane, isoxathion, propiconazole with ODS adosorption. In case of XAD, same downward curve in low concentrations was observed only for isoxathion. For the other compounds, good linearities were obtained and good coefficient of determination (R^2) was obtained (Table 1). Sensitivity of the proposed method was comparable to that of conventional SPE method. When 200 mL of water sample was used in the SPE method, slope of calibration curve would be double of the proposed method for 50 mL sample. If same volume was used in the two methods, the proposed method gives twice sensitivity compared to the SPE method. Detection limits were determined from 3 times of deviation of blank signals; they ranged from 0.002 to 2.3 μg L^{-1}. The guidelines specify that the allowable limits of the pesticides range from tens to thousands of μg L^{-1} (Table 1). The method described here had sensitivity sufficient to detect pesticides present at concentrations lower than the guideline levels when only a 50 mL sample of water was analyzed.

3.4. Water sample analysis

The applicability of this method was confirmed by comparing the recovery of pesticides from natural water that had been spiked with golf link pesticides at a concentration of 20 μg L^{-1} using the method described here with the recovery obtained using the conventional SPE method [2,28]. As shown in Table 2, good recoveries were obtained for most of the pesticides using the method described in the present study. For some pesticides, recoveries were too high (>120%) in case of XAD. It can be said that the resin matrix might be extracted from XAD in SFE process to interfere the results. This can be observed in the chromatogram for blank sample with XAD (Fig. 4). This effect was small in analysis with ODS. In the conventional SPE analyses, recoveries were mostly lower (71% in average) compared to the present method for 20 μg L^{-1} pesticides whereas they were quantitative when water containing 1 mg L^{-1} pesticides was determined with the conventional SPE. Recoveries for some of pesticides such as simazine ($\log K_{ow}$ 0.73), terbucarb and metalaxyl ($\log K_{ow}$ 1.64) were relatively low even in the present method. Values of K_{ow} for these compounds were low compared to those of the other compounds ($10^{2.8–5.18}$). Bensulide and iprodione were not detected in the examined concentrations. These compounds were difficult to detect even in direct injection of acetone solution and guideline levels are very high compared to the examined concentrations.

In our prefecture, pesticides are rarely detected in water samples. However, several water samples evaluated in this study were found to contain pesticides. The results obtained using the method described here agreed with the data generated by the conventional SFE method as shown in Table 3. Also, chromatograms for the standard (20 μg L^{-1}) and water sample which was found to contain propyzamide are shown in Fig. 4. Determinations by the two

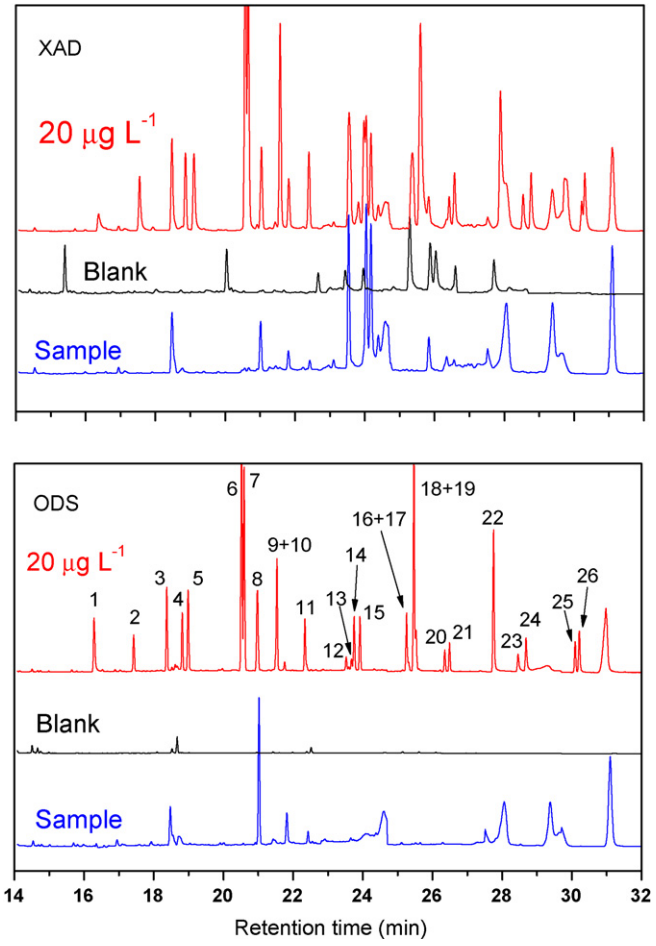

Fig. 4. Chromatograms for the sample and standard solutions. (1) pencycuron, (2) simazine, (3) propyzamide, (4) diazinon, (5) chlorothalonil, (6) terbucarb, (7) tolclofosmethyl, (8) metalaxyl, (9) dithiopyr, (10) fenitrothion, (11) chlorpyrifos, (12) pendimethalin, (13) captan, (14) methyldymron, (15) isophenphos, (16) naprozamide, (17) butamifos, (18) flutolanil, (19) isoprothiolane, (20) trichlopyrbutoxyethyl, (21) isoxathion, (22) mepronil, (23) iprodione, (24) propiconazole, (25) iprodione and (26) pyridaphenthion.

Table 3
Results of wastewater analysis.

Sample no.	Propyzamide found (μg L^{-1})		
	SFE cartridge	Batch ODS	Batch XAD
1	11.7 ± 0.7	11.3 ± 2.7	9.0 ± 0.9
2	5.8 ± 0.3	4.5 ± 0.8	5.3 ± 1.2
3	3.3 ± 0.1	3.0 ± 0.3	3.5 ± 0.2
4	3.1 ± 0.8	2.6 ± 0.4	3.0 ± 0.4

methods were performed in the same day or in two days. As can be seen in Fig. 4, there were interference peaks in the blank signals in case of XAD. On the other hand, flat chromatogram for the blank was obtained in ODS method. For low level analysis such in μg L^{-1} order, ODS was preferred in this method rather than XAD. The XAD resin would be suitable for high concentration samples because particles are relatively large and treatment was easier in the adsorption/extraction processes.

4. Conclusions

Supercritical fluid extraction was found to be useful for water analysis when it was coupled with batch-wise adsorption. Indeed, the results of this study revealed that the pesticides were adsorbed

onto the particulate adsorbents very simply using only a stirrer in a small beaker. Although the adsorption characteristics of the pesticides are related to their octanol/water partition coefficients, K_{ow}, good recoveries were obtained when a sufficient adsorbing time was adopted. Additionally, the recoveries obtained using this method with ODS and XAD are compatible with those obtained using the conventional SPE method. ODS was better than XAD resins due to lower interference and shorter adsorbing time. Finally, the operation time and cost of operation of the proposed method were lower than those associated with conventional SPE.

Laser induced fluorescence

ABSTRACT

An ultrasensitive laser-induced fluorescence detector was used with capillary electrophoresis for the study of 5-carboxy-tetramethylrhodamine. The raw signal from the detector provided roughly three orders of magnitude dynamic range. The signal saturated at high analyte concentrations due to the dead time associated with the single-photon counting avalanche photodiode employed in the detector. The signal can be corrected for the detector dead time, providing an additional order of magnitude dynamic range. To further increase dynamic range, two fiber-optic beam-splitters were cascaded to generate a primary signal and two attenuated signals, each monitored by a single-photon counting avalanche photodiode. The combined signals from the three photodiodes are reasonably linear from the concentration detection limit of 3 pM to 10 μM, the maximum concentration investigated, a range of 3,000,000. Mass detection limits were 150 yoctomoles injected onto the capillary.

1. Introduction

Capillary electrophoresis provides outstanding resolution and near-Gaussian peaks. As a result, trace components can be detected in the presence of interfering compounds present at many orders of magnitude higher concentration. The dynamic range of the detector limits the ability to determine simultaneously the amounts of both trace and abundant components.

In capillary electrophoresis, absorbance measurements are limited to two or three orders of magnitude in dynamic range, whereas fluorescence detectors are able to achieve perhaps four orders of magnitude dynamic range. The latter tend to employ photomultiplier tubes as photodetectors with 16-bit analog-to-digital converters (ADC). The ADCs are typically operated so that the noise in the measurement is larger than the least significant digit in the ADC. A single measurement will typically have a dynamic range of less than 10,000; averaging the signal from many measurements in the presence of uncorrelated noise can improve the dynamic range to a limited extent [1]. Higher dynamic range ADC converts are becoming available but are seldom employed in fluorescence detection.

In principle, photon-counting detectors can achieve an arbitrary dynamic range limited only by the size of the register used to accumulate counts. However, photon counters have a finite dead time during which they do not respond to a second photon [2]. In a paralizable detector, the arrival of a second photon restarts the dead time. At very high incident rates, the detector will saturate and record no signal at all. For commercial avalanche photodiode photon counters, the dead time is on the order of 50 ns, and the detector will saturate as the incident photon rate approaches 20 MHz. The dead-time characteristic of detectors has received significant attention from the atomic and nuclear physics communities, and a number of models are available to correct for dead-time effects [3,4].

There are cases where very high-dynamic range is desirable, for example when detecting minute amounts of enzymatic product in the presence of a very large excess of substrate [5,6]. We report a simple method to increase dynamic range without limit in fluorescence detection and employ this method to produce over six orders of magnitude dynamic range while retaining yoctomole detection limits. In this system, fluorescence generated in a sheath-flow cuvette is collected by a microscope objective and imaged onto a gradient index-coupled fiber optic. The light captured by the fiber is sent to a cascade of fiber-optic beam-splitters, repeatedly dividing the signal into successively lower intensity channels. These beam-splitters require no alignment, are robust, and are inexpensive.

Each channel is equipped with a dedicated avalanche photodiode photon counting module. The highest intensity signal is used to characterize components present at very low levels and the most attenuated signal is used to characterize the highly abundant components. In principle, an arbitrary number of splitters can be

doi:10.1016/j.talanta.2009.07.060

cascaded to generate an arbitrary dynamic range measurement; we demonstrate this approach with a cascade of two splitters and three photodiodes.

2. Materials and methods

2.1. Reagents

Unless specified, reagents were from Sigma. Water was from a Barnstead Nanopure water supply. 5-Carboxy-tetramethyl rhodamine (TAMRA) was from Invitrogen. Capillaries were from Polymicro Technologies.

2.2. Capillary electrophoresis

The capillary electrophoresis system was similar to others developed by this group [7–9]. Briefly, a 23-cm long, 20-μm ID, and 150-μm OD uncoated fused silica capillary was used for the separation. The separation was performed using a running buffer composed of 10 mM sodium tetraborate, 35 mM sodium deoxycholate, and 5 mM methyl-β-cyclodextrin. The running voltage was 18 kV. Injection was for 1 s at 1 kV. Counts were recorded at 50 Hz.

2.3. High-dynamic range, ultrasensitive laser-induced fluorescence detector

The instrument was equipped with a post-column sheath-flow cuvette for fluorescence detection [10,11]. The optical design of the high-dynamic range detector is shown in Fig. 1. The majority of the system was identical to that described earlier. Excitation was provided with a 10 mW diode-pumped solid-state (DPSS) laser at 532 nm (Coherent) that was focused in a sheath-flow cuvette. Fluorescence was collected by a 0.45 NA microscope objective, passed through a 580 DF40 bandpass filter, and imaged onto a GRIN-lens coupled fiber optic.

We employed fiber-optic beam-splitters to divide the fluorescence into two channels; one channel retained most of the original intensity and the second presented an attenuated version. The beam-splitters (Thorlabs) have a nominal 99:1 split ratio at 850 ± 40 nm. However, the split ratio degraded at the 580 nm wavelength of the fluorescence. One splitter generated a split ratio of ~15:1 and the other generated a split ratio of ~4:1. The splitters were placed in series, where the intense output of the first splitter was directed to a single-photon counting avalanche photodiode (APD1) and the attenuated output was directed to the second splitter. The outputs of that splitter were connected to two additional single-photon counting avalanche photodiodes (APD2 and APD3). PerkinElmer SPCM single-photon counting modules were employed in the experiment; all three had nominal dead time of 55 ns.

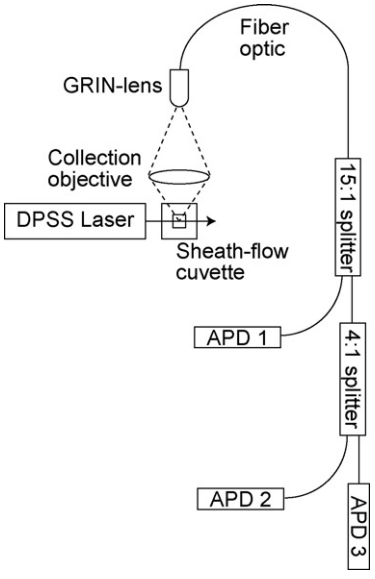

Fig. 1. Optical diagram. Fluorescence is divided with a cascade of fiber-optic beam-splitters into three channels. APD 1 provides the highest sensitivity but saturates at relatively low signals. APD 3 provides the poorest sensitivity but saturates at relatively high signals.

The fiber-optic cables attached to these beam-splitters are relatively transparent in the visible portion of the spectrum. Room light striking the fibers will increase the dark count. We cover the fibers with an opaque plastic sheet to eliminate this source of background signal.

The outputs of the photodiodes were digitized at 50 Hz by counters (National Instruments) in a PC. The data were then processed on a Macintosh computer using Matlab. Data were treated with a three point median filter to remove spikes due to light scatter from particles, and then convoluted with a 44-point wide Gaussian function with 5-point (100 ms) standard deviation. The MatLab routine cftool was used to fit a Gaussian function to the TAMRA peak; peak area was estimated by multiplying the peak amplitude with the standard deviation.

3. Results and discussion

3.1. Single avalanche photodiode detector

We employed the most sensitive photodiode of Fig. 1 to construct a calibration curve for the injection of 45 pL of various concentrations of 5-carboxy-tetramethylrhodamine. The data were treated with a 3-point median filter to remove the occasional noise spike associated with the passage of a particle through the detector and then convoluted with a 100 ms wide Gaussian filter, which matched the width of the electrophoretic peak.

Determining the linearity of wide dynamic range signals is not straightforward. We measured the signal for samples prepared by tenfold serial dilution. A simple plot of signal *vs.* concentration is virtually guaranteed to generate a high correlation coefficient in a least-squares plot. Instead, we inspect the slope of the least-squares fit of a straight line to the logarithm of concentration *vs.* the logarithm of signal; the slope should be close to 1.0 if the signal is linearly related to concentration.

Fig. 2 presents a log–log plot of the calibration data. The signal indeed increased linearly with concentration from 10 pM to 10 nM; the log–log plot generated a slope of 0.92 ± 0.04. The signal saturated at higher concentrations.

The concentration detection limit (3 s) was 3.4 pM and the mass detection limit was 150 ymol (100 copies) injected onto the capillary. The linear dynamic range from the detection limit to the start of the nonlinear portion of the calibration curve was 3000. The peaks in the linear portion of the calibration curve generated 300,000 ± 20,000 theoretical plates.

3.2. Paralizable detector

The observed photon count rate, N_{obs}, from a paralizable detector is related to the true photon count rate, N_{true}, and the detector dead time, t_d [4].

$$N_{obs} = N_{true} e^{-N_{true} t_d} \quad (1)$$

A plot of the incident and observed count rates predicted from Eq. (1) is shown in Fig. 3 for a paralizable photodetector with a 55-ns dead time, the nominal dead time for our photodiodes. The

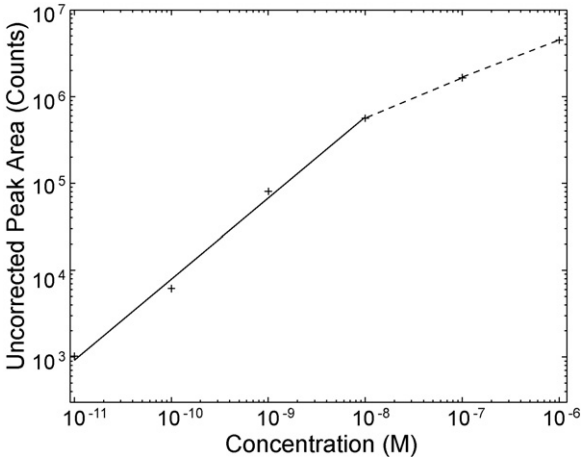

Fig. 2. Log–log calibration curve for uncorrected peak area for diode 1. The straight line is the result of a linear regression analysis to the log-log data for concentrations of 10^{-11}, 10^{-10}, 10^{-9}, and 10^{-8} M; slope = 0.92 ± 0.04, r = 0.9980. The dashed lines are to guide the eye.

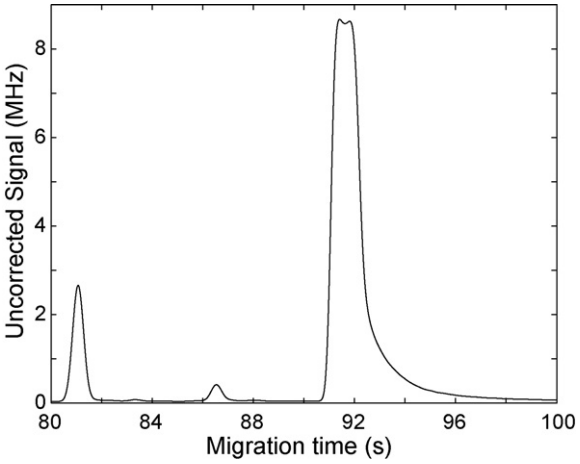

Fig. 4. Uncorrected electropherogram of a 1 μM solution of TAMRA recorded with photodiode 1. Data were treated with a 3-point median filter and then convoluted with a Gaussian filter with a standard deviation of 100 ms. Note the dip at the center of the peak at 92 s due to detector saturation.

observed count rate is within 5% of the true count rate for signals less than 1 MHz, but becomes highly nonlinear at higher count rates. The observed signal reaches a maximum at an incident count rate equal to $1/t_d$ and then decreases at higher count rates. The maximum signal is $1/(t_d\, e)$.

Fig. 4 presents the electropherogram generated by a 1 μM TAMRA solution. The lower amplitude impurity peaks at 81 and 86.5 s are Gaussian in shape, whereas the main peak is severely distorted, showing a truncated peak with a dip at the center. This dip occurs because N_{obs} is not monotonically related to N_{true}; the true count rate near the dip exceeds $1/t_d$. The signal exceeds the maximum predicted for a 55-ns dead-time detector; Eq. (1) is not accurate for very high signals.

An inverse function can be used to estimate N_{true} for $N_{true} < 1/t_d$. Several models have been presented for the inverse function. The most common correction function is [12]

$$N_{true} \approx \frac{N_{obs}}{1 - N_{obs} t_d} \tag{2}$$

A second order term can be included, which improves the accuracy of the inverse function [4].

$$N_{true} \approx \frac{N_{obs}}{1 - N_{obs} t_d - (N_{obs} t_d)^2} \tag{3}$$

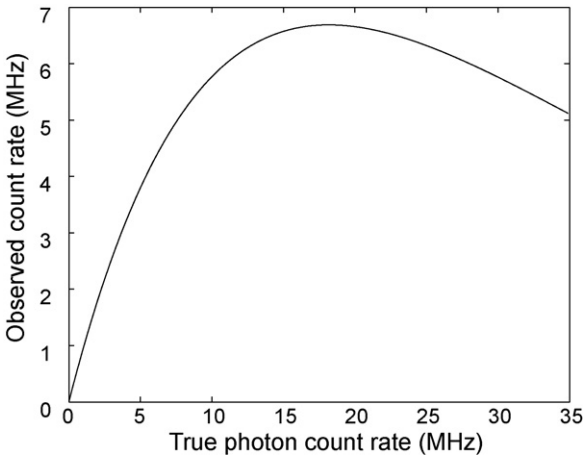

Fig. 3. Plot of Eq. (1) for a paralizable detector with a dead time of 55 ns. The observed count rate maximizes near 6 MHz and decreases at more intense signals.

The latter correction is accurate to within 2% for $N_{true} < 0.65/t_d$ ($N_{obs} < 0.34/t_d$).

We employed Eq. (3) with t_d = 55 ns to correct the nonlinear response of the photodiode. The resulting calibration curve was reasonably linear from the detection limit to 100 nM concentration (slope of the log–log plot = 0.91 ± 0.04, r = 0.9974). The non-monotonic relationship between N_{true} and N_{obs} prevented an accurate correction of the 1 μM data. The detection limit was not affected by this procedure, and the linear dynamic range was increased to ~30,000.

3.3. Fiber-optic beam-splitter cascade

We employed a cascade of two fiber-optic beam-splitters to divide the fluorescence intensity. The first beam-splitter divided the intensity in ~15:1 ratio; the second divides intensity by ~4:1. The splitting ratios were determined by first correcting the signal from each photodiode for detector dead time and then comparing the signal intensity of low concentration samples. The first photodiode received the vast majority of the fluorescence signal and was useful for the lowest amplitude signals; the third diode received only 2% of the fluorescence signal and was useful for higher amplitude signals.

The beam-splitters have some loss. We measured the baseline signal with the APD directly connected to the GRIN lens and the signal after going through the beam-splitters. The signal from photodiode 1 was attenuated by about 35%. 5% of that loss was due to light directed to the other photodiodes and could be recovered by summing the photodiode signals. The detection limit of a shot-noise limited experiment scales inversely with the square-root of the signal. A 30% decrease in signal corresponds to 20% degradation in detection limit. That loss of performance is accompanied by a two order of magnitude increase in dynamic range and should be acceptable in most experiments.

Fig. 5 presents the electropherogram generated by the 1 μM sample as observed by the three photodiodes. The traces have been corrected for the detector dead time with Eq. (3) and scaled based on the measured fiber-optic beam-splitter ratio. Although the peak signal from photodiode 1 could not be corrected by Eq. (3), the lower amplitude signals were well within the linear range of the photodiode. The corrected signal from photodiode 3 was multiplied by 10,000 to highlight trace components, and the corrected and scaled signal from photodiode 2 was multiplied by 100 to highlight intermediate amplitude components. The trace component at 77 s was

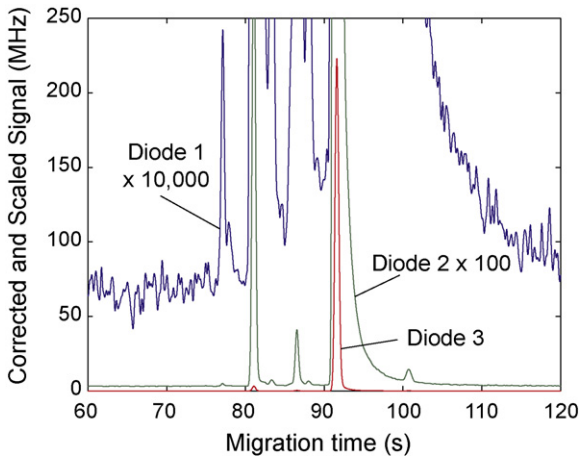

Fig. 5. Corrected electropherogram of a 1 μM solution of TAMRA and recorded with three photodiodes. The signals from the photodiodes have been filtered and corrected for detector dead time. The signals from photodiodes 2 and 3 have also been scaled to account for the attenuation introduced by the fiber-optic beam-splitter cascade. Finally, the corrected signal from diode 1 has been multiplied by 10,000 and the corrected and scaled signal from diode 2 has been multiplied by 100 to highlight low and medium abundance components.

roughly four orders of magnitude less intense than the main TAMRA peak.

The high-dynamic range allows a detailed characterization of peak shape. In particular, the main peak shows a modest amount of tailing in the photodiode 3 signal, which becomes much more prominent in the higher sensitivity signal of photodiode 1. That tailing is not the result of the convolution filter employed to treat the data. The convolution function is symmetrical and cannot introduce tailing. The effect of the filter is shown in Fig. S1 of the supporting information for this paper.

Fig. 6 presents the calibration curves generated by combining the scaled peak areas from the three diodes; photodiode 1 was used for corrected and scaled signals up to 1 MHz, photodiode 2 was used for corrected and scaled signals between 50 kHz and 100 MHz, and photodiode 3 was used for signals between 50 kHz and 1 GHz. The combined calibration curve generated a log–log slope of 0.93 ± 0.02, $r = 0.9981$ ($n = 20$), ranging from the detection limit of 3×10^{-12} M to 1×10^{-5} M, a range of 3,000,000 in concentration. The slope is not within experimental error of unity; the origin of that discrepancy is not clear, but may be associated with the photophysical phenomena described below. Because the slope is not unity, it is necessary to construct a calibration curve using at least two concentrations of analyte to determine the slope. In practice, the splitter combination should be evaluated across a wide concentration range to characterize its performance.

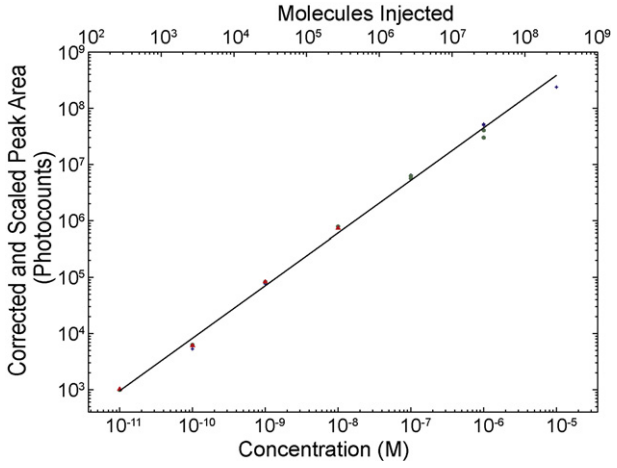

Fig. 6. Log–log calibration curve combining peak area for the three diodes. Red "Δ" is the corrected area for diode 1 (from 10^{-11} to 10^{-7} M), green "o" is the corrected and scaled area for diode 2 (from 10^{-10} to 10^{-6} M), and black "+" is the corrected and scaled area for diode 3 (from 10^{-10} to 10^{-5} M). The line is a least-squares fit of a line to the log–log data; the slope is 0.93 ± 0.02, $r = 0.9981$, $n = 20$. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of the article.)

Of course, additional beam-splitters and detectors can be added to the system to increase the dynamic range to higher concentrations. However, we are near the limits provided by the electrophoretic and spectroscopic properties of this dye. There are three phenomena that occur at higher analyte concentrations to generate nonlinear responses. First, dimer formation occurs at sub-millimolar concentrations of highly conjugated aromatic dye molecules [13]. These dimers have different molar absorptivity than the free dye and will lead to deviations from Beer's law. Antonov has reported a dimer dissociation constant of 3×10^{-4} M for rhodamine 6G, a similar dye to TAMRA. Second, capillary electrophoresis peak shapes become distorted as the ionic strength of the sample approaches the ionic strength of the buffer; in our system, analyte concentration can be increased to ~1 mM before electrophoretic phenomena distort peak shape. Finally, the fluorescence signal will become nonlinear when absorbance across the stream radius becomes significant, which again will become important for tetramethyl rhodamine concentration greater than a few hundred micromolar.

We also point out that Merz and Mort employed a liquid-crystal programmable attenuator in the emission channel of a fluorescence detector [14]. This device was used to keep the fluorescence intensity within the linear dynamic range of their photodetector and was particularly useful at high analyte concentrations. Unfortunately, a calibration curve was not generated to evaluate the performance of this system.

Finally, the dynamic range of the instrument can be improved at lower concentrations. Most simply, the capillary inner diameter can be increased, allowing an increase in injection volume by at least one order of magnitude. As the ultimate improvement, a beam-splitter cascade can be incorporated into a single molecule detector [15], which would allow the widest possible dynamic range in fluorescence detection—nine or ten orders of magnitude should be possible, limited only by the photochemistry of the dye molecule.

Hydrogen peroxide scavenging

ABSTRACT

We propose a novel approach for assessment of total antioxidant activity by monitoring kinetics of hydrogen peroxide (H_2O_2) scavenging after its injection into liquid sample under study. H_2O_2 is known to be the strongest oxidant, really presented in human body in contrast to the majority of the model oxidative systems used for evaluation of antioxidant activity. In addition, kinetic approach, being more informative than the commonly used determination of the final product, obviously provides better discrimination of potential antioxidants. Prussian Blue based sensor due to its high sensitivity and operational stability allowed to monitor kinetics of hydrogen peroxide consumption in turbid and colored samples. The pseudo-first order kinetic constants of hydrogen peroxide scavenging in the presence of different food additives correlated with total antioxidant activity of these samples evaluated via standard procedure based on lipid peroxidation. However, in contrast to the standard method, the proposed kinetic approach is expressed and does not require fresh biological tissues.

1. Introduction

Recent attention of clinical chemists is paid to a so-called oxidative stress, recognized as one of the major risk factors in progression of disease-related pathological complications in diabetes, atherosclerosis, renal disease, cancer, aging and other conditions [1–5]. Oxidative stress arises due to imbalance between oxidative and reductive processes, and in particular due to imbalance in the antioxidant status. This provides an interest to the compounds, which are able to decrease the rate of oxidizing reactions, usually referred to as antioxidants.

Methods to estimate the antioxidant activity can be divided in the two general groups [6]. One group involves analysis of oxidized products, for example of lipid peroxidation, in the presence of the samples or individual substances under study [6]. However, this approach is time consuming and requires fresh biological tissues. This provided the interest for determination of antioxidant activity by addition of powerful oxidants and investigation of their decomposition by the samples under study [6–8]. Among the most widely used tests are: total radical-trapping antioxidant parameter (TRAP) based on generation of free radicals by thermal decomposition of 2,2-azo-bis-2-amidinopropane hydrochloride with subsequent measurement or luminol-enhanced chemiluminescence [9,10], scavenging of diphenylpicrylhydrazyl radical (DPPH) [11–13], a procedure based on inhibition of the production of the ABTS (2,2a-azinobis(3-ethylbenzthiazoline)-6-sulfonic acid) radical cation [14], the ferric reducing antioxidant power (FRAP) method [15,16], based on the reduction of a Fe^{3+} complex of tripyridyltriazine, the latter monitored by means of spectrophotometry, etc. Unfortunately, the spectrophotometric and luminescence assays used in the majority of tests have limits raised by color and turbidity of real samples. A separate group of antioxidant tests is based on investigation of redox properties of the samples (compounds) under study in most cases by means of electrochemistry [17].

The major disadvantage of the known methods for accessing of total antioxidant activity is that the majority of the used oxidizing compounds do not present in human body. This makes doubtful any correlation between their reactivity with potential antioxidants and, hence, the usefulness of the latter.

Hydrogen oxides are involved in biochemical reaction pathways. Strategies have been developed for measuring the antioxidant activity as the ability to scavenge free radicals generated in aqueous and lipophilic phases. However, the lifetime of the natural free radicals is extremely low, so their concentration in biological liquids is almost negligible. Hydrogen peroxide is much more stable than hydroxide radicals. It can be recognized as a natural oxidant, since it is detected in blood [18]. Hydrogen peroxide is definitely more powerful oxidant than oxygen; the difference in the correspondent electrochemical potentials exceeds 1 V

[19]. Moreover, thermodynamically hydrogen peroxide in neutral media is similarly powerful oxidant as hydroxide radical [19]. On the other hand, H_2O_2 is less reactive compared to free radicals providing the latter also to be decomposed by the compounds able to consume hydrogen peroxide.

Hydrogen peroxide scavenging measured by photometric or fluorometric assays has been used in combination with the accepted methods for evaluation of antioxidant activity (lipid peroxidation, ABTS, DPPH tests) [20–22]. A positive correlation has been reported [21].

Another disadvantage of the accepted assays for evaluation of antioxidant activity *in vitro* is the detection of the final product rather than the kinetics of its accumulation/consumption. The choice, however, was dictated by the analytical protocols used. On the contrary, kinetic approach is much more informative, which would obviously allow better discrimination of potential antioxidants.

We propose the new method for estimation of total antioxidant activity based on kinetics of hydrogen peroxide scavenging in the presence of potential antioxidants. A choice of hydrogen peroxide as an oxidant is provided by the knowledge that H_2O_2 is the most powerful oxidant presented in human body (see above).

The proposed approach for estimation of total antioxidant activity involves application of electrochemical sensor for hydrogen peroxide for measurement of H_2O_2 (as oxidizing compound) added to food samples. Starting from 1994 our team pioneered the use of electrochemically deposited films of Prussian Blue (ferric hexacyanoferrate) for development of chemical and biological sensors with amperometric detection [23–25]. During the last 15 years the fundamental research work has been carried out in order to achieve the most advantageous H_2O_2 transducer. Compared to the most widely used platinum, Prussian Blue modified electrodes are characterized by: (i) three orders of magnitude higher electrochemical rate constant in both H_2O_2 reduction and oxidation and (ii) three orders of magnitude improved selectivity in hydrogen peroxide reduction [26]. The electrochemical rate constant is proportional to sensitivity if the latter is limited by the electrochemical reaction rather than diffusion. Even in case of ultramicroelectrodes operating in improved diffusion conditions, the Prussian Blue modified ones provide at least the 100 times improved responses compared to platinum.

Even in case of conventional electrodes the improved electrocatalytic properties of Prussian Blue allow low-potential H_2O_2 detection with advantageous analytical characteristics: (i) the sensitivity of 1–2 A M^{-1} cm^{-2}, which is at the upper limiting sensitivity level [27], (ii) the detection limit of 1×10^{-7} M in FIA mode, and (iii) linear calibration range starting from the detection limit and extending over more than three orders of magnitude of hydrogen peroxide concentration [24–26]. Moreover, on the basis of Prussian Blue based nano-electrode arrays [28] the record electrochemical sensor has been elaborated [29].

In current study we propose to assess the antioxidant activity by evaluating the kinetic constants of H_2O_2 consumption. The approach is advantageous over existing systems because of both the use of natural oxidant and monitoring the kinetics of its scavenging, which obviously provides better screening of potential antioxidants. Antioxidant activity evaluated in course of the proposed method and a standard protocol of lipid peroxidation were found to be in a good agreement. However, in contrast to the latter the proposed approach is express, simple and cheap, which opens a wide area for it's use in screening of food products.

2. Experimental

Experiments were carried out with MilliQ water from a Millipore MilliQ system. All inorganic salts, and hydrogen peroxide (30% solution) were obtained at the highest purity from Reakhim (Moscow, Russia) and used as received. Perfluorosulfonated ionomer (Nafion analogue) was purchased from Plastpolymer (St. Petersburg, Russia) as 8% solution in iso-propanol.

Samples of juices and wines were bought in a local supermarket. Sublimated fresh juices of cranberry, carrot, sea-buckthorn, beet were kindly supported by LTD "Victoria" (Russia). Bergenia extract was produced by LTD "Provantsal" (Russia).

Lipid membrane samples were prepared by homogenization of rat cerebral cortex in 20 mM TRIS buffer, pH 7.4 with the ratio of tissue-buffer of 10. Then the homogenate was centrifuged ($3600 \times g$, 10 min, 4 °C) using Eppendorf (Germany) 5417R centrifuge. Protein concentration was determined according to Lowry method.

Peroxidation of cerebral cortex was carried out at 37 °C upon continuous stirring by injection of 50 μM of hydrogen peroxide. Products of lipid peroxidation were detected according to their reaction with 2-thiobarbituric acid [30–32] monitoring optical density at 532 nm with spectrophotometer Cintra 10e GBS (UK).

Prussian Blue based screen-printed sensors for hydrogen peroxide were obtained from "Rusens" LTD (Moscow, Russia). Sensor contained carbon auxiliary electrode encircling working disk (Ø2 mm), the latter modified with Prussian Blue, and Ag|AgCl reference. Analytical characteristics in H_2O_2 detection were: sensitivity 0.4–0.5 A M cm^{-2}, detection limit 1×10^{-7} M. For stabilization of H_2O_2 sensor a 2 μl drop of 1% iso-propanol solution of perfluorosulfonated ionomer was applied to working electrode surface and dried at a room temperature.

Monitoring of hydrogen peroxide with screen-printed sensors has been carried out upon stirring using PalmSens electrochemical interface interfaced to an IBM PC. Operational stability of Prussian Blue modified electrodes was investigated in flow-through system consisted of a Cole Parmer (Vernon Hills, IL) peristaltic pump (7519-10), homemade flow-through wall-jet cell with 0.5-mm nozzle positioned at 1–2-mm distance from the surface of disk electrode. Amperometric batch measurements were performed in stirred solutions of food samples (20 ml) with applied potential of 0 mV *vs* Ag|AgCl. Once a stable baseline current was reached (within 5–10 min), an aliquot of H_2O_2 sample solution ($2–5 \times 10^{-5}$ M) was injected. After achieving of maximum response (within 10 s) the kinetics of current decay was investigated. A supporting electrolyte used was 0.025 M phosphate buffer, pH 6.0, containing 0.1 M KCl.

Concentration of hydrogen peroxide in stock solutions was controlled by optical density at 230 nm with an LKB-Ultraspec UII spectrophotometer (Broma, Sweden).

3. Results and discussion

3.1. Operational stability of Prussian Blue based hydrogen peroxide sensors

Prussian Blue films onto the electrode surfaces are stable in cyclic voltammetric conditions. However, operational stability of Prussian Blue modified electrodes is affected by both (i) thermodynamic instability of the reduced form of the electrocatalysis, Prussian White, and (ii) an ability of the hydroxyl anions, the product of H_2O_2 reduction, to solubilize the inorganic polycrystal [26].

To investigate operational stability of H_2O_2 sensors a continuous flow of hydrogen peroxide in wall-jet cell was chosen. Despite for investigation of kinetics of H_2O_2 consumption the batch regime is more convenient, the harder conditions providing faster inactivation of the electrocatalyst ensures a validity of the kinetic study in batch regime.

Operational stability of Prussian Blue based hydrogen peroxide sensors was investigated under continuous flow of 0.1 mM of H_2O_2

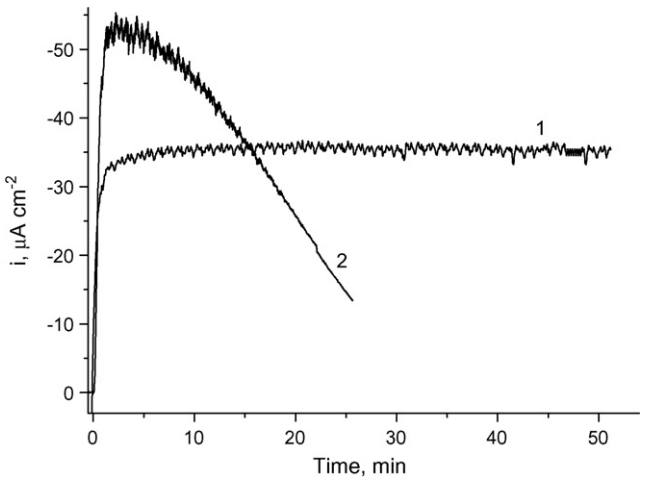

Fig. 1. Operational stability of Prussian Blue modified electrodes under continuous flow (0.7 ml min^{-1}) of 0.1 mM H_2O_2 in wall-jet cell: (1) Prussian Blue covered with 1% perfluorosulfonated ionomer and (2) naked Prussian Blue.

in wall-jet cell. A seen in Fig. 1, the naked Prussian Blue based sensor in such hard conditions maintains its maximum current only within 3–4 min. Afterwards a rather sharp decay occurs, and after 20 min the sensor loses 50% of its initial sensitivity. In order to stabilize the sensor a drop of perfluorosulfonated ionomer solution (1% in isopropanol) was applied onto the top surface of Prussian Blue film. Operational stability of the sensor stabilized with polymer film was investigated in similar conditions. As seen in Fig. 1, despite the 1.5 times lower sensitivity, the resulting sensor displayed a completely stable response in such hard conditions for more, than 50 min. Taking into account, that flow-through wall-jet regime provides faster inactivation of the electrocatalyst, we conclude, that such operational stability is enough for investigation of kinetics of hydrogen peroxide consumption is batch regime.

3.2. Kinetics of hydrogen peroxide consumption

Electrochemical sensor for hydrogen peroxide with high sensitivity and high operational stability allowed to monitor kinetics of hydrogen peroxide consumption (H_2O_2 scavenging activity) in turbid and colored samples which was previously impossible using photometric or fluorometric assays.

Kinetics of hydrogen peroxide consumption monitored by means of perfluorosulfonated ionomer stabilized Prussian Blue based sensors was investigated in batch regime under stirring. After injection of hydrogen peroxide to a final concentration of $2–5 \times 10^{-5}$ M in buffer solution a stable baseline was achieved (data not shown). This is not surprising taking into account excellent operational stability of the stabilized Prussian Blue based sensors in much harder conditions—continuous flow of 0.1 mM of H_2O_2 (see above).

Since easily oxidizable compounds are able to generate anodic (positive current) response of the Prussian Blue based sensors, the kinetics of H_2O_2 consumption was investigated as follows. First, the sensor was immersed in food sample under study, and operated until a stable baseline achieved. Afterwards, hydrogen peroxide was injected in the sample to a final concentration of $2–5 \times 10^{-5}$ M. Since the sensor is completely stable under such conditions, the decay of the current response is only due to H_2O_2 consumption. An ability of food samples to inactivate the electrocatalyst was independently checked controlling sensor sensitivity in buffer solutions before and after exposing.

Fig. 2 displays the usual continuous monitoring of hydrogen peroxide after its injection using the Prussian Blue based sensor. A seen, some food products do not show an ability to decompose hydrogen peroxide. In case of cranberry juice sublimate after injection of hydrogen peroxide a stable cathodic current is observed. However, beet juice displayed high hydrogen peroxide scavenging activity. After injection of hydrogen peroxide, the current has sharply increased, and then exponentially decreased (Fig. 2a). We have found that hydrogen peroxide is unstable in the majority of food samples: dry red and white grape wines, grape, apple, grapefruit, orange juices, food additives (sublimated sea-buckthorn, bergenia, beet juices).

Current decay in chronoamperograms of H_2O_2 sensors in the presence of food samples can be for simplicity assumed to obey pseudo-first order kinetics. Indeed, in some cases treatment of the decay in semi-logarithmic plots gives perfect linearization (Fig. 2b). For samples, which do not display a straight line in semi-logarithmic plots in the whole time scale, an initial slope has been taken for consideration. From the slope in semi-logarithmic plots the kinetic constant k of hydrogen peroxide elimination is determined (the example in Fig. 2b gives $k \approx 2 \times 10^{-3}$ s^{-1}).

We propose to use the kinetic constant of hydrogen peroxide elimination as a relative indicator of total antioxidant activity. Obviously, the higher the kinetic constant is, the more powerful is the antioxidant. The kinetic constants of hydrogen peroxide elimination have been found to be quite different in various food samples (Table 1). As expected, freshly squeezed grapefruit juice is more powerful antioxidant than the juice commercially available. Orange juices from different suppliers display significant differ-

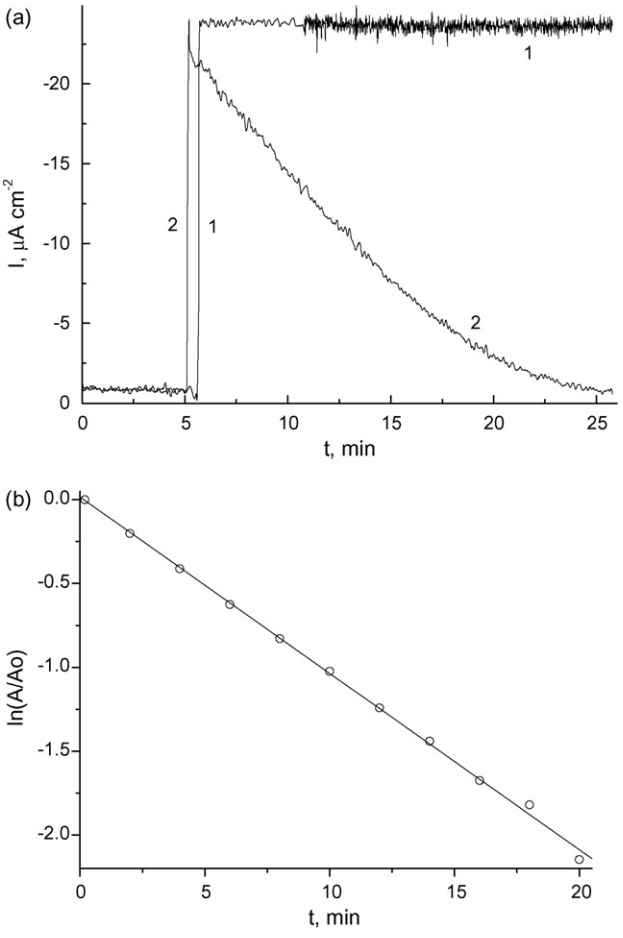

Fig. 2. (a) Response of the Prussian Blue based hydrogen peroxide sensor after addition of 5×10^{-5} M of H_2O_2 in 0.1 M phosphate buffer, pH 6.0 phosphate buffer containing sublimates of cranberry (1) and beet juice (2); (b) relative (to peak current) current decay in semi-logarithmic plots.

Table 1
Antioxidant activity of different food samples.

Sample	k ($\times 10^3$ s^{-1})
Grapefruit juice, freshly prepared	4.0 ± 0.3
Grapefruit juice, Rich (Russia)	2.0 ± 0.3
Orange juice, Rich (Russia)	1.2 ± 0.3
Orange juice, Dobryi (Russia)	0.4 ± 0.1
White dry wine "Baron de Valls" (France)	1.8 ± 0.3
Red dry wine "La Bifora Rosso" (Italy)	1.0 ± 0.3
White dry wine "Tsinandali" (Georgia)	0.08± 0.01
Bergenia juice sublimate	5.0 ± 0.5
Sea-buckthorn juice sublimate	2.2 ± 0.3
Beet juice sublimate	2.1 ± 0.4
Cranberry juice sublimate	$<1 \times 10^{-5}$
Carrot juice sublimate	$<1 \times 10^{-5}$

ence in antioxidant activity. Wine samples display sufficiently high antioxidant power, except for 'Tsinandali' wine. Solutions of juice sublimate display as the highest antioxidant activity (bergenia), as the absence of an ability to decompose hydrogen peroxide (cranberry). The significant variation in kinetic constants of H_2O_2 elimination in food samples points to its potential use as a relative indicator of antioxidant activity.

3.3. Validation of the kinetic approach for accessing of antioxidant activity

Certainly, any approach for accessing of antioxidant activity cannot be accepted without correlation with the direct protocol based on lipid peroxidation. Since the highest variation in kinetic constant of H_2O_2 elimination was found for sublimates of juices (Table 1), these particular food additives were taken for validation of the proposed kinetic approach.

As seen in Fig. 3, optical density at 532 nm in the presence of juice sublimates in incubation mixture was always lower than in control series. The lower optical density at the certain time indicates the higher antioxidant activity. The total antioxidant activity of juice sublimates accessed by the direct method can be presented as a row:

bergenia ≈ cranberry > beet > sea-buckthorn > carrot

Comparing this row with the results of proposed kinetic approach (Table 1), we conclude, that except for cranberry juice sublimate, both protocols give similar relative antioxidant activity. The difference in antioxidant activity of cranberry can be explained considering different mechanisms of inhibition of lipid peroxidation. Indeed, the latter can be inhibited by both a decrease of peroxidation reaction rate, as well as by a decrease of oxidant penetration in lipid phase. Cranberry juice sublimate having a minor activity in peroxide elimination, can affect transport properties of the oxidant. Indeed, the antimicrobial effect of cranberry juice with one of the mechanisms affecting lipid membranes is known [33,34].

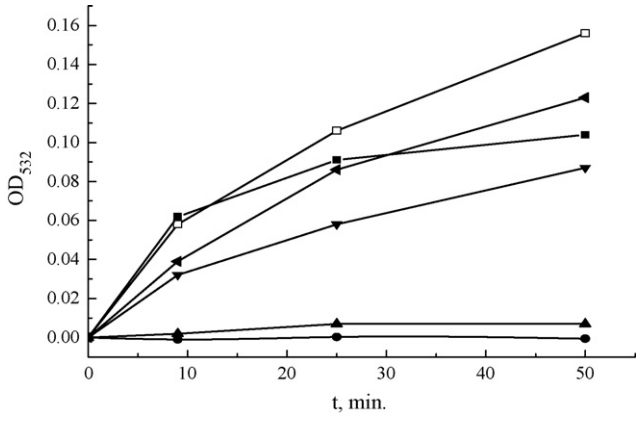

Fig. 3. Peroxidation kinetics of cerebral cortex homogenate (□ – control) and in the presence of juice sublimates (0.1 mg/ml): ◄ – carrot; ■ – sea-buckthorn; ▼ – beet; ▲ – cranberry; ● – bergenia; oxidation by 50 μM H_2O_2.

Hence, the kinetic approach for accessing of total antioxidant activity based on hydrogen peroxide scavenging is correlated with the standard direct method based on lipid peroxidation.

4. Conclusion

The proposed kinetic approach for accessing of total antioxidant activity shows positive correlation with the standard protocol based on lipid peroxidation, which confirms the possibility for its use for express screening of potential antioxidants. The use of natural oxidant (hydrogen peroxide) for this aim is obviously advantageous.

The proposed approach is based on kinetics of oxidant scavenging, rather than on the detection of the final products, which is obviously much more informative. We believe that monitoring of free radicals scavenging would also improve the accepted antioxidant activity tests.

ABSTRACT

In this work it is explained, by the first time, the application of programs SQUAD and HYPNMR to refine equilibrium constant values through the fit of electrophoretic mobilities determined by capillary zone electrophoresis experiments, due to the mathematical isomorphism of UV–vis absorptivity coefficients, NMR chemical shifts and electrophoretic mobilities as a function of pH. Then, the pK_a values of tenoxicam in H_2O/DMSO 1:4 (v/v) have been obtained from ^{1}H NMR chemical shifts, as well as of oxicams in aqueous solution from electrophoretic mobilities determined by CZE, at 25 °C. These values are in very good agreement with those reported by spectrophotometric and potentiometric measurements.

1. Introduction

Capillary electrophoresis technique has been in development over the last three decades, it has been widely used for compound mixture resolution. Comparing with other methods of separation, capillary electrophoresis offers high resolution, is convenient for aqueous solutions, employs small volumes and needs shorter times for analysis [1–3]. In contrast with the extensive use of capillary zone electrophoresis (CZE) as a separation method, few reports have been published on its application to obtain acid dissociation constants. Although some clear advantages can be identified over other methods, for instance: non-high purity samples can be treated, concentrations as low as 10^{-5} M might be employed, to increase the selectivity it is possible to add organic modifiers to the aqueous solutions [1–6].

One of the main advantages of CZE is that some level of impurities do not interfere with the pK_a value determination, because it depends only on the migration time of the peak of the substance under study [7,8].

Non-steroidal anti-inflammatory drugs (NSAIDs) are a well-known class of drugs that present anti-inflammatory, analgesic and antipyretic properties. In general, they are used to reduce pain in different arthritis and other post-operative conditions as well as chemopreventive and chemosuppresive effects in some kind of cancers such as colon cancer, lung cancer, breast cancer, etc. A group of NSAID, the oxicams (Fig. 1), is particularly important because they reduce the side effects, due to prostaglandins inhibitions, such as gastrointestinal toxicity. Oxicams drugs were designed under the isosteric replacement paradigm; i.e. groups or molecular fragments are replaced for other molecular moieties with similar stereo-electronic features looking for pharmacological activity enhancement [9]. These drugs are also important because their great therapeutic potential as well as their chemical properties, which result in dynamic features extremely sensitive to the micro environment [10].

It is well known that acid–base character is very important in pharmacology, the physicochemical characterization of compounds that display biological activity includes the determination of their acidity constants [11].

In this contribution we demonstrate that the behavior of absorbance, chemical shifts and effective mobility of a Brønsted acid–base system, as a function of pH, is mathematically equivalent

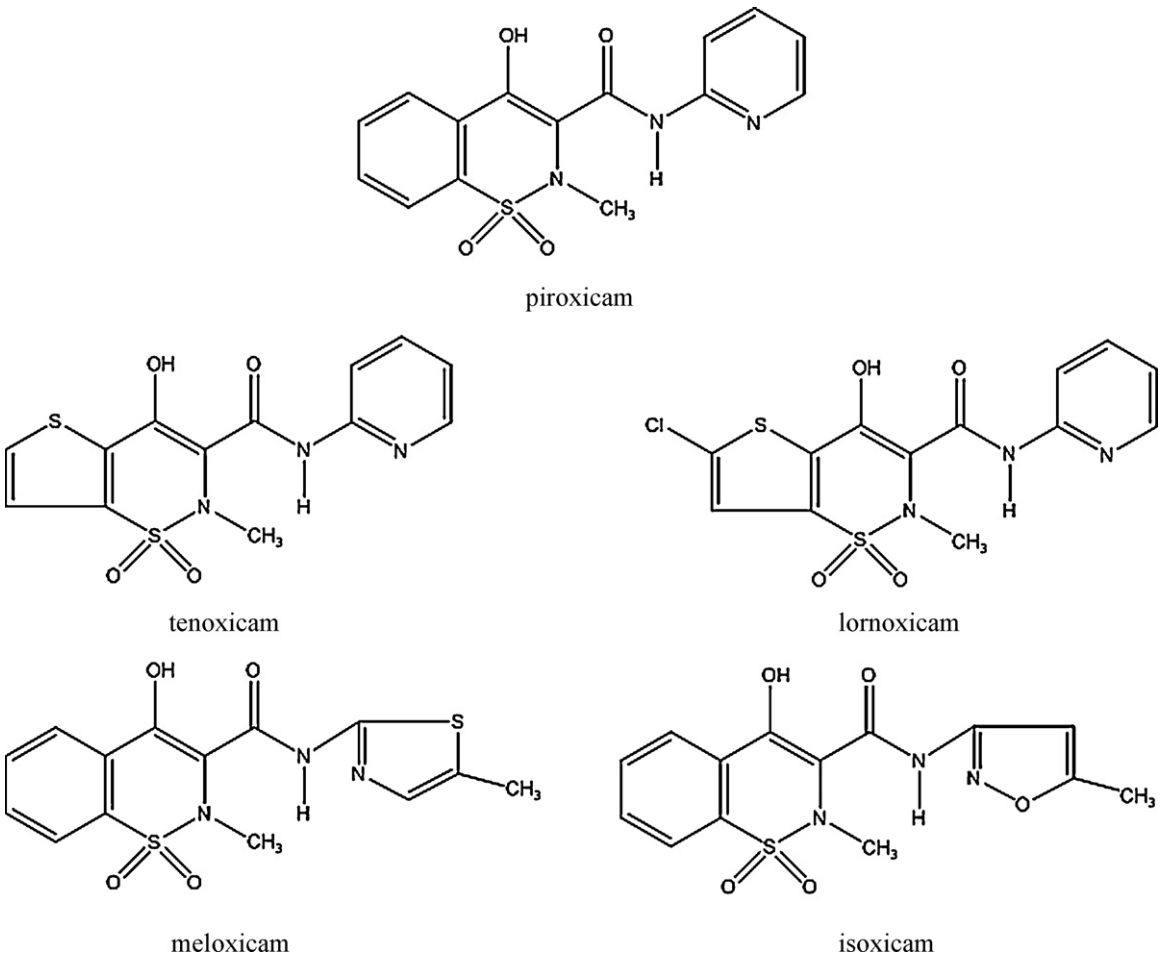

Fig. 1. Chemical structure for all the oxicams included in this study.

for the three properties. Then we report the use of SQUAD [12,13] and HYPNMR [14,15] (developed to refine equilibrium constants through the input of absorbances and NMR chemical shifts, respectively) to refine equilibrium constants through chemical shifts and effective mobility values, without any modification to the programs. This work shows that, as long as the measured property gives similar curves as a function of the pH, we can introduce the experimental data to any of these programs. We apply these programs to obtain the acid dissociation constants of tenoxicam in H_2O/DMSO 1:4 (v/v) from ^1H NMR chemical shifts. On the other hand, the programs are also employed to refine the pK_a values of five oxicams, from electrophotetic mobilities determined by capillary zone electrophoresis data at 25 °C with aqueous phosphates buffers. The pK_a refined by this way are comparable to those calculated from spectrophotometric and potentiometric measurements [9,16].

2. Theory

2.1. Properties with a linear dependence with concentration or species fractions

There are several physicochemical properties (or responses to a perturbation, R) that, in some controlled conditions, have a linear behavior with concentrations of the species that produce them. This linearity may be described by Eq. (1).

$$R = R_1 + R_2 + \cdots + R_n = k_1C_1 + k_2C_2 + \cdots + k_nC_n \quad (1)$$

where R is the overall response of the system, R_i, C_i and k_i are the contribution to the overall response, the concentration and the response factor (independent of the species concentrations and responses) of the i-esim species, respectively.

If the species are related through fast chemical equilibria or kinetic exchange, the overall response may be understood as a weighed mean of the contribution of all the present species, with weights equal to some kind of fractions of the species.

For example, if the species $L^{z_L}, HL^{(z_L+1)}, \ldots, H_jL^{(z_L+j)}, \ldots, H_nL^{(z_L+n)}$ are related by the global formation equilibria, defined by Eq. (2):

$$L^{z_L} + jH^+ \rightleftarrows H_jL^{(z_L+j)} \quad \text{with} \quad \beta_j \quad \text{where} \quad j \in \{1, 2, \ldots, n\} \quad (2)$$

It is possible to calculate the molar species fractions [17], given by

$$f_o = f_L \equiv \frac{[L^{z_L}]}{[L']} = \left(\frac{1}{1 + \beta_1[H^+] + \beta_2[H^+]^2 + \cdots + \beta_j[H^+]^j + \cdots + \beta_n[H^+]^n} \right) \quad \text{and} \quad f_j = f_{H_jL} \equiv \frac{\left[H_jL^{(z_L+j)}\right]}{[L']} = f_o\beta_j[H^+]^j \quad (3)$$

where $[L']$ represents the sum of the concentrations of the $(n+1)$ species of the component L in the system. The fractions of the species given by Eq. (3) may be the weights in the weighed mean of some properties, as it is explained in de following sections.

2.2. Absorbance in spectrophotometry

In the common way, spectrophotometry requires the accomplishment of the ideal Beer's and additive laws for the absorbance of the existent chemical species. Then, the absorbance of the system, at a given wavelength ($A^{(\lambda)}$) and optic path length (ℓ), follows Eq. (4) [18]:

$$\begin{aligned} A^{(\lambda)} &= A_L^{(\lambda)} + A_{HL}^{(\lambda)} + \cdots + A_{H_jL}^{(\lambda)} + \cdots + A_{H_nL}^{(\lambda)} \\ &= \epsilon_L^{(\lambda)}\ell[L^{z_L}] + \epsilon_{HL}^{(\lambda)}\ell[HL^{(z_L+1)}] + \cdots + \epsilon_{H_jL}^{(\lambda)}\ell[H_jL^{(z_L+j)}] + \cdots + \epsilon_{H_nL}^{(\lambda)}\ell[H_nL^{(z_L+n)}] \\ &= \epsilon_L^{(\lambda)}\ell f_L[L'] + \epsilon_{HL}^{(\lambda)}\ell f_{HL}[L'] + \cdots + \epsilon_{H_jL}^{(\lambda)}\ell f_{H_jL}[L'] + \cdots + \epsilon_{H_nL}^{(\lambda)}\ell f_{H_nL}[L'] \\ &= (\epsilon_L^{(\lambda)}f_L + \epsilon_{HL}^{(\lambda)}f_{HL} + \cdots + \epsilon_{H_jL}^{(\lambda)}f_{H_jL} + \cdots + \epsilon_{H_nL}^{(\lambda)}f_{H_nL})\ell[L'] = \epsilon_{L'}\ell[L'] \end{aligned} \tag{4}$$

Thus, Eq. (4) demonstrates that absorbance or molar absorptivity coefficient of L' may be written as the weighed mean through molar fractions of all species in the system.

2.3. Chemical shifts in NMR with fast kinetic chemical exchange

In NMR, when a fast chemical exchange of the H^+ (or OH^-) is present in the equilibria (Eq. (2)), the chemical shifts of the same nuclei (N_i, different to acids H nuclei) in L' show also a linear behavior given by Eq. (5) [14]

$$N_i\delta_{L'} = N_i\delta_L f_L + N_i\delta_{HL}f_{HL} + \cdots + N_i\delta_{H_jL}f_{H_jL} + \cdots + N_i\delta_{H_nL}f_{H_nL} \tag{5}$$

because the chemical shifts are the weighed mean through the relative abundance of species, due to the nuclei respond to the mean chemical environment surrounding them.

2.4. Equivalent conductivity and electrophoretic mobility

The electrophoretic mobility (u_{H_jL}) of an electrically charged species ($L^{z_{H_jL}}$) is given by Eq. (6) [19]:

$$z_{H_jL}\lambda_{H_jL} = Fu_{H_jL} \tag{6}$$

where z_{H_jL} is the electric charge of the species $H_jL^{z_{H_jL}}$, λ_{H_jL} is its equivalent conductivity and F is the constant of Faraday.

Then, for a set of species defined by equilibria of Eq. (2) faster than its motion into an electric field, electrophoretic mobility follows Eq. (7) [20]:

$$u_{L'} = u_L f_L + u_{HL}f_{HL} + \cdots + u_{H_jL}f_{H_jL} + \cdots + u_{H_nL}f_{H_nL} \tag{7}$$

and introducing Eq. (6) in Eq. (7) it can be demonstrated that:

$$u_{L'} = \frac{z_L\lambda_L}{F}f_L + \frac{z_{HL}\lambda_{HL}}{F}f_{HL} + \cdots + \frac{z_{H_jL}\lambda_{H_jL}}{F}f_{H_jL} + \cdots + \frac{z_{H_nL}\lambda_{H_nL}}{F}f_{H_nL} \tag{8}$$

Eq. (7) shows that electrophoretic mobility of L' is a weighed mean of electrophotetic mobilities of species, with weights equal to the molar species fractions.

Even more, if the equivalent conductivities of each one of species are nearly equal between them,

$$\frac{\lambda_L}{F} \approx \frac{\lambda_{HL}}{F} \approx \cdots \approx \frac{\lambda_{H_jL}}{F} \approx \cdots \approx \frac{\lambda_{H_nL}}{F} = \frac{\lambda}{F} \tag{9}$$

Eq. (8) accepts the approximation given in Eq. (10).

$$u_{L'} \approx (z_L f_L + z_{HL}f_{HL} + \cdots + z_{H_jL}f_{H_jL} + \cdots + z_{H_nL}f_{H_nL})\frac{\lambda}{F} \approx \bar{z}\frac{\lambda}{F} \tag{10}$$

Eq. (10) presents electrophotetic mobility of L' as a weighed mean with weights equal to the electric charge fractions of species and also shows that it is, in principle, directly proportional to mean number of electric charge ($\bar{z}$).

3. Experimental

3.1. NMR experiments for tenoxicam

3.1.1. Instrumentation

All the spectra were obtained on a Bruker AVANCE DMX 500 NMR spectrometer, using a 5 mm ID *z*-gradient probe.

3.1.2. Reagents

DMSO-d_6 (Sigma–Aldrich), D_2O (Sigma–Aldrich), IUPAC pH 4.000 and 7.000 buffers (Radiometer), 1 M HCl and 1 M NaOH aqueous solutions (Titrisol, Merck).

3.1.3. Solutions

50 mg of tenoxicam were solved in 1 mL of D_2O/DMSO-d_6 1:4 (v/v), due to the low solubility of tenoxicam in water. To this solution aliquots of HCl or NaOH solutions were added to change pH of the solutions, as required.

3.1.4. pH measurements

pH values were measured in accord with the procedure described by Mukerjee and Ostrow [21], with a radiometer potentiometer PHM210 equipped with a Ag/AgCl/glass combined microelectrode PHC3359-8.

3.1.5. Spectroscopic procedures

One-dimensional ^1H and ^{13}C NMR spectra, DEPT (135° and 90°), *z*-gradient-HSQC and gradient-HMBC ^1H–^{13}C correlation spectra, were acquired for unequivocal assignment. The chemical shifts of ^1H or ^{13}C were related to tetramethylsilane (TMS) or DMSO-d_6, respectively as internal standards.

3.2. CZE experiments for oxicams

3.2.1. Instrumentation

Experiments were carried out using a P/ACE MDQ Beckman system with DAD, employing a fused silica capillary of 50 μm I.D. × 50.2 cm (effective length: 40 cm); the sample was injected under pressure for 10 s at 1.0 psi, a constant voltage of 20 kV was applied at 25 °C. For pH lower than 4 reverse polarity was employed. Acetone marker was used to take into consideration the electroosmotic flow (eof). The wavelength for the main channel of the UV detector were 245 nm, 255 nm, 260 nm, 250 nm and 240 nm, for piroxicam, tenoxicam, meloxicam, lornoxicam and isoxicam, respectively. The acetone marker and the oxicam under study were simultaneously monitored. The buffer pH was measured with a combined glass electrode connected to a MettlerToledo pH/Ion analyzer, after calibration with pH 4, 7 and 10 buffer solutions.

3.2.2. Conditioning of capillary

Prior sample injection, capillary was conditioned with 0.1 M NaOH solution for 5 min, then deionized water passed through for 5 more minutes, finally it was rinsed for 15 min with phosphates buffer solution of pH 7. Between consecutive runs, capillary was successively rinsed for 1 min with 0.1 M NaOH solution and water, buffer solution at the corresponding pH was then passed for 2 min. Capillary is stored full of deionized water.

3.2.3. Reagents

Piroxicam, tenoxicam and isoxicam were purchased from Sigma, Boehringer Ingelheim laboratories supply meloxican, lornoxicam was directly extracted from tablets (Bosporon, 8 mg), purchased from Tedec-Meiji Farma, S.A., NaH_2PO_4 and Na_2HPO_4 were used as supplied (99% of purity) by Fluka, H_3PO_4 (J.T. Baker)

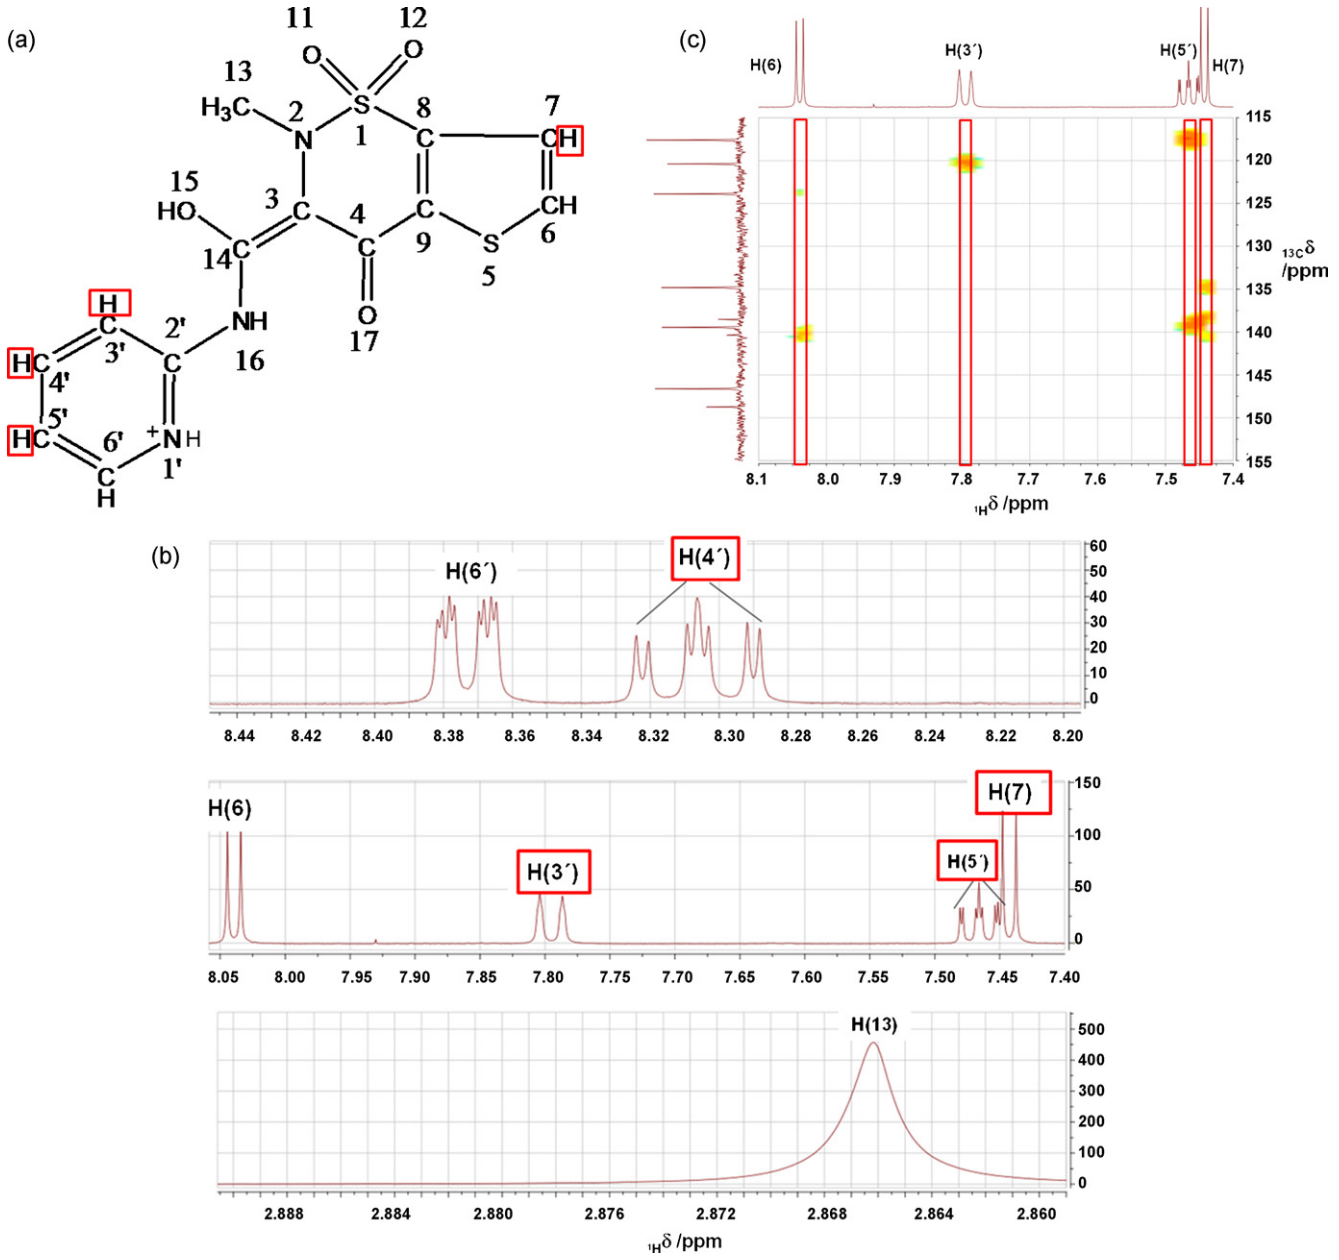

Fig. 2. (a) Developed formula of the fully protonated tenoxicam species (H_2Tenox^+), with numbering to each nucleus, or each set of nuclei, given elsewhere [22]. Hydrogen atoms in positions 3′, 4′, 5′ and 7 – H(3′), H(4′), H(5′) and H(7) – have been marked with a rectangle. (b) One-dimensional ^{1}H NMR spectrum for tenoxicam with the assignation of each nucleus given to each signal: pH < 1. (c) Partial two-dimensional gradient-HMBC spectrum for tenoxicam that permits to give the unequivocal assignment of the nuclei to the structure: pH < 1.

was used without further purification (85.4%). Water was deionized using a MilliQ deionizer in order to obtain a resistivity of 18.2 MΩ cm.

3.2.4. Solutions

Phosphates buffer solutions 50 mM were made from H_3PO_4, $H_2PO_4^-$, HPO_4^{2-} and PO_4^{3-} 0.5 M stock solutions, adjusting to the required pH value with NaOH and HCl (0.1 M).

For all oxicams individual solutions were prepared by solving 5 mg of the drug in 0.5 mL of NaOH (0.1 M) adding deionized water up to a final volume of 10 mL, all the injected samples contained acetone (5% v/v) as electroosmotic flow marker.

3.2.5. Procedure

For all the oxicam solutions at every pH value a set of at least three runs was made. The effective electrophoretic mobilities ($u_{Ox'} = u_{eff}$) were computed as the difference between the oxicam apparent mobility (u_{app}) and the neutral marker mobility (u_{eof}), taking into account the total and effective capillary lengths (50.2 and 40.0 cm, respectively) as well as the applied voltage [2–4]. When inverse polarity voltage was applied, an effective length of 10.2 cm was considered. Each reported mobility is the mean over all the carried out for each pH. The equation used to determine u_{eff} from experimental electropherograms is the operating definition given by Eq. (11).

$$u_{eff} = u_{app} - u_{eof} = \frac{L_t L_d}{V}\left(\frac{1}{t_{Ox'}} - \frac{1}{t_{eof}}\right) \quad (11)$$

where L_t is the total length of the capillary, L_d is the effective length (from injection to detector), V is the applied voltage, $t_{Ox'}$ the migration time of the oxicam peak and t_{eof}

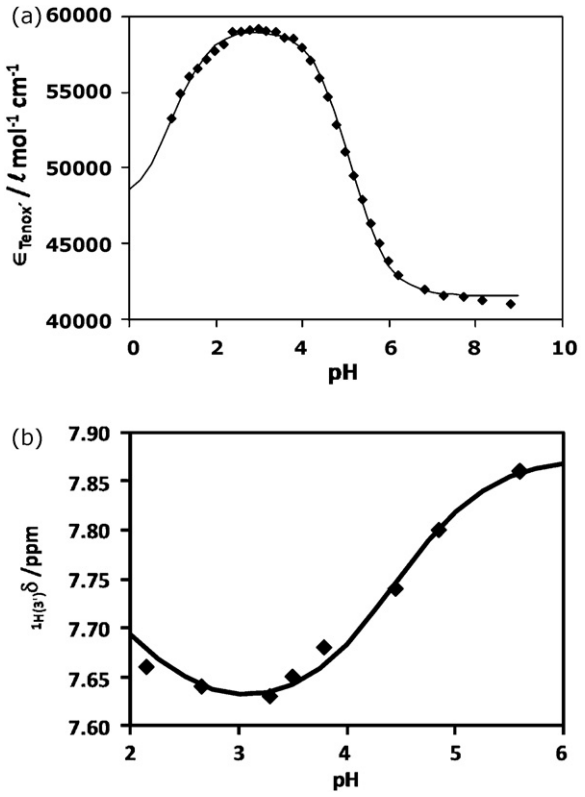

Fig. 3. (a) Mean molar absorptivity coefficients of tenoxicam (from 1.0×10^{-4} M in aqueous solutions) as a function of pH at 350 nm and 25 °C [23,24]. (b) ^{1}H(3′) chemical shifts of tenoxicam (from 0.09 M in H_2O/DMSO 1:4 (v/v) solutions) as a function of pH at 25 °C.

the time related to the migration due to the electroosmotic flow.

4. Results and discussion

4.1. Sigmoidal functions of absorbances and ^{1}H chemical shifts as a function of pH

Eqs. (4) and (5) indicate that absorbances and chemical shifts of a set of species related by the chemical equilibria given in Eq. (2), as functions of pH, should look very similar.

Given the chemical structure (Fig. 1), the oxicams studied here may present up to two pK_a values. In order to obtain these values for tenoxicam, its mean absorptivity coefficients or chemical shifts of any H nucleus (Fig. 2) may be plotted versus the solution pH (Fig. 3).

Fig. 3 clearly shows that the shape of this kind of functions is a superposition of sigmoid curves. The markers represent experimental results while solid lines the fitting achieved with SQUAD [12,13] or HYPNMR [14] programs, in agreement with Eqs. (4) (Fig. 3a) and (5) (Fig. 3b), and the refined values are presented in Table 1.

It is important to remember that the code of the program SQUAD, in FORTRAN, has been published by Legget [13] and is completely free for any one that could compile it. HYPNMR may be acquired from Protonic Software [15].

Fig. 3a shows the behavior of molar absorptivity coefficients (for a wavelength of 350 nm) of tenoxicam at different pH values. Experimental details are found elsewhere [23,24].

Fig. 3b shows the behavior of chemical shifts of ^{1}H(3′) nuclei (see Fig. 2) for 0.09 M tenoxicam mixtures in water 20%–DMSO 80% (H_2O/DMSO 1:4 (v/v)) at several pH values. Chemical shifts

* This parameter has been estimated from the approximation given by Eq. (10) and maintained constant during refining.

placed in the location of concentrations of the corresponding component present in the system. It is remarkable that the processing of this information can be achieved without any modification of the code of the programs. On the other hand, the standard deviation of the regression (σ_{reg}) in Table 1 for chemical shifts has been obtained by refining with SQUAD or HYPNMR the signals of the four protons marked as H(3′), H(4′), H(5′) and H(7) in Fig. 2.

The results given in Table 1 also demonstrate that both programs (SQUAD and HYPNMR) arrive practically to the same set of pK_a values and species absorption parameters, from a statistical point of view. It is due to the mathematical isomorphism of the last row of Eq. (4) with Eq. (5).

Then, the refining of equilibrium constants and species mobility values through experimental electrophoretic mobilities – determined by CZE experiments – should be well achieved with the aid of both programs (as it is demonstrated in the present paper for oxicams), due to the isomorphism of Eq. (7) with the last row of Eqs. (4) and (5).

4.2. Sigmoidal functions of electrophoretic mobilities with pH

Effective mobility of oxicams is plotted as a function of the solution pH in Fig. 4.

Jiménez et al. have indicated that for each inflexion point that occurs in the curve a pK_a value should be expected [3]. On the other hand, sigmoid curves with at least one or two inflexion points are expected in agreement with Eqs. (7), (8) and (10).

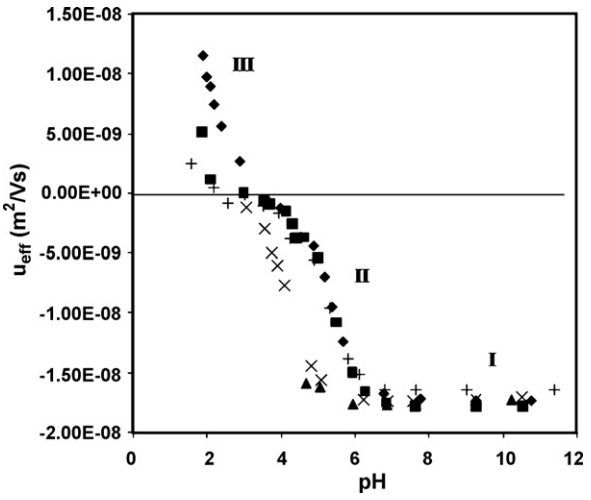

Fig. 4. Effective mobility (u_{eff}) vs. pH, piroxicam (♦), tenoxicam (■), lornoxicam (+), meloxicam (×) and isoxicam (▲).

Observing Fig. 4 we can notice two inflexion points, far enough to point out the presence of two pK_a values. Isoxicam is an exception because of its low solubility in acid solutions, however in a different solvent this possibility is not ruled out. In the high pH region (I) the mobility takes almost constant negative values, indicating the predominance of an anionic species. As the pH decreases a new species with zero electric charge is formed, increasing the system effective mobility and given place to the first inflexion point (region II). This increase continues until mobility reaches a value close to zero. Finally, a last very substantial change in mobility is observed in the acid pH (region III) for piroxicam, tenoxicam and lornoxicam, indicating the apparition of a mono-positive charged species and the second pK_a value for the system. Beyond this region a constant value for mobility is expected, which would indicate the positive ion predominance. The two inflexion points in pH confirm that piroxicam, tenoxicam and lornoxicam have two pK_a values, as it was previously pointed out from their chemical structure. Meloxicam and isoxicam have lost its electrophoretic signal below an acid pH value, relatively high (pH < 3.0 for meloxicam and pH < 4.6 for isoxicam).

Isoxicam and meloxicam are hardly soluble in acid solutions (pH < 5), limiting the experimental pK_a determination to one of the two values in water solutions. Because of the similar chemical structure of the studied oxicams, it is possible to propose a general set of acid–basic equilibria to rationalize the observed experimental behavior.

Considering the general case of an oxicam (HOx), which presents two dissociation equilibria, with constants K_{a1} and K_{a2} that involve one single positive, one zero and one single negative charged species:

$$H_2Ox^+ \rightleftarrows HOx + H^+ \quad K_{a1}$$

$$HOx \rightleftarrows Ox^- + H^+ \quad K_{a2}$$

as well as the global formation equilibria

$$Ox^- + H^+ \rightleftarrows HOx \quad \beta_1 = \frac{1}{K_{a2}}$$

$$Ox^- + 2H^+ \rightleftarrows H_2Ox^+ \quad \beta_2 = \frac{1}{(K_{a1}K_{a2})}$$

Then, Eq. (7) may be particularized to this set of species:

$$u_{eff} = u_{Ox'} = u_{Ox^-}f_{Ox^-} + u_{HOx}f_{HOx} + u_{H_2Ox^+}f_{H_2Ox^+}$$
$$= u_{Ox^-}f_{Ox^-} + u_{H_2Ox^+}f_{H_2Ox^+} \quad (12)$$

Glutarate ($Glut^{2-}$)	[28]	55.89 ± 0.84

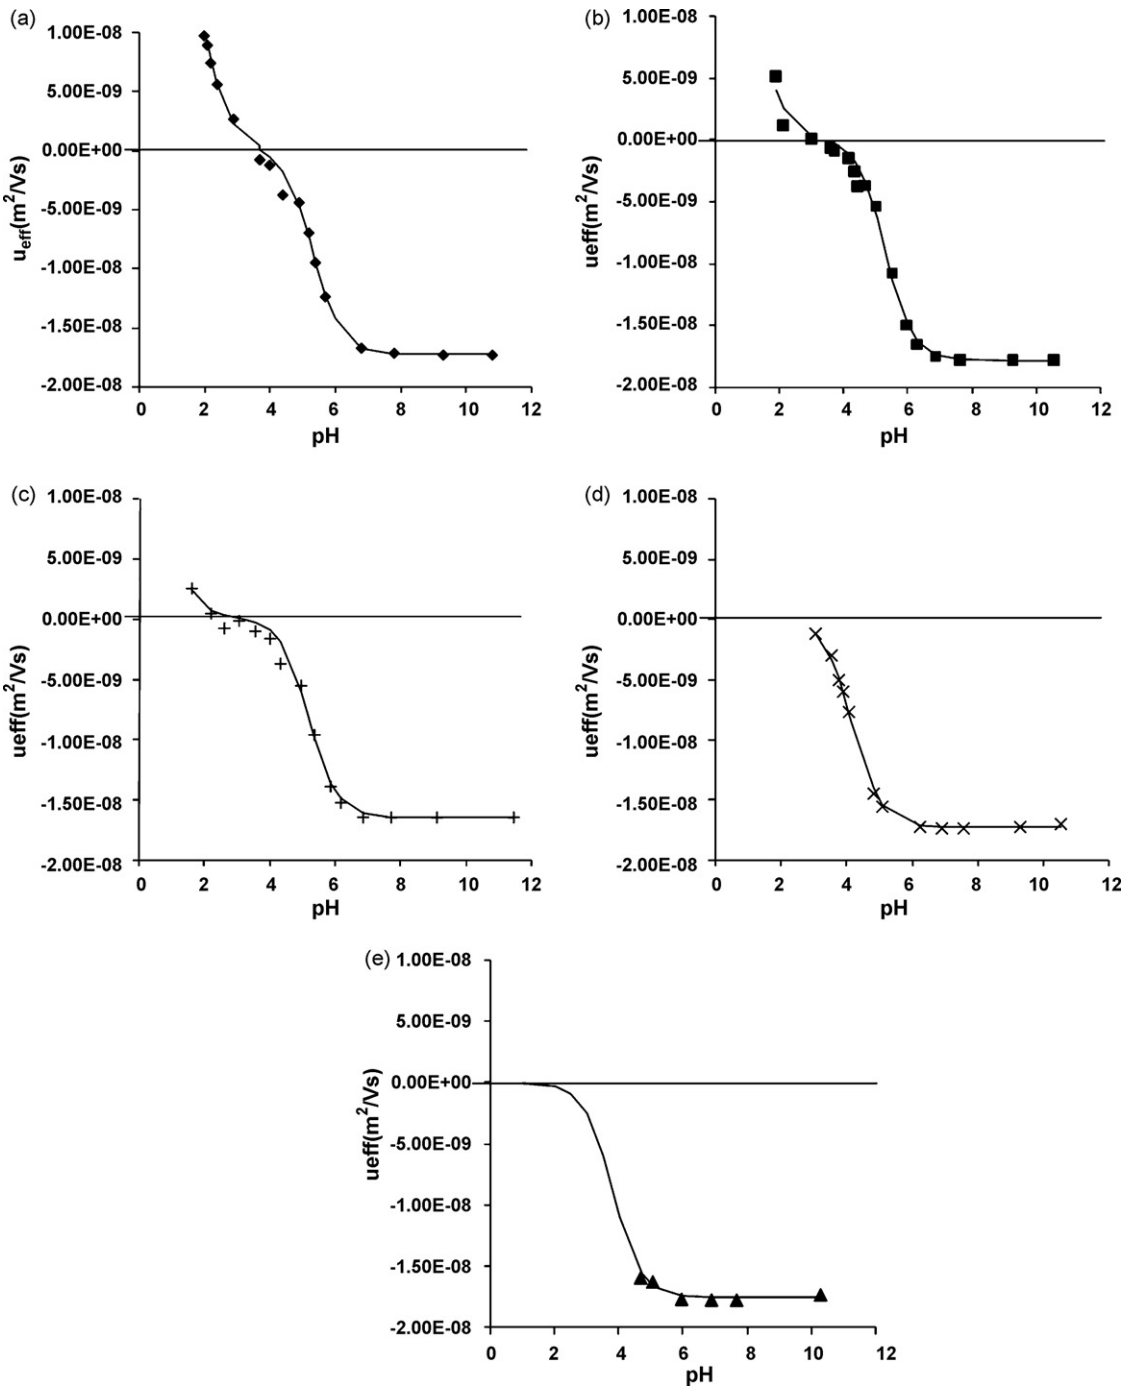

Fig. 5. Predicted behavior employing the chemical model (solid line) compared to the experimental mobility measured for (a) piroxicam, (b) tenoxicam, (c) lornoxicam, (d) meloxicam, (e) isoxicam.

The last member in Eq. (12) may be written due to the electrophoretic mobility of any zero charged species is equal to zero.

Introducing the set of Eqs. (3) into Eq. (12) it can be demonstrated that

$$u_{eff} = u_{Ox'} = \frac{u_{Ox^-} + \beta_2[H^+]^2 u_{H_2Ox^+}}{1 + \beta_1[H^+] + \beta_2[H^+]^2} \quad (13)$$

where u_{Ox^-} and $u_{H_2Ox^+}$ are the individual mobilities for the deprotonated and protonated species of the oxicam, respectively.

Employing Eq. (13) the proposed acid–base model may be used to fit the experimental effective mobilities as a function of pH. The global formation constants used in Eq. (13), given in Table 2, were refined by fitting the experimental data with SQUAD [12,13] or HYPNMR [14] programs. The effective mobilities calculated for the anionic species in the same refinement process are shown in Table 3. In all cases it was assumed that the effective mobility of the cationic species is equal to the corresponding absolute value of the anionic species, as it is assumed in Eq. (10). The experimental observations are well reproduced by the model, as it is shown in Fig. 5.

From the effective electrophoretic mobility of each species in Table 3 it is possible to obtain its equivalent conductivity, according to Eq. (6), as it can be seen in Table 4. A comparison of these

* The values obtained in this work and reported in this table are averages of those shown in Tables 1 and 2.

values with those of similar species reported in scientific literature [25–28]; demonstrate that they are plausible enough as it is shown in the same Table 4.

Even though the equivalent conductivity is an important parameter because it indicates the ion capacity by one equivalent for transporting charge, it is rarely reported in literature on electrophoresis methods.

Table 5 compiles literature pK_a experimental values reported by different analysis methods for oxicams in aqueous solution and solvent mixtures. A comparison of the pK_a reported values by Bernhard and Zimmermann [9] with those determined in the present work allows establishing that they are in good agreement for both pK_a values in the case of piroxicam, tenoxicam and lornoxicam, even in those cases where the solvent mixture is H_2O/EtOH [16].

For meloxicam and isoxicam Bernhard and Zimmermann [9] as well as Tsai et al. [16] have found only one pK_a value, using spectrophotometric and potentiometric methods, respectively. We also found only one pK_a value as it was discussed before and it is in agreement with both cited works.

The use of effective electrophoretic mobilities obtained from CZE has shown several advantages such as small analysis time, few quantity and low purity of the substance under study, acceptable precision and good agreement with other experimental methods. Moreover, from the mobility values it is straightforward calculating properties like charge and equivalent conductivity of ions. The charge of ions is particularly important in order to propose the number of species involved in the system.

5. Conclusions

In this work we have determined the pK_a values of tenoxicam in H_2O/DMSO 1:4 (v/v) from ^{1}H NMR chemical shifts. Moreover, by employing experimental data derived from CZE, the pK_a values have been refined for the drugs: piroxicam, tenoxicam, lornoxicam, and one pK_a for meloxicam and isoxicam in aqueous solutions at 25 °C, with the aid of the programs SQUAD and HYPNMR. The values obtained are in good agreement with those reported by spectrophotometric and potentiometric methods. In fact, even though the use of SQUAD and HYPNMR to obtain pK_a values from effective electrophoretic mobilities has been demonstrated for oxicams, it may be applied to other molecules [30,31].

Acknowledgments

The authors are indebted with UNAM through PAPIIT-IN218408 and PACIVE CONS111 projects as well as CONACyT through 46124 project, by partial financial support. The authors also grateful to A. Vacca and P. Gans the copy of program HYPNMR, Rafael García-Barrera for the samples of meloxicam, and J. Havel and A. Soto-Guerrero for helpful comments. DR-B and AR-H want to acknowledge CONACyT by scholarship to follow postgraduate studies and support for sabbatical leave on FESC-UNAM during 2009, respectively.

Flexible NH_3 sensor
Polypyrrole (PPy)
In situ self-assembly
Layer-by-layer (LBL)

ABSTRACT

Novel flexible NH_3 gas sensors were formed by the *in situ* self-assembly of polypyrrole (PPy) on plastic substrates. A negatively charged substrate was prepared by the formation of an organic monolayer (3-mercapto-1-propanesulfonic acid sodium salt—MPS) on a polyester (PET) substrate using a pair of comb-like Au electrodes. Two-cycle poly(4-styrenesulfonic acid) sodium salt/poly(allylamine hydrochloride) (PSS/PAH) bilayers (precursor layer) were then layer-by-layer (LBL) deposited on an MPS-modified substrate. Finally, a monolayer of PPy self-assembled *in situ* and PPy multilayer thin films self-assembled LBL *in situ* on a $(PSS/PAH)_2$/MPS/Au/Cr/PET substrate. The thin films were analyzed by atomic force microscopy (AFM). The effects of the precursor layer (PSS), the deposition time of the monolayer of PPy and the number of PPy multilayers on the gas sensing properties (response) and the flexibility of the sensors were investigated to optimize the fabrication of the film. Additionally, other sensing properties such as sensing linearity, reproducibility, response and recovery times, as well as cross-sensitivity effects were studied. The flexible NH_3 gas sensor exhibited a strong response that was comparable to or even greater than that of sensors that were fabricated on rigid substrate at room temperature.

1. Introduction

The fabrication of organic electronic devices on plastic substrates has attracted much interest recently, because of the proliferation of handheld portable consumer electronics. Plastic substrates have many attractive characteristics, such as biocompatibility, flexibility, lightness, shock resistance, softness and transparency [1]. A new trend towards the direct integration of sensors on flexible substrates has become evident. Flexible multisensor platforms that support temperature, humidity and gas detection will be manufactured at very low-cost and integrated into smart textiles or radio frequency identification (RFID) tags for logistics applications [2,3]. The development of sensors should be consistent with the future goal of the development of the completely plastic RFID tag, and extensible to the sensing of various gases. The main challenge is not only their manufacture, but also the stability of their mechanical, electrical and gas sensing properties.

Conducting polymers such as polythiophene, polypyrrole (PPy) and polyaniline have been intensively studied because of their remarkable mechanical and electrical properties, which can be exploited in actuators, sensors and electrochromic devices [4–6]. Among conducting polymers, PPy has attracted much particular interest because it is easily synthesized; it has relatively good environmental stability, and its surface charge characteristics can easily be modified by changing the dopant species in the material during synthesis.

Many approaches for fabricating PPy films have been proposed. They include chemical deposition by dip-coating [6,7], vapor deposition polymerization [8], UV-photopolymerization [9], deposition of Langmuir–Blodgett film [10], and electrochemical deposition [11,12]. The layer-by-layer (LBL) self-assembly of multilayer films based on sequential adsorptions of ionized polyelectrolytes and oppositely charged materials in aqueous solutions has been developed [13,14]. LBL self-assembly has many advantages over other methods, including simplicity, low-cost, low temperature of deposition, controllable thickness (from nanometers to micrometers) and the lack of any need for complex equipment. Therefore, the preparation of PPy multilayered films using LBL and *in situ* self-assembly has been studied [15–18]. Notably, the surfaces coated by PPy in these studies were deposited on rigid substrates, such as ceramics or SiO_2/Si. Recently, Ferrer-Anglada et al. [19] adopted the electrochemical method to prepare PPy and polyaniline on plastic substrate as a pH sensor. However, no attempt has been made to form a flexible NH_3 gas sensor based on PPy thin films by LBL *in situ* self-assembly. In this work, flexible NH_3 gas sensors were fabricated by the *in situ* self-assembly of monolayer of PPy and the LBL *in situ* self-assembly of PPy multilayer thin films on a flexible substrate (polyester film—PET). Poly(styrenesulfonic acid) sodium salt (PSS) assembled with poly(allylamine hydrochloride) (PAH) was a precursor layer before the PPy thin film was self-assembled *in situ*. The thin films were observed by atomic force microscopy (AFM). The effects of the precursor layer (PSS), the deposition time

of the monolayer of PPy and the number of PPy multilayers on the gas sensing properties (response) and the flexibility of the sensors were investigated. The other gas sensing properties, such as sensing linearity, reproducibility, response and recovery times, as well as cross-sensitivity effects were also investigated.

2. Experimental

2.1. Materials

3-Mercapto-1-propanesulfonic acid sodium salt (MPS), poly(allylamine hydrochloride) (PAH; Mw = 15,000), poly-(styrenesulfonic acid) sodium salt (PSS; Mw = 70,000), pyrrole monomer (98%), *p*-toluene sulfonic acid (*p*-TSA) and ferric chloride ($FeCl_3$) were obtained from Aldrich. All used deionized water (DIW) were prepared using a Milli-Q Millipore (Bedford, MA, USA) purification system, and the resistivity of water was above 18.0 MΩ/cm.

2.2. Preparation of substrates

The structure of the flexible NH_3 gas sensors was the same as that in our earlier study [20]. The interdigited gold electrodes (IDE) were made by sputtering first Cr (50 nm thick) and then Au (250 nm thick) at temperature from 120 to 160 °C. The gap between electrodes was 0.2 mm. The substrates were first immersed in a bath that contained a solution of H_2O_2/H_2SO_4 (1:2 volume ratio) for 3 min. The substrates were thoroughly rinsed with DIW after each step. This process made the substrates hydrophilic. The negatively charged MPS/Au surface was prepared by immersing the hydrophilic Au/Cr/PET substrate in 2.0 mM aqueous MPS for 24 h, rinsing it with DIW and then drying it at 80 °C. A cyclic PSS/PAH bilayer film architecture was produced by alternately depositing PAH (pH 4) and PSS (pH 1) aqueous solution onto the negatively charged MPS-modified substrate. For each layer produced, the immersion time was about 10 min and rinsing and drying followed each immersion. Therefore, a two-cycle PSS/PAH bilayers film was fabricated by repeating the above processes, yielding, a negatively charged $(PSS/PAH)_2$/MPS/Au/Cr/PET substrate.

2.3. Preparation of monolayer of PPy and PPy multilayered films

The active solution for use in PPy contained the oxidizing agent ($FeCl_3$) and *p*-TSA, and was later adjusted to pH 1 by adding HCl; then the pyrrole monomer was added. The optimal film of PPy was produced using a solution of 0.006 M $FeCl_3$, 0.026 M *p*-TSA and 0.02 M pyrrole, as described in the literature [16,18]. The active solution was stirred for 15 min. A monolayer PPy was self-assembled *in situ* as a thin film on the $(PSS/PAH)_2$/MPS/Au/Cr/PET substrate. The PPy multilayered thin films, composed of $(PPy/PSS)_n$, were deposited on the $(PSS/PAH)_2$/MPS/Au/Cr/PET substrate in the same manner as the PSS/PAH multilayered thin films, where *n* is the number of coated layers. The optimal deposition time in PPy active solution and PSS solution was 5 and 10 min, respectively. Table 1 presents the various compositions of interest. Fig. 1(a) schematically depicts an *in situ* self-assembly of a PPy monolayer film on PET substrate over time. Fig. 1(b) schematically depicts an LBL *in situ* self-assembly of a PPy/PSS multilayered thin film on a PET substrate. Fig. 2 presents the flexibility of the PPy multilayer thin film assembled on a PET substrate.

2.4. Instruments and analysis

The surface microstructure of the thin film that was coated on a PET substrate was investigated using a field emission scanning electron microscope (FE-SEM, JEOL, JSM 6335F) and an atomic force

microscope (AFM, Ben-Yuan, CSPM 4000) in tapping mode. The electrical and sensing characteristeristics were measured using a bench system at room temperature, as shown in Fig. 3. Each sensor was connected in series with a load resistor and a fixed 5 V was continuously supplied to the sensor circuit from a power supply (GW, PST-3202). The resistance of the sensor was determined from the voltage at the ends of the load resistor using a DAQ device (NI, USB-6218) in various concentrations of gas. The desired NH_3 gas concentrations, obtained by mixing a known volume of standard NH_3 gas (100,000 ppm) with N_2, were injected into the chamber. The cross-sensitivity experiment was performed by measuring the resistance of the sensor upon controlled concentration of 5, 200 and 1000 ppm for NO_2, CO and H_2 gases, respectively. The gas inside the chamber was uniformly distributed using a fan. After some time, the chamber was purged with air and the experiment was repeated for another cycles. All experiments were performed at room temperature, and the relative humidity was 53 ± 3 RH%. Flexibility experiments were performed in which the sensors were bent to various degrees as their responses were monitored as a function of the period of exposure to NH_3 gas. The bending angle was measured using a goniometer.

3. Results and discussion

3.1. Microstructure of surface

Fig. 4 presents the surface morphology of the *in situ* self-assembled of manolayer of PPy and PPy multilayered thin films on a modified PET substrate, analyzed using tapping-mode AFM. The size of each image is 5 μm × 5 μm. Table 2 presents the roughness and sphere size of various PPy thin films that were deposited on the modified PET substrate. Fig. 4(a)–(c) (Samples 1–3) presents the surface morphology of *in situ* self-assembled films of a monolayer of PPy fabricated on a modified PET substrate using various PSS concentrations. The PPy films all had typical granular patterns and the size of spheres ranged from 50 to 58 nm. Fig. 4(a) (Sample 1) indicates that less PPy *in situ* self-assembled as films on modified PET substrate than in Samples 2 and 3 (Fig. 4(b) and (a)) because the charge on the previously grown layer of Sample 1 was lower than that of Samples 2 and 3. Therefore, Sample 1 exhibited some imperfections in packing. Fig. 4(b) and (d)–(f) (Samples 2 and 4–6) presents the surface morphologies of the *in situ* self-assembled films of monolayers of PPy at various times. Clearly, the surface roughness and sphere size increased from 12.4 to 35.3 and from 50 to 78 nm, respectively, as the deposition time of the monolayer of PPy increased. The films of PPy were completely covered with fine grains after 5 min. Fig. 4(b), (g) and (h) (Samples 2, 7 and 8) presents the surface morphologies of LBL *in situ* self-assembled films of PPy multilayers for various numbers of PPy/PSS bilayers. The surface topography of the alternate PPy and PSS deposited LBL film reveals a similar structure is similar to that of monolayer of PPy films. The size of the spheres of PPy multilayered exceeded that of single-layered PPy thin films. The surface roughness and sphere size increased from 12.4 to 42.6 and from 50 to 82 nm, respectively, as the number of PPy/PSS bilayers increased. This difference between the surface morphologies of the *in situ* self-assembled monolayer of PPy and the PPy multilayered thin films may be associated with the different molecular orientations of PPy [16,17].

Table 2
Roughness and sphere size of various PPy thin films deposited on a modification of PET substrate.

Sample number	RMS (nm)	Size cluster circular (Φ) (nm)
1	10.6	58 ± 25
2	12.4	50 ± 22
3	11.7	53 ± 25
4	14.8	52 ± 30
5	20.1	68 ± 47
6	35.3	78 ± 42
7	38.0	74 ± 50
8	42.6	82 ± 60

3.2. Flexibility and response properties of monolayer of PPy and PPy multilayered thin films

Fig. 5 plots the effect of the concentration of PSS, the deposition time of the monolayer of PPy and the number of PPy/PPS bilayers in the *in situ* self-assembled PPy thin films on their flexibility characteristics. At each bending angle, the sensors were exposed to 50 ppm NH_3 gas. Table 3 presents the corresponding responses. The sensor response (S) was given by $S = (R_{gas} - R_{air})/R_{air}$ ($\Delta R/R_{air}$), where R_{gas} and R_{air} are the electrical resistances of the sensor in the tested gas and air, respectively.

3.2.1. Effect of concentration of PSS on flexibility and response of monolayer of PPy thin films

Fig. 5(a) plots the effect of the concentration of PSS on the flexibility characteristics of the *in situ* self-assembled PPy thin monolayer films. When the concentration of PSS exceeded 1 mg/mL, the deviations of the responses of Samples 2 and 3 were both under 10% when the sensors were bent downward at an angle of up to 60° from horizontal. In the LBL *in situ* self-assembly process, before the PPy monolayer and the PPy/PSS multilayered coating systems were constructed, two-cycle PSS/PAH bilayers (precursor layer) were deposited on the MPS-modified substrate to improve the combinability of the surface and the first monolayer of the film of PPy. Additionally, the polyanion PSS layer on the substrates is importantly involved in the formation of the PPy thin film, which involves the simultaneous polymerization of the pyrrole monomer and oxidation of the PPy molecules [16–18]. Therefore, in a more dilute PSS solution, less charge remained on the previously grown layer, and so less Fe^{3+} is adsorbed on the PSS, causing poorer polymerization of PPy on the surface [16]. In a more concentrated PSS solution, some PPy molecules aggregate and become entangled with each other (as observed in Fig. 4(c)), increasing the size of the spheres. Therefore, Sample 2 had a higher response than Sample 3 (Table 3).

3.2.2. Effect of deposition time of PPy on flexibility and response of monolayer of PPy thin films

Fig. 5(b) plots the effect of deposition time of PPy on the flexibility characteristics of the *in situ* self-assembled monolayer of PPy

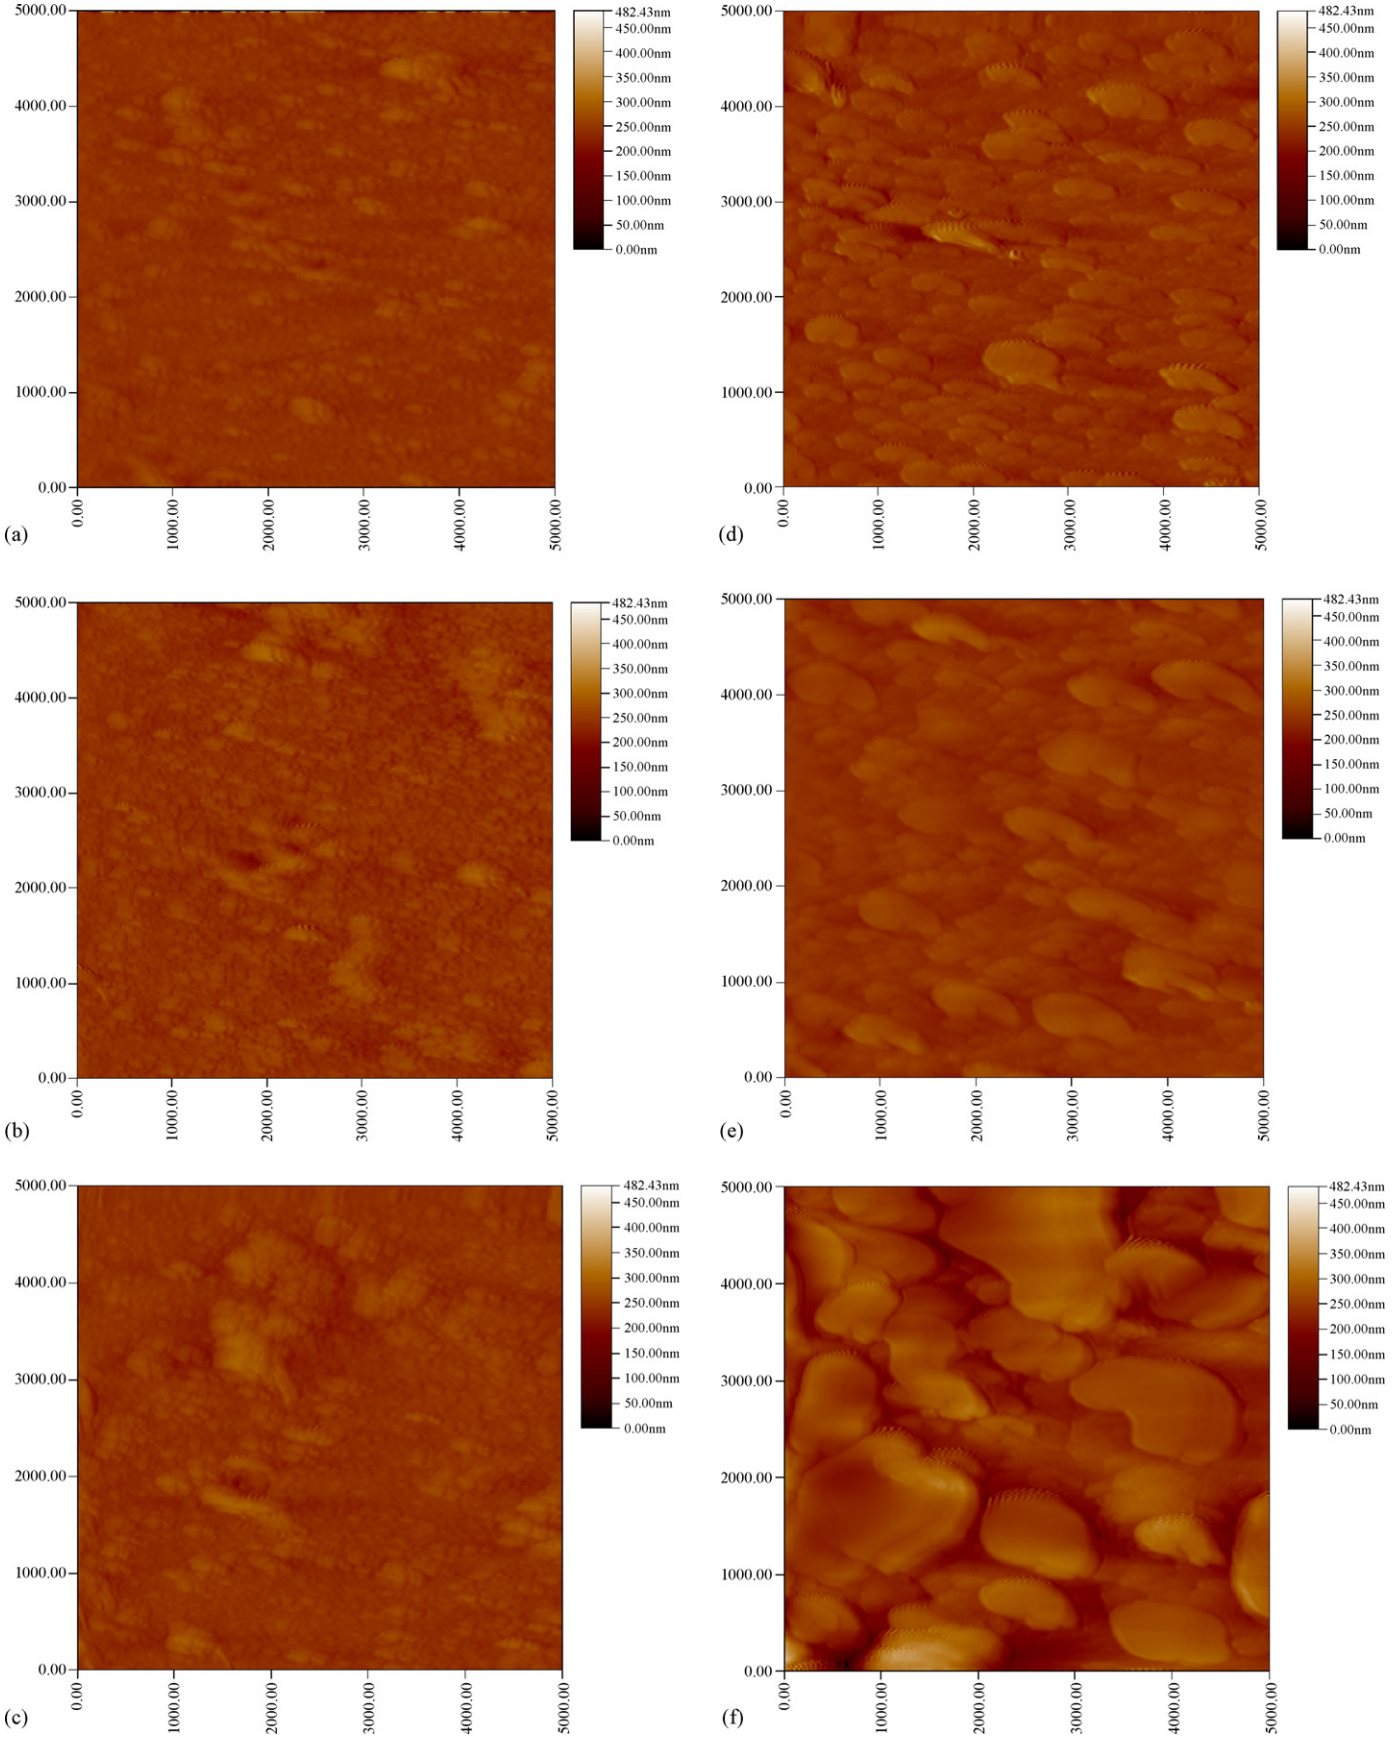

Fig. 4. AFM micrographs of various PPy thin films assembled *in situ* on modified PET substrate (compositions as shown in Table 1); (a) Sample 1, (b) Sample 2, (c) Sample 3, (d) Sample 4, (e) Sample 5, (f) Sample 6, (g) Sample 7 and (h) Sample 8.

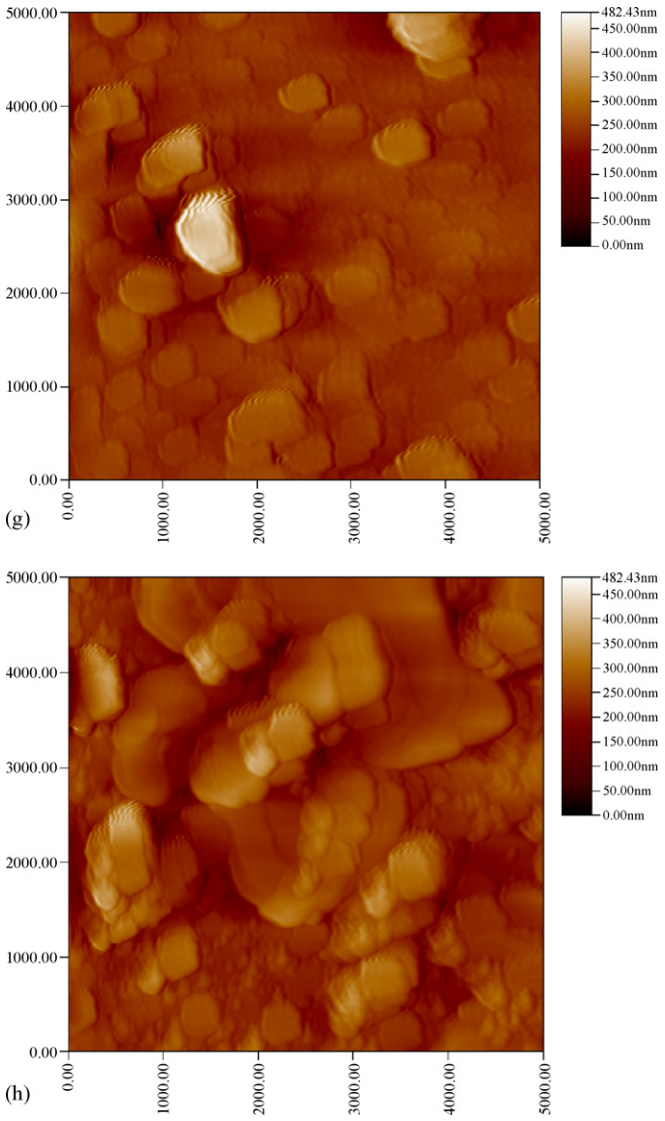

Fig. 4. (*Continued*).

thin films. When the sensors were bent downward at an angle of up to 60° from horizontal, the response deviation increased with the deposition time of the monolayer of PPy on a modified PET substrate increased (Samples 2 and 4–6). In the LBL *in situ* self-assembly process, the PSS layer, acting as an intermediate electrostatic adhesive, helped to maintain the positions of PPy, even when the substrate was bent. Consequently, a large PPy adheres to the PET surface less strongly than a small PPy (as observed in Figs. 4(b) and (d)–(f); Table 2). The sensor response decreased as the deposition time of the monolayer of PPy on the modified PET substrate increased (Table 3). Therefore, PPy in the thin film assemblies was small, so the surface area was large, favoring the adsorption of gas molecules.

3.2.3. *Effect of number of PPy/PPS bilayers on flexibility and response of PPy multilayer thin films*

Fig. 5(c) plots the effect of the number of PPy/PPS bilayers on the flexibility of the LBL *in situ* self-assembled PPy multilayer thin films. In the PPy/PSS multilayer thin film, PPy was reinforced by two adjacent PSS layers as intermediate electrostatic glue and therefore, the PSS molecules helped to keep the PPy in their positions even when the substrate was bent. However, the spheres of multilayered PPy were too large to adhere to the PET surface when the substrate was bent (as observed in Fig. 4(b), (g) and (h); Table 2). Therefore, the $(PPy/PSS)_1$ multilayer thin film (Sample 2) was more flexible than that of $(PPy/PSS)_2$ (Sample 7) and $(PPy/PSS)_5$ (Sample 8). The sensor response decreased as the number of PPy/PPS bilayers increased (Table 3). This result was reasonable because of the effect of the size of PPy (as described in Section 3.2.2). Sample 2 showed the highest response (77.75) and greatest flexibility (within 8%), and so Sample 2 was chosen to study the other gas sensing properties.

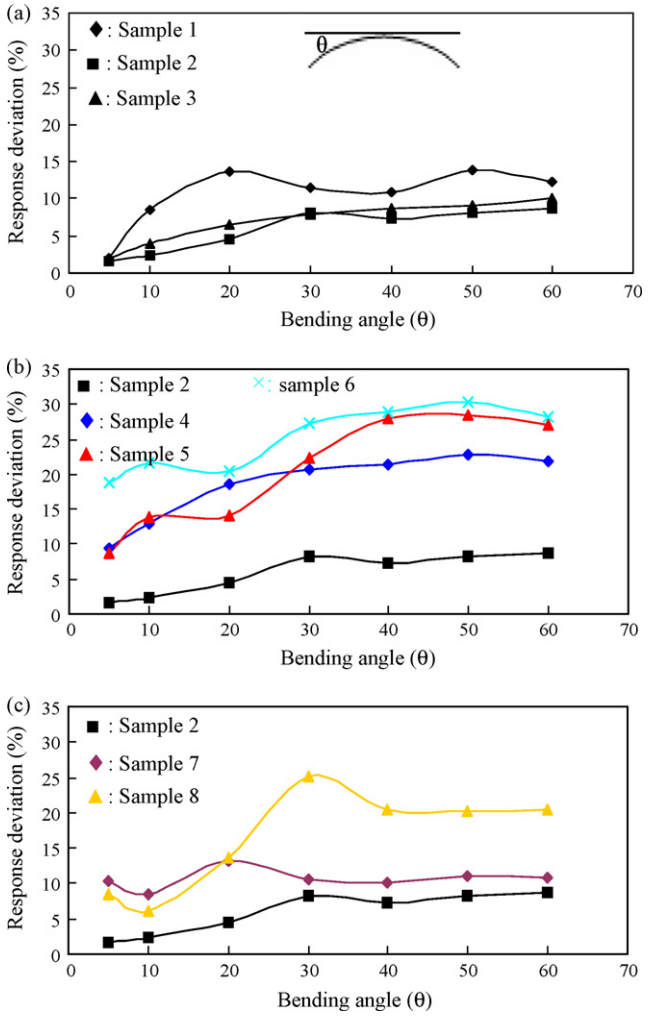

Fig. 5. Flexibility of various PPy thin films assembled *in situ* on modified PET substrate in response to 50 ppm NH_3 gas (compositions as shown in Table 1); (a) effect of concentration of PSS, (b) effect of deposition time of monolayer of PPy and (c) effect of number of PPy/PPS bilayers.

3.3. Gas sensing characteristics of flexible gas sensor

Fig. 6 plots the responses of Sample 2 to various concentrations of NH_3. Fig. 7 plots the results of calibration curve of Sample 2, and the slope and linear correlation coefficient were calculated, as shown in Table 4. The linear sensing characteristics in the ranges 5–50 ppm and 50–200 ppm differed. A steep decrease in slope

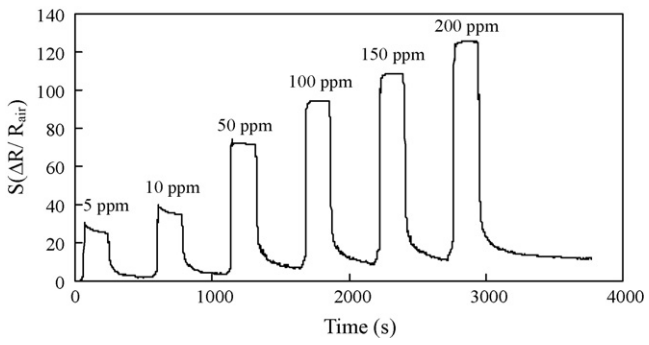

Fig. 6. Response (S) as a function of time (s) for various concentrations of NH_3 gas on Sample 2 sensor (with compositions as shown in Table 1).

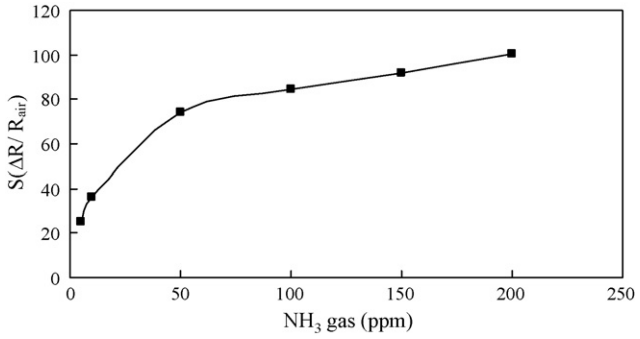

Fig. 7. Response (S) of Sample 2 sensor as function of concentration of NH_3 gas (with compositions as shown in Table 1).

Table 4
Linear sensing characteristics of Sample 2 sensor at different concentrations of NH_3 gas.

Concentration (ppm)	Sensing characteristics	
	Slope	Linearity[a]

50–200	0.1646	0.9996

[a] Correlation coefficient.

was observed from 50 to 200 ppm of NH_3 gas. This behavior was related to the adsorption of NH_3 gas molecules on the surface of the PPy film. Therefore, at the concentration of NH_3 increased (50–200 ppm), suggesting the absence of active sites for adsorption, causing the steep decrease in the slope. Therefore, the respondent sensitivity of Sample 2 to a low concentration of NH_3 gas was much higher than that to a high concentration of NH_3 gas. The NH_3 gas sensing properties of the present flexible NH_3 sensor were compared with the sensor fabricated on rigid substrate in Table 5. The response of Sample 2 exceeded that of sensors made from electrosynthesized and chemical polymerized PPy film on Al_2O_3 or SiO_2 substrate: Sample 2 had a detection limit of 5 ppm of NH_3 gas [10,21–26]. Fig. 8 plots the real-time response of Sample 2. The response (RT_{90}) and recovery time of Sample 2 were 12 and 52 s, respectively, at the testing concentration of 50 ppm of NH_3. Moreover, five gas on/off cycles produced similar responses, indicating the reproducibility of Sample 2. Table 6 presents the results on the cross-sensitivity effects of NO_2, CO and H_2 gases on the sensor. NO_2, CO and H_2 gases may be regarded as having undesirable cross-sensitivity effects with NH_3.

4. Conclusions

A novel flexible NH_3 gas sensor was successfully fabricated by layer-by-layer *in situ* self-assembly of a PPy thin film on a modified PET substrate. The gas sensing properties (response) and flexibility characteristics of the fabricated sensors depended strongly on the architecture of the PPy layer. A precursor layer was optimally fabricated with 1 mg/mL concentration of PSS, a deposition time of PPy of 5 min and an *in situ* self-assembled monolayer PPy thin film for use in a novel flexible NH_3 gas sensor for future low-cost and flexible applications. The novel flexible NH_3 gas sensor had very high flexibility, a very high response and acceptable linearity ($R^2 = 0.9976$) between 5 and 50 ppm, a very fast response (12 s), a short recovery time (52 s), high reproducibility and an undesirable cross-sensitivity effect. The flexible NH_3 gas sensor exhibited a sensing performance that is comparable to or even greater than that of the sensors fabricated on the rigid substrate at room temperature.

ABSTRACT

An innovative block copolymer capillary coating P(MAn-alt-St)$_{127}$-b-PSt$_{592}$, synthesized by maleic anhydride and styrene, was developed as a new kind of coating for capillary electrophoresis. The covalent bond coating was effectively applied in the separation of raw material (4-nitrobenzaldehyde) and production (2-[hydroxy(4-nitrophenyl)methyl]-cyclopent-2-enone) in a Baylis–Hillman reaction using ammonium acetate with 20% tetrahydrofuran (v/v) as the buffer solution. Electroosmotic flow measurement gave an instantly stable value after 70 times continued injection in 5 days and showed that P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ coatings could suppress electroosmotic flow effectively compared with the bare capillary. The effects of tetrahydrofuran and the pH of buffer on the separation were investigated. The characteristics of the coatings to form micelles similar to surfactants were detected by atomic force microscopy. Moreover, the superiority of this coating was further applied in the separation of four aromatic amines.

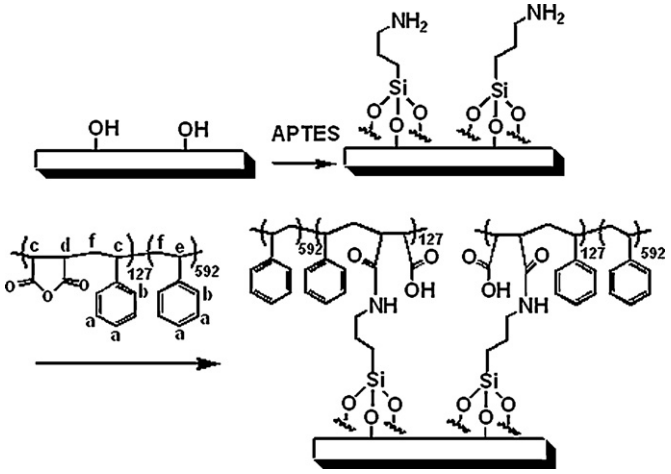
1. Introduction

Capillary electrophoresis (CE) is a separation technique with high efficiency, short analysis time, a small amount of sample and reagent consumption, which has been widely utilized for analysis. An understanding and control of the chemistry of capillary surface is essential to exploit the power of CE.

Since surfactant coatings are inexpensive, flexible and easy to apply in manipulating the surface charge of the capillary, they have become increasingly popular in capillary coatings [1–3]. Numerous types of surfactant coatings have been employed, including: "aggregate coating" and "semi-permanent coating" [4].

However, for "aggregate coatings", some of the surfactant monomers must be present in the running buffer to maintain the coatings; the major shortcoming is that free surfactant molecules in the background electrolyte could interfere with the separation or detection scheme. Furthermore, the presence of surfactant would suppress ionization in mass spectrometry (MS) detection, and thus would make these surfactant coated capillaries incompatible with this increasingly popular and powerful method. For "semi-permanent coating", attributed to form bilayer at the capillary wall [3], the coatings are sufficiently stable and the excess surfactants are removed from the capillary, so separations are performed with no surfactant in the running buffer. But perhaps the main drawback is their irreproducibility.



Many kinds of block copolymer have been used in capillary coatings as an alternative choice in recent years [5,6]. Some block copolymers have played an important role in the separation of proteins, deoxyribonucleic acids and oligonucleotides as separation medium [7,8]. The most interesting thing is that these block copolymer coatings have high sieving ability and can self-assemble to transient networks with appropriate mesh sizes or star like micelle structures [9] in selective conditions and the driving force mainly comes from the hydrophobicity in one of the blocks.

Among these block copolymers, only few of them such as the amphiphilic triblock copolymer $E_{99}P_{69}E_{99}$ (F127) forming micelles

Scheme 1. Coating processes of P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ block copolymer.

in solution [9] and block copolymer consisting of polyethylene glycols end-capped with micelle-forming fluorocarbon tails [10] used as surfactants in CE separation. Some other block copolymers also can form micelles on Si [11] or SiO_2 [12] but not in capillary. Unfortunately, these block copolymers are physically adsorbed or dynamically coated in capillary with low reproducibility. However, covalent bonding has been reported as an effective measure to improve reproducibility of polymer coatings [13–15]. Therefore, exploring new kinds of covalent bonded block copolymer acting as surfactants will be an active area of research.

In this work, a novel covalent bonded block copolymer coating in the capillary, which can be expected to play the role of surfactants in the CE separation, has been investigated. We have synthesized a well-defined block copolymer having alternating segments constituted by maleic anhydride (MAn) and styrene (St): P(MAn-alt-St)$_m$-b-PSt$_n$ (Scheme 1). The segment in the block copolymer can easily be hydrolyzed resulting in an amphiphilic block copolymer which can form uniform nanoscale structures by self-assembly. The architectural particles in nanoscale size were constructed by PSt segment as a hydrophobic head group and P(MAn-alt-St) segment as a hydrophilic tail, which was similar to the configuration of surfactants. Thus the innovative capillary coatings have been developed and applied in the separation of the raw material (4-nitrobenzaldehyde) (NBA) and production (2-[hydroxy(4-nitrophenyl)methyl]-cyclopent-2-enone) (HNE) [16] in the Baylis–Hillman reaction. In addition, the separation of four kinds of aromatic amines by the coated capillary has further confirmed that the copolymers indeed play the role as surfactants.

2. Experimental

2.1. Instrumentation

A 1229 high performance capillary electrophoresis (HPCE) analyzer (Beijing Institute of New Technology and Application, Beijing, China) was used to carry out all electrophoretic experiments. Unless stated otherwise, separations were performed at 25 °C in block copolymer coated capillaries (Yongnian Optical Fiber Factory, Hebei, China) of 75 μm I.D. × 70 cm (55 cm effective).

Capillary coating process was as follows: The bare capillary was washed [17] with 1.0 M NaOH for 2 h, followed with pure water, 1.0 M HCl for 10 min, then with pure water and acetone. After complete removal of acetone by nitrogen, tetrahydrofuran (THF) and 3-aminopropyltriethoxysilane (APTES) (50/50, v/v) were flowed through the capillary and kept at room temperature (25 °C) for 12 h. After the reaction, the modified capillary was washed repeatedly with chloroform for 5 min. The modified capillary was coated by rinsing with the block copolymer solution (30.0 mg block copolymer dissolved in 1.0 mL chloroform) for 1 h. Then it was placed at room temperature for 3 h before rinsing with methanol for 2 min. A detection window (about 2 mm width) was made directly by burning off the block copolymer inner capillary and polyimide coating outside.

Prior to injection, the coated capillaries were sequentially rinsed with water and running buffer for 2 min each. A sample was separated at +20 kV and siphoned for 10.0 s in 15.0 cm height. The separated bands were detected by UV absorption at 254 nm and acquired at 4 Hz. Peaks were identified by spiking relative standard HNE, NBA and aromatic amines in sample solutions and the peaks with increased height were considered to be the targets.

Elemental analysis was carried out on FLASH EA1112 (Thermo, America) and the characterization of polymer coating was detected by an S-4300 scanning electron microscope (SEM, Hitachi, Japan). Atomic force microscopy (AFM) phase images were obtained by a Nano-Scope III MultiMode AFM Digital Instruments at room temperature. Si tips were used with a resonance frequency of approximately 300 kHz and a spring constant of about 40 N m^{-1}. The scan rate was in the range 0.5–1.2 Hz. Three flat glass of similar material to the capillary were coated with block copolymer for AFM measurements in air.

Gel permeation chromatography (GPC) was performed on a set of a Hitachi L-2130 pump with a Waters 2410 refractive index detector, and a Waters 2487 ultraviolet detector with the combination of Hersteller MZ-Gel SDplus 5 μm, porosity 10^3, 10^4, 10^5, and 10^6 Å. THF was used as the eluent with a flow rate of 1.0 mL/min and polystyrene standards were used for calibration.

^{1}H nuclear magnetic resonance (^{1}H NMR) observation of the block copolymers was performed on Bruker Avance 400 spectrometer (Bruker biospin, Switzerland) (400 MHz). A 4.0-mg block copolymers dissolved in 0.5 mL deuterated chloroform containing 0.03% tetramethylsilane for NMR measurements.

2.2. Chemicals

APTES was purchased from Acros (New Jersey, USA). P-phenylenediamine, aniline, 4-bromoanilines, α-naphthylamine, NBA, THF, dimethyl sulfoxide (DMSO), chloroform, sodium dodecyl sulfate (SDS), cetyl trimethyl ammonium bromide (CTAB) and other chemicals were analytical reagent grade and obtained from Beijing Chemical Factory (Beijing, China). Sodium deoxycholate (SDC) was purchased from Beijing Aoboxing Biological Technology Ltd. (Beijing, China). Azo-bis-isobutryonitrile (AIBN) was purchased from Shanghai Chemical Plant (Shanghai, China) and MAn was obtained from Guangfu reagent (Tianjin, China). They were re-crystallized before use. Styrene (St) was got from Shanghai Chemical Plant (Shanghai, China) and (S)-benzyl dithiobenzoate (BTBA) utilized without further purification. HNE was synthesized in our laboratory [16]. DMSO was used as the neutral marker in the electroosmotic flow (EOF) determination.

2.3. Solutions preparation

All solutions were prepared in triply distilled water produced by a distillation apparatus model SZ-97 (Yarong Biochemical Instrument Co., Shanghai, China) and stored at 4 °C. CE running buffers, unless stated otherwise, were composed of 30.0 mM boric acid, and adjusted to pH 10.5 with 1.0 M NaOH or 30.0 mM ammonium acetate, adjusted to pH 7.0 with 1.0 M ammonia before THF was added. Before use, all the running buffers were filtered through a membrane filter with 0.45 μm pores and degassed by sonication for 2 min.

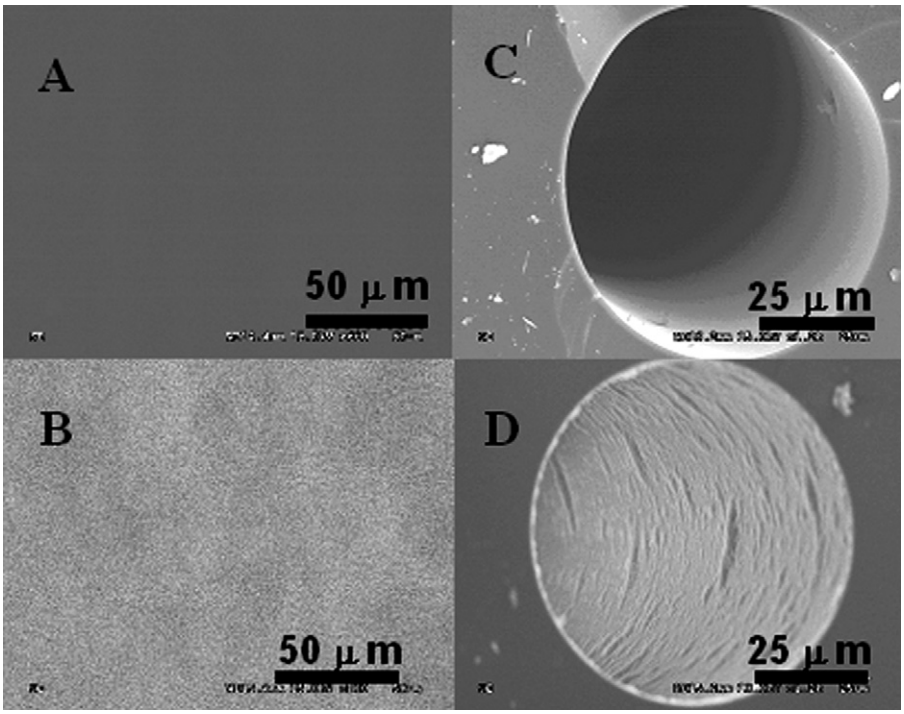

Fig. 1. Scanning electron micrograph of glasses and capillaries. (A) Bare glass; (B) glass coated by P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ block copolymer; (C) bare capillary; (D) capillary coated by P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ block copolymer.

Standard stock solutions of HNE and NBA stock solutions were prepared in 50% THF at concentrations of 0.1 and 0.5 M, respectively. Standard stock solutions of aromatic amines were dissolved in 50% THF at a final concentration of 1.0 mg/mL. Working solutions were diluted from the stock solutions with 50% THF by 10–10^4-fold; these were stored in the dark at −20 °C.

2.4. Synthesis of the block copolymer

A typical reversible addition-fragmentation chain transfer initiating [18] system was used in the combination of BTBA and AIBN. The copolymerization took place in a 50.0 mL boiling flask-3-neck under nitrogen. $[MAn]_0:[St]_0:[BTBA]_0:[AIBN]_0 = 100:1000:1:0.2$ in molar ratio, $[MAn]_0 = 10.0$ mM, in 5.0 mL 1,4-dioxane, magnetic stirring at 60 °C for 38 h. When the reaction was completely finished, purity process of the block P(MAn-alt-St)$_m$-b-PSt$_n$ copolymer was as follows: the polymer sample was first dissolved in 15.0 mL 1,4-dioxane, then after adding polymer solution into an excess of ether, the polymer was precipitated, filtered, and dried at 50 °C in a vacuum oven for 24 h. Finally, 3.3 g P(MAn-alt-St)$_m$-b-PSt$_n$ copolymer was produced by this procedure.

2.5. Coating on glass

To investigate the mechanism of the coated block copolymer on the separation, a coating on glass was carried out. The pretreatment of the glass (1 cm × 1 cm, microscopic slides purchased from Sail Brand, China) was as follows: washed with water, 1.0 M NaOH aqueous solution for 2 h and then with 1.0 M HCl for 10 min, followed by washing with pure water and acetone. The THF and APTES (50/50, v/v) were coated on the glass after the glass dry and kept at room temperature (25 °C) for 12 h. The block copolymer solution (30.0 mg/mL, 50.0 μL) was tiled on the glass and dry.

3. Results and discussion

3.1. Preparation of block copolymer coating

The preparation of the P(MAn-alt-St)$_m$-b-PSt$_n$ block copolymer was described in Section 2.4. In order to characterize the structure and the average size of the block copolymer, elemental analysis, ^{1}H NMR and GPC were measured.

^{1}H NMR results based on the following signal assignment δ (ppm): 7.4 (CH, cycle, a in Scheme 1), 6.9 (CH, cycle, b in Scheme 1), 3.8 (CH, c in Scheme 1), 2.6–2.4 (CH, d in Scheme 1), 2.2–1.9 (CH, e in Scheme 1), 1.8–1.3 (CH_2, f in Scheme 1). The result of elemental analysis showed that C was 79.7%, H was 6.4%. On the basis of the results above and GPC data (Mn is 9.4 × 10^4 and polydispersity is 1.1), it has been known the structure of the block copolymer is P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ (Scheme 1). All of the results demonstrated that a well-defined block copolymer of P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ with narrow polydispersities has been obtained.

The anhydride groups on the MAn of the block copolymer reacted with the amido of APTES and carboxylic groups can be electronegative in basic buffer solution. This process was illustrated in Scheme 1.

SEM has been utilized successfully for the purpose of observing the morphologies of coatings in capillary and films on glass. The morphologies of block copolymer coatings on the capillary surface are important parameters to evaluate the coating stability and reproducibility. In this regard, the morphologies of the block copolymer coated on the glass and in capillary were observed by SEM. Fig. 1 shows the SEM micrographs of capillaries and glasses before and after coated by P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ block copolymer. Fig. 1 indicates that the coated glass (Fig. 1B) was whiter than the uncoated (Fig. 1A). The possible reason was that the block copolymer coating altered the refraction. Furthermore, this result also proved that the copolymer coating on the glass was very smooth. On the other hand, the SEM results shows that a uniform and dense polymer coating had attached onto the capillary inner

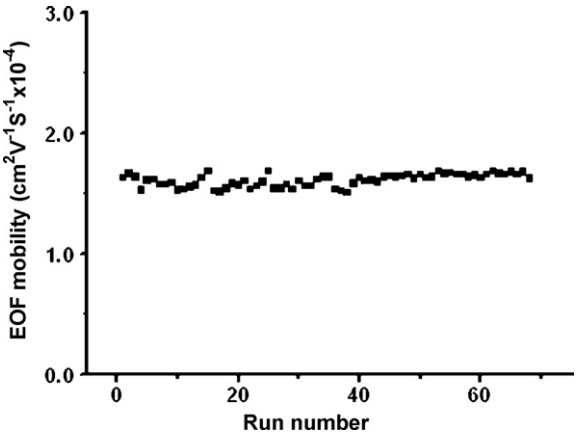

Fig. 2. Coating stability of the block copolymer reflected as EOF mobility vs continuous run for 5 days. Experimental conditions: buffers, 30.0 mM borate (pH 10.5)/THF (80/20) (v/v); neutral marker, 1.0% DMSO. Capillary: 75 μm I.D. × 70 cm (55 cm effective); injection: siphoned for 10.0 s in 15.0 cm height; voltage: +20 kV; UV detection: 254 nm.

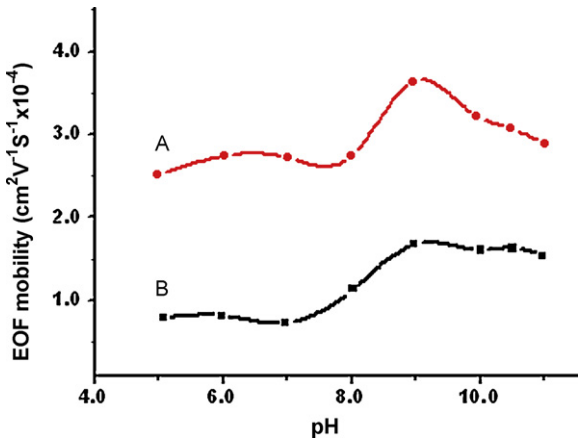

Fig. 3. Effect of changing pH on EOF mobility measured (A) in a bare capillary, and (B) in P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ block copolymer coated capillary. Experimental conditions: pH 5.0–7.0: 30.0 mM ammonium acetate/THF (80/20) (v/v); pH 8.0–10.5: 30.0 mM borate/THF (80/20) (v/v); other conditions are the same as in Fig. 2 except for different pH.

wall with a wrinkly surface (Fig. 1D), which is much different from bare capillary (Fig. 1C).

3.2. Stability of the coated capillary

In order to confirm the further application value, stability test was performed by continuous run and the results are shown in Fig. 2. EOF measurements under a number of conditions could indirectly determine the stability of coated capillaries. The reproducibility was evaluated using the relative standard deviations (RSDs) of the EOF. In the tests, the 30.0 mM borate (pH 10.5)/THF (80/20) (v/v) buffer solution and 1.0% DMSO as a neutral marker were used, respectively. The P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ block copolymer coated capillary could endure more than 70 consecutive electrophoresis runs with good repeatability and result in a RSD value of 3.4% (n = 70). The capillary-to-capillary RSD was obtained by using 35 runs (7 consecutive runs performed in 5 different capillaries) and resulted in a RSD value of 3.3%. All RSDs of the EOF were below 3.5%, and thus, very good reproducibility was observed. Though the lifetime of covalently bonded capillaries was longer than 3 months, it should be mentioned that the capillaries must be filled with water and sealed once they were taken off from the equipment.

In consideration of the importance of EOF in the evaluation of coated capillary, the effect of pH on the EOF mobility has been investigated. Fig. 3 shows the effect of pH on EOF mobility in coated capillary and in bare capillary at pH values ranging from 5.0 to 11.0. Compared with the bare capillary, the copolymer coated capillary generated a low EOF mobility because the carboxylic groups of the copolymers could effectively cover on the capillary wall. Furthermore, the EOF mobility could also be restrained by the addition of THF. In addition, the copolymer coating showed an excellent performance in EOF, which is stable in basic solution.

3.3. Separation of HNE and NBA with block copolymer coated capillary

In our early study of the Baylis–Hillman reaction, micellar electrokinetic chromatography (MEKC) in capillary has been used to detect the raw material NBA and production HNE [16]. Thus the new method has been expected to find whether the block copolymer coatings can replace the surfactants in CE, which can provide the possibility of the combination of CE and MS without desalting in the future.

3.3.1. Optimization of organic additive

Because the copolymer can self-assemble to nanoscale [18] structure, the optimization concentration of organic additive in the buffer solution should be an important factor. The organic additive can affect critical micelle concentrations (CMCs) of block copolymers [19] and the separation selectivity as the copolymer coating is strongly influenced by the organic additive in the solution. Furthermore, the P(MAn-alt-St) segment in the block copolymer can easily be hydrolyzed [18] and as a result the block copolymer can form uniform nanoscale structures by self-assembling. These nanoscale structures constructed by PSt segment as a hydrophobic head group, and P(MAn-alt-St) segment as a hydrophilic tail which provided reactive anhydride or carboxylic groups on the surface of head group. Thus, several kinds of organic solvent have been investigated according to their polarities (data were not shown). The polarities of the organic solutions are as follows [20]: acetonitrile, 11.8; acetone, 9.0; ethanol, 5.8; tetrahydrofuran, 5.8; methanol, 5.7; 2-propanol, 5.5; and 1,4-dioxane, 1.5. Among the eight kinds of organic solvent, only THF and ethanol as additives can contribute to the block copolymer coating forming micelles at a certain extent and redound to the separation of HNE and NBA.

In this section, various THF concentrations in the running buffer (borate and ammonium acetate) were tested to study their effects on the system. The data in Table 1 show that the optimal THF concentrations for the two kinds of buffer were both 20% (v/v). For borate, with the concentration of THF increased from 10% to 20% (v/v), the resolution of HNE and NBA increased distinctly. However, when THF concentration exceeded 20% (v/v), the resolution decreased and finally HNE and NBA cannot be well resolved. The trend for THF concentration in ammonium acetate was similar with that in borate (Table 1, line 3). This phenomenon may be due to the

Table 1
Effect of THF concentrations on the separation of HNE and NBA[a].

	THF (%)						
	10	15	18	20	21	25	30
Rs							
Borate	0.6	1.2	1.3	1.7	1.5	0.6	0.4
Ammonium acetate	1.5	1.5	1.4	1.7	1.6	1.5	1.4

[a] Experimental conditions: 30.0 mM borate (pH 10.5) and THF at different ratio; 30.0 mM ammonium acetate (pH 7.0) and THF at different ratio. Capillary: 75 μm I.D. × 70 cm (55 cm effective); injection: siphoned for 10.0 s in 15.0 cm height; voltage: +20 kV; UV detection: 254 nm. *Rs*: resolution between HNE and NBA.

Table 2
Influence of buffer concentrations and pH on the resolutions of HNE and NBA[a].

Buffer	Concentration (mM)	*Rs*	pH	*Rs*
Ammonium acetate	10.0	1.6	4.8	0.5
	20.0	1.6	5.0	1.3
	30.0	1.7	7.0	1.7
	40.0	1.6	9.0	1.6
	50.0	1.4	10.5	1.6
	60.0	1.5	10.7	1.2

	20.0	1.5	9.0	0.8
	30.0	1.9	9.3	1.6
	40.0	2.1	9.8	1.7
	50.0	1.7	10.5	2.1
	60.0	1.9	11.0	0.9

[a] Experimental conditions: ammonium acetate (pH 7.0)/THF (80/20) (v/v), and borate (pH 10.5)/THF (80/20) (v/v) at different concentrations; 30.0 mM buffer/THF (80/20) (v/v), at different pH values, other conditions are the same as in Table 1.

THF at a lower concentration assisting the block copolymer in forming micelles which resemble surfactants in the separation process. Therefore the hydrophobic analytes were enveloped in the micelles and different analytes were separated similar to the separation process in MEKC. However, excess THF in the buffer solution will make the analytes be extracted from the micelles and result in decreased resolution. This phenomenon that the resolution of the analytes decreased when THF was added to the buffer solution was also observed in MEKC using bare capillary.

The experiment results also showed that the baseline separation was achieved when the additive of ethanol concentration was as high as 50% (v/v) and the migration time was prolonged about 21 min. Thus, 20% THF in the buffer solution (v/v) was finally selected.

3.3.2. *Optimization of buffer solution*

In order to investigate the influence of the buffer composition in the separation of the HNE and NBA, experiments were performed on buffer concentration and pH.

The influence of different kinds of buffer solution and their concentrations were investigated in detail. Results in Table 2 show that baseline resolution, low conductivity (current $\leq$70 μA) and high reproducibility were achieved for ammonium acetate and borate buffer solutions. Only minor improvements in the resolution of HNE and NBA were obtained when the buffer concentration increased from 10.0 to 60.0 mM with the cost of the high conductibility instead. Consequently, 30.0 mM was selected for further experiments.

On the other hand, the influence of buffer pH on the resolution was evaluated respectively ranging from 4.8 to 10.7 for ammonium acetate buffer and 8.0 to 11.0 [21] for borate buffer (Table 2). Table 2 shows that the resolution increased with the increasing of pH before 10.5 and decreased at 11.0, thus the optimum pH at 10.5 was chosen for the borate buffer in the separation. Ammonium acetate buffer at pH 7.0 [22] could yield baseline separation and provide the possibility of the combination of CE and MS without desalting in the future. So the ammonium acetate buffer at pH 7.0 was finally selected for the separation.

The temperature effect on the separation was also investigated [23] ranging from 20 to 40 °C. Although the resolution has not been improved, the migration time decreased with the increasing of temperature. Furthermore, in consideration of yielding lower current and smaller Joule heat, 25 °C was selected.

Therefore, a baseline separation of HNE and NBA was carried out (Fig. 4) by using P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ block copolymer coated capillary and 30.0 mM ammonium acetate (pH 7.0) added with 20% (v/v) THF as buffer solution.

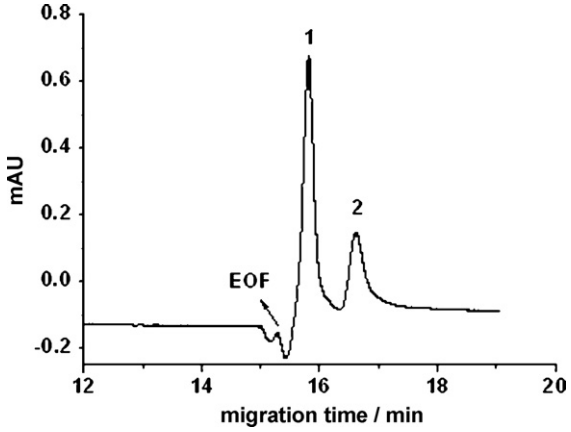

Fig. 4. Electropherogram of HNE and NBA samples in P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ block copolymer coated capillary. Experimental conditions: 30.0 mM ammonium acetate (pH 7.0)/THF (80/20) (v/v), others are the same as in Fig. 2. Peak identity: 1. HNE, 10.0 mM; 2. NBA, 5.6 mM.

3.3.3. *The separation of HNE and NBA by using the coated and bare capillary*

In order to prove that the P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ block copolymer coating acted as surfactants, the influence of different kinds of common surfactants (CTAB, SDS and SDC) and varies concentration using bare capillary was investigated (Fig. 5). Compared with the chromatograms obtained from the coated capillary (Fig. 4), it indicated that HNE was always in front of NBA in the block copolymer coated capillary but behind it in the bare capillary with surfactants. On the basis of observed result, all subsequent experiments were performed on the effect of surfactants concentration to resolution. The most widely used method for resolution (*Rs*) calculation is the tangent method as follows [24]: $Rs = 2(t_2 - t_1)/(W_2 + W_1)$, where t_1 and t_2 are the migration times of the two components, and W_1 and W_2 are the corresponding widths of the peaks.

Fig. 5 also shows that the resolution increased with the concentration of surfactants and baseline separation ($Rs = 1.5$) occurred at concentration 12.2 mM for SDS, 2.0 mM for CTAB and 5.0 mM for SDC, respectively. According to the literature, the CMCs of the three surfactants were 8.1 mM for SDS [25], 1.3 mM for CTAB [25] and 3.1 mM for SDC [26], respectively. From these data, it was concluded that baseline separation was obtained only when the concentrations of the surfactants were above the CMCs. It was found that the block copolymer coating had formed micelles in the buffer solu-

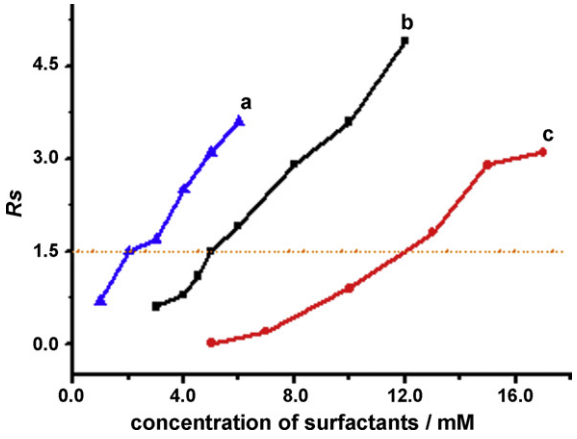

Fig. 5. Effect of varying surfactants and concentrations on the separation of HNE and NBA using bare capillary. Experimental conditions: 30.0 mM borate (pH 10.5); (a) CTAB, (b) SDS, (c) SDC, others are the same as in Fig. 2.

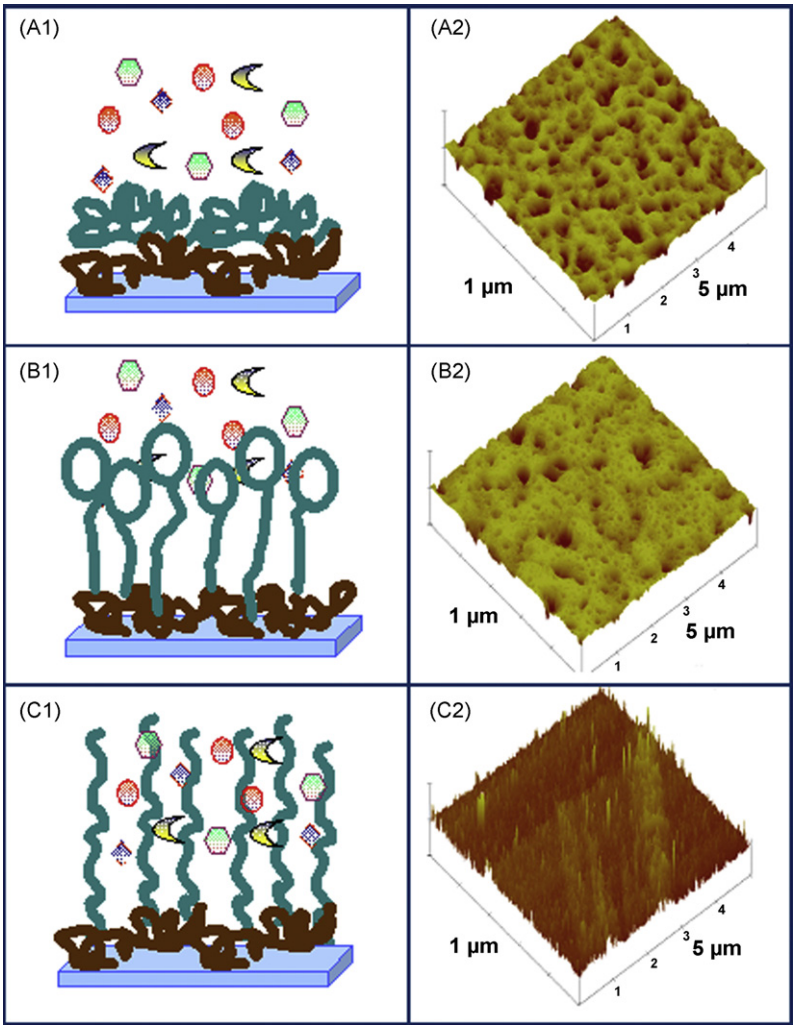

Fig. 6. Schematic illustration of block copolymer morphologies in different CE procedure (A1–C1); AFM images of block copolymer coating after dipping in water for 5 min (A2); coating after dipping in 20% THF for 30 min (B2); coating after dipping in 100% THF for 30 min (C2).

tion and the concentration of the copolymer coating micelles was approximately equivalent to or higher than CMCs of those surfactants when the *R*s was 1.5 (Fig. 5). The resolution results obtained from the coated capillary (Fig. 4) also showed that the copolymers indeed play the role as surfactants.

3.3.4. *Effect of copolymer morphologies on separation*

As described in Section 3.3.1, THF was used as an organic additive and played an important role in self-assembling of the block copolymer. PSt is soluble in some organic solvents independent of pH while MAn is soluble in water when it is protonated. Although P(MAn-alt-St) segment provides reactive anhydride which turns into carboxylic groups in the basic buffer solution, P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ block copolymer are insoluble in a buffer solution without organic solvents. When there was no THF in the buffer solution, the block copolymer like dendritic tentacles docked on the inner wall of capillary. However, when THF was used as an organic additive and added into the buffer solution, micelles with hydrophobic head group and hydrophilic tail were formed spontaneously. The phenomenon was similar to F127, which could self-assemble to star like micelle structures above its critical micelle concentration with the P blocks forming the core and the E blocks dangling outside [9].

It has been reported that images of some double-chained quaternary ammonium surfactants reveal the presence of spherical aggregates spaced uniformly over the silica surface. To determine whether this micelle-type coating formed on the capillary surface during CE, Baryla and co-workers employed AFM imaging to study surfactant adsorption in a common electrophoretic buffer [1].

Therefore, to reveal the relationship between resolution and morphology, the copolymers morphologies in different solution were investigated by AFM (Fig. 6). Generally, when the length of the copolymer is invariable, the morphologies of micelle formed by block copolymers in solutions can be easily tuned by change of THF concentration. Fig. 6A2 shows that after the coating on glass dipped in water for 5 min, the P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ block copolymer formed a film, and the copolymer was insoluble since the hydrophobic block of PSt dominated the composition of the block copolymer in this situation. However, when dipped in 20% THF (v/v) for 30 min, the film expanded obviously (Fig. 6B2) due to the dendrite tentacles of copolymers being extended, meanwhile, the height of the copolymer coating increased obviously because the coating layer became 60.0 nm thicker than that formed in Fig. 6A2. After the coating was dipped in 100% THF for 30 min, it became more compact (Fig. 6C2); the reason might be that the formed micelle cores of block copolymers (Fig. 6B2) had been disrupted by THF. The results of AFM indicate that the coatings could form micelles and could play the role of surfactants in the analytes separation.

Fig. 6A1–C1 shows the schematic illustration of the separation procedure of copolymers according to the AFM results. The mechanism of this block copolymer coating in the separation process

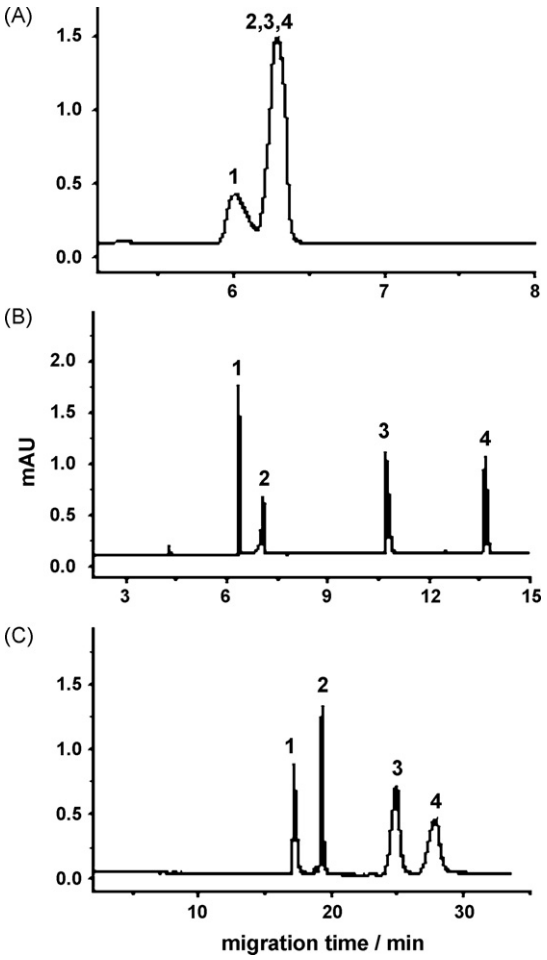

Fig. 7. Electropherograms of amines samples in bare capillary and P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ block copolymer coated capillary. Experimental conditions: (A) bare capillary, 30.0 mM NaH_2PO_4 (pH 7.0)/THF (90/10) (v/v); (B) bare capillary, 30.0 mM NaH_2PO_4 (pH 7.0, 15.0 mM SDS); (C) capillary coated by P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ block copolymer, buffer is same as (A).Other conditions are the same as in Fig. 2. Peak identity: 1. P-phenylenediamine, 0.6 mM; 2. aniline, 0.5 mM; 3. 4-bromoanilines, 1.0 mM; 4. α-naphthylamine, 0.7 mM.

was also displayed that P(MAn-alt-St)$_{127}$-b-PSt$_{592}$ block copolymer could form micelles and assist in the separation. Thus a novel covalently bonded block copolymer acting as surfactants was developed.

3.4. Separation of aromatic amines

The separation of four UV-absorbing organic amines shown in Fig. 7 was performed using the block copolymer coated (Fig. 7C) and uncoated (Fig. 7A and B) capillaries. When using the buffer solution of 30.0 mM NaH_2PO_4 (pH 7.0)/THF (90/10) (v/v), the four organic amines cannot be well separated on the bare capillary. However, using the same buffer solution on the coated capillary, all the analytes were baseline separated. In order to show that the coating polymer acts as surfactants, different concentrations of SDS were added to the buffer solution of 30.0 mM NaH_2PO_4 [27] (pH 7.0). As a result, 15.0 mM SDS reached the resolution (Fig. 7B) comparing with the coated capillary (Fig. 7C). This result further testified the former supposition that coating block copolymer play the similar role as surfactants when THF as an additive in the buffer solution.

4. Conclusion

A novel block copolymer coating was developed and proposed as a valid alternative to surfactants in the separation of the raw material and production in a Baylis–Hillman reaction. Compared with using surfactants in the bare capillary for the separation, the main features of the coating were the excellent chemical stability, a very good capillary-to-capillary and run-to-run repeatability, and the possibility of CE-MS detection without desalting of the buffer solution in the future. The efficacy of the developed coating was also proven at the separation of four amines, obtaining baseline separation and further testified the function of copolymer coating similarly to surfactants. This remarkable analytical result was validated by testing the optimum organic solution as an additive and observing morphology using SEM and AFM. This integrated approach could be considered as an alternative strategy for simplify operating process of CE-MS detection and providing possibility of the online detection in reactions and separations.

Ozone detection
Gold nanoislands
Surface plasmon resonance

ABSTRACT

Gold nanoislands interact with gaseous ozone to produce a surface plasmon resonance shift, similarly to the interaction of ozone and gold nanoparticles in water. Gold nanoislands are produced by sputtering, which significantly simplifies the synthesis and produces controlled size for the gold nanoislands. The shift of surface plasmon resonance peak was monitored while gold nanoislands were exposed to variable concentration of gaseous ozone. The shift was then correlated with ozone concentration. Our current results indicate sensing gaseous ozone at concentration of as low as 20 μg/L is achievable. Gold nanoislands were reversed to their original wavelength and were able to cycle between the wavelengths as ozone was introduced and removed. Potentially, this system can be useful as a sensor that identifies the presence of ozone at low part-per-billion concentrations of ozone in gaseous media.

1. Introduction

The objective is to develop an ozone sensor for the drinking water industry and other industries that electrolytically produce gaseous ozone. Tighter control of the generation system will produce significant energy cost savings while maximizing the efficacy of the ozone treatment. Up to now this task has been complicated by the complex nature of the ozone decomposition pathways and the irreversible oxidization of the reagents/sensing element [1,2]. Electrochemically based measurements have also been problematic due to poor sensitivity and electrode fouling [2].

In a previous paper this group reported that aqueous solutions of gaseous ozone produced a shift in the surface plasmon resonance of colloidal gold nanoparticles [3]. This was surprising on two fronts. First, in ozone methods, ozone irreversibly oxidizes the analytical reagent(s) thereby making a reversible sensor impossible. Even in prior gold surface interactions utilizing gold crystals and monolayer surfaces the ozone decomposed on the surface, but the surface was unaffected by the ozone [4–6]. Surface spectroscopy indicated that oxygen covered the surface and that an electron transfer from the Au substrate into the oxygen adlayer occurred [4]. The oxygen could be removed by heating the surface to 600 K; this desorption exhibits first-order kinetics. The Au–O bond dissociation energy is about 58 kcal/mol. Other papers confirmed the need for high temperature and that the ozone decomposes on the metallic surface [6–8]. Based on UV–Vis spectral data observing the 254 nm ozone peak from the gold colloidal solutions, the decomposed ozone does not produce surface oxygen.

The second surprising finding was that the shift in the surface plasmon resonance from the colloidal gold nanoparticles was reversed to the original wavelength upon removal of ozone. This is unexpected since most reports of analytical utilization of surface plasmon resonance claimed irreversibility since the plasmonic shift was due to irreversible aggregation of the gold nanoparticles or other surface modifications. It was observed that the colloidal gold nanoparticles were able to reproducibly cycle between the surface plasmon resonances wavelength as ozone was introduced and removed. Based on particle size experiments there was no evidence of aggregation. Since our long-term goal is a reversible gaseous ozone sensor, the surface plasmon resonance signal was usable, but the colloidal solution had to be replaced by a solid state system.

Initially, gold nanoislands were made using vapor deposition followed by thermal curing. As was the case in the aqueous system, the surface plasmon resonance of the gold nanoislands exhibited a cycling effect when gaseous ozone was introduced and removed. The difficulty with this production approach was that the process to make the nanoislands was not very reproducible both in size and distribution of the gold nanoislands. This paper discusses an alternative solid state system and the characterization of the gold nanosurface, the gold nanosurface interaction with ozone, the desirable performance characteristic(s) of the sensor, the optimal size for gold nanosurface, the current sensor configuration, and the sensor performance characteristics.

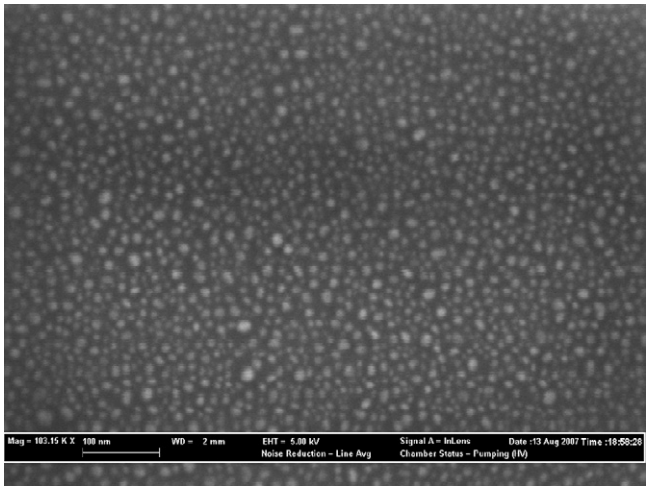

Fig. 1. SEM images of typical gold nanoislands produced by sputtering process on a polished aluminum substrate.

2. Experimental

Ozone generation was performed using a water-cooled Ozone Research Equipment Corporation Model O3B9-0 generator. The cooling water and fan are turned on first. Oxygen pressure from the oxygen cylinder is reduced down to 6 psi by a regulator. The generator is turned on and the electric current set to 1.3 amps. This setting should produce approximately 9 g per hour of ozone. Ozone concentration was determined by measuring absorbance at 254 nm on HP 8453 Photodiode UV–Vis. Molar absorptivity of 3300 M^{-1} cm^{-1} was used to calculate the concentration of ozone. A 10 cm quartz sample cuvette was used to lower the detection limit of ozone. PerkinElmer, Lambda 950 Reflectance Spectrophotometer, employing an integrating sphere was used to collect absorbance spectra of gold nanoislands. Varian's Cary 50 spectrophotometer was used to collect UV–Vis spectra of gold nanoislands sputtered onto transparent substrates, such as polished quartz and indium tin oxide-coated glass plates.

Previously (1), the gold nanoislands were produced using Physical Vapor Deposition (PVD) onto glass or indium tin oxide-coated glass. The current work uses a sputtering procedure to produce gold nanoislands. This greatly reduces synthesis time and it also provides very good control of sputtering parameters, which improves reproducibility. Gold nanoislands were generated using Anatech Hummer V Sputter Coater. Typical settings for the sputter coater: 70–80 mtorr vacuum, high voltage set to generate current above 10 mA and coating time: 1–5 min. The next step is to anneal the gold coating at 375 °C for 15 min. This temperature was selected to reduce the time to produce nanoislands. Lower temperatures require longer annealing time but can be used as well.

3. Results and discussion

In the prior vapor deposition investigation, the gold nanolayers where reproducible, but the thermal curing to produce gold nanoislands did not produce consistent nanoisland surfaces. By using sputtering technology it was possible to reproducibly make the desired gold nanoislands. To prove that gold nanoislands were produced by the sputtering technique, the surfaces were subjected to AFM and SEM imaging. It should be noted that in most vapor deposition techniques for gold, a thin chromium layer is first placed upon the substrate surface to enhance the mechanical stability of the gold layer. For sputtering, the initial chromium layer was not needed. Fig. 1 shows a typical SEM image of sputtered gold nanoislands on a polished aluminum substrate. Unlike the vapor deposition work, the sputtered nanoislands are evenly distributed across the surface. Fig. 2 shows the AFM image of 25 nm (a) and 14 nm (b) gold nanoislands on quartz substrate.

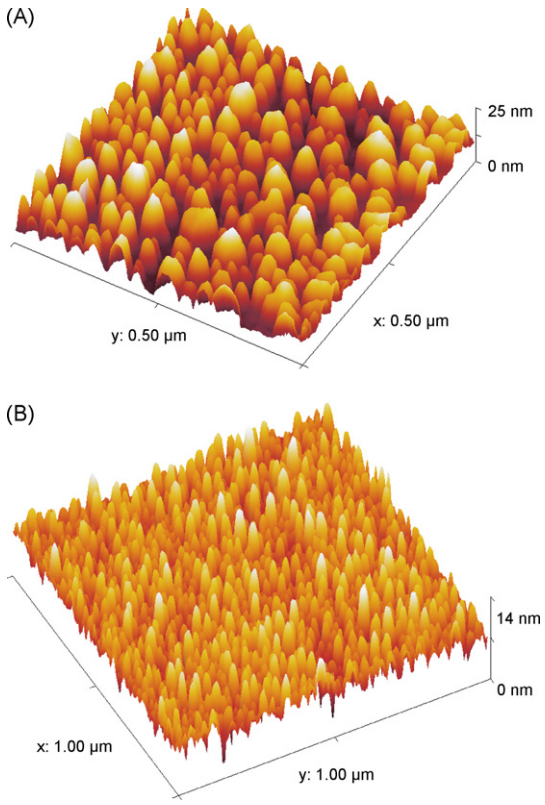

Fig. 2. AFM images of 25 nm (a) and 14 nm (b) gold nanoislands on quartz substrate.

For comparison purposes Fig. 3 shows the spectra for a gold thin film (top line) that produces a broad absorbance after 600 nm and exhibits no surface plasmon resonance, sputtered gold nanoislands exhibiting surface plasmon resonance, and sputtered nanoislands exhibiting a red-shift in surface plasmon resonance from 520 to 540 nm in response to gaseous ozone. The presence and concentration of ozone was monitored by measuring the ozone absorbance peak at 254 nm. Upon ozone depletion, the surface plasmon resonance peak for the gold nanoislands completely return to the

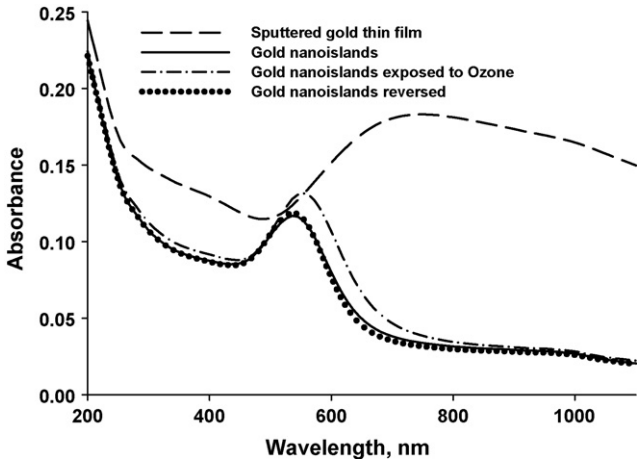

Fig. 3. Overlaid UV–Vis spectra of: dashed line, gold thin film on quartz; solid line, gold nanoislands; dot-dashed line, gold nanoislands exposed to ozone gas; dotted line, gold nanoislands reversed by heating at 375 °C for 15 min.

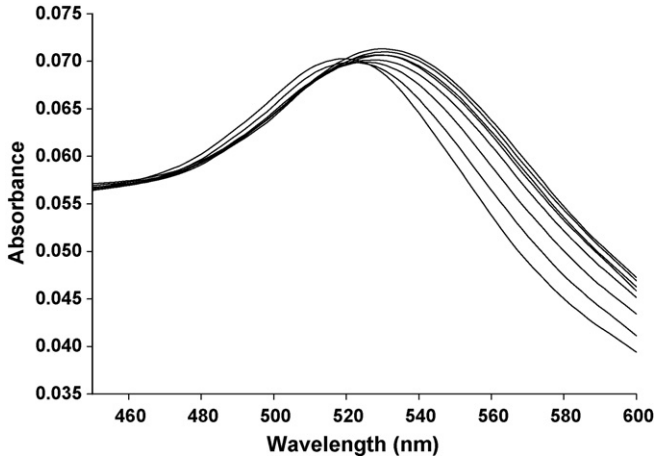

Fig. 4. Overlaid UV–Vis spectra of 25 nm gold nanoislands with surface plasmon absorbance max at 520 nm exposed to concentrations of ozone, increased in increments form 20.9 μg/L to 166.1 μg/L. Ozone causes a red-shift in the surface plasmon absorbance max.

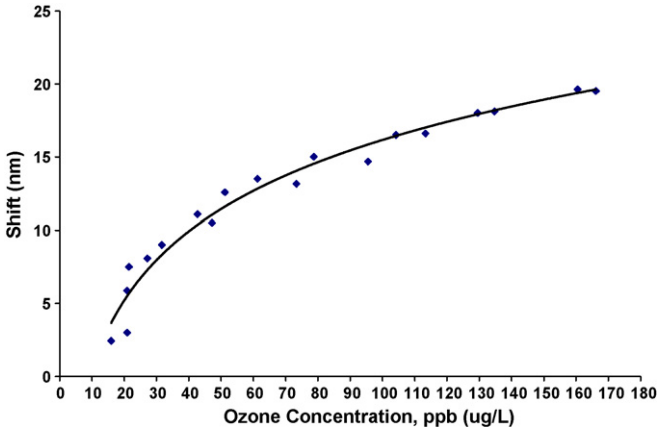

Fig. 5. Shift of the 25 nm gold nanoislands surface plasmon max (520 nm) as a function of ozone concentration.

original position and intensity at 520 nm. For comparison purposes aqueous colloidal suspension of gold nanoparticles produced a surface plasmon shift from 519 to 540 nm, for vapor deposited chromium/gold the shift was from 549 to 565 nm, and for ITO with gold vapor deposited the shift was from 558 to 583 nm upon exposure to gaseous ozone. Comparison among the various gold nanodomain systems show that the nanoislands reported in this work produced about 50% more sensitivity toward gaseous ozone.

Based on the spectral evidence it appears that the mechanism suggested for a thin gold film of ozone to oxygen decomposition that is adhered to the metal surface is not the same for nanoislands. For nanoislands as long as the ozone 254 nm peak persists, the surface plasmon shift is observed. Once the ozone peak disappears, the surface plasmon shift reverses. In addition unlike gold thin films, high temperatures are not needed to promote the surface plasmon reversal. Clearly, the ozone is directly influencing the surface plasmon resonance and when it decomposes, the oxygen that is produced does not interact with the gold nanoislands. This was further verified by testing pure oxygen's interaction with the gold nanoisland. No surface plasmon shifts were observed and after oxygen treatment the nanoislands still produced a surface plasmon shift when ozone was introduced.

The desirable performance characteristic(s) of an ozone sensor are described in the "Disinfectant Residual Measurement Methods" reference [9]. The ideal method/technique would be specific for only ozone itself and not respond to its decomposition products. It needs to be selective over possible interferences by at least 500. A detection limit of 0.01 mg/L for ozone with a precision of at least 0.1% and an accuracy of at least 0.5% is needed. The system must be easily, absolutely calibrated. A working linear range of five orders of magnitude is desirable but not mandatory for all situations. The system cannot require dilution of the water or gas sample to mask or minimize potential interferences. The system must work equally well (and satisfy the above requirements) in batch and automated modes of operation. The system must be operable by a technician and not require specialized skills or unusual or ultra-complex instruments. The measurement should be made in less than 1 min. The whole process must be relatively cost-effective.

The response of the gold nanoislands sensor to gaseous ozone was investigated by exposing it to different ozone concentrations. Fig. 4 shows the spectra exhibiting the amount of red-shift, in nm, with increasing ozone concentration. Fig. 5 is a calibration plot of spectral shift (nm) of the gold nanoislands surface plasmon resonance peak versus ozone concentration. The calibration plot shows that with the current design, the detection of gaseous ozone at concentration of less than 20 ppb (μg/L) is possible. Starting with the 20 ppb data point, a curve with an equation of $y = 6.8\ln(x) - 15.19$ produced a correlation coefficient of 0.9659. Comparison between the vapor deposition nanoislands and the sputtered nanoislands show that the sputtered nanoislands are about two orders of magnitude more sensitive to ozone.

Based on this group's aqueous gold nanoparticle investigations, it is expected that the size and density of gold nanoislands affects the response performance of the sensor. The current work shows evidence that different size and density of gold nanoislands may in fact affect the observed wavelength for the sensor. Direct comparison of ~25 nm versus ~50 nm nanoislands showed that the larger nanoislands were less sensitive to ozone. The absorbance maximum of the surface plasmon shifts from 520 to 532 nm was identical. The smaller particles increase in sensitivity may be due to the fact that they are more densely packed and thus interparticle distance is smaller. The interparticle distance is known to affect the surface plasmon shift. This finding suggests that the useful range of the sensor can be controlled by nanoisland size. The majority of this work was performed with 20–30 nm gold nanoislands.

Potential interfering gases like oxygen and nitrogen did not produce a surface plasmon resonance shift. However, as was the case with solution nanoparticles, the nanoisland surface was destroyed by nitrous oxide. The presences of the non-interfering gases during the reversal of the gold nanoislands did not affect surface plasmon resonance reversibility.

Future sensor designs will place gold nanomaterials in a substrate material that is resistant to ozone, cost-effective, and interference-free to the detection scheme. The substrate does not need to be transparent in the UV–Vis region of electromagnetic spectrum, since a reflective mode can be used to collect absorbance spectra of the gold nanoislands. The substrate should also provide open access to the surface of gold nanoislands.

4. Conclusions

It has been demonstrated that fabrication of a fast and cheap sensor material that can be used for detection of ozone is possible. The observed ozone-induced surface plasmon resonance shift of gold nanoislands is reversible. The surprising aspect of this material is it stability to ozone. The observed ozone response and reversibility is very reproducible an ozone detection limit of 20 μg/L was achieved.

Oxybutynin

ABSTRACT

The development of a cyclodextrin-MEEKC method for the analysis of oxybutynin and five related impurities is described. Experimental design strategies were applied in order to reach baseline separation of the compounds in a short analysis time. Mixture design made it possible to find the best composition for the microemulsion acting as pseudostationary phase, which was constituted by 89.1% 10 mM borate buffer pH 9.2, 1.7% *n*-heptane, 9.2% SDS/*n*-butanol in 1:2 ratio. The addition of (2-hydroxypropyl)-β-cyclodextrin to the background electrolyte was found to improve analysis performance. A Doehlert design, for the factors cyclodextrin concentration and voltage, was carried out and Derringer desirability function led to the identification of 18 mM and 29 kV as the optimal values. Applying the optimum conditions, separation of all the compounds, including the enantiomers of impurity 1, was obtained in less than 12 min. The method was validated according to ICH guidelines for drug assay and determination of impurities and was applied to oxybutynin tablet analysis.

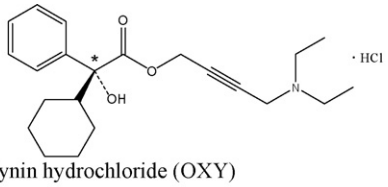
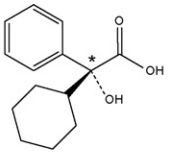
1. Introduction

Capillary electrophoresis is today a well established technique applied in pharmaceutical quality control [1] since it combines high resolution power, high speed and reduced cost of analysis [2–4]. The plain environment used in capillary zone electrophoresis and the continuous improvement of instrumentation make it possible to obtain good repeatability and reliability of analysis. Nevertheless, when pseudostationary phases are used, the complexity of the environment can give repeatability problems which can in turn lead to a lack of confidence during method application. This is probably the main reason why up to now only a few papers have appeared concerning the use of microemulsion electrokinetic capillary chromatography (MEEKC) in pharmaceutical quality control [5–11]. Nevertheless, the methods that have been proposed have been validated showing satisfactory performances and indicating MEEKC as a powerful tool for drug analysis.



In the present paper a cyclodextrin-MEEKC method is reported which was developed for the determination of oxybutynin and five related impurities in drug substance and drug product. Oxybutynin hydrochloride (4-(diethylamino)but-2-ynyl(RS)-2-cyclohexyl-2-hydroxy-2-phenylacetate hydrochloride, OXY) is a tertiary amine antimuscarinic which is used for the management of urinary frequency, urgency, and incontinence in neurogenic bladder disorders and in idiopathic detrusor instability [12]. According to the information provided by the producer (Sanofi-Aventis, Sisteron, France), OXY is administered as racemate and may present five principal impurities (reported in Fig. 1), with different acid–base properties.

Determination of OXY has been carried out in pharmaceuticals [13–16] and in biological samples [17–19], and OXY plasma protein binding was examined enantioselectively by high-performance frontal analysis [20]. Other methods were also developed for the separation of OXY enantiomers [21,22] and for the determination of OXY and its major metabolite desethyloxybutynin in biological samples [23–25].



To the best of our knowledge, no method has been reported for the determination of oxybutynin and its impurities in drug substance and/or drug product, apart from the HPLC methods reported in the current Ph. Eur. [26] and USP [27]. Using capillary electrophoresis with MEEKC operative mode for this purpose is the analytical novelty described in this paper. Due to the different acid–base properties of the compounds, an electrokinetic capillary chromatographic method was considered suitable to approach the problem. In particular, the optimized method used a microemulsion system as background electrolyte to which (2-hydroxypropyl)-β-cyclodextrin was added to improve the separation. The presence of a complex system made the use of a multivariate strategy necessary for the optimization of the variables [28,29]. In a previous paper [9], the advantages of using mixture design [29] to optimize a MEEKC method were demonstrated for the first time. In the present work, mixture design

was again used to optimize the microemulsion composition and Doehlert design [29] was applied to optimize the process factors voltage and cyclodextrin concentration. Validation of the method was then carried out following ICH guidelines [30].

2. Experimental

2.1. Chemicals

All chemicals used in this study were of analytical-reagent grade with no further purification. Sodium tetraborate decahydrate was from BDH Laboratory Supplies (Poole, UK). *n*-heptane, *n*-butanol, sodium dodecyl sulphate (SDS), β-cyclodextrin, methyl-β-cyclodextrin, (2-hydroxypropyl)-β-cyclodextrin (HPβCD), (2-hydroxypropyl)-γ-cyclodextrin (HPγCD), heptakis(2,3,6-tri-O-methyl)-β-cyclodextrin were from Sigma–Aldrich (St. Louis, MO, USA). Methanol (HPLC grade) was obtained from Riedel-de Haën (Seelze, Germany), sodium hydroxide from Merck (Darmstadt, Germany).

Working standards of OXY and its impurities, Ditropan® tablets (labelled to contain 5 mg OXY) and excipients (lactose anhydrous, microcrystalline cellulose, calcium stearate) were kindly donated by Sanofi-Aventis (Sisteron, France). Flufenamic acid (FLU), employed as internal standard, was obtained from Sigma–Aldrich (St. Louis, MO, USA).

A Simplicity 185 system (Millipore, Billerica, MA, USA) was employed to purify water previously treated by electrode ionisation using an Elix system (Millipore) and ultrapure water was used throughout this study.

2.2. Solutions, microemulsions and sample preparation

Standard stock solutions of OXY (40 mg/mL), FLU (internal standard, 10 mg/mL) and OXY impurities (1 mg/mL each) were prepared in methanol. All these solutions were stored at 4 °C and used within one week. Working standard solutions were prepared daily by diluting the appropriate volume of each of the stock solutions with 10 mM sodium borate pH 9.2 directly in a vial to 500 μL.

The aqueous phase of the microemulsion system was constituted by 10 mM sodium borate pH 9.2 and was prepared adding an accurately weighed amount of sodium borate to a volumetric flask. Microemulsions were prepared by mixing in a beaker the aqueous phase with a proper amount of cosurfactant (*n*-butanol), then adding an accurately weighed amount of surfactant (SDS) and finally an appropriate amount of oil (*n*-heptane). The addition of each component was made only after reaching a complete dissolution of the previously mixed compounds and all mixtures were continuously stirred to obtain optically transparent microemulsion systems. All microemulsions were prepared on a w/w basis.

The considered percentage of the microemulsion components was 88.0–93.9% for the aqueous phase, 0.1–2.0% for the oil phase and 6.0–10.0% for the mixture surfactant/cosurfactant in 1:2 ratio. The optimized microemulsion consisted of 89.1% 10 mM borate buffer, 1.7% *n*-heptane, 9.2% SDS/*n*-butanol in 1:2 ratio. The optimum BGE was obtained by adding to this microemulsion an appropriate weighed amount of HPβCD in order to reach a concentration value of 18 mM.

The optical transparency of the microemulsions was verified in a previous paper [9] by measuring their transmittance at 550 nm [31]. All microemulsions were filtered before use through 0.45 μm cellulose acetate syringe filters and further stirred for at least 5 min.

The solution for tablet assay was prepared as follows: 20 tablets were weighed and finely powdered. An accurately weighed portion of the powder, corresponding to about 80 mg of OXY, was transferred into a 25 mL beaker. The contents were diluted adding by a manual pipette 10.000 mL of methanol solution containing 0.5 mg/mL internal standard, then sonicated for 10 min and shaken again. An aliquot of 1 mL of the mixture was then centrifuged and 500 μL of the supernatant were introduced into a vial for analysis. The final test concentration of OXY was about 8 mg/mL.

2.3. Equipment and capillary electrophoretic conditions

A 300 Ultrasonik ultrasonic bath (Ney Company, Bloomfield, USA) was used to sonicate solutions and a Metrohm 691 pH Meter (Metrohm, Herisau, Switzerland) was employed to measure pH. Microemulsions were stirred with a multiple magnetic stirrer Multipoint HP15 (Variomag, Daytona Beach, FL, USA).

CE analyses were performed by an Agilent Technologies ^{3D}CE system (Agilent Technologies, Waldbronn, Germany), driven by ^{3D}CE ChemStation software (Rev. A.09.01, Agilent Technologies) and equipped with an on-column UV–visible diode-array detector and an air thermostating system. The vial carousel was at room temperature.

The separations were carried out in an uncoated fused-silica capillary (50 μm inner diameter, 375 μm outer diameter) which was 48.5 cm long (40.0 cm to the detector), purchased from Composite Metal Services (Ilkley, UK). The detection wavelength was 195 nm.

The separation run was carried out in positive polarity mode. Sample introduction was performed hydrodynamically from the inlet side and the injection time of both the sample and the subsequent buffer plug was 5 s at 50 mbar.

Prior to the first use, the capillary was conditioned by flushing, sequentially, 1 M NaOH and water for 5 min each. At the beginning of each day, the capillary was rinsed with 0.1 M NaOH for 2 min and then with water for 2 min. Between the runs, the capillary was flushed as follows: 1 min with methanol, 1 min with 1 M NaOH, 1 min with 0.1 M NaOH, 2 min with water and finally 4 min with run buffer. Due to the particular complexity of the background electrolyte, in order to maintain good system performance, particular care had to be taken in instrument maintenance and cleaning, with special regard to capillary, electrodes and prepunchers.

2.4. Calibration curves

The corrected peak area ratios (analyte to internal standard) were plotted against the corresponding concentration of analyte in order to obtain the calibration graphs. For the calibration curve of impurity 1, which corresponded to two enantioseparated peaks in the electropherogram, the sum of I_1 enantiomers corrected areas/internal standard corrected area ratio was plotted versus I_1 concentration.

Five different concentrations of each analyte were prepared and the solutions were analysed twice. FLU concentration was kept constant at 0.5 mg/mL throughout all the experiments. The regression curve for OXY ranged from 3.2 to 9.6 mg/mL (40–120% of the test concentration) and the considered ranges for the impurities were from the respective LOQ to 0.08 mg/mL (1% of the test concentration).

2.5. Calculations and software

Resolution value R_5 (I_3/I_4) was calculated according to the formula

$$R = 2(t_{RB} - t_{RA}/w_B + w_A)$$

where t_{RA} and t_{RB} are the migration times and w_A and w_B are the corresponding widths at the bases of adjacent peak pairs, respectively [32].

Due to the different characteristics of the last migrating peaks, for which different concentration values of the analytes were involved (OXY, 8 mg/mL; I_4 and I_5, 0.08 mg/mL), resolution values R_6 (I_4/OXY) and R_7 (OXY/I_5) were calculated using the statistical method [33,34]:

$$R = \frac{M1_b - M1_a}{w_{Sb} + w_{Sa}}$$

where $M1_a$ and $M1_b$ are the mean migration times for adjacent peak pairs (first statistical moment), w_{Sa} and w_{Sb} are the widths derived from statistical moments $= \sqrt{(M2)}$, where $M2$, the second statistical moment, is the peak variance which is a measure of lateral spreading. The detailed information for this calculation method is summarised in the software manual [33].

Experimental design was generated and statistical analysis of experimental data was performed using NEMROD-W software package [35]. During optimization, the electrophoretic experiments were run in a randomized order using a test solution containing 8 mg/mL OXY, 0.08 mg/mL OXY impurities and 0.5 mg/mL FLU (internal standard).

3. Results and discussion

Experimental design [28,29] is the methodology of planning and carrying out experiments in order to extract the maximum amount of information from the data in the lowest number of runs. In general, when applying this technique to the optimization of analytical methods, some preliminary experiments have to be carried out depending on the investigated analytes to obtain information on the behaviour of the system under study and, thus, to efficiently plan the experiments to be run.

In the present work, the analytes were three basic (OXY, I_4, I_5), one acid (I_1) and one neutral (I_2) chiral substances, and one achiral basic substance (I_3). Due to the presence of analytes with different acid–base properties, the possibility of using a pseudostationary phase was taken into account. In a first step, MEKC using different surfactants was tested but failed to obtain good separations. Therefore, it was decided to test a microemulsion system optimized in a previous paper by the authors for the determination of ketorolac and its related substances [9]. Microemulsions are thermodynamically stable, transparent, isotropic dispersions composed of oil (O) and water (W) stabilized by an interfacial film of surfactant (S) molecules, suitably combined with a cosurfactant (CoS) [36]. In this case the microemulsion was made up of 90.0% 10 mM borate buffer pH 9.2, 2.0% *n*-heptane, and 8.0% SDS/*n*-butanol in 1:2 ratio. Using this system as pseudostationary phase, and performing a CE run on a mixture of the analytes kept at low concentrations (0.04 mg/mL), promising results were obtained as a good separation was achieved for all the peak pairs in about 11 min. However, the obtained resolution was not high enough to be maintained performing the analysis on the test sample, where the concentration of OXY (8 mg/mL) was 100 times the concentration of OXY impurities (0.08 mg/mL).

Therefore, needing to improve the separation, the use of a suitable neutral cyclodextrin was taken into consideration as an additional component of the BGE, due to the ability of cyclodextrins (CDs) in inclusion complexation of a number of drugs. Neutral CDs, having no charge and presenting a hydrophilic external surface, are not expected to interact with the anionic oil droplets [2]. The CDs could be though completely distributed into the aqueous phase of the bulk solution to give a second pseudostationary phase which acts in competition with the anionic oil droplet of the microemulsion [37]. This phase migrates with an identical velocity with the bulk solution and is capable of solubilizing selectively certain types of solutes depending on their size, shape and hydrophobicity [2].

Different CDs, reported in Section 2, were tested and HPβCD and HPγCD were found the most suitable on the basis of selectivity. However, the use of different concentration levels of HPγCD resulted in an inversion of the migration order of the analytes.

This behaviour could lead to problems when applying experimental design since resolution cannot be univocally measured. For this reason, HPγCD was discarded and HPβCD was preferred as this problem was not evidenced with the latter.

Adding 15 mM HPβCD to the microemulsion system, the resulting migration order was: I_{1A}, I_{1B}, FLU, I_2, I_3, I_4, OXY, I_5. The first two peaks, I_{1A} and I_{1B}, corresponded to the enantioseparation of I_1. This separation was presumably due to the fact that this acidic compound, negatively charged, has a low affinity for the negatively charged oil droplets, and conversely presents a significant interaction with the chiral cyclodextrin. It is worthwhile noting that for the aims of this work the chiral separation of OXY impurities was not required and it could even constitute a drawback. In fact, by splitting the peak in two the related heights become lower and this worsens the LOD and LOQ concentration values.

The following step of the work concerned the multivariate optimization of the microemulsion system by mixture design and the optimization of the process factors concentration of cyclodextrin and voltage. The experiments were performed using a test sample made up of 8 mg/mL OXY, 0.08 mg/mL OXY impurities and 0.5 mg/mL FLU.

3.1. Optimization of microemulsion composition by mixture design

The microemulsion system, from a statistical point of view, is a mixture and its study involves mixture design, *i.e.* a special response surface study where the response is a function of the different proportions of the components [29,38,39]. In this design each component can range between 0 and 1 according to the values assumed by the other components and the investigated experimental domain has a triangle shape. When upper and lower boundaries are present, the size of the experimental region is restricted. In the present study the component constraints were selected according to the literature [40,41] and corresponded to the values considered in a previous work by the authors for the analysis of ketorolac and its impurities [9]. The investigated experimental domain was inside the existence field of the microemulsion and no phase-diagram was used.

The ranges for the mixture variables were: x_1, 10 mM sodium borate (aqueous phase, W), 88.0–93.9%; x_2, *n*-heptane (oil phase, O), 0.1–2.0%; x_3, SDS/*n*-butanol in 1:2 ratio (surfactant, S/cosurfactant, CoS) 6.0–10.0%. For the presence of constraints, the size of the experimental region was restricted and a transformation of components (x_i) into new variables, called pseudocomponents (z_i), was necessary [29,38]. The pseudocomponents are combinations of the original components that rescale the constrained data area so that the minimum allowable amount of each component is zero. This transformation allows a more accurate estimation of model coefficients to be obtained with respect to that obtainable using the original component system [29,38].

The optimization of the system involved the critical resolution values among the analytes and analysis time (t), measured as migration time of the last peak (I_5).

In order to optimize the microemulsion system, a Scheffé special cubic regression model [29,38] was hypothesised among the response and the pseudocomponents:

$$y = \beta_1 z_1 + \beta_2 z_2 + \beta_3 z_3 + \beta_{12} z_1 z_2 + \beta_{13} z_1 z_3 + \beta_{23} z_2 z_3 + \beta_{123} z_1 z_2 z_3$$

where β_i terms are called the linear blending terms and correspond to the responses at the vertices, *i.e.* represent the expected response from a pure mixture of x_i and all other components set at zero. The quadratic terms β_{ij} are called nonlinear blending terms and are estimated at experimental points representing a 50:50 mixture of two components [39]. The cubic term β_{ijz} is estimated from a mixture of the three components and represents the interaction among them [39].

Table 1
Mixture design experimental plan and responses.

The model coefficients were calculated by a 13-run mixture design with three replicate experiments at the centre for estimating the experimental variance. The experimental plan that defined the percentage of the components to be used to prepare the different microemulsions is reported in Table 1 with the measured responses. The experiments were run keeping HPβCD concentration at 15 mM and voltage at 27 kV. No problems were observed for the resolutions between I_1 and FLU, FLU and I_2, I_2 and I_3. For these responses a resolution value above 3 was observed in all electropherograms, thus it was decided to discard them for the statistical treatment. Critical resolution values were observed for the last migrating peaks, thus the responses R_5 (I_3/I_4), R_6 (I_4/OXY) and R_7 (OXY/I_5) were maintained for the statistical treatment. For these responses the coefficients of the postulated model were calculated and the analysis of variance (ANOVA) [29,42] showed that for all the considered responses the regression model was significant and valid.

It was then possible to draw the contour plots in order to study the relationship between the response and the component proportions (Fig. 2). In these plots the response is projected onto a plane of the factors by means of isoresponse curves, where the isoresponse lines correspond to the same predicted values of the considered response. By examining the contour plots it is possible to find the proportions among the components in order to optimize the response, considering that moving towards one vertex the percentage of the relative component increases until the maximum permitted with the consequent reduction of the other components.

As regards response R_5, the obtained isoresponse lines are reported in Fig. 2a. In this case a maximization of the response is obtained by moving towards high levels of S/CoS and low levels of borate buffer. As for the oil phase, using high percentages of S/CoS, resolutions higher than 1.5 can be obtained in the whole investigated domain. The same trend can be observed for the other two resolutions R_6 (Fig. 2b) and R_7 (Fig. 2c): high values of S/CoS and low values of aqueous phase are necessary to obtain a baseline separation. As for analysis time, for which the contour plot is represented in Fig. 2d, this response is speeded up by using high percentages of water and low percentages of S/CoS, while the oil effect is not important in the investigated experimental domain.

Thus, there was a clear conflict between the conditions required to maximize the responses related to resolution and those required to minimize analysis time. In order to overcome this conflict and to find a good compromise among the responses, Derringer's desirability function (D) was used [29]. To apply this tool, each response has to be transformed into a partial desirability function d_i cor-

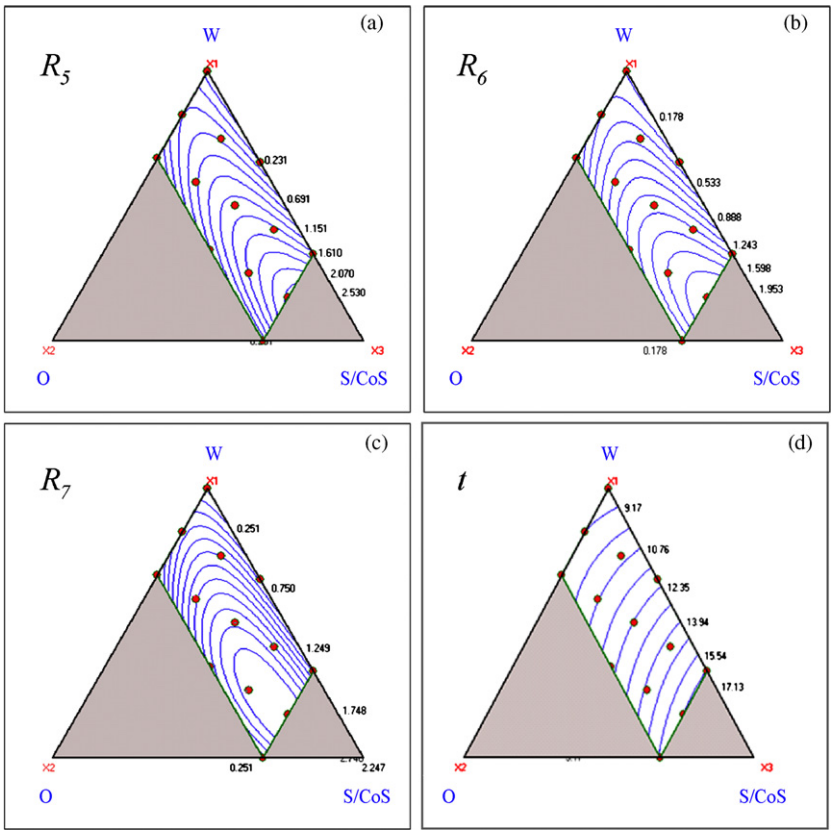

Fig. 2. Contour plots: (a) response I_3/I_4 resolution (R_5); (b) response I_4/OXY resolution (R_6); (c) response OXY/I_5 resolution (R_7); (d) response analysis time (t).

responding to defined optimization criteria and then an overall desirability function D is calculated by way of the geometric mean. For the resolution responses R_5, R_6 and R_7 a minimum and desired value of 1.5 was set, while for the response analysis time only values below 14 min were accepted. From the total desirability function, calculated as $D = \sqrt[4]{d_1 d_2 d_3 d_4}$, the most effective formulation in terms of both selectivity and analysis time was found to consist in 89.1% aqueous phase, 1.7% oil phase and 9.2% S/CoS. The selected microemulsion showed good technological properties with regard to stability and gave a good separation of the analytes, as shown in Fig. 3.

3.2. Optimization of voltage and CD concentration by Doehlert design

After finding the optimal microemulsion composition, with the aim of speeding up the analysis while maintaining a good separation among the compounds, experimental design was applied to optimize the values of the process factors voltage (V) and concentration of cyclodextrin (CD conc.). Having to deal with only two variables, a response surface study [29] was deemed suitable. Applying this approach, a map of the experimental domain span by the selected ranges of considered factors is determined by means of a quadratic polynomial model.

In this study the following quadratic model was assumed:

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_{11} x_1^2 + \beta_{22} x_2^2 + \beta_1 x_1 x_2 + \varepsilon$$

where y represents the experimental response, x_i the independent evaluated factors, β_0 the intercept, β_i the model coefficients obtainable by multiple regression and ε the experimental error.

Estimation of the coefficients of this model can be carried out using different designs such as central composite design, Box-Behnken design, and Doehlert design [29]. In general, a good optimization strategy produces a set of experimental conditions that provide the optimum response with the smallest possible number of trials. From this point of view, Doehlert design is an efficient design and it was selected for this study. In fact, this kind of matrix makes it possible to study the problem in-depth and to

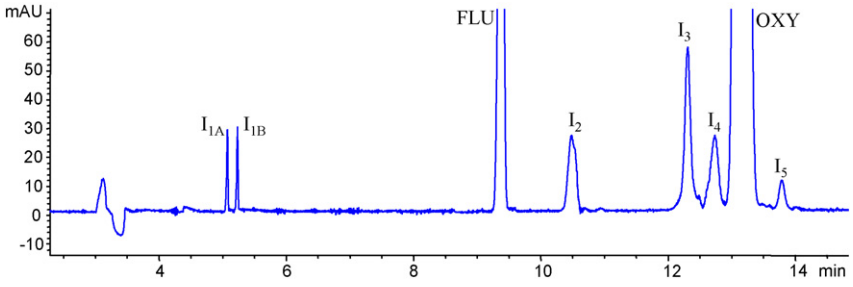

Fig. 3. Electropherogram of OXY and its impurities referring to the optimal microemulsion composition: voltage, 27 kV; temperature, 20 °C. BGE: microemulsion constituted by 89.1% 10 mM borate, 1.7% *n*-heptane, 9.2% SDS/*n*-butanol in a ratio of 1:2; 15 mM HPβCD. Hydrodynamic injection: 50 mbar, 5 s. Detection wavelength: 195 nm.

Table 2
Doehlert design experimental plan and responses.

Exp. No.	CD conc. (mM)	V (kV)	R_5	R_6	R_7	t (min)
1	20	27	1.17	1.80	2.68	12.60
2	12	27	2.83	1.47	2.00	13.74
3	18	30	2.24	1.75	1.66	10.11
4	14	24	2.66	1.87	2.71	17.45
5	18	24	1.68	2.27	3.58	16.86
6	14	30	2.86	1.62	1.89	10.36
7	16	27	2.02	1.62	2.17	12.47

9	16	27	2.19	1.92	2.78	12.98
10	16	27	2.04	1.81	2.68	13.26

draw the relative response surfaces, requiring a number of experiments equal to $k^2 + k + n$, where k is the number of factors and n is the number of replicates at the centre of experimental domain. It also offers the advantage of allowing the factors to be studied at a different number of levels, and permitting the study of some factors in a more in-depth way. In this study, the effect of cyclodextrin concentration on the responses was more deeply evaluated fractionating its range of variation, 12–20 mM, into five levels, while voltage, ranging from 24 to 30 kV, was studied at three levels.

The experimental plan, comprehensive of four replicates at the centre of the experimental domain, is reported in Table 2 together with the responses. In most of the 10 obtained electropherograms, good separations were achieved.

The response surfaces, as a function of concentration of HPβCD and voltage, are reported in Fig. 4. The best results for response R_5 were obtained by setting high voltages and low concentrations of CD (Fig. 4a). In any case, the most important effect was due to HPβCD concentration, which had to be set at low values in order to maximize the response. For the responses R_6 (Fig. 4b) and R_7 (Fig. 4c), low voltages and high concentrations of CD were necessary to obtain the maximization. For the response analysis time, represented in Fig. 4d, its minimization is obtained using high voltages and any concentration of CD.

Also in this case desirability function, as represented in Fig. 5, allowed the best conditions to be found. For the resolutions, a target value above 1.5 was again set as target; for analysis time, the desired response had to be 12 min or less. The plots showed that voltage was critical and high values were required. Fixing voltage at 29 kV, almost every concentration of cyclodextrin yielded good results. The selected optimal conditions were concentration of HPβCD 18 mM and voltage 29 kV.

Applying the optimized conditions, the analysis of OXY and the impurities was run in about 12 min, as shown in the related electropherogram (Fig. 6). Validation of calculated models was carried out by evaluating the agreement between the predicted value and the measured value for every response, thus confirming the predictive ability of the models.

3.3. Validation

Validation was carried out according to ICH guidelines [ICH]. The performance parameters selectivity, robustness, linearity, range, accuracy and precision were evaluated and, for the impurities, also limits of detection and quantitation were assessed. The test mixture for validation process consisted of 8 mg/mL OXY and 0.08 mg/mL for each of the related substances (corresponding to 1%, w/w with respect to the main component), unless otherwise described.

3.3.1. Selectivity

A baseline resolution of all the analytes was obtained, and the critical resolution values were calculated as the following ($n = 4$, $\alpha/2 = 0.025$): R_5, 2.22 ± 0.25; R_6, 1.66 ± 0.24; R_7, 1.73 ± 0.31. No

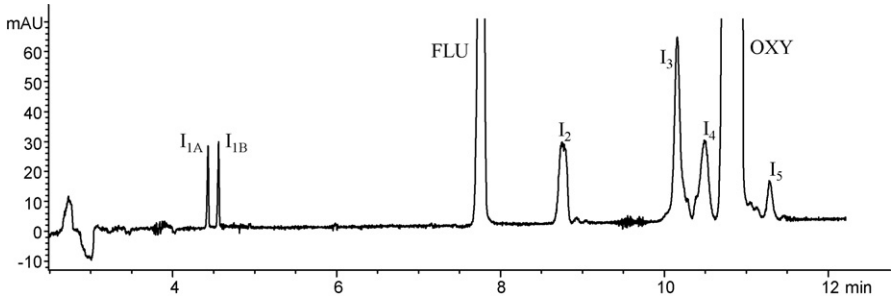

Fig. 6. Electropherogram of OXY and its impurities referring to optimal conditions: voltage, 29 kV; temperature, 20 °C. BGE: microemulsion constituted by 89.1% 10 mM borate, 1.7% *n*-heptane, 9.2% SDS/*n*-butanol in a ratio of 1:2; 18 mM HPβCD. Hydrodynamic injection: 50 mbar, 5 s. Detection wavelength: 195 nm.

interference in the electropherogram was observed due to the presence of the excipients of the dosage form.

3.3.2. Robustness

Robustness was tested by means of full factorial design, where the combinations of *k* factors are investigated at two levels consisting of 2^k experiments [29].

The selected responses were the same taken into consideration during the optimization phase, *i.e.* the critical resolutions R_5, R_6, R_7 and analysis time. As for the selected factors, mixture components were not considered as the optimal microemulsion composition was located in wide zones of the response surfaces where the responses were near constant. On the other hand, the effect of a small variation of the process factors voltage and HPβCD concentration, with the addition of temperature, was evaluated considering the following ranges, symmetric around the optimized values: X_1, CD conc., 17–19 mM; X_2, voltage (V), 28–30 kV, X_3, temperature (T), 19–21 °C. The experiments planned for the three factors describe the corners in a cube and are reported in Table 3 with the measured responses.

Table 3
Robustness testing full factorial design experimental plan and responses.

Exp. No.	CD conc. (mM)	V (kV)	T (°C)	R_5	R_6	R_7	t (min)
1	17	28	19	1.97	1.72	2.43	15.59
2	19	28	19	1.66	1.60	1.88	13.88
3	17	30	19	1.81	1.72	2.20	12.95
4	19	30	19	1.67	1.55	1.90	11.16
5	17	28	21	1.62	1.49	1.52	14.30
6	19	28	21	1.79	1.70	2.39	14.60
7	17	30	21	1.94	1.83	1.42	10.80
8	19	30	21	1.81	1.63	1.78	11.62

Graphic interpretation of effects [43] is reported in Fig. 7, where each bar is related to an effect. The length of the bar is proportional to the absolute value of the effect and the critical factors can be identified as those exceeding the reference lines. In this case only voltage exerted a negative effect on response analysis time.

3.3.3. Migration time and peak area precision

System repeatability was evaluated performing six replicate injections in three consecutive days for a total of $n = 18$ runs. Within-day RSD ranges were 0.6–0.8% for OXY and 1.5–3.8% for

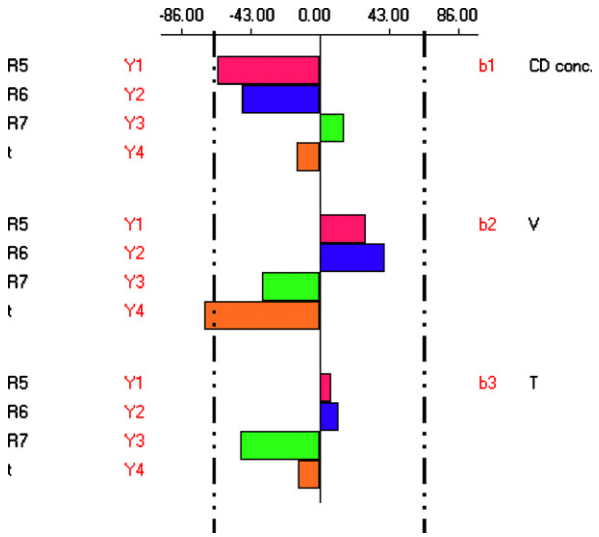

Fig. 7. Robustness testing graphic analysis of effects.

OXY-related substances. Between-day RSD were 1.5% for OXY and 11.4% for OXY-related substances. As concerns analysis time, the calculated within-day RSD values were included in the range 1.8–5.6% and between-day RSD was 8.4%.

3.3.4. LODs and LOQs

The LOD and LOQ of the impurities were calculated from S/N of approximately 3:1 and 10:1, respectively. The obtained values for LOD were: I_1, 12 μg/mL; I_2, 3 μg/mL; I_3, 4 μg/mL; I_4, 5 μg/mL, I_5, 4 μg/mL. As concerns LOQ, the following values were found: I_1, 20 μg/mL (0.250%, w/w); I_2, 5 μg/mL (0.0625%, w/w); I_3, 8 μg/mL (0.100%, w/w); I_4, 7 μg/mL (0.0875%, w/w); I_5, 8 μg/mL (0.100%, w/w). Values of LOQ were validated measuring the RSD corrected area of eight replicate injections keeping each impurity at LOQ concentration, and values in the range 2.9–5.6% were obtained.

3.3.5. Linearity

The linearity range for OXY was 3.2–9.6 mg/mL (40–120% of the test concentration) and the corresponding equation was $y = 1.5171x - 0.6319$ ($R_2 = 0.9989$). For OXY-related substances the linearity range was from the respective LOQ values to 0.08 mg/mL, corresponding to 1% (w/w) with respect to the main component. Values of correlation coefficients ranged from 0.9961 to 0.9973.

Accuracy and precision were evaluated by three replicate runs at three concentration values covering the linearity range, performing the assay of a known added amount of analyte in the sample. For OXY the obtained recoveries were from $99.0 \pm 1.5\%$ to $101.2 \pm 1.9\%$ and the maximum RSD was 0.7%. For OXY impurities, the recoveries were included in the interval ranging from $98.3 \pm 4.7\%$ to $101.5 \pm 2.9\%$, with a maximum observed RSD equal to 3.7%.

3.3.6. System suitability test

System suitability criteria were established choosing the critical resolution values as performance parameters and selecting as limits the lowest and the highest resolution values measured during system precision study [44,45], corresponding to: $2.10 < R_5 < 2.45$, $1.48 < R_6 < 1.72$, $1.54 < R_7 < 1.88$.

3.4. Application

The developed method was applied to a real sample of Ditropan® tablets, labelled to contain 5 mg OXY. The obtained results ($n = 4$, $\alpha/2 = 0.025$) were in agreement with the declared composition. Recovery was $97.4 \pm 1.5\%$ with RSD 1.2% and no OXY impurity was detected.

4. Conclusions

A cyclodextrin-MEEKC method was developed by means of a multivariate strategy involving, first, mixture design for optimizing microemulsion composition and, secondly, response surface study for selecting the optimal values for process factors. Baseline separation of the parent compound and its related substances was obtained in less than 12 min. The experimental plan used for optimizing the proportions of the microemulsion components can be proposed for a general use in MEEKC. Good results were obtained in terms of selectivity and analysis time, thus demonstrating the validity and versatility of the proposed approach. The analysis performances were then further improved by means of Doehlert design, which took into account voltage and cyclodextrin concentration and made it possible to find the optimum by applying desirability function.

ABSTRACT

This paper presents a material that has both hydrophilic and hydrophobic domains, obtained by combination of a polyampholyte with a surfactant. This material was fully characterized by different spectroscopic techniques and microscopy.

Bisphenol-A (BPA) was chosen as a model molecule to study the interaction with compounds of intermediate polarity. We explored the kinetics and equilibrium of BPA on the surface of the polyampholyte–surfactant complex and found a significantly high loading capacity (2.02 mmol g^{-1}) and complete binding from solutions at concentration levels below 100 μmol L^{-1}.

The complex was encapsulated in agarose gel to be used as solid phase for extraction of BPA from food simulants in contact with polycarbonate bottles under different treatments. Bisphenol was preconcentrated, extracted and analysed by liquid chromatography with an amperometric detector. The instrumental detection limit of the technique was 10 μg L^{-1}, which was lowered to 0.14 μg L^{-1} by the preconcentration step. The BPA released from baby bottles was 2.1 ng cm^{-2} (σ_{n-1}: 0.1) in the first use with distilled water.

1. Introduction

Bisphenol-A (BPA), 2,2-bis(4-hydroxyphenyl) propane, is a chemical substance used mainly in the production of polycarbonate and epoxy resins [1]. A great variety of materials (storage containers, milk bottles, infant feeding bottles, microwave ovenware) derived from polycarbonate cause environmental contamination when they are in contact with water or food due to the leakage of non-polymerized monomers or residues from hydrolysis.

It has been reported that BPA has a weak affinity for estrogen receptors [2], has potential for disrupting thyroid hormone action [3], affects the proliferation of human prostate cancer cells [4] and blocks testosterone synthesis [5] at ng L^{-1} doses.

Due to these toxicological properties, many analytical methodologies, including sample preparation, separation and detection of BPA, have been developed [1].

In 2004, the EU Commission established a specific migration limit (SML) of BPA from food plastic materials of 600 ng g^{-1} [6]. Migration testing is usually carried out with food simulants instead of food, because its analysis usually presents some drawbacks. Simulants have been selected to model different categories of food (aqueous, acidic, alcoholic and fatty) to simplify the testing and evaluate whether a plastic is suitable for a given application [7].

Separation, identification and quantitation of BPA are reliably carried out with mass spectrometric methods, namely liquid chromatography–tandem mass spectrometry [8] and gas chromatography–tandem mass spectrometry [9]. Other methods such as liquid chromatography coupled to fluorescence or electrochemical detection and immunochemical methods have also been reported [1]. When food simulants are used, the sample preparation consists of a preconcentration step by solvent evaporation, liquid–liquid extraction, solid phase extraction (SPE), solid phase microextraction or stir bar sorptive extraction [1].

SPE is by far the most widely used technique for the extraction of BPA-containing liquids [9–12]. The technique uses a copolymer formed with the hydrophilic *N*-vinylpyrrolidone, which acts as a hydrogen acceptor, and the hydrophobic divinylbenzene, which provides reversed-phase retention (Oasis HLB).

A number of different approaches have been used to prepare new sorbents in order to improve particular features such as selectivity or capacity. Synthetic strategies such as the molecularly imprinting technique or the construction of immunoaffinity monoliths have been applied to generate selective binding sites in bulk or surfaces of polymeric matrixes [13–15].

This paper presents a material that combines a hydrophilic network with hydrophobic regions, and exhibits a notably high loading capacity for BPA. The network is a polyampholyte obtained by reaction of methacrylic acid, ethylene glycol, diglycidyl ether and 2-methylimidazole (poly(EGDE–MAA–2MI)) [16–18], following a new synthetic procedure. The acid form of this polymeric material binds dodecyl sulfate on the surface. The interactions between surfactants and polyelectrolytes have been well reviewed [19–21] and the dominating factor that influences binding is the electrostatic charged neutralization of the polyion by oppositely charged surfactants. The electrostatic binding is an endothermic process driven by entropy. The positive entropy is attributed to the recovery of translational entropy of released counterions by the bound surfactant.

The new material was fully characterized by spectroscopy (^{13}C Nuclear Magnetic Resonance in the solid-state, Fourier Transform-Infrared), thermogravimetry, elemental analysis, nitrogen adsorption and scanning electron microscopy.

The kinetics and sorption equilibrium of BPA on the surface were also studied. The material was also encapsulated in agarose beads and tested as sorbent for the BPA released from baby bottles into food simulants, under different treatments. The analysis was completed by liquid chromatography with electrochemical detection (HPLC-ED), and the performance of the method is discussed.

2. Materials and methods

2.1. Reagents

2-Methylimidazole (2MI; 99 wt%; pK_a: 7.86), bisphenol-A (BPA 99 wt%, MW: 228.29), methacrylic acid (MAA; 99 wt%; pK_a: 4.66), ethylene glycol diglycidyl ether (EGDE; 50 wt% in ethylene glycol dimethyl ether), phenol (99 wt%), methylparaben (99 wt%), propylparaben (99 wt%) and diethyl phthalate (99 wt%) were purchased from Sigma–Aldrich, and benzoyl peroxide from Fluka. Sodium dodecylsulfate (SDS; MW: 288.38; solubility at 20 °C: 10 g in 100 g of water; critical micelle concentration (CMC): 8.2 mmol L^{-1}) and dodecylbenzene sulfonic acid sodium salt (SBDS; MW 348.5; solubility at 20 °C: 32.8 g in 100 g of water; CMC: 1.2 mmol L^{-1}) were purchased from ICN Biomedical.

Baby bottles (250 cm^3) from one brand made of polycarbonate were washed twice with distilled water before use; no further treatment was performed.

Acetonitrile, isopropyl alcohol and methanol from Baxter were HPLC grade. BPA-free distilled water was used for all aqueous solutions. Spectroscopic grade potassium bromide was used for infrared pellets. Hydrochloric acid, sodium chloride, sodium hydroxide, disodium hydrogen phosphate and potassium hydrogen phosphate were of analytical grade.

2.2. Synthesis of the polyampholyte modified with the surfactant

The polyampholyte was synthesized according to previous reports [16–18], from methacrylic acid, ethylene glycol diglycidyl ether and 2-methylimidazole. Then it was washed with water, dried at 60 °C for 24 h and milled in particles with an average diameter of 200 μm. The particles were treated with 0.1 mol L^{-1} HCl to obtain the acid form of the polyampholyte (poly(EGDE–MAA–2MIH$^+$)), and 50 mg were put in contact with three aliquots of 4 mL of 20 mmol L^{-1} sodium dodecyl sulfate (SDS) solution. The adsorption of dodecyl sulfate (DS) on the surface of the poly(EGDE–MAA–2MIH$^+$) was expected to take place under these conditions (Scheme 1). The complex poly(EGDE–MAA–2MIH$^+$)–DS was rinsed with distilled water, filtered, and let to dry at room temperature. Sodium dodecylbenzene sulfonate (SDBS) was also used for the formation of the complex since it absorbs radiation at 273 nm and can be monitored spectrophotometrically.

2.3. Characterization of the poly(EGDE–MAA–2MIH$^+$)–DS complex

The Fourier Transform-Infrared (FTIR) spectra of poly(EGDE–MAA–2MIH$^+$)–DS and polyampholyte were recorded on a Spectrum 1000 PerkinElmer spectrometer using KBr pellets. The material was dried and placed in a desiccator at 20 °C prior to pellet preparation.

High-resolution ^{13}C Nuclear Magnetic Resonance (NMR) solid-state spectra were recorded using the ramp $\{^1H\} \rightarrow \{^{13}C\}$ CP-MAS (cross-polarization and magic angle spinning) sequence with proton decoupling during acquisition. All the solid-state NMR experiments were performed at room temperature in a Bruker Avance II-300 spectrometer equipped with a 4-mm MAS probe. The operating frequency for carbons was 75.46 MHz and the spinning rate was 10 kHz. Samples of two batches of each material were studied.

Thermogravimetric measurements were carried out with a TA Instrument SDT Q600, under nitrogen flux over a temperature range from 30 to 400 °C with a heating rate of 10 °C min^{-1}. The average sample size was 10 mg and the measurements were carried out in triplicate.

The surface of two batches of each polymer was characterized using a scanning electron microscope Field Emission SEM (Zeiss Gemini DSM 982) operated at a 0.3 kV acceleration voltage.

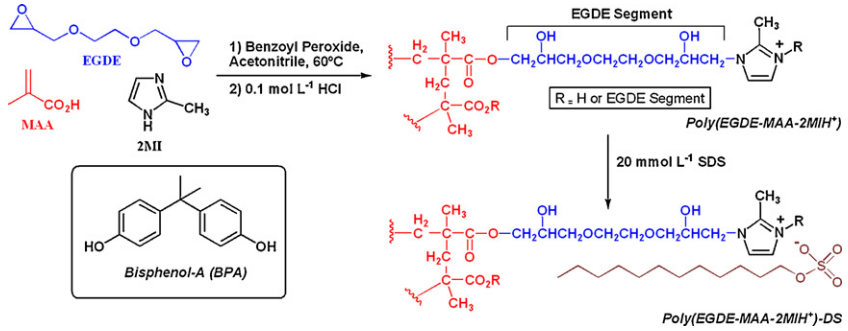
Elemental analysis was performed with a CE440 Elemental Analyser device (Exeter Analytical).

The nitrogen adsorption isotherm was collected at 77 K on a Micromeritics Gemini 2360 system. Specific surface area was calculated using the Brunauer–Emmett–Teller equation (BET).

2.4. Surfactant adsorption isotherms

For binding studies, SDS was replaced with SDBS, whose concentration was determined by UV measurements.

Kinetic experiments were performed with a 4 mmol L^{-1} SDBS standard solution under forced convection.



The adsorption isotherm was performed with aliquots of 80 mg of acid polyampholyte dispersed in 10.0 mL of SDBS standard solutions in a concentration range between 0.20 and 8.0 mmol L^{-1}. The suspensions were mixed and thermostated at 20.0 ± 0.5 °C for 16 h to reach equilibrium. The SDBS concentration in the supernatant and standard solutions was analysed spectrophotometrically at 273 nm.

2.5. Bisphenol-A (BPA) uptake

BPA in solution was analysed by liquid chromatography with electrochemical detection (HPLC-ED). The chromatographic system consisted of an HPLC SpectraSYSTEM Isocratic Pump P100, a Rheodyne injection valve (Model 7125) with a 20-μL sample loop, a guard column, and a C-18 bonded column (Hewlett-Packard) 5 μm, 200 mm × 4.6 mm. The mobile phase was methanol:aqueous solution containing 10 mmol L^{-1} KNO_3 and 0.25 mmol L^{-1} H_2SO_4 as supporting electrolyte in a proportion of 55:45, at a flow rate of 0.8 mL min^{-1}.

Amperometric detection was performed with a microprocessor-controlled electrochemical analyser. A thin-layer cell (7 μL volume), equipped with a glassy carbon working electrode (BAS, 7 mm^2 area) and a stainless steel block as auxiliary electrode, operated at +1 V vs. Ag/AgCl.

Stainless steel, PTFE and PEEK were used for the flow system connections.

Scheme 1. Chemical structure of bisphenol-A (BPA) and synthesis of the poly(EGDE–MAA–2MIH$^+$) and poly(EGDE–MAA–2MIH$^+$)–DS complex.

The linear range for BPA was verified up to 800 μg L^{-1}. All the samples were filtered and properly diluted for HPLC analysis.

Kinetic experiments of BPA sorption on the complex were carried out with 50 mg of poly(EGDE–MAA–2MIH$^+$)–DS in contact with 125 mL of 500 μmol L^{-1} BPA (114 mg L^{-1}) dissolved in 10:90 methanol:water, under forced convection.

The sorption isotherm experiments were performed with aliquots of 40 mg of poly(EGDE–MAA–2MIH$^+$)–DS dispersed in 200 mL of BPA standard solutions in a concentration range between 75 and 800 μmol L^{-1} (17 and 183 mg L^{-1}), in the same medium. The suspensions were mixed and thermostated at 20.0 ± 0.5 °C for 1 h.

For the adsorption isotherm of BPA on the polyampholyte without surfactant, 200 mg of polymer and 25 mL of BPA aqueous solution in the range between 3.7 and 216 μmol L^{-1} were used.

2.6. Preconcentration and analysis of BPA released from baby bottles

The linear concentration range of the HPLC-ED analytical technique was examined injecting BPA solutions prepared in 60:40 isopropanol:methanol, with five concentration levels (0.050, 0.100, 0.200, 0.300 and 0.500 mg L^{-1}), in triplicate.

The detection and the quantification limits (LoD and LoQ) were calculated as 3 and 10 times the standard deviation of five replicate runs of the procedure blank, respectively.

The extraction process of BPA from baby bottles consisted of a migration assay by using food-simulating liquids, and a preconcentration step prior to detection. A new extraction sorbent was prepared by including poly(EGDE–MAA–2MIH$^+$)–DS in agarose gel. Sorbent beads were obtained by mixing 200 μL of 1% agarose solution at 60 °C with 50 mg of poly(EGDE–MAA–2MIH$^+$)–DS in 4 mm × 4 mm cavities, and cooling at room temperature.
