Solid phase extraction (SPE) for the analysis of trace concentrations of metal ions in various samples has received much attention in recent years. This technique reduces solvent usage and exposure, disposal costs, and extraction time. Various adsorbents, such as octadecyl functional groups bonded on silica gel, C_{18} [34], glycerol–silica gel [35], chelating adsorbents [36], Amberlite XAD resins [37], Chromosorb resins [38] and other sorbents [39,40] have been used for adsorption of metal chelates in the preconcentration and separation of metal ions.

Amberlite XAD resins have physically or chemically been loaded with the various ligands to prepare new chelating resins and explored extensively for metal enrichment. Their attractive features are easy regeneration for multiple sorption–desorption cycles, good mechanical stability and reproducible sorption characteristics. The impregnation of polymer matrices with common chelating ligands is an easy way to design chelating collectors. Amberlite XAD-2 [41], Amberlite XAD-4 [42], Amberlite XAD-7 [43], Amberlite XAD-16 [44] and Amberlite IRC-718 [45] have been used as a support for such preparations.

In this paper we introduce a procedure for the separation and preconcentration of trace amounts of uranium, thorium and zirconium ions using Amberlite XAD-2000 resin impregnated with α-benzoin oxime, prior to their simultaneous spectrophotometric determination by Arsenazo III as a chromogenic reagent using multivariate calibration techniques (partial least squares) with preprocessing by orthogonal signal correction.

2. Experimental

2.1. Reagents

All reagents were of analytical grade, purchased from the Merck Company. Standard stock solutions (1000 μg mL^{-1}) of thorium(IV) and uranium(VI) and zirconium(IV) were prepared by dissolving appropriate amounts of $UO_2(NO_3)_2{\cdot}6H_2O$, $Th(NO_3)_4{\cdot}5H_2O$ and $ZrOCl_2{\cdot}8H_2O$, in water, respectively. Stock solutions of diverse elements were prepared from the high purity salts of the cations (all from Merck, Germany). Amberlite XAD-2000 (styrenedivinylbenzene copolymer, surface area: 620 $m^2\,g^{-1}$, pore diameter: 4.2 nm and bead size 20–60 mesh) was supplied by Sigma.

2.2. Instrumentation and software

A Perkin Elmer (Lambda 25) spectrophotometer with 10 mm quartz cells was used for UV–vis spectra acquisition. A Metrohm model 744 digital pH meter, equipped with a combined glass-calomel electrode, was employed for the pH adjustments.

The data were processed on a Toshiba computer with Pentium IV as central processing unit (2 Gb RAM) using MATLAB software, version 7.6. PLS and other calculations were carried out using PLS-Toolbox, version 4.0 (Eigenvectors Company).

2.3. Preparation of chelating resin

Amberlite XAD-2000 resin obtained from the supplier contained organic and inorganic impurities. To remove the contaminants, it was washed successively with methanol, water, 1.0 mol L^{-1} HNO_3, water, 1.0 mol L^{-1} NaOH and water. For the impregnation of the resin, 1.0 g of clean and dry XAD-2000 resin beads were added to the solution of α-benzoin oxime in methanol (10 mL of 0.01 mol L^{-1}) and equilibrated with constant stirring for 1 h. The ligand penetrated into the resin bed and was held up strongly. The treated beads were loaded in a glass column (10 cm long and 1 cm i.d.) and washed with deionized water.

2.4. Recommended procedure for solid phase extraction

The general procedure for the extraction of U(VI), Th(IV) and Zr(IV) ions on the impregnated resin was as follows. The column containing 1.0 g of modified resin was first washed with 25 mL water. This step pre-wets the surface of the resin prior to ion extraction. Then 50 mL of the sample solution containing 10.0 μg U(VI), Th(IV) and Zr(IV) (pH = 3), was passed through the column (flow rate = 10 mL min^{-1}). The extracted U(VI), Th(IV) and Zr(IV) were then stripped from the column using 5.0 mL of a 1 mol L^{-1} solution of hydrochloric acid (flow rate = 5 mL min^{-1}) into a 10.0 mL volumetric flask. The uranium, thorium and zirconium concentrations were then determined spectrophotometrically using Arsenazo III as a metallochromic indicator.

2.5. Recommended procedure for spectrophotometric determination

A solution containing no more than 35.0 μg of U(VI), 35.0 μg of Th(IV) and 22.0 μg of Zr(IV) was transferred into a 10.0 mL volumetric flask and 1.0 mL of 0.1% Arsenazo III solution was added. The concentration of hydrochloric acid was adjusted to 0.1 mol L^{-1} by using appropriate volumes of either NaOH or HCl solution. The volume was made up to the mark with distilled water and the solution was mixed. After 15 min, the absorption spectra were recorded between 600 and 700 nm against a reagent blank in a 10 mm cell.

2.6. Analysis of the real samples

A 250 mL of tap water, well water, and seawater samples were filtered through 0.45 μm membrane filter, adjusted to the optimum pH and subjected to the recommended column procedure for the preconcentration and determination of metal ions. To 1.0 g of ceramic samples in a platinum crucible, 10 mL of HF, 1 mL of H_2SO_4, and 1 mL of $HClO_4$ were added and heated to 150 °C on a hot plate. The process was repeated three times. The residue was cooled and dissolved in 50 ml of 0.1 mol L^{-1} HCl and diluted up to 100 mL. Suitable aliquots were taken and subjected to preconcentration and determination by the procedure described above.

3. Results and discussion

In the preliminary experiments, the effect of chemical medium on the reaction between U(VI), Th(IV), and Zr(IV) ions and Arsenazo III was studied. For this purpose, absorption spectra of the U(VI), Th(IV) and Zr(IV) ions in the range of 600–700 nm, in the different concentrations of hydrochloric acid and also different pH values (adjusted by hydrochloric acid and sodium hydroxide) were examined. 0.1 mol L^{-1} hydrochloric acid was found to be optimum medium for this analytical work, to compromise the sensitivity and selectivity of all three metal ions.

Fig. 1 shows the absorption spectra in aqueous solution of the individual uranium, thorium, and zirconium complexes and Arsenazo III at 0.1 mol L^{-1} HCl. As this figure shows, there is a clear overlapping of the three spectra. This prevents the simultaneous determination of the uranium, thorium, and zirconium by direct UV–vis absorbance measurements. To overcome this problem a suitable and simple technique, which presents a good recovery, is PLS regression. Spectra of mixtures of uranium and thorium solutions between 600 and 700 nm wavelengths by 1 nm intervals were recorded, and then the data were digitized and stored for late treatment.

3.1. Individual calibration

Individual calibration curves were constructed with several points as absorbance versus uranium, thorium, and zirconium ions concentration. For constructing the individual calibration lines the absorbances were measured at 650, 620 and 630 nm against a blank for uranium, thorium, and zirconium, respectively. The linear regression equation for the calibration graph for uranium for the concentration range of 0.2–3.5 μg mL^{-1} was $A = 0.0937C + 0.0304$ ($r^2 = 0.9991$, $n = 10$), for thorium for the concentration range of 0.2–3.5 μg mL^{-1} was $A = 0.0933C + 0.0125$ ($r^2 = 0.9989$, $n = 10$) and for zirconium for the concentration range of 0.2–2.2 μg mL^{-1} was $A = 0.0993C + 0.113$ ($r^2 = 0.9988$, $n = 10$).

3.2. Multivariate calibration

The determination of the uranium, thorium and zirconium in mixtures by spectrophotometry using multivariate calibration involves constructing calibration and prediction sets. An experimental design was used to maximize statistically the information content in the spectra. A training set of 36 samples was taken (Table 1). The concentrations of uranium, thorium, and zirconium were 0–3.5, 0–3.5, and 0–2.1 μg mL^{-1}, respectively. For the prediction set, 6 mixtures were prepared (see Table 3). The chemometrics calibrations were computed with the PLS and OSC-PLS algorithms, using the correlation for the training set concentration and its current data.

Fig. 2 shows the score plot for when the PLS and OSC-PLS are used. The score plots are shown for comparison of the results obtained from PLS and OSC-PLS. The results show that score plots have better results when OSC-PLS is used. Score plots reveal the geometrical placement of the solutions in principal components space. The experimental noise can destroy this relation but by removing the noise using OSC filtering, the OSC-PLS score plots depicted in a more clear way the location of the solutions in the scores map which are the same as triangular experimental design was used in preparation of calibration and prediction solution sets.

For the evaluation of the predictive ability of multivariate calibration models, the root mean square error of prediction (RMSEP) and relative error of prediction (REP) can be used (Table 2):

$$\mathrm{RMSEP} = \left[\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2\right]^{0.5}$$

$$\mathrm{REP\%} = \frac{100}{\bar{y}}\left[\frac{1}{n}\sum_{i=1}^{n}(yi - \hat{y}i)^2\right]^{0.5}$$

3.3. Selection of optimum number of factors

The optimum number of factors (latent variables) to be included in the calibration model was determined by computing the prediction error sum of squares (PRESS) for cross-validated models using a high number of factors (half the number of total standard + 1), which is defined as follows:

$$\text{PRESS} = \sum (yi - \hat{y}i)^2 \quad (1)$$

where y_i is the reference concentration for the ith sample and $\hat{y}_i$ represents the estimated concentration. A cross-validation method was employed to eliminate only one sample at a time and then OSC-PLS algorithm models the remaining **Y** matrix and corresponding **X** matrix. By using the established calibration model the concentration of the sample, left out was predicted. This process was repeated until each standard had been out once. A plot of the PRESS against the number of factors for each individual component indicates a minimum value for optimal number of factors. For finding the fewest number of factors the *F*-statistics was used to carry out the significance determination [46]. Fig. 3 shows the PRESS obtained by optimizing the calibration matrix of the spectrophotometric data with PLS and OSC-PLS.

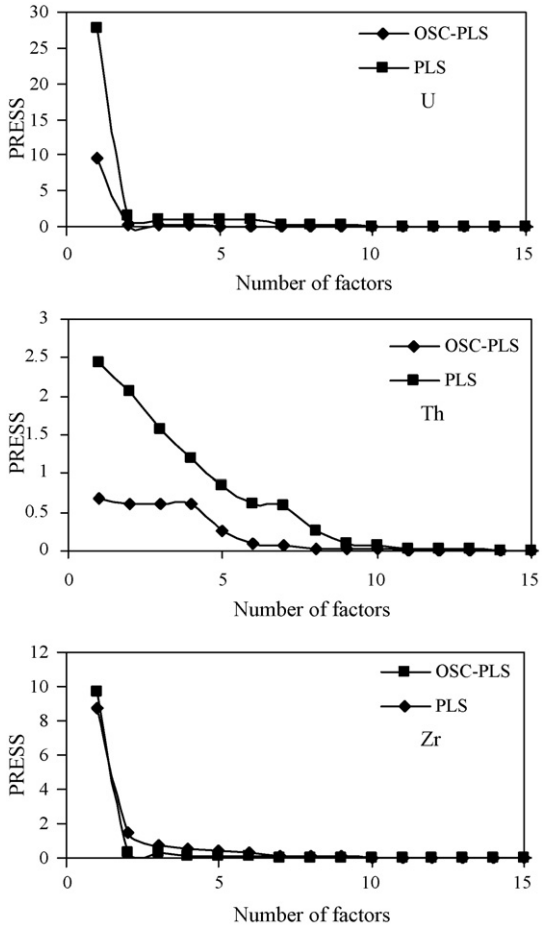

Fig. 3. PRESS versus number of principal components.

3.4. Determination of uranium, thorium, and zirconium in synthetic mixtures

The predictive ability and validation of the calibration model were assessed using six three-component of U(VI), Th(IV), and Zr(IV) mixtures. The results obtained by applying OSC-PLS based calibration model to five synthetic samples are listed in Table 3.

3.5. Optimum conditions for solid phase extraction

3.5.1. Effect of pH

The pH of the sample solution is a very important factor in the separation of metal ions by chelation, and determines the values of the conditional stability constants of the metal complexes on the surface of the sorbent. Thus, the effect of pH on the extraction of uranium, thorium, and zirconium ions was studied. To do this, the pH of 50 mL aqueous samples containing 10 μg U(VI), Th(IV), and Zr(IV) was varied from 2.0 to 6.0. The pH was adjusted by using 0.1 mol L^{-1} of nitric acid and sodium hydroxide solutions. The resulting percent recovery-pH plots are shown in Fig. 4, which indicate that sorption

H_2SO_4	86.7	84.1	64.2	98.4	99.6	99.1	100.1	99.6	99.1

is maximum and quantitative in the pH range of 3.0–6.0 for uranium, 2.5–5.0 for thorium and 2.0–4.0 for zirconium. Consequently, a solution pH of 3.0 was used in further experiments.

3.5.2. Choice of eluent

In order to choose a proper eluent for the retained U(VI), Th(IV) and Zr(IV) ions after extraction of 10 μg of uranium, thorium, and zirconium in a 50 mL solution by the impregnated resin, the uranium, thorium, and zirconium ions were stripped with 5.0 mL of varying concentrations of different mineral acids, and the results are listed in Table 4. The results revealed that a 5.0 mL of 1 mol L^{-1} concentration of hydrochloric acid and sulfuric acid could afford the quantitative elution of U(VI), Th(IV), and Zr(IV) from the column. However, the use of sulfuric acid as elutant was avoided due to its interfering effect in the spectrophotometric determination of uranium, thorium, and zirconium using Arsenazo III. Subsequent elutions of U(VI), Th(IV), and Zr(IV) were carried out with 1 mol L^{-1} HCl solution.

3.5.3. Effect of flow rate

The effect of flow rates of the sample and stripping solutions through the Amberlite XAD-2000-α-benzoin oxime column on the retention and recovery of uranium, thorium, and zirconium ions was investigated. It was found that, in the range of 0.5–10.0 mL min^{-1}, the retention of uranium, thorium, and zirconium by the impregnated resin is not affected by the sample solution flow rate. On the other hand, quantitative stripping of U(VI), Th(IV), and Zr(IV) ions from the column was achieved in a flow rate range of 0.5–5.0 mL min^{-1}, using 5 mL of 1 mol L^{-1} hydrochloric acid. At higher flow rates, larger volumes of 1 mol L^{-1} HCl were necessary for quantitative stripping of uranium, thorium, and zirconium.

3.5.4. Effect of the amount of resin

The effect of sorbent amount on the retention and the recovery was studied for U(VI), Th(IV) and Zr(IV) ions and the results are shown in Fig. 5. As it is seen from Fig. 5, the recovery yields increased with increasing amounts of impregnated resin up to 0.8 g and remained almost constant in the range of 0.8–1.8 g. However, a further increase in the amount of sorbent resulted in some decreased recovery of the metal ions, most probably because the retained metals cannot be completely eluted with 5 mL of eluent (1 mol L^{-1} HCl). According to these results, the optimum amount of resin for the column was found to be 0.8–1.8 g using 5 mL of eluent.

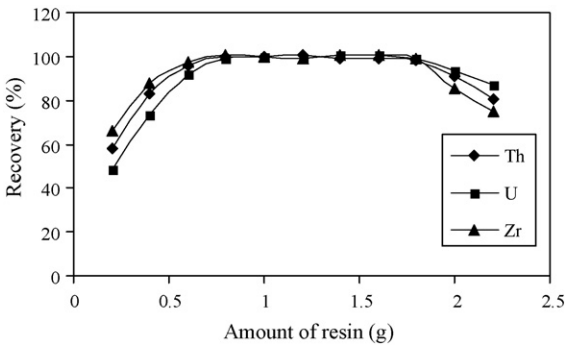

Fig. 5. Effect of amount of resin on extraction efficiency of U(VI), Th(IV), and Zr(IV) ions. Conditions: sample volume, 50 mL; pH, 3; amount of metal ions, 10 μg; eluent, 5 mL of 1 mol L^{-1} HCl; sample flow rate, 10 mL min^{-1}; eluent flow rate, 5 mL min^{-1}.

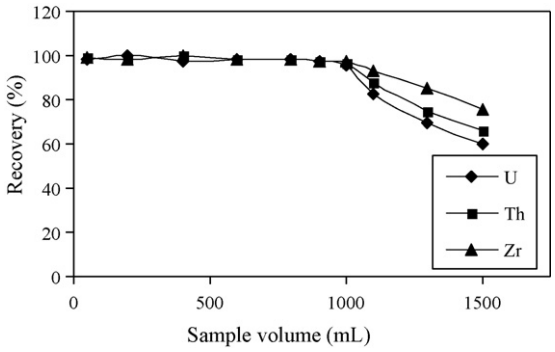

Fig. 6. Effect of sample volume on extraction efficiency of U(VI), Th(IV), and Zr(IV) ions. Conditions: pH, 3; amount of resin, 1 g; amount of metal ions, 10 μg; eluent, 5 mL of 1 mol L^{-1} HCl; sample flow rate, 10 mL min^{-1}; eluent flow rate, 5 mL min^{-1}.

3.5.5. Effect of sample volume

In order to deal with real samples, especially water samples containing very low concentrations of the metal ions, the maximum applicable sample volume must be determined. The recoveries of 10 μg of U(VI), Th(IV), and Zr(IV) ions from different volumes of aqueous solutions are shown in Fig. 6. As seen, the recoveries were found to be quantitative until a sample volume of 1000 mL is reached; hence, 1000 mL was chosen as the largest sample volume to work. Consequently, since the final solution volume to be measured by spectrophotometric method was 10 mL, the preconcentration factors for uranium, thorium, and zirconium ions were evaluated as 100.

3.5.6. Total sorption capacity

The total sorption capacity of modified Amberlite XAD-2000 was determined for each of U(VI), Th(IV), and Zr(IV) ions by the batch method [38]. Here, 0.2 g of the chelating resin was equilibrated with each metal ion solution (50 mL, 50 μg mL^{-1}) for 3 h at the optimum pH. Then, the metal ions were stripped off from the resin with 10 mL of 1 mol L^{-1} HCl and their concentrations were determined with

Table 5
Tolerance limits of some cations and anions on the sorption and determination of uranium, thorium, and zirconium.

Ion	Tolerance limit (μg mL^{-1})
Li^+, Na^+, K^+, Cl^-, NO_3^-	>2000

spectrophotometric method. The sorption capacities calculated for uranium, thorium, and zirconium ions were found to be 3.6, 3.3, and 2.6 mg g^{-1}, respectively.

3.6. Effect of diverse ions on the recovery

In order to assess the possible analytical applications of the recommended procedure, the effect of foreign ions on the separation and preconcentration of uranium, thorium, and zirconium ions was studied. A fixed amount of analytes was taken with different amounts of foreign ions and the recommended procedure was followed. Tolerable limit was defined as the highest amount of foreign ions that produced an error not exceeding ±5% in the determination of investigated analyte ions by the combination of the column solid phase extraction and the spectrophotometric method determination methods. The results are summarized in Table 5. As it is seen, large numbers of ions used have no considerable effect on the determination of uranium, thorium, and zirconium ions.

3.7. Precision studies and limit of detection

The limit of detection (LOD) of the proposed method for the determination of uranium, thorium, and zirconium was studied under the optimal experimental conditions. The LOD, defined as three times the standard deviation of 10 measurements of the blank solution divided by the slope of the calibration curve and the enrichment factor, was evaluated as 0.50, 0.54, and 0.48 μg L^{-1} for uranium, thorium, and zirconium, respectively. The reproducibility of the proposed method for extraction and determination of 10 μg uranium, thorium, and zirconium from 100 mL water ($n = 10$) was also studied. The relative standard deviations (R.S.D.) of these determinations were 3.3% for uranium, 3.7% for thorium, and 3.9% for zirconium.

3.8. Applications

The accuracy of the proposed method was tested by separation and determination of U(VI), Th(IV) and Zr(IV) ions in tap water, well water and synthetic seawater samples. In order to validate the method, analytes were determined in spiked real samples. The results obtained are shown in Table 6. As is evident, the uranium, thorium, and zirconium ions added can be quantitatively recovered from the water matrices. Also this method was applied to the determination of uranium, thorium, and zirconium in ceramic materials. Since in ceramic materials the concentration of zirconium is higher than uranium and thorium, determination of uranium and thorium was carried out after addition of fluoride ion (1×10^{-3} mol L^{-1}) as a masking agent for zirconium. The results are given in Table 7. As seen, there is good agreement between the results obtained by proposed method and ICP-OES method.

4. Conclusions

A new method for the preconcentration and simultaneous spectrophotometric determination of uranium, thorium, and zirconium using solid phase extraction and orthogonal signal correction partial least squares method is proposed. The results demonstrate that α-benzoin oxime loaded Amberlite XAD-2000 is an effective sorbent for trace amounts of U(VI), Th(IV) and Zr(IV) ions that can be used for their preconcentration or removal from their dilute sample solutions. The simultaneous determination of uranium, thorium, and zirconium using Arsenazo III as a metallochromic indicator is very difficult due to the high spectral overlap observed in the absorption spectra of these components. To overcome the drawback of spectral interferences, PLS multivariate calibration approaches are applied. The proposed preconcentration and determination method gives a low limit of detection and good R.S.D. values. The developed SPE method possesses a high potential for the separation of uranium, thorium, and zirconium ions from host of coexisting alkali, alkaline earth, transition and heavy metal ions. The method can be successfully applied to the separation and determination of uranium, thorium, and zirconium in real samples.

Langmuir–Blodgett film
p-tert-Butylthiacalix[4]arene
Anodic stripping voltammetry
Mercury(II) ion

ABSTRACT

The π–A isotherms and UV–vis spectra of the transferred films suggested that the monolayer of *p-tert*-butylthiacalix[4]arene can coordinate with Hg^{2+} at the air–water surface. From these observations, a glassy carbon electrode coated with Langmuir–Blodgett film of *p-tert*-butylthiacalix[4] arene as a new voltammetric sensor is designed for the determination of trace amounts of Hg^{2+}. Compared with bare glassy carbon electrode and modified glassy carbon electrode using direct coating method, the Langmuir–Blodgett film-modified electrode can greatly improve the measuring sensitivity of Hg^{2+}. Under the selected conditions, the Langmuir–Blodgett film-modified electrode in 0.1 mol L^{-1} H_2SO_4 + 0.01 mol L^{-1} KCl solution shows a linear voltammetric response for Hg^{2+} in the range of 5.0×10^{-10} to 1.5×10^{-7} mol L^{-1}, with a detection limit of 2.0×10^{-10} mol L^{-1}. The proposed method was also applied to determine Hg^{2+} in water samples (tap, lake and river water). In addition, the fabricated electrode exhibited a distinct advantage of simple preparation, non-toxicity, good reproducibility and good stability.

1. Introduction

Mercury is one of the most toxic elements in environment, because of its high reactivity, its extreme volatility and its relative solubility in water and living tissues. It can have several effects on human health even at very low concentrations, especially organo-mercury compounds. Therefore, the determination of mercury is necessary and urgent, particularly at trace levels [1]. Some analytical techniques have been employed in mercury analysis, such as atomic absorption spectrometry (AAS) [2], atomic fluorescence spectrometry (AFS) [3,4], X-ray fluorescence [5] and UV spectrophotometry [6]. These techniques, commonly used for trace measurement of mercury(II) ion in the laboratory, are not suitable for the task of in situ testing and monitoring. Electrochemical methods, in particular differential pulse anodic stripping voltammetry (DPASV), are the most favourable techniques for the determination of metal ions because of its low cost, high sensitivity, easy operation and the ability for carry out speciation analysis.

Chemically modified electrodes (CMEs) have received increasing attentions in the past decades, which enhance the sensitivity and selectivity of electrochemical analysis techniques [7]. A number of articles discussed the determination of mercury(II) ion by CMEs. The modifiers used include organic chelating groups [8–10], polymer [11–14], sol–gel [15,1,16] and nanoparticles [17]. However, most of these procedures have difficulties achieving the sensitivity required for the determination of low levels of mercury(II) ion in some real samples. In recent years, a great deal of keen interest has been devoted to the Langmuir–Blodgett (LB) films. This is due to the fact that the LB technique is a useful way of forming sequential layers of ultrathin organic films [18] and can precisely control the thickness and order of a film at the molecular scale [19].

Calixarenes, cyclic oligomers of phenol–formaldehyde condensates, have received a lot of attention as a basis for molecular and ionic recognition because of their conformational and structural flexibility [20]. A number of calixarenes derivations have been successfully employed in ion selective electrodes (ISEs) [21,22]. Thiacalixarenes have recently emerged as new members of the calixarene family. The presence of four sulfur atoms (which possess lone pairs and vacant 3d orbitals) in the place of methylene groups imparts many novel features and properties compared with conventional calixarenes. The specific metal-binding property should be one of the most noticeable features of these thiacalix class ligands [23]. Xiaojun Hu and co-workers [24] investigated the molecular recognition of thiacalixarenes to Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+} and Ag^{+} by UV spectroscopy and solvent extraction. C. Dridi et al. [25] reported that *p-tert*-butylthiacalix[4]arene with amide moiety was used as a receptor material for Hg^{2+} detection by impedance measurements. We recently reported that GCE modified with a LB film of *p-tert*-butylthiacalix[4]arene (TCA) was used

for determination for Cu^{2+}, Cd^{2+} and Pb^{2+} [26,27]. In this approach, a glassy carbon electrode (GCE) modified with LB film of TCA is designed for the determination of trace amounts of Hg^{2+}. Compared with bare GCE and modified GCE using direct coating method, the LB film-modified electrode can greatly improve the measuring sensitivity of Hg^{2+}. The UV–vis spectra and surface pressure–area isotherms suggested that TCA has effective molecular recognition to Hg^{2+}. The fabricated electrode of LB film exhibited excellent sensitivity and reproducibility for preconcentration and stripping analysis of Hg^{2+} ion in water.

2. Experimental

2.1. Apparatus and reagents

All electrochemical techniques were carried out on the CHI 650 Electrochemical analyzer (CH Instruments Company, USA). A traditional three-electrode system consisting of a saturated calomel reference electrode (SCE), a platinum wire auxiliary electrode, and a LB film of TCA (LB TCA) modified GC working electrode (the geometric diameter of GCE is 3 mm), were employed. The electrochemical cell consists of a 10 mL vessel supplied with an electrical spiral stirrer. LB films were formed and deposited on GCE by using JML-04 LB trough (Shanghai Zhongchen Company, China). UV–vis spectra were measured by Model UV-2102 spectrophotometer (UNICO Company, Shanghai, China). A model AFS-9800 atomic fluorescence spectrometry (Beijing Kechuang haiguang Instruments Co. Ltd., Beijing, China) was employed.

All reagents were analytical grade and were used without any further purification. The aqueous solutions were prepared with redistilled water. TCA was purchased from Tokyo Kasei Kogyo Company (Japan) and its structure is shown in Fig. 1. Stock solutions (1.0×10^{-3} and 1.0×10^{-6} mol L^{-1} of $Hg(NO_3)_2$) were prepared by dissolving $Hg(NO_3)_2$ solid reagent into 0.1 mol L^{-1} HNO_3 and stored darkly. The working standard solutions, for optimization studies, were prepared daily by suitable dilution of above stock solution. High grade nitrogen was used for deoxygenated of samples and solvents during analysis.

2.2. Preparation of modified electrode

Before immobilization, the GCE was polished with 0.1 μm aluminum slurry, rinsed thoroughly with redistilled water and sonicated successively in ethanol and redistilled water, respectively, each for 3 min. The electrodes were pretreated with electrochemical method by cycle scan between ±1 V in 0.5 mol L^{-1} H_2SO_4. A sample of TCA chloroform solution (3.0×10^{-4} mol L^{-1}) was spread on pure water subphase surface at about 25 °C. A Wilhelmy balance was used as the surface pressure sensor and situated in the middle of the trough. After evaporation of the chloroform solvent for 30 min, the monolayer of TCA was compressed with a rate of 10 mm min^{-1} and then transferred onto the GCE (vertical dipping) with rate of 2.5 mm min^{-1} under a surface pressure of 30 mN m^{-1}. This modified electrode was named LB-TCA/GCE. The multilayer films were assembled by sequential monolayer transfer. For comparability, a direct modified GCE of TCA was prepared by direct drop smearing of some TCA solution on GCE surface. After drying for 30 min, a direct coating TCA-GCE was obtained.

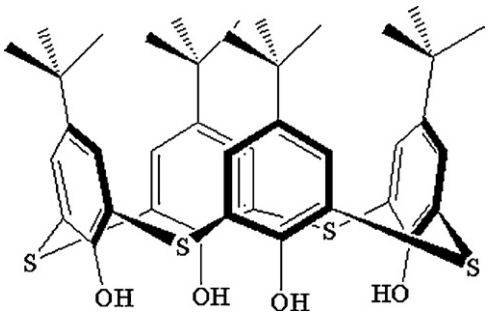

Fig. 1. The chemical structure of *p-tert*-butylthiacalix[4]arene (TCA).

For UV–vis measurement, the LB film of TCA must be transferred on quartz slice. The quartz slices were cleaned in sulfuric acid containing potassium dichromate and rinsed with deionized water before use. LB films of TCA anchored on quartz slices were performed with a vertical dipping method at 30 mN m^{-1} (during the up- and downward, the dipping speed was 2.5 mm min^{-1}). The transfer ratio was almost unity during the upward and downward cycles. Therefore, the transformations of monolayer were Z-type.

2.3. Analytical procedure

Analytical determination of Hg^{2+} was performed by differential pulse anodic stripping voltammetry. The accumulation step was carried out under potential of −0.6 V for a certain period of time while stirring solution. After resting solution for 30 s, the differential pulse voltammograms were recorded from −0.2 to +0.6 V. After each determination, the LB-TCA/GCE was held at 0.6 V for at least 1 min, and then dipped into 0.02 mol L^{-1} EDTA solution of 5 min for renovating it. All measurements were carried out at room temperature (25 ± 1 °C).

3. Results and discussion

3.1. π–A isotherm

The π–A isotherm of TCA on the pure water surface is presented in Fig. 2(curve a). At a relatively high area per molecule, the surface pressure is low, and further compression shows a continuous rise of isotherms. During the compression process of the apparently condensed phase, a sharp rise curve at the air–water interface was displayed. The collapse pressure was 58 mN m^{-1} and the limiting area of per molecule in condensed state was 0.18 nm^2 obtained by extrapolating the linear part of the isotherm to π = 0. Obviously, this result means that TCA can form a stable monolayer on the water surface. On the other hand, if the subphase aqueous solution contained 1.0×10^{-4} mol L^{-1} Hg^{2+}, an absolute change isotherm was observed (Fig. 2, curve b). This different isotherm implied that TCA molecule can coordinate to Hg^{2+} ion and forms a monolayer at the air–water interface.

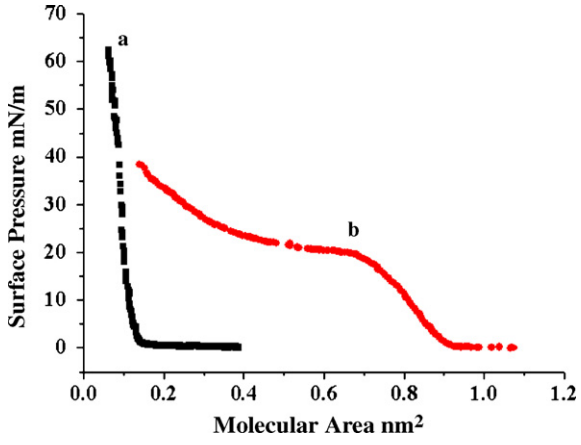

Fig. 2. π–A isotherms of TCA on (a) pure water, (b) aqueous subphase containing 1.0×10^{-4} mol L^{-1} Hg^{2+}.

Shi and co-workers [28] reported that the isotherm of TCA was influenced dramatically owing to the electrostatic repulsion among bound metal cations, when the metal ions were added into the subphase and there was the coordination between TCA and metal ions. On the other hand, from π–A isotherm, we can deduce that the Hg^{2+} ion was not situated inside the TCA cavities (if that is so, mercury ions in the subphase would not significantly affect the limiting area of TCA monolayer [29]). Thus, we may deduce that the TCA molecule coordinates with Hg^{2+} ion, through bridging-sulfur atom and its neighboring phenolic oxygen atoms, and forms a monolayer at the air–water interface.

3.2. UV–vis spectra of LB-TCA films

In order to confirm the above results, UV–vis spectra of monolayer transferred to quartz slices were measured. The UV spectra of TCA in chloroform solution were also studied. Compared to *p-tert*-butylcalix[4]arene, whose absorption bands at 280.0 and 288.0 nm are characteristic adsorption of the phenyl moiety [30], TCA shows the absorption bands at 292.0 and 302.0 nm which are mainly due to the sulfur atoms induced into TCA molecule. In the case of transferred films, a red shift of the absorption peaks was observed as compared with solution spectrum (from 292.0 to 297.0 nm and 302.0 to 307.0 nm, respectively). Such behavior was due to the formation of J-aggregates [31].

Fig. 3 shows the UV–vis spectra of the films transferred from the monolayer of TCA on aqueous Hg^{2+} ion (1.0×10^{-4} mol L^{-1}) solution (Fig. 3, curve b) in comparison with those on deionized water (Fig. 3, curve a). In the spectrum of the transferred film prepared from the subphase containing Hg^{2+} ion, the bands at 298.0 and 307.0 nm of ligand (TCA) LB film were disappeared and a strong band at 311.5 nm was observed. These spectral changes indicate that coordination of TCA, through sulfur and phenoxo anion, to Hg^{2+} ion exits. Of course, this phenomenon can be explained by hard soft acid and base (HSAB) principle. In this principle, hard acids are preferably coordinated to hard bases, and soft acids to soft bases. Accordingly, Hg^{2+} is soft acids, and sulfur atom and phenoxo group are soft bases. Thus, it can be understood easily why TCA molecule can coordinates to Hg^{2+} ion, and Hg^{2+} can change remarkably the monolayer isotherm of TCA.

3.3. Electrochemical impedance spectroscopy and cyclic voltammetry characterization of the LB-TCA/GCE

It is well known that electrochemical impedance spectroscopy (EIS) is an effective tool for studying the interface properties

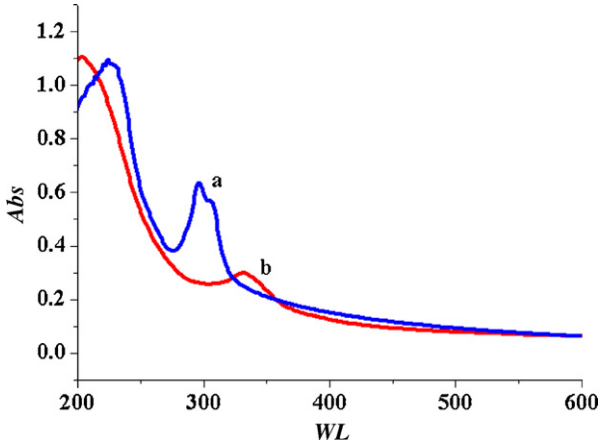

Fig. 3. The UV–vis spectra of 15-layer LB films of TCA transferred from pure water subphase (a) and from a 1.0×10^{-4} mol L^{-1} Hg^{2+} subphase (b).

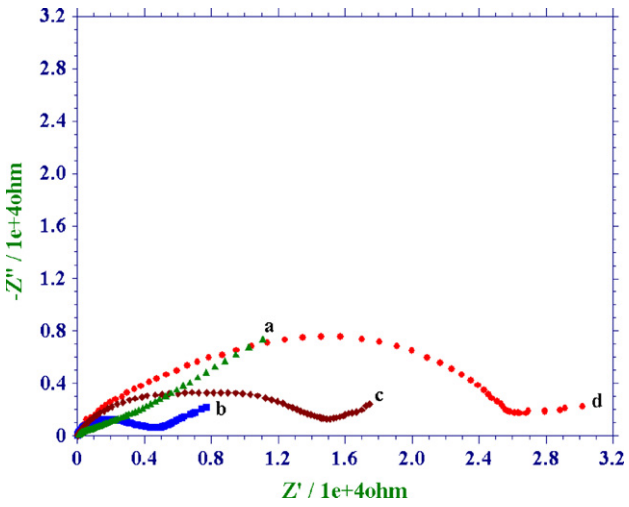

Fig. 4. Electrochemical impedance spectroscopy (EIS) of a clean, freshly polished bare GCE (a) and different layers modified GCE (b–d) in 1×10^{-3} mol L^{-1} $Fe(CN)_6^{4-/3-}$ and 0.1 mol L^{-1} KCl solution; (b) 1 layer, (c) 2 layers, (d) 3 layers. The frequency range is from 1 MHz to 0.01 Hz, and the perturbation signal is 5 mV.

of surface-modified electrodes. R_{et}, the semicircle diameter at higher frequencies in Nyquist plot of EIS can be used to describe the interface properties of the electrode, because it controls the electron transfer rate of the redox probe at the liquid/solid (solution/electrode) interface. Its value varies when different substances are adsorbed on the electrode surface [32]. Fig. 4 shows the results of ac impedance spectroscopy on bare GCE and different layers of LB-TCA/GCE in the solution of equimolar 1.0×10^{-3} mol L^{-1} $Fe(CN)_6^{3-/4-}$ ions, respectively. As the result, the Nyquist plot exhibits an almost straight line at bare GCE (Fig. 4, curve a), that is the characteristic of a diffusing limiting step of the electrochemical process. At the LB-TCA/GCE, the Nyquist plots are composing from a semicircle portion and a linear part (Fig. 4, curves b–d). The semicircle portions are observed at higher frequencies, which correspond to the electron transfer limited process, and the linear parts are observed at lower frequencies, which attribute to a diffusing limited electron transfer. It can also be seen that the diameter of the semicircle at the high frequency increases along with the increasing layer numbers of TCA film modified on the electrode surface. The respective semicircle diameter corresponds to the electron transfer resistance (R_{et}) at the electrode surface [33]. After fitting suitable

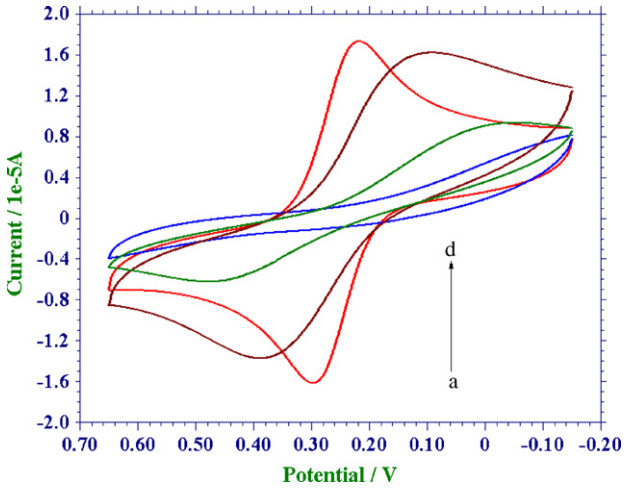

Fig. 5. Cyclic voltammograms of 1×10^{-3} mol L^{-1} $Fe(CN)_6^{3-}$ and 0.1 mol L^{-1} KCl solution at a clean, freshly polished bare GCE (a), and different layers modified GCE (b–d) with scan rate $\nu = 0.10$ V s^{-1}; (b) 1 layers, (c) 2 layers, (d) 3 layers.

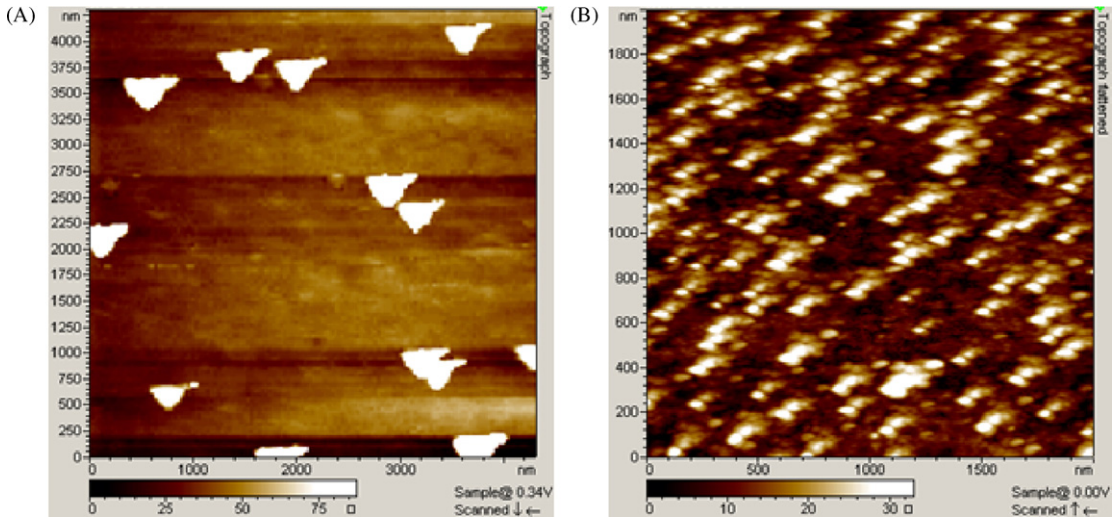

Fig. 6. AFM 2D topography images of bare silicon surface (A, scan area: 4 μm × 4 μm) and the silicon covered with a layer of TCA LB film (B, scan area: 2 μm × 2 μm).

circuit and calculation, R_{et} obtained is about 4, 12.7 and 24 kΩ for 1 layer, 2 layers and 3 layers (Fig. 4, curves b–d) TCA film, respectively. This result suggests that TCA acts as a blocking layer for electron and mass transfer that hinders the diffusion of ferricyanide toward the electrode surface, which obviously also prove that TCA film is successfully immobilized on the GCE surface.

The cyclic voltammetry of ferricyanide is also a valuable and convenient tool to monitor the barrier of the modified electrode. Therefore, it was chosen as a marker to investigate the change of the electrode behavior after each layer modifier. The experiment further confirmed that the TCA was successfully assembled on GCE surface. Fig. 5 shows cyclic voltammograms (CVs) of TCA modified electrodes with different layers in the solution of 1.0×10^{-3} mol L^{-1} $K_3Fe(CN)_6$. Well-defined CV, characteristic of a diffusion-limited redox process, was observed at the bare GCE (Fig. 5, curve a). After modifying the electrode, the redox peak currents decreased and the peak potential separation increased remarkably by increasing the modified layer (Fig. 5, curves b–d). The redox peak of $K_3Fe(CN)_6$ disappeared at 3 layers TCA film-modified GCE. For reason is that the LB-TCA can act as a bulwark for blocking the electron and mass transfer, and it hinders the diffusion of ferricyanide toward to the electrode surface. On the basis of the EIS and CV results, we can conclude that TCA is successfully immobilized on the GCE surface as LB film form.

3.4. Atomic force microscopy of LB-TCA films

Atomic force microscope (AFM) was employed to observe the structure of TCA LB films. Silicon was used as substrates to substitute GCEs. Silicon substrates were sonicated successively in ethanol and redistilled water, respectively, each for 10 min. Then the substrates were dipped in piranha solution (1:3 mixtures of H_2O_2 and H_2SO_4) for 20 min. Later, they were again ultrasonic cleaned in redistilled water for 5 min. Finally, the pretreated silicon was kept in redistilled water for further using. Fig. 6 shows typical contact mode AFM images of the bare silicon surface and the silicon covered with a layer of TCA LB film that was transferred from air–water interface to silicon surface under the surface pressure of 30 mN m^{-1}. The bare silicon has no impurity on its surface and shows very even surface (Fig. 6A). The compact and well-ordered structure of TCA LB film was observed (Fig. 6B) which is formed by aggregates of TCA molecules during compressing process, which also indicate successfully immobilization of TCA molecules on the substrate surface.

3.5. Electrochemical behavior of Hg^{2+} on the LB-TCA/GCE

The ability of the LB-TCA/GCE for recognition and preconcentration of Hg^{2+} was studied. Fig. 7 shows the DPVs of 1×10^{-8} mol L^{-1} Hg^{2+} in 0.1 mol L^{-1} H_2SO_4 + 0.01 mol L^{-1} KCl solutions at bare GCE (curve a) and GCE modified of TCA by direct coating method (curve b). At bare GCE and GCE modified using direct coating method case, a small anodic peak could be discerned at about +0.10 and +0.11 V, indicating some adsorption of Hg^{2+} could have occurred at the electrode surface. However, this miniscule peak provided evidence for the absence of significant preconcentration of Hg^{2+} at these two kind electrodes. In contrast, when LB-TCA/GCE was applied, a well-defined anodic stripping peak with peak potential of +0.12 V appeared after accumulation at negative potential (curve c). Under the same operating condition, the peak current was 6 times comparing to that of direct coating TCA/GCE and 20 times comparing to that of bare GCE. And there was no electrochemical response of LB-TCA/GCE itself in this medium (Fig. 8, curve a). So this peak was due to the oxidation of Hg^0 to Hg^{2+}, and Hg^0 was produced by the reduction of Hg^{2+} at the accumulation step under negative potentials. If the cyclic scan was performed after precon-

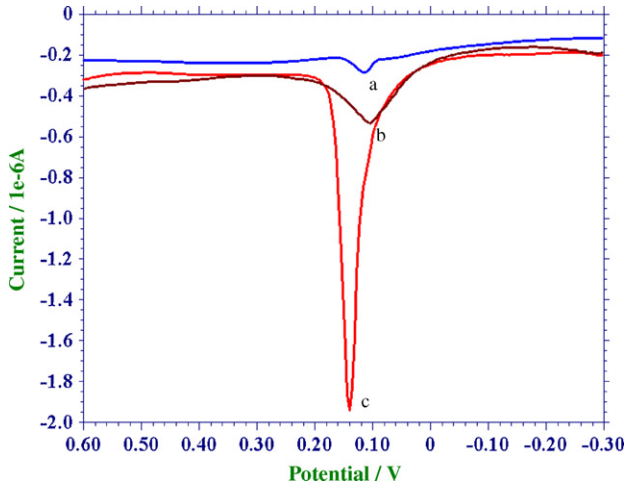

Fig. 7. Differential pulse anodic stripping voltammograms of 1.0×10^{-8} mol L^{-1} Hg^{2+} in 0.1 mol L^{-1} H_2SO_4 + 0.01 mol L^{-1} KCl at different glassy carbon electrodes: (a) bare GCE, (b) modified GCE using direct coating method, (c) LB-TCA/GCE (2 layers). Accumulation time: 90 s; accumulation potential: −0.6 V.

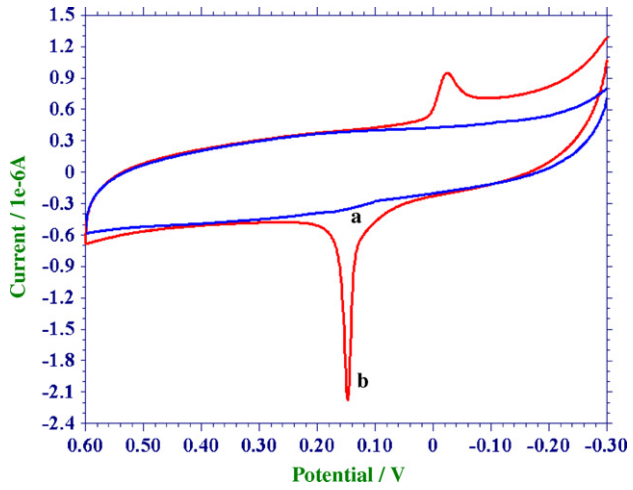

Fig. 8. Cyclic voltammograms of blank solutions (a) and 1.0×10^{-8} mol L^{-1} Hg^{2+} (b) at LB-TCA/GCE (2 layers); other experimental conditions are the same as those described in Fig. 7.

centration, a small reduction peak at −0.1 V was appearance (Fig. 8, curve b) during the reverse scan. It implied that majority of Hg^{2+} was stripped out from the surface of electrode and diffused into solution. Because the oxidation peak current was more sensitive to reduction peak current, the anodic peak of Hg^{2+} was systematically studied by differential pulse anodic stripping voltammetry for analytical applications.

3.6. Mechanism of the method

To investigate the mechanism of the method, the preconcentration step was performed under open-circuit condition. Subsequently, the electrode was removed from the accumulation cell, rinsed thoroughly with water, and placed in quiescent blank electrolyte solution. Then, an initial potential of −0.6 V (versus SCE) was applied to the working electrode for 20 s, and the differential pulse anodic stripping voltammograms (DPASV) were recorded. A distinct anodic peak could be discerned at about +0.11 V, due to the oxidation of Hg^0 to Hg^{2+}. Thus, the possible mechanism of electrode reaction can be described as follows:

Accumulation step:

$$\text{LB-TCA/GCE (surface)} + Hg^{2+}\text{ (solution)} \rightarrow \text{LB-TCA/GCE} - Hg^{2+}\text{ (surface)}$$

Reduction step:

$$\text{LB-TCA/GCE} - Hg^{2+}\text{ (surface)} + 2e \rightarrow \text{LB-TCA/GCE} - Hg^{0}\text{ (surface)}$$

Stripping step:

$$\text{LB-TCA/GCE} - Hg^{0}\text{ (surface)} \rightarrow \text{LB-TCA/GCE (surface)} + Hg^{2+}\text{ (solution)} + 2e$$

Table 2
Influence of other metal ions on the peak current of 5×10^{-8} mol L^{-1} Hg^{2+}.

Interferent	Concentration	Signal change (%)
Fe^{3+}	1×10^{-6} mol L^{-1}	2.0
Mn^{2+}	1×10^{-6} mol L^{-1}	2.4
Co^{2+}	1×10^{-6} mol L^{-1}	1.5
Ni^{2+}	1×10^{-5} mol L^{-1}	2.6
Zn^{2+}	1×10^{-6} mol L^{-1}	2.3
Cr^{3+}	1×10^{-5} mol L^{-1}	−1.8
Cd^{2+}	1×10^{-6} mol L^{-1}	−3.4
Ti^{4+}	1×10^{-5} mol L^{-1}	−1.2
Ag^{+}	1×10^{-7} mol L^{-1}	4.2
Pb^{2+}	1×10^{-6} mol L^{-1}	−4.3
Al^{3+}	1×10^{-6} mol L^{-1}	−1.4
Cu^{2+}	1×10^{-6} mol L^{-1}	−2.3

In real operation procedure, the accumulation step and reduction step were performed simultaneously under potential of −0.6 V.

3.7. Analytical applications and methods validation

3.7.1. Optimum condition of determination

The influences of supporting electrolytes were investigated in $HClO_4$, H_2SO_4, HNO_3, HAc-NaAc, phosphate buffer solution and B-R buffer solution, respectively. The results showed that voltammetric peaks were observed in all these electrolyte solutions, but the electrochemical responses in 0.1 mol L^{-1} H_2SO_4 + 0.01 mol L^{-1} KCl solutions were the best shape and largest stripping peak current among these solutions. Therefore, this supporting electrolyte was employed in following experiments.

Accumulation potential (E_{acc}) and accumulation time (t_{acc}) are very important parameters for stripping techniques and have non-negligible influence on the efficiency of preconcentration and the sensitivity of determination. E_{acc} between −1.4 and −0.4 V were investigated in a solution of 1.0×10^{-8} mol L^{-1} Hg^{2+} for accumulation of 90 s under every potential. Then DPV was performed with the same operation parameters. The results shown that the anodic peak currents were higher in E_{acc} interval of between −0.6 and −0.8 V. At more positive potentials a decrease of the anodic peak current was caused by the inefficient reduction of Hg^{2+} to Hg^0 at the electrode surface. Thus −0.6 V was chosen as the E_{acc} in all experiments. The anodic peak currents were linearly increscent as the t_{acc} increases, and start to reach a plateau around 210 s with the mercury concentration of 1.0×10^{-8} mol L^{-1}. For all we know, the longer accumulation time, the higher sensitivity is gotten in stripping voltammetry, but narrow detect range is emerged. In this detection system containing 1.0×10^{-8} mol L^{-1} Hg^{2+}, accumulating saturation was reached by preconcentration of 210 s. Considering the detect limit and linear range, t_{acc} 90 s was chosen in following study. The peak currents were linearly relationship with Hg^{2+} concentrations in nearly three quantitative orders under 90 s preconcentration time.

The relationship between peak currents and the modified layers of LB-TCA was also investigated. 1-Layer of LB-TCA/GC had a low efficiency of preconcentration and a low peak current. When the layers of LB-TCA were ≥3, the peak currents were decreased grad-

ually by increasing the LB-TCA layer. This phenomenon was due to their high resistance which blocked electron transfer between Hg and electrode. The best response was obtained when 2-layer LB-TCA was used, which was employed in following experiment.

3.7.2. Calibration curve, detection limit, reproducibility and stability

Series concentrations of standard solutions of Hg^{2+} were detected under the optimized working conditions described above. A linear relationship could be established between i_{pa} and the concentration of Hg^{2+} in the range of 5.0×10^{-10} to 1.5×10^{-7} mol L^{-1}. The linear regression equation and correlation coefficient are:i_{pa} (μA) $= 0.665 + 1.028\times10^{8}c$ ($r = 0.998$)where i_{pa} was the oxidation peak current in μA and c was the concentration of Hg^{2+} in mol L^{-1}. Based on the signal-to-noise ratio of 3 (S/N), the detection limit was obtained as 2.0×10^{-10} mol L^{-1}. These values confirmed the sensitivity of the proposed method for the determination of Hg^{2+}. To estimate the reproducibility of the proposed electrode, the R.S.D. of five times successful measurement the peak current of 1×10^{-8} mol L^{-1} Hg^{2+} was calculated to be 3.9%, which demonstrated the good reproducibility of the proposed electrode. The stability of the electrode was examined by repetitive scanning in 1×10^{-8} mol L^{-1} Hg^{2+} solution. 108.4% of the initial response was remained after continuous scanning for 30 potential cycles. The LB-TCA/GCE can be stored about 4 weeks and the decrease of the response was got as 3.96%, which indicated that LB-TCA/GCE had good stability.

The proposed LB-TCA/GCE for Hg^{2+} determination was compared with other macrocyclic kinds of modified electrode and the results were listed in Table 1. Among macrocyclic modified electrodes [25,34,9,35,36], most of their detection limits were between 1.0×10^{-8} and 1.0×10^{-7} mol L^{-1}. The higher sensitive detect limit of 2.0×10^{-10} mol L^{-1} was achieved by use of a LB film *p*-allylcalix[4]arene modified GCE [36]. This research suggests that designed and modified electrode with LB techniques as voltammetric sensors might be a very promising direction in trace analysis of electrochemistry.

3.7.3. Interference studies

For analytical application of the proposed method, possible interference by coexisting metal ions were evaluated by analyzing sample solutions containing a fixed amount of Hg^{2+} (5.0×10^{-8} mol L^{-1}) spiked with various excess amount of species under the same experimental conditions. The results showed that no interference was observed in the presence of 1.0×10^{-5} mol L^{-1} alkaline metal ions and earth metal ions. Table 2 lists the interference data of Fe^{3+}, Mn^{2+}, Co^{2+}, Ni^{2+}, Zn^{2+}, Cr^{3+}, Cd^{2+} Ti^{4+}, Ag^{+}, Pb^{2+}, Al^{3+} and Cu^{2+} for determination of 5.0×10^{-8} mol L^{-1} Hg^{2+}. Most of these coexisting ions bring the detection signal deviation below 5% under sufferable coexisting amount. The only trouble may be from Ag^{+}. It bring 4.2% signal increase when $[Ag^{+}]/[Hg^{2+}] = 2$ is present.

3.7.4. Analysis of real samples

To evaluate the practical applicability of the proposed method, it was employed to the detection of Hg^{2+} in tap water, lake water and river water samples. No distinct signal of Hg^{2+} was observed when the tap water and lake water samples were analyzed. Thus, the proposed method was applied to detect water samples spiked with Hg^{2+} standard solution at a certain concentration. The determination of Hg^{2+} concentration was performed by the calibration curve method. The mean recovery of 4.00×10^{-8} mol L^{-1} Hg^{2+} was 105.77%. In addition, the results were compared with those obtained by AFS and were shown in Table 3. At 95% confidence level, no difference between results from the proposed and AFS methods had been established. Therefore, this proposed method could be applied to the determination of a trace level of Hg^{2+} in real samples.

4. Conclusions

In the present work, a new voltammetric sensor for the detection of trace amounts of Hg^{2+} based on a calixarene derivative LB film-modified GCE was designed. The recognition mechanism of this electrode for Hg^{2+} in aqueous solution was discussed and some experimental parameters were optimized. By using this LB film-modified electrode, trace amounts of Hg^{2+} could be detected with LOD of 2.0×10^{-10} mol L^{-1} by differential pulse anodic stripping voltammetry with accumulation of 90 s under −0.6 V. This research suggest also that designed and modified electrode with LB techniques might be a very promising basis for analytical sensing.

Inductively coupled plasma atomic emission spectrometry

ABSTRACT

A new method that utilizes 1-(2-aminoethyl)-3-phenylurea-modified silica gel as a solid-phase extractant has been developed for preconcentration of trace Sc(III) prior to the measurement by inductively coupled plasma atomic emission spectrometry (ICP-AES). Experimental conditions for effective adsorption of trace level of Sc(III) were optimized using batch and column procedures in detail. The optimum pH value for the separation of Sc(III) on the new sorbent was 4 and complete elution of Sc(III) from the sorbent surface was carried out using 1.0 mL of 0.1 mol L^{-1} HCl. Common coexisting ions did not interfere with the separation and determination of the analyte. The maximum static adsorption capacity of the sorbent at optimum conditions was found to be 32.5 mg g^{-1} while the time of 95% adsorption was less than 2 min. The detection limit of present method was found to be 0.091 μg g^{-1}, and the relative standard deviation (RSD) was lower than 3.0% (n = 8). The method was successfully applied for the preconcentration of trace Sc(III) in the environmental samples with satisfactory results.

1. Introduction

The rare earth elements (REEs) are a particularly useful suite of trace elements. With the development of new materials, REEs were applied in many industrial fields, such as superconducting materials, permanent magnets, fluorescent materials, and solid-state laser areas and so on. So, the industrial usage of REEs is growing rapidly [1]. Scandium belongs to the rare element group which possesses special physical and chemical features, especially surface activity. Compared to other rare earth elements, scandium is the first element with lowest density. And it is forecasted as "Boron-like" element in Mendeleev elements' period table [2]. For the research of lanthanide and Y, scandium is believed to be important for a reference element. Furthermore, scandium could be a surrogate for Al in estimating global dust fluxes to the oceans [3]. It also has emerged as an element of technological promise especially in the fields of laser research, radio and illuminations engineering and also in space applications as scandium-based alloys with Ti, Ce, W and Cr [4]. So, the research of scandium becomes very important. However, it often happens that the trace scandium remains unseparated from REEs, which makes a fatal defect for the determination. Therefore, the preconcentration and determination of scandium from samples need to be paid more attention [5].

A number of instrumental methods are now available for accurate determination of scandium such as neutron activation analysis (NAA) [3,6], inductively coupled plasma-mass spectrometry (ICP-MS) [7,8], atomic absorption spectrometry (AAS) [9] and inductively coupled plasma atomic emission spectrometry (ICP-AES) [10,11]. In comparison, ICP-AES is a timesaving, simple, and well-available technique and has now been established as a powerful analytical technique for the determination of scandium in real samples [5,10]. However, its detection capability is usually insufficient due to the matrix interferences and the very low content of scandium. Therefore, a separation/preconcentration step is required.

Nowadays, solid-phase extraction (SPE) becomes the most common technique for environmental sample pretreatment because of its advantages of high recovery, short extraction time, high enrichment factor, low cost, and low consumption of organic solvents over liquid–liquid extraction [12,13].

In SPE procedure, the choice of appropriate sorbent is a critical factor to obtain full recovery and high enrichment factor. Among the many types of solid phase used in SPE, silica gel immobilized with various organic compounds such as a metal chelating agent for metal ions' removal, extraction, separation and preconcentration from different matrices, has received great attention for its good mechanical and thermal stability and its less susceptibility to swelling, shrinking and microbial and radiation decay [14]. The modified silica gel are used in the fields of normal or selective solid-phase extraction of the target species [15–17]. Such variations in the behavior of the modified solid sorbents are mainly dependent

doi:10.1016/j.talanta.2009.09.009

on the presence of some active donor atoms or groups such as O, N, S and P into the incorporated organic modifier [18].

In our work, 1-(2-aminoethyl)-3-phenylurea chemically modified silica gel (SG-AEP) was synthesized and characterized. The new sorbent showed great affinity, relatively high adsorption capacity, less equilibrium time and easy elution for Sc(III). Parameters that affect the sorption and elution efficiency of the metal ions were also studied. Then, the method was applied to preconcentrate trace Sc(III) from environmental samples with satisfactory results.

2. Experimental

2.1. Chemicals and reagents

Unless otherwise stated, all water is double distilled water and all reagents used were of analytical and spectral purity. Standard labware and glassware used were repeatedly cleaned with HNO_3 and rinsed with double distilled water, according to a published procedure [19].

All single element REE, Y, Sc (as oxides) of 1.0 mg mL^{-1} standard stock solutions were made by dissolving rare earth oxides in hydrochloric acid with the exception of CeO_2 that was dissolved in a mixture of HNO_3 and H_2O_2 and later converted to HCl medium. Single element working standards were prepared by dilution of the stock solution with 0.5 mol L^{-1} HCl according to a published procedure [10]. Silica gel (100–200 mesh, Mouping Kangbinuo Chemical Factory, Yantai, China), ethylenediamine (EDA) (The First Reagent Factory, Shanghai, China), isopropyl isocyanate (Weiwei Reagent Factory, Shanghai, China) were used in this work. *N*,*N*′-Dicyclohexylcarbodiimide (DCC) was purchased from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China) and 3-chloropropyltrimethoxysilane was purchased from Wuhan University Chemical factory (Wuhan, China).

2.2. Instruments and apparatus

An IRIS Advantage ER/S inductively coupled plasma emission spectrometer (Thermo Jarrel Ash, Franklin, MA, USA) was used for all metal ions determination. The instrumental parameters were those recommended by the manufacturer. The wavelength of scandium selected is 363.074 nm [20]. A pHs-3C digital pH meter (Shanghai Lei Ci Device Works, Shanghai, China) was used for the pH adjustments. Infrared spectra (4000–400 cm^{-1}) in KBr were recorded on a Nicolet NEXUS 670 FT-IR spectrometer (Nicolet, Madison, WI, USA). Thermogravimetric analysis (TG) was carried out on a STA 449 C (Netzsch, Germany). An YL-110 peristaltic pump (General Research Institute for Non-ferrous Metals, Beijing, China) was used in the column process. A PTFE (polytetrafluoroethylene) column (45 mm × 3.0 mm i.d, Tianjin Jinteng Instrument Factory, Tianjin, China) was used.

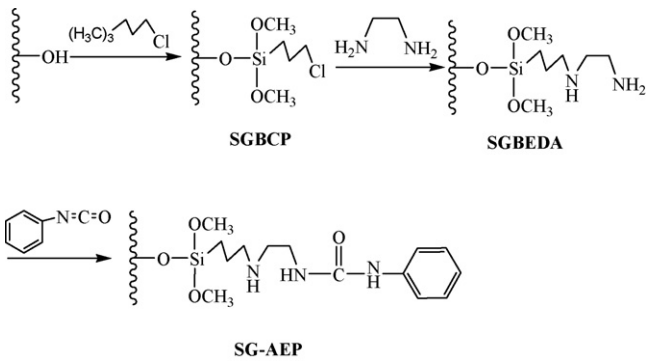
2.3. Sample preparation

The reference materials (GBW08302, Tibet soil and GBW07602, shrubbery leaves) were purchased from National Research Center for Certified Reference Materials (Beijing, China). Orange leaves were obtained from Anning village, Lanzhou, China. Fish was purchased from Hualian market, Lanzhou, China. Fish and orange leaves were dried in an oven at 80 °C to constant weight. A 1.0 g fish or orange leaves sample was weighted and transferred into a digestion tube, and then 5 mL of concentrated HNO_3 was added into it. The tube was left at room temperature for one night. Then it was placed in a digester block and heated slowly until the temperature was up to 165 °C. This temperature was maintained until ceasing the evolution of brown fumes. After the tube was cooled down, 1.3 mL perchloric acid was added into it. Then the temperature was raised to 210 °C until evolution of white fumes began. The volume was adjusted to 100 mL with double distilled water after the tube was cooled down [21].

Kaolin ore was obtained from Beijing Chemical Factory (Beijing, China). The sample (0.2 g) was weighed into a PTFE beaker, and 5 mL of 70% $HClO_4$ and 10 mL of 48% HF were added. Following the directions found in the literature [5], the beaker was heated on a sand bath to incipient dryness. The mixed acid ($HClO_4$ + HF) was repeated three times to complete digestion of the silicate matrix. Finally, the sample was transferred into flasks and diluted to 50 mL with 0.2% HCl.

2.4. Preparation of new sorbent

2.4.1. Preparation of SG-AEP



Activation of silica gel surface was first accomplished by refluxing in a concentrated hydrochloric acid for 4 h to remove any adsorbed metal ions, then filtered and repeatedly washed with water until the filtrate is neutral and dried in an oven at 160 °C for 8 h to remove surface-adsorbed water. Then 10.0 g of dry activated silica gel was suspended in 150 mL dry toluene containing 10 mL of 3-chloropropyltrimethoxysilane and refluxed overnight. The product silica gel phase was filtered off, washed with toluene, ethanol and diethyl ether and dried in an oven at 60 °C for 6 h. The product was silica gel-bound 3-chloropropyl phase (SGBCP). For the synthesis of silica gel-bound amines phase, a 10.0 g amount of SGBCP was suspended in 75 mL of dry toluene and 10 mL of ethylenediamine were added to the suspension and refluxed for 12 h. The product (SGBEDA) was filtered off, washed with toluene, ethanol and diethyl ether and dried in an oven at 60 °C for 6 h.

Chemically immobilized silica gel with 1-(2-aminoethyl)-3-phenylurea was synthesized according to the following procedure. A 5.0 g amount of SGBEDA and 2.0 mL phenyl isothiocyanate were suspended in 30 mL of ether under N_2 atmosphere and stirred for 40 h at room temperature. The product SG-AEP was filtered off, washed with ethanol and dried under vacuum at 80 °C for 8 h. The synthetic route of SG-AEP is illustrated in Scheme 1.

2.4.2. Characterization of SG-AEP

The modified silica gel was confirmed by IR analysis as shown in Fig. 1. Comparison of the IR spectrum of SG-AEP with that of SGBCP, many new peaks appeared in the spectrum. According to the literature [22,23], the new peaks can be assigned as follows: the peak at 1639.10 cm^{-1} is due to $\nu_{C=O}$, the peaks at 754.71 cm^{-1} are caused by δ_{N-H}. The bands around 3420.75 cm^{-1} can be assigned to ν_{N-H}. The peaks at 1447.41, 1501.48, 1555.25 and 1603.21 cm^{-1} are due to the benzene ring characteristic vibrations in the SG-AEP.

Thermogravimetry (TG) curves of SGBCP and SG-AEP were presented in Fig. 2(a) and (b), respectively. As seen in Fig. 2, the starting temperature of weight loss for SG-AEP occurred at 171.4 °C, which

Scheme 1. Synthetic route of the SG-AEP.

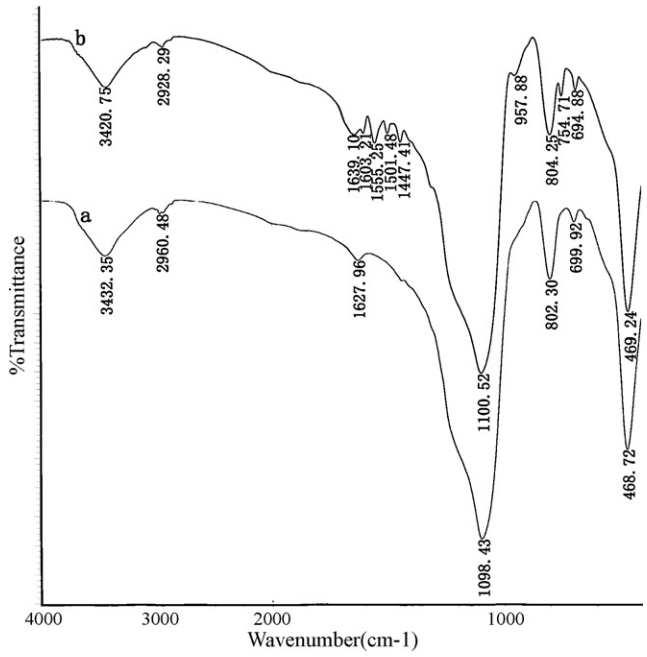


Fig. 1. IR spectra of SGBCP (a) and SG-AEP (b).

is lower than SGBCP (319.8 °C). The TG curves indicated that the weight loss of SG-AEP is step by step from 171.4 to 800 °C, and the rate of the fastest weight loss for SG-AEP is higher than SGBCP. At 800 °C the weight losses of SGBCP and SG-AEP are 7.50% and 13.02%, respectively. All of the results confirmed that 1-(2-aminoethyl)-3-phenylurea is chemically bonded to activated silica gel.

Consequently, the above experimental results suggest that activated silica gel is successfully modified by 1-(2-aminoethyl)-3-phenylurea.

2.5. Procedures

2.5.1. Batch method

The data are given on the simple mean of three replicates, whereas those of the applications were repeated eight times from which the statistical evaluation is pertained.

A portion of standard or sample solution containing Sc(III) was transferred into a 25 mL beaker, and the pH value was adjusted to the desired value with 0.1 mol L^{-1} HNO_3 and 0.1 mol L^{-1} $NH_3{\cdot}H_2O$. Then the volume was adjusted to 10 mL with double distilled water. 40 mg of SG-AEP was added, and the mixture was shaken vigorously for 30 min to facilitate adsorption of the metal ions onto the sorbents. The concentrations of the metal ions in the solution were directly determined by ICP-AES. The adsorbent was then eluted with HCl at optimum concentration and volume. Then the desorbed metal ions were measured by ICP-AES.

2.5.2. Column SPE procedure

A total 50 mg of SG-AEP was packed in the PTFE column plugged with a small portion of glass wool at both ends. Before use, 0.5 mol L^{-1} HCl and double distilled water were successively passed through the microcolumn in order to equilibrate, clean and neutralize it. A suitable aliquot of the sample solution containing 1.0 μg mL^{-1} Sc(III) in a volume of 10 mL was passed through the column after adjusting its pH to 4, at a flow rate of 2.0 mL min^{-1} controlled with a peristaltic pump. The bound metal ions were stripped off from the gel column with 0.1 mol L^{-1} HCl. The analytes in the eluate were determined by ICP-AES.

3. Results and discussion

3.1. Effect of pH

The pH value plays an important role with respect to the adsorption of different ions on oxide surfaces. Therefore, solution pH value is the first parameter to be optimized. According to the recommended procedure (batch method), several metal ions, viz. Sc(III), La(III), Er(III), Ce(III), Ho(III), Nd(III), Sm(III), Ir(IV) and Y(III) were tested and determined at different pH value, namely pH 1, 2, 3, 4, 5 and 6. Aliquots of 10 mL of the solutions were tested by equilibrating 40 mg sorbent. The results showed that the SG-AEP had excellent adsorptive selectivity towards Sc(III) from pH 4–6 than any other ions. It could be seen in Fig. 3 that the optimum pH for quantitative extraction (>95%) of Sc(III) occurred at pH ≥ 4. In order to avoid hydrolyzing at higher pH, pH 4 was selected as the enrichment acidity for further study. In addition, Ce(III) and Ir(IV) were not enriched by SG-AEP at pH 4; La(III), Er(III), Ho(III), Nd(III), Sm(III) and Y(III) could be adsorbed by SG-AEP about 20–50% at pH 4, but they do not interfere with enrichment and determination of Sc(III).

3.2. Effect of shaking time

Modification of silica gel surface with organic complexing agents results in producing metal ion extractors that need only a few minutes to complete the metal ion extraction processes in comparison with other organic adsorbents [24], and this is another

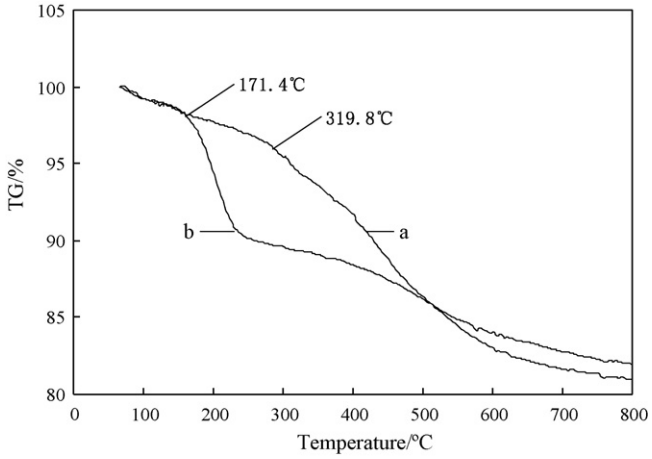

Fig. 2. TG curves of SGBCP (a) and SG-AEP (b).

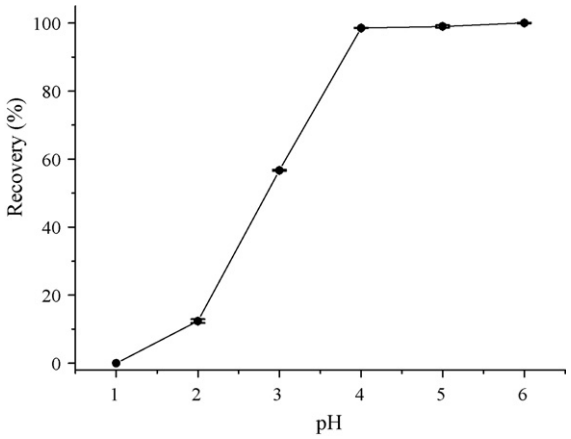

Fig. 3. Effect of pH on adsorption of 1.0 μg mL^{-1} Sc(III) on SG-AEP. Other conditions: shaking time 30 min, temperature 25 °C.

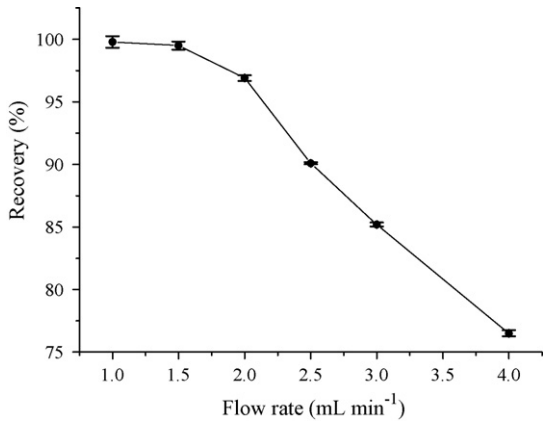

Fig. 4. Effect of solution flow rates on adsorption of 1.0 μg mL^{-1} Sc(III) on SG-AEP. Other conditions: 50 mg of SG-AEP, volume 10 mL, pH 4, temperature 25 °C.

advantage of using silica gel as inorganic solid support for immobilization of chelating compounds.

In this work, different shaking time (ranged from 2 to 30 min) was studied for the percentage extraction of Sc(III) by SG-AEP. The results showed that the adsorption of Sc(III) was over 95% sorption during the first 2 min, which indicated that kinetics of adsorption equilibrium was very fast.

3.3. Effect of flow rate

The flow rate of the sample solution affects the retention of cations on the adsorbent and the duration of complete analysis. Therefore, the effect of the flow rate of sample solution was examined under the optimum conditions by passing 10 mL of sample solution through the microcolumn with a peristaltic pump. The flow rates were adjusted in range of 1.0–4.0 mL min^{-1}. As shown in Fig. 4, it was found that the retention of the studied ion was practically not changed up to 2.0 mL min^{-1} flow rate. The recovery of the analyte decreases slightly when the flow rate is over 2.0 mL min^{-1}. Thus, a flow rate of 2.0 mL min^{-1} is employed in this work.

3.4. Maximum sample volume, enrichment factor and elution condition

In order to explore the possibility of enriching low concentration of the analyte from large volume of solution, the effect of sample volume on the retention of metal ion was also investigated. For this purpose, 50, 100, 150, 200, 250 and 300 mL of sample solutions containing 1.0 μg Sc(III) were passed through the microcolumn at the optimum flow rate. Quantitative recovery (>95%) was obtained for the sample volume of 150 mL for Sc(III), and at greater volume percent of recovery decreased.

The elution condition was studied by using various concentrations and volumes of HCl solution for the desorption of retained Sc(III). The obtained results were shown in Table 1. It was found that 1.0 mL of 0.1 mol L^{-1} HCl was sufficient for complete elution for Sc(III) (recovery >95%). Therefore, 1.0 mL of 0.1 mol L^{-1} HCl solution was used as eluent in further experiments. Thus, the high enrichment factor of 150 was obtained.

Table 1
Eluent data (%) for Sc(III) adsorbed on SG-AEP.

	Concentration (mol L^{-1})[a]					
	0.01	0.05	0.1	0.5	1	2
Recovery (%)						
HCl	75.2	90.1	98.6	99.2	100	100
Eluent volume (mL)[b]	0.5	1.0	1.5	2.0	2.5	3.0
	75.6	96.3	97.5	99.1	99.8	100

[a] 2 mL.
[b] 0.1 mol L^{-1} HCl.

3.5. Adsorption capacities

The capacity of the adsorbent is an important factor because it determines how much adsorbent is required to quantitatively remove a specific amount of metal ions from the solutions. The adsorption capacity was tested following the batch procedure. 20 mg of sorbent was equilibrated with 10 mL of various concentrations of Sc(III) for 1 h. In order to reach the "saturation", the concentration of Sc(III) was increased till the plateau value (adsorption capacity value) obtained. The maximum adsorption capacity has been found to be 32.5 mg g^{-1} for Sc(III).

3.6. Stability tests

To test the stability, the sorbent material was subjected to several loading and elution bath operations. The sorption conditions are referenced according to the above experiments. The elution operations were carried out by shaking the adsorbent with 20 mL of 0.1 mol L^{-1} HCl for 1 h in order to ensure complete equilibration. Then the adsorbent was treated with doubly distilled water until neutral equilibration was reached. The operating capacity was calculated from the loading and elution tests. The results from three tests yielded <5% error up to 12 cycles of repeated experiments. The adsorbent showed better reusability and stability towards Sc(III).

3.7. Effects of coexisting ions

The effects of common coexisting ions on the adsorption of Sc(III) on SG-AEP were investigated. In these experiments, solutions of 1.0 μg mL^{-1} of Sc(III) containing the added interfering ions were treated according to the recommended procedure. The tolerance limit was set as the amount of ions causing recoveries of the examined element to be less than 95%. The results showed that 100-fold Ce(III), Ir(IV), 30-fold La(III), Er(III), Ho(III), Nd(III), Sm(III), Y(III), 1500-fold K(I), Na(I), Cl^-,1000-fold Ca(II), Mg(II), SO_4^{2-} and 50-fold Co(II), Ni(II), Zn(II), Cd(II) ions did not interfere with the separation and determination of the analyte. The results showed that SG-AEP had a high selectivity towards Sc(III) and have a potential to be applied to analyze real sample.

3.8. Analytical precision and detection limits

Under the selected conditions, eight portions of standard solutions were enriched and analyzed simultaneously following the general procedure. In accordance with the definition of IUPAC, the detection limit of the method was calculated based on three times the standard deviation of eight runs of the blank solution [25], the

Table 2
Analytical results for the determination of Sc(III) in certified reference materials.

Sample	Concentration of Sc(III) (μg g^{-1})	
	Found by the proposed method[a] (μg g^{-1})	Certified value (μg g^{-1})
GBW07602 (shrubbery leaves)	0.31 ± 0.03	0.29 ± 0.06

	0.5	0.69 ± 0.16	98.6	0.67 ± 0.44	97.1
	1.0	1.18 ± 0.22	98.3	1.16 ± 0.23	97.5

–: not detected.
[a] The value following "±" is the standard deviation ($n = 8$).

detection limit of this method was found to be 0.091 $\mu g\,g^{-1}$ for Sc(III). The relative standard deviation (RSD) of the eight replicate determinations was lower than 3.0%, which indicated that the method had good precision for the analysis of trace Sc(III) in solution samples.

3.9. Application of the method

In order to ascertain the accuracy of the suggested procedure, the method was applied to the determinations of trace Sc(III) in the certified reference materials (GBW08302, Tibet soil and GBW07602, shrubbery leaves), fish, orange leaves and kaolin ore sample. The results were listed in Tables 2 and 3. The analytical results for the standard materials were in good agreement with the certified values. The analytical results for fish, orange leaves and kaolin ore were in agreement with the electrothermal atomic absorption spectrometry (ET-AAS) method. The results indicate that the proposed method is reliable.

3.10. Comparison with other methods

Several methods have been reported for the determination of scandium in various types of samples including geological materials such as solvent extraction, extraction chromatography, ion exchange, chemical precipitation, flotation, electrophoresis, and liquid membrane separation [4,11,26–30] as well as their combined techniques [20]. However, these methods are complicated, time-consuming and/or reagent-consuming, sensitivity lowly, costs highly and the scandium yield of those methods is low [5,30]. In compared with those methods mentioned above, the present method possessed the advantages of excellent adsorptive selectivity, short analysis time, high enrichment factor, low consumption of organic solvents and low costs. Though it takes relatively long time for preparation of the material than the reported literature [5], it shows more mild reaction conditions. In addition, the synthetic method of the adsorbent is very simple. It also shows better or comparable capacity value to other solid support used for enrichment of Sc(III) mentioned above.

4. Conclusions

In this study, a simple, rapid, sensitive and reliable method was established for determination of trace level of Sc(III) in environmental samples based on silica gel modified with 1-(2-aminoethyl)-3-phenylurea as a solid-phase extractant. The most important characteristics of 1-(2-aminoethyl)-3-phenylurea-modified silica gel are its faster sorption and easy elution for Sc(III), and excellent adsorptive selectivity towards Sc(III) over other ions. Moreover, the synthetic method is very simple. This new developed method has been successfully applied to the analysis of trace Sc(III) in environmental samples. The precision and accuracy of the method are satisfactory. In summary, we have demonstrated that the new sorbent has high analytical potential for analysis of trace scandium from environmental samples.

MSPQC

ABSTRACT

The early clinic identification of commonly encountered *Candida* species became more important with the increasing human candidiasis. In this paper, a new MSPQC-PLS (multi-channel series piezoelectric quartz crystal biosensor combined with partial least square) method was proposed for early identification of the most frequent *Candida* species encountered in human pathology. This method was based on these fact that (1) MSPQC method is a real-time monitoring method based on the sensitive frequency response to the change of electric parameters of the culture media caused by the growth of microorganisms; (2) various *Candida* species produce significantly different types of frequency curves in 1 or 2 days' culture period; (3) this difference can be identified by the partial least square technique. Using the proposed method, three species (*Candida albicans*, *Candida glabrata*, and *Candida tropicalis*) from a collection of 53 clinical strains of *Candida*, isolated from hospitalized patients, were identified with a classification rate of 98.1%. New proposed MSPQC-PLS method is simple, rapid and convenient to perform. It can identify clinical *Candida* species directly without passing through pure culture process. This will save identification time greatly. It could be popularized in clinical microbiology laboratories.

1. Introduction

Nosocomial candidiasis has become an important cause of morbidity and mortality [1–3]. Invasive candidiasis is the predominant fungal infection in the intensive care unit setting, neutropenic patients and post-surgery units [4–6]. *Candida* species Account for 70–80% of invasive bloodstream fungal infections, and they represent the fourth most common nosocomial bloodstream infection [7–9]. Among the *Candida* species causing invasive infections, *Candida albicans* is by far the species most commonly isolated, causing up to two-thirds of all cases of invasive candidiasis. *C. albicans*, *Candida tropicalis*, and *Candida glabrata* account for about 80% of fungal isolates encountered in the clinical laboratory [1,10]. Hence early identification of these commonly encountered *Candida* species is very important for doctor to do optimal antifungal therapy and patient management.

Commercially available identification systems used in routine were automatic identification system, such as ID32C of VITEK2, manual identification system like API *Candida*. These identification system were based on the identification of physiological and nutritional (sugar assimilation and/or fermentation, enzymatic tests) characteristics of pure yeast colonies which isolated from the raw clinical samples. So it usually need up to 5 days between the receipt of patient material and presentation of identification results to the clinician [11]. It is more serious for blood samples, because several days will be taken for positive reporting.

Some novel approaches for the rapid identification of clinically relevant microorganisms, including genotypic techniques base on PCR and spectroscopic techniques combined with chemometrics, were also performed on isolated pure colonies [12–17]. These techniques especially genotypic techniques showed some serious drawbacks, such as sensitivity to contamination and mutations, complicated protocol, reagent costs, etc., and are not up to now applied in routine.

MSPQC is a bioelectrochemical device based on the series piezoelectric quartz crystal (SPQC) sensor [18,19]. It attracted the attention of many analysts because of its sensitive response, low cost and easy operation. MSPQC system, which composed of eight single channels SPQC system, has been proposed to detect pathogens in clinical samples, to test susceptibility of clinical *Escherichia coli* isolates against ampicillin [20,21].

Chemometrics is the technique for extracting useful information from detected data. In this paper, MSPQC combined with PLS method was proposed for early identification of *Candida* species without preisolation of pure colonies from raw clinical species. This method was based on the fact that fingerprints response curve of *Candida* species while growing in our self-prepared culture media can be detected by MSPQC system, and these curves can be differentiated by the partial least square (PLS) technique effectively. For the reasonable explanation of those special frequency curves, the

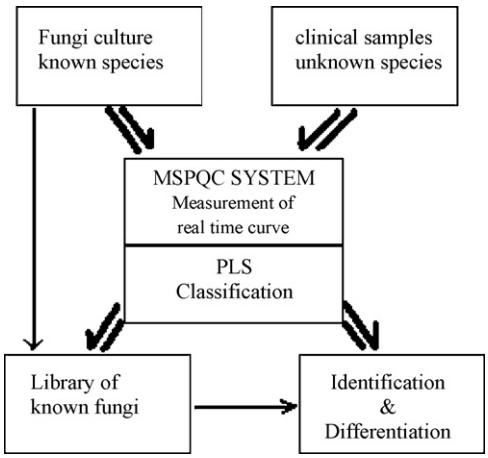

Fig. 1. Schematic representation of the MSPQC-PLS concept.

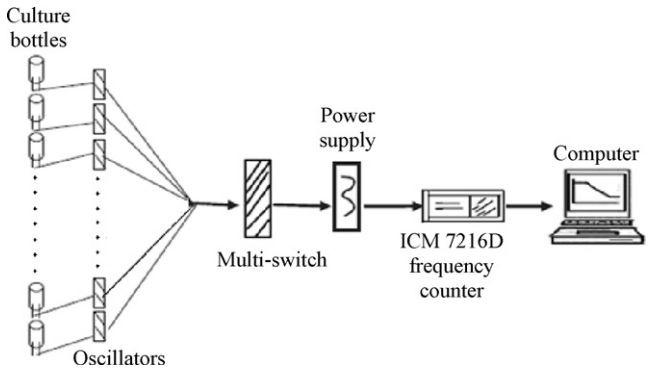

Fig. 2. Diagram of MSPQC system.

impedance characters of the three types of *Candida* species were studied by impedance analyzer.

The concept of the MSPQC-PLS system is shown in Fig. 1. First, real-time frequency curve of known clinical *Candida* species was detected by MSPQC system. These species and curves are made up of our library of known fungi. Then, the library was connected to a data processing and classification module via a specifically designed PLS algorithm. The PLS trained the data library to got a regression coefficient matrix which possess the ability of pattern recognition. The matrix was called "prediction machine". For an unknown clinical species, importing the data of frequent curve record by MSPQC system to the PLS system, the prediction machine will recognize the curve belong to which species' curve pattern, and give out the early identification result of *Candida* species.

2. Materials and methods

2.1. Strains

Fifty-three *Candida* strains provided by Xiangya Hospital of Central South University, Changsha, China, were isolated from different hospitalized patients and identified by standard identification system API20C.AUX (bioMerieux, France). Prior to use for identification, isolated strains were stored at room temperature in Sabouraud dextrose broth. For long preservation, these strains were frozen at −20 °C in distilled water.

2.2. Culture media

All the culture media used in our experiment were prepared by ourselves.

YC broth: beef extract, 2 g; yeast extract, 1 g; glucose, 40 g; YC nutrient fluid, 16 ml; ionized water, 1000 ml; pH 7.0–7.2.

Sabouraud dextrose broth: peptone 10 g, dextrose 40 g, distilled water 1000 ml; pH 5.4.

2.3. MSPQC system

The diagram of MSPQC is shown in Fig. 2. It is composed of 32 detection cells and 32 oscillator circuits. For single detection cell and oscillator circuit, an AT-cut 9 MHz piezoelectric quartz crystal coated with 0.5 mm silver disc at two sides was connected to the self-made TTL oscillated circuit and a pair of conductive stainless steel electrodes. The temperature of culture bottle was maintained at 37 ± 0.2 °C. 32 oscillator circuits share universal frequency counter, computer, and temperature controller system. The frequency outputs were switched alternately by multi-switches. Using the MSPQC, 32 samples can be tested at the same time. The on-line curves of frequency shift vs. culture time could be seen in screen by using self-developed software, so the growth of microorganism could be observed in real time. All frequencies and corresponding test times were autosaved by computer with TXT format.

2.4. MSPQC method for recording the frequency curve

Fungi were grown on Sabouraud dextrose agar plates at 37 °C overnight. The next day, the cells were harvested and suspended in 10 mL sterile water, the concentration were adjusted to 9.0×10^8 cfu/mL and 1.0×10^2 cfu/mL, respectively. 1 mL fungi suspension was transferred into culture bottles which contained 9 mL YC broth. Culture bottles were placed into MSPQC system and incubated at 37 ± 0.2 °C for a period of 1–3 days. At the same time, the on-line curves of frequency shift vs. culture time was recorded by using self-developed software. To avoid contamination, all glassware, culture media and equipment were sterilized. For comparison, the capacitance and resistance curves of fungi (9.0×10^8 cfu/mL) growth were recorded by HP-4192A LF impedance analyzer (Hewlett Packard) at 37 ± 0.2 °C.

2.5. Method for building the library of known fungi and creating the prediction machine

Each fungus sample can be represented by frequency shift data vector, $x = (x_1, x_2, x_3, \ldots, x_n)$, where x_n was the frequency shift measured by MSPQC system after frequency detect time(FDT). The FDT was defined as the time at which oscillating frequency shift of MSPQC changed rapidly [22]. If frequency shift was recorded at a interval of 10 min by MSPQC system, then x_1 was the frequency shift measured at 10 min after the FDT and x_2 was the frequency shift measured at 20 min after the FDT, x_n is the frequency shift measured at $n \times 10$ min after the FDT. Frequency shift data vector of total clinical collected fungi detected by MSPQC formed a data matrix. This data matrix is the library of known fungi. Every row of the data matrix represented one clinical sample. Then PLS was used to train the library. 70% of the total samples in library were selected randomly as the training set. Through the training, the characteristic of data vectors of each species was extracted by the PLS algorithm respectively and a $n \times 3$ regression coefficient matrix Y was construct (see Eq. (1)). Each column of the matrix Y denoted the characteristic of one type of species. So the number of fungi species need to be differentiated was equal to the column number of Y. The rest of 30% of the total samples were selected as the testing

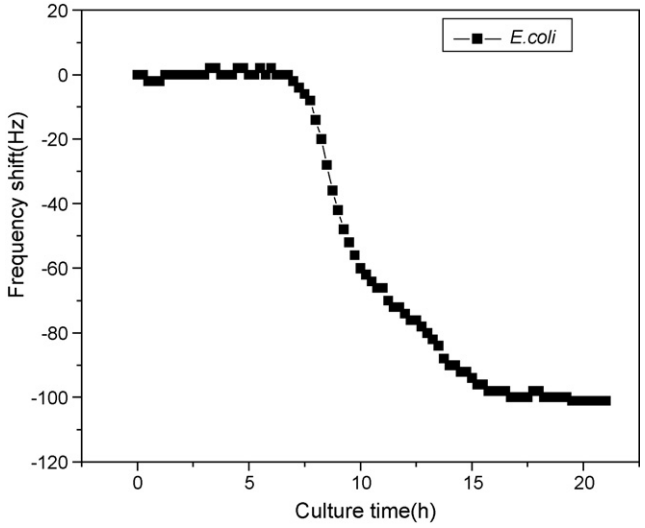

Fig. 3. Typical frequency curve of *E. coli*.

set to confirm the validity of the Y

$$\begin{bmatrix} x_{11}, x_{12}, \ldots, x_{1n} \\ x_{21}, x_{22}, \ldots, x_{2n} \\ \vdots \quad \ddots \quad \vdots \\ x_{m1}, x_{m2}, \ldots, x_{mn} \end{bmatrix}_{m\times n} \xrightarrow{PLStrainning} \begin{bmatrix} Y_{11}, Y_{12}, Y_{13} \\ Y_{21}, Y_{22}, Y_{23} \\ \vdots \quad \ddots \quad \vdots \\ Y_{n1}, Y_{n2}, Y_{n3} \end{bmatrix}_{n\times 3} \tag{1}$$

For an unknown sample X, a 1×3 vector Z was obtained by $X \times Y$ (see Eq. (2)). Sample X was regarded as the same species which show maximal value in vector Z. The regression coefficient matrix Y was called as "prediction machine".

$$\begin{bmatrix} X_1, & X_2, & \ldots, & X_n \end{bmatrix}_{1\times n} \times \begin{bmatrix} Y_{11}, Y_{12}, Y_{13} \\ Y_{21}, Y_{22}, Y_{23} \\ \vdots \quad \ddots \quad \vdots \\ Y_{n1}, Y_{n2}, Y_{n3} \end{bmatrix}_{n\times 3} = \begin{bmatrix} Z_1, & Z_2, & Z_3 \end{bmatrix}_{1\times 3} \tag{2}$$

2.6. Early identification of Candida species

The simulating clinical blood sample was prepared by adding 1 mL of 1.0×10^2 cfu/mL known *Candida* species to 1 mL human fresh blood. They were added individually to MSPQC bottle which contained 8 mL culture media. These culture bottles then were placed into MSPQC system and incubated at $37 \pm 0.2\,^{\circ}C$ for a period of 1–3 days. Then the real-time frequency shift curve was transformed to a data vector X and the simulating sample was identified by PLS system.

3. Results and discussion

3.1. Theory

MSPQC system is based on the monitoring electric parameter change of the culture media caused by the growth of microorganism. The theory basis for the SPQC can be represented by the following

$$\Delta F = \frac{\pi F_0^2 C_m (4\pi F_0 G_0 C_d + 4\pi^2 F_0^2 C_d^2 tg\theta - G_0^2 tg\theta)}{[G_0^2 - 2\pi F_0 C_0 G_0 tg\theta + 4\pi^2 F_0^2 C_d (C_0 + C_d)]^2} \Delta G \tag{3}$$

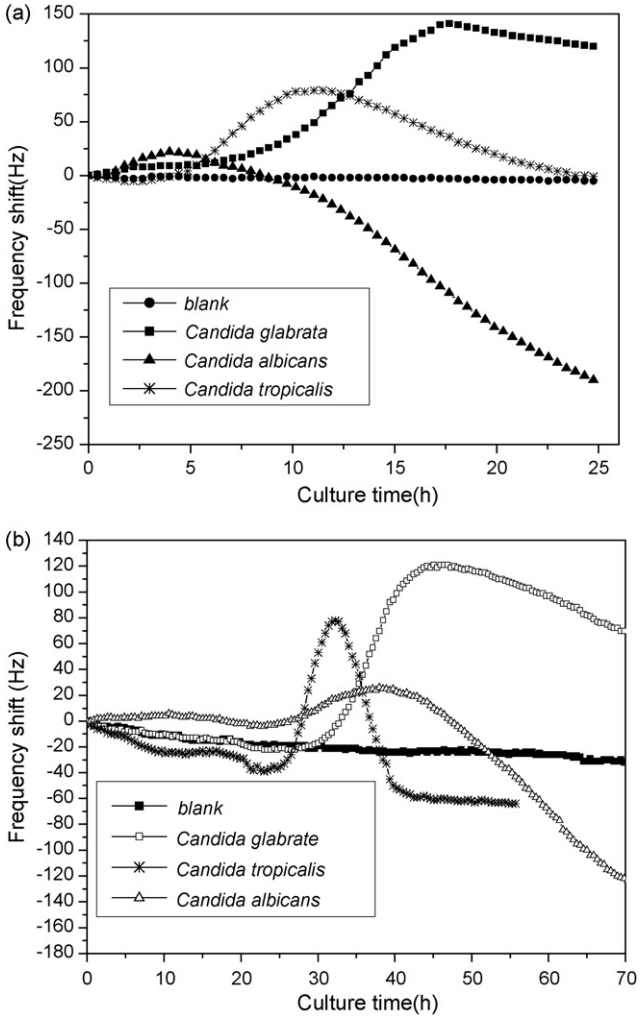

Fig. 4. Typical frequency curve of three species of *Candida* cultured in YC broth with the initial concentration: (A) 9.0×10^7 cfu/ml; (B) 1.0×10^1 cfu/ml.

where F_0 is the resonant frequency of the crystal, C_m and C_0 are the dynamic capacitance and static capacitance of the crystal respectively, C_d is the capacitance of solution which mostly based on the solution permittivity and parasitic capacitance between the leading wires of the electrode. G_0 is the solution conductance, θ is the phase shift. $\Delta F = F_i - F_0$, F_i is the oscillating frequency of crystal. From Eq. (3), the change of F is mainly dependent on solution conductivity and permittivity if other above-mentioned parameters are kept as constant. So the conductivity and permittivity change of the culture media caused by the growth of microorganism can be represented by the sensor frequency change. The typical frequency curve of *E. coli* detected by SPQC is shown in Fig. 3.

This curve was related to the metabolism of *E. coli*: at the first stage, oscillating frequency varied slowly because bacterium adjusted itself to new culture. After a few hours, bacterium came into an exponential growth stage and oscillating frequency started to decrease rapidly. Finally, when the growth of bacterium reached saturation, frequency arrived at the second flat stage. For the fungi, different species shows different way of metabolism. Further more, the same species in different culture medium, or at different stages of growth may also show different morphology and different ways of metabolism. These led to more specific diversity of MSPQC response in the grown process. These specific diversity were the basis of identification of fungi species.

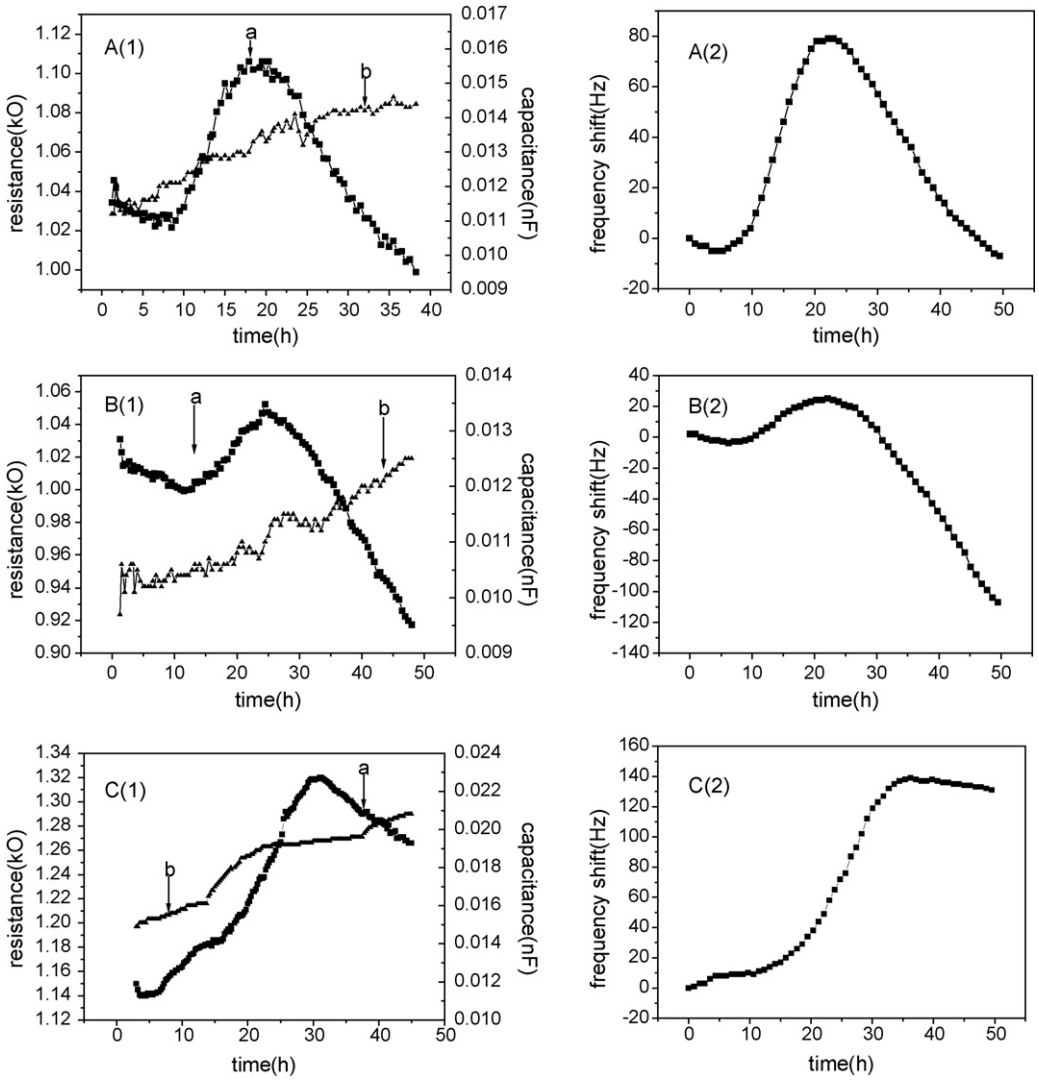

Fig. 5. The resistance curves[A(1)a, B(1)a, C(1)a], capacitance curves [A(1)b, B(1)b, C(1)b] and frequency shift curves [A(2), B(2), C(2)] between the two electrodes caused by the growth of three *Candida* species. A for *C. tropicalis*; B for *Candida albicans*; C for *C. glabrata*.

3.2. Typical frequency curve of three species of Candida

Typical frequency curves of three species of *Candida* (*C. albicans*, *C. glabrata*, *C. tropicalis*) in YC broth with high initial concentration are shown in Fig. 4(A). It showed clearly that three *Candida* species produced significant different type of frequency curve in 1 days' culture. For *C. tropicalis*, it showed a clear upward at first and then downward trend; *C. glabrata*, showed a clear upward trend; *C. albicans*, showed a clear downward trend after a unconspicuous upward trend. And from Fig. 4(B), it can be seen that *Candida* species gave out the same pattern of frequency curve no matter cultured with high initial concentration or low initial concentration. The only difference between the curve of high and low initial concentration was the FDT. For high initial concentration, the FDT of each *Candida* species was about 3–5 h (see Fig. 4(A)). For low initial concentration, the FDT of each *Candida* species was about 25–30 h (see Fig. 4(B)). Anyway, the three different species of *Candida* showed different pattern of frequency curve. Those diversity was easily recognized by PLS system.

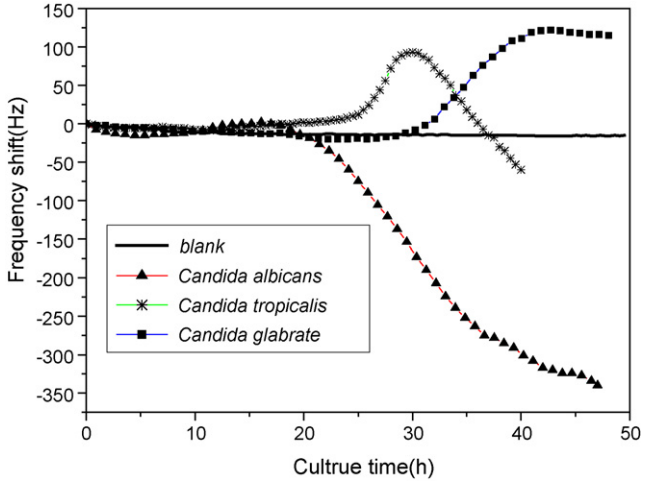

Fig. 6. Typical frequency curve of three species of *Candida* in simulating blood sample.

(✱) Testing samples of *C. albicans*. (◇) Training samples of *C. tropicalis*. (□) Testing samples of *C. tropicalis*.

3.3. Impedance changing curve of three species of Candida

Fig. 5 shows the resistance and capacitance change between the two electrodes of culture bottle while *Candida* species were growing in YC broth.

From Fig. 5, it can be seen that the capacitance between the two electrodes changed about 0.003–0.005 nF during the growing period of these *Candida* species. It means that there is no significant change in capacitance. But for the resistance between the two electrodes changed about 100 Ω and the pattern of the resistance changing curve is the same as the pattern of frequency shift curve produced by *Candida* species in comparative experiment. It clearly showed that the reason of producing those typical frequency curve was mainly related to the resistance changed by the growth of *Candida* species.

3.4. Typical frequency curves of three Candida species in simulating blood sample

As pathogens in raw clinical materials are always in low concentration, frequency curve of *Candida* species in simulating blood sample with low initial concentration were determined. From Fig. 6, it can be seen that the pattern of frequency curve was not affected by human blood. There is no significant difference in frequency curve between the simulating experiment and the low initial concentration experiment. This result means that raw clinical samples can be identified by proposed method directly without passing through pure culture process.

3.5. Construction of the prediction machine

A total of 53 clinical fungi were used to construct the prediction machine. All the fungi used here were pure culture species. Three types of frequency curve were identified. They were produced by *C. albicans*, which showed a clear downward trend after a unconspicuous upward trend, by *C. glabrata*, which showed a clear upward trend curve, by *C. tropicalis*, a clear upward and downward trend, respectively. Fig. 7 is a three-dimensional plot differentiated by PLS classification which was based on 53 samples of the three types of frequency curve caused by three species of *Candida*. Seventy percent of the 53 samples were used as the training set and the rest 30% were used as the testing set. From Fig. 7, it can be seen clearly that frequency curve produced by three types of fungi were successfully classified into three types by the PLS program.

Table 1
Identification result for 53 *Candida* species.

Candida species	Number of sample	Classification rate
C. albicans	23	100%
C. tropicalis	13	100%
C. glabrata	17	94.1%

Table 2
Identification result of early identification in simulating clinical blood samples.

Candida species	Number of sample	Prediction accuracy	Average identification time (h)
C. albicans	6	100%	46.5
C. tropicalis	6	83.3%	52.3
C. parapsilosis	5	100%	49.6

Table 1 shows very satisfying result. Only one *C. glabrata* sample was misclassified. The total classification rate of the 53 clinical samples was 98.1%. So the three types of clinically commonly encountered *Candida* species can be identified by proposed method in about 1 day.

3.6. Early identification of Candida species in simulating clinical blood samples

Simulating clinical blood sample were prepared by adding 1.0×10^2 cfu/mL dilutions of known *Candida* species to human fresh blood. A total of six *C. albicans*, five *C. glabrata*, six *C. tropicalis* were identified from the simulating blood samples. The PLS prediction machine which trained from 53 known fungi of the four *Candida* species was used to predict simulating clinic blood samples, the results are shown in Table 2. Only one *C. tropicalis* sample was misclassified. The average identification time of each *Candida* species was about 50 h. This is much shorter than the time needed in clinical routine. It means that several days can be saved using the new proposed method.

4. Conclusion

A MSPQC-PLS system was constructed to identify the most frequent *Candida* species encountered in human pathology with a single measurement. A "fingerprint frequency curve" of the sample measured by MSPQC can be recognized and classified by PLS. Pure cultures of clinical fungi can be identified by proposed method in about 1 day, with the classification rate of 98.1%. The identification of *Candida* species in simulating clinic blood samples showed that the proposed method has a potential capacity to identify *Candida* species directly without pure culture process. Proposed method enables early classification and differentiation of fungi at species level.

ABSTRACT

Cigarette smoking can damage DNA and induce spontaneous mutagenesis or carcinogenesis. Here, we describe a novel strategy for in situ monitoring of cigarette smoke-induced DNA oxidation damage and offer a method for screening natural compounds that protect DNA against tobacco smoke. The present protocol takes advantage of a fast and simple magnetic separation/mixing method and a highly sensitive chemiluminescence (CL) ELISA. The DNA immobilized on the magnetic beads was oxidized by the smoke in the absence or presence of natural compounds, and then oxidative DNA was conveniently held by magnetic force, whereas the complex tobacco smoke matrix and any remaining compounds were completely eliminated by extensive washing, and possible interferences were thus removed and oxidative damage was then sensitively monitored by CL ELISA. A library of 32 natural products was then screened and three were found to protect DNA from oxidative damage and thus may be promising compounds for the development of new drugs. Moreover, the protection effect of these three natural compounds against DNA oxidation damage was successfully classified by directly spiking them in the reference cigarettes. In addition, the potential to screen a mixture in a complex sample matrix, such as crude extracts, was also demonstrated, and hence the proposed technique can screen compounds within a complex matrix and enhance the screening throughput.

1. Introduction

Cigarette smoke is a complex mixture of literally thousands of compounds, of which more than 60 are known carcinogens, mutagens, and cocarcinogens. Tobacco smoke contains high levels of tumor promoter and reactive oxygen species (ROS) [1–5], which includes superoxide, hydroxyl and peroxyl radicals, and is capable of causing oxidative damage to cellular DNA involving base oxidation and DNA strand structure changes such as strand breaks, interstrand/intrastrand cross-links, and DNA-protein cross-links [6,7]. DNA oxidation damages appear to be prominent in the etiology and progression of numerous cancers as well as coronary, carotid atherosclerosis and autoimmune diseases [8,9]. In addition, the role of natural products in life science is of great interest both to the general public and to experts in different disciplines including medicine, nutrition, health, and food science [10]. Therefore, it is important to study the damaging effects of cigarette smoke on DNA and screen natural protective compounds against such damages.

8-Hydroxy-2′-deoxyguanosine (8-OHdG) (Fig. 1) is one of such important oxidative DNA lesions formed by the oxidation of the C-8 position of 2′-deoxyguanosine, which has often been used as a biomarker of oxidative DNA damage [11,12]. Current evidence suggests that 8-OHdG lesions are present in DNA during cellular replication and carcinogenesis [13–18], and its level have been shown to increase in Alzheimer's disease or on exposure to tobacco smoke [19–21]. Thus it can be regarded as a sensitive and stable biomarker of DNA oxidative damage to estimate the toxicity of internal and external factors. Hence, here we used 8-OHdG as the biomarker for DNA oxidative damage induced by cigarette smoke.

Many powerful analytical techniques have been developed to determine 8-OHdG. HPLC coupled with electrochemical and radioactive detectors, post-labeling assays [22,23] and GC/MS with selected ion monitoring [24,25] after DNA digestion are the most commonly used techniques for 8-OHdG detection. All of these detection methods are sensitive, but they are bulky, expensive and often require specialized and cumbersome technical processing. The application of various immunological approaches has made a seminal contribution to the quantitative assessment of bulky as well as subtle structural alterations produced in damaged DNA [26–29]. High affinity polyclonal and monoclonal antibodies able to specifically recognize the 8-OHdG lesion in DNA hydrolysates have been developed and utilized for several biomonitoring studies [30]. To avoid cumbersome DNA degradation or the use of expensive equipment, Musarrat et al. developed an immunoslot blot assay

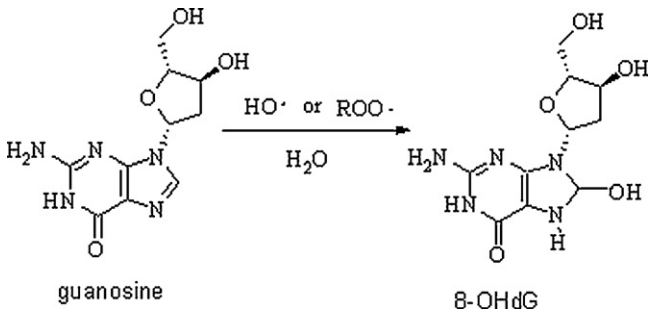

Fig. 1. Mechanism of formation of 8-OHdG after G attacked by ROS.

to detect DNA lesions oxidized by methylene blue plus light and H_2O_2, where polyclonal antibodies specific for the 8-OHdG moiety in oxidized DNA were used for sensitive detection and quantitation of this biomarker of oxidative damage to unhydrolyzed DNA [31]. Yarborough et al. reported an ELISA procedure for the detection of 8-OHdG in single cells, and found that the amount of 8-OHdG in oral cells of smokers was 1.6-fold higher than in nonsmokers [32].

In this article, we demonstrate a novel strategy for in situ monitoring of cigarette smoke-induced DNA oxidative damage and describe a method for screening natural compounds that protect DNA against tobacco smoke. Magnetic beads (MB) and chemiluminescence (CL) detection, which offers unique advantages including simple instrumentation, high sensitivity, low detection limit, wide linear ranges and feasibility for apparatus miniaturization in analytical tests [33–38], were used to establish this sensitive and simple 8-OHdG detection method and the screening platform for natural protective compounds. A library of 32 natural products was then screened and three were found to protect DNA from oxidative damage and thus may be promising compounds for the development of new drugs.

2. Experimental

2.1. Materials

2.1.1. Chemicals

All chemicals were of analytical reagent grade and were used as received. Goat anti-8-OHdG polyclonal antibody and HRP-labeled donkey anti-goat IgG (1 mg/mL) were bought from AbD Serotec. HRP CL substrate was obtained from Milipore Co. Carboxyl BioMag®Plus magnetic beads (MB, 1.5 μm, 20 mg/mL) were obtained from Polyscience, Inc. BSA was bought from Sino-American Biotechnology Co. N-3-Dimethylaminopropyl-N′-ethylcarbodiimide hydrochloride (EDC) was purchased from Alfa Aesar. Research cigarettes (Liqun) were obtained from China Tobacco ZheJiang Industrial Co. Ltd. Before smoking, cigarettes were conditioned for 24 h in an environmental chamber that was maintained at a temperature of 20 °C and 60% relative humidity. The DNA (5′-NH_2-AAAAAAAAAAATGGTGGAGAGTGTGTGGA-3′) was acquired from Shanghai Invitrogen Biotechnology Co. Ltd. Natural products were from Shanghai U-sea Biotech Co. Ltd. and other chemical reagents were obtained from Sinopharm Chemical Reagent Co. Ltd.

2.1.2. Buffers

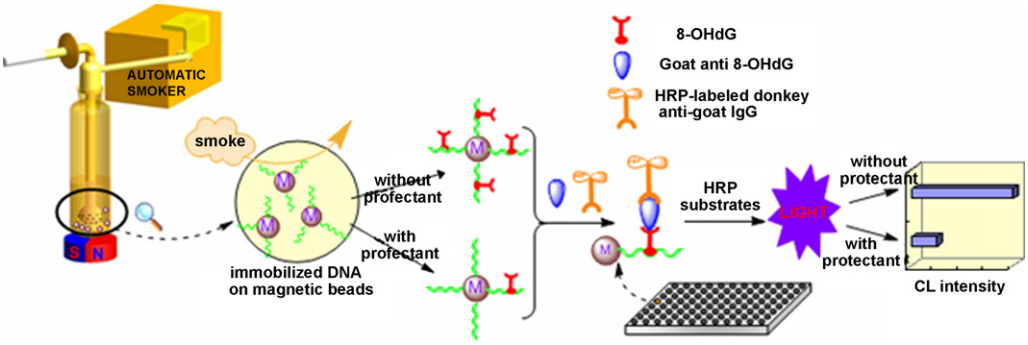
The water was prepared using Milli-XQ equipment. The buffer for immobilization of DNA on MB was 0.1 M imidazole buffer, pH 6.0. Reaction buffer for antigen–antibody immunoreactions was phosphate buffer solution (PBS), consisting of 9-g sodium chloride, 6-g disodium phosphate and 0.4-g sodium dihydrogen phosphate in 1-L buffer, pH 7.4 and PBS (K+) consisting of 6.8-g potassium dihydrogen phosphate, 0.944-g sodium hydrate in 1-L buffer, pH 6.8. Wash buffer (WB) was PBS with the addition of 0.1% Tween 20 (TW). Blocking buffer was PBS consisted of 0.02% BSA for blocking the residual reactive sites on the capture antibody and reducing the nonspecific absorption effects.

2.1.3. Apparatus

Cigarette smoke was generated by an automated smoker (Borgwaldt Technik Co.) that was operated according to the standard of Federal Trade Commission (FTC) protocol. CL measurements were performed with a computerized Fluoroskan Ascent (Thermo Electron Corporation).

2.2. Online DNA oxidation with smoke ROS and DNA protectant screening procedure

120-μg MB was first washed 3 times and then added to 100 μL of imidazole buffer (pH 6.0) containing 2-mg N-3-dimethylaminopropyl-N′-ethylcarbodiimide hydrochloride (EDC). The solution was continuously shaken for 30 min to ensure the activation of the carboxyl groups, and then reacted with 80-pmol DNA for 1 h at 37 °C. The conjugates were washed three times with WB by a magnetic separation/mixing process and then stored in PBS–0.5% TW buffer at 4 °C until use. Each cigarette was smoked according to the FTC protocol. The protocol specifies that the cigarette should be puffed in such a way that one puff would last 2 s with puff volume of 35 mL and frequency of 1 puff/min. The puff volume was calibrated using a bubble calibrator matched with the automated smoker. The smoke was passed through a gas dispersion tube connected to a frit disk to the trapping solvent containing the DNA–MB conjugates. For screening, the compounds were first mixed with the DNA–MB conjugates in the trapping solution, or the compound solution was spiked into the cigarette by a syringe. After smoking, the interaction between DNA and the smoke was kept at 37 °C for 80 min, and the DNA–MB conjugates were then separated from the smoke solution by magnetic force and washed in PBS–0.1% TW buffer for four times. The obtained DNA–MB conjugates were blocked and then stored at 4 °C for use. All reactions were run in triplicate at least.



2.3. CL ELISA procedure

In a typical experiment, after the elimination of the blocking buffer, goat anti-8-OHdG diluted with blocking buffer was added and reacted with the oxidized DNA obtained as described above at 37 °C for 1 h. Then, the HRP-labeled donkey anti-goat IgG diluted with blocking buffer was added and reacted for another 1 h and the resultant MB was washed with WB for three times, the CL signals on the surface of MB were detected with 100 μL of CL HRP substrate.

3. Results and discussion

3.1. The principle

The method consists of the following four steps: (1) DNA oxidative damage: DNA is immobilized on the surface of MB by covalent binding, online DNA oxidation is carried out with tobacco smoke and natural products are screened for the protection of DNA against oxidative damage; (2) impurity elimination and 8-OHdG purification: oxidative DNA is conveniently held by a magnetic force, whereas the complex tobacco smoke matrix and any remaining compounds are completely eliminated, and possible interferences are thus removed; (3) 8-OHdG-antibody immunoreaction: anti-8-OHdG antibody is added, which reacts with 8-OHdG induced by oxidative DNA damage. A HRP-labeled secondary antibody is then added; (4) CL detection: the CL signal on the surface of mag-

Scheme 1. Schematic representation of the magnetic bead-based immunoassay to monitor cigarette smoke-induced oxidative DNA damage and screening of potential compounds for DNA protection.

netic beads is directly determined with CL HRP substrate. The principle of in situ monitoring of cigarette smoke-induced DNA oxidation damage and screening of natural products for DNA protection is depicted in Scheme 1. Since ROS produced by cigarette smoke is often of transient species, we combined a gas–liquid reactor with an automatic smoker, and the radical intermediates in the combustion were simultaneously and effectively captured by the DNA in the gas–liquid reactor as the smoking cigarette was 'puffed'. Oxidation of DNA by cigarette smoke was done without using the Cambridge filter, therefore, the smoke was considered as whole smoke containing both the particulate phase and the gas phase.

3.2. Choice of reaction media

Several factors were taken into account when we choose the solvent mixture to trap the ROS of cigarette smoke. First, the solvent should have good solubility and allow adequate dispersion of the smoke. Second, the contact time between the smoke and the solvent should be as long as possible to ensure there is sufficient time for the ROS in the smoke to dissolve into the liquid phase. Third, the surfactant could disperse the smoke into tiny bubbles and greatly facilitate the interaction of smoke with the liquid phase, with larger contact area between the smoke and liquid [3]. Taking these factors into consideration, we tested water and some other buffers containing the non-ionic surfactant Tween-20 (TW), which does not affect DNA, and were used to collect the cigarette smoke. After the oxidized DNA was collected in these smoke-trapping solutions, the CL signals of 8-OHdG were detected using an enhanced CL assay kit. As shown in Fig. 2, we found that, when using PBS–0.5% TW as the smoke-trapping buffer, the CL signals reached maximum. Thus PBS–0.5% TW was used in the subsequent experiments.

3.3. Optimization of assay conditions

Several parameters were investigated systematically in order to establish optimal conditions for in situ monitoring of cigarette smoke-induced DNA oxidation damage using CL ELISA, including the amounts of DNA and the dilution coefficient of the antibody. First, as the concentration of DNA increased, CL intensity increased and then almost leveled off above 80 pmol for 120 μg MB (Fig. 3), possibly due to that 80 pmol DNA has saturated ROS produced by cigarette smoke. Hence, subsequent work employed 80 pmol DNA for 120 μg MB.

Goat anti-8-OHdG polyclonal antibody from AbD Serotec has been tested in both a competitive ELISA and paraffin sections and shown to have high specificity towards 8-hydroxydeoxyguanosine and 8-hydroxyguanosine nucleotides. Partial cross-reactivity was also observed for this antibody with 8-mercaptoguanosine and 8-bromoguanosine whereas 2-deoxyadenosine, 7-methylguanosine, guanosine monophosphate and guanosine showed no reactivity. In our methodology, this polyclonal antibody was employed to recognize the formation of 8-OHdG moiety on the DNA backbone after

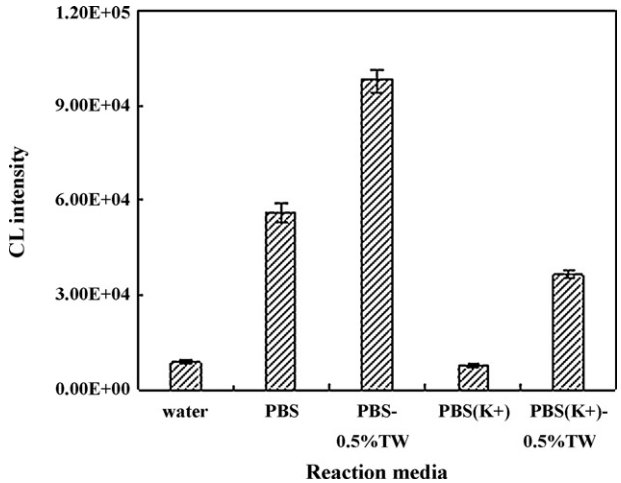


Fig. 2. CL signal versus different cigarette smoke-trapping solutions. Experimental conditions: 3 mL reaction solution containing 120 μg MB and 80 pmol DNA, four puffs of cigarette smoke, 80-min contact time between DNA and smoke, 10,000-fold-diluted primary antibody and 1000-fold-diluted secondary antibody.

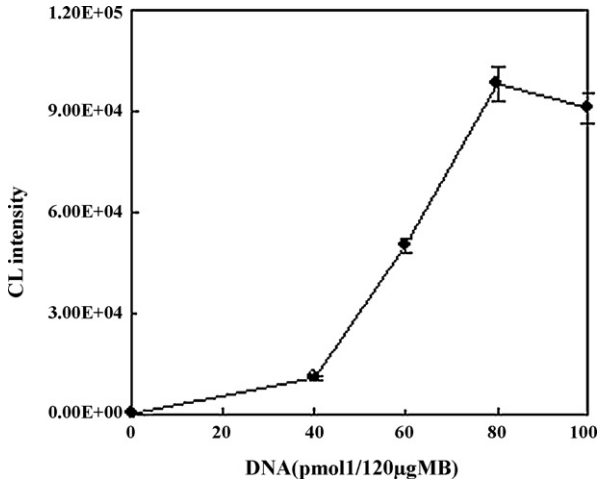

Fig. 3. CL intensity versus the concentration of DNA immobilized on MB. Experimental conditions: 3 mL reaction solution containing 120 μg MB, four puffs of cigarette smoke, 80-min contact time between DNA and smoke, 10,000-fold-diluted primary antibody and 1000-fold-diluted secondary antibody.

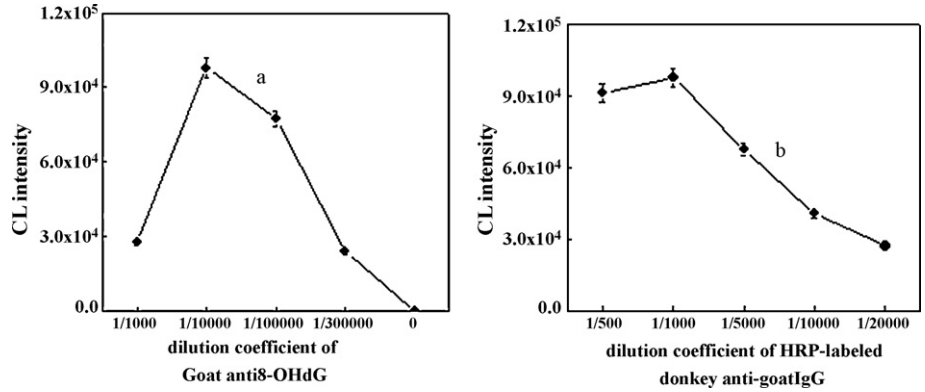

Fig. 4. CL intensity versus the dilution coefficient of the antibody. Experimental conditions: 3 mL reaction solution containing 120 μg MB, 80 pmol DNA, 1000-fold-diluted HRP-labeled secondary antibody (a) and 10,000-fold-diluted primary antibody (b), four puffs of cigarette smoke and 80-min contact time between DNA and smoke.

oxidation by the smoke. In CL ELISA procedure, CL intensity could be affected by the dilution coefficient of the antibody. Fig. 4 illustrated the CL intensity versus different dilution coefficients of primary and secondary antibodies, respectively. As the amount of antibodies increased, CL signal increased and reached maximum at 1/10,000 for primary antibody (a) and 1/1000 for second antibody (b). Thus, 10,000-fold-diluted goat anti-8-OHdG and 1000-fold-diluted HRP-labeled donkey anti-goat IgG were selected for use in subsequent studies.

3.4. Monitoring of cigarette smoke-induced DNA oxidation damage

The CL signal produced from 8-OHdG, which represent DNA oxidation damage arising from cigarette smoke here, can be also greatly affected by the amount of cigarette smoke and oxidation time. First, as shown in Fig. 5, the CL intensity increased when the amount of smoke was increased from one to four puffs and then maintained at almost the same level with four to five puffs of cigarette smoke. After that, the level decreased gradually, possibly an excess of ROS resulted in the formation of secondary oxidation products such as oxazolone, spiroiminodihydantoin, and guanidinohydantoin [39–41]. Thus four puffs of cigarette smoke were used in subsequent experiments. Furthermore, Fig. 5 also indicates that the CL intensity was almost constant after 4-h reaction of DNA with four puffs of cigarette smoke at 37 °C. We chose 80-min contact time between DNA and smoke to screen natural products because it is sufficient to observe intense CL and could greatly shorten the screening time.

3.5. Screening of natural compounds for protection against DNA oxidation damage

It is well known that some compounds play an important role in eliminating ROS and protecting DNA from oxidative damage. For example, flavonoids are the most widely studied with respect to their antioxidant and biological activities. They have powerful antioxidant activities in vitro, being able to scavenge a wide range of ROS, such as superoxide, hydroxyl and peroxyl radicals [42–47]. Kanazawa et al. [48] investigated bioavailable flavonoids to suppress the formation of 8-OHdG in HepG2 cells. Moreover, Traber et al. [49] reported that antioxidant micronutrient supplementation could inhibit DNA damage induced by cigarette smoke. Lee et al. [50] found that β-carotene and red ginseng could inhibit the formation of 8-OHdG in smokers. Thus a small natural compound library listed in Table 1 was used to evaluate our technique for screening of compounds providing effective protection of DNA against cigarette smoke. The library contained 32 natural compounds. As shown in Fig. 6, we found that three compounds, quercetin, sodium danshensu and baicalein, completely inhibited the formation of 8-OHdG (relative to the Control group) with a very low CL emission. Six natural compounds including scutellarin, notoginsenoside R1, puerarin, naringenin, rhein and panaxsaponin Rg1 partially protected DNA from oxidative damage caused by cigarette smoke. The other 23 natural compounds exhibited no obvious protection of DNA against oxidative damage.

To investigate the dose of each compound required to inhibit the formation of 8-OHdG and protect DNA from oxidative damage, a scavenging activity (SA) of the natural compounds was defined as

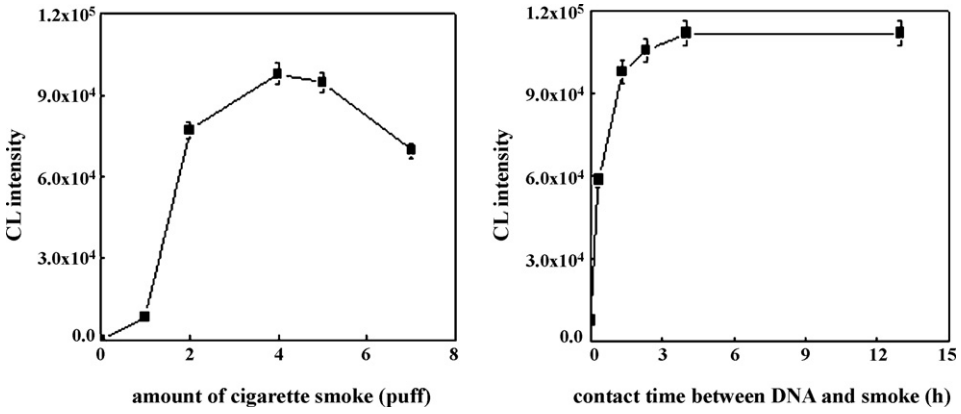

Fig. 5. CL intensity versus the amount of cigarette smoke and the contact time between DNA and smoke. Experimental conditions: 3 mL reaction solution containing 120 μg MB and 80 pmol DNA, 10,000-fold-diluted primary antibody and 1000-fold-diluted secondary antibody.

Table 1
Natural compound library used for screening of DNA protectant against tobacco smoke. 10^{-4}-M natural compounds, other conditions were the same as described in the caption of Fig. 2. Each result represents the mean value of triplicate measurements.

Natural compound	%SA	Natural compound	%SA

Tanshinone I	0	Aloin	0
Cryptotanshinone	0	Oleanolic acid	0

follows:

$$SA = \frac{CL_{control} - CL_{natural\ product}}{CL_{control}} \times 100\%$$

where $CL_{control}$ is the chemiluminescence of the control group and $CL_{natural\ product}$ is the chemiluminescence of natural product added. The SA plots for several natural compounds are shown in Fig. 7. This figure shows a similar dose dependence of SA for the three most effective compounds (quercetin, sodium danshensu and baicalein) in addition to naringenin and scopoletin. When their concentration was low, the SA was also very low. Concentrations of 10^{-4} M, or higher, of quercetin, sodium danshensu and baicalein completely inhibited DNA oxidation in our experiments. However, for naringenin, even at a concentration of 0.5 mM, the SA was only 36% while for scopoletin, SA was not dose dependent. Thus their protection against DNA damage was very weak.

The potential to screen a mixture in a complex sample matrix, such as crude extracts, is another feature of the present method. Because of the combination of magnetic force separation and highly sensitive CL ELISA, our technique avoids effects of the sample and oxidation byproducts on the assay. To demonstrate the potential

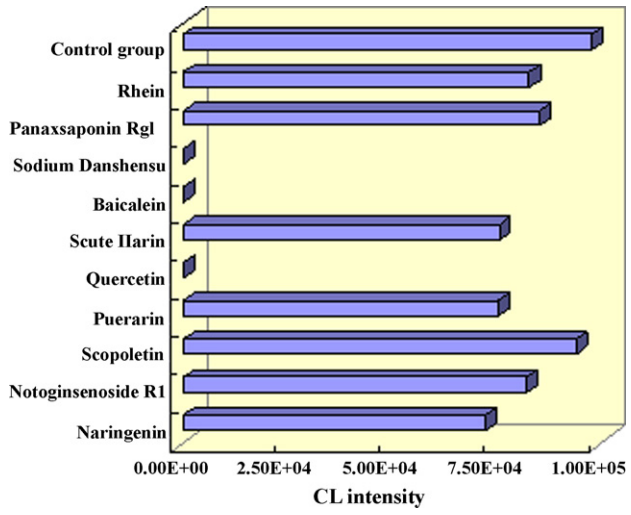

Fig. 6. Screening of natural compounds for the protection against DNA oxidation damage. Experimental conditions: 10^{-4} M of the natural compound, 3 mL reaction solution containing 120 μg MB and 80 pmol DNA, four puffs of cigarette smoke, 80-min contact time between DNA and smoke, 10,000-fold-diluted primary antibody and 1000-fold-diluted secondary antibody. Each result represents the mean value of triplicate measurements.

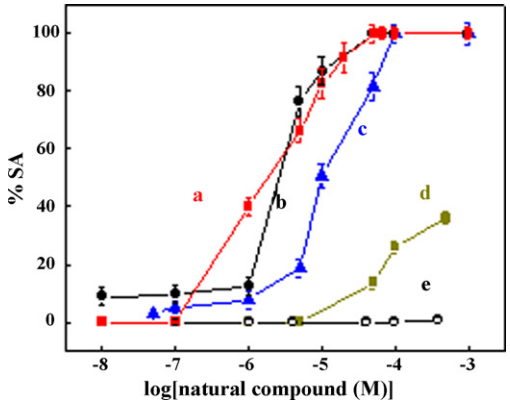

Fig. 7. SA plots for sodium danshensu (a), baicalein (b), quercetin (c), naringenin (d) and scopoletin (e). Experimental conditions: 3 mL reaction solution containing 120 μg MB and 80 pmol DNA, four puffs of cigarette smoke, 80-min contact time between DNA and smoke, 10,000-fold-diluted primary antibody and 1000-fold-diluted secondary antibody.

of the present method for screening a complex mixture, three crude extracts, baicalein-rich fractions, sodium danshensu-rich fractions and quercetin-rich fractions (their contents were 60, 40 and 95%, respectively, quantified by HPLC–UV) were assayed, and they yielded 87.6, 72.3 and 57.2% SA, respectively. As shown in Fig. 8, although with a relatively low concentration, they show prominent protection of DNA. When the amount of baicalein in the crude extract was the same as the corresponding natural compound (pure baicalein), their SA was nearly equivalent. The other two crude extracts had the similar results. These results show that the presence of a DNA protectant in a complex sample matrix can be clearly identified. This finding confirms that our new technique can screen compounds within a complex matrix and enhance the screening throughput.

3.6. Evaluation of natural compounds for protection against DNA oxidation damage in research cigarettes

To demonstrate the protection effect of natural compounds against DNA oxidation, 1 mg of baicalein, sodium danshensu, quercetin, naringenin and scopoletin in 20% ethanol were directly spiked into one cigarette tobacco, respectively, and a cigarette containing the same volume of 20% ethanol was used as control sample. After the solvent evaporation, the above cigarettes were smoked, and their influences on DNA were assayed by CL ELISA (Fig. 9). Compared with control cigarette without any natural compound, the signal of 8-OHdG was intensively inhibited in

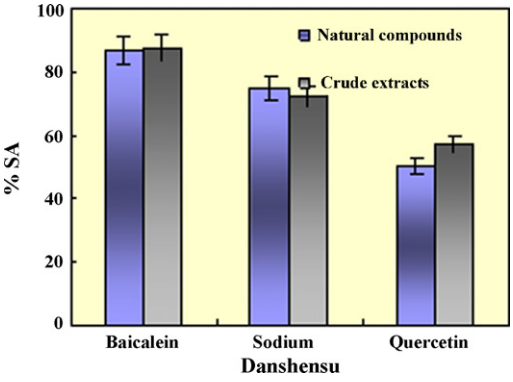

Fig. 8. SA comparison between the crude extracts and natural compounds. Experimental conditions: the amount of them is the same, 2.7 μg/mL for baicalein, 2.0 μg/mL for sodium danshensu, and 3 μg/mL for quercetin, other conditions were the same as described in the caption of Fig. 2.

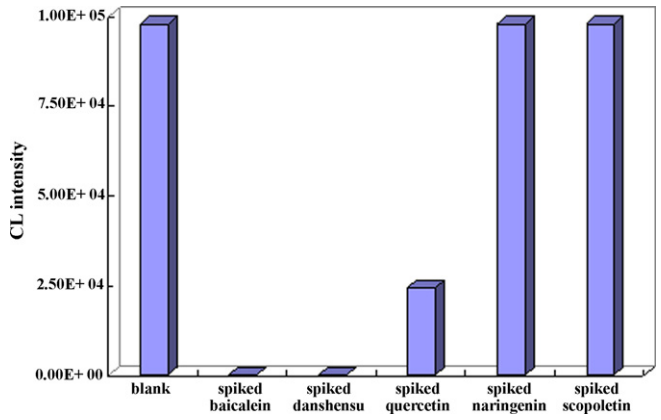

Fig. 9. CL intensity versus cigarette spiked with different natural compounds. Experimental conditions: the content of natural compounds was 1 mg/cigarette, and other conditions were the same as described in the caption of Fig. 2. Each result represents the mean value of triplicate measurements.

the cigarettes spiked with either baicalein, danshensu or quercetin while cigarettes spiked with naringenin and scopoletin have no obvious protection of DNA. These data indicate that our natural compounds indeed exert protection effects against smoke-induced DNA oxidative damage even in the real cigarette samples. The reasons may be: (1) ROS was partly consumed at the burning site by the natural compounds when the cigarette was 'smoked' and thus reduced the harm to DNA; (2) partial natural compounds, which were not so near to the burning site and thus had not been destroyed at a high temperature, volatilized together with the smoke into the trap solution and protected the DNA from the destruction.

4. Conclusions

In conclusion, we have developed a novel strategy for in situ monitoring of cigarette smoke-induced DNA oxidation damage and offer a method for screening natural compounds that protect DNA against tobacco smoke. The present protocol couples a fast and simple magnetic separation/mixing method with a highly sensitive CL ELISA, and thus oxidative DNA is conveniently maintained in situ by magnetic force and sensitively monitored. Moreover, a gas–liquid reactor and an automatic smoker are combined to ensure that transient ROS was simultaneously and effectively captured by the DNA on the MB surface, i.e. DNA was online oxidized as the smoking cigarette is 'puffed'. In addition, the potential to screen a mixture in a complex sample matrix, such as crude extracts, was also demonstrated and provides a key advantage of the present method as compared to other screening methods. Our results indicate that three natural compounds, quercetin, sodium danshensu and baicalein, can greatly protect DNA from oxidative damage caused by cigarette smoke and further successfully evaluated in the spiked cigarettes and thus these natural products may be promising compounds for the development of new drugs and the preparation of low-harm cigarettes. The search for more effective products for the protection of DNA against oxidative damage induced by other oxidants is underway in our group.

LA–ICP-MS
On-line isotope dilution

ABSTRACT

A method has been developed based on an on-line isotope dilution technique couple with laser ablation/inductively coupled plasma mass spectrometry (LA–ICP-MS), for the determination of boron in p-type silicon wafers. The laser-ablated sample aerosol was mixed on-line with an enriched boron aerosol supplied continuously using a conventional nebulization system. Upon mixing the two aerosol streams, the isotope ratio of boron changed rapidly and was then recorded by the ICP-MS system for subsequent quantification based on the isotope dilution principle. As an on-line solid analysis method, this system accurately quantifies boron concentrations in silicon wafers without the need for an internal or external solid reference standard material. Using this on-line isotope dilution technique, the limit of detection for boron in silicon wafers is 2.8×10^{15} atoms cm^{-3}. The analytical results obtained using this on-line methodology agree well with those obtained using wet chemical digestion methods for the analysis of p-type silicon wafers containing boron concentrations ranging from 1.0×10^{16} to 9.6×10^{18} atoms cm^{-3}.

1. Introduction

In general, direct analyses of solid samples are preferable to conventional wet analytical methods because of their chemical-, labor-, and time-saving features. As non-destructive methods, although X-ray fluorescence (XRF) and neutron activation analysis (NAA) have been used with varying degrees of success for direct solid elemental analyses, but the poor sensitivity for light elements provided by XRF and the inconvenience of handling radioactive materials and the dependence on large irradiation facilities required for NAA make them unsuitable for routine determinations. Several destructive systems—with prior excitation followed by instrumental determination—have been developed as more practical approaches for direct solid sample analyses. Among them, spark source optical emission spectrometry (spark source-OES), spark source mass spectrometry (SSMS), glow discharge mass spectrometry (GD-OES), glow discharge mass spectrometry (GD-MS), laser microprobe mass spectrometry (LAMMA), and secondary ion mass spectrometry (SIMS) are widely known techniques employing single excitation sources. Because both sampling and excitation processes are generally performed simultaneously, single-excitation-source instruments sometimes provide poor analytical sensitivity and poor spatio-temporal resolving power [1,2]. To decouple the sampling and excitation processes, instruments featuring dual excitation sources have been developed to improve the analytical performance. Thus, sparks [3–12], arcs [13,14] and laser beams [15–19] have all been applied to generate aerosols that are then transported to an inductively coupled plasma mass/optical spectrometer (ICP-MS/OES) using a stream of inert gas. Among such instruments, LA–ICP-MS is the most commonly used analytical technique that has received the most attention in recent years.

Although the potential of LA–ICP-MS has been recognized in various scientific fields, this technique also suffers from severe matrix effects—as do all solid mass spectrometric techniques—as a result of the varying ablation yields associated with differences in the material properties between the solid standards and the samples. To overcome the matrix and calibration problems, various approaches have been used to develop effective calibration methods for quantification. For conventional quantification techniques, a matrix-matched standard is typically required to calibrate the laser ablation processes and the ICP response. Because of the limited availability of standards, matrix-matched synthetic laboratory standards are always needed to produce calibration curves for quantification purposes [20,21]. As noted by Becker et al. [22], however, the preparation of synthetic laboratory standards is often the most time-consuming step in solid state mass spectrometry, it is

doi:10.1016/j.talanta.2009.09.013

not feasible for all types of samples, and it can lead to homogeneity problems.

To overcome the difficulties resulting from conventional quantification techniques, on-line solution-based calibration methods have been developed as simple, rapid quantification procedures for LA–ICP-MS analyses. Indeed, Günther and coworkers [23–25] and Chenery and coworkers [26,27] developed dual-gas introduction systems to perform the solid/liquid calibration. They suggested that the concentration of at least one element in the sample should be determined by another independent analytical technique to obtain the relative sensitivity factor (RSF), which is defined as the certified concentration of the internal standard element in the standard divided by the measured concentration of the internal standard element in the sample [28,29]. Simultaneous solution nebulization and laser ablation sample introduction have also been developed as techniques to overcome mass discrimination effects in LA–ICP-MS, due to the occurrence of space charge effects, which are major sources of uncertainty when measuring isotope ratios [30]. However, according to Horn et al. [31], the balance between the gas flows of the liquid nebulizer and laser ablation systems can cause inferior transport efficiencies in both introduction systems. To overcome this problem, a single gas sample introduction system has also been developed to optimize the gas flow rates for both sample introduction systems [29].

To compensate for the matrix effects observed in LA–ICP-MS, standard addition methods [22,32] have also been developed for the determination of trace elements in various sample matrices, where neither matrix-matched standard reference materials nor high-purity blank targets were available. This calibration strategy consists of on-line mixing the dried aerosol containing known amounts of the analyte(s) from the nebulizing system to the ablated aerosol from the LA cell. Becker [32] found that, when using the standard addition method, the advantages of solid/liquid calibration are introduced without sacrificing the rapid, sensitive, and spatially specific characteristics of the LA–ICP-MS measurement. In view of the transient nature of the LA–ICP-MS signal, however, it is almost impossible to correct the signal drift—resulting from instrument instability and fluctuations in the laser firing and transport processes—when using the standard addition mode. In addition, the restricted amount of sample available for the number of measurements required is another limiting factor affecting the use of the standard addition method for quantification. To overcome these problems, an effective solution-based quantitative strategy—on-line isotope dilution analysis (IDA) in LA–ICP-MS (on-line LA–ID-ICP-MS)—has been used for the successful determination of trace elements in environmental and minute solid samples [33–35].

Isotope dilution mass spectrometry (IDMS) is one of the few methods capable of achieving analytical results that are not affected by signal drifts, matrix effects, or analyte losses. Therefore, according to Fernández et al. [34], the incorporation of isotope dilution into LA–ICP-MS can eliminate some common fractionation and matrix effects that cannot be addressed using other calibration procedures. Although isotope dilution techniques have been applied widely as calibration methods for various solid state mass spectrometers (e.g., SIMS [36], SSMS [37], and LA–ICP-MS [38–40]), the isotope-diluted powders still must be prepared using time-consuming and laborious procedures in which they are mixed with an internal standard solution or enriched isotope standard, dried, homogenized in a ball-mixer/mill, and pressed into the form of a pellet. As a result, the merits of the LA–ICP-MS and IDMS approach might be deteriorated because of the need for the pelletization procedure and the uncertainty of the total isotopic exchange between the sample and the spiking isotope during the mixing step. To eliminate the inconvenience of preparing the pellet sample, Becker et al. [33,35] developed a new analysis procedure to determine trace elements in solid samples: on-line isotope dilution in LA–ICP-MS equipped with a single gas sample introduction system.

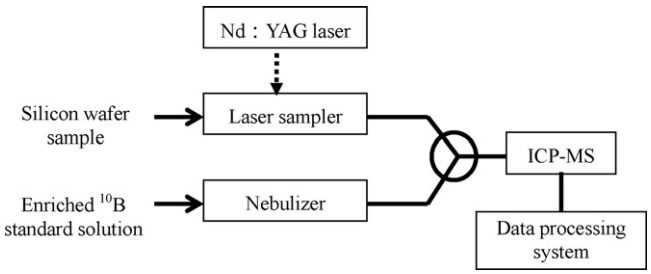

Fig. 1. Experimental setup for on-line isotope dilution LA–ICP-MS.

In view of the high demand for the determination of trace impurities, particularly in high-purity solid materials for the microelectronics industry, in this study we developed an on-line LA–ID-ICP-MS method for the determination of boron in silicon wafers. Although internal standards are usually used in solid state mass spectrometry, Ramendik [41] noted that the relative systematic errors can be as high as 30–50% which is unsatisfactory for routine analysis, when we ignore the dependence of the RSF on the sample matrix and the experimental conditions. Pisonero et al. [42] observed a range of 15–30% for the differences between the concentrations of boron obtained using a wet chemical method and LA–ICP-MS, individually, when they used NIST SRM 610 (silicate sample) and Si as the external calibration material and internal standard element, respectively, for quantitative analysis of metallurgical-grade Si. Because on-line solution-based isotope dilution in laser ablation ICP-MS is a simple, accurate, and precise quantification procedure, our aim in this study was to establish a new calibration method—combining IDA and LA–ICP-MS without the use of solid standard reference materials or internal standard element—and to verify the extent to which this technique could be applied to the accurate and precise determination of boron in high-purity silicon wafers.

2. Experimental

2.1. Instrumentation

A PerkinElmer Sciex laser sampler model 320 was used for ablation of the silicon wafer samples. The laser system, which contained a neodymium-doped yttrium aluminum garnet (Nd–YAG) laser with a fundamental wavelength of 1064 nm, could be operated under either a Q-switched or free-running mode and either a single-shot mode or at a repetition rates of up to 10 Hz. The wafer was secured by a sample holder in a quartz cell mounted on a programmable *xyz*-translation stage operated via computer control. A Teflon disk was inserted between the wafer and the sample holder to adjust the defocus distance from the laser; the desired area of the silicon wafer sample was then subjected to the laser shot. During laser ablation, the sample surface was monitored using a CCD camera and displayed on a TV screen.

After laser ablation, the sample was transported through Tygon plastic tubing (I.D.: 10 mm; length: 1.0 m) to be on-line mixed with the sample aerosol from a cross-flow nebulizer equipped with a Scott-type spray chamber (PerkinElmer Sciex). Subsequently, the mixed sample aerosol was introduced into the ICP-MS system (PerkinElmer Sciex Elan 5000, Thornhill, Ontario, Canada) for detection of the signal intensity of the boron isotopes. Fig. 1 provides a schematic representation of the LA–ICP-MS and solution nebulization system. Table 1 summarizes the instrumental parameters and operating conditions of the laser ablation and solution nebulization system coupled to ICP-MS.

Table 1
Instrumentation and parameters.

Laser ablation system	
Model	PE Sciex Laser Sampler 320
Type	Solid state Nd:YAG
Wavelength	1064 nm
Operating mode	Q-switched
Ablation time	30 s
Laser beam energy	330 mJ
Pulse width	10 ns
Q-switched delay	240 μs
Focusing position	On sample surface
Spot diameter	40 μm
ICP-MS	
Model	PE Sciex Elan 5000
RF power	1250 W
Plasma gas flow rate	15 L min^{-1}
Auxiliary gas flow rate	0.8 L min^{-1}
Acquisition mode	Peak hopping
Sampler cone	Platinum
Skimmer cone	Platinum
Dwell time	10 ms
Sweeps/reading	20
Readings/replicate	150
Replicate	1
Points per peak	1
Mass resolution	Normal
Nebulizer	Cross-flow
Spray chamber	Scott-type

2.2. Materials and reagents

PTFE vessels and polyethylene containers were used throughout to avoid boron contamination. One side polished silicon (1 0 0) p-type wafers (diameter: 20 cm; thickness: 725 μm; Taisil Electronic Materials Corp., Taiwan) were sliced into 2 cm × 2 cm pieces prior to use. All reagents, of analytical or higher grade, were obtained from E. Merck. Nitric acid (Tracepure grade) was further treated in-house by sub-boiling. High-purity water that had been deionized using a Milli-Q system (Millipore, Bedford, MA, USA) was subsequently purified through sub-boiling distillation and passage through a boron-selective anion-exchange resin (Amberlite IRA-742, Rohm and Haas, France) to remove trace amounts of boron. The boron isotope standard SRM 951 (^{10}B/^{11}B ratio = 0.2473; ^{10}B = 19.827%; ^{11}B = 80.173%) and the enriched isotope ^{10}B standard SRM 952 (^{10}B/^{11}B ratio = 18.798; ^{10}B = 94.949%; ^{11}B = 5.051%) were purchased from the National Institute of Standards and Technology (NIST, USA).

2.3. Experimental procedure

Upon connecting the laser ablation system and the nebulization system through a Y-shaped connector, the enriched boron standard was introduced continuously into the ICP-MS system to measure the enriched boron isotopic signal. The spot position and focusing position of the laser ablation system were aligned to provide the maximum and consistent signal with reasonable stability. Once a steady boron isotope signal from the nebulization system was established, the laser was switched on. After a suitable sampling time, the laser ablation system was switched off. This process yielded a signal profile with respect to the elapsed time. For example, in Fig. 2(a) the incipient region represents the continuous signal of the enriched boron standard solution obtained from the nebulization system; the plateau represents the steady-state signal arising from the mixing of the sample aerosol from the nebulization and laser ablation systems. The transient intensities of the boron isotopes measured by the ICP-MS system were further transformed into time-dependent ratios [$R(t) = {}^{10}B/{}^{11}B$; Fig. 2(b)] and corresponding boron mass flow profiles [Fig. 2(c)]. Table 2 sum-

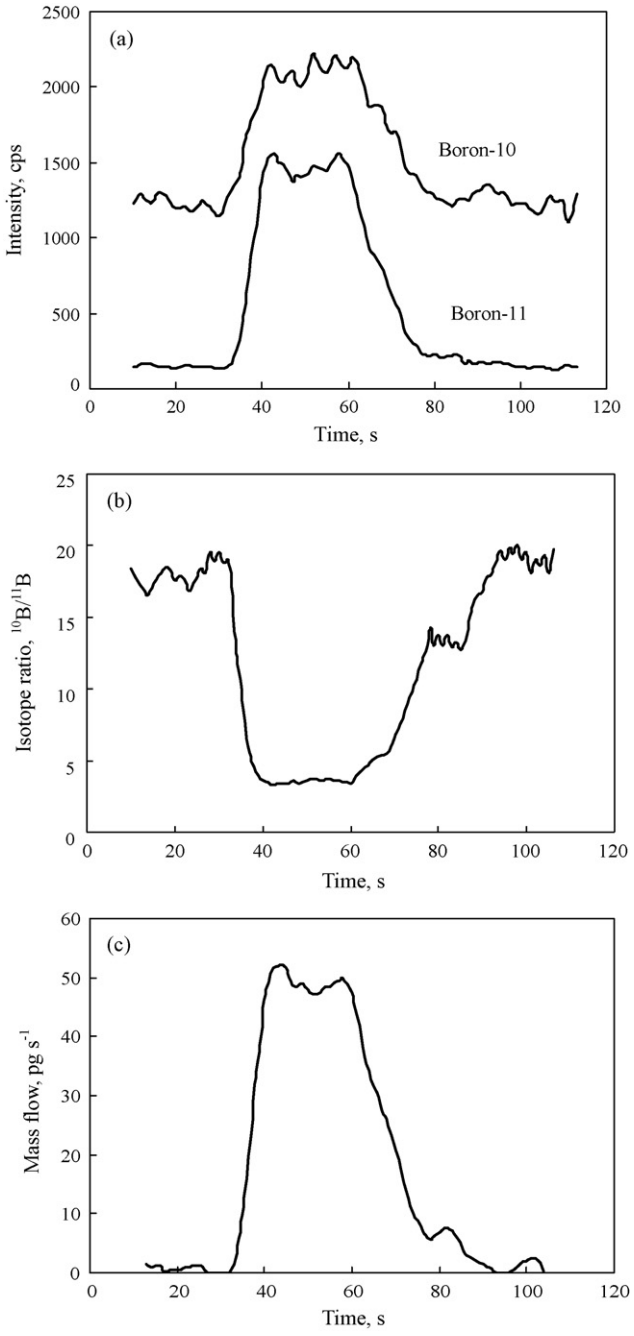

Fig. 2. (a) Plot of the boron isotopic signal profile with respect to time. (b) Plot of the time-dependent isotope ratio ^{10}B/^{11}B. (c) Corresponding mass flow profile of boron.

Table 2
Typical operating conditions for on-line isotope dilution analysis.

Spike standard (NIST SRM 952)	^{10}B/^{11}B = 18.80
^{10}B abundance	94.949%
^{11}B abundance	5.051%
Measured enriched ^{10}B/^{11}B ratio	12.09
Mass discrimination factor	1.56
Carrier gas flow rate (laser sampler)	0.5 L min^{-1}
Weight of sample ablated in a laser firing	0.032 mg
Nebulizer gas flow rate	0.5 L min^{-1}
Enriched spike concentration	24.7, 397 ng g^{-1}
Enriched spike delivery rate	0.026, 0.41 mg s^{-1}

marizes the typical operating conditions for the isotope dilution analyses.

3. Result and discussion

3.1. Calibration and data processing of on-line dilution analysis

The principle of IDMS involves altering the natural ratio between two isotopes in a sample, by adding an accurately known quantity of an isotope spike, and then measuring the isotope ratio in the mixture. The concentration (C) of the analyte in the sample can be deduced using the equation

$$C = \frac{W_{sp} \times K}{W_s} \times \left(\frac{h_{sp}^2 - R \times h_{sp}^1}{R \times h_s^1 - h_s^2} \right) \quad (1)$$

where W_{sp} is the mass of the spike; K is the ratio of the natural atomic weight and the atomic weight of the enriched material; W_s is the mass of the sample; h_s^1 and h_s^2 are the isotope abundances of isotopes 1 and 2 in the sample, respectively; and h_{sp}^1 and h_{sp}^2 are the isotope abundances of isotopes 1 and 2 in the spike, respectively.

Fig. 1 displays a schematic representation of the on-line-LA–ICP-IDMS system. In essence, the data manipulation was performed according to the procedure described previously by Rottmann and Heumann [43]. Fig. 2(a) presents the transient signals of the boron isotopes measured by the ICP-MS system, plotted as the ^{10}B and ^{11}B signal profiles over time. After correcting the background levels of the measured boron isotopes, each data point of the time-dependent isotope ratio [$R(t)$] was calculated based on the net signal intensities of the measured isotopes; Fig. 2(b) displays the results for boron in a silicon wafer with respect to the measured isotope ratio ^{10}B:^{11}B. When no boron was ablated from the wafer, we measured the ^{10}B:^{11}B ratio of the spike solution (ca. 18.8). An aerosol containing boron from the sample shifted the isotope ratio in the direction of the natural isotopic composition, as is evident in the significant negative band obtained during the laser ablation process. Subsequently, we converted the isotope ratio curve in Fig. 2(b) into a mass flow diagram [$M_s(t)$] of boron by using the equation [44]

$$M_s(t) = M_{sp} \times \left(\frac{h_{sp}^{10} - R(t) \times h_{sp}^{11}}{R(t) \times h_s^{11} - h_s^{10}} \right) \quad (2)$$

where M_{sp} is the mass flow of the enriched boron spiked into the system and $h_s^{isotope}$ and $h_{sp}^{isotope}$ are the abundances of the respective boron isotopes in the sample and in the spike. Because M_{sp} is determined by the nebulization (transport) efficiency of the boron-enriched standard solution, at a given nebulizer gas flow rate, it can be obtained from the difference between the mass of the standard solution consumed and the mass of the drain solution of the nebulization system during the measurement process.

Although we could readily obtain the absolute boron mass from the area under the band in the mass flow diagram, obtaining the concentration of boron in the silicon wafer required us to determine the weight of the sample ablated in each laser firing at a constant laser power. We determined the weight of the sample ablated by using a fixed volume of an HF/HNO_3 mixture as an absorbing solution to grab and dissolve the ablated aerosol after the laser firing. Because the silicon wafer used in this study comprised over 99.9% pure silicon, we calculated the weight of the sample ablated simply from the silicon concentration in the absorbing solution. In this study, the average weight of sample ablated, obtained from 25 measurements, was 0.032 mg; the relative standard deviation of all of the individual determinations was less than 14%.

3.2. Optimization of dual sample introduction system

To ensure the best conditions for the LA–ICP-IDMS-based determination of boron in the silicon wafers, we evaluated several parameters that could influence the performance of the dual sample introduction system with a sliced p-type silicon wafer. In general, silicon wafers feature both polished and rough sides. To avoid reflection loss of the laser beam energy, in this study we chose the rough side to be the test side. Günther et al. [44] found that improved sensitivity and lower background levels could be achieved by optimizing the gas flows, mixing behavior, and tuning parameters for a system involving simultaneous introduction of a solution aerosol and a laser-induced aerosol. They also reported that the total flow rate for the transport of laser-ablated material into the ICP system was inappropriately high when they optimized each individual system (laser ablation and liquid nebulization) separately. Accordingly, to maintain the stability and excitation capability of the plasma, improve the transport efficiency, and minimize excessive dilution of the ablated material, we investigated the optimal gas flow rates for the laser ablation and solution nebulization systems under a total flow rate of 1.0 L min^{-1}, which provided the most favorable conditions for good detection sensitivity for the determination of boron.

To characterize our dual introduction system, we optimized each individual system separately. Fig. S1 displays the effect of two different gas flow rates (total flow rate: 1.0 L min^{-1}) on the signal intensity of boron obtained when using the dual sample introduction system. The signal intensities in Fig. S1 were obtained by introducing Ar gas at a flow rate of X L min^{-1} through the nebulization system and $(1.0 - X)$ L min^{-1} through the laser ablation system. The signal intensities increased upon increasing the nebulizer gas flow rate from 0.2 to 0.5 L min^{-1}, with an abrupt increase in the signal intensity occurring when the gas flow rate ratio increased from 0.6/0.4 to 0.5/0.5 (laser sampler/nebulizer). Curve "b" presents the variation in the signal intensities obtained when introducing X L min^{-1} of the blank solution aerosol from the nebulization system and $(1.0 - X)$ L min^{-1} of the ablated sample aerosols from the laser ablation system. The signal intensities increased upon decreasing the gas flow rate of the laser sampler system from 0.8 to 0.6 L min^{-1}, reaching a maximum when the gas flow rate ratio was 0.6/0.4 (laser sampler/nebulizer). A compromise gas flow rate ratio of 0.5/0.5 for the laser ablation and solution nebulization systems was chosen to be optimal for all subsequent experiments. Table 2 summarizes the optimized parameters for the on-line isotope dilution analysis process.

3.3. Optimization of on-line isotope dilution analysis

Mass discrimination relies on discrepancies between the natural isotope ratio and the measured isotope ratio. According to Diemer et al. [45], the repeatability of the correction for mass discrimination is one of the dominating sources of instrumental uncertainty during ICP-IDMS measurement. Because of the intrinsic mass difference of 10% between ^{10}B and ^{11}B, measurement of the boron isotope ratio might suffer from a severe mass discrimination effect [46]. To correct this mass discrimination effect, we measured the isotope ratio of the boron standard solution (NIST SRM 952) and obtained a mass discrimination factor by dividing the certified isotope ratio by the measured isotope ratio. The isotope ratio measured in the sample analysis could then be corrected by multiplying by the mass discrimination factor [47]. Based on the results presented in Fig. 2(b), we obtained a mass discrimination factor of 1.56 and, in turn, used the corrected isotope ratio and Eq. (2) to calculate the mass flow of boron.

To minimize the error resulting from the uncertainty of the concentration of the ^{10}B-enriched spiked boron solution, in this study

Table 3
Boron concentrations in Si wafers.

Method	Concentration, 1×10^{16} atoms cm^{-3}		
	Wafer 1	Wafer 2	Wafer 3
LA–ICP-MS (this study)[a]	1.25 ± 0.29	669 ± 58	1360 ± 110
Wet chemical[b] [49]	1.32 ± 0.057	693 ± 3.6	1470 ± 51
Four-point probe [50]	0.931	433	953

[a] $n = 3$; seven sites per sample.
[b] $n = 3$.

we also determined the concentration of boron in the enriched spike solution and the resulting boron isotopic ratio of the spiked sample. The concentration of enriched spike solution was determined using the reversed-ID technique and a certified standard (NIST SRM 951). Because the optimal performance of the ID technique is achieved by controlling the resulting isotope ratio of the analyte within a range from 0.1 to 10 after mixing with the enriched spike solution [48], we estimated the approximate concentration of boron in a silicon wafer based on the relationship between the resistivity and boron dopant concentration provided by Taisil Electronic Materials Corp. After determining the approximate concentration of the analyte, two appropriate amounts of the enriched spike solutions (24.7 and 397 ng g^{-1}) was intentionally added to maintain the isotopic ratio within the favorable range from 0.1 to 10 during the on-line isotope dilution analysis. As indicated in Table 2, we set the calculated enriched spike delivery rates to 0.026 and 0.41 mg s^{-1} for the determination of boron in silicon wafer.

3.4. Analytical features and applicability

To demonstrate the applicability of this on-line system, we determined the concentrations of boron in several silicon wafers. Because no certified values for the analyte's contents in the silicon wafers were available, we validated the accuracy of our on-line methodology through inter-method comparative analysis with wet chemical digestion and electrical four-point probe measurements. Table 3 reveals that the results obtained using our on-line method to analyze three different silicon wafers agreed well with the values obtained using the wet chemical method (the difference being less than 10%), but were significantly different (25–35%) from those obtained using the four-point probe method, presumably because only the levels of electroactive boron in the silicon crystal can be determined through electrical measurement. In contrast, both the electroactive and -inactive fractions of boron in the silicon wafers were measured using both our newly developed method and the wet chemical method.

We estimated the detection limit of our developed analytical method from seven individual measurements after on-line introducing enriched boron standard solution into the system. Each enriched boron isotope ratio was calculated using the same procedure described above. The limit of detection of this method, based on three times the standard deviation (3σ) of the calculated results, was 2.8×10^{15} atoms cm^{-2}. We also tested the precision of this method through the analyses of three replicate silicon wafer samples; the average coefficient of variation was ca. 8% for higher-concentration samples. Overall, the high performance of our proposed analytical method—evaluated in terms of the detection limit, accuracy, and precision—indicates that on-line-LA–ICP-IDMS hyphenated systems are suitable for use for the determination of trace boron in silicon wafers.

4. Conclusion

Similar to SIMS, LA–ICP-MS exhibits excellent multi-elemental and isotopic performance in bulk analysis, microanalysis, and depth profile analysis, but accurate determination of trace elements in solid samples, such as silicon wafer, remains a difficult task for either technique. To overcome the difficulties encountered in the quantitative determination of trace boron in silicon wafers, we combined on-line IDMS with LA–ICP-MS to establish an on-line-LA–ICP-IDMS system incorporating a reliable solid/liquid calibration method. A distinct feature of this on-line-LA–ICP-MS technique is that neither an internal standard nor a matrix-matched standard is required for the quantitative analysis of silicon wafers. In future studies, we will focus on the applicability of this on-line LA–ICP-IDMS quantification concept to the determination of trace analytes in various other matrices for which the on-line sample weight measurement apparatus is available.

ABSTRACT

In this paper, the interaction of DNA molecules with aqueous CdTe quantum dots (CdTe QDs), CdTe/SiO_2 composite nanoparticles (CdTe/SiO_2 NPs), and Mn-doped ZnSe quantum dots (Mn:ZnSe d-dots) was studied with ethidium bromide as a probe. The purpose of this work was to study the damage of DNA molecules induced by these three kinds of water-soluble nanoparticles. It was found that ionic strength, pH value and UV irradiation influenced the PL emission properties of CdTe QDs, CdTe/SiO_2 NPs and Mn:ZnSe d-dots, and also influenced the interaction of DNA molecules with them. Among the three kinds of nanoparticles, DNA molecules were most easily damaged by CdTe QDs whether in the dark or under UV irradiation. The CdTe/SiO_2 NPs led to much less DNA damage when compared with CdTe QDs, as a silica overcoating layer could isolate the QDs from the external environment. Mn:ZnSe d-dots as a new class of non-cadmium doped QDs demonstrated almost no damage for DNA molecules, which have great potentials as fluorescent labels in the applications of biomedical assays, imaging of cells and tissues, even in vivo investigations.

1. Introduction

Semiconductor nanocrystals, also named quantum dots (QDs), have attracted a lot of attentions in the past few decades due to their unique optical properties and applications, which endow them as ideal optical probes used in biomedicine and biotechnology [1,2]. Their photoluminescence (PL) can be tuned by simply controlling particle size and the varied PL emitted from QDs with different size can be simultaneously excited with a single excitation light source. Simultaneously, QDs possess high surface-to-volume ratios and their sizes can be well controlled during the synthesis process, making them good candidates for interfacing with biological systems. Furthermore, fluorescence of QDs is intrinsic, bright, and prolonged, endowing QDs with "*in situ*" imaging functionality which surpasses the sensitivity and resolution capability of organic dyes and proteins.

QDs can be synthesized by two kinds of chemical methods, which are organometallic synthesis and aqueous synthesis, respectively. Contrast to organometallic method, aqueous synthesis is more reproducible, cheaper and less toxic, and the prepared QDs have high stability and biological compatibility, which are more suitable for biomedical applications. Although the popularity of QD labeling soars, whether QDs synthesized by aqueous synthesis or organometallic synthesis, they are still facing an unsolved problem, which is the toxicity of these cadmium-containing nanoparticles induced by heavy metal ions used in the process of synthesis released upon oxidative and/or photolytic degradation [3].

In 2006, Hardman reviewed the toxicity of QDs depending on physicochemical and environmental factors [4]. It is suggested that QD size, charge, concentration, outer coating bioactivity (capping material, functional groups), and oxidative, photolytic, and mechanical stability have each been shown to be determining factors in QDs toxicity. Several researches about cytotoxicity of QDs have been published [5–13]. Besides cytotoxicity of QDs, QDs can also damage DNA molecules. Green and Howman [14] reported the observation of DNA damage in plasmid nicking assays with water-soluble CdSe/ZnS QDs. They attributed the effect of QDs to free radicals both photogenerated and surface oxide generated, which suggested that there may be serious issues to address concerning the use of such materials in DNA based assays or in in vivo applications, as well as highlighting potential toxicological and environmental implications. Han and co-workers [15] investigated the calf thymus DNA (ctDNA) damaged induced by water-soluble CdSe QDs using nucleic acid molecular "light switches" as probes. It was found that the ctDNA damage caused by CdSe QDs was not due to photo-induced liberation of Cd^{2+}, but due to the production of free radicals and reactive oxygen species. More recently, Biju and co-workers [16] investigated the strand breakages and nucleobase damages in plasmid DNA by CdSe-ZnS QDs under different conditions of photoactivation. The results confirmed that the production of reactive oxygen intermediates by QDs induced the breakage and damage of DNA molecules, which

doi:10.1016/j.talanta.2009.09.014

showed possibilities of QDs in nucleus-targeted photodynamic therapy.

The effects of QDs on biomolecules have been an important issue to obstruct the development of QD biomedical applications. Depositing a silica layer with the capability of impeding surface ruin of QDs and inhibiting the release of heavy metal ions is an effective way to solve the problem. In addition, a new class of potential non-cadmium fluorescence emitters – transition metal ion-doped quantum dots (d-dots) – can also overcome the toxicity of QDs induced by heavy metal ions [17,18].

In this paper, we explored another fluorescent method for systematically investigated the DNA damage induced by a series of water-soluble nanoparticles, including CdTe QDs, CdTe/SiO_2 composite nanoparticles (CdTe/SiO_2 NPs), and Mn-doped ZnSe QDs (Mn:ZnSe d-dots). Ethidium bromide (EB) is a fluorescent compound, which is normally used to probe DNA structure in drug–DNA and protein–DNA interactions by its intercalating in the DNA double helix to enhance its fluorescence [19]. Once the double helix structure of DNA molecules is destroyed, the fluorescence of EB will be quenched. The previous reports [14,16] had demonstrated that the double helix structure of DNA molecules were damaged by QDs via gel electrophoreses analyses method. In this paper, we applied the fluorescent method and chose EB as the probe to study the damage of DNA molecules, which is very simple, and rapid. The experimental results showed that Mn:ZnSe d-dots led to the least damage of DNA molecules among the three kinds of nanoparticles mentioned above, which can be used as biocompatible fluorescence labels in in vitro and in vivo biomedical applications.

2. Experimental

2.1. Materials

All chemicals used are of analytical reagent grade without further purification. Mercaptosuccinic acid (MSA) (99%), and poly(dimethyldiallyl ammonium chloride) (PDDA, Mw = 70,000 g/mol) were purchased from J&K Chemical Co. Tellurium powder (~200 mesh, 99.8%), $CdCl_2{\cdot}2.5H_2O$ (99%), $NaBH_4$ (99%), mercaptopropionic acid (MPA) (99%), ethidium bromide (EB) (>95%), Herring Sperm DNA (DNA), cyclohexane, Triton X-100, n-hexanol, tetraethoxysilane (TEOS), 3-aminopropyltrimethoxysilane (APS), 3-(trihydroxysilyl)-propylmethylphosphonate (THPMP), selenium powder (~200 mesh, 99.9%), $Zn(NO_3)_2{\cdot}6H_2O$ (99.9%), $MnCl_2{\cdot}4H_2O$ (99.9%) were purchased from Sigma–Aldrich Chemical Co. The water used in all experiments has a resistivity higher than 18 MΩ/cm.

2.2. Instrument

Fluorescence measurements were performed on a ShimadzuRF-5301 PC spectro fluorophotometer. The photobleaching experiments were also performed on the spectrofluorometer. In both experiments, a 1 cm path-length quartz cuvette was used. The transmission electron microscope (TEM) images of nanoparticles were obtained with JEOL-2010 electron microscope operating at 200 kV and JEOL-3010 electron microscope operating at 300 kV. For TEM, the samples were prepared by dropping the aqueous nanoparticles solution onto carbon-coated copper grids with the excess solvent evaporated.

2.3. Preparation of CdTe QDs, CdTe/SiO_2 NPs, and Mn:ZnSe d-dots

The aqueous phase synthesis of CdTe QDs was based on our previous report [20]. Briefly, the precursor solution of CdTe QDs was formed in water by adding fresh NaHTe solution to 10 mM N_2-saturated $CdCl_2$ solution at pH 11.2 in the presence of MSA as the stabilizing agent. The molar ratio of Cd^{2+}/MSA/HTe^- was set at 1:1.5:0.2. The CdTe precursor solution was subjected to reflux at 100 °C under open-air conditions with condenser attached. CdTe QDs with PL emission wavelength at 547 nm were obtained. The synthesis of CdTe QDs with MSA as stabilizer was less time consuming and the obtained QDs had high quantum yield. According to the calculation method in Ref. [20], the concentration of CdTe QDs is 2.0×10^{-6} mol/L.

CdTe/SiO_2 NPs were synthesized by reverse microemulsion method based on our previous report [21]. Briefly, we mixed 7.5 mL cyclohexane, 1.77 mL Triton X-100, 1.8 mL n-hexanol, 400 μL aqueous solution of as-prepared CdTe QDs, 40 μL PDDA solution (0.075%, v/v) and 60 μL NH_4OH to form microemulsion. Then adding 100 μL TEOS to the microemulsion system to initiate the hydrolysis, the reaction progressed in the dark for 24 h of stirring. Then adding 50 μL TEOS to the reaction system, after stirring for 30 min, 10 μL APS and 40 μL THPMP were injected into the reaction system. The reaction system was then kept under stirring for one more day. The microemulsion was broken by adding 20 mL of acetone to the reaction system and the resultant precipitate was amine-funcationalized CdTe/SiO_2 composite nanoparticles which were washed in sequence with iso-propyl alcohol, ethanol and water. Ultimately, CdTe/SiO_2 composite nanoparticles were dispersed in 1 mL water, obtaining 1 mL CdTe/SiO_2 NPs aqueous solution.

In this research, Mn:ZnSe d-dots were prepared in aqueous solution by nucleation doping method based on our recent report [22]. Generally, we prepared Mn:ZnSe d-dots by nucleation doping method and the synthesis procedure of Mn:ZnSe d-dots is operated as follows: in a typical experiment, 0.2 mL $MnCl_2$ solution (1.25×10^{-2} M) and 90 mL H_2O were loaded into a 250 mL three neck flask and degassed for 30 min by bubbling with nitrogen. Fresh NaHSe solution was added to N_2-saturated $MnCl_2$ solution at pH 11.2 in the presence of MPA as stabilizing agent. The reaction was then switched from nitrogen bubbling to nitrogen flow and subjected to a reflux at 100 °C for 40 min. 10 mL of the stock solution of $Zn(NO_3)_2$ (1.25×10^{-2} M) was injected and the reaction was refluxed for 5 h. The precursor concentration of Zn^{2+} is 1.25 mM, and precursor ratios of Mn-to-Se-to-Zn and Zn-to-MPA are 1:35:50 and 1:33, respectively. The freshly produced CdTe QDs and Mn:ZnSe d-dots were dialyzed with pH 11.2 PBS buffer solution (2 mM) just before the experiments to avoid the influence of residual reagents in solution.

2.4. Damage assays of DNA molecules

DNA and EB aqueous solution were prepared using pH 7.4 PBS buffer solution (2 mM), and the concentrations were 2.8×10^{-4} M and 5.39×10^{-5} M, respectively. With the aim of keeping the initial concentration of QDs consistent for each experiment, 20 μL CdTe QDs, 50 μL CdTe/SiO_2 NPs, and 160 μL Mn:ZnSe d-dots were taken and diluted to 2 mL with water, and used as stock solution. For a typical DNA damage experiment, 400 μL DNA solution, 100 μL EB solution, and 100 μL nanoparticles were added to cuvettes and diluted to 3 mL with PBS buffer solution (2 mM) for 16 h incubation. For UV irradiation experiment, nanoparticles were irradiated firstly with 150 W xenon lamp for 60 min continuous intensive excitation at 280 nm and then added to the reaction system.

3. Results and discussion

3.1. Characteristics of CdTe QDs, CdTe/SiO_2 NPs and Mn:ZnSe d-dots

PL emission spectra of the three kinds of nanoparticles used in this study were shown in Fig. 1. From Fig. 1, it can be seen that PL emission wavelength of CdTe QDs is at 547 nm. The TEM

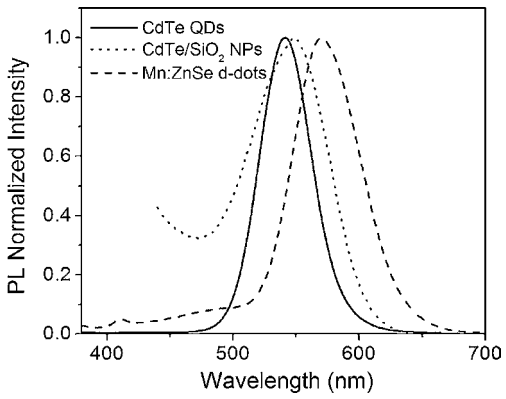

Fig. 1. The PL spectra of CdTe QDs, CdTe/SiO_2 NPs, and Mn:ZnSe d-dots.

image of CdTe QDs (Fig. 2A) shows the diameter of CdTe QDs is 2.5 nm. CdTe/SiO_2 NPs prepared by using above CdTe QDs have similar PL emission spectrum with maximum PL emission wavelength at 549 nm. The average diameter of CdTe/SiO_2 NPs was 40 nm determined by TEM image (Fig. 2B). The PL emission spectrum of Mn:ZnSe d-dots exhibited three distinct emission bands. These bands center at 410 nm, 480 nm, and 570 nm, which can be assigned to ZnSe band edge, trap state, and Mn^{2+} $^4T_1 \rightarrow {}^6A_1$ emission, respectively. Also from the TEM image (Fig. 2C), it can be seen that the diameter of Mn:ZnSe d-dots was 3.8 nm.

3.2. The PL emission properties of CdTe QDs, CdTe/SiO_2 NPs and Mn:ZnSe d-dots

PL emission properties of nanoparticles are related with the surface structure properties of nanoparticles. Once the surface structure of nanoparticles is destroyed, the PL emission intensity of nanoparticles will decrease greatly. So before evaluating the DNA damage induced by CdTe QDs, CdTe/SiO_2 NPs and Mn:ZnSe d-dots, it is necessary to study the factors that affect the PL emission properties of the three kinds of nanoparticles.

Fig. S1 shows the effect of ionic strength and pH value on PL emission properties of CdTe QDs, CdTe/SiO_2 NPs, and Mn:ZnSe d-dots. It can be seen that the effect of different ionic strength on the PL emission intensity of CdTe QDs, CdTe/SiO_2 NPs has the similar trend, but CdTe/SiO_2 NPs are more insusceptible than the naked CdTe QDs. When the concentration of NaCl was up to 50 mM, the PL emission intensity of CdTe/SiO_2 NPs was still preserved 90% and there was not any precipitation in the CdTe/SiO_2 NPs solution. In the same ionic strength solution, the PL emission intensity of CdTe QDs was preserved 80%, which was lower than that of CdTe/SiO_2 NPs. As to the Mn:ZnSe d-dots, the effect of ionic strength on PL emission of Mn^{2+} $^4T_1 \rightarrow {}^6A_1$ has a different trend compared with that of CdTe QDs, and CdTe/SiO_2 NPs. When the concentration of NaCl was 5 mM, the PL emission of Mn^{2+} $^4T_1 \rightarrow {}^6A_1$ reached the maximum, and the PL emission of Mn^{2+} $^4T_1 \rightarrow {}^6A_1$ was preserved above 80% whether Mn:ZnSe d-dots dispersed in lower or higher ionic strength solution. As compared with the effect of ionic strength, pH value can influence the PL emission properties of the three kinds of nanoparticles greatly. From the results shown in Fig. S1, it can be seen that the nanoparticles dispersed in higher pH buffer solution, exhibit higher PL emission intensity. When the pH value declined down to 4.24, the PL emission intensity of CdTe/SiO_2 NPs was 60% as compared with that in alkalescent solution (pH 11). However, in the same pH buffer solution, the PL emission intensity of CdTe QDs nearly decreased to zero and the flocculates began to appear. For Mn:ZnSe d-dots in pH 4.24 PBS buffer solution, the PL emission intensity of Mn^{2+} $^4T_1 \rightarrow {}^6A_1$ was about 40% compared with that in alkalescent solution (pH 11). In acidic solution (pH < 6), the surface structure of CdTe QDs is not as perfect as that in alkalescent solution, which is caused by incomplete ionization of stabilizers. CdTe/SiO_2 NPs have a layer of silica overcoating, which can protect the surface structure of CdTe QDs to weaken the effect of pH value. Mn:ZnSe d-dots investigated in this study were prepared by nucleation method which had the doped nuclei covered by the host shell. The ZnSe host shell can also impair the effect of pH value on the Mn^{2+} $4T_1 \rightarrow 6A_1$ emission.

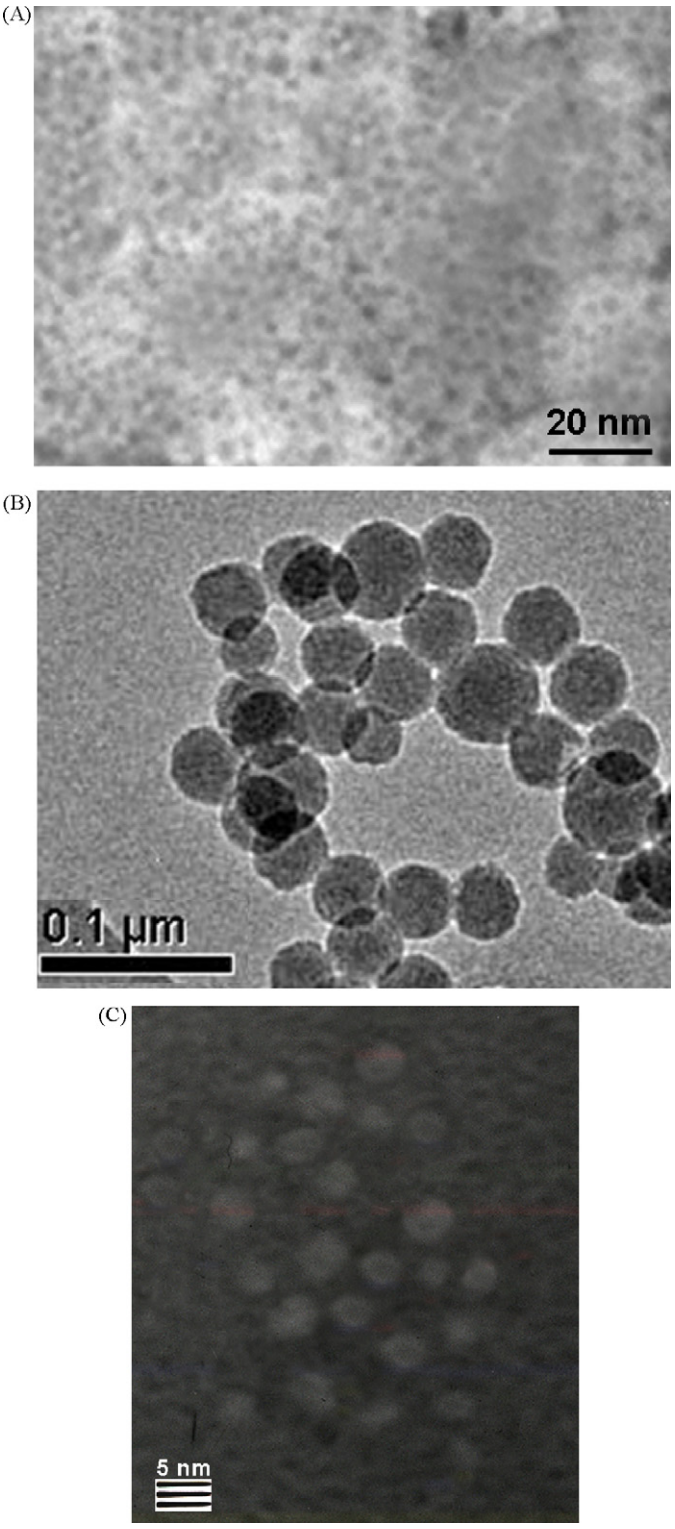

Fig. 2. The TEM images of CdTe QDs (A), CdTe/SiO_2 NPs (B), and Mn:ZnSe d-dots (C).

Besides the chemical stability, the photostability of nanoparticles is also a key issue for fluorescent labels. The photostability of CdTe QDs, CdTe/SiO_2 NPs and Mn:ZnSe d-dots was studied by using a 150 W xenon lamp for continuous intensive excitation at 280 nm and the results were shown in Fig. S2. With the UV irradiation, the PL emission intensity of CdTe QDs decreased gradually. After 60 min UV irradiation, the PL emission intensity of CdTe QDs was preserved only 20% compared with that of CdTe QDs before UV irradiation and some flocculates appeared in the aqueous solution, which implied that CdTe QDs began to aggregate and the surface structure of CdTe QDs had been destroyed. Different from CdTe QDs, CdTe/SiO_2 NPs have much better photostability. During 1 h UV irradiation, the PL emission intensity of CdTe/SiO_2 NPs retained constantly, which indicated that the silica network structure can well protect CdTe QDs embedded in silica nanoparticles. With regard to Mn:ZnSe d-dots, the PL emission intensity of Mn^{2+} $^4T_1 \rightarrow {}^6A_1$ were also kept constantly during the whole 1 h UV irradiation process, which is 90% as compared with Mn:ZnSe d-dots before UV irradiation. The extraordinary photostability of Mn:ZnSe d-dots is also due to the unique structure of d-dots. Mn:ZnSe d-dots prepared by nucleation doping method have a ZnSe host overcoating layer to protect the nuclei with the dopant Mn^{2+} ions, which avoids the photobleaching of Mn^{2+} $^4T_1 \rightarrow {}^6A_1$ emission induced by UV irradiation.

3.3. The interaction of DNA with CdTe QDs, CdTe/SiO_2 NPs and Mn:ZnSe d-dots

In this study, the assay system contains EB, DNA and nanoparticles. The fluorescence spectra of EB, EB incubated with CdTe QDs, EB incubated with DNA, and EB incubated with DNA and CdTe QDs for overnight were shown in Fig. 3. It can be seen that the fluorescence intensity of EB molecules was low and it was not influenced by CdTe QDs. The fluorescence intensity of EB was enhanced greatly in the presence of DNA, because the strong binding of EB to DNA results in the intercalation of the planar phenanthridinium ring between adjacent base pairs on the double helix [23]. However, the fluorescence intensity of EB and DNA system was weakened by adding CdTe QDs, which could be attributed to the interaction between DNA molecules and CdTe QDs-the strand breakages and nucleobase damages of DNA molecules inducing by QDs [14–16]. So the quenching of the fluorescence of EB is due to the damage of double helix structure of DNA molecules, which can be used to probe the damage of DNA molecules by nanoparticles. The optimal ratio of DNA interacting with EB in solution was determined by the fluorescence method. 100 μL EB (5.39×10^{-5} M) and different volumes of DNA (2.8×10^{-4} M) was mixed and diluted to 3 mL with PBS buffer solution (pH 7.4). The fluorescence signals of the mixed solution

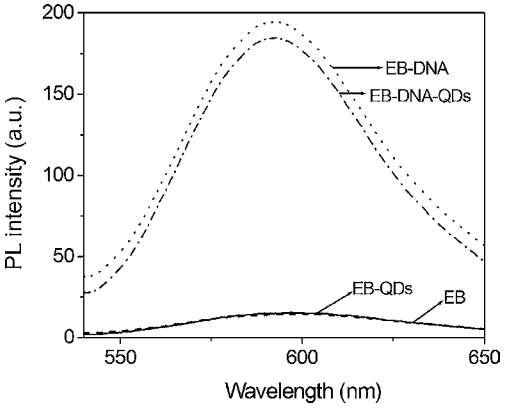

Fig. 3. The PL spectra of EB, EB-CdTe QDs, EB-DNA, EB-DNA incubated with CdTe QDs.

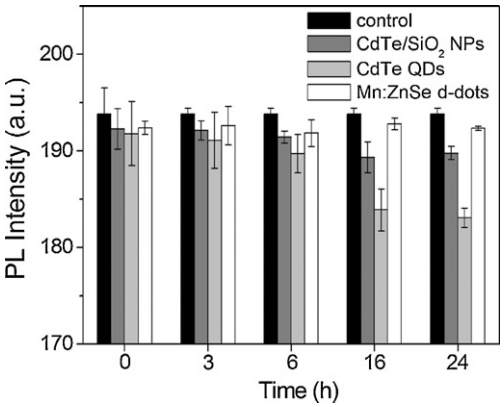

Fig. 4. The effect of incubate time on fluorescence quenching of EB-DNA induced by CdTe/SiO_2 NPs, CdTe QDs and Mn:ZnSe d-dots. The fluorescence intensity was the average value of three times.

increased with the increase of DNA volume (Fig. S3). When DNA volume increased to higher than 400 μL, the fluorescence intensity tended to be constant. Based on this result, the DNA volume was fixed at 400 μL in further experiments.

The emission wavelength of the three kinds of nanoparticles used in this study is at or shorter than 570 nm, which will not overlap with the fluorescence of EB in the presence of DNA molecules (EB-DNA). Furthermore, the PL emission of the three kinds of nanoparticles in experimental system is very weak due to the dilution before used. So the PL emission of the three kinds of nanoparticles will not interfere with the fluorescence of EB-DNA for the determination of DNA damage.

Incubation time is an important factor for studying the DNA damage caused by nanoparticles. Fig. 4 shows the results of the DNA damage caused by the three kinds of nanoparticles with the increase of incubation time. Within 6 h incubation time, both EB-DNA fluorescence quenching and the difference of the quenching by the three nanoparticles did not exhibit clearly, which indicated that DNA molecules had not been damaged obviously by the three kinds of nanoparticles during 6 h incubation. But after an overnight incubation (16 h), the fluorescence of EB-DNA was quenched evidently by CdTe QDs, indicating that quite amounts of DNA molecules were damaged by CdTe QDs. Under the same condition, CdTe/SiO_2 NPs performed less effect to DNA molecules than CdTe QDs, which due to the overcoating of a silica layer. Mn:ZnSe d-dots almost exhibited no damage of DNA molecules, which did not quenched the fluorescence of EB-DNA considerably even after 24 h incubation time. Thus, the incubation time was fixed 16 h in the following experiments to study the DNA damage induced by the three kinds of nanoparticles.

Based on the study above, ionic strength can affect the PL emission properties of the three kinds of nanoparticles, which can also affect the DNA damage caused by them. The results (Fig. 5) showed that with the increase of ionic strength, the fluorescence of EB-DNA decreased. In the same ionic strength solution, the fluorescence quenching of EB-DNA by CdTe QDs was the most among the three kinds of nanoparticles. While NaCl concentration of assay system was up to 50 mmol/L, the high ionic strength interfered the fluorescence of EB-DNA and the interaction of EB and DNA, so DNA damage cannot be well shown. Compared with CdTe QDs, CdTe/SiO_2 NPs and Mn:ZnSe d-dots did not quench the fluorescence of EB-DNA greatly, especially Mn:ZnSe d-dots, which hardly quenched the fluorescence of EB-DNA in varied ionic strength solution.

Besides the effect of ionic strength, pH value also influences the DNA damage induced by CdTe QDs, CdTe/SiO_2 NPs and Mn:ZnSe d-dots. The effect of pH value on EB-DNA fluorescence with the three kinds of nanoparticles was shown in Fig. 6. The phenomenon of flu-

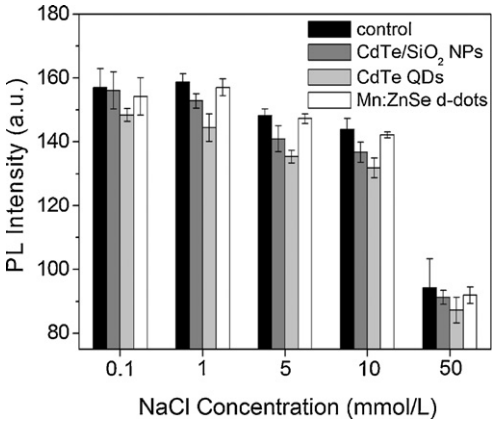

Fig. 5. The effect of different ionic strength on fluorescence quenching of EB-DNA induced by $CdTe/SiO_2$ NPs, CdTe QDs and Mn:ZnSe d-dots. The fluorescence intensity was the average value of three times.

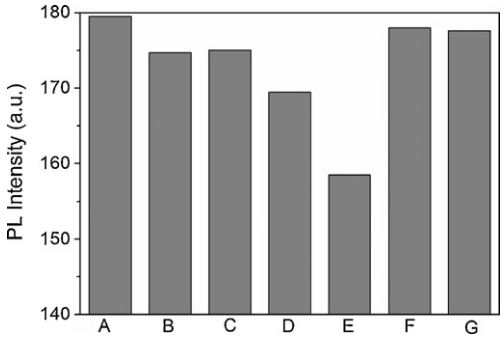

Fig. 7. The effect of UV irradiation on fluorescence quenching of EB-DNA induced by $CdTe/SiO_2$ NPs, CdTe QDs and Mn:ZnSe d-dots. (A) Control (EB-DNA), (B) $CdTe/SiO_2$ NPs incubated with EB-DNA for overnight, (C) $CdTe/SiO_2$ NPs after 1 h UV irradiation incubated with EB-DNA for overnight, (D) CdTe QDs incubated with EB-DNA for overnight, (E) CdTe QDs after 1 h UV irradiation incubated with EB-DNA for overnight, (F) Mn:ZnSe d-dots incubated with EB-DNA for overnight, and (G) Mn:ZnSe d-dots after 1 h UV irradiation incubated with EB-DNA for overnight.

orescence quenching of EB-DNA by the three kinds of nanoparticles in different pH buffer solutions was analogous with that in different ionic strength solutions. CdTe QDs showed the most fluorescence quenching effect among the three kinds of nanoparticles. Simultaneously, when the assay system was in acidic buffer solution (pH < 6), the fluorescence quenching of EB-DNA induced by CdTe QDs was more than that of EB-DNA in alkalescent buffer solution, which suggested that DNA damage in acidic buffer solution was more than that in alkalescent buffer solution. This phenomenon could be attributed to the detachment of the stabilizers from the QD surface and release of Cd^{2+} and free radicals generated by Cd^{2+} [16]. Because the silica overcoating layer can protect the CdTe QDs, $CdTe/SiO_2$ NPs have more resistance than CdTe QDs to pH effect (Fig. S1), which leads to less fluorescence quenching of EB-DNA by $CdTe/SiO_2$ NPs. Although the surface property of Mn:ZnSe d-dots is also influenced by pH value, doped ions of d-dots can hold charge carriers in the internal structure of the d-dots [14], which will not damage the DNA molecules, so the fluorescence of EB-DNA is almost constant. Remarkably, when $CdTe/SiO_2$ NPs and Mn:ZnSe d-dots were added to the assay system with pH 4.22, the fluorescence of EB-DNA was enhanced instead of quenching. As mentioned in Section 2, the pH value of Mn:ZnSe d-dots solution was 11.2. While d-dot solution was added to the assay system with pH 4.22, the pH value of assay system was increased to about 5 and there was no damage for DNA molecules in the assay system. Therefore, the assay system exhibited higher fluorescence of EB-DNA.

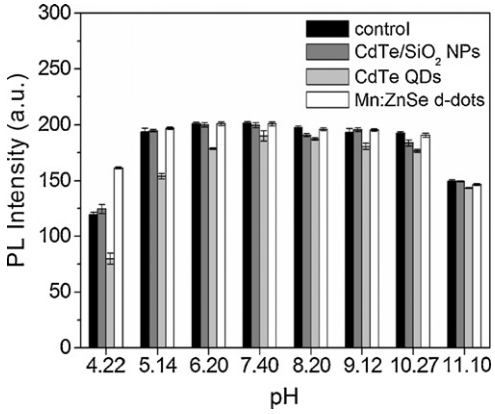

Fig. 6. The effect of different pH value on fluorescence quenching of EB-DNA induced by $CdTe/SiO_2$ NPs, CdTe QDs and Mn:ZnSe d-dots. The fluorescence intensity was the average value of three times.

Though the experimental system was stored in the dark, CdTe QDs also result in DNA damage, which could be due to the free radicals generated by the slow oxidation and gradual desorption of surface oxide into solution, that is consistent with the results published previously [14–16]. $CdTe/SiO_2$ NPs have a silica overcoating to isolate CdTe QDs from the external environment, thus $CdTe/SiO_2$ NPs lead to less DNA damage. As for Mn:ZnSe d-dots, the doped ions Mn^{2+} could hold the charge carriers in the internal structure which avoids the generation of free radical, so the damage of DNA caused by Mn:ZnSe d-dots is neglectable.

The ionic strength and pH value are both environmental factors influencing the DNA damage induced by three kinds of nanoparticles. Besides that, UV irradiation also plays a critical role in studying DNA damage by three kinds of nanoparticles. For studying the effect of UV irradiation, CdTe QDs, $CdTe/SiO_2$ NPs, and Mn:ZnSe d-dots were irradiated firstly with 150 W xenon lamp for 60 min continuous intensive excitation at 280 nm. We compared the fluorescence of EB-DNA incubated with the three kinds of nanoparticles before and after UV irradiation, and the results were shown in Fig. 7. From Fig. 7, it can be seen that the column E represented the fluorescence intensity of EB-DNA incubated with CdTe QDs without UV irradiation, and column F represented the fluorescence intensity of EB-DNA incubated with CdTe QDs surviving from 1 h UV irradiation. The fluorescence quenching of column E was lower than that of column F, which suggested that CdTe QDs after 1 h UV irradiation provoked a statistically significant DNA damage compared with that without UV irradiation. During the UV irradiation, reactive oxygen species (ROS) produced by resonance energy transfer from excited QDs to surrounding oxygen molecules, which should take the main responsibility for the DNA damage [15,24–26]. As for $CdTe/SiO_2$ NPs, the fluorescence intensity of EB-DNA had no difference between adding $CdTe/SiO_2$ NPs with and without UV irradiation (column B and column C). That may be due to the protection of silica network which can prevent the photobleaching of CdTe QDs by UV irradiation (Fig. S2) and inhibit the resonance energy transfer from excited QDs to oxygen molecules, thus $CdTe/SiO_2$ NPs after UV irradiation do not result in more DNA damage than $CdTe/SiO_2$ NPs before UV irradiation. Similarly, fluorescence quenching of EB-DNA by Mn:ZnSe d-dots was subtle essentially, which is less than that induced by $CdTe/SiO_2$ NPs, and furthermore the difference of fluorescence quenching induced by d-dots before and after UV irradiation was also neglectable. For Mn:ZnSe d-dots, luminescence results from recombination of the exciton as well as from energy transfer to Mn^{2+} d–d levels [27], and doped ions Mn^{2+} could hold the charge carriers in the internal structure [14], simultaneously, the excited Mn^{2+} ions coated by

host ZnSe layer, which all inhibited the excited Mn^{2+} ions reacting with the surrounding oxygen molecules. So the PL emission intensity of Mn^{2+} $^4T_1 \rightarrow {}^6A_1$ were not influenced by UV irradiation and the Mn:ZnSe d-dots with 1 h UV irradiation do not lead to DNA damage either.

All results show that the Mn:ZnSe d-dots are highly biocompatible, possibly because the d-dots were synthesized without cadmium ions and the coated ZnSe outlayer is a type of non-toxic, chemically stable wide band gap semiconductor. On the other hand, the Mn:ZnSe d-dots used are directly synthesized in aqueous solution, which do not carry residual organic molecules. The low DNA damaged by Mn:ZnSe d-dots may bring some potential applications, for example, as a new gene delivery agent [28]. With these excellent properties and biocompatibility in mind, this kind of water dispersed Mn:ZnSe d-dots might be a highly promising probe for biological applications.

4. Conclusions

In this work, the DNA damage induced by water-soluble CdTe QDs, CdTe/SiO_2 NPs and Mn:ZnSe d-dots was systematically studied for the first time with EB as the probe. It was found that the ionic strength, pH value, and UV irradiation influenced PL emission properties of the three kinds of nanoparticles, which also influenced the DNA damage caused by the three kinds of nanoparticles. The results indicated that CdTe QDs led to more DNA damage than CdTe/SiO_2 NPs and Mn:ZnSe d-dots, which was due to the free radicals generated by the slow oxidation and gradual desorption of surface oxide into solution. When CdTe QDs were irradiated by UV source for 1 h, the more DNA damage by CdTe QDs should be attributed to the photo oxidation of QDs companied with the generation of reactive oxygen species, which can be avoided by CdTe/SiO_2 NPs and Mn:ZnSe d-dots. All results clearly demonstrated that Mn:ZnSe d-dots resulted in the least DNA damage among the three kinds of nanoparticles, which can be used in various biomedical applications as highly biocompatible fluorescent labels.

ABSTRACT

Electrochemical solid phase nano-extraction, a novel sample preparation technique, was used for the determination of trace iodide in iodised table salt based on the silver sulfate nanoparticle-modified carbon paste electrode. Electrochemical solid phase nano-extraction was realized in the exchange between the sulfate anion in nanoparticles and an iodide anion from aqueous solution. The released silver cation serves as the electrochemical probe for the determination of iodide. The extraction follows a Freundlich adsorption isotherm, and can be used in the detection of iodide in the concentration range 5.0×10^{-12}–4.0×10^{-9} M. The amount of iodide in iodised table salt was determined as 0.875 ± 0.002 μg/g, which is about 2.5% of the addition amount of iodate with a relative deviation of 5.92% and a standard addition recovery of 90–110%. The large amounts of chloride and iodate did not interfere with the detection.

1. Introduction

Solid phase micro-extraction (SPME) was developed by Pawliszyn and co-workers as a solvent-free green sample preparation method [1–3], and have been widely used in many areas [4–6]. If the adsorbent consists of nanoparticles, the method is called solid phase nano-extraction (SPNE) [7,8]. The SPNE method retains all the advantages of SPME, and has some new characteristics, such as a larger specific adsorption area, multiple active sites for recognitions of the analyte(s), controllable surface states, and modificative solid nanoparticle surface. The combination of electrochemistry with SPNE (ESPNE) is a new technique for sample preparation. In ESPNE, electrochemistry offers a way to control the redox states of extractants and analytes, and the un-uniformed electric field on nanoparticle-modified electrode surface offers a dielectric force for the separations. Some examples have shown the possibility for integration of analysis with separation [9–12]. The carbon paste electrode (CPE), composed of a flexable mixture of solid and liquid phase, offers a renewable electrode surface for the solid and liquid extractants, and very suitable for ESPNE [13].

Iodine is one of the biologically important elements, an adult human requires 100–150 μg/day, and it has been suggested that potassium iodate or potassium iodide should be added to table salt called iodised table salt [14]. In practice, however, long-term storage of iodised table salt under adverse conditions results in some loss of iodine due to the inverse disproportional reaction [15]. The trace iodine detection methods, such as UV–visible spectrophotometry [16], catalysis [17], chromatography [18], ion-selective electrode [19], cyclic voltammetry (CV) [20], and ICP-AES [21] with chemical oxidation and liquid–liquid extraction techniques cannot be used directly, and they all suffer from interference by chloride [22] and iodate. Therefore, it is important to develop a method that can determine iodide directly and without interference by the large amounts of chloride and iodate.

We modified the surface of graphite powder in a CPE with Ag_2SO_4 colloidal nanoparticles (ssn-CPE) and used it to extract iodide from aqueous solution. The amount of iodide extracted was determined directly by anodic stripping of silver with differential pulse voltammetry (DPV). This method was investigated for the detection of iodide in iodised table salt without interference by iodate or chloride, and the results are reported here.

2. Experimental

2.1. Instrument and reagents

Electrochemical experiments were carried out on a CHI electrochemical system (CHI620B, CHI Co., USA) with three electrodes;

doi:10.1016/j.talanta.2009.09.015

a piece of platinum wire as the auxiliary electrode, an in-house built silver sulfate-modified CPE as the working electrode and a KCl-saturated calomel electrode as the reference electrode. All potentials reported here are with respect to this reference electrode.

Graphite powder (200 #, spectrophotometrically pure), epoxy resin, polyacetamide resin, castor oil (chemically pure), ethyl benzoic acid, potassium sulfate, silver nitrate, citric acid, sodium hydrogen phosphate, sodium iodide, sodium nitrate, and other chemicals were all analytical grade. All solutions were prepared with ultra-pure MilliQ-treated water (18.2 MΩ from MilliQ A-10). All the electrolyte solutions were de-oxygenated by sparging with high-purity nitrogen gas for 20 min before use. All experiments were done at room temperature (~20 °C).

The iodised table salt used in this work was purchased from a supermarket, which composed of sodium chloride (>97%) and potassium iodate (35 ± 15 mg/kg) followed the national standard of table salt.

2.2. Preparation of the working electrode

The basic electrode was prepared as follows. Graphite powder, epoxy resin and polyacetamide resin were mixed into a paste with a weight ratio of 8:3:2, pressed tightly into a clean glass tube (inner diameter ~ 4 mm) with a copper wire at the other end as an electrode, and left to solidify in air for 72 h. Then, the upper end of the electrode was scraped out to produce an ~1 mm cavity to accept the carbon paste. This solid graphite–epoxy composite electrode (GECE) with a small cavity was used as the basis of the Ag_2SO_4-modified electrode (ssn-GECE).

K_2SO_4 solution (5.0 mL of 5.0 mmol/L) was mixed with 10.0 mL of 10 mmol/L $AgNO_3$ in an ultrasonic bath, and a colloidal solution was obtained. A 1.0 g sample of graphite powder was added to the colloidal solution, stirred with a glass rod and heated at 110 °C to evaporate water, leaving the Ag_2SO_4-modified graphite powder.

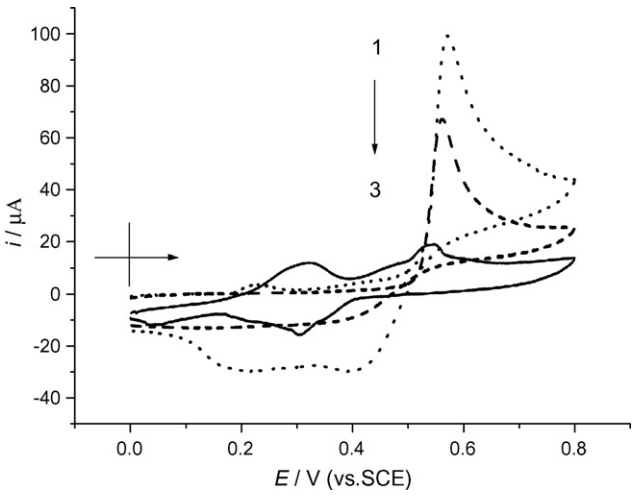
This powder was mixed with castor oil in a weight ratio of 1:1 to give a uniform paste, which was used to fill the cavity in the prepared basic GECE, polished on glass-paper, and used as the working electrode. The paste in the working electrode cavity can be renewed for the new measurement after usage. The prepared carbon paste can be stored in air for several months without loss of its activity.

3. Results and discussion

3.1. The electrochemical behaviour of iodide at the modified electrode

The different electrodes in 0.5 M $NaNO_3$ electrolyte solution (pH 3.2) including 0.5 mM NaI, gave the CV curves shown in Fig. 1.

The iodide on the bare CPE (with castor oil and ethyl benzoate) shows only one irreversible oxidation peak at 0.559 V (Fig. 1, curve 2) without the reduction peak due to the extraction of iodine into the organic phase. Iodide at the ssn-CPE had a CV with cathodic peaks at 0.400 V and at 0.192 V, and anodic peaks at 0.233 V and at 0.570 V (Fig. 1, curve 1). The ssn-CPE in the electrolyte solution without iodide had a CV with anodic peaks at 0.320 V and 0.530 V, and cathodic peaks at 0.306 V and 0.040 V (Fig. 1, curve 3). Comparison of curve 1 with curves 2 and 3 reveals that the first oxidation peak, at 0.233 V, belongs to the oxidation of a silver atom deposited at the initial potential, which is 0.087 V negative shifts compared than oxidation peak (at 0.320 V in curve 3) of silver at silver sulfate nanoparticles. The sharp oxidation peak at 0.570 V belongs to the oxidation of iodide, and was sensitized by silver sulfate (at



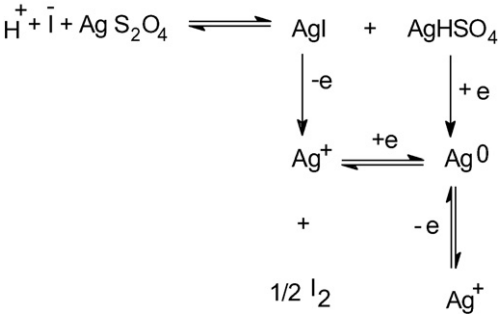


Fig. 1. The CVs of silver sulfate-modified CPE (ssn-CPE) with (1, dot line) and without (3, solid line) iodide and bared CPE with iodide (2, dash line). In 0.5 M $NaNO_3$ electrolyte solution (pH 3.2) including 0.5 mM NaI. Scan rate, 100 mV/s, quiet time, 12 s.

0.530 V). The corresponding reduction peak at 0.400 V belongs to the reduction of iodine. The reduction peak at 0.200 V belongs to the reduction of silver in the sulfate precipitate. Without iodide, the free silver gives reduction peaks at 0.306 V and 0.040 V, and oxidation peaks at 0.320 V and 0.530 V, which will sensitise the oxidation of iodide. In the iodide solution, there is an exchange reaction between iodide and sulfate, and silver hydrosulfate is released. The whole process can be described as

(1)

Eq. (1) offers two methods for the determination of iodide. If the concentration of iodide in aqueous solution is very large, all released silver cations are combined with iodide ions, and the oxidation of iodide in silver iodide can be used for its detection. If the concentration of iodide is very low, one of the silver cations combines with iodide and another is released as silver hydrosulfate, which serves as a sensitive electrochemical probe for the measurement of iodide and this is the method chosen for the ultra-trace iodide analysis described here.

The first anodic peak at 0.233 V is proportional to the square-root of the scan rate and the regression equation is:

$$i_{pa}(\mu A) = -3.891 + 12.31\nu^{1/2} \quad (2)$$

R is 0.9995, SD is 2.12.

This relationship indicates that the oxidation is a diffusion-controlled process. The silver cation released is not adsorbed on the electrode surface or on the surface of the silver sulfate precipitate but diffuses to the bulk solution. This is one piece of evidence that supports the suggested mechanism in Eq. (1).

3.2. The effects on the ESPNE

3.2.1. The influence of the amount of modifier (Ag_2SO_4)

The loading amount of modifier, colloidal Ag_2SO_4, influences the extraction of iodide directly. Different volumes of Ag_2SO_4 colloidal solution at a given concentration were used in the modification of the CPE. The modified CPE was used in the CV experiments under the same experimental conditions. The anodic peak current was plotted against the volume of the colloidal solution/g of graphite powder; there was a sharp peak with a maximum at 20 mL, as shown in Fig. 2. The anodic peak current increased linearly with the volume of colloidal solution in the range 2–20 mL/g. The regression equation is:

$$i_{pa}(\mu A) = 9.053 + 0.353V \quad (3)$$

R is 0.9996, SD is 0.103.

The anodic peak current reached a maximum at 20 mL/g and then decreased exponentially with the increase of the volume/g of colloidal solution with the regression equation:

$$i_{pa}(\mu A) = 12.71 + 3.4654e^{((V-20)/19.43)}, \quad (4)$$

$\chi^2 = 0.00954$.

As described above, the extraction is an anion-exchange process between iodide and sulfate, the anodic peak current is dependent on the amount of exchange, the exchange ratio, the exchange time and the coverage of the electrode surface at a fixed concentration of iodide. The coverage of the graphite powder surface was lower with a lower volume of colloidal solution, and all the sulfate anions in the silver sulfate modified at the surface were exchanged with iodide 100% at a given exchange time. So, the peak current is directly proportional to the coverage of the surface and to the volume of the colloidal solution. With an increase of the volume of the colloidal solution, the extraction timescale limited the amount of iodide in the contacting solution that diffused to the electrode surface. The extraction reached a maximum at about 20 mL. After this, the coverage was increased with the volume of colloidal solution/g of graphite, but the exchange ratio decreased exponentially due to the limited amount of iodide anion available to diffuse to the electrode surface at a given time and a given concentration.

3.2.2. The influence of extraction time

The extraction time, t_e, is the length of time between the electrode contacting the sample solution for the ion exchange and the beginning of the CV experiments. The anodic peak current plotted

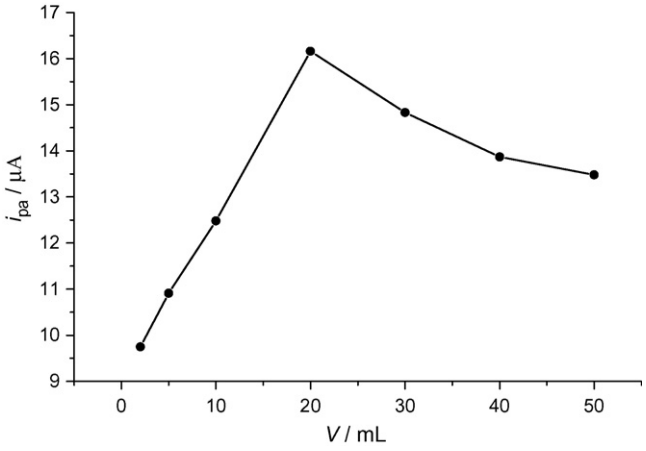

Fig. 2. The relation between anodic peak current and volume of colloidal solution for the CPE modification. The experimental conditions were the same as those in Fig. 1.

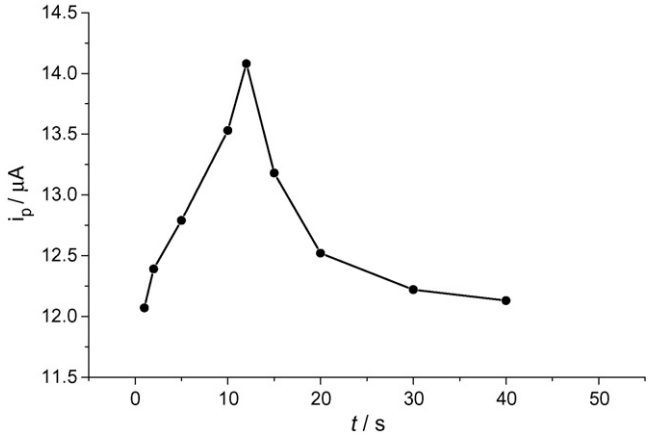

Fig. 3. The relation of anodic peak current with extraction time. The other experimental conditions were the same as those in Fig. 1.

versus extraction time is shown in Fig. 3. The anodic peak current increased linearly with extraction time in the range 2–20 s with the regression equation:

$$i_{pa}(\mu A) = 69.364 + 0.5541t_e, \quad (5)$$

R is 0.9973, SD is 0.325.

This result indicates that the extraction follows the linear adsorption process as described above. After 20 s, the anodic peak current is not changed greatly with extraction time; i.e. 20 s is the saturated extraction time for a given concentration of iodide.

3.2.3. The influence of quiet time

The extraction process is the exchange between iodide and sulfate anions. The amount of silver released was determined by the oxidation peak current of silver deposited on the electrode surface at the negative potential. The quiet time, t_q, is the length of time from the start-point of the applied potential of −0.400 V at the electrode for the electrochemical deposition of the released silver cation to the potential scanning or CV experiment. So, t_q is very important for the evaluation of the extraction. The anodic peak current plotted *versus* t_q is shown in Fig. 4.

The anodic peak current increased linearly with t_q in the range 2–12 s with the regression equation:

$$i_{pa}(\mu A) = 11.97 + 0.1692t_q \quad (6)$$

R is 0.9936, SD is 0.108.due to the electrochemical deposition of a silver cation and the linear extraction as described above. With increased $t_q > 12$ s, the anodic peak current decreased exponentially with the regression equation:

$$i_{pa}(\mu A) = 12.15 + 1.93e^{-((t_q-12)/4.854)} \quad (7)$$

R is 0.9786, SD is 0.193.

With increased t_q of the extraction at a higher concentration of iodide, the reduction of silver in the nanoparticles may be reduced to a silver atom, and extracted into the organic phase without taking part in the extraction and oxidation process. This reduction process has an apparent first-order rate constant of 0.206 s^{-1}. The optimal t_q was chosen as 12 s in the following experiments.

3.2.4. The influence of solution pH

The solution pH is another important factor that influences the extraction, because hydrosulfate is a weak acid with an acid dissociation constant k_{a2} of 1.21×10^{-2}. The CV experiments were done at a scan rate of 100 mV/s, extraction time 20 s, quiet time 12 s in solutions of different pH controlled with a phosphate buffer system. The anodic peak current plotted *versus* the solution pH is shown in

Fig. 5A. The anodic peak current does not change greatly with solution pH in the range 2–4; the maximum point is located at pH 3.2, and then decreased sharply at pH ≥ 4.2, which may be due to the formation of silver hydroxide.

The anodic peak potential was not changed with solution pH in the range 2.2–4.2, but increased linearly at pH > 4.2 with the regression equation:

$$E_{pa}(\mathrm{V}) = 0.506 + 0.0143\mathrm{pH} \quad (8)$$

R is 0.9979, SD is 0.0015.

This is evidence for the formation of silver hydroxide.

3.2.5. The influence of the concentration of iodide

The concentration of iodide is the most important factor for the extraction. Under the optimal Freundlich adsorption isotherm with the adsorption constant K_F, the differential pulse voltammetric experiments were done with 0.5 M $NaNO_3$ electrolyte solution (pH 3.2) including different concentrations of iodide, with extraction time 20 s and quiet time 12 s. The anodic peak current obtained from the experiments plotted *versus* the concentration of iodide is a curve. According to the Freundlich adsorption theory [23], the plot of the logarithm of the anodic peak current *versus* the logarithm of the concentration of iodide in aqueous solution was a straight line with the regression equation:

$$\log(i_{pa}) = 1.5887 + 0.498\log(c, M) \quad (9)$$

R is 0.9966, SD is 0.0512.

This result indicates that the SPNE of iodide follows the Freundlich adsorption isotherm with an adsorption equilibrium constant of $K_F = 38.79$ and $n = 2.008$, which means two iodides can be extracted with Ag_2SO_4.

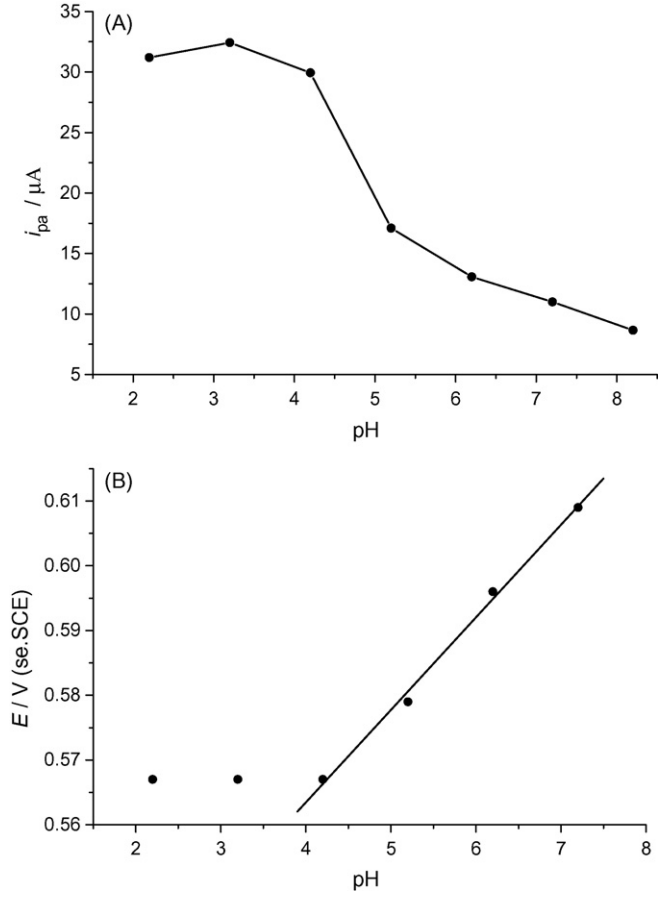

Fig. 4. The relation of anodic peak current with quiet time. The other experimental conditions were the same as those in Fig. 1.

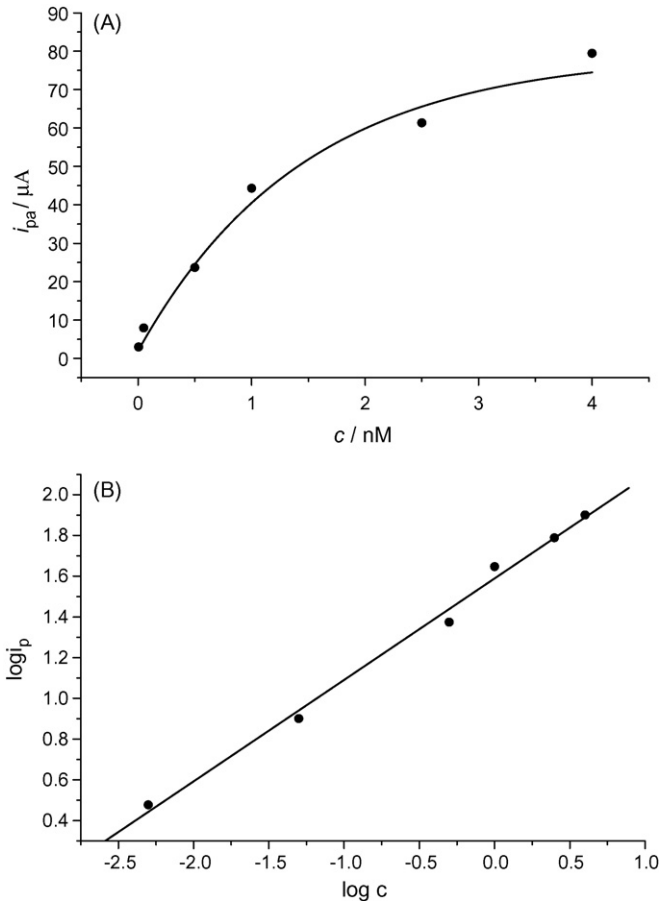

Fig. 5. The relations of anodic peak current (A) and peak potential (B) with solution pH. The other experimental conditions were the same as those in Fig. 1.

3.3. Determination of iodide

3.3.1. The standard working curve

The relationship between anodic peak current and concentration of iodide is a non-linear curve with a saturation growth-rate function as:

$$i_{pa}(\mu\mathrm{A}) = \frac{113.1c}{1.828 + c} \quad (10)$$

R is 0.9921, SD is 3.92.

The saturation growth-rate function is commonly used to describe a population growth model in terms of the nutrient concentration. In our case, the amount of iodide extracted depended directly on the concentration of iodide in solution, with a maximum rate of 113.1, and a half-saturation growth constant of 1.828.

The non-linear relationship can be further linearised by replacement of concentration *c* with: $x = 113.1c/(1.828 + c)$.

The plot of anodic peak current *versus* *x* is a straight line with the regression equation:

$$i_{pa}(\mu\mathrm{A}) = 1.394 + 0.9746x \quad (11)$$

R is 0.9928, SD is 3.76.

The linear range of the detection is in the concentration range of 0.005–4.0 nM with correlation coefficient of 0.9928. The limit of detection (LOD) is 5.0 pM, and the standard deviation is 3.76 pM.

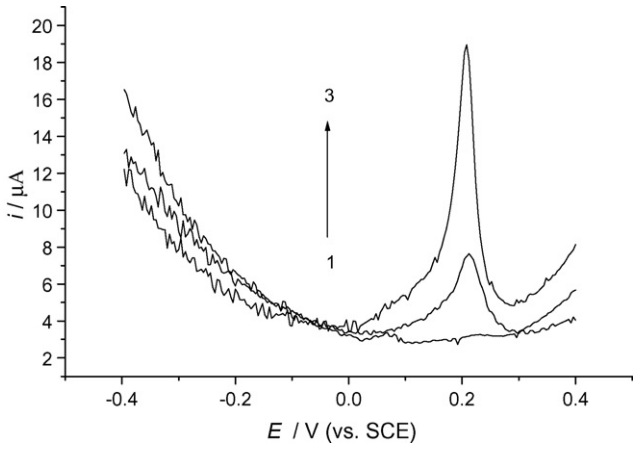

Fig. 6. The DPV curves of iodide in table salt sample solution (2), after standard addition of standard solution (3) and electrolyte solution (1), quiet time = 12 s, pH 3.2.

3.3.2. The determination of iodide in iodised table salt

Sodium iodate is suggested for addition to table salt to make iodised table salt. The analytical methods used in the determination of total iodine, do not consider the residue of iodide in iodised table salt. There is no suitable method in the literature to determine iodide directly in iodised table salt. The principle of the method developed in this work may be suitable for this target, because the exchange reaction is specific for iodide, not iodate.

The sample solution was 1.0 g of iodised table salt dissolved in 50 mL of water and 5.0 mL of this was added to 15 mL of the KNO_3 electrolyte and buffer solution. The DPV experiments were done 10 times under optimal conditions. The average anodic peak current was 4.34 ± 0.26 μA. The concentration of iodide was calculated as 0.050 ± 0.003 nM. The amount of iodide in the table salt was calculated as 0.875 ± 0.002 μg/g. The national standard for iodine in iodised table salt is 35 μg/g. So, about 2.5% of iodide was present in the table salt sample. Iodide is a very active species, and may be responsible for the deterioration of iodised table salt during long-term storage due to the disproportionate reaction of iodide and iodate. This result proved that the method is highly selective for iodide rather than iodate or chloride.

Typical DPV curves of the sample solution and the standard addition solution are shown in Fig. 6. In the electrolyte solution, there is no any anodic peak (Fig. 6, curve 1). After addition of 5.0 mL table salt solution into the 15.0 mL electrolyte solution, the resulted solution includes 0.0825 M NaCl and 1.44 mM KIO_3, the solution gives out an anodic peak with 4.34 μA peak current, calculated as 0.05 nM, After addition of fivefold standard iodide, the peak current increases to 15.89 μA, and concentration of iodide was calculated as 0.275 nM. This experiment results indicate that the anodic peak is related to the iodide, and more than 10^{5-8} times of chloride and iodate do not interference the detection of iodide. From these experiments, the standard addition coverages were obtained in the range of 90–110%.

4. Conclusions

This paper describes the solid phase nano-extraction of iodide from iodised table salt on graphite powder surface modified with silver sulfate nanoparticles in a carbon paste electrode. Some important points are summarized as follows.

(1) The extraction mechanism is the exchange reaction between a sulfate anion in a nanoparticle of silver sulfate precipitate and iodide from aqueous solution, depending on the extraction time, solution pH, and the concentration of iodide
(2) The extraction isotherm follows a Freundlich adsorption isotherm.
(3) The extraction can be used directly in the electrochemical determination of iodide with an electrochemical probe of silver without interference by large amounts of chloride or iodate.
(4) The electrochemical method is a powerful tool in the sensitive, selective and rapid detection of iodide in iodised table salt and in the study of solid phase nano-extraction processes.

ABSTRACT

UV-induced carbonyl generation with formic acid is used for gaseous sample introduction into an atomic fluorescence spectrometer for the determination of ultra-trace nickel. Compared with conventional carbonyl generation, no toxic gas CO is involved in this work, and volatile $Ni(CO)_4$ is generated with a single reagent formic acid under the irradiation of UV light (253.7 nm, 15 W). The reaction conditions, including reaction medium, UV irradiation time and reaction temperature, are optimized for the best signal. Under the optimized conditions, a limit of detection of 10 ng L^{-1} for nickel is obtained without any analyte-preconcentration, which is comparable to that using in situ trapping technique. Interferences from common transition metal ions, noble metal ions and mineral acids are also investigated. The proposed method is applied to the analysis of three certified reference materials and two organic acid samples for trace nickel, with analytical results in good agreement with certified values or those obtained by electrothermal atomic absorption spectrometry. This is a simple, fairly green and highly sensitive method for ultra-trace nickel determination.

1. Introduction

Determination of nickel is of great importance due to its both essentialness in low concentration and toxicity in high concentration to living organism [1,2]. The most popular analytical methods for the determination of metal elements are analytical atomic spectrometry, including flame atomic absorption spectrometry (FAAS), electrothermal atomic absorption spectrometry (ET-AAS), inductively coupled plasma-optical emission spectrometry (ICP-OES) and inductively coupled plasma mass spectrometry (ICP-MS). Unfortunately, the far low concentration level of nickel in many environmental or clinical samples (usually ng mL^{-1} or sub-ng mL^{-1}) makes it difficult to directly determine nickel without pre-concentration. Therefore, numerous pre-concentration techniques are usually applied prior to nickel measurement, such as liquid–liquid extraction [3], ion exchange [4], cloud point extraction [5], solid phase extraction [6], and membrane filtration [7]. Indeed, these enrichment methods offer advantages of both enhancement of the nickel concentration before spectrometric detection and preliminary separation of nickel from a complex sample matrix, and thus successfully conquer the difficulty of nickel determination in the ng mL^{-1} or sub-ng mL^{-1} concentration level. However, such methods are very vulnerable to analyte contamination and loss as a consequence of tedious manipulation steps and many reagents involved during the pre-concentration process. Moreover, these enrichment steps are often labor- and time-consuming. Therefore, a simple and sensitive analytical method for nickel determination is demanded for the analysis of many real samples.

Nickel can rapidly react with carbon monoxide to form a stable gaseous tetracarbonyl at ambient temperature and pressure. This was first used by Vijan in 1980 [8] for nickel determination. Generally, nickel chemical vapor generation (CVG) consists of three different types: $NaBH_4$–CO system [9–12], electrochemical reduction–CO system [13] and $NaBH_4$–HCl system [14–16]. As far as the $NaBH_4$–CO system concerned, the main principle is that dissolved nickel ion is reduced by $NaBH_4$ to nickel free atoms which subsequently combine carbon monoxide to form gaseous $Ni(CO)_4$, with a detection limit achievable as low as 4 ng L^{-1} [10]. Since nickel is ubiquitous naturally, this system is often bothered by the high blank problem resulted from the nickel impurity in $NaBH_4$ and CO, and a purification of reagents is usually required. Therefore, Johansson et al. [13] developed electrochemical reduction of nickel ion as an alternative to $NaBH_4$ reductant, but this technique was not generally applicable to the analysis of real samples because of heavy memory effect and the uncontrollable change in the electrode. The third type, $NaBH_4$–HCl system, is virtually the scope expansion of the traditional hydride generation (HG). Guo and Huang found that

doi:10.1016/j.talanta.2009.09.016

volatile nickel species could be generated by reaction in an aqueous solution with sodium or potassium borohydide at room temperature without using poisonous carbon monoxide [14]. Later, several studies by Sturgeon and coworkers [17] and other chemists [15,16] made this system feasible to real sample analysis for trace nickel, even though such a system intrinsically had the defect of unstable nickel volatile species, which resulted in low transportation efficiency.

Photochemical vapor generation (photo-CVG) is a newly emerging research field in analytical chemistry, providing a significant alternative to traditional CVG. Due to its unique features such as simple reaction and instrumentation, greener analytical methods in most cases, less interference especially from transition metals, and cost-effectiveness [18], many efforts have been made to apply it in analytical atomic spectrometry. In 2004, Sturgeon and coworkers [19] made a broad study in the UV photo-CVG as a sample introduction tool and expanded its scope to 20 elements including nickel, and this interested many chemists to further investigate its analytical application [20,21]. Additionally, Sturgeon developed this method to synthesize $Ni(CO)_4$ [22] and organic species of selenium [23], providing a novel means of synthesizing organic metal compounds with high yield. It is worthwhile to further explore its application for the determination of trace nickel concentration. Therefore, this work aims to develop an atomic fluorescence spectrometric method to determine ultra-trace nickel without any pre-concentration, by using UV-induced carbonyl generation for sample introduction with a single reagent formic acid.

2. Experimental

2.1. Apparatus

As illustrated in Fig. 1, the experimental set-up mainly consists of two parts: a laboratory-constructed flow-through photochemical reactor and a commercial atomic fluorescence spectrometer (AFS-2202E, Beijing Haiguang Instrument Co., Beijing, China). A quartz tube (4/6 mm, i.d/o.d.) coiled around a UV lamp (253.7 nm, 15 W, Philip, Holland) is used as the photochemical reactor. The quartz tube has 26 turns with 25 mm in diameter suiting the size of the UV lamp in order to maximize the UV irradiation onto the reactor. The whole photochemical reactor is mounted in a black box to prevent the UV light from leaking. A hot plate is used for heating the flow-through photochemical reactor, and a thermometer is inserted into the black box near the photochemical reactor to monitor the reaction temperature. Because the photochemical reaction for the production of nickel carbonyl is temperature-dependent, the cooling water used in our previous work [21] is eliminated to increase the temperature. Polytetrafluoroethylene tubing is used to deliver the solutions. A nickel hollow cathode lamp (Hebei Ningqiang Lighting Co., Ltd, China) is specially designed for the AFS measurement. More detailed information about the AFS instrument can be found in a previous publication [21], but its working parameters are summarized in Table 1.

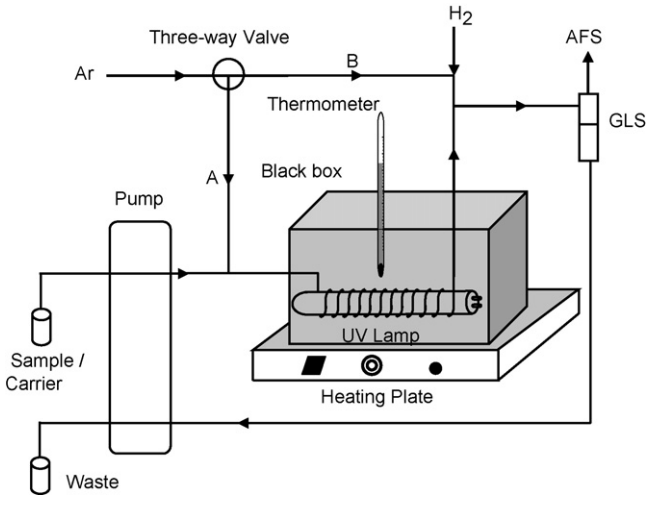

Fig. 1. Schematic diagram of the instrumentation.

Table 1
AFS instrumental parameters.

Parameter	Setting
Lamp current (mA)	80
Voltage of PMT (V)	−300
Atomizer height (mm)	10
Carrier gas flow rate (Ar, mL min^{-1})	300
Shied gas flow rate (mL min^{-1})	1200

For comparison of the analytical results, a SpectrAA 220Z polarized Zeeman electrothermal atomic absorption spectrometer (Varian, USA) is used for the determination of Ni in formic and acetic acid samples. Pyrolysis and atomization temperature of 800 °C and 2600 °C, respectively, are used.

2.2. Reagents

All reagents used in this work are at least of analytical grade. Doubly distilled water (DDW) is used throughout the whole work. 1000 mg L^{-1} Ni(II) standard stock solution is prepared by dissolving 0.1273 g spectropure NiO in 2 mL concentrated nitric acid and subsequently diluting with DDW to 100 mL. After step diluting the standard stock solution, the final working standard solutions are prepared in formic acid with proper concentrations. Chemicals HCOOH, HCl, H_2SO_4, HNO_3 and $HClO_4$ are all purchased from Kelong Chemical Reagents Factory (Chengdu, China.). Formic acid is distilled at 100.8 °C (formic acid boiling point) for its purification prior to use. All vessels used in the experiments are soaked in 1% (v/v) nitric acid overnight and cleaned sequentially with tap water and DDW before use.

2.3. Procedures

For the computer-programmable operation procedure, the nickel and formic acid mixed solution is sucked (Ar flow set to path A) for 40 s into the photochemical reactor in the first step (to fulfill the reaction coil). In the second step, the three-way valve is immediately switched to path B to prevent the Ar flow from purging the sample solution out of the flow-through photochemical reactor, and the peristaltic pump pauses for 120 s; meanwhile the sample channel is shifted from the sample solution to the carrier solution, 20% (v/v) formic acid. During this 120 s interval, sample solution is subject to UV irradiation to generate nickel carbonyl. In the third step (14 s), the peristaltic pump is activated again and the Ar flow is turned back to path A to propel the reaction solution into the gas–liquid separator (GLS). The resultant nickel carbonyl is subsequently introduced into AFS for the peak area measurement of the atomic fluorescence signal. In the fourth step, the peristaltic pump pauses for 6 s to make ready for the next measurement. In the first and the third step, the pump is set at 100 and 120 rpm, respectively.

Caution: UV exposure. Besides, $Ni(CO)_4$ is extremely toxic, and proper ventilation is highly recommended.

3. Results and discussion

3.1. Nickel carbonyl generation

The possible mechanism of photochemical vapor generation remains largely in a state of "discussion", due to the complicated nature of the photoreactions. It is believed that under the UV irradiation, formic acid may follow either of two following anaerobic photolytic decomposition pathways [22]:

$$H - COOH \xrightarrow{UV} H^{\bullet} + {}^{\bullet}COOH \rightarrow H_2 + CO_2 \quad (1)$$

$$H - COOH \xrightarrow{UV} HCO^{\bullet} + {}^{\bullet}OH \rightarrow CO + H_2O \quad (2)$$

Guo and Huang reported that the reaction product of nickel salt with tetrahydroborate might be nickel hydride [14], for the generated nickel volatile species was highly unstable. Only one Ni-containing volatile species naturally exists, namely $Ni(CO)_4$. So the possible pathway for generation of $Ni(CO)_4$ in this work is most probably based on the fact that the photo-generated radicals could behave as a precursor for the reducing species, which plays a role in the reduction of Ni^{2+} to Ni^0. Although Khriachtchev et al. [24] and Langford et al. [25] reported that for formic acid decomposition, Eq. (1) occurred 6-fold more frequently than Eq. (2), the reaction of Ni with CO is known to occur very quickly (Mond process), resulting in rapid consumption of photo-generated CO, and this may substantially accelerate the reaction of Eq. (2). Therefore, the generation of $Ni(CO)_4$ in this work may be followed as:

$$Ni(II) + \text{reducing species (radicals)} \rightarrow Ni(0)_{sol} \quad (3)$$

$$Ni(0)_{sol} + 4CO \rightarrow Ni(CO)_4 \quad (4)$$

In fact, Guo and Sturgeon used GC–MS to identify the volatile species generated in the UV irradiation of nickel salt and formic acid mixture [22]. The resultant fragmentation patterns were in fair agreement with the previously reported mass spectrum of $Ni(CO)_4$.

3.2. Effect of reaction medium

It is structurally evident that only low molecular weight organic acids can photo-generate $CO^{\bullet}$ radical, which accounts for the generation of $Ni(CO)_4$. So in this work, five aliphatic organic acids, namely formic acid, acetic acid, propionic acid, oxalic acid, and malonic acid, are initially tested for $Ni(CO)_4$ generation. These organic acids have similar structures, and are prone to be decomposed under UV light irradiation. Within 4 min UV irradiation, no obvious nickel signal is detected in the medium of oxalic acid (from 0.025 mol L^{-1} to 0.5 mol L^{-1}) and malonic acid (from 0.05 mol L^{-1} to 0.1 mol L^{-1}). The other three acids can be used to photo-generate volatile Ni-containing species (Fig. 2) among which formic acid is the best choice. In our previous work for Hg cold vapor generation under UV irradiation, it was found that the simpler the organic structures, the higher the generation efficiency [26]. Considering the structures of the five acids studied, formic acid is the simplest one, thus the best performance for volatile Ni-containing species generation. Besides, Guo and Sturgeon underlined that oxalic and malonic acid may firstly proceed in a CO_2 lost pathway [27], which would further make it difficult for the generation of $CO^{\bullet}$ radical, thus $Ni(CO)_4$ was hardly generated.

The effect of formic acid concentration on the atomic fluorescence signal of Ni is shown in Fig. 2. When the formic acid concentration is below 20% (v/v), the nickel carbonyl generation efficiency increases almost linearly with formic acid concentration. However, further increase of formic acid concentration cannot lead to a signal plateau, but a decrease of nickel signal. With high concentration of formic acid, more active radicals are generated and they

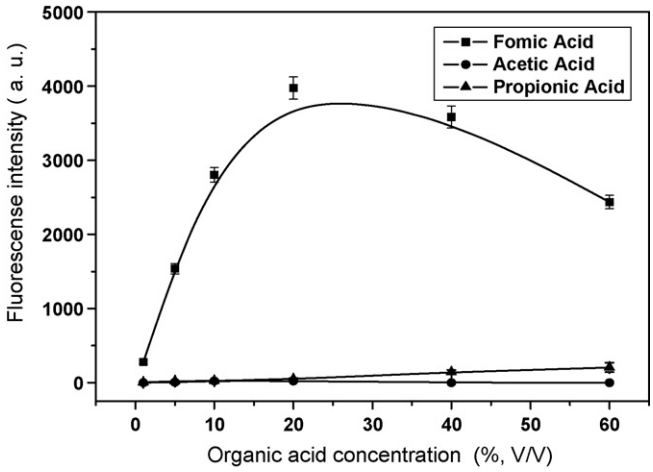

Fig. 2. Effect of the different organic acids on the nickel carbonyl generation. Analyte concentration: 10 μg L^{-1} Ni^{2+}.

are prone to recombine with each other, leading to lower reducing ability. On one hand, excess CO might be produced with high concentration formic acid, and this would lower the atomization efficiency; on the other hand, high concentration of H^+ is likely to capture the Ni precursor generated [9], resulting in inferior generation efficiency. Therefore, 20% (v/v) formic acid concentration is used in this work.

3.3. Reaction coil materials

Three types of materials, glass, PTFE and quartz, are selected to construct the reaction coil. It is known that UV light can be blocked by the glass material, so no appreciable nickel signal can be obtained with a glass coil. In several previous work of photo-induced CVG, PTFE tubes were used [27,28]. It was found that the nickel carbonyl generation efficiency in PTFE was half in a quartz coil, so a quartz reaction coil (4/6 mm, i.d/o.d.) is chosen for use in this work.

3.4. Reaction temperature

It is well-known that $Ni(CO)_4$ will decompose into Ni and CO in liquid phase at 60 °C. As shown in Fig. 3, when the temperature is below 333 K (60 °C), the release of nickel carbonyl from liquid phase increases linearly with the temperature. Further increase of the

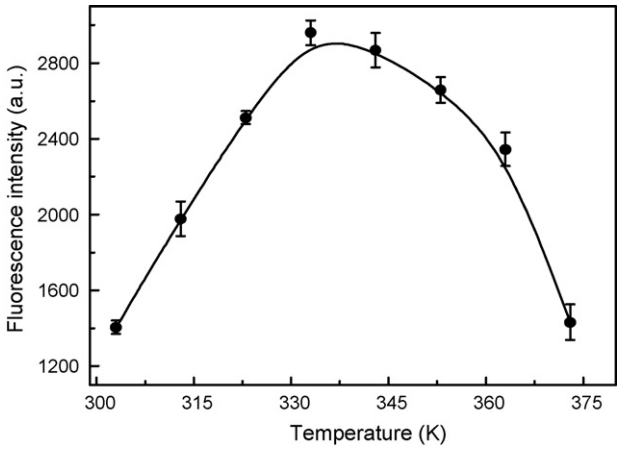

Fig. 3. Effect of temperature on the nickel carbonyl generation. Analyte concentration: 5 μg L^{-1} Ni^{2+}.

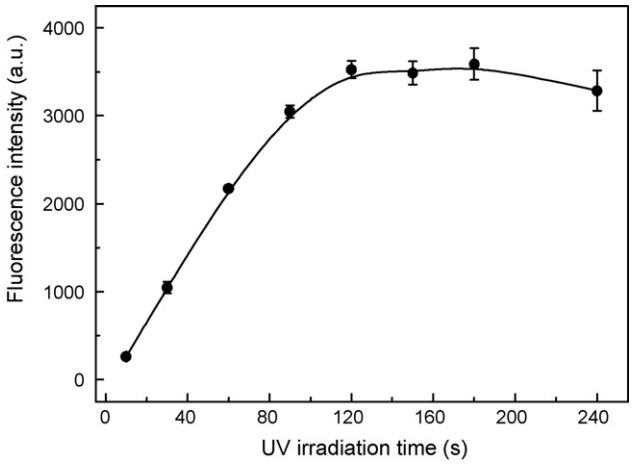

Fig. 4. Effect of UV irradiation time on the nickel carbonyl generation. Analyte concentration: 5 μg L^{-1} Ni^{2+}.

reaction temperature leads to a sharp decrease of analyte signals. When the reaction temperature is below the critical decomposition temperature of $Ni(CO)_4$ in liquid phase, increasing the temperature accelerates the UV-induced nickel carbonyl generation, leading to rapid release of volatile $Ni(CO)_4$ and high transport efficiency. In order to obtain the best signal, reaction temperature of 333 K (60 °C) was used in the following work.

3.5. UV irradiation time

As reported previously, the photo-induced CO• generation is more difficult than the generation of "H•" [24,25]. Also in our previous work for mercury photo-CVG, 5 s UV light irradiation time was enough [20,26]. In this work, the nickel carbonyl generation efficiency is largely associated with the irradiation time, probably partially because of the use of a difference type of UV lamp. A high pressure mercury lamp and a low pressure mercury lamp were tested and the CVG efficiencies are compared. It is found that the low pressure mercury lamp leads to a better signal-to-noise ratio, and thus it is used throughout this work. The intense UV radiation from the high pressure mercury lamp may decompose the carbonyl products. As illustrated in Fig. 4, 120 s irradiation is needed to reach the signal plateau, which is much longer than that needed for the case of mercury [20,26] using a high pressure mercury lamp. In Guo and Sturgeon's work for photosynthesis of nickel carbonyl [22], they also found that longer irradiation time could increase the generation efficiency.

It was initially believed that if prolonged UV irradiation time would lead to higher generation efficiency, increasing the number of the UV lamps might also promote the generation process and accordingly decrease the irradiation time. However, the case is totally different from what was expected. Simply increasing the number of the UV lamps (at fixed temperature, 60 °C) has no obvious effect on nickel carbonyl generation. The reason for such phenomenon remained unclear at the present stage.

3.6. Hydrogen gas flow rate

In order to atomize the photo-generated nickel carbonyl, additional energy must be provided. Without an Ar–H_2 flame for atomization, nickel atomic fluorescence signal cannot be observed. However, excess amount of H_2 would sharply decrease the signal, which was similar to the situation for Se [21]. Hydrogen flow rate at 20 mL min^{-1} is enough for $Ni(CO)_4$ atomization. The temperature of the Ar–H_2 flame at 20 mL min^{-1} H_2 is about 800 °C, much higher than the decomposition temperature needed for $Ni(CO)_4$ in gas phase.

Table 2
Interference of common ions with nickel determination.

Coexisting ion	[M] (μg L^{-1})	[M]/[Ni(II)]	Recovery (%)
Cl^-	50,000[a]	10,000	96
NO_3^-	50,000[a]	10,000	97

3.7. Effect of concomitants

To evaluate the analytical applicability of the proposed method, the effect of some concomitants (several alkaline and alkaline earth salts as well as some transition and heavy metals) was studied (Table 2), with Ni(II) concentration fixed at 5 μg L^{-1}. Four mineral acids typically used for solid sample treatment, namely nitric acid, hydrochloric acid, perchloric acid and sulfuric acid, were investigated in the interference study (Fig. 5). All these acids depress signals sharply. In order to identify which ion is responsible for the signal depression (H^+ or acid anion), four corresponding salts containing the same anion with each acid, were studied, and the results are also illustrated in Fig. 5. It can be concluded that both H^+ and acid anions contributed to the signal depression.

3.8. Analytical figures of merit and sample analysis

Under the optimal conditions, the analytical performance of the proposed method for the determination of nickel was evaluated (Table 3). The LOD (3σ) of the proposed method is 10 ng L^{-1}, without any analyte enrichment step. Compared with other analytical atomic spectrometric techniques, such as GF-AAS [29], ICP-OES [29], ETV-ICP-MS [30] and in situ trapping GF-AAS [10] (Table 4), this approach represents one of the most sensitive yet simplest ones for ultra-trace nickel determination.

Table 3
Analytical characteristics of the proposed method.

Details	Value
Sample volume (mL)	4
Calibration equation (C in μg L^{-1})	$I_f = 1267.7C - 19.4$
Upper linear range (μg L^{-1})	8
Correlation coefficient (R)	0.9994
Limit of detection (ng L^{-1})	10
Precision at 5 μg L^{-1} (RSD, $n = 11$)	3.2%

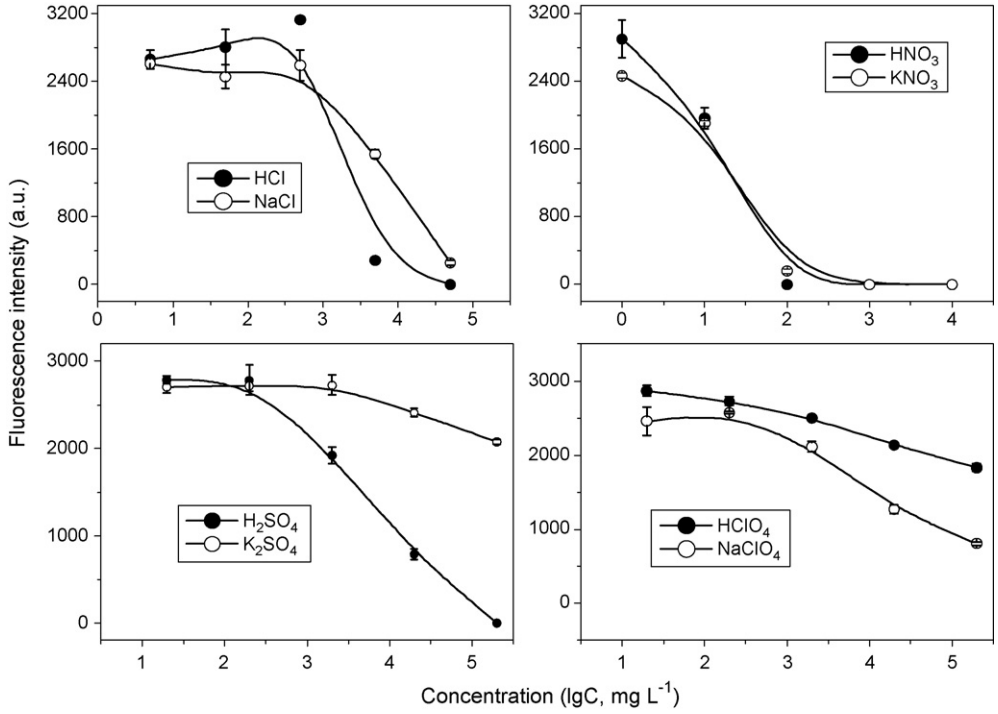

Fig. 5. Interference of common mineral acids and their corresponding salts on the nickel carbonyl generation. Analyte concentration: 5 μg L^{-1} Ni^{2+}.

Table 4
Comparison of LODs with other analytical atomic spectrometric techniques.

Techniques	LOD (ng L^{-1})	Pre-concentration	Ref.
GF-AAS	70	No	[29]
GF-AAS	4	Yes, in situ trapping	[10]
ETV-ICP-MS	3	No	[30]
ICP-MS	0.4	No	[29]
ICP-OES	500	No	[29]
CVG-ICP-OES	1800	No	[15]
CVG-AFS	10	No	This work

To validate the accuracy of the proposed method, three certified reference materials (GBW 08607 water, GBW 09101 human hair and GBW 07605 tea) were analyzed (Table 5) for nickel. Water samples were diluted directly for analysis. For solid samples, firstly they were digested with 1 mL nitric acid, heated to dryness, and dissolved and diluted with DDW. Before analysis, the samples were further diluted with 20% (v/v) formic acid. The total dilution factor was 1000. The *t*-test concludes that analytical results (Table 5) agree very well with the certified values, at the confidence level of 95%.

This method is further applied to nickel analysis in formic and acetic acid samples. The analytical scheme of formic acid sample is based on our previously reported sample matrix-assisted chemical vapor generation [31]. For comparison, these samples were further analyzed by electrothermal atomic absorption spectrometry, and the analytical results of the two methods also agree with each other very well (Table 5).

Table 5
Analytical results of real samples.

Samples	This work (μg g^{-1})[a]	Certified (μg g^{-1})	GF-AAS (μg g^{-1})[a]
GBW 08607 water	0.520 ± 0.050	0.517 ± 0.006	–
GBW 09101 human hair	3.15 ± 0.20	3.17 ± 0.40	–
GBW 07605 tea	4.5 ± 0.4	4.6 ± 0.5	–

[a] Average ± one standard deviation of three trials.
[b] μg L^{-1}.

4. Conclusions

UV-induced carbonyl generation for the atomic fluorescence spectrometric determination of ultra-trace nickel enjoys many advantages over conventional nickel determination technologies. Firstly, only formic acid is required for the analysis of liquid samples, so the contamination from reagents can be largely minimized; secondly, the use of toxic CO is eliminated; thirdly, the products of the method are CO_2 and H_2O, so it represents a greener analytical methodology [32,33] for nickel determination; and fourthly, it is highly sensitive. UV-induced carbonyl generation can be possibly extended to determine other carbonyl-forming elements, such as Fe, Co, W and Mo [34,35]. Besides, the proposed carbonyl generation can serve as a sample introduction method for nickel determination by other atomic spectrometric techniques, such as GF-AAS and ICP-MS/OES.

Ephedra plant

ABSTRACT

The secondary metabolites of different *Ephedra* plants are various. Therefore, the discrimination of different *Ephedra* plants is significant. An objective, easy-to-use, rapid and pollution-free approach is proposed for discriminating *Ephedra* plants of different species, habitats and picking times on the basis of diffuse reflectance Fourier transform near infrared spectroscopy (FT-NIRS) measurements and multivariate analysis. The Fourier transform near infrared diffuse reflectance spectra (NIRDRS) were acquired from 37 pulverized samples of *Ephedra* plants put in glass vials in the near infrared (NIR) region between 10 000 and 4000 cm^{-1}, averaging 64 scans per spectrum at a resolution of 4 cm^{-1}. After spectra processing and data pre-processing, spectral data were analyzed respectively with three multivariate analysis techniques: discriminant analysis (DA), self-organizing map (SOM) and back-propagation artificial neural network (BP-ANN). The proposed method could distinguish not only the *Ephedra* plants of three species and two habitats but also the plants picked at different times of day without special sample treatment and the use of chemical reagents. The performance indexes of the DA model were 84.2–91.9% and the prediction accuracies of both the SOM and the BP-ANN models reached 93.3–100.0%.

1. Introduction

Ephedra plants (Ephedraceae) are widely distributed in the world. Among them, *Ephedra sinica* (*E. sinica*), *Ephedra intermedia* (*E. intermedia*) and *Ephedra equisetina* (*E. equisetina*) are dominant and economically important species in China and their main habitats are in Inner Mongolia, Xinjiang, Shanxi, Gansu and so on. The secondary metabolites contained in *Ephedra* plants mainly include alkaloids, essential oils, tannins, flavonoids and organic acids [1–3]. They are very important for the plants' survivals because they play a significant role in defending against herbivores, microbes, viruses or competing plants [4–6]. The levels and types of plant secondary metabolites represent adaptive characters that have been subject to natural selection during evolution, that is, plant secondary metabolites are primarily decided by the plant species and habitats [2,4,6–8]. In addition, the levels of plant secondary metabolites change with the plants' phenophases and metabolic rhythms [9]. On the other hand, plant secondary metabolites are unique sources for pharmaceuticals, food additives, flavors, and other industrial materials [10,11]. The secondary metabolites of *Ephedra* plants of different species, habitats and picking times are various so that the applications of these plants are divergent [2,12]. For example, *E. sinica* is usually used for extracting (−)-ephedrine and *E. intermedia* for (+)-pseudoephedrine; *E. sinica*, *E. intermedia* and *E. equisetina* have been authorized to be used as herbs in China and Japan [13,14]. Hence, the identification of *Ephedra* plants of different species, habitats and picking times could help the research of phytoecology of *Ephedra* and the utilization of *Ephedra* plants.

The regular approaches to the authentication of *Ephedra* plants of different species and habitats are made with morphological and histological methods [13,14]. However, the application of these methods is seriously limited to practitioners' experience due to the subjectivity and complexity of the methods. Analytical methods such as chemical analysis [13], chromatographic analysis [12–14], and DNA sequence analysis [7] have also been used for these purposes with the disadvantages that are time-consuming and polluting. The discrimination between the plants picked at different times of day is meaningful because it can demonstrate whether the chemical components (especially volatile components, e.g. 4-vinylanisole, a marker compound for *E. sinica*) of the plants are divergent [9,12]. To our knowledge, however, there have not so far been any publications focused on the identification of *Ephedra* plants of different species and habitats with FT-NIRS, and of different times of day.

Near infrared spectroscopy (NIRS) has been proved to be a powerful analytical tool. The chemical and physical information about a sample can be extracted simultaneously from its NIR data by multivariate analysis techniques [15,16]. Compared with the meth-

doi:10.1016/j.talanta.2009.09.018

Table 1
37 samples of *Ephedra* plants from four Chinese habitats.

Species	Habitat	Picking time	Number of samples
E. sinica	Shanxi	10:00–11:30 am	10
	Shanxi	4:30–5:00 pm	6
	Shanxi	Unknown	10
	Inner Mongolia	Unknown	6
E. intermedia	Xinjiang	Unknown	2
	Gansu	Unknown	1
	Inner Mongolia	Unknown	1
E. equisetina	Xinjiang	Unknown	1

ods described above [7,12–14], NIRS possesses many advantages. NIR results are obtained from the measured data, and not from the experience; the operation of NIR analyzer is very easy: the lengthy skill training is unnecessary; the sample preparation is minimal; the analysis time is inherently rapid: the measurement of a spectrum is accomplished within seconds; and chemicals are not used in the analytic process. Moreover, multiple NIR modes mainly including diffuse reflection [17], reflection [18] and transmission [19] have been developed to satisfy various requirements; the remote NIR analysis [20] and in situ NIR analysis [21] have been implemented with optical fiber probes. Particularly, diffuse reflectance NIRS is suitable for the analysis of powders and solids. At present, NIRS technique is widely used in various fields, such as foods [22,23], pharmaceuticals [24], and chemicals [25].

In this contribution, the feasibility of the discrimination of *Ephedra* plants of different species, habitats and picking times is evaluated with diffuse reflectance FT-NIRS. The optimization of the spectral measurement conditions, spectra processing approaches, data pre-processing methods, and data analysis techniques is also discussed.

2. Experimental

2.1. Samples

Whole plants were collected for each sample. A total of 37 samples consisting of *E. sinica*, *E. intermedia* and *E. equisetina* were obtained from four main Chinese habitats Inner Mongolia, Xinjiang, Shanxi and Gansu. Thereinto, 16 samples of *E. sinica* from Shanxi were picked by us between 10:00 and 11:30 am and between 4:30 and 5:00 pm. The details of the sample collection are shown in Table 1.

The samples of *E. sinica*, *E. intermedia* and *E. equisetina* were respectively divided into the calibration and validation samples for the identification of *Ephedra* plants of different species. However, it was unfortunate that there was no sample of *E. equisetina* in the validation samples. The samples of *E. sinica* from Shanxi and Inner Mongolia and the samples of *E. sinica* from Shanxi picked in the morning and afternoon were divided respectively in the same way for the discrimination of *Ephedra* plants of different habitats and picking time sections. The details of the sample utilization are presented in Table 2.

All samples were discriminated with reference to morphological characters. After that, they were put in open vessels and stored at $22 \pm 1\,^{\circ}C$ and $55 \pm 5\%$ RH for a long time until their moisture contents became uniform. The herbaceous stems [13] of each sample were pulverized and separated by a series of sieves into six different portions with the size ranges 20–40 mesh, 40–60 mesh, 60–80 mesh, 80–100 mesh, 100–200 mesh, and 200–300 mesh.

2.2. Near infrared instrument and measurement

The NIRDRS were measured with Antaris II FT-NIR analyzer (Thermo Fisher Scientific, USA), furnished with an indium gallium arsenide (InGaAs) detector and an integrating sphere attachment. The instrument was controlled with RESULT 3.0, a software package accompanying this analyzer.

The pulverized samples of equal size range were poured severally into circular glass vials of the same diameter up to a certain thickness and weight to maintain a uniform bulk density. Subsequently, each circular vial was placed on the circular detection window of the integrating sphere module and the position of the vial was adjusted to keep the bottom of the vial concentric with the detection window.

All the NIRDRS were acquired under the same measurement conditions, i.e. scan region: 10 000–4000 cm^{-1}; number of scans: 64; resolution: 4 cm^{-1}; and sample thickness: 20 mm. The room conditions for the spectral measurement were identical with those for the sample store. The measurement background, the gold-plated inner wall of the integrating sphere, was measured to deduct the interference of water vapor and CO_2 in the air. Each pulverized sample was loaded and was measured five times [26].

2.3. Spectra processing and data pre-processing

Spectral noise is generally reduced by smoothing techniques [15]. Baseline offset and drift can be corrected respectively with the first and second derivatives [15]. In the diffuse reflectance measurement, the light travels various distances because the distribution of sample particles is uneven and the particle sizes are different.

Table 2
Utilization of the samples of *Ephedra* plants.

Discrimination	*Ephedra* plant	Number of calibration samples	Number of validation samples
Species	*E. sinica*	9	3
	E. intermedia	3	1
	E. equisetina	1	0
Habitat	*E. sinica* from Shanxi	21	5
	E. sinica from Inner Mongolia	5	1
Picking time	*E. sinica* from Shanxi picked between 10:00 and 11:30 am	8	2
	E. sinica from Shanxi picked between 4:30 and 5:00 pm	5	1

The scattering effects can be eliminated with multiplicative signal correction (MSC) [27]. Accordingly, six techniques of spectra processing, consisting of absorbance, Savitzky–Golay smoothing, Norris smoothing, first derivative, second derivative, and MSC, were explored for the optimal prediction performance of individual calibration models [28]. Additionally, the segment size taken into account during the smoothing process is an important parameter. The measurement sensitivity is low for the large segment size and the noise is high for the small segment size. Hence, the size was chosen case by case.

The NIRDRS data over the spectral range were used in the analysis. The data sets reached 3112 dimensions. The high dimensional datasets possessed collinearity because some spectral variables had a high correlation with the other ones. To avoid the overfitting problem caused by the collinearity, the data containing redundant information were compressed by dimension reduction before modeling to improve the modeling speed and the model stability.

The spectra processing and data pre-processing were finished in TQ Analyst 8.0 (Thermo Fisher Scientific, USA), a chemometric analysis software.

2.4. Data analysis

The prevailing modeling method for discrimination is DA, which can classify a group of analytes into predefined subgroups based on a set of linear functions of input variables [29]. ANN, involving several non-linear data analysis and modeling tools that can model complex relationships between inputs and outputs, is also used in qualitative analysis. SOM, a type of ANN, is trained by unsupervised learning to map a low-dimensional, typically two-dimensional, representation of the calibration and validation samples. BP-ANN, one of the most popular ANN, minimizes the global error of the system by modifying node weights in the supervised learning procedure [15].

In this investigation, the data analysis was performed respectively with the linear DA and the non-linear ANN, including the SOM trained by unsupervised learning and the BP-ANN trained by supervised learning, to compare prediction performances of the models obtained by various data analysis methods. The two- and three-dimensional maps of the DA can visualize the analytical results of the calibration samples. The ANN of the same architecture was used in the discrimination of *Ephedra* plants of different species, habitats and picking time sections. The two-dimensional distribution maps in the output layer of the SOM (10×10) visually displayed the outcomes of the calibration and validation of the models. The three layer BP-ANN was composed of one input layer with 10 neurons, 1 hidden layer with 10 neurons, and 1 output layer with 1 neuron.

The data analysis was performed using the chemometric analysis software TQ Analyst 8.0 (Thermo Fisher Scientific, USA) for the DA and the mathematical modeling software Matlab 6.5 (The MathWorks, USA) for both the SOM and the BP-ANN.

3. Results and discussion

3.1. Conditions for spectral measurement

The resolution and number of scans are important parameters of NIRDRS measurement. In high-resolution spectral measurement, the data are large, but the noise is high; in low-resolution spectral measurement, the situation is opposite. The resolution of 4 cm^{-1} was adopted for the qualitative analysis after attempting the resolution of 2 cm^{-1}, 4 cm^{-1}, 8 cm^{-1}, 16 cm^{-1}, and 32 cm^{-1}. When the number of scans is increased, the consuming time in the spectral measurement is extended while the noise is counteracted greatly; when the number of scans is decreased, the situation is reversed.

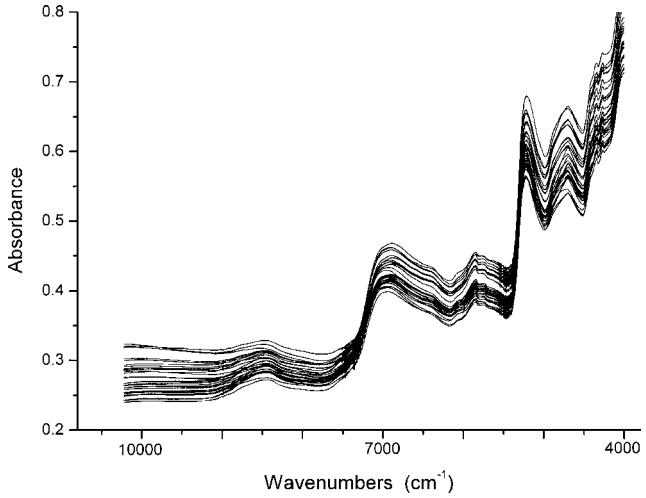

Fig. 1. Raw NIRDRS of 37 samples of *Ephedra* plants.

It was found that the optimal number of scans was 64 from the intercomparison of the numbers 16, 32, 64, and 128.

The sample thickness is one factor influencing NIRDRS. It was noted that the sample absorbance was large and steady once the sample thickness was more than 8 mm by comparing the NIRDRS measured respectively with the thickness of 1 mm, 2 mm, 4 mm, 8 mm, 16 mm, and 20 mm. Finally, the sample thickness of 20 mm was used in the measurement because there was a sign at 20 mm high on the outside surface of the sample vial.

For the same pulverized samples of *Ephedra* plants with different particle sizes, their physical characters are various and their chemical characters may be diverse. It was demonstrated that the optimal size range for the identification was 100–200 mesh based on the prediction performances of the models established respectively by the pulverized samples with different size ranges.

Fig. 1 indicates the raw NIRDRS of 37 samples of *Ephedra* plants.

3.2. Discrimination of Ephedra plants of different species

The NIRDRS of *Ephedra* plants of different species were processed first with smoothing techniques. The five-point Norris smoothing was used in the DA and the seven-point Savitzky–Golay smoothing in the ANN. The methods for subsequent processing were first derivative and MSC. The dimensions of the spectral data were reduced to 9 principle components (PCs) for the DA and to 10 PCs for the ANN. The cumulative contribution rates of 9 and 10 PCs were 98.7% and 99.9% in sequence.

Ephedra plants of different species could be discriminated respectively with the DA, SOM and BP-ANN.

The performance index of the DA model was 84.2%. In Fig. 2, the calibration samples of *Ephedra* plants of three species are logically distributed with the DA in three corresponding spaces, not only two-dimensionally but also three-dimensionally.

The prediction accuracy of the SOM model was 95.0%. Fig. 3 displays the outcomes of the calibration and validation of the SOM model. *E. sinica*, *E. intermedia* and *E. equisetina* are successfully classified in three areas painted with light gray, gray and dark gray. The calibration and validation samples of *Ephedra* plants of three species are expressed by the capitals (A, B and C) and the lowercases (a, b and c), respectively. Although one "b", presenting one validation sample of *E. intermedia*, is located in one light gray block (8,8) describing *E. sinica*, the light gray block is adjacent to two gray blocks (7,8 and 8,9) describing *E. intermedia*.

This small discrimination error can be attributed to the operation error of the NIRDRS measurement and the different sizes of the

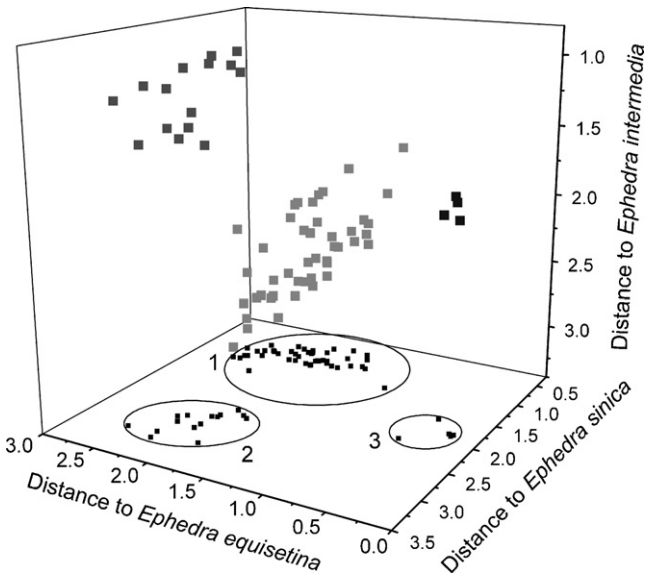

Fig. 2. Projection maps of the DA of the calibration samples of *Ephedra* plants of three species. *E. sinica*, *E. intermedia* and *E. equisetina* are respectively labeled by (1), (2) and (3) in the two-dimensional map, and represented with light gray, gray and dark gray spots in the three-dimensional map.

calibration sample sets of three subgroups, *E. sinica*, *E. intermedia* and *E. equisetina*.

In the NIRDRS measurement, the operations were mostly composed of the loading of the pulverized sample and the laying of the sample vial. The operation error should be taken into account in modeling to avoid erroneous discrimination. In this study, each pulverized sample was loaded and measured five times; all the five spectra were used in the analysis. When the operation error exceeded some scope, however, one out of the five spectra of one calibration sample would be identified mistakenly as one spectrum of another calibration sample in the same subgroup in the modeling. In the analysis of the validation and unknown samples, not only the same discrimination error as described above was existent, but also the spectrum would be identified mistakenly as a spectrum of a sample in another subgroup when the operation error exceeded the scope permitted in the analysis of the calibration samples in the same subgroup.

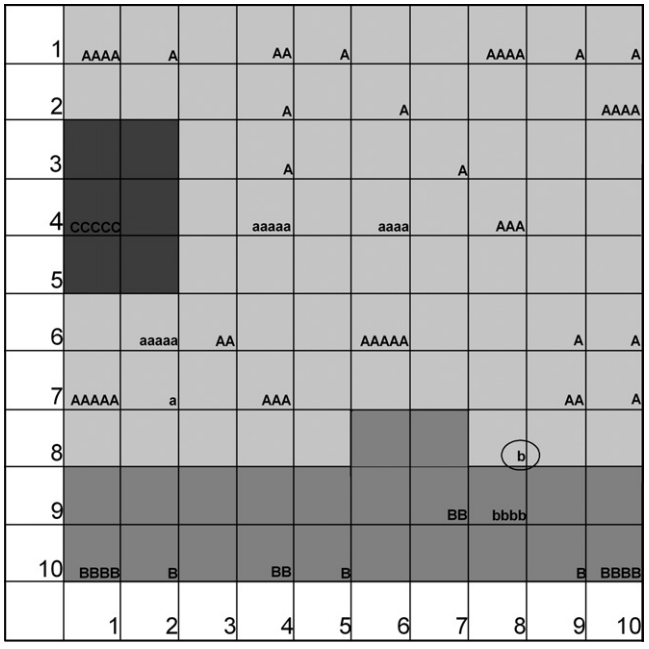

Fig. 3. Two-dimensional distribution map of *Ephedra* plants of three species in the output layer of the SOM (10 × 10): light gray blocks for *E. sinica* (A, a), gray for *E. intermedia* (B, b), and dark gray for *E. equisetina* (C, c); capitals (A, B, C) for calibration samples, and lowercases (a, b, c) for validation samples.

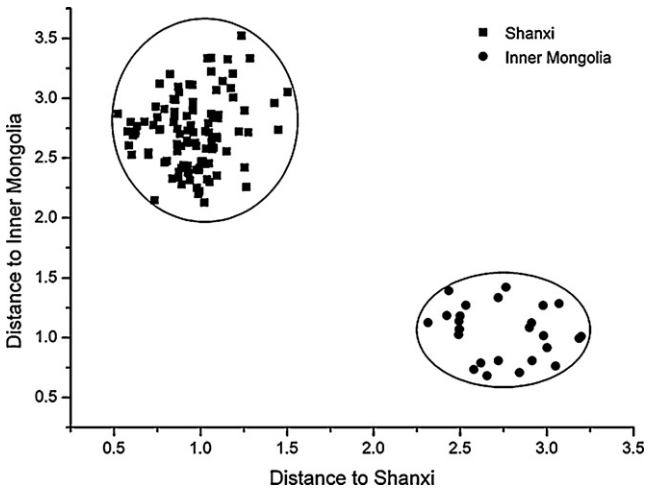

Fig. 4. Two-dimensional projection map of the DA of the calibration samples of *E. sinica* from Shanxi and Inner Mongolia.

Furthermore, the calibration sample set of *E. sinica* was the largest in the three subgroups, that is, the calibration sample set of *E. sinica* had the most diversity. Thus, one sample unused in the modeling would be identified as *E. sinica* most easily.

For the two reasons above, in Fig. 3, there are same letters of different numbers in only one block. The number is small when the variances among the samples and the operation errors are large. There is also one "b" in a light gray block.

The prediction accuracy of the BP-ANN model for the discrimination was 95.0% when the goal error between the training network output and the ideal output was defined as 10^{-5}.

3.3. Discrimination of E. sinica from different habitats

The NIRDRS of the samples of *E. sinica* from different habitats were processed by the five-point Savitzky–Golay smoothing technique and MSC. The dimensions of the spectral data were reduced to 10 PCs and the cumulative contribution rate was 99.8% for the three data analysis methods used.

E. sinica from different habitats could be identified respectively with the DA, SOM and BP-ANN.

The performance index of the DA model was 91.9%. Fig. 4 demonstrates that the DA assigns the calibration samples of *E. sinica* from Shanxi and Inner Mongolia into two separate two-dimensional zones.

The prediction accuracy of the SOM model was 100.0%. In the SOM distribution map (Fig. 5), the calibration and validation samples of *E. sinica* from two habitats are completely separated into two areas, marked respectively by light gray and gray, without any errors.

The prediction accuracy of the BP-ANN model was 100.0% when the goal error between the training network output and the ideal output was defined as 10^{-5}.

3.4. Discrimination of E. sinica from Shanxi picked at different times of day

The techniques of spectra processing and data pre-processing for this task were the same as those used in Section 3.3. Neverthe-

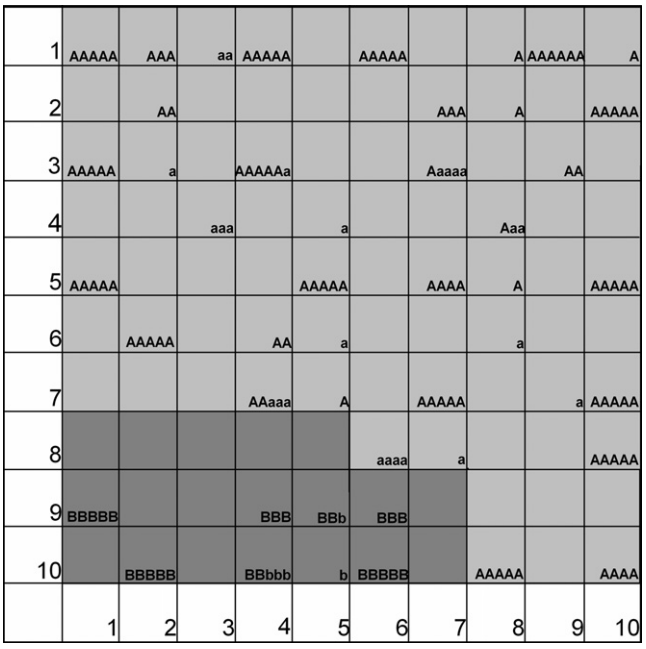

Fig. 5. Two-dimensional distribution map of *E. sinica* from two habitats in the output layer of the SOM (10 × 10): light gray blocks for Shanxi (A, a), and gray for Inner Mongolia (B, b); capitals (A, B) for calibration samples, and lowercases (a, b) for validation samples.

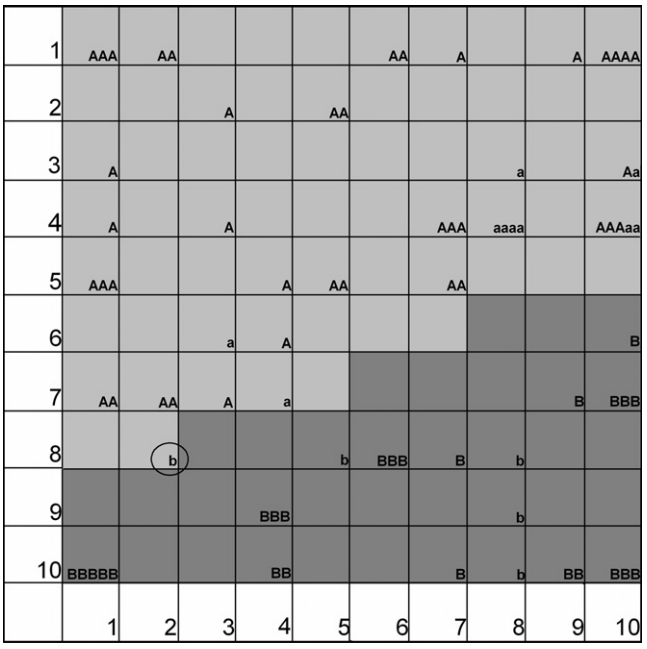

Fig. 7. Two-dimensional distribution map of *E. sinica* from Shanxi picked during two time sections in the output layer of the SOM (10 × 10): light gray blocks for 10:00–11:30 am (A, a), and gray for 4:30–5:00 pm (B, b); capitals (A, B) for calibration samples, and lowercases (a, b) for validation samples.

less, the cumulative contribution rate of 10 PCs was 99.7% for the three data analysis methods.

E. sinica from Shanxi picked at different times of day could be distinguished respectively with the DA, SOM and BP-ANN.

The performance index of the DA model was 88.1%. Fig. 6 describes that the DA reasonably divides the calibration samples of *E. sinica* from Shanxi picked in the morning and afternoon into two separate two-dimensional regions.

The prediction accuracy of the SOM model was 93.3%. The results of the calibration and validation of the SOM model are shown in Fig. 7. *E. sinica* from Shanxi picked during two time sections are readily separated into two areas painted with light gray and gray. The calibration and validation samples picked between 10:00 and 11:30 am and between 4:30 and 5:00 pm are indicated by the capitals (A and B) and the lowercases (a and b), respectively. In despite

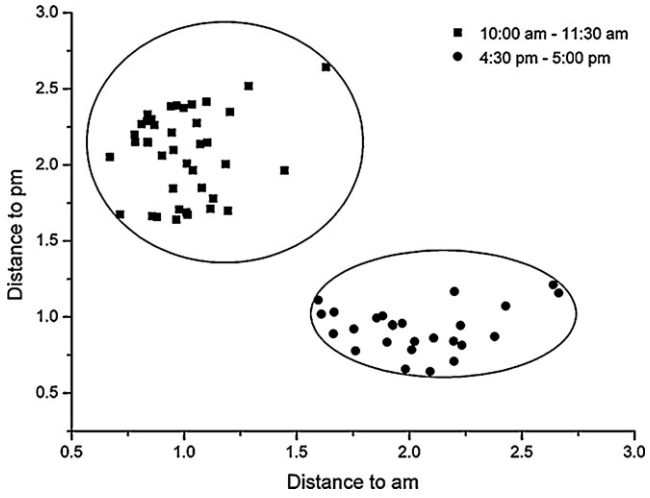

Fig. 6. Two-dimensional projection map of the DA of the calibration samples of *E. sinica* from Shanxi picked between 10:00 and 11:30 am and between 4:30 and 5:00 pm.

of the position of one "b", which describes one validation sample picked in the afternoon, is fixed in one light gray block (2,8) representing the sample picked in the morning, the light gray block is surrounded with two gray blocks (2,9 and 3,8) representing the samples picked in the afternoon. The reasons for the small discrimination error are similar to those in Fig. 3.

The prediction accuracy of the BP-ANN model for this task was 93.3% when the goal error between the training network output and the ideal output was defined as 10^{-5}.

The results obtained in this task suggest that there is significant difference between *E. sinica* picked in the morning and afternoon. This fact implies that the chemical components of *E. sinica* are modulated by time of day.

In all the three tasks, the prediction performances of the three models of the DA, SOM and BP-ANN for the discrimination of *E. sinica* from different habitats are the best. It can be explained by the following reasons. *E. sinica* from two habitats are distinguished more easily than *Ephedra* plants of three species because the exact probability of the discrimination of one sample in a group is larger between few subgroups than many subgroups. *E. sinica* from Shanxi and Inner Mongolia are also distinguished more easily than those from Shanxi picked during two time sections for the difference between the former is larger than the later.

The three multivariate analysis techniques adopted in the investigation are all valid. The best prediction performance and visualization function is achieved with the SOM.

4. Conclusions

The relationships between *Ephedra* plants and the NIRDRS have been established. The experiment has proved that *Ephedra* plants of different species, habitats and picking times can be reliably discriminated by diffuse reflectance FT-NIRS combined with multivariate analysis techniques without special sample treatment and the use of chemicals. The approach established is a useful tool for the research of phytoecology of *Ephedra* and the utilization of *Ephedra* plants. The discrimination between the plants picked in the morn-

ing and afternoon is the most notable because it infers that the chemical components of *E. sinica* are modulated by time of day. The prediction performance and visualization function of the SOM model are the best among the DA, SOM and BP-ANN.

In this experiment, each pulverized sample was loaded and measured repeatedly. All the spectra obtained from the calibration samples were used in the modeling. This strategy can reduce the impacts of the operation error on the identification and improve the prediction performances of the models established because it increases the representative spectra used in the modeling.

ABSTRACT

A fully automated, rapid and highly sensitive HPLC method with automated sample pre-treatment by column-switching system and fluorescence detection has been developed for the trace quantitative determination of the new antidepressant reboxetine (RBX) in human plasma. A simple pre-column derivatization procedure with 7-flouro-4-nitrobenzo-2-oxa-1,3-diazole (NBD-F) reagent was employed. Paroxetine (PXT) was used as an internal standard. Plasma samples containing both RBX and PXT, after filtration, were derivatized by heating with NBD-F in borate buffer of pH 8 at 70 °C for 30 min. The derivatized plasma samples were injected into the HPLC system where an on-line sample clean up was achieved on the pre-treatment column (Co-sense Shim-pack MAYI-ODS) with a washing mobile phase (acetonitrile:2% acetic acid; 40:60, v/v) at a flow rate of 5 mL min^{-1} for 1 min. After an automated on-line column switching to the analytical Hypersil phenyl 120A column (250 mm × 4.6 mm, 5 μm), the separation of the derivatized RBX and PXT was performed using a mobile phase consisting of sodium acetate buffer (pH 3.5):tetrahydrofuran:acetonitrile (55:35:10, v/v/v) at a flow rate of 2.0 mL min^{-1}. The eluted derivatives were monitored by a fluorescence detector set at an excitation wavelength of 470 nm and an emission wavelength of 530 nm. Under the optimum chromatographic conditions, a linear relationship with good correlation coefficient ($r = 0.9995$, $n = 5$) was found between the peak area ratio of RBX to PXT and RBX concentration in the range of 2–500 ng mL^{-1}, with limits of detection and quantification of 0.5 and 1.7 ng mL^{-1}, respectively. The intra- and inter-day precisions were satisfactory; the relative standard deviations were 2.25 and 3.01% for the intra- and inter-day precisions, respectively. The accuracy of the method proved as the mean recovery values were 100.11 ± 2.24% and 100.99 ± 2.98% for the intra- and inter-day assay runs, respectively. The proposed method involved simple and minimum sample preparation procedure and short run-time (<12 min) and therefore it can be applied to the routine therapeutic monitoring and pharmacokinetic studies of RBX.

1. Introduction

Reboxetine (RBX); (RS)-2-[(RS)-α-(2-ethoxyphenoxy) benzyl-morpholine methane sulphonate, was first introduced in 1997 as the first drug of the new selective noradrenalin reuptake inhibitor (SNRI) antidepressant class [1]. It has similar therapeutic potency to tricyclic antidepressants [2,3]. The drug does not affect dopamine or serotonin reuptake, and it has low affinity for adrenergic, cholinergic, histaminergic, dopaminergic and serotonergic receptors [4]. RBX provides an alternative rational for patients resistant to the conventional antidepressants therapy with an advantage of significantly improved adverse effects profile [5,6]. In contrast to certain serotonergic drugs, there is no evidence of any withdrawal syndrome upon sudden discontinuation or tapering of RBX therapy [7]. RBX is also prescribed in the treatment of narcolepsy [8], panic disorders [9], and Parkinson's disease [10]. RBX is rapidly and extensively absorbed following oral administration. The maximum plasma concentration is achieved within 2–2.5 h after a 4 mg oral dose; and it is highly bound (~98%) to plasma proteins mainly α1-acid glycoprotein [11]. It is eliminated mainly via urine with a relatively short elimination half-life (~13 h), therefore it is given twice daily [12].

Most psychiatric patients are usually subjected to simultaneous poly-pharmacotherapy to achieve successful control of the symptoms. Therefore, careful monitoring and subsequent optimization of dosing regimen of potent drugs, such as RBX, in the plasma of the patients are extremely necessary. Because of the small doses of RBX, its concentrations in plasma samples are expected to be quite low [11]. For these reasons, a sensitive, selective, and accessible method is required for quantitative determination of RBX in plasma. Considerable efforts have been made to provide competent analytical techniques for the determination of RBX in plasma.

These techniques include two related gas chromatography with mass detector [13,14], and several HPLC methods with UV or fluorescence [15–21], mass [22,23] and tandem mass [24] detectors. All these methods involved lengthy liquid–liquid or solid-phase extraction for RBX from the plasma samples prior to their analysis. Indeed, these pre-treatment procedures are cumbersome and time-consuming. They will also lead to large amount of errors in the recovery of RBX. Accordingly, these methods do not meet the needs of pharmacokinetic studies, which require an accurate and rapid feedback for the analytical information of pre-clinical and clinical specimens. Moreover, the cost and complexity of the instrumentation of HPLC–MS limited its applications in clinical laboratories.

The present work describes, for the first time, the development of a new automated highly sensitive and accurate HPLC method with fluorescence detection for the determination of RBX in plasma. The method involved a pre-column derivatization with 7-fluoro-4-nitrobenzo-2-oxa-1,3-dizole (NBD-F), and an automated highly efficient on-line pre-treatment procedure by using a bio-sample analysis column-switching system (co-sense for BA) equipped with a Shim-pack MAYI-ODS bio-sample pre-treatment column. The method was successfully applied to the determination of RBX in spiked human plasma samples.

2. Experimental

2.1. Chemicals and materials

Reboxetine (RBX) and 7-flouro-4-nitrobenzo-2-oxa-1,3-diazole (NBD-F) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Paroxetine (PXT) was obtained from SmithKline Beecham Pharmaceuticals (Brentford, England). Human plasma samples were collected from normal healthy volunteers at King Khaled University Hospital (Riyadh, Saudi Arabia), and they were kept frozen at −20 °C until analysis. Acetonitrile, tetrahydrofuran and all the other solvents were of HPLC grade (Merck, Darmstadt, Germany). All other materials were of analytical grade.

2.2. Preparation of stock solutions

2.2.1. Reboxetine (RBX) and paroxetine (PXT) standard solutions

An accurately weighed amount (10 mg) of each of RBX and PXT was quantitatively transferred into a 10-mL volumetric flask, dissolved in distilled water, and completed to volume with the same solvent to produce stock solutions of 1 mg mL^{-1}. The stock solutions were further diluted with water to obtain working standard solutions containing 2000 ng mL^{-1} and 400 ng mL^{-1} for RBX and PXT, respectively.

2.2.2. 7-Fluoro-4-nitrobenzo-2-oxa-1,3-diazole (NBD-F) derivatizing reagent

An accurately weighed amount (5 mg) of NBD-F was transferred into a 10-mL volumetric flask, dissolved in 10 mL acetonitrile, completed to volume with the same solvent to produce a stock solution of 0.05% (w/v). The solution was freshly prepared and protected from light during use.

2.2.3. Borate buffer solution

Weighed amounts of boric acid (0.62 g) and potassium chloride (0.75 g) were dissolved in 100 mL distilled water. A volume of 4.0 mL of 0.2 mol L^{-1} NaOH and 40 mL of ethanol were added and the mixture was diluted to 200 mL with distilled water. The pH of the solution was adjusted to 8 ± 0.1 by a calibrated pH-meter (Microprocessor pH meter BT-500, Boeco, Germany).

2.3. Chromatographic system

HPLC apparatus consisted of a Shimadzu system (Shimadzu Corporation, Kyoto, Japan) equipped with two solvent delivery systems (LC-20AD VP) with FCV-12AH high-pressure flow channel changeover valve, DGU-20AS on-line degasser, SIL-20A auto-sampler, co-sense BA LC system, CTO-20A column oven, SPD-20A UV–vis detector, SPD-M20A photodiode-array detector, RF-10A XL fluorescence detector, and CBM-20A system controller. The pre-treatment column was a Shim-pack MAY1-ODS (10 mm length × 4.6 mm i.d., 12 nm pore diameter, and 50 μm particle diameter). The chromatographic separations were performed on an analytical column Hypersil 120A (250 mm length × 4.6 mm i.d., 5 μm particle diameter) manufactured by Phenomenex (USA). The column temperature was kept constant at 25 ± 2 °C. Separations were performed in isocratic mode. The pre-treatment mobile phase consisted of acetonitrile:2% acetic acid (40:60, v/v) pumped for 1 min at a flow rate of 5 mL min^{-1}. The analytical mobile phase used for the separation consisted of 10 mmol L^{-1} sodium acetate buffer (pH 3.5):tetrahydrofuran:acetonitrile (55:35:10, v/v/v) pumped at flow rate of 2.0 mL min^{-1}. The mobile phases were filtered by a Millipore vacuum filteration system equipped with a 0.45 μm pore size filter, degassed by ultrasonication, and further by passing through the DGU-20AS on-line degasser. The samples (50 μL each) were injected by the aid of the auto-sampler. The fluorescence detector was set at 470 nm as an excitation wavelength and 530 nm as an emission wavelength. The system control and data acquisition were performed by Shimadzu "LC solution" software (Shimadzu Corporation, Kyoto, Japan). The ratio of peak area of RBX to that of the internal standard (paroxetine; PXT) was used for the quantitation.

2.4. Sample preparation, derivatization and quantitation

The stock solutions of RBX and PXT were brought to room temperature, and working stock solutions of RBX (2000 ng mL^{-1}) and PXT (400 ng mL^{-1}) were prepared. The calibration standard samples were prepared by spiking blank human plasma with RBX to yield concentrations of 0, 2, 5, 10, 20, 50, 100, and 500 ng mL^{-1}. The spiked plasma sample was filtered through a 0.45 μm pore size Millipore filter or mixed with an equal volume of acetonitrile, vortexed for 30 s, and centrifuged for 20 min at 13,000 rpm by Biofuge Pico centrifuge (Heraeus Instruments, Germany). A 500 μL of the filterate (or the supernatant solution) was transferred into a screw-capped reaction tube using a micropipette followed by 200 μL of the working solutions of the internal standard (PXT), 1000 μL of the borate buffer solution, and 200 μL of the NBD-F solution. The tube was capped, swirled, and left to stand in a thermostatically controlled water-bath (MLW type, Memmert GmbH, Co. Schwa Bach, Germany) at 70 °C for 30 min. After cooling the tube rapidly to room temperature, a volume of 100 μL of HCl was added, mixed, and 50 μL of the resulting solution was injected into the HPLC system with the aid of the auto-sampler. The calibration curve was constructed by plotting the peak area ratio of RBX to PXT versus the concentration of RBX. The data were analyzed by least square regression and the intercept, slope, and correlation coefficient were calculated. The linear regression equation was used for calculating the concentrations of RBX in the spiked plasma samples based on their peak area ratios.

3. Results and discussion

3.1. Design and strategy for the method development

Reboxetine molecule contains weak chromophoric activity, and does not have a native fluorescence, therefore the determination

of its low concentrations in plasma by HPLC using UV or fluorescence detectors was not possible without pre-derivatization. The previously reported HPLC methods for the determination of RBX after its pre-derivatization suffered from inadequate sensitivity, and the multiple tedious liquid–liquid or solid-phase extraction procedures. The use of MS and/or MS–MS detectors overcome the sensitivity problem, however no doubt the sensitivity achieved by these expensive detectors did not compensate their high cost, and instrumental complexity. For these reasons, the present work was directed towards the development of a new highly sensitive HPLC method employing a non-extractive automated pre-treatment procedure with column-switching system.

In our previous studies [25,26], we described non-extractive pre-treatment procedures prior to HPLC analysis of some therapeutic amines in plasma samples after pre-column derivatization with the 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD-Cl), the chloro analogue of NBD-F. The methods offered adequate sensitivity, however the rapid elution of massive amounts of derivatized polar biogenic amines was problematic, as special care was necessary to achieve good resolution between the peaks of the analytes and those of the derivatized plasma endogenous amines. Therefore, the present study was devoted to overcome such problems by using a special configuration setup composed of a co-sense system equipped with a pre-treatment Shim-pack MAYI-ODS column. The Shim-pack MAYI-ODS column is an inner surface type reversed-phase packing material [27–30]. As well, it has the ability to trap the low molecular weight compounds like most of the drugs while allowing the high molecular size plasma proteins to be washed out to the waste by size exclusion mechanism.

RBX doses are small, thus its concentrations in plasma are expected to be very low, and consequently highly fluorogenic derivatizing reagent was required prior to its fluorescence-based HPLC analysis. RBX contains a piprazinyl NH group, which was proved to react with NBD-Cl giving a fluorescent aduct [26]. However, NBD-F is known to be several times more reactive than NBD-Cl. Therefore, the present study was devoted to investigate NBD-F as a derivatizing reagent for RBX. The preliminary investigations in this study revealed the high reactivity of RBX with NBD-F, and the produced RBX-NBD derivative was found to be highly fluorescent, and exhibited its highest fluorescence intensity at 530 nm after excitation at 470 nm. For these reasons, it is anticipated that the employment of NBD-F as a derivatizing reagent for RBX (for the first time in this study) would lead to the development of highly sensitive assay. Fig. 1 presents the scheme of the reaction of both RBX and PXT (internal standard) with NBD-F.

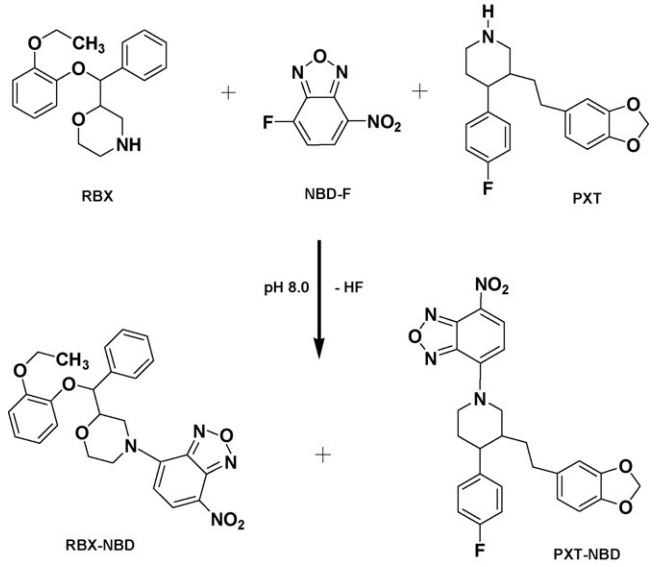

Fig. 1. A scheme for the reaction of RBX and PXT with NBD-F.

3.2. Optimization of the derivatization reaction conditions

The different experimental conditions (concentration of NBD-F, pH of the reaction medium, reaction time, and temperature) affecting the derivatization reaction were thoroughly investigated. The experiments were initiated with studying the effect of the NBD-F reagent concentration. Owing to the presence of labile fluoride in the chemical structure of NBD-F, a daily fresh solution is recommended. In order to select the optimum NBD-F concentration, the reaction was carried out using varying concentrations (0.01–1%, w/v) of NBD-F reagent. The maximum detector signal was obtained when the concentration of NBD-F reagent was 0.05% (w/v), therefore this concentration was used in all the subsequent experiments. The reaction was found to proceed satisfactorily in 0.1 mol L^{-1} borate buffer of pH 8.0 ± 0.1. The reaction was found to go to completion by heating the solution for 30 min in a water-bath at 70 °C. Under these conditions, significantly high background fluorescence was observed. This was attributed to the hydrolysis of NBD-F to the corresponding hydroxy derivative namely, 7-hydroxy-4-nitrobenzo-2-oxa-1,3-diazole (NBD-OH). This background fluorescence of NBD-OH was fortunately found to be quenched by decreasing the pH of the reaction medium to less than one [31]. Therefore, acidification of the reaction mixture by adding 100 μL of HCl prior to the injection into the HPLC system was necessary. This remarkably decreased the background signal without affecting the reaction product, thus increased the sensitivity. The stability of the derivatized RBX was investigated by repeated injections from the same reaction mixtures at different time intervals over a period of forty-eight hrs. No significant variation in the peak area values was observed, indicating the stability of RBX-NBD for at least 2 days at room temperature.

3.3. Optimization of chromatographic system

3.3.1. Pre-treatment phase

The outer surface of the packing material (silica gel) of the pre-treatment column (Shim-pack MAYI-ODS) is coated with a water-soluble polymer. The inner surfaces of the silica pores are chemically bonded with octadecylsilane (ODS) groups. Therefore, the column is an internal reversed-phase with a hydrophilic polymer coating, constructed as shown in Fig. 2A. Proteins and other macromolecules are blocked by the hydrophilic polymer coating and cannot enter the micropores. Instead, they pass out of the pre-treatment column through the particles and directly to the waste. On the other hand, the small RBX molecules penetrate into the micropores, where they are trapped in the stationary phase. Consequently, the column selectively excludes macromolecules such as proteins. In the conventional HPLC procedures, such proteins are eliminated before the analysis by adding a protein-precipitating reagent (e.g., organic solvent or acid) followed by the separation of the proteins by centrifugation. As well, solid-phase or liquid–liquid extraction procedures for small analytes may also be necessary. This manual process complicates the operations and may lower the analysis accuracy, therefore an automatic deproteinization process is desirable. In the system described herein, the pre-filtered derivatized plasma was directly injected into the system, transported by the pre-treatment mobile phase to the Shim-pack MAYI-ODS pre-treatment column where the free or derivatized endogenous plasma proteins are washed out. In general, the pre-treatment process usually increases the overall analysis time depending on the length of time selected for washing. In the present study, washing time of 2 min at a flow rate of 2.5 mL min^{-1} or 1 min at a

flow rate of 5 mL min^{-1} was similarly adequate, and accordingly the later settings were selected before the column-switching to the analytical column. The 50-μm silica gel based particles keep the maximum operating pressure inside the pre-treatment column as low as 20 MPa, ensuring high durability. This is advantageous against pressure fluctuations due to flow-path switching or gradient analysis. In the present study, the pressure was approximately 8 MPa when the flow rate of the pre-treatment mobile phase was 5 mL min^{-1}.

3.3.2. Analytical phase

After the pre-selected period of washing, the high-pressure flow channel selection valve is rearranged in a way that the analytical mobile phase passes through the pre-treatment column in the reverse direction thus pushing the derivatized RBX, trapped in the Shim-pack MAYI-ODS column, into the analytical column for separation and subsequent detection. This is shown in Fig. 2B. The isocratic separation of RBX and PTX (IS) was investigated by changing the composition of the mobile phase. Several experiments have shown that the employment of an appropriate ratio of sodium acetate buffer solution in organic solvent (acetonitrile) improved the shape and the resolution of the chromatographic peaks. Different ratios of sodium acetate and organic solvents in the mobile phase were tested. Good separation was achieved when the ratio of aqueous sodium acetate:acetonitrile was 55:45% (v/v). Better separations were achieved when acetonitrile was gradually replaced by tetrahydrofuran, and the best separation was achieved when the mobile phase composed of sodium acetate:tetrahydrofuran:acetonitrile (55:35:10, v/v/v), and the flow rate was 2 mL min^{-1}. It was found that the shape and symmetry of the chromatographic peaks of both RBX and PXT were affected by the concentration and pH of the sodium acetate buffer, and the best results were obtained when the concentration was 10 mmol L^{-1}, adjusted to pH 3.5 with acetic acid. Different analytical columns were tested; these columns were reversed-phase C18, amino-, cyano-, and phenyl-columns. The best results were achieved when phenyl column (with the specifications given in Section 2) was used. The obtained chromatographic parameters and performance data for RBX and PXT are presented in Table 1. Experiments conducted without pre-treatment (i.e., using non-co-sense mode) resulted in poor quality chromatograms with high background signal from the derivatizing reagent. More important finding is the appearance of interfering peaks from plasma endogenous amines just prior to and after the RBX peak (Fig. 3A). Under the same chromatographic conditions, the use of co-sense mode resulted in symmetrical and well-resolved peaks (Fig. 3B). The run-time was less than 12 min, with retention times of 7.6 and 9.4 min for RBX and PXT, respectively. The small increase noticed in the retention times in the later case is of course due the pre-selected washing time.

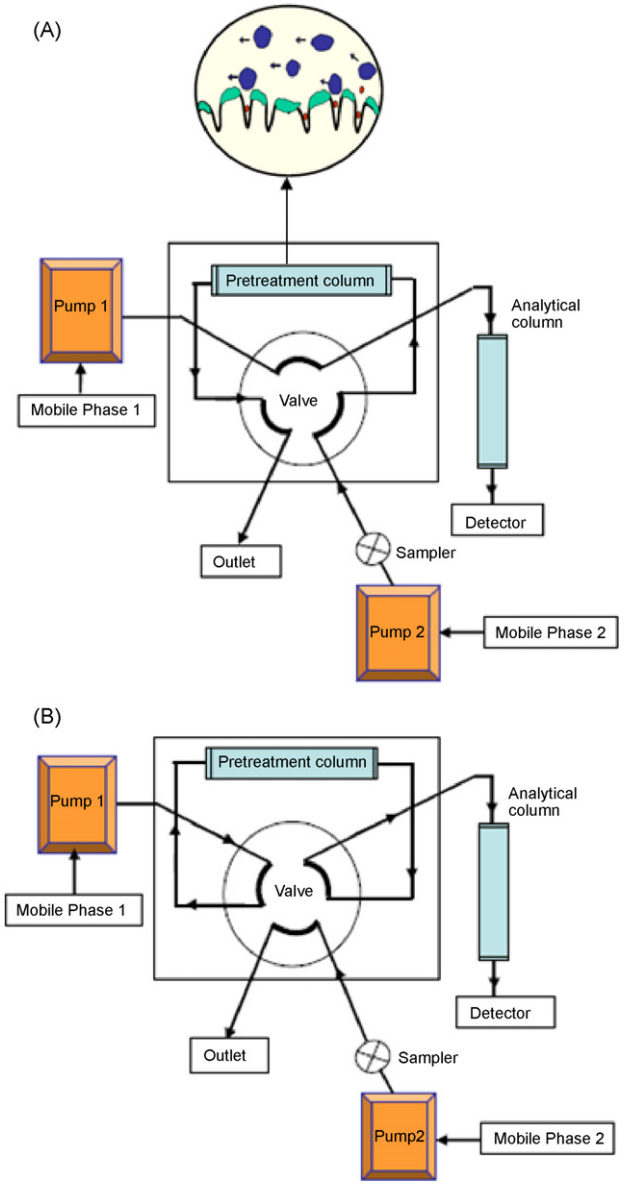

Fig. 2. Washing (A) and analytical (B) phases of the proposed HPLC method. Panel (A) shows a flow diagram for the co-sense system before column switching; pathways of the analytical and washing mobile phases are separated. The washing mobile phase takes the sample from the auto-sampler through the pre-treatment column to the waste. Panel (B) shows a flow diagram for the system after column switching; the analytical mobile phase takes the trapped drugs from the pre-treatment column, in the reverse direction, to the analytical column. Mobile phase 1 is the analytical mobile phase, while mobile phase 2 is the washing mobile phase: ( ) protein; ( ) drug; ( ) water-soluble polymer; ( ) ODS layer.

Table 1
Chromatographic parameters and performance data of the proposed HPLC method for determination of RBX in plasma.

Parameter	Value
Retention time for RBX (min)	7.6
Retention time for PXT (min)	9.4
Capacity factor (k') for RBX	3.44
Resolution between RBX and PXT peaks	3.16
RBX peak asymmetry factor at 10% peak height	1.28
Number of theoretical plates (N)	2602
Height equivalent to theoretical plate (μm)	96
Correlation coefficient	0.9995
Slope (b)±SD	0.0264 ± 0.0003
Intercept (a)±SD	0.0044 ± 0.007
Linearity range (ng mL^{-1})	2–500
LOD (ng mL^{-1})	0.5
LOQ (ng mL^{-1})	1.7

3.4. Validation of the method

3.4.1. Selectivity, linearity, and sensitivity

The selectivity of the method was evaluated by conducting the experiments using batches of blank human plasma to identify the peaks due to the unreacted reagent and the derivatized biogenic plasma components. The typical chromatograms obtained from using the blank plasma spiked with 8 ng mL^{-1} of internal standard (PXT) and plasma spiked with the same concentration of PXT together with RBX (2 and 20 ng mL^{-1}) analyzed without pre-treatment by the co-sense system are given in Fig. 3A. The same

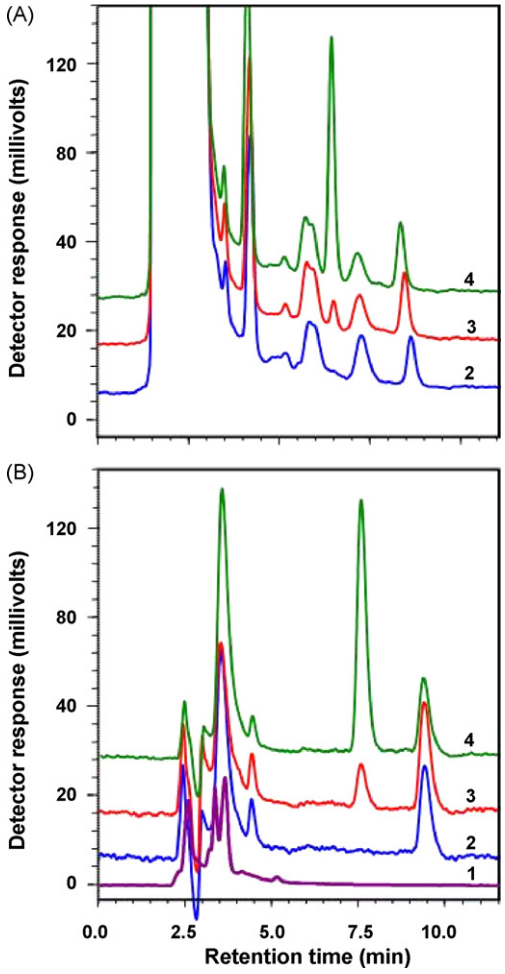

Fig. 3. Typical chromatograms obtained without the use of co-sense mode (A), and those obtained using the co-sense mode (B). Chromtaograms of unspiked blank plasma (chromatogram 1); chromtaograms of plasma spiked with the internal standard PXT, 8 ng mL^{-1} (chromatogram 2); plasma sample spiked with PXT, 8 ng mL^{-1} and RBX, 2 ng mL^{-1} (chromatogram 3) and plasma sample spiked with PXT, 8 ng mL^{-1} and RBX, 20 ng mL^{-1} (chromatogram 4).

experiments in addition to an unspiked blank plasma sample were repeated using the proposed method with employment of the on-line pre-treatment co-sense system; the chromatograms are given in Fig. 3B. Obviously, with employment of the co-sense system in the second case, complete separation of RBX and PXT peaks from those due to the reagent and endogenous plasma constituents was achieved. These results confirm the efficiency of the co-sense system in the pre-treatment of plasma samples.

Under the optimized conditions, linear relationship with good correlation coefficient ($r = 0.9995$, $n = 5$) was found between the peak area ratio of RBX to PXT versus RBX concentration in the range of 2–500 ng mL^{-1}. The regression equation of the calibration curve obtained was $Y = 0.0044 \pm 0.007 + 0.0264 \pm 0.0003X$; where X and Y are the RBX concentration and detector signal, respectively. The limit of detection (LOD) and limit of quantification (LOQ) were calculated according to the ICH guidelines for the validation of analytical procedure [32]. The calculation was based on the standard deviation of the intercept and the slope of the calibration curve using the formula: LOD or LOQ = $\kappa\sigma/S$, where $\kappa = 3.3$ for LOD and 10 for LOQ, σ is the standard deviation of the intercept, and S is the slope of the calibration curve. LOD and LOQ were found to be 0.5 and 1.7 ng mL^{-1}, respectively. These small values of LOD and LOQ confirmed the high sensitivity of the proposed method.

3.4.2. Precision and accuracy

Intra-day precisions were studied at three concentration levels (2, 50, and 100 ng mL^{-1}) of RBX and 40 ng mL^{-1} of PXT (IS). Repeated aliquots were prepared for each concentration level. The spiked plasma samples were derivatized according to the general procedure and analyzed by the proposed method. The mean recovery value was found to be 99.76% with RSD of 0.45%. The inter-day precision was carried out on three RBX concentration levels (5, 100 and 500 ng mL^{-1}) and 40 ng mL^{-1} of PXT on 4 different days. The mean recovery value was found to be 98.36% with RSD of 1.44%. Obviously, the small values of RSD confirmed the high precision of the proposed method.

Similarly, the accuracy of the proposed method was determined by the recovery studies of RBX from plasma samples spiked with different concentrations of RBX covering the linear range of the method; all samples were spiked with 40 ng mL^{-1} of PXT (IS). The samples were subjected to the analysis by the proposed method within a single day (intra-day) and on 4 different days (inter-day). The ratios of RBX peak area to PXT peak area versus the concentration of RBX were then interpolated from the linear regression equation. The recovery values (presented as percentages) were calculated using the formula: calculated experimental concentration/nominal concentration $\times$ 100. The mean recovery values were found to be $100.11 \pm 2.24\%$ and $100.99 \pm 2.98\%$ from intra-day and inter-day analysis, respectively, indicating the accuracy of the proposed method (Table 2).

3.4.3. Robustness and ruggedness

In order to measure the extent of the method robustness, some of the critical reaction conditions as well as the chromatographic parameters were changed while keeping the other parameters unchanged. The changes made were within the range of 1–10% of the optimum recommended conditions. The studied parameters included the pH of the reaction medium, the temperature and time of the derivatization reaction, the composition of the mobile phase, percentage of tetrahydrofuran and acetonitrile, concentration and pH of sodium acetate buffer. The chromatographic profile including capacity factor (k'), retention time (Rt), peak symmetry, resolution and column efficiency was calculated and compared to those of the system suitability (Table 1). The results revealed that the method was robust for these small changes and the results were not significantly different.

The ruggedness of the method was evaluated by applying the recommended analytical procedures on the same HPLC system (independently on different days) on the analysis of series of spiked plasma samples. The results obtained were comparable indicating the ruggedness of the method.

3.4.4. Sample carry-over

Sample carry-over is a major problem, which may significantly affect the accuracy and precision of different HPLC methods for bioanalysis. It is usually caused by the residual analyte from a sample analyzed earlier in the analysis run. It does not necessarily involve only the next sample in the sequence but it can affect several samples analyzed later on a sequence. Carry-over from analyte residues can occur via dislodgment from a sample's flow-path (including injection loops, auto-sampler needles and seals, switching valves, connection tubings, and columns) through a chromatographic system. Adsorption of basic and hydrophobic compounds to the sampling needles and rotor seals of the auto-samplers may also be another cause of carry-over problems. The effect is more likely to be in the systems involving pre-treatment for the sample and subsequent column-switching. In such systems, the mobile phase used to flush the sample from the sample loop into the pre-treatment column is usually polar and poor in organic solvent. This is necessary to help washing out the plasma constituents while the drug

Table 2
Intra-day and inter-day recovery of RBX from spiked human plasma.

Intra-day			Inter-day		
Added conc. (ng mL^{-1})	Measured conc. (ng mL^{-1})	Recovery (%)	Added conc. (ng mL^{-1})	Measured conc. (ng mL^{-1})	Recovery (%)
2	2.08	104.14	2	2.08	104.14
5	4.86	97.23	5	4.86	97.23
10	10.02	100.2	20	21.10	105.50
50	49.57	99.14	50	50.60	101.20
100	100.01	100.01	100	97.5	97.50
			500	501.8	100.36
	Mean ± SD	100.11 ± 2.25		Mean ± SD	100.99 ± 3.01

molecules are retained in the pre-treatment column. When the column switching occurs, the retained compounds are flushed into the analytical column by the aid of the analytical mobile phase. The problem arises because such pre-treatment mobile phases, poor in organic solvents, are not suitable enough to completely wash the whole quantity of many compounds, specially the hydrophobic ones, into the pre-treatment column. Consequently, some significant amounts may remain adsorbed onto different parts of the sample flow-path.

In the present study, this carry-over problem was satisfactorily solved in two ways. First, the auto-sampler used during the analysis was of type Sil-20A (Shimadzu, Japan), which includes a specially treated outer needle surface with improved needle seal composition which prevents adsorption of the samples to the auto-sampler parts [33]. Secondly, the mobile phase used for the pre-treatment was very rich in organic solvent (composed of 40% (v/v) of acetonitrile in 2% acetic acid). It was necessary to use such mobile phase composition in order to ensure the washing out of the relatively nonpolar derivatives formed between the excess NBD-F reagent and the plasma constituents during the derivatization reaction. This shortened the time required for the pre-treatment phase to only 1 min at a flow rate of 5 mL min^{-1}. At the same time, it positively added to the degree of elimination of the carry-over problems, which was practically observed during this study.

4. Conclusion

A highly sensitive HPLC method with fluorescence detection has been developed for the determination of RBX in plasma samples. The method employed non-extractive automated "co-sense" for sample pre-treatment, and mild derivatization conditions for RBX with the highly reactive fluorogenic reagent NBD-F. The outstanding feature of using such system is the no need for the extraction of RBX from the plasma and no need to use a guard column to protect the analytical column against the huge amount of plasma proteins. As well, the run-time was short (<12 min). These qualities added the property of the high throughput to the method. The analytical results demonstrated that the proposed method is suitable for the accurate quantification of RBX in human plasma. The performance of the method makes it valuable for the combined pharmacokinetic studies and bioavailability evaluation of RBX in human subjects after oral administration of the therapeutic doses.

ABSTRACT

Interest in tungsten occurrence and geochemistry is increasing due to increased use of tungsten compounds and its unknown biochemical effects. Tungsten has a complex geochemistry, existing in most environmental matrices as the soluble and mobile tungstate anion, as well as poly- and heteropolytungstates. Because the geochemistry of tungsten is substantially different than most trace metals, including the formation of insoluble species under acidic conditions, it is not extracted from soil matrices using standard acid digestion procedures. Therefore, the current work describes a modification to a commonly used acid digestion procedure to facilitate quantification of tungsten in soil matrices. Traditional soil digestion procedures, using nitric and hydrochloric acids with hydrogen peroxide yield <1 up to 50% recovery on soil matrix spike samples, whereas the modified method reported here, which includes the addition of phosphoric acid, yields spike recoveries in the 76–98% range. Comparison of the standard and modified digestion procedures on National Institute of Standards and Technology Standard Reference Materials yielded significantly improved tungsten recoveries for the phosphoric acid modified method. The modified method also produces comparable results for other acid extractable metals as the standard methods, and therefore can be used simultaneously for tungsten and other metals of interest.

Published by Elsevier B.V.

1. Introduction

Recently, interest in tungsten geochemistry and occurrence in groundwater has increased due to specific human toxicological events, related to local natural deposits of tungsten ore [1–3]. Additionally, industrial (e.g. tungsten carbide tools), mining, civilian recreational (e.g. lead shotshell replacement), and military (e.g. kinetic penetrators and small arms ammunition) activities are potential sources of tungsten in the environment [2–4]. Tungsten metal is not found in nature, but oxyanion species of tungsten are found in a variety of minerals, which can dissolve to yield the thermodynamically stable tungstate in most environmental matrices [2–4]. The chemistry of tungstate is not limited to the soluble monomeric species, as polymerization with other common oxyanions, such as molybdate, phosphate, and silicate, can yield a plethora of ill-defined poly-species with variable biogeochemical properties [3,5–7]. Because of the complex speciation of tungsten, particularly the anionic nature, it does not behave as traditional cationic metals in soils [3,6]. Tungsten sorption to soil has been studied, and tungsten species have been shown to be more mobile under alkaline conditions, similar to other anionic compounds, such as arsenic [8–11].

One of the most fundamental pieces of information needed to investigate geochemistry of metals in the environment is quantitation of the amount of the metal present, or at least the fraction of that metal that could become 'environmentally relevant' [12]. However, due to the complex chemistry of tungsten, traditional acid digestion techniques do not extract tungsten from soil that could become mobile under normal environmental conditions, primarily due to the precipitation of insoluble tungstates or the polymerization of tungstates onto soil particles [6,11,13].

Traditional acid digestion techniques often use nitric and hydrochloric acids, usually with hydrogen peroxide, to solubilize metals for analysis by inductively coupled plasma atomic emission spectroscopy or inductively coupled plasma mass spectrometry (ICP-AES and ICP-MS) [12]. Due to the precipitation of insoluble species, low extraction efficiencies and matrix spike recoveries are observed for tungsten using these procedures [13]. Total dissolution procedures are also reported which can dissolve the entire sample matrix, yet usually involve hydrofluoric acid or other complex and potentially hazardous acid cocktails, and require specialized digestion and analytical equipment (e.g. fluoropolymer vessels and sample introduction systems) [14–16].

Some researchers have also investigated the use of alkaline extractions, however, these procedures often do not extract all tungsten species with equal effectiveness, and do not work well for simultaneous extraction of other metals, necessitating at least two digestions/analyses be performed for a complete metals characterization [13,14,17]. Furthermore, alkaline digestion is more

effective with sodium versus ammonium hydroxide, which can lead to plasma instabilities and interferences necessitating sample dilution which raises analyte reporting limits [14,17].

The modified procedure described in the current work capitalizes on tungsten's ability to polymerize with oxyanion acids, particularly phosphoric acid, to yield acid soluble tungsten species for measurement by ICP-AES or ICP-MS, while simultaneously allowing determination of other metals extracted during the digestion procedure. The modification involves the addition of phosphoric acid to a standard nitric acid and hydrogen peroxide digestion procedure to promote tungsten solublization [12–14]. The phosphoric acid modified procedure was tested on standard reference materials and test field soils. Results were compared for tungsten and other metals routinely measured by ICP-AES following acid digestion. Tungsten recoveries are greatly improved using the modified procedure, with only minor differences observed for some metals between the modified and standard digestion procedures.

2. Experimental

2.1. Reagents

All chemicals used were of trace metal grade purity and used without further purification; the deionized (DI) water used had a resistivity of 18.3 MΩ cm. Trace metal grade nitric acid, hydrochloric acid, phosphoric acid, and hydrogen peroxide were purchased from Fisher Scientific (Pittsburg, PA) and used as received. Single element and mixed analyte standards for tungsten and other metals were purchased from SPEX CertiPrep (Metuchen, NJ) and CPI (Santa Rosa, CA).

2.2. Soil sample preparation

Standard reference soil materials (SRM 2709 and 2710) were purchased from the National Institute of Standards and Technology (NIST), and used as received. A tungsten-spiked soil was formed by mixing a Grenada Loring soil (GL) with metallic tungsten (<1 μm particles). The soil was aged approximately 3 years to oxidize the metallic tungsten. The silty loam soil of the Grenada Loring series (Alfilsols order) was collected from the Brown Loam Experimental Station, Learned, MS. The use of this soil in other geochemical investigations of tungsten has been previously described [10,11,18]. Finally, field soil 1 (FS-1), and field soil 2 (FS-2) were collected from training ranges where tungsten munitions have been previously used [19]. The soils were collected in bulk, mixed, and sieved (<1 cm) to remove plant debris and rocks. FS-1 is an iron-rich clay and FS-2 is a sandy soil. The three test soils were air-dried, ground with a mortar and pestle, and sieved through a #40 ASTM sieve to improve sample homogeneity similar to the NIST reference soils [20].

2.3. Digestion procedures

Three digestion procedures were compared for the present work, two published versions of US EPA method 3050B [12], and a third modified from the standard procedures by adding phosphoric acid to the acid cocktail, as described below and outlined in Table 1. All acid digestions were conducted on a DigiPrep hotblock digestion system (SCP Science, Champlain, NY), using fluoropolymer digestion vessels to prevent tungsten polymerization onto borosilicate glass vessel walls. Each digestion batch included a matrix blank, blank spike, and NIST standard reference soils, as well as the three test soils (GL, FS-1, FS-2), digested in triplicate.

2.3.1. Nitric acid digestion

The first procedure follows the US EPA method 3050B nitric acid and hydrogen peroxide digestion protocol [12]. Briefly, one half gram of dried, ground, and sieved soil was placed in a fluoropolymer digestion vessel, to which 5 mL of 1:1 nitric acid:DI water was added and the mixture heated at 95 °C for 30 min. Then, 4 sequential additions of 2.5 mL of concentrated nitric acid were added, with 30 min of heating between each acid addition. After the final nitric acid addition, the mixture was heated for 2 h. The samples were allowed to cool to room temperature before 3 mL of 30% hydrogen peroxide was added, followed by heating for 15 min. Finally, 2 mL of hydrogen peroxide were added, and the mixture heated for an additional 2 h. Five milliliters of hydrogen peroxide was generally sufficient for complete reaction with the samples tested, although more can be added as needed for other soil matrices. The digestate was then cooled to room temperature and filtered through a Whatman #40 filter and diluted to 50 mL with 1% nitric acid.

2.3.2. Nitric and hydrochloric acids digestion

The second digestion procedure also follows USEPA 3050B where hydrochloric acid is added to increase the solubility of certain elements for ICP-AES determination [12]. A second 0.5 g aliquot of each of the solid samples was weighed into fluoropolymer vessels and digested following the above described procedure, except that after the second 2 h heating period, 5 mL of concentrated hydrochloric acid was added to the digestion vessel with a final 15 min of heating. After cooling, the digestates were filtered and diluted to volume as described above.

Table 1
Procedures for the three acid digestions compared in the current work.

	Nitric acid	Nitric–hydrochloric acids	Phosphoric–nitric acids
Sample mass and digestion vessel	0.5 g in PTFE vessels	0.5 g in PTFE vessels	0.5 g in PTFE vessels
1st acid addition	5 mL of 1:1 nitric acid	5 mL of 1:1 nitric acid	5 mL 1:1 nitric acid + 1 mL concentrated phosphoric acid
Heating	30 min at 95 °C	30 min at 95 °C	30 min at 95 °C
Acid additions	4–2.5 mL concentrated nitric acid each with 30 min heating	4–2.5 mL concentrated nitric acid each with 30 min heating	4–2.5 mL concentrated nitric acid each with 30 min heating
Heating	120 min at 95 °C	120 min at 95 °C	120 min at 95 °C
1st hydrogen peroxide addition	3 mL 30% hydrogen peroxide	3 mL 30% hydrogen peroxide	3 mL 30% hydrogen peroxide
Heating	15 min at 95 °C	15 min at 95 °C	15 min at 95 °C
2nd hydrogen peroxide addition	2 mL 30% hydrogen peroxide	2 mL 30% hydrogen peroxide	2 mL 30% hydrogen peroxide
Heating	120 min at 95 °C	120 min at 95 °C	120 min at 95 °C
Hydrochloric acid addition		5 mL concentrated hydrochloric acid	
Heating		15 min at 95 °C	
Dilution to volume	Filter and dilute to 50 mL with 1% nitric acid	Filter and dilute to 50 mL with 1% nitric acid	Filter and dilute to 50 mL with 1% nitric acid

2.3.3. Phosphoric and nitric acids digestion

The third digestion procedure was developed specifically to increase tungsten extraction. A third 0.5 g aliquot of each of the solid samples was weighed into fluoropolymer vessels and digested following the above described nitric acid procedure, with the modification of adding 1 mL of concentrated phosphoric acid with the initial 5 mL of 1:1 nitric acid:deionized water. The digestate was then filtered and diluted as described above.

Aliquots of the 50 mL digestate solutions were further diluted with 1% nitric acid prior to analysis as needed such that analyte concentrations were within the calibration range of the analytical instrumentation (generally 1:4 dilution).

2.4. Instrumentation

Metal concentrations in the diluted digestates, including tungsten, were determined by Inductively Coupled Plasma Atomic Emission Spectroscopy (ICP–AES, following modifications of EPA Method 6010C [21]), using a PerkinElmer (Wellesley, MA) Optima 5300DV equipped with a MiraMist nebulizer and cyclonic spray chamber. The plasma was operated at 1400 W and nebulizer gas flow rate of 0.65 mL/min. Tungsten was quantified using the 207.912 nm emission line with analyte confirmation at 224.876 nm using axial plasma viewing. Due to the low concentration of tungsten in the standard reference soil 2709, tungsten was also measured by Inductively Coupled Plasma Mass Spectrometry (ICP-MS following modifications of EPA Method 6020A [21]), using a PerkinElmer Elan DRC-II equipped with a MiraMist nebulizer and Scott spray chamber. The ICP-MS plasma was operated at 1250 W and nebulizer gas flow of 0.85 mL/min. Tungsten was quantified at m/z 182 with confirmation using m/z 184 after correction for ^{184}Os.

2.5. Calibration and quality control

The ICP-AES was calibrated using NIST-traceable calibration standards. Scandium, added on-line using a mixing-T, was used as an internal standard to correct for instrumental drift during analysis. Calcium, magnesium, sodium, potassium, aluminum, and iron were calibrated using mixed analyte standards containing 0, 0.100, 1.000, 10.00, and 100.0 mg/L of each analyte. All other analytes, including tungsten, were calibrated using mixed analyte standards containing 0, 0.100, 1.000, and 10.00 mg/L of each element. The ICP-MS was calibrated using standards containing 0, 0.001, 0.010, and 0.100 mg/L tungsten, and used holmium as the internal standard.

All calibration responses were linear and had correlation coefficients of at least 0.9999. A second source calibration verification standard was analyzed immediately after calibration following standard US EPA Method 6010C procedures [21]; analyte recoveries were within ±10% of the nominal value (4.000 and 0.040 mg/L for ICP-AES and ICP-MS, respectively). Continuing calibration verification standards and blanks were analyzed periodically throughout the analytical batch, with recoveries within ±10% of the nominal value (5.000 and 0.050 mg/L for ICP-AES and ICP-MS, respectively) and subsequent blanks below the instrument reporting limits (<0.020 and <0.001 mg/L for ICP-AES and ICP-MS, respectively).

3. Results and discussion

3.1. Tungsten

The tungsten concentrations measured in the two standard reference materials, using the three digestion procedures, and associated quality control samples are listed in Table 2. The digestion blanks for all three procedures were below the instrument reporting limit (<0.040 mg/L including dilution factor), indicating that contamination was not present in the acids or vessels used. However, the blank spike sample, consisting of aqueous 10 mg/L tungsten from a NIST-traceable standard shows a marked difference among the three digestion procedures. The nitric acid method yielded a blank spike recovery of 39%, while the nitric–hydrochloric acid procedure recovery was 43%, both were well below the phosphoric–nitric procedure recovery of 98%. The nitric and nitric–hydrochloric procedures produced a yellow precipitate consisting of insoluble tungstic and polytungstic acids that was captured by the filtration process resulting in poor

Table 2
Comparison of the modified digestion procedure to two standard methods for extraction of tungsten from two standard reference materials and three test soils. Concentrations are in mg/kg ± standard deviation of triplicate digestions for soils and mg/L for liquid quality control samples determined by ICP-AES, values in parentheses were determined by ICP-MS.

	Tungsten concentration (mg/kg)	Tungsten concentration (mg/L)	Reported value recovery (%)	Matrix spike recovery (%)
Sample	Nitric acid			
Digestion blank		<0.04		
Digestion blank spike (10 mg/L)		3.9		39
SRM 2709 (2 mg/kg)	<4 (<0.1)		NA (NA)	
SRM 2710 (93 mg/kg)	27.4		29	
Grenada Loring	210 ± 30			39
Field soil 1	90.2 ± 11			0.4
Field soil 2	440 ± 28			47
Sample	Nitric–hydrochloric acids			
Digestion blank		<0.04		
Digestion blank spike (10 mg/L)		4.3		43
SRM 2709 (2 mg/kg)	<4 (0.2)		NA (10)	
SRM 2710 (93 mg/kg)	50.0		54	
Grenada Loring	221 ± 25			56
Field Soil 1	190 ± 22			3.7
Field Soil 2	737 ± 145			25
Sample	Phosphoric–nitric acids			
Digestion blank		<0.04		
Digestion blank spike (10 mg/L)		9.8		98
SRM 2709 (2 mg/kg)	<4 (0.5)		NA (25)	
SRM 2710 (93 mg/kg)	79.9		86

Field soil 1	483 ± 191			76
Field soil 2	1695 ± 203			79

NA—concentration measured is below instrument reporting limit.

spike recovery [6,22]; the phosphoric–nitric digestion produced no precipitate, and therefore the soluble phosphotungstates formed during the modified phosphoric–nitric digestion procedure were not removed by filtration. Improved recoveries for the nitric and nitric–hydrochloric acid procedures were not obtained by rinsing the filtrate with 2% phosphoric acid, indicating that the precipitates are stable once formed.

The NIST standard reference soil material results listed in Table 2 show a similar trend as the blank spike samples. The reference soil 2709 has a total tungsten concentration determined by Neutron Activation Analysis reported by NIST of 2 mg/kg, which is below the ICP-AES reporting limit for the current study, although, this demonstrates that matrix interferences are not present, which could yield a false positive. However, ICP-MS analysis indicated that increased tungsten recoveries in reference soil 2709 were obtained using the phosphoric–nitric digestion procedure compared to the standard techniques. The phosphoric–nitric procedure yielded 0.5 mg/kg tungsten, which is approximately 25% of the reported value, however, this is a higher recovery than either the nitric or nitric–hydrochloric digestions.

The reference soil 2710 has a total tungsten concentration determined by Neutron Activation Analysis reported by NIST of 93 mg/kg. The nitric acid digestion procedure yielded a concentration of 27.4 mg/kg, whereas the nitric–hydrochloric acid digestion yielded 50 mg/kg, which represent 29 and 54% recovery, respectively. The phosphoric–nitric acid procedure yielded a concentration of approximately 80 mg/kg, or 86% recovery. These recoveries are in line with values reported by others when standard acid digestion procedures are used for tungsten determinations [13,17].

It should be noted that all three acid digestion procedures tested are not intended to be total dissolutions, but rather are strong extractions, therefore, 86% tungsten recovery for the reference soil 2710 by the phosphoric–nitric method compared to Neutron Activation Analysis is considered acceptable. Furthermore, some of the tungsten may be present in these samples in silicate phases, which would normally only be extracted by a total dissolution technique (e.g. hydrofluoric acid, [15,16]), or a solid phase analysis technique, such as Neutron Activation or X-ray Fluorescence Spectroscopy. This likely explains the low recovery observed in the reference soil 2709, even with the phosphoric–nitric digestion procedure. However, in light of the two standard acid digestion procedures extracting less tungsten in all matrices, the phosphoric–nitric acid procedure performs well. Additionally, the tungsten concentrations reported by NIST are not certified values, but presented for 'information purposes only', and therefore may have some inherent error associated with them. A total dissolution procedure using a four acid cocktail, including hydrofluoric acid [16], was performed on the reference soils 2709 and 2710 to verify the NIST reported concentrations. Reference soil 2709 yielded a tungsten concentration of 2.2 ± 0.05 mg/kg determined by ICP-MS, while reference soil 2710 yielded a tungsten concentration of 97.8 ± 0.4 mg/kg determined by ICP-AES. These values are 110 and 105% of the NIST reported concentrations, respectively.

The three digestion procedures are also compared in Table 2 on the three test soils, with similar trends in tungsten extraction and matrix spike recovery observed. The nitric acid procedure yielded tungsten concentrations of 210 ± 30, 90.2 ± 11, and 440 ± 28 mg/kg for the GL, FS-1, and FS-2 samples, respectively. Tungsten concentrations in the nitric–hydrochloric digestion procedure samples were approximately the same for the GL soil (220 ± 25 mg/kg) as the nitric acid procedure, although the concentrations measured for the FS-1 and FS-2 samples were about a factor of two higher than those measured with the nitric acid procedure. The phosphoric–nitric procedure yielded the highest tungsten concentrations, 762 ± 44, 483 ± 191, and 1695 ± 203 mg/kg for the GL, FS-1, and FS-2 soils, respectively, further suggesting that the two standard methods have a low bias for tungsten extraction.

The lower concentrations determined by the standard methods explains the poor matrix spike recovery values listed in Table 2. The nitric acid digestion yielded a spike recovery of 39% for the GL soil, but less than 1% for FS-1, and 47% for the FS-2 sample. The nitric–hydrochloric acid procedure yielded slightly higher tungsten recoveries than the nitric acid procedure, with the GL spike recovery being 56%, but only 4 and 25% for the FS-1 and FS-2 samples, respectively. Finally, the matrix spike recoveries for the phosphoric–nitric procedure were 98, 76, and 79% for the GL, FS-1, and FS-2 samples, respectively, substantially higher than the standard methods. FS-1 contains a high amount of iron, and therefore it is possible that an iron–tungstate phase is causing exceptionally low extraction of tungsten, even lowering the phosphoric–nitric digestion, which was 76%. The FS-2 sample is a sandy soil, which could facilitate the formation of polytungstates on the silicon dioxide particles, resulting in low tungsten recovery, although the phosphoric–nitric procedure yielded 79% recovery. These experiments demonstrate that the phosphoric–nitric modified procedure greatly improves tungsten extraction from soils compared to the unmodified standard procedures.

3.2. Other metals

In addition to tungsten, other metal analyses in soils may also be required simultaneously, therefore, the digestate solutions were analyzed for 20 other metals to determine the comparability of the three procedures for determination of other metals. The addition of phosphoric acid could potentially lower recoveries of metals that form insoluble phosphate salts, such as lead, aluminum, iron, nickel, and cobalt, therefore, extraction efficiencies and matrix spike recoveries were tested and compared.

The digestion blanks listed in Table 3 show only 2 analyte detections, 0.081 mg/L iron in the phosphoric–nitric digestion solution, and 0.104 mg/L calcium in the nitric–hydrochloric acid digestion solution. However, these major cations are present at several orders of magnitude higher concentrations in soil matrices, suggesting these blank levels are acceptable. The blank spike recoveries listed in Table 3 for all elements measured from the three digestion procedures are within ±10% of the nominal spike concentration indicating no bias among the three digestion procedures for the elements determined.

Table 3 lists other metal concentrations for the two NIST standard reference soils determined using the three digestion procedures. The acid leachable metals concentrations reported by NIST are not certified values (only the total metals concentrations are certified by NIST), but are listed for 'information purposes only'. However, the recoveries listed generally agree among the three procedures, indicating that low recoveries are not an issue for these soil matrices and that the phosphoric–nitric procedure can be used for simultaneous determination of other metals. For example, Co determined by the nitric acid procedure yielded 90 and 101% recovery for the standard reference soils 2709 and 2710, respectively, in agreement with recoveries obtained for the nitric–hydrochloric procedures (93 and 100%, respectively). In comparison, the phosphoric–nitric procedure produced cobalt recoveries of 105 and 102% for the reference materials 2709 and 2710, respectively, indicating similar extraction efficiencies for the three digestion procedures. Similar agreement is observed for other analytes listed in Table 3 (e.g. arsenic, barium, calcium, cadmium, lead, strontium, and zinc). Elements such as chromium, copper, iron, potassium, magnesium, molybdenum, and nickel appear to have a slightly higher extraction efficiency by the phosphoric–nitric procedure, compared to the standard digestion procedures, although the difference is generally less than a 10% increase.

Table 3
Comparison of the modified digestion procedure to standard methods for extraction of other metals from two standard reference materials.

There appears to be a significant increase in extraction efficiency for titanium and vanadium in standard reference soil 2709 when using the phosphoric–nitric procedure. A similar trend is also observed for reference soil 2710, which has increased titanium extraction by the phosphoric–nitric procedure. These results suggest that reference material 2709, in particular, may possess a refractory vanadium and titanium phase that is sensitive to the presence of phosphoric acid.

Listed in Table 4 are the additional metals concentrations in the three test soils determined using the three digestion procedures. Because there are no reference values for the concentrations of metals in these soils, as there is with the NIST standard reference materials, the values obtained for the standard nitric and nitric–hydrochloric acid procedures are used as the reference values. The concentrations determined by the phosphoric–nitric procedure are listed in Table 4, and the relative recovery of each analyte compared to the standard digestion procedures.

The matrix spike recoveries for the Grenada Loring soil are all within ±20% of the nominal value except for aluminum, iron, and manganese, primarily due to the spike concentrations being less than 10% of the sample concentration for aluminum and iron, and less than 20% of the manganese concentration in the samples. Similarly, the matrix spike recoveries for most elements in the FS1 and 2 samples are acceptable (±20%) except where the spike concentration was small relative to the amount of metal present in the sample (e.g. aluminum, iron, copper, lead, and zinc in FS-1, and copper, iron, and lead in FS-2).

Aluminum, chromium, copper, potassium, magnesium, sodium, nickel, titanium, and vanadium tend to have higher extraction efficiencies by the phosphoric–nitric procedure in at least one of the test soil matrices compared to the nitric or nitric–hydrochloric digestion procedures. However, chromium, copper, and nickel are only elevated in the GL soil, which has relatively low concentrations of these elements (<20 mg/kg), suggesting that this could be a matrix anomaly, or an effect of being near the instrument reporting limit. For example, the agreement between the three digestion procedures is excellent for copper in the field soils 1 and 2 that have much higher concentrations.

It is also possible that the phosphoric acid improves extraction efficiency of anionic species, such as vanadium, due to surface complexation competition. The major cations (aluminum, potassium, magnesium, and sodium) could also be elevated due to the presence of additional acid (phosphoric) in the digestion cocktail, although a similar trend would be expected for the nitric–hydrochloric procedure compared to the nitric acid only procedure, which is not observed. However, the anomalies observed with the major cations only indicate a potential increased efficiency extraction, toward the recoveries of a total dissolution method, and therefore are not necessarily a negative effect, the comparability of the modified phosphoric–nitric procedure for the determination of metals still demonstrates its utility.

4. Conclusions

An acid digestion method modified from standard procedures is described for the quantitative recovery of tungsten from soil matrices. The modified method involves the addition of phosphoric acid to the acid cocktail to form stable polymeric phosphotungstate species for the acid solubilization of tungsten from soils. The method was tested on NIST standard reference soils and three test soils and shown to improve tungsten solubilization and yield acceptable matrix spike recoveries. Additionally, other common metals were determined in the digestate solutions with similar recoveries obtained to the standard methods, although some anomalies were observed. However, the modified procedure generally performed similarly to the standard digestion

procedures and can be used for tungsten and other metals simultaneously.

ABSTRACT

To our knowledge, we report the first fluorescence aptasensor for detecting human neutrophil elastase (HNE) in homogeneous solution. The biosensor contains a short DNA scrambled sequence strand (SS) complementary to part of the aptamer sequence or the loop of molecular beacon (MB). The aptamer-HNE recognition event involves competition between the molecular beacon and loose HNE aptamer for the binding the short DNA strand. The new biosensor can detect as little as 0.34 nM of HNE, and the response is linear in the tested concentration range of 0.34–68 nM with the detection limit of 47 pM.

1. Introduction

Neutrophil granulocytes are primary antimicrobial effector cells of the innate immune system and contribute to the first line of defence against infectious agents or nonself substances that penetrate the body's physical barriers [1]. The human neutrophil elastase (HNE), a serine proteinase, is the principal enzyme released from neutrophils [2]. It is capable of solubilising fibrous elastin, cartilage proteoglycans, several collagens and fibronectin, hence facilitating the migration of cells to inflammatory regions. HNE is thought to physiologically participate in disease resistance by facilitating the degradation and phagocytosis of pathogenic bacteria [3]. Uncontrolled activity of HNE has been shown to contribute to the pathogenesis of rheumatoid arthritis [4], chronic obstructive pulmonary disease [5], adult respiratory distress syndrome [6], glomerulonephritis [7], and chronic and burn wounds [8,9].

Lin et al. [10] identified a specific high-affinity DNA ligand targeted to HNE using an in vitro selection technique (SELEX). The DNA ligand folds into a G-quartet structure with duplex ends. According to Davis's work [11], the fluoresceinated DNA ligand equally effective as an anti-HNE antibody in detecting HNE can be useful in diagnostic applications based on flow cytometry. Charlton et al. [12] applied the DNA aptamer ligand to the field of diagnostic imaging.

Fluorescence spectroscopic methods offer high sensitivity and selectivity and applicability in nonseparation detection and in situ monitoring [13–16]. Nutiu and Li [17], for example, described aptamer-based fluorescent reporters for detecting for thrombin over the range of 10 nM–1.0 μM that a structural switch releases a dabcyl-labeled nucleotide strand from the fluorophore-labeled aptamer. Li et al. [18], on the other hand, prepared a molecular aptamer beacon (MAB) for recognizing the thrombin producing significant fluorescent signal change, which is attributed to a significant conformational change at low concentration (112 pM). Lerga and O'Sullivan [19] developed thrombin MAB labeling fluorescein and coumarin to selectively detect Ca^{2+} and Mg^{2+} with detection limit (40 μM) for determination of total water hardness in tap and bottle water. Heyduk and Heyduk [20] introduced a fluorescent assay involving thrombin-induced coassociation of two aptamers with analyte resulted in bringing the two short fluorophore-labeled oligonucleotides into proximity. Change of fluorescence resonance energy transfer was even at the lowest thrombin concentration tested (50 pM).

In our research, we proposed a sensitive method for HNE analysis in homogeneous solution. The molecular beacon was designed by appending fluorescein to 5′-ends and dabcyl quencher to 3′-ends. The HNE aptamer was free-labeled in order to retain the bioactivity. The short DNA scrambled sequence was complementary to the binding sites of the HNE aptamer or the loop of molecular beacon. Our biosensor involves aptamer-HNE recognition, competition between the molecular beacon and loose HNE aptamer for binding the short DNA strand, and monitoring the extent of

competition through highly sensitive fluorescence detection of the captured HNE.

2. Experimental

2.1. Materials and reagents

HNE from human plasma (SERVA Electrophoresis GmbH, Heidelberg, Germany) was dissolved in a storage buffer (50 mM Tris–HCl, 50 mM NaCl, 3.0 mM KCl, 1.0 mM $MgCl_2$, pH 7.5) to yield 3.39 μM solutions. This standard was divided into 100 μL aliquots and stored at −20 °C. Immediately before use, each aliquot was warmed to 4 °C and diluted with a storage buffer solution to the required concentration. HNE concentration mentioned in our work was the molarity of HNE storage solution before fluorescence measurements.

Oligonucleotides used in the study were customer-designed and synthesized by Sangon Biotechnology Co. Ltd. (Shanghai, China) as follows.

The HNE aptamer: 5′-TAGC GATA CTGC GTGG GTTG GGGC GGGT AGGG CCAG CAGT CTCGT,
The molecular beacon (MB): 5′-fluorescein-CCTA GCGC GTGG GTTG GGGC TAGG-Dabcyl,
Four scrambled sequence (SS):
S12: 5′-CCCA ACCC ACGC; S14: 5′-GC CCCA ACCC ACGC; S16: 5′-CCGC CCCA ACCC ACGC; S19: 5′-TAC CCGC CCCA ACCC ACGC.

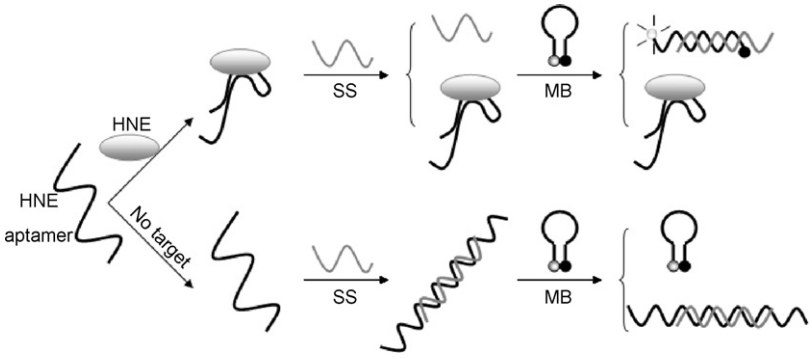
Ultrapure water used to prepare all of the solutions was obtained through a Nanopure Infinity Ultrapure water system (Barnstead/Thermolyne Corp., Dubuque, IA) with an electrical resistance larger than 18.3 MΩ. All buffer solutions and ultrapure water were sterilized and used throughout experiments. Sodium chloride, potassium chloride, human serum albumin (HSA), magnesium chloride and Tris–HCl were purchased from China National Medicines Co. Ltd. (Beijing, China).

2.2. Fluorescence measurements

If not otherwise specified, the following concentrations of oligonucleotides were used for fluorescence measurements: 40 nM for aptamers, 40 nM for the SS and 40 nM for the MB. MB was dissolved in storage buffer to form hairpin duplex, while HNE aptamer and SS were dissolved in ultrapure water to keep flexible structure. The binding buffer (pH 7.5) consisted of 100 mM Tris–HCl, 850 mM NaCl, 16 mM KCl, 5.0 mM $MgCl_2$ and 0.12% HSA (wt.%).

To perform the fluorescence experiments, 50 μL HNE solution of a specific concentration and 100 μL binding buffer were incubated with 50 μL HNE aptamer for 45 min. After the addition of 50 μL of a SS solution, the mixture was incubated for 10 min at 10 °C and then added 50 μL MB solution.

All fluorescence measurements were performed in 50 mM Tris–HCl (pH 7.5), 300 mM NaCl, 6.0 mM KCl, 2.0 mM $MgCl_2$ and 0.02% HSA (wt.%). All fluorescence spectra were recorded on a Hitachi F-4500 fluorescence spectrometer (Hitachi Ltd., Japan) controlled by FL Solution software to fit a curve and determine the peak height. A quartz fluorescence cell with an optical path length of 1.0 cm was used. The excitation was made at 495 nm with a recording emission range of 500–600 nm. All excitation and emission slits were set at 5 nm. The fluorescence spectrum of all mixtures was recorded at 10 ± 2 °C.



3. Results and discussion

3.1. Experimental principle

Scheme 1 illustrates the concept of the competitive-binding process coupled with fluorescence increase in this design. Before the addition of target, HNE aptamer (the long black coil) kept flexible structure in the blank experiment. SS (the short grey coil) was introduced in this homogeneous solution, and naturally binds to the aptamer. When MB (the short coil with two rotundities) was introduced, the hybridization of SS with MB would not take place immediately, which kept the fluorescence off. In the presence of HNE (the ellipse), the flexible structure of aptamer was transformed into a HNE-aptamer duplex assembly with G-quartet structure. Upon addition of SS and MB, the corresponding complementary sections of SS would hybridize with MB producing a strong concentration-dependent fluorescent signal.

3.2. Fluorescence increase of HNE binding

Fig. 1 demonstrates fluorescence spectra of MB solutions, a mixture of aptamer/SS/MB, an assembly of aptamer/HNE/SS/MB and a duplex of SS/MB. The sample containing MB only (Fig. 1, curve a) shows rather low fluorescence intensity for its hairpin structure keeping the fluorophore and the quencher into proximity. A slight fluorescence increase was observed when the MB was added into solution containing aptamer and SS (curve b). It can be interpreted as that a small quantity of MB captured SS dissociated from aptamer/SS. In the presence of HNE (17 nM, curve c), a significant fluorescence intensity increase (102%) was recorded at the emission peak around 518 nm. Binding of target proteins forces the aptamers to undergo a conformational change, while MB opens its hairpin structure leading to an increase in fluorescent signal. When

Scheme 1. Schematic representation of the aptamer-based HNE sensor. HNE: the ellipse; unmodified aptamer: the long coil; DNA scrambled sequence (SS): the short coil; DNA molecular beacon (MB): the short coil with two rotundities.

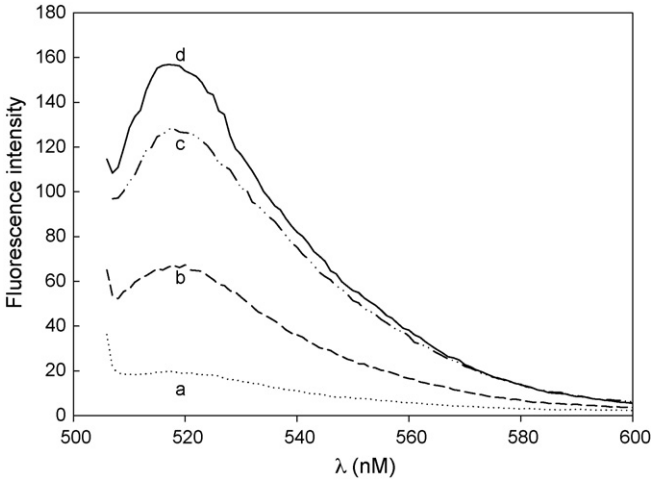


Fig. 1. Fluorescence spectra of solutions containing MB (a), a mixture of aptamer, SS and MB (b), a mixture of aptamer/HNE, SS and MB (c), and a complex of SS/MB (d). The relative standard deviations obtained by five repeated measurements were not more than 5%.

binding buffer contains SS and MB without addition of aptamer (curve d), the fluorescence intensity recorded was the maximum fluorescence intensity obtainable corresponding to the complete hybridization of MB with SS. This observation shows that SS could hybridize really with MB inducing fluorescence increase and HNE could be detected using the proposed method.

3.3. Experimental conditions of target detection

The efficiency of the competitive-binding process depends on the amount of SS released from aptamer and the ability of SS to force the MB stem apart. To investigate the effect of SS strand length on the performance of this method, the aptamer and aptamer/HNE assembly were hybridized with specific SS with a 12-, 14-, 16- or 19-nucleotide segment. As shown in Fig. 2, S12 provides the lowest fluorescent signal in the presence of HNE (curve a′) and also the least background (curve a). S12 has the least number of complementary oligonucleotides, which are too short to promote efficient hybridization with MB. The number of adjacent nucleotides on aptamer-SS binding region was 14 in the assay with S14, S16 or S19. The extra –CG sequence was designed to hybridize with the stem region of MB. The extra sequence might be beneficial to increase the ability of the corresponding SS to force the MB stem apart and restore the fluorescence. When the number of nucleotides rose from 14, 16 to 19, the decreasing background fluorescence in absence of HNE (curves b, c and d) seemed due to the ever increasing hybridizing force between the aptamer and the corresponding SS strand. In presence of HNE (curve b′, c′ and d′), a longer SS strand would induce higher fluorescence increase. In particular, S19 provides the best signal increase for HNE sensing. The extra length of the S19 strand (5′-TAC sequence) might loose the inner molecular interaction between the MB stem sections, which probably lead to fluorescence signal increase. Therefore, S19 was used as optimum SS in the experiment.

We also investigated the effects of pH on the response of the proposed sensor to HNE over the pH range from 7.0 to 9.0 and

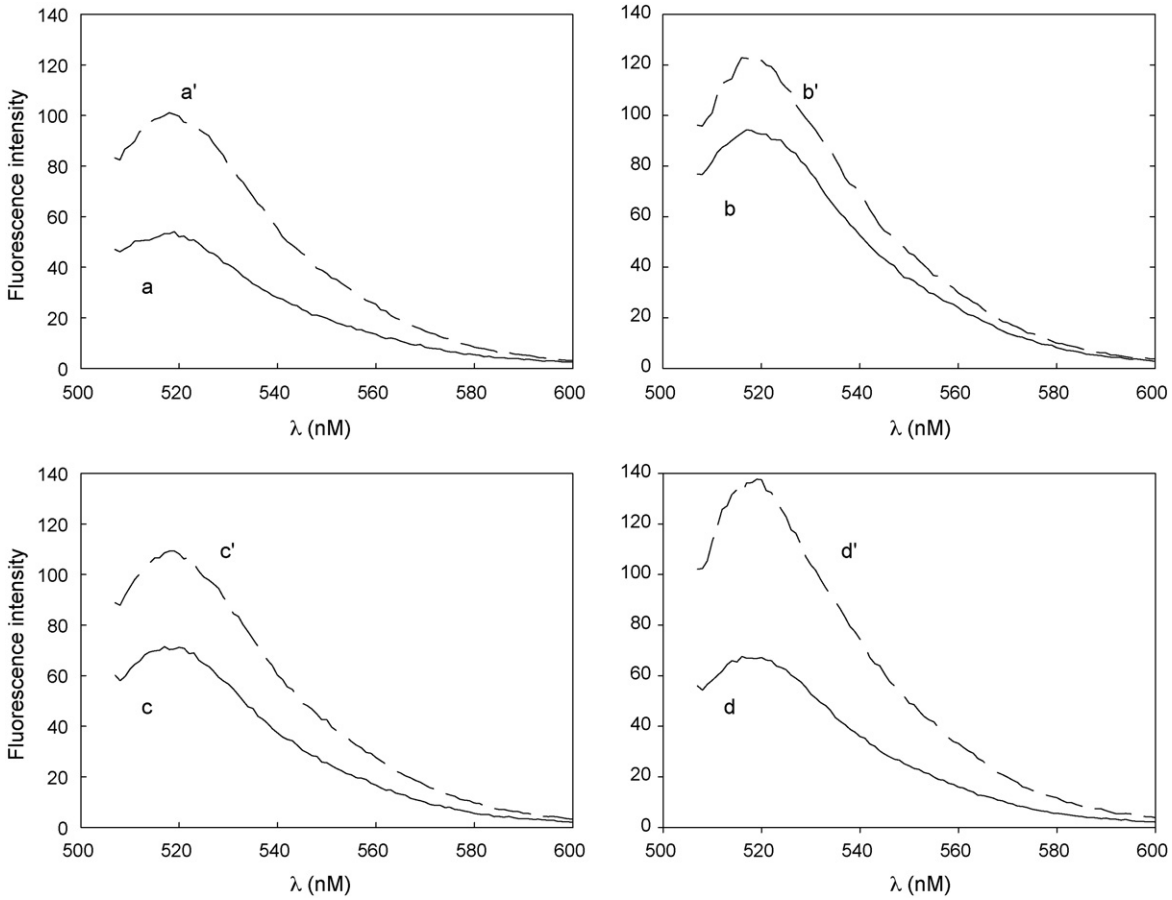

Fig. 2. Fluorescence spectra of the sensor using S12 (a and a′), S14 (b and b′), S16 (c and c′) and S19 (d and d′) with and without HNE respectively. The relative standard deviations obtained by five repeated measurements were not more than 5%. S12: 5′-CCCA ACCC ACGC; S14: 5′-GCCC CAAC CCAC GC; S16: 5′-CCGC CCCA ACCC ACGC; S19: 5′-TACC CGCC CCAA CCCA CGC.

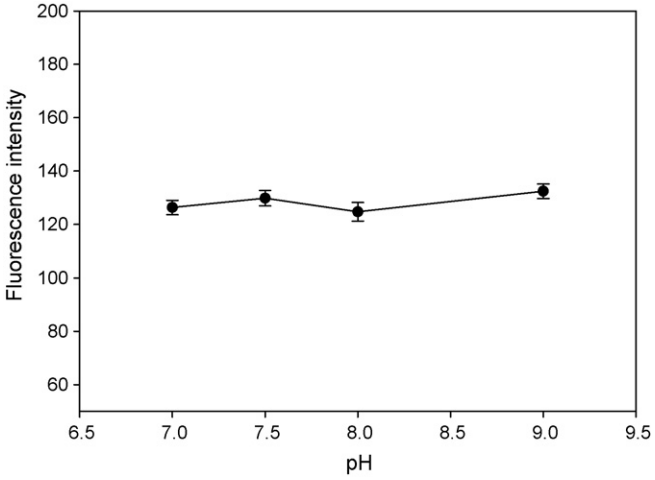

Fig. 3. The effect of pH of the incubating solution on the activity of the sensor containing HNE (17 nM). The standard deviations obtained by five repeated measurements were shown as the error bars.

the results are shown in Fig. 3. As can be seen, the sensor can be carried out in this pH range. There is no obvious change in the fluorescence of the assay when the pH of the buffer increases from 7.0 to 9.0. This indicates that competitive-binding reaction can occur over a wide pH range. An ideal pH of 7.5 was chosen for the sensor experiments, which is also a general pH value in immunology.

Thermal denaturation experiments were performed (Fig. 4) to investigate the relationship between fluorescence signal and incubation temperature. For this purpose, we increased the incubation temperature from 10 to 24, 37 or 45 °C. The binding event of aptamer/S19 is less efficient at high temperatures in the absence of HNE (Fig. 4, closed circles), resulting in the increase in fluorescence background. The low fluorescence intensity at 45 °C in absence or presence of HNE was possible due to the thermal quenching of the fluorescence. After introducing the analyte (Fig. 4, open circles), a high incubation temperature might lead to the HNE protein denaturalization. As a result, more aptamer dissociated from aptamer/HNE conjugate and hybridized with S19, bringing fluorescence intensity to decrease. This phenomenon indicated that the optimum incubation temperature was 10 °C.

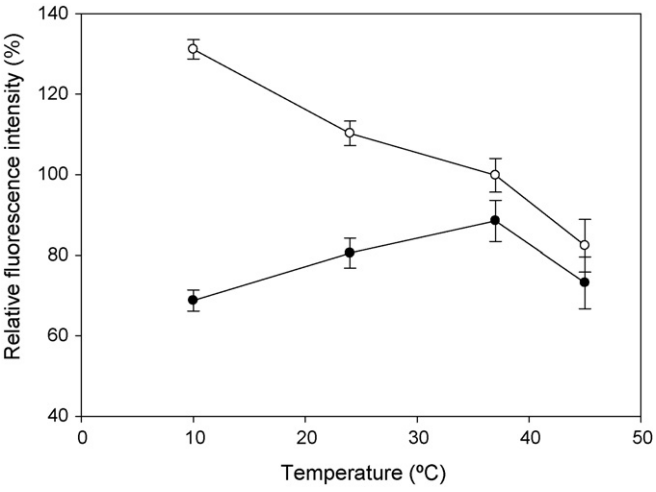

Fig. 4. The DNA aptamer mixture was incubated at 10, 24, 37 and 45 °C with (open circles) and without (closed circles) 17 nM HNE. The standard deviations obtained by five repeated measurements were shown as the error bars.

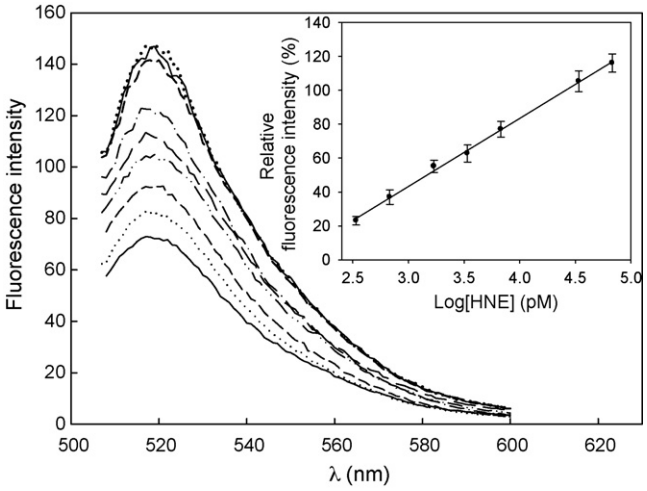

Fig. 5. Fluorescence spectra of sensors in the presence of HNE at different concentrations (from bottom to top): (1) 0.067 nM; (2) 0.34 nM; (3) 0.68 nM; (4) 1.7 nM; (5) 3.4 nM; (6) 6.8 nM; (7) 34 nM; (8) 68 nM; (9) 110 nM. Inset shows the linear fluorescence responses to the logarithm of HNE concentration in the range of 0.34–68 nM. The illustrated error bars represent the standard deviation of three measurements obtained at each HNE concentration.

3.4. Analytical performance of the aptamer-based sensor

Fig. 5 shows the change in fluorescence signal as a function of the HNE concentration. With the increased amount of HNE, the fluorescence intensity of the aptamer probe is increased. The relative fluorescence intensity R (%) was calculated from the equation $R(\%) = ((F_{\text{target}} - F_{\text{no target}})/F_{\text{no target}}) \times 100\%$, where F is the fluorescence intensity, and the subscripts "target" and "no target" refer to the case in the presence and absence of HNE respectively. Significantly, the aptamer-based sensor exhibited a high degree of sensitivity for HNE (Fig. 5, inset). And the response is linear in the tested concentration range of 0.34–68 nM ($r = 0.9980$). The linear regression equation was expressed as

$$\text{Relative fluorescence intensity}\,(\%) = 40.12\ \log[\text{HNE}] - 77.09$$

The detection limit (at S/N = 3) calculated from the slope of the calibration curve in the lowest concentration range was 47 pM.

3.5. Specificity of the HNE fluorescence sensor

Due to the inherent specificity of the aptamer toward its target protein, the fluorescence change of the HNE biosensor is highly

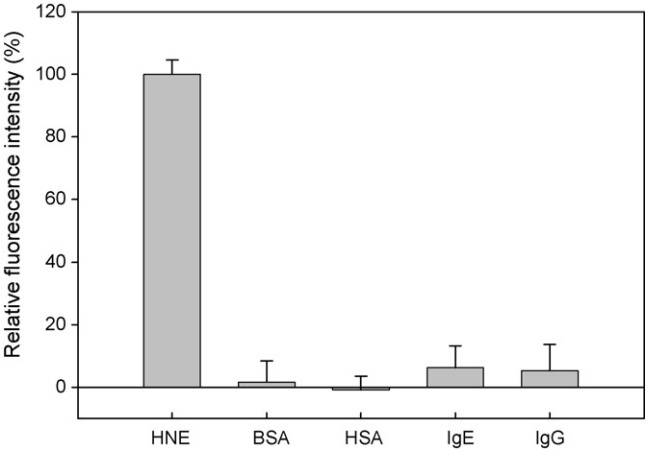

Fig. 6. Selectivity for the proposed sensor of five proteins. The sensor was exposed to HNE (17 nM) or other four proteins (BSA, HSA, IgE and IgG, 85 nM) respectively. Error bars were estimated from at least three independent measurements.

selective. Aliquots of the aptamer was incubated with either HNE (17 nM) or some other proteins commonly present in serum such as bovine serum albumin (BSA), human serum albumin, immunoglobulin E (IgE) and immunoglobulin G (IgG). The relative responses to fluorescence changes of the interfering protein, even at 5-fold higher concentrations (85 nM) than those used for HNE, are negligible in comparison to those from HNE (seen in Fig. 6). Hence the developed biosensor could exhibit a high degree of selectivity for the HNE detection, as expected.

4. Conclusion

We have developed a fluorescence aptasensor for the detection of protein HNE in homogeneous solution using MB. The proposed sensor was designed to observe its fluorescence intensity increase, which was attributed to the difference in structure-switching between the free aptamer and its HNE binding complex. The proposed strategy has been proved applicable in HNE aptasensing. This is of paramount importance for a new selective and highly sensitive method of HNE detection.

ABSTRACT

Despite biological variability the spectral characteristics of undiluted human urine show relatively low autofluorescence at short UV (250–300 nm) excitation. However with dilution the fluorescence intensity remarkably increases. This paper examines the mechanisms behind this effect, by using excitation–emission matrices. Corrections for the inner filter effect were made for improved understanding of the spectral patterns. We focused on three major fluorophores (tryptophan, indoxyl sulfate and 5-hydroxyindole-3-acetate) that are excited at these wavelengths, and whose content in urine is strongly linked with various health conditions. Their fluorescence was studied both individually and in combinations. We also examined the effect of ammonium on the fluorescence of these major fluorophores individually and in combinations. Through these studies we have identified the leading effects that reduce the UV fluorescence, namely higher concentration of indoxyl sulfate producing the inner filter effect and concentration quenching and quenching of fluorophores by ammonium. This result will assist in broader utilisation of UV fluorescence in medical diagnostics.

1. Introduction

Human urine is a complex biological fluid containing a range of chemical compounds produced by the body, some of which are fluorescent [1–3]. The concentration of fluorophores in urine is influenced by many factors including body metabolism, dietary intake, age and disease [1,2]. Thus the measurement of autofluorescence of urine is, in principle, able to provide an indication of a number of health conditions, including urinary tract infection, proteinuria, renal disorder, nephrotic syndrome, hepatopathy, and neuronal ceroid lipofuscinosis [3–6]. However, despite the simplicity and speed of the fluorescence measurement, urine fluorescence is underutilised in medical diagnostics. One of the key impediments is the observed high inter- and intra-individual variability of the fluorescence properties. Moreover, the broad spectral features of individual fluorophores tend to overlap, making the data interpretation quite complex and the identification of chemical constituents extremely difficult. Upon closer inspection, the spectral characteristics of urine fluorescence are somewhat less variable at short UV excitation wavelengths (250–300 nm), corresponding to the region where the key, most abundant indole fluorophores, tryptophan and its metabolites can be excited (Supplemental material, Table 1) [7]. These fluorophores are directly linked to cellular metabolism and, indirectly, to various health conditions. However, they are practically difficult to observe in undiluted healthy human urine that shows very weak fluorescence with short UV excitation [5]. Thus the majority of earlier studies have focused on analyzing diluted urine [7]. The dilution greatly enhances the fluorescence of tryptophan and its metabolites, but it tends to compromise the fluorescence from less abundant components observable in other spectral regions, possibly reducing the diagnostic potential of such measurement. Moreover, it would be preferable to be able to use undiluted urine for diagnostics due to simpler procedures.

Our work is aimed at a better understanding of urine fluorescence by identifying and quantifying the factors responsible for low intensity of fluorescence when excited at 250–300 nm. The principles governing the observed fluorescence intensity of fluorophores are well established; they include the value of fluorophore quantum yield, the possibility of fluorescence quenching occurring at higher concentrations, and the reduced intensity of exciting light (or emitted light or both) known as the inner filter effect [8,9].

doi:10.1016/j.talanta.2009.09.020

As urine is a multicomponent liquid, there is an additional possibility of energy transfer [5]. However, no detailed investigations of these factors have been reported. We focused on studying the three most abundant, high quantum yield fluorophores excited at 250–300 nm, indoxyl sulfate, tryptophan and 5-hydroxyindole-3-acetate and the abundant non-fluorescent ammonium known for its quenching properties. A clearer understanding of the interactions between the key fluorophores and other components in urine is essential to broaden the potential of fluorescence as a diagnostic tool.

2. Experimental methodology

2.1. Urine samples

Urine samples were collected from a local pathology laboratory where they were analyzed for pH, protein, glucose, bilirubin, nitrate, specific gravity, blood, ketones, urobilinogen and leukocyte esterase. The presence of red blood cells, white blood cells, casts, epithelial cells and crystals was also tested for these samples (using iQ200 Sprint, IRIS Diagnostics Division, Chatsworth, CA). Semi-quantitative culture on chromogenic agar plates was also carried out to test for the presence of bacteria. A total of 46 human urine samples were used in this study, including samples from 35 males (age 2–90 years) and 11 females (age 5–90 years). These samples showed no abnormal laboratory findings, *i.e.*, they were culture-negative as well as negative for other abnormal findings such as protein, glucose, bilirubin, nitrate, specific gravity, blood, ketones, urobilinogen, leukocyte esterase and they had pH within the range of 5–7. They are referred to as healthy human samples. The urine samples were stored in a refrigerator (4 °C) and examined within 48 h after collection.

2.2. Other materials and reagents

L-Tryptophan, indoxyl sulfate and 5-hydroxyindole-3-acetate were obtained from Sigma–Aldrich (Sydney, Australia). Stock solutions of 300 μmol indoxyl sulfate, 50 μmol of L-tryptophan and 24 μmol of 5-hydroxyindole-3-acetate were prepared in deionised water. The required dilutions of ammonia (Unilab, Sydney, 28%, v/v) were made in milli-Q water. We also used 'simulated urine' that consisted of a mixture of 300 μmol indoxyl sulfate, 50 μmol of L-tryptophan and 24 μmol of 5-hydroxyindole-3-acetate (at approximately physiological concentrations) with a pH of 5.1.

2.3. Measurement of autofluorescence

The fluorescence was measured using a Fluorolog Tau3 system (JY Horiba, Edison, NJ) in 10 mm quartz cuvettes at room temperature. The fluorescence emission spectra after excitation at various wavelengths as well as the excitation/emission matrices (EEMs) were obtained. These three-dimensional plots of fluorescence intensity as a function of excitation and emission wavelengths represent the complete fluorescence characteristics of the sample. In order to cover the broad spectral region of relevance in the most time-efficient way, four separate smaller EEMs were obtained and digitally integrated into a single one using MATLAB. In EEM measurements the spectral band passes were 5 nm in both excitation and emission. The spectra were corrected for optical system response.

2.4. Measurement of absorption

The absorption was measured using double beam CARY absorption spectrometer system (Varian Inc., USA) in 10 mm quartz cuvettes at room temperature.

2.5. Liquid chromatography–mass spectrometry (LC–MS) analysis

The mass spectrum was obtained on a Shimadzu LCMS 2010 EV system with an SIL 20 AL autosampler. The mobile phase was water–acetonitrile (9:1, v/v) in the isocratic mode, with a flow rate of 0.2 mL/min. The analysis was performed with the Electron Spray Ionisation (ESI) probe.

3. Results and discussion

3.1. Spectral characteristics of undiluted healthy human urine

The literature on urine fluorescence is surprisingly scarce in spite of its easy availability [5,7] and it is therefore worthwhile to present some examples of urine spectral characteristics. Fluorescence characteristics of urine are variable and strongly sample-dependent. Two examples of excitation/emission matrices of undiluted healthy samples with different spectral features are shown in Fig. 1a and b. The observed differences are due to variations in the relative composition of fluorophores in the urine. The fluorescence is observed mainly at 300–450 nm excitation wavelength range and we note that one of the samples (Fig. 1a) shows similar characteristics to that reported by Kusnir and Leskova [5]. The identification of the fluorescence features is difficult due to the similarities in the spectral properties of the component fluorophores and large spectral widths; however, the spreading of the spectral features in a two-dimensional EEM makes the task easier. The major fluorophores which are likely to contribute to urine fluorescence at 300–450 nm excitation are 4-pyridoxic acid, pterins, flavins and porphyrins [4,7].

It is apparent from Fig. 1a and b that autofluorescence of urine excited in 250–300 nm range is very weak when compared to longer UV (300–450 nm) excitation. This property was consistently observed in all samples examined in this study and in our earlier work [6]. In order to establish the level of individual variability at the short UV excitation wavelengths we used a larger set of 40 samples taken from a mixed age/gender population (Fig. 1c). The fluorescence spectra when excited at 290 nm for all these samples have a similar spectral pattern with some intensity variations. The peak fluorescence was observed at 420 ± 15 nm and the peak intensity varied by ±50%. We were unable to identify any sub-classes in these spectra based on gender or age, by using the Principal Component Analysis.

Thus, we have established that the key fluorescence features of undiluted healthy human urine are observed at 300–450 nm excitation and are highly variable, while shorter UV excitation produces only very weak fluorescence that is much more consistent. This finding is in agreement with the earlier literature that introduced the terms "group A" and "group B" fluorophores excited at 250–300 nm, and 300–450 nm, respectively [5,7]. Accordingly, the EEM in Fig. 1a and b shows very prominent but less abundant group B fluorophores, some of which are of direct dietary origin and highly variable, while the group A fluorophores, which are more abundant, are barely observed. This low intensity of group A fluorophores is generally attributed to fluorescence quenching [5,7].

3.2. Spectral characteristics of diluted healthy human urine

The dilution of the urine profoundly affects the excitation/emission matrices. This is shown in Fig. 2 where we compared the EEMs for healthy human urine at various dilutions (1:30, 1:300 and 1:1000). In undiluted urine we observed features at 365 nm/470 nm (where 365 nm refers to peak excitation wavelength and 470 nm to peak emission wavelength), 380 nm/520 nm

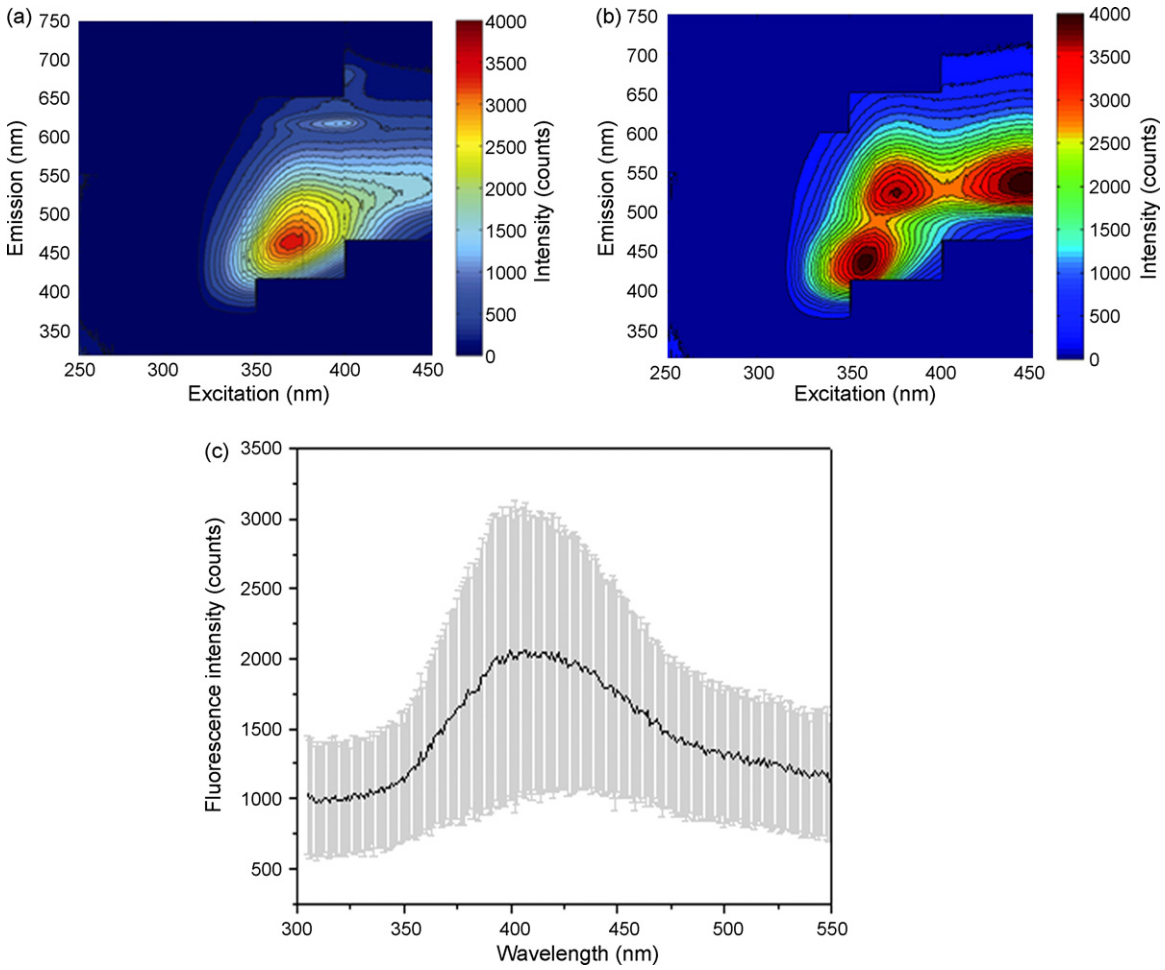

Fig. 1. (a and b) Excitation/emission matrices of two representative undiluted healthy human urine samples. (c) The mean emission spectrum for 40 undiluted healthy human urine samples at 290 nm excitation (black line). The error bars represent standard deviation.

and at 400 nm/625 nm (attributable to group B fluorophores). These disappear at 1:30 dilution, and a moderately intense emission peak at 325 nm/425 nm emerges (tentatively attributed to 4-pyridoxic acid [7]) and a very weak 290 nm/350 nm feature attributable to one of group A fluorophores. At 1:300 dilution, the peak at 325 nm/425 nm practically disappears but the 290 nm/350 nm peak becomes more intense. With 1:1000 dilution, this peak dominates the spectrum. This result shows that by adjusting the dilution, especially in the range from 1:30 to 1:1000 it is possible to enhance emission of various fluorophores that are not observable without dilution. This is because the undesired absorption of excitation light at lower dilutions that underpins the inner filter effect is reduced or eliminated at higher dilutions [8]. Thus, high dilution expands the spectral window available for fluorescence observation. Consequently, high dilution makes it possible to start observing the group A fluorophores (Fig. 2b and c). As the dilution is increased, at some point, the quenching starts to be reduced as well, and this additionally enhances the fluorescence from group A fluorophores (Fig. 2d). We now discuss the details of these two effects and the influence they have on the EEMs of urine.

3.3. The inner filter effect

The recorded fluorescence intensity may not be proportional to the fluorophore concentration due to a well known phenomenon known as the inner filter effect [10]. This can be due to high absorption of excitation light by the sample (primary inner filter effect) and by reabsorption of emitted light (secondary inner filter effect) [10]. Both can be completely accounted for and the spectra can be corrected. The correction for the primary inner filter effect can be done using the following equation [10,11],

$$\beta_i = \frac{\alpha_i L_i}{1 - \exp(-\alpha_i L_i)} \quad (1)$$

where β_i is the inner filter correction factor by which the spectra need to be multiplied, α_i is the optical density for the sample at the excitation wavelength and L_i is the cuvette dimension. In deriving this equation, two assumptions are made that the optical density for the emitted light is negligible and the fluorescence is collected from the full length of the cuvette. This correction requires the knowledge of the absorption spectra that are presented in Fig. 3. The absorption spectrum of human urine (Fig. 3a) indicates that the absorbance, especially in the region 250–350 nm, is quite high (note that the absorption spectra in Fig. 3 were taken at 1:10 dilution as compared to physiological conditions). It is well known that in order to avoid the inner filter effect, the optical density of the sample for fluorescence measurement should be less than 0.05 [8,9,12]. Thus, Fig. 3a indicates that the primary inner filter correction factors are significant in the range below 300 nm, especially for undiluted urine. At the same time, the absorbance in 300–500 nm range is negligible; hence, the secondary inner filter correction (equation not shown) is not required. On these grounds our EEMs and the underlying spectra have been corrected by using Eq. (1) so that the issue of quenching can be addressed.

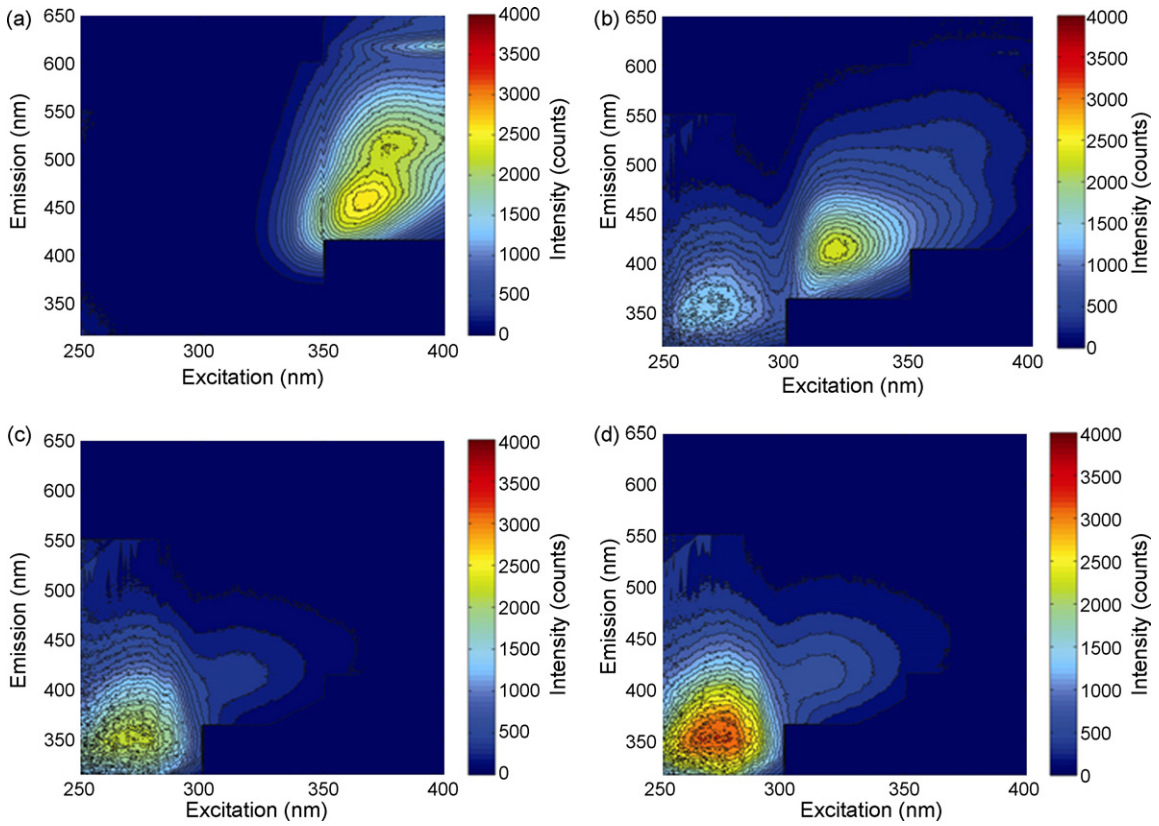

Fig. 2. Excitation/emission matrices of healthy urine sample. (a) Undiluted urine and (b–d) diluted 1:30, 1:300 and 1:1000, respectively.

It is illustrative to see the influence of the inner filter effect in the EEM matrices of a selected component of urine, indoxyl sulfate (Fig. 4a–c), which produces dramatically varying spectral features as the dilution is varied. The EEM of indoxyl sulfate at physiological concentration of 300 μmol shows a peak at 300 nm/380 nm. At 1:10 and 1:1000 dilutions, the peak excitation changes to 280 nm but the emission maximum remains the same, *i.e.*, 380 (±10) nm.

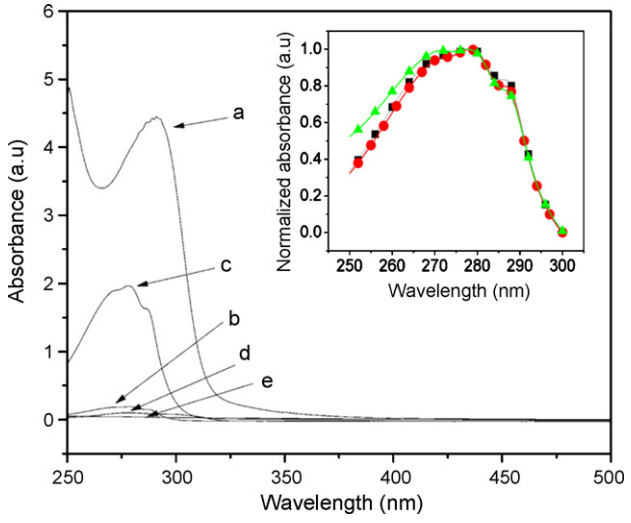

Fig. 3. Comparison of optical absorption spectra. (a) Healthy human urine, (b) tryptophan (50 μmol), (c) indoxyl sulfate (300 μmol), (d) 5-hydroxyindole-3-acetate (24 μmol), which were all diluted 1:10 in double distilled water and (e) 19 mmol of ammonium in distilled water. The inset shows the absorption spectra of 300 μmol of indoxyl sulfate at various dilutions. (-■-) undiluted, (-●-) diluted 1:1, (-▲-) diluted 1:30.

This result shows that interpreting peaks in emission spectra or excitation/emission matrices needs to be done with a great deal of caution, as major shifts and spectral shape changes can be observed at higher fluorophore concentration, when the inner filter effect is operational. Indeed, Fig. 3c indicates that indoxyl sulfate at physiological concentration contributes significantly to the total absorption of undiluted urine (OD = 17 at peak) and that the fluorescence data for indoxyl sulfate must be corrected for the inner filter effect. However, these matrices can be corrected, by using the inner filter correction (Eq. (1)), provided the inner filter effect does not reduce fluorescence to unobservable levels. Fig. 4d shows an EEM corrected for the inner filter effect, and we note that the corrected EEM shows a close similarity with the EEM for a highly diluted fluorophore (Fig. 4c).

3.4. Fluorescence quenching in urine

With the inner filter effect fully accounted for, we are able to establish the extent of fluorescence quenching in this complex fluid. In order to capture the key features of all quenching processes, we focused on the most abundant group A fluorophores, indoxyl sulfate, tryptophan and 5-hydroxyindole-3-acetate [7]. The fluorescence of these three fluorophores was studied in isolation as well as in mixtures, including a representative 'simulated urine' with selected urine components (indoxyl sulfate, tryptophan and 5-hydroxyindole-3-acetate) at typical physiological concentrations of 300, 50 and 24 μmol, respectively. In order to establish the significance of the inner filter effect we also measured the absorbance of these three fluorophores (see Fig. 3 where a 1:10 dilution was used to obtain measurable values). As indicated earlier, the absorbance of indoxyl sulfate at physiological concentration is high, and the other two fluorophores did not show significant absorption in the examined region.

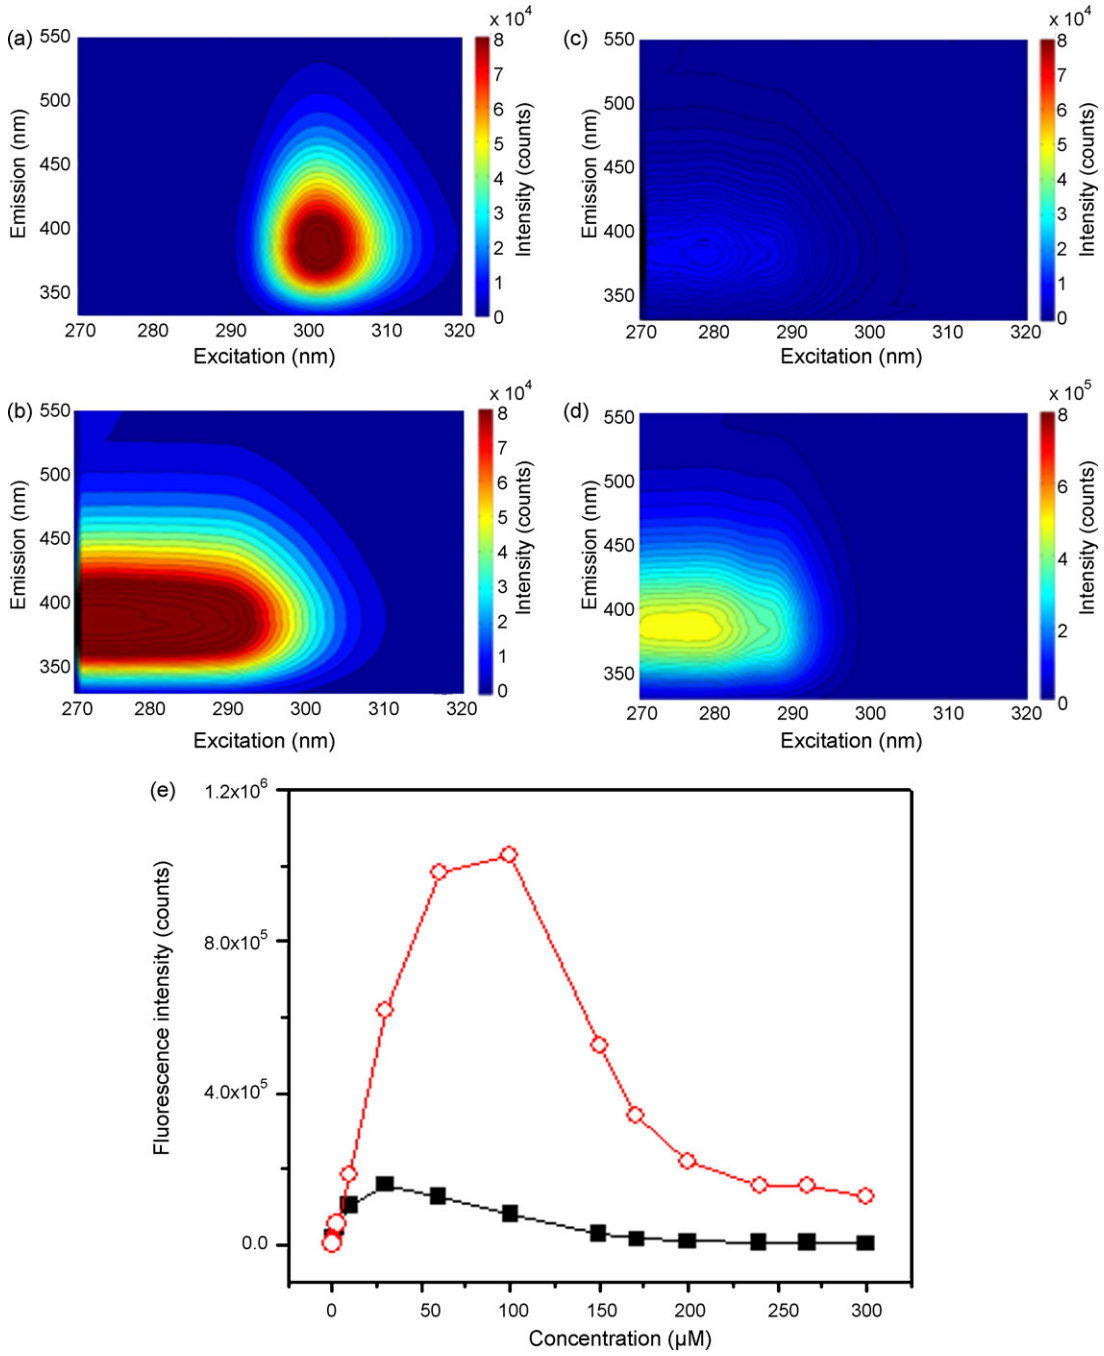

Fig. 4. Excitation/emission matrices of indoxyl sulfate. (a) Indoxyl sulfate at a concentration of 300 μmol, (b) diluted 1:1000 in double distilled water, (c) diluted 1:10 in double distilled water, (d) 1:10 dilution corrected for the inner filter effect and (e) fluorescence intensity at 280 nm/380 nm *versus* concentration of indoxyl sulfate; (-■-) uncorrected data; (-○-) data corrected for the inner filter effect; note the different colour scale in (d).

We measured the fluorescence of indoxyl sulfate as a function of dilution. Fig. 4e shows the peak fluorescence intensity at 280 nm/380 nm, of indoxyl sulfate at various concentrations, before and after correcting for the inner filter effect. It shows that the fluorescence intensity at 300 μmol concentration after correcting for the inner filter effect is lower than that of the 30 μmol concentration, confirming that at physiological concentration (300 μmol), indoxyl sulfate exhibits concentration quenching. Consequently, indoxyl sulfate in undiluted healthy human urine must also be subject to concentration quenching (self-quenching). We examined the other two fluorophores, tryptophan and 5-hydroxyindole-3-acetate below and at physiological concentrations. These did not show the self-quenching effect (data not presented).

Common mechanisms behind concentration quenching include collisional quenching and dimer formation. The dimers are known to show a relatively weak fluorescence compared with fluorescent monomers [13]. In order to test this possibility, we used liquid chromatography/mass spectrometry (LCMS) to detect the presence of indoxyl sulfate dimers at physiological concentration. The peak at 463 (mass/charge) in the LCMS (Supplemental material, Fig. 2) indicates that dimers are indeed formed, but at a low relative concentration of 10% compared with the monomers. Also, aggregate formation if significant, could change the shape and shift the maxima of absorption bands [14]. The absorption spectra of urine as well as its key fluorescent component at varying dilutions, do not suggest much influence of aggregate formation, as seen by the

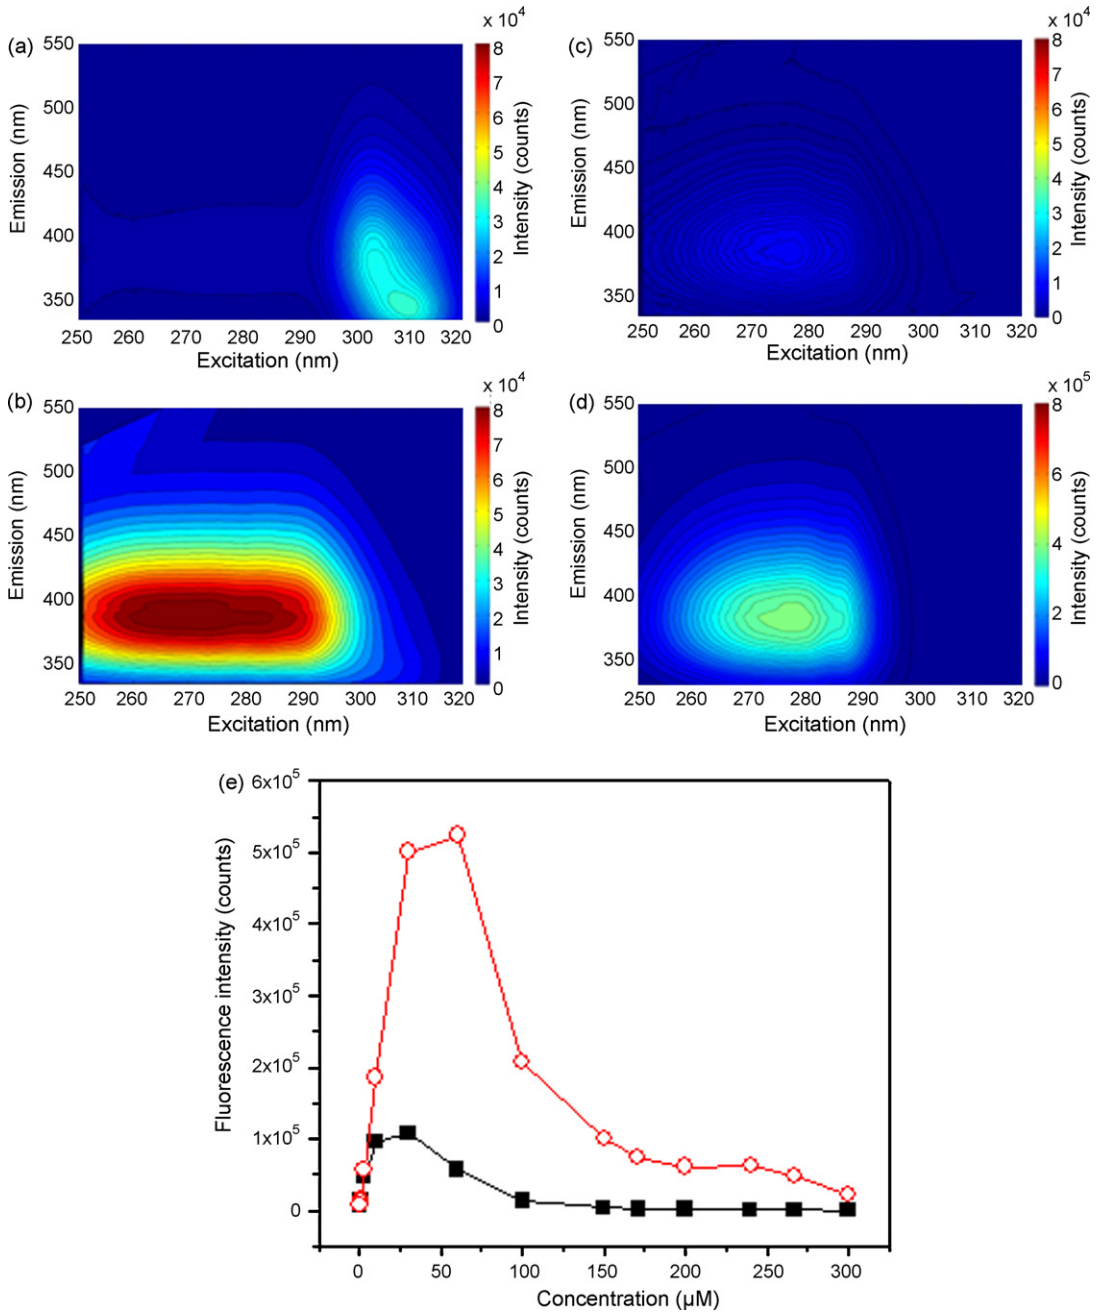

Fig. 5. Excitation/emission matrices of 'simulated urine' containing indoxyl sulfate (300 μmol), tryptophan (50 μmol) and 5-hydroxyindole-3-acetate (24 μmol). (a) Undiluted; (b) diluted 1:1000; (c) diluted 1:10; (d) diluted 1:10, with spectra corrected for inner filter effect. Note the different colour scale in (d). All dilutions were made in double distilled water. (e) Fluorescence intensity at 280 nm/380 nm of 'simulated urine' as a function of indoxyl sulfate concentration. (-■-) uncorrected data; (-○-) data corrected for the inner filter effect.

almost identical absorption of indoxyl sulfate at physiological concentration and at two dilutions (Fig. 3, inset). Thus we infer that the fluorescence reduction due to dimer or aggregate formation is very minimal. We therefore propose collisional quenching as the major mechanism of concentration quenching by indoxyl sulfate at physiological concentrations.

We also studied the mutual interactions between the three key group A fluorophores (tryptophan, 5-hydroxyindole-3-acetate and indoxyl sulfate) at physiological concentrations and at various dilutions. In the presence of indoxyl sulfate, the fluorescence of tryptophan as well as 5-hydroxyindole-3-acetate showed reduced fluorescence (data not shown). The fluorescence intensity of the 'simulated urine' (a combination of these three fluorophores) was also very weak, with a peak at 310 nm/340 nm (Fig. 5a–c). This is consistent with the spectral position for the 5-hydroxyindole-3-acetate peak (Supplemental material, Table 1), although in light of a very strong inner filter effect, an unambiguous assignment is not possible. Overall, the trend observed in Fig. 5 with dilution is similar to that in Fig. 4, *i.e.*, a deformed peak at 1:10 dilution which, after correction for the inner filter effect, reveals a pure indoxyl sulfate feature, more clearly observed at 1:1000 dilution. This is an indication that indoxyl sulfate reduces the fluorescence of tryptophan and 5-hydroxyindole-3-acetate when these are in combination. Moreover, the maximum fluorescence intensity at physiological concentration of the 'simulated urine' (Fig. 5a) is significantly lower than that of indoxyl sulfate alone

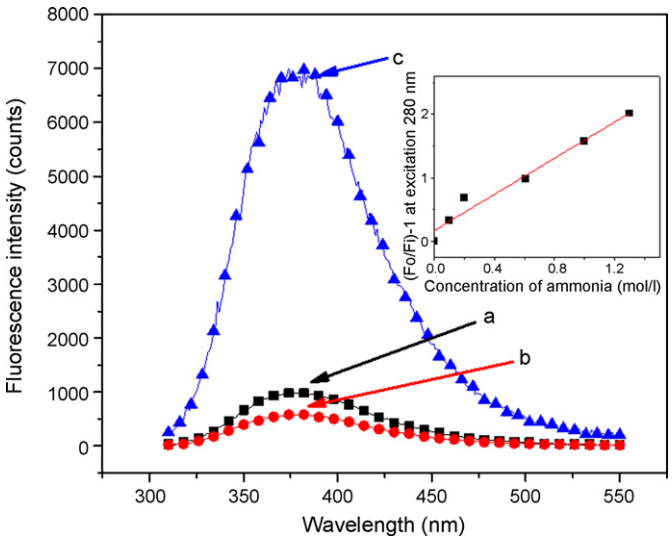

Fig. 6. Effect of the addition of varying amounts of ammonium on the fluorescence spectra of 'simulated urine' containing tryptophan (50 μmol), indoxyl sulfate (300 μmol) and 5-hydroxyindole-3-acetate (24 μmol), at 280 nm excitation. (a) 'Simulated urine', without any ammonium, (b) 'simulated urine' with 19 mmol of ammonium and (c) 'simulated urine' with 19 mmol of ammonium, diluted 1:10 with double distilled water. The inset shows the Stern–Volmer plot representing the fluorescence quenching of the 'simulated urine' by ammonium (fluorescence intensity at 380 nm for excitation at 280 nm as a function of ammonium concentration).

(Fig. 4a), confirming energy transfer between these fluorophores and indoxyl sulfate. Similar to the case of pure indoxyl sulfate, the concentration quenching was confirmed by observing the concentration trends in peak fluorescence intensity of the 'simulated urine' before and after correcting for inner filter effect (Fig. 5e).

Finally, we explored the effect of other non-fluorescent components in urine, on its fluorescence. As previously, we focused on the key group A fluorophores, indoxyl sulfate, tryptophan and 5-hydroxyindole-3-acetate and their interaction with a major non-fluorescent component ammonium. Ammonium was selected because it is reported to be an efficient quencher of indole fluorophores [15], and this behaviour is confirmed in our study. Moreover, its physiological concentration tends to be high, and a 24 h sample of normal human urine contains 19 mmol (0.7 g) of ammonium, derived from protein metabolism and from glutamine in kidneys. The concentration of ammonium varies depending on blood and tissue fluid acidity [16]. Fig. 6 shows that the addition of a physiological amount of ammonium lowers the fluorescence of the 'simulated urine' by a factor of two. To understand the quenching effect in detail, the Stern–Volmer quenching constant was calculated using the following equation [12]:

$$\frac{F_0}{F} = 1 + K[Q] \quad (2)$$

where F_0 and F are the fluorescence intensities in the absence and presence of quencher (ammonium), [Q] is the concentration of quencher and K is the Stern–Volmer constant. The K value was calculated to be approximately 1.4 L/mol. The Stern–Volmer plot is shown in Fig. 6(inset).

Our additional quenching studies, with each of the three fluorophores independently, showed that ammonium quenched the fluorescence of all the three examined fluorophores, tryptophan, indoxyl sulfate and 5-hydroxyindole-3-acetate (data not presented). Fig. 6 also shows that dilution reduces the quenching of 'simulated urine' by ammonium, as expected. However, the fact that in Fig. 6 the emission peak of 'simulated urine' does not change with dilution indicates that the concentration quenching is not due to reabsorption. This result is consistent with the increased intensity observed for the human urine at shorter UV region with dilution (Fig. 2). Separately, we observed that ammonium also reduced the fluorescence of each of the three examined fluorophores in a concentration dependent way (data not shown). The overall conclusion from this study is that the key indole fluorophores in healthy human urine are quenched by the presence of ammonium. The mechanism behind this quenching is the sensitivity of indole fluorophores to the local environment [12,17–19]. The electron transfer from excited fluorophores to ammonium has been reported to be the cause of this quenching [15].

A survey of the literature indicates that the fluorescence properties of human urine are also affected by factors other than those examined here. For example, the pH can rebalance the fluorescence intensities of component fluorophores in favour of certain components such as, pterin and 4-pyridoxic acid [7,20,21]. Undiluted healthy human urine has a pH between 5 and 7.5. As the pH is increased from 8 to 10, the quantum yield and mean life time of the indole fluorophores increases three-fold as compared with that at pH between 3 and 7.5 [12]. This means that the quantum yield of indole fluorophores in normal urine is suboptimal. Pterin and 4-pyridoxic acid contribute significantly to the fluorescence of undiluted healthy human urine at 300–450 nm excitation. The 4-pyridoxic acid and pterins have high fluorescence intensity in an acidic medium (pH 4–7) as compared to a basic medium [22,23]. These fluorophores therefore exhibit optimal fluorescence at the pH of undiluted normal human urine. This is in contrast to the indole fluorophores whose quantum yield is not at their peak in healthy human urine. The overall picture of fluorescence quenching in urine is also more complex. In addition to ammonium, urine contains other known quenchers. A 24 h sample of human urine contains hippuric acid, whose carboxyl group is able to quench the indole fluorophores in urine. All these effects additionally contribute to the main quenching mechanisms discussed here, *i.e.*, the autoquenching of indoxyl sulfate, quenching of tryptophan and 5-hydroxyindole-3-acetate by indoxyl sulfate and the quenching of indole fluorophores by ammonium.

4. Summary

Despite high concentration of UV excitable (250–300 nm) fluorophores, the fluorescence of undiluted healthy human urine is weak. However, with dilution, the fluorescence intensity increases substantially. Although this is generally attributed to fluorescence quenching and/or inner filter effect, the existing literature does not provide any explanation concerning the factors contributing to the relatively low UV fluorescence of undiluted healthy human urine. A detailed understanding of the factors influencing UV fluorescence of human urine could contribute to harnessing fluorescence as a diagnostic tool.

In this work, we analyzed the fluorescence of undiluted healthy human urine samples as well as three major UV-excitable fluorophores in urine: tryptophan, indoxyl sulfate and 5-hydroxyindole-3-acetate, in order to understand the key fluorescence features in this complex biological fluid. Both undiluted (physiological concentration) as well as various dilutions were studied. We also established the effect of physiological concentration of another major component of urine, ammonium, on the fluorescence of key urine fluorophores and their mixtures.

Our findings indicate that the key factors contributing to the reduction of fluorescence observed in the undiluted healthy human urine samples excited in the shorter UV wavelength include high concentration of indoxyl sulfate contributing to the inner filter effect and the concentration quenching of fluorophores by ammonium. This work fills a gap in the existing literature concerning the factors influencing UV fluorescence of human urine.

Phytohormone

ABSTRACT

Salicylic acid (SA) is a biological substance that acts as a phytohormone and plays an important role in signal transduction in plants. It is important to accurately and sensitively detect SA levels. A gold electrode modified with copper nanoparticles was used to assay the electrocatalytic oxidation of salicylic acid. It was found that the electrochemical behavior of salicylic acid was greatly improved at copper nanoparticles, indicating that anodic oxidation could be catalyzed at copper nanoparticles. And the pH had remarkable effect on the electrochemical process, a very well-defined oxidation peak appeared at pH 13.3 (0.2 M NaOH). The kinetics parameters of this process were calculated and the heterogeneous electron transfer rate constant (k) was determined to be 1.34×10^{-3} cm s^{-1}, and $(1-\alpha)n_\alpha$ was 1.22. The gold electrode modified with copper nanoparticles could detect SA at a higher sensitivity than common electrodes. The electrode was used to detect the SA levels in oilseed rape infected with the fungal pathogen *Sclerotinia sclerotiorum*. The results showed that the SA concentration reached a maximum during the 10th–25th hours after infection. This result was very similar to that determined by HPLC, indicating that the gold electrodes modified with copper nanoparticles could be used as salicylic acid sensors.

1. Introduction

Over the past three decades, the use of oilseed rape (*Brassica napus* L.) as an source of plant oil and protein in human and animal nutrition has increaseed. The fungal pathogen *Sclerotinia sclerotiorum* affects plant development and has a strong negative impact on the quality and production of oilseed rape. In China, the pathogen causes heavy losses in yield of oilseed rape [1]. However, no immune or highly resistant cultivars of oilseed rape are currently available to breeders, and genetic sources of resistance to the pathogen are also limited [2].

Plants routinely respond to insect feeding, pathogen infection, or environmental stress by an array of defense mechanisms. These responses confer protection at the damaged site, as well as throughout the plant, by the systemic accumulation of defense-related proteins in healthy tissues, distant to the damaged site. The induction of systemic defense responses is thought to be regulated by low-molecular-weight plant hormones, such as jasmonic acid, methyl jasmonate and salicylic acid (SA) [3]. A sensitive and reliable quantification method for these hormones in plant extracts is essential because of the significance of these compounds as putative signaling molecules. The determination of the levels of these hormones in oilseed rape tissues will help in the study of the disease resistance mechanism and will aid in the genetic engineering of cultivars of oilseed rape with increased resistance.

Among these plant hormones, SA plays an important role in signal transduction in plants [4]. Many methods have been used to detect SA, for example, UV spectrophotometery [5], fluorescence [6] and chromatography [7].

Electrochemistry is a sensitive and convenient method for the determinations of many molecules. Unfortunately, using ordinary electrodes (Pt, Au, carbon paste, and graphite), the electrochemical behavior of SA is poor; no stable electrochemical responses could be

doi:10.1016/j.talanta.2009.09.023

observed [8], or high potential was needed [9]. Then it was difficult to study its real electrochemical behavior using ordinary electrodes.

For molecules with poor electrochemical behavior, modified electrodes have given good results [10]. Many kinds of materials have been used to modify electrodes, such as polymers [11], thiols self-assembling monolayers [12], inorganic polynuclear transition metal hexacyanometallate films [13], polyacid films [14] and metal particles [15]. Due to their favorable properties, such as simple operation, good repeatability and rapid response, noble metals have been used to prepare particles-modified electrodes, such as gold [16], silver [17] and platinum [18]. However, such noble metals exhibited severe electrode poisoning in the detection of carbohydrates and amino acids [19], it was important to adopt other materials to modify electrode to carry out those researches. Copper nanoparticles have also been used to modify electrodes because they can cause unique catalysis in some systems [20]. For example, Zen et al. have used copper nanoparticle-modified electrode to detect glucose [21] and *o*-dihydrophenolic compounds [22]. In this paper, the anodic oxidation of SA at a copper nanoparticles-modified gold electrode was studied. The results showed that the electrochemical behavior of SA at this kind of modified electrode could be greatly improved. The electrode was used to detect the SA levels in oilseed rape infected with the fungal pathogen, *Sclerotinia sclerotiorum*, and the results were very similar to those obtained by HPLC, indicating that the copper nanoparticles-modified gold electrode has a potential application in the detection of SA.

2. Materials and methods

2.1. Reagents and instrumentation

Salicylic acid (SA) was obtained from Sigma. The SA stock solution (2.5 mmol L^{-1}) was prepared by dissolving the required amounts of SA in 0.2 mol L^{-1} sodium hydroxide solution. Other reagents were of analytical grade. All solutions were prepared with double distilled water.

A DL-180A ultrasonic cleaning device (Shanghai ZX equipment Ltd., China) was used to clean the electrodes. Cyclic voltammetry (CV) experiments were carried out in oxygen-free water under nitrogen using a CHI660A electrochemical workstation (CH Instruments, China) coupled to a conventional three-electrode cell. The electrodes for Scanning Electron Microscopy (SEM, S-3000N, Hitachi, Japan) studies were dried at room temperature before each test.

2.2. Detection of salicylic acid by using high performance liquid chromatography

Isolation and measurement of salicylic acid in plant materials was carried out by a high performance liquid chromatography (HPLC) system equipped with UV detector (Shimadzu, Japan). Separation was achieved on a Kromasil ODS column (200 mm × 4.6 mm, I.D.; 5 μm; Bohus, Sweden). The mobile phase was methanol: 5% acetate (50:50, v/v) and the flow rate was maintained at 0.7 mL min^{-1}. UV detection was set at 278 nm for salicylic acid detection.

2.3. Preparation of the modified electrode

The gold electrode was prepared by inserting a gold fiber (0.2 mm diameter) into a glass tube and then the tube was heated to seal the gold fiber. The tube was then polished to expose the gold, thus forming the gold electrode. Prior to each experiment, the electrode was polished with 0.05 μm alumina slurry, sonicated in acetone and twice distilled water for 3–5 min, respectively. The copper nanoparticles-modified gold electrode (nano-Cu/Au) was constructed by applying −0.3 V for 25 s in a 0.2 M acetate buffer solution (pH 4.0) containing 5.0 mM $CuCl_2$ according to a previously published protocol [20].

2.4. Electrochemistry measurement

The working electrodes were glassy carbon electrode (GC), Pt, Au or nano-Cu/Au electrodes, the auxiliary electrode was a platinum wire, and the reference electrode was a saturated calomel electrode (SCE). All the potentials given in this paper were calculated against the SCE. The cathodic current was assigned to be negative, and the anodic current was assigned to be positive. Each measurement was repeated at least three times and was conducted at 25 °C.

2.5. Treatment of plant materials

The oilseed rape samples were grown in a plant growth room at 15–21 °C up to the four-true-leaf stage, and then the leaves were excised for study. *S. sclerotiorum* mycelial discs (2 mm thick and 3 mm in diameter) were excised from the colony edge of 5-day-old culture and put on the upper sides of detached leaves. The inoculated leaves were incubated at 22 °C under conditions of above 95% relative humidity. Non-wounded control leaves were collected at 0 h. The infected leaves were collected at 5, 10, 20, 30 and 35 h after inoculation. Collected leaves were immediately flash-frozen in liquid nitrogen to terminate any metabolic activity and stored at −80 °C until they could be analyzed.

Samples (0.1 g fresh weight) of frozen leaves were homogenised in 0.5 mL cold water (4 °C) and stirred overnight. The extract was subjected to ultrasonication in KQ-500DB ultrasound cleaning bath (Ultrasound instrument Co., Ltd., Kunshan, China) for 60 min, the working frequency and power were 40 kHz and 500 W, respectively. After that, the extract was centrifuged at 12,000 rpm for 10 min. Before the electrochemical measurement, the solutions of extracts were adjusted with NaOH to obtain a 0.2 M NaOH final concentration.

3. Results and discussion

As was found by other research groups [8,9], using an Au electrode, the electrochemical responses of SA were poor and no well-defined peak of its oxidation could be seen (Fig. 1, curve c), compared with a blank solution (curve a in Fig. 1). However, a very well-defined oxidation peak appeared when using the nano-Cu/Au (Fig. 1, curve d) in the same solution. This peak was not observed in

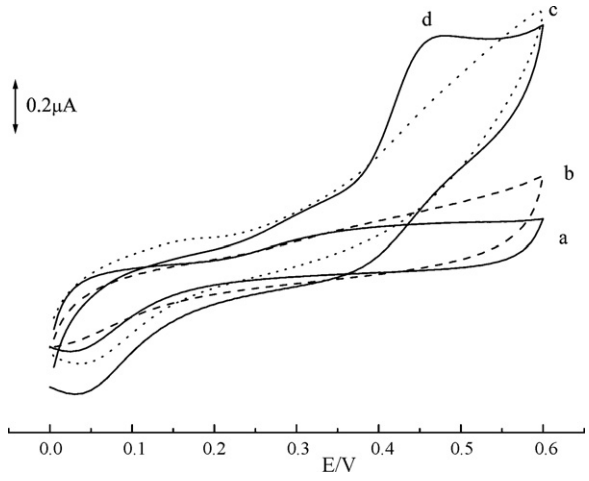

Fig. 1. The CV curves at Au (a and c) and nano-Cu/Au (b and d) electrodes in 0.2 M NaOH with (c and d) or without (a and b) 2.5 mM SA at a scan rate of 100 mV s^{-1}.

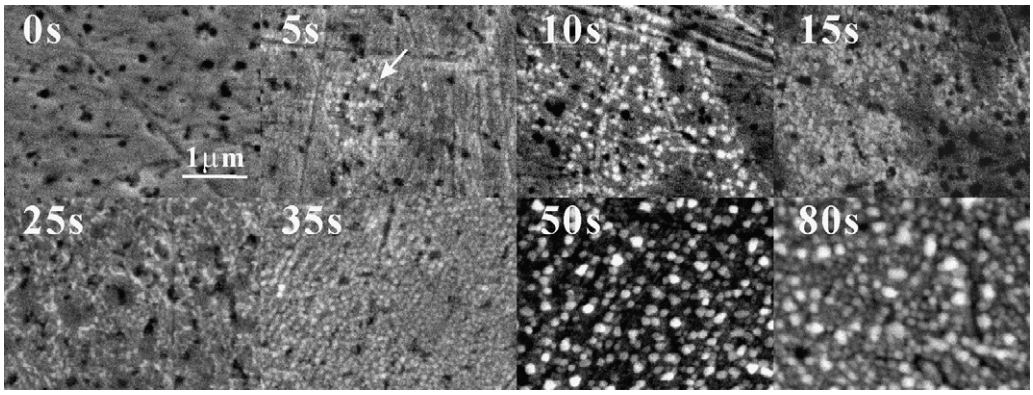

Fig. 2. SEM images of a copper nanoparticles-modified gold electrode with different deposition times.

the blank solution at the same electrode, indicating that the electro-oxidation of SA was greatly improved using a nano-Cu/Au, and that copper nanoparticles could catalyze its anodic process. And the peak at copper nanoparticles-modified gold electrode was very stable, after one cycle, the anodic current decreased from 0.576 μA to 0.482 μA, after that, the current became to steady, no evident decrease was observed after 25 cycles (0.479 μA), indicating that the electro-oxidation of SA at Cu electrode was stable enough to study the electrochemical behavior of SA.

The experiments were also carried out at GC and Pt electrodes. Just as we have known, the electrochemical behavior of SA was poor at ordinary GC electrode [8,9]. But an oxidation peak appeared at *ca.* 0.55 V in the same solution at Pt electrode (figures are not given), indicating that the electro-oxidation of SA could be obtained at Pt electrode, but this electrochemical behavior was not stable, the peak decreased rapidly along with continued CV scan, after 25 cycles, no well-defined peak could be found. This indicated that, although the oxidation of SA could be obtained at Pt electrode, it still could not be used to study its electrochemical behaviour disappointedly.

The response for different pH values had been studied; it was found that the pH had remarkable effect on the electrochemical process. NaOH was adopted to adjust the pH of solution. It was found that if pH was under 12, no well-defined peak of SA oxidation could be seen. When pH was 12.6, there was a flat peak appearing at 0.55 V, and the current was 0.225 μA. The peak current rose with increasing pH value from that pH. There was a very well-defined oxidation peak appeared at 0.468 V when pH reached 13.3 (0.2 M NaOH), and the current was increased to 0.479 μA. Then, the experiment was carried out in 0.2 M NaOH.

The surface morphology of the modified electrodes was observed using scanning electron microscopy (SEM) after their preparation (Fig. 2). The results showed that the bare Au electrode was clean, and had some holes of about 100–200 nm on its surface. After the beginning of copper deposition, a few of particles (<50 nm) appeared on the surface. With continued deposited time, the particles began to appear (less than 100 nm) and had spread over the surface after 25 s, however, the 100–200 nm holes are remained. Eventually, the copper nanoparticles began to stack on the surface, and the holes disappeared. After 80 s, the layer of copper nanoparticles became to about 300 nm thick. And this result is similar to Pan' experiment [20], in which 200 nm Cu particles with spherical shape were obtained by applying 0.0 V for 180 s in the same kind of solution. The electrochemical responses of SA using these modified electrodes with different deposition times were assayed, as shown in Table 1. It was found that the peak rose with increasing deposited time. After 25 s, the peak began to stable. Then 25 s was found to be the optimum deposition time. In subsequent experiments, 25 s was used to deposit the copper nanoparticles.

Table 1
The peak potentials and currents for different copper deposited times.

Deposited time/s	5	10	15	20	25	35
Peak potential/V	0.495	0.479	0.475	0.471	0.468	0.467
Peak current/μA	0.395	0.44	0.465	0.471	0.479	0.483

The CV curves for the anodic oxidation of SA at the nano-Cu/Au electrode at various scan rates are shown in Fig. 3. It can be found that the peak potentials shifted positively with the rising scan rate, while the peak current increased. As expected for a diffusion-controlled reaction, the I_{pa} of SA oxidation increased linearly with $\upsilon^{1/2}$ (figures are not given). The slope of the straight line ($r = 0.995$) of I_{pa} versus $\upsilon^{1/2}$ is $(1.16 \pm 0.03) \times 10^{-6}$ A V$^{-1/2}$ s$^{1/2}$. The plot of peak potential (E_{pa}) versus the logarithm of the scan rate is a straight line ($r = 0.991$) (figures are not given). From the straight line, the slope and the intercept determined as 0.0242 and 0.494, respectively. For an irreversible process, the peak potential (E_{pa}) could be represented by the equation [23]:

$$Ep = K + \frac{2.3RT}{2(1-\alpha)n_\alpha F}\log\upsilon$$

$$K = E^{\circ\prime} + \frac{RT}{(1-\alpha)n_\alpha F}\left(0.78 + \frac{2.3}{2}\log\left(\frac{(1-\alpha)n_\alpha FD}{k^2RT}\right)\right)$$

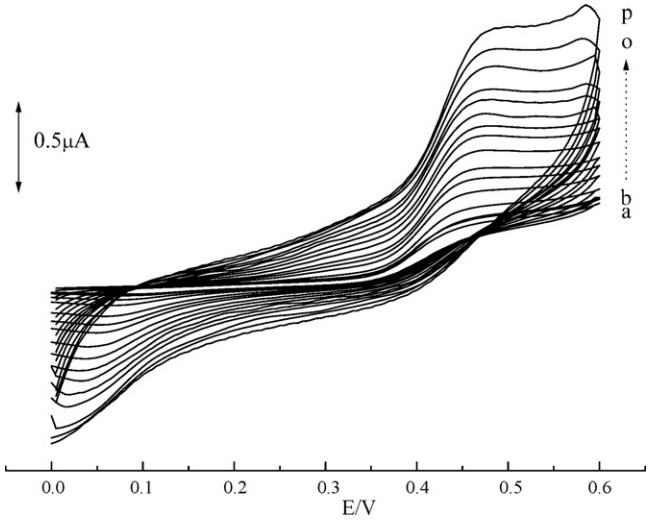

Fig. 3. The CV curves for 2.5 mM SA at a nano-Cu/Au electrode at various scan rates (mV s^{-1}): (a) 2; (b) 3; (c) 5; (d) 10; (e) 20; (f) 30; (g) 40; (h) 60; (i) 80; (j) 100; (k) 120; (l) 150; (m) 180; (n) 240; (o) 300 and (p) 400. The other conditions are as in Fig. 1.

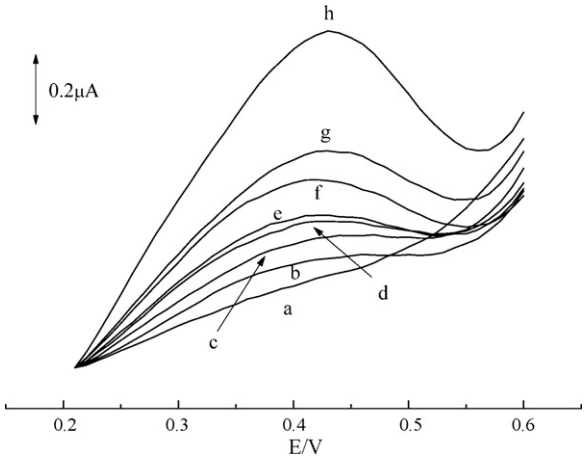

Fig. 4. DPVs of the nano-Cu/Au electrode for different concentrations of SA. (a) 0 μM; (b) 1 μM; (c) 2 μM; (d) 10 μM; (e) 20 μM; (f) 50 μM; (g) 0.2 mM and (h) 1 mM.

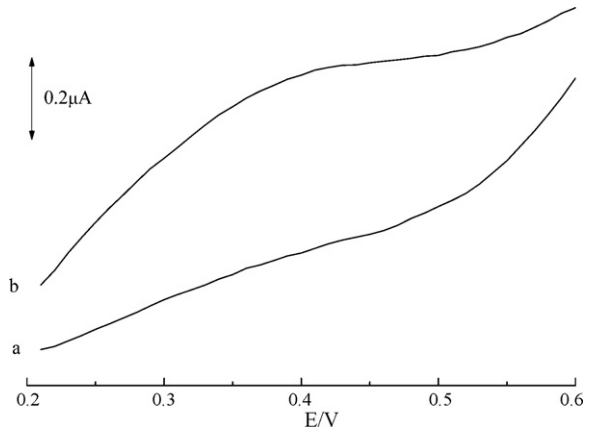

Fig. 5. DPVs of the nano-Cu/Au electrode in buffer (a) and extract of oilseed rape leaves after inoculating with fungal pathogen *Sclerotinia sclerotiorum* for 30 h (b). The other conditions are as in Fig. 4.

where υ is the scan rate, $E^{\circ\prime}$ is the standard electrode potential, k is the heterogeneous electron transfer rate constant, and D is the diffusion coefficient (for SA, it is 1.11×10^{-5} cm^2 s^{-1} [24]). Therefore, the $(1-\alpha)n_\alpha$ was calculated as 1.22, and k was 1.34×10^{-3} cm s^{-1}. For the bare Au electrode, these parameters could not be calculated at all because of the lack of a well-defined peak.

The electrochemical responses of the nano-Cu/Au electrode in various concentrations of SA solution were studied. Differential pulse amperometry (DPV) was chosen to test these responses. We found a DPV peak appearing at 0.4 V (Fig. 4), and the logarithm of the current and SA concentration had a good linear relationship down to 0.8 μM ($\log I = -5.38 + 0.264 \log C$), with a correlation coefficient of 0.992, and a detection limit of 0.1 μM, which is higher than that obtained at carbon paste electrode (12.3 μM) [8] and glassy carbon electrode by voltammetry (3.6 mM) [25], and is similar to that obtained at glassy carbon electrode by DPV (0.65 μM) [9].

The interference experiments were carried out. It is well known that, ascorbic acid is a major interferent existing in life widely. Its concentration in oilseed rape is 26.33 mg per 100 g fresh weight [26]. It was found that seven times the usual concentration of ascorbic acid could not interfere with the detection of SA. Then the nano-Cu/Au electrode has a good anti-interference effect for ascorbic acid.

The nano-Cu/Au electrode was used to detect SA in oilseed rape leaves infected by *Sclerotinia sclerotiorum*. It was found that after inoculating with the fungal pathogen *Sclerotinia sclerotiorum* for 30 h, a peak appeared at 0.4 V compared with a blank solution (Fig. 5). The concentration was calculated as 8.58 μM confirmed by the linear equation, which is close to the result obtained by HPLC-UV (9.42 μM), indicating that the nano-Cu/Au electrode has a high sensitivity for SA; it could be used as an SA sensor after further research.

The interferent in biosystem was also considered in the study. It is known that salicylic acid is changed to 2, 5-dihydroxybenzoic acid by an enzymatic hydroxylation pathway through the cytochrome P-450 microsomal system [27]. And that compound could be also oxidized at electrode [28], and then in this experiment, when copper particles-modified electrode was adopted to detect SA in real sample, 2, 5-dihydroxybenzoic acid maybe would interfere with the detection, which was an avoidless factor in the real plant sample.

The electrode was then used to monitor the change in SA level during infection with *Sclerotinia sclerotiorum* (Fig. 6). It was found that the SA level rose rapidly after inoculation with *Sclerotinia sclerotiorum* and reach a plateau after 10 h, at which point the SA concentration in oilseed rape leaves was four times that of the original, non-inoculated leaves. This SA level persisted until 20 h after inoculation, thereafter the SA concentration began to decline, and after 35 h the SA level returned to the initial value. For different parallel samples, there is little difference in the absolute intensities of peaks, but the trends are all the same basically. We think the difference maybe is resulted from several factors, such as the diversity of leaves, the avoidless difference in infection with the fungal pathogen *Sclerotinia sclerotiorum*.

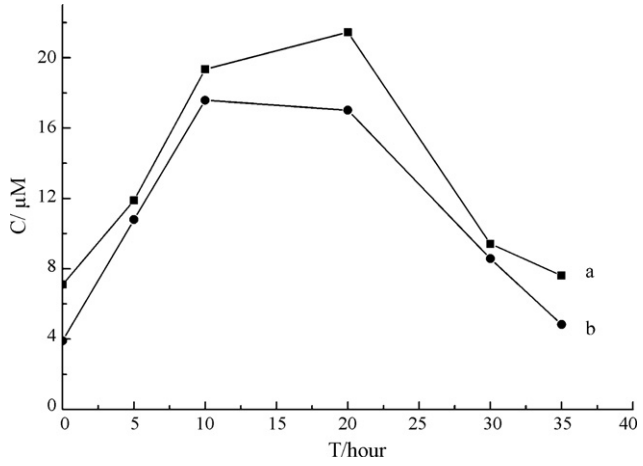

Fig. 6. The change of SA level in oilseed rape leaves after inoculating with fungal pathogen *Sclerotinia sclerotiorum* for different times as determined by HPLC (a) and the nano-Cu/Au electrode (b). The other conditions are as in Fig. 4.

SA plays an important role as a signaling molecule in the plant defense responses. Our results showed a sharp increase in the levels of SA in the leaves infected by *Sclerotinia sclerotiorum* 10 h after inoculation. The high levels of SA in the leaves might be due to stimulation of the octadecanoid pathway and signal transduction. Due to scavenging mechanisms, the SA concentration in cells returns to low levels to avoid potential toxic effects. These results indicate that SA signaling has an important role in the response to infection by *Sclerotinia sclerotiorum*.

4. Conclusions

Salicylic acid is considered to act as a phytohormone and plays an important role in signal transduction in plants. Its poor electrochemical behaviour at ordinary electrodes limits detection of its concentration. Here we report the anodic oxidation of SA at a copper nanoparticles-modified gold electrode. We found that the

electrochemical behavior of SA at this kind of modified electrode was greatly improved. The electrode was used to detect the SA levels in oilseed rape infected with the fungal pathogen *Sclerotinia sclerotiorum*. The electrode showed results is very similar to those obtained by HPLC, indicating that the electrode could be used as a sensor for SA detection.

Flame atomic absorption spectrometry

ABSTRACT

In this study, oil-in-water formulations were optimized to determine sodium, potassium, calcium, magnesium, zinc, and iron in emulsified egg samples by flame atomic absorption spectrometry (FAAS). This method is simpler and requires fewer reagents when compared with other sample pre-treatment procedures and allows the calibration to be carried out using aqueous standards. Different oily phases such as corn oil, decyl oleate and octyl stearate were tested, as well as Tween 80, Triton X-100 and Triton 114 were analyzed as surfactants. The optimum type and proportion of formulations were determined and their use depended on the element studied. The emulsion preparation was performed by a conventional method that involves mixing both phases at 60 °C by magnetic stirring and phase inversion to change the water-to-oil ratio by increasing the volume of the surfactant–water external phase and correspondingly decreasing the volume of internal phase. The accuracy of the method was further confirmed by determining the metals in a whole egg powder CRM and recoveries ranged from 97.5% for Mg to 102.2% for Na, with relative standard deviations lower than 2.3%. The precision of the procedures was determined through repeatability (intra-day precision) and intermediate precision (inter-day). The repeatability presented RSD values lower than 4.2%. The intermediate precision was evaluated using the RSD and *F*-test. The RSD values to intermediate precision was lower than 5.3% and the computed *F*-values were lower than tabulated *F*-values, indicating no significant difference between the results obtained on different days. The proposed method including, sample emulsification for subsequent metal determination for FAAS, has proved to be sensitive, reproducible, simple and economical.

1. Introduction

Knowledge of the mineral composition of hen eggs is increasingly required for different purposes; these include the estimation of accumulation of toxic species from the hen egg and the role of egg composition in human nutrition [1].

The egg is a system naturally emulsified by components such as phospholipids, lipoproteins and proteins [2]. Eggs are included in several food products exercising various functions. As emulsifier (e.g. mayonnaise) it forms a strong and cohesive film around oil droplets which stabilizes them against coalescence and interacts to form network structures which gives viscoelasticity to products, with unique sensory and textural characteristics [3].

The quality of food products has received great attention due to its influence on human nutrition and health. In this context, the determination of trace metals in foods has become an important field in food analysis [4–6]. However, the accurate determination of trace metals in hen eggs is still an analytical challenge, due to their low concentration level and the difficulties that arise from matrix characteristics. Flame atomic absorption spectrometry (FAAS) is a powerful detection technique for determining trace elements. The advantages of FAAS include well-known interferences, low operator skill required for operation, and comparatively low cost of instrumentation and maintenance [7]. One disadvantage, however, is the sample pre-treatment which is a necessary step for determining trace elements in complex matrices such as egg. Due to its high viscosity and content of organic matter, direct egg analysis is particularly difficult.

Methods for egg sample treatment involving digestion with acids and peroxides reported in the literature [1,8,9], have attempted to improve digestion by combining the use of these reagents with ultraviolet [10] or microwave radiation [2,11–13]. All these procedures result in additional steps, which may lead to inconveniences such as sampling errors, contamination and losses during handling [10].

Direct emulsification with surfactants provides a rapid procedure for sample preparation since this approach does not require any destruction of the organic matrix [14]. It simply reduces the

Table 1
Instrumental parameters for metal determination in emulsified egg samples.

Metal	Wavelength (nm)	Slit width (nm)	*I* (mA)	Integration time (s)	Flame
Na	589.0	0.8	3.0	3.0	C_2H_2–air
K	766.5	0.8	4.0	3.0	C_2H_2–air
Ca	422.7	1.2	4.0	3.0	N_2O–C_2H_2
Mg	285.2	1.2	2.0	3.0	C_2H_2–air
Zn	213.9	0.5	6.0	3.0	C_2H_2–air
Fe	248.3	0.2	8.0	3.0	N_2O–C_2H_2

viscosity and the organic content of the sample, making the properties of the egg emulsion close to those capable of being analyzed by FAAS, while maintaining the system's homogeneity and stability. In an earlier study, emulsification of egg samples was satisfactorily used for the determination of Se in whole hen eggs by graphite furnace atomic absorption spectrometry (GFAAS). The oil-in-water emulsion stabilized the sample, maintaining the system's homogeneity, and reduced the viscosity and the organic content of the sample, thus allowing egg sample analysis by GFAAS [15].

The goal of this study was to investigate the use of emulsions as sample preparation for a routine determination of Na, K, Ca, Mg, Zn and Fe in whole chicken eggs by FAAS. The expected advantages of this procedure are the higher stability and easy handling of sample emulsions, allowing the use of aqueous standards for calibration. The reliability of the procedure was checked by analyzing standard reference material.

2. Experimental

2.1. Instrumentation/procedure

All measurements were carried out using an ANALYTIK Jena AG (Jena, Germany) model novAA 300 atomic absorption spectrometer equipped with SpectrAA (Varian, Australia) hollow cathode lamps as the radiation source. An acetylene–air or acetylene–nitrous oxide flame was used; the gas flow rates and the burner height were adjusted in order to obtain the maximum absorbance signal for each element. Other instrumental parameters were set to the values shown in Table 1.

2.2. Reagents

All reagents were of analytical grade, and all emulsions were prepared with distilled and deionized water that was further purified by a Milli-Q high purity water device (electrical resistivity of 18.0 MΩ cm) (Millipore, USA). Laboratory glassware was kept overnight in 10% (v/v) HNO_3 in ethanol solution and shortly before use was washed with water and dried in a dust free environment. Concentrated nitric acid used in this study was supplied by Merck (Germany). Na, K, Ca, Mg, Zn and Fe standard solutions (1000 mg L^{-1}) were obtained from the National Institute of Standards and Technology (NIST, USA) and diluted as necessary to obtain working standards. The non-ionic surfactants Triton X-100 (Fluka, Switzerland), Triton 114 (Sigma–Aldrich, USA) and Tween 80 (Fluka) were tested for emulsion preparation. Commercial corn oil, decyl oleate (DEG, Brazil) and octyl stearate (Galena, Brazil) were tested as the oily phase. The certified reference material (CRM) RM 8415 whole egg powder (NIST) was used to check the accuracy of the proposed method.

2.3. Emulsion preparation

Oil-in-water emulsions were prepared using a specific sequence in order to guarantee their stability. Aliquots of surfactant, oil and egg sample or reference material were weighed and placed in an 80 mL beaker, and then water at 60 °C was added with continuous agitation until the required volume was reached. Magnetic stirring (3000 rpm) was maintained during 15 min at room temperature (22 °C). The total volume of the system was 50 mL, which was attained by increasing the volume of the surfactant–water external phase and correspondingly decreasing the volume of internal phase. A blank emulsion was prepared in the same way without sample addition.

Table 2
Variables and levels of 2^3 factorial design for preparation of emulsions.

Factor	Level		
	Low (−1)	Medium (0)	High (+1)
Emulsifier (%, w/v)	1.0	2.0	4.0
Oil (%, w/v)	1.0	2.0	4.0

2.4. Experimental design

A preliminary factorial design was applied to investigate the influence of oil and emulsifier amounts on emulsion stability. Since the egg is itself an emulsified system the oil added to the sample was already stabilized, therefore in order to establish the best formulation only oil and emulsifier quantities were regarded as factors. Their influence on the emulsion stability was evaluated using a 2^3 full factorial design (Table 2). The design required a total of 9 experiments per oil/emulsifier combination.

2.5. Determination of creaming behaviour

Stability of optimized emulsion was monitored by measuring the extent of gravitational phase separation. The best formulations from experimental planning, showed in Table 3, were monitored by this creaming test. For the measurement of physical stability, 10 mL of each prepared egg emulsion were poured into graduated tubes and kept at room temperature (25 °C). The volume of the separated cream layer in each tube was recorded after 1, 2, 7 14 and 21 days of storage. The emulsion stability index (ESI) was calculated as percentage: ESI (%) = (remaining emulsion height/initial emulsion height) × 100. The ESI was calculated to show the stability of the emulsions since the larger the ESI value the higher emulsion stability.

2.6. Application to real samples

Fresh eggs from domestic hens (*Gallus gallus*) commercially available were purchased from commercial establishments, including supermarkets in Santa Maria city as well as directly from small-scale farms. A total of six different samples were analyzed, consisting of pooled samples from the same carton of six eggs each.

2.7. Sample preparation regarding individual metal determination

Although there is general procedure described for the preparation of the emulsions, in this study it was necessary to consider that

Table 3
Optimized formulation compositions and determinable metals for each.

Formulation	Oily phase (%)		Emulsifier (%)		Metal
1	Corn oil	4.0	Triton 114	2.0	K
2	Octyl stearate	4.0	Tween 80	4.0	K, Ca, Mg, Zn
3	Decyl oleate	2.0	Triton 114	1.0	K, Mg
4	Octyl stearate	2.0	Triton 114	1.0	K, Ca, Mg, Fe
5	Octyl stearate	4.0	Triton X-100	4.0	Na

the metals were present in different concentrations in egg samples and, therefore, appropriate sample amounts that make the concentration of the element fall within analytical curve must be used. Sample amounts varied between 0.6 and 4.0% (w/v) according to the expected amount of the analyte in the sample. For components present in larger concentrations, such as sodium and potassium, the emulsion should be prepared with a maximum sample amount of 0.6%. For calcium amounts between 0.6 and 1.0% can be used and for magnesium, between 0.6 and 2.0%. Finally, for zinc and iron amounts between 2.0 and 4.0% must be used.

3. Results and discussion

Four criteria were used to choose the components and their relative quantity in the emulsion: (i) the emulsion should contain only the components necessary to stabilize the sample, in other words, sample, surfactant, water and an oily component; (ii) the emulsion should be stable for a reasonable period and not produce coalescence or creaming; (iii) the emulsion should present low viscosity to allow correct sample aspiration; and (iv) all components should present low background during the FAAS measurement and low metal contamination.

3.1. Formulation studies

The oil-in-water emulsion was chosen mainly due to its characteristics of long-term stability and low viscosity [16]. After choosing the type of appropriate emulsion, the next step was to select the emulsifier, since the optimum tensoactive characteristics for each oil–water system are determined by the hydrophilic–lipophilic balance (HLB). Surfactants with HLB values between 9.6 and 16.7 are considered hydrophilic (water-soluble), and tend to form oil-in-water emulsions [17]. Triton 114, Triton X-100 and Tween 80 have HLB values of 12.4, 13.5 and 15.0 respectively. It should also be taken into account that it is better to use emulsifiers without foaming properties in order to avoid heterogeneous distribution of the oil drops in the final emulsion. Furthermore, for analytical purposes, other factors should be considered such as surfactant solubility and low background during the FAAS measurement [14,18]. Non-ionic emulsifiers such as Tween 80, Triton X-100 and Triton 114 satisfy all these requirements and are inexpensive and readily available in most analytical laboratories. Corn oil, decyl oleate, and octyl stearate were chosen due to their low cost and easy obtainment.

The oil/surfactant ratio was determined by experimental planning. In all of the experiments in which the amount of oil was smaller than the amount of emulsifier, the separation of phases took place immediately after preparation. This shows that an excess of emulsifier in relation to oily phase favors the emulsion instability. The diverse combinations presented different behaviors of stability and the best formulations are presented in Table 3. Table 3 also present the metals possible of being determined in each formulation. The selection criteria are discussed in Section 3.3.

In spite of formulations stability and metal determination possibility, it was necessary to determine the level of contamination by the metals studied in the oils and surfactants investigated. The surfactant metal content was determined after its dilution in water. However, oil was measured after stabilization with an emulsifier, which was used as a blank. Table 4 presents the metal contents of oils and surfactants selected for this study. Triton 114 and Tween 80 presented high content of sodium and Triton X-100 high potassium and calcium content. The oily components presented low contamination, with exception of corn oil, which contains Ca in some level. Contamination limited the choice of surfactant and oil.

Table 4
Concentration levels of metals (mg kg^{-1}) in oils and surfactants used in this study.

	Na	K	Ca	Mg	Zn	Fe
Corn oil	0.1	1.3	26.4	0.9	<LOD	9.2
Octyl stearate	14.4	1.4	6.6	<LOD	0.7	0.7
Decyl oleate	0.6	0.7	1.7	0.3	<LOD	12.4
Triton 114	367	3.8	8.7	0.4	1.5	8.8
Tween 80	82	<LOD	<LOD	<LOD	0.6	10.2
Triton X-100	1.3	342	32.1	<LOD	0.2	3.5

LOD = limit of detection.

Table 5
Calibration curves and regression parameters for metal determination in emulsified egg sample.

Metal	Range (mg L^{-1})	Regression equation[a]	R^2	C_0 (mg L^{-1})	LOD (mg L^{-1})
Na	1.0–8.0	$A = (0.0032 + 0.2038\,C)/(1 + 0.0728\,C)$	0.9999	0.0263	0.02
K	1.0–10.0	$A = -0.003549 + 0.104891\,C$	1.0000	0.0426	0.04
Ca	0.5–8.0	$A = 0.001232 + 0.110905\,C$	0.9996	0.0395	0.11
Mg	0.5–4.0	$A = (0.0147 + 0.4702\,C)/(1 + 0.2392\,C)$	0.9944	0.0139	0.01
Zn	0.05–0.4	$A = 0.001455 + 0.13473\,C$	0.9923	0.0357	0.03
Fe	0.1–2.0	$A = -0.001426 + 0.02232\,C$	0.9979	0.2412	0.07

C (mg L^{-1}) = concentration of element in standard solution.

3.2. Formation and stabilization of the emulsion

The spontaneous formation of emulsion rarely occurs, but rather this process requires a sequence of steps: (i) formation of droplets of the internal phase and (ii) stabilization of these droplets in the external phase. Moreover the application of energy in the form of heat and mechanical stirring is necessary [19].

The increase of the temperature reduces the interfacial tension, however the heat can favor the separation of the phases due to the increased kinetic energy of the droplets. Usually emulsions are prepared at temperatures between 70 and 80 °C, and the aqueous phase is heated up 5 °C more than the oily phase. However, the maximum temperature used in this work was 60 °C due to the presence of proteins in the egg matrix, but was high enough to stabilize the emulsion.

Since the behavior of stable systems depends on the preparation conditions, care was taken to assure that the procedure was carried out in exactly the same way for all experiments [20]. Providing a finely dispersed oil-in-water emulsion with long-term stability is phase inversion to change the water-to-oil ratio by increasing the surfactant–water external phase volume and correspondingly decreasing the internal phase volume [19]. In the initial period of stirring the droplets necessary for the emulsification are formed. If the stirring exceeds the necessary period for ideal stability, adhesion can take place due to collision among the droplets. This period of time is usually determined empirically. In this study, the stipulated time was 2 min of manual mechanical stirring to reach emulsification, followed by magnetic stirring at 3000 rpm for 15 min at room temperature for complete stabilization of the system.

Creaming test may also be used to determine emulsion stability [21,22]. The final appearance of all emulsions was milky white and all egg emulsions presented relatively high values of ESI, since emulsion composition was previously optimized by experimental planning. The octyl stearate/Tween 80/egg sample combination presented highest values of ESI ($ESI_{1\ day} = 100\%$ to $ESI_{21\ days} = 97.5\%$). The octyl stearate/Triton X-100/egg sample combination presented lower values of ESI ($ESI_{1\ day} = 97.6\%$ to $ESI_{21\ days} = 93.9\%$). Emulsions containing CRM presented a precipitate after 24 h. The precipitate was probably formed from the solid content that was not stabilized by the micelles due to the lyophilization process, however homogeneity was re-established by shaking the mixture.

3.3. Analytic applicability study and validation

Ideally, a single emulsion should be used for determination of all elements, however this was not possible mainly due to: (1) the presence of the analytes as contaminants in both surfactants and oil components (Table 4) and (2) different metal contents in the samples. Based on these criteria, the metals that could be analyzed in the same emulsion are showed in Table 3.

The characteristics of an analytical method are defined by the figures of merit, which should be determined experimentally. The proposed method was validated for six metals (Na, K, Ca, Mg, Zn and Fe). Figures of merit presented were linearity of the analytical curves, accuracy and precision. In addition, sensitivity was determined by characteristic concentration (C_0).

The advantages of the emulsification procedure for fatty samples have been described in the literature. When properly stabilized, the emulsified sample is compatible with most analytical instrumentation, allowing the use of simple calibration procedures due to the minimization of interferences [14]. In this study, calibration with aqueous standards was possible and the linearity ranges were selected to span the metal concentrations expected in real samples. Analytical curves were constructed by evaluating the relation between response (peak height and absorbance) and concentration by linear regression analysis yielding the results shown in Table 5. In all instances, a linear fit was found to be adequate for the purpose. Table 5 also presents the values found for characteristic concentration and limit of detection (LOD) for all elements.

The accuracy of the method was further confirmed by determining the metals in a whole egg powder CRM. The results are shown in Table 6. Statistical comparison by means of the *t*-test showed that there was no significant difference between the values obtained with the proposed method and the certified values.

The precision of the procedures was determined through repeatability (intra-day precision). Six egg emulsions were assayed during the same day, under the same experimental conditions. Intermediate precision (inter-day) was evaluated by assaying freshly prepared emulsions on three different days ($n = 3$). The repeatability presented good RSD values for all metals. The intermediate precision was evaluated using the RSD and *F*-test. The computed *F*-values were lower than tabulated *F*-values, indicating no significant difference between the results obtained on different days. All precision data are shown in Table 6.

3.4. Real samples analysis

The proposed method was applied to the determination of Na, K, Ca, Mg, Zn and Fe in fresh egg samples. We aimed to provide a baseline of these elements in eggs from six different suppliers (commercial and farm eggs). Six determinations were made for each element and the results are listed in Table 7. There was no significant difference among the content of the major components (Na, K, Ca and Mg) in the eggs from different suppliers. The largest variations were in the minor component contents, Zn and Fe, which ranged from 7.4 to 12.2 $\mu g\,g^{-1}$ and from 24.5 to 44.2 $\mu g\,g^{-1}$, respectively.

Information on egg metal composition is being sought [1,8–12,23], despite the interest, data are still limited. Ca, Mg, Zn and Fe levels obtained in this study were similar to those reported by Shang and Hong [23]. There are no literature reports for Na and K levels. The proposed method could be of interest in poultry and nutriology research and can be recommended for routine analyses. It can also be applied for metal determination in eggs from other bird species.

4. Conclusion

Ideally a single emulsion should be used for the determination of all selected elements, however, this was not possible due to the sur-

factant metal content and the different levels of each metal in egg samples. The main advantages of the proposed method over traditional digestion methods are that it does not require a long sample treatment or large amounts of organic solvents or inorganic acids and it is simple and shows good accuracy and reproducibility. As the challenges and main requirements for emulsion application in atomic spectrometry involve the attainment of stable emulsions with low viscosity, the proposed method including emulsification and subsequent metal determination for FAAS fulfilled these requisites and proved to be sensitive, reproducible, simple, and economical.

ABSTRACT

Single strand DNA (ssDNA) was used to modify nanogold to obtain a nanogold-aptamer resonance scattering (RS) probe (NGssDNA) for Hg^{2+}, based on the formation of stable thymine-Hg^{2+}-thymine (T-Hg^{2+}-T) mismatches and aggregation of the released nanogold particles. After removing the aggregated particles by filtrate membrane, the excess NGssDNA in the filtration solution exhibit catalytic effect on the gold particle reaction between $HAuCl_4$ and ascorbic acid (AA) that appear as RS peak at 596 nm. When Hg^{2+} concentration increased, the RS intensity at 596 nm decreased. The decreased intensity is linear to Hg^{2+} concentration in the range of 0.00008–0.888 ng/mL Hg^{2+}, with detection limit of 0.000034 ng/mL. The nanogold-aptamer catalytic RS assay was applied to determination of Hg^{2+} in water with satisfactory results.

1. Introduction

Application of new analytical reaction and novel material is a good way to obtain good analytical method. Aptamers are short single stranded oligonucleotides, which is selected from synthetic and random sequence library in vitro via a combinatorial chemistry technique known as SELEX. It can bind specifically to a wide range of target molecules, such as proteins, polypeptideor, some other organic compounds or metal ions with very small dissociation constants. Due to their high affinity, easy and quick preparation in vitro and functionalized, more and more aptamers are used to study the specific functions and interactions of protein [1,2], and applied in bioassays with naked-eye, spectrophotometric, fluorescence, electrochemical and surface plasmon resonance (SPR) detections [3–5]. Nanogold is one of the best nanoparticles in nanoanalytical chemistry. Being unique optical and electrical properties, high catalytic activity and good biocompatibility, it is widely applied in nanocatalytic, bioanalysis and other fields [6]. Recently, nanogold has been utilized to aptamer assay to develop visual colorimetric, fluorescence, SPR, electrochemical aptamer methods [7,8]. However, there is no report about nanogold catalytic reaction of Au(IV)-AA-cetyltrimethyl ammonium bromide and the aptamer-nanogold catalytic resonance scattering (RS) assay. RS is simple, rapid and sensitive, and has been applied to the analysis of proteins, nucleic acids, inorganic ion, based on the simple molecular interaction between analyte and small molecules such as dye. However, the selectivity for most RS methods remains to be improved. Recently, some highly selective reactions such as immunoreaction, and enzyme-catalyzed reaction have been utilized to develop some highly selective sensitive RS assays for protein antigen and enzyme [9–11]. However, highly selective and sensitive RS assays for metal ions have not been reported yet. In this paper, a novel aptamer-nanogold catalytic RS assays was proposed to detect environmental endocrine disrupting chemicals Hg^{2+} [12], based on T-Hg^{2+}-T mismatches, nanogold aggregation, aptamer-nanogold catalytic reactions and RS effect of gold particles.

2. Experimental

2.1. Apparatus

A model of Cary Eclipse fluorescence spectrophotometer (Varian Company, Palo Alto, CA) was used to record the RS intensity, with the excited and emission slit of 2.5 nm, and PMT voltage of 500 V, emission filter of 1%T attenuator. A model of RF 540 fluorescence spectrophotometer (Shimadzu, Japan) was also used to record the RS intensity. A model of F732-V cold atomic absorption apparatus (Shanghai Huaguang Instrument Factory, China) was used for the determination of mercury, using $SnCl_2$ reduced procedure and an absorption line of 253.7 nm. A model of 79-1 magnetic heat agitator (Zhongda Instrumental Plant, Jiangsu, China), a model of SK8200LH ultrasonic reactor (Kedao Ultrasonic Instrument Limited Company, Shanghai, China) and a model of H-600

transmission electron microscope (TEM) (Electronic Stock Limited Company, Japan) were used.

2.2. Reagents

Single strand DNA used in this paper was purchased from Sanbo Yuanzhi Biotechnology Limited Company, Beijing, China. The aptamer for Hg^{2+} is reference to the articles of Yang's research group [13]. Its sequence is 5′-TTTCTTCTTTCTTCCCCCCTTGTTTGTTGTTT-3′, and a random DNA sequence is 5′-AAACGGCAAACATCCCCCCAAGTAAGAAGAAA-3′. 1.0% $HAuCl_4{\cdot}4H_2O$ (National Pharmaceutical Group Chemical Reagents Company, China) was used to prepare nanogold. 0.20 mol/L Na_2HPO_4 and 0.20 mol/L NaH_2PO_4 solutions were used to prepare different pH phosphate buffer solution according to a certain volume ratio. 2.00×10^4 ng/mL Hg^{2+} standard solution, 1.0% tri-sodium citrate (Shanghai Chemical Reagent Plant, Shanghai, China), 2 mol/L NaCl solution, 0.05 mol/L cetyltrimethyl ammonium bromide (CTAMB), 0.05 mol/L tetradecyl pyridinium bromide (TPB), 0.05 mol/L stearyl dimethyl benzyl ammonium chloride (SDBAC) were prepared. Nanogolds were prepared by citrate reduction of $HAuCl_4$ according to the procedure described in the reference [11]. All reagents were of analytical grade and the water was doubly distilled.

2.3. Preparation of the aptamer-nanogold probe

A different amount of ssDNA, a 400 μL pH 7.0 Na_2HPO_4–NaH_2PO_4 buffer solution, a 375 μL 58.0 μg/mL nanogold solution were added into a 5 mL marked tube in turn, mixed well, and holding for 5 min at room temperature. Then added 22.5 μL 2 mol/L NaCl solution, and diluted to 1.5 mL. Another 5 mL marked tube without ssDNA was used as contrast tube. The RS intensity at 540 nm ($I_{540\,nm}$) was measured. Results indicated that 2.04 nmol (18.0 μL) ssDNA is the minimum amount interacting with 375 μL nanogold to form aptamer-nanogold probe.

A 1.8 mL 0.17 μmol/L ssDNA and 37.5 mL 58.0 μg/mL nanogold solution were added into a 50 mL conical bottle, mixed well, and holding for 5 min at room temperature, in order that ssDNA interact with nanogold fully to form aptamer-nanogold probe (NGssDNA). Its concentration, calculated as Au, is 55.3 μg/mL NGssDNA.

2.4. Procedure

A 400 μL pH 7.0 Na_2HPO_4–NaH_2PO_4 buffer solutions, a 393 μL 55.3 μg/mL NGssDNA and a certain amount of Hg^{2+} solution were added into a 5 mL marked tube in turn, mixed well. Then a 22.5 μL 2 mol/L NaCl solution was added, diluted to 1.5 mL with doubly distilled water, mixed well. The reaction solution was filtered by 0.15 μm filtrate membrane and the filtrate solution was obtained for use.

A 10 μL 9.69×10^{-3} mol/L $HAuCl_4$ solution, 140 μL 0.1 mol/L HCl solution, 80 μL the filtrate solution (diluted 10 times) and 400 μL 0.05 mol/L CTMAB solution were added into a 5 mL marked tube in turn, diluted to 2.5 mL with water. Then 7.5 μL 0.057 mol/L AA solution was added, diluted to 3.0 mL with water. The mixing solution was placed in 60 °C water for 15 min, and then rapid cooled to room temperature. The RS spectra were recorded by means of synchronous scanning excited wavelength λ_{ex} and emission wavelength λ_{em} ($\lambda_{ex} - \lambda_{em} = \Delta\lambda = 0$) on fluorescence spectrophotometer. The RS intensity at 596 nm ($I_{596\,nm}$) and the blank solutions without Hg^{2+} $(I_{596\,nm})_b$ were recorded. The value of $\Delta I_{596\,nm} = [(I_{596\,nm})_b - I_{596\,nm}]$ was calculated.

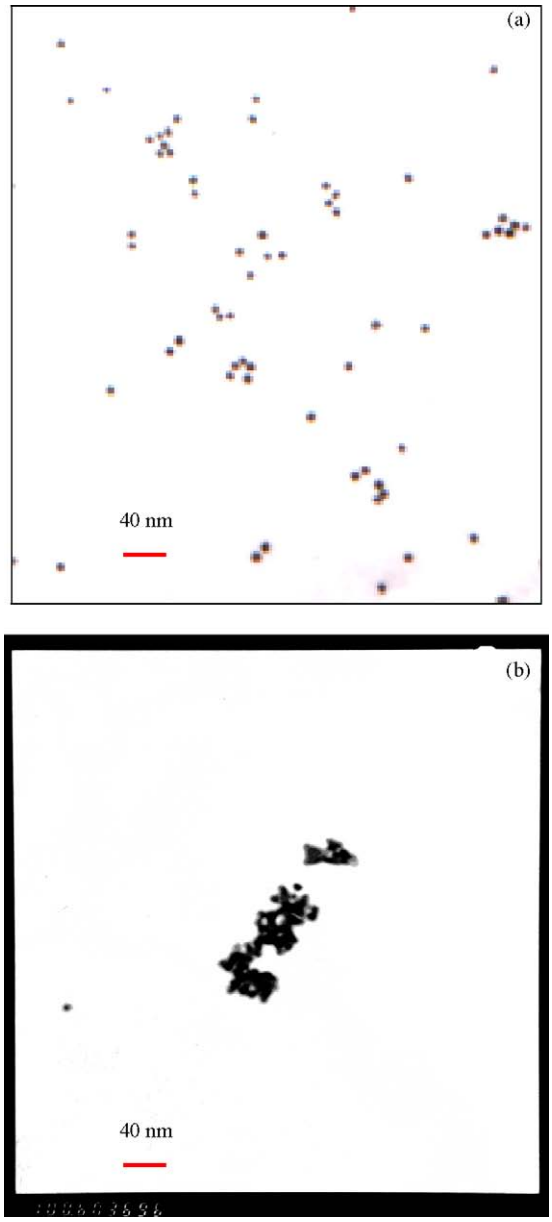

Fig. 1. Transmission electron microscope of NGssDNA-Hg^{2+} system. (a) 14.5 μg/mL NGssDNA; (b) 14.5 μg/mL NGssDNA-600 nmol/L Hg^{2+}-0.03 mol/L NaCl-pH 7.0, amplified 100,000 times.

3. Results and discussion

3.1. Transmission electron microscope

Transmission electron microscope (TEM) showed that the 10 nm nanogold particles are spherical and evenly distributed. ssDNA were found to interact with nanogold to form stable aptamer-nanogold complex. The NGssDNA is dispersed and the size of nanogold is unchanged (Fig. 1a). If Hg^{2+} was added, stable T-T mismatches of T-Hg^{2+}-T were formed, and the nanogolds released from the NGssDNA. In the presence of high concentration of salt, the nanogolds aggregated to form large clusters as in Fig. 1b.

3.2. Circular dichroism

One way to study the nucleic acid structure change is by investigating the circular dichroism (CD) properties, which arise from the chirality of the individual molecule. CD is able to provide infor-

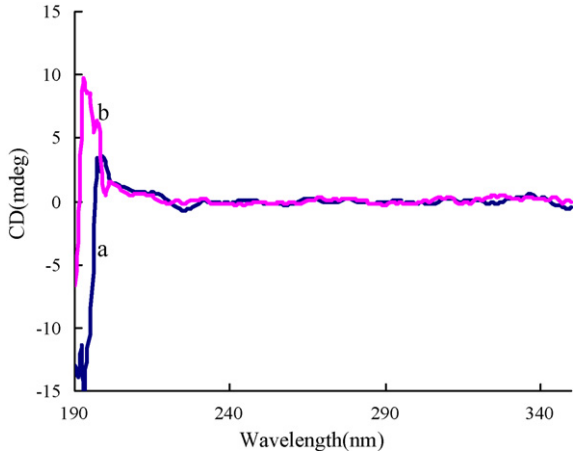

Fig. 2. CD spectra of Hg^{2+}-NGssDNA system. (a) 14.5 μg/mL NGssDNA-0.03 mol/L NaCl-pH 7.0; (b) a-40.0 ng/mL Hg^{2+}.

mation on the secondary structure by measuring the difference in left and right absorbance of the macromolecule ($\Delta\varepsilon=\varepsilon_L-\varepsilon_R$). Fig. 2 showed that, at wavelength of 195 nm, the absorption of the NGssDNA-Hg^{2+} system was stronger than the NGssDNA system, because the absorption of double strand DNA was stronger than the ssDNA [14]. This indicated that there is double strand DNA in the system.

3.3. Absorption spectra

ssDNA were found to interact with nanogold to form stable aptamer-nanogold complex (NGssDNA) in the presence of pH 7.0 Na_2HPO_4–NaH_2PO_4 buffer solution and 0.03 mol/L NaCl solution. The NGssDNA system exhibited one max absorption peak at about 516 nm as shown in Fig. 3a. This indicated that the nanoglod size did not change after coated ssDNA. Upon addition of Hg^{2+}, it combined with ssDNA to form more stable and double strand T-Hg^{2+}-T complex by T-T mismatches. This enables the ssDNA cannot interact with nanogolds. That is, the NG was released from the NGssDNA. Thus, the nanogolds aggregated to form bigger clusters in the presence of 0.03 mol/L NaCl, that exhibit a new and unobvious absorption peak at long wavelength as in Fig. 3c, and the color changes from red to blue which lead the peak absorption value

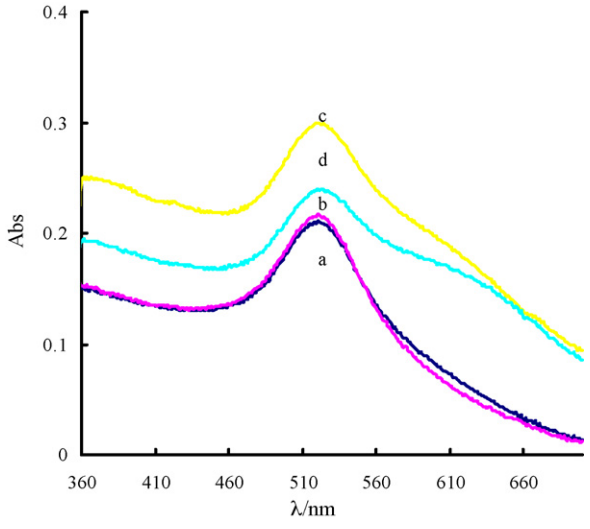

Fig. 3. Absorption spectra of NGssDNA-Hg^{2+}. (a) 14.5 μg/mL NGssDNA-0.03 mol/L NaCl-pH 7.0; (b) a-0.133 nmol/L Hg^{2+}; (c) a-40.0 ng/mL Hg^{2+}; (d) a-66.7 ng/mL Hg^{2+}.

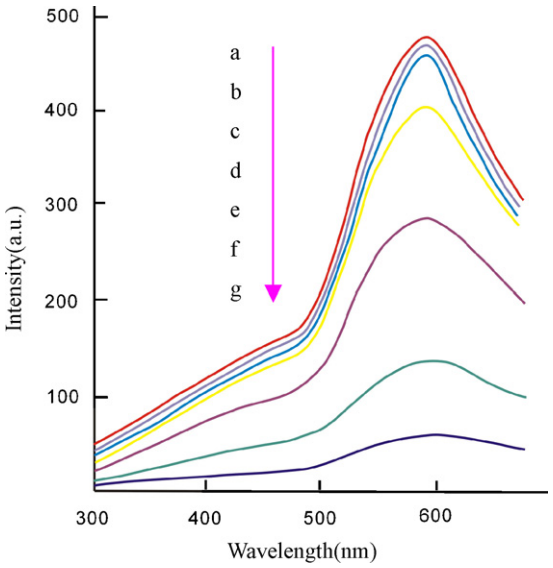

Fig. 4. RS spectra of Hg^{2+}-NGssDNA-$HAuCl_4$-AA catalytic system. (a) 3.23×10^{-5} mol/L $HAuCl_4$-5 mmol/L HCl-6.7 mmol/L CTMAB-0.14 mmol/L AA-NGssDNA filtrate solution; (b) a-0.0107 ng/mL Hg^{2+}; (c) a-0.0424 ng/mL Hg^{2+}; (d) a-0.107 ng/mL Hg^{2+}; (e) a-0.356 ng/mL Hg^{2+}; (f) a-0.712 ng/mL Hg^{2+}; (g) a-0.888 ng/mL Hg^{2+}.

increased at low concentration of Hg^{2+}. With further increasing of the Hg^{2+} concentration, the absorbance at 516 nm decreased considerably and the new peak was more obvious because the nanogolds aggregated into the larger particles. This can lead to false analytical results. In addition, other bivalent cations interfere with the spectrophotometric determination of Hg. This indicated that the aptamer spectrophotometric assay for Hg^{2+} was not good.

The absorption spectra of NGssDNA nanocatalytic system indicated that in the absence of Hg^{2+}, the amount of NGssDNA in the filtrate solution is the most and the catalytic reaction product of gold particles is the most, so the absorption value is maximum. The concentration of NGssDNA in the filtrate solution decreased with the Hg^{2+} concentration increased. Thus, the absorption values decreased linearly. However, the catalytic spectrophotometric assay was not sensitive, so it was not good for detection of Hg^{2+}.

3.4. RS spectra

The 10 nm nanogold particles exhibited weak RS signal at about 540 nm. After it was coated by ssDNA to form NGssDNA in the presence of pH 7.0 Na_2HPO_4–NaH_2PO_4 buffer solutions and 0.03 mol/L NaCl solution, its signal is also weak. Upon addition of Hg^{2+}, the RS intensity at 540 nm increased linearly. Thus, 0.0266–333.4 ng/mL Hg^{2+} can be detected rapidly and simply by the aptamer-nanogold RS probe. However, its sensitivity is not high. Hg^{2+}-NGssDNA-$HAuCl_4$-ascorbic acid catalytic system has a strong RS peaks at 596 nm. In the absence of Hg^{2+}, the concentration of NGssDNA in the filtrate solution and the RS intensity are the highest . The concentration of NGssDNA in the filtrate decreased as the Hg^{2+} concentration increased. Thus, the catalytic capacity decreased, which leaded the RS intensity weaken linearly at 596 nm as in Fig. 4.

3.5. Catalytic effect of nanogold on the reaction of $HAuCl_4$-AA

In the presence of CS such as CTMAB, yellow Au^{3+} exhibited an absorption peak at 396 nm. It was reduced quickly to colorless Au^{+} by ascorbic acid, that was observed in the process of preparing nanogold rod [15]. With addition of AA, the absorption peak decreased, and there is no scattering signal. This indicated that

Table 1
Analytical features for the nanogold catalytic systems.

Nanogold size (nm)	CS	Linear range (ng/mL)	Regress equation	Coefficient	Detection limit (ng/mL)
10	CTMAB	0.480–96.0	$\Delta I = 8.56C + 1.5$	0.9972	0.06
	TPB	0.480–48.0	$\Delta I = 8.39C + 3.7$	0.9709	0.06
	SDBAC	0.480–38.4	$\Delta I = 7.41C + 2.1$	0.9748	0.07
30	CTMAB	0.960–96.0	$\Delta I = 5.99C + 8.0$	0.9983	0.2
	TPB	2.40–48.0	$\Delta I = 8.05C + 2.4$	0.9841	0.3
	SDBAC	4.80–38.4	$\Delta I = 7.41C + 2.1$	0.9516	0.7
50	CTMAB	0.96–192	$\Delta I = 3.39C + 3.5$	0.9991	0.3
	TPB	4.80–48.0	$\Delta I = 4.02C + 1.3$	0.9762	1.2
	SDBAC	9.60–38.4	$\Delta I = 3.29C + 7.3$	0.9868	3

the AA reduction of Au^+ to Au was very slow in the absence of nanogold particles. Upon addition of gold nanoparticles as catalyst, the big gold particles form considerably, and the RS peak intensity at 596 nm increase linearly. In the absence of CS, $AuCl_4^-$ would be reduced quickly to gold particles by AA, although nanogold particles were not added. The effect of nanogold catalyst concentration on the increased RS intensity at 596 nm (ΔI) was showed in Table 1. For the 10, 30, and 50 nm nanogold catalytic systems, the regress equation slope for the 10 nm nanogold catalytic system is bigger than the correspondence other systems. In them, the 10 nm nanogold exhibited strongest catalytic effect in the presence of CTMAB, and was chosen for the assay. In the nanocatalytic system, CTMAB was the best stabilizer and disperser for gold particles, because it forms stable micelle in cationic charges that interact with $AuCl_4^-$. When $AuCl_4^-$ was reduced catalytically by AA to atom Au coated on nanogold in big size that was also enwrapped by CTMAB to an electric double layer on the surface of gold particle, this avoids gold particle aggregations [14].

3.6. Optimization of conditions for Hg^{2+}-NGssDNA

The system of NGssDNA has been reported for Hg^{2+} assay with naked-eye, and spectrophotometry, based on forming stable double strand mismatches of T-Hg^{2+}-T. The naked-eye assay is a qualitative one, and the absorption peak wavelength varied with Hg^{2+}concentration. Our work showed that the RS assay for Hg^{2+} was better than the above two assays, and its analytical conditions were optimized. The effect of pH 5.3–8.0 Na_2HPO_4–NaH_2PO_4 buffer solution on the $\Delta I_{540\,nm}$ was tested. When pH is 7.0, the system has the maximum of $\Delta I_{540\,nm}$. Because phosphate is an electrolyte, the effect of Na_2HPO_4–NaH_2PO_4 buffer solution concentration on the $\Delta I_{540\,nm}$ was also tested. When the concentration of Na_2HPO_4–NaH_2PO_4 is 53.3 mmol/L, the system has the maximum of $\Delta I_{540\,nm}$. So the 53.3 mmol/L pH 7.0 Na_2HPO_4–NaH_2PO_4 buffer solution was chosen. The effect of NGssDNA concentration on $\Delta I_{540\,nm}$ was considered, $\Delta I_{540\,nm}$ attained the maximum when the concentration is 14.5 μg/mL. Accordingly, a 14.5 μg/mL NGssDNA was chosen. NaCl can disturb the surface charge balance of nanogold particles to lead the aggregation that is a good aggregation reagent for nanogold particles, and was chosen for use. The results demonstrated that $\Delta I_{540\,nm}$ attained the maximum when the NaCl concentration is 0.03 mol/L. Thus, a 0.03 mol/L NaCl was chosen.

3.7. Separation of NGssDNA and aggregation nanogold

Commonly, centrifugation is used to separate nanogold. However, the operation time is long and precious centrifugation apparatus should be purchased. Membrane separation is fast and low-cost, and was chosen for use. The influence of 150, 250 and 500 nm filtrate membrane on the separating NGssDNA and the aggregated nanogold was tested. The results showed that the 150 nm filtrate membrane attained the maximum sensitivity, and was selected for use. The influence of volume of the filtrate solution on $\Delta I_{596\,nm}$ was shown in Fig. 5. The $\Delta I_{596\,nm}$ increased as the volume increased within 0–80 μL. $\Delta I_{596\,nm}$ attained the maximum when the filtrate amount is 80 μL. Accordingly, 80 μL the diluted filtrate solution was chosen.

3.8. Optimization of conditions for NGssDNA catalytic system

Catalytic reactions, including inorganic catalytic reaction and enzyme catalytic reaction, have been utilized to amplify analytical signal in analytical chemistry [15–18]. The above two catalytic reactions were also applied in RS analysis with good results. Nanocatalytic reaction is a new, sensitive and important way to amplify analytical signal. It is well known that gold particles were more stable than the silver, copper particles. Thus, a stable and convenient nanogold catalytic-gold particle system is necessary to explore. Study showed that NGssDNA has a strong catalytic effect on $HAuCl_4$-AA-CTMAB reaction to form stable gold particle. It was convenient and was chosen for use. The effect of HCl, $HAuCl_4$, AA and CTMAB concentration, reaction time and temperature on $\Delta I_{596\,nm}$ were studied separately. The results showed that 10 μL 9.69×10^{-3}mol/L $HAuCl_4$, 140 μL 0.1 mol/L HCl solution, 400 μL 0.05 mol/L CTMAB, 7.5 μL 0.057 mol/L ascorbic acid, in 60 °C water for 15 min, giving max $\Delta I_{596\,nm}$, and were chosen for use.

3.9. Effect of foreign substances

According to the procedure, the influence of foreign substances on the determination of 0.133 ng/mL Hg^{2+} was tested, with a relative error of ±10%. Table 2 showed that 50 times Pb^{2+}, 40 times Zn^{2+}, 250 times Cd^{2+}, etc., did not interfere with the determina-

Pd^{2+}	30	3.5	Cd^{2+}	250	−6.5

Table 3
Analytical results for Hg^{2+} in waste water samples.

Sample	Average (ng/mL, $n=5$)	RSD (%)	Added Hg^{2+} (ng/mL)	Found Hg^{2+} (ng/mL)	Recovery (%)	CV-AAS (ng/mL)
No. 1	24.9 ± 0.6	2.5	20.0	18.9	94.5	25.8
No. 2	18.0 ± 0.3	1.6	20.0	19.6	98.0	18.3
No. 3	23.1 ± 0.5	2.2	20.0	19.7	98.5	23.8
NESS 1490113[a]	9.02 ± 0.50	5.5	20.0	19.8	99.0	9.22
NESS 1400114	21.1 ± 0.7	3.3	20	19.7	98.5	20.9

[a] Certified values for NESS1490113 and 1400114 are 9.66 ± 1.09 ng/mL Hg and 20.2 ± 1.6 ng/mL Hg, respectively.

tion, which indicated that this method had good selectivity. This is owing to the specificity of aptamer reaction.

3.10. Working curve

According to the procedure, the working curve between Hg^{2+} concentration ($C_{Hg^{2+}}$) and their corresponding $\Delta I_{596\,nm}$ was drawn. The linear range was 0.00008–0.888 ng/mL. The regression equation was $\Delta I_{596\,nm} = 414.0C + 0.1$, with a correlation coefficient of 0.9965, and a 0.000034 ng/mL of detection limit. Compared with the reported methods [19–22], this aptamer-nanogold catalytic RS method is one of the most sensitive, and the cost is lower. Compared with the reported RS method for Hg [23], this RS assay is more sensitive, and the gold particles are stable than the Cu_2O particles.

3.11. Analysis of Hg^{2+} in wastewater

Wastewater samples were digested by aqua regia after centrifugation [23]. A 25 mL wastewater sample was pipetted to a 50 mL tested tube, and 3 mL aqua regia solution were added. Then the sample was digested in a boiling water bath for about 1 h to convert all species Hg to Hg^{2+}, and the sample solution was diluted to 25 mL with water. Finally, a certain volume of the digested solution was used to detect Hg^{2+} content according to the procedure. The results were agreement with that of the cold vapor atomic absorption spectrophotometry (CV-AAS). In the sample solution, a-20.0 ng/mL Hg^{2+} was added, then the Hg^{2+} content was also measured according to the procedure, and the recovery was obtained as in Table 3, the recovery was in the range of 94.5–99.0%, and relative standard deviation was in the range of 1.6–5.5%. This showed that this RS assay is precision and accuracy. Moreover, two national environmental standard sample (NESS) for mercury were determined by the nanogold-aptamer catalytic RS assay and CV-AAS, respectively. Both results were all agreement with the certified values. This results indicated that this RS assay is accuracy.

4. Conclusions

Hg^{2+} interact with the ssDNA to form stabile T-Hg^{2+}-T mismatches that cannot combine with nanogold particles. When the NGssDNA probe interacted with Hg^{2+} to form T-Hg^{2+}-T mismatches, and the released nanogolds cause aggregation under high concentration of NaCl. Coupled this feature with membrane filtration technique and nanogold catalytic reaction, a novel aptamer-nanogold catalytic RS assay, using Hg^{2+} as a model, has been established. The new RS method was applied to determine Hg^{2+} in wastewater, with high sensitivity and selectivity, rapidity and simplicity.

ABSTRACT

The application of ionic liquids based microwave-assisted extraction (ILMAE) was successfully developed for extracting three alkaloids *N*-nornuciferine, *O*-nornuciferine, and nuciferine from lotus leaf. Seven kinds of 1-alkyl-3-methylimidazolium with different cations and anions were investigated in this work and 1.0 M 1-hexyl-3-methylimidazolium bromide ([C_6MIM]Br) solution was selected as solvent. In addition, the microwave parameters including irradiation power, extraction time and solid–liquid ratio were optimized. Compared with the regular MAE and conventional heat-reflux extraction (HRE), the proposed approach exhibited higher efficiency (0.9–43.7% enhanced) and shorter extraction time (from 2 h to 2 min), which indicated ILMAE was an efficient, rapid and simple sample preparation technique. Moreover, the proposed method was validated by the linearity, reproducibility, and recovery experiments. Good linearity was observed with the regression coefficients (r^2) between 0.9998 and 0.9999. The recoveries of all methods were in the range of 94.6% and 105.5% with RSD lower than 6.6%, which indicated that the proposed method was credible.

1. Introduction

Medicinal plants have served as an important source of drugs for treating diseases since ancient times. In modern pharmaceutical industries, despite the remarkable progress in synthetic organic chemistry of the twentieth century, over 25% of prescribed medicines in industrialized countries derive directly or indirectly from plants. This percentage can reach 50% when the over-the-counter (OTC) market is taken into consideration [1,2]. In recent years, the validated analytical methods (μHPLC, CE, CEC, LC/MS^n, LC/NMR, LC/SPE/NMR, etc.) [3–6] are developing rapidly to guarantee the safety and efficacy of medicinal products. However, the importance of sample preparation has always been ignored. The metabolites extraction from solid plant samples is usually achieved by using well-established methods such as heat-reflux extraction (HRE) and Soxhlet extraction, which have some drawbacks including time-consuming, laborious, and using of a large amount of toxic and hazardous organic solvents. To overcome the above-mentioned problems, microwave-assisted extraction (MAE) has attracted broad interest as an alternative extraction technique with unique advantages of rapidness, high efficiency and low cost [7,8].

Ionic liquids (ILs), also known as molten salts, are a new class of nonmolecular ionic solvents with a melting point fixed at or below 100 °C. The potential of ILs in both academic and industrial fields is related to their unique properties of negligible vapor pressure, high thermal stability, low or virtually no volatility and ease of handling. ILs are therefore regarded as an attractive alternative or replacement to conventional volatile organic solvents (VOS) [9–12]. Over the past few years, ILs have attracted extensive attention in modern chemistry. The initial research interests are focused on organic synthesis [13], catalysis [14], and the process of green chemistry [15]. Recently, application of ILs has also extended into areas of analytical chemistry including electrochemistry, separation science, mass spectrometry, and spectroscopy. Due to the distinct features compared to conventional volatile organic solvents, sample pretreatment techniques using ILs have been successfully applied in liquid–liquid extraction, liquid-phase microextraction, solid-phase microextraction and aqueous two-phase systems extraction [16–20]. It has been found that ILs as solvents and co-solvents can efficiently absorb microwave energy [21]. Therefore, ILs as solvent is of promising potential in the application of the preparation of various useful substances from solid samples such as trans-resveratrol from *Rhizma Polygoni* Cuspidati [22], three phenolic alkaloids liensinine, isoliensinine, and neferine from traditional Chinese herbal medicine "Lien Tze Hsin" [23], and polyphenolic compounds from medicinal plants [24].

Lotus leaf is the leaves of *Nelumbo nucifera* Gaertn. It is a traditional Chinese medicine for losing weight and has been commonly used for clearing heat, removing heatstroke, cooling blood, and stanching blood [25]. The major phytochemicals present in lotus leaf are three aporphine alkaloids, *N*-nornuciferine, *O*-nornuciferine, and nuciferine (Fig. 1). Total alkaloids have been found with biological functions of lowering hyperlipemia [26] and level of cholesterol [27], resisting karyokinesis as well as antimicrobial activity [28]. Recently, nuciferine is newly reported to show anti-HIV activity [29]. Presently, the alkaloids from this medicinal plant are mainly extracted by HRE, which is time-consuming and laborious [30–32]. The aim of this work was to develop a rapid, effective, validated and environmental friendly ionic liquids based microwave-assisted approach for extraction of three alkaloids from this herbal medicine, and compare the results with the conventional reference methods. Herein we systematically investigated the performance of various ILs with different cations and anions as well as the microwave parameters which demonstrated that the proposed ILMAE approach has great potential for the ease of quality assessment of medicinal plants by providing the rapid and facile alkaloids extraction.

2. Experimental

2.1. Chemicals

All chemical solvents in this study were at least of analytical reagent grade, while reverse osmosis Milli-Q water (18 MΩ, Millipore, Bedford, MA, USA) was used throughout. Acetonitrile used for HPLC analysis was of chromatographic grade and purchased from Merck, Darmstadt, Germany.

Three alkaloids *N*-nornuciferine, *O*-nornuciferine, and nuciferine used for HPLC-UV determinations were isolated from lotus leaf and were confirmed by comparing their ^{1}H NMR, ^{13}C NMR, MS and MS^{2} with those given in the references [33–35]. All ionic liquids were gained from Chemer, Hangzhou, China, and used as received.

Lotus leaf was purchased from a local drug store, Hangzhou, China. All samples were dried, milled, passed through a stainless steel sieve and stored in closed desiccators at 4 °C until use. The same batch of sample was used through this study to be representative of variable hardness and density.

2.2. Apparatus

A domestic microwave-assisted extraction unit (Glanz, Shunde, China) with a 2450 MHz magnetron was used. It was modified in our laboratory with the addition of a water condenser. The whole system was run at atmospheric pressure and could be employed at the maximum power of 700 W.

An Agilent 1100 liquid chromatography equipped with a G1311A QuatPump, a G1322 Degasser, a G1314A variable wavelength detector (VWD), a model 7725i injection valve with a 20 μL loop was used for HPLC analysis, and an Agilent ChemStation for data treatment. An Agilent Zorbax Extend C18 (150 mm × 4.6 mm i.d., 5 μm, 120 Å) was used as the LC analytical column. Preparative HPLC was performed using a Varian Prepstar pump equipped with a Varian 210 UV detector (Varian Co., USA). A reversed-phase Shim-pack PRC ODS column (250 mm × 20 mm, 10 μm) was used for preparation. MS and MS^{2} figure were obtained from a Bruker Esquire 3000 mass spectrometer. ^{1}H and ^{13}C NMR spectra were performed in a Bruker Advance 500 NMR spectrometer.

2.3. Ionic liquids based microwave-assisted extraction

Ionic liquid-based microwave-assisted extraction was performed in microwave unit. 0.5 g of dried sample was mixed with 10 mL of different ILs solutions and then the suspension was extracted by MAE. The optimum anion, cation, concentration of selected IL, microwave power, irradiation time, and solid–liquid ratio were systematically studied in this work. After irradiation, the extracts obtained were cooled down to the room temperature, then diluted to 50 mL with deionized water, and filtrated through a 0.45 μm filter prior to HPLC analysis.

2.4. Conventional reference extraction method

Two HRE methods including acid extraction and organic solvent extraction were selected following the reference methods for extraction of the three alkaloids from lotus leaf [30–32].

The process of acid extraction: 0.5 g sample was mixed with 15 mL hydrochloric acid aqueous solution (pH 2) in a round-bottom flask (100 mL) and the suspensions were boiled at 100 °C for 2 h in an open system.

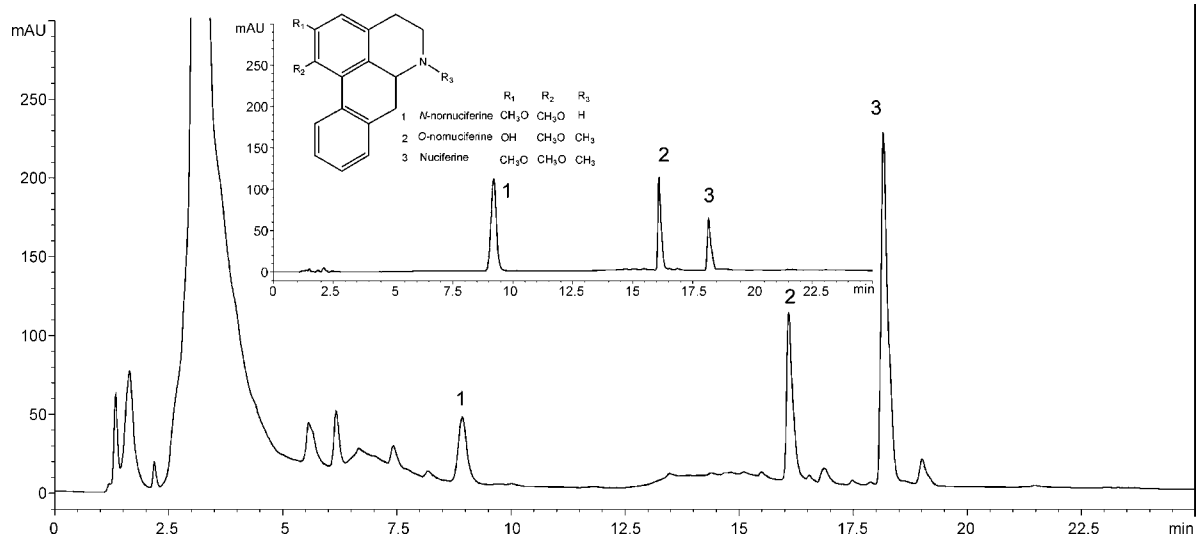

Fig. 1. HPLC chromatogram of three alkaloids in the [C_6MIM]Br extract. Inset: HPLC chromatogram of mixture of three standard alkaloids.

The process of organic solvent extraction: 0.5 g sample was mixed with 15 mL 95% ethanol in a round-bottom flask (100 mL) and the suspensions were boiled at 80 °C for 2 h in an open system.

After extraction, the obtained extracts were cooled down to the room temperature, then diluted to 50 mL with identical solvent, and filtrated through a 0.45 μm filter prior to HPLC analysis.

2.5. HPLC analysis and quantification

The diluted extracts were directly injected into the liquid chromatography. The mobile phase composed of solvent A (0.1% triethylamine aqueous solution) and solvent B (CH_3CN) was delivered at a flow rate of 0.8 mL min^{-1}. The gradient elution was programmed as follows: 0–5 min, 20–30% B; 5–10 min, 30% B; 10–13 min, 30–60% B; 13–20 min, 60–80% B. The UV detection wavelengths were 280 nm. Each injection volume was 20 μL and the column temperature was ambient. Under these conditions, the three alkaloids were baseline separated. *N*-nornuciferine, *O*-nornuciferine, and nuciferine were identified by comparing their retention time with corresponding peaks in the standard solution. A comparison of the chromatograms of the three alkaloids obtained from standard solutions with those contained in ILs extract is shown in Fig. 1.

2.6. Purification of standards of three alkaloids

Dried and powdered lotus leaf (1 kg) was extracted with 16 L of 95% ethanol for 2 h and repeated with three times. Then, the extract solutions were combined and evaporated under reduced pressure and 40 °C to about 200 mL. The concentrated solution was dissolved in 2 L 1.0% hydrochloric acid aqueous solution. The supernatant after centrifugation was adjusted to pH 10 with ammonia, and then extracted with chloroform (three times). The crude alkaloids which were obtained after solvent evaporation were dissolved in the mobile phase solvent, and then were injected into preparative HPLC. Methanol–0.2% ammonia aqueous solution was used as eluent solvents at 6 mL min^{-1} flow rate under 280 nm. Volume ratios of eluent solvents were 60:40, 65:35, 70:30, for *N*-nornuciferine, *O*-nornuciferine, and nuciferine, respectively.

3. Results and discussion

3.1. Screening of the ILs

The structure of ILs has significant influence on its physicochemical properties, which might greatly affect the extraction efficiency of target analytes [23]. The effects of changing the anion and the alkyl chain length of the cation of 1-alkyl-3-methylimidazolium-

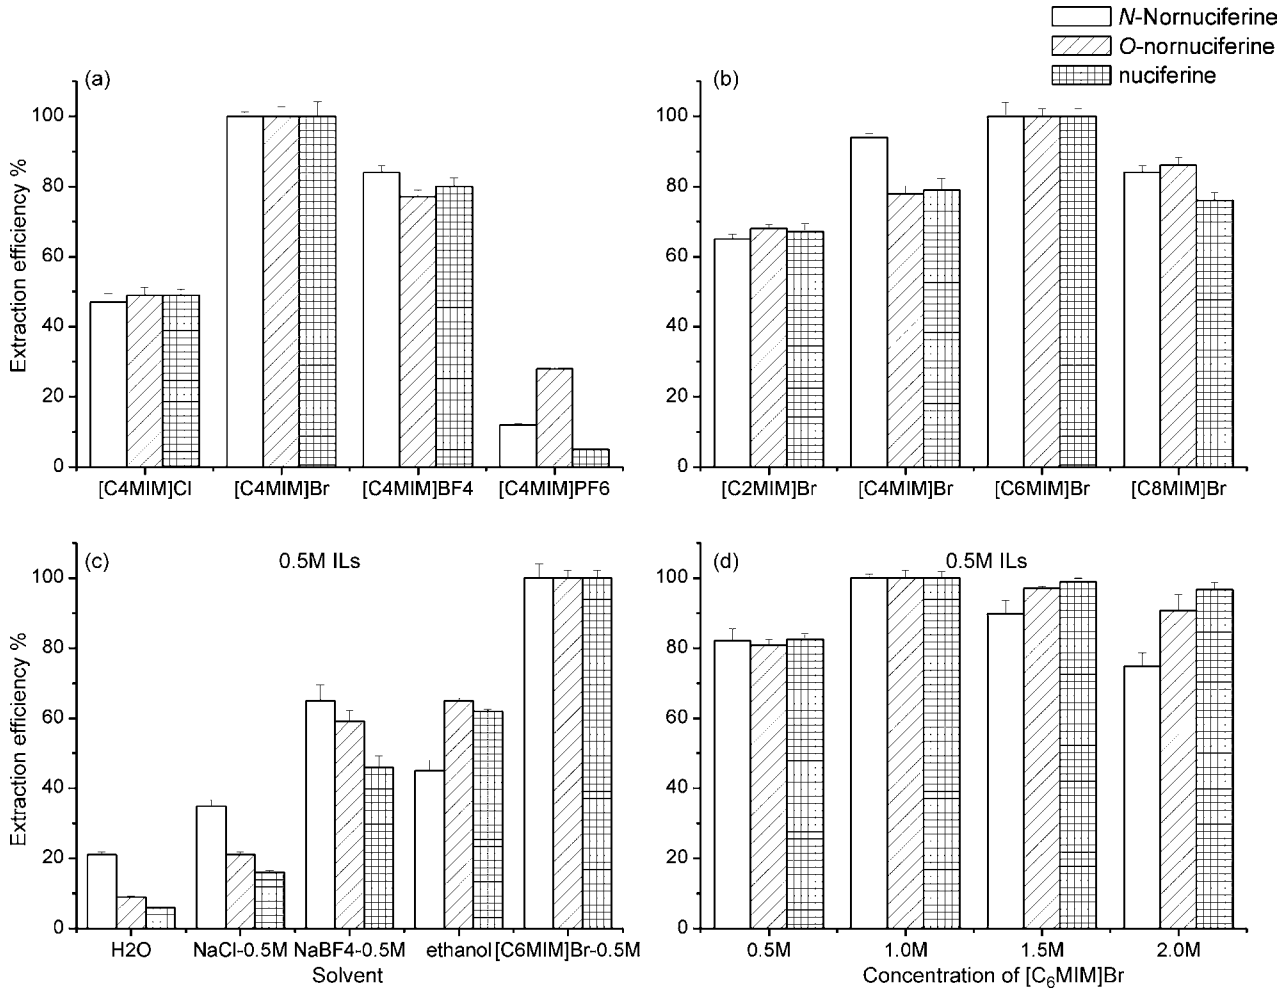

Fig. 2. Effect of ILs anions (a), ILs cations (b), compared [C_6MIM]Br with other solvents (c) and [C_6MIM]Br concentrations (d) on the extraction efficiency of target analytes. Sample: 0.5 g, extractant volume: 10 mL; irradiation power: 280 W; extraction time: 2 min. The extraction efficiency is expressed as the observed values of target analytes and the maximum amount in each curve was taken to be 100%.

Table 1
Some physicochemical properties of the studied ILs.

Cation	Anion	MW	Form (25 °C)	Solubility in H_2O (g/100 mL)
[C_2MIM]Br	Br^-	191	Solid	Totally miscible[a]
[C_4MIM]Cl	Cl^-	174.5	Solid	Totally miscible[a] [10]

type ILs (see Table 1) on the extraction efficiency were studied in this work.

3.1.1. Anion effect

The anion identity is considered to be fore mostly important and has the most dramatic effect on the properties [10]. It is readily apparent from Table 1 that in the series of ILs studied here, the identity of the anion greatly influences the water miscibility. Therefore, the 1-butyl-3-methylimidazolium ILs with four different anions (Cl^-, Br^-, BF_4^-, PF_6^-) were studied. Among them, the former three ILs are hydrophilic and could miscible in any proportion with water, however, [C_4MIM][PF_6] is relatively hydrophobic and is only sparingly water soluble. The results obtained were given in Fig. 2a. Fig. 2a shows that Br^- is more efficient than others. This result indicated the extraction efficiency of alkaloids was mainly anion-dependent, which was similar to the previous studies [24,36]. It probably because [C_4MIM]Br solution had stronger multi-interactions including π–π, ionic/charge–charge and hydrogen bonding with alkaloids [22]. Besides, [C_4MIM]Br solution had slightly higher acidity, which might facilitate the extraction of target alkaloids from lotus leaf [30–32]. By contrast, the extraction efficiency of [C_4MIM][PF_6] is the lowest possibly due to its hydrophobicity.

3.1.2. Effect of the alkyl chain length

With the same anion of Br^-, a series of 1-alkyl-3-methylimidazolium cations including C_2mim^+, C_4mim^+, C_6mim^+, and C_8mim^+ were evaluated. The results were shown in Fig. 2b. It showed that extraction efficiency increased significantly when the alkyl chain length was increased from ethyl to hexyl. However, increasing alkyl chain length from hexyl to octyl dramatically decreased the extraction efficiency. The length of the alkyl chain is related with the water miscibility of the Br^- IL [10], and this property may be related with the extraction efficiency.

Considering the effect of both anion and cation, [C_6MIM]Br was selected for the subsequent evaluation (Fig. 2c).

3.1.3. Concentration effect

It has been proven that, polar molecule could strongly absorb the microwave energy [37,38], and therefore water is always selected as the co-solvent in various MAE process. To find out the optimum IL concentration for microwave-assisted extraction of three alka-

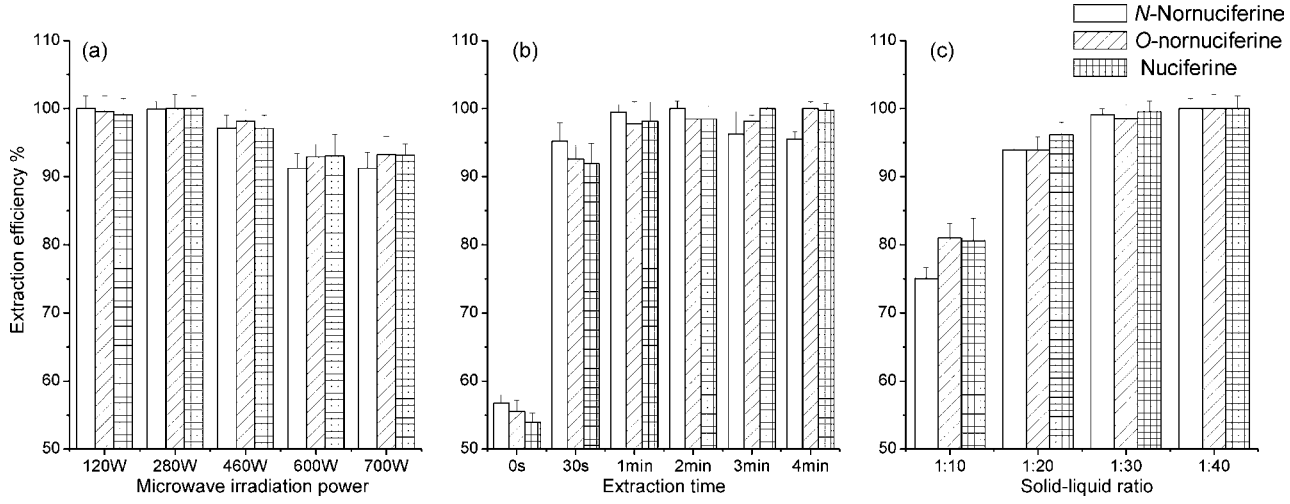

Fig. 3. Effect of microwave irradiation power (a), extraction time (b), and solid–liquid ratio (c) on the extraction efficiency of target analytes with 1.0 M [C_6MIM]Br. Sample: 0.5 g. The extraction efficiency is expressed as the observed values of target analytes and the maximum amount in each curve was taken to be 100%.

Table 2
Comparison of extraction efficiencies under different extraction methods.

loids, extraction was carried out in IL water solution of different concentrations (from 0.5 to 2 M). Based on the results in Fig. 2d, the extraction efficiency increased when the IL concentration over the range of 0.5–1.0 M. When it further increased, however, slight decrease was observed. Finally, 1.0 M of [C_6MIM]Br was selected in the following experiments.

3.2. Optimization of the MAE parameters

The univariate method was used in all instances to optimize the three parameters: irradiation power, extraction time and solid–liquid ratio.

3.2.1. Irradiation power

The irradiation power effect of this method has been examined as it has been claimed to influence interactions and equilibrium rates and controls partition of analytes between sample and extracting phase. To examine the effect of the microwave power on the extraction efficiency, extractions were carried out at 120, 280, 460, 600, and 700 W, respectively, with a constant irradiation time of 2 min. From Fig. 3a, irradiation power did not significantly influence the extraction efficiency. Irradiation power of 280 W (40% of the maximum value) could reach a little higher efficiency of three alkaloids than others.

3.2.2. Extraction time

To optimize extraction time, extractions were carried out at 280 W when microwave irradiation was changed within 4 min. As shown in Fig. 3b, when the extraction time increased from 0 to 1 min, the extraction efficiency of the three alkaloids increased dramatically. When the variable was changed from 1 min to 4 min, slight improvements were observed. Therefore, 2 min was selected for further experiments.

3.2.3. Solid–liquid ratio

The solid–liquid ratio is a crucial factor that should be studied to increase the extraction efficiency of three alkaloids. Larger solvent volumes could make procedure complex and unnecessary waste while smaller ones would make the targets extraction incomplete. A series of extractions were carried out with different solid–liquid ratios (1:10, 1:20, 1:30, and 1:40 g mL^{-1}) to evaluate the effect of the solid–liquid ratio. Fig. 3c indicated that the extraction efficiency increased obviously with the increase of the solvent volume before the solid–liquid ratio reached 1:30, and then the efficiency was not significantly improved with the further increase of the solvent amount. Thus, a solid–liquid ratio of 1:30 was used in the present study.

Based on the above experiment, the optimum MAE conditions were found to be: 1.0 M [C_6MIM]Br as extraction solvent, microwave irradiation power of 280 W, extraction time of 2 min, solid–liquid ratio of 1:30 (g mL^{-1}).

3.3. Comparison of the proposed ILMAE approach with the conventional methods

For the comparison of the extraction efficiency of ILMAE with other conventional extraction techniques, HRE including acid extraction, organic solvent extraction and regular MAE extraction were carried out to extract three alkaloids from lotus leaf (Table 2). From Table 2, the proposed approach not only obviously increased the extraction efficiency (0.9–43.7% enhanced), but also dramatically reduced the total extraction time (from 2 h to 2 min).

In order to further demonstrate the use of ILs, the regular MAE process was used to compare with the proposed ILMAE approach. All experiments were carried out under the same MAE conditions except the extractant. 80% ethanol which was optimized as the best

Table 3
Calibration graphs of the proposed method.

Analytes	Linearities	Correlation coefficients	Calibration range (mg/L)	LOD (μg/L)	LOQ (μg/L)
N-nornuciferine	$y = 49864x + 28.324$	$R^2 = 0.9999$	0.412–165.0	13.6	45.3
O-nornuciferine	$y = 41646x + 36.714$	$R^2 = 0.9998$	0.500–160.0	6.01	20.1
Nuciferine	$y = 31173x + 12.888$	$R^2 = 0.9999$	1.075–344.0	23.6	78.9

The linearity plotting at 280 nm and x was analytes concentration as g mL^{-1} and y was the peak area.

solvent was used in the regular MAE. Results shown in Table 2 indicated that the extraction efficiency of ILMAE was slightly higher than that of organic solvent (95% EtOH) HRE method, and much higher than that of regular MAE and acid HRE methods. This showed that, compared with HRE and regular MAE technique, the proposed approach used only small amount of ILs could obtain higher extraction efficiency (0.9–43.7% enhanced) in shorter extraction time (from 2 h to 2 min), which indicated that the aqueous ILs solutions were excellent extractant and ILMAE was a more rapid and effective sample preparation method. Even though ILs are more expensive than most organic solvents and water, the ILMAE method is still economical considered the saved time and potential recycle of ILs. On the other hand, although wastes have been left after extraction in our method as happened in traditional techniques, it is a much safer and greener process since no waste have been vented to the air during the extraction.

3.4. Analytical performance of the proposed method

To evaluate the proposed IL-based MAE approach, some parameters such as linearity, reproducibility, and recovery were determined under the above optimized conditions. The results were summarized in Table 3. Calibration graphs plots in the form of peak area versus standard concentration of each compound were run for all analytes. Good linearity was observed with the regression coefficients (r^2) between 0.9998 and 0.9999. The limits of detection (LODs) and the limits of quantification (LOQs) of the analytes were ranged from 6.01 μg L^{-1} to 23.6 μg L^{-1} and from 20.1 μg L^{-1} to 78.9 μg L^{-1}, respectively. The reproducibility study was carried out on three repeated extraction with all MAE and HRE methods. From Table 2, all methods had good reproducibilities (RSD obtained was between 0.9% and 6.5%). Moreover, the extracts were spiked with known quantities of standards. The recoveries of the four methods were in the range of 94.6% and 105.5% with RSD lower than 6.6%. The method validation studies indicated that the proposed method was credible.

4. Conclusions

An efficient ILMAE method has been developed for extraction and quantification of three alkaloids *N*-nornuciferine, *O*-nornuciferine, and nuciferine from lotus leaf. The optimum MAE conditions were studied. Compared with regular MAE and conventional HRE methods, the present approach obtained higher extraction efficiency (0.9–43.7% enhanced) and obviously reduced extraction time (from 2 h to 2 min), which demonstrated that the aqueous ILs solutions were excellent extractant and ILMAE was a simple, rapid, effective extraction method. Moreover, considering the unique properties of ILs, the ILMAE method proposed will have a broad potentiality as an environmental friendly technique in sample preparation.

Glycosidase

ABSTRACT

Immobilization of enzyme on detonation nanodiamond (dND, 3–10 nm) and its application for efficient proteolysis have been demonstrated. By evaluation of the Michaelis constant (K_m) and maximum velocity (V_{max}) of immobilized enzyme, its activity was not impaired significantly by immobilization. And enzyme immobilized on dNDs exhibited much better thermal and chemical stabilities than its free counterpart and maintained high activity even after 10 times reuse. The efficient proteolysis by trypsin immobilized on dNDs (dND-trypsin) is demonstrated with the digestion of myoglobin (or other model protein) in a short time (5 min). Large numbers of identified peptides obtained by dNDs-trypsin enable a higher degree of sequence coverage and more positive identification of proteins than those obtained by in-solution digestion and the commercial immobilized trypsin beads, respectively. Moreover, immobilization of peptide-*N*-glycosidase F (PNGase F) on dNDs was realized and resulted in faster sequential glycosidase digestion of glycopeptides in less than 10 min.

1. Introduction

The rapid progress in genomics and proteomics has resulted in an increasing demand to identify and characterize proteins as efficiently and rapidly as possible [1]. Proteolysis is the key step for positive sequencing in proteomics research integrated with mass spectrometry (MS) analysis. Digestion with protease is generally performed in solution, which presents a number of drawbacks limiting the progress in high-throughput protein identification. To reduce the appearance of interfering autolysis peptides, the concentration of enzyme is always kept very low (1:20 to 1:100) and thus results in current enzymatic proteolysis ranging from several hours to overnight. If a high concentration of free enzyme is used, the digestion proceeds quicker but enzyme autolysis products become more abundant. Meanwhile, the use of long incubation times inevitably leads to more digestion artifacts like transpeptidation, non-specific cleavage, deamidation, and oxidation [2,3]. To solve these problems, the immobilized enzyme has been developed for characterization of proteins with the advantage of reducing autolysis product formation, allowing the use of higher enzyme concentrations that yield shorter digestion times, and reducing the interference of enzyme fragments on MS results [4]. Meanwhile, immobilized enzymes have the possible reusability and easy removal from the digestion medium.

Several reports have demonstrated the feasibility and performance of proteolysis using enzyme immobilized on various supports, such as poroszyme beads [5], porous glass beads [6], porous silicon matrix [7], zeolite nanocrystals [8], sol–gel supports [9], membrane [10], magnetic beads [11], polymer [12], and porous monolithic materials [13]. However, the poor biocompatibility properties of the most supports mentioned above are not advantageous for the immobilization of enzymes directly. The surface of these supports needs some intricate modification to satisfy with bio-analysis. Meanwhile, numerous enzyme immobilization methods have been developed [14,15]. In brief, enzymes could be physically adsorbed, trapped, or covalently bonded onto different supports. The physical adsorption method has been proposed for its simplicity and low cost, but its major disadvantage is that enzyme is easily desorbed from support [16]. Enzyme could also be trapped within matrix directly by some entrapment methods, such as sol-gel technique etc. [17]. However, due to the slow diffusion to achieve the mass transfer of both substrate and product, the digestion proceed was slow. In comparison, the covalence method is a little more complicated, but the stability of enzyme toward chemical denaturants and organic solvent can be enhanced when enzyme is firmly immobilized on support [18].

Nanodiamond, a carbon derivative nanomaterial, has a great potential for biological applications, due to its chemical stability, biological compatibility, non-toxicity and the unbleachable fluorescence from nitrogen vacancy centers [19–21]. The surface of nanodiamond provides a unique platform for conjugation of

doi:10.1016/j.talanta.2009.09.029

biological molecules. It has been reported that the modified surface of nanodiamond can be conjugated with bio-molecules such as DNA [22], antigen [23], cytochrome *c* [24] and hormone [25]. Recently, nanodiamond prepared by detonation (dND) came into focus as a potential useful material for bio-applications due to its unique properties, such as small size of diamond nucleus, chemically active surface area, stability towards corrosive media, etc. [26,27]. Because the surface of dND is covered with a variety of functional groups including carboxyl, lactone, ketone, hydroxy, and some alkyl groups, which may be easily activated for conjugation of biological molecules. Also, the small particle size makes less effect to the activity of immobilized enzyme.

In this study, we report the covalent immobilization of enzyme on dNDs, which realized by the diimide-activated amidation of dND-bound carboxylic acids under the experimental conditions designed to avoid denaturing of bonded enzyme. As the core of immobilized enzyme, dNDs can provide a high binding rate of enzyme and good dispersibility in aqueous solution. The trypsin immobilized on dND particles (dND-trypsin) was successfully applied for proteolysis of model proteins. High efficient proteolysis was demonstrated with peptide mapping analysis of myoglobin and bovine serum albumin by MALDI-TOF MS. Meanwhile, peptide-*N*-4-(*N*-acetyl-beta-D-glucosaminyl) asparagine amidase F (PNGase F) was immobilized onto dNDs, and it could complete the glycosidase digestion of glycopeptides in less than 10 min.

2. Experimental

2.1. Materials and chemicals

Detonation nanodiamond was purchased from Gansu Lingyun Nanomaterial Corp. (Lanzhou, China). Chemical reagents, 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride (EDC) and *N*-hydroxysuccinimide (NHS) were purchased form Alfa Aesar (Ward Hill, MA, USA). Bovine serum albumin (BSA), horse heart myoglobin (Myo), fetuin, peptide-*N*-4-(*N*-acetyl-beta-D-glucosaminyl) asparagine amidase F (PNGase F), casein, α-cyano-4-hydroxycinnamic acid (CHCA), 2-(*N*-morpholino)ethanesulfonic acid (MES) and NH_4HCO_3 were from Sigma–Aldrich (Mississauga, ON, Canada). 2,5-Dihydroxybenzoic acid (DHB) was obtained from LaserBio Labs (Sophia-Antipolis, France). Porcine trypsin (sequence grade) was purchased from Promega (Madison, WI, USA). Poroszyme bulk immobilized trypsin was purchased from Applied Biosystems (Foster, CA, USA, Part # 2-3127-00; http://www.appliedbiosystems.com/). Analytical grade acetonitrile (ACN) and trifluoroacetic acid (TFA) were from Merck (Darmstadt, Germany). Water used for all experiments was purified using a Milli-Q Plus system (Millipore, Bedford, MA, USA), with resistance ≥18.2 MΩ/cm.

2.2. Preparation of enzyme immobilized dNDs

dNDs were further carboxylated and oxidized with strong oxidative acid treatments following the procedure of Huang and Chang [24]. Carboxylic acid groups on the surface of carboxylated and oxidized dND particles were activated by carbodiimide and subsequently reacted with NHS to provide a reactive site for covalent attachment to enzyme, as previously described [28,29]. dNDs (1 mg) and 7 mg of NHS were prepared in a 50 mM MES buffer solution (pH 6.1). Under the assistant by ultrasonic, 8 mg of EDC was added quickly, and the mixture was continually stirred at room temperature for 1 h. The suspension was then centrifuged and rinsed thoroughly with MES buffer solution to remove excess EDC, NHS and byproduct urea. The precipitate of the estered dNDs was redispersed in 1 mL of MES buffer solution. Then enzyme (2 mg) was added and stirred at 4 °C for 6 h. After immobilization, the pellet was washed with MES buffer solution, and then with 1 mL of glycine solution (1 M) to block unreacted epoxy groups. Finally, the pellet was washed with water in consecutive washing/centrifugation cycles to yield a light gray powder after drying in vacuum. And the supernatant solution was collected to measure the immobilized amount of enzyme. The amount of enzyme immobilized onto dNDs (μg/mg) was determined from changes in enzyme solution before and after the estered dNDs redispersed using the Bradford assay [30]. Two kinds of enzymes, trypsin and PNGase F, were immobilized onto dNDs in this study, respectively.

2.3. Characterization of enzyme immobilized on dNDs

dNDs, trypsin powder, and dND-trypsin particles were characterized by using Fourier transform infrared (FT-IR), respectively. FT-IR spectra were collected using a Nexus 470 FT-IR spectrometer (Nicolet, Madison, WI, USA). All samples were dehydrated before analysis. Absorbance spectra were acquired using 32 scans and an instrumental resolution of 4 cm^{-1}. The size and morphology of dNDs and dND-trypsin particles were observed using a JEOL model JEM-2011 (HR) transmission electron microscope, TEM, (Tokyo, Japan) at 200 kV, respectively.

2.4. Properties of enzyme immobilized on dNDs

The activity of enzyme against casein was determined by Keay's method [31]. Here, one unit (U) of enzyme activity is the quantity of enzyme that releases 1.0 μg tyrosine (Tyr)/min at pH 8.0 and 37 °C. The relationship between the initial rate of the reaction and the casein concentration (*S*) (0.25–4.0%) in PBS buffer solution (pH 8.0) at 37 °C was measured. The Michaelis–Menten kinetic parameters (i.e., Michaelis constant, K_m, and maximum effective velocity, V_{max}) were calculated from Lineweaver–Burk double reciprocal plots.

Thermal stability of enzyme was determined by measuring the residual activity of enzyme after it exposed to 60 °C for several hours with a given time interval. pH stability of enzyme was investigated by measuring the residual activity of enzyme after pre-incubated in PBS buffer with different pH. Ethanol solution was chosen as denaturant for enzyme. Enzyme was treated by ethanol solution with volume percentage ranged from 10% to 60% (v/v) at 37 °C for 30 min, and then the residual activity of enzyme was determined. To investigate the operational stability of dND-trypsin particles, it was repeatedly used to hydrolyze casein at the same conditions mentioned above. After the proteolysis of casein, the dND-trypsin particles were collected and washed five times with PBS buffer solution (pH 8.0) to start a new run. The supernatant was saved for quantitative analysis. These results were expressed in a normalized form with the highest value of each set assigned to 100% activity.

2.5. Protein digestion

Model proteins, myoglobin (Myo), bovine serum albumin (BSA) and fetuin were dissolved in 25 mM NH_4HCO_3 buffer solution separately, denatured at 95 °C for 15 min and digested with modified trypsin (enzyme-to-protein ratio of 1:50 (w/w)) overnight at 37 °C. To stop the digestion, the activity of trypsin was denatured by boiling at 95 °C for 10 min at last.

For tryptic digestion of protein by porozyme bulk immobilized trypsin beads, model proteins were dissolved in 25 mM NH_4HCO_3 buffer solution, and digested with trypsin beads (Applied Biosystems) (beads-to-protein ratio of 12:1 (v/w)) for 5 min at 37 °C with vortex. After centrifugation, beads and insoluble material were removed, and tryptic peptides were analyzed by MALDI-TOF MS.

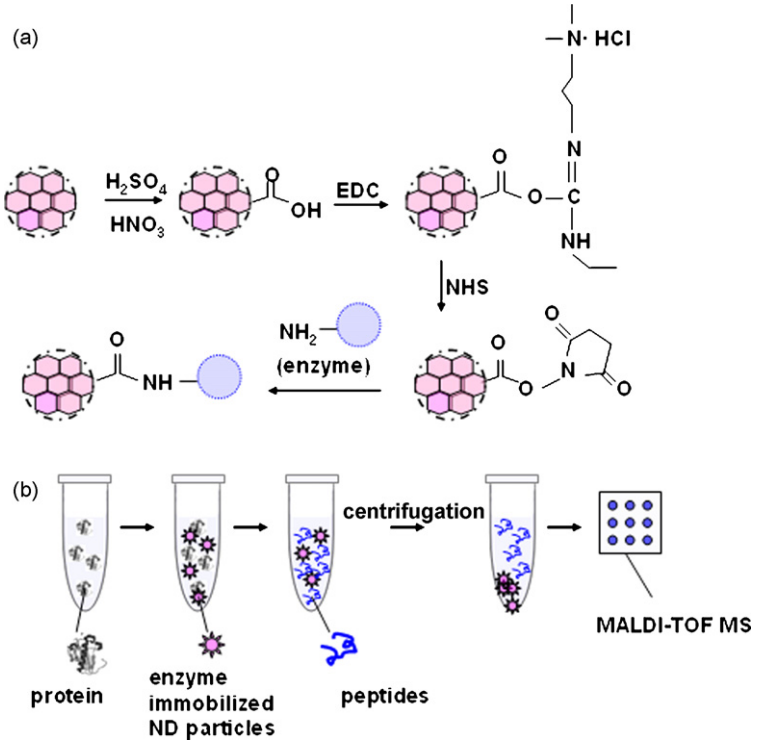
dND-enzyme particles (1 mg) were suspended in 100 μL of 25 mM NH_4HCO_3 buffer solution. 10 μL of dND-trypsin particles

solution was added into each model protein solution. After incubation at 37 °C for 5 min, dND-enzyme particles were retained by centrifugation at 16,000 rpm for 5 min, and the supernatant was transferred to MS analysis.

2.6. MALDI-TOF MS analysis

A 4700 proteomics analyzer (Applied Biosystems, Framingham, MA, USA) performed in positive ion mode was applied for the measurement of peptide fragments. 1 μL of sample solution was dropped on a MALDI plate. After the solvent evaporated, 1 μL of matrix solution (4 mg/mL CHCA dissolved in 50% aqueous acetonitrile containing 0.1% TFA) was dropped on the sample layer. The MS instrument was operated at an accelerating voltage of 20 kV. A Nd:YAG laser with 200 Hz pulse at 355 nm was used. GPS Explorer software obtained from Applied Biosystems with Mascot (Matrix Sciences, London, UK) as a search engine and NCBI as a database were used to identify proteins by peptide fingerprint mass spectra.

The mass spectra of tryptic glycopeptides from fetuin were analyzed by an Axima MALDI-QIT-TOF MS instrument (Shimadzu Corp., Kyoto, Japan) with the nitrogen pulsed laser (337 nm). For QIT measurements, the matrix system was 10 mg/mL DHB dissolved in a 0.1% (v/v) TFA and 50% (v/v) acetonitrile solution. The measurements were carried out in positive ion mode.



3. Result and discussion

3.1. Preparation and characterization of dND-enzyme

dNDs was chosen for enzyme immobilization due to its important characteristics, such as consistency, stability, easy handling and good biological compatibility. Moreover dNDs have some other advantages, including (1) high surface/mass ratio and the existence of large amount of stabilizer (i.e., carboxylic acid groups) on their surface which can provide a higher binding rate of enzyme; (2) high dispersibility in liquid media due to the oxidized, hydrophilic surface. Remarkably, the carboxylic acid groups on their surface can readily bio-conjugate with enzyme using a mild coupling agents carbodiimide, which cut short the complicated and time-consuming procedures of surface modification for enzyme immobilization.

The chemical functionlization of dNDs is shown in Scheme 1a. Enzyme was covalently immobilized on the particles surface by coupling it to the carboxyl groups of dNDs. FT-IR was used to evaluate the surface functional groups in the immobilized procedure. Fig. 1 shows the FT-IR spectra of dNDs, trypsin powder, and dND-trypsin particles. In the spectrum of dNDs (Fig. 1(a)), bands in the region 1123.2–1205.4 and 1682.2 cm^{-1} can be assigned to the C–O–C stretching vibration and the C=O stretching vibration, respectively. After enzyme immobilized on dNDs, these functional groups were disappeared. But the functional groups of trypsin, such as amide I (R–CONHR', C=O stretching) at 1651.4 cm^{-1} and the amide II (R–NHR', NH deformation, N–H bending and C–N stretching) at 3320.3 cm^{-1} and 1538.7 cm^{-1} (Fig. 1(b)) were emerged in the spectrum of dND-trypsin particles (Fig. 1(c)). These results illustrated that enzyme was successful covalent bonded on dNDs surfaces.

Fig. 2 presents the TEM images obtained from dNDs before and after enzyme immobilized. dND particles had a spherical shape with an average diameter of 3–10 nm (Fig. 2(a)). After the enzyme immobilization of dNDs, a blurry and loose layer was generated on dNDs surface, and increased the particles size by more than 0.5–1 nm (Fig. 2(b)). Although the enzyme immobilized dNDs was sonicated in isopropyl alcohol before TEM measurements, the immobilization was not destroyed. The immobilization ability of dNDs for enzyme was evaluated by measuring the UV absorption value of supernatant enzyme solution after immobilization procedure. The amount of enzyme immobilized on dNDs was calculated about 223 ± 30 μg/mg, which increased more than about seven times compared with the magnetic nanoparticles (~200 nm) prepared in Lin's work (32 μg/mg) [32].

Scheme 1. Schematic illustrating (a) the immobilization of enzyme onto dNDs *via* a process of diimide-actived amidation, (b) the procedure for protein digestion using enzyme immobilized dNDs.

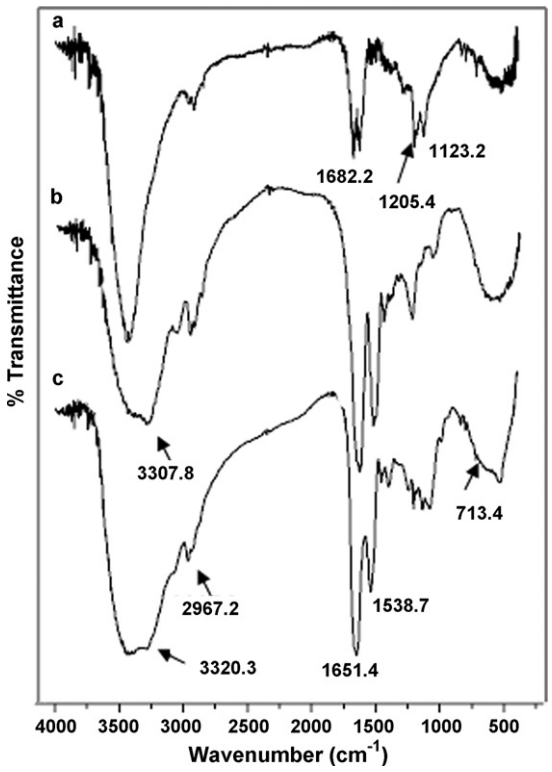


Fig. 1. FT-IR spectra of (a) dND particles, (b) trypsin, and (c) dND-trypsin particles.

3.2. Properties of enzyme immobilized on dNDs

One of the most important characteristics of an enzyme is its affinity for the substrate, usually assessed by the values of Michaelis constant (K_m) and maximum effective velocity (V_{max}). The most commonly used transformation is the double reciprocal or Lineweaver–Burke plot. The Lineweaver–Burke equation is

$$\frac{1}{V} = \frac{1}{V_{max}} + \left[\frac{K_m}{V_{max}}\right]\frac{1}{S}$$

in which the value of $1/V$ are plotted against $1/S$. From the slope and intercept of the plot of $1/V$ versus $1/S$ (Supporting Information, Figure S1), the K_m values of dND-trypsin and free trypsin were found to be 127.7 and 67.9 mg/mL, and V_{max} to be 353.5 and 1303.8 μg/min, respectively. In the experiment, the increase in K_m and the decrease in V_{max}, generally observed in the literature for enzyme immobilization, and is results from the combination of numerous effects such as chemical modification of enzyme during the immobilization reaction, chemical environment in the proximity of the reactive site, and diffusion effects. For example, trypsin immobilized on Sepharose beads was rather sluggishly exhibiting K_m value 2 orders of magnitude higher than free enzyme [33]. However, the values of free trypsin and dND-trypsin were of the same order of magnitude. This means that the catalytic function of trypsin was not impaired significantly by its immobilization. The initial activities of free trypsin and dND-trypsin in the hydrolysis of casein (1 mg/mL) were about 61.0×10^3 U/mg free enzyme and 14.0×10^3 U/mg immobilized enzyme (or 3.13×10^3 U/mg dried particles), respectively, which were better than other method for immobilizing enzyme [34,35].

Properties of the immobilized enzyme and free enzyme were compared in order to study the real stabilization of immobilized enzyme under various conditions. Trypsin as a model enzyme was employed for investigation. These results showed that the inactivity rate of immobilized trypsin was much lower than that of free form (Fig. 3). In Fig. 3(a), at 60 °C, the dND-trypsin retained 82% of its initial activity after 3 h incubation, and still retained its activity at 50%, even after 7 h incubation. However, free trypsin only retained about 76% and 14% of its initial activity after 1 and 3 h incubation, respectively. Therefore, the thermal stability of trypsin immobilized on dNDs shows remarkably higher durability than its free form, which may be attributed to the stabilization of weak intermolecular forces and the prevention of enzyme autolysis [36]. Meanwhile, since trypsin is firmly connected to the surface of dNDs by covalent bonds, pH stability and denaturant stability of dND-trypsin were also increased than its free form (Fig. 3(b) and (c)). Furthermore, the operational stability of dND-trypsin was evaluated by successive batch processes. As demonstrated in Fig. 3(d), the relative activity of dND-trypsin decreased slowly as the cycle number increased. But at least 70% of its initial activity was still reserved after reusing 10 times, which is much better than previous report [37]. These results demonstrate that the immobilization of enzyme on dNDs has benefit to enhance its stability.

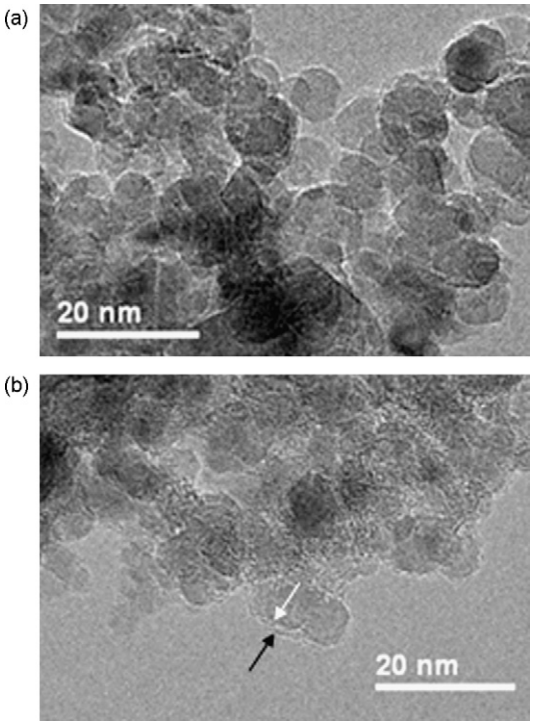

Fig. 2. TEM image of (a) dNDs and (b) enzyme immobilzed dNDs.

3.3. Performance of different digestion approaches for protein identification

Generally, the immobilized enzyme has been developed for characterization of proteins with the advantage of reducing autolysis product formation, allowing the use of high enzyme concentrations for short digestion times. The feasibility and performance of dND-trypsin were demonstrated by the tryptic digestion of model proteins, Myo (MW 16.9 kDa) and BSA (MW 66.0 kDa). The digestion procedure using dND-trypsin is illustrated in Scheme 1b. For control experiment, the digestion of these model proteins was also performed by free trypsin in-solution (for 5 min or 12 h) and poroszyme immobilized trypsin beads (for 5 min), respectively.

Fig. 4(a) displays peptide mass fingerprinting (PMF) spectra of the tryptic fragments of Myo and BSA (40 ng/μL) obtained by dND-trypsin in a short time (5 min) and peaks marked with asterisk correspond to peptides derived from model protein. Table S1 (Supporting Information) presents the identified peptide

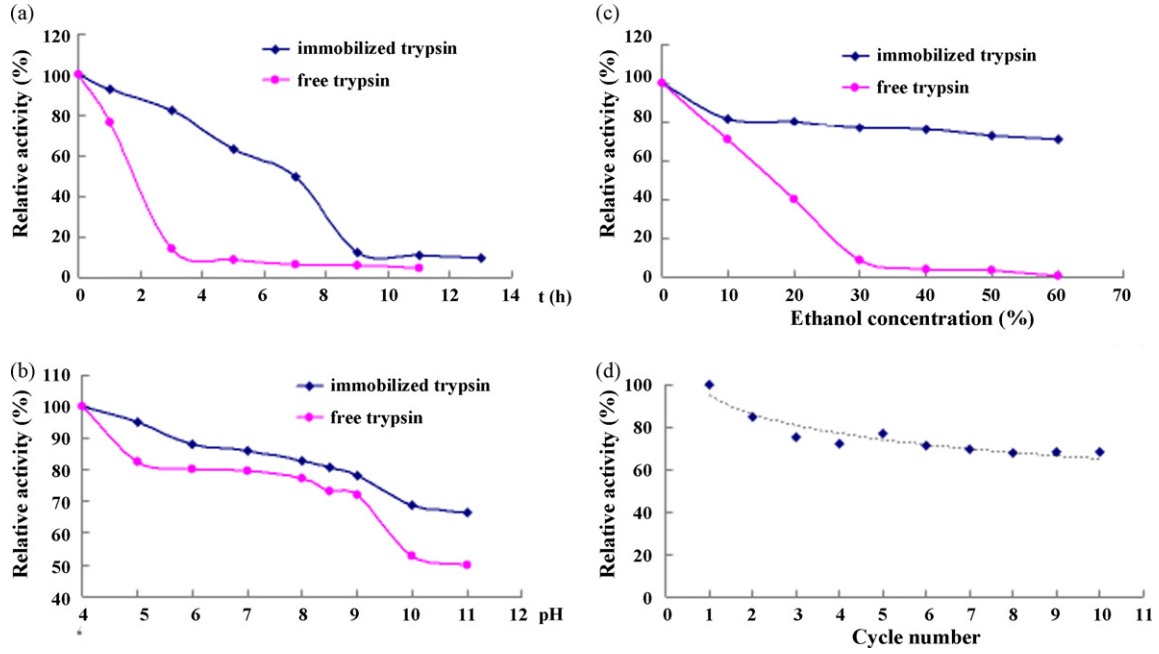

Fig. 3. Properties of enzyme under various conditions (a) thermal stability of free and the immobilized trypsin at 60 °C, (b) pH stability of free and the immobilized trypsin at 25 °C (free trypsin for 24 h, immobilized trypsin for 72 h), (c) denaturalized stability of free and the immobilized trypsin (37 °C, 30 min), (d) operational stability of dND-trypsin.

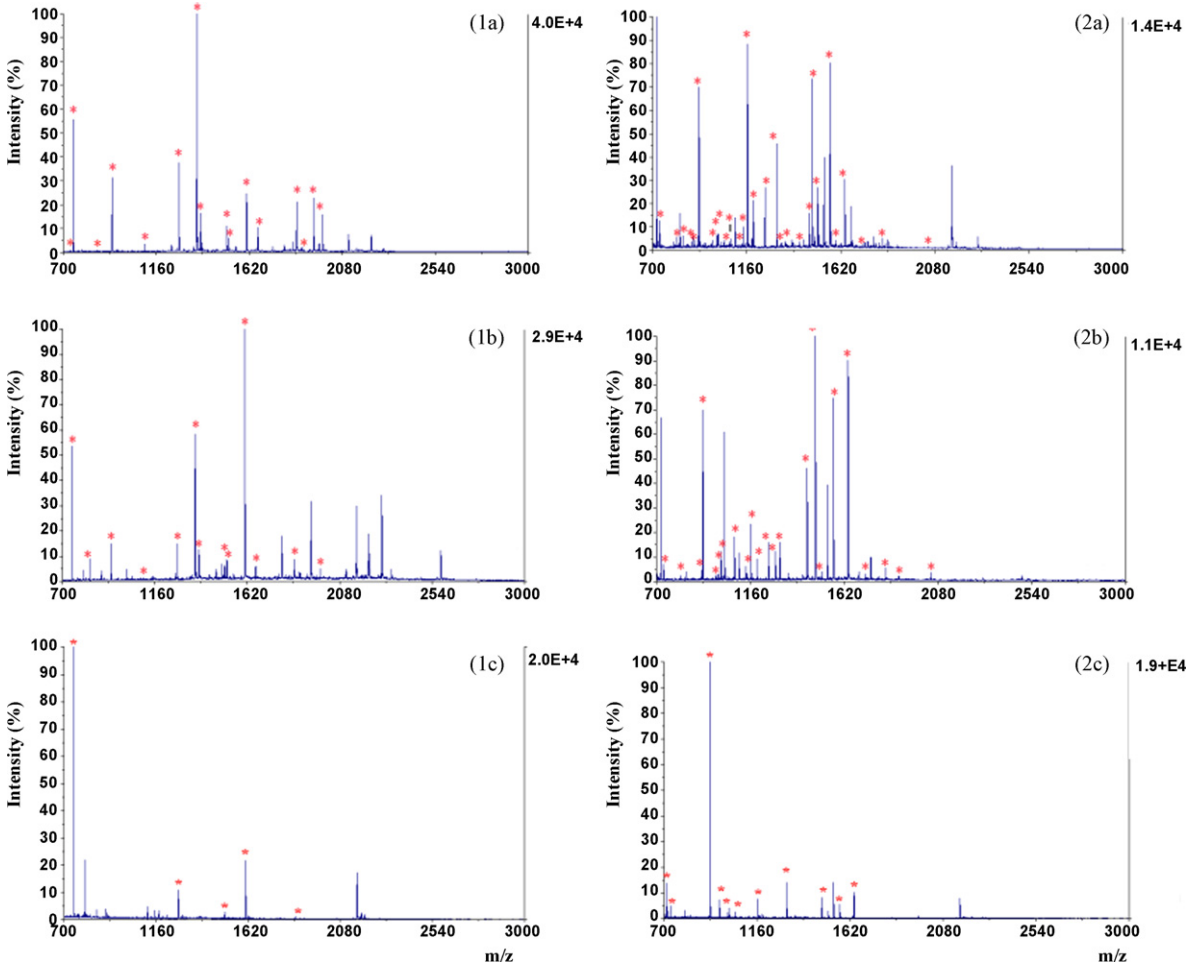

Fig. 4. MALDI-TOF mass spectra of the tryptic fragments of (1) Myo and (2) BSA (40 ng/μL) obtained from (a) 5-min digestion using dND-trypsin particles, (b) in-solution digestion for 12 h, and (c) 5-min digestion using poroszyme immobilized trypsin beads, respectively. All matched peptides were marked with asterisk.

Table 1
Summary of MALDI-TOF MS results obtained from 5-min digestion using dND-trypsin particles compared with in-solution digestion for 12-h and 5-min digestion using poroszyme immobilized trypsin beads (Applied Biosystems).

Protein	Myo			BSA		
Digestion approach	dND-trypsin	In-solution	Poroszyme	dND-trypsin	in-solution	Poroszyme
Sequence coverage (%)	83	73	41	35	32	27
Peptides matched	16	13	5	29	23	19
Protein scores	166	149	66	220	194	159

residues obtained from 5 min digestion using dND-trypsin particles. A total of 16 and 29 tryptic peptides from Myo and BSA were identified with the corresponding amino-acid sequence coverage of 83% and 35%, respectively. However, model proteins could not be digested and positively identified by free trypsin in-solution digestion in 5 min (data not show), which might be attributed to the low concentration of enzyme to reduce the appearance of interfering autolysis peptides. After it incubated for 12 h with free trypsin in solution, model proteins were fully digested and given good quality of mass spectra (Fig. 4(b)). As can be clearly seen from the comparison of these spectra, dND-trypsin digestion approach is comparable or better than in-solution digestion (for 12 h). It indicates protein can be digested totally in 5 min by dND-trypsin.

In Fig. 4(c), tryptic peptides obtained using poroszyme immobilized trypsin beads (for 5 min, Applied Biosystems) show lower response than that obtained by dND-trypsin. And there are a few tryptic peptides assigned to model protein. For example, in Fig. 4 1(c), only five peptides from Myo were assigned with the corresponding amino-acid sequence coverage of 41%. All mentioned above may be attributed to the lower enzyme binding rate and bigger size of poroszyme immobilized trypsin beads than that of dND-trypsin particles. Meanwhile, the surface of poroszyme may be lead to the adsorption of peptides, which was avoided by washing the beads before MS analysis in the manufacturers' instruction. However, the high binding rate of enzyme immobilized onto dNDs reduced the adsorption of peptides on particles. Table 1 compares the MALDI-TOF MS results obtained from 5 min digestion using dND-trypsin, 12 h in-solution digestion and 5 min digestion using poroszyme immobilized trypsin beads (Applied Biosystems). These results show dND-trypsin particles offers more efficient proteolysis than others digestion approach, which attributed to the reasons as following: (1) the use of high enzyme concentration yielding shorter digestion times and reducing the interference of enzyme fragments; (2) the high dispersibility of dND-trypsin in solution increases its affinity to substrates; (3) the small particle size and the surface functional groups of dNDs provide higher binding rate and much more enzyme than poroszyme beads. Therefore, dND-enzyme has a potential application for proteome analysis.

3.4. Application of dND-PNGase F for digestion

PNGase F is widely used to remove *N*-glycans from glycoproteins or glycopeptides for the identification of glycosylation sites and oligosaccharide heterogeneity in glycoproteins. To evaluate the feasibility of immobilized method, PNGase F was also covalently immobilized onto dNDs. The tryptic digestions of fetuin were used to test the performance of dND-PNGase F particles. Fig. 5 shows the mass spectra of tryptic fetuin peptides before and after incubation with PNGase F. The tryptic glycopeptides of fetuin at m/z 5004.6 (the peptide Val_{160}–Arg_{187} containing $Hex_6HexNAc_5$ at N_{176}) and its deglyco-peptide at m/z 3017.2 (^{160}VVHAVEVALATFNAES***N***GSYLQLVEISR^{187}) were all observed in mass spectra of tryptic fetuin peptides (Fig. 5(a)). The MS/MS fragmentation of isolated glycopeptides ions at *m*/*z* 5004.6 was displayed in Figure S2 (Supporting Information). After incubation for 6 h with free PNGase F in-solution, the glycopeptides (at

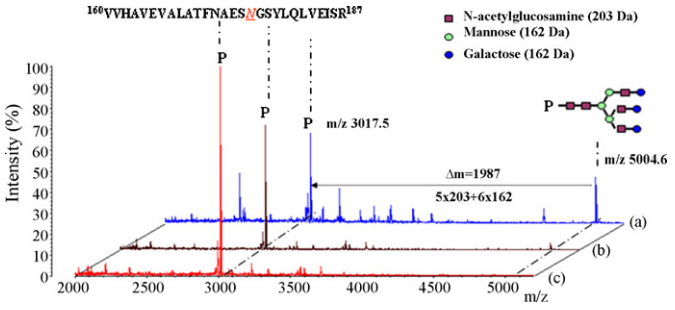

Fig. 5. MALDI-QIT-TOF mass spectra of tryptic fetuin peptides (a) before incubation with PNGase F enzyme, (b) after incubation with the free PNGase F in-solution for 6 h and (c) after incubation with dND-PNGase F particles for 10 min.

m/*z* 5004.6) was partly deglycosylated, so the signal intensity of glycopeptide (at *m*/*z* 5004.6) was decreased but still alive, and that of deglyco-peptide (at *m*/*z* 3017.2) was increased (Fig. 5(b)). However, after the tryptic fetuin peptides was treated by dND-PNGase F particles for 10 min, the peak of glycopeptides (at *m*/*z* 5004.6) was almost disappeared and the signal intensity of deglycopeptide (at *m*/*z* 3017.2) was obviously increased (Fig. 5 (c)). Therefore, the PNGase F immobilized onto dNDs can also successfully applied in the deglycan proteolysis of glycopeptides within a short time.

4. Conclusion

In summary, enzyme immobilized on dNDs (3–10 nm) has been prepared by a simple and one step reaction. The binding rate and amount of enzyme immobilized on dNDs with high surface/mass ratio and large amount of stabilizer (i.e., carboxylic acid groups) was higher than those of micro- and macroscale supports. Compared with free enzyme, the immobilized enzyme showed higher stability to temperature, acid, alkali and ethanol, and exhibited good operational stability. Meanwhile, the dND-trypsin coupled with MALDI-TOF MS demonstrates a promising strategy for the efficient proteolysis of protein. In this modified manner, very short digestion time with the high sequence coverage was achieved. Furthermore, using dND-PNGase F, *N*-glycans were effectively removed from glycopeptides in a short time. These results are expected to open up a new application of dNDs in proteomics. And, it is worth noting that, since the surface of dNDs provides a unique platform for conjugation of biological molecules, the application approach of dNDs may find much potential in proteomic study.

Preconcentration
Flow-injection-flame atomic absorption spectrometry (FI-FAAS)

ABSTRACT

A new cadmium(II)-imprinted polymer based on cadmium(II) 2,2′-{ethane-1,2-diylbis[nitrilo(*E*)methylylidene]} diphenolate-4-vinylpyridine complex was obtained via suspension polymerization. The beads were used as a minicolumn packing for flow-injection-flame atomic absorption spectrometry (FI-FAAS) determination of cadmium(II) in water samples. Sorption effectiveness was optimal within pH range of 6.6–7.7. Nitric acid, 0.5% (v/v) was used as eluent. Fast cadmium(II) sorption by the proposed material enabled to apply sample flow rates up to 10 mL min^{-1} without loss in sorption effectiveness. Enrichment factor (EF), concentration efficiency (CE) and limit of detection (LOD, 3σ) found for 120-s sorption time were 117, 39.1 min^{-1} and 0.11 μg L^{-1}, respectively. Sorbent stability was proved for at least 100 preconcentration cycles (RSD = 2.9%). When compared to non-imprinted polymer the new Cd(II)-imprinted polymer exhibited improved selectivity towards cadmium(II) against other heavy metal ions, especially Cu(II) and Pb(II), as well as light metal ions. Accuracy of the method was tested for ground water and waste water certified reference materials and fortified water. The method was applied to Cd(II) determination in natural water samples.

1. Introduction

Cadmium presence in biosphere is related to both natural (mainly volcanic activity and rock weathering) and anthropogenic emission sources. Elevated cadmium concentration in waters, soil and as a consequence in food is caused by its various applications in many branches of industry. The metal is used in electroplating, in nickel–cadmium batteries, alloys and as a coating for other metals. Cadmium compounds have been mainly applied as pigments, they are also used as semiconductors [1].

Exposure to cadmium has been proved to have adverse effect on heart, lungs, bones and especially kidneys. Having been accumulated in liver and kidneys it is excreted very slowly and the process may last even for 20–30 years [2,3]. Moreover, cadmium has been classified as a carcinogen (Group IA) by International Agency for Research on Cancer [4]. Due to its toxicity both to humans and animals cadmium concentration in the environment should be monitored, hence appropriate guideline values for cadmium content have been introduced; for drinking water they are as follow: WHO 3 μg L^{-1} [5], EU 5 μg L^{-1} [6], US EPA 5 μg L^{-1} [7].

For many years flame atomic absorption spectrometry (FAAS) has been a standard analytical tool for determination of metals in various matrices owing to its wide application range, simplicity in operation and low cost of analysis [8]. However, cadmium content in many natural water samples is frequently below the quantification limit achieved with this technique, therefore introducing a preconcentration step prior to FAAS determination is required. Coupling flame atomic absorption spectrometer with flow-injection system (FI-FAAS) for on-line column preconcentration of metal ions is an interesting alternative to classic off-line solid-phase extraction (SPE) technique [9]. The system is generally a cheaper alternative to graphite-furnace atomic absorption spectrometry (GFAAS)—it enables to achieve comparable parameters and allows to eliminate some interference effects. FI separation and preconcentration methods offer several favorable features, among them: high sample throughput and enrichment efficiencies, low sample and reagent consumption, high reproducibility, low risk of contamination and simple automated operation [10].

The search of selective sorbents and their application to cadmium ions separation and preconcentration still attracts much attention [11]. One of the most promising groups of new sorbents are ion-imprinted polymers (IIPs). Ion-imprinting idea is based on formation of a complex of given metal ion (serving as a template) with an appropriate ligand and its subsequent immobilization in

doi:10.1016/j.talanta.2009.09.021

a cross-linked polymeric matrix. Upon metal ion extraction from the polymeric body spatially prearranged binding sites are left in the sorbent structure. Therefore, due to their predetermined selectivity thus obtained synthetic materials are able to recognize and preferentially bind the metal ion which was used as a template in the polymerization process which offers new possibilities in separation science. Analytical applications of IIPs have been reviewed by Rao et al. [12,13].

A number of ion-imprinted polymers have already been proposed for separation and preconcentration of various metal ions; however, the highest interests have been shown to transition elements and actinides and lanthanides. Recently, Saraji and Yousefi reported synthesis of a new Ni(II)-imprinted polymer dedicated to selective solid-phase extraction of nickel(II) from water samples [14]. The polymer was based on Ni(II)-dithizone complex trapped in copolymer of 4-vinylpyridine and ethyleneglycol dimethacrylate. Dakova et al. presented a new sorbent for preconcentration and speciation of mercury obtained via copolymerization of methacrylic acid and trimetylolpropane trimethacrylate in the presence of Hg(II)-1-(2-thiazoylazo)-2-naphtol complex [15]. The polymer was used for Hg(II) and total Hg preconcentration and determination in water samples with the use of CV-AAS. A new cadmium(II)-imprinted polymer was recently obtained by Singh and Mishra who immobilized Cd(II)-(*p*-sulphophenylazo)-1,8-dihydroxynaphtalene-3,6-disulphonate (Cd(II)-SPANDS) in phenyl-formaldehyde resin [16]. Zhai et al. presented a Cu(II)-imprinted polymer for selective enrichment of trace copper(II) from biological and natural water samples by solid-phase extraction: (2*Z*)-*N*,*N*′-bis-(2-aminoethylic)-but-2-enediamine was used as a chelating ligand and pentaerythritol triacrylate was chosen for a crosslinker [17]. Shirvani-Arani et al. described synthesis of a nanopore samarium(III) imprinted polymer along with its application to Sm(III) separation from other lanthanide ions and preconcentration via solid-phase extraction [18]. The sorbent is based on a ternary complex of samarium(III) with 5,7-dichloroquinoline-8-ol and 4-vinylpyridine embedded in styrene-divinylbenzene matrix.

Herein, synthesis of a new Cd(II)-imprinted polymer has been presented along with its analytical characteristics and applicability to determination of trace cadmium in water samples with the use of flow-injection-flame atomic absorption spectrometry technique.

2. Experimental

2.1. Reagents and solutions

For synthesis of the complex cadmium oxide extra pure was obtained from Merck (Darmstadt, Germany), salicyl aldehyde pure, etylenediamine pure for analysis and pyridine pure for analysis were purchased from Aldrich (Milwaukee, WI, USA). Sodium chloride pure for analysis, dimethylsulfoxide min. 99.5% (DMSO), benzoylperoxide (BPO) 75% and 4-vinylpyridine 95% for the sorbent synthesis were obtained from POCh (Gliwice, Poland), Riedel-de Haën (Seelze, Germany), Merck and Aldrich, respectively. Styrene and divinylbenzene 55% were purchased from Fluka (Buchs, Switzerland). Gelatin was used as protecting colloid.

Cadmium(II), copper(II), zinc(II), iron(III), lead(II), nickel(II), manganese(II), calcium(II), magnesium(II) and potassium(I) standards were prepared from Titrisol® solutions (Merck). Britton-Robinson buffers (a mixture of 0.04 mol L^{-1} acetic acid, 0.04 mol L^{-1} phosphoric acid, 0.04 mol L^{-1} boric acid and 0.2 mol L^{-1} sodium hydroxide in appropriate ratios) were used for buffering purposes. Sodium hydroxide, acetic acid and boric acid were obtained from POCh. Nitric acid and hydrochloric acid, both of analytical grade, were obtained from Merck. Deionized water after reversed osmosis was used throughout the work. Composition of the fortified water used in applicability studies corresponded to SPS-SW2 Batch 105 (Reference Material for Measurement of Elements in Surface Water), Spectrapure Standards AS (Oslo, Norway). Two certified reference materials (CRMs), namely EnviroMAT Ground Water, High (ES-H-2 CRM) and EnviroMAT Waste Water, High (EU-H-3 CRM), SCP Science, Canada were applied to evaluate the method accuracy.

2.2. Instrumentation

FIAS 400 (PerkinElmer) coupled with PE 3100 flame atomic absorption spectrometer (PerkinElmer) was used for metal ions preconcentration and determination. Cadmium was determined at 228.8 nm and air-acetylene flame was used with the gases flow rates as recommended by the manufacturer. Deuterium background correction was used for all measurements. Inductively Coupled Plasma Mass Spectrometer (ICP-MS), ELAN DRC-e (PerkinElmer) was applied to additional cadmium determinations at ultra-trace concentrations. A home-made microcolumn (5 mm × 3 mm i.d.) and Tygon (Saint-Gobain Performance Plastics, Charny, France) red–red tubings (1.14 mm i.d.) were used in the study. Elmetron CPI-551 pH-meter (Zabrze, Poland) was used for pH measurements. IR spectra and elemental analyses were obtained with IFS 48 spectrometer (Bruker) and EuroEA 3000 Elemental Analyzer, respectively.

2.3. Preparation of salen/Cd(II) complex

Salen/Cd(II) complex (cadmium(II) 2,2′-{ethane-1,2-diylbis[nitrilo(*E*)methylylidene]} diphenolate) was obtained in a four-step procedure as follows. A suspension of CdO powder (0.05 mol; 6.42 g) in salicylic aldehyde (0.10 mol; 12.21 g; 10.6 mL) and a small amount of water (2 mL) was heated at 110 °C for 6 h. The crude cadmium(II) bis(2-formylphenolate) was collected under reduced pressure and recrystallized from pyridine to give cadmium(II) bis(2-formylphenolate)–pyridine (1:1) complex [19]. The complex was then heated in an open flask in an oil-bath at 180 °C for 2 h to remove pyridine completely. The pure cadmium(II) bis(2-formylphenolate) (0.01 mol; 3.55 g) was refluxed (6 h) with 1.2-fold molar excess of ethylenediamine (0.36 g; 0.40 mL; 0.006 mol) in EtOH (30 mL). The resulting complex was collected under reduced pressure. Elemental analysis indicated 90% conversion of cadmium(II) bis(2-formylphenolate) into the complex. Yield 3.01 g (80%): yellow powder. IR (KBr): 3055, 3014, 2894, 2855, 1631, 1596, 1542, 1471, 1443 cm^{-1}. Calculated for $0.9\,C_{16}H_{14}N_2O_2Cd{\cdot}0.1\,C_{14}H_{10}O_4Cd$ (%): C, 50.41; H, 3.64; N, 6.66. Found: C, 50.14; H, 3.58; N, 6.69.

2.4. Preparation of sal/Cd-4VP-S/DVB beads

Sorbent beads were prepared via suspension polymerization. Dispersion medium consisting of 0.34 g of NaCl, 2.6 g of gelatine and 125 mL of distilled water was placed in a thermostatted reactor and heated up to 90 °C upon stirring (600 rpm). Salen/Cd(II) complex (0.151 g, 0.398 mmol) was dissolved in 7.5 mL of DMSO, then 0.09 mL (0.776 mmol) of 4-VP was added and the whole was thoroughly mixed. Organic phase comprised 3 mL of styrene (25.8 mmol), 7 mL of divinylbenzene (25.8 mmol), 0.38 g of BPO and solution of the complex. The organic phase was purged with argon for 5 min and subsequently added dropwise to the aqueous medium. Polymerization mixture was heated over 5 h upon mechanical stirring. Thus obtained spherical beads were filtered, thoroughly washed with hot water and dried in a vacuum dryer. Prior to analytical application the polymer was sieved and the

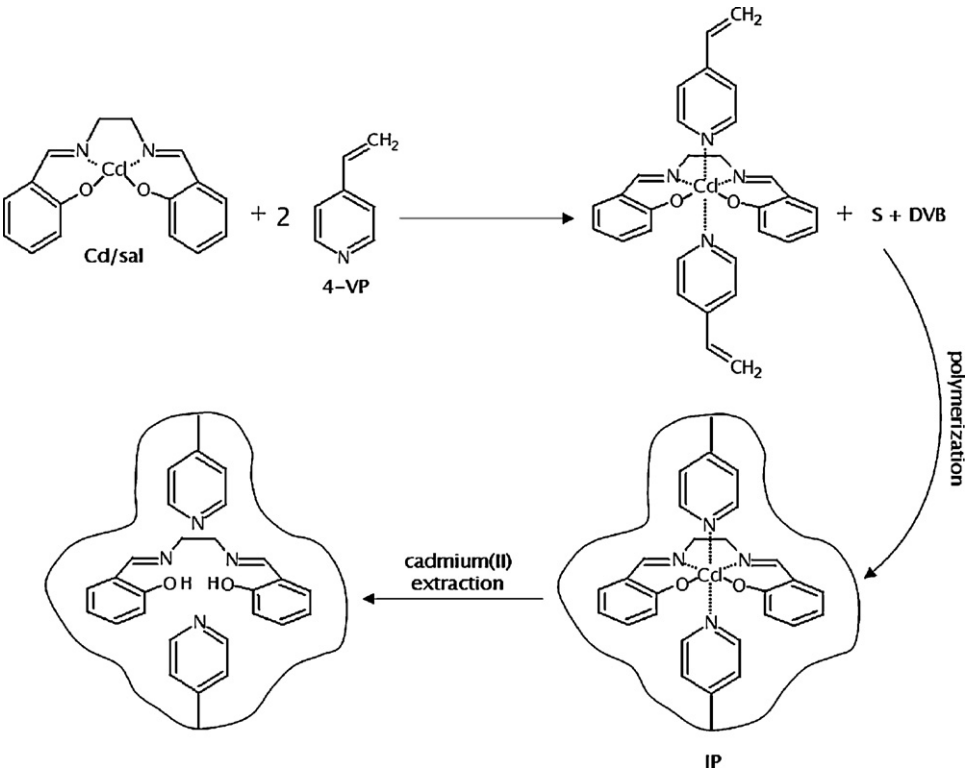

Fig. 1. Schematic representation of ion-imprinting process for the new cadmium(II)-imprinted polymer.

following fractions were collected: >80 μm: 49.2%, 63–80 μm: 30.1%, <63 μm: 20.7%. To avoid column backpressure the fraction 63–80 μm was used as a packing material. Cadmium ions built into the polymeric matrix in the imprinting process were extracted with 1 M HCl. Non-imprinted polymer was prepared in a similar way, however salen (0.102 g, 0.382 mmol) was added instead of salen/Cd complex. The proposed structure of the obtained cadmium(II)-imprinted polymer was presented in Fig. 1.

2.5. Sample preparation

All solutions for preliminary studies (including optimalization process and analytical characteristics of the sorbent) were prepared via dilution of cadmium(II) stock solution with deionized water and were buffered to appropriate pH.

Tap water was collected from laboratory installation and used without any additional preparation. Vistula River water was filtered through 0.45 μm cellulose acetate membrane filters (Sartorius, Goettingen, Germany) and refrigerated until used. All samples were adjusted to appropriate pH with Britton-Robinson buffer.

2.6. Preconcentration procedure

The measuring set-up consisted of two peristaltic pumps, a cylindrical minicolumn filled with the polymer, a two-positional valve and a flame atomic absorption spectrometer. Each preconcentration cycle comprised three steps: preconditioning, sorption and elution. In the preconditioning step pump 1 was activated for the time needed for a sample to fill the tubes before the minicolumn, then the valve position was changed (pump 1 stopped, pump 2 activated) and acid solution was passed through the sorbent for conditioning purposes. In the second step pump 1 was activated for the required sorption time and the sample was loaded onto the polymeric bed. Ten seconds before changing the valve position pump 2 was activated and acid was transferred via a capillary to the nebuliser and the signal was set zero. In the last step pump 1 was stopped, the valve position changed to *inject*, the eluate was directed to the nebulizer and analytical signal was recorded. Schematic representation of the set-up and the detailed program were described elsewhere [20]. If not otherwise stated all results refer to 35 mg of the sorbent. In preliminary studies 15 s loading time was applied to increase sample throughput. For evaluation of the figures of merit and for CRMs and real water analysis (Sections 3.7 and 3.8) loading time was elongated to 120 s.

3. Results and discussion

3.1. Elution conditions

Nitric and hydrochloric acid solutions within concentration range of 0.1–2% (v/v) were tested as eluent. Cadmium(II) standard (50 μg L^{-1}, pH 6.8) was loaded onto the sorbent, then eluted with a given acid solution (elution time: 30 s) and analytical signal was measured. It was proved that starting from eluent concentration of 0.5% (v/v) the kind and concentration of acid did not improve Cd(II) elution effectiveness which was equal for both acids. Nitric acid 1% (v/v) was chosen as eluent for further studies.

3.2. Optimal pH

As sorption effectiveness of an analyte on a given sorbent may vary depending on the loading solution pH, finding the proper pH is one of the most crucial issues in working conditions optimization. For this reason a set of Cd(II) solutions (50 μg L^{-1}) was prepared within pH range of 4–9 and subjected to the preconcentration procedure. The influence of the solution pH on analytical signal presented in Fig. 2 indicates that sorption was the most effective within the pH range of 6.6–7.7, therefore for further studies all samples were buffered to pH 6.8.

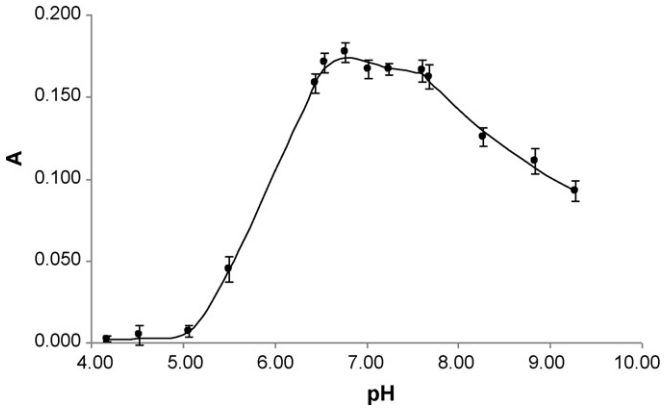

Fig. 2. Dependence of analytical signal on the loading solution pH; loading time: 15 s, eluent: 0.5% HNO_3.

3.3. Sorbent stability test

For sorbent stability evaluation Cd(II) solution (50 μg L^{-1}, pH 6.8) was loaded onto the sorbent and 0.5% HNO_3 was applied as an eluent. Analytical signal (absorbance) was recorded for each preconcentration cycle. No descending trend was observed for at least 100 consecutive preconcentration cycles (RSD 2.9%) which proves good stability of the sorbent in the working conditions.

3.4. Sample flow rate and sorption efficiency

On-line preconcentration as a non-equilibrium process requires special attention to be paid to sample flow rate. In set sorption time applying high sample flow rate may seem favorable in terms of obtaining high enrichment factor due to higher sample volume loaded onto the column. However, sorption effectiveness, being limited by the sorption kinetics, may be deteriorated. For the presented sorbent the dependence of sorption effectiveness on sample flow rate was evaluated for constant sample volume passing through the column bed (i.e. 4 mL) and variable sorption time. No signal decrease was observed upon raising the sample flow rate in the whole tested range, i.e. 4–10 mL min^{-1}. Sample flow rate of 8.0 mL min^{-1} was applied in further studies.

Table 2
Analytical figures of merit of the proposed method.

Parameter	
Preconcentration time (s)	120
Elution time (s)	30

Table 4
Comparison of analytical performance of the presented sorbent with other reported cadmium(II)-imprinted polymers.

Cadmium(II)-imprinted polymer	Optimal sorption pH	Equilibrium sorption time (min)	LOQ (10σ) ($\mu g\,L^{-1}$)	RSD (%)	EF; sample volume (mL)	Stability (no. cycles)	Ref.
PF-Cd(II)-SPANDS	6.0	50	–	–	–	5 (recovery ca. 95%)	[16]
Poly-Cd(II)-DAAB-VP	6.0	60 (recovery ≥ 95%)	0.21	3.7 (100 $\mu g\,L^{-1}$)	200; 2000	20 (2–5% error)	[21]
Cd(II)-IP based on a dual-ligand monomer	6.0	20 (recovery 95%)	0.47	2.4 (10 $\mu g\,L^{-1}$)	200; 1000	15	[22]
sal/Cd-4VP-S/DVB	6.6–7.7	20	0.36	2.9 (50 $\mu g\,L^{-1}$)	117; 16	100	This work

Sorption efficiency was evaluated for sample flow rate of 8.0 mL min^{-1}, Cd(II) 50 $\mu g\,L^{-1}$, pH 6.8 and sorption time 15 s. Cadmium(II) standard was loaded onto the sorbent, the filtrate was collected and Cd(II) content was determined by ICP-MS. The procedure was repeated four times. Sorption efficiency was found at 95.3%.

3.5. Sorption capacity

To assess the equilibrium sorption time for the Cd(II)-imprinted polymer, 35 mg of the sorbent was packed in a minicolumn, then a portion of Cd(II) standard solution (1 mg L^{-1}, pH 6.8, 5 mL) was loaded onto the bed (flow rate 8.0 mL min^{-1}) in a closed circuit for loading time from 1 to 60 min. Afterwards cadmium(II) content was determined in each standard portion with the use of FAAS. It was found that the amount of cadmium(II) ions sorbed onto the polymer was constant starting from 20-min loading time.

For sorption capacity evaluation cadmium(II) standard solutions at concentration up to 130 mg L^{-1} (pH 6.8, portion volume 5 mL) were loaded onto the bed in a closed circuit for 30 min. The initial and equilibrium cadmium(II) concentration in a portion of a given standard solution were determined via FAAS. The maximum sorption capacity of the sorbent was found from Langmuir isotherm according to Eq. (1):

$$\frac{C_e}{Q} = \frac{C_e}{Q_{max}} + \left(\frac{1}{Q_{max}}\right) \times b \quad (1)$$

where C_e stands for equilibrium concentration (mg L^{-1}), Q is the amount of Cd(II) ions sorbed per 1 g of the sorbent (mg g^{-1}), Q_{max} denotes the maximum sorption capacity (mg g^{-1}) and b is Langmuir sorption equilibrium constant.

The maximum sorption capacity found for the presented Cd(II)-imprinted polymer was 0.48 mg g^{-1} (4.27 μmol g^{-1}).

3.6. Sorbent selectivity study

Selectivity study was performed for nine potential interfering ions including heavy metal ions (Cu(II), Zn(II), Ni(II), Fe(III), Mn(II), Pb(II)), alkaline and alkaline earth ions (K(I), Mg(II), Ca(II)). The results obtained both for the imprinted (IP) and the non-imprinted polymer (NIP) have been collected in Table 1.

When compared to the non-imprinted polymer the new cadmium(II)-imprinted polymer was found to be considerably less prone to interferences from other heavy metal ions as well as from light metal ions. The strongest effect was observed for Cu(II) and Pb(II) ions.

3.7. Analytical figures of merit

Analytical characteristics of the method obtained for 120-s sorption time has been presented in Table 2. Enrichment factor (EF) was calculated as a ratio of the calibration line slope found when applying preconcentration step ($S_{FI\text{-}FAAS}$) to the one obtained without it (S_{FAAS}) (2). Consumptive index (CI) was characterized as the volume of a sample (V_s) consumed to achieve a unit EF (3). Concentration efficiency (CE) was calculated as the product of EF and the sampling frequency f expressed in samples analyzed per minute (4):

$$EF = \frac{S_{FI\text{-}FAAS}}{S_{FAAS}} \quad (2)$$

$$CI = \frac{V_s}{EF} \quad (3)$$

$$CE = EF \times \left(\frac{f}{60}\right) \quad (4)$$

Limit of detection and limit of quantification were found for 3σ (LOD) and 10σ (LOQ) divided by the calibration line slope ($S_{FI\text{-}FAAS}$), where σ stands for standard deviation of signal for the blank.

3.8. Application to cadmium(II) determination in water samples

The method accuracy was examined with the use of fortified water and two certified reference materials: ground water (ES-H-2) and waste water (EU-H-3). Cadmium(II) content found in CRMs was in good agreement with the certified values which proves the method accuracy. The presented method was applied to cadmium(II) determination in several water samples: tap water, river water and spring water. As cadmium content in the real samples used in the study was below the quantification limit of the method the samples were beforehand spiked with cadmium. The FI-FAAS results were compared with those obtained by ICP-MS (reference technique) and relative error was calculated. The standard addition method (SAM) was employed for calibration purposes. The obtained results (Table 3) indicate that the presented method may be successfully applied to trace cadmium(II) determination in water samples.

4. Conclusions

The paper reports synthesis and analytical application of a new sorbent dedicated to on-line flow-injection preconcentration and flame atomic absorption spectrometry determination of cadmium(II). The new Cd(II)-imprinted polymer exhibits good sorption properties which combined with its high working stability makes it a suitable packing material for minicolumn preconcentration of cadmium(II). The presented method enables to achieve high enrichment factor and limit of quantification sufficient for trace cadmium analysis. Employing the ion-imprinting technique resulted in achieving a polymer of enhanced selectivity towards cadmium(II) over all investigated metal ions, especially lead(II) and copper(II). Application of sal/Cd-4VP-S/DVB beads as a new sorbent in flow-injection system enabled FAAS cadmium(II) determination at levels found in natural water samples.

When compared to other reported cadmium(II)-imprinted polymers, sal/Cd-4VP-S/DVB beads offer comparable LOQ and RSD along with superior sorption kinetics and the sorbent stability (Table 4). Employing flow-injection system, apart from the obvious benefit of the process automation, enabled cadmium(II) preconcentration with high enrichment factor obtained with low sample consumption and satisfactory sample throughput.

ABSTRACT

Two different derivatizing reagents were tested for the development of a fast and sensitive method for the determination of selenites (Se^{IV}) in human urine. The reagents were sodium tetraethylborate ($NaBEt_4$) and tetraphenylborate ($NaBPh_4$), respectively, and the procedure is based on in situ derivatization of selenites in aqueous medium. Selenite ions are converted to diethylselenide (DESe) or diphenylselenide (DPhSe) and subsequently collected from the headspace by solid phase microextraction using a silica fiber coated with polydimethylsiloxane (HS-SPME). Finally, they are quantitated by GC/MS in SIM mode. Ethylation over phenylation was proved preferable for the headspace extraction because of the higher volatility of the diethyl-derivative of selenites. The optimization of the HS-SPME conditions was performed both in aqueous and urinary solutions. Under the optimum conditions for HS-SPME, the gas chromatographic conditions were also optimized. Between the two alkylation reagents tetraethylborate was proved more efficient and the quantitation was satisfactory. Aqueous certified reference materials were analyzed to evaluate the accuracy of the method. The precision of the method was 4.2% and the calculated detection limit was 0.05 $\mu g\,L^{-1}$ for human urine.

1. Introduction

Selenium is a challenging element, because it is essential at low levels and toxic at higher levels. This range is very narrow depending on its various chemical forms like species or oxidation state [1–3]. Selenites are found in water, environmental and biological matrices and are the most important form either as nutrient or as a possibly toxic species [4]. Consequently, the quantification of selenium species is of increasing importance and accurate analytical methods are necessary for its monitoring [1,3,5].

The determination of selenites is usually based on sensitive analytical techniques like hydride generation atomic absorption spectrometry [6–9] or hyphenated techniques, including capillary electrophoresis [10,11] and gas or liquid chromatography [4,12,13]. The gas chromatographic determination of selenium is based on coupling GC by one or more of several commercially available detectors. Gas chromatography is very promising because it eliminates potential interferences and can serve also as a powerful separation technique for speciation studies. In several reports the GC has been directly coupled to various detectors like AED [12], MIP/AED [2,13], AAS [14], ICP/MS [15,16], MS [4,17] or FID [17]. Liquid chromatography is preferred for the separation of selenoaminoacids, which are coupled to different detectors such as ICP/MS [18,19], MS/MS [7], UV or AFS [20] and amperometric detection [21]. In addition, other techniques were used for organoselenium speciation like IC-ICP-MS [22], ID-ICP-MS [23], ETV-ICP-MS [24], ETAAS [25], CE-ICP-MS [10], HG-ICP-MS [26] and HG-AFS [27].

Also, preconcentration techniques are used for the determination of inorganic and organic selenium. Conventional preconcetration techniques are liquid–liquid extraction and solid phase extraction. Modern preconcentration methods of selenium determination such as solid phase extraction, solid phase microextraction, isotachophoresis and cryogenic trapping were reviewed by Wake et al. [28]. Also, dispersive liquid–liquid microextraction was able to use for the extraction of selenium derivative [29].

SPME is a very helpful tool for chromatographic separations. Solid phase microextraction (SPME) appears as an interesting separation and preconcentration technique for both inorganic and organoselenium compounds. It can be regarded as an environmental friendly technique, due to elimination of use of liquid solvents. Nevertheless, its precision is poor as compared to liquid–liquid extraction. SPME with a derivatization procedure has been used for the speciation of organoselenium and various other organometallic compounds [30–34]. The derivatives are collected directly or from the headspace on a silica fiber coated with polydimethylsiloxane

Table 1
Optimum operating conditions for GC-MS with HS-SPME.

Operating conditions	Ethylation	Phenylation
Column DB-5MS	30 m × 0.25 mm i.d. × 0.10 μm	30 m × 0.25 mm i.d. × 0.10 μm
Injection mode	Splitless	Splitless
Injector port temperature	230 °C	250 °C
Oven temperature	40 °C (1 min) to 250 °C (0 min)	40 °C (1 min) to 250 °C (1 min)
Ramp	45 °C min^{-1} ramp	30 °C min^{-1} ramp
Carrier gas	Helium; 4.2 mL min^{-1}	Helium; 4.2 mL min^{-1}
Pressure conditions	Constant pressure at 39.8 psi	Constant pressure at 39.8 psi
Transfer line temperature	250 °C	250 °C
MS model	5973 MSD	5973 MSD
SIM ions (m/z)	78, 80, 82 (selenium) 107, 110, 111 (ethylselenide) 136, 138, 139, 140 (diethylselenide)	78, 80, 82 (selenium) 152, 153, 154, 155, 157 (phenylselenide) 232, 233, 234 (diphenylselenide)
Electron ionization	70 keV	70 keV
SIM dwell time	50 ms	50 ms
MS quad/source temperature	150 °C/230 °C	150 °C/230 °C

(PDMS). In this way, SPME can be successfully applied for one-step preconcentration and extraction of analytes.

Selenite ions (Se^{IV}) can be measured by GC if a derivatization reagent is employed. They can be transformed by ethylation reagents to diethylselenide (DESe), a more volatile and less polar compound, which is amenable for gas chromatography to be carried out. Suitable and useful reagents for alkylation purpose are sodium tetraethylborate ($NaBEt_4$) and sodium tetrapropylborate ($NaBPr_4$) [3,4,14]. Another group of reagents which was reported for increased sensitivity is 4-chloro-o-phenylenediamine or 4,5-dichloro-1,2-phenylenediamine compounds, however, sodium tetraethylborate ($NaBEt_4$) can be generally recommended [12]. Practically selenates (Se^{VI}) could not be derivatized with the developed method, and a small peak, not always measurable, was observed in the chromatogram just after that of selenite. This observation is in agreement with the remarks of Guidotti [4] according to which selenates are not derivatized as selenites in SPME and GC separations.

The aim of this work is to investigate and compare the performance of two different derivatization reagents, i.e. sodium tetraethylborate ($NaBEt_4$) and sodium tetraphenylborate ($NaBPh_4$), respectively, for the development of a fast and sensitive method for selenium determination in human urine by HS-SPME coupled to GC/MS.

2. Experimental

2.1. Instrumentation

An Agilent quadrupole mass spectrometer MSD 5973 (Hewlett Packard, Waldbronn, Germany) was used as detector for selenium determination. An Agilent 6873 K gas chromatograph equipped with a DB-5MS (30 m length, 0.25 mm i.d., 0.1 μm film, Supelco) capillary column was employed. Helium was the carrier gas. The GC/MS optimum operating conditions are listed briefly in Table 1. The manual SPME fiber holder (57330-U) and polymer-coated fibers (Supelco 57342-U) were purchased from Supelco (Deisenhofen, Germany). The fibers were coated with a 100 μm film of polydimethylsiloxane (PDMS). 15-mL glass vials closed with PTFE-coated silicone rubber septa were employed for the solid phase extraction procedure.

2.2. Reagents and materials

A stock solution of selenite (Na_2SeO_3) containing 1000 mg L^{-1} Se in 0.5 mol L^{-1} HNO_3 (Merck, Darmstadt, Germany) was used. Lowercase selenite standards with concentrations ranging from 1 mg L^{-1} down to 0.1 μg L^{-1} (as Se) were prepared by diluting with Milli-Q ultrapure water (18.2 MΩ cm, 25 °C, Millipore, USA). The solutions were stored at 4 °C.

Sodium tetraethylborate ($NaBEt_4$) and sodium tetraphenylborate ($NaBPh_4$) both were purchased from (99.5%) Sigma–Aldrich Newburgport, MA, USA. A 20% (m/v) solution was freshly prepared by dissolving 0.40 g $NaBEt_4$ in 2 mL Milli-Q water, and was always kept at 4 °C. Similar solution of $NaBPh_4$ was also freshly prepared. Acetate buffer solution with pH values of 5.2 ± 0.1 was prepared by mixing appropriate amounts of sodium acetate (CH_3COONa) (2 mol L^{-1}) and acetic acid (CH_3COOH) (2 mol L^{-1}) in a final volume of 1 L. For optimization of pH in the range 3.0 to 8.4, addition of acetic acid and sodium hydroxide was required.

The accuracy of the method was validated using aqueous certified reference materials NIST 1643e Trace elements in water and standard reference material 2670 Freeze-Dried Urine.

2.3. Ethylation/phenylation and SPME

Variable volumes of the acetate buffer and equal volumes of Milli-Q water or standard solution or urine were transferred into glass vials. Suitable quantity of $NaBEt_4$ or $NaBPr_4$ solution was added and the vials were closed with PTFE-coated septum. The contents of the vial were stirred at 900 rpm with a 6-mm magnetic bar.

The PDMS fiber was exposed to the headspace at 25 °C (for $NaBEt_4$) or 65 °C (for $NaBPr_4$) for 20 min. The fiber was removed from the vial and immediately transferred into the GC injection port at 230 °C (for $NaBEt_4$) or 250 °C (for $NaBPr_4$) and left there for complete desorption of the analytes (4 min).

Three different total mixture volumes were examined: 6 or 10 mL in 15-mL glass vials and 25 mL in 40-mL glass vial, respectively. 15-mL glass vial was finally chosen because of better reproducibility observed in comparison to 40-mL vial either using $NaBEt_4$ or $NaBPr_4$ for alkylation. In addition, 10 mL total mixture volume (headspace/liquid ratio, 1:2) was proved preferable over 6 mL (headspace/liquid ratio, 3:2) because of better sensitivity and repeatability.

3. Results and discussion

Gas chromatographic parameters were optimized by varying one parameter while holding the others constant. The transfer line from column to MS was also heated at 250 °C. Under the optimum conditions the peak of selenite as diethylselenide appears after 1.82 min while that of diphenylselenide appears after 6.61 min (Fig. 1). The optimization of GC and HS-SPME parameters was per-

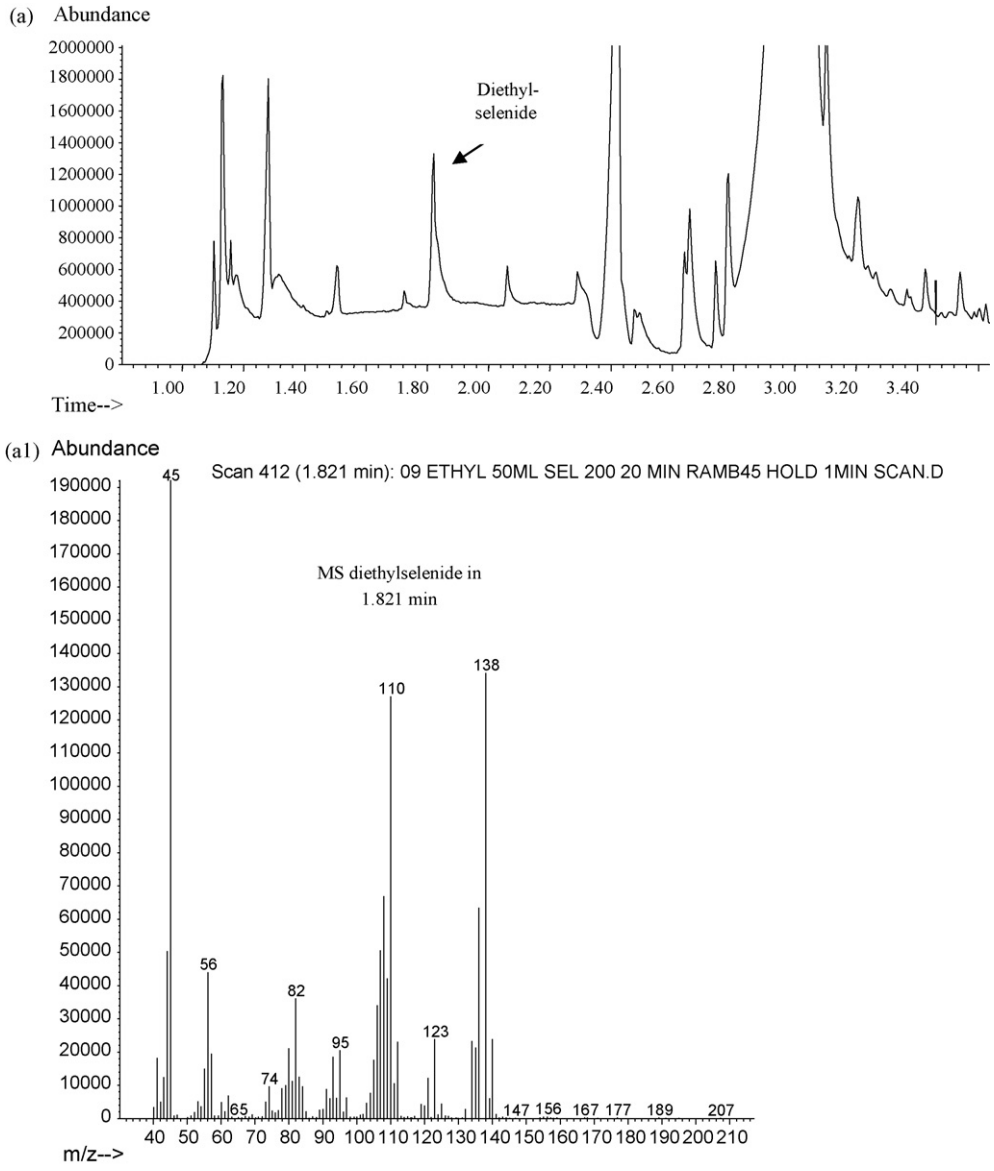

Fig. 1. Typical chromatograms obtained from the determination of selenite by HS-SPME and GC/MS. (a) Chromatogram with the peak of diethylselenide, (a1) MS diethylselenide in 1.821 min, (a2) MS boroxine, triethyl in 3.041 min. (b) Chromatogram with the peak of diphenylselenide.

formed in the scan mode while for quantification the selected ion monitoring (SIM) mode was applied using ions with m/z values listed in Table 1. The two alkylation processes were optimized as it is described below.

3.1. Optimization of GC/MS and HS-SPME with $NaBEt_4$

3.1.1. Optimization of GC parameters

The helium flow conditions were selected under constant pressure and variable flow rate. Helium flow rate was studied at three levels, i.e. 2.2 mL min^{-1} (17.4 psi), 4.2 mL min^{-1} (29.73 psi) and 6.2 mL min^{-1} (39.3 psi), respectively. The results are illustrated in Fig. 2a. It is shown that at higher flow rate of helium (6.2 mL min^{-1}) smaller peak area is obtained. On the one hand with higher carrier gas flow rate, selenite as diethylselenide is coming faster and on the other hand at 2.2 mL min^{-1} no well-resolved peak was obtained. Thus, the flow rate was adjusted to 4.2 mL min^{-1} for subsequent work.

The temperature program of the GC capillary column was subsequently investigated. Initial temperature was selected to be at 40 °C because selenite as diethylselenide is a volatile compound. Hold times at 40 °C were studied in the range of 1–4 min and the results are shown in Fig. 2b. The sensitivity was better at 1 min hold time for diethylselenide and sharper peaks are obtained.

The temperature ramp from 40 to 250 °C was then optimized keeping the above two conditions constant. The fast ramp (i.e. 45 °C min^{-1}) was preferred than the slower one (e.g. 15 °C min^{-1}) (Fig. 2c). Use of 45 °C min^{-1} resulted in narrow peaks without tailing. In addition, the peak of diethylselenide was not overlapped with other compounds. The total chromatographic time with hold time 1 min at 40 °C and ramp 45 °C min^{-1} up to 250 °C was 5.87 min. Selenite as diethylselenide is coming at 1.821 min. All the above optimum parameters were maintained constant during the following HS-SPME optimization.

3.1.2. Optimization of HS-SPME parameters

All the experiments for optimization of HS-SPME parameters were done using 100 μm PDMS fiber, based on the results of Dimitrakakis et al. [3] according to which among four different types of

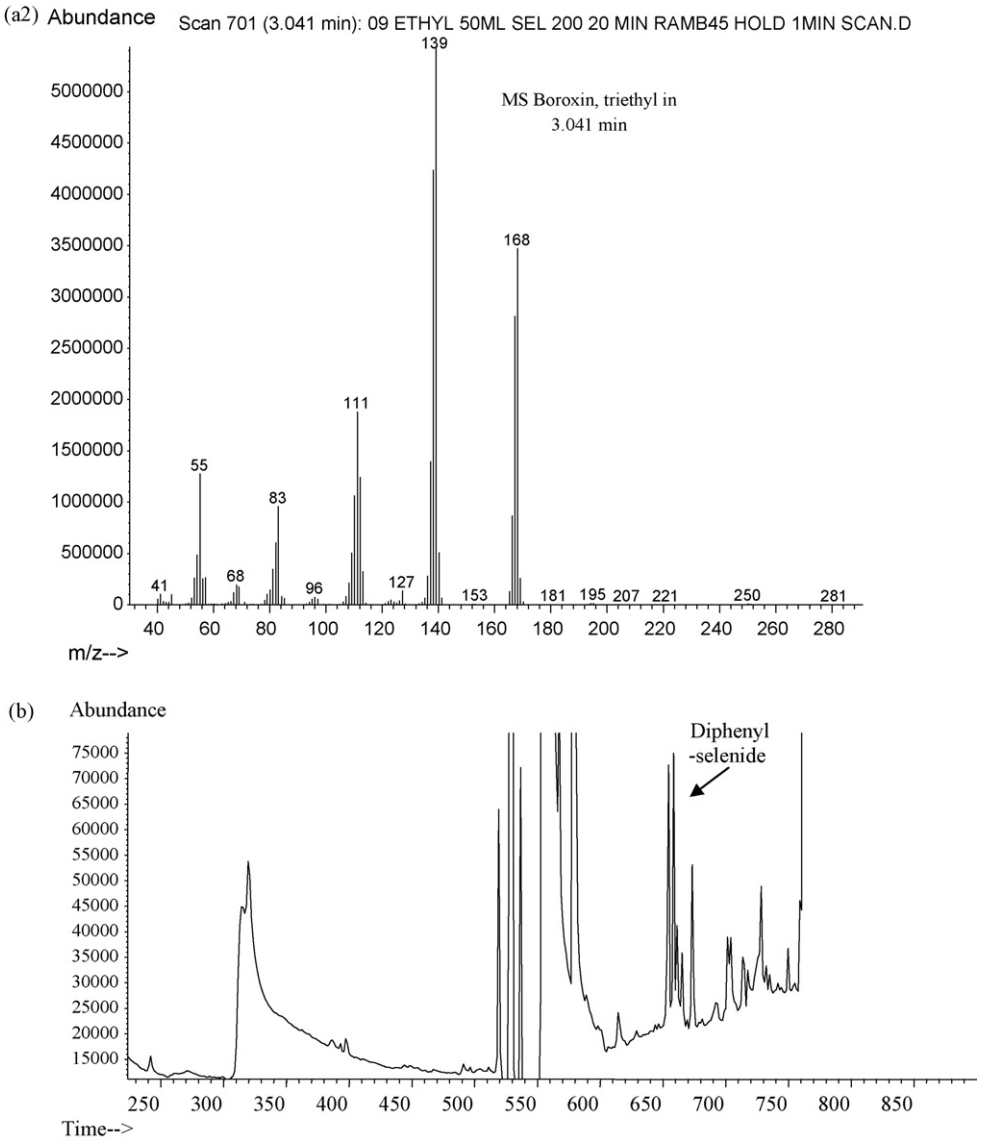

Fig. 1. (*Continued*).

SPME fibers the 100 μm PDMS was proved more efficient because of its constant response and best repeatability.

The pH of the acetate buffer solution was studied in the range of pH 3.0–8.4. This is a very important parameter which defines the efficiency of the derivatization reaction. The optimum value was found to be 5.2 ± 0.1. This finding is in accordance with previously reported values for ethylation by tetraethylborate [3,12].

The effect of temperature was studied for ethylation of selenite and HS-SPME sampling at 25, 45 and 65 °C respectively (Fig. 3a). Eventually, 25 °C was found to be preferable in terms of higher sensitivity obtained. At this temperature, selenite was extracted efficiently without peak overlapping with other compounds, for example, boroxine, which is formed during the ethylation reaction. Ethylated selenite and boroxine (B_3O_3 M.W. = 81) give ions with similar *m*/*z* in MS spectrum. A useful difference to distinguish is ion *m*/*z* 168 (triethylboroxine) which appears only in boroxine in contrast to selenite.

The effect of increasing the extraction time (10, 20 and 30 min) was studied at 25 °C and the results are presented in Fig. 3b. The duration of HS-SPME defines the efficiency to collect selenite from the solution. The signal obtained at ten minutes extraction is only 50–60% of the one obtained at thirty minutes sampling. At 20 min most selenite was extracted as diethylselenide, thus all further analyses were conducted with this extraction time as a compromise to avoid time consumption.

The amount of $NaBEt_4$ was studied using 25, 50, 75, 100 μL of a 20% (m/v) solution. 50 μL was eventually chosen in order also to limit high production of boroxine product when the derivatization reagent is used in excess (Fig. 3c).

The inlet port temperature was examined in order to achieve quantitative desorption of the analyte from PDMS fiber. Variable desorption temperatures in the range 210–250 °C were studied and 230 °C was found as optimum.

3.2. Optimization of the GC/MS and HS-SPME with $NaBPh_4$

Following the same procedure as described above, the use of $NaBPh_4$ was optimized as alkylation reagent. Several of the above-described optimum parameters (volume of solution 10 mL, 15-mL vials) were maintained the same throughout this optimization. Tetraphenylborate ($NaBPh_4$) is capable of converting selenite to diphenylselenide (DPhSe). Diphenylselenide has higher molecular weight and certainly is less volatile as compared to diethylselenide. After preliminary experimentation in the range 190–250 °C,

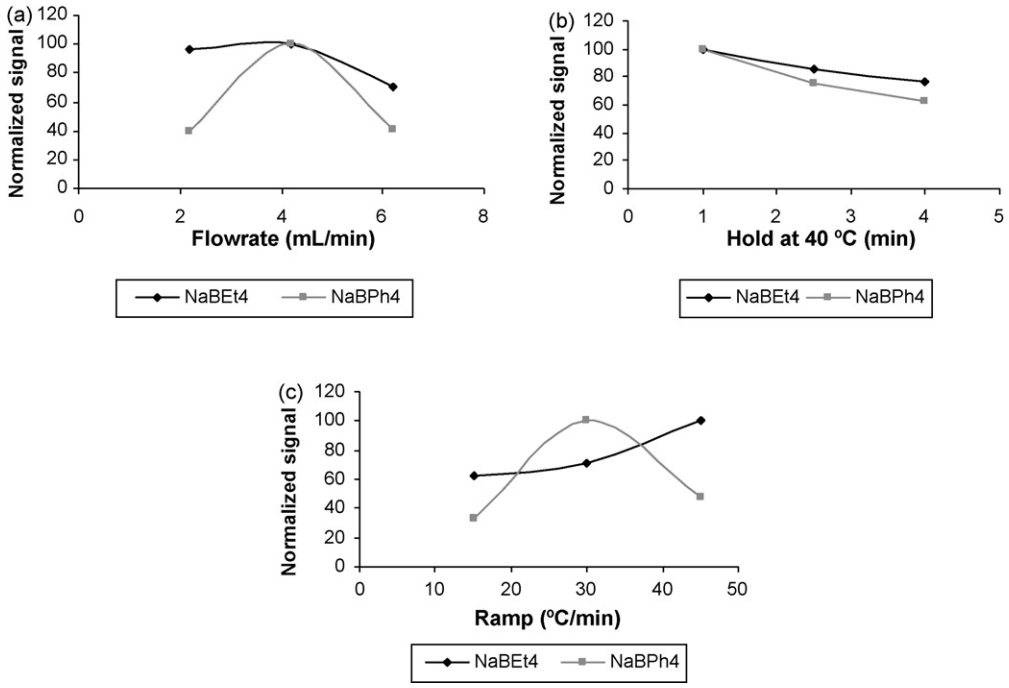

Fig. 2. Optimization of GC/MS with $NaBEt_4$ or $NaBPh_4$ of (a) helium flow rate under constant pressure for selenite determination, (b) hold time at initial temperature 40 °C, (c) ramp from 40 to 250 °C.

the inlet port temperature was set at 250 °C, in order to ensure complete desorption of the less volatile diphenylselenide from the PDMS fiber.

3.2.1. Optimization of GC parameters

As regards to the GC oven program, the same parameters were examined as from $NaBEt_4$. The helium flow conditions were examined under constant pressure and variable flow rate of helium. The effect on the signal is the same as in the ethylation process (Fig. 2a) thus 4.2 mL min^{-1} was selected for further investigation. Hold times at 40 °C were studied in the range of 1–4 and 1 min was selected (Fig. 2b). The temperature ramp from was also optimized among 15, 30, 45 and 30 °C min^{-1} was eventually selected (Fig. 2c).

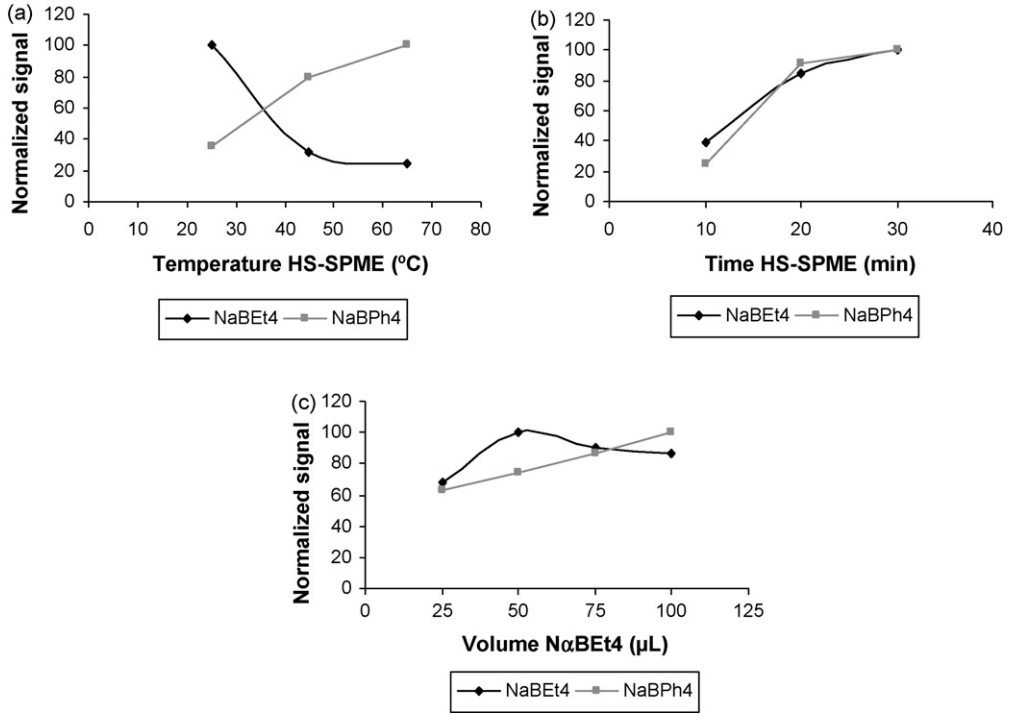

Fig. 3. Comparative curves for the optimization of HS-SPME with $NaBEt_4$ or $NaBPh_4$. Effect of (a) extraction temperature, (b) the extraction time during HS-SPME on selenite normalized signal and (c) 20% (m/v) $NaBEt_4$ volume used in HS-SPME on selenite normalized signal.

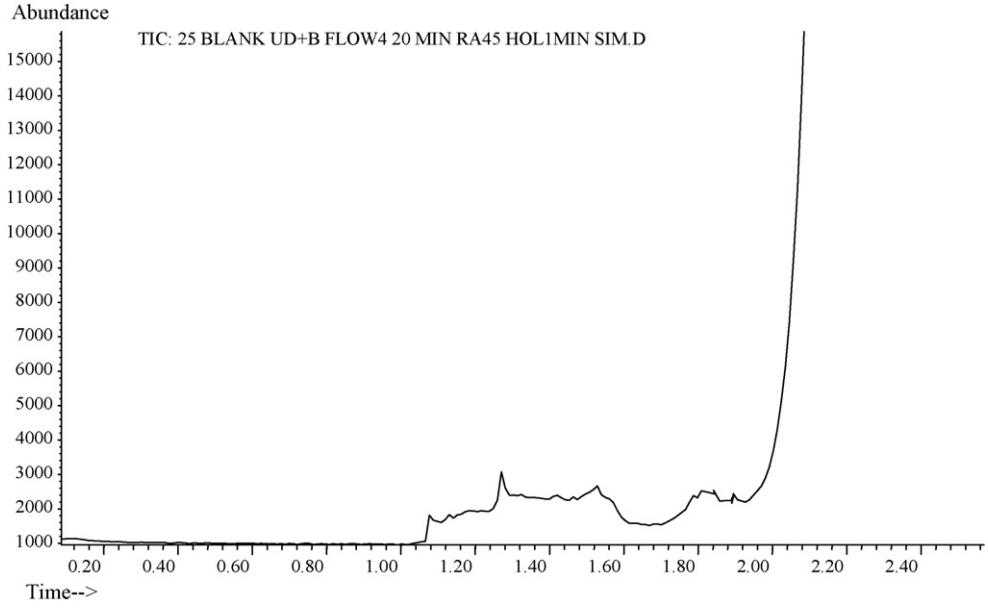

Fig. 4. Chromatogram of blank urine matrix from which selenium was removed by preliminary ethylation and one-hour degassing.

3.2.2. Optimization of HS-SPME parameters

The effect of temperature of the HS-SPME was investigated and the higher signal in the examined range was obtained at 65 °C (Fig. 3a), which are in accordance with previously reported observations about the use of tetraphenylborate for other analytes [20–22]. After experimentation in the range 10–30 min, 20 min was chosen as compromised extraction time (Fig. 3b). The volume of derivatization reagent was also investigated and the higher signal was obtained using 100 μL volume of the phenylation reagent (Fig. 3c).

3.3. Comparative calibration studies for ethylation and phenylation

Calibration curves for the determination of selenite after ethylation or phenylation and HS-SPME were done under optimum conditions for aqueous solutions. The regression equation was $[y = (444 \pm 6.6) \times 10^2\ c_{Se} + 20.3 \times 10^2]$ and the correlation coefficient $r = 0.9997$. Phenylation procedure can be useful in case of selenium speciation in samples where diethylselenide is to be determined. The regression equation for the phenylation was $[y = (69 \pm 4.3) \times 10^2\ c_{Se} + 12 \times 10^2]$ and the correlation coefficient $r = 0.9943$. It is evident that in terms of sensitivity, the ethylation procedure was preferable over the phenylation one by an order of magnitude and consequently it was applied for the determination of selenite in urine.

Next, the standard addition procedure was applied to blank urine matrix from which selenium was completely removed by preliminary ethylation and one-hour degassing (Fig. 4). It is worth mentioning that at 1.821 min no measurable peak was obtained. The regression equation was in this case $[y = (414 \pm 9.5) \times 10^2\ c_{Se} + 59 \times 10^2]$ and the correlation coefficient $r = 0.9995$. As there is no remarkable difference in sensitivity obtained in urine matrix as compared to that in aqueous matrix, it is reasonable to conclude that the compounds which are normally present in human urine do not interfere significantly with the determination of selenite. The detection limits were calculated by the 3 s criterion (i.e. three times the standard deviation of a series of blank measurements) for both procedures and are given in Table 2.

Table 2
The analytical performance characteristics of the proposed method.

Parameter	Water	Urine
Range ($\mu g\,L^{-1}$)	0.08–10	0.10–20
Regression coefficient (r)	0.9996	0.9995
Sensitivity	$(444 \pm 6.5) \times 10^2$	$(414 \pm 9.4) \times 10^2$
Recovery (%) [$n = 5$, $\gamma = 2.5\ \mu g\,L^{-1}$]	101 ± 5.0	95.0 ± 5.7
LOD (c_L, $\mu g\,L^{-1}$)	0.03	0.05
RSD (s_r, %, $n = 5$)	5.5	4.2

The accuracy of the method was studied by analyzing two certified referents materials. In standard reference material Trace elements in Water NIST-1643e the certified concentration was $11.97 \pm 0.14\ \mu g\,L^{-1}$ and the calculated recovery was 97.0 ± 3.7 and $87.8 \pm 3.0\%$ using $NaBEt_4$ and $NaBPh_4$, respectively. The standard reference material 2670 Freeze-Dried Urine had a certified value of $0.030 \pm 0.008\ \mu g\,mL^{-1}$ and the found value using $NaBEt_4$ was $0.029\ \mu g\,mL^{-1}$, i.e. $96.7 \pm 7.7\%$ recovery. The performance characteristics of the developed method were compared to those reported in literature and listed in Table 3. Concerning urine matrix, the limit of detection for Se was calculated as $0.05\ \mu g\,L^{-1}$, the precision (RSD) was 4.2% and the mean recovery after 5 replicates was $95.0 \pm 5.7\%$.

Table 3
Comparison of the performance of several SPME-GC methods for selenites.

Ref.	Technique	Matrix	RSD (%)	c_L of selenite ($\mu g\,L^{-1}$)
This work	HS-SPME-GC-MS	Water	5.5	0.03 (ethylation)
This work	HS-SPME-GC-MS	Urine	4.2	0.05 (ethylation)
[3]	HS-SPME-GC-MIP-AED	Water	6.9	2.7 (ethylation)
[3]	HS-SPME-GC-MIP-AED	Water	4.4	1.8 (propylation)
[5]	HS-SPME-GC-MS	Water	10.1	0.08
[10]	HS-SPME-GC-AED	Water		0.0073 (ethylation)
[10]	HS-SPME-GC-AED	Water		0.055 (4,5-dichloro-1,2-phenylenediamine)

4. Conclusions

Determination of selenites in human urine samples can be performed directly in the urine matrix after alkylation using tetralkylate reagents. Both tetraethylborate and tetraphenylborate reagents were capable to alkylate selenites in moderate acidic solutions in reasonable extraction time. Under optimized conditions of HS-SPME, the performance of sodium tetraethylborate was proved better than that of tetraphenylborate in all terms. The use of phenylation could be recommended as an alternative procedure only in case of presence of diethylselenide in the sample matrix. The analytical performance characteristics of the proposed method make the method useful as a screening and monitoring method for the determination of selenite in urine samples.

Oligopeptide grafting

ABSTRACT

We developed a method to graft a tripeptide (glutathione) onto 5-hydroxy-1,4-naphthoquinone, an electropolymerizable molecule. The resulting thin conducting polymer presents a well-defined and stable electroactivity in neutral buffered solution, due to the embedded quinone group, and is able to covalently graft amino-modified DNA probe strands. It is shown that the bioelectrode presents positive current change following DNA hybridization. This makes a "signal-on" direct electrochemical DNA sensor. The results were obtained with low target concentration (50 nM) and the selectivity is excellent as a single-mismatch sequence can be discriminated from the full-complementary target.

1. Introduction

Biosensors are of great interest nowadays. These devices need immobilization of biomolecules (bioprobes) on the sensor surface. To achieve this, several procedures are currently described [1]. One can use adsorption on the surface [2], inclusion into an organic [3] or an inorganic [4] matrix, covalent binding [3,5], complexation (using biotin–avidin association for example) [6]. Adsorption is simple to achieve, but generally poorly reproducible, and unstable. Inclusion into polymer or inorganic matrixes usually makes bioprobes, in particular DNA, inaccessible for subsequent reactions. Complexation using antibody–antigen association is efficient and widely used, as this avoids any risk of bioprobe denaturation due to immobilization. However, in this configuration, the antibody–antigen system (which is heavy) is inserted between the biosensor surface and the bioprobe, then hinders some interactions between the surface and the probe. Therefore, the direct covalent binding of the biomolecule onto the biosensor surface seems more pertinent and presents the advantage to be irreversible, i.e. more stable during the biosensor lifetime, and 'keeps in contact' the biomolecule and the surface. Its eventual drawback is that it may denaturate the immobilized bioprobe due to a lack of control of the linking regions and the linker reactivity. That is why the choice of the linker (the molecule or the reactive group which belongs to the sensor surface and binds the bioprobe) is of great importance.

Glutathione (γ-L-glutamyl-L-cysteinyl-glycine) is a tripeptide, bearing one primary amine, two amide groups, two carboxylic groups and one thiol group (see Scheme 1). It contains an unusual peptide link between the amine group of cysteine and the carboxyl group of the glutamyl side chain. The thiol group carried by this molecule is one of the most stable thiol group in a biomolecule. For this reason, glutathione is well-known to have antioxidant properties. Glutathione is then currently associated with drugs, in order to protect them from oxidizing species (free radicals for example), and, in addition, make them more soluble in water. The p*K*a associated to the carboxylic acid, the thiol and the primary amine groups are, respectively, 2.1 (COOH on glutamyl), 3.5 (COOH on glycine), 9.6 (SH) and 8.7 (NH_2) [7]. Therefore, at neutral pH, the molecule carries the equivalent of one negative charge. As glutathione is an oligopeptide bearing reactive amine, carboxylic groups and considering properties described above, this molecule of interest has been described in the literature as a linker for biomolecules immobilization on surfaces [8–10]. However, very few works reported electrochemical biosensor using glutathione as the binding element [9].

Scheme 1. Synthesis of 5-hydroxy-3-γ-L-glutamyl-L-cysteinyl-glycine-1,4-naphtoquinone (HNQ–Glu) from HNQ and glutathione, in one step. Proton's numbering corresponding to NMR attribution.

In this work, we developed a new electrogenerated polyquinone film substituted by glutathione. An original and direct procedure was used to chemically graft glutathione on 5-hydroxy-1,4-naphthoquinone. The resulting 3-(γ-L-glutamyl-L-cysteinyl-glycine)-5-hydroxy-1,4-naphthoquinone (HNQ–Glu) presents 3 functional groups: the hydroxyl group for electropolymerization (molecules of the hydroxynaphthoquinone family present the property to electropolymerize into a conducting polymer, via the hydroxyl group [11,12]), the quinone group for its redox and sensing properties, and the glutathione oligopeptide as a precursor for subsequent biomolecule linkage, via amine or carboxylic groups.

The synthesis and characterizations of the HNQ–Glu monomer are first described. After that, electrosynthesis of a conducting polymer is performed, by co-electropolymerization of a mixture of HNQ–Glu and unmodified HNQ, leading to poly[5-hydroxy-1,4-naphthoquinone-*co*-3-(γ-L-glutamyl-L-cysteinyl-glycine)-5-hydroxy-1,4-naphthoquinone], so-called poly(HNQ-*co*-HNQ–Glu) in the following. By this method, the quinone, carboxylic and amine functions are preserved in the polymer. The electroactivity of poly(HNQ-*co*-HNQ–Glu) film is investigated in neutral aqueous phosphate buffer (PBS), the modified electrode presents a well-defined, stable and reversible redox couple.

The quinone is well-known to be particularly sensitive to its chemical environment, in terms of pH or redox state. Therefore, the quinone group of poly(HNQ-*co*-HNQ–Glu) can be used as a redox reporter for chemical or electrochemical modifications of its vicinity. These modifications can be generated by change in ion concentration, for example. It has been shown in a previous work that in PBS the quinone groups of a poly(quinone) film exchange mainly sodium cations [13]. Therefore, the cyclic voltammograms of a poly(HNQ-*co*-HNQ–Glu) film, in the quinone redox domain, must change if sodium cation diffusion is modified. This can be generated by heavy molecules or charged molecules immobilized at the vicinity of the film surface, influencing the diffusion layer by steric hindrance or electrostatic effect. The transduction mechanism has been thoroughly investigated in some of our previous papers [14,15].

In this work, DNA probe strands (modified by an amine group at their 3′-end) are linked to the poly(HNQ-*co*-HNQ–Glu) copolymer via a free carboxylic group of the Glu moiety. After hybridization, the biosensor presents an increase in the redox current of the quinone group. As these current changes are mainly due to the faradic component instead of the capacitive one, Square Wave Voltammetry (SWV) is employed instead of classical voltammetry to characterize and emphasize the current variations. Addition of a probe strand which is perfectly complementary to the immobilized probe strand leads to a clear signal increase, whereas addition of a non-complementary sequence (random) or even a single-mismatch one does not generate significant change in current.

2. Materials and methods

2.1. Chemicals

N′-(3-Dimethylaminopropyl)-N-ethylcarbodiimide hydrochloride (EDC), N-hydroxysuccinimide (NHS) and phosphate buffer saline (PBS, 0.137 M NaCl; 0.0027 M KCl; 0.0081 M Na_2HPO_4; 0.00147 M KH_2PO_4, pH 7.4) were provided by Sigma. Aqueous solutions were made with ultrapure (18 MΩ) water. 5-Hydroxy-1,4-naphthoquinone (HNQ) 1-naphthol (1-NAP) and L-glutathione were purchased from Fluka. Acetonitrile (ACN, HPLC grade) was supplied by Aldrich. All other reagents used were of analytical grade. Oligonucleotides were provided by Eurogentec. The probe strand (PROBE) is a 37-mer sequence bearing an amino group on its 3′-end (5′-TC-CCT CAT AGT CGC ACC CAT CTC TCT CCT TCT-AGCCT-3′C_7NH_2). Targets are 30-mer sequences: COMP (3′-GGA GTA TCA GCG TGG GTA GAG AGA GGA AGA-5′) is the complementary one. MISMATCH (3′-GGA GTA TCA GCG TGG GTA AAG AGA GGA AGA-3′) presents one mismatch base, and the random sequence RANDOM (3′-TTG AAC CAG TAT CCA TGC ATT CCG CCT AAG-5′) is non-complementary. As explained above, the transduction mechanism of this biosensor is closely related to the conformational changes of the ODN strands upon hybridization. For this reason, in this work, we preferred to have a total control of the spatial conformation of the probe-target hybrid (double strand). For this, we needed to use probe and targets of ca. the same length. However, our probe was chosen slightly longer (37b) than the target sequences (30b) to let some bases as spacers at both ends of the probe.

2.2. Electrochemical methods

For electrochemical experiments, a conventional one-compartment, three-electrode cell was employed. An *EG&G 263A* potentiostat was used with the *Echem* software (Ecochemie). The working electrodes were glassy carbon (GC) disks (Aldrich) of 0,07 cm^2 area or gold plates (2 cm^2 area) for FTIR and XPS characterizations. The auxiliary electrode was a platinum grid and the reference electrode a commercial Saturated Calomel Electrode (SCE, MetrOhm, France). Electrodes were polished prior to each use with alumina slurry (1 then 0.3 μm).

The electrochemical synthesis of this copolymer poly(HNQ-*co*-HNQ–Glu) was carried out by electrooxidation of 5×10^{-2} M HNQ + 5×10^{-2} M HNQ–Glu + 10^{-3} M 1-naphthol (1-NAP) + 0.1 M $LiClO_4$ in acetonitrile, on gold or GC electrodes, under a dried argon atmosphere, by potential scans at 50 mV s^{-1} from 0.4 to 1.05 V

versus SCE. Without 1-NAP, no polymerization occurs, while electrooxidation of a solution containing only 10^{-3} M 1-NAP does not lead to any film. This indicates that 1-NAP acts as an electropolymerization initiator.

Hybridization was detected by recording the modification of the redox process of the quinone group, using Square Wave Voltammetry (SWV). The following parameters were used: pulse height 50 mV, pulse width 50 ms, scan increment 2 mV, frequency 12.5 Hz. The medium was PBS, bubbled with argon for 20 min before and during SWV measurements. The SWV scans were repeated (usually two or three times) until complete stabilization of the signal (i.e. no difference observed between two successive responses). Differential currents (Δi) were calculated by subtracting the current obtained after probe grafting from the current obtained after the considered experiment.

All electrochemical experiments were conducted at room temperature (22 °C). After modifications, electrodes were kept in the dark, away from oxygen and humidity in a dry argon atmosphere. In these conditions, the electrodes are stable (no significant decrease of its electroactivity) for ca. 2 weeks. The modified electrodes were used only for one cycle of electropolymerization-probe grafting-hybridization, then polished prior to re-use.

2.3. X-ray photoelectron spectroscopy (XPS)

X-ray Photoelectron Spectroscopy (XPS) data were recorded on a Thermo VG Escalab 250 (Al anode). XPS signals were fitted with a sum of Gaussian (70%)/Lorenzian (30%) functions, and calibrated by assuming a 285 eV binding energy for aromatic and aliphatic carbons.

2.4. NMR

All NMR spectra were recorded on a Bruker Avance III 300 MHz spectrometer. D_2O was used as solvent for all NMR measurements. The temperature was set at 298 K. Water resonance was suppressed with a low-power presaturation [16]. Data were processed using TOPSPIN 2.1 software (Bruker). Proton chemical shifts are referenced using residual HDO as an internal standard (4.70 ppm).

2.5. Grafting and hybridization conditions

As described before, poly(HNQ-*co*-HNQ–Glu) films present two carboxylic functions which are free to react with a coupling agent. As γ-L-glutamyl-L-cysteinyl-glycine is a peptide, it was natural to use a binding reaction currently used in peptide chemistry, i.e. formation of an amide bond from a carboxylic group and a primary amine (amidation). Under normal conditions, amidation is slow. To increase reactivity, the carboxyl group can be transformed into an ester group with the coupling agent N′-(3-dimethylaminopropyl)-N-ethylcarbodiimide hydrochloride (EDC). In aqueous solution, to obtain a better reactivity of the intermediate ester towards the primary amine carried on the DNA probe, another molecule must be used: N-hydroxysuccinimide (NHS). Indeed, water molecules act as nucleophilic molecules and induce hydrolysis of the intermediate ester. NHS competes with water and therefore increases the coupling yield.

Practically, poly(HNQ-*co*-HNQ–Glu) films were dipped into 1 mL of distilled water containing 0.1 μM probe (PROBE), 1.5×10^{-2} M EDC and 3×10^{-2} M NHS at 37 °C. After 20 h, the ODN immobilization reaction was stopped: the electrode was washed with distilled water (5 min) then with PBS (2 h at 37 °C) in order to remove non-covalently bound ODN.

At this stage, the electrodes were characterized by SWV, as explained in Section 2.2. Only those which present peak currents of 3 ± 0.5 μA were selected for the following steps.

For hybridization experiments, 1 mL of PBS solutions containing 50 nM of target (COMP, MISMATCH or RANDOM) were used. The electrode bearing the probe strand was dipped in the target solution then heated at a temperature above the melting temperature of the corresponding duplex (e.g. 72 °C for the PROBE/COMP duplex) during 2 h, and slowly cooled down to room temperature. After that, the electrode was washed in PBS for 1 h at 25 °C in order to remove the non-hybridized strands.

2.6. Fluorescence experiments

The apparatus used is an *Aminco-Bowman* Series 2 spectrofluorometer. Fluorescent targets (COMP*, MISMATCH* and RANDOM*) are modified with fluorescein (*Eurogentec*) on their 5′-end. These labeled targets were used following the same hybridization protocol than for the unlabelled targets, using 2 cm^2 GC plates as electrodes instead of 0.07 cm^2 GC disks. For quantification, dehybridization was performed in order to make spectrofluorometric analysis in solution and not directly onto the polymer surface.

The dehybridization protocol consists in a washing procedure made of 4 steps. To remove unspecific association, the three first steps consist in soaking the film in 2 mL of PBS, at 25 °C, under magnetic stirring, during 5 min (step 1), 10 more min (step 2), and 30 more min (step 3). After each step, the 2-mL solution is removed, stored for subsequent fluorescence experiments, and replaced by a fresh one. After these extensive washing steps, the fourth step consists in soaking the film in 2 mL of pure water at 80 °C during 10 min. Under these very stringent conditions, the hybrids which are present on the film are denatured and the target strands withdrawn towards the solution, which is stored for subsequent fluorescence experiments.

To determine the ODN concentration in these solutions, calibration curves were first obtained, for each fluorescent strand (in the range 0.25–10 nM). ODN concentrations were then converted into surface concentrations, which were found in the 0–15 pmol cm^{-2} range.

3. Results and discussion

3.1. Synthesis of HNQ–glutathione (HNQ–Glu)

3.1.1. Synthesis of 5-hydroxy-3-γ-L-glutamyl-L-cysteinyl-glycine-1,4-naphthoquinone (HNQ–Glu)

The reaction of thiols on various hydroxynaphthoquinone derivatives led, in one step, to substituted quinone rings, under mild conditions [17]. It is one of the most elegant substitution reactions on quinone rings, which are known to be quite unreactive in usual conditions. Therefore, the grafting reaction of glutathione onto hydroxynaphthoquinone derivatives appears highly interesting and original (to our knowledge, this reaction has not been described elsewhere).

5-Hydroxy-3-γ-L-glutamyl-L-cysteinyl-glycine-1,4-naphthoquinone (HNQ–Glu) was synthesized in one step from 1 equiv. of 5-hydroxy-1,4-naphthoquinone (HNQ) and 2 equiv. of γ-L-glutamyl-L-cysteinyl-glycine in 25 mL ethanol at 60 °C (Scheme 1). The solution was stirred for 15 min at this temperature and cooled at room temperature. The mixture was then allowed to stand for 2–3 days at 5 °C in the dark. The precipitate obtained was filtered and washed with ethanol. Evaporation of the solvent led to a brown/orange powder. Finally, a recrystallization step was made. The powder was dissolved in hot ethanol, filtered, then activated charcoal was added, and the mixture was filtered again. After one or 2 days at 4 °C, needles appeared at the bottom of the flask, which were separated by filtration, washed with cold ethanol (−18 °C) and kept for further analysis.

Table 1
NMR chemical shifts and multiplicity in D_2O at 298 K.

Proton	δ (ppm)	Multiplicity
Glu-H_α	3.76	t
Glu-$H_{\beta1}/H_{\beta2}$	2.13	m
Glu-$H_{\gamma1}/H_{\gamma2}$	2.52–2.51	m
Cys-H_α	4.53	d
Cys-$H_{\beta1}/H_{\beta2}$	2.92–2.90	m
Gly-H_α	3.92	s
H_2	–	–
H_8	7.72	d.d
H_7	7.78	t
H_6	7.40	d.d

The yield is ca. 40%. The purity of HNQ–Glu was verified by TLC and its structure was confirmed by FTIR (in KBr pellets, ν/cm^{-1}): 3028 [ν(N—H), weak]; 2975,2932 [asym. and sym. ν(C—H) of –CH_2–, strong], 1713 [ν(C—O), acid, strong]; 1661, 1559 [ν(C—C_{ar}), strong], 1630 [ν(C—O) of quinone, strong], 930 (δC—H_{ar}, 1H, weak), 759 (δC—H_{ar}, 3 adj. H, weak). A typical band of the ν(C—S) bond was found at 550 cm^{-1} (weak). The HNQ–Glu melting point is 250 °C versus 164 °C for HNQ.

NMR was performed in several deutered solvents, as MeOD, CD_2Cl_2 or D_2O. It was found that the whole HNQ–Glu molecule is only partially soluble in organic MeOD or CD_2Cl_2, whereas its solubility is acceptable in D_2O. This is due to the opposed behaviour between the glutathione part and the juglone part. If the second one is easily soluble in organic solvents, that is not the case for the glutathione moiety. The NMR identification was therefore performed in D_2O. L-Glutathione (Glu) and 5-hydroxy-1,4-naphthoquinone (Jug) were analyzed in D_2O and used as references. Their NMR spectra were compared to that of HNQ–Glu. Their profiles are identical. Proton's chemical shifts and attributions of HNQ–Glu are reported in Table 1 (see Scheme 1 for numbering). It can be noted that β protons of the glutamic acid present the same chemical shift (2.13 ppm) whereas the γ ones are slightly different (2.52–5.51 ppm), as well as the β protons of the cysteine moiety (2.92–2.90 ppm). The H_2 proton was expected but cannot be seen. This can be explained by interactions with the Glu moiety at close vicinity.

3.1.2. Electrosynthesis of poly(HNQ-co-HNQ–Glu)

Due to its relatively high molecular weight, the glutathione moiety induces a strong steric hindrance on the HNQ moiety. Moreover, the carboxylic acids (negatively charged) may change the ion-exchange properties of the polymer. This is why we chose to make a copolymer with an equivalent proportion (1:1) of HNQ and HNQ–Glu instead of poly(HNQ–Glu). Conditions are described in Section 2.2.

The voltammograms obtained during electrosynthesis of poly(HNQ-*co*-HNQ–Glu) films present during the first cycles an oxidation wave situated above 1 V. After a few cycles, a redox couple appears around 0.85/0.90 V. Currents increase gradually with potential scans (Fig. 1).

The FTIR spectrum of the resulting film (synthesized on a gold plate) is presented on Fig. 2. A peak at 3059 cm^{-1} of medium intensity can be attributed to free N—H stretch (asymmetric vib.). Bands situated between 3000 cm^{-1} and 2800 cm^{-1} concern CH_2 stretching vibrations. The presence of several peaks (asym. νCH_2, 2954 cm^{-1} and 2924 cm^{-1}; sym. νCH_2, 2860 cm^{-1} and 2870 cm^{-1}) shows that two different –CH_2– groups are present in the glutathione moiety: –CH_2– close to carboxyl groups and –CH_2– close to amine groups. The bands present in the 2000–700 cm^{-1} range are typical for the HNQ moiety, with a shoulder at 1737 cm^{-1} due to ν(C=0) of the carboxylic acid group, two strong bands at 1670

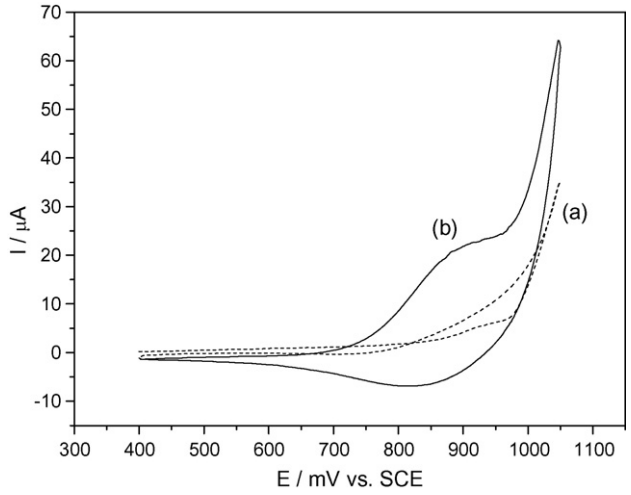

Fig. 1. Cyclic voltammograms recorded during electrosynthesis of a poly(HNQ-*co*-HNQ–Glu) film in ACN + 0.1 M $LiClO_4$ + 5×10^{-2} M HNQ + 5×10^{-2} M HNQ–Glu + 2×10^{-3} M 1-naphthol on a GC electrode under argon atmosphere. Scan rate: 50 mV s^{-1}. Electrode surface: 0.07 cm^2. (a, dashed line), fist cycle; (b, plain line) 50th cycle. Film thickness after 50 scans: ca. 100 nm (measured by SEM).

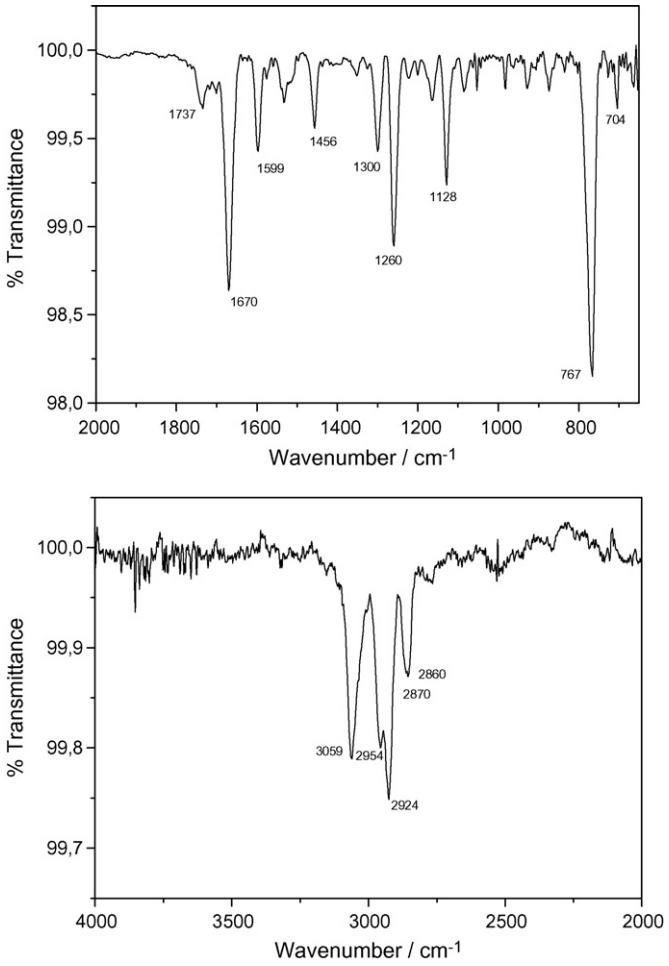

Fig. 2. FTIR spectra of the poly(HNQ-*co*-HNQ–Glu) film electrodeposited on a gold substrate, in the 650–2000 cm^{-1} and 2000–4000 cm^{-1}.

and 1599 cm^{-1} are due to $\nu(C{=}C)_{ar}$ of the aromatic structure and of the quinone group, bands at 1260 and 1300 cm^{-1} are attributed to $\nu(C{-}O{-}C)_{as}$ of the furan cycle and a strong band at 767 cm^{-1} is typical for naphthalene structure.

3.2. XPS characterization of poly(HNQ-co-HNQ–Glu) films

The poly(HNQ-*co*-HNQ–Glu) films were analyzed by X-Ray Photoelectron Spectroscopy (XPS). Fig. 3 presents spectra of C, N and S. Carbon atoms are present in the polymer structure as well as in the Glu moiety whereas nitrogen and sulfur belong only to Glu.

The C1s spectrum displays four peaks, at 285 eV, 286.2 eV, 287.7 eV and 289.1 eV. They can be respectively attributed to C—C and C=C (present into the polymer backbone and the Glu moiety), C—O, C—S and C—N (polymer backbone and Glu), C=C (of the quinone group), and O—C=C or O=C—N (of the carboxylic and amide groups belonging to the Glu moiety).

Scheme 2. The proposed structure for poly(HNQ-*co*-HNQ–Glu).

The N1s spectrum displays 2 peaks, at 400.7 eV and 402.5 eV. These peaks can be attributed to the amide (–NH—C=C) and amine groups ($-NH_2$) respectively.

The S2p spectrum displays two peaks (as it is a 2p level) at 164.1 eV and 165.3 eV. It corresponds to the only sulfur present in the Glu moiety, which binds Glu and HNQ via a C—S bond.

The calculations from the peak surfaces, using the sensitivities for C, N and S which are respectively 1, 1.80 and 1.67, give an experimental atomic ratio N/S of 2.95. This ratio corroborates very well with the theoretical ratio (3:1) of the Glu structure. The experimental C/S ratio equals to 99. The theoretical one equals to 20:1 for the HNQ–Glu moiety, whereas no sulfur belongs to the HNQ molecule. This indicates that the ratio between the HNQ moieties and the HNQ–Glu moieties in the copolymer is around 4, that means 1 HNQ–Glu for 4 HNQ. Scheme 2 presents a proposed structure for poly(HNQ-*co*-HNQ–Glu) film, deduced from XPS and FTIR results.

3.3. Electroactivity of poly(HNQ-co-HNQ–Glu) films

The electroactivity of the copolymer film was investigated in phosphate buffer saline (PBS). In the cathodic potential domain of potential (between −0.9 V and 0.25 V), a redox couple develops at −0.51/−0.63 V (Fig. 4a).

The observed peaks are due to quinone electroactivity. By charge integration, 5×10^{-10} mol cm^{-2} of quinone are estimated to be electroactive for a 100-nm thick film (thickness determined by SEM at grazing angle). The redox systems present excellent stability upon cycling (several hundreds of cycles without significant current decrease, as shown in Fig. 4a). Of interest is the fact that the potential range is low enough to avoid interference with many electroactive species that can be present in biological media. Moreover, in applications for DNA grafting and hybridization detection, this behaviour avoids any risk of nucleobases oxidation, as they are oxidized at much higher potentials. At last, it is known that the redox system of the quinone group exchanges cation and not anion. More precisely, it has been shown by electrogravimetric experiments [13] that quinone exchanges mainly sodium cations in neutral PBS medium. This behaviour is a strong advantage of poly(HNQ-*co*-HNQ–Glu) film over other more classical polymer films. Indeed, DNA strands (which are negatively charged) are not able to play the role of counterions for this polymer which

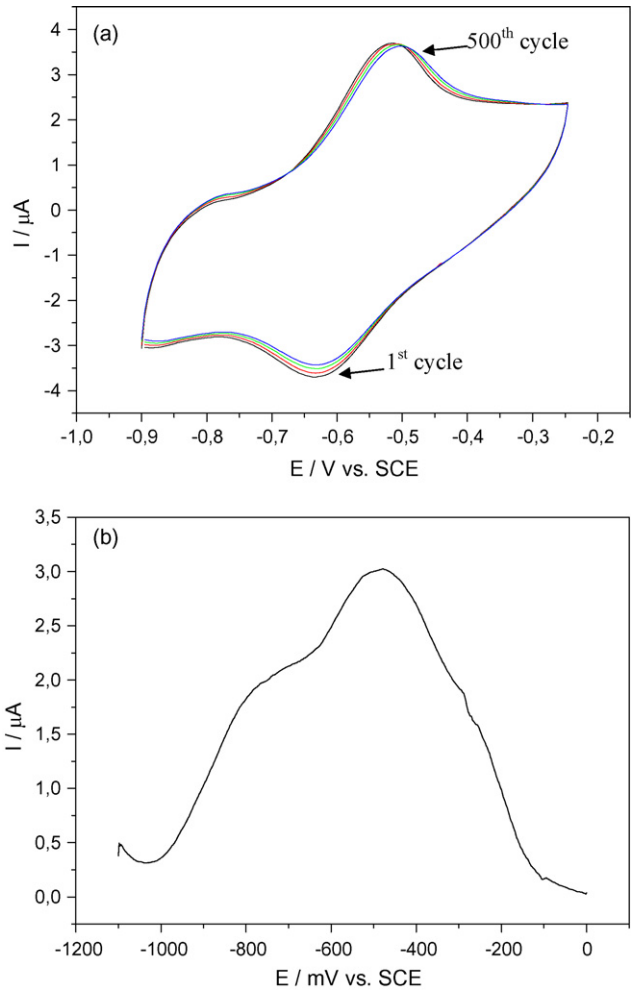

Fig. 4. (a) Cyclic voltammograms of a poly(HNQ-*co*-HNQ–Glu)-modified electrode recorded in PBS under argon atmosphere. Scan rate: 50 mV s^{-1}. Electrode surface: 0.07 cm^2. Film thickness: 100 nm. Several voltammograms were recorded between the first and the 500th without significant current decrease. (b) Square wave voltammogram (SWV) of a poly(HNQ-*co*-HNQ–Glu)-modified electrode recorded in PBS under argon atmosphere. Parameters: pulse height 50 mV, pulse width 50 ms, scan increment 2 mV, frequency 12.5 Hz, potential domain (−1.1 V; 0 V vs. SCE).

exchanges cations. As poly(HNQ-*co*-HNQ–Glu) polymer is neutral or negatively charged, it repels probe DNA strands (which still remain available for hybridization), and prevents non-specific adsorption of target strands. This property is interesting for the film to be used in biosensor matrix.

3.4. SWV of poly(HNQ-co-HNQ–Glu) films

As shown on Fig. 4a, the voltammograms present a strong capacitive component. We have shown in a previous work that DNA hybridization induces more change on the faradic current than on the capacitive current [13]. Therefore, square wave voltammetry (SWV), which is able to suppress much of the capacitive component, was chosen as the best analytical tool to study the influence of DNA grafting or hybridization on the film electroactivity. SWV was performed on the poly(HNQ-*co*-HNQ–Glu)-modified electrode before treatment with the ODN probe (Fig. 4b). The potential was swept from −1100 mV versus SCE to 0 V versus SCE (oxidation scan). Two oxidation peaks appear in this range. The main peak presents a maximum at around −500 mV/SCE, and the second one appears as a shoulder at around −800 mV/SCE. These peaks correspond to the redox process of the quinone group.

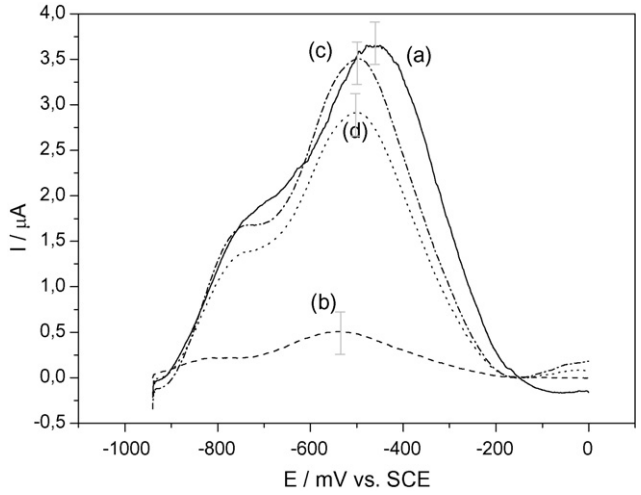

Fig. 5. SWV of a poly(HNQ-*co*-HNQ–Glu)-modified electrode. (a) Before PROBE grafting; (b) after PROBE grafting; (c) after incubation with PROBE without EDC nor NHS; (d) after incubation with EDC and NHS, without PROBE. Medium: PBS, under argon atmosphere. Parameters: pulse height 50 mV, pulse width 50 ms, scan increment 2 mV, frequency 12.5 Hz, potential domain −0.95/0 V versus SCE. Results obtained from 3 sets of independent experiments. Reproducibility is materialized by error bars.

This electroactivity involves ion exchange at the polymer/solution interface. Therefore, changes made on this interface will affect electroactivity. The presence of DNA at the interface strongly influences the ionic flux, therefore the switching rate of the polymer, and as a consequence the recorded current.

Two main explanations for the current change could be envisaged: electrostatic effect (due to the polyelectrolyte character of ODN strands) and/or steric effect (due to the fact that ODN are relatively large molecules). Due to the strong ionic force used in our experiments, the charges localized on the double-stranded ODN (dsODN) backbone are totally screened. The electrostatic effect can be neglected. The steric effect is therefore predominant.

An interesting particularity of ODN is that the double-stranded state (after hybridization) presents a conformation which is very different from the single-stranded state (before hybridization). One can assume that the single-stranded ODN (ssODN) behaves as a classical polymer chain. This means that it is folded as a statistical coil. On the contrary, the double-stranded ODN can be modeled as a rigid cylinder [18–20]. Therefore, steric hindrances generated by ssODN or dsODN are very different. This influences the ionic transport dynamics.

This model has been thoroughly developed in previous papers [14,15] and is the basic principle of the transduction mechanism which is concerned in this work. We have shown that, under certain conditions, dsODN generate a lower steric hindrance than ssODN. Considering that the peak current is controlled by ions transport through the polymer/solution interface, this allows to conclude that ssODN grafting onto the surface generates a current drop; Conversely, the hybridization event (i.e. formation of dsODN) will lead to a current increase.

3.5. Electrochemical detection

3.5.1. Probe grafting

The probe ODN (PROBE) was grafted as described in Section 2. SWV was used to characterize grafting. A SWV curve was recorded before PROBE grafting, and another one was recorded, in the same conditions, after PROBE grafting. As shown on Fig. 5, the current intensity is high for the unmodified film (before grafting, curve a, plain line), and strongly diminishes after grafting (curve b, dashed

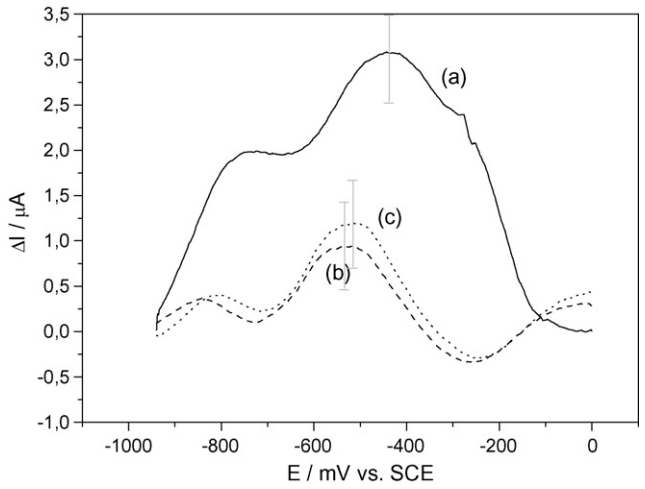

Fig. 6. Differential SWV (Δi) obtained after incubation of the probe-grafted poly(HNQ-*co*-HNQ–Glu) with complementary TARGET (curve a); incubation with RANDOM (curve b); incubation with MISMATCH (curve c). Medium: PBS, under argon atmosphere. Parameters: pulse height 50 mV, pulse width 50 ms, scan increment 2 mV, frequency 12.5 Hz, potential domain −0.95/0 V versus SCE. Differential currents (Δi) were obtained by subtraction of the current obtained after probe grafting. Results were obtained from 3 sets of independent experiments. Reproducibility is materialized by error bars.

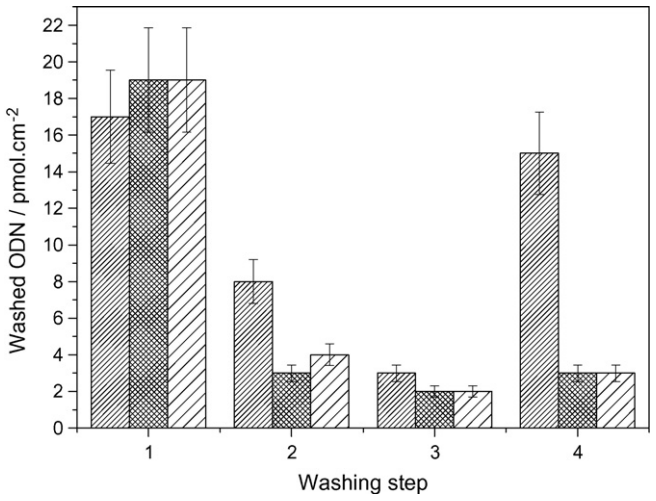

Fig. 7. ODN surface concentration deduced from fluorescence analysis. The fluorescence measurements were made as explained in Section 2, by 3 steps: (1) washing in PBS at 37 °C during 5 min; (2) washing in PBS at 37 °C during 10 additional min; (3) washing in PBS at 37 °C during 30 additional min; (4) washing in pure water at 80 °C during 15 min. The left-handed bars correspond to the COMP target; The central bars correspond to the RANDOM target; The right-handed bars correspond to the MISMATCH target. Results obtained from 3 sets of independent experiments. Reproducibility is materialized by error bars.

line). This can be attributed to the steric hindrance generated by the PROBE strands immobilized on the film surface. As shown, only 10% of the initial electroactivity remains after grafting.

During probe grafting, the electrodes were dipped into three different media: water containing reactants, pure water, and then PBS. To be sure that the current change is only due to probe grafting, blank experiments were performed. The first consisted of the same experiment as above, without NHS nor EDC. The second consisted of the same experiment as above, without ODN probe. The only case for which a significant current change occurs is for probe grafting. Probe alone in solution (curve c) does not lead to any change (this could indicate that there is no probe adsorption), whereas esterification with NHS and EDC (without ODN probe) leads only to a slight (20%) current drop (curve d).

We do no discuss the potential shift which appears between SWV (Figs. 5 and 6), because it cannot be interpreted as it would be for classical voltammetry. Indeed, SWV is a complex technique which subtracts what is called a reverse current (Ir, negative) from a forward current (If, positive).

3.5.2. Hybridization and selectivity

A similar experiment was performed to characterize target hybridization onto the grafted film. A SWV was recorded after PROBE grafting, before addition of the COMP target; another SWV experiment was recorded, in the same conditions, after COMP hybridization (target concentration: 50 nM). To make changes more visible, differential currents (Δi) were plotted. Δi corresponds to the current difference between two SWV recorded for two different electrode states. For example, the Δi which characterizes COMP hybridization corresponds to the difference between the SWV recorded after COMP hybridization and the one recorded before COMP addition.

As shown on Fig. 6 (curve a), a positive response ($\Delta i > 0$, meaning that the current increases upon hybridization) is obtained consecutively to addition of the full-complementary strand.

To be sure that the positive response is truly due to hybridization and not an artefact, a similar experiment was performed under the same conditions, with a non-complementary (RANDOM) strand. As previously, SWV was recorded before and after RANDOM addition. The resulting differential current is plotted on Fig. 6, curve b. As shown, current variations are weak. This result indicates that the current change observed after addition of the COMP sequence is truly due to hybridization.

In a last experiment, the selectivity was checked. A similar experiment than above was performed and a MISMATCH sequence was added (i.e. a sequence which differs from the COMP sequence by only one base, a G being replaced by a A). As shown on Fig. 6, curve c, the current change is weak. This means that the biosensor is selective and discriminates one mismatching base in a 30-bases sequence.

3.5.3. Sensitivity

The results concerning hybridization with a full-complementary target were obtained with a target concentration of 50 nM, in 1 mL PBS solution, at 72 °C for 2 h. As shown in Fig. 6, the current change upon hybridization is ca. 3 μA in these conditions, with a S/N ratio of around 3. This sensitivity is comparable to that obtained on another system developed by our group [15]. We have tested with various target concentrations, with 10 nM, the S/N ration is around 2 while with 1000 nM target concentration, the current change recorded is not more than 3 μA, but is reached faster, after 30 min instead of 2 h. These results illustrate the fact that the current change is limited by the surface concentration of hybrids, i.e. the probe surface concentration and not by the target concentration, as soon as the quantity of target is sufficient. For example, 1 mL at 1 nM contains 1 pmol of target, which corresponds approximately to the probe quantity on our electrodes.

3.5.4. Fluorescence experiments

Besides the electrochemical experiments, we have performed fluorescence experiments in order to demonstrate the stability of the probe grafting as well as the selectivity of the target hybridization.

A systematic procedure was followed, in four steps, as described in Section 2. Three different targets were studied: COMP*, MISMATCH* and RANDOM*. As shown in Fig. 7, the first wash removes quite high quantities (around 18 pmol cm^{-2}) for the three targets. This corresponds to elimination of unspecifically adsorbed ODN. Since the second wash (still under mild conditions, 37 °C), the

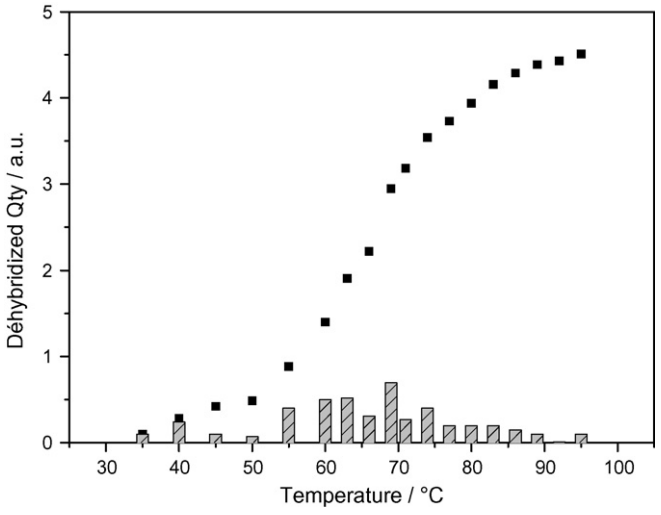

Fig. 8. Dehybridized COMP sequence as a function of the temperature. Nineteen washes were performed, from 35 °C up to 95 °C, in PBS. Bars indicate the dehybridized quantity (fluorescence intensity) corresponding to each wash at a given temperature. The curve (in black squares) is obtained by successive integration of dehybridized quantities.

results begin to be sequence-specific. Indeed, there are at least two times more desorbed COMP* sequences (equivalent to around 8 pmol cm^{-2}) than MISMATCH* or RANDOM* ones (equivalent to around 4 pmol cm^{-2}). We suppose that a part of hybridized COMP* targets may dehybridize even under these mild conditions. At the third wash, desorption is low for all (around 2 pmol cm^{-2}).

The results are different for the 4th step (dehybridization under stringent conditions, 80 °C in pure water. At this temperature, one can assume that all previously hybridized COMP* are denatured). Fluorescence remains low for MISMATCH* and RANDOM* targets (equivalent to around 3 pmol cm^{-2}), whereas it reaches five times more, i.e. 15 pmol cm^{-2} for COMP*. These data show that hybridization occurs efficiently on the modified electrode, and is highly sequence-specific.

In addition to these results, we performed an original and complementary experiment. This time, dehybridization was performed in PBS instead of pure H_2O, not only at 80 °C but at increasing temperatures from 35 °C up to 95 °C and fluorescence was followed stepwise, as a function if temperature. As shown (Fig. 8), fluorescence increases significantly for temperatures above 55 °C. The shape of the curve corresponds to the melting temperature of the PROBE-COMP* duplex (given at 72 °C in homogenous conditions). This result demonstrates without any doubt that dehybridization is responsible for this behaviour.

4. Conclusion

The modification of 5-hydroxy-1,4-naphthoquinone by γ-L-glutamyl-L-cysteinyl-glycine (glutathione) has been obtained by a direct and elegant method. The resulting 2-(γ-L-glutamyl-L-cysteinyl-glycine)-5-hydroxy-1,4-naphthoquinone (HNQ–Glu) presents 3 functional groups: the hydroxyl group for electropolymerization, the quinone group as the redox reporter, and the glutathione oligopeptide as a precursor for subsequent biomolecule linkage, via amine or carboxylic groups.

It is shown that the co-electrooxidation of HNQ–Glu and unmodified HNQ leads to poly(HNQ-*co*-HNQ–Glu), into which the quinone group remains electroactive, even in neutral buffered solution.

The poly(HNQ-*co*-HNQ–Glu)-modified electrode allows to detect directly DNA hybridization with a "signal-on" current (i.e. a current increase in Square Wave Voltammetry curve).

This DNA sensor is selective as a positive response is detected when a complementary DNA strand is added, while no significant signal change is observed consecutively to addition of a non-complementary or a mismatch sequence.

The molecular recognition is detected by changes in the electroactivity of the quinone group. This is due to the fact that DNA strands generate both steric hindrance and electrostatic effect on the electrode surface, which influences the quinone electroactivity.

The high selectivity could be explained by the fact that as the Glu moiety is negatively charged and poly(HNQ-*co*-HNQ–Glu) film is a cation (sodium) exchanger, non-specific adsorption of DNA strands are prevented.

The high selectivity as well as the "signal-on" response make this film original and efficient to be used in a direct DNA biosensor. This is, to our knowledge, the only work reported in the literature concerning an electrochemical DNA sensor using glutathione as the binding element. This approach can be generalized with other polypeptides, providing that a thiol group is available.

Tubular electrodes

ABSTRACT

In this work a single interface flow system (SIFA) with potentiometric detection was for the first time implemented and applied to the determination of nitrate in waters and plant extracts. The analytical potential of the SIFA system was exploited not only to transport the sample towards detection but also to carry out, in a reproducible and automated way, the tasks associated with sample pre-treatment, namely ionic strength, pH adjustment and interfering species suppression. The advantageous aspects of combining a SIFA system with potentiometry with enhanced simplicity, ease of implementation and automation were further discussed and emphasised.

The obtained results showed relative deviations lower than 5%, for both types of samples, with sampling rates of about 40 h^{-1}.

In addition, an innovative and straightforward process for constructing plastic membrane ion selective electrodes with a tubular configuration able to be coupled to flow-based analytical systems is also proposed. The developed approach, consisting of assembling the electrode inside a flow tubing connector is very simple to implement, robust, particularly adequate to be combined with flow methodologies and maintains all dynamic and analytical characteristics exhibited by previous assembling processes.

1. Introduction

Single interface flow analysis (SIFA) was recently proposed by Ribeiro et al. [1] as a new flow strategy for the automated handling of solutions and implementation of reaction schemes. This flow approach relies on the establishment of two dynamic concentration gradients between two adjoining solutions (sample and reagent) at the single interface where these are put in contact for reaction development prior to transport towards detection.

The formed concentration gradients are a consequence of the mutual penetration/interdispersion of the neighbouring zones due to the higher velocity of the flowing stream at its central zone, when compared to more peripheral ones, characteristic of a laminar flow. In opposition to more conventional flow techniques, in SIFA systems, whatever might be the residence time, a physical or a chemical equilibrium is never attained. In fact, the interface or reaction zone progresses continuously in opposite directions with time, as more and more solutions zones are involved in the mutual penetration process. This way, the width of the reaction zone increases and since there is a continuous supply of fresh sample and reagent solutions the analytical signal becomes broader although its magnitude is almost unaffected by dilution phenomena. Parameters such as flow rate and reactor length that affect zone penetration also influence analytical peak broadness. With respect to the profile of the analytical signal obtained, it could vary from an almost Gaussian peak, if a spectrophotometer is used and a coloured product reaction is formed at the single interface, to a typical sigmoid curve, in the case of for instance a potentiometric detector, the sigmoidal shape (Fig. 1) portraying the intermixing process between the adjoining solutions [2]. Nevertheless, the profile of the analytical signal is representative of the continuous point-to-point molar ratio variation that results from the mixing of the individual solutions at the interface. This feature provides a high analytical versatility since it makes possible to select any point of the analytical profile, referenced in terms of a detection time (t_D), which may be regarded as combining the most favourable reaction conditions concerning sample and reagent concentrations. Another important advantage of SIFA systems is their operational simplicity. This arises from the fact that no compelling sample or reagent volumes have to be used, in opposition to other flow techniques, which simplifies analytical system implementation and optimisation. Moreover, since no specific sample and reagent insertion devices are required, the number of flow manifold components is reduced with a concomitant restraint in the potential sources of errors or malfunctions.

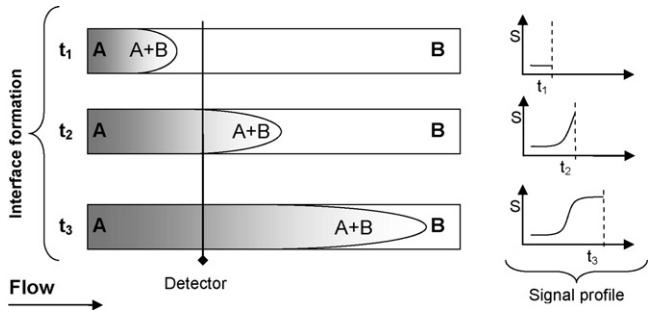

Fig. 1. Scheme of the single interface formation between two adjoining solutions (A and B) and analytical signal profile obtained for increasing detection time (t_1 to t_3).

These characteristics make SIFA systems very attractive for coupling with potentiometric detectors where the single interface could be exploited for sample pre-treatment, such as pH and ionic strength adjustment or interferences suppression, for the formation of electroactive species, for carrying out standard addition methods, to increase detector selectivity or to implement titrimetric methodologies.

Potentiometric techniques have a widespread use in routine analysis although most of the times they rely on direct potentiometric measurements carried out in batch procedures by using well defined volumes of sample that frequently require a previous conditioning. These aspects could constitute an important shortcoming in terms of analytical efficiency that could be overcome by resorting to a flow-based technique. The simplicity and efficiency of coupling flow-based techniques with potentiometric detection has been demonstrated with distinct analytical purposes [3]. The enhanced detector selectivity prevents the need for extensive sample pre-treatments and greatly simplifies flow manifold configuration. At the same time, the expeditious sample handling provided by flow analysis capitalises the fast potentiometric detector response enabling a high sampling rate, while repeatability is favoured by the continuous detector conditioning that the flowing stream is able to assure.

In this work, a SIFA system was for the first time coupled to a potentiometric detector, more specifically a tubular ion selective electrode with plastic membrane, and the analytical capability of this association was assessed in the determination of nitrate ion in waters and plant extracts. Moreover, a new strategy for constructing plastic membrane electrodes with a tubular configuration and without internal reference solution is proposed.

2. Experimental

2.1. Reagents and solutions

All reagents were of analytical quality grade or equivalent. Solutions were prepared with water (specific conductivity <0.1 μS cm^{-1}) obtained from a Milli-Q (Millipore) equipment. Ions stock solutions were prepared by rigorous weighing and dissolution of appropriate salts amounts. Working solutions were subsequently obtained by accurate dilution.

Nitrate ion sensor was prepared by mixing 0.2 g of a mixture of 4,7-diphenyl-1,10-phenantroline/nickel complex in 2-nitrophenyl octyl ether [4] (Fluka) with 0.08 g of vinyl polychloride (Fluka) previously dissolved in tetrahydrofuran (Fluka).

For obtaining the non-conductive epoxy resin, Araldit M (Fluka) and Ren HY5162 (Huntsman Advanced Materials) hardener were mixed in a 100:40 mass ratio. The graphite based conductive resin was prepared by adding graphite (Merck) to the non-conductive epoxy resin in a 1.4:1 mass ratio.

2.2. Equipment

The plastic membrane tubular detectors were constructed by using Gilson connectors (ref. F1410153) as the physical supports that accommodate the graphite based conductive resin. The detector was coupled to the flow system by means of Gilson end-fittings (ref. 4911031) and rubber rings of 1.6 and 2.0 mm of internal and external diameter, respectively.

The flow system comprised a B-2031 automatic burette (Crison Instruments) equipped with a 5 mL syringe (Hamilton), a 3-way solenoid valve (ref. 161T031, NResearch) and a detection system combining a tubular electrode selective to nitrate, a double junction reference electrode AgCl/Ag (ref. 90-02, ThermoOrion) filled with a ref 90-00-02 internal solution (ThermoOrion) and a ref. 90-00-03 external solution (ThermoOrion) and a potentiometer (ref. 2002, Crison Instruments). The reference electrode was coupled to the flow system by employing a homemade [5] acrylic support. All tubing, including the reaction coil, was made of PTFE with 0.8 mm i.d. (Omnifit). A Kipp & Zonnen BD 111 recorder was used to trace the analytical signals, when required.

Control of the analytical system and data acquisition and processing was achieved by means of a microcomputer equipped with a PCL711B interface card (Advantech). The control software was developed in QuickBasic 4.5 and permitted to operate the automatic burette (by RS232C protocol) as well as the solenoid valve. The latter was actuated by TTL signals by resorting to a CoolDrive (NResearch) power drive.

The determination of nitrate in water samples by the reference method was carried out by resorting to a PerkinElmer 50 spectrophotometer and the determination of the same ion in plant extracts was accomplished by using a model 761 Compact IC ion chromatographer (Metrohm) equipped with a Metrosep Anion Dual ref. 6.1006.020 column (Metrohm) and a conductimetric detector.

2.3. Construction of the tubular electrode

The utilisation of a common tubing connector as the assembling support piece for the plastic membrane nitrate ion selective electrode has main advantages, namely low cost, commercial availability and ease of inclusion in a flow manifold. The tubular electrode was constructed in a sequence of steps that included (Fig. 2): (i) transversal perforation of the connector for insertion of a coaxial cable; (ii) filling of the central interior zone of the connector with graphite based conductive epoxy resin; (iii) connection of the coaxial cable to the resin through the transversal hole; (iv) hardening of the epoxy resin; (v) electric insulating of both exposed

surfaces of the conductive epoxy resin as well as the transversal hole by covering them with non-conductive resin; (vi) hardening of the non-conductive resin; (vii) perforation of a 1.0 mm-diameter longitudinal hole through the resin layers at the centre of the connector; (viii) deposition of a few drops of nitrate sensor solution on both extremities of the hole; (ix) dry out of the electrode overnight.

The sensor was coupled to the flow system by means of two end-fittings and rubber o-rings.

2.4. Sample preparation

Water samples were analysed by both the reference method and the developed procedure without any additional treatment.

Plant extracts were prepared by using the following procedure: to 0.1 g of plant leaves, previously dried and powdered, 150 mL of water were added and the suspension stirred for 30 min at room temperature. After being diluted to 200 mL in a volumetric flask the suspension was passed through a 0.45 μm filter.

2.5. Flow system

The analytical flow system, pictured in Fig. 3, was kept as simple as possible in order to emphasise the analytical potential of the single interface flow approach. With this purpose the solutions were propelled by aspiration instead of propulsion, which would require further manifold components and a more complex configuration. Indeed, the utilisation of an additional burette for sample insertion and propulsion would increase significantly the time required for the analysis, considering that each sample replacement would be a time-consuming step, and it would result as well in the consumption of larger sample volumes.

In order to guarantee a reproducible steady stream assuring a well definition of the interface contour without irregularities or fluctuations, an automatic burette equipped with a 5 mL syringe was selected as solutions propelling unit (by aspiration).

The interface was established between the sample and a total ionic strength adjustment buffer (TISAB). This way, pH buffering, ionic strength adjustment and interferences suppression can be performed on-line (along with the interface generation) carrying out the necessary sample conditioning before potentiometric detection.

In terms of operation of the developed flow system, the establishment of the interface between the sample and the total ionic strength adjustment buffer (TISAB) could have been achieved in two distinct arrangements: either by aspirating first the sample (leading solution) and then the TISAB solution (tailing solution) or by inverting the sequence of insertion, being the TISAB solution the leading one. The solution that was inserted in the reaction coil was determined by the solenoid valve position. Since the first option determined lower sample consumption and reduced the electrode exposure to sample matrix constituents it was the one selected for the assays.

The analytical cycle (Table 1) started by switching off the solenoid valve and insertion of the sample solution for cleaning the sample channel. Subsequently, the solenoid valve was switched on and the TISAB solution was aspirated into the analytical system for cleaning, electrode conditioning and baseline establishment. In a third step, the solenoid valve was again switched off and the sample solution was inserted in the analytical path, establishing a single reaction interface that produced an analytical signal when passed through the tubular electrode.

2.6. Reference procedure

For the determination of nitrate in waters the reference methodology described in "Standards Methods for the Examination of Waters and Wastewaters", 20th Ed. (1998), was followed. This is based on direct spectrophotometric measurement of sample absorption at 220 nm.

The determination of nitrate in plant extracts was carried out by ion chromatography with conductimetric detection similar to [6], by using a solution of Na_2CO_3 2.0×10^{-3} mol L^{-1} and $NaHCO_3$ 2.4×10^{-3} mol L^{-1} as mobile phase, at a flow rate of 0.5 mL min^{-1}. Sample volume was 20 μL.

3. Results and discussion

3.1. Evaluation of the nitrate ion selective electrode intrinsic characteristics

The developed tubular electrodes selective to nitrate ion were evaluated concerning their dynamic and analytical characteristics in a single-channel low dispersion flow injection system by using nitrate standard solutions prepared in Na_2SO_4 0.033 mol L^{-1} as

Table 1
Experimental conditions used for the potentiometric determination of nitrate ion by using a SIFA based analytical flow system and the corresponding analytical figures of merit.

Reactor length: 10 cm
TISAB solution composition: PbO, 0.01 mol L^{-1}; $Pb(CH_3COO)_2$, 0.02 mol L^{-1}; NH_4SO_3, 0.015 mol L^{-1}; $NaNO_3$, 1×10^{-5} mol L^{-1}

Step	Solenoid valve	Flow rate (mL min^{-1})	Inserted volume (μL)	Description
Experimental protocol				
1	Off	1.70	160	Sample replacement
2	On	1.70	1000	Reactor cleaning and electrode conditioning
3	Off	0.800	140	Sample analysis

Analytical figures of merit
Sampling rate: 40 h^{-1}
Sample volume used in the analysis: 300 μL
Detection limit: 1.6×10^{-4} mol L^{-1} (6 s); 4×10^{-5} mol L^{-1} (8 s); 2×10^{-5} mol L^{-1} (10 s)
Lower limit of linear regression: 3×10^{-4} mol L^{-1} (6 s); 7×10^{-5} mol L^{-1} (8 s); 3×10^{-5} mol L^{-1} (10 s)

ionic strength adjuster, as described in a previous work [7]. Suitable and efficient coupling was attained as no leaking was observed. Additionally, baseline potential value variation was not higher than 0.2 mV, highlighting the construction procedure adopted. The obtained results were similar, both in terms of dynamic and analytical characteristics, to those presented in the referred work for tubular electrodes operated under similar experimental conditions. Therefore, this aspect will not be further discussed.

During the flow methodology development the constructed detector was periodically tested in order to assess its intrinsic response characteristics. The detectors constructed were substituted, or the plastic membrane replaced, whenever the slope observed was inferior to 45 mV dec^{-1} or when the response time became significantly higher than the original values.

3.2. System performance

System performance assays were carried out with aqueous solutions solely, assuring that no significant differences of density between the different standards were verified. This aspect is of utmost importance considering the flow strategy here explored, since the profile generated by two adjoining solutions moving along the flow system is different for solutions with distinct density.

With the purpose of evaluating the influence of the reactor length and flow rate on the single interface profile, studies were carried out involving the utilisation of solutions with different nitrate ion concentrations. The selected concentration values, between 3.00×10^{-5} and 1.00×10^{-2} mol L^{-1}, corresponded to nitrate values usually found in water samples and plant extracts and lay within the nitrate electrode linear working range. Reactors with 10, 20 and 30 cm length and flow rates of 800, 320 and 160 μL min^{-1} were assessed in this study.

The obtained results showed that, as expected, the broadness of the interface increased for longer reaction coils and for lower flow rates. This behaviour is a direct consequence of the greater residence time of the interface within the flow system and the subsequent increase in the mutual interpenetration of the neighbouring conditioning and nitrate standard solutions.

From the results obtained in these studies it was evident that the proposed flow system enabled a simple, fast and reproducible (analytical signal variation was lower than 0.3 mV) single interface implementation. Moreover, it was also realised that the electrode showed a Nernstian behaviour, which made possible to calibrate the flow system by correlating, for a given detection time (t_D, time interval between sample insertion and measurement), analytical signal height and nitrate concentration, being clear that the found slope increased with t_D until a value equivalent to the one obtained under stationary conditions. This performance was observed for all assayed experimental conditions. As an example, Fig. 4 exhibits the calibration curves obtained for 4 distinct t_D (6, 8, 10 and 12 s) when using a 10 cm reactor and a 800 μL min^{-1} flow rate. This feature could represent a valuable asset in terms of analytical capability since it enables the gathering of multiple calibration curves at variable t_D for the same set of standard solutions, which could be used for accuracy assessment purposes.

The obtained results have also demonstrated that a wide range of t_D, covering almost the entire interface span, could be used for calibrating the single interface flow system. Effectively, this time interval is limited by both a minimum value below which the sensitivity of the detector is gradually lower and a maximum value above which the ionic strength adjustment is inappropriate or, considering a more global perspective, sample pre-treatment is insufficient. Nevertheless, the possibility of utilisation of a variety of t_D, with similar system performance, could be considered interesting in a sense that, depending on the purpose of the analysis or, for instance, the number of samples to be analysed a shorter or a longer t_D could be used, which would yield different sampling rates or sensitivity. On the other hand, the selection of a given t_D to calibrate the analytical system should also take into account the characteristics of the sample matrix. Anticipating a high analyte concentration along with a high interferences level, a short t_D close to the lower boundary of the interface zone should be selected. This way, the higher dispersion endured by the sample in the TISAB solution (present in a higher concentration ratio) allowed a more efficient sample conditioning. On the contrary, if the sample presents both low analyte and low interferences concentration levels, then a higher t_D within the upper interface zone should be used. In these conditions, despite the lower TISAB/sample concentration ratio, TISAB levels are high enough to assure a proper sample conditioning. Moreover, since in this zone of the interface sample dispersion is minimal it assures an increment in the sensitivity thus a lower detection limit.

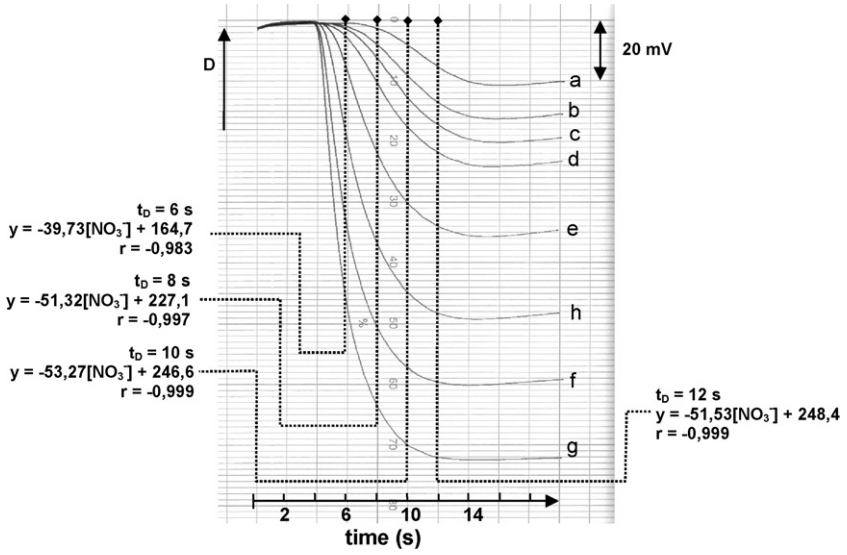

Fig. 4. Analytical signal profiles obtained at increasing detection times for nitrate ion standard solutions with distinct concentrations (mol L^{-1}): a—3.00×10^{-5}; b—5.00×10^{-5}; c—7.00×10^{-5}; d—1.00×10^{-4}; e—3.00×10^{-4}; f—1.00×10^{-3}; g—3.00×10^{-3}; h—1.00×10^{-2}. Experimental conditions: reactor length = 10 cm; flow rate = 800 μL min^{-1}. Calibration curves, representing $E = m \times \log[NO_3^-] + b$, correspond to each of the detection times assayed. D—dispersion coefficient.

Table 2
Concentration of interferences in the solutions assayed (mol L^{-1}).

Interferences	Solution I	Solution II	Solution III
Cl^-	1.00×10^{-4}	1.00×10^{-3}	1.00×10^{-2}
HCO_3^-	5.00×10^{-4}	1.00×10^{-3}	5.00×10^{-3}
NO_2^-	1.00×10^{-5}	5.00×10^{-5}	1.00×10^{-4}

Furthermore, the flow system configuration and the selected experimental procedure guaranteed no carry over effects during the analysis of samples or standards. The volumes aspirated provided an efficient cleaning of sample tubing, reactor as well as good electrode conditioning.

3.3. Interferences suppression

Despite the intrinsic selectivity, the nitrate ion selective electrode with the sensor based in the 4,7-diphenyl-1,10-phenanthroline/nickel complex exhibit a lack of selectivity mainly in the presence of chloride, nitrite and hydrogencarbonate [4,8,9]. Aiming at minimising the interfering effect of these species, Mitrakas and Alexiades [10] proposed the TISAB solution composed of PbO, 0.01 mol L^{-1}, $Pb(CH_3COO)_2$, 0.02 mol L^{-1}, KCH_3COO, 0.01 mol L^{-1} and NH_2SO_3H, 0.01 mol L^{-1} (pH 6.8). Lead(II) oxide and lead(II) acetate enabled the flocculation of organic compounds as well as the precipitation and/or complexation of chloride and the removal of hydrogencarbonate. Sulfamic acid is used to eliminate nitrite while potassium acetate facilitates pH buffering and ionic strength adjustment. When using a direct potentiometric batch procedure, well defined volumes of TISAB of known concentration are used. Moreover, the final solution is homogeneous. On the contrary, in a SIFA system no definite solutions volumes are used and no physical equilibrium is ever reached. Therefore, a study of TISAB solution efficiency in removing interferences in the developed flow approach was carried out by preparing various nitrate solutions with concentrations of 1.00×10^{-4}, 1.00×10^{-3} and 1.00×10^{-2} mol L^{-1}, respectively, with the referred interfering species present at different concentrations, as presented in Table 2. It should be noted that the highest concentration values tested for hydrogencarbonate concentration exceeded the values found in Portuguese potable waters, while for chloride (7.0×10^{-3} mol L^{-1}) and nitrite (1.1×10^{-5} mol L^{-1}) exceeded the allowed maxima defined by the European Union legislation [11].

The results obtained in the analysis of the prepared solutions by using the developed procedure (with a 10-cm reactor and at a flow rate of 800 μL min^{-1}, in order to maximize sampling rate) showed that at high hydrogencarbonate concentrations a $Pb(HCO_3)_2$ precipitate was formed, which affected repeatability due mainly to accumulation of the solid all over the flow system. To overcome this situation the TISAB solution was tested for pH values of 4.5, 4.0 and 3.5 obtained upon addition of further sulfamic acid. It was verified that the formation of precipitate actually diminished although for pH 4.0 and 3.5 an unwanted pronounced reduction of the analytical signal was also observed.

Table 3
Nitrate ion concentration values found in water samples by using the reference methodology and the developed flow approach (t_D = 10 s).

Water sample	$[NO_3^-]_{ref.\ meth.}$[a] (±SD) (mol L^{-1})	$[NO_3^-]_{flow}$[a] (±SD) (mol L^{-1})	RD (%)

[b] Lower than the detection limit.

Since the residence time determines the sample/TISAB mutual interdispersion the influence of flow rate on TISAB solution ability to suppress the interfering effects, was also object of study. Flow rates of 800, 320 and 160 μL min^{-1} were evaluated. It was anticipated that a lower flow rate would provide an improved mutual dispersion along with an enhanced reaction development that would contribute to a more efficient suppression of interferences. For the distinct levels of interferences assayed it was confirmed that the interfering effect increased as the interference/nitrate molar ratio increased. In fact, for nitrate concentrations of 1.00×10^{-3} mol L^{-1} and 1.00×10^{-2} mol L^{-1}, the profile of the potentiometric signals obtained in the presence or absence of interference was identical up to a dispersion coefficient of about 2.2. For these concentration levels this behaviour was similar for the three assayed flow rates. In opposition, for nitrate 1.00×10^{-4} mol L^{-1}, the interferences produced a more pronounced deviation than the one observed for higher nitrate concentrations. Moreover, the deviation was more prominent for the lower flow rate. Fig. 5 shows that the solutions prepared with interferences concentrations signalled as I and II in Table 1 exhibit signal profiles that were identical to the signal profile obtained in the absence of interferences, up to a dispersion coefficient of about 2. For the lower assessed flow rate that was not verified. These results demonstrated the faster response of the electrode for the primary ion with respect to the interfering species, which enabled the attenuation of the potentiometric signal deviation induced by the latter and are in agreement with the results described by Trojanowickz and co-workers [12] that applied the same strategy to improve the selectivity of electrodes sensitive to chloride ion.

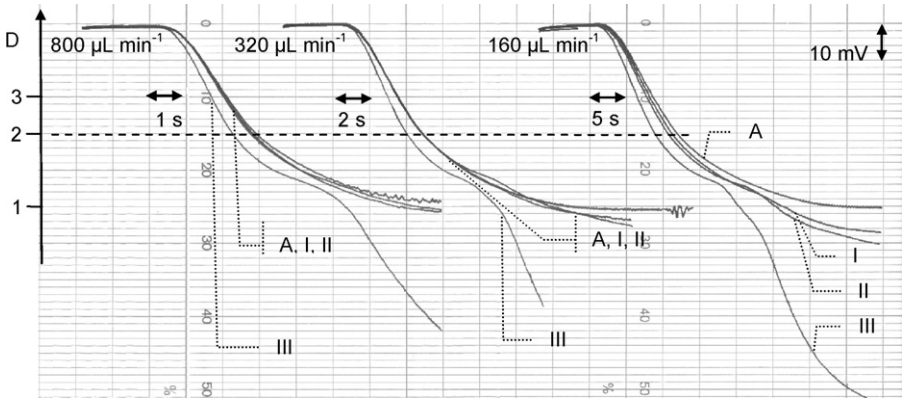

Fig. 5. Study of the influence of flow rate in the interface signal profile carried out by using a nitrate ion solution 1.00×10^{-4} mol L^{-1} in the absence (A) and in the presence of distinct interfering species concentrations referred as I, II and III (see Table 1 for composition). D—dispersion coefficient.

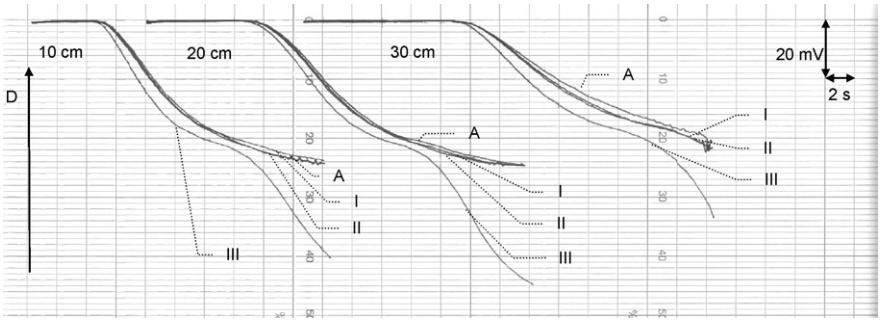

Fig. 6. Study of the influence of reactor length (10, 20 and 30 cm) in the interface signal profile carried out by using a nitrate ion solution 1.00×10^{-4} mol L^{-1} in the absence (A) and in the presence of distinct interfering species concentrations referred as I, II and III (see Table 1 for composition). D—dispersion coefficient.

It was also assessed the possibility of reduction of the analytical signal deviation by increasing reactor length, which would increase the reaction time between the sample and TISAB solution and therefore reduce the interfering effect. By using 20 and 30 cm reaction coils it was observed that for the same dispersion coefficient the deviation in the signal profile was more pronounced for longer reactors (Fig. 6). This behaviour can be justified by the fact that long coils originated broader interfaces and thus the residence time required to reach a given dispersion coefficient was raised, which concomitantly increases electrode exposure to interferences. Accordingly, a 10 cm reactor was selected for the analysis, which also assured higher sampling rates.

The results obtained in the interferences suppression study put in evidence the importance of the flow system operational interval calibration, previously discussed. The selection of a given t_D should take into account the interferences level usually found in the samples in order to enhance accuracy. Table 1 presents the experimental conditions selected for the determination of nitrate in water samples as well as the respective analytical figures of merit considering distinct sampling times.

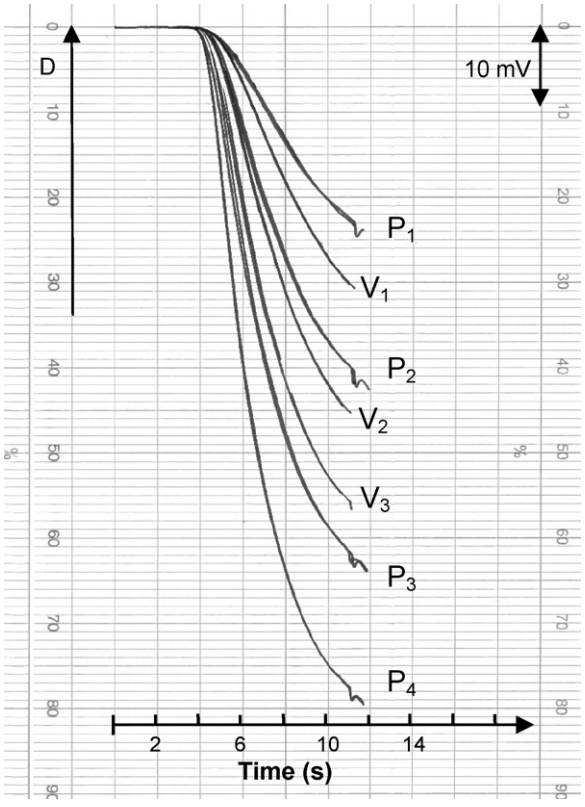

Fig. 7. Analytical signal profiles obtained in the determination of nitrate ion concentration in vegetable extracts. P_1, P_2, P_3 and P_4—nitrate standard solutions of 1.00×10^{-4}, 2.00×10^{-4}, 5.00×10^{-4} and 1.00×10^{-3} mol L^{-1}, respectively; V_1—sprout extract; V_2—parsley extract; V_3—lettuce extract. Experimental conditions as described in Table 1 and Fig. 3.

3.4. Sample analysis

Bearing in mind the low concentration of ions usually found in water samples the analyses were carried out by using a t_D of 10 s, which permitted to measure low nitrate levels, required by the regulations for water quality, without impairing sample conditioning. The obtained results are displayed in Table 3. No significant statistical differences were found for the results obtained by both the developed and the reference methodologies as confirmed by a paired Student's t-test ($t_{found} = 1.21 < t_{tabulated} = 3.18$; $n = 4$; 95% confidence level). These results demonstrate the efficient sample on-line treatment regarding ionic strength adjustment, pH buffering and interferences suppression. Precision of the SIFA system was also adequate as corroborated by r.s.d. < 3%.

Sampling rate was about 40 h^{-1}, appreciably higher than the one afforded by the reference methodology (20 h^{-1}).

Due to the greater matrix complexity, for the determination of nitrate in plant extracts t_D values of 7, 8 and 10 s were assayed, in order to find out the most appropriate (Fig. 7). The obtained results showed deviations that were more pronounced for higher t_D. These results demonstrated that for a convenient sample pretreatment a higher dispersion of the sample in the TISAB solution would have to be accomplished. Thus, a 7 s t_D was selected for the analysis. Under these circumstances relative deviations lower than 6% were obtained for all samples analysed (Table 4) revealing that an effective sample on-line treatment occurs within the time period selected. The accuracy of the developed procedure was confirmed by a paired Student's t-test ($t_{found} = 2.15 < t_{tabulated} = 2.57$; $n = 6$; 95% confidence level). r.s.d. was lower than 5%.

The nitrate levels found in this type of samples were comparable to those previously published [10,13,14]. The developed flow methodology revealed noteworthy advantages regarding the chromatographic method supported on higher sampling rate (40 h^{-1}

Table 4
Concentration values (g kg^{-1} of dry matter) obtained in the determination of nitrate ion in plant extracts by both ionic chromatography (I.C.) and the developed flow approach, at a detection time of 7 s.

versus 4 h^{-1}) and lower cost of implementation, maintenance and analysis.

4. Conclusions

SIFA approach enables the implementation of analytical flow systems with simplified optimisation and operation. These advantageous features arise from the fact that neither a specific sample insertion device nor a compelling sample volume are required for a reliable system performance. In the developed procedure solutions management was achieved by means of just a single propelling unit and a single solenoid valve. This characteristic is advantageous both in terms of cost-effectiveness, ease of miniaturisation and operational errors minimisation since the number of manifold components is reduced and no rigorous reproducible volumes have to be measured. SIFA techniques are easily coupled to potentiometric detectors with an additional advantage that is the possibility of selection of any point of the analytical signal profile, corresponding to a given residence time or to particular dispersion conditions, to carry out the measurements or to assure an adequate sample pre-conditioning.

The developed procedure was applied to the determination of nitrate in waters and plant extracts guaranteeing that all steps of sample pre-treatment, namely pH and ionic strength adjustment and interferences suppression, were adequately achieved at the single interface.

The proposed process for the construction of tubular electrodes selective to nitrate is simple, cost-effective, does not require expensive equipment and enabled the easy coupling of the electrodes to flow-based analytical systems. Despite this simplicity, the developed electrodes exhibit an analytical performance similar to those obtained by more intricate or expensive processes. Moreover, being a generic construction method it can be easily applied to the preparation of plastic membrane electrodes selective to other species simply by selecting the appropriate sensor.

In the developed application, the constructed electrode could be used for more than 2 months without loosing its response characteristics.

ABSTRACT

A new, multisyringe flow injection set-up has been developed for the completely automated determination of trace thiazide compounds with diuretic action in different types of samples. The proposed instrumental set-up exploits for the first time, a low pressure on-line solid phase extraction–liquid chromatography–chemiluminescence detection method. This novel combination of sample treatments in flow systems expands the current applicability of low pressure liquid chromatography due to the isolation/preconcentration of the target compounds, besides high selectivity and sensitivity.

For the determination of three thiazide compounds named hydroflumethiazide, furosemide and bendroflumethiazide, the proposed set-up provided with the preconcentration of only 1 mL of sample, limits of detection of 3, 60 and 40 $\mu g\,L^{-1}$, respectively. Furthermore wide linear dynamic ranges of 6–4000, 140–20,000 and 90–40,000 $\mu g\,L^{-1}$, respectively, were obtained. Besides of this, a high injection throughput of $12\,h^{-1}$ was also achieved. As in sports, thiazide diuretics are prohibited substances, the proposed method has been applied to their determination in urine samples. Furthermore the potential of the proposed method as a fast-screening approach for emerging contaminants in waters has been also tested by applying it to well water and leachates from a solid waste landfill.

1. Introduction

Flow injection/sequential injection techniques (FI/SI) [1] are well established tools for the automation of analytical methodologies, but their initial capability for multi-analyte determinations, is basically limited to (i) simple two analyte determinations based on speciation [2], (ii) the chemometric deconvolution of overlapped spectras [3] and (iii) determinations based on the sum parameters or total indices [4,5].

Initially, the separation and quantification of several organic compounds with similar molecular structures in a FI/SI manifold was not a feasible task. Nonetheless, the development of hybrid porous silica monolithic columns (MC) [6] for liquid chromatography (LC), provided high performance LC separations at relatively lower back-pressures, making feasible its accomplishment in Sequential Injection Analysis (SIA) systems [7,8]. This technique was defined as Sequential Injection Chromatography (SIC) [9,10], allowing faster, cheaper and environmentally friendlier [11] LC separations.

Among the different FI techniques, Multisyringe Flow Injection Analysis (MSFIA) [12–15] also revealed its potential for the accomplishment of LC schemes [16], this variant was named Multisyringe Chromatography technique (MSC) [17]. Due to its inherent characteristics the MSC technique owns high capabilities in terms of versatility, simplifying the implementation of in-line pre- and post-column sample treatments commonly used in LC separations. But at the moment the major part of the current applications of this technique have been focused to the direct analysis with UV spectrophotometric detection of pharmaceuticals (in pharmaceutical formulations) [18–20]. So the high versatility of SIC and overcoat MSC techniques for the implementation of automated sample treatments has been scarcely exploited.

On the one hand, the few studies accomplished by the moment about this topic, are based on: (i) the determination of amino acids after automated derivatization with o-phthalaldehyde by using SIC technique [21], (ii) the automated sample filtration and dilution for the accomplishment of pharmacological studies about acyclovir also exploiting SIC [22], (iii) the development of an hybrid FIA-HPLC system with chemiluminescence (CL) detection for the generation of solvent gradients [23], or the (iv) implementation of in-line solid phase extraction (SPE) on the MSC technique for the determination of hydrochlorothiazide and losartan potassium in different types of water samples containing high loads of them [24].

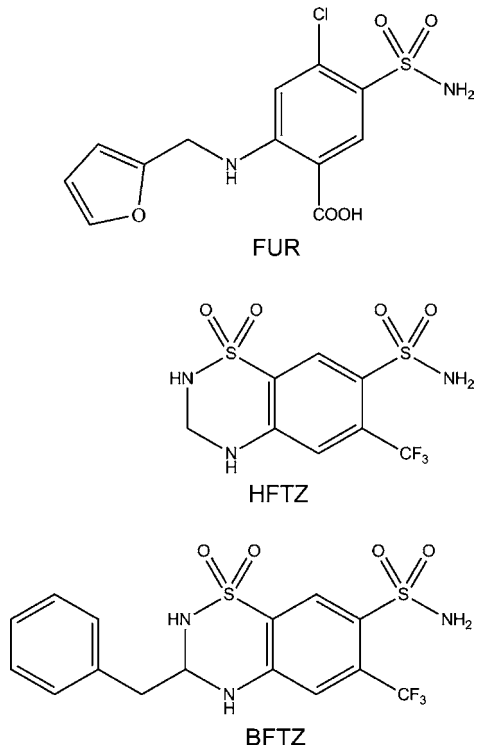

Fig. 1. Molecular structures of: furosemide (FUR, $pK_{a_1} = 3.9$), hydroflumethiazide (HFTZ, $pK_{a_1} = 8.9$), and bendroflumethiazide (BFTZ, $pK_{a_1} = 8.5$).

On the other hand, the relatively low selectivity and sensitivity achieved by this type of techniques remains a drawback. It is widely known that some very advantageous sample treatments for improved selectivity and sensitivity are SPE and CL detection. The development of a SPE–LC–CL system would be a complicated task, but this could be simplified, exploiting the high versatility of the MSC technique.

The development of a fast SPE–LC–CL system could be a powerful tool for the determination, as for example, of thiazide compounds such as hydroflumethiazide (HFTZ), furosemide (FUR) and bendroflumethiazide (BFTZ) (Fig. 1), which present a diuretic action in humans. These compounds present CL emission by reaction with Tris(2,2′-bipyridylruthenium(III)) ($[Ru(bipy)_3]^{3+}$) [25,26]. Diuretics are a group of substances with pharmacological action over hypertension and heart or renal failure [27], but also are misused by athletes for fast weight loss (before competition in sports divided by weight categories) and also for dilution of other doping agents in the urine (prior to anti-doping controls). Diuretics are on the list of forbidden substances by the World Anti-Doping Agency (WADA) [28]. By this reason, fast and quick methods for the determination of diuretics in human urine samples are essential. The most recently developed analytical methodologies for the determination of diuretics in urine are based on complex methodologies and instrumentation, such as: (i) capillary electrophoresis–electrospray ionization–mass spectrometry [29], (ii) gas chromatography–mass spectrometry (after derivatization) [30], (iii) capillary electrophoresis–amperometric detection [31] or (iv) hollow fiber-based liquid–liquid–liquid microextraction coupled to high performance liquid chromatography with UV detection [32]. Beside this, several pharmaceuticals used commonly as diuretics are recognized as emerging contaminants in waste wasters [33]. In fact, in several cities from Italy, some diuretics have been detected in wastewaters by means of SPE combined with HPLC–MS/MS [34]. They have been found even at low $\mu g\ L^{-1}$ concentrations.

This work is aimed to solve an important drawback of low pressure chromatographic techniques, this is their limited selectivity and sensitivity. By this reason, the first on-line SPE–MSC–CL system has been developed and characterized for the determination of diuretics in potentially polluted well water, wastewater and human urine samples.

2. Experimental

2.1. Reagents and sorbents

Hydroflumethiazide (HFTZ), furosemide (FUR) and bendroflumethiazide (BFTZ) were purchased from Sigma–Aldrich (Germany). Stock solutions of 1000 mg L^{-1} HFTZ, BFTZ and FUR were prepared in methanol (Scharlau, Spain) and were stored at 4 °C in dark glass flasks. Standards were obtained from proper dilution of stock solutions and acidified to pH = 3 with H_2SO_4.

Other chemicals were of analytical-grade quality and they were used without purification. Millipore-quality water was used to prepare solutions. Acidified water to pH = 3 by using H_2SO_4 (Scharlau) was used as carrier for SPE. The $[Ru(bipy)_3]^{2+}$ reagent 10 mmol L^{-1} stock solution was prepared by dissolving 0.374 g Tris(2,2′-bipyridyl)dichlororuthenium(II) hexahydrate 99.95% metals basis (Sigma–Aldrich) in 0.05 L water. The oxidant 20 mmol L^{-1} stock solution was prepared by dissolving 0.664 g of ammonium cerium(IV) sulfate dihydrate 95% (Sigma–Aldrich) in 0.05 L of diluted H_2SO_4.

Acetonitrile (Scharlau) was used as mobile phase organic modifier. Potassium dihydrogen phosphate (Scharlau) 10 mmol L^{-1} is used as mobile phase buffer. Mobile phase was degassed for 15 min in an ultrasonic bath and filtered through a 0.45-μm Nylon membrane.

The solid reversed-phase materials tested for SPE were C18 (octadecyl), SDB-XC (poly(styrenedivinylbenzene)) and SDB-RPS (poly(styrenedivinylbenzene) modified with sulphonic groups) sorbent disks (Empore 3M, St. Paul, MN).

2.2. Instrumentation and software

Fig. 2 depicts the proposed flow system. A multisyringe automatic burette (MS) from Crison (Alella, Barcelona, Spain) was used to drive the liquids to the flow network. The burette was equipped with four syringes (S1–S4), which were all mounted on a common metallic bar and every one of them were provided with a solenoid valve (V1–V4); as a result, the four syringes were operated simultaneously. Depending on the position of the solenoid valves, the fluids contained in syringes were loaded (PK, pickup) or dispensed (DP, dispense) to the flow network (on) or the reservoirs (off). Syringe S1 (5 mL) acted as a flow carrier and was connected to an additional three-way solenoid valve (V5, MTV-3-N1/4UKG, 2 bar maximum pressure, Takasago, Japan) allowing the sample introduction into the flow network. A second syringe of 5 mL (S2) is used for the handling of the mobile phase for the elution, separation and detection of the previously isolated target compounds. S3 and S4 are both of 1 mL, and are used for the post-column injection of the two reagents required for the CL emission. V1, V3 and V4 do not suffer any significantly high pressure, so N-Research (West Caldwell, NJ) solenoid valves (maximum pressure 2 bar) were used. V2 suffers higher pressures than 2 bar, by this reason a two way connector made of polyoxymethylene was used to connect S2 with V2, which is situated outside the MS module. V2 is a Takasago MTV-3-1/4UKGH (Takasago), which allows a maximum pressure of 6 bar.

All the tubing of the system was made of polytetrafluoroethylene (PTFE) 0.8 mm i.d. except the holding coil (HC), which is a

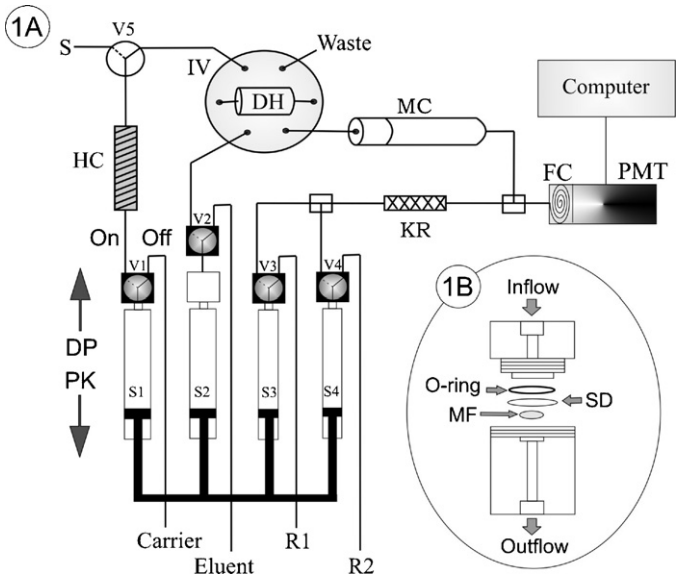

Fig. 2. Schematic depiction of the proposed multisyringe flow set-up for the determination of thiazide compounds. (A) General set-up: S, sample; HC, holding coil; V1–V5, three-way solenoid valves; DP, dispense; PK, pickup; off, normally open position of the solenoid valves (syringes connected with the reservoirs); On, normally closed position of the solenoid valves (syringes connected to the flow network); S1–S4, syringes; R1, Tris(2,2′-bipyridyl)dichlororuthenium(II) solution; R2, cerium(IV) solution; IV, injection valve; DH, disk holder for SPE; MC, monolithic column; KR, knotted reactor; FC, spiral-shaped flow cell; PMT, photomultiplier. (B) Amplified view of the DH: SD, sorbent disk; MF; microporous silica frit.

4 m long × 1.5 mm i.d. PTFE tube (7 mL volume). The two three-way confluence points were made also from PTFE.

A six-port injection valve (IV) (Crison) is used as interface between the sample loading – SPE – waste and the elution–LC–CL flow networks. In the injection loop of the IV is placed a miniaturized SPE device (Sciware, Palma de Mallorca, Spain) (Fig. 2), which is named disk holder (DH). The DH was a polyoxymethylene cylindrical block (2 cm long × 0.8 mm i.d.) with a central cavity of 1 cm diameter, in which an extraction disk of 0.9 cm diameter was accommodated in order to pass through it the different fluids involved in the SPE.

Extracted compounds are separated at room temperature by means of LC on a reversed-phase monolithic porous silica MC functionalized with octadecyl (C18) groups (25 mm length × 4.6 mm i.d.; Phenomenex) coupled with a guard column of the same material (5 mm length × 4.6 mm i.d.). The column was conditioned and cleaned according to the specifications of the manufacturer. A knotted reactor (KR; 60 cm length × 0.8 mm i.d.) is used for the generation of the $[Ru(bipy)_3]^{3+}$ from $[Ru(bipy)_3]^{2+}$ and Ce^{4+}.

The flow cell (FC; Sciware) was made from a PEEK plate to keep a PTFE body airtight. To this end, a spiral-shaped channel (4 cm long, 0.14 cm wide, 0.09 cm deep, 50 μl inner volume, 0.8 cm^2 effective light emission surface area) was carved into it; the spiral diameter was 0.9 cm. The FC was placed in front of a model H5784 photomultiplier tube (PMT, Hamamatsu, Japan) with a photosensitive wavelength range 04 (195–850 nm) and a photosensitive area of 0.5 cm^2. No wavelength discrimination was done in the detector. The FC and the PMT were both accommodated in a black plastic box protecting the detection system from external light.

A signal amplifier module [35] (Sciware) was used to supply the PMT with a feedback voltage of 0.3–0.8 V and obtain a signal gain (G) linear over the range 1–1000. The best results were obtained using a voltage of 0.80 V (G = 1000). The resultant scale for CL measurements is from 0 to 10000 counts. Instrumental control and data acquisition were accomplished by using the AutoAnalysis 5.0 (Sciware), which is based on dynamic link libraries (DLLs) [36] appropriate DLLs were used to operate the MS, the IV and the CL detector. MS DLL contemplates the use of the additional V5.

2.3. Analytical procedure

Table 1 summarizes the analytical procedure developed for the determination of HFTZ, FUR and BFTZ with the proposed SPE–MSC–CL system. The entire procedure complains 12 steps. On the steps 1–5 the SPE procedure is carried out, adjusting the volumes or repeating the steps, the volume of preconcentration can be easily modified. Once the sample matrix is isolated from the flow network, the elution of the previously retained species in the DH is accomplished, followed by LC with CL detection (steps 6–12).

3. Results and discussion

3.1. Chemiluminescence detection of diuretics

For the sensitive detection of the target compounds, chemiluminescence detection was chosen. The MSFIA technique is a useful tool for the micro-fluidic handling of complex matrix samples prior to CL detection [37].

The on-line chemical generation of $[Ru(bipy)_3]^{3+}$ from $[Ru(bipy)_3]^{2+}$ and Ce^{4+} was selected as a potentially appropriate detection system for the target compounds and preliminary studies were carried out by direct CL measurements (100 μL of sample were loaded into the HC and subsequently injected to the detector). The initial conditions were: 10 mmol L^{-1} $[Ru(bipy)_3]^{2+}$; 20 mmol L^{-1} Ce^{4+} in 0.25 mol L^{-1} H_2SO_4; 1 mg L^{-1} HFTZ, 10 mg L^{-1} FUR and 10 mg L^{-1} BFTZ, injection flow rate = 7 mL min^{-1}. With these experimental conditions the three target compounds exhibited repeatable CL signal (RSD's: HFTZ = 2.3%, FUR = 3.7%, BFTZ = 2.1%).

The concentration of $[Ru(bipy)_3]^{2+}$ was studied between 1 and 10 mmol L^{-1} (Fig. 3A) and a concentration of 7.5 mmol L^{-1} was selected. Once the previous concentration was adopted, the con-

11	CL	Stop data acquisition	
12	MS	PK 4.7 mL at 15 mL min^{-1} (off/off/off/off/off)	Adjustment of syringe volumes

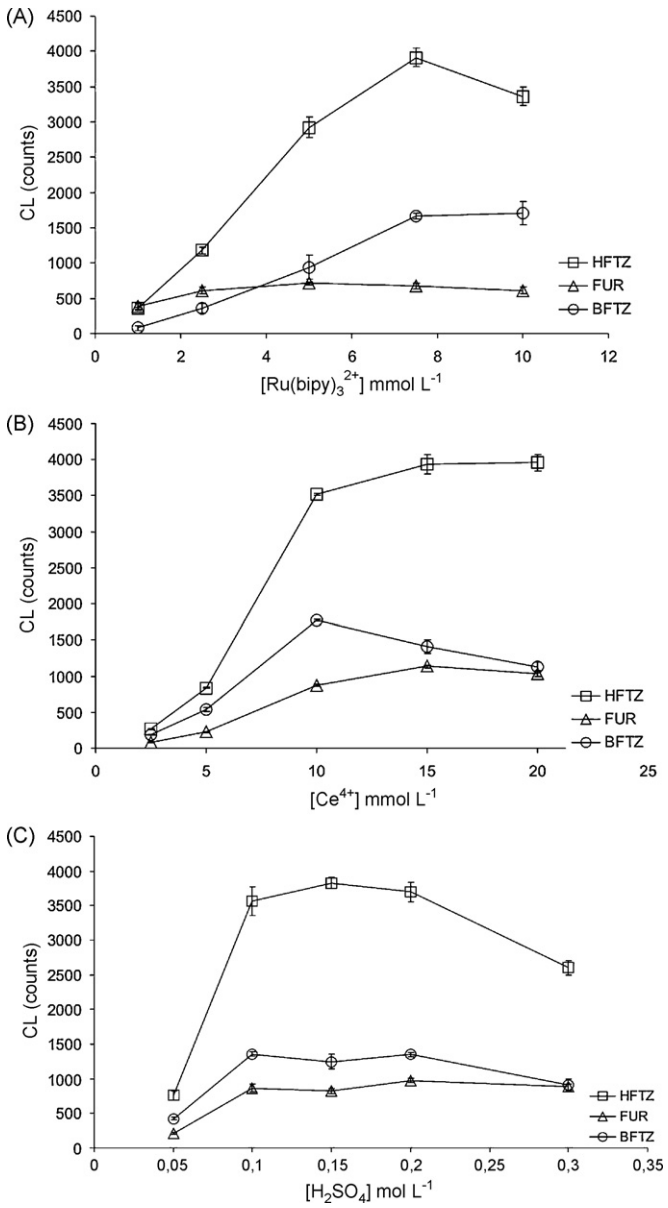

Fig. 3. Influence on the emitted CL (peak height) of (A) the concentration of Tris(2,2′-bipyridyl)dichlororuthenium(II) in S3, (B) the concentration of Ce^{4+} in S4 and (C) the concentration of H_2SO_4 in S4.

centration of Ce^{4+} was studied in the range of 2.5–20 mmol L^{-1}, as is shown in Fig. 3B a concentration of 10 mmol L^{-1} Ce^{4+} was selected for further experiments. The next experiment consists in the adjustment of the H_2SO_4 concentration of the Ce^{4+} solution, this was studied between 0.05 and 0.3 mol L^{-1} (Fig. 3C), lower H_2SO_4 concentrations induced short-term stability of Ce^{4+} solution, in a compromise between signal peak height and solution stability, a concentration of 0.2 mol L^{-1} H_2SO_4 was adopted for further experiments.

3.2. Solid phase extraction

In order to achieve the SPE of the target compounds for sample matrix clean-up and/or preconcentration, thus accomplishing it without increase significantly the back-pressure, sorbent disks were chosen instead of particulate resins. By this way, from the 6 bar maximum pressure allowed by V2, only 0.25 bar are employed for SPE procedure. Remaining a total of 5.75 free bars, that could be employed for the post-SPE liquid chromatographic separation. The three target compounds are highly polar by this reason an appropriate sorbent material could be SDB-RPS disks, but also were tested SDB-XC and C18 disks. The three types of disks were of an initial diameter of 47 mm, of which a smaller portion of 0.9 mm diameter is placed on the miniaturized SPE device, being the final effective surface extraction area of 0.6 mm diameter.

Changing the initial carrier composition by a mixture of 0.01 mol L^{-1} H_3PO_4–$H_2PO_4^-$/ACN (60:40) adjusted to pH = 3, no significant differences are observed in the obtained CL signals. So this was selected as the initial composition of eluent, and also 2 mL min^{-1} flow rates for preconcentration and elution were initially adopted. ACN was selected as organic modifier according to the specifications of the MC manufacturer. A preconcentration volume of 1 mL of sample was adopted.

The instrumental set-up for these experiments is the same as in Fig. 2, but without the MC. So, with this SPE–CL instrumental set-up, the three types of disks were tested. As can be seen in Table 2, SDB-RPS disks showed the best performance in terms of repeatability, obtaining adequate standard deviation values for the three target diuretics (RSD ≤ 3%). RSD's higher than a 5% were obtained for BFTZ using SDB-XC and for BFTZ and HFTZ using C18. In terms of sensitivity, higher signals were obtained for HFTZ and BFTZ by using SDB-RPS, but for FUR higher signals were obtained by using C18. Finally, SDB-RPS disks (90% adsorbent particles linked by 10% PTFE, 0.5 ± 0.05 mm in width, 60 Å pore diameter, 450 m^2 g^{-1} surface area and 12 μm average particle size) were chosen for further experiments.

The flow rate for the preconcentration of the target compounds was studied (Fig. 4A) in the range of 1–3 mL min^{-1}. Higher flow rates caused higher RSD's and a decrease of the life time of the sorbent disk. A flow rate of 2.5 mL min^{-1} was selected for further experiments. The percentage of organic modifier for the elution of the target compounds from the sorbent disk was studied between 20 and 50% ACN, as is seen in Fig. 4B, at least a 30% ACN is required in the mobile phase for the satisfactory elution of the three compounds.

In order to study the durability of the sorbent disk, a standard solution (mixture of 1 mg L^{-1} HFTZ, 10 mg L^{-1} FUR, 10 mg L^{-1} BFTZ) was analyzed 40 times with the same disk portion. For the first ten injections, the RSD was a 3%. For the next ten injection series, the RSD's were of 3.5% (11–20 injections), 4.5% (21–30 injections) and slightly higher than a 5% (31–40 injections). In conclusion, the same disk portion could be used satisfactorily for at least 30 injections.

3.3. Chromatographic separation

By using the complete SPE–MSC–CL set-up, the separation of the target compounds in the short 25 × 4.6 mm MC was studied follow-

Table 2
Results obtained in the selection of an appropriate sorbent material for SPE of HFTZ, FUR and BFTZ (n = 3). CL emission is expressed in hundreds of counts.

Sorbent material	HFTZ (1 mg L^{-1})		FUR (10 mg L^{-1})		BFTZ (10 mg L^{-1})	
	RSD (%)	CL emission	RSD (%)	CL emission	RSD (%)	CL emission
SDB-RPS	1.6	17	3.0	6	1.4	15
SDB-XC	0.6	10	2.6	6	8.2	5
C18	9.2	3	1.5	12	7.0	10

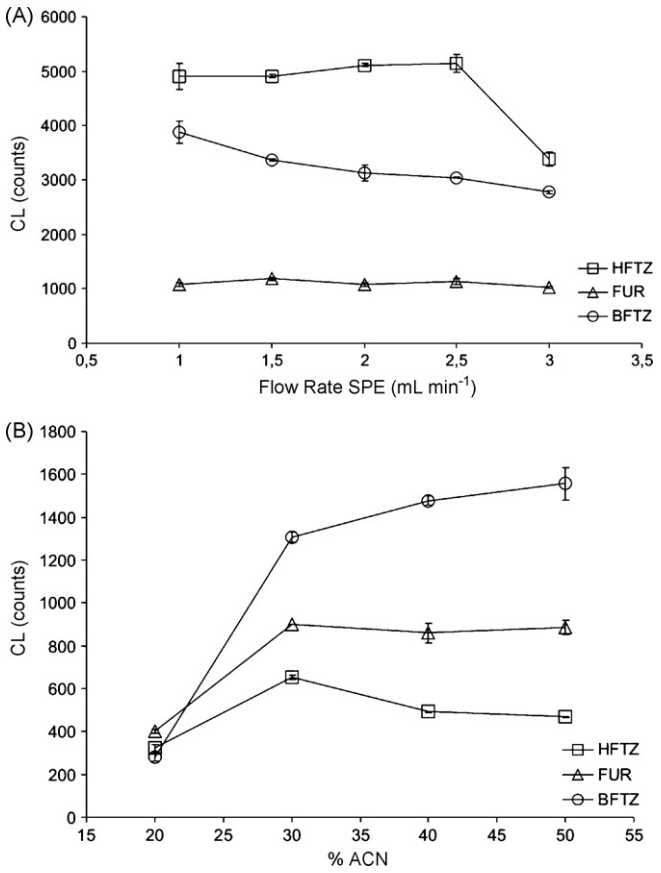

Fig. 4. Influence on the emitted CL (peak height) of (A) the flow rate for the SPE of the target compounds and (B) the percentage of organic modifier.

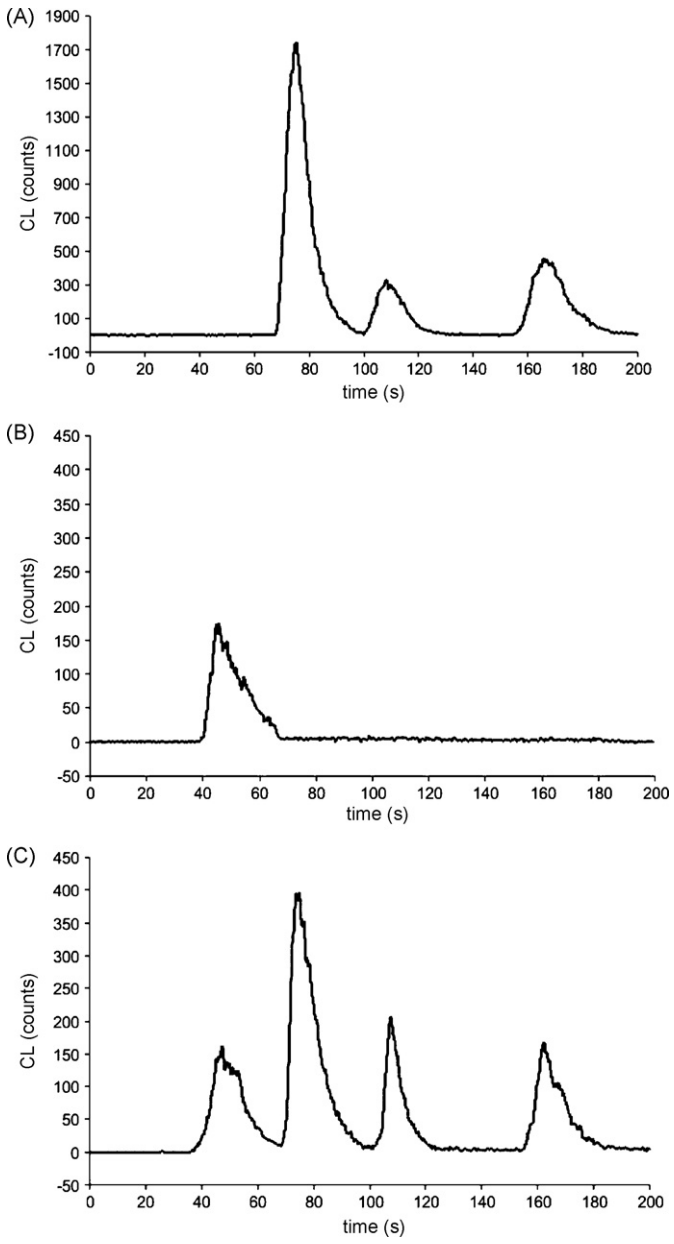

Fig. 5. Some examples of the obtained chromatograms working with the proposed SPE–MSC–CL system under the final experimental conditions. (A) Standard solution (HFTZ = 1.5 mg L^{-1}, FUR = 5 mg L^{-1}, BFTZ = 5 mg L^{-1}), (B) blank of an urine sample, (C) spiked urine sample (HFTZ = 1 mg L^{-1}, FUR = 10 mg L^{-1}, BFTZ = 5 mg L^{-1}). Standard/sample volume in (A) is 1 mL, in (B) and (C) is 3 mL. (B) and (C) have been diluted 10-fold.

ing the procedure detailed in Table 1. The maximum mobile phase flow rate allowed by V2 (maximum pressure 6 bar) was estimated measuring the column back-pressure and increasing the flow rate. The maximum allowable flow rate (for mobile phases containing between 20 and 50% ACN) was 1.5 mL min^{-1} (pressure = 5.75 bar). Finally, in order to avoid short-term damage of V2, a final flow rate for the LC separation of 1.3 mL min^{-1} was selected for further experiments.

The percentage of organic modifier (ACN) was studied in the range of 20–50% ACN. By using a 20% ACN the three peaks were separated. Increasing the content of ACN to a 30%, no peak overlapping was observed, thus improved separation conditions were achieved. With a 40% ACN, HFTZ and FUR peaks partially co-eluted obtaining these two signals overlapped, and with a 50% ACN, the three compounds co-eluted in a single peak. Finally a 35% ACN was tested, achieving a good peak separation and a reduced mobile phase and reagents consumption.

In order to improve the LC procedure, the addition of methanol to the mobile phase was studied between 1 and 10% methanol. Best results were obtained with a 10% methanol, but this induced a severe precipitation of Ce^{4+} inside the flow cell, causing overpressure problems and decreasing signal repeatability. Finally, a 3% methanol was selected. The final eluent composition is H_3PO_4–$H_2PO_4^-$/ACN/CH_3OH (62:35:3) adjusted to pH = 3. By the addition of methanol peak tailing was reduced, thus signal peak height and elution of BFTZ were slightly improved. The selected composition of the mobile phase showed good compatibility with the CL reagents, a factor to have in consideration as one of the main sources of problems in LC–CL systems. Fig. 5A shows a typical chromatogram obtained by working under the selected conditions.

Mass calibration was done injecting sample volumes between 1 – 20 mL containing an identical amount of total mass (2 μg HFTZ, 2 μg FUR, 2 μg BFTZ). No significant analyte loss (<5%) was observed when the preconcentration volume was increased from 1 to 7.5 mL. If the volume is increased up to 10 mL, a 10% analyte loss for HFTZ is observed, and FUR and BFTZ are still completely retained. Finally for a 20 mL sample volume, a 50% and a 60% of analyte breakthrough are observed for HFTZ and FUR, respectively, while no significant breakthrough is observed for BFTZ.

3.4. Analytical performance

Once the final instrumental set-up was established and the influence of the main variables examined, the performance of the

Table 3
Figures of merit of the proposed SPE–MSC–CL system. Parameters were calculated by using 1 mL of sample volume.

Analytical parameter	HFTZ	FUR	BFTZ
Linear dynamic range ($\mu g\,L^{-1}$)	6–4000	140–20,000	90–40,000
Limit of detection ($\mu g\,L^{-1}$)	3	60	40
Limit of quantification ($\mu g\,L^{-1}$)	6	140	90
Repeatability (%) ($n = 10$)	4.6	4.9	3.5
Sensitivity ($L\,\mu g^{-1}$) ($n = 6$)	1.244 ± 0.059	0.066 ± 0.002	0.093 ± 0.001
Regression coefficient ($n = 6$)	0.997 ± 0.002	0.994 ± 0.002	0.996 ± 0.003
Retention time (s)	75	108	165

proposed methodology was assessed. The analytical figures of merit of the proposed set-up are summarized in Table 3. Wide linear working ranges were achieved for the three analytes, which is typical in methods based on CL detection. The limits of detection (LOD) and quantification (LOQ) were estimated as 3 and 10 times the standard deviation of the absorbance for 10 injections of the blank. LOD and LOQ were calculated by using a sample volume of 1 mL, and they could be improved by increasing sample volume, in accordance with the mass calibration done. The repeatability of the proposed method was estimated as the relative standard deviation (RSD) for 10 consecutive injections of a standard containing 1 mg L^{-1} HFTZ, 10 mg L^{-1} FUR and 10 mg L^{-1} BFTZ. The sensitivity (slope) and regression coefficient were calculated from six day-to-day regression curves. The injection throughput (IT) obtained by using the entire SPE–MSC–CL method was 12 h^{-1}, if a sample volume of 1 mL is used (it is decreased to 7 and 5 h^{-1} for sample volumes of 5 and 10 mL, respectively). Another highlight of the proposed system is the low mobile phase consumption, with the concomitant saving of organic solvents. Only are required 1.65 mL ACN and 0.14 mL MeOH per determination. Furthermore is also presented a low consumption of CL reagents being achieved 400 determinations with only 1 g of $[Ru(bipy)_3]^{2+}$.

3.5. Interference tests

The CL evoked by $[Ru(bipy)_3]^{2+}$ can be used to determine a wide variety of organic compounds, but also, this CL reaction system cannot be applied directly to samples with a matrix of high complexity. In this work, we attempt to remove the potential interferences by means of on-line SPE–MSC prior CL detection, expanding by this way the analytical applicability of this CL reaction system. By this reason, in order to ensure this selectivity, a group of chemical compounds were tested as potential interfering compounds.

In order to do this, 100 mg L^{-1} standards of each one of the selected compounds were prepared and analyzed with the proposed configuration of the SPE–MSC–CL set-up. Different types of responses were obtained:

(1) Compounds which are removed by SPE and/or LC, or that are no CL emitters in the proposed experimental conditions. This was observed when ibuprofen, ketoprofen, trimethylamine, uric acid, glycine, phenol, ethylenediaminetetraacetic acid and p-aminocinnamic acid standards were analyzed.
(2) Compounds that exhibited CL emission with the proposed experimental conditions, but does not interfere due to their different retention times in the MC. This was observed analyzing a standard of Naproxen, this compound was extracted by SPE and quantified with good sensitivity by MSC–CL, obtaining similar results in sensitivity than for BFTZ, but with a retention time (tret = 192 s) higher than those of BFTZ.
(3) Compounds as oxalic acid, ascorbic acid or hydrazine that evoke intense CL emission with $[Ru(bipy)_3]^{2+}$ but are poorly retained by SPE and MC (approximately tret = 50 s). Experimental results confirmed that oxalic and ascorbic acids are almost totally removed by SPE, and due to the high concentration of the tested standard, only a small residual part of them arrives to the detector. Anyway, the retention times of these compounds are lower than those of HFTZ, not being interferences. Considerably higher concentration than 100 mg L^{-1} of these compounds could be a real interference. Nonetheless, hydrazine seems that is slightly more retained by SPE than oxalic and ascorbic acids. A concentration of hydrazine 20-fold higher than HFTZ causes a positive interference of a 5%, if the concentration of hydrazine is higher than 1 mg L^{-1}.
(4) Compounds which were CL emitters in the proposed experimental conditions, and have similar retention times than some of the analytes. This is the case of the thiazide diuretic hydrochlorothiazide (HCTZ), which has a retention time similar than HFTZ. The interference of 1-fold HCTZ over HFTZ is a 8%, if HCTZ concentration is at least 0.1 mg L^{-1}.

3.6. Application of the proposed SPE–MSC–CL system

The proposed methodology was assessed by analyzing HFTZ, FUR and BFTZ in spiked environmental and biological samples. The two environmental samples were a water sample from a well located in the vicinity of an urban solid waste landfill and a leachate from a solid urban waste landfill. The two biological samples were two human urine samples collected from healthy volunteers.

All samples were filtered through a 0.45 μm pore filter, spiked with a concrete amount of target compounds and adjusted to pH = 3. Furthermore, non-spiked samples were analyzed in order to test the baseline behavior and if they contain significant interferences. None of the two environmental samples exhibited significantly higher CL emission than the blank, nonetheless the two urine samples exhibited CL emission at low retention times, this drawback was avoided by means of diluting 10-fold the urine samples, avoiding possible interferences with the HFTZ signal peak. An example of a blank and a spiked urine samples are shown in Fig. 5B and C, respectively.

Table 4 shows the results obtained from the analysis of the detailed spiked samples with the proposed system. Environmental samples were spiked at the $\mu g\,L^{-1}$ level and a volume of 5 mL of sample was used. Urine samples were spiked at the mg L^{-1} level, and after dilution, a volume of 2.5 mL of urine 1 and 1 mL of urine 2 were used. In all instances, relative standard deviations between 1.8 and 4.4% for environmental and 2.7–5.5% for urine samples, were obtained. Furthermore, the absolute recoveries were between 94 and 108% in all instances.

The proposed method due to its wide linear dynamic range, can be applied satisfactorily to samples containing $\mu g\,L^{-1}$ levels of the target compounds, and also at mg L^{-1} level in high concentrated matrices, allowing sample dilution.

3.7. Comparison with other current analytical methodologies for the determination of diuretics

Due to the current relevance about the determination of diuretics in urine samples for anti-doping controls, several improved methodologies have been developed recently [29–32]. They are

Table 4
Results obtained in the determination of HFTZ, FUR and BFTZ in spiked environmental and biological samples by means of the proposed SPE–MSC–CL system. For all samples $n = 3$.

Urine 2	10	9.57	4.1	96

based on highly expensive and time-consuming instrumentation, thus lower levels in terms of automation, being required in some cases time-consuming manual sample derivatization (at least 2 h) [30] or extraction (50 min) [32] treatments prior to GC–MS and HPLC-UV, respectively.

As an alternative to chromatography, recently developed capillary electrophoresis (CE) methods for diuretics have provided improved injection throughputs, as for example a highly selective and sensitive CE-ESI-MS method for the determination of 12 diuretics [29], providing almost no sample pretreatment and an IT = 3 h^{-1}. Another alternative is based on CE with amperometric detection [31], which provides an improved IT = 6 h^{-1} and a wider linear dynamic range of three order of magnitude, but with a concomitant lower selectivity than CE-ESI-MS.

On the one hand, the proposed SPE–MSC–CL system provides a higher automation degree in front of the previously commented systems, is a low cost system, both referring to the low cost of the used instrumentation and furthermore the low cost per analysis. It provides a wide linear range as with CE-amperometry, and similar sensitivity than the previous systems with only 1 mL of sample. The proposed method provides higher injection throughputs (IT = 12 h^{-1}), and is highly versatile being easily adapted to different preconcentration volumes or types of samples.

On the other hand, the multi-analyte determination by the proposed system becomes limited in comparison with high performance chromatographic or electrophoretic techniques coupled with mass spectrometric detectors. But having in account the necessity to have fast-screening systems for organic compounds (pharmaceuticals, pesticides, personal care products, etc.), the proposed system provides an standard analytical tool – which is applied in this work to the determination of some thiazide diuretics – that meets the main corollaries for fast-screening, such as: rapid and reliable response, simplification of operations, thus avoiding the extensive use of high cost and maintenance instrumentation.

If we are talking about the development of simplified methodologies for the determination of emerging organic pollutants in environmental samples, the proposed SPE–MSC–CL provides an smart, versatile and downsized efficient instrument to carry out analytical tasks in this field, but it is still work to be done in this field, in terms of selectivity, and overcoat in the obtention of improved sensitivity to the low ng L^{-1} range.

4. Conclusions

For the first time, the potential of the versatility of monolithic column-based chromatographic separations in low/medium-pressure flow systems have been fully exploited, allowing the implementation of on-line pre- and post-column sample treatments in a smart, miniaturized and expeditious fashion, being this achieved through the versatile fluidic handling allowed by the MSFIA technique. To prove this, a novel methodology for the determination of three known diuretics (HFTZ, FUR and BFTZ) has been developed. The proposed method is the first on-line completely automated method which combines SPE with low pressure LC and CL detection. This allowed the fast, selective and sensitive determination of the target compounds, thus a concomitant saving of reagents/solvents. This improved performance, allowed for the first time the application of syringe-based (SIC and MSC techniques) multicommuted LC separations to the determination of target compounds in complex samples (environmental and human urine samples) at the $\mu g\,L^{-1}$ level, instead their usual applications in simple commercial formulations of pharmaceuticals, herbicides and other types of products at the $mg\,L^{-1}$ level. This is transduced in an improved applicability of this type of techniques, being fast and low cost screening valuable tools, for vanguard strategies to carry out difficult tasks as the anti-doping controls, or the detection of emerging contaminants in waters.

ABSTRACT

An integrated analyzer based on the multisyringe flow injection analysis approach is proposed for the automated determination of dissolved oxygen in seawater. The entire Winkler method including precipitation of manganese(II) hydroxide, fixation of dissolved oxygen, dissolution of the oxidized manganese hydroxide precipitate, and generation of iodine and tri-iodide ion are in-line effected within the flow network. Spectrophotometric quantification of iodine and tri-iodide at the isosbestic wavelength of 466 nm renders enhanced method reliability. The calibration function is linear up to 19 mg L^{-1} dissolved oxygen and an injection frequency of 17 per hour is achieved. The multisyringe system features a highly satisfying signal stability with repeatabilities of 2.2% RSD that make it suitable for continuous determination of dissolved oxygen in seawater. Compared to the manual starch-end-point titrimetric Winkler method and early reported automated systems, concentrations and consumption of reagents and sample are reduced up to hundredfold. The versatility of the multisyringe assembly was exploited in the implementation of an ancillary automatic batch-wise Winkler titrator using a single syringe of the module for accurate titration of the released iodine/tri-iodide with thiosulfate.

1. Introduction

Determination of dissolved oxygen (DO) in natural waters is of high importance in the evaluation of water quality and in getting knowledge on the atmospheric gas diffusion processes, the circulation of water masses, and the occurrence of biological and chemical reactions. It is thereby an important indicator of the metabolism activity [1]. DO is consumed in the metabolic degradation of biomass and in the respiratory activity of specimens. On the contrary, DO concentration increases by the photosynthetic activity of phytoplankton, which can in superficial layers even lead to an over-saturation of oxygen with respect to steady-state conditions at a given temperature and salt content [1,2]

In the classical end-point Winkler titration method [3], dissolved oxygen is chemically bound to manganese(II) hydroxide precipitate (1) in a strongly alkaline milieu, which results in a brownish oxidized manganese oxyhydroxide precipitate (2). Following the fixation of DO, the acidification of the reactant mixture leads to the oxidation of previously added iodide in the liquid phase to molecular iodine (3). Iodine forms the tri-iodide complex with surplus of iodide ions (4). The liberated tri-iodide is then titrated with standardized thiosulfate using either potentiometric-assisted or starch-based end-point detection (5) [3–6].

$$Mn^{2+} + 2OH^- \rightarrow Mn(OH)_2\downarrow \quad (1)$$

$$Mn(OH)_2\downarrow + (1/2)O_2 \rightarrow MnO(OH)_2\downarrow \quad (2)$$

$$MnO(OH)_2\downarrow + 4H^+ + 2I^- \rightarrow Mn^{2+} + 3H_2O + I_2 \quad (3)$$

$$I^- + I_2 \leftrightarrow I_3^- \quad (4)$$

$$I_3^- + 2S_2O_3^{2-} \rightarrow 3I^- + S_4O_6^{2-} \quad (5)$$

The Winkler titration method has proven precise and robust for determination of DO regardless of the actual matrix components of the sample, e.g., the contents of dissolved salts or organic matter, which in contrast can severely influence the diffusive membrane passage of oxygen when resorting to amperometric detection by the Clark electrode. The electrode further requires a constant approach flow of the sample to the membrane. Due to a considerable delay time and the consumption of DO by the sensor itself, its application to small changes in the concentration or low contents of DO is troublesome [1,4]. The Winkler method is however not free from drawbacks. It is a lengthy steady-state procedure involving a large number of manual operations and the consumption of considerable amounts of reagents along with the requirement of a precisely metered sample volume for accurate results. As a result, the classical method lacks suitability for expeditious on-board measurements in monitoring campaigns.

Several researchers selected spectrophotometric detection as an improvement of the end-point detection compared with the use of visual starch indicator or potentiometric assistance in terms of reduction of sample handling, accuracy, sample throughput, easiness of the assays, and avoidance of the human factor on reliability [7,8].

However, the choice of the appropriate detection wavelength has been a matter of controversy. Labasque et al. [9] have recently confirmed that detection at 466 nm, that is, the isosbestic point of molecular iodine and tri-iodide, provides sufficient sensitivity for the determination of DO at the expected concentration range in fresh and marine waters (5–15 mg L^{-1} DO). Further, measurement at the isosbestic point renders enhanced method ruggedness with no need to cope with the usage of surplus of iodide.

To expedite the Winkler method while assuring decreased consumption of chemicals and minimum risks of sample contamination, flow-based kinetic methods should be regarded as appealing alternatives to the batch-wise classical titration. Flow approaches have been proven suitable in the mechanization of sample preparation methods as well as wet-chemical based analytical procedures. Analytical flow-based procedures are of widespread use whenever fast, economic, reliable and automated analyses of a large number of samples of similar origin are called for. Distinct flow techniques have been proposed over the last three decades differing in the way of liquid propulsion, sample introduction, operation schemes, flow pattern, and manifold configurations, as extensively described in recent monographs [10–13].

A survey in the literature revealed the lack of robust, fully automatic flow-based setups capitalized on the Winkler method for determination of DO. In fact, there are only two reports on the implementation of the Winkler chemistry in flow injection setups [14,15]. Yet, several semi-automated methods comprising a manual step for fixation of molecular oxygen with further in-line optical or electrochemical detection of the evolved iodine/tri-iodide have been reported and characterized [16–18]. This is most likely due to the formation of water insoluble manganese hydroxides within the flow network and the eventual accumulation of the precipitates in the reaction coils that demands for a thorough rinsing of the manifold to prevent clogging of the flow conduits [14].

In this work, multisyringe flow injection analysis (MSFIA) launched in 1999 [19,20] and reviewed lately [21,22] is exploited as an analytical tool for construction of a compact, portable, and multipurpose Winkler-based spectrophotometric flow-through analyzer with the capability of operating as an automatic batch titrator as well. The overall Winkler method encompassing in-line precipitation of manganese(II) hydroxide, reaction with dissolved oxygen in the sample, in-line dissolution of the evolved oxidized manganese oxyhydroxide, generation of molecular iodine and tri-iodide and downstream spectrophotometric detection of the colored iodine species is fully integrated in a single MSFIA assembly. The advantages of MSFIA with respect to former flow injection systems for DO determination [14,23] include the instrumental robustness and versatility in fluid handling as a result of the use of a syringe pump rather than a peristaltic pump as liquid driver, software-assisted system configuration with no need for manifold re-design, integration of multicommutation valves, and – as a multichannel flow technique – the possibility of usage of merging flows at will.

2. Materials and methods

2.1. Reagents

Distilled water was used throughout for the preparation of the overall solutions. All chemicals were of analytical-reagent grade (Scharlab, Barcelona, Spain) and used as received. A solution of 0.25 mol L^{-1} manganese chloride was used as a reagent 1 (R1) in syringe 2. A solution composed of 1.0 mol L^{-1} sodium iodide and 0.8 mol L^{-1} sodium hydroxide solution was used as reagent 2 (R2) in syringe 3. Reagent 3 (R3) being 2.0 mol L^{-1} sulfuric acid was pumped by syringe 4. A 0.1 mol L^{-1} sulfuric acid used as a carrier solution was propelled by syringe 1. The reagents were not sparged with nitrogen prior to use as this would be impracticable in shipboard assays.

Chemicals for the classical Winkler titrimetric procedure are detailed as follows: 3.0 mol L^{-1} manganese chloride (R1c), 4.0 mol L^{-1} sodium iodide and 8.0 mol L^{-1} sodium hydroxide (R2c), and 5.0 mol L^{-1} sulfuric acid (R3c). Potassium iodate was dried at 105 °C overnight and used to prepare a 0.0023 mol L^{-1} KIO_3 solution. A 0.2 mol L^{-1} sodium thiosulfate solution was used as a titrant of iodine/tri-iodide and standardized against 10 mL of 0.0023 mol L^{-1} potassium iodate, which was previously mixed with 1 mL of R3c and 1 mL of R2c according to the standard protocol [5]. A 30% (w/v) starch solution in glycerol was used as iodine end-point indicator.

Surrogate seawater (SSW) was prepared as detailed elsewhere [1] by dissolving the following components in distilled water: 3.0 mg L^{-1} NaF, 20 mg L^{-1} $SrCl_2{\cdot}6H_2O$, 30 mg L^{-1} H_3BO_3, 100 mg L^{-1} KBr, 700 mg L^{-1} KCl, 1470 mg L^{-1} $CaCL_2{\cdot}2H_2O$, 4000 mg L^{-1} Na_2SO_4, 10,780 mg L^{-1} $MgCl_2{\cdot}6H_2O$, 23,500 mg L^{-1} NaCl, 20 mg L^{-1} $Na_2SiO_3{\cdot}9H_2O$, and 200 mg L^{-1} $NaHCO_3$.

For calibration purposes, standards were prepared by sparging SSW with nitrogen, air, or oxygen for at least 15 min. Oxygen was generated in the laboratory by the catalytic decomposition of hydrogen peroxide (about 10% (v/v)) continuously added to an initial small volume of potassium permanganate solution. A solution of 0.1 g L^{-1} methylene blue was used for visual inspection of displaced volumes in the flow network.

2.2. Flow analyzer

The implemented MSFIA system for in-line determination of DO is depicted in Fig. 1 wherein the tubing dimensions are indicated. A multisyringe piston pump module (model Bu4S) [19,21] was purchased from Crison Instruments S.A. (Allela, Barcelona, Spain). The module was equipped with three glass syringes of 1 mL each (S2, S3, S4) from Hamilton Bonaduz AG (Bonaduz, Switzerland) and one polypropylene syringe of 10 mL (S1) from Sciware SL (Palma de Mallorca, Spain). Solenoid head valves allowed the connection of each syringe either with the manifold (ON) or with the respective solution reservoir (OFF) for refilling. Two additional 3-way solenoid valves (V5 and V6) were powered by 12 V supply ports of the syringe module. The module was connected in series via a RS232C serial interface to a PC for remote software control.

All liquid contacted parts such as confluences and valve components were of chemical resistant polymers, namely, ETFE, PMMA, PEEK, and PTFE. PTFE tubing was used for the flow lines of the manifold.

An USB-2000 miniature spectrophotometer from Ocean Optics Inc. (Dunedin, FL, USA) had been integrated into the multisyringe module and was directly attached to a cuvette support (Sciware SL) holding a 1.0-cm pathlength flow cuvette from Starna (type 75.15 SOG, Essex, UK). A white LED was used as light source and powered by a stabilized constant current source (Sciware SL). Dual-wavelength detection was done for compensation of the schlieren effect using a reference wavelength of 620 nm. The analytical wavelength was affixed at 466 nm, that is, the isosbestic point wavelength of tri-iodide and iodine. So, the difference of the absorbance at 466 nm and absorbance at 620 nm was applied as analytical signal throughout.

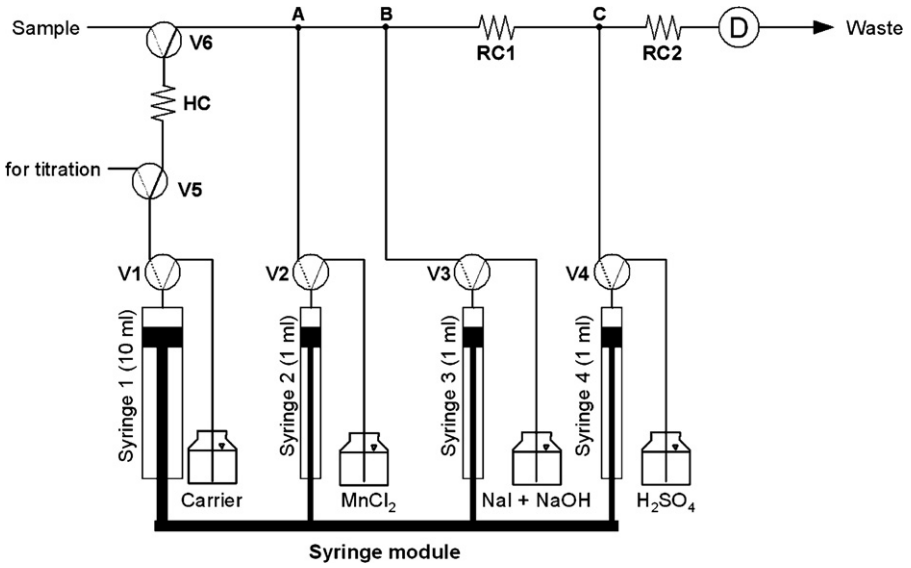

Fig. 1. Schematic illustration of the MSFIA system and batch-wise titrator for automatic Winkler determination of dissolved oxygen. HC: holding coil (280 cm, 1.5 mm i.d.) RC1: reaction coil 1 (120 cm, 1.5 mm i.d.), RC2: reaction coil 2 (75 cm, 0.8 mm i.d.), D: detector: integrated flow-through spectrophotometer (λ_{Det}: 466 nm, λ_{Ref}: 620 nm) with white LED. V1–V6: 3-way multicommutation solenoid valves with normally closed position (ON, activated) dotted and normally open (OFF, deactivated) straight. A, B, C: confluences for reagents, the distance between A and B was about 4 cm.

2.3. Software

The software package AutoAnalysis 5.0 (Sciware SL) was used for instrumental control, data acquisition, and integration of the analytical readouts [24]. The basic protocol can be adapted to the individual instrumental assembly by additional dynamic link libraries, which are amenable to communicate with the assembled instruments and detector devices. User-friendly software tools for method development such as loops, procedures, variables, user inquiries, waiting steps, and conditional definitions are available for method creation.

2.4. Analytical protocol

The main steps of the analytical protocol are given and commented in Table 1. In brief, after cleaning of the sample channel, if required, a large sample volume (4 mL) was aspirated into the holding coil. Afterwards, a 600 μL of the sample volume were propelled forward towards the confluences A and B (see Fig. 1). Volumes of 35 μL of R1 (manganese chloride) and R2 (sodium hydroxide and sodium iodide), respectively, were then injected simultaneously into a continuous flow of 350 μL sample. The composite plug (350 μL sample merged with 35 μL of each R1 and R2) was dispensed further in RC1 in order to promote the mixing between the DO and in situ generated manganese(II) hydroxide precipitate and increase the dispersion of injected solutions. After refilling of the syringes and halting the flow for 80 s in order to promote the reaction, the manganese oxyhydroxide precipitate was pushed downstream to merge with sulfuric acid at the confluence C. This led to the dissolution of the precipitate whereupon the iodide in the composite segment was in-line oxidized to iodine/tri-iodide prior to reaching the spectrophotometric detector. After each aspiration step, a waiting time of 1 s was implemented to release negative pressure in the manifold and to improve the repeatability of the procedure.

By the integration of the solenoid valve 5 (generally not used), S1 (10 mL) could be alternatively used as a high-precision burette for automatic batch titration of released iodine/tri-iodide in the classical Winkler procedure exploiting sodium thiosulfate as titrant. A software protocol was programmed for repeated user-defined dispensing of titrant volumes as low as 5 μL along with the automated refilling of the syringe and summation of the total volume of titrant consumed for end-point detection. The titration of 2 mL of 0.023 mol L^{-1} potassium iodate in surplus of iodide gave a relative standard deviation better than 0.3%.

2.5. Calibration method

External calibration was effected with about 300 mL SSW solutions purged with nitrogen, air, and oxygen and mixtures thereof. A sparging time of 15 min was proven sufficient for steady-state gas saturation. After in-line analysis of the standards, the unknown content of oxygen was determined by the application of the classical Winkler titration protocol. Hence, Winkler bottles of approximately 100 mL were filled carefully with the calibration standards, to which 0.5 mL of R1c and 0.5 mL of R2c were added. The bottles were sealed and incubated for at least 1 h at room temperature in the darkness. Thereafter, 0.5 mL of R3 was added and the formed iodine/tri-iodide was quantified by titration with thiosulfate using starch as indicator.

3. Results and discussion

3.1. System configuration and preliminary considerations

Of particular challenge in this work was the injection of minute, well-defined volumes of both R1 and R2 into the sample to create a single composite mixing zone. Therefore, syringes of 1 mL were used for injection of both R1 and R2 in adjacent confluences and a 10 mL syringe for the sample whereby the maximal achievable reagent to sample volume ratio in the assembled multisyringe set-up was 1:10. To avoid a severe dilution of the composite reaction zone by the downstream addition of acid in order to dissolve the manganese precipitates a small syringe (1 mL capacity) was utilized for reagent addition.

The analytical procedure was set to utilize a large sample volume, into which small volumes of R1 and R2 were injected. This was done in order to prevent the reactant zone to be affected by the oxygen content in the carrier solution during sample aspiration and propelling into the reaction coil. As the maximal usable volume of sample was limited by the volume of RC1 but former

Table 1
Automated procedure for in-line dissolved oxygen quantification exploiting multisyringe flow injection analysis.

Instrument	Instruction[a]	Description
MS[b]	Pickup 10 μL at 1.5 mL min^{-1} [1-Off 2-Off 3-Off 4-Off 6-Off]	Overcome of syringe backlash
MS	Pickup 400 μL at 0.4 mL min^{-1} [1-On 2-Off 3-Off 4-Off 6-On]	Aspiration of 4 mL sample
MS	Dispense 60 μL at 1.0 mL min^{-1} [1-On 2-Off 3-Off 4-Off 6-Off]	Dispense of 600 μL sample to the reagents' confluence
MS	Dispense 35 μL at 1.0 mL min^{-1} [1-On 2-On 3-On 4-On 6-Off]	Confluent injection of R1 and R2 into sample flow
MS	Dispense 65 μL at 1.0 mL min^{-1} [1-On 2-Off 3-Off 4-On 6-Off]	Dispersion of precipitate and mixing with dissolved oxygen by further dispensing of 650 μL sample
MS	Full aspiration at 1.5 mL min^{-1} [1-Off 2-Off 3-Off 4-Off 6-Off]	Syringe refilling
Wait	Wait 80 s	Reaction time for oxygen fixation
Spectrophotometer	λ_{Det}: 466 nm/λ_{Ref}: 620 nm at 3.3 Hz	Measurement start
MS	Dispense 350 μL at 0.4 mL min^{-1} [1-On 2-Off 3-Off 4-On 6-Off]	Dissolution of $MnO(OH)_2$ by acid merging flow and in-line detection of formed iodine/tri-iodide
Spectrophotometer	Stop measure	Measurement stop

[a] All volumes and flow rates refer to a syringe size of 1 mL. For syringe 1, a factor of 10 has to be taken into account. The solenoid valve V5 was set to position "Off" throughout this procedure.
[b] MS: multisyringe module.

dispersion in the HC had to be considered, a 4-fold larger volume of sample than RC1 of sample was applied.

The handling of the manganese precipitates in the flow-through manifold might be cumbersome as well. Thus, the reaction coil was made of PTFE tubing with an inner diameter of 1.5 mm in order to minimize the risk of tubing blockage by the in-line generated precipitates.

Analytical detection was effected at the isosbestic wavelength of iodine and tri-iodide, that is, 466 nm, aimed at operating at a dynamic working range of 0–15 mg L^{-1} DO while keeping the blank value as low as possible, and at preventing eventual errors as a result of the different molecular absorptivity of iodine and tri-iodide. In addition, a reference wavelength at 620 nm was selected to overcome potential interferences from schlieren effects.

3.2. Selection of chemical variables

Exploration of the effect of the reagent concentrations on the analytical response in the multisyringe-flow procedure was done in a univariate mode in the order of reagent addition of the classical Winkler method. The overall reagents were used in excess to the actual concentrations of the parameter investigated for a stoichiometric ratio of Mn^{2+}:OH^-:I^-:H^+ of 1:2:3:4 (see reactions under Section 1). The idea behind this investigation was to keep the blank readouts at the lowest possible level, yet with sufficient analytical sensitivity to analyze hypoxic seawater samples. To this end, surrogate seawaters sparged with nitrogen, air, and oxygen were analyzed for each combination of experimental factors. Analytical results are compiled in Table 2.

Diluted sulfuric acid fixed to a concentration of 0.1 mol L^{-1} was selected as a carrier to serve concomitantly as a washing solution for precluding the accumulation of precipitate onto the inner walls of the manifold tubing. As a result, an additional step for manifold cleaning as elsewhere reported [14] was not required. Adverse effects of the chemical composition of the carrier on the chemical yield of formation of manganese oxyhydroxide were avoided by isolation of the reactant zone from the carrier by the sample segment itself.

To mimic the addition of 1.0 mL of 3.0 mol L^{-1} Mn(II) to 125 mL Winkler bottles in the standard protocol [6], the concentration of R1 was originally affixed to 0.25 mol L^{-1} Mn(II) to cope with the 10-fold dilution of the reagent in the multisyringe flow setup. The influence of the Mn(II) concentration in R1 on the analytical response was studied over the range of 0.06–0.48 mol L^{-1}. Increased concentrations were not assayed to prevent the undue formation of the manganese(II) hydroxide precipitate. Experimental results are given in Table 2. While the blank value was not affected significantly, peak height of oxygen saturated SSW increased about 80% and reached a plateau level at a concentration of 0.24 mol L^{-1} and onwards. Therefore, the original concentration of 0.25 mol L^{-1} was selected for further experiments.

The effect of increasing concentrations of sodium hydroxide in the range of 0.3–1 mol L^{-1} on the peak signals of nitrogen and air saturated SSW was not significant, yet, the analytical readouts for oxygen saturated SSW increased linearly up to 0.8 mol L^{-1} (see Table 2), which was therefore chosen for the remainder of the work.

As to the concentration of iodide studied over the range of 0.5–2 mol L^{-1}, the peak height of oxygen saturated SSW increased up to 1.25 mol L^{-1} and decreased slightly for higher concentrations. The peak height of nitrogen saturated SSW decreased to a stable level from 0.5 to 1.0 mol L^{-1} NaI, the latter being selected to attain a robust blank signal.

Table 2
Effect of the reagent concentrations on the analytical readouts in the multisyringe flow-based determination of dissolved oxygen.

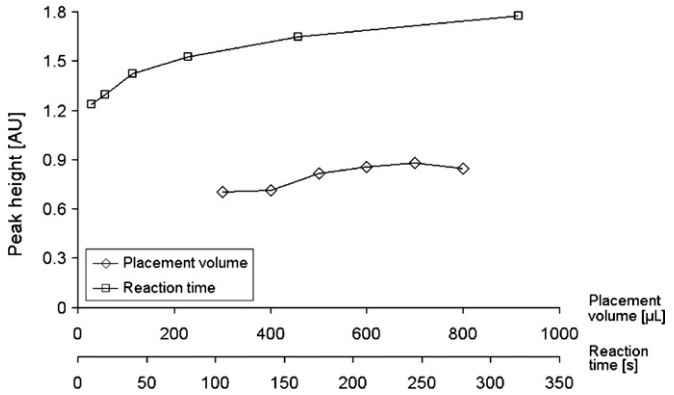

Fig. 2. Evaluation of the effect of placement volume and reaction time on the analytical readouts for air and oxygen saturated SSW, respectively, applying injection volumes for both R1 and R2 of 65 µL.

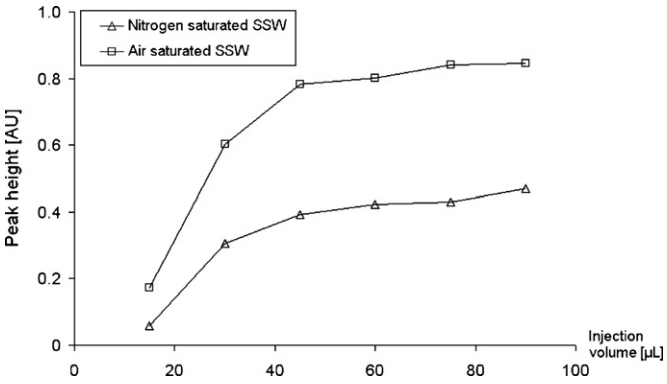

Fig. 3. Evaluation of the influence of the injection volumes of R1 (0.25 mol L^{-1} $MnCl_2$) and R2 (0.8 mol L^{-1} NaOH and 1 mol L^{-1} NaI) for a reaction time of 80 s on the analytical readouts.

The influence of the sulfuric acid concentration in R3 was studied over the range of 1–3 mol L^{-1}. In order to warrant a fast and quantitative in-line dissolution of the generated manganese oxyhydroxide precipitate along with the minimization in the consumption of acid, a concentration of 2.0 mol L^{-1} sulfuric acid was selected as R3.

3.3. Selection of physical variables

The dependences of the reagent volumes, injection mode and flow rates upon the method's sensitivity were investigated. For the final dispense step including in-line acid merging, dissolution of the manganese hydroxides, and formation of iodine/tri-iodide, the peak heights of air saturated SSW decreased linear with increasing flow rates (for S1) in the range of 3–8 mL min^{-1} by about 10%. Therefore, a flow rate of 4 mL min^{-1} was applied as a compromise between time of analysis and signal height.

For sample aspiration, likewise a flow rate of 4 mL min^{-1} was applied as a compromise between time of analysis and bubble evolving. For further flow operations, flow rates of 10 mL min^{-1} were utilized as a compromise between flow in the system backpressure and sample throughput.

After aspiration a total sample volume of 4 mL, a first sample fraction was dispensed to confluences A and B before the injection of R1 and R2, whose effect on the analytical response was studied over the range of 300–800 µL. Experimental results are shown in Fig. 2. The sensitivity was maximal for a displacement volume of 600 µL and onwards due to the decreased contact of the leading edge of the composite reaction zone with the acidic carrier in the manifold tubing.

The influence of halting the flow in RC1 for development of the reaction between dissolved oxygen and the in-line formed manganese(II) hydroxide was evaluated over the range of 10–320 s. The longer the reaction time the better were the yields of formation of manganese oxyhydroxide, whereas the blank value did not increase significantly. Experimental data are given in Fig. 2. As a compromise between time of analysis and sensitivity, a fixation time for dissolved oxygen of 80 s was chosen for further experiments.

The simultaneous injection of equal volumes of R1 and R2 into the sample flow was studied over the range of 15–90 µL each. The injection of reagents was followed by a forward flow of further sample in RC1 in order to increase the dispersion and thus promoting the reactions. This ancillary sample volume had to be limited to 1080 µL minus the volume of the injection step to prevent the flowing of the manganese precipitates ahead of the confluence C. The evaluation of the dependence of reagent volumes upon the blank and the analytical signal is shown in Fig. 3. The increase in reagent volumes lead to enhanced signals for both nitrogen and air saturated SSW up to ca. 50 µL. Aiming at affixing the blank value down to 0.4 AU, that is, one fourth of the response working range, a confluent injection of 35 µL for both R1 and R2 into 350 µL sample followed by a sample forward flow of 650 µL was selected for the remainder of the work. It should be noted that integrated absorbance peaks were in all instances $\leq$1.5 AU to prevent operating in the range of maximum photometric uncertainty.

3.4. Analytical performance and real sample analysis

The analytical curve was constructed by using six standard solutions prepared in sparged SSW as described in Section 2.5. A linear response was encountered up to 19 mg L^{-1} with a mean sensitivity of $0.029 \pm 0.002 \cdot AU \cdot [O_2]^{-1}$ and a mean blank value of 0.33 AU. If needed, ca. 2.2-fold improved sensitivity can be obtained by selection of a wavelength down to 440 nm as reported by Muangkaew et al. [15]. Compared with this later work, blank and sensitivity values were about 33% lower in this work yet significant improvements were achieved with respect to reproducibility and reagents' consumption, thus demonstrating the green chemical credentials of the devised multisyringe-based assembly.

The relative standard deviations of ten consecutively performed measurements of air saturated and nitrogen saturated SSW were 2.1% and 2.3%, respectively. A detection limit of 0.8 mg L^{-1} was calculated as the concentration of dissolved oxygen yielding a signal equal to the blank plus three times the standard deviation of the blank.

The multisyringe flow analyzer features an injection throughput of 17 h^{-1} where the sample aspiration and fixation time of dissolved oxygen were the limiting steps. It has to be noted that the sample had to aspirated at a reduced flow rate in order to avoid the evolvement of gas bubbles as a consequence of the negative pressure in the holding coil.

It has been proven that the blank signals did not depend upon the oxygen content of the reagents as sparging with nitrogen did not alter the signals significantly. Sparging of the sample carrier with nitrogen led to a signal decrease of 5%. The acid catalyzed oxidation of iodide to iodine was also negligible as demonstrated by replacing the manganese reagent R1 by water. The blank signal was likely attributed to the permeability to atmospheric oxygen of the 350 µm-thick PTFE connecting tubes (dead volume ca. 60 µL) from S2 and S3 to the confluences A and B, respectively, where the reagents remain for >6 min reaching oxygen saturation before being injected. This would further explain the decrease of the blank signal at high concentrations of iodide because the higher is the ionic strength the lower is the dissolved concentration of oxygen in aqueous solutions.

Table 3
Comparison of results obtained by the multisyringe flow-based determination of dissolved oxygen with those obtained with the classical Winkler titration method.

Sample	Classical Winkler [mg L^{-1}][a]	MSFIA-analyzer [mg L^{-1}]	Difference [%]	Salinity [%][b]
Seawater 1	6.60	6.96 ± 0.04	+5.6%	3.7
Seawater 2	6.39	6.54 ± 0.08	+2.4%	3.8
Seawater 3	6.48	6.24 ± 0.07	−3.7%	3.8
Seawater 4	6.53	6.67 ± 0.15	+2.1%	3.7
Seawater 5	4.63	4.69 ± 0.12	+1.3%	3.1
Seawater 6	5.94	6.41 ± 0.11	+8.0%	3.9
Seawater 7	4.90	5.34 ± 0.06	+8.9%	3.7
Seawater 8	6.28	6.08 ± 0.07	−3.2%	4.0
Seawater 9	3.80	3.58 ± 0.05	−5.8%	3.7
Seawater 10	1.21	1.30 ± 0.02	+7.3%	3.7
Seawater 11	1.76	1.89 ± 0.04	+7.1%	3.9

From seawater samples 10, 11, and 12 oxygen was partly stripped out by gasification with nitrogen.
[a] The titrant volume error was ±5 μL, representing in the present case an SD of 0.02 mg L^{-1}.
[b] Determined as the dry substance of 0.45 μm pore-filtered seawater after 24 h at 150 °C.

A slight memory effect has been observed after analyzing samples with high oxygen content, which mostly affected the first peak of repeated measurements. This effect was likely due to the permeation of oxygen into the pores of the PTFE tubing. Remains of oxidized manganese precipitate onto the tubing walls of the flow system as reported elsewhere [15] were not observed in our flow setup as a consequence of the usage of an acidic carrier.

For ascertainment of the accuracy of the proposed flow system and evaluation of matrix effects on the content of dissolved oxygen, 11 coastal Mediterranean surface seawater sample (air saturated) were analyzed and the results compared with the classical Winkler method. The samples were analyzed without any prior treatment as recommended by Grasshoff et al. (1999) [6]. To cover the concentration working range, three seawater samples were sparged with nitrogen for 1–2 min, decreasing by this the original oxygen content. A good agreement was found as shown in Table 3 between both methods with relative deviations between −5.8% and +8.9% (average 5%). It should be pointed out that an important error source was surely the transfer of the in-line evaluated samples to smaller Winkler bottles for verification by the classical Winkler method. The averaged RSD for sample measurements ($n = 5$) by resorting to the proposed analyzer was generally <2%. The *t*-test of comparison of means revealed the inexistence of significant differences at a 95% confidence level, thus, demonstrating the accuracy of the in-line Winkler procedure.

4. Conclusion

A versatile flow-through analyzer based on multisyringe flow injection analysis has been proposed for the determination of dissolved oxygen in seawater. It features the implementation of the entire Winkler methodology in a completely enclosed, automated tubing set-up. Physical and chemical parameters were studied thoroughly; the optimized system featured high sample frequency and satisfying sensitivity and repeatability with a remarkable decrease in the consumption of reagents and sample compared to the classical Winkler method. The analyzer can further be tuned to operate as a high-precision, automatic batch titrator of the iodine/tri-iodide with sodium thiosulfate generated in the classical Winkler procedure. The multisyringe flow system was successfully applied to the analysis of seawater samples with results in good agreement with the classical Winkler method. Due to its intrinsic characteristics and low frequency of maintenance, this analyzer is particularly suited to semi-continuous monitoring of dissolved oxygen in shipboard analysis. However, as common in all flow techniques, variation of the ambient temperature have to be named as a possible error source, altering both the reaction rate and the viscosity of the solutions with consequent changes in dispersion and mixing as well as in the solubility of oxygen. Temperature control bears the potential to increase the reproducibility required for shipboard monitoring purposes.

Glassy carbon and pencil graphite electrodes

ABSTRACT

7,12-Dimethylbenz[*a*]anthracene (DMBA), is a widely studied polycyclic aromatic hydrocarbon that has long been recognized as a very potent carcinogen. Initially, the electrochemical oxidation of DMBA at the glassy carbon and pencil graphite electrodes in non-aqueous media (dimethylsulphoxide with lithium perchlorate) was studied by cyclic voltammetry. DMBA was irreversibly oxidized in two steps at high positive potentials, resulting in the ill-resolved formation of a couple with a reduction and re-oxidation wave at much lower potentials. Special attention was given to the use of adsorptive stripping voltammetry together with a medium exchange procedure on disposable pencil graphite electrode in aqueous solutions over the pH range of 3.0–9.0. The response was characterized with respect to pH of the supporting electrolyte, pre-concentration time and accumulation potential. Using square-wave stripping mode, the compound yielded a well-defined voltammetric response in acetate buffer, pH 4.8 at +1.15 V (vs. Ag/AgCl) (a pre-concentration step being carried out at a fixed potential of +0.60 V for 360 s). The process could be used to determine DMBA concentrations in the range 2–10 nM, with an extremely low detection limit of 0.194 nM (49.7 ng L^{-1}). The applicability to assay of spiked human urine samples was also illustrated. Finally, the interaction of DMBA with fish sperm double-stranded DNA based on decreasing of the oxidation signal of adenine base was studied electrochemically by using differential pulse voltammetry with a pencil graphite electrode at the surface and also in solution. The favorable signal-to-noise characteristics of biosensor resulted in low detection limit (*ca.* 46 nM) following a 300-s interaction. These results displayed that the electrochemical DNA-based biosensor could be used for the sensitive, rapid, simple and cost effective detection of DMBA–DNA interaction.

1. Introduction

Polycyclic aromatic hydrocarbons (PAHs) are a large group of organic compounds with two or more fused aromatic rings. They are widespread environmental contaminants resulting from incomplete combustion of organic materials during both natural events and human activities, such as forest fires and volcanic eruptions, and burning of fossil fuels and petroleum products during industrial production, food processing, of machinery operation, including automobiles, airplanes and ships [1]. In view of the large amount of environment pollution studies being carried out on PAHs because some of these compounds are highly carcinogenic and mutagenic, the need has arisen for developing suitable quantitative methods for their determination and monitoring in various types of matrices. PAHs themselves are relatively non-reactive chemicals toward biological macromolecules under physiological conditions. In mammalian system they are metabolized principally in the liver to yield both detoxification products, which are more polar and excretal, and bioactivation products, which are more reactive and genotoxic. Their biological effects are actually attributed to the oxidation process that occurs during biotransformation of the mother compounds. PAH metabolites, including bay-region diol epoxides and free radical cation intermediates formed by monooxygenation and one-electron oxidation, respectively, are molecules that may bind to cellular DNA forming covalent DNA adducts responsible for carcinogenic process [2–5]. Some PAHs are activated exclusively by one of these mechanisms, and others are activated by a combination of both. Recent studies have demonstrated that activation of PAHs can also be achieved by light irradiation [2]. When the skin concomitantly exposed to environmental contaminants and

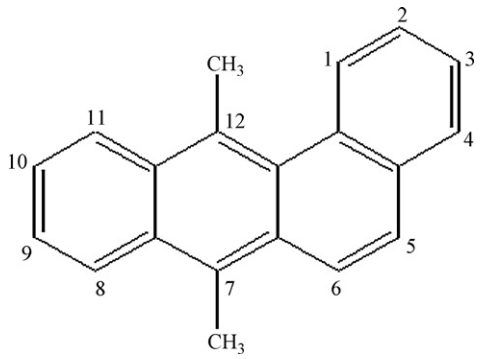

Fig. 1. Chemical structure of DMBA.

sunlight, these chemicals may be activated by photo-irradiation to cause cellular damages and exert toxicity including carcinogenicity.

DNA adducts generated by carcinogenic chemicals or their metabolites are directly related to tumor formation. Therefore, the investigation of DNA interactions is of great importance in order to understand the action mechanisms of some DNA-damaging agents and the design of preventive strategies [3,6–8]. Furthermore, this interaction could be used for rapid detection and quantitative determination of compounds hazardous for all living organisms in the environment, food and clinical samples [9–13].

7,12-Dimethylbenz[*a*] anthracene (DMBA) (its structure is shown in Fig. 1) is one of the PAHs used extensively in experimental studies as a presumptive prototype mutagen, a signal transduction modulator and a known breast and skin carcinogen [14]. The CH_3 groups at C-7 and-12 play an important role in the carcinogenic activation of DMBA [15]. The relationship between the interaction of DMBA with DNA and its carcinogenic potency has been recognized for over 40 years [16]. This compound has been investigated more intensively than any other PAH in terms of its biological activities and biotransformation.

For the above reasons, mostly analytical methods have been employed to characterize and determine DMBA–DNA adducts, and to understand the mechanism of metabolic activation of PAHs in living organisms. So far, chromatographic methods such as GC and HPLC [4,17–24], fluorescence, NMR and mass spectroscopic studies [4,18,25–28], ^{32}P-postlabeling methods [29–32], immunoassay and immunohistochemistry [33–35] are used for these purposes. However, since experimental complications and tediousness or high-cost, most of these methods are not affordable for most laboratories. Although electrochemical techniques were introduced in DNA biosensor technology with a certain delay, as compared to other sophisticated methods, there is a growing interest for design of electrochemical genosensors for biomedical, environmental and forensic applications during the last years. In addition to their useful role in environmental applications, it seems straightforward to employ such electrodes in cancer chemotherapy where DNA is main target. This is mainly due to the capability of fast and sensitive detection by using a relatively low-cost, low-power and pocket-size portable instrumentation. Nonetheless, electrochemical biosensors that detect toxins, pollutants and carcinogenic or mutagenic agents, in particular PAHs [36–41], based on the changes in the oxidation peak of the bases caused by the interaction DNA-analyte, have been scarce so far.

A survey of the literature indicates that very little attention has been paid to the redox behavior of DMBA. In those early reports, electrochemical properties of DMBA was not well documented, only the oxidation potentials of DMBA and related polycyclic carcinogenic hydrocarbons have been studied in non-aqueous medium by cyclic voltammetry using platinum or glassy carbon electrodes [42,43]. Furthermore, there have not yet been any literature reports about the electrochemical detection of the interaction between DMBA and DNA. Therefore, this study is the first attempt describing the detailed voltammetric assay of DMBA and electrochemical investigation of its interaction with DNA.

The current paper is broadly divided into three sections. The first part involves cyclic voltammetric studies of DMBA in non-aqueous solvent at surface of glassy carbon and pencil graphite electrodes. Secondly, special attention will be given to the use of adsorptive stripping voltammetry on disposable pencil graphite electrode in aqueous solutions for the quantification of DMBA in bulk forms and spiked human urine samples. Finally the detection of DMBA–DNA interaction based on the changes of adenine signal using differential pulse voltammetry on pencil graphite electrode will be discussed.

2. Experimental

2.1. Caution

DMBA is a hazardous chemical and should be handled with extreme caution using the guidelines for carcinogenic materials developed by National Cancer Institute [44].

2.2. Apparatus

Cyclic voltammetry (CV) on the glassy carbon electrode (GCE, φ: 3 mm) was performed with BAS 100B/W electrochemical analyzer (Bioanalytical System, USA). Voltammetric measurements with the pencil graphite electrode (PGE) were carried out using electrochemical system μAutolab type III (EcoChemie, The Netherlands) driven by a GPES software version 4.9 (EcoChemie) in connection with a personal computer. The raw voltammograms of differential pulse (DPV) and square-wave (SWV) voltammetry were treated by using Savitzky and Golay filter (level 2) of the GPES software, followed by the moving average baseline correction with a peak width of 0.01 V.

In all measurements, the reference electrode was an Ag/AgCl (3 M NaCl) (Model RE-1, BAS, USA) and the auxiliary electrode was a platinum wire. The measurements with the GCE and PGE were carried out in a standard 10 mL and homemade 5 mL glass one-compartment voltammetric cell, respectively, at a laboratory temperature (20 °C). For stripping analysis, two cells were used, a pre-concentration cell containing the analyte solution and measurement cells containing a blank background electrolyte. Before use, glass cells were soaked into 3 M HNO_3, and rinsed several times with water and working buffer. If no stated otherwise, the convective transport was provided with a magnetic stirring of 400 rpm.

2.3. Chemicals

DMBA standard and native double-stranded fish sperm DNA (ds-DNA) were kindly provided by Merck and Sigma, respectively. All other reagents were of analytical grade quality. Stock solutions of 4×10^{-3} M (corresponding to *ca.* 1 mg mL^{-1}) DMBA were prepared daily by dissolving appropriate amounts of the compound in dimethylsulphoxide (DMSO). When it was necessary, more dilution of working solutions was prepared with the use of same solvent. CV experiments were recorded in DMSO and ionic strength was maintained at 0.1 M with lithium perchlorate ($LiClO_4$) as the supporting electrolyte. In case of stripping analysis in aqueous solutions, three different supporting electrolytes, namely acetate (0.1 M, pH 4.8), phosphate (0.1 M, pH 3, 7.4 and 9) and Britton–Robinson (0.1 M, pH 6) buffer solutions containing 0.02 M NaCl were used. The supporting electrolyte under voltammetric investigation of the DMBA–DNA interaction was a phosphate buffer solution (0.05 M, pH 7.4) containing 0.02 M NaCl, which served as physiological

medium. The stock solution of the ds-DNA (1 mg mL^{-1}) was prepared in TE solution (10 mM Tris–HCl, 1 mM EDTA, pH 8.00).

Solutions at all stages of the study were made with deionized water (Milli-Q quality), and were kept in the dark and in refrigerator.

2.4. Procedures

2.4.1. Pretreatment of glassy carbon electrode

Before each measurement, GCE was thoroughly polished with aqueous slurry of alumina powder (φ: 0.01 μm) on a damp smooth polishing cloth (BAS velvet polishing pad), and then was subjected to an electrochemical treatment by keeping it for 60 s at +1.6 V in DMSO/0.1 M $LiClO_4$ mixture.

2.4.2. Fabrication and pretreatment of pencil graphite electrode

The preparation of PGE was carried out as described earlier [45]. In brief, a mechanical pencil Model T 0.5 (Rotring, Germany), was used as a holder for pencil lead (Tombo, Japan), which were purchased from a local bookstore. All leads had a total length of 60 mm and a diameter of 0.5 mm. Electrical contact to the lead was achieved by wrapping a metallic wire around the metallic part of the pencil. A total of 10 mm of lead was immersed in solution per measurement. Such length corresponds to an active electrode area of 15.9 mm^2. Each measurement was performed using a new pencil surface.

To obtain a more sensitive and stable analytical signal, PGE surface was pretreated by applying a potential of +1.4 V for 60 s (in case of cyclic voltammetric studies, +1.6 V for 90 s) in the selected supporting electrolyte without stirring.

2.4.3. Adsorptive stripping voltammetric procedure

For stripping studies, the pre-concentration/medium exchange/voltammetry scheme was adopted. Required aliquot of the DMBA working solutions were placed in a pre-concentration cell containing a buffer solution. The pretreated bare PGE (unless otherwise indicated) was kept in the cell, and the solution was stirred at a chosen accumulation potential throughout the selected the accumulation period. The electrode was then placed in the measurement cell containing the same buffer solution, previously washed with water and with the blank background electrolyte. Subsequently, an anodic sweep was carried out towards more positive potentials using the selected voltammetric technique. The measurements were made at room temperature. The common instrumental parameters for SWV (unless otherwise indicated) were as follows: pulse amplitude, 25 mV; frequency, 50 Hz; step potential, 16 mV; rest period, 10 s; stirring rate, 400 rpm.

2.4.4. Determination in spiked urine samples

Blank urine samples were obtained from a healthy and non-smoking donor (male, age 30 years). An aliquot volume of sample was fortified with DMBA dissolved in DMSO to achieve final concentration of 4×10^{-5} M, and treated with 4.95 mL acetonitrile then the volume was completed to 10 mL with the same urine sample. The samples tubes were vortexed for 1 min and then centrifuged for 10 min at 5000 rpm for removing of unknown endogenous chemicals (an unspiked sample of the same urine was kept as a blank). Appropriate volumes of the supernatant were mixed with the acetate buffer (0.1 M, pH 4.8)/0.02 M NaCl in the voltammetric cell. The pretreated bare PGE was immersed in the solution for 360 s at a fixed potential of +0.60 V using 400 rpm stirring rate (pre-concentration step). The electrode was then washed with water and with the blank acetate buffer (pH 4.8), and transferred into the measurement cell containing the acetate buffer at pH 4.8 (with 0.02 M NaCl). Subsequently, the square-wave voltammogram was recorded from +0.40 to +1.40 V in steps of 16 mV at 50 Hz with a pulse amplitude of 25 mV. Successive measurements were carried out by repeating the above assay protocol on a new PGE surface using a new pre-concentration solution.

2.4.5. Electrode preparation for DMBA-DNA interaction studies

DNA immobilization: The ds-DNA was immobilized onto the pretreated PGE surface by adsorptive accumulation for 300 s at +0.5 V in supporting electrolyte containing 10 μg mL^{-1} of DNA under stirred conditions. The electrode was then gently rinsed with a clean supporting electrolyte for 5 s for removal of the unbound ds-DNA at the electrode surface.

Interaction of surface-confined DNA with DMBA: After the DNA immobilization step described above, the ds-DNA-coated PGE was transferred to the stirred supporting electrolyte containing DMBA concentration of 1 μg mL^{-1} (unless otherwise indicated). The adsorption, at open circuit conditions, was allowed to proceed for 300 s (unless otherwise indicated). The biosensor was then rinsed for 5 s in a clean supporting electrolyte.

Interaction of solution-phase DNA with DMBA: DMBA in the concentration level of 1 μg mL^{-1} was added to supporting electrolyte containing DNA at a concentration of 10 μg mL^{-1}. A PGE was first pretreated as described above and subsequently immersed into the mixture solution. The accumulation of the mixture was performed for 300 s while holding the potential at +0.5 V under stirred conditions. The electrode was then washed with a clean supporting electrolyte for 5 s.

Signal transduction: The oxidation signals of DMBA and adenine were measured by using DPV (amplitude: 50 mV; step potential: 8 mV; scan rate: 16 mV s^{-1}) between +0.45 and +1.40 V in a fresh supporting electrolyte.

Successive measurements were carried out by repeating the above assay protocol on a new PGE surface using a new pre-concentration solution.

3. Results and discussion

3.1. Cyclic voltammetry on the glassy carbon and pencil graphite electrodes in non-aqueous solution

The voltammetric oxidation of 8×10^{-4} M DMBA solution on the GCE and PGE was investigated in DMSO without prior accumulation time. DMBA exhibited one distinct and well-defined oxidation peak (peak I) with a maximum at about +1.15 V and one broad peak (peak II) at more positive potential (*ca.* +1.33 V) at scan rate of 100 mV s^{-1} for both electrodes as depicted by cyclic voltammograms given in Fig. 2A and B. It seems to be relatively high background current of PGE arising from clays and polymers present in pencil graphite. However, its usage was proved to be much more sensitive, yielding current densities (obtained by subtracting the background currents from the recorded currents) *ca.* two times higher than those obtained by using GCE.

The initial oxidation step (peak I) could be due to the one-electron transfer which corresponds to the formation of DMBA radical cation intermediate, benzylic radical. As reported on the literature data [15], the CV of DMBA in dimethylformamide under reversible conditions revealed that the oxidation of this compound involves only one electron. The point concerning the broad peak (peak II), which follows the initial oxidation of DMBA, remained obscure. Bearing in mind the anodic voltammetric behavior of benzo[*a*]pyrene, unsubstituted PAH compound, in non-aqueous solvents which has been previously discussed [46], we suggest that peak II could be attributed to either the oxidation of the product from solvent interaction with the DMBA cation radical or the formation of DMBA dication. No corresponding reduction peaks were observed on scan reversal, indicating irreversibility of

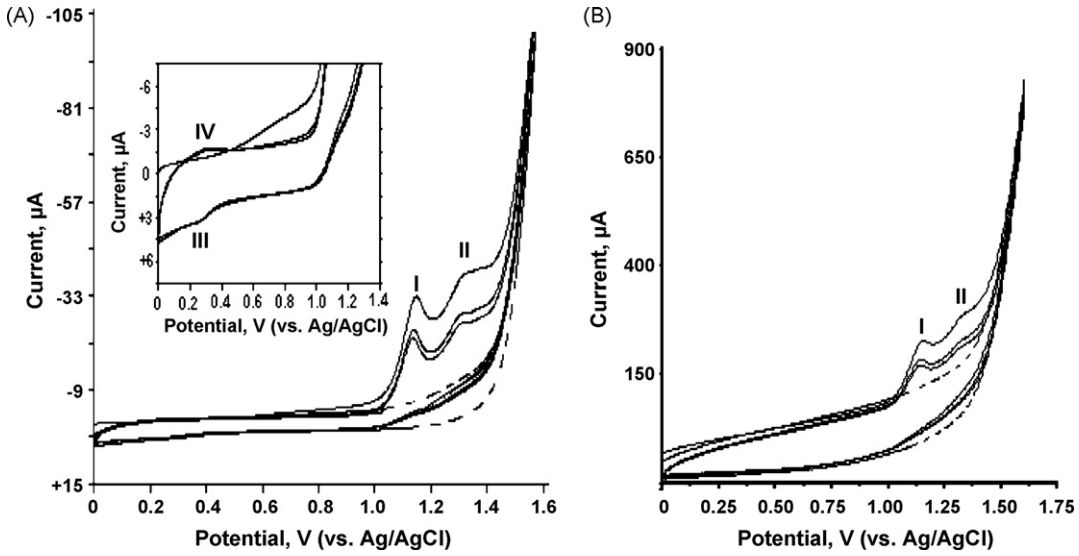

Fig. 2. Repetitive cyclic voltammograms of 8×10^{-4} M DMBA solutions in DMSO for GCE (A) and for PGE (B). Scan rate, 100 mV s^{-1}. Inset: enlargement of reversible redox couple for A. Dashed lines represent background current.

the processes. At lower concentrations of DMBA, these two processes became ill-defined waves, their shape changing from peak to sigmoidal. For the reverse scan and in subsequent scans, a new reversible redox couple producing a reduction (wave III) and re-oxidation (wave IV) wave, appeared in considerably lower positive potential region (Fig. 2A, see inset: enlargement of reversible redox couple). However, this couple was poorly defined in DMSO, where the product solubility may be low. The appearance of these closely spaced waves supported that a chemical reaction subsequent to the electron step occurs, giving rise to species more readily oxidized than DMBA. If successive scans are made, it can be observed that the oxidation process at more positive potentials decreases as the number of scans increase, while the intensity of this couple increases slightly, which confirms this couple arises from the product of follow-up chemical reaction of the DMBA oxidation. Such behavior was also observed and became more pronounced for the oxidation of benzo[*a*]pyrene in the same solvent (our unpublished results will be reported elsewhere soon).

Since the initial oxidation step was more intense, it was selected for analysis purposes. When the scan rate was varied from 5 to 1000 mV s^{-1} at GCE, a 160-mV positive shift in the peak potential was observed as expected for an irreversible oxidation with the simultaneous increase in the peak current. Plotting the logarithm of peak current versus logarithm of scan rate gave up a straight line (correlation coefficient 0.997) with a slope of 0.51. The slope means that process is predominantly controlled by diffusion, although partially coupled to weak adsorption in the whole scan rate range studied. Furthermore, a linear dependence of the peak current upon the square root of the scan rate (correlation coefficient 0.994) was found, demonstrating a diffusional behavior.

3.2. Stripping analysis on the pencil graphite electrode in aqueous solution

Under the voltammetric investigation leading to analytical methodologies, we planned to study in aqueous samples, not only to alleviate the need for a high volume of organic solvents but in order to make possible the application of proposed method in PAHs-contaminated aquatic environments. For this reason the diluted aqueous solutions of DMBA ($\leq 4 \times 10^{-5}$ M) were used due to its low solubility in water. In order to confirm the adsorption of DMBA on working electrodes, preliminary medium exchange experiences were then performed. The PGE electrode was kept in contact with a quiescent solution of assayed concentration of DMBA in background electrolyte for a fixed accumulation time under open circuit. Then it was transferred to another cell containing only the clean electrolyte and the voltammogram was recorded. On the contrary, when the experiment was repeated maintaining the electrode in a stirred solution of DMBA, the voltammogram recorded presented higher peak current. These facts indicate that DMBA undergoes an adsorptive pre-concentration on the electrode surface. Adsorptive stripping voltammetric (AdSV) behavior of DMBA was studied by CV, DPV and SWV techniques after medium exchange.

At first, basic voltammetric behavior of DMBA in aqueous solutions was investigated using CV measurements. Before the measurements, 4×10^{-5} M DMBA in stirred various types of electrolyte solutions (all in 0.1 M containing 0.02 M NaCl), including acetate, phosphate and Britton–Robinson buffers over the pH range of 3–9 was accumulated on the working electrodes (PGE or GCE) using a 300-s open circuit accumulation. Cyclic voltammograms were recorded in the potential range of 0 V to +1.6 V at scan rate of 100 mV s^{-1}. In all of the investigated pH values, two anodic peaks observed in concentrated non-aqueous solutions merged into a single one (Fig. 3A). No peaks were observed in the cathodic scan which indicated that the process was irreversible. Since the DMBA concentration was lower, redox couple could not also be detected. Cyclic voltammogram obtained using the GCE exhibited a similar behavior at comparable potentials; however the peak separation from the background was not better, giving rise to inaccurate measurements of the currents. Furthermore, the GCE severed surface contamination, and the single-use PGE was much superior. For this reason, further electroanalytical experiments were realized using PGE.

The attention was then turned to the effect of solution condition such as pH, which is a critical factor affecting both the rate and equilibrium state of the accumulation process and the rate of the electrode reaction. Due to the poorly resolved stripping signals obtained by CV, the effect of solution acidity on oxidation process was studied using DPV and SWV. Voltammograms were carried out in stirred 4×10^{-5} M DMBA solution with an open circuit mode at 300 s. In application of both DPV and SWV, the appearance of two distinct anodic peaks, together with the improvement of their shapes could be seen between pH 3–7.4. Fig. 3B obtained by applying square-wave scan is representative. At pH 9.0, the second peak

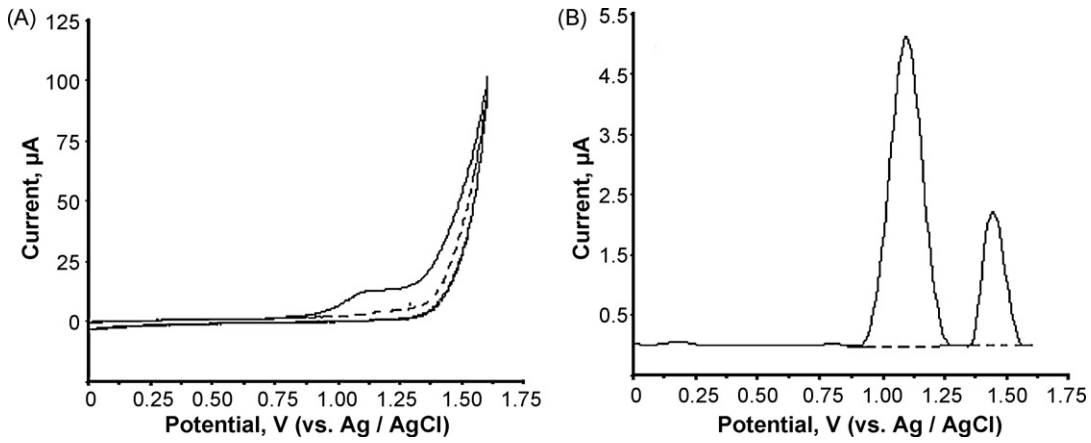

Fig. 3. Cyclic (A) and square-wave (B) voltammograms of 4×10^{-5} M DMBA solution in acetate buffer pH 4.80. CV conditions: scan rate, 100 mV s^{-1}; SWV conditions: pulse amplitude, 20 mV, frequency, 25 Hz, step potential, 8 mV. Dashed lines represent background current.

was not extracted from the background discharge that occurred at less positive potential. The pH did not indicate a significant change in the peak potential over the range studied. For the first peak, a 55- and 70-mV negative shift was only observed upon increasing the pH from 3 to 9 using DPV and SWV, respectively. For the first oxidation step, the peak intensities reached a maximum in acetate buffer pH 4.8. Moreover, the application of square-wave mode for the stripping of adsorbed DMBA was proved to be much more sensitive, yielding signals *ca.* 2.5 times higher than those obtained by applying differential pulse scan. The second oxidation step exhibited a similar behavior however the peak currents were smaller than those of the first one. For remainder of the work, SWV technique was applied in acetate buffer at pH 4.8 by considering the primary oxidation peak.

Further optimization of the analytical signal focused on studying the effect of pre-concentration/stripping conditions, such as accumulation potential and time. The influence of the accumulation potential either at open circuit potential or at a potential range from +0.1 V to +0.8 V was studied with accumulation time of 300 s in stirred 4×10^{-5} M DMBA solution. The value for the stripping current obtained at +0.1 V was nearly equal to the value obtained at open circuit voltage. The maximum peak current was obtained at an accumulation potential of +0.6 V because of an increased accumulation rate, due to more favorable alignment of the molecule by the electric field at the electrode–solution interface. After fixing the accumulation potential at this value, the deposition time was varied between 30 and 480 s. The increasing the peak currents were obtained at a fast rate up to about 360 s and starting to level off for longer times above this value. The peak potentials undergo a small displacement towards more negative potentials; this indicates the need of a larger energy to attain the stripping of the adsorbate from the electrode. For further analytical studies, the deposition stage was carried out at +0.6 V for a pre-concentration time of 360 s.

Square-wave stripping voltammograms at different concentrations of DMBA were recorded under the maximum current experimental conditions. The use of DMBA oxidation at about +1.15 V as the first analytical peak allowed quantification in the range of 2 nM to 10 nM with a regression equation of i_p (μA) = 0.217 C (nM) − 0.134 (correlation coefficient, 0.992). A detection limit of 0.194 nM was estimated based on signal-to-noise characteristics of the data for S/N = 3. The repeatability of the stripping signal was realized in terms of relative standard deviation for ten identical measurements carried out at a concentration level of 6 nM DMBA of a new PGE surface using a new solution in the cell and found to be 5.1%. A variation of the DMBA concentration was found to have a slight influence on the peak potential. The peak potential shifted towards more negative values when the concentration was increased.

The selectivity of such determination could be limited by interactions of structurally similar compounds with DMBA. However, this is not a case of samples with one class of compounds or one analyte present.

Since DMBA solutions undergo photooxidation in air and light, they were freshly prepared and kept in dark-colored, tightly closed containers. However, to check its stability, the voltammograms of stock solutions in DMSO stored in the dark and in refrigerator were recorded after two-week periods. When the voltammograms were compared with those of samples freshly prepared they did not show any appreciable change, demonstrating that DMBA solutions were stable for this period. Taking into account that the stability of aqueous solutions containing PAHs is a major problem due to their tendency to be absorbed on surfaces of polyethylene containers [47], all solutions were stored in glass vials. In daily laboratory practice, no significant decrease was evident among the calibration samples throughout the study period.

In view of the sensitivity (extremely low detection limit) of the proposed method, PGE electrode was applied to the determination of DMBA in simulated human urine.

The presence of proteins, major components of the sample matrix which could be adsorbed on the electrode surface together with analyte is an important drawback of adsorptive voltammetric techniques. In case of our study, when the voltammograms were recorded in 1:100 blank urine dilutions smooth curves were not obtained in the potential range from +0.4 to +1.4 V comparing to those of the background electrolyte. To obviate this problem, the extraction with acetonitrile followed by centrifugation protocol, that was quick and easy, was applied together with a medium exchange procedure. After medium exchange technique (analogous to solid phase extraction methods), none of the potentially interfering electroactive urine components contributed to the response and DMBA could easily be measured as shown in Fig. 4.

In order to check if the linearity persists, a new calibration plot was carried out in urine samples. In this case, the voltammetric response measured in urine was linearly related to the concentration of DMBA within the range of 0.2–0.8 μM according to the equation: i_p (μA) = 2.39 C (μM) + 0.025 (correlation coefficient, 0.999) with a detection limit of 0.04 μM. Under these conditions a decrease in the signal was observed comparing to that obtained in aqueous solution without urine. The matrix of the sample did not reduced the reproducibility of the signal as demonstrated by recording three voltammograms for each of the urine samples containing DMBA in the concentration range mentioned above. In

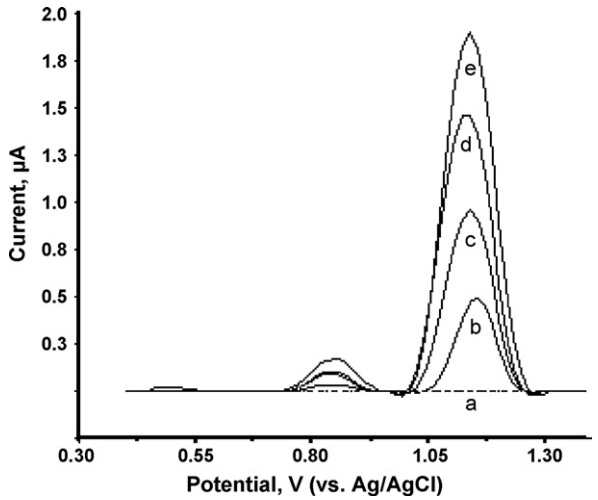

Fig. 4. Square-wave voltammograms obtained for the determination of DMBA in spiked urine. Blank urine (a), urine spiked at a DMBA level of 0.2 μM (b), 0.4 μM (c), 0.6 μM (d), 0.8 μM (e). For operating conditions, see Section 2.4.4.

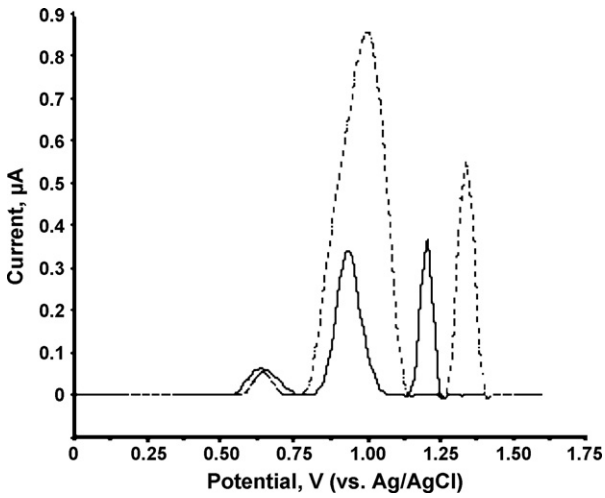

Fig. 5. Differential pulse voltammograms for 4×10^{-5} M (10.3 μg mL^{-1}) DMBA (dashed line) and 10 μg mL^{-1} DNA (solid line). Supporting electrolyte, phosphate buffer pH 7.40.

urine, results were characterized by higher precision comparing to those obtained in aqueous solutions, probably due to the fact that concentration in urine samples was relatively higher. An average relative standard deviation was found to be 2.9%. There was no degradation of the DMBA in solution during the experiments.

3.3. Interaction with DNA on the pencil graphite electrode

Before interaction differential pulse voltammograms for DNA and DMBA in phosphate buffer (pH 7.40) are shown in Fig. 5. Under the conditions of the experiment, the redox behavior of original ds-DNA immobilized PGE exhibited two oxidation processes of guanine (G, *ca.* +0.93 V) and adenine (A, *ca.* +1.20 V) residues. DMBA produced two oxidation peaks at around +1.05 and +1.40 V with a pre-concentration step on PGE at open circuit condition for 300 s in a stirred supporting electrolyte (explained above). Guanine and DMBA (first peak) oxidation peaks coincided with each other, whereas separation of adenine and DMBA (first and second peaks) oxidation peaks was possible even if at high concentration of DMBA. That is why we could compare only adenine oxidation peak changes.

Fig. 6 displays the DPV signals, which were monitored in blank supporting electrolyte, obtained before/after interaction of 1 μg mL^{-1} DMBA with 10 μg mL^{-1} ds-DNA both at the electrode surface and in solution. In the case of both interaction protocols (following the association with DMBA), a considerable diminution in peak current was observed.

It is known that planar condensed aromatic ring systems play a major role in their intercalative DNA binding, primarily involving stacking interactions. Binding of the intercalators to DNA results in a significant change in DNA conformation, and can be followed by electrochemical methods [48,49]. On the other hand, it is reported the synthesis of two detectable DNA adducts by the electrochemical oxidation of DMBA in the presence of dA. A covalent bond is formed specifically at the 12-CH_3 and 7-CH_3 group of DMBA for the N-7 and N-3 position of adenine, respectively [15]. Taking into account these findings, the decrease in the adenine signal could be attributed to either the penetration into the DNA double-helix between adjacent base pairs (non-covalent interaction) or forming adducts through covalently binding to sites in DNA.

The reproducibility of DNA biosensor protocol was also evaluated from three repetitive measurements for the concentration 10 μg mL^{-1} DNA and 1 μg mL^{-1} DMBA. In the absence of DMBA, measurements yielded a reproducible result with a mean peak height of 374 nA and a relative standard deviation of 3.74%, indicating that the preparation of working electrode was satisfactory. After interaction of DMBA at electrode surface or in solution, the series resulted in mean peak heights of 166 and 159 nA and relative standard deviations of 4.86 and 13.46%, respectively. Following a 5 min accumulation, the detection limits of DMBA, which were esti-

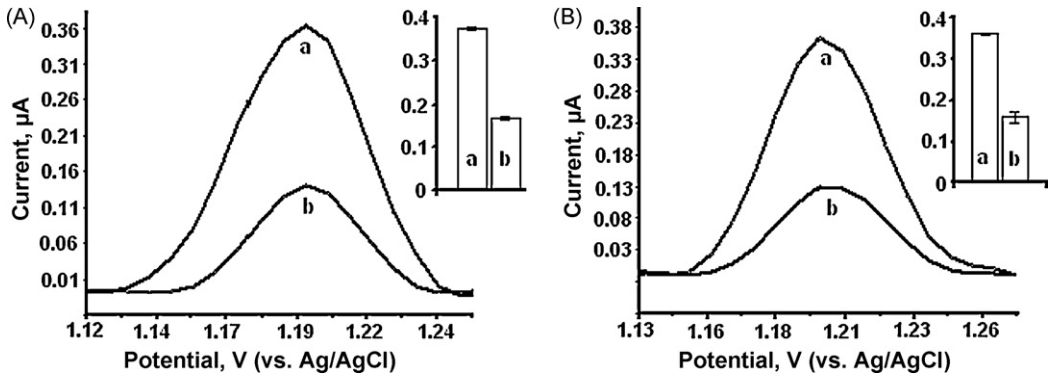

Fig. 6. Differential pulse voltammograms for 0 (a) and 1 μg mL^{-1} (b) DMBA after the interaction of surface-confined DNA (A) and solution-phase DNA (B) at a 5-min accumulation. Inset: the results were also demonstrated with bar charts. For operating conditions, see Section 2.4.5.

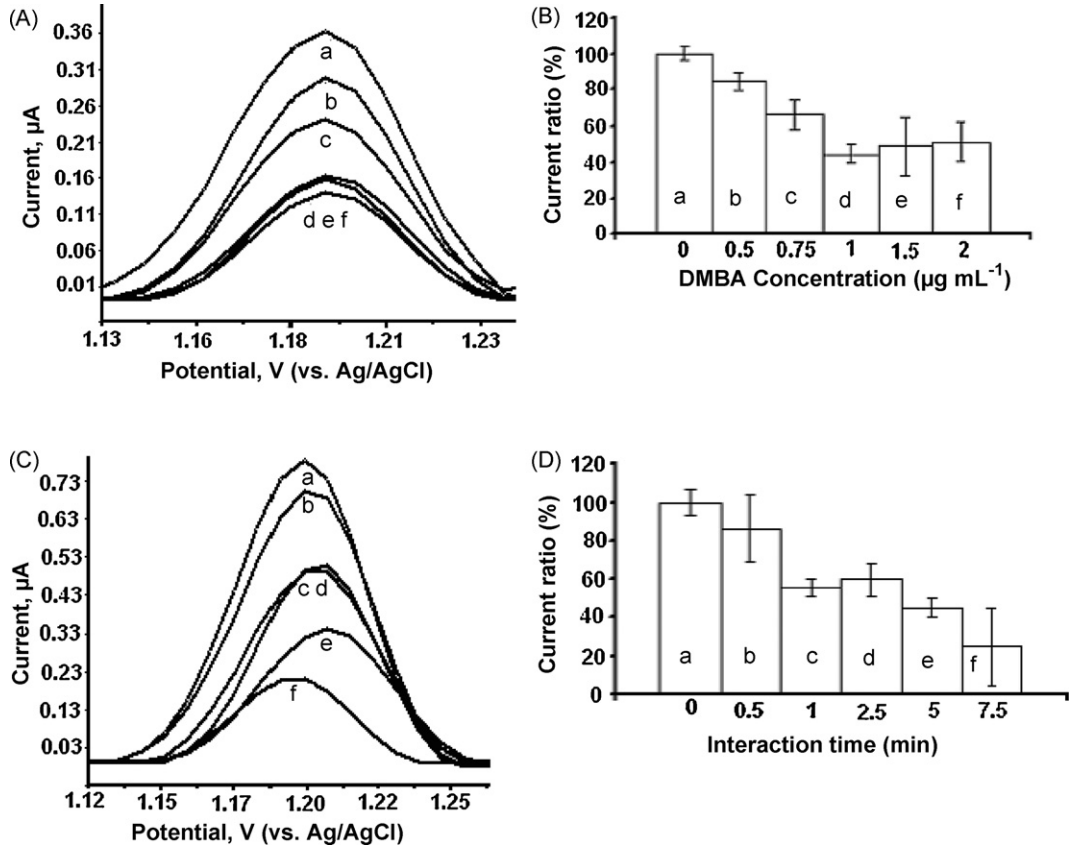

Fig. 7. The effect of DMBA concentration (A) and accumulation time (C) upon the DPV response of adenine after interaction of surface-confined DNA for 5 min (A) and with 1 μg mL^{-1} DMBA (C). The results were also shown as the peak current ratio (B and D). For operating conditions, see Section 2.4.5.

mated from the signal-to-noise characteristics of the data (S/N = 3), were found as 11.8 and 11.9 ng mL^{-1} (corresponding to *ca.* 46 nM) for interaction of surface-confined and solution-phase ds-DNA, respectively. Bearing in mind that the size (ring number), and conformation of the molecule play a major role in its DNA binding [40,50], four-ring structure of DMBA may account for its higher sensitivity. Such detection limits are low enough for assays of polluted environmental samples. The results obtained by the interaction in solution phase were found to be less suitable for this study because of the relatively poor reproducibility. Thus, the assay protocol at the electrode surface was chosen for remaining parts.

The dependence of DMBA concentration (in the range 0–2 μg mL^{-1}) on the adenine signal was shown in Fig. 7A and B. In the presence of DMBA, adenine oxidation peaks decreased linearly with concentration up to 1 μg mL^{-1} according to the equation: i_p (μA) = −0.294 C (μg mL^{-1}) + 0.465 (correlation coefficient, 0.999), and almost leveled off for more concentrated solutions. In repetitive measurements, the relative standard deviation values of DMBA measurements did not exceed 8% in the range 0.5–1 μg mL^{-1}, whereas the higher values (above 10%) occurred at the concentration above the linearity of calibration curve. Since the linear range looks shorter, the improvement in application of assay protocol would be resulting in relatively wide range of DMBA concentration.

Fig. 7C and D displays the influence of DMBA interaction time (in the range 0–7.5 min) at ds-DNA immobilized PGE surface upon the changes in the adenine signal. There was a decrease on adenine signal till 1 min. The response remained nearly constant from 1 min to 2.5 min then decreased again. The time-dependent profile which differs from compound to compound is due to the binding kinetics of the analyte-DNA interaction [49]. The optimum time for interaction of DMBA with ds-DNA was found as 5 min, since the changes at the adenine peak before/after the interaction with DMBA could clearly be observed following this accumulation time.

4. Conclusion

In the present study, the DMBA molecule was chosen for two specific reasons. First, it is a highly interesting and valuable tool in investigations of bioactivation processes as they relate to the etiology of several important pathological conditions. Second, it is a synthetic model PAH compound of controlled laboratory environment. Thus, the present observations dealing with voltammetric studies on DMBA may be similar to the finding of other large hydrocarbon systems.

We note that elucidating the mechanism of DMBA electrochemical oxidation is not an easy task and is beyond the scope of the present work. It only shows how the compound is oxidized in aqueous and non-aqueous media at carbon-based electrodes. Although the sufficient data are not available to determine the exact oxidation mechanism, it is hoped that knowledge of the voltammetric oxidation behavior of DMBA would help with a better understanding of the carcinogenic and oxidative pathways of PAHs in their metabolism and provide a more comprehensive picture.

The anodic voltammetry of aromatic hydrocarbons has been studied in great detail in acetonitrile, dimethylformamide, methylene chloride, propylene carbonate and nitrobenzene. The stability of the intermediates formed is affected markedly by the solvent, undergoing a series of chemical and additional electrochemical steps. In case of our study, DMSO was selected as the solvent. For medicine purposes, DMSO has proved a popular choice due to its suitability as fatty emulsions for the intravenous administration of

DMBA, maintaining the stability [51]. This encouraged its use in a clinical measurement sensor for the animal assays in future.

GCE is the most common carbon-based electrode in current use. However, anodic voltammetry at GCE is more frequently used for research purposes than for routine analytical determinations because of its passivation which can decrease of the sensitivity. Although disposable PGE is relatively new type of carbon electrode, it has become of interest in the field of sensitive and simple monitoring of toxic compounds including carcinogenic compounds by virtue of its high electrochemical reactivity, good mechanical rigidity, low-cost, low technology and ease of modification. In the environmental sense, disposable PGE in combination with field-based experiments can be much more attractive than the electrodes commonly used in the laboratory, i.e. GCE, because of the avoiding the need for extensive time delays, and considerable risk of contamination or loss of analyte of interest [52]. In this study, the PGE combined with more highly sensitive and accurate AdSV could allowed to an attractive trace analysis of DMBA from the aqueous solutions with the detection limit that reached the level as low as 0.194 nM (49.7 ng L^{-1}). This value is comparable to those obtained by commonly used chromatographic techniques for environmental carcinogens [53]. Therefore this technique could not only be used for monitoring the efficiency of destruction of DMBA in laboratory wastes, but serve as a model for the determination of trace risk chemicals in contaminated aquatic environments [54].

Following PAHs exposure, most of the absorbed compounds via different exposure pathways, i.e. inhalation, dermal contact, and ingestion of contaminated food are metabolized and eliminated in urine as phenols [55] while only a smaller amount is excreted unchanged in urine [56]. However, measurement of unmetabolized PAHs, instead of metabolites, in urine can be very useful for several reasons: their elimination is directly associated to previous exposure; they are less susceptible to intra-individual variability; they are characterized by a high degree of specificity [57]. With this aim, the possibility of measuring the DMBA in simulated human urine was also demonstrated. Owing to the complexity of the biological samples in which chemical carcinogens are sought, conventional biomonitoring methods are often time-consuming, labor intensive and expensive. They often incorporate a preliminary separation, involving extraction, filtration, fractionation, drying of extracts, redissolution and other steps. Using proposed technique, no sample pretreatment was required, other than precipitation in the presence of *ca.* 50% acetonitrile and dilution steps. Solvent addition is expected to increase DMBA solubility and reduce its absorption on container walls as well as to eliminate the influence of proteins. The performance of the stripping step in clean electrolyte was very convenient from the point of eliminating possible interferences with similar redox potential (not or slightly adsorbed) in urine. However, its detection limit found urine samples (0.04 μM corresponding to 10.3 μg L^{-1}) was not low enough to reach the levels expected in urine after the exposure to PAHs through especially multiple media [55]. We plan to undertake the investigations to improve the sensitivity together with the selectivity by combining HPLC with proposed adsorptive stripping technique at PGE.

In this study it was also presented for the first time a new screening tool for DMBA. Such use of DNA interaction as a basis for electrochemical biosensor results in a simple, cost effective, rapid, reliable and sensitive detection of DMBA. This promising approach might be a key step not only to detect very low concentrations of DMBA, but also to clarify its reaction mechanism concerning its role in the tumor formation.

Due to the fact that PAHs are very hydrophobic, they tend to be stored in fat tissue, liver and kidney (common target organs) [51]. Considering this knowledge, the preliminary investigation (experiments in vitro) was performed in these tissues of the rats which were first treated with DMBA dissolved in olive oil as orally, and then followed for tumor production. The use of proposed method represented satisfactory results giving well-defined voltammetric responses in the tissue extracts. Studies on laboratory animals are continuing in the development of these measurements.

ABSTRACT

A highly selective membrane electrodes based on a two newly synthesized nickel (II) Schiff bases, [NiL^1] and [NiL^2] where L^1 and L^2 are N,N/bis(salicylaldehyde)4,5-dimethyl-1,2-phenylenediamine (H_2L^1) and N,N/bis(salicylaldehyde)4,5-dichloro-1,2-phenylenediamine (H_2L^2) were used as a neutral carrier ionophores for static and hydrodynamic potentiometric mode of operations for the determination of periodate. Under static mode of operation, the sensors displayed a near-Nernstian slope of -66.1 ± 0.8 and -59.9 ± 1.1 mV decade^{-1} of activity and detection limits to 5.2×10^{-6} and 7.3×10^{-6} mol L^{-1} for the sensors based on [NiL^1] and [NiL^2], respectively. Under hydrodynamic mode of operation (FIA), the slope of the calibration plot, limit of detection, and working linear range were -71.1 mVdecade^{-1} of activity, 7.3×10^{-6} and 1.0×10^{-5} to 1.0×10^{-3} mol L^{-1}, respectively. The response time of the sensors in whole concentration ranges was very short (<10 s). The response of the sensors was independent on the pH range of 3–8. A tubular version was further developed and coupled to a flow injection system for ascorbic acid (AA) determination in beverages and pharmaceutical preparations. This approach was achieved by selecting a 50-cm reactor and an overall flow of 3 mL min^{-1}, and injecting volume 100 μL of AA standards in a 1.0×10^{-4} mol L^{-1} IO_4^- solution. Under these conditions, a linearity range of 2–13 μg mL^{-1}, with a slope of 4.97 mV (mg/L)$^{-1}$ ($r^2 = 0.9995$), detection limit 0.9 mg L^{-1} and a reproducibility of ±1.1 mV ($n = 5$) was recorded. This simple and inexpensive flow injection analysis manifold, with a good potentiometric detector, enabled the analysis of ~50 samples h^{-1} without requiring pretreatment procedures. An average recovery of 98.8% and a mean standard deviation of 1.3% were obtained.

1. Introduction

L-Ascorbic acid (Vitamin C) is a γ-lactone synthesized by plants and many animals (except primates). It is a water-soluble vitamin usually used as a dietary supplement in pharmaceutical preparations and in manufactured food and beverages as an antioxidant, preventing color changes and alterations of aroma and flavor as well as extending the storage time of the products [1]. This vitamin is among the compound of major biological importance, it plays a key role in the protection against biological oxidation processes participating in many metabolic reactions. It has also been used in the treatment and prevention of common cold, mental illness and infertility. Traditionally, ascorbic acid has been used clinically in the treatment and prevention of scurvy, but it is also important in the regulation of the immunological system and in the tissue reconstruction, which assist the formation of collagen. However, an excess of ascorbic acid can cause gastric irritation and diarrhea and it is metabolized to oxalic acid, which can cause renal problems [2]. On the other hand, the ascorbic acid ingestion is associated to increase absorption of metal transition (as inorganic iron and copper), metabolism of folic acid, amino acid and in biosynthesis of suprarenal hormone, minimizing the stress effect [1].

There is a frequent citation about ascorbic acid as an important exogenous antioxidant. Its chemoprotective action is attributed to two mechanisms of action. It is indeed a good scavenger of free radicals and several reactive oxygen species produced during the metabolic pathways of detoxification [3]. It justifies its association to protection against cancer agents by the prevention of formation of carcinogens precursors' compound [4]. In addition, AA has a reducing property by donation of one electron giving the semi-dehydroascorbate radical (DHA). It also regenerates tocopherol from tocopheroxyl radical providing membrane protection [5,6]. Thus, vitamin C determination is very important for biological and food industry.

Ascorbic acid has been monitored by different analytical methods in pharmaceutical formulations, foods and biological fluids.

Some of these methods are based on spectrophotometry [7,8], chromatography [9–11], electrophoresis [12,13] and electrochemistry [14–17]. Most of these methods, however, utilize expensive instrumentation, suffer from lack of selectivity, involve careful control of the reaction conditions or derivatization reactions, and require time-consuming pretreatment steps which are not easily applied to colored or turbid samples and affect their usefulness for routine analysis.

Therefore, a more rapid, accurate and simple method is always a target of research. This justifies the attention attracted by electrochemical methods; they possess quick response, low cost, simplicity of instrumentation, high sensitivity and possibility of miniaturization.

Periodate is a good oxidizing agent for α-diols, α-aminoalcohols, and similar compounds. The reaction proceeds at room temperature and usually takes place under mild conditions. Periodate potentiometric sensors have been reported for determination of different compounds, namely dopamine [18], glycerol [19,20], 2,3-butanediol [21], carbohydrates [22], and metal ions [23]. The same principal could be applied to ascorbic acid determination, avoiding tedious sampling pre-treating procedures and enhancing the selectivity and quickness of the procedure. In addition, for an industrial routine control of the analyte the continuous mode of operation is of regular selection. This may be achieved by means of flow injection systems that are particularly attractive in view of their versatility, simplicity and suitability for large-scale analyses.

The goal of the present work is to devise a highly selective periodate membrane electrode with good response properties, such as slope and response time, using the selective coordination chemistry between Schiff bases and Ni(II). Salophens have been found to be potentially useful for this purpose, due to the relative simplicity for their synthesis and the promising results already obtained for periodate based on Ni(II)-salophens. Accordingly in this work, two Ni(II)-salophen structures have been synthesized, well characterized and examined for preparation of periodate selective membrane electrodes.

2. Experimental

2.1. Reagents

$Ni(CH_3COO)_2.4H_2O$, salicylaldehyde, 4,5-dimethyl-*o*-phenylenediamine and 4,5-dichloro-*o*-phenylenediamine were supplied by Aldrich (St. Louis, MO). Tridodecylmethylammonium chloride (TDMAC), *o*-nitrophenyloctyl ether (*o*-NPOE), poly(vinyl chloride) (PVC) were used as received from Fluka (Ronkonkoma, NY). All anions used in selectivity measurements were in the form of sodium or potasium salt and used as received from Aldrich (St. Louis, MO). Tetrahydrofuran (THF) employed to cast membranes was from Sigma-Aldrich. L(+) Ascorbic acid was purchased from Riedel-de Haën. All potentiometric measurements were carried out in 1.0×10^{-2} mol L^{-1} acetate buffer solution adjusted to pH 4.7.

2.2. Equipment

All potentiometric measurements were made at 25 °C with an Orion pH/mV meter (model SA 720) and periodate PVC membrane sensors in conjunction with an Orion Ag/AgCl double junction reference electrode (model 90-02) with 10% (w/v) KNO_3 in the outer compartment. A combination Ross glass pH electrode (Orion 81-02) was used for all pH measurements. The analytical output signal was transferred to a commutation point that enabled the reconnection of the signal to one of six ways out. Each way presented an electrical antenna connector that provided suitable adaptation to one selective electrode. The selective electrodes had no internal reference solution and an epoxy-graphite matrix as conductive solid contact [24]. Batch trials were carried out with electrodes of conventional configuration, and flow ones with electrodes of tubular shape.

The flow injection analysis (FIA) system manifold consisted of a two-channel Ismatech MSREGLO model peristaltic pump. The manifold was connected with polyethylene tubing (Tygon, 0.7 mm i.d.) and an Omnifit injection valve (Rheodyne, Model 7125) with sample loop of 100 μL volume. The potential signals were recorded using an Orion pH/mV meter (model SA 720) connected to a PC through the interface ADC 16 (Pico Technology, UK) and PicoLog for windows (version 5.07) software.

IR measurements (KBr Pellets) were carried out on a Unicam-Mattson 1000 FT-IR. Elemental analyses were carried out on Elementar Vario EL. Ni-content was determined by Perkin Elmer Atomic Absorption Spectrometer. ^1H NMR measurements were performed on JEOL-270 MHz NMR DMSO-d_6 as a solvent and TMS as an internal reference. Molar conductivities of complexes were measured by using Jenway 4010 conductivity meter. Magnetic moments were determined on a Sherwood Scientific magnetic moment balance (Model ML1) at room temperature using Hg $[Co(SCN)_4]$ as a calibrant.

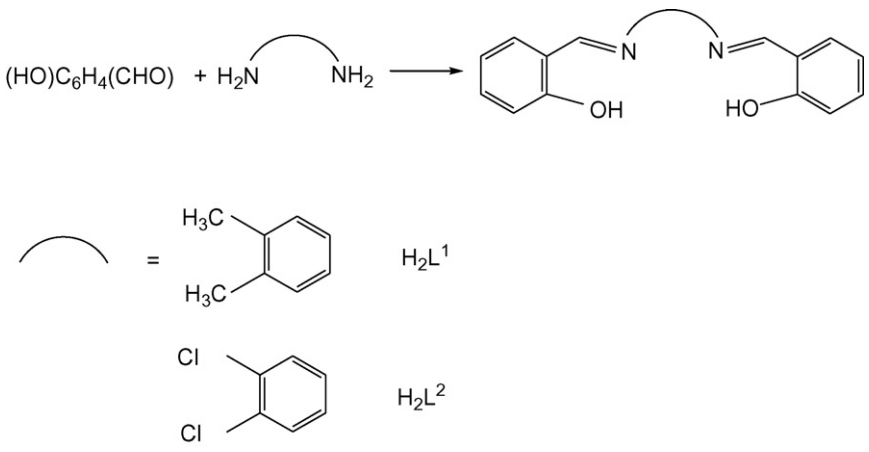
2.3. Syntheses of the ligands

The ligands H_2L^1 as described as in literature [25] and H_2L^2 were synthesized by a similar way according to the synthetic route shown in Scheme 1.

To a hot methanolic solution containing 10 mmol of the amine, 2.11 mL (20 mmol) of salicylaldehyde was added dropwise. The yellow solution obtained was refluxed for 2 h. After cooling, the precipitate Schiff base was collected by filtration and recrystallized from methanol. The ligands were dried in a desiccator over anhydrous $CaCl_2$ under vacuum.

Characteristics of the ligands are as follows:

H_2L^1 ($C_{22}H_{20}N_2O_2$): Yield 63%. Color Yellow. M.P. 148–150 °C. Elemental analysis Calc.(%): C, 76.72; H 5.85; N 8.13. Found: C 76.21; H 5.72; N 7.98. IR (KBr pellet. cm^{-1}): 3428 (ν_{OH}); 1617 ($\nu_{HC=N}$); 1278 ($\nu_{C\text{-}O}$). ^1H NMR (DMSO-d_6, 270 MHz): δ 11.80 (s, 2H; OH); 8.88 (s, 2H; HC=N); 7.50–7.80 (m, 8H; aromatic); 7.30 (s, 2H, aromatic); 2.46 (s 6H; CH_3 attached to diamine benzene ring).



H_2L^2 ($C_{20}H_{14}N_2O_2Cl_2$): Yield 70%. Color Yellow. M.P. 142–144 °C. Elemental analysis Calc.(%): C, 62.35; H 3.66; N 7.27; Cl 18.40. Found: C 62.19; H 3.60; N 7.25; Cl 18.38. IR (KBr pellet. cm^{-1}): 3444 (ν_{OH}); 1616 ($\nu_{HC=N}$); 1279 (ν_{C-O}). ^1H NMR (DMSO-d_6, 270 MHz): δ 10.90 (s, 2H; OH); 8.92 (s, 2H; HC=N); 7.65–7.80 (m, 8H; aromatic); 7.35 (s, 2H, aromatic).

2.4. Syntheses of the complexes

To a hot 20 mL methanolic solution containing 10 mmol of the ligand, 20 mL of a methanolic solution containing 2.48 g (10 mmol) of $Ni(CH_3COO)_2.4H_2O$ was added. A red precipitate appears immediately. After stirring for 1 h the formed red complexes were filtered, collected and then washed for several times with hot methanol until the filterate became colorless. The complexes were dried in a desiccator over anhydrous $CaCl_2$ under vacuum.

The dried ligands and complexes were subjected to elemental and spectroscopic analyses. The complexes are air-stable, non-hygroscopic, insoluble in H_2O, partly soluble in ethanol, methanol and completely soluble in DMSO, DMF and CH_2CL_2. Decomposition occurs with concentrated nitric acid, and the resultant solution was used after suitable dilution for metal analysis. Characteristics of the complexes are as follows:

NiL^1 ($C_{22}H_{18}N_2O_2Ni$): Yield 80%. Color Red. M.P. >300 °C. Λ_m (Ω^{-1} cm^{-1} mol^{-1}) 4.2. Elemental analysis Calc.(%): C, 65.87; H 4.52; N 6.98; Ni 14.63. Found: C 65.73; H 4.52; N 6.77; Ni 14.58. IR (KBr pellet. cm^{-1}): 1613 ($\nu_{HC=N}$); 1288 (ν_{C-O}); 542 (ν_{Ni-N}); 412 (ν_{Ni-O}).

Scheme 1.

^{1}H NMR (DMSO-d_6, 270 MHz): δ 8.79 (s, 2H; HC=N); 7.60–7.85 (m, 8H; aromatic); 7.40 (s, 2H, aromatic); 2.46 (s 6H; CH_3 attached to diamine benzene ring).

NiL^2 ($C_{20}H_{12}N_2O_2Cl_2Ni$): Yield 76%. Color Red. M.P. >300 °C. Λ_m (Ω^{-1} cm^{-1} mol^{-1}) 6.7. Elemental analysis Calc.(%): C, 54.35; H 2.73; N 6.33; Cl 16.04; Ni 13.28. Found: C 54.05; H 2.67; N 6.30; Cl 15.95; Ni 13.10. IR (KBr pellet. cm^{-1}): 1615 ($\nu_{HC=N}$); 1290 (ν_{C-O}); 536 (ν_{Ni-N}); 419 (ν_{Ni-O}). H NMR (DMSO-d_6, 270 MHz): δ 8.89 (s, 2H; HC=N); 7.70–7.85 (m, 8H; aromatic); 7.4 (s, 2H, aromatic).

2.5. Membrane sensors formation and EMF measurements

A 10 mg portion of either [NiL^1] or [NiL^2] complex was mixed with 5 mg TDMAC, 350 mg of the plasticizer and 190 mg of PVC. The mixture was dissolved in ~5 mL THF. The membrane solutions were cast into conductive supports of conventional or tubular shapes and left drying overnight. The sensors were conditioned before use by soaking in 10^{-2} mol L^{-1} IO_4^- solution (for at least 12 h) and stored in the same solution when not in use. Calibration was made by immersing the periodate membrane sensor in conjunction with a double junction Ag/AgCl reference electrode in 50 mL beakers containing 10 mL aliquots of standard 1.0×10^{-6}–1.0×10^{-2} mol L^{-1} IO_4^- solution. The pH of the solutions was adjusted to 4.7 using 0.01 mol L^{-1} acetate buffer. Potential readings were carried out for periodate starting from low to high concentrations until stabilization occurred. The potential response was plotted as a function of the logarithm of IO_4^- concentrations. The calibration plot was used for subsequent measurements of unknown IO_4^- concentrations.

For FIA measurements, a series of portions (100 μL) of IO_4^- test solutions covering the range 1.0×10^{-2}–1.0×10^{-6} mol L^{-1} was injected into a flow stream of 10^{-2} mol L^{-1} acetate buffer of pH 4.7, flowing at 3 mL min^{-1}. The periodate sensor was used as a working sensor against Ag/AgCl double junction reference electrode. Each solution was measured in triplicate. The average potentials at maximum heights were plotted against log [IO_4^-].

2.6. Ascorbic acid determination

A 10 mL portion of a standard 5.0×10^{-4} mol L^{-1} $NaIO_4$ solution was transferred into a 50-mL beaker and the periodate sensor in conjunction with the reference electrode was immersed in the solution. After stabilization of the potential within ± 2 mV, a 1.0 mL aliquot containing 0.5–50 mg mL^{-1} of ascorbic acid (pH 3–6) was added, the solution stirred and the potential reading recorded after 60 s. A blank experiment was conducted under the same conditions using a 1.0 mL aliquot of water instead of the sample test solution. The potential reading was recorded after the same reaction time. The concentrations of IO_4^- in the presence and absence of ascorbic acid were calculated from the calibration graph. The concentration of the reducing compounds was calculated from the concentration of periodate consumed: 1 mol of IO_4^- = 1.0 mol of ascorbic acid.

For continuous measurements (FIA), a flow stream of 0.01 mol L^{-1} acetate buffer of pH 4.7 carrier solution and 1.0×10^{-4} mol L^{-1} periodate solution were allowed to pass through the flow-cell at a flow rate 3 mL min^{-1}. Successive 100 μL aliquots of the standard ascorbic acid and unknown test sample solutions were injected into the flowing stream. The corresponding potential change was measured and recorded versus time. A typical calibration plot was made and used to determine the concentration of ascorbic acid in the unknown samples.

3. Results and discussions

3.1. Elucidation structure of the complexes

Physical characteristics, elemental analysis and magnetic susceptibility data of the ligands and complexes show the formation of 1:1 [Ni:L]. Magnetic susceptibility values of the complexes at room temperature are consistent with square planar geometry around Ni(II) ion. The molar conductance values of the synthesized complexes were determined using 1×10^{-3} mol L^{-1} DMF solution are in the range 4.2–6.7 Ω^{-1}cm^2 mol^{-1}. These results suggest the presence of a non-electrolytic nature in the same solvent [26]. Also these values indicate that there are no anions existing in the outer sphere coordination.

The IR spectra of the complexes, in comparison with those of the free ligands, display certain changes, which give an idea about the type of coordination and their structure. Free Schiff bases show a very strong absorption at 1616 and 1617 cm^{-1} characteristic of azomethine ($\nu_{C=N}$) group [27]. Coordination of the Schiff bases to the nickel ion through the azomethine nitrogen atom is expected to reduce the electron density in the azomethine link and thus, lower the $\nu_{C=N}$ absorption frequency. Hence this band undergoes a shift to lower frequency to 1608–1615 cm^{-1} after complexation, indicating coordination of the azomethine nitrogen to nickel [28,29]. The free ligands exhibit a broad band at 3418–3444 cm^{-1}, which may be assigned to the ν(OH) and this band is absent in the spectra of all the complexes, conferring the deprotonation of the Schiff bases prior to coordination. The hydroxy protons are displaced by the metal leading to higher ν(C—O) (1288–1290 cm^{-1}) compared to the IR of the free ligands, suggesting that the other coordinating atom is phenolic

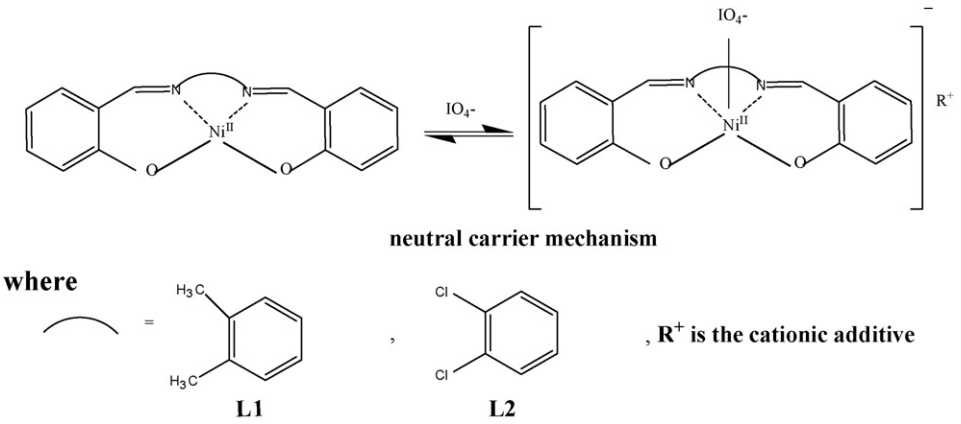


Fig. 1. Proposed mechanism for the potentiometric response of either NiL^1 or NiL^2-based PVC membrane sensors towards periodate.

oxygen [30]. The binding of the metal to the ligand through nitrogen and oxygen atom is further supported by the appearance of new band in 534–542 cm^{-1} and 412–419 cm^{-1} ranges due to ν(M-N) and ν(M-O) [31], respectively, in the spectra of all the complexes.

The IR spectral evidences were further substantiated by ^1H NMR of the free ligands and their Ni(II) complexes. The Chemical shift observed for the OH protons in the free ligands was not observed in any of the complexes. This confirms the bonding of oxygen to the metal ion (C—O—Ni).

The presence of a sharp singlet for the —C(H)═N proton in both the free ligands and their Ni(II) complexes clearly indicates that the magnetic environment is equivalent for all such protons, suggesting that the presence of a planar ligand in these complexes[32]. The multiplets of aromatic protons appearing within the range are less affected by chelation. In the ligand H_2L^1 the signal of —CH_3 is unaffected by chelation.

On The basis of the physical and spectral data of the Schiff bases and The complexes discussed above, one can assume that Ni(II) ions are bonded to the Schiff bases via the phenolic oxygen and the imino nitrogen as illustrated in Fig. 1.

3.2. Response characteristics of periodate sensors

The potentiometric response characteristics of the electrodes assembled with the different membranes are shown in Fig. 2. The sensor based on [NiL^1] shows a linear response towards periodate over the concentration range of 9.0×10^{-6}–1.0×10^{-3} mol L^{-1} in a 0.01 mol L^{-1} acetate buffer solution of pH 4.7 with a slope of -48.7 ± 1.2 mV decade^{-1} of activity and detection limit 7.2×10^{-6} mol L^{-1}. The sensor assembled with [NiL^2] displays a linear response towards periodate ranging from 3.2×10^{-5}–1.0×10^{-3} mol L^{-1} with a slope of -49.2 ± 0.7 mV decade^{-1} of activity and detection limit 1.78×10^{-5} mol L^{-1}.

On the other hand, the addition of ionic additive (e.g. TDMAC) improves the potentiometric properties of anion-selective sensors. This is in accordance with the results reported previously that the cationic sites in neutral carrier-based electrodes can stabilize the formation of the negatively charged product (NiL^1-IO_4^-) in the membrane phase as well as lower the electrical membrane resistance and improve the potentiometric response characteristics of the membrane electrodes [33–35]. Addition of 10 mol% of TDMAC relative to the ionophore to the membranes showed an enhancement of the potentiometric response characteristics. These membrane electrodes exhibited a slope of -66.1 ± 0.8 and -59.9 ± 1.1 mV decade^{-1} of activity, and decreased the detection limits to 5.2×10^{-6} and 7.3×10^{-6} mol L^{-1} for the sensors based on [NiL^1] and [NiL^2], respectively.

The influence of the pH on the potentiometric response of periodate-based membrane sensors was tested using 10^{-4} and 10^{-3} mol L^{-1} IO_4^- solutions over the pH range 2–10. Adjustment of pH was carried out using NaOH and/or HCl. From pH-potential profiles, it is apparent that there is no change in potential response within the pH range 3–8 for both [NiL^1] and [NiL^2] membrane-based sensors. The sensor significant response at high pH values (>8.5), which outcomes probably from the ability of hydroxide ions to compete favorably for the axial coordination site of the central metal. At pH <3, there was also interference due to the increase of hydrogen ion concentration.

Dynamic response time is an important factor for any ion selective electrode. In this study, the practical response time was recorded by immediate changing of IO_4^- concentration from 1.0×10^{-6} to 1.0×10^{-3} mol L^{-1}. The actual potential versus time trace showed in whole concentrations range that the sensors reach the equilibrium response in a very short time (<10 s). These results

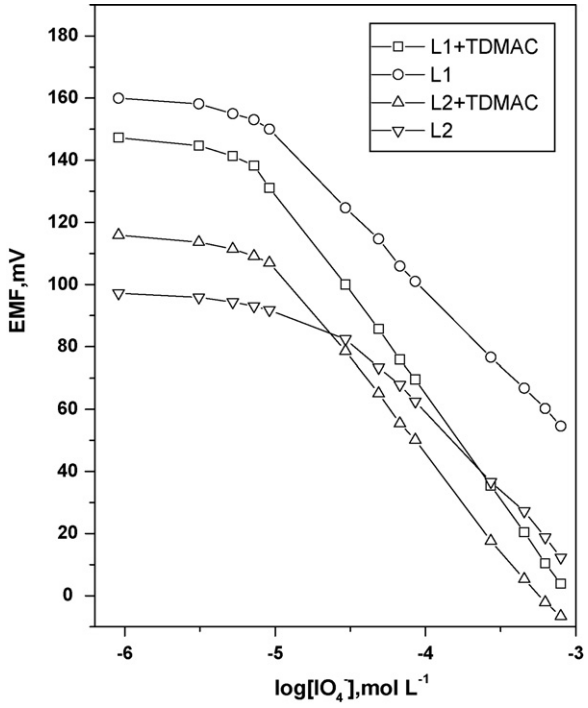

Fig. 2. Potentiometric response of periodate based membrane sensors in 0.01 mol L^{-1} acetate buffer, pH 4.7.

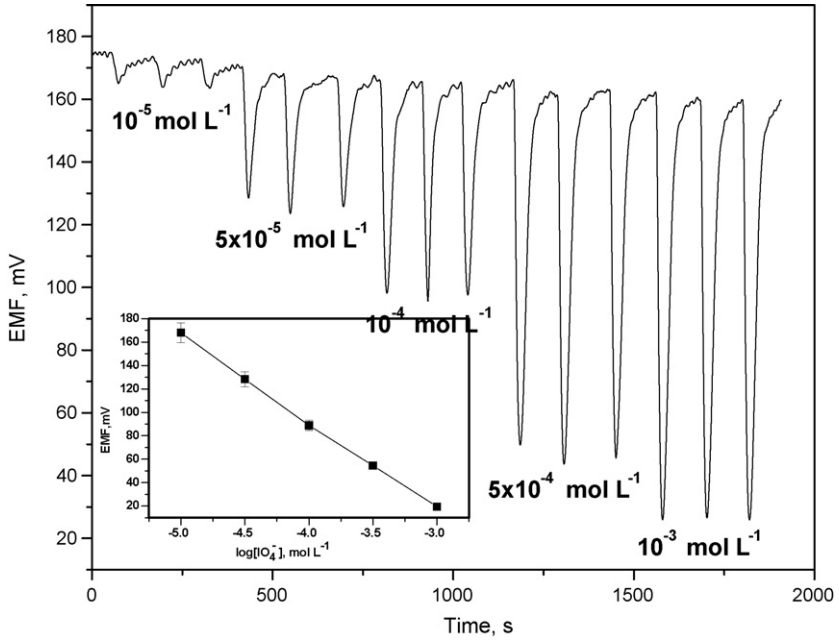

Fig. 3. Transient potentiometric signals obtained in triplicate for periodate membrane based sensor. Conditions: carrier solution, 0.0.1 mol L^{-1} acetate buffer pH 4.7 flow rate, 3.0 mL min^{-1}; injection valve, 100 μL.

indicate that both sensors are amenable for use with automated systems.

For continuous periodate measurements, a tubular-type detector incorporating a [NiL^1] + TDMAC based membrane sensor was prepared and used under hydrodynamic mode of operation for continuous IO_4^- quantification. The general intrinsic response features of the detector revealed that the dependency of the peak height, peak width, and time to recover the base line depend on the flow rate of the carrier buffer solution and the sampling volume. The linear response range of the detector was evaluated by using a set of sodium periodate solutions (1.0×10^{-6}–1.0×10^{-3} mol L^{-1}), with 0.01 mol L^{-1} acetate buffer of pH 4.7, sample loop volume 100 μL and flow rate 3 mL min^{-1}. It was found that the detection unit presented a Nernstian response with concentrations ranging from 1.0×10^{-5} to 10^{-3} mol L^{-1} with a detection limit 7.3×10^{-6} mol L^{-1}, slope of -71.9 ± 0.8 mV $decade^{-1}$ of activity and a reproducibility of ±0.9 mV ($n = 6$). A typical FI-diagram is shown in Fig. 3. These good analytical features of the detector opened the possibility of its application to the indirect determination of ascorbic acid by monitoring the periodate concentration changes caused by the oxidation reaction of the analytes.

3.3. Sensor selectivity

The selectivity of potentiometric anion sensors is introduced via an ion-selective membrane deposited on top of the transducer element. Because sensors are often designed for certain applications and well-defined conditions, this membrane does not necessarily have to be specific for the analyte as long as strong interferents are absent or present only in low concentrations. Receptors with Lewis acidic metal centers as anion binding sites are often applied for anion sensors with selectivities deviating from the Hofmeister series. The metal center can be either ionic (complexed in an organic ligand), or can be covalently bound as part of an organometallic structure. Depending on the organic ligand and the metal center this class of receptors applied in ISEs contains both charged and neutral receptors.

In the present work the selectivity of the sensors has been determined by the matched potential method (MPM) [36]. By this method, the selectivity coefficient is defined as the activity ratio of the primary ion ($A = 1.0 \times 10^{-5}$ mol L^{-1} IO_4^- ions) and the interfering ion ($B = 10^{-2}$ mol L^{-1}) that gives the same potential change in a reference solution (1.0×10^{-6} mol L^{-1} IO_4^- ions). All potentiometric measurements are carried out in 10^{-2} mol L^{-1} acetate buffer pH 4.5. First, the change in potential upon changing the primary ion activity is measured. Then, the interfering ion would be added to an identical reference solution until the same potential change is obtained. The selectivity coefficient K is determined as:

$$K^{pot} = \frac{\Delta A}{aB} \quad (1)$$

where $\Delta A = \acute{a}A - aA$, aA is the initial primary ion activity and $\acute{a}A$ is the activity of A, in the presence of the interfering ion, aB. The selectivity coefficient values determined were compiled in Table 1. The selectivity coefficients of [NiL^1] and [NiL^2] membrane sensor without membrane additives were in the order: $IO_4^- > SCN^- > I^- > ClO_4^- > NO_3^- > NO_2^- > Br^- > IO_3^- > F^- = Cl^-$ > Ascorbate > SO_4^{2-} and $IO_4^- > SCN^- > I^- > ClO_4^- > Cl^- > Br^- > NO_3^- > IO_3^- > NO_2^-$ > Ascorbate > $F^- > SO_4^{2-}$, respectively. Membrane electrodes doped with cationic sites (e.g. TDMAC 10 mol%) exhibited almost the same selectivity order of membranes containing no additives with an improvement in the potentiometric selectivity

Table 1
Selectivity coefficients (K^{pot}, j) of periodate PVC membrane sensors.

Ion	[NiL^1]	[NiL^1]+TDMAC	[NiL^2]	[NiL^2]+TDMAC
IO_4^-	0	0	0	0
IO_3^-	−3.12	−3.21	−2.78	−2.85
Ascorbate	−3.49	−3.27	−3.14	−3.21
ClO_4^-	−2.08	−2.15	−2.12	−2.21
I^-	−1.66	−1.77	−1.48	−1.49

NO_2^-	−2.76	−2.66	−2.88	−2.68
Cl^-	−3.34	−2.90	−2.36	−2.12
Br^-	−2.87	−2.86	−2.64	−2.61
F^-	−3.33	−3.45	−3.53	−3.5
SCN^-	−0.95	−1.02	−0.74	−0.88
SO_4^{2-}	−3.64	−3.42	−3.77	−3.31

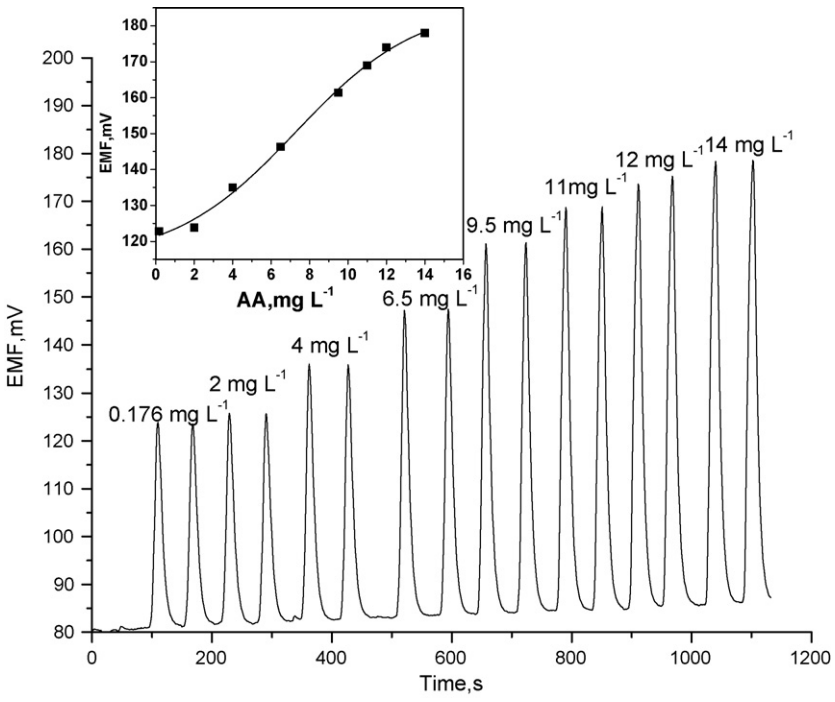

Fig. 4. Transient potentiometric signals obtained in triplicate for periodate membrane based sensor. Conditions: carrier solutions, 0.01 mol L^{-1} acetate buffer pH 4.7 and 1.0×10^{-4} mol L^{-1} IO_4^- solution; flow rate, 3.0 mL min^{-1}; injection valve, 100 μL.

towards periodate anion, in comparison with membrane sensors prepared without cationic additive site. The improvement was obtained over perchlorate, iodide, iodate, and thiocyanate (i.e., the lipophilic anions), whereas no improvement was obtained over the other anions. This selectivity order clearly showed that the response mechanism is neutral carrier mechanism and due to strong coordination affinity between the metal center in the ionophore and the anion leading to a non-Hofmeister selectivity sequence.

3.4. Hydrodynamic monitoring of ascorbic acid

The injection of ascorbic acid in a periodate carrier solution provides the oxidation of periodate within the carrier. The subsequent increase in periodate concentration is detected by a positive potential change at the potentiometric sensor. The relative consumption of periodate may therefore be used to the indirect monitoring of ascorbic acid. The overall reaction expressed in Eq. (2), where k is the overall reaction rate constant and AA ascorbic acid.

$$IO_4^- + AA \xrightarrow{k} IO_3^- + \text{Product} \quad (2)$$

Under specific pH conditions, the reaction kinetics follows a second order behavior expressed as follows:

$$\frac{d[IO_4^-]}{dt} = -k\,[IO_4^-][AA] \quad (3)$$

The potential E of periodate sensor used for monitoring the reaction is given by Nernest equation:

$$E = K' - \text{Slope}\,\ln[IO_4^-] \quad (4)$$

Differentiating Eq. (4) with time gives:

$$\frac{dE}{dt} = -\text{Slope} \times \frac{1}{[IO_4^-] \times d[IO_4^-]/dt} \quad (5)$$

Combination of Eqs. (5) and (3) shows that the change in potential with time depends on AA concentration.

Periodate concentration was an important parameter in the procedure for AA determination. With a concentration lower than 10^{-5} mol L^{-1} in the flow system, the baseline was noisy and recorded peak heights were not measurable because the remaining periodate concentration approached the practical limit of detection. For periodate concentrations within the 10^{-4}–10^{-2} mol L^{-1} range, baseline noise was about ±1.8 mV, washing time reached

[a] Mean of five determinations.

a constant value of 11 sets, and the tendency for linearization of the relation between AA concentration and recorded peak height was observed. This was due to the combination of Nernstian response of the electrode and kinetics of AA oxidation which, in the initial development steps, tends to be of first order relatively to periodate. Better linearity ($r^2 > 0.995$) was observed for $IO_4^- = 1.0 \times 10^{-4}$ mol L^{-1}. For periodate concentrations higher than 10^{-3} mol L^{-1}, linearity decreased and lower peaks were recorded. In this situation, AA concentrations were very low relative to periodate, so that the relative oxidant consumption underwent a pronounced reduction. Also, an oscillating baseline was observed, probably due to inefficient mixing conditions associated with the fast electrode response.

As can be seen in Fig. 4 with an injected volume 100 μL, it gives a linearity range from 2.0 to 13 mg mL^{-1} with a slope = 4.97 mV (mg/L)$^{-1}$ ($r^2 = 0.9995$) and detection limit 0.9 mg L^{-1}.

The influence of some excipients commonly present in injection forms of pharmaceutical preparations was evaluated. Glucose, saccharose, fructose, sodium chloride, and poly(ethylene glycol) were selected for this evaluation. This study was based on performing recovery trials of AA solutions with the excipients just mentioned. The influence of the interfering substances was evaluated at interferent/AA concentration ratios of 1:1, 1:10, and 1:100 (w/w) for AA concentrations of 5.0×10^{-4} and 1.50×10^{-2} mol L^{-1}. The recorded values showed that the interference of these excipients was generally not perceptible. However, the interference of this preservative was not recorded on the analyzed injection forms because a −0.3% relative error was obtained by an independent method and its concentration was not specified in these preparations.

3.5. Ascorbic acid determination in pharmaceuticals and beverages

In order to check the usefulness of the proposed sensors for resolving real samples, we addressed the determination of AA in real food samples as soft drinks as well as pharmaceuticals under static and hydrodynamic mode of operations. Many marketed beverages have the intentional addition of ascorbic acid, either by its antioxidant properties or by a supplementary vitamin addition. The samples analyzed by the proposed method were obtained from the local market and their content in ascorbic acid estimated by the proposed potentiometric method is presented in Table 2. A blank sample was used to control and ascertain the accuracy of the analytical results. Analytical data support the application of the proposed potentiometric method for the routine control ascorbic acid.

To widen the range of application of the proposed method, the analysis of pharmaceuticals was also established. Generally, these samples have high vitamin C contents. A different marketed formulation was used as a case study to prove this possible application. Table 3 gives the mean results obtained by either static or hydrodynamic modes of operations. Average values obtained varied between 98.5 and 99.1% of labeled amounts. The potentiometric method is well compared with the standard method [37]. Considering as null hypothesis that the two methods agree, a paired two-tail test for 5% level of significance gave a calculated $t_{(0.662)}$ below the tabulated one ($t_{0.025,11} = 2.20$), therefore accepting the null hypothesis. Comparison of variances attained for each sample was made by the *F*-test using the same assumptions as for the Student's *t*-test.

Table 4
Comparison of the proposed sensor with some other reported methods.

4. Conclusions

Potentiometric membrane sensors for periodate based on a newly synthesized and well characterized Ni(II)-Schiff bases with high sensitivity and good selectivity were developed and utilized in batch and hydrodynamic modes of operation. The sensors offer the advantages of fast response, reasonable selectivity, low cost and possible interfacings with computerized and automated systems. Interfacing the sensor in a flow injection analysis system offers adequate analysis speed, good reproducibility, high sample throughputs and excellent response characteristics. Direct analysis of ascorbic acid was possible under static and hydrodynamic mode of operations with a linear range 2.0–13 μg mL^{-1} with a sample rate ~50–55 sample h^{-1}. Some of the analytical features of developed method were compared with other methods based on different techniques (Table 4). As this table shows, our simple and inexpensive method is comparable with other complicated and expensive methods. Most of these methods, however, utilize expensive instrumentation [10–13,15], suffer from lack of selectivity [7,8,15], involve careful control of the reaction conditions or derivatization reactions [7,8,12,13], and require time-consuming pretreatment steps which are not easily applied to colored or turbid samples and affect their usefulness for routine analysis [7,8].

Electrothermal atomic absorption spectrometry

ABSTRACT

A combined method with dispersive liquid–liquid microextraction (DLLME) and electrothermal atomic absorption spectrometry (ETAAS) has been developed for determining gold(III). Dicyclohexylamine, a new extractant for gold(III), showed excellent performance in DLLME. Acetone was indispensable to the quantitative extraction of gold(III), contributing to decrease in hydration, decrease in the difference in the dielectric constants between the supernatant phase and the sedimented phase, and dissolution of a part of chloroform as an extraction solvent to the supernatant phase as well as improvement of dipersibility. In DLLME using a mixture of 1.0 mL of acetone and 100 μL of chloroform containing 50 mmol L^{-1} of dicyclohexylamine, gold(III) could be extracted selectively and effectively from 8 mL of a sample solution in the presence of iron(III), cobalt(II), nickel(II), copper(II), palladium(II), and platinum(IV) at pH 1. The extracted gold(III) was determinable by ETAAS; the detection limit was 0.002 μg L^{-1} (three times the standard deviation of the blank values, $n = 8$) as a gold(III) concentration in 8 mL of sample solution. The proposed method was applicable to the determination of gold in platinum metal and its alloy as well as effluent without any interference by the matrices.

1. Introduction

Gold, which has important characteristics such as high ductility, corrosion resistance, low impedance, and catalytic properties, is widely utilized in the electronic, electroplating, fine-chemical, and jewelry industries [1]. Because it is precious, gold is carefully recovered after use through various techniques such as electrolysis and ion exchange [2,3]; however, complete recovery cannot be achieved, and a small amount of gold is lost through routes such as effluents. To estimate the amount of gold lost through an effluent, a method in which gold can be sensitively determined without any interference by the major ions generally contained in the effluent is necessary.

Other precious metals, including platinum, are also key materials for various industries [1]. With the expansion of its applications, such as in fuel cells, a growing demand for high-purity platinum is expected [4,5]. Because platinum metal contains significant impurities, including gold, an accurate and precise method of analysis is required.

For the determination of gold, electrothermal atomic absorption spectrometry (ETAAS) is a powerful tool [6]; however, the sensitivity is sometimes insufficient and the presence of matrices seriously interferes with the analyses of effluents, metals, and alloys. Therefore, a separation and preconcentration technique is extensively applied to the ETAAS determination of gold [6].

Liquid–liquid extraction (LLE) is an effective method for the separation and preconcentration of gold(III) [7–12]. Amine compounds, including *n*-trioctylamine [9], *n*-octylaniline [10], *N*-phenylbenzylamine [11], and *N*-*n*-octylaniline [12], are conveniently utilized for the extraction of gold(III) and other elements. However, there are some problems with the use of LLE, including the large amounts of harmful organic solvents needed, the long extraction time required for quantitative extraction, and difficulty in the treatment of wastewater generated after extraction.

To overcome these problems, various types of LLE techniques have been proposed. Among them, microextraction techniques have been investigated intensely. Homogeneous liquid–liquid extraction (HoLLE) based on a ternary solvent system [13–17] is one of the most useful microextraction techniques. HoLLE utilizes the phase separation phenomenon from a homogeneous solution, and the analytes are rapidly and efficiently extracted into a separated phase. HoLLE is available for the separation and

preconcentration of some elements [14–17], but there has been no report on the separation and preconcentration of gold(III). Dispersive liquid–liquid microextraction (DLLME) [18] has also attracted attention recently [19–27]. In DLLME, as in HoLLE, an aqueous sample solution, a water-miscible organic solvent as the disperser solvent, and a water-immiscible organic solvent as the extraction solvent are used; however, the extraction solvent has only to disperse finely into solution. In general, a mixture of disperser solvent and extraction solvent is swiftly injected using a microsyringe, and a gentle shaking is applied to extract the analyte quantitatively into the dispersed extraction solvent. The selection of a dispersive solvent which gives favorable dispersibility of the extraction solvent is important to achieve effective extraction of analyte [18–27]. DLLME is conveniently applicable to the separation and preconcentration of various elements prior to their ETAAS determination [19–27]; for gold(III), however, only DLLME using victoria blue R has been reported [25].

In this work, we investigated a combined method with DLLME and ETAAS for determining gold(III). For DLLME using acetone as a water-miscible organic solvent and chloroform as a water-immiscible organic solvent, we tested 11 kinds of amine compounds as extractants and found that dicyclohexylamine, which has not been used for the extraction of gold(III), was excellent. It is noteworthy that DLLME using dicyclohexylamine has rather high selectivity; gold(III) could be determined by ETAAS without any interference even in the presence of large amounts of other elements. In this paper, we report the results of investigations of the DLLME of gold(III) with amine compounds and discuss the role of acetone as a water-miscible organic solvent in the extraction of gold(III) with dicyclohexylamine. The potential of ETAAS combined with DLLME using dicyclohexylamine is also demonstrated through the determination of gold in effluent, platinum metal, and platinum alloy.

2. Experimental

2.1. Apparatus

A Hitachi 180-80 polarized Zeeman atomic absorption spectrometer (flame- and electrothermal-type) was used to measure gold and other elements. The pH measurement and ultrasonic irradiation were carried out using a Horiba F-22 pH meter and an AS ONE US-2 ultrasonic cleaner (120 W, 38 kHz), respectively. A Kubota Model 5400 centrifuge was used to form the sedimented phase.

2.2. Reagents

Purified water obtained by a Simplicity UV (Millipore) was used for all experiments. Standard solutions of gold(III) and the other elements (1000 mg L^{-1}) were purchased from Kanto Chemical. Eleven kinds of amine compounds, ethylenediamine (guaranteed reagent grade, GR, Wako Pure Chemical Industries), diethylenetriamine (GR, Wako Pure Chemical Industries), *N*-butyldimethylamine (>98%, Tokyo Chemical Industry), triphenylamine (GR, Kanto Chemical), *N*-methyldiphenylamine (97%, Acros Organics), *N*-methylaniline (GR, Kanto Chemical), *N*-phenylbenzylamine (99%, Acros Organics), benzylamine (GR, Kanto Chemical), dibenzylamine (>97%, Tokyo Chemical Industry), cyclohexylamine (>99%, Tokyo Chemical Industry), and dicyclohexylamine (>99%, Tokyo Chemical Industry), were used as extractants without any further purification (the structures are summarized in Fig. 1S in the Supplementary Material). The other reagents, including chloroform, acetone, hydrochloric acid, and sodium hydroxide, were of GR or analytical reagent grade.

2.3. Procedures

2.3.1. Extraction behavior of gold(III) with some amine compounds

As a test solution, 0.1 mol L^{-1} hydrochloric acid spiked with gold(III) (4 mg L^{-1} or 10 μg L^{-1}) was used.

For DLLME, the test solution (5 mL) was taken into a 10 mL glass centrifuge tube. To the solution, a mixture of 0.90 mL of acetone and 90 μL of chloroform containing 50 or 200 mmol L^{-1} of amine compound was swiftly injected using a glass syringe equipped with a stainless needle. After the cloudy solution was gently shaken by hand for approximately 10 s, the solution was centrifuged at 3000 rpm for 8 min. Gold in the supernatant phase was determined using flame atomic absorption spectrometry (FAAS) under the operating conditions shown in Table 1. The extraction percentage was calculated based on the initial amount of gold in the test solution and the amount in the supernatant phase, which was calibrated using the supernatant phase spiked with an appropriate amount of gold(III) after the blank test.

For LLE, 1 mL of chloroform containing 1–200 mmol L^{-1} of amine compounds and 0–10 mL of acetone was added to 50 mL of the test solution containing 4 mg L^{-1} of gold(III). The solution was then stirred vigorously. The concentration of gold(III) in the supernatant solution was measured using FAAS after centrifugation. The extraction percentage was calculated in the same manner for DLLME.

2.3.2. Determination of gold by ETAAS after DLLME using dicyclohexylamine

For the optimization of the extraction conditions, a purified water-based solution containing 10 μg L^{-1} or 0.2 μg L^{-1} of gold(III), in which the pH was adjusted using hydrochloric acid and/or sodium hydroxide solution, was used as a test solution. Effluent samples, which were obtained from a jewelry factory, were digested with hydrochloric acid on heating [28] after filtration using a membrane filter (Nihon Millipore, Omnipore membrane, pore size of 0.45 μm). The pH of the sample solutions was approximately 1. For analyses of platinum metal and its alloy, approximately 0.1 g of a platinum metal (Pt, 99.95%) or platinum alloy (Pt, 94.82%; Cu, 5.16%) was dissolved in 20 mL of aqua regia on heating. The solution was then diluted with 0.1 mol L^{-1} hydrochloric acid.

To 8 mL of the test solution or the sample solution, a mixture of 1.0 mL of acetone and 100 μL of chloroform containing 50 mmol L^{-1} of dicyclohexylamine was swiftly injected. The cloudy solution was gently shaken, and ultrasonic irradiation was carried out for 5 min. The solution was then centrifuged.

Gold in the sedimented phase was determined using ETAAS under the operating conditions summarized in Table 1. Solutions

for the calibration curve were prepared using 8 mL of 0.1 mol L^{-1} hydrochloric acid spiked with appropriate amounts of gold(III). A blank test was also carried out using 0.1 mol L^{-1} hydrochloric acid or the purified water-based solution after the treatment with hydrochloric acid or aqua regia. To optimize the extraction conditions, gold in the supernatant phase was determined using ETAAS. The extraction percentage was evaluated in a manner similar to that used for the extraction behavior of gold(III), as mentioned above.

3. Results and discussion

3.1. Extraction of gold(III) with some amine compounds

The extraction of gold(III) using 11 kinds of amine compounds was investigated using DLLME as well as LLE in order to select the appropriate amine compound for the extraction. Since the extraction of gold(III) with amine compounds has been carried out in the acidic region [9–12], 0.1 mol L^{-1} hydrochloric acid was used for the experiments. As a water-miscible organic solvent, acetone was chosen because it has been widely utilized as a disperser solvent for DLLME [18,19,24,25].

3.1.1. Comparison of extraction behavior of gold(III) by LLE and DLLME

The results of the extraction of gold(III) using a series of amine compounds by LLE, in which 50 mL of the test solution containing 4 mg L^{-1} of gold(III) and 1 mL of chloroform containing an amine compound were used without acetone, are shown in Fig. 1. For *N*-methylaniline and *N*-phenylbenzylamine [11], gold(III) was quantitatively extracted. *N*-Methyldiphenylamine gave 57% of the extraction. For the other amine compounds, however, less than 30% of gold(III) was extracted, and no extraction of gold (III) was observed for dicyclohexylamine.

The results for DLLME of gold(III) using the amine compounds are summarized in Fig. 1. For aromatic amines, including *N*-methylaniline and *N*-phenylbenzylamine [11], the extraction percentages decreased compared to those for LLE when a mixture of 0.9 mL of acetone and 90 μL of chloroform containing 200 mmol L^{-1} of the corresponding amine compound was added to 5 mL of the test solution. In contrast, the extraction percentages were considerably improved with the use of *N*-butyldimethylamine, benzylamine, dibenzylamine, cyclohexylamine, and dicyclohexylamine. From the results of DLLME, the extraction of gold(III) with dibenzylamine and dicyclohexylamine, which gave more than 80% of the extraction, was further investigated using 5 mL of the test solution containing a much lower concentration of gold(III) (10 μg L^{-1}). The extraction of gold(III) was almost 100% with the use of both 50 and 200 mmol L^{-1} of dicyclohexylamine in chloroform, whereas 50 and 200 mmol L^{-1} of dibenzylamine extracted 67% and 88% of gold(III), respectively. These results indicate that dicyclohexylamine is an excellent extractant for DLLME of gold(III). The molecular-structural characteristics, including bulkiness, the strong basicity (pK_a = 10.4 [29]), and the high lipophilicity of dicyclohexylamine may contribute to the effective extraction of gold(III).

3.1.2. Role of acetone on extraction of gold(III) with dicyclohexylamine

In DLLME, a water-miscible organic solvent is used to disperse the water-immiscible organic solvent as an extraction solvent [18–27]. The efficient dispersion of the extraction solvent accelerates the extraction of analytes. In our experiments using acetone as a disperser solvent, however, the extraction efficiency in DLLME using amine compounds was not necessarily improved compared with that in LLE as shown in Fig. 1, which suggests that acetone may also have other functions in the extraction. The role of acetone in the extraction of gold(III) with dicyclohexylamine was therefore examined using the LLE technique.

The effect of the stirring time on the extraction of gold(III) with dicyclohexylamine using 0–10 mL of acetone is shown in Fig. 2. In the absence of acetone, gold(III) was not extracted after stirring for 2 h; the extraction percentages retained almost 0% for at least 24 h. In contrast, the extractability was dramatically improved in the presence of acetone (Fig. 2). When 1–10 mL of acetone was used, the solution became cloudy just after the stirring was started. The extraction percentages increased as the amount of acetone added was increased. In these cases, gold(III) was extracted after 1 min, and the extraction percentages were almost constant when further stirring was carried out (Fig. 2). The extraction of gold(III) was also observed without dicyclohexylamine; the extraction percentages after stirring for 1 h were 0.4% for 4 mL of acetone, 3.1% for 8 mL, and 11% for 10 mL. On the other hand, 68% of gold(III) was extracted even when 1 mL of chloroform containing 200 mmol L^{-1} of dicyclohexylamine was slowly added to a mixture of 50 mL of 0.1 mol L^{-1} hydrochloric acid containing 4 mg L^{-1} of gold(III) and 10 mL of acetone and the mixture was allowed to stand statically

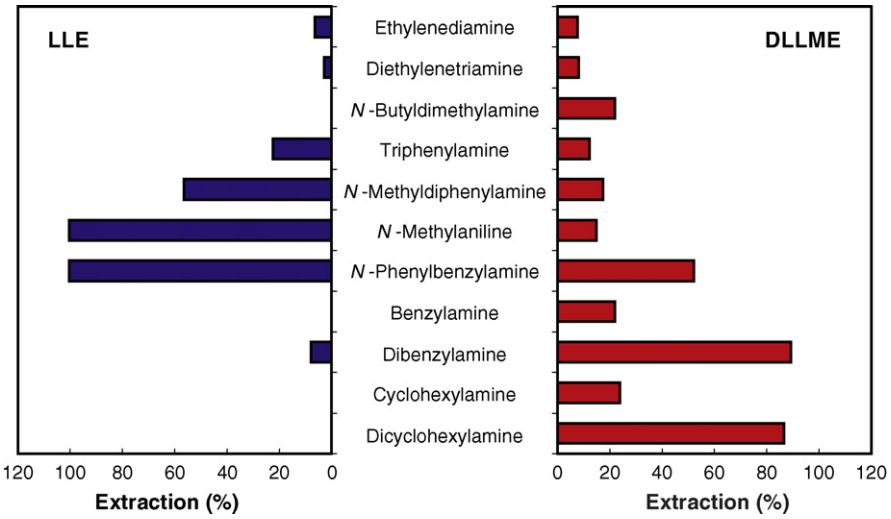

Fig. 1. Extraction of gold(III) with 11 kinds of amine compounds using normal LLE and DLLME techniques. Aqueous phase, 0.1 mol L^{-1} HCl containing 4 mg L^{-1} of Au(III); organic phase, chloroform containing 200 mmol L^{-1} of amine compound. LLE: 50 mL of aqueous phase and 1 mL of organic phase was stirred for 1 h. DLLME: 1 mL of the mixture of 0.90 mL of acetone and 90 μL of organic phase was injected swiftly to 5 mL of aqueous phase, and the cloudy solution was gently shaking for 10 s.

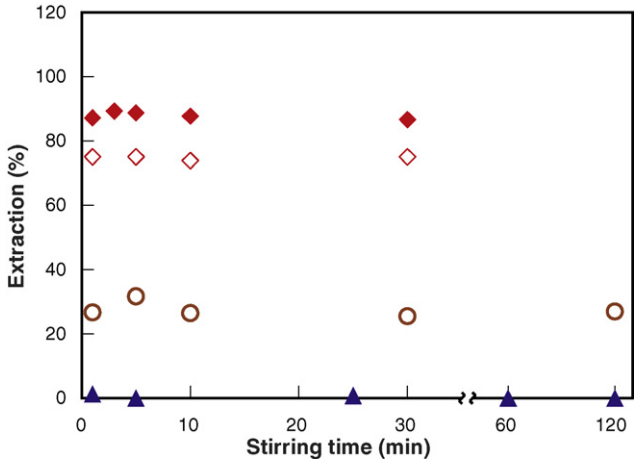

Fig. 2. Extraction percentage of gold(III) as a function of stirring time on LLE. Aqueous phase, 50 mL of 0.1 mol L^{-1} HCl containing 4 mg L^{-1} of Au(III); organic phase, 1 mL of chloroform containing 200 mmol L^{-1} of amine compound. Acetone, 10 mL (♦), 8 mL (◊), 1 mL (○), or not added (▲).

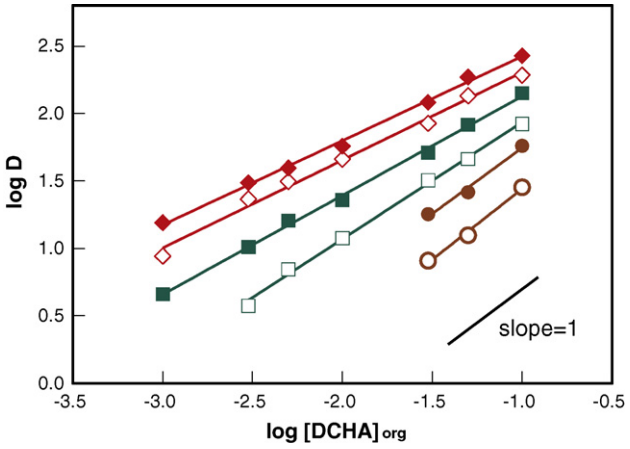

Fig. 3. Relationship between the distribution ratio of gold(III) (D) and the initial concentration of dicyclohexylamine in chloroform ($[DCHA]_{org}$) on LLE using various amounts of acetone. Aqueous phase, 50 mL of 0.1 mol L^{-1} HCl containing 4 mg L^{-1} of Au(III); organic phase, 1 mL of chloroform containing 200 mmol L^{-1} of amine compound. Acetone, 10 mL (♦), 8 mL (◊), 4 mL (■), 3 mL (□), 2 mL (●), 1 mL (○).

for 260 h, whereas the extraction of gold(III) was not observed in the absence of acetone. These results suggest that acetone is not merely the disperser.

It has been reported that in the extraction of some elements with aliphatic tertiary amines [30–32], the extraction percentages were considerably improved by the addition of water-miscible organic solvents, including methanol, ethanol, and acetone, which are generally utilized as disperser solvents in DLLME [18–27]. Such phenomena have been attributed to the decrease in hydration as the mole fraction of water decreased [30–32], resulting in the increased stability of negatively charged chloro-complexes in solution [31]. The enhancement of the extraction percentage is also discussed from the standpoint of the differences in the dielectric constants between the aqueous phase and the organic phase [32]. The contents of water and the water-miscible organic solvent in the organic phase as well as that of the water-miscible organic solvent in the aqueous phase increased as the added amount of water-miscible organic solvent was increased. The difference in the dielectric constants between the aqueous phase and the organic phase was therefore decreased. The decreases in hydration and in the differences in the dielectric constants resulted in the effective extraction of some elements [32]. In the case of the gold(III) extraction with dicyclohexylamine, acetone would play similar roles in addition to acting as a disperser solvent.

When the added amount of acetone increased, the volume of the sedimented phase increased due to the increase in the distribution of acetone and water to chloroform [32]. In our experiment, a similar tendency was observed, but all the volumes of the sedimented phases with various amounts of acetone were less than those of chloroform added. These results indicate that the supernatant phase is a homogeneous ternary solvent mixture containing water, acetone, and chloroform; that is, acetone promotes the dissolution of chloroform into the supernatant phase. The dissolution of chloroform to the supernatant solution and the phase separation arise reversibly, and the separated chloroform is expected to extract gold(III) effectively. Such an extraction, which is inherently similar to HoLLE [13–16], would also take place in DLLME of gold(III) with dicyclohexylamine.

The relationship between the distribution ratio of gold(III) (D) and the initial concentration of dicyclohexylamine in chloroform ($[DCHA]_{org}$) was examined in the presence of 1–10 mL of acetone. The D value was corrected based on the volume of the sedimented phase. As shown in Fig. 3, linear relationships between log D and log $[DCHA]_{org}$ were obtained under all amounts of acetone. The slopes for 1 mL and 2 mL of acetone were 1.05 and 0.98, respectively. These results indicate that the dominant extracted species of gold(III) should be 1:1 for tetrachloroaurate(III) ion:protonated dicyclohexylamine under these conditions. The extraction of gold(III) with dicyclohexylamine may obey the ion-pair mechanism, as it does with the other amine compounds [9–12]. However, the slope gradually decreased with an increase in the amount of acetone, which may have been caused, in part, by a dissociation of the extracted species occurring in the sedimented phase. The variation of the dicyclohexylamine concentration in the sedimented phase and the extraction of gold(III) without dicyclohexylamine would also be possible reasons.

3.2. Optimum conditions for DLLME of gold(III) with dicyclohexylamine

As mentioned above, dicyclohexylamine was useful as an extractant for the DLLME of gold(III). We optimized the conditions for DLLME of gold(III) with dicyclohexylamine using 8 mL of the test solution.

3.2.1. Water-miscible organic solvent

The influence of some water-miscible organic solvents, including acetone, acetonitrile, methanol, and acetic acid, was investigated. As shown in Fig. 4, acetone was the most suitable of the investigated solvents in terms of effective extraction and ease of handling. The extraction percentage of gold(III) increased with an increase in the amount of acetone used, whereas gold(III) was not extracted in the absence of acetone. The quantitative extraction of gold(III) was achieved using 1.0–1.5 mL of acetone. Therefore, 1.0 mL of acetone was used in this method.

3.2.2. Water-immiscible organic solvent as extraction solvent

Chloroform was a convenient extraction solvent in gold(III) extraction using dicyclohexylamine because of the easy dissolution of dicyclohexylamine and the efficient extraction of gold(III). Fig. 5 shows the effect of the volume of chloroform, which contained 50 mmol L^{-1} of dicyclohexylamine, on both the extraction of gold(III) and the volume of the sedimented phase. The extraction percentage of gold(III) increased with an increase in the volume of chloroform and reached approximately 100% when more than 100 μL of chloroform was used. Additionally, the volume of the sedimented phase increased with an increase in the volume of chloroform used, whereas each volume of the sedimented phase after

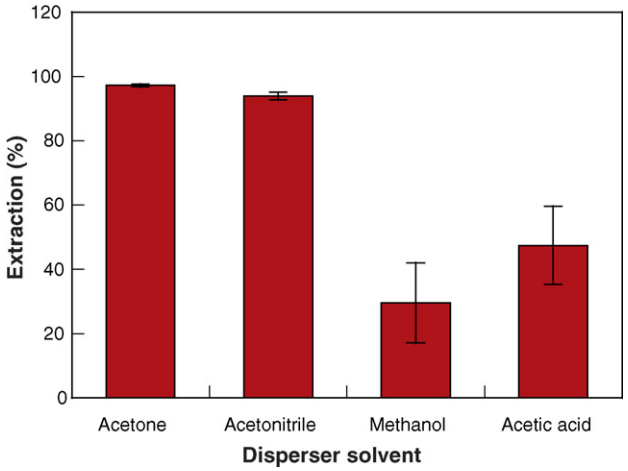

Fig. 4. Effect of some disperser solvents on DLLME of gold(III) with dicyclohexylamine. Aqueous phase, 8 mL of 0.1 mol L^{-1} HCl containing 10 μg L^{-1} of Au(III); mixture solution, 1.0 mL of disperser solvent and 100 μL of chloroform containing 50 mmol L^{-1} of dicyclohexylamine; shaking, 10 s; ultrasonic irradiation, 5 min. The results were shown at mean ± standard deviation (n = 3).

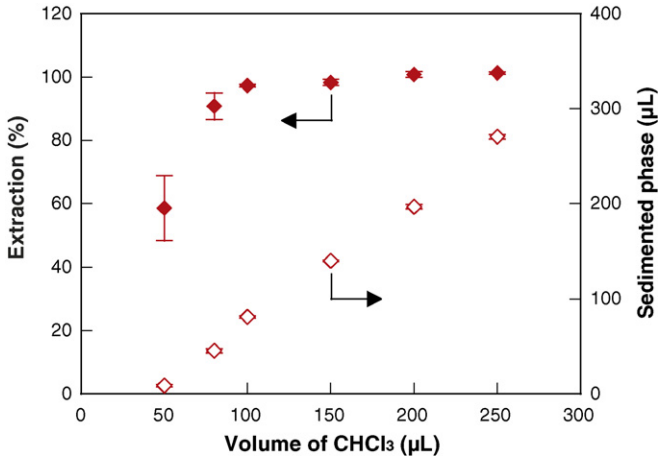

Fig. 5. Effect of volume of chloroform on DLLME of gold(III) with dicyclohexylamine. Aqueous phase, 8 mL of 0.1 mol L^{-1} HCl containing 10 μg L^{-1} of Au(III); mixture solution, 1.0 mL of acetone and 50–250 μL of chloroform containing 50 mmol L^{-1} of dicyclohexylamine; shaking, 10 s; ultrasonic irradiation, 5 min. The results were shown at mean ± standard deviation (n = 3).

the extraction scarcely varied. Due to the quantitative extraction of gold(III) and the high enrichment factor, 100 μL of chloroform was used in this method.

3.2.3. Dicyclohexylamine

When the extraction was carried out using a mixture of acetone and chloroform not containing dicyclohexylamine, 26 ± 2.8% (mean ± standard deviation, n = 3) of gold(III) was extracted. The extraction percentage increased with an increase in the concentration of dicyclohexylamine; more than 90% of gold(III) was extracted with the use of more than 30 mmol L^{-1} of dicyclohexylamine in chloroform. In this method, 50 mmol L^{-1} of dicyclohexylamine was used.

3.2.4. Extraction time

When a mixture of 1.0 mL of acetone and 100 μL of chloroform containing 50 mmol L^{-1} dicyclohexylamine was injected, the extraction percentage of gold(III) was 66 ± 7.1% (n = 3) without shaking due to the insufficient dispersibility of chloroform [19]. However, the extraction percentage of gold(III) was significantly improved to 95 ± 1.6% (n = 3) when the mixture was gently shaken by hand for a few seconds. In this method, ultrasonic irradiation was applied after the gentle shaking for just in case. Since the irradiation time, ranging from 1 to 30 min, did not affect the extraction percentages, ultrasonic irradiation for 5 min was employed. It may be possible to omit the ultrasonic irradiation, depending on the sample.

3.2.5. Extraction pH

The relationship between the extraction percentage of gold(III) and the pH or acidity of the test solution is shown in Fig. 6. In the initial pH range of 1–3, gold(III) was quantitatively extracted. The extraction percentage of gold(III) decreased with an increase in the concentration of hydrochloric acid in the range of 1–3 mol L^{-1}, which might be due to the formation of tetrachloroauric acid ($HAuCl_4$) and/or interference by chloride ions. On the other hand, the extraction percentage also decreased with an increase in the initial pH in the range of 3–7. In this range, the pH in the supernatant phase was significantly shifted to the basic region after the extraction, whereas the pH shift was slight or negligible at an initial pH below 3. The insufficient extraction at an initial pH above 3 would be due to a lack of the protonated form of dicyclohexylamine as well as the ligand displacement of tetrachloroaurate(III) ion in the test solution. In this method, the extraction was carried out using a sample solution adjusted to pH 1.

3.2.6. Selectivity

The extraction of other elements, including iron(III), cobalt(II), nickel(II), copper(II), palladium(II), and platinum(IV), was also investigated at an initial pH range of 1–3 and an acid concentration range of 1–3 mol L^{-1}. Iron(III), cobalt(II), nickel(II), and

[a] Mean ± standard deviation ($n = 3$).

copper(II) were scarcely extracted under the conditions used for the investigation (the obtained results are shown in Fig. 2S in the Supplementary Material). For palladium(II), the extraction was negligible at an initial pH below 1, whereas the formation of the precipitate was observed at an initial pH above 3 (Fig. 2S). Although the extraction percentage of platinum(IV) slightly increased with an increase in acidity in the test solution, platinum(IV) was not extracted at an initial pH of 1–3 (Fig. 2S). These results indicate that DLLME using dicyclohexylamine is quite selective for gold(III). It is known that the extractability of gold(III) is higher than those of palladium(II) and platinum(IV) in the ion-pair extraction of their chloro-complexes [33]. In our experiments, the selectivity might have been emphasized by the use of small amounts of dicyclohexylamine.

3.3. Calibration curve and detection limit

The relationship between the absorbance of gold in the ETAAS measurement and the concentration of gold(III) was investigated. A straight line ($R^2 = 0.996$) was obtained with the use of 8 mL of the test solution containing 0.02–1.0 $\mu g\,L^{-1}$ of gold(III). The enrichment factor, which was calculated based on the slopes for the calibration curves with or without the extraction [25], was 60. The detection limit, defined as three times the standard deviation for the procedural blank ($n = 8$), was 0.002 $\mu g\,L^{-1}$ of gold(III) in 8 mL of sample solution; this value was slightly lower than the detection limit in the combined method with DLLME and ETAAS reported previously [25].

3.4. Interference

The effect of ions generally contained in various water samples on the extraction of gold(III) was investigated. The concentration of the ions (1.1×10^7 $\mu g\,L^{-1}$ of sodium, 4.1×10^5 $\mu g\,L^{-1}$ of potassium, 1.3×10^6 $\mu g\,L^{-1}$ of magnesium, 4.2×10^5 $\mu g\,L^{-1}$ of calcium, 1.6×10^6 $\mu g\,L^{-1}$ of phosphate, and 2.8×10^6 $\mu g\,L^{-1}$ of sulfate) in the test solution used for the investigation was nearly equal to that in seawater [1]. More than 87% of gold(III) was extracted in the presence of large amounts of these ions (Table 1S in the Supplementary Material). The obtained results indicate that the method proposed here is useful for determining gold(III) in various water samples, including effluents.

The effect of excessive amounts of platinum(IV) and copper(II), which were scarcely extracted at an initial pH of 1 (Fig. 2S), was also investigated. Gold(III) was extracted at more than 92% in the presence of 2000 $\mu g\,L^{-1}$ of platinum(IV) and copper(II) (Table 2S in the Supplementary Material). These results indicate that the proposed method is also applicable to the determination of gold as an impurity in platinum metal and alloys containing platinum and copper.

3.5. Application

The method proposed here was applied to the determination of gold(III) in effluents. The obtained results are shown in Table 2. In all of the effluent samples, gold(III) was precisely determined. The gold(III) spiked to the effluent samples was quantitatively recovered, and no significant interference was observed.

The determination of gold in platinum metal and its alloy was also attempted. As shown in Table 3, gold was determined in both samples, and satisfactory results were obtained in the recovery tests.

4. Conclusion

Dicyclohexylamine as an extractant for gold(III) showed excellent performance in DLLME using acetone as a disperser solvent and chloroform as an extraction solvent. The results of the investigation using the LLE technique suggest that acetone used as a disperser solvent in DLLME also contributes to decrease in hydration, decrease in the difference in the dielectric constants between the supernatant phase and the sedimented phase, and dissolution of a part of chloroform as an extraction solvent to the supernatant phase. The extraction of gold(III) in DLLME using dicyclohexylamine is, therefore, quite efficient. Gold(III) can be selectively extracted from a sample solution at pH 1 even in the presence of other elements, such as iron(III), cobalt(II), nickel(II), copper(II), palladium(II), and platinum(IV). The combined method with DLLME and ETAAS can readily determine gold(III) at a sub-$\mu g\,L^{-1}$ level using only 8 mL of the sample solution without interference by the matrices and can be applied to the determination of gold in platinum metal and its alloy as well as effluent. The proposed method should be useful for the analyses of other water samples and the determination of gold in various materials, including metals, alloys, and salts.

ABSTRACT

The porous Cu film was deposited on a Pt/Ti/Si substrate by electrochemical deposition accompanied by hydrogen evolution at very high current densities. CuO films with similar morphologies were obtained by subsequent annealing of the porous copper films. The morphology, composition and structure of the porous Cu and porous CuO were investigated by FE-SEM, EDS and XRD methods. The complete transformation of Cu to CuO after annealing was indicated. The sensing performances of the porous CuO film were evaluated in alkaline solution with the porous CuO film showing a wide linearity range from 1 μM to 2.5 mM with sensitivity of 2.9 mA cm^{-2} mM^{-1}, and detection limit of 0.14 μM. The sensor showed good selectivity to conventional intermediates such as AA and UA and long term stability.

1. Introduction

Research on the development and improvement of existing amperometric glucose sensors has been performed over at least the past 45 years since Clark and Lyons reported on the first enzyme electrode [1]. The majority of known amperometric glucose sensors is based on the immobilization of enzymes, such as glucose oxidase (GO_x), and electrochemical detection of hydrogen peroxide or they are based on the use of redox mediators [2–4]. Even though enzymatic sensors show good sensitivity and excellent selectivity, such sensors suffer from the intrinsic nature of enzymes which results in bad long term stability [2]. To overcome this limitation numerous non-enzymatic sensors were proposed recently. Most of these sensors are based on the utilization of precious metals like bare platinum or gold electrodes [3–6]. However, these electrodes were also not optimal as they showed low sensitivity, poor selectivity and were poisoned by intermediates and chloride [7]. More recently, some of these drawbacks were overcome by taking advantages of special physical and chemical properties of different nanomaterials, such as nanoparticles [8–11], nanowires [12], and nanoporous films [13,14]. When utilizing nanomaterials, it becomes possible to minimize the influence of interferences such as ascorbic acid and uric acid [15]. Nonetheless, low sensitivity and costliness still limits the practical application of many nanomaterials based sensors.

Recently, nanostructured cupric oxide (CuO) was investigated for glucose sensing. Zhuang et al. reported CuO nanowires grown on a copper electrode for glucose detection [16]. The obtained sensor showed very high sensitivity and good stability. However, the synthesis of CuO nanowires was still tedious and involved multiple steps. The instability of copper in air and in the electrolyte may also affect sensing properties of such a sensor. The use of copper (II) oxide nanorod bundles modified basal plane pyrolytic graphite electrode (bppg) toward carbohydrates sensing was also reported [17]. A more robust sensor was prepared by modification of glassy carbon (GC) electrode with Nafion by CuO nanospheres [18]. The analytical performance, mainly sensitivity and response time, is still significantly lower than that of CuO nanowire electrode.

In this paper, we report on a highly sensitive and robust porous CuO glucose sensor fabricated by utilization of porous CuO electrode. Porous CuO electrode was prepared by deposition of porous Cu and subsequent annealing. The analytical performance was investigated by characterizing the sensitivity, detection limit, linearity range, selectivity, and stability of the sensor.

2. Experimental details

2.1. Reagents

Sulfuric acid, hydrochloric acid, copper (II) sulfate pentahydrate, and sodium hydroxide were obtained from Duksan Pure Chemicals (Korea). L-Ascorbic acid (AA), uric acid (UA), and D-(+)-glucose were

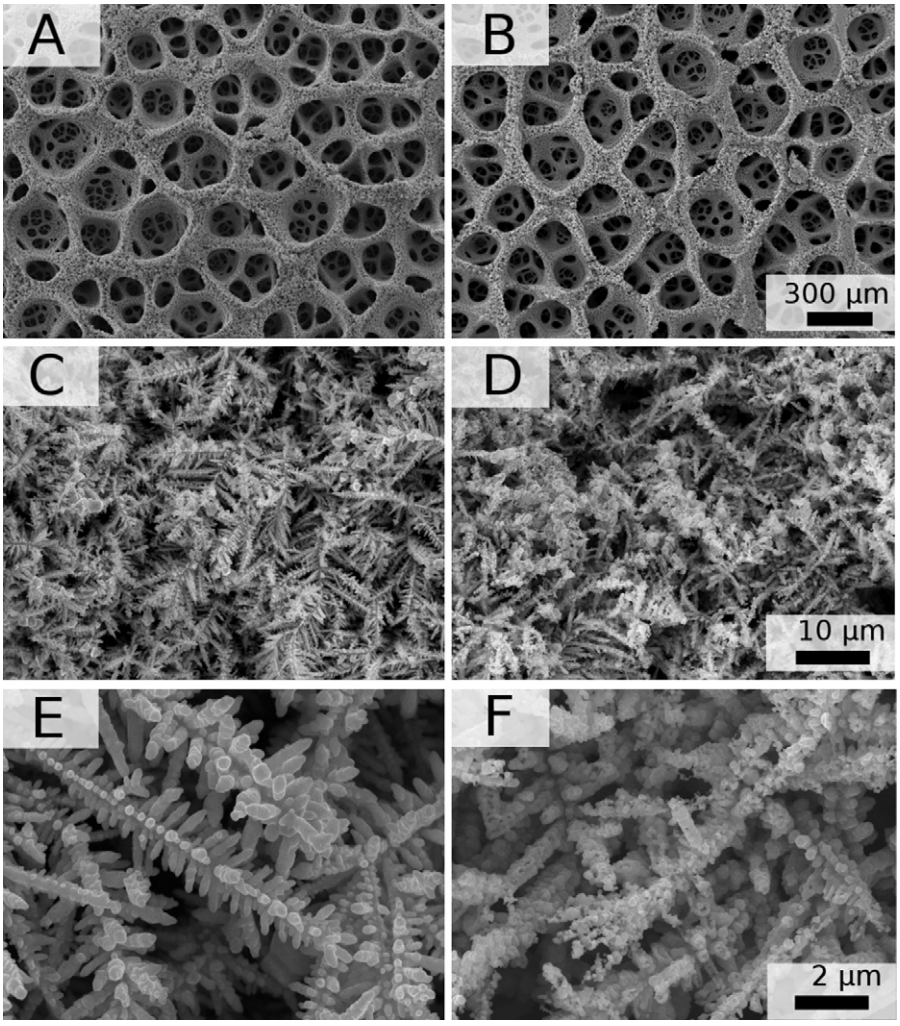

Fig. 1. FE-SEM images of as-deposited porous copper film (A, C, and E) and cupric oxide structures obtained after heating porous copper (B, D, and F) taken with magnifications 60 (A, B), 2000 (C, D), and 15,000 (E, F).

purchased from Sigma–Aldrich. All of the solutions were prepared in deionized (DI) water. All chemicals were used as received.

2.2. Instruments

The electrochemical experiments were performed using an electrochemical workstation (Zahner® Elektrik IM6ex, Germany). Hg/HgO (0.098 V *vs*. NHE) and Pt plate were used as the reference and counter electrodes, respectively. The chemical composition was measured by energy dispersive X-ray analysis (EDS) performed in a field emission scanning electron microscope (FE-SEM) (JEOL JSM-7000F) with which the morphology of the deposited films was also examined. The structural properties were examined by X-ray diffractometry (XRD) (Bruker AXS with Cu Kα radiation at 40 kV and 40 mA).

2.3. Electrode preparation

With a thin 10 nm thick Ti layer used for adhesion, a 200 nm thick Pt thin film was deposited onto a Si (1 0 0) oriented wafer by using electron beam evaporation after which the wafer was diced into 5 mm × 25 mm pieces. To prepare the working electrode, a strip of sticky tape with a hole of 2 mm diameter was put on the surface of Pt/Ti/Si slide, and then the edges and the back side of the slide were covered by insulating varnish. Prior to copper deposition, the slides were electrochemically cleaned in 1 M H_2SO_4 solution by cycling potential in the potential window 0.4–1.6 V *vs*. Hg/HgO. The porous copper films were galvanostatically (current density was controlled as 3 A cm^{-2}) electrodeposited on the tape covered Pt/Ti/Si structure from a solution containing 0.4 M $CuSO_4 \times 5H_2SO_4$, 1.5 M H_2SO_4 and 50 mM HCl [19]. The deposition was performed at room temperature from an unstirred solution for 20 s. After deposition the porous Cu/Pt/Ti/Si substrate (porous Cu electrode) was washed with DI water and dried in nitrogen. Before annealing, the tape and varnish were removed from the slide. Porous CuO was obtained by heating the porous copper at $T = 500\,^{\circ}C$ for 5 h in ambient environment. To eliminate any possible influence of the Pt substrate on the electrochemical experiments, Pt was covered by varnish again

2.4. Electrochemical experiments

All of the electrochemical experiments were carried out at room temperature in a standard three-electrode system. The porous CuO/Pt/Ti/Si electrode (porous CuO electrode) was evaluated as a glucose sensor in 0.1 M NaOH solution. Cyclic voltammetry (CV) measurements were carried out in the potential range of 0–0.8 V *vs*. Hg/HgO. The amperometric curves were obtained after adding the desired amount of glucose with the solution being stirred constantly. The current density in this paper was reported as the ratio

of the recorded current to the geometrical area of the electrode. All potentials are quoted against Hg/HgO reference electrode.

3. Results and discussion

3.1. Preparation and characterization of the porous CuO electrode

The porous Cu films were deposited by hydrogen bubble dynamic synthesis [20]. This technique involves extremely fast electrochemical deposition of metal along with hydrogen evolution at very high cathodic current densities. Previously it was reported that Au substrate which has much lower overpotential for the hydrogen evolution than Cu, should be used to obtain porous structure, where pore sizes of the copper increase with the distance away from the substrate [19]. This type of structure, where big pores are located near the top of an electrode and sub-layers with smaller pores located near the substrate is ideal for sensing of highly active electrochemical species. The main advantage of highly porous film is high surface area. Whereas in most porous films the distribution of pores is uniform resulting in difficulties of the transport of electroactive species to the inner space of the porous film because of the small pores on the top, here that problem is overcome since wide pores at the top allow the species to enter the porous film more efficiently. Recently, Zhuang et al. showed that the oxidation of glucose on CuO nanowires is diffusion controlled [16]. We have come to the same conclusion for the CuO porous film in our experiments (the linear dependence of glucose oxidation peak current on the square root of sweep rate was obtained) (not shown). It means that using porous films with non-uniform pores would result in better efficiency compared to traditional porous films. Following [19] we performed electrodeposition of porous Cu on gold (Au/Si/Ti) substrate. However, after heating at $T = 500\,^{\circ}C$ the thin layer of gold becomes non-conductive, which makes it unsuitable for use as a working electrode in electrochemical experiments. As platinum also has a much lower overpotential for the hydrogen evolution compare to Cu, the Au thin film was replaced by a thin layer of Pt.

Fig. 1(A, C, and E) shows the FE-SEM images of porous Cu film electrodeposited on the Pt/Ti/Si structure taken at different magnifications. It can be seen that the top layer of the porous film consists of pores of about 200–300 μm in diameter and smaller holes could be seen in the inner sub-layers. The walls of the structure are composed of dense ramified deposits (see Fig. 1C and D). The branch size is smaller than 100 nm, which is similar to the porous copper deposited on Au substrate [19]. The porous CuO structures obtained after heating of porous Cu is shown in Fig. 1(B, D, and F). As can be seen by comparing images of porous Cu (Fig. 1A and B) the obtained CuO film retained the structure of the porous Cu template. The entire dense structure was also retained. At high magnification one can see that the nanoscale morphology was slightly different (Fig. 1E and F). The as-deposited films have dendrite structure and consist of branches about 10 μm long with smaller branches of about 1 μm long and 70–100 nm in diameter. Porous branches were formed after the heat treatment. It is believed that the formation of such voids in the branches is due to the Kirkendall effect [21,22].

The X-ray diffraction peaks of as-deposited porous copper and porous CuO are shown in Fig. 2(A). For comparison the standard diffraction patterns for Cu and CuO (JCPDS 004-0836 and 045-0937) are also presented. The as-deposited copper film is indexed as (fcc) phase. It is believed that since copper easily oxidizes in air and more so in this cause due to the very high surface area, the small peak at *ca.* 36° for as-deposited film is from copper oxide. It can be seen that after heating at 500 °C copper is completely converted to pure monoclinic CuO with the lattice constants $a = 4.686$, $b = 3.427$, $c = 5.129$ Å, and $\beta = 99.53°$, which match well the standard XRD

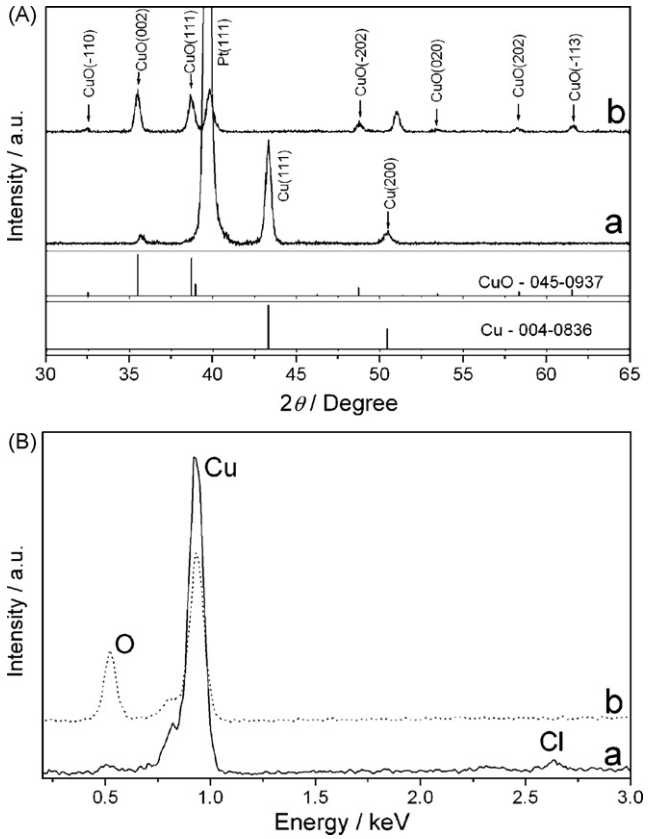

Fig. 2. (A) XRD patterns and (B) EDS spectra of (a) as-deposited porous copper and (b) porous CuO film formed after heat treatment.

data (JCPDS 045-0937). The peak around 51.3° could be indexed as (1 1 2), though the intensity of this peak from the standard polycrystalline sample should be very low. To examine chemical purity and composition of as-deposited and annealed samples, EDS was also performed. Fig. 2(B) shows the EDS spectra of porous films (a) before and (b) after heat treatment.

The as-deposited copper film consists of copper with some traces of oxygen and chlorine and no chlorine was observed after heat treatment. The observed oxygen is likely due to the presence of surface oxides and chlorine is from HCl. The composition of CuO samples was found to be Cu:O = 56.6 ± 0.4:43.4 ± 0.4 (for four samples). The XRD and EDS results confirm that porous Cu was completely transformed to CuO.

3.2. Electrocatalytic oxidation of glucose

Voltammetry in the potential window from 0 V to 0.8 V was used to investigate and compare the catalytic activities of bare platinum film, copper film, and porous CuO electrodes. Fig. 3(A) shows CVs for (a) bare platinum film, (b) copper film, and (c) porous CuO electrodes in a 0.1 M NaOH solution with presence of 2.5 mM of glucose.

It is clear (Fig. 3(A) (a)) that the bare platinum film electrode is not active for glucose oxidation in applied potential window, as only small background current was observed. The typical voltammogram of glucose oxidation on copper was observed when the copper film was used. It should be noted that in alkaline solution the potential of copper oxidation is lower than the onset of glucose oxidation, which means that a thin film of copper oxide was formed and copper oxide instead of copper should be considered. The oxidation of glucose on the copper film electrode starts at approximately 0.35 V with broad peak at around 0.69 V. On the

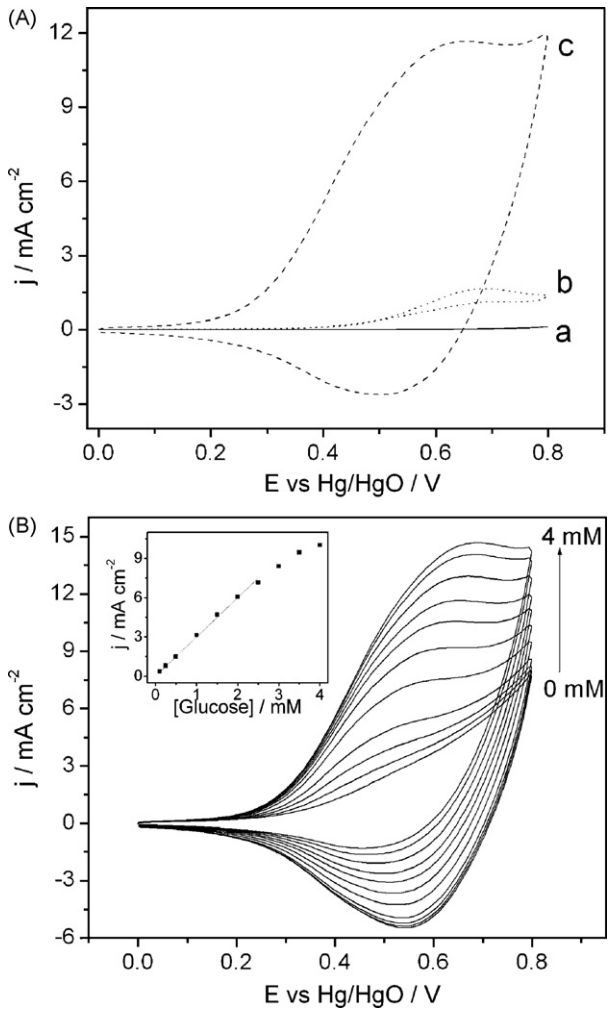

Fig. 3. (A) CVs of (a) bare platinum electrode, (b) bare copper electrode, and (c) porous CuO electrode in the 0.1 M NaOH + 2.5 mM glucose solution. (B) Shows the voltammetric response of a porous CuO electrode to the addition of 0.1 mM, 0.15 mM, 0. 25 mM, and subsequent addition of 0.5 mM of glucose until total concentration of 4 mM was obtained. Inset shows the dependence of the current at $E = 0.65$ V on the concentration of glucose. The scan rate was 50 mV/s.

other hand, the oxidation of glucose on a porous CuO electrode commences at more negative potential *ca.* 0.2 V with peak at around 0.64 V, indicating the enhanced catalytic properties of porous CuO electrode toward oxidation of glucose.

The concentration dependence of electrochemical activity of porous CuO electrode toward oxidation of glucose was also studied. Fig. 3(B) presents the CVs of the porous CuO electrode recorded in 0.1 M NaOH electrolyte in the absence of glucose and in presence of 0.1 mM, 0.25 mM, 0.5 mM and so on until 4 mM with successive addition of 0.5 mM. The increase of glucose concentration produces the gradual increase of current around 0.65 V. The current at chosen voltage of 0.65 V was found to be linear in the range of 0.1–2.5 mM with the correlation coefficient of 0.998 (Fig. 3(B) inset). This linear dependence can be used for calibration in analytical application of porous cupric oxide electrode.

3.3. Amperometric sensing of glucose

To find the optimal conditions for the amperometric sensing of glucose, the effect of applied potential on the response current of the sensor was investigated. Fig. 4 shows the amperometric curves of cupric oxide electrode in 0.1 M NaOH solution with successive addition of 0.5 mM glucose at applied potentials of 0.55–0.7 V. In the range of 0.55–0.65 V the oxidation current of glucose increased with increasing potential. With increasing potential further the side reaction takes place on the electrode, which results in the increase of the background current and leads to the inhibition of glucose oxidation. Thus a constant potential of 0.65 V was chosen for further amperometric investigations.

Fig. 5(A) illustrates typical amperometric responses to successive addition of glucose concentration indicated. The lower right inset shows the increased section of amperometric curve after addition of low concentration of glucose. The upper left inset presents a typical current–time curve of cupric oxide electrode under successive injections of 10 μM of glucose. The corresponding dependence of oxidation current on the concentration of glucose is shown in Fig. 5(B). The oxidation current increased with each addition of glucose until saturation at concentrations higher than 20 mM was observed. For comparison the dependence of oxidation current on the concentration of glucose for platinum film electrode is also presented. It can be seen that platinum is not active for glucose oxidation. The inset shows the calibration curve of glucose oxidation on the porous cupric oxide electrode in the concentration range of 1 μM to 2.5 mM. One can see that oxidation current linearly increases in this range of concentrations

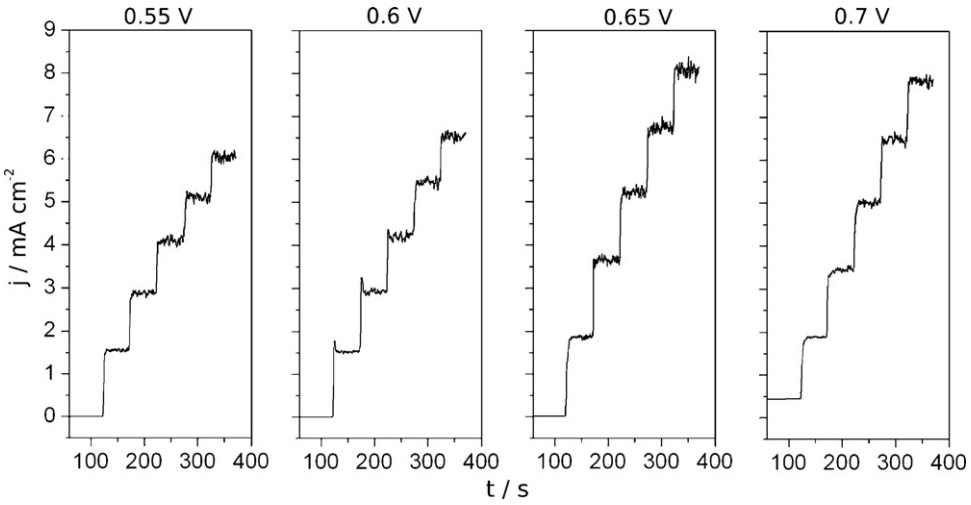

Fig. 4. Amperometric response of a porous CuO electrode with successive addition of 0.5 mM glucose to 0.1 M NaOH at different applied potentials.

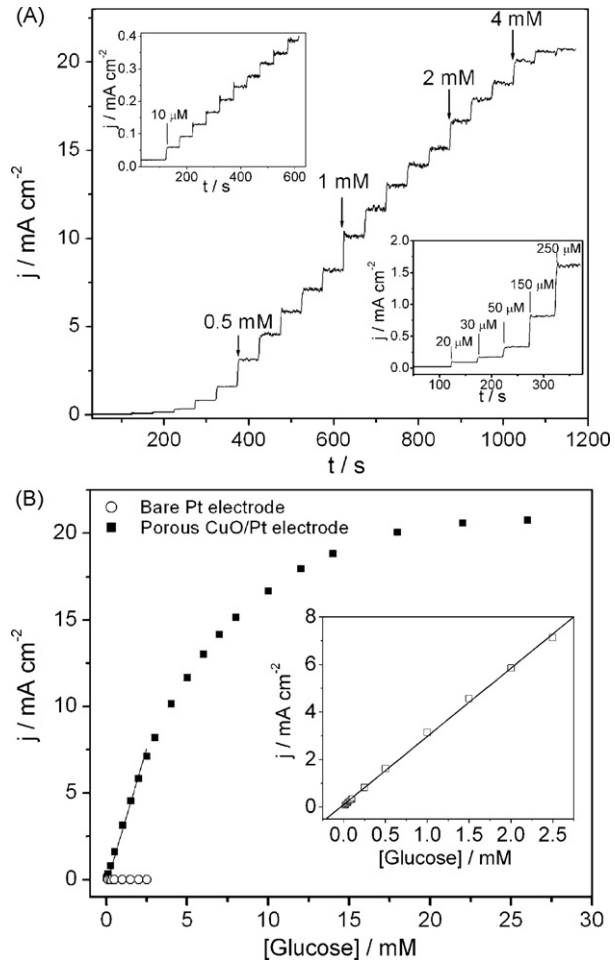

Fig. 5. (A) Amperometric response of a porous CuO electrode at 0.65 V on the addition of glucose indicated. The lower right inset shows the magnified view of the amperometric response at low concentrations of glucose. The upper left inset shows the response of a porous CuO electrode to successive addition of 10 μM glucose. (B) The calibration curve of the porous CuO electrode toward glucose. Inset—the linear range of the calibration curve.

with correlation coefficient 0.999. The sensitivity of porous CuO electrode is 2.9 mA cm^{-2} mM^{-1}, which is higher than 0.4 and similar to 2.45 mA cm^{-2} mM^{-1} for CuO nanospheres [18] and CuO nanowires [16] electrodes, respectively. Also the sensitivity of porous CuO electrode is significantly higher than that of other glucose sensors based on the use of precious metal nanomaterials [8,12,13,15,23–26] and enzymes [27–32]. The important analytical performances of our porous CuO electrode were compared with other Cu or Cu oxide based sensors as summarized in Table 1. As one can see the porous CuO electrode shows the highest sensitivity. The high sensitivity for this CuO electrode can be attributed to the high surface area of the electrode and high efficiency of the electrode morphology. A detection limit of 1.4×10^{-7} M was obtained

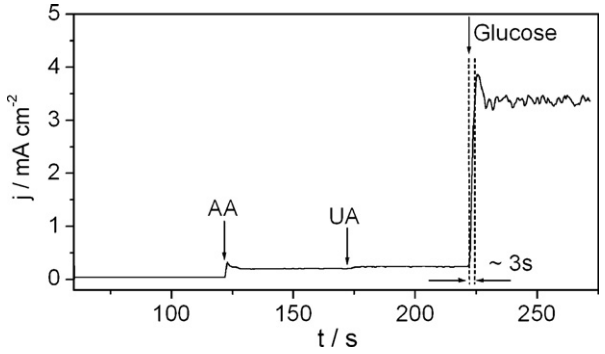

Fig. 6. Current–time profile of a porous CuO electrode with addition of 0.05 mM AA, 0.1 mM UA, and 1 mM glucose.

(detection limit (*dl*) was calculated as $dl = 3\sigma_b/m$, where σ_b is the standard deviation of the background current, and m the slope of the linear part of the calibration curve [30]).

3.4. Selectivity and response time

It was reported that the presence of chloride ions in the solution can significantly affect the glucose oxidation [18]. To investigate this, voltammetric and amperometric response to 0.5 mM of glucose in 0.1 M NaOH with presence and absence of 0.15 M NaCl was also investigated (data not shown). The change of both voltammetric and amperometric responses was found to be negligible in the presence of chloride, indicating the tolerance of CuO electrode to the presence of chloride ions in the solution.

It is also well known that the non-enzymatic sensor usually suffers from the interfering species, such as AA and UA. The normal physiological level of glucose is 3–8 mM and that of AA and UA is about 0.1 mM [16]. However, usually due to the high electron transfer rate, the interference oxidation current can be comparable with the one of glucose oxidation. Therefore, the selectivity of the porous CuO electrode was investigated against AA and UA. Fig. 6 presents amperometric curve for the porous CuO electrode in 0.1 M NaOH with successive additions of 0.05 mM AA, 0.1 mM UA, and 1 mM glucose. The defined concentrations were chosen to compare obtained data with results obtained on the CuO nanowrires and CuO nanospheres electrodes [16,18]. By setting the current density of the porous CuO electrode to 1 mM glucose at 100%, the response to the addition of 0.05 mM AA, and 0.1 mM UA was 5.1% and 1.1%, respectively. The obtained selectivity is even better than that found for the CuO nanospheres electrode, where Nafion, which sometimes is utilized for improvements of selectivity, was used. A similar result was observed when the opposite sequence (glucose, UA, and AA) was used (not shown). This result demonstrates that amperometric detection of glucose on the porous CuO electrode can be performed with negligible interference from AA, and UA.

Also, the ability of the glucose sensing in real blood serum samples was evaluated. Here 0.4 mL of serum samples were added

Table 1
Comparison of the performance of the porous CuO glucose sensor with that of reported glucose sensors base on utilization of Cu or Cu oxide in NaOH solution.

Electrode materials	Reference electrode	Potential (V)	Sensitivity (mA cm^{-2} mM^{-1})	Dynamic range (M)	Detection limit (M)	References
DMG-CuNPs	SCE	0.65	0.7	1.0×10^{-6} to 5.0×10^{-3}	5.0×10^{-7}	[35]
CuO NWs	Ag/AgCl	0.33	2.45	4.0×10^{-7} to 2.0×10^{-3}	4.9×10^{-8}	[16]

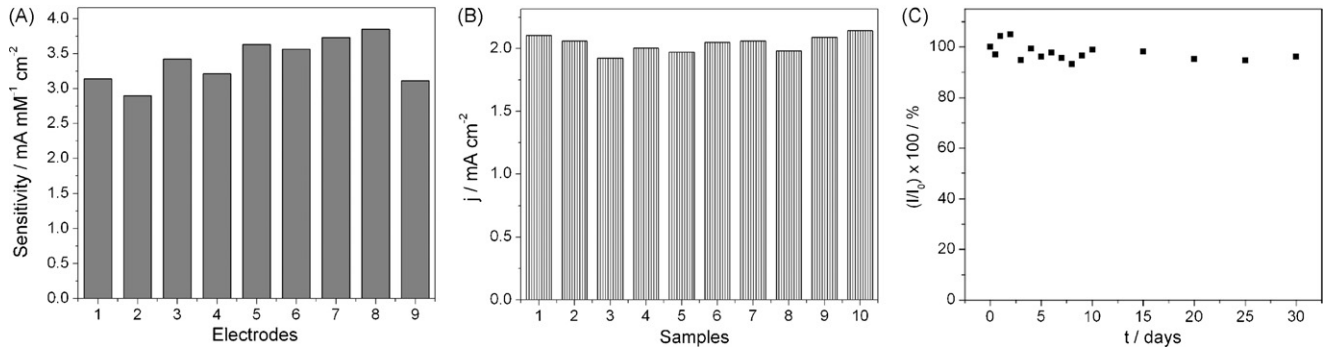

Fig. 7. (A) Sensitivity values measured on nine different porous CuO electrodes in glucose concentration range 0.5–2.5 mM. (B) The amperometric response of one porous CuO electrodes to ten 0.5 mM glucose samples. (C) The variation of amperometric response taken over 1 month of a CuO electrode to addition of 0.5 mM glucose.

to 10 mL of 0.1 M NaOH solution and the amperometric response was recorded at 0.65 V. According to the calibration curve the current response corresponded to the glucose concentration around 6.5 mM. The hospital analysis, however, showed that the glucose level in the blood sample was 4.6 mM. This result demonstrates that beside the interference from the AA and UA there are, probably, other compounds that have to be taken into account. It is of interest that when CuO nanowires [16] or copper nanocluster/multiwall carbon nanotube [33] modified electrodes were used for the detection of glucose the deviation between experimentally and clinically obtained data was small. So far the exact reason of the unexpected high oxidation currents obtained on the CuO porous electrode when blood serum was added is not clear, however, we believe that it is related to the high surface area of the CuO porous electrode. Thus, the kinetics of glucose oxidation on CuO was estimated as described below.

Even though the exact mechanism of glucose oxidation on the CuO is not clearly known [16,33] it can be proposed that the kinetics of this process is faster than the oxidation of glucose on precious metals, as it was found that this process is diffusion controlled (described above). In the case of precious metals high roughness electrodes were proposed which resulted in an increase of the response of sluggish oxidation of glucose [12,15]. This reaction is proportional to the real surface area of the electrode. On the other hand, fast oxidation of intermediates such as AA takes place on the outer surface of electrode and is thus proportional to the geometrical area of the electrode. In the case of CuO electrode, however, the kinetics of glucose and AA oxidation are probably different. To study this, the kinetics for glucose, AA, and UA oxidation on a porous CuO electrode were determined by the Tafel plots. The Tafel slopes were obtained as about 120 mV dec^{-1}, 190 mV dec^{-1}, and 260 mV dec^{-1} for glucose, AA, and UA, respectively. The results show that the reaction activity of glucose oxidation on a porous CuO electrode is higher than that for AA and UA. Also, from the kinetic theory of electrode reaction, the value of Tafel slope about 118 mV dec^{-1} for glucose oxidation on porous CuO electrodes indicates that a single electron exchange is involved in the rate-determining step (assuming a transfer coefficient of $\alpha = 0.5$). Assuming that the glucose oxidation mechanism is similar with the one described by Fleischmann et al. [34], the abstraction of hydrogen atom from the α-carbon with electron transfer to the electrode is most likely to be the rate-determining step of glucose oxidation.

We can conclude that due to the high activity of glucose oxidation on CuO the area of porous electrode could be involved in this reaction only partially. On the other hand for the oxidation of intermediate compounds with sluggish reaction activity the efficiency of utilization of whole surface area is higher. This is probably the reason of higher responses obtained for real blood samples. Additional experiments are needed to find the role of blood components in the CuO sensor response.

The response time defined as 95% of the response current density was within 3 s (see Fig. 6), which is smaller than the response time for most glucose sensors.

3.5. Reproducibility and stability

The reproducibility and stability of the amperometric glucose sensor were also evaluated. The sensitivity for nine porous CuO electrodes in the glucose concentration range of 0.5–2.5 mM was measured (Fig. 7(A)). The relative standard deviation (RSD) was 15.45%, which is relatively high. The mean value of sensitivity was 3.43 ± 0.53 mA cm^{-2} mM^{-1}. The high value of RSD can be related to the dendrite nature of the growth. It is believed that sensitivity is strongly dependent on the morphology of porous electrode at the nanoscale. By analyzing porous Cu and porous CuO films by FE-SEM we found that the sizes of smallest branches vary in size at different electrodes. Probably this is why we obtained slight deviation between different electrodes. Further investigations on the optimization of deposition conditions are needed to improve the reproducibility.

Ten successive measurements of current density response to the addition of 0.5 mM of glucose at one chosen porous CuO electrode yielded an RSD of 3.35%, demonstrating that the porous CuO sensor is stable and suitable for repeated detection of glucose (Fig. 7(B)). The long term stability was investigated by measuring the response to 0.5 mM glucose over 1 month. The sensor was stored in air and was tested each day for 10 days and every fifth day over the next 20 days. Fig. 7(C) shows the variation of current during the investigation. For convenience the response on the first day was set to 100%. The results demonstrate that the response was almost the same over the entire investigation period, implying that the electrode can be used in long term routine applications. It is worthy to mention that even after 6 months of storage in air the response of the sensors did not change. The good reproducibility and long term stability of porous CuO electrode can be attributed to both the good stability of CuO in the alkaline solution [18] and good stability of the porous structure itself.

4. Conclusions

In this paper the porous CuO film was prepared by a simple method, comprised electrochemical deposition of Cu on Pt/Ti/Si substrate and subsequent annealing in air. The porous CuO film was evaluated as a glucose sensor. The prepared sensor shows excellent analytical performances including robustness, high sensitivity, wide range of linearity, low detection limit, good selectivity and stability and can be reliably used for the detection of glucose in analytical purposes. Due to the high efficiency of the electrode morphology the highest sensitivity among non-enzymatic sensors based on Cu or CuO was achieved. Moreover, the sensor preparation

technique is very simple and can be easily arranged for the mass production. We believe that the proposed technique can be used for the preparation of other metal oxide based electrochemical sensors

Derivative
Monolith

ABSTRACT

Based on combination of chiral recognition ability of β-cyclodextrin (β-CD) derivatives and flexibility of monolithic material, a series of chiral stationary phases (CSPs) were prepared by the immobilization of β-CD and three of its derivatives to the epoxy-activated poly(glycidyl methacrylate-co-ethylene dimethacrylate) monolith under mild condition. Immobilization condition for the connection reaction by different functional groups and bonding ways was studied to obtain good enantiomer selectivity. Prepared CSPs were evaluated by separating racemic mixtures of eight amino acids and two chiral drugs with capillary electrochromatography (CEC).

1. Introduction

Chiral separation comprises one of the most attractive tasks of modern day chemistry because of the quintessential nature of life [1]. The development of life science, modern pharmaceutical industry, and asymmetric synthesis raises more requests for chiral recognition and separation.

Chromatographic technique has proven to be one of the best methods for the direct separation and analysis of enantiomers. Chiral stationary phases based on proteins, cyclodextrins, cellulose derivatives and macrocyclic antibiotics are widely used in the separation of chiral compounds [2,3]. Native cyclodextrins (α, β, and γ-CD) and modified cyclodextrins (CDs) are classical chiral selectors which were first employed in 1982 [4] as mobile phase additives in high performance liquid chromatography (HPLC). The hydroxyl groups of CDs can be functionalized with hydrophobic or hydrophilic groups to further enhance complex forming ability and selectivity towards certain analytes. Shortly after, the versatility of CDs as chiral selectors in chromatography was exploited in different electromigration methods. CDs and their derivatives have already been used in many electroseparation modes [5–25] such as capillary zone electrophoresis (CZE) [5,6], capillary gel electrophoresis (CGE) [7], isotachophoresis (ITP) [8], micellar electrokinetic chromatography (MEKC) [9] and capillary electrochromatography (CEC) [10].

CEC, a hybrid method of capillary electrophoresis (CE) and HPLC, has received considerable attention in recent years and has evolved as a powerful technique in the analysis of enantiomers. For the first time, Mayer and Schurig [10] separated enantiomers by opentube-capillary electrochromatography (o-CEC) using capillaries coated with a polydimethylsiloxane (PDMS) bound permethylated CD (Chirasil-Dex). In particle packed CEC, CDs are employed either as a mobile phase additive or are directly bonded to the packing material. Immobilized CDs and their various neutral, positively or negatively charged derivatives become suitable chiral selectors in CEC.

The monolithic stationary phase [11,12], has attracted increasing attention because of its easy preparation, excellent properties and high performance for chiral separation. The monolithic stationary phase is directly bonded to the inner wall of the capillary, and no supporting frits are necessary. In addition, the pore structure of the monolith could be easily controlled through adjusting the composition of reaction mixture to ensure good permeability. A further improvement was achieved by utilizing CDs as chiral selectors in monolithic stationary phases [13] as it was described earlier for HPLC [14].

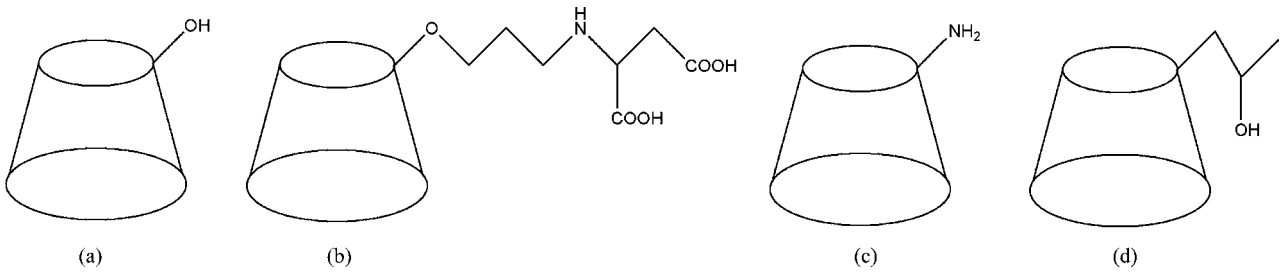

Fig. 1. Structure of derivatives of β-CD. (a) β-CD; (b) Asp-β-CD; (c) NH_2-β-CD; (d) HP-β-CD.

Organic polymeric monolithic material [15–24] possessing a bimodal structure, large through pores, and small diffusion pores has benefits of good permeability, a fast mass transfer property, a strong enrichment capability, high stability and ease of modification, which can be widely used as the stationary phase for CEC and microcolumn HPLC (m-HPLC). The chiral selectors can be immobilized by grafting through polymerization [15–21] or copolymerized [22–24]. Polyrotaxane [15], polyacrylic [19], poly(cyclopentadiylvinylene) [20], polymethacrylate [15,18,21–23] and polyacrylamides [16,17,24] polymer monolith were employed to immobilize CD for chiral recognition. In previous researches of monolithic column with CDs as chiral selectors, only few of modified β-CDs were coated onto the monolith matrix by reaction of hydroxy group. The advantages of β-CD derivatives, such as multi-functional group, diversified chiral selectivity, have not been fully utilized to extend application range.

Based on combination of chiral recognition ability of β-CD derivatives and flexibility of monolithic material, organic polymer chiral monolith poly(glycidyl methacrylate-co-ethylene dimethacrylate) was prepared by chemical grafting of the β-CD and series of its derivatives to surface of monoliths by different functional groups through direct or indirect bonding ways. Aspartate-β-CD, a new β-CD derivative, was immobilized to stationary phase as chiral selector. The synthesis conditions were investigated carefully. The novel monolithic CSP was evaluated by the separation of several racemic drugs and amino acids in CEC modes.

2. Materials and methods

2.1. Chemicals and materials

Glycidyl methacrylate (GMA), ethylene dimethacrylate (EDMA), γ-methacryloxypropyltrimethoxysilane (γ-MAPS), and cyclohexanol, 1-dodeanol and azobisisobutyronitrile (AIBN) were ordered from Acros Chemical Co. (NJ, USA). Deionised water (18 MΩ) was prepared using a CLEAR SG system (Barsbüttel, Germany). β-CD was ordered from Tianjin Kermel chemical reagents development centre (Tianjin, China). NH_2-β-CD and hydroxypropyl-β-CD (HP-β-CD) were synthesized according to the procedures described in Refs. [25,26]. Aspartate-β-CD (Asp-β-CD) was designed and synthesized firstly in our previous research [27]. Fig. 1 shows the structure of β-CD and its derivatives. All the other reagents used in experiments were of chromatographic grade.

Fused silica capillaries with 75 μm I.D. and 375 μm O.D. were purchased from Yongnian Optical Fiber Factory (Hebei, China).

The C_{18} solid-phase extraction column was conditioned with 3 ml methanol followed by 3 ml distilled water. 0.1 M NaOH solution (0.1 ml) was added to 1.0 ml human plasma sample including mexiletine, then vortex-mixed. The treated sample, after centrifugation (10 min, 4000 r/min), was applied to the column and adjusted the flow rate about 1 ml/min. The column was then washed with 2 ml hexane and 2 ml ether, respectively. The ether-eluent was collected in test-tube, then was blow-dried by nitrogen gas in 60 °C water bath. The residue was resolved in pH 4.5 buffer (0.5 ml, 5 mM), then filtered by 0.45 μm millipore filter after 10 min ultrasonic extraction for injected.

2.2. Instrumentation

Electrophoresis experiments were performed on Agilent CE instrument equipped with ultraviolet detector set at 200 nm (CA, USA). An HPLC pump, Elite P200 (Dalian, China) was used to flush the columns during the preparation. Scanning electron microscope, S-4300 (Hitachi, Japan), was adopted to observe the structure of the monolithic stationary phase. IR spectrometer (SpectrumOne, PE Co., USA) was used to verify the connections of chiral selectors.

2.3. Preparation of monolithic columns

The capillary was washed in turn by 0.1 M HCl and 0.1 M NaOH for 30 min, respectively. After the subsequent flushing by H_2O for 10 min, it was dried by nitrogen gas. A solution of 50% (v/v) γ-MAPS dissolved in acetone was prepared and purged with nitrogen for 10 min. The capillary was then washed with 10-column-volume of the solution. Thereafter, the capillary was placed at room temperature for 24 h with both ends sealed. Finally, the capillary was washed with acetone to remove the residual reagents and dried by a nitrogen stream. Thus, the inner wall of the capillary was modified by a layer of γ-MAPS.

The mixture of EDMA (0.12 g), GMA (0.18 g), cyclohexanol (0.405 g) and 1-dodeanol (0.045 g) were prepared with AIBN (1 wt% with respect to the monomers) in it. The homogeneous mixtures were purged with nitrogen for 10 min. After that, the mixture was introduced into a modified capillary to a length of 25 cm with another 8.5 cm empty. Then with both ends sealed, the capillary was heated at 40 °C by water bath for 12 h. After the polymerization, the column was washed by ethanol and water in turn.

2.4. Immobilization of derivatives of β-CD having amino group

2.4.1. Direct chemical bonding

The monolithic column was filled with solution of NH_2-β-CD (0.1 g/ml) or Asp-β-CD (0.03 g/ml) containing 0.1 M Na_2CO_3 (pH 10.5). With both ends of the capillary sealed, the capillary was heated at 60 °C by water bath for 16 h to bond derivatives of β-CD to epoxy group. Scheme of chemical bonding procedure was shown in Fig. 2(a).

2.4.2. Indirect chemical bonding by glutaraldehyde spacer

The bare monolithic column was filled with 1 M $NH_3{\cdot}H_2O$ for 6 h at 60 °C to open the epoxy group. After that, the column was washed by water to remove excessive $NH_3{\cdot}H_2O$. Then the column was filled with 10% glutaraldehyde solution for 12 h at room temperature to bond aldehyde group with amino group. After washing

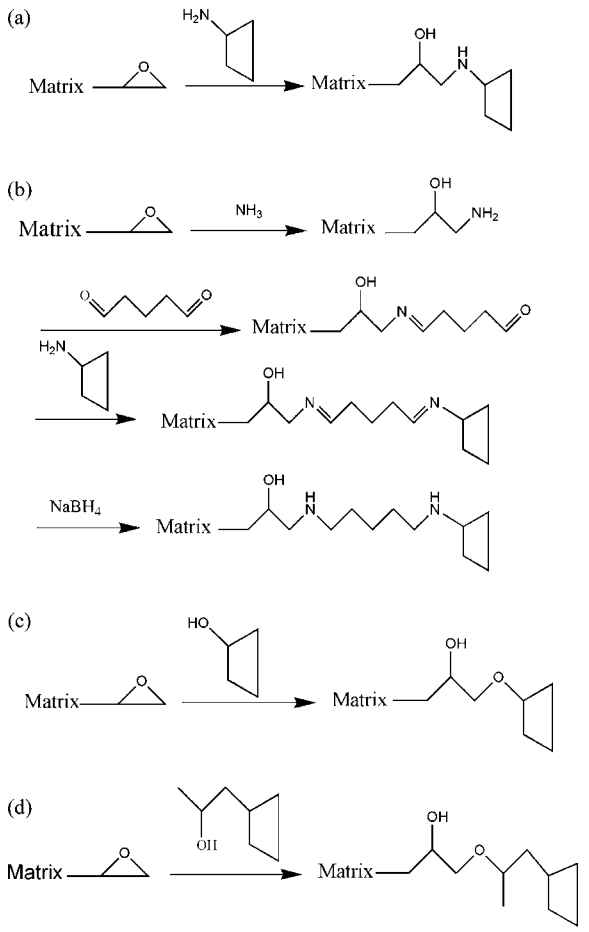

Fig. 2. Scheme of chemical bonding procedure. (a) Direct bonding by amino group, (b) indirect bonding by amino group, (c) bonding with β-CD, and (d) bonding with HP-β-CD.

with water to remove glutaraldehyde residual, the capillary was eluted by solution of derived β-CD (NH_2-β-CD 0.1 g/ml or Asp-β-CD 0.03 g/ml) at least 12 h to bond derivatives of β-CD to glutaraldehyde. Afterwards, the column was washed by water to remove residual of reactants. 2% $NaBH_4$ phosphate solution (pH 8.2) was used to reduce double bond C=N to single bond C–N. Scheme of chemical bonding procedure was shown in Fig. 2(b).

2.5. Immobilization of β-CD and its derivatives by hydroxyl

The monolith was flushed by solution of β-CD or HP-β-CD (both 60 mg/ml) containing 3.5% M NaOH slowly for 16 h to bond β-CD to epoxy group. Afterwards, the column was washed by water to remove residual of reactants. Scheme of chemical bonding procedure was shown in Fig. 2(c and d).

2.6. CEC procedure

After reaction, the column was washed by water to remove the residual of reactants. A detection window was later made by removing the outer coat of capillary with a razor. The monolithic chiral column was equilibrated by buffer for 30 min. The capillary column was installed on the CE instrument and equilibrated by applying a potential difference of 10 kV until the current was stable (about 7 mA). UV absorption wavelength was set at 200 nm. The mobile phase was 5 mM phosphate buffer or acetate buffer (pH 3.5–8.5). Voltage −10 kV was applied to the columns fabricated with NH_2-β-CD and Asp-β-CD. +10 kV was applied to the columns fabricated with β-CD and HP-β-CD. Electrokinetic injections were made at ±2 kV for 2 s.

Immobilization conditions.

	Bonding way	Temperature (°C)	Reaction time (h)	Concentration (mg/ml)
NH_2-β-CD	Direct	60	16	30
	Indirect	Room temperature	12	30
Asp-β-CD	Direct	60	16	100
	Indirect	Room temperature	12	100
β-CD	Direct	Room temperature	16	60
HP-β-CD	Direct	Room temperature	16	60

3. Results and discussion

3.1. Preparation and optimization of chiral monolithic column with β-CD and its derivatives

A number of factors could control the immobilization rate and efficiency including the temperature of reaction and concentration of reactants, pH, solvent nature and reaction time. The concentrations of reactants, reaction time and temperature were found to be the determining factors in the preparation of chiral stationary phase. The optimized reaction conditions are listed in Table 1.

3.1.1. Direct and indirect immobilization

The immobilization could be carried out either by direct or indirect ways. The spacer glutaraldehyde could help to overcome the steric hindrance effect and provide other possibility to chemical bond functionalized chiral selectors. According to our experiments, there were no significant differences between the CSPs prepared by glutaraldehyde spacer and direct grafting. Both of the chiral columns could accomplish separation of enantiomers. In addition, indirect immobilization procedure was performed at room temperature, which is beneficial to stability of monolithic matrix.

3.1.2. Influence of reaction temperature

The temperature is important for the direct immobilization of derivatives of β-CD by amino group because that high temperature can improve the reaction of amino group and epoxy group. We grafted the NH_2-β-CD and Asp-β-CD to bare monolith at four different temperatures, room temperature, 50 °C, 60 °C and 70 °C. The CSP prepared at room temperature showed no chiral separation ability at all. At the other three conditions, all the stationary phases can easily accomplish separation of D,L-phenylalanine. But, better symmetry of peaks and separation efficiency was achieved by the monolithic column prepared at 60 °C. Higher temperature may cause the deconstruction of polymer matrix. Mild reaction condition is preferred to acquire better long-term stability.

Although hydroxy is weaker nucleophilic reagent than amino group, the immobilization by hydroxy was performed well at room temperature in our experiments. When indirect chemical bonding by amino group was employed, the grafting was implemented by reaction of aldehyde group with amino group which could be performed well enough at room temperature.

3.1.3. Optimization of reaction time

Reaction time can also affect the immobilization. When the reaction time is not long enough, the immobilization quantities of β-CD and its derivatives were not sufficient for the chiral separation. Meanwhile, longer reaction time might cause the converse disconnection of functional groups at high temperatures. In case of the immobilization of derivatives of β-CD by amino group, 16 h is the optimized reaction condition compared to 14 h and 18 h. For

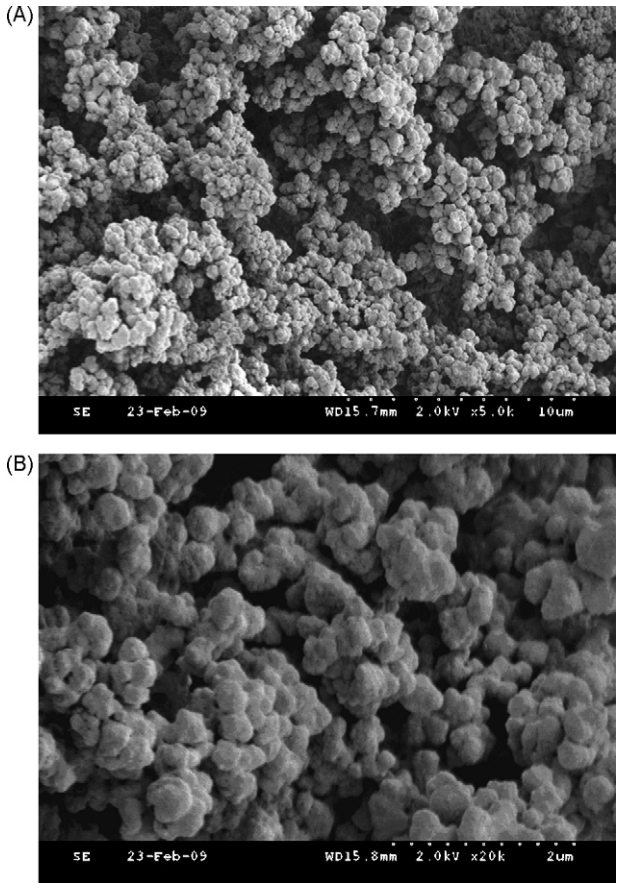

Fig. 3. Electron micrograph scanning of the monolith. (a) 5000× and (b) 20,000×.

indirectly chemical bonding, 12 h were found sufficient for reaction of aldehyde group and amino group.

Considering immobilization quantity of β-CD by hydroxy and time consume, 16 h showed the best immobilization effect. Both β-CD and HP-β-CD can be grafted to monolith matrix successfully to achieve chiral separation ability with 16 h reactions at room temperature.

3.1.4. Effect of concentration of reactant solution

The concentration of reactants solution can affect the immobilization significantly. Higher concentrations of β-CD amino derivatives will improve their nucleophilic attack ability by increasing the density of reactants. When the concentration reaches close to saturation, the derivatives incline to separate out from the solution and block the pore of monolithic column. Three concentrations were investigated to select optimized concentration of reactants. The highest concentrations in both the derivatives (Asp-β-CD, 0.03 g/ml; NH_2-β-CD, 0.10 g/ml) are close to the saturation concentration. In following experiments, they were chosen as the optimized conditions for Asp-β-CD and NH_2-β-CD for both direct and indirect bonding, respectively.

The separation results of columns immobilized β-CD and HP-β-CD showed that concentrations higher than 60 mg/ml could get maximum immobilization quantity. Further increase in concentration of β-CD and HP-β-CD would cause higher solution viscosity which leads to the poor permeability during the grafting.

3.2. Characterization of chiral monolith

3.2.1. Structure of monolithic stationary phase

SEM was used to study the morphology of the monolithic stationary phases. Short lengths of the capillary columns were sectioned and sputtered with gold for observing the cross-section of the monolithic columns. The scanning electron micrograph shown in Fig. 3 reveals the structure of chiral monolithic stationary phase, which forms a dense network of polymer bundles that are highly convoluted. The pore size distribution of the monolith is characterized by mercury intrusion porosimeter. It could be seen that rather large pores are formed (Fig. 4). By measurement, the total pore volume of the porous polymer is 1.65 cm^3/g, and the specific surface area is 64 m^2/g. According to the pore size distribution curve, the pores radius smaller than 150 nm represent 8.6%, and the diameters of more than 88% pores are through the range of 100–2400 nm. Such a large pore structure could enable the fast transfer of molecules in it.

3.2.2. Infrared spectroscopy

Fig. 5 shows the infrared spectroscopy of bare monolithic material and chiral stationary phases immobilized chiral selec-

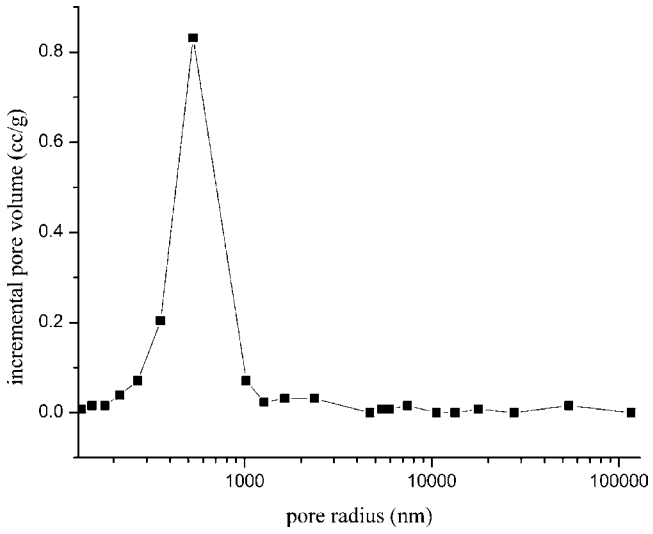

Fig. 4. Pore size distribution curve of the monolith measured by mercury intrusion porosimeter.

Table 2
Effect of pH on the separation with Asp-β-CD fabricated column.

Sample	pH	t_D (min)	t_L (min)	α
Phenylalanine	3.5	4.770	9.545	2.001
	4.5	2.587	4.038	1.561
	5.5	2.445	2.575	1.053
	6.5	2.125	3.912	1.841
	7.5	2.007	4.360	2.172
	8.5	1.470	2.217	1.508
Sample	pH	t_1 (min)	t_2 (min)	α
Mexiletine hydrochloride	3.5	No separation		
	4.5	4.800	9.184	1.913
	5.5	1.949	2.427	1.245
	6.5	2.447	4.881	1.995
	7.5	8.232	8.667	1.053
	8.5	No separation		

t: retention time. α: separation factor.

tors. The characteristic absorptions of bare GMA/EDMA matrix were 2928 cm^{-1}, 1729 cm^{-1}, 1258 cm^{-1}, 1151 cm^{-1}, and 908 cm^{-1}. According to the structure of material, 2928 cm^{-1} is assigned to stretching vibration of $-CH_2-$, 1729 cm^{-1} and 1151 cm^{-1} are the stretching vibration adsorption peak of carbonyl group and asymmetric stretching vibration absorption peak of –C–O–C–, respectively, 908 cm^{-1} confirms the existence of epoxy group. After immobilizing β-CD and its derivatives, disappearance of characteristic absorption 908 cm^{-1} proves that chiral selector is connected to epoxy group. Meanwhile, 1078 cm^{-1}, 536 cm^{-1} and 450 cm^{-1} showed in chiral stationary phase according to the characteristic absorption of β-CD which confirms successful immobilization of chiral selector.

3.3. Evaluation of chiral monolith

3.3.1. Investigation of separation condition

Since various parameters might affect the elution and separation of analytes, optimization of the operation conditions should be carried out to achieve better separation.

3.3.1.1. Effect of pH. The pH of mobile phase showed obvious effect on separation of charged analytes. Samples with different p*I* or pKa will have different electrophoresis behaviors under different pH environments. Amine and aspartate moieties of NH_2-β-CD and Asp-β-CD provide not only immobilization sites but also electric interactions. To obtain the optimum separation result, the effects of pH value of the mobile phase were studied in the range from 3.5 to 8.5 when amino acid and chiral drug were selected as sample. From Table 2, we could see that the variation of pH influenced the separation significantly. With the consideration of both analysis time and the detection sensitivity, pH 5.5–8.5 was chosen as the optimum condition.

3.3.1.2. Selection of the separation buffer. In our work, we also found that there were no obvious differences on the peak shape and the resolution of with either acetate or phosphate as the buffer. However, as far as the detection of the chiral compounds, Joule heat effect and the pH range of buffer were concerned, the phosphate was chosen as the running buffer in the following separation.

3.3.1.3. Effect of separation temperature. Temperature of column during separation procedure will also affect the migration time and resolution. Fig. 6 shows the heating effect on separation of phenylalanine on the Asp-β-CD fabricated column. Appropriate

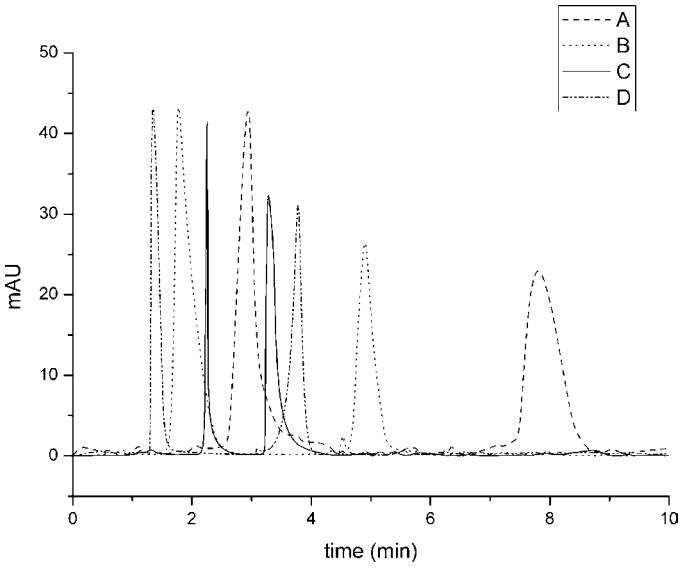

Fig. 6. Effect of separation temperature. (A) 10 °C; (B) 15 °C; (C) 20 °C; (D) 25 °C. *Column*: fabricated with Asp-β-CD; *sample*: phenylalanine; *voltage*: −10 kV; *injection*: −2 kV, 2 s; *mobile phase*: phosphate, 5 mM, pH = 6.5.

heating improved the chiral separation by decreasing the viscosity of mobile phase to short the migration time. But at the same time, over heating would lead to deterioration of the separation by Joule heat effect. When temperature increased from 10 °C to 20 °C, the migration time shortened significantly. But, when the temperature was raised to 25 °C, the symmetry and column efficiency was deteriorated compared to 20 °C.

3.3.2. Evaluation of chiral monolithic stationary phase by separating amino acids and racemic drugs

Racemic mixtures of eight amino acids and two drugs were separated by prepared chiral capillary monolithic columns. The p*I* of amino acids is varying from 5.5 to 10.76. All the samples could be baseline separated under selected condition, demonstrating the prospect of monolithic chiral stationary phase in the separation of enantiomers. Separation time, separation factors and resolution are shown in Table 3. Based on Table 3, monolithic columns fabricated with Asp-β-CD and HP-β-CD showed stronger separation abilities compared to other two types of columns.

All the derivatives have the same hydrophobic cavity as β-CD, but functional groups can also provide other interaction to

R_S: resolution factor.

improve the chiral separation. For Asp-β-CD, aspartic acid itself has strong stereoselectivity which also contributes to the chiral selection. The hydroxyl of introduced hydroxypropyl group in HP-β-CD could improve the combination of β-CD and guest molecule, increase the solubility of β-CD, form intermolecular hydrogen bond to increase the interaction between chiral selector and enantiomers.

Separation results demonstrate that functional groups of β-CD derivatives promote the chiral recognition significantly. As an example, the electropherograms of D,L-phenylalanine by four different monolith columns are shown in Fig. 7.

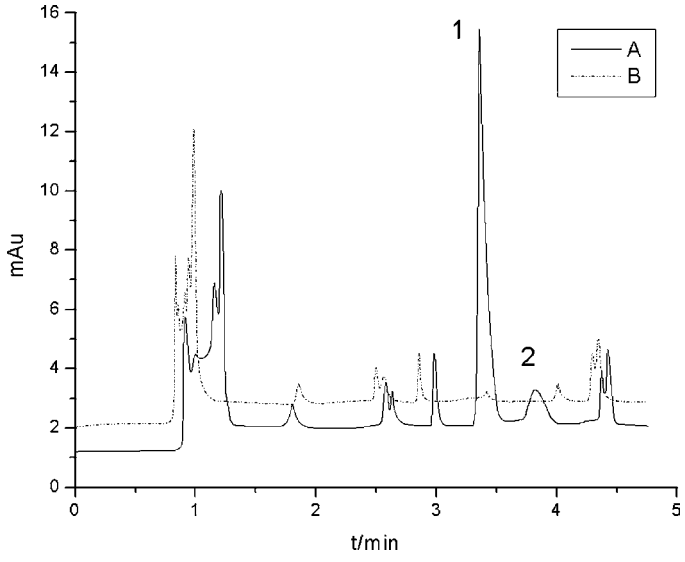

Fig. 8. Separation of mexiletine hydrochloride in human plasma sample by Asp-β-CD fabricated monolithic column. (A) Plasma sample; (B) free plasma. 1 and 2, the enantiomers' peaks of mexiletine hydrochloride. Mobile phase: phosphate/trolamine buffer, 5 mM, pH = 4.5; *temperature*: 20 °C; *voltage*: −10 kV; *injection*: −2 kV, 2 s.

3.3.3. Application

Monolithic column fabricated with Asp-β-CD was applied to the separation of mexiletine hydrochloride enantiomers in human plasma sample. Because of complex matrixes, as little as possible trolamine was added to phosphate buffer to decrease absorption between the sample and the solid phase. Fig. 8 shows the electropherogram of mexiletine hydrochloride extracted from the plasma sample. From Fig. 8, two enantiomers were separated by baseline, the migrate times were 3.46 and 3.84 min, respectively. Some components in plasma were determined, too. But they did not interfere the determination of the enantiomers. Thus, the method was applied to the complex matrix sample, and the column had good selectivity.

4. Conclusion

Based on combination of chiral recognition ability of β-CD derivatives and flexibility of monolithic material, a novel type of monolithic chiral column modified with β-CD and its derivatives has been developed and evaluated by separations of chiral compounds. Prepared chiral monolithic stationary phases showed promising potential in HPLC, preparative chromatography and industry production.

o-Phenylenediamine (OPD)

ABSTRACT

We describe herein the combination of electrochemical immunoassay using nanoporous gold (NPG) electrode with horseradish peroxidase (HRP) labeled secondary antibody–gold nanoparticles (AuNPs) bioconjugates for highly sensitive detection of protein in serum. The electroactive product of *o*-phenylenediamine (OPD) oxidized with H_2O_2 catalyzed by HRP was reduced in the Britton–Robinson (BR) buffer and the peak current of which was used to determine the concentration of antigen (Ag) in the analyte. The active surface area of NPG electrode was larger than that of a bare flat one. The presence of AuNPs enhanced the immobilized amount of HRP labeled antibody (Ab), which improved the sensitivity of the immunoassay when used as the secondary antibodies. As a result of these two combined effects, the sensitivity of the immunoassay for the determination of target protein was increased significantly. Using hepatitis B surface antigen (HBsAg) as a model, we demonstrate a dose response in the range of 0.01–1.0 ng/mL with a detection limit of 2.3 pg/mL. Analytical results of several human serum samples obtained using the developing technique are in satisfactory agreement with those given by enzyme-linked immune-absorbent assays (ELISA). In addition, the technique was about 100 times more sensitive in the detection of HBsAg than ELISA. All these demonstrated the feasibility of the present immunoassay method for clinical diagnosis.

1. Introduction

Sensitive measurement of proteins is a critical need in many aspects of modern biochemical and biomedical research, especially in early cancer detection, while maintaining minimum sample amount and operational simplicity [1–5]. Due to the highly sensitive and selective nature of the recognition between antigen (Ag) and antibody (Ab), immunoassay has been considered as a major analytical method for the determination of proteins [6–9]. Signal amplification and noise reduction are crucial for obtaining low detection limits and high sensitivity in clinical immunoassays [10]. Much attention has been focused on signal amplification by using an enzyme such as horseradish peroxidase (HRP) and alkaline phosphatase [11–14]. The detection methods commonly used in enzyme amplification immunoassay are amperometry [15,16], spectrophotometry [17], fluorometry [18], and chemiluminometry [19]. Electrochemical method has attracted increasing interest for the high sensitivity, low cost, and reliable results.

In the past decade, the applications based on nanoparticles (NPs) in immunoassay have attracted wide interest due to their unique optical, electronic, and mechanic properties. Various NPs such as gold, silver, silica, and quantum dots have been extensively used for ultrasensitive optical and electrochemical bioassays. Among them, gold nanoparticles (AuNPs) have been used for analytical and biomedical purposes for many years due to the advantage of rapid and simple chemical synthesis, a narrow size distribution, and efficient coating by thiols or other biomolecules. Recently, AuNPs have been widely used for signal amplification in DNA biosensors and clinical immunoassays [20–26].

Hepatitis B virus (HBV) is one of the most important causes of liver disease, and it can induce chronic or acute hepatitis. A total of nine HBV serotypes have been described [27]. The first virological marker to appear in the circulation, hepatitis B surface antigen (HBsAg), can be found in filamentous or spherical surface antigen particles in addition to virions. It is generally accepted that the diagnosis of infection by hepatitis B virus (HBV) is based on the presence of the HBsAg in the blood, since that it can generally be detected while still in the incubation period [28]. On the fast development of the clinical diagnostic technologies, there were some case reports on detection of HBsAg in human serum using capillary

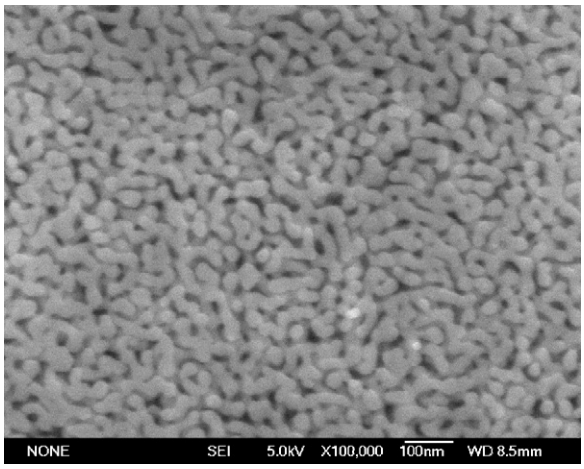

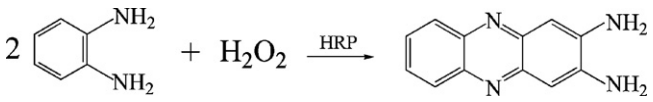

Fig. 1. SEM image of the NPG structures.

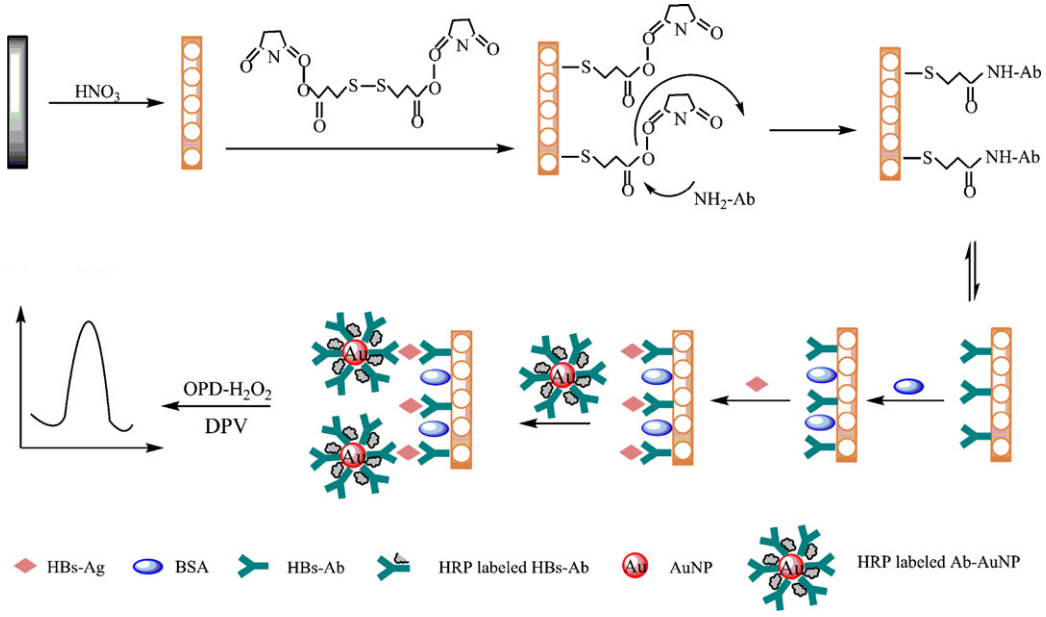
electrophoresis with chemiluminescence detection [29], as well as the nanoparticle-based time-resolved detection method [30,31]. Currently, electrochemical immunosensor based on gold nanoparticle or chitosan membranes [32–36], cross-flow chromatography [37] and photolithography [38] technologies were reported, while enzyme-linked immunosorbent assay (ELISA) was still the main means to clinically diagnose HBV [39,40]. However, ELISA method has the shortcoming of low sensitivity. Therefore, it is necessary to develop more sensitive assays to detect the low concentration of HBsAg in clinical serum samples.

Our group had constructed a sensitive electrochemical DNA sensor based on nanoporous gold (NPG) electrode and multifunctional encoded AuNPs [41]. The active surface area of NPG electrode was ~9 times higher than that of a bare flat one. In present work, an electrochemical immunosensor using NPG electrode with HRP label secondary antibody–AuNPs bioconjugates for highly sensitive detection of protein was established. As a platform model, measurements of HBsAg were performed in the range of 0.01–1.0 ng mL^{-1} with a detection limit of 2.3 pg/mL. The immunosensors were used to analyze HBsAg in human serum samples. Analytical results of clinical samples show that the developed

Scheme 2. The reaction equation of OPD and H_2O_2 catalyzed by HRP.

immunoassay is comparable with the ELISA method, implying a promising alternative approach for detecting HBsAg in the clinical diagnosis.



2. Experimental

2.1. Materials

HBs Ag, HBs Ab, and HRP labeled HBs secondary Ab were purchased from Maybio Co. Ltd. (China). 3,3′-Dithiodipropionic acid di (*N*-succinimidyl ester) (DTSP) was purchased from Tokyo Chemical Industry Co. Ltd. (Japan). DTSP solution (4 mM) was prepared in dimethylsulfoxide (DMSO). PBS buffer (10 mM, pH 7.4) was employed for preparing HBsAg and HBsAb solution. Hydrogen tetrachloroaurate (III) trihydrate ($HAuCl_4{\cdot}3H_2O$, 99.9%) and trisodium citrate were used for preparing AuNPs. Other solutions such as 3% bovine serum albumin (BSA), H_2O_2 (4.0×10^{-3} M), *o*-pheneylenediamine (OPD) (5.0×10^{-2} M, prepared in methanol), HAc–NaAc buffer (pH 4.8) and Britton–Robinson (BR) buffer (pH 7.8) were also used. All the reagents were analytical grade and used without further purification. Deionized and doubly distilled water was used throughout.

2.2. Apparatus

Cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) measurement were performed on a CHI 660C electrochemical working station (CH Instrument Company, USA) with a conventional three-electrode system comprised of platinum wire as auxiliary electrode, Ag/AgCl electrode as reference electrode, and different modified NPG electrode as working electrode. Differential pulse voltammetry (DPV) measurement was carried out by CHI 832B electrochemical analyzer (CH Instrument Company, USA) with a three-electrode system consisted of a glassy carbon electrode (GCE) as working electrode, an Ag/AgCl

Scheme 1. Schematic illustration of the stepwise process of modified electrode.

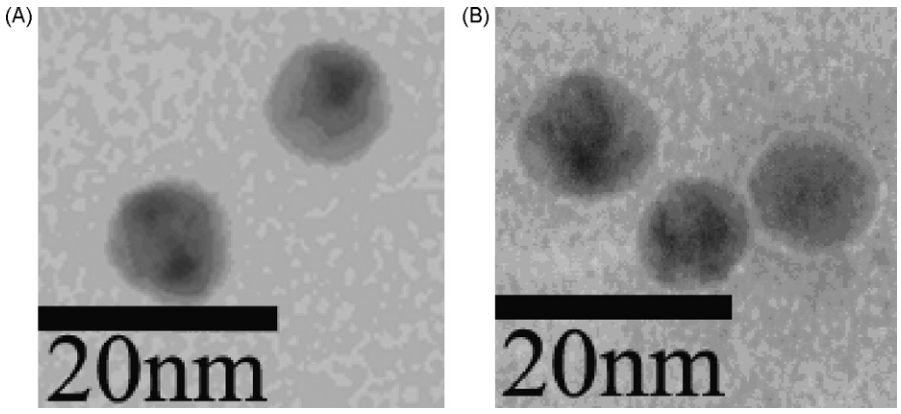


Fig. 2. TEM images of AuNPs (A), HRP labeled Ab–AuNPs (B).

electrode as reference electrode, and a platinum wire as an auxiliary electrode. UV–vis spectra were carried out on a Cary 50 UV–vis–NIR spectrophotometer (Varian). Transmission electron microscopy (TEM) image was taken with a JEOL JEM-1200EX instrument (HITACHI).

2.3. Procedure

2.3.1. Preparation of NPG electrode

NPG was prepared according to the previous work of our group by selective dissolution of silver from silver/gold alloy [41]. Briefly, a piece of commercially available 9-carat white gold leaf (Au/Ag alloy, 50:50 wt%, 100 nm thick) was floated onto 1:1 concentrated nitric acid for 1 h. Then the NPG foil was carefully coated onto pretreated GCE using a variation of electroless deposition in which the leaf adhered on the GCE surface via physical adsorption after being washed repeatedly with triply distilled water to remove the NO_3^- and Ag^+ which would interfere signal detection during electrochemical analysis. The electrode was then intentionally parched in infrared light for 1 h. Thus, NPG was modified onto the GCE to get the NPG electrode.

2.3.2. Synthesis of AuNPs

AuNPs were synthesized by reducing tetracholoroauric acid with trisodium citrate referred to literature [42]. Briefly, 100 mL of 0.01% $HAuCl_4$ solution was boiled with stirring and 2.5 mL 1% trisodium citrate solution was added quickly to the boiling solution. After reaction for 10 min, the solution was left for stirring and cooling down. The AuNPs solution was stored at 4 °C when not in use.

2.3.3. Preparation of HRP labeled HBs secondary Ab modified Au nanoparticles (HRP labeled Ab–AuNPs)

HRP labeled Ab–AuNPs bioconjugate was prepared according to the published procedure [43]. First, the pH of AuNPs solution was adjusted to 9 with 0.1 M NaOH, and then 30 μL HRP labeled HBsAb solution was added into 500 μL AuNPs solution without dilution. After stirring for 15 min, the AuNPs were tagged with HRP labeled Ab on the surface. The excess of Ab was removed by centrifugating the mixture at 10,000 rpm for 20 min. After being washed one more time in PBS (pH 7.4), HRP labeled Ab–AuNPs was dispersed to 100 μL PBS (pH 7.4) and was stored at 4 °C for further use.

2.3.4. Sandwich immunoassay procedures

After careful cleaning by deionized and doubly distilled water and PBS, respectively, the NPG electrode was dipped into a 4 mM DTSP solution to create Au–S bond between the NPG electrode and DTSP for 2 h [44]. After thorough rinsing with acetone to remove physically adsorbed DTSP, a drop of 250 μg/mL HBsAb solution was dripped onto the surface of the DTSP/NPG electrode and the modified electrode was stored at room temperature overnight. The unbound HBsAb was washed away by PBS and then BSA was employed to block the unreacted succinimidyl groups by soaking the Ab/DTSP/NPG electrode into 500 μL 3% BSA solution for 3 h. After the electrode was rinsed once again, the reaction between HBsAb and HBsAg was performed by immersing the modified electrode into 500 μL different concentrations of HBsAg solution and incubated for 60 min at 37 °C. Finally a drop of HRP labeled Ab–AuNPs solution was dripped onto the Ag/Ab/DTSP/NPG electrode to perform the sandwich immunocomplex for 90 min.

2.3.5. Electrochemical analysis

1 mL 5.0×10^{-2} M OPD solution, 2 mL 4.0×10^{-3} M H_2O_2 solution, 2 mL HAc–NaAc buffer (pH 4.8), and double distilled water were added to the 10 mL colorimetric tube in turn and the mixture was vibrated to get a uniform solution. The modified electrode was dipped into 300 μL of above substrate solution at 37 °C to catalyze the reaction between OPD and H_2O_2.

After the redox reaction between OPD and H_2O_2 catalyzed by HRP labeled on the modified electrode was finished 1 h later, 1 mL 0.2 M BR buffer (pH 7.8) was added into reaction cell for DPV measurement of the reduction signal of the product of OPD. DPV was performed in the degassed solution by scanning the potential from

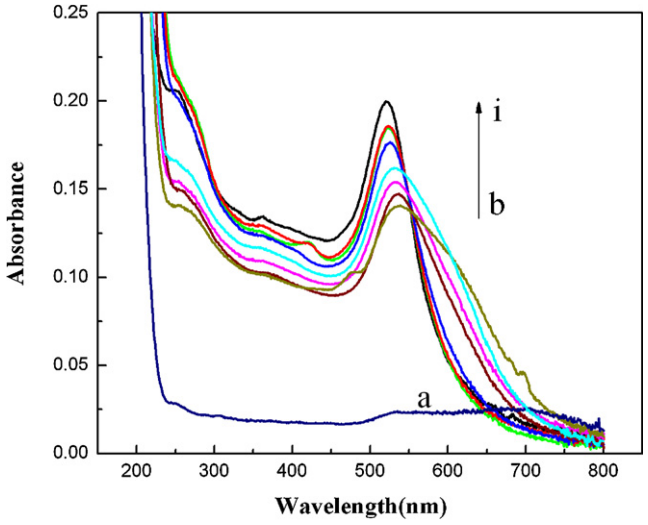

Fig. 3. Ultraviolet spectroscopy of (a) AuNPs, (b–h) HRP labeled Ab–AuNPs (1, 2.5, 5, 10, 20, 30 L, and 40 μL HRP labeled Ab were added to AuNPs solution).

−0.3 to −0.8 V with amplitude of 25 mV and a step potential of 12 mV at 5 Hz. All experiments were conducted at room temperature.

3. Results and discussion

In the current study, NPG electrode and AuNPs modified with the HRP labeled secondary Ab were used to perform an immunoassay for the determination of HBsAg. The characteristics of the NPG electrode surface are shown in Fig. 1. The new electrochemical immunoassay involves a binding event between DTSP-coated NPG electrode and HBsAb, and the formation of sandwich immunocomplex between the HBsAb labeled on the NPG electrode and the HRP labeled HBsAb–AuNPs is shown in Scheme 1. The electroactive product of OPD oxidized with H_2O_2 catalyzed by HRP tagged on the immunocomplex was reduced in the BR buffer and its peak current was used to determine the concentration of antigen (Ag) in the analyte. The product of H_2O_2–OPD redox system catalyzed by HRP is 2,3-diaminophenazine (DAP) and the equation is shown in Scheme 2.

3.1. The characterization of the HRP labeled Ab–AuNPs conjugate

TEM were recorded to prove the formation of HRP labeled Ab–AuNPs conjugate as shown in Fig. 2A and B. There were distinct differences between the TEM images of AuNPs and HRP labeled Ab–AuNPs because the electron beam could permeate HRP labeled Ab but could not permeate AuNPs after dyed with acetate uranium. Obviously, HRP labeled Ab–AuNPs were surrounded by a transparent ring indicating that HRP labeled HBs Ab had tagged onto the surface of AuNPs.

UV–vis spectrum was also performed to characterize the formation of the HRP labeled Ab–AuNPs conjugate as shown in Fig. 3. The presence of NaCl could cause the aggregation of AuNPs, and the aggregation could be prevented when the AuNPs were functionalized with HRP labeled Ab [43]. The increase in HRP labeled Ab stabilizes the AuNPs by preventing their aggregation that is visible from the shift of the maximum absorbance peak from curve a (AuNPs aggregated with NaCl) to curve i (pure AuNPs). It can be seen that the spectrum of HRP labeled Ab–AuNPs conjugate solutions (curves b–h) became more and more similar to that of pure AuNPs when the volume of HRP labeled HBs Ab added to AuNPs solution was ranged from 1 to 40 μL. Furthermore, the absorbance of curves g and h became almost the same. The results showed that the Ab–AuNPs conjugate was formed and 30 μL HRP labeled Ab was selected as the optimal volume.

3.2. Electrochemical characterization of the fabrication process of the immnuocomplex

CV and EIS measurements were performed in PBS (10 mM, pH 7.4) solution containing 0.1 M KCl and 5 mM $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$. The CV of ferricyanide was chosen as a marker to investigate the changes of the electrode behavior after each assembly step. The CV curves showed the changes of the electrode behavior after each assembly step. As shown in Fig. 4A, stepwise modification on the NPG electrode was accompanied by a decrease in the amperometric response and an increase in the peak-to-peak separation between the cathodic and anodic waves, showing the electron-transfer kinetics of $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ is obstructed. After the NPG electrode was functionalized with DTSP, the electron transfer between the electrochemical probe and electrode surface was inhibited, owing to the electrostatic repulsion of DTSP and the negatively charged electrochemical probe. When HBsAb and BSA were immobilized on the electrode surface, the peak currents of the

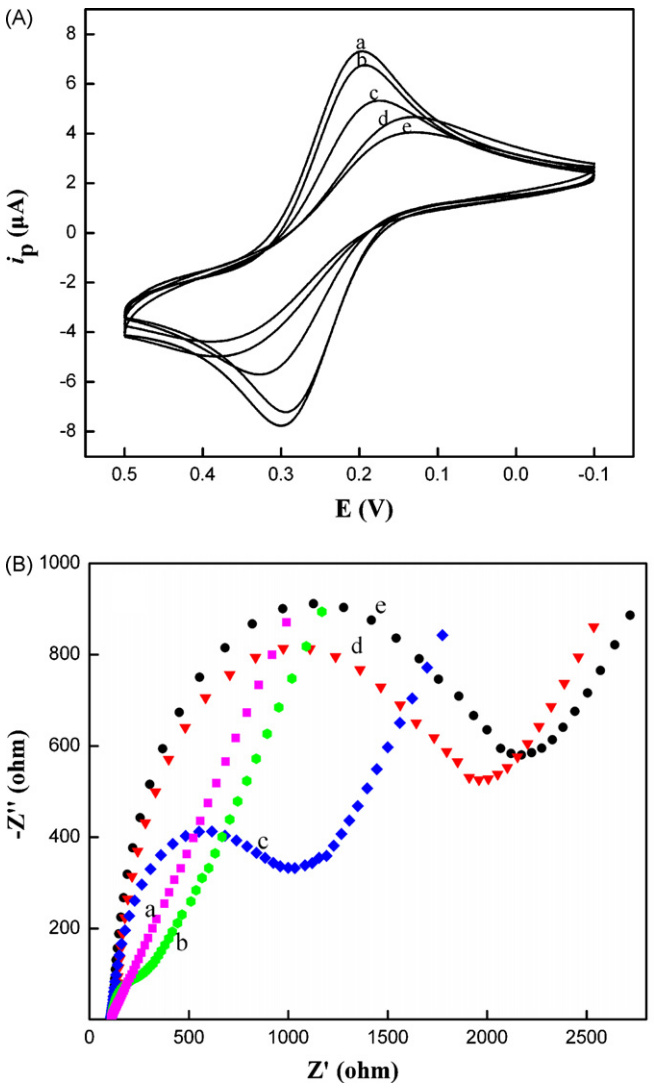

Fig. 4. Cyclic voltammograms (A) and electrochemical impedance spectroscopy (B) of the modified NPG electrode recorded in PBS (10 mM, pH 7.4) containing 0.1 M KCl and 5 mM $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$. (a) NPG electrode, (b) DTSP/NPG electrode, (c) Ab/DTSP/NPG electrode, (d) Ag/Ab/DTSP/NPG electrode, and (e) HRP labeled Ab–AuNPs/Ag/Ab/DTSP/NPG electrode. The scan rate was 100 mV s^{-1}; the frequency range was from 0.1 Hz to 10 kHz with a signal amplitude of 5 mV and the scan rate was 100 mV s^{-1}.

redox couple of $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ decreased again. In particular, after HBs antigen molecules were combined with the antibody molecules, and the HRP labeled Ab–AuNPs were combined with the HBsAg, an obvious disappearance of the anodic peak and cathodic peak was observed.

EIS can also give detailed information on the impedance changes in the modification process. The semicircle portion of the impedance spectra, corresponding to the electron-transfer-limited process, became larger and larger after each modification step, as shown in Fig. 4B. Both CV and EIS showed the successful conjugation on the electrode surface.

3.3. Optimization of experimental conditions

In order to achieve maximum electrochemical response, several factors such as Ab concentration, incubation time, and pH of DPV measurement were investigated.

The effect of Ab concentration was studied in the range of 10–250 μg/mL. The Ab/DTSP/NPG electrodes with different Ab

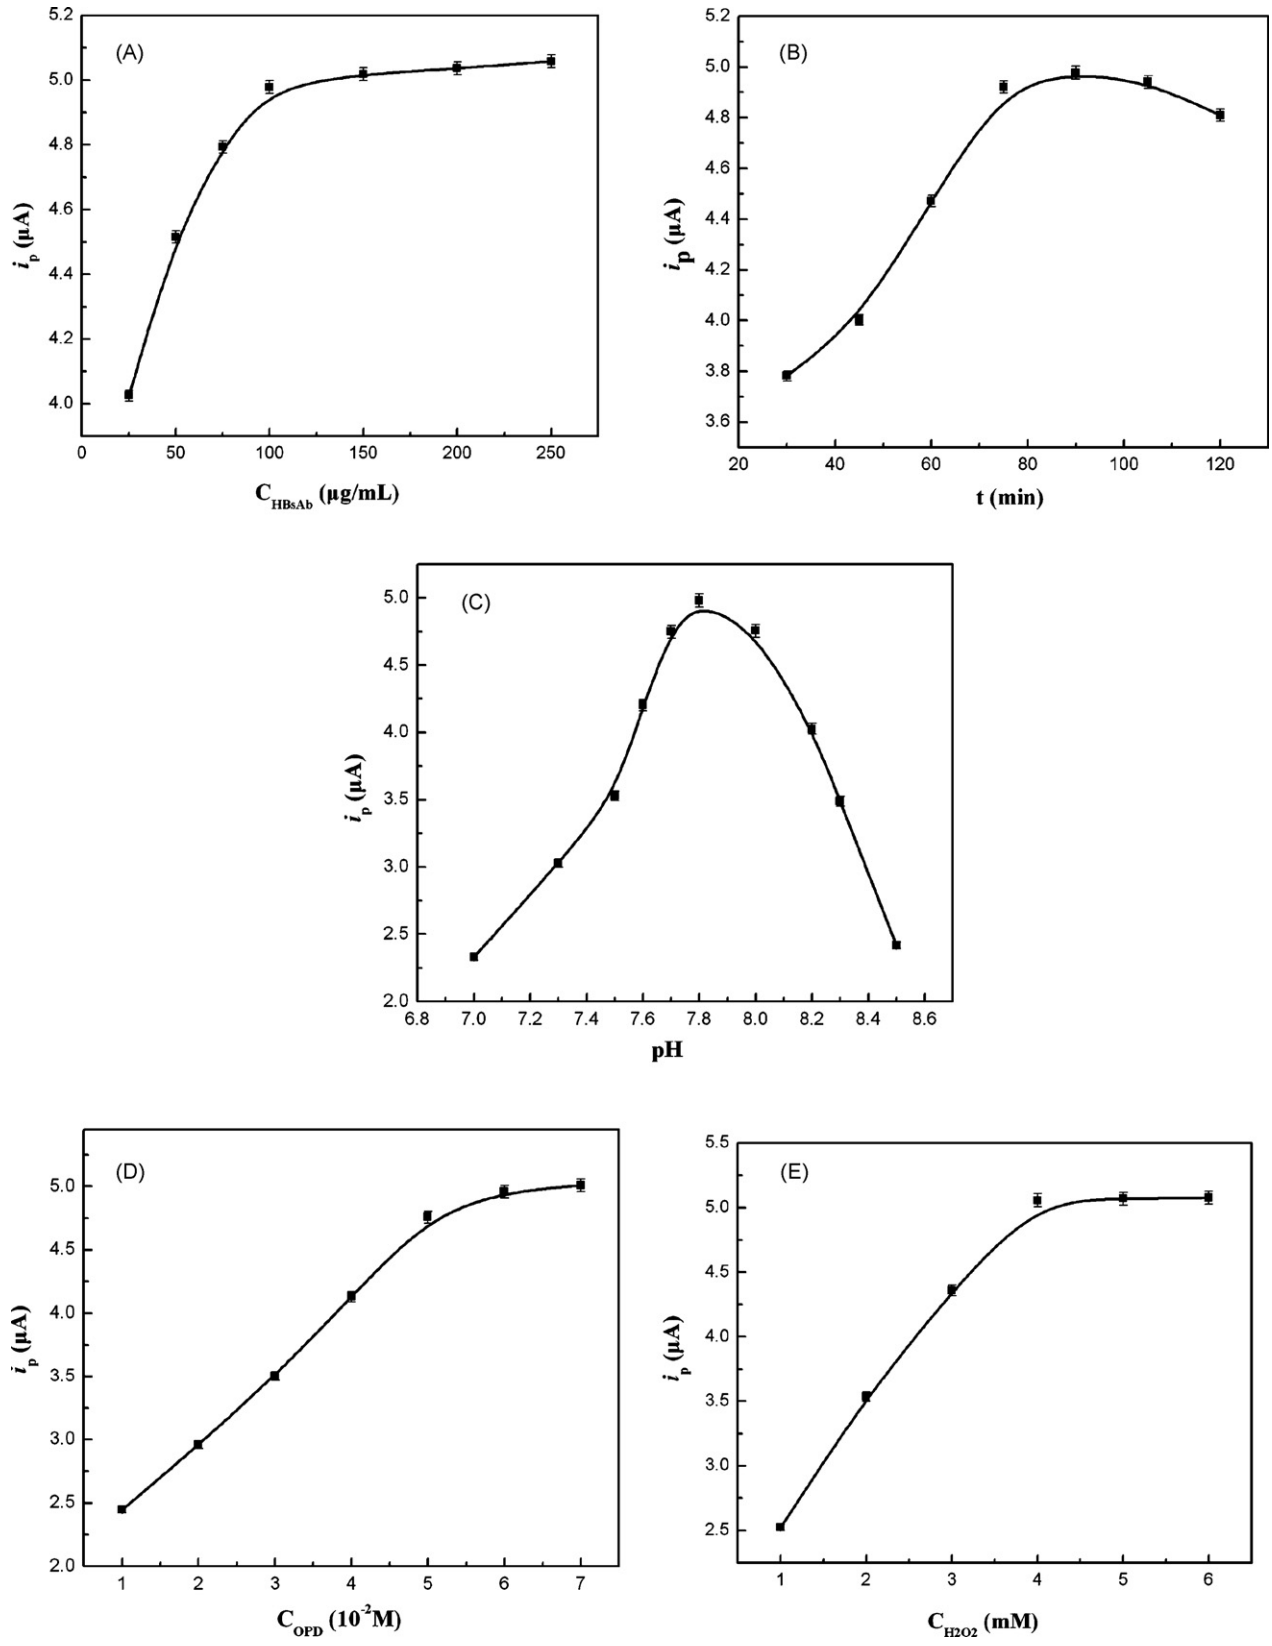

Fig. 5. Dependence of DPV peak currents of the enzyme-catalyzed analysis on Ab concentration (A), incubation time of Ag/Ab/DTSP/NPG electrode and HRP labeled Ab–AuNPs (B), pH value of BR buffer (C), OPD concentration (D), and H_2O_2 concentration (E), when one parameter changes while the others were under their optimal conditions.

concentration were immersed in 0.5 ng/mL HBs Ag solution respectively and then reaction to HRP labeled Ab–AuNPs. As shown in Fig. 5A, DPV response increased with the increase in concentration of Ab and then reached a plateau at 250 μg/mL. So 250 μg/mL of Ab solution were chosen as the optimal concentration.

The incubation time between HRP labeled Ab–AuNPs and Ag/Ab/DTSP/NPG electrode was another important parameter for the immunoassay. The influence of the incubation time was investigated as shown in Fig. 5B, when the concentrations of the HBsAg and HBsAb were 0.5 ng/mL and 250 μg/mL, respectively. The DPV response increased rapidly at first and reached on an equilibration step after 90 min, and then decreased slowly. Thus, the incubation time of 90 min was selected for the subsequent assays.

The pH value for DPV measurement was an important factor to the current response which was studied as shown in Fig. 5C. The immunoassay demonstrated the maximum response was obtained when the pH of the substrate solution was coordinated by adding 1 mL pH 7.8 BR buffer.

The effect of the concentrations of H_2O_2 and OPD were also studied as shown in Fig. 5D and E. 8×10^{-4} M H_2O_2 and 5 mM OPD was used as an optimal condition.

3.4. Detection of HBsAg

The product of OPD oxidized with H_2O_2 catalyzed by HRP was easily undergone the reductive reaction at −0.56 V at the experiment condition and the DPV response was in proportion to the concentration of the product as shown in Fig. 6.

The DPV response was enhanced by employing the AuNPs as the supporting material for the secondary HBsAb because one AuNP could be labeled by several HRP labeled Ab molecules. The results showed that the DPV response increased with the increase in the concentration of the target Ag ranging from 0.01 to 1.0 ng/mL based on the amplification of AuNPs (Fig. 6A). The linear range for target Ag was 0.01–0.1 ng/mL with the equation of $\Delta i_p = 1.3555 + 25.5077 C_{Ag}$ (ng/mL) ($R = 0.9976$; Fig. 6B). The relative standard deviation (RSD) was obtained to be 7.6% at a target Ag concentration of 0.01 ng/mL with 11 independent experiments. A detection limit of 2.3 pg/mL of target Ag could be further estimated using 3σ.

3.5. Reproducibility of the immunoassay

The reproducibility of current method was investigated with intraassay and interassay precision. The intraassay precision was evaluated by assaying one HBs level for three reduplicate measurements, whereas the interassay precision was estimated by measuring one HBs level with three different electrode prepared independently at the same experimental conditions. The intraassay and interassay variation coefficient obtained from 0.5 ng/ml HBsAg were 2.5% and 4.7%, respectively. These results showed the good reproducibility of the immunoassay.

3.6. The selectivity of the immunoassay

The selectivity of the immunoassay was also studied in the incubation solution with 0.05 ng/mL HBsAg and with some possible interfering substances, i.e., L-glutamic acid, D-glucose, hemoglobin, C-reactive protein, AFP, and BSA as shown in Table 1. When the concentrations of the interferences were much higher than the concentration of HBsAg, the relative deviation of the HBsAg solution was less than 3.0% compared with the concentration of HBsAg without the interference. From the results, we could demonstrate that the current immunoassay could response to HBsAg specifically.

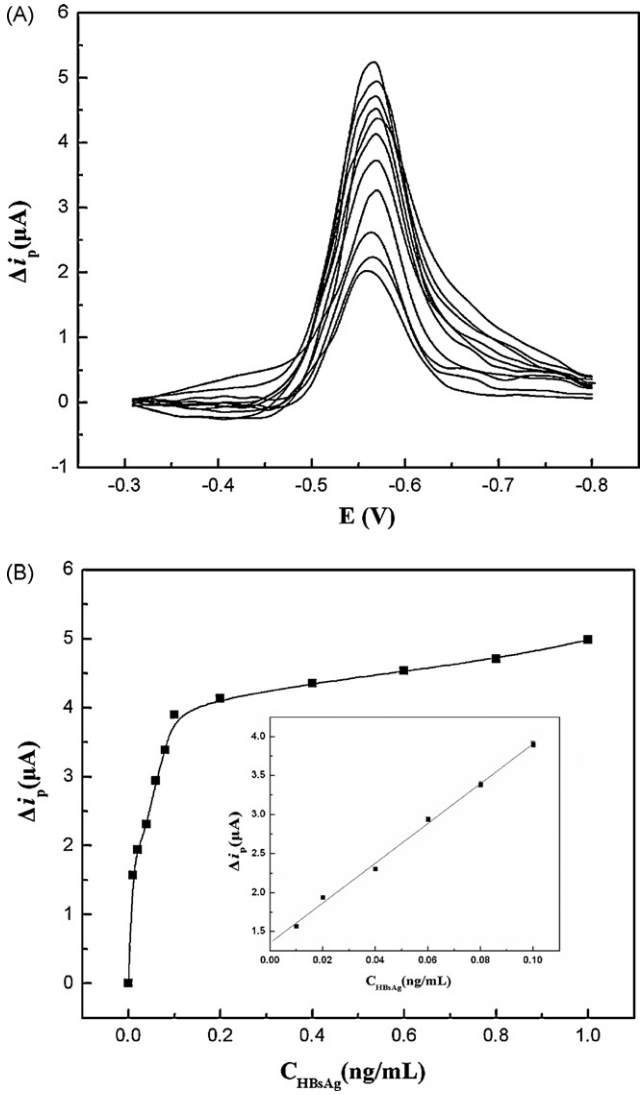

Fig. 6. DPV curves of HRP labeled Ab–AuNPs/Ag/Ab/DTSP/NPG electrode obtained with HBsAg concentrations of 0.01, 0.02, 0.04, 0.06, 0.08, 0.1, 0.2, 0.4, 0.6, 0.8, and 1.0 ng/mL (A), and calibration curves for sandwich immunoassay of HBs Ag (B). (Inset) Plot of DPV peak current vs HBsAg concentration from 0 to 0.1 ng/mL.

3.7. Detection of HBs Ag in clinical serum samples

In order to investigate the possibility of the newly developed technique to be applied for clinical analysis, several serum specimens, which were obtained from our college hospital, were examined by the developed immunoassay and the ELISA method. The HBs Ag level in some samples was beyond the kinetic range of the proposed method, thus appropriate dilution before assay

Table 1
Comparison of serum HBsAg levels determined using two different methods.[a]

Sample	Proposed method (ng/mL)	ELISA (ng/mL)	Relative deviation (%)
1	162	174	−6.8
2	233	214	8.8
3	541	515	5.0
4	0.056	–[b]	–
5	0.09	–	–
6	0.958	1	−4.4

[a] Each value is the average of three measurements.
[b] The concentraton of HBsAg was too low to be detected by ELISA. When the HBsAg concentration was more than 1 ng/mL, an appropriate dilution of sample was needed in the pre-incubation step in the proposed method.

Table 2
The relative responses of 0.05 ng/mL HBsAg in the presence of interference on the established bioassay (compared to the response mere 0.05 ng/mL HBsAg).[a].

Possible interference	Interfering concentration (μg/mL)	Current ratio
L-Glutamic acid	1	1.0125
D-Glucose	1	0.9924
Hemoglobin	140	1.0200
C-reactive protein	1	0.9789
AFP	1	1.0153
BSA	10	0.9867

[a] Each value is the average of three measurements.

was necessary. As shown in Table 2, there is no significant difference between the results given by two methods which are in concordance with the results obtained using the standard methods proposed by ELISA, that is, the developed immunoassays may provide a feasible alternative tool for determining HBs Ag in human serum in clinical laboratory.

Safety precaution: Patients with a high serum HBs Ag concentration often suffer from infectious blood liver disease. Thus, all tools in contact with clinical sera were disinfected after use.

4. Conclusion

In the present work, a novel ultrasensitive method based on NPG electrode and AuNPs was used for electrochemical determination of HBs Ag. The combination of the big active surface area of NPG electrode and the advantages of the AuNPs, including biocompatibility and amplification, enhanced the sensitivity of the method significantly. The results showed that the method was sensitive enough for determination of HBsAg in human serum samples with good precision and accuracy. The samples could be diluted to minimum even eliminate the disturbance of other proteins in serum to meet the low detection limit of this method. It can be expected that the new method would be widely used for highly sensitive clinical analysis and other biotechnology applications.

2-(Benzoacridine)-5-acetic acid (BAAA)
1-Imidazole-2-(5-benzoacridine)-ethanone (IBAE)

ABSTRACT

Dual-sensitive probe of 1-imidazole-2-(5-benzoacridine)-ethanone (IBAE) for the determination of free amines with fluorescence detection and online highly sensitive atmospheric chemical ionization-mass spectrometry identification (APCI-MS) has been developed. 2-(Benzoacridine)-5-acetic acid (BAAA) reacts with coupling agent *N,N′*-carbonyldiimidazole (CDI) to form a highly activated amide intermediate 1-imidazole-2-(5-benzoacridine)-ethanone (IBAE), which is dual-sensitive probe. The amide intermediate (IBAE) reacts preferably with amines in dimethylformamide (DMF) solvent to give the high yields of derivatives. IBAE-amine derivatives are not only sensitive to fluorescence but also to MS ionizable efficiency. The percent ionization δ values change from 0 to 57.32% in aqueous acetonitrile and from 0 to 62.14% in aqueous methanol. The relative standard deviations of the peak areas with fluorescence detection for each amine are <1.24% (40 ng/ml, $n=6$). The fluorescence detection limits (at a signal-to-noise ratio of 3) are in the range of 0.15–0.50 ng/ml. The online APCI-MS detection limits are in the range of 2.07–8.51 ng/ml (at a signal-to-noise ratio of 3). Therefore, the facile IBAE intermediate derivatization allowed the development of a highly sensitive and specific method for the quantitative analysis of trace levels of amines in environmental water.

1. Introduction

Most aliphatic and aromatic amines may occur as biodegradation products of organic matter such as proteins, amino acids, and other nitrogen containing organic compounds. Volatile amines not only have an unpleasant smell but also possess hazards. Moreover, they may react with nitrosating agents, leading to the formation of potentially carcinogenic *N*-nitrosamine compounds [1–5]. Therefore, it is important to determine certain amino compounds in real environmental samples. Gas chromatography is frequently used to determine amines using various derivatization reagents [6]. Other methods including enzymatic [7,8] and ion-exchange chromatographic detection [9] have been described for the determination of amines in various matrixes. These methods usually have limitations because of low sensitivity. Therefore, chemical derivatization is necessary in order to increase detection sensitivity and improve selectivity by pre-column or post-column HPLC derivatization methods [10,11]. Other techniques used to improve detection limits are microcolumn LC [12] and capillary electrophoresis [13]. Several common fluorescent derivatizing reagents [14–20] have also been developed fully. However, there have also been many reports describing various shortcomings in application, and to date no method has been shown to overcome all these problems. For example, the (2-phthalimidyl)benzoyl chloride (PIB-Cl) method offers high sensitivity, but it is not suitable for aromatic amines [21,22]. Although 7-fluoro-4-nitrobenzo-2-oxa-1,3-diazole (NBDF) is more reactive than 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD-Cl) for amino compounds, data reported previously indicate that the two reagents themselves show ~30–50% decomposition in methanol–water solution within 25 min when exposed to daylight [23]. Recently 9-fluorenylmethyl chloroformate (FMOC) [24], 1-(9-fluorenyl)ethyl chloroformate (FLEC) [25], and 2-(9-anthryl)ethyl chloroformate (AEOC) [26] reagents have been used for the derivatization of amines, amino acids, and peptides for chiral or nonchiral separation in LC or CE. These reagents result in good UV absorption and very high sensitivity with laser-induced fluorescence detection. However, for effective derivatization, an

0039-9140/$ – see front matter © 2009 Elsevier B.V. All rights reserved.
doi:10.1016/j.talanta.2009.09.041

excess of reagent must be used, and the derivatized solution must be extracted with pentane to remove an excess of reagent [27,28], because it interferes with the separation of derivatives and is detrimental to column performance. The 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate (AQC) method is rapid and convenient and gives stable derivatives. However, only 10% of the fluorescent intensity in aqueous solution relative to that in pure acetonitrile solution is observed for its derivatives. Thus, the detection limits for the early eluted amine derivatives are usually higher than those for later ones [29].

In our previous studies [1,30–33], we described the synthesis of several fluorescent labeling reagents and their applications for common amino compound analysis. These probes exhibited very high fluorescence sensitivities; however, they gave relatively low MS ionization potential and were great disadvantage to online highly sensitive MS identification. The principal purpose of this study is to develop a new dual-sensitive probe for the rapid determination of amino compounds with fluorescence detection and online highly sensitive MS identification. The results indicate that the prepared 1-imidazole-2-(5-benzoacridine)-ethanone (IBAE) intermediate is a dual-sensitive probe, and reacts rapidly with amino compounds to give the high yields of derivatives without the need of catalysts. Derivatives are not only sensitive to fluorescence but also to MS ionizable potential with little matrix interference. To the best of our knowledge, this is the first time that IBAE probe and its further applications for the determination of amino compounds have been reported.

2. Experimental

2.1. Instrumentation

Experiments were performed using a 1100 Series LC/MSD-Trap-SL electrospray ion trap liquid chromatography/mass spectrometry consisted of a vacuum degasser (model G1322A), a quaternary pump (model G1311A), an autosampler (model G1329A), a fluorescence detector (FLD) (model G1321A), and a diode array detector (DAD) (model G1315A). The mass spectrometer from Bruker Daltonik (Bremen, Germany) was equipped with an atmospheric pressure chemical ionization (APCI). Fluorescence excitation and emission spectra were obtained at an F-7000 fluorescence spectrophotometer (Hitachi, Japan). The semi-preparative HPLC system, which used to obtain the single IBAE-butylamine derivative, was Waters Delta 600 (Waters, USA).

2.2. Materials and reagents

Acetonitrile and methanol were of chromatographic grade from Jining Chemical Reagent Co. (Shandong, China). All reagents used in this study were of analytical grade unless otherwise stated. Catalysts including triethylamine, pyridine, 4-dimethylaminopyridine (DMAP) were purchased from Shanghai Chemical Reagent Co. (Shanghai, China). *N*,*N*′-Carbonyldiimidazole (CDI) was purchased from Sigma Chemical Co. (St. Louis, MO). Dichloromethane, chloroform, DMF and other reagents were of analytical reagent grade. All amines used in experiments were of chromatographic grade and purchased from Jining Chemical Reagent Co.

2.3. Synthesis of 1-imidazole-2-(5-benzoacridine)-ethanone (IBAE)

2.3.1. Synthesis of 2-(benzoacridine)-5-acetic acid (BAAA)

Benzoacridine was conveniently prepared according to the method as previously described [34]. 2-(Benzoacridine)-5-acetic acid (BAAA) was synthesized as follows: benzoacridine (10 g), KOH (13 g) and dimethylsulfoxide (80 ml) were mixed in a 250-ml round-bottom flask and rapidly heated to 100–110 °C for 60 min with vigorous stirring. A solution of 13 ml ethyl bromoacetate in 30 ml dimethylsulfoxide was added dropwise within 1 h with stirring. The contents of the flask were continuously heated at 100–110 °C for 30 min. After cooling, the mixture was transferred into a solution containing 300 ml water and 20 g KOH, and continuously heated at 100 °C for 30 min. After the solution was cooled to ambient temperature, the mixture was filtrated; the result solution was adjusted to pH 3.0 with 4 mol/l HCL solution. The precipitated solid was recovered by filtration, washed with water. The crude product was dried at room temperature for 48 h and recrystallized twice from acetic acid to afford a yellow crystal 6.7 g, yield 56.8%. m.p. 289.1–289.4 °C. Found: C: 78.89%, H: 5.22%, N: 4.85%. Calculated: C: 78.87%, H: 5.23%, N: 4.84%. IR (KBr): 3320.98 (ν_{O-H}), 3023.15 (ν_{Ar-H}), 1605.94 (Ph–C=O), 1571.62, 1488.63, 1449.10, 1383.14, 1293.15, 757.07, 658.65. LC–APCI-MS: *m*/*z* 304.2 $[M+H]^+$ in positive-ion mode; MS/MS: *m*/*z* 246.0 (molecular core moiety).

2.3.2. Synthesis of intermediate of 1-imidazole-2-(5-benzoacridine)-ethanone (IBAE)

IBAE was prepared by the reaction of BAAA with CDI as follows: To a solution of BAAA (2.0 g) in 50 ml acetonitrile in a 100 ml round-bottom flask, CDI (3.0 g) was added. The contents of the flask were rapidly heated to reflux. After a 60 min period, the mixture was transferred into 300 ml of ice-water with stirring for 10 min; the precipitated solid was recovered by filtration, washed with water, and dried at room temperature for 48 h. The crude product was recrystallized 3 times from acetonitrile (3 × 30 ml) to afford a yellow crystal 1.9 g, yield (81.54%). m.p. >239 °C (decomposition). Found: C: 74.52%, H: 4.20%, N: 11.94%. Calculated: C: 74.78%, H: 4.25%, N: 11.89%. IR (KBr): 3040.5, 3022.36 (Ar), 1747.82 (–C=O in carboxylic group), 1643.00 (–C=O in acridine ring), 1485.83, 1398.86, 1292.55, 1226.79, 750.64. LC–APCI-MS: *m*/*z* 354.0 $[M+H]^+$ in positive-ion mode; MS/MS: *m*/*z* 246.0 (molecular core moiety).

2.4. Preparation of standard solutions

The standard solutions of BAAA and IBAE (approximate 4.0×10^{-3} mol/l) were prepared by dissolving appropriate amounts of BAAA and IBAE in 10 ml of acetonitrile or DMF solvents, respectively. Standard solutions (50 ng/ml) of amines from methylamine to dodecylamine were prepared by the dilution of the stock acetonitrile solutions of each amine (1 mg/ml) with acetonitrile. A standard solution of the coupling agent CDI (10 mg/ml) was prepared by dissolving 0.1 g CDI in 10 ml of acetonitrile.

2.5. Chromatographic method and MS condition

HPLC separation of amine derivatives was carried out on an Hypersil BDS C_{18} column (200 mm × 4.6 mm i.d, 5 μm) by a gradient elution. Eluent A was 30% of acetonitrile consisting of 10 mM ammonium/formic acid buffer (pH 3.75); B was 95% acetonitrile. Gradient conditions: initial = 90% A + 10% B; 0–30 min = from 90% A + 10% B to 100% B (kept for 10 min, injection 10 μl). The flow rate was constant at 1.0 ml min^{-1}. The fluorescence excitation and emission wavelengths were set at λ_{ex} = 272 and λ_{em} = 505 nm, respectively. Online MS ion source: dry gas temperature, 350 °C; nebulizer pressure, 60.0 psi; dry gas flow, 5.0 l/min; APCI Vap Temp 450 °C; corona current (nA) 4000 (pos); capillary voltage, 3500 V.

2.6. Derivatization procedure

Method A: To 100 μl of a standard mixture of amines was successively added 100 μl each of derivatizing reagent (BAAA, 4.0×10^{-3} mol/l), and CDI solution into a screw-capped tube. The mixture was allowed to react in a water-bath at 80 °C for 5 min.

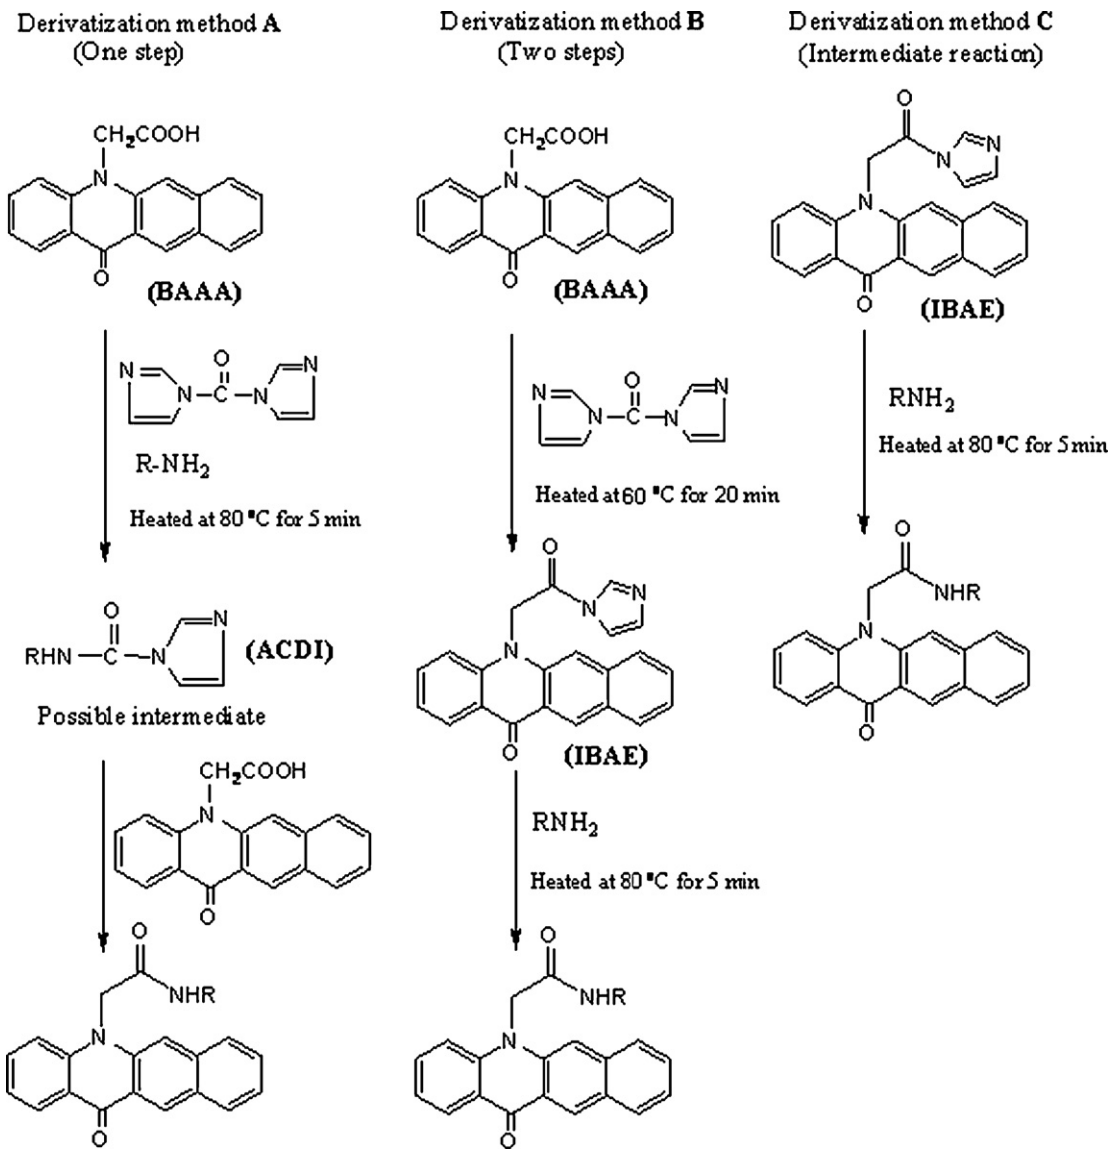

Fig. 1. The scheme of derivatization procedure using three kinds of different methods.

After the reaction was completed, the mixture was cooled to room temperature in a water-bath. A 10-μl volume of the crude reaction mixture was diluted to 100 μl with acetonitrile. The diluted solution (10 μl) was injected directly onto the chromatograph (Fig. 1, Method A).

Method B: To 100 μl of BAAA acetonitrile solution (BAAA, 4.0×10^{-3} mol/l), 100 μl CDI was added. This mixture was allowed to react at 60 °C for 20 min to form an activated amide intermediate without further purification. After activation of BAAA, 100 μl of standard mixture of amines was added, and the tube was sealed again and heated at 80 °C for 5 min. After the reaction was completed, the mixture was cooled to room temperature in a water-bath, and diluted with acetonitrile and injected directly onto the chromatograph (Fig. 1, Method B).

Method C: To 100 μl of a standard intermediate solution (IBAE: 4.0×10^{-3} mol/l), 100 μl amine solution was added. The mixture was allowed to react in a water-bath at 80 °C for 5 min. After the reaction was completed, the mixture was cooled to room temperature in a water-bath, and diluted with acetonitrile. A 10 μl volume of solution was injected directly onto the chromatograph (Fig. 1, Method C).

2.7. Samples preparation

Water samples collected from different sampling sites were analyzed using the developed method. Once water samples (50 ml) had been collected, they were immediately neutralize to pH 3.0 with 0.2 mol/l HCl and filtered through a 0.45-μm membrane filter. The neutralized solution was concentrated to dryness by a rotary evaporator. The residue was re-dissolved with 80% aqueous acetonitrile (ACN/H_2O, v/v). The resulting solution was then immediately cooled to 0–5 °C to avoid volatilization of amines, and stored in brown glass bottles in a refrigerator. All analyses were immediately subjected to derivatization and analysis by HPLC within one day after sampling.

2.8. Theoretical parts: estimation of the percent ionization fraction (δ)

The intramolecular isomerization of probe molecule **A** is shown in Fig. 2. The formation of quaternary ammonium ion **AB** results in the corresponding fluorescence quenching. The ionization δ values of the quaternary ammonium ion **AB** can be easily obtained by the

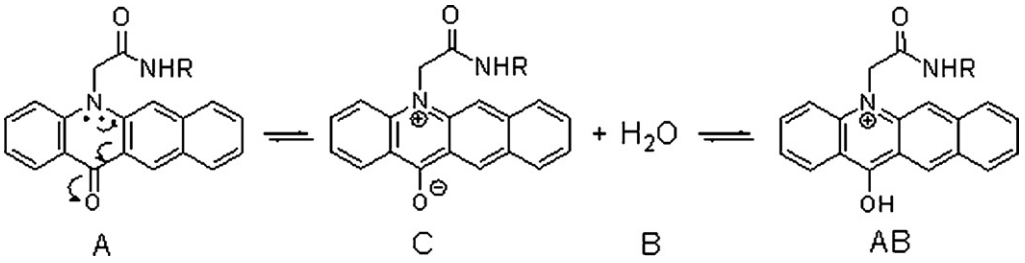

Fig. 2. The scheme of intramolecular keto–enol isomerization.

determination of the differences in fluorescence intensity in the presence of various amount of water in acetonitrile or methanol. When probe **A** is dissolved in aqueous acetonitrile or methanol, the forward and reverse reactions occur at equal rates, so the chemical equilibrium can be expressed as:

$$\mathbf{A} + \mathbf{B} \Leftrightarrow \mathbf{AB} \tag{1}$$

where **A** and **B** are the reactants, **A** is the fluorescence probe, **B** is the proton-solvent (proton donor, H_2O) and **AB** is the product (proton acceptor). When equilibrium is achieved, the quenching constant K in aqueous acetonitrile is given by

$$K = \frac{[\mathrm{AB}]}{[\mathrm{A}][\mathrm{B}]} \tag{2}$$

where [A], [B] and [AB] are the corresponding equilibrium concentrations in the aqueous acetonitrile, respectively. According to the law of conservation of mass, the percentage of ionization fraction δ can be defined as:

$$\delta = \frac{[\mathrm{AB}]}{[\mathrm{A}]_0} = \frac{[\mathrm{AB}]}{[\mathrm{A}] + [\mathrm{AB}]} \tag{3}$$

We also suppose that initial concentration of **A** in pure acetonitrile is $[A]_0$, corresponding fluorescence intensity is F_0, the relationship between fluorescence intensity and the concentration of probe **A** can be expressed:

$$F_0 = K'\phi_f[\mathrm{A}]_0 \tag{4}$$

where K' is the constant depended on the relative parameters of instruments, ϕ_f is the quantum yield of **A.** When **A** is partially ionized by **B** to form corresponding quaternary ammonium ion **AB**, the fluorescence intensity of unionized probe **A** is F, in this case, the fluorescence intensity F can be expressed quantitatively as:

$$F = K'\phi_f(1-\delta)[\mathrm{A}_0] \tag{5}$$

where $\delta = [\mathrm{AB}]/[\mathrm{A}]_0$.

By combination of Eqs. (4) and (5) we obtained:

$$\frac{F_0 - F}{F} = \frac{K'\delta[\mathrm{A}]_0}{K'(1-\delta)[\mathrm{A}]_0} \tag{6}$$

This Eq. (6) can be reorganized into:

$$\frac{F_0 - F}{F} = \frac{\delta}{1-\delta} \tag{7}$$

This Eq. (7) can be reorganized into:

$$\delta = \frac{F_0/F - 1}{F_0/F} \tag{8}$$

Thus, the percent ionization fraction δ value can be calculated by Eq. (8) by the combination of each F value obtained in the presence of various volume percentage of water (here, assumption that the percent ionization fraction $\delta = 0$ in pure acetonitrile and pure methanol).

3. Results and discussion

3.1. Fluorescence for representative IBAE-butylamine derivative

The recorded spectra of IBAE-butylamine derivative in aqueous acetonitrile (50%, ACN/H_2O, v/v) showed an excitation maximum at λ_{ex} 272 nm and an emission maximum at λ_{em} 505 nm. An increase in solvent polarity resulted in obvious red-shift in fluorescent emission spectra. The emission intensities in pure methanol and acetonitrile exhibited 2.64–2.34 times stronger than that in pure water with peak red-shift about 12 and 47 nm, respectively. The quenching in aqueous acetonitrile and methanol for IBAE-amine derivative should be attributed to the formation of quaternary ammonium ion AB by the protonation reaction with H_2O as described in Fig. 2.

3.2. Effect of temperature on fluorescence intensity in various solvents

The effects of temperature on the fluorescence spectra of IBAE-butylamine in solvents from group 1 to group 5 were investigated over the temperature range from 10 to 70 °C in 10 °C increments. The analysis of fluorescence intensity (I_{em}) of IBAE-butylamine derivative at different temperature in various solvents led to a linear correlation between I_{em} and T (see Table 1). With solvents from group 1 to group 5, IBAE-butylamine fluorescence intensity remarkably decreased with increasing temperature from 10 to 70 °C. There was an exception of methanol, the fluorescent intensities of IBAE-butylamine in methanol solvent increased with increasing temperature. In addition, the formic acid from group 3 was irreversible to fluorescence; this was probably due to the fact that the derivative was mostly protonated by its nitrogen atoms in molecular core structure in relatively strong formic acid solvent, resulting in the irreversible fluorescence emission. When aqueous organic solvents were used, such as aqueous acetonitrile or aqueous methanol, fluorescence intensities constantly increased with increasing solvent temperature. It was probably due to the fact that the IBAE-butylamine molecules were first solvated by several H_2O molecules by hydrogen bond acting force and resulted in the decrease of direct collision frequency between IBAE-butylamine and solvent molecules. Methanol was a kind of protic solvent and similar to water (HOH), where one of the hydrogens was replaced with the methyl group. Therefore IBAE-butylamine molecules could also be solvated by methanol molecules as did of water molecules resulting in an increase of fluorescence with the increase of solvent temperature. It was similar to the case of aqueous acetonitrile and aqueous methanol. In addition, the tested solvent volume in cell (4-mL) increased with increasing temperature from 10 to 40 °C or 10 to 70 °C; however, the tested temperatures for these solvents were below their boiling points and resulted in a very small change to IBAE-butylamine concentration. Therefore, the influence of the volume change of solvent on the fluorescence intensity could be ignored.

Table 1
Effects of temperature on fluorescence intensity of IBAE-butylamine derivative in various solvents[a].

[a] Concentration of IBAE-butylamine in each solvent is kept at 5.0×10^{-7} mol/l.
[b] The test is not carried out as the temperature is close to or beyond the boiling point.
[c] Linear regression was carried out at the temperature range of 10–40 °C.
[d] The test is not carried out because the temperature is below the freezing point.

3.3. Effects of solvent and basic catalyst on derivatization

Several types of solvents were tested in this study for derivatization, including acetonitrile, ethyl acetate, acetone, chloroform, dichloromethane, DMF and methyl sulfoxide (DMSO). Derivatization was carried out at 80 °C for 5 min using DMAP as basic catalyst. Each value was an average of six runs with DMF solvent taken as 100%. The results indicated that DMF gave the highest detector responses. All derivatization was, therefore, performed by the use of DMF as reaction co-solvent. In addition, DMF was used as the derivatization co-solvent in preference to other solvents as it easily avoided the problem of precipitation of hydrophobic long chain amine derivatives. Several base catalysts, including triethylamine, pyridine and DMAP were evaluated as reaction catalysts. The results indicated that the derivatization yields in the absence of the basic catalysts were in good agreement with the cases of using triethylamine, pyridine and DMAP. Therefore, catalysts were not used for all subsequent derivatization experiments.

3.4. Temperature conditions, time effects and reagent concentration for derivatization

The peak heights for all amines became constant at 80 °C for 5 min. When below 80 °C the reaction rate was decreased and led to a long derivatization time. Therefore, derivatization temperature selected was set at 80 °C for all experiments. Constant fluorescence intensity could be obtained with the addition of 3–4-fold molar reagent excess to total molar amines; further increasing the excess of reagent did not significantly alter the reaction time and temperature needed for the derivatization reaction to be completed.

3.5. Percent ionization and MS cleavage mode of IBAE-amine derivatives

IBAE-amine derivatives actually exhibited excellent ionization efficiency under LC–MS conditions. This should be attributed to the intramolecular keto–enol isomerization as described in Fig. 2. This property was of great importance to perform a sensitive MS detection as the main characteristic of APCI derived from the fact that the molecule in MS ion chamber was first solvated by water molecules [35]. The fluorescence intensity of probe **A** molecule in the presence of varying amount of water is shown in Table 2. On the basis of the obtained data, the percentage of ionization (δ) values for representative IBAE-C4 was evaluated according to the Eq. (8), which indicated that the estimated δ values in aqueous acetonitrile were in the range of 0–57.32% with increasing amount of water from 0 to 100% (v/v). The δ values in aqueous methanol were in the range of 0–62.14% with increasing amount of water from 0 to 100% (v/v).

With aqueous acetonitrile as solvent, the percent ionization δ values versus the added volume percent of water showed a good linear relationship in the range 0–60% of water ($\delta = 0.763 + 0.256v$, $r = 0.9927$, v : the added volume percent of water). Although a good linear relationship in the range 60–100% of water was also observed ($\delta = -47.35 + 1.018v$, $r = 0.9893$), the linear relationship had been deviated from the original curve. It could not express the linear relationship of actual concentration of initial form **A** versus fluorescence. This should be attributed to the fact that the molecules of IBAE-amine derivatives in the presence of water (<60%) existed mainly as form **A** as described in Fig. 2. When the percentage of water is >60%, molecular structure of form **A** had been partially converted to no-fluorescent quaternary ammonium ion **AB** (see Fig. 2). In other words, the actual concentration of form **A** in the

Table 2
The fluorescence intensity of IBAE-butylamine in the presence of varying amount of water and corresponding calculated ionization fraction δ values (IBAE-butylamine concentrations were kept constant at 5.0×10^{-7} mol/l for each tested solution).

H_2O% (v/v)	Solvent					
	Acetonitrile			Methanol		
	Emission wavelength (nm)	Relative intensity	Ionization fraction, δ (%)	Emission wavelength (nm)	Relative intensity	Ionization potential, δ (%)
100	520	309	57.32	518	265	62.14

70	507	550	24.03	515	481	31.29
60	506	612	15.47	514	556	20.57
50	505	629	13.12	511	586	16.29
40	503	639	11.74	509	602	14.00
30	501	656	9.39	508	626	10.57
20	499	680	6.08	506	647	7.57
10	495	700	3.31	506	662	5.43
0	473	724	0	506	700	0

presence of water (>60%) is lower than the initial concentration of the probe molecule **A**. This result was also similar to the case of using aqueous methanol (<50%, MeOH/H_2O, v/v). In aqueous methanol, $\delta = 1.108 + 0.315\nu$ ($r = 0.9914$, ν : the added volume percent of water in methanol in the range of 0–50%). The estimation of percent ionization δ values revealed that the probe molecule **A** provided the desired ionization efficiency in commonly used aqueous acetonitrile or methanol, which was usually used in LC–MS separation as mobile phase composition. To evaluate the effects of pH on fluorescence and ionization efficiency in APCI-MS ion source, two mobile phase compositions containing 10 mM of aqueous ammonium/formic acid buffer–acetonitrile in 70:30 volume ratios were used and their pH values were, respectively, adjusted to pH 3.75 and 8.65 by adding an appropriate amount of ammonium and formic acid. The results indicated that fluorescence intensities for all 12 amine derivatives with pH 3.75 mobile phase were 1.42 times less than those obtained with pH 8.65 mobile phase (chromatogram was not shown). MS ion current responses at pH 3.75 and 8.65 were also compared under the same APCI-MS conditions proposed. With pH 3.75 mobile phase, the strong MS ion current responses for amine-derivatives were observed (Fig. 3a). However, no ion current responses for amine-derivatives were observed when mobile phase pH was adjusted to pH 8.65 (Fig. 3b). The main merits of the prepared probe molecule compared with our previously reported [30–33] indicated that IBAE-amines could be easily obtained a sensitive fluorescent detection using relatively high pH buffers (pH > 4.0), at the same time, it could also be achieved highly sensitive APCI-MS identification using relatively low pH buffers (pH < 8.65). Our experiments also indicated that the mobile phases with a pH range of 4.0–6.0 did not cause significant changes in retention values for all IBAE-amine derivatives tested in LC separation (data are not shown).

As expected, the IBAE-amine derivative produced an intense molecular ion peak at m/z $[M+H]^+$ under APCI-MS in positive-ion mode. The collision-induced dissociation spectra of m/z $[M+H]^+$ produced the fragment ions at m/z 258.6, m/z 245.5 and m/z 230.6, respectively. MS ion current chromatogram and corresponding cleavage mode for the representative IBAE-C_8 derivative are shown in Fig. 4(a: MS/MS, b: MS). The fragment ion at m/z 258.6 derived from the cleavage of C–CO bond of the N-linked side chain. A modified McLafferty rearrangement mechanism gave the specific fragment ion at m/z 245.5, the characteristic fragment ion derived from the cleavage of N–C bond of the N-linked side chain, followed by the rearrangement of one hydrogen atom toward the benzoacridine core structure. The selected reaction monitoring, based on the m/z $[M+H]^+ \rightarrow m/z$ 258.6 and m/z 245.5 transitions, was specific for IBAE-amine derivatives.

3.6. Analytical performance

A standard consisting of 40 ng/ml amine derivatives (C_1–C_{12} amines) was prepared to examine the method repeatability. The relative standard deviations (R.S.D.s; $n = 6$) of the peak areas and retention times were <1.24% and <0.086%, respectively.

Precision and accuracy: The precision and accuracy values for all 3-day validated quality control for the 12 amines were examined by using triplicate set of spiked blank water samples at the concentration of 15, 25, and 40 ng/ml (low, medium, and high),

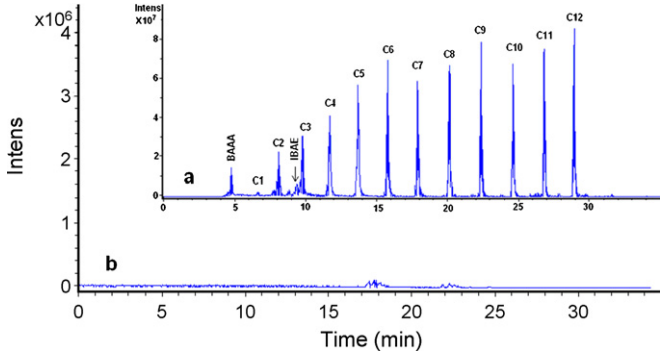

Fig. 3. (a and b) Ion current chromatogram for standard amine derivatives (20 pmol, 10 μl injection and followed into post-column mass spectrometer, **a** at pH 3.75; **b** at pH 8.65). [a] Relative standard deviation was determined at 40 ng/ml of each IBAE-derivatives (n = 6).
[b] Signal-to-noise ratio of 3.

respectively. The intra- and inter-assay accuracy, determined at each quality control level throughout the validated runs (each batch, n = 6), remained below 103.6% and 104.91%. The mean intra- and inter-assay precision for all amines levels were <4.32% and 4.84%, respectively.

The linearity was established over a 1000-fold concentration range for amines with analysis of serial standards in the concentration range of 0.1–200 ng/ml (corresponding injected amounts of amines from 1.0 to 2000 pg). Linear ranges and detection limits using fluorescence detection for amines by methods C are listed in Table 3. All of the amines were found to give linear responses over this range, with correlation coefficients of >0.9995. The linear regression analysis for higher concentrations of amines was not tested as the responses were over the range of linearity. As expected, amines exhibited a wide linear range. The fluorescence detection limits were in the range of 0.15–0.50 ng/ml. The online APCI-MS detection limits were in the range of 2.07–8.51 ng/ml.

Discrimination using derivatization methods A, B and C for labeling amines based on the fluorescence responses is significantly observed. The chromatograms are shown in Fig. 5a–c. A significant decrease in detector response in method A for the labeled IBAE-amine derivatives is observed. It is possible that amino functional groups of alkylamines are superior to a carboxylic group from BAAA molecules when reacting with CDI. This procedure probably forms another intermediate *N*-alkylcarbonylimidazole ACDI (see Fig. 1). Subsequently, the condensation reaction of ACDI with BAAA molecules is a slow reaction because the carboxylic ions from BAAA molecules are weak basicity, which results in remarkably

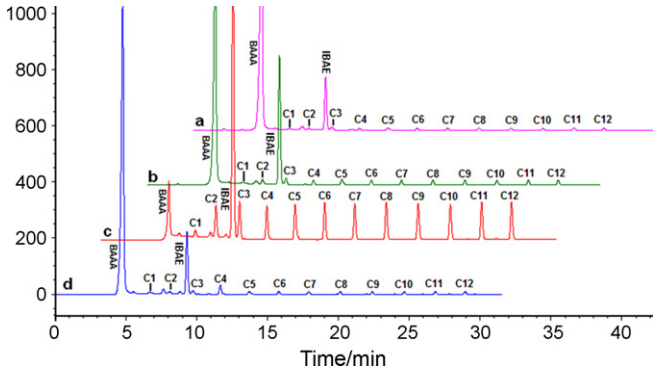

Fig. 5. (a–d) Chromatograms for amine standard solutions derivatized by applying: (a) method A; (b) method B; (c) method C; (d) method C in the presence of small quantity of water (>10%, w/w) in derivatization solution. C1, methylamine; C2, ethylamine; C3, propylamine; C4, butylamine; C5, pentylamine; C6, hexylamine; C7, heptylamine; C8, octylamine; C9, nonylamine; C10, decylamine; C11, undecylamine; C12, dodecylamine; DMA, dimethylamine; BAAA, benzoacridine-5-acetic acid; IBAE, 1-imidazole-2-(5-benzoacridine)-ethanone.

low detection responses for amine derivatives (Fig. 5a). Method C gives the highest fluorescence responses; it is probably because the derivatization in method C (direct intermediate reaction) is a rapid nucleophilic substitution reaction (Fig. 5c). In method B (two steps method), an obvious decreases in detector responses for the labeled IBAE-amine derivatives are observed (Fig. 5b). This result derives from the reason that the intermediate solution contains an excess amount of CDI coupling agent. When amines are subsequently added into the intermediate solution, amines, at least in part, firstly react with the excess amount of CDI to give, in part, the intermediate ACDI as described in method A. It is obvious that method C is superior to methods A and B, and therefore, the derivatization method C is selected in all cases in this study. In addition, derivatization in the presence of a small quantity of water in derivatization solution has been tested and compared with method C. When the amount of water in derivatization solution is >10% (w/w), a significant degradation in detector responses is observed (see Fig. 5d). The peak of intermediate IBAE is significantly reduced, the corresponding peak height of by-product BAAA is simultaneously intensified. It should be attributed to the reagent hydrolysis to form corresponding BAAA (m/z 289.8 $[M+H]^+$; MS/MS: m/z 246.0, molecular core moiety). If the amount of water in derivatization solution in method C is less than 5% (w/w), the derivatization yields for amine-derivatives are similar to the case of without water. As observed, the presence of BAAA (major by-product) does not interfere with the separation of amine derivatives. The similar results for the MS ion current chromatogram are also observed (ion current chromatogram is not shown). Comparing of derivatization of primary with secondary amine such as ethylamine/dimethylamine and butylamine/diethylamine, a greater degree of deviation for the detection response is observed, where the latter is 10–12 times less reactive than the former. The common trait of this type of nucleophilic substitution reaction is steric requirements for solute molecules. Secondary amines possess two alkyl groups around the nitrogen atom, which can assume much more spatially demanding configurations than those of primary amines for a nucleophilic substitution reaction. Aniline and benzenic ethylamine as representative aromatic amines are also evaluated, where the latter is similar to the case of alkylamines such as methylamine or ethylamine. But, aniline hardly reacts with the intermediate. There is no denying the fact that the basicities of amino functional groups of aromatic amines are weaker than those of alkylamines [35], which result in low detection responses.

3.7. The application of the method C

Fig. 6 shows the application of this method for the determination of amines present in an environmental wastewater. The contents of amines from two different sampling sites are listed in Table 4. The

quantitative analysis is carried out by fluorescence, corresponding components are simultaneously identified by online APCI-MS. Generally, the amine compositions depend on the type of wastewater samples. While C1–C5 amines in wastewater samples remain the high levels. The contents of >C5 amines in wastewater are also detected with the exception of being C6 and C7 amines are not determined in wastewater. As can be seen from Fig. 6, ethylamine (C2) is, in part, co-eluted with an impurity, and thus the quantitative analysis of ethylamine is performed by the corresponding peak height. Because the certified reference material was not available, therefore, the established IBAE method was compared with our previously reported method using BCEOC-Cl as labeling reagent for the determination of amines in the same sample (No. 2). The results with IBAE derivatization were in good agreement with those obtained using BCEOC-Cl as labeling reagent (data were not shown).

4. Conclusions

Although amine compound analysis is a relatively mature technique, current liquid chromatographic technology still needs improvement in the speed, accuracy and sensitivity of the analysis. The proposed method offers a number of advantages: (1) derivatization of amines used intermediate IBAE is relatively simple with little matrix interference; (2) derivatives are not only sensitive to fluorescence but also to MS ionizable efficiency with only changing mobile phase pH values; (3) maximal yields close to 100% are observed with a 4–6-fold molar reagent excess; (4) catalysts are not required for the derivatization. A possible disadvantage of this method is that the reaction of IBAE with amines in derivatization solution must be kept as small quantity of water as possible. Complete derivatization for further higher chain amines (>C12), in fact, can easily be achieved under the HPLC derivatization conditions proposed. The proposed method has been successfully applied to the determination of free amines in environmental wastewater with satisfactory results. In this study, the developed LC–MS technology was only used for the sensitive identification of amine derivatives. In addition, a possible advantage of this method is that the reagent IBAE may be used by on-line and on-column derivatization; corresponding work is in progress in our laboratory.

Scanning electron microscopy (SEM)
Light scattering (LS)
Dark-field light scattering images

ABSTRACT

A facile solution-phase synthesis route of highly uniform Cu_2O nanospheres (Cu_2O NPs) with the size of 57.7 ± 4.7 nm was developed, and then the nanoparticles were applied to live cell imaging under a common dark-field microscope. Starting from copper(II) salts, the synthesis of Cu_2O NPs was made in the presence of cetyltrimethylammonium bromide (CTAB) by reducing the copper(II) with sodium borohydride ($NaBH_4$) in aqueous medium and by aging process in the air. Monitoring of morphology evolution process of Cu_2O NPs with scanning electron microscopy (SEM) and measuring of the UV–visible spectra showed that the synthesis of Cu_2O NPs follows the reduction–oxidation coupled process of Cu^{2+} into Cu^0 species at first and then the resulted Cu^0 species into Cu_2O NPs in the air. Light scattering (LS) features have been measured with a common spectrofluorometer and a common dark-field microscope, and it was found that the as-prepared Cu_2O NPs display strong blue scattering light and can be applied for cell imaging. If incubated with human bone marrow neuroblastoma, transferrin-conjugated Cu_2O NPs can get into the cells and show strong pure blue light in cytoplasm. Further investigations showed that the Cu_2O NPs could be applied for probes for conformation of proteins.

1. Introduction

Copper oxide, a p-type metal oxide semiconductor with a direct band gap about 2.2 eV, has attracted interest of researchers due to its unique optical properties [1] and applications in photodegradation [2], gas sensing [3], catalysis such as a catalyst of a carbon nanofibers [4]. Therefore, efforts on the syntheses and applications of nanoparticles related to copper element have been made recently. Methods such as γ-ray irradiation reduction [5], electrochemical deposition [6], solid-state [7] or liquid-phase [8,9] have been reported for the synthesis of cuprous oxide nanoparticles (Cu_2O NPs). Of these methods, a variety of capping agents such as sodium dodecyl sulfate [10] and reducing agents such as ascorbic acid [11–13] have been employed [1,3,5,8,9,13–17], and the following synthesis generally involves in the step that directly reduces the copper(II) salt into Cu_2O NPs, which, however, needs complicated multiple procedures [4,18] or to be in a medium of organic solvents participating in [1,3]. However, we recently noticed an indirect method, that is at first reducing copper(II) into Cu^0 species and then oxidizing the Cu^0 species into Cu_2O NPs [8], which, although indirect, is interesting since it is based on the slow oxidation of Cu^0 state into Cu^+ state in the air and only once addition of all reactants needed without annealing step involved, making operation so easy to handle that different morphology of Cu_2O NPs could be available [8].

Light scattering (LS) features of metallic nanoparticles (NPs) are unique and it has increasingly reported that metallic nanoparticles have become promising optical probes due to their photostability and colorful features. Recent efforts on light scattering optical properties of metallic nanoparticles with dark-field microscopy have prompted our interest since that could supply good imaging ways [19–21]. Up to now, the light scattering imaging of metallic nanoparticles is mainly concentrated on gold and silver nanoparticles [22–25]. It is regretted that gold NPs have relatively low light scattering power [26], and silver nanoparticles, although having strong light scattering ability, cannot supply stable light scattering features because general synthesis protocols of silver nanoparticles are apt to produce somewhat faceted particles with slightly different shapes [27]. Therefore, finding a substitute with high scattering power through simple process is meaningful and compulsory.

Herein, we report a facile low-cost solution-phase synthesis method of Cu_2O NPs in ambient conditions by reducing copper(II) salts in water in the presence of CTAB with $NaBH_4$ and then by

doi:10.1016/j.talanta.2009.09.042

aging the produced Cu^0 species in the air. The available Cu_2O NPs are highly uniform with the size of 57.7 ± 4.7 nm, and can scatter strong blue color light. Due to the high scattering power, we apply the as-prepared Cu_2O NPs for scattering imaging of live cell by using the human bone marrow neuroblastoma as model cells.

2. Experimental

2.1. Materials

All regents were prepared by dissolving their commercial products in doubly distilled water (18.2 MΩ). Sodium borohydride ($NaBH_4$) and copper sulfate ($CuSO_4{\cdot}5H_2O$) were commercially obtained from Huanwei Fine Chemical Co., Ltd. (Tianjin, China) and Chujiang Chemical Co., Ltd. (Wuhan, China), respectively. Cetyltrimethylammonium bromide (CTAB) was purchased from Sinopharm Group Chemical Regent Co., Ltd. (Shanghai, China). Polystyrene sulfonate (PSS, MW 20 kD) and Transferrin was purchased from Sigma–Aldrich Co., Ltd. (Shanghai, China). Proteins BSA, lysozyme and trypsin were commercially obtained from Sigma (Steinheim, Germany). Prion protein (PrP^C) was prepared in our laboratory. HEPES buffer (1.0 mM, pH 7.4) was used to control the acidity. Glass slides (12.7 mm × 76.2 mm × 1 mm) for the light scattering imaging were commercially obtained from Shitai Experimental Instrument Co. Ltd., Haimen (Jiangsu, China).

2.2. Apparatus

The absorption and light scattering spectra were measured with a Hitachi U-3010 spectrophotometer and a Hitachi F-4500 fluorescence spectrophotometer (Hitachi Ltd., Tokyo, Japan), respectively. For the measurements of light scattering spectra, the excitation and emission monochromators of the spectrofluorometer should be coupled and simultaneously scanned by keeping $\lambda_{em} = \lambda_{ex}$. An S-4800 scanning electron microscope (SEM, Hitachi Ltd., Tokyo, Japan) was employed for monitoring the morphology change of Cu_2O NPs during the whole synthesis process. The optical light scattering imaging of Cu_2O NPs was made with an Olympus BX51 inverted microscope coupled with a tungsten lamp and a highly numerical dark-field condenser (U-DCW, 1.2-1.4, Tokyo, Japan) and the images were captured with a Nikon Coolpix-4500 digital camera. In order to get the dark-field light scattering spectra of single nanoparticle, an imaging spectrograph (Micro Spec TM 2300i, Acton Research Corporation) coupled with a CCD detector (Roper Scientific, Inc.) were employed. A 100 × /1.3 oil Iris objective (UPLANFLN) was used for subsequent collection of dark-field light scattering signals of the single nanoparticle. All circular dichroism (CD) measurements are obtained on a J-810 CD spectrometer. The phase structures of the Cu_2O NPs were analyzed by X-ray powder diffraction (XD-3 system, Purkinje General Instrument Co. Ltd., Beijing, China) with Cu Kα (1.5405 Å) radiation source. An MVS-1 vortex mixer (Beide Scientific Instrumental Ltd., Beijing, China) was employed to mix the solutions.

2.3. Synthesis of Cu_2O NPs

Cu_2O NPs were prepared as the method of preparing positively charged Au nanospheres [28] following a solution-phase process [1,9]. Firstly, 0.16 mL of 0.1 M copper sulfate, 1.6 mL of 0.1 M CTAB and 1.24 mL of doubly distilled water were added into a 10-mL clean test tube. After shaking vigorously for several seconds by vortex mixer, 7 mL of 0.04 M freshly prepared ice-cold $NaBH_4$ was added. By keeping the vigorous shaking, the mixture initially displays light brown and then deep red after 15 min. The mixture solution was then left undisturbed allowing slow oxidation of air by keeping in a 27 °C water bath throughout the procedure under which temperature the crystallization of CTAB could be prevented. About 9 h after the reaction started, some yellow flocculent precipitates get produced, and about 16 h, a bright yellow transparent solution of Cu_2O NPs could be obtained. The yielding products are stable at least 1 month if stored in a 4 °C refrigerator. Samples prepared for SEM and dark-field imaging were made by separating Cu_2O NPs from excessive CTAB by centrifuging at 27 °C for 15 min at 12,000 rpm. After repeating the centrifugation twice, the precipitate was collected and redispersed in about 200 μL of deionized water for characterization.

Drops of 5 μL of redispersed solution were pipetted onto the aluminum foils and the glass slides respectively for the measurements of SEM and dark-field scattering light imaging after they dried in the air. SEM measurements were performed with a voltage of 20 kV and a working current of 10.0 μA. Dark-field light scattering image was performed on the Olympus BX51 inverted microscope fitted with a transmitted dark-field condenser and a 100× objective.

2.4. Preparation of transferrin-conjugated Cu_2O NPs

Cu_2O NPs were functionalized with transferrin following the report previously with minor modifications [24]. Briefly, 10 mg/mL polystyrene sulfonate solution containing 1.0 mM NaCl was added to the Cu_2O NPs suspension with a 1:10 volume ratio and allowed to react for 30 min. The particles were then collected *via* centrifugation at 9000 rpm for 10 min, resuspended in HEPS buffer. Transferrin solution, which had been previously diluted in the same HEPES buffer, was then mixed with PSS-capped nanoparticles and allowed to react for 45 min. The nanoparticles were then centrifuged and redispersed into PBS buffer (pH 7.4) to form a stock solution.

2.5. Cell culture for imaging analysis

Human bone marrow neuroblastoma (SK-N-SH cells) was cultured in DMEM medium plus 5% fetal bovine serum at 37 °C under 5% CO_2. Typically, a 1-mL suspension of SK-N-SH cells (about 10^5 cells/mL) was plated onto a cover slip, grown for 2–3 days, then treated with 0.1 mM transferrin-conjugated Cu_2O NPs for 3 h, rinsed with PBS buffer, fixed with paraformaldehyde and sealed with a small amount of glycerol.

2.6. Cu_2O NPs as probes for configuration of proteins

Into a 1.5-mL plastic vial, 40 μL of HEPES buffer (pH 7.4), 80 μL of the prepared Cu_2O NPs, which was centrifuged for 10 min at a speed of 8000 rpm in order to remove CTAB and redispersed with the same amount of ultra pure water (18.2 MΩ), and an appropriate volume of proteins including bovine serum albumin (BSA), lysozyme, trypsin and prion (PrP^C) were added. The above mixture was finally diluted with ultra pure water to the total volume of 400 μL. After vortex-mixed and placed for 30 min at room temperature, the mixture was transferred to CD measurements.

3. Results and discussion

3.1. Synthesis of Cu_2O NPs

Our preparation of Cu_2O NPs starts by using copper(II) salts in water in the presence of CTAB with $NaBH_4$. 15 min later after the start of the redox reaction, we found that the mixture gets deep red, and following undisturbed placement in the air makes the color of mixture get changes gradually. By monitoring the UV–visible absorption changes in the following processes, we found that an absorption band at 568 nm (Fig. 1), which is the characteristics of

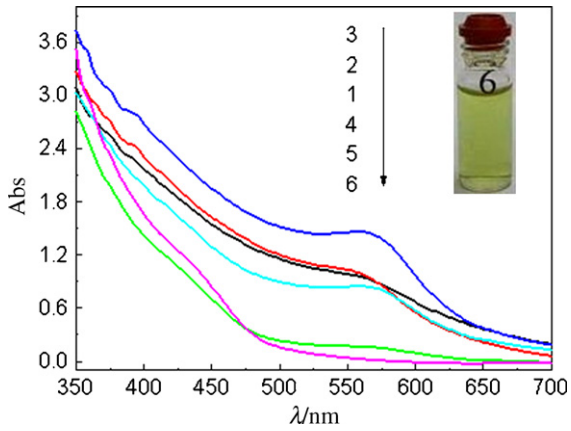

Fig. 1. UV–visible absorption spectra of the reaction mixture when exposing to air. Blue curve, 15 min; red curve, 2 h; black curve, 9 h; cyan curve, 11 h; green curve, 12 h; magenta curve, 16 h. All the molar ratio of CTAB/$NaBH_4$ is 0.57. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

the plasmon resonance absorption (PRA) band of copper nanoparticles (Cu^0 NPs) [8,29,30], gradually appears. After 12 h, however, the PRA band gradually decreases, indicating that depletion of Cu^0 NPs occurs. At 16 h, a broad absorption from 370 nm to 450 nm increases, indicating that Cu_2O NPs have formed (see following further identification with XRD analysis). During the slow oxidation process in the air, the appearance and disappearance of the 568 nm PRA band indicate our preparation of Cu_2O NPs proceeds by the way of the formation of Cu^0 [8].

The synthesis of Cu_2O NPs by the way of the formation of Cu^0 starting from the reduction of Cu^{2+} species into Cu^0 species and then completion after the oxidation of the Cu^0 species into Cu^+ species could be further monitored in terms of the state of the formed species at various stages by SEM. Fig. 2A–C shows images of the reaction mixture after the reaction occurred at 2 h, 8 h and 16 h. It was found that particles were so small that it was difficult to be precipitated by centrifuging at the initial time. At 2 h, it was observed that the particles are irregularly spherical with the size about 15 nm (Fig. 2A). In the following period, these spheres gradually grew up to the size of about 50 nm (Fig. 2B), and there are some cubic particles having rough surfaces with the size of about 100 nm (which are marked in red circles in Fig. 2B). Fig. 2C shows that cubic particles are dissolved and highly uniform spheres with smooth surface if the aging is made further are available. These nanospheres are 57.7 ± 4.7 nm in size by averaging 20 particles at random.

From SEM images above, we could confirm that morphology evolution of the Cu_2O NPs was time-dependent and involves in a dynamic mutative process. After the initial formation of the red solutions immediately, the reaction mixture kept red up to 8 h. During this period, Cu^0 species are in the solutions owing to the excessive reducing agent of $NaBH_4$. After the reaction occurred at 8 h, however, the deep red color diminished gradually and yellow flocculent precipitates appear, indicating the beginning of oxidation process. It could be visually observed that the oxidation process occurred preferentially in the upper solution and then continuously extended to the whole solution because Cu^0 species in the upper solution can react relatively sufficiently with oxygen in the air. The process undergoes such transition state and these yellow flocculent precipitates are corresponding to cubic particles even if larger

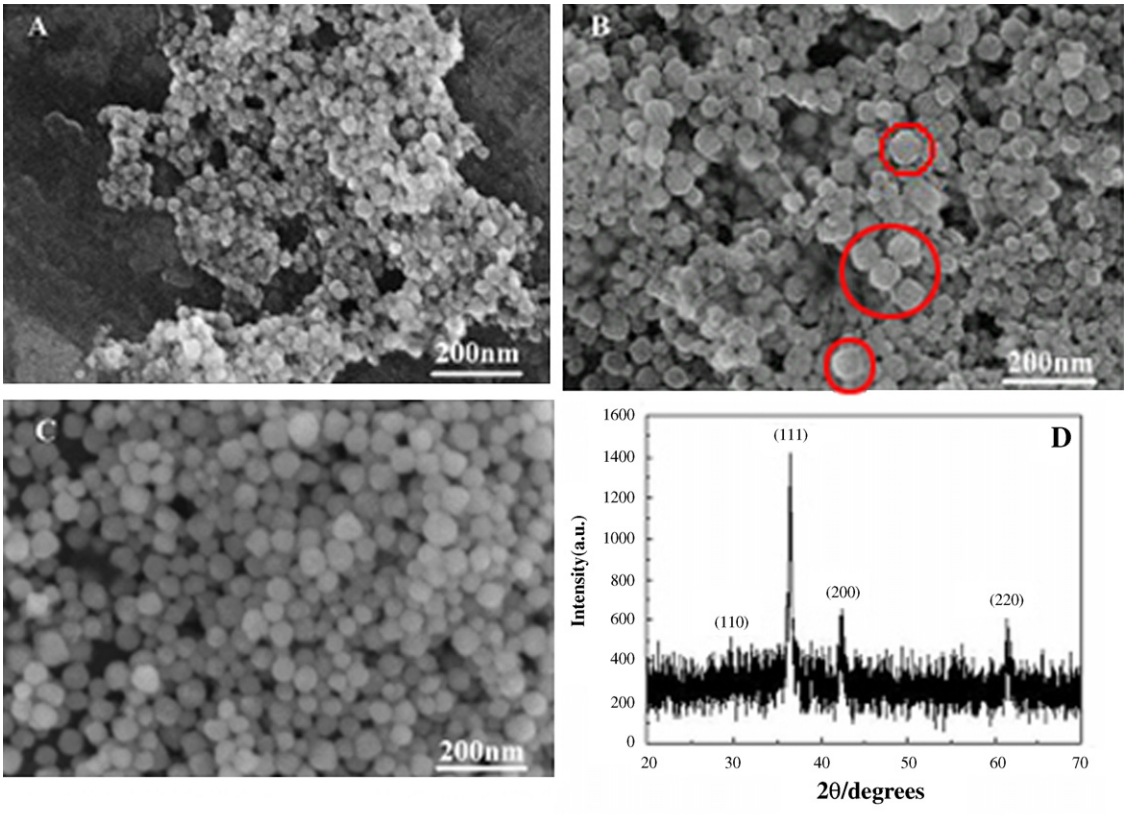

Fig. 2. Time-course of the oxidation process of Cu^0 NPs into Cu_2O NPs as monitored by SEM imaging. 2 h for (A), 8 h for (B) and 16 h for (C). (A) Cu^0 NPs, deep red; (B) the transition state with yellow flocculent precipitates, and the red circles indicate some large particles formed; (C) Cu_2O NPs, which is bright yellow transparent solution and it is obviously that the large particles in (B) are obviously dissolved. All the molar ratio of CTAB/$NaBH_4$ in (A), (B) and (C) is 0.57. (D) XRD pattern of the as-prepared Cu_2O NPs. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

than 100 nm in SEM images (Fig. 2B marked in red circles). After the reaction occurred at 16 h, yellow flocculent precipitates dissolved gradually and regular spherical products could be gained.

Fig. 2D displays the XRD pattern of the as-prepared Cu_2O NPs when the molar ratio of CTAB/$NaBH_4$ is 0.57. All the three diffraction peaks are indexed according to pure cubic phase of Cu_2O, which is consistent with the values in the standard card (JCPDF 05-0667). No other diffraction peaks arising from possible impurities such as Cu^0 and CuO species are detected, indicating that only Cu_2O NPs were obtained. The relative intensity of planes {1 1 1}, {2 0 0}, {2 2 0} is 1:0.44:0.43, being identical to the typical relative intensity of 1:0.40:0.43, indicating the equal growth rate for various faces.

By optimizing the experimental conditions, we got a conclusion that Cu_2O NPs are highly uniform and have smooth surfaces when the molar ratio of CTAB/$NaBH_4$ is 0.57, and else we could get irregular aggregations and the products are even inhomogeneous. It has been well known that CTAB can effectively prevent nanoparticles from aggregation. So we can control oxidation growth speed and aggregation by adjusting the molar ratios of CTAB/$NaBH_4$. This is one important factor influencing the morphology of Cu_2O NPs.

It has been known that the preparation of gold seeds at the initial time is very important in the synthesis of gold nanoparticles [11]. Similarly, Cu^0 nanoparticles at the initial time should be small and homogeneous. Under the conditions of high reaction temperature or slow addition of $NaBH_4$, the nucleation is so rapid that morphology of initial seed nanoparticles would be inhomogeneous, influencing the oxidation process of Cu_2O NPs. In addition, the temperature during the preparation should be controlled since crystallization of CTAB should occur if the temperature is too low. So we should control the reaction at 27 °C, which could not only prevent CTAB from crystallization but also can slow down the formation speed of nuclei.

3.2. *Plasmon resonance light scattering features of Cu_2O nanoparticles*

Fig. 3 displays the characteristics of the light scattering spectra during the oxidation process. From the results in Fig. 3, we can find LS intensity of Cu_2O NPs in solution is strong compared with the initial solution. It has reported that silver and gold are efficient plasmon scatterers following the order of Ag > Au > Cu > Al [26]. In other words, Cu NPs have weak plasmon scattering power. Before the reaction occurred at 9 h, Cu^0 species are dominant in the mixture, so the solution LS intensity is weak. At 11 h, a weak LS peak

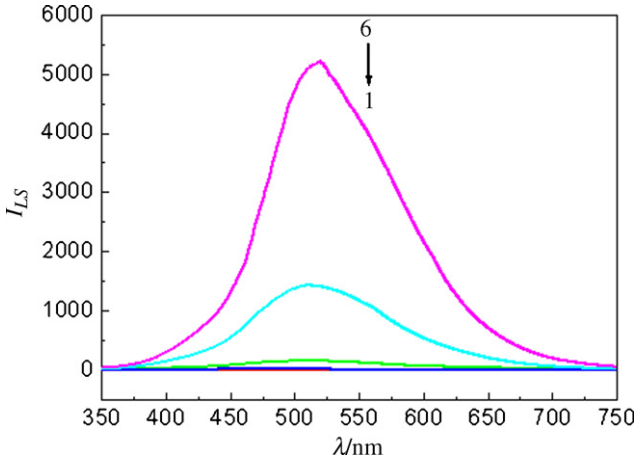

Fig. 3. The corresponding light scattering spectra of reaction mixture at different time: curve 1, 15 min; curve 2, 2 h; curve 3, 9 h; curve 4, 11 h; curve 5, 12 h and curve 6, 16 h. Curves 1–3 overlapped throughout. All the molar ratio of CTAB/$NaBH_4$ is 0.57.

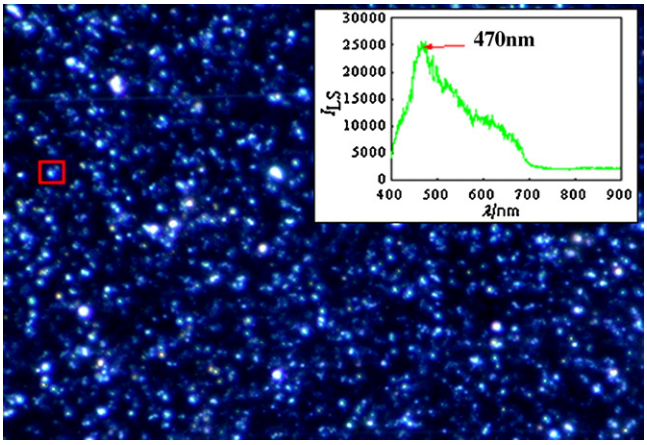

Fig. 4. Dark-field light scattering images of the as-prepared Cu_2O NPs. The molar ratio of CTAB/$NaBH_4$ is 0.57. The inserted picture is the dark-field light scattering spectrum of single Cu_2O in the square.

at 520 nm emerges, indicating the formation of Cu^+ species. At last, a very strong LS peak located at 520 nm is observed, indicating the formation of Cu_2O NPs. From the investigations on the LS spectra during the oxidation process, we can conclude that the LS intensity of the solution gets increased after the oxidation process and we can get promising Cu_2O NPs with special scattering properties.

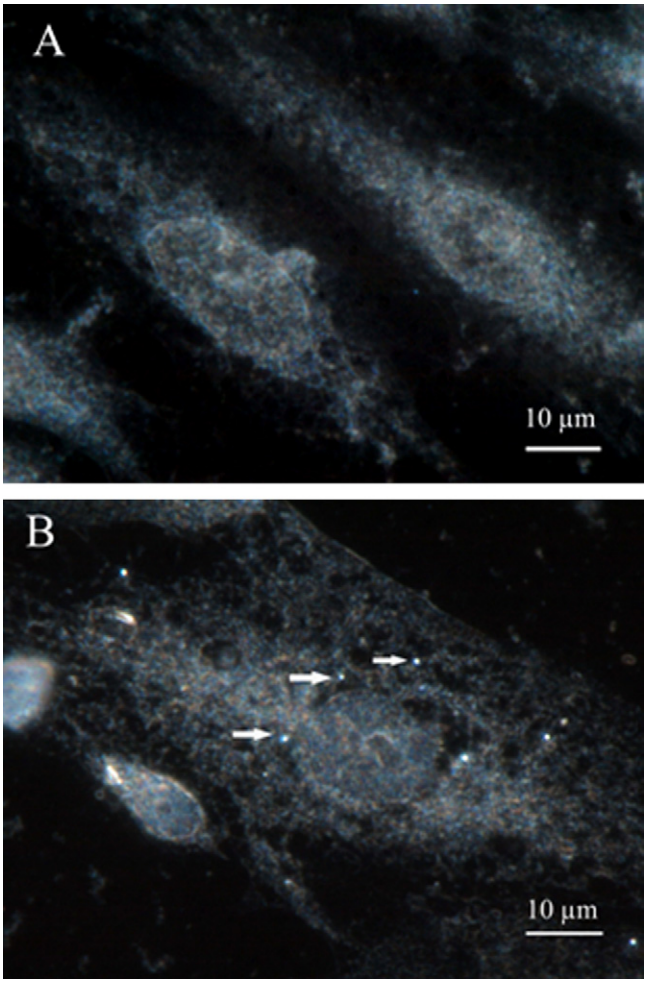

Fig. 5. Dark-field light scattering images of SK-N-SH cells after incubation with CTAB-capped Cu_2O NPs (A) and transferrin-conjugated Cu_2O NPs (B) for 3 h, respectively. Arrows indicate the Cu_2O NPs entered into cytoplasm in image (B).

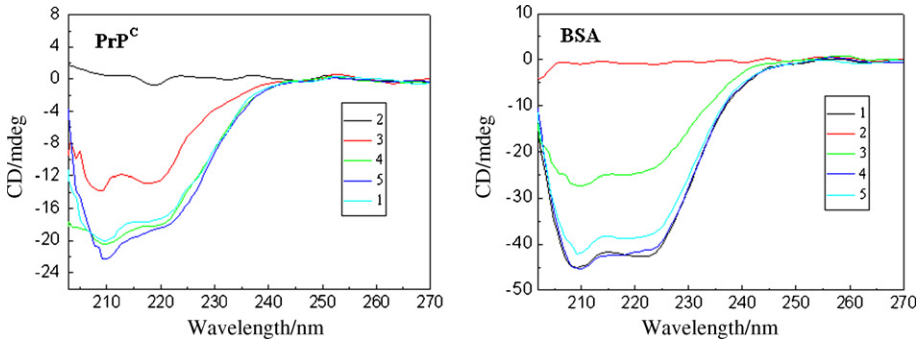

Fig. 6. CD properties of PrP^C and BSA after their interaction with Cu_2O NPs, CTAB and Cu^{2+} ion. Curves 1–5 are respectively protein, Cu_2O NPs, Cu_2O NPs and protein, Cu_2O NPs and Cu^{2+} ion, Cu_2O NPs and CTAB. Concentration of PrP^C, and BSA is 0.07 mg/mL and 0.05 mg/mL. The amount of copper element and CTAB is in accordance with those contained in the corresponding Cu_2O NPs solution. All the acid condition is HEPES buffer pH 7.4.

3.3. Dark-field light scattering imaging of cells

Resonance light scattering features from metallic nanoparticles are specific and it has increasing number of reports showing that elastic light scattering features from metallic nanoparticles can be measured so as to infer the position and local environments of nanoparticle, or relative orientation (in the case of nanorods) [31]. Considering the special applications of light scattering in those fields, we made efforts to investigate the light scattering optical properties of Cu_2O NPs.

From dark-field light scattering images in Fig. 4, we can see that Cu_2O NPs scatter pure blue light without any other interference color. The light scattering color of Cu_2O NPs is monochromic, which is different from silver colloids whose scattering colors are various. The inserted picture in Fig. 4 displays the light scattering spectrum of single Cu_2O nanoparticle deposited on the surface of a glass slide. It has a light scattering peak located at 470.0 nm in the blue region. Comparison with the light scattering features of Cu_2O NPs in solution, the light scattering spectrum of single nanoparticle on the glass substrate has 50 nm blue-shifted. One possible reason for the blue shift concerns the dielectric function at the metal/surface or metal/solvent interface [19,32]. It is probably associated with strong fields away from the substrate [23]. In addition, this measured shift is physically possible to the different response of the detectors of spectrofluorometer and CCD. Even though, the strong light scattering light emission of Cu_2O NPs could be identified and could be further applied. In such case, we consider applying Cu_2O NPs as an optical probe for live cell imaging with the light scattering properties by dark-field microscopy.

Fig. 5 shows the light scattering images of the human bone marrow neuroblastoma after incubation with CTAB-capped Cu_2O NPs (A) and transferrin-conjugated Cu_2O NPs (B) for 3 h, respectively. As indicated by the arrows in Fig. 5B, the transferrin-conjugated Cu_2O NPs can get into the cells and show strong pure blue light in cytoplasm since the uptake of transferrin-conjugated Cu_2O NPs may be due to the receptor-mediated endocytosis, while the CTAB-capped Cu_2O NPs cannot get into the cells (Fig. 5A). It is obviously that our present work identifies the possibility of Cu_2O NPs as a novel optical probe to image the proteins in living cells due to its special light scattering optical properties.

3.4. Cu_2O NPs as probes for configuration of proteins

In the experiment, we unexpectedly found that the prepared Cu_2O NPs can not only show their application in imaging protein in living cells but also can lead to CD property changes of proteins. In the control experiment we investigate the effect of CTAB and Cu^{2+} ion on the CD characteristics of proteins. After the individual interaction of PrP^C, BSA, lysozyme and trypsin with CTAB and Cu^{2+} ion under the experimental condition, four kinds of proteins show no obvious CD changes. However, to some extent, Cu_2O NPs can selectively lead to obvious CD changes with proteins such as PrP^C and BSA (Fig. 6) but lysozyme and trypsin cannot. Decreasing of CD indicates that the tertiary structure of proteins does not show obvious changes while a local structural alteration of proteins occurs [33,34]. This local alteration is maybe due to the hydrolytic ability of proteins on the substrate.

4. Conclusion

In this contribution, we obtained highly uniform Cu_2O NPs upon slow oxidation of Cu nanostructures *via* a facile low-cost solution-phase method at 27 °C. To our knowledge, this is the first report about the investigations on the light scattering properties of Cu_2O NPs *via* dark-field light scattering images and light scattering spectrum of a single particle. The results showed that Cu_2O NPs have relatively strong pure blue light scattering emission after undergoing the oxidation process. Furthermore, the present application of Cu_2O NPs shows high promise for Cu_2O NPs which possibly not only lead to the local structural alteration of proteins but also act as a novel optical probe applied in cell or molecular biology imaging due to their special scattering optical properties.

ABSTRACT

This study compares and evaluates the effect of various matrices on liquid chromatography (LC) coupled with tandem mass spectrometry (MS/MS) analysis. Permanent post-column infusion (PCI) was used to quantify matrix effects. In this way, the suppressed or enhanced signal of the target material resulting from different co-eluting matrix components could be assessed. Twenty-four biological samples from *in vivo* and *in vitro* experiments were selected for this study. In addition, 7 sample components were further analyzed after sample preparation by protein precipitation. Multiple regression analysis was used to investigate the collinear relationship between matrix effects and co-eluted components at different time intervals. We found that salt was the dominant factor which impacted changes in signal detection. In order to eliminate it, we used ammonium formate as a modifier of the mobile phase which resulted in charge-state redistribution profiles so that a homogeneous matrix formed. By employing pulse gradient chromatography in the presence of 5 mM ammonium formate, favorable improvements of enhanced signal intensity and reduced matrix effects were obtained. These experiments also indicated the feasibility of using analogue IS during bio-analysis which contributed to an overall faster assay that would be suitable for drug discovery and development purposes.

1. Introduction

Evaluating matrix effects is of the utmost importance when developing a quantitative liquid chromatography/tandem mass spectrometry (LC–MS/MS) method. Co-eluting compounds originating from the matrix can cause signal enhancement or suppression. When the compounds and target material enter the ion source at the same time, the ionization efficiency of the target material might be influenced [1]. In this way, the matrix can affect the reproducibility and accuracy of the method. With an increase in the number and types of biological samples required for pharmacokinetic studies, an understanding of the matrix effects becomes increasingly important in order to obtain timely and accurate bio-analysis [2–7].

Several solutions can be employed to minimize the interference caused by matrix components. Extensive cleanup procedures prior to LC–MS/MS analysis can help to reduce the introduction of matrix components [8,9]. Improved chromatographic separation can often reduce the interference of the matrix components with the target materials [10]. Another approach is to dilute the final sample extract as much as possible in order to simultaneously dilute the matrix components [11,12]. Standard additions of each material of interest into the sample may also be used to compensate for matrix effects [13]. In some cases, researchers opt to use an ionization source, such as APCI, which is less sensitive, thus minimizing the matrix effects [14]. One of the most effective options to compensate for signal changes is the use of isotope-labeled analogues [15]. However, in most cases, the matrix effects cannot be completely eliminated, despite the use of the aforementioned operational strategies. In addition, most of the approaches are time-consuming, laborious and do not contribute to efficient analytical performance. Moreover, isotope-labeled internal standard (IS) may not be available for some materials because of difficulties in synthesis and/or cost, especially for pharmacokinetic screening study experiments.

There is a need for more simple solutions to the problem of matrix effects. Dilute and shoot and protein precipitation (PPT) are popular techniques because of their simplicity. Sample preparation with PPT is widely used in bio-analysis of plasma samples. Overall, PPT offers a generic and fast sample preparation technique that can be easily automated to deal with biological samples. Fast gradients and short columns can be utilized during high-throughput LC–MS/MS assays to reduce run time. Electro-spray ionization (ESI) techniques have achieved great popularity because of their high selectivity and sensitivity for the determination of trace substances.

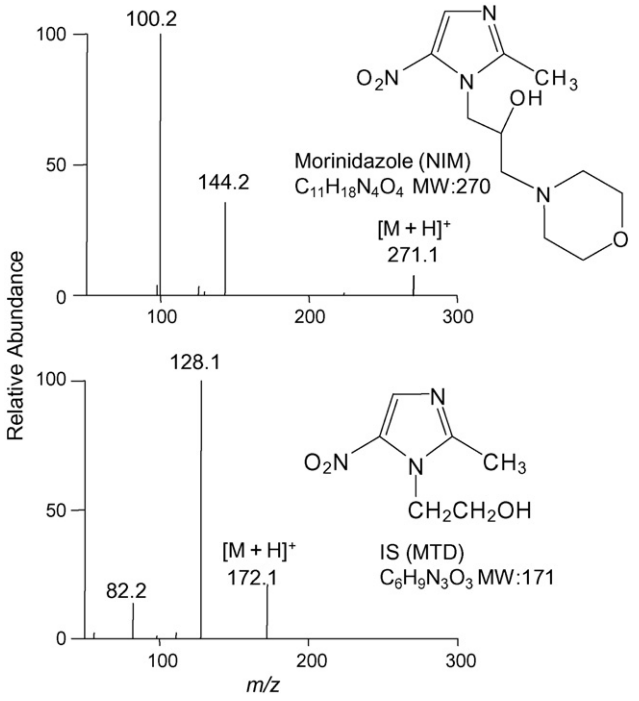

Fig. 1. MS/MS product ion spectra of the protonated molecules ([M+H]$^+$) of morinidazole (NIM) and IS (metronidazole: MTD), as well as their chemical structures.

In this study, we first investigated matrix effects stemming from 24 biological matrices from both *in vivo* and *in vitro* studies of morinidazole (NIM, Fig. 1), a National Class I Antimicrobial Drug. It belongs to the nitroimidazole group of antibiotics, and is mainly used in amoebas, trichomoniasis and anaerobic bacterial infections. First the percentage of morinidazole in each matrix was analyzed. Then multiple regression analyses were used to identify the collinear relationship between matrix effects and co-eluted matrices components during different time points of special pulse gradient chromatography. A pulse gradient with ammonium formate was utilized and was found to eliminate matrix effects. The feasibility of using an analogue IS metronidazole (MTD, Fig. 1) for the rapid bio-analysis of morinidazole was also evaluated. It is hoped that the work presented here will help to establish methods for efficient LC–ESI-MS/MS bio-analytical assays.

2. Experimental

2.1. Chemicals

Analytical reference standards of morinidazole and metronidazole were supplied by Jiangsu HengRui Medicine Co., Ltd. (Lianyungang, China). HPLC-grade methanol was purchased from Merck (Darmstadt, Germany). Ammonium formate was obtained from Aldrich (Milwaukee, WI, USA). Other organic solvents and chemicals used were of analytical grade and were obtained from Shanghai Chemical Reagent Co. (Shanghai, China). Deionized water was generated from a Millipore Direct-Q® 3 UV water purifying system (Bedford, USA). Hank's balanced salt solution (HBSS) was purchased from Sigma–Aldrich. Human liver microsomes were obtained from DB Gentest (USA), the other microsomes were prepared in our laboratory according to the method of differential centrifugation. Animal samples obtained by experiments which were conducted according to protocols approved by the Review Committee of Animal Care and Use at the Shanghai Institute of Materia Medica (Shanghai, China). Human plasma samples were provided by Renji Hospital (Shanghai, China) and approved by ethical committee. Healthy volunteers were enrolled in this study after providing written informed consent.

All biological material was stored at −80 °C until use.

2.2. Instrumentation

A TSQ Quantum triple stage quadrupole mass spectrometer (Thermo Finnigan, San Jose, CA, USA) was interfaced via an ESI probe with an Agilent 1100 series liquid chromatograph that included a vacuum degasser, a binary pump, an autosampler, and a thermostatted column compartment (Waldbronn, German). The Agilent Chemstation and Finnigan Xcalibur software packages were used for controlling the LC–MS/MS system, data acquisition and processing. Protein concentration was determined using the Bradford method by measuring the absorbance at 595 nm with a Bio-Rad 550 Microplate Spectrophotometer (BIO-TEK Instruments, Inc., USA). An automated biochemical analyzer (Hitachi-7080) was used for the component analyses of the matrices.

2.3. LC–MS/MS conditions

An Agilent Zobax SB C18 LC column (50 mm × 2.1 mm, 5 μm) with a solvent flow rate of 0.35 mL/min was used. The sample injection volume was 10 μL. Approximately 63 mg of ammonium formate was dissolved in 10 mL of water to prepare the stock solution at a concentration of 100 mM. Mobile phase A (ACN/H_2O, 2:98, v/v, 5 mM $HCOONH_4$) and mobile phase B (ACN/H_2O, 90:10, v/v, 5 mM $HCOONH_4$) were prepared by the addition of ammonium formate stock solution and the required volume of water or ACN. The solvent gradient adopted was as follows: 0–0.1 min, linear from 0 to 100% B; 0.1–0.4 min, isocratic 100% B; 0.4–0.41 min, linear from 100 to 0% B; and 0.41–4 min, isocratic 0% B. All MS/MS data for morinidazole were collected in positive ion mode by selected reaction monitoring (SRM) of the transition m/z 271 → 100; for metronidazole the transition m/z 172 → 128 was monitored. The ESI-MS was operated in positive ion mode with the following instrument settings: spray voltage, 4700 eV; sheath gas pressure, 35(a.u.); aux gas pressure, 10(a.u.); capillary temperature, 300 °C.

2.4. Sample preparation

Protein precipitation extraction was performed using a 4:1 ratio of methanol to sample. In brief, a 20 μL aliquot of each sample was mixed with 80 μL of MeOH, vortexed for 5 min, and then centrifuged at 21 885 × g for 10 min. The resulting supernatant (10 μL) was used directly for LC–MS/MS analysis.

Selected tissues including the abdominal fat, testicle, bladder, spleen, stomach, ileum, colon, kidney, liver, lung, heart, and brain were excised from SD rats, rinsed in ice-cold saline before gentle blotting on absorbent paper and weighing. The tissues were homogenized in 4 volumes of ice-cold saline. The tissue homogenate samples were stored at −80 °C until analysis. The plasma samples were derived from mouse, rat, rabbit, dog, monkey, and human, respectively.

2.5. Post-column infusion experiments

A blank pretreated biological sample was injected during continuous post-column infusion of a 100 ng/mL solution of morinidazole and metronidazole at a flow rate of 5 μL/min. The chromatographic area of interest was determined by comparing the SRM chromatographic profiles for morinidazole or metronidazole obtained with an injection of the blank pretreated biological sample and an equivalent injection of mobile phase. Each experiment was performed in duplicate. The instrumental setup for permanent

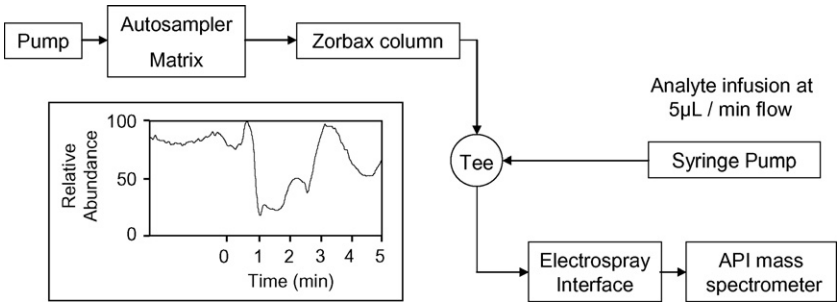

Fig. 2. The instrumental setup for permanent post-column infusion and the chromatographic run map for infusion profiles of analyte standards after injection of bio-matrices.

post-column infusion and the chromatographic run map is shown in Fig. 2.

2.6. Matrices component determination

The concentration of albumin (ALB) in the sample prepared by protein precipitation was determined by Bradford quantification at 595 nm. The linear range of protein assayed by the Bradford method was 25–400 ng/mL (R^2 = 0.996). The content of triglyceride (TG), total cholesterol (TC), Na, K, P, and Cl was determined using an auto biochemical analyzer.

2.7. Multiple regression analysis

SPSS Statistics 14.0 software was employed for multiple regression analysis to identify collinear relationships between the variables measured. The percentage of enhancement or suppression of the signal at different times in the chromatogram is related to the different matrices components co-eluted at the different time intervals.

3. Results and discussion

3.1. Analysis of pharmacokinetic samples by a post-column infusion method using pulse gradient chromatography in the presence of 24 different bio-matrices

The matrix effects were evaluated during method development of the simultaneous analysis of morinidazole and metronidazole in 24 biological samples. The differences in the RICs illustrate signal suppression of −52 to 100% from 1 to 2 min, −90 to 300% from 2 to 3 min, and −40 to 300% from 3 to 5 min.

Table 1 provides an overview of the results obtained with the continuous post-column infusion experiments. The different time intervals where the matrix impacted the chromatographic analysis are documented for each combination of bio-fluid, sample preparation technique, and ionization type. For reporting purposes, the matrix effect was expressed as the percentage of suppression or enhancement of the signal. Because of the variable nature of the matrix effect, the percent matrix effect is a relative indicator of the degree of suppression or enhancement.

The data indicates that the representation of matrix effects is variable in different biological samples and both signal suppression and enhancement occurred. Signal suppression was more common than signal enhancement in our study. The variety of matrix effects was unpredictable and unsystematic across the time span of chromatographic analysis. For example, within 2–3 min of retention time, the signal changed from 90% suppression to 300% enhancement. These types of results can lead to large variances in exposure assays and thus influence the estimate of drug concentrations during preclinical development experiments.

In our study, a special pulse gradient was used for quick and reliable quantification of morinidazole and metronidazole in biomatrices. The start proportion and the elution proportion were set at 0% B and 100% B, the start proportion segment (SPS) was very short (0.1 min) and the elution proportion segment was only 0.3 min. The column equilibrium segment lasted from 0.4 to 4 min (Fig. 3, top). The retention time of NIM and IS was almost the same (Fig. 3, bottom). The pulse gradient method was extremely simple to optimize. Separation of the analytes from the sample matrix components and organic solvent was optimized by simply tuning the SPS, rather than tuning the mobile phase composition (for isocratic elution) or gradient steepness (for conventional gradient elution). In addition, the pulse gradient method overcomes eluotropic effects more effectively than isocratic and conventional gradient methods.

3.2. Matrices component analysis results

The mechanism and the origin of the matrix effect are not fully understood, but it may originate from the competition between an analyte and the co-eluting, undetected matrix components reacting with primary ions formed in the HPLC–MS/MS interface. Matrix ion-suppression or enhancement is considered to more likely be a problem when using protein precipitation, which is often used as a routine sample preparation procedure for LC–MS/MS assays in drug discovery because of its simplicity [16]. The use of protein precipitation may cause ion-suppression or enhancement in ESI due to a lack of selectivity (co-elution of endogenous compounds such as lipids, phospholipids, fatty acids, and inorganic salts) that affect the ESI droplet de-solvation process [17,18]. Thus, we investigated the concentration of TG, TC, ALB, P, Na, K, and Cl in different blank matrices prepared by protein precipitation. The result is shown in Table 2. The data indicated that different matrices samples had different concentration of components.

3.3. Correlations of matrix effects and matrices components under a special pulse gradient chromatography by multiple regression analysis

The results of matrix effects and the determination of matrices components had several general trends. First, the variability in matrix effects observed in plasma from different species was caused by different concentrations of ALB. In addition, the variability in matrix effects observed in different lots of plasma was also believed to be from variations in protein content. Protein and TG in the tissue homogenate samples likely accounted for differences in the signal at the MS interface. Similar components resulted in similar matrix effects in post-column chromatography. For example, high concentrations of salts restrained the intensity of the signal of NIM and IS. Lipids, phospholipids, fatty acids, amino acids, and proteins caused both an enhancement and suppression of signals in the mass spectra. We then introduced multiple regression anal-

ysis in order to investigate possible correlations between the many simultaneous variables which were measured.

Multiple regression procedures estimated a linear equation of the form:

$$Y = a + b1 \times X1 + b2 \times X2 + \ldots + bp \times Xp$$

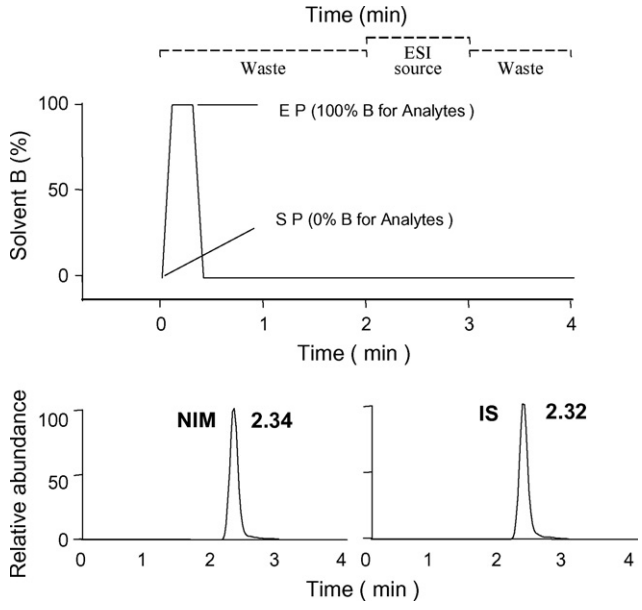

Fig. 3. Pulse gradient program (top) and LC–ESI-MS/MS chromatograms for NIM and IS (bottom).

where *Y*, extent of matrix effects (−%: suppression; +%: enhancement); *X*1, *X*2, . . ., *Xp*, the different matrices components; *a* is a constant; *b* is the regression coefficient (or *B* coefficient(s)). If the *B* coefficient is positive, then the relationship of this variable with the dependent variable is positive; if the *B* coefficient is negative then the relationship is negative; if the *B* coefficient is equal to 0 then there is no relationship between the variables.

We investigated the relationship of matrix effects and matrices components at different time intervals under a special gradient system using SPSS. In the time interval of 0–1, 1–2 and 3–5 min, the tolerance of variables was all greater than 0.1, which means there was an absence of a linear relationship among the matrix effects, matrices components and different times of the chromatogram map. For the region of 2–3 min (the retention time), regarding TG, TC and ALB, the tolerance was also greater than 0.1; regarding P, Na, K, and Cl, the tolerance was smaller than 0.1. The data showed that collinearity was present among P, Na, K, Cl and matrix effects at the specified retention time. The linear equation was as follows:

$$E\ (\mathrm{NIM}) = 53.887\,\mathrm{P} + 10.336\,\mathrm{Na} - 23.284\,\mathrm{K} - 8.997\mathrm{Cl}$$

$$E\ (\mathrm{TMD}) = 25.657\,\mathrm{P} + 1.613\,\mathrm{Na} - 9.217\,\mathrm{K} - 2.004\,\mathrm{Cl}$$

This indicated that salt was the major agent responsible for matrix effects and different inorganic salts contributed differently within various retention time intervals. P and Na enhanced the signal intensity in the mass spectra while K and Cl suppressed it. Thus the neutral salt ammonium formate was used a mobile phase modifier to alter the signal intensity of the target material in the mass spectra.

Table 2
The concentration of triglyceride (TG), total cholesterol (TC), albumin (ALB), P, Na, K, and Cl in different matrices.

3.4. Ammonium formate enhances signal intensity

To enhance analytical performance, the LC-electrolyte effects [19–21] were studied by modifying the acetonitrile/H_2O-based mobile phases with various concentrations of electrolytes (e.g. $HCOONH_4$), and testing the analyte response and matrix effect levels. The data showed that the positive ion ESI response for morinidazole and metronidazole varied as the concentrations of the tested electrolytes changed providing different spectra for the analyte response. These results indicate that the magnitude of the LC-electrolyte effect on the analyte response depends on the concentration of the electrolyte modifier in the mobile phase. For $HCOONH_4$, the maximum positive ion ESI response of the analyte was observed when the electrolyte concentration in the mobile phase was 0.2 mM and the response increased by 7.4-fold. Further decreasing the $HCOONH_4$ concentration to 0.04 mM did not improve the ESI response compared with that obtained at 0.2 mM. A significant increase in the analyte response was observed when the $HCOONH_4$ concentration in the mobile phase was between 0 and 25 mM, ranging from 3.7 to 5.7 times higher than the results obtained in an experimental run containing no electrolyte.

3.5. Use of a special pulse gradient in the presence of ammonium formate to minimize matrix effects

The favorable effect of the special pulse gradient in the presence of ammonium formate effects in reducing matrix effects was found to depend on the concentration of the utilized electrolyte modifier. Fig. 4 shows that the matrix effects which resulted from rat plasma were minimized more when the concentration of ammonium formate was increased. The use of a lower concentration of $HCOONH_4$ (0.04 mM) failed to significantly reduce the duration of ionization suppression. The best result was achieved with a 5 mM $HCOONH_4$-modified mobile phase and showed that suppression was maintained for less than 1 min, making fast LC analysis possible. $HCOONH_4$ acts to redistributes the charges in the mobile phase to a homogeneous state.

By weighting these two factors, we utilized 5 mM $HCOONH_4$ (rather than 0.2 mM) in the mobile phase because it provided both reproducible chromatographic retention times and a favorable high detection response for morinidazole and IS. Fig. 5 shows the extent of enhancement and suppression contributed by 24 blank biological samples prepared using protein precipitation at different chromatographic time intervals obtained with the continuous post-column infusion of NIM and IS (MTD). To NIM, there was about 60% suppression in most biological samples from 0 to 1 min; there were 47% enhancement or 17% suppression during the retention time interval of 2–3 min. To IS, there were 80% suppression from 0 to 1 min and 43% suppression from 2 to 3 min. A 5 mM $HCOONH_4$-modified mobile phase minimized the matrix effects contributed by most biological samples obtained from preclinical pharmacokinetic experiments.

Multiple regression analysis was also used to examine the collinear relationship among the experimental variables for pulse

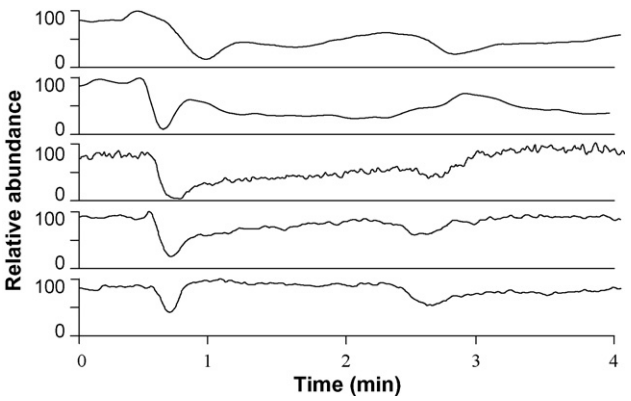

Fig. 4. Infusion chromatograms exhibiting the effect of rat plasma on the response to post-column infusion of NIM (100 ng/mL) in the positive ion ESI mode. The concentration of $HCOOCH_4$ in the mobile phase from top to bottom is: 0, 0.04, 0.2, 1, and 5 mM.

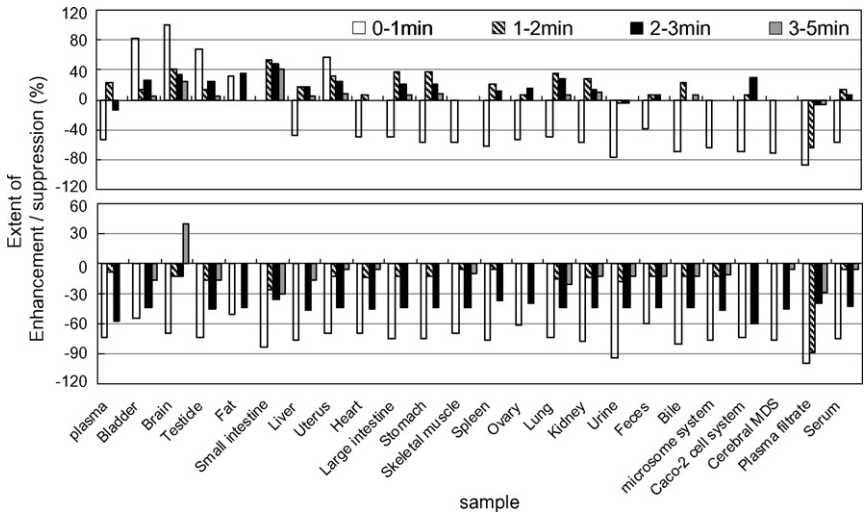

Fig. 5. Extent of enhancement/suppression contributed by 24 blank biological samples at different times of the chromatogram map obtained with the continuous post-column infusion of NIM (top) and IS (bottom) under the special pulse gradient with 5 mM $HCOONH_4$ in the mobile phase.

gradient chromatography in the presence of 5 mM $HCOONH_4$. During the interval of 2–3 min (the retention time), for TG, TC and ALB, the tolerance was also greater than 0.1; for P, Na, K, and Cl, the tolerance was smaller than 0.1. The data showed that collinearity was present among P, Na, K, Cl and the matrix effects at the retention time of interest. The linear equation was the following:

$$E(NIM)_{add} = 3.955\,P - 0.42\,Na - 2.586\,K - 0.087\,Cl$$

$$E(TMD)_{add} = -1.025\,P + 0.008\,Na + 0.451\,K - 0.432\,Cl$$

This indicated that salt was still the major agent to cause matrix effects but the influence on signal intensity was much smaller than without $HCOONH_4$ in the mobile phase. We concluded that ammonium formate was a suitable mobile phase modifier resulting in charge-state redistribution profiles and a homogeneous matrix.

3.6. Ammonium formate contributes to the feasibility of using structural analogue IS

Differences in ion-suppression between analytes and structurally different IS may also be problematic. The presence of a matrix effect can dramatically shift the response of the target analyte, thus affecting sensitivity, or it can adversely affect the accuracy/precision of a bio-analytical method by impacting the analyte/IS response ratio. Normally, the use of a co-eluting stable isotope analog as an IS is considered to solve the accuracy/precision problem since the analyte/IS response ratio is expected to remain unaffected even when the absolute responses of the analyte and IS are affected significantly. Wang et al. demonstrated that a slight difference in retention times between the analyte and the SIL IS was significant enough to change the analyte to IS peak area ratio and affect the accuracy of the method [22]. However, isotopically labeled IS may not be available for some analytes due to difficulties associated with synthesis and/or cost. Alternatively, a structural analogue can be used, but the IS has to elute close to the compound of interest and preferably show similar behavior in the source to compensate for any matrix effects.

We selected the structural analogue metronidazole as an IS for the correction of ion-suppression or enhancement effect. The data indicates that they have similar physical characteristics; moreover, their chromatographic retention time is very close: the analyte is 2.32 min, IS is 2.34 min. However, as shown in Table 1, the matrix effects between NIM and MTD were distinctively different. The variability of the analyte/IS response ratio is severe: it varied from 0.25 to 9.2 in different biological samples. The results are shown in Fig. 6.

In our study, the presence of ammonium formate impacted the use of a structural analogue as the IS. The RSD was calculated to show the variability of the target material/IS response ratio in different biological samples. As a result, because of ammonium formate, the variance of the ratio changed. The RSD in plasma from different species changed from 6.7 to 37.1 and the RSD in 24 different matrices samples varied from 7.3 to 77.8. Therefore, it was concluded that a structural analogue can serve as an IS to compensate and correct for the response of the target material in the ion source.

3.7. Analytical method validation and application for analysis of NIM in 24 bio-matrices

Method validation was performed, including sensitivity, linearity, and precision. The experiments on plasma standard solutions were carried out using the conditions reported in Section 2. Sensitivity was expressed by the instrumental limit of detection (LOD) and limit of quantitation (LOQ) for the target compound. LOD and LOQ were defined as the lowest analyte amount with a signal-to-noise ratio (S/N) of 3 and 10, respectively. LOD was found to be 80 pg/mL and the LOQ was 250 pg/mL. To assess the linearity, five point calibration curves were calculated over the linear range of the instrument response. Linear regression plots were calculated using peak area versus absolute injected amount; five replicates were analyzed for each concentration. The linear regression equa-

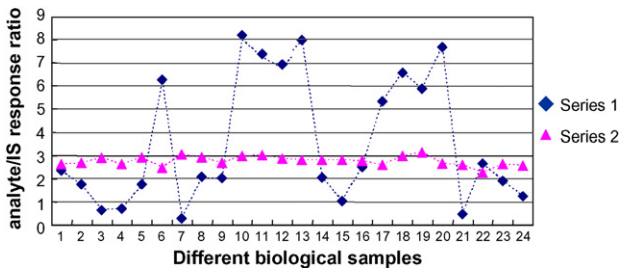

Fig. 6. The analyte/IS response ratio in 24 different animal tissues. Series 1: no electrolyte in the mobile phase. Series 2: 5 mM $HCOONH_4$ in the mobile phase. Samples 1–24: plasma, bladder, brain, testicle, fat, small intestine, liver, liver, large intestine, stomach, muscle, spleen, ovary, plasma filtrate, cerebral MDS, Caco-2 cell system, kidney, lung, serum, feces, urine, bile, and microsome.

tion was $Y = 0.0714626 + 0.109117X$. Linearity was expressed as the squared correlation coefficient (R^2) where values higher than 0.9953 were obtained. In this study, NIM was spiked in 24 biological matrices at 3 concentrations (1, 10, 100 ng) and its concentration was redetermined. Using the above linear regression equation, precision was calculated as the intraday and inter-day repeatability of the method provided the % RSD values less than or equal to 10% for the plasma samples from six different species (mouse, rat, rabbit, dog, monkey, and human). The % RSD values were less than 15% for all the 24 biological samples, indicating a satisfactory level of precision at the selected concentration levels.

4. Conclusions

Matrix effects during HPLC–MS/MS analysis of large numbers of biological samples from preclinical pharmacokinetic drug studies were investigated. It was determined that the shift in the MS signal for co-eluted compounds follow a co-linear relationship with regards to retention time. Using pulse gradient chromatography with 5 mM $HCOONH_4$ as the mobile phase modifier resulted in a charge-state redistribution profile and a homogeneous matrix. The combination of a special pulse gradient with ammonium formate was favorable towards reducing matrix effects and contributed to the use of a structural analogue IS. These results suggest that an ideal ESI modifier and an appropriate pulse gradient would be valuable towards developing a simple and rapid bioanalysis method for the analysis of preclinical pharmacokinetics samples.

ABSTRACT

Tin octoate is used as a catalyst in the synthesis of polydimethylsiloxane (PDMS), a room temperature vulcanizing (RTV) silicone rubber. This rubber is largely used in the medical field due to its great biocompatibility. In this framework, a high-speed and costless analytical method for the determination of stannic ions, Sn(IV), in the presence of stannous ions, Sn(II), has been developed.

The separation of these two ions was carried out using differential pulse polarography (DPP). For this purpose, the tin species contents in the catalyst is quantitatively extracted under inert condition to avoid any changes in the ratio Sn(IV)/Sn(II). Polarography showed well-shaped oxidation and reduction peaks respectively at −650 and −860 mV for stannous ions. The peak of the stannic ion was well separated and appeared at −1210 mV. Many parameters such as extraction process, extraction time, pH, chelating agents and polarographic conditions were optimized. We have also demonstrated that no oxidation of the stannous ions occurred during the sample preparation.

The dosing range considered in this study extends between 10 and 40 μg/mL, corresponding to 6.8% and 27.2% of the degradation product (Sn(IV)) in the catalyst, regarding to the sampling. Finally this method was successfully validated using the total error concept.

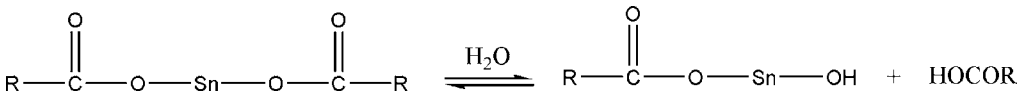
1. Introduction

Silicone polymers are used in medical and pharmaceutical applications since the 1960s. Common silicon medical components and assemblies includes airways, balloon catheter, tubing for feeding, drainage,. . .. Silicone elastomers are one of the mostly used synthetic and nondegradable polymers. Reasons for their widespread use in medical and pharmaceutical applications are biocompatibility, minimal tissue reaction, biological inertness, chemical and thermal stability, good mechanical properties, easy processability and sterilizability. Due to the excellent diffusional properties, they allow drugs to be delivered in a therapeutic amount that might have not been possible with other polymer systems. For all these reasons, they have been used in many implants and in particularly in silicone-enzyme elastomers such as lipase silicone elastomers. In such delivery system, the enzyme was added as a powder and mixed with the resin before curing in the presence of stannous octoate (catalyst) [1].



Tin-2-ethylhexanoate or tin octoate ($Sn(Oct)_2$) is commonly used as catalyst for long-term implant products made of a 50/50 (w/w) mixture of poly(dimethylsiloxane) (PDMS) and an active substance. This kind of elastomer is generally prepared by mixing 3 components: the silicone base (hydroxyterminated PDMS), a crosslinker and a catalyst (Fig. 1).

In our awaited use of the elastomer, this one plays the role of reservoir for the substance as well as the matrix for the controlled drug release. In this way the mechanical properties of these room temperature vulcanisation (RTV) silicone rubbers are extremely important and a particular attention must be done on its synthesis. As it is well known, the catalyst takes an important place in the polymerisation process and it may lead to poor quality of the product if no attention is paid to its purity and its storage. So, several parameters such as moisture, oxidation conditions and age of the catalyst are very important to control. The studies of Labouriau et al. [2], and related papers [3,4], suggest that degradation by oxidation and/or by hydrolysis might be important points. Indeed, as shown below, tin octoate in the presence of moisture produces hydroxyl derivative (1) or tin hydroxyoctoate, and also 2-ethylhexanoic acid

or octanoic acid

(1)

Moreover, octanoic acid is always formed when tin octoate is allowed to age in an open flask. The presence of this carboxylic acid in RTV silicones can lead to degradation by protonating the siloxane chain and then reducing the barrier for hydrolysis of the polymer. Furthermore, these authors have clearly demonstrated that for an aging or a degraded catalyst, the amount of stannic ions (Sn(IV)) is directly linked to the importance of these phenomena.

For all these reasons, and considering their economic impact on a silicone-enzyme elastomers manufacture, it seems very important to develop a method for the determination of stannic ions in the catalyst before its use in such polymerisation process. This method will have to allow the selective determination of stannic ions in presence of stannous ions. Already in the sixties, Fritz and Latwesen [5] have proposed a separation of tin ions from other metallic elements by partition chromatography but only in its more oxidative state. In such a way, no selective determination of a specific oxidation state of tin could be achieved.

In order to avoid the formation of Sn(IV) due to the oxidation of Sn(II) and also to ensure accurate measurements, the determination of stannic ions should be as direct as possible without preliminary separation of Sn(IV) and Sn(II) and/or preconcentration of stannic ions. In the scope of this study, a simple mathematical approach (univariate treatment) is more appropriate than a partial least square multivariate calibration as proposed in the work of González et al. [6] and was thus selected.

Considering a direct and selective determination of stannic ions in the presence of stannous ions, only two methods seem to be suitable: redox titration and polarography. Several polarographic methods [7–14] were published before the years 2000, but they are generally complex, time-consuming or not adapted to the simultaneous determination of tin species.

On the other hand, inductive coupled plasma–mass spectroscopy (ICP–MS) methods can only determine the total tin concentration, and are not suitable. This technique seems to be more relevant for the selective determination of different organotin rather than inorganic tin species [15,16]. Gas chromatography coupled with mass spectrometry (GC/MS) for the determination of mercury and tin compounds (especially organometalics) are published [17,18]. However, these methods are expensive and are not able to selectively determine stannous and stannic ions. Furthermore, several methods have been reported for the determination of tin by ion chromatography but they do not seem promising for the simultaneous determination of tin species [19,20].

More recently, Gholivand et al. showed that atomic absorption spectroscopy (AAS) can be applied for the determination of stannous ions in the presence of stannic ions or for a total tin determination [21]. This assay requires extraction (mixed micelle-mediated cloud point extraction) of Sn(II) or total tin species using a complexing agent. Although this method allows the determination of Sn(II) in samples containing Sn(IV), the determination of stannic ions has to be calculated using total tin determination. Thus, tin species are not really selectively determined.

Consequently, a new method allowing the separation of stannic ions from stannous ions in order to monitor the degradation product, i.e. the stannic ions, has been developed and fully validated [22–24]. The selected method is based on differential

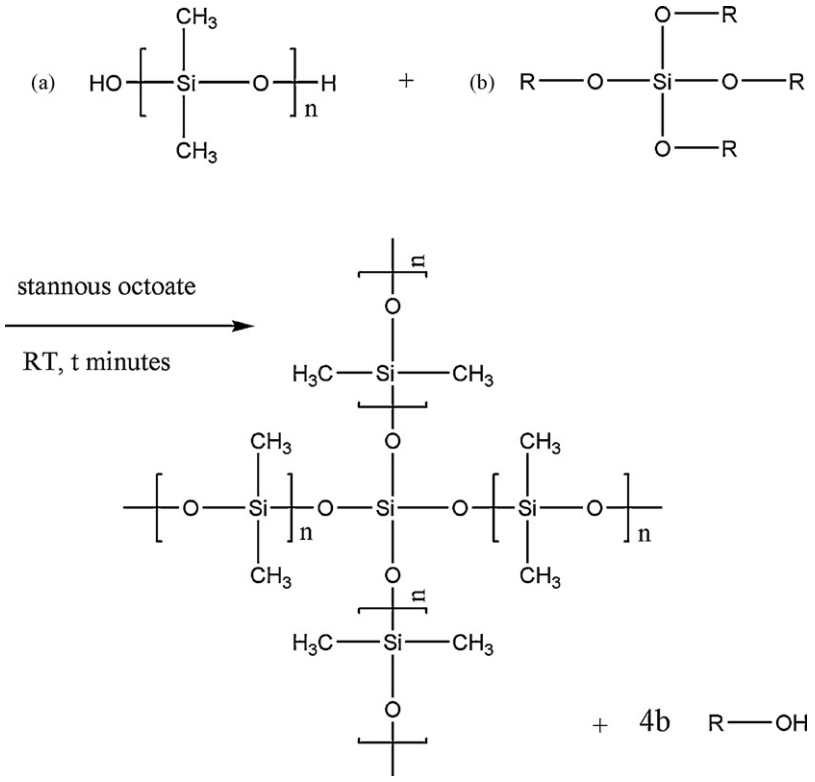

Fig. 1. Representation of a silicone condensation cure mechanism. Coefficients (a and b) related to the polymerisation process, RT: room temperature, *t*: reaction time.

pulse polarography (DPP) that enables the selective separation of tin species, and allowed the accurate determination of stannic ions.

2. Experimental

2.1. Reagents and apparatus

2.1.1. Reagents

Water used for the preparation and dilution of all aqueous solutions was of Milli-Q grade (Millipore, Bedford, MA, USA). Nitrogen (alphagaz 1, 99.999%) purchased from Air Liquide (Milmort, Belgium) was used to remove the dissolved oxygen.

Solution of hydrochloric acid 2 M and sodium hydroxide 2 M were prepared for adjusting the pH of analysed solutions. Analytical grade of these acid and base were obtained from Merck (Darmstadt, Germany). Sodium malonate (99.0%) was acquired from Fluka (Buchs, Switzerland). Sodium carbonate and sodium hydrogencarbonate (99.8% and 99.7% respectively), constituting the buffer solution, were both purchased from Riedel-de Haën (Seelze, Germany). Appropriate amounts of sodium malonate, sodium carbonate and sodium hydrogencarbonate were dissolved to reach final concentrations of 0.5, 0.2 and 0.2 M, respectively.

Liquid/liquid extractions were performed using heptane (for spectroscopy, 99.3%, Merck) as the organic phase.

During the development phase, Oxygen (alphagaz 1, 99.995%) supplied by Air Liquide was used to modify the tin species ratio in aqueous solutions. Standard stock solutions of Sn(II) were prepared by dissolving appropriate amounts of chloride stannous (99%, Sigma–Aldrich, Saint Louis, MO, USA) in hydrochloric acid 0.2 M.

Standard reference of stannic ions at 1000 μg/mL was obtained from Merck. Tin octoate was purchased from NuSil Technology (Carpinteria, CA, USA).

2.1.2. Apparatus

The polarograms were obtained with a Metrohm Model 746 VA processor (Metrohm AG, Herisau, Switzerland) and a Metrohm 694 VA stand with a multimode electrode (MME) operating in Static Mercury Drop Electrode (SMDE) mode. The three electrodes system was completed by means of a Ag/AgCl (3 M KCl) reference electrode and a Pt auxiliary electrode.

The pH of the analysed solutions was measured with a Radiometer analytical IONcheck 10 (Villeurbanne, France) pH meter. The apparatus was daily calibrated using 3 buffers solutions at pH 4.01, 7.00 and 9.21 (Mettler-Toledo, Urdorf, Switzerland).

2.2. Procedure

2.2.1. Extraction step from tin octoate

Liquid/liquid extractions were achieved with a homemade extraction cell (Fig. 2) allowing transfer of tin species in aqueous medium, from the organic matrix, under inert conditions. An aliquot of tin octoate (250 mg) was introduced in the extraction cell and dissolved in 50 mL of deoxygenated heptane. The extraction process was performed under nitrogen, to avoid oxidation of stannous ions, with 50.0 mL of 2 M aqueous hydrochloric acid. The stirring is carried out by bubbling of nitrogen with a flow rate of 20 L/h. The extraction step is performed during 5 min.

2.2.2. Electrochemical determination conditions

Polarographic measurements were carried out using the following procedure: 5.0 mL of aqueous phase resulting from the extraction step was transferred into a 50.0 mL volumetric flask containing 35 mL of degassed sodium malonate (0.5 M) in buffer solution ($NaHCO_3/Na_2CO_3$, 0.2 M both). 5 mL of sodium hydroxide solution (2 M) was previously introduced into the volumetric flask in order to ensure a pH near 9.8 after the addition of the sample. A pH adjustment at 9.8 was made in the volumetric flask by addition of 2 M sodium hydroxide solution. The polarographic measurement is performed on an aliquot of 10 mL. The values of the instrumental parameters are described in Table 1.

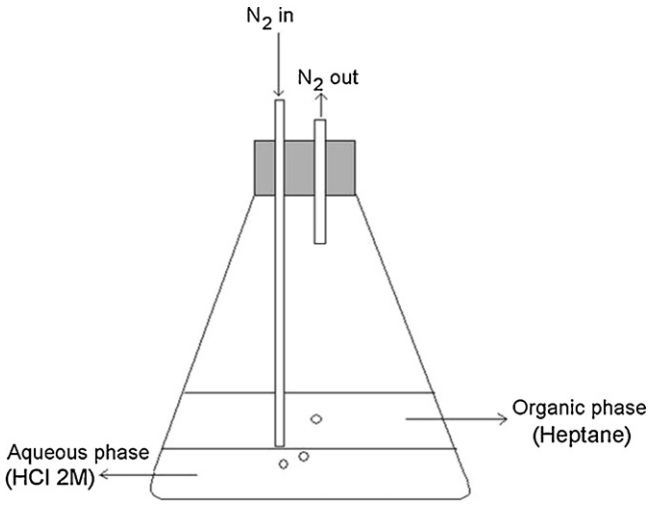

Fig. 2. Tailor-made extraction cell for the liquid/liquid extraction of tin species.

2.2.3. Standard solutions

Standards references of stannic ions at 996 and 999 μg/mL were employed as independent stock solutions for the preparation of the calibration and the validation standards, respectively. Dilutions of the first one were performed in volumetric flasks containing the complexing agent in the pH 9.8 buffer to reach final concentrations of 9.96, 14.94, 19.92 and 39.84 μg/mL. These solutions are used as calibration standards (CSs).

The second stock solution was diluted in 2 M aqueous hydrochloric acid to reach final concentrations of 99.9, 149.5, 199.8 and 399.6 μg/mL. These solutions are used as the aqueous phase in the liquid/liquid extraction of different portions of 250 mg of stannous octoate. After an extraction of 5 min, 5.0 mL of the aqueous phase are diluted in a 50.0 mL volumetric flask containing the complexing agent in the pH 9.8 buffer. These solutions are used as validation standards (VSs) and prepared in duplicates ($n = 2$) from two stock solutions available.

Two independent extractions of 250 mg of stannous octoate in presence of 2 M aqueous hydrochloric acid as the aqueous phase are also performed. These solutions are used as the initial point of the standard addition method (see Section 3.2.1). The resulting mean response was subtracted from all the responses obtained for the analyses of the VSs.

All CSs and VSs were extemporaneously prepared under nitrogen. The concentration levels targeted for the VSs were of 10, 15, 20 and 40 μg/mL representing a degradation of the catalyst of 6.8%, 10.2%, 13.6% and 27.2% for tin octoate sample of 250 mg.

Table 1
Setting of the instrumental parameters for the determination of stannic ions by differential pulse polarography.

Polarographic mode	SMDE	Potential step	6 mV
T step	0.6 s	Sweep rate	10 mV s^{-1}
Pulse amplitude	−50 mV	Sweep start potential	−1000 mV
Pulse time	10 ms	Sweep end potential	−1450 mV
Measure time	5 ms	*E* peak	−1250 mV

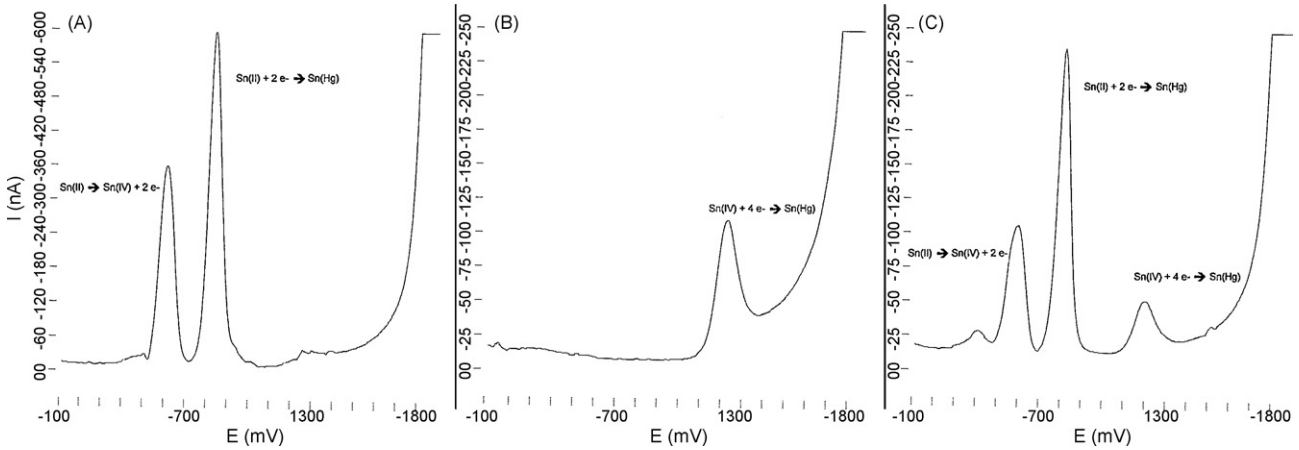

Fig. 3. Polarograms of tin species solutions in carbonate/bicarbonate solution (0.2 M) and malonate ions (0.5 M). (A) Stannous ions at 30 μg/mL, (B) stannic ions at 30 μg/mL and (C) stannous and stannic ions both at 10 μg/mL.

2.2.4. Computations

The e.noval software v2.0 (Arlenda, Liège, Belgium) was used to compute the validation results of the analytical method as well as to get the accuracy profiles.

3. Result and discussion

3.1. Method development

The separation of tin species by differential pulse polarography is only achievable if a chelating agent is used. Previously, Lejeune et al. [25] have reported the use of sodium fluoride for the analysis of stannous ions in the presence of stannic ions. However, fluoride forms a strong complex with tin species resulting on a rejection of polarographics waves to very low negatives potentials, particularly for stannic ions. Indeed, only the stannous ions are detected at −790 and −654 mV for the oxidation wave ($Sn^{2+} \rightarrow Sn^{4+}$) and the reduction wave ($Sn^{2+} \rightarrow Sn^{0}$), respectively [25]. In our case, stannic ions are the degradation product of tin octoate. It thus seems more suitable to follow the abundance of these ions rather than the decrease of stannous ions. So, in order to achieve the direct and specific determination of stannic ions in presence of stannous ions, other chelating agent must be chosen. Moreover, the tin species of the catalyst must be extracted to ensure their polarographic analysis in an aqueous medium. Thus, to find the optimum extraction and analysis conditions, the influence of various parameters was investigated.

3.1.1. Malonate ions, the chelating agent allowing the separation of tin species

In order to reduce the rejection of the Sn(IV) wave when using fluorides, another chelating agent that forms weaker complex had to be selected. According to Handbook Series in Inorganic Electrochemistry [26], the malonate ions (mal) seem to be adequate. Sn(II) and Sn(IV) reacts with sodium malonate, in presence of carbonate ions, to form stable complex with a different complex constant in basic medium. However, in high pH conditions, malonate form with Sn(II) and Sn(IV) complexes of relatively low stability ($\log K_{ML} < 6$) while carbonate allows the formation of very stable complexes ($\log K_{ML} > 15$). Moreover, carbonate forms stable hydroxo-complexes that allow the metal to remain in aqueous solution. On the other hand, the use of carbonate as chelating agent without malonate ions leads to drastically different results and avoid a selective determination of stannic ions in presence of stannous ions. So, it seems that in basic medium, both ions (malonate and carbonate) are involved in the chelating process allowing the separation of tin species. As can be seen from Fig. 3, in a supporting electrolyte composed by malonate, carbonate and hydrogencarbonate at pH 9.8, two waves for stannous ions are detected at −610 and −840 mV (Fig. 3A), due to the oxidation and the reduction waves respectively.

Oxidation wave : $Sn^{2+} \rightarrow Sn^{4+} + 2e^{-}$

Reduction wave : $Sn^{2+} + 2e^{-} \rightarrow Sn(Hg)$

Moreover, stannic ions wave (at −1210 mV) is well separated from two others (at −610 and −840 mV (Fig. 3B)), proving in this way that the separation of both ions is achievable by polarographic method (Fig. 3C).

Reduction wave : $Sn^{4+} + 4e^{-} \rightarrow Sn(Hg)$

3.1.2. Influence of extraction step on stannous and stannic ions

As the selective determination of the tin species is possible in an aqueous medium by polarographic method, an adequate extraction step must be selected and developed [27]. However, extraction procedure of the tin species is the main restricting step in this analytical process. Indeed, a controlled inert atmosphere is necessary to prevent a modification of the Sn(II)/Sn(IV) ratio. Oxygen, in solvents part as well as in the extraction cell, quickly reacts with stannous ions leading to the increase of stannic species and thus impairing a reliable quantitative analysis of the Sn(II)/Sn(IV) ratio in the raw catalyst.

To avoid this, a tailor-made extraction cell has been used (Fig. 2). Two glass tubes (the nitrogen inlet and outlet) create and maintain inert condition into the extraction cell. Moreover, the nitrogen inlet tube is placed at the border of the two phases in order to mix them together and thus to allow the extraction of tin species from organic to aqueous medium.

This original device avoids the modification of the tin ratio as demonstrated by the following results. Indeed, portions of several aqueous stannous solutions containing 500 μg/mL, were either submitted to the extraction process or not and then analysed as previously described. The ratio of stannic ions detected for the same stannous solution was computed and showed a mean percentage of degradation caused by the extraction process of $5.1 \pm 0.7\%$ ($n = 11$). This result is acceptable regarding to the final objective of the method. In a second time the same experiments were performed on aqueous stannic solutions in order to demonstrate that stannic ions were not affected by the extraction procedure. These experiments were performed on stannous solution at 10, 20 and 40 μg/mL. For

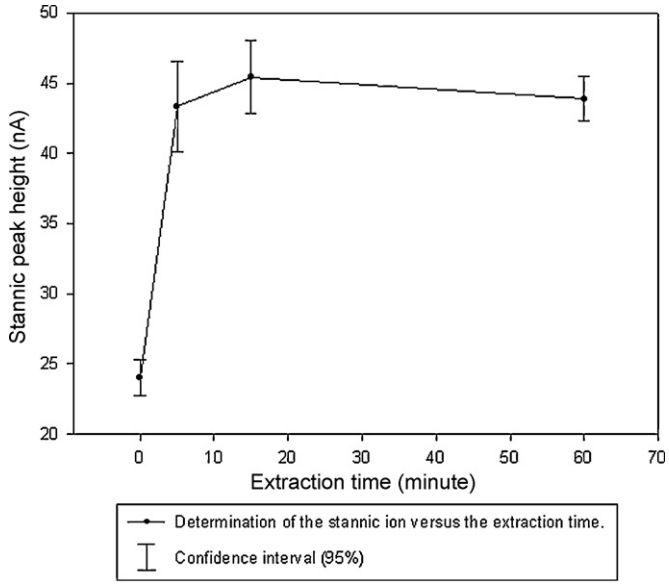

Fig. 4. Determination of the optimal extraction time of stannic ions ($n = 3$).

these concentration levels the mean percentage of degradation was $0.5 \pm 3.0\%$ ($n = 28$). These experiments clearly demonstrate that stannic ions are not affected by the extraction procedure.

3.1.3. Determination of the optimal extraction time

Regarding the rapid oxidation problem of the stannous catalyst part, the extraction time must be as short as possible while being quantitative.

Four extraction times have been tested: 0, 5, 15 and 60 min. A very light hand agitation of the extraction cell without bubbling was carried out to represent the 0 min extraction time point. This experiment is realised as previously described on several portions (250 mg) of the same catalyst to monitor the stannic ions recovered after the extraction step.

The transfer of the mineral compounds (like tin) is quickly achieved. As it can be seen from Fig. 4, a plate of maximum extraction is reached after only 5 min. This is demonstrated by the confidence interval (95%) analysis from each extraction time (0, 5, 15 and 60 min). By this analysis, only the 0 min extraction time point can be differentiated from the others, showing that within only 5 min, stannic ions extraction is completed.

Regarding the results, an extraction time of 5 min was selected to achieve a quantitative and rapid extraction while always keeping in mind that a short time of treatment decreases the risk of a change in the tin species ratio.

3.1.4. Influence of pH on stannic polarographic response

The supporting electrolyte is an important part of the analytical system. Indeed, an ionic medium is necessary to obtain an analytical response. However the supporting electrolyte takes often place in the electrochemical reaction itself. As previously mentioned, malonate and carbonate allow the separation of the stannous and the stannic compounds in the basic medium envisaged. Moreover, it seems obvious that in such ionic solution, pH is a critical parameter to study.

So, three independent solutions of stannic ion standard at a concentration of 30 μg/mL were analysed at pH: 9.0, 9.2, 9.4, 9.6, 9.8 and 10.0 (number of replicate in each series = 3) in the presence of bicarbonate/carbonate solutions at 0.2 M and malonate at 0.5 M.

These experiments highlight that the intensity of the response depends on the pH at which complex formation occurs. As illustrated in Fig. 5, the analytical response for the stannic peak is dramatically influenced by the increase of the pH of the buffered supporting electrolyte. However, a too high pH involves a decrease in the analytical response due to a competition between the complex stability at this pH and the hydroxide precipitation of tin.

In conclusion, the optimal pH for the analysis of the stannic ions is equal to 9.8.

3.2. Analytical method validation

3.2.1. Standards preparation

Analytical method validation is an essential step in the life cycle of any analytical method. The experimental conditions used to assess the validity of a method should be as representative as possible of its future routine application. One condition is to prepare the validation standards in the matrix in which the analyte of interest will be present in the forthcoming daily application of

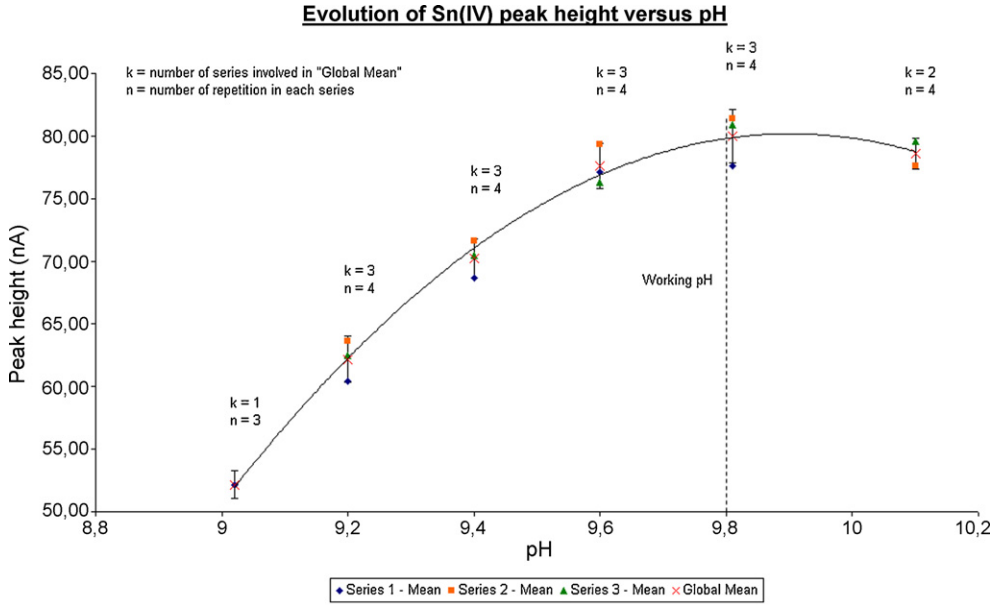

Fig. 5. Influence of the working pH on the intensity of the stannic peak response.

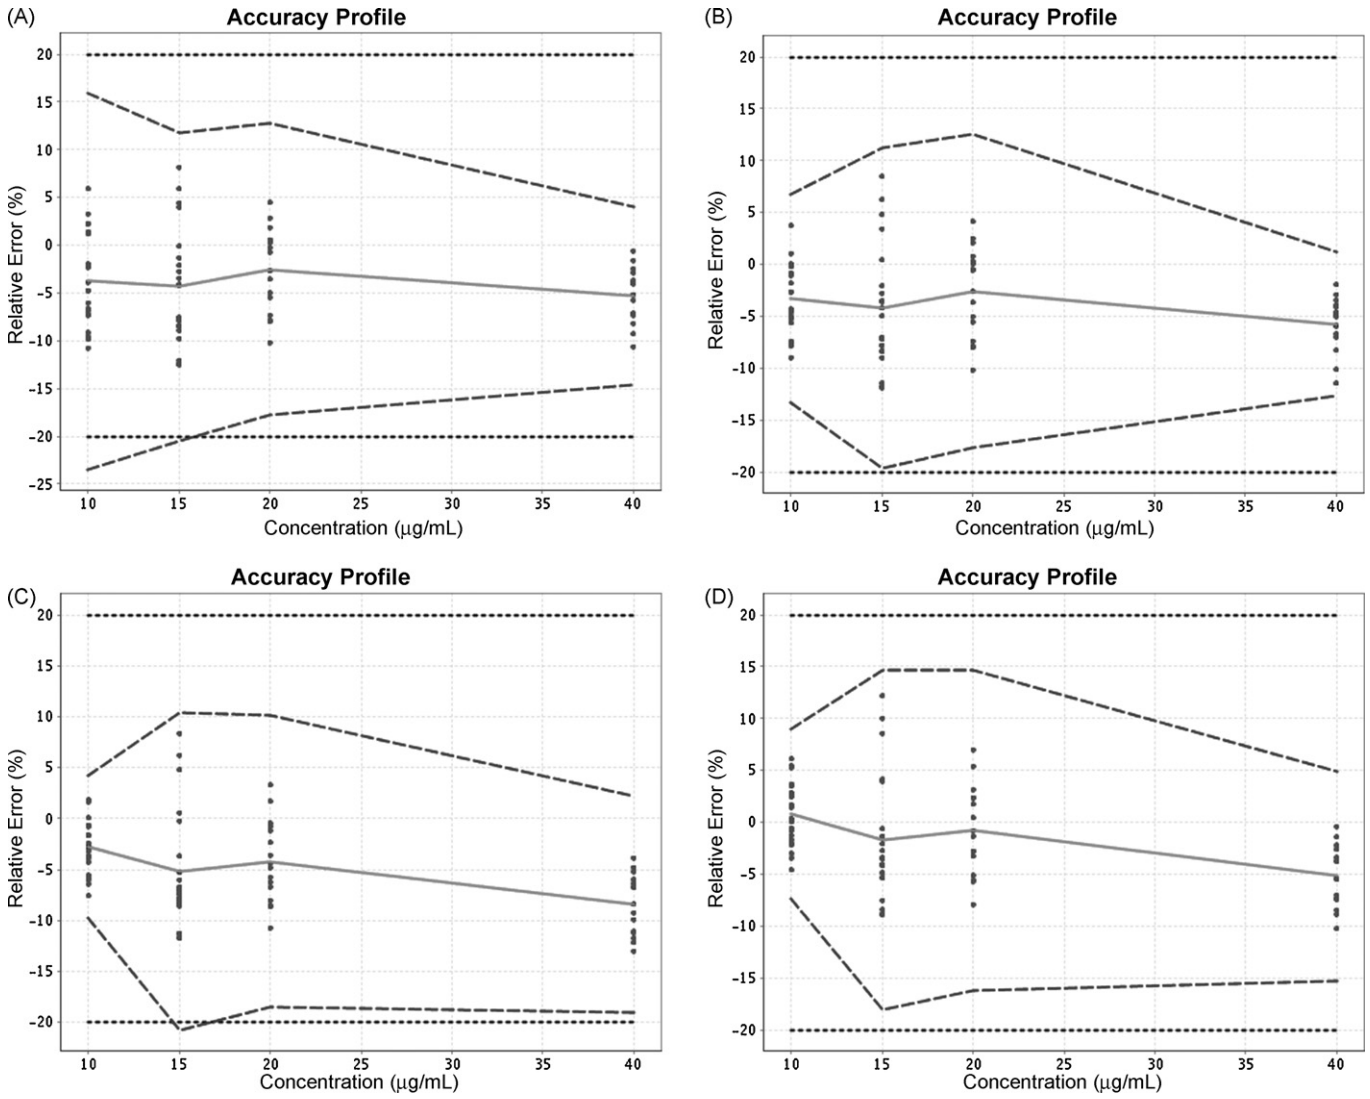

Fig. 6. Accuracy profile obtained for the validation study of the method considering (A) linear regression, (B) weighted $1/x^2$ linear regression, (C) linear regression through 0 fitted using only the smallest concentration level, (D) linear regression through 0 fitted using only the highest concentration level; plain line: relative bias, dashed lines: 95% β-expectation tolerance limits, dotted curves: ±20% acceptance limit and dots: relative back-calculated concentrations of the validation standards.

the method. Nonetheless, the reconstitution of the matrix without the tin parts is difficult and irrelevant. Thus the use of the stannous octoate as matrix was selected. However, a natural degradation of the product is always present leading to the presence of a natural amount of stannic ions from the matrix itself that would interfere with the preparation of the VSs. To circumvent this, the standard addition method was used on the validation standards in order to adequately estimate the analytical signal due to the endogenous stannic ions of the matrix. Once estimated, this signal was substracted to the response of each validation standard analysed. In a preliminary study no matrix effect on the CSs was highlighted. The CSs were therefore prepared directly in the supporting electrolyte.

3.2.2. Method performance

The method validation was carried out using the accuracy profile approach based on tolerance intervals for the total measurement error [24,28,29]. This approach reflects more directly the performance of individual assays and will result in fewer rejected in-study runs than the current procedure that compares point estimates of observed bias and precision. The concept of accuracy profile was also used to select the most appropriate regression model for calibration, to evaluate matrix effect, to determine the lower limit of quantitation (LLOQ) and the range over which the method can be considered as valid. For this approach two parameters must be set by the analyst, the acceptance limits on one hand and the risk of having future measurements falling outside those acceptance limits on the other hand $(1-\beta)$.

Due to the objective of this method (determination of the degradation product of a catalyst), the present acceptance limits were set at ± 20% and the risk (=$1-\beta$%) of having future results outside the acceptance limits was set at 5% maximum. The calibration curve was prepared in the supporting electrolyte in order to reach four concentration levels of stannic ion ranging from 10 to 40 µg/mL. Triplicate calibration standards were analysed at each concentration level for 3 runs.

Several regression models were tested in order to select for the most appropriate response function. This was achieved by preparing validation standard, in presence of stannous octoate during the extraction step, at the same four concentration levels and analysing them in four replicates during 3 runs. The concentrations of the validation standards were back-calculated using the various response

Table 2
Validation results of the polarographic method with the linear regression through 0 fitted using only the highest concentration level as standard curve.

Response function ($p=3$; $n=3$)	Linear regression through 0 fitted using only the highest concentration level model; calibration range ($m=4$): 10–40 μg/mL		
	Run 1	Run 2	Run 3
Slope	2.841	2.917	3.218
Trueness ($p=3$; $n=8$) (μg/mL)		Relative bias (%)	
10		0.8	
15		−1.8	
20		−0.8	
40		−5.2

functions tested in order to determine, by concentration level, the mean relative bias, the standard deviation intermediate precision as well as the upper and the lower β-expectation tolerance limits at 95% level and finally draw their corresponding accuracy profiles [24,28,29] (cf. Fig. 6).

As shown in Fig. 6, the linear regression (Fig. 6A) and the linear regression through 0 fitted using only the smallest concentration level (Fig. 6C) response functions were not acceptable at the lower concentration. Two other models were evaluated and presented an acceptable accuracy profile: the weighted ($1/x^2$) linear regression (Fig. 6B) and the linear regression through 0 fitted using only the highest concentration level (Fig. 6D) model. Nevertheless, only the last one lead to the lowest bias over the whole dosing range while keeping an acceptable variability. Furthermore, this regression model is the simplest one and will allow a calibration with only the highest level concentration in routine use. The response function obtained by applying this regression model is presented in Table 2.

Trueness [23,28–30] expressed in terms of relative bias (%) was then assessed from the validation standards at the four concentration levels. As can be seen in Table 2, the bias did not exceed the value of 2.0% for the concentrations between 10 and 20 μg/mL and was near 5.0% for the highest concentration level.

The precision of the analytical method was determined by computing the relative standard deviations (RSD) for repeatability and time-different intermediate precision at each concentration level of the validation standards [22–24,28,30–32]. The RSD values presented in Table 2 did not exceed 6.5%.

Accuracy takes into account the total error, i.e. the sum of systematic and random errors, related to the test result [22–24,28,30].

Table 3
Determination of Sn(IV) in independent sample of stannous octoate.

Sample	Concentration of stannic ions (μg/mL)	Mean concentration per Batches ± SD (μg/mL)	Percentage of degradation (%)
Batch-A 1 (T0)[a]	10.04	10.09 ± 0.05 ($n=3$)	6.9
Batch-A 2 (T0)	10.08		
Batch-A 3 (T0)	10.14		
Batch-B 1 (T0)	11.75	11.90 ± 0.13 ($n=3$)	8.1
Batch-B 2 (T0)	11.93		
Batch-B 3 (T0)	12.01		
Batch-A 4 (T3)	13.19	13.54 ± 0.22 ($n=6$)	9.2
Batch-A 5 (T3)	13.79		
Batch-A 6 (T3)	13.37		
Batch-A 7 (T3)	13.54		
Batch-A 8 (T3)	13.65		
Batch-A 9 (T3)	13.67		

[a] Time after first use of the catalyst flask; T0: first use; T3: use after 3 months.

As shown in Table 2, the relative upper and lower β-expectation tolerance limits (%) did not exceed the acceptance limits settled at ±20% for each concentration level.

The analytical method can be considered as valid over the concentration range investigated [22–24,28,30]. Therefore, the lowest amount of stannic ions that can be quantitatively determined under the experimental conditions with a well-defined accuracy, i.e. the lower limit of quantification, is equal to 10 μg/mL [23,24,28,29].

The most important conclusion that can be made at the end of this validation phase is that, thanks to the predictive attribute of the β-expectation tolerance interval, it is expected that during the routine use of the validated analytical method less than 5% of future results will fall outside the tolerance limits and thus outside the acceptance limits of ±20%.

3.3. Results obtained during routine use

This method was then used in routine. As stated in the validation section, the linear regression through 0 fitted using only the highest concentration was selected as response function. The calibration standard at 40 μg/mL was prepared in the supporting electrolyte as previously described.

Two batches (named Batch-A and Batch-B, respectively) of stannous octoate (29.30% of Sn) were analysed. The Batch-A was used during 3 months for multiple polymerisations before being re-analysed. After each use of the catalyst, it was stored under inert atmosphere by bubbling of nitrogen during 15 min.

As can be seen in Table 3, the concentration of stannic ions in the catalyst in Batch-A and Batch-B was equal to 10.09 ± 0.05 μg/mL ($n = 3$) and 11.90 ± 0.13 μg/mL ($n = 3$) respectively. Considering the sampling, the degradation of the stannous octoate was 6.9% and 8.1% respectively. After a 3 months use of the first catalyst (i.e. Batch-A), the concentration of stannic ions reached 13.54 ± 0.22 μg/mL, corresponding to a degradation of the catalyst of 9.2%.

4. Conclusions

Our study has showed that a separation of stannous and stannic ions can be achieved from stannous octoate (catalyst) with simplicity, rapidity and accuracy.

Indeed, after a liquid/liquid extraction procedure of 5 min in inert atmosphere, a simple differential pulse polarography analysis in aqueous medium is performed. The electrolyte support used for this analysis contains malonate and carbonate ions both contributing to the chelating process. Two well-defined oxidation and reduction peak of stannous ions (−610 and −840 mV) and a well separate reduction peak of stannic ions (−1210 mV) were observed.

Finally, the developed method was successfully validated according to regulatory authorities' requirements and shows acceptable trueness and precision regarding to the final objective of the method.

Moreover, this method could allow to investigate the link between the Sn(IV)/Sn(II) ratio and the polymerisation performance of the catalyst.

ABSTRACT

A novel method for the retention of arsenate [As(V)] combining time-controlled solid-phase extraction with living bacterial biomass is presented. As(V) retention was carried out by exposing the extractant, consisting of a living double-mutant of *Corynebacterium glutamicum* strain ArsC1-C2, to the sample for a retention time of 1–7 min, before the arsenic distribution equilibrium between the sample solution and the extractant was established. The amount of As(V) retained in the biomass was measured by inductively coupled plasma-mass spectrometry (ICP-MS) after the sample had been treated with nitric acid. A theoretical model of the retention process was developed to describe the experimental retention-time profiles obtained with the bacterial cells. This relationship provided a feasible quantification of the retention process before steady-state was reached, providing that the agitation conditions and the retention time had been controlled. An analytical procedure for the retention/quantification of As(V) was then developed; the detection limit was 0.1 ng As(V) mL^{-1} and the relative standard deviation 2.4–3.0%. The maximum effective retention capacity for As(V) was about 12.5 mg As (g biomass)$^{-1}$. The developed procedure was applied to the determination of total arsenic in coal fly ash, using a sample that had undergone oxidative pre-treatment.

1. Introduction

Arsenic is a ubiquitous and extremely toxic metalloid that enters the environment from natural and anthropogenic sources [1]. The adverse health effects that arsenic can produce in living creatures are well known [2], as its concentration-dependent beneficial effects in treating infections in humans [3]. However, the biological implications of arsenic differ with the chemical form involved [4], and the many species of arsenic have posed a great challenge in the development of analytical tools for their isolation. Interest in measuring the chemical species of arsenic in environmental samples has recently grown, as speciation plays an important role in the toxicity and mobility of arsenic. Therefore, effective methodologies to monitor total As content and/or particular As species leaching from environmental solid samples, such as coal fly ash, are crucial, especially in evaluating the potential impact of As on groundwater quality.

Many techniques have been tested for their ability to fractionate arsenic species, including the most common instrumental techniques of voltammetry [5], spectrophotometry [6], inductively coupled plasma-mass spectrometry (ICP-MS) [7–9], and atomic absorption spectrometry (AAS) [10–12]. These techniques are frequently used in combination with a previous separation technique, mainly electrophoresis and chromatography [8–14]; the use of solid phases in arsenic preconcentration/separation procedures prior to its determination with ICP-MS has also been exploited [15,16]. Other analytical developments have been based on advances in the use of microorganisms, such as yeast, algae, fungi, and bacteria, as specific sorbents [17–19]. In these applications, bacteria have proven to be advantageous because they are relatively small, simple, with fast rates of division and tremendous metabolic/catalytic diversity especially in extreme environments. In addition, many bacterial species are environmentally benign and able to use nutrients unavailable to other organisms.

Bacteria can be used for analytical purposes either as dead (suspension and immobilized) [20,21] or living [22] preparations. However, with living bacteria, genetic manipulation of bacterial metabolic processes allows for improvements in both the specificity of the retention process and the accumulation of analyte. The ability of bacteria to retain arsenic involves genetic determinants typically organized in an *ars* operon [23]. The arsenic operon generally comprises either three (*arsRBC*) or five (*arsRDABC*) genes organized into a single transcriptional unit. The three-gene system (the most common) encodes the arsenic transcriptional

repressor (*arsR*), a membrane-located arsenite permease (*arsB/acr3*) that functions as an arsenite efflux pump, and an arsenate reductase (*arsC*) that converts arsenate [As(V)] to arsenite [As(III)] before it is pumped out of the cell. The genes of the five-gene *ars* operon and those of numerous *ars*-type operons are configured according to many variations [23,24]. Genetically modified bacteria have been shown to improve the retention of As in studies in which phosphate uptake [25] and the arsenic detoxification pathway [26] have been exploited. The high affinity and specificity of the arsenic regulatory protein ArsR and of other *ars*-encoded proteins, such as ArsB, have been exploited in the development of whole-cell bacterial biosensors for arsenic by their incorporation into fusion constructs containing the bacterial luciferase genes (*lux* and *luc* operons) [27,28].

The Gram-positive saprophytic soil bacterium *Corynebacterium glutamicum* is a member of the Actinobacteria and highly As-resistant. The As(III) resistance of *C. glutamicum* is due to the lack of the aquaglyceroporin system (*glpF*) [23] involved in the uptake of As(III) [29]; the As(V) resistance is accomplished by the presence of two arsenate reductases (ArsC1 and ArsC2) responsible of the intracellular chemical reduction of As(V) to As(III) [23,29,30] with a further efficiently release of As(III) due to the presence of the arsenite permease pumps (Acr3-1 and Acr3-2) [31]. A *C. glutamicum* double-mutant strain was recently obtained by disruption of the *arsC1-arsC2* genes [32]. This mutant strain might be able to selectively retain large amount of As(V), as the intracellular reduction of As(V) and the uptake of As(III) would be now inactive processes. The aim of this work was to use this novel coryneform double-mutant strain, lacking in the ArsC1 and ArsC2 arsenate reductases, as an efficient extractant for As(V) for very short retention times, before partitioning equilibrium is reached. The As(V)-retention process before the steady-state situation was adopted to develop an analytical procedure based on the selective retention of As(V) on complex matrices, prior to the determination of arsenic in the bacterial biomass by ICP-MS.

2. Theoretical considerations

Mathematical modeling of analyte–cell interactions helps in understanding and predicting their behavior, and thus in meaningfully guiding experimental work. For very long sampling times, a steady-state situation is usually reached for any retention process, which is characterized by the partitioning equilibrium constant. However, for short sampling times, net retention by the cells of the analyte species formerly present in the solution can, under controlled conditions at a diffusion-limited rate, be described by the following exponential equation [22]:

$$q = [1 - e^{-Abt}] \left[\frac{C_0}{b}\right] \quad (1)$$

where q is the amount of the analyte retained at any time by the bacterial cells, and the parameters A and b are related to the area of the retention surface, the diffusion-layer thicknesses, the diffusion coefficients of the analyte, the volumes of the liquid and solid phases, and the partition constant. However, for the initial phases of the retention process, Taylor's approximation, $e^{-E} \approx 1 - E$, can be applied such that Eq. (1) can be simplified as:

$$q = AtC_0 \quad (2)$$

that is, for a t constant value, proportionality between q and C_0 allows a quantitative analysis to be carried out until retention equilibrium is reached.

In contrast to the above-described scenario, for active-transport systems, many of the cellular homeostatic mechanisms are directly linked to solute transport, since the retention of chemical species usually requires metabolic energy, and transport processes are regulated by the energy states of cells. In these cases, retention is a non-diffusion-limited process with a metabolic-energy-limited rate. This process is typically modeled by a hyperbolic function similar to that describing the autocatalytic biomass growth rate, which follows Monod-type kinetics:

$$q = \frac{q_m C}{q_{1/2} + C} \quad (3)$$

where q is the amount of the analyte retained during uptake, q_m the maximum retention amount, $q_{1/2}$ the analyte concentration in the sample solution corresponding to the half-retention value, and C is the analyte concentration in the sample solution at any time. However, for values of $C < q_{1/2}$, the hyperbolic rate model can be reduced to a first-order rate equation:

$$-\frac{dC}{dt} = q_m C \quad (4)$$

Reordering and carrying out integrations with the following initial ($C = C_0$, $t = 0$) and boundary ($C = C$, $t = t$) conditions, one obtains:

$$C = C_0 e^{-q_m t} \quad (5)$$

After the following transformation

$$C_0 - C = C_0(1 - e^{-q_m t}) \quad (6)$$

has been made and considering that $q = ((C_0 - C)/m)V$ is the amount of analyte retained by mass, m, units (dry weight) of bacteria and, V, the sample volume, then

$$q = \frac{V}{m} C_0 (1 - e^{-q_m t}) \quad (7)$$

After Taylor's transformation, which is possible for the first moments of the retention process, an equation similar to Eq. (2) is derived:

$$q = \frac{V}{m} q_m t C_0 \quad (2')$$

This clearly shows that the amount of retained analyte at non-steady-state conditions for a t constant value is linearly proportional to the initial concentration, C_0, in the liquid solution. This result indicates that a quantitative analysis can be carried out before the retention equilibrium is reached.

3. Experimental

3.1. Instruments and operating conditions

Retained As was measured by ICP-MS using a Varian spectrophotometer (Varian Inc., Palo Alto, CA). The sample solutions were pumped by a peristaltic pump from tubes arranged on an ASX 500 model 510 autosampler (CETAC, Omaha, NE) and aspirated into the argon plasma. Further details of the instrumental settings are given in Table 1. The torch position and ion lenses were optimized and tested daily by short-term stability testing in the standard mode to maximize ion signals and stability. The mass-scanning data acquisition mode was used for optimization and a mixed internal-standard solution (5 μg L^{-1}) of ^{89}Y and ^{115}In was used to correct short-term drift.

The optical density ($OD_{600\,nm}$) of the growing cell culture was measured on a UV–vis spectrophotometer (Hitachi V-200). Temperature was controlled by a "digital dry bath" (Labnet International D1100). The acidity of the aqueous phase was measured, when necessary, with a pH-meter (Crison model Digit 505). Chemicals and bacterial biomass (dry weight) were weighed on a Mettler AE 240 semi-microanalytical balance (sensitivity ±0.01 mg).

3.2. Chemicals

Arsenite and arsenate stock solutions (1000 mg L^{-1}) were prepared by dissolving, respectively, suitable amounts of sodium arsenite and *di*-sodium hydrogen arsenate in appropriate volumes of de-mineralized water. Standard stock solutions (1000 mg L^{-1}) of other elements were prepared from their salts by a conventional method. Working solutions were prepared immediately prior to their use by appropriately diluting the stock solutions.

Tryptone soy agar (TSA; Oxoid) medium (40 g L^{-1}) was composed of tryptone (1.5%, w/w), soy peptone (0.5%, w/w), sodium chloride (0.5%, w/w), and agar (1.5%, w/w) and adjusted to pH 7.3 ± 0.2; TSB medium (tryptone soy broth) was the same as TSA but without agar. Minimal medium for corynebacteria low in phosphate (MMCLP) consisted of the following: glucose (20 g L^{-1}), ammonium sulfate (10 g L^{-1}), urea (3 g L^{-1}), monopotassium phosphate (0.1 g L^{-1}), magnesium sulfate heptahydrate (0.41 g L^{-1}), sodium chloride (50 mg L^{-1}), iron(II) sulfate monohydrate (2 mg L^{-1}), manganese sulfate monohydrate (2 mg L^{-1}), biotin (50 μg L^{-1}), and thiamine (200 μg L^{-1}) for liquid MMCLP, with the addition of 1.5% of agar for solid MMCLP. This medium contained ten times less phosphate than conventional minimal medium for corynebacteria (MMC) [33].

All media were sterilized by autoclaving for 20 min at 120 °C. Chemicals used in this study were of analytical reagent grade and were obtained from Merck. Distilled, deionized water (resistance 18 MΩ cm) was used to prepare the samples and standards. The pH of the sample was adjusted as necessary with HCl and NaOH and buffered using TAB solution. TAB solution consisted of *N*-(2-hydroxyethyl)-piperazine-*N*′-2-ethanesulfonic acid (HEPES) (75 mM), potassium chloride (150 mM), and magnesium chloride (1 mM) at pH 7.3 ± 0.2 [25].

3.3. Bacterial strains and mutants

C. glutamicum RES167 (a restriction-deficient strain derived from *C. glutamicum* ATCC 13032) was used as the type strain for the arsenic studies. *E. coli* DH5α and S17-1 strains were used, respectively, for subcloning and as the donor strain in conjugation experiments [34]. Bacterial cultures were grown in complex (TSA/TSB) or defined (MMCLP) medium for 24–48 h at 37 °C (*E. coli*) or 30 °C (corynebacteria). When necessary, antibiotics kanamycin (Kan) and apramycin (Apr) were added to the cultures at final concentrations of 12.5 mg L^{-1} for corynebacteria and 50 mg L^{-1} for *E. coli*. Construction of the double-mutant strain *C. glutamicum* ArsC1-C2 was recently reported [32]. Briefly, small internal fragments from the *C. glutamicum* arsenate reductase genes *arsC1* and *arsC2* (both involved in the conversion of arsenate to arsenite) were PCR-amplified and subcloned into the *E. coli* mobilizable vectors pK18mob and pOJ260 [35], yielding plasmids pKC1int and pOJC2int, respectively. Both plasmids were transferred from the donor strain *E. coli* S17-1 to the recipient strain *C. glutamicum* RES167, and the transconjugant *C. glutamicum* ArsC1-C2 was selected under antibiotic pressure. Since pKC1int and pOJC2int are suicide plasmids for *C. glutamicum*, the transconjugant *C. glutamicum* ArsC1-C2 was obtained only after integration of the vectors into the chromosomal *arsC* genes (see Fig. 1 for details). The resulting mutant, ArsC1-C2, is unable to transform As(V) to As(III) such that the former As species accumulates intracellularly.

3.4. Procedures

3.4.1. Bacterial cultivation

C. glutamicum strains (wild-type and mutant strain ArsC1-C2) were precultured overnight in TSB medium, and the precultures (0.6 mL) used to inoculate 60 mL of MMCLP medium in 250-mL Erlenmeyer flasks. These cultures were incubated with continuous stirring (200 rev min^{-1}) until they reached an OD_{600} = 2. Cells were harvested, washed twice in 30 mL of TAB solution, and resuspended in 2 mL of TAB solution, which allowed storage of the cells in a non-growing state ("resting cells") until needed for further analyses.

3.4.2. As retention

A volume of 100 μL of "resting cells" was added to 900 μL of sample solution at pH 7.3 ± 0.2 for retention times of 1–7 min (or as indicated) at a temperature of 37 °C. The slurry was filtered through nitrocellulose filters (0.45-μm pore diameter; Whatman) and the cells retained on the filters were washed twice with 5 mL of TAB solution. Filtering and washing were carried out using a "ten place filter manifold" (Hoefer FH 225V) connected to a vacuum pump (ILMVAC GmbH, diaphragm pump MP104E). The filters, which contained the retained cells, were treated with 0.2 mLof 70% nitric acid at 70 °C for 120 min. The digested material (filter and cells) was diluted with water of high-pressure liquid chromatography quality (HPLC-quality water) to bring each sample to a final volume of 10 mL with 1% of HNO_3. The amount of arsenic retained by the "resting cells" biomass was directly determined by ICP-MS. The amount of As present in the supernatant fraction was measured (when necessary) by treating an aliquot of the liquid obtained from the filtered sample (including the washing steps) with 70% nitric acid at 70 °C for 120 min and then subjecting the sample to ICP-MS. The digestion procedure with 70% nitric acid at 70 °C, prior to the analysis stage, ensures the volatilization of chloride ions [36,37] and allowed an accurate determination of As by ICP-MS without any noticeable effect from ^{75}Ar–Cl species. The included experimental data represent the mean of three independent assays.

3.4.3. Coal fly ash preparation

The coal fly ash reference material was prepared as follows. Air-dried coal fly ash samples were ground fine enough to pass through a 200-mesh (74-μm) sieve and then ashed at 750 °C for 1 h to remove carbonaceous material. A sample containing 0.1 g of fly ash was placed in an open Teflon capsule together with 10 mL of hydrofluoric acid (d = 1.13, 40% (w/w)) and the mixture heated until near dryness. To ensure complete oxidation of the organic matter, 20 mL of sulfuric acid (d = 1.84, 96% (w/w)) and 20 mL of nitric acid (d = 1.42, 69.8% (w/w)) were added to the capsule and the sample was allowed to evaporate to dryness. Next, 25 mL of hydrochloric acid (d = 1.19, 37.9% (w/w)) and 10 mL of hydrogen peroxide (33%) were added and the sample was heated until complete dissolution of the residue. The pH was adjusted to 7.3 ± 0.2 using NaOH, with sufficient sodium tartrate added so as to avoid precipitation. Spiking studies with NIST material were carried out by treating solid samples with different amounts of As(V) standard solutions prior to the dissolution procedure. Measurements were calibrated either

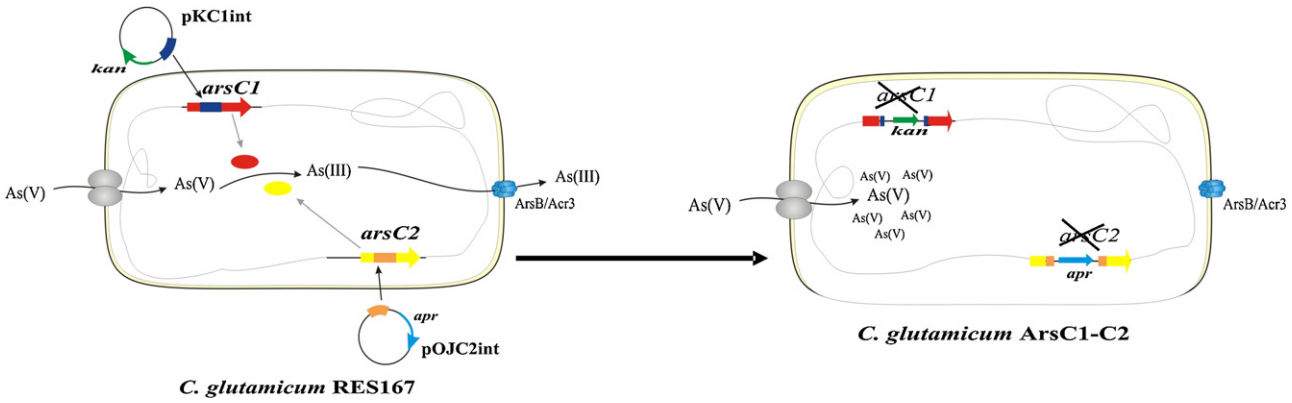

Fig. 1. Construction of the double-mutant *C. glutamicum* ArsC1-C2. Suicide plasmids pKC1int and pOJC2int contain internal fragments of the *arsC1* and *arsC2* genes. Disruption of the *arsC* genes in strain ArsC1-C2 allows the selective retention/accumulation of As(V) by the mutant.

by treating the As(V) standards in the same way as the samples via bacterial preconcentration, or by directly using As(V) standard aqueous solutions.

4. Results and discussion

4.1. Optimization of the retention system

The effect of phosphate present in the sample solution on As(V) retention by the mutant *C. glutamicum* ArsC1-C2 at pH 7.3 and temperature of 37 °C is shown in Fig. 2 for several retention times. An inverse relationship between phosphate concentration and retained As(V) was noted even for retention times as long as 3 h (data not shown), in agreement with the fact that cellular incorporation of As(V) proceeds by the same pathway as phosphate uptake [25]. However, in repeat experiments with As(III) alone and mixtures of As(V) and As(III), only minor amounts of As(III) were retained (Fig. 3) independent of the phosphate concentration present in the sample solution. Strain ArsC1-C2 is unable to accumulate As(III) due to the presence of arsenite permease pumps (Acr3/ArsB) involved in the removal of As(III) from the cell (see Fig. 1) [23,31]. Therefore, the mutant *C. glutamicum* ArsC1-C2 accumulates As(V) rather than As(III) under phosphate-free conditions even at As(III) concentrations 75 times higher than those of As(V). The effect of Sb(III) and Sb(V) on As(V) retention was similar to that of As(III) (Fig. 3).

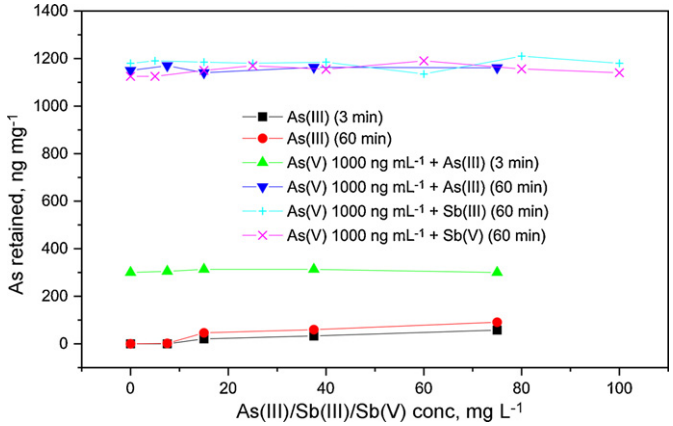

Fig. 3. Effect of As(III), Sb(III) and Sb(V) concentrations on As(V) retention (in the absence of phosphate) by the mutant strain ArsC1-C2 at the selected conditions (pH 7.3 and 37 °C) as measured during two retention times.

The effect of temperature on As(V) retention was also studied in the range of 4–38 °C. As(V) retention initially increased with increasing temperature, but became nearly constant between 20 and 38 °C (data not shown). For this reason, all subsequent As-retention experiments were carried out at 37 °C. Another important factor with respect to the cellular environment was the pH of the sample solution, since As(V) retention was greatly improved at neutral pH (Fig. 4), with pH 7.3 optimal for the experimental conditions

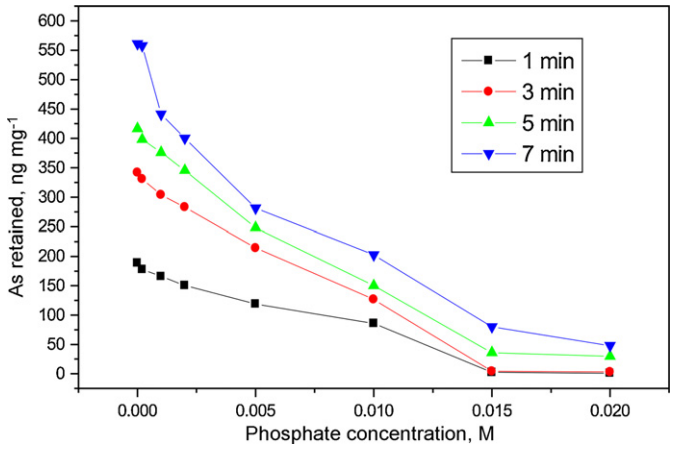

Fig. 2. Effect of phosphate concentration on the retention of As(V) (1000 ng mL^{-1}) by the mutant strain ArsC1-C2, at the selected conditions (pH 7.3 and 37 °C) as measured during four retention times.

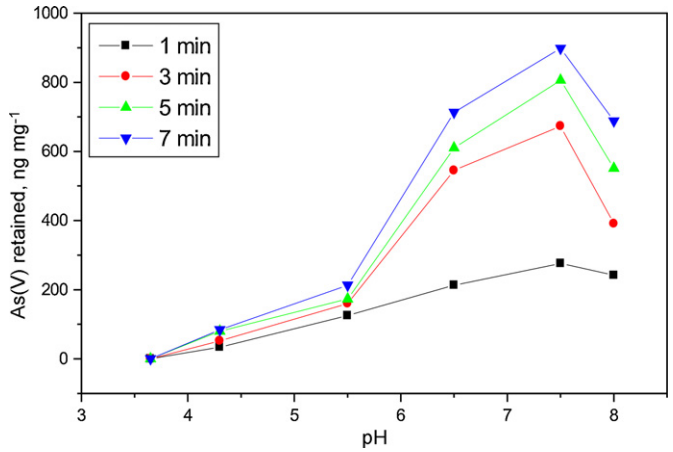

Fig. 4. Effect of pH on the retention of As(V) (1000 ng mL^{-1}) in the absence of phosphate at 37 °C by the mutant strain ArsC1-C2, as measured during four retention times.

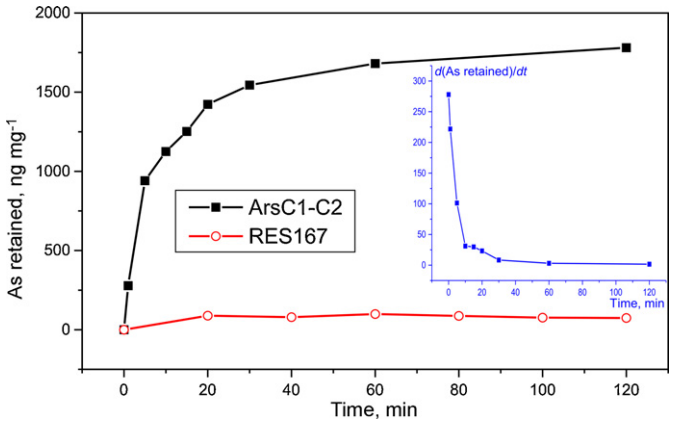

Fig. 5. Effect of time on the retention of As(V) (1000 ng mL^{-1}) by the ArsC1-C2 mutant strain and by the parent strain *C. glutamicum* RES167 at the selected conditions (pH 7.3 and 37 °C). The inset shows the corresponding derivative plot for the ArsC1-C2 mutant.

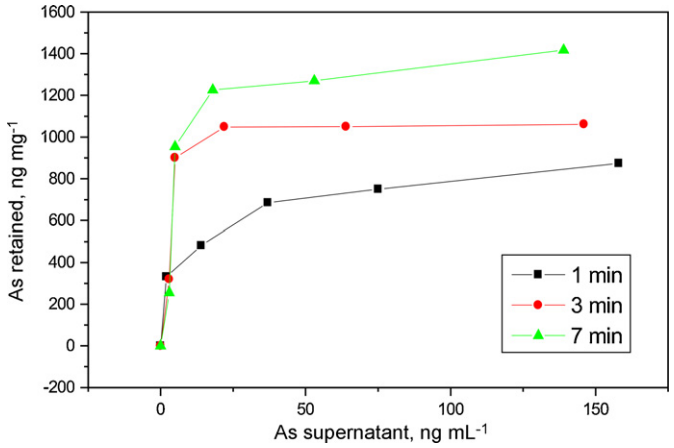

Fig. 6. Plot of the amount of As(V) retained by the mutant strain ArsC1-C2 *vs.* the concentration of nonretained As(V) present in the supernatant, at the selected conditions (pH 7.3 and 37 °C) and for three retention times.

used in this study. Working at this pH, the retention process occurs with no pH variation. Nonetheless, the retention procedure was always carried out using TAB-buffered samples.

The effect of time on As(V) retention is shown in Fig. 5. The arsenic retention profile showed two well-differentiated stages. The first stage covered the initial 20 min, when the amount of arsenic retained increased rapidly, while during the second stage, from 20 to 120 min (Fig. 5), arsenic retention increased more slowly. The inserted derivative plot in Fig. 5 confirms this conclusion, showing that the retention rate was highest during the early stage of the retention process. Fig. 5 also shows that the mutant strain ArsC1-C2 accumulated up to 25-fold more As(V) that the parent strain *C. glutamicum* RES167.

4.2. Retention equilibrium

The retention percentage was derived by comparing the amount of As(V) retained by the biomass with the total arsenic content in the original sample solution. As expected, the retention percentage decreased with increasing amounts of As(V) present in the sample solution. Consequently, a more useful parameter, q_m, the maximum amount of As(V) retained per mass unit (dry weight) of bacterial cells, was determined for several As(V) concentrations and retention times. Thus, the amount of As(V) retained by the bacterial biomass was mathematically modeled, fitting the equations according to Marquardt nonlinear regression techniques (MicroCal Origin). The χ^2 value and the smallest relative error, as indicated by the values of the derived variables, were used to ascertain the suitability of the models' fit with the experimental data. The results showed that hyperbolic equations were the best theoretical model to describe the retention of As(V) by the corynebacterial "resting cells" (Table 2). This, in turn, allowed determination of the parameter q_m. However, for As(V) concentrations below $q_{1/2}$, it was theoretically derived that a first-order rate equation could also be used to describe the retention process. Accordingly, the amount [q, in mg As (g bacteria)$^{-1}$] of arsenic retained per mass unit (dry weight) of bacterial cells increased linearly, $q = (0.52 \pm 0.08) \times 10^{-3}\ C_0$, at As(V) concentrations (C_0, ng mL^{-1}) in the original sample solution in the range of 0–1500 ng mL^{-1} ($r = 0.98909$). This relationship shows that, at least for analytical purposes, "resting cells" can be successfully used as the extractant for As(V) and that the amount of the analyte retained at saturation will not be fully reached within the concentration range established in this study.

Fig. 6 shows the retention isotherms of As(V) for the "resting cells". The Langmuirian shape indicates that the data fit reasonably well with a two-site Langmuir model, implying that the tendency of As(V) to be retained decreased with increased As(V) loading of the bacterial mass. However, assuming a one-site Langmuirian sorption and solutions in which the As(V) concentration is low, the results explain the retention of As(V) with good precision (Table 3). The equilibrium constant, b, determined from low concentrations of As(V), is of greater general interest for analytical applications and was obtained from the experimental data (slope of the plot $1/q$ versus $1/C$ in the Langmuir isotherms). The theoretical maximum monolayer retention capacity, q_m (mg g^{-1}), was also derived, while the essential characteristics of the Langmuir isotherm could be expressed in terms of the dimensionless constant separation factor, $R_L = 1/(1 + bC_0)$. The value of R_L in the range of 0–1 at all initial analyte concentrations confirms the favorable retention of arsenic process. The Gibbs free energy of the retention process was $\Delta G = -RT\,Lnb$, where b (in L mol^{-1}) is the equilibrium constant for the Langmuir isotherm. The parameters for the As(V)-bacterium system are given in Table 3, which shows the favorable, very-high-affinity retention of the bacterial cells for As(V). The negative value of the Gibbs free energy indicates the spontaneity of the retention process, in agreement with the values obtained from the hyperbolic model (Table 2), showing that "resting cells" exhibit large preconcentration abilities for short retention times.

Table 2
Values obtained for each parameter after fitting the experimental retention and kinetics data to hyperbolic functions.

Parameter	Value	
q_m or q'_m (mg g^{-1})	3.54 ± 0.5	2.2 ± 0.4
$q_{1/2}$ (mg L^{-1}) or $q'_{1/2}$(min)	1.8 ± 0.3	4.2 ± 0.3
χ^2	0.37812	0.18432
Equations used	Retention, $q = \frac{q_m C}{q_{1/2}+C}$	Kinetics, $q = \frac{q'_m t}{q'_{1/2}+t}$

Table 3
Parameters obtained for the Langmuir isotherm used to model the retention process.

Langmuir isotherm, $\frac{1}{q} = \frac{1}{q_m bC} + \frac{1}{q_m}$	
Parameter	Value
b (L mg^{-1})	0.81
q_m (mg g^{-1})	3.9
R_L	0.08–0.62
r	0.9899
ΔG (kJ mol^{-1})	−0.3

Table 4
Spiking studies ($n = 3$).

Sample	Content ($ng\,mL^{-1}$)	Added ($ng\,mL^{-1}$)	Found ($ng\,mL^{-1}$)	Recovery (%)
Deionized water	–	10	10.2 ± 0.4	102.0
		20	19.5 ± 0.7	97.5
		30	30.6 ± 0.8	102.0
		40	40.2 ± 0.8	100.5
	Content ($ng\,mg^{-1}$)	Added ($ng\,mg^{-1}$)	Found ($ng\,mg^{-1}$)	Recovery (%)
NIST SRM 1633a	145 ± 15	0	144.8 ± 4.4	99.86
		100	247.3 ± 5.6	100.94
		200	347.6 ± 4.3	100.75
		400	547.9 ± 4.9	100.53

Alternatively, the amount of As(V) retained at equilibrium can be evaluated using the distribution coefficient (K_D) of As(V) between the bacterial cells and the aqueous phase. The K_D ($= 25.4\,L\,g^{-1}$) value obtained ($r = 0.9907$) was affected by the concentration of As(V) [C_0 ($ng\,mL^{-1}$)] in the original sample solution and decreased with the initial As(V) concentration ($ng\,mL^{-1}$). The best-fitting equation obtained was: $\log K_D = (-1.5 \pm 0.1)\ \log C + (5.6 \pm 0.5)$ ($r = 0.9909$), from which it is possible to derive a very high theoretical value for K_D, as in the case of strongly diluted solutions. The K_D values determined at low concentrations of As(V) were higher than those previously reported for other inorganic species and bacteria [22,38,39]. This result indicated that, under the established conditions, bacterial cells were far from having reached As(V) saturation. A maximum value for the amount of As(V) retained per mass unit of bacterial cells was experimentally established as $12.5\,mg\,As\,(g\,cells)^{-1}$, in accordance with the above comments.

4.3. Kinetic modeling

The As(V) retained by "resting cells" with time was theoretically better modeled according to a hyperbolic function (Table 2). The half-retention time was very short, indicating that the retention kinetics is very rapid. The same conclusion was derived from the data in Fig. 5 (inserted graph), which shows that the specific retention rate reaches a maximum value at early phases of the retention process but then sharply decreases after 15 min. Fig. 5 also shows that, as a whole, As(V) retention follows a two-step process, in which the surface binding of As(V) is initially very rapid and can be described by an external diffusion-controlled model. The experimental data obtained from this early stage of the retention process fit well along a straight line, $q = (0.27 \pm 0.02)t$ ($r = 0.99812$), where q is the amount of As(V) retained ($mg\,g^{-1}$) and t is the retention time (min) in the range 0–10. Afterwards, in the second step, retention increased slowly, eventually reaching with the bacterial surface pseudo-equilibrium that was controlled by an intracellular diffusion process.

4.4. Analytical applications

As theoretically stated in Eq. (2) and experimentally demonstrated above, the amount of As(V) retained by corynebacterial mutant "resting cells" is simultaneously dependent upon the initial As(V) concentration and the retention time. This means that it would be possible to retain the same amount of As(V) under a variety of external conditions. It is clear that the amount of As(V) retained is improved with longer retention times. However, in most analytical applications, short analysis times are preferable. Consequently, in the following, all data characterizing the performance of the analytical procedure for As(V), carried out under optimal conditions, were based on a 3-min retention time. The precision for 10 replicate determinations of 50 ng As(V) mL^{-1} was 2.4% relative standard deviation (R.S.D.). The lower limit of detection under the selected optimal conditions was 0.1 $ng\,mL^{-1}$ (3σ). The enhancement factor, which is based on the ratio of the slope of the calibration line derived from the preconcentration procedure using the "resting cells" to the slope obtained from direct measurements of aqueous standards solutions, was found to be about 25. The between-batch precision ($n = 7$) was better than 3.0% for As(V) concentrations of 50 $ng\,mL^{-1}$. These results show that the procedure described herein can be used routinely and that it does not require the use of time-consuming methods.

The effect of several ions, Na(I), K(I), Ca(II), Mg(II), Hg(II), Cd(II), Ni(II), Fe(III), Cu(II), Mn(II), Zn(II), V(V), Cr(VI), Al(III), Si(IV), and Pb(II), as well as tartrate and chloride anions, on the retention of As(V) was evaluated individually and in combination. When added in concentrations of up to 100 $mg\,L^{-1}$, none of these ions interfered (<5%) in the retention/determination of As(V). The effect of the presence of different concentrations of As(III), Sb(III), and Sb(V) on the retention of As(V) was also studied, but again no interference was observed.

For practical applications of the developed procedure, phosphate-free samples are the most appropriate for As(V) fractionation. However, samples containing known amounts of phosphate can also be studied, as long as phosphate-matched standards are used. Nonetheless, the retention capacity of the bacterial cells is decreased in the presence of phosphate. In this study, the reliability of the procedure was tested using a phosphate-free reference coal fly ash sample (NIST SRM 1633a coal fly ash), which served as a suitable complex matrix for a preliminary application. The coal fly ash reference material was certified for total As, but the sample treatment described in Section 3.4.3 assured full transformation of total arsenic into As(V). The assayed value ($144.8 \pm 4.4\,ng\,mg^{-1}$) of the arsenic in the NIST standard reference material was in close agreement with the certified value ($145 \pm 15\,ng\,mg^{-1}$). The recovery of arsenic from artificial samples (Table 4) and from the reference coal fly ash was between 97.5% and 102.0%. These results demonstrate the utility of the mutant strain for the retention of As(V), and its accurate determination with no matrix effect.

5. Conclusion

A novel methodology for the selective retention of arsenate at non-steady-state conditions using a double-mutant strain of corynebacteria was optimized. Moreover, our study demonstrated not only that the double-mutant strain *C. glutamicum* ArsC1-C2 is a good biomaterial for the efficient extraction of As(V), particularly from phosphate-free matrices, but also that the method can be used for screening purposes in aqueous samples. The results showed that the developed analytical procedure based on the selective retention of As(V) on complex matrices, such as coal fly ashes, allowed the accurate determination of total arsenic by ICP-MS, when a previous oxidation to As(V) is ensured. The method is generally applicable to specialised facilities for the use of the bacterial cells, which

represents an important drawback for general analytical laboratories set-ups. The good analytical characteristics, obtained with these engineered bacterial cells when used as extractants, provide the basis for new, improved analytical applications using this and similar kinds of materials.

ABSTRACT

Simultaneous quantification of Cd^{2+} and Pb^{2+} in solution has been correctly targeted using the kinetic information from a single non-specific potentiometric sensor. Dual quantification was accomplished from the complex information in the transient response of an electrode used in a Sequential Injection Analysis (SIA) system and recorded after step injection of sample. Data was firstly preprocessed with the Discrete Wavelet Transform (DWT) to extract significant features and then fed into an Artificial Neural Network (ANN) for building the calibration model. DWT stage was optimized regarding the wavelet function and decomposition level, while the ANN stage was optimized on its structure. To simultaneously corroborate the effectiveness of the approach, two different potentiometric sensors were used as study case, one using a glass selective to Cd^{2+} and another a PVC membrane selective to Pb^{2+}.

1. Introduction

Automated systems based on flow-injection techniques, namely Flow-Injection Analysis (FIA) and Sequential Injection Analysis (SIA), have been used in analytical chemistry during the last three decades [1,2]. With these, species detection for either qualitative or quantitative purposes can be accomplished by using different detection principles; when the systems employ sensors at the detection stage, specially simple and efficient analytical systems can be devised. Selectivity of used sensors plays an important role given it determines discrimination capability [3]. Early applications based on flow-injection techniques were developed using highly selective sensors, but the lack of availability of specific sensors for all needs fostered the proposal of a new approach. This alternate solution to the lack of sensor variety is the use of sensors with less restrictive response characteristics and the attempt to take advantage of multidimensional information that they can provide [4].

Detection of a single analyte in the simpler cases does not represent a challenge for low-selective sensors; but for multi-species detection in complex matrices, these sensors provide signals with multiple analyte dependence that makes mandatory the use of chemometric tools for deconvolution. This multicomponent aspect can be derived either from a high dimensional signal [5,6] or from the use of sensor arrays [7].

Calibration models for multiple component determinations have been built with different multivariate tools such as Multiple Linear Regression [8–10], Multivariate Curve Resolution [11,12], Principal Component Regression [13–15], Partial Least Squares [13,16–18], Non-linear Iteratively Partial Least Squares [10], Non-linear Least Squares [9], Support Vector Machines [19] and Artificial Neural Networks (ANNs) [20–23]. From this set of tools, ANNs have outstood due to its ability to model both linear and non-linear responses (with respect to the analytes). Models based on ANNs are sometimes created from high-dimensionality information, for example a mass spectra or a voltammogram. In such cases, preprocessing must be done to compress the signals while preserving enough amount of relevant information. Usual approaches for data preprocessing are Principal Component Analysis (PCA) [2,13,15,18,24], Fourier Transform [20] and Discrete Wavelet Transform (DWT) [25]. Among these tools, DWT has certain interesting advantages because, besides to compression, the technique also filters and smoothes signals.

Analytical use of sensors is carried out normally in steady state conditions, but recent applications have explored the advantages of using their dynamic signals. These can be derived from chemical kinetics or from their use immersed in flowing solutions. This additional characteristic represents an advantage, since the richer content of information supplied by the dynamic response of a sensor after, e.g. a step profile insertion of the sample improves the discrimination ability between primary and interfering species [13,26].

From this departure point, FIA systems combined with spectrophotometric detection were applied to resolve ternary mixtures of metallic cations [14] or binary mixtures of antibiotics [16]. Dynamic signals recorded from an array of potentiometric sensors coupled to an SIA system were reported for the resolution of ternary and quaternary mixtures of cations in water samples [20]. Heavy metals have also been the goal of multi-species determination based on transient signals. Relevant to this communication is the work reported in [26], where a flow-injection system coupled to a sensor array was used for the simultaneous quantification of two metallic ions in solution from the dynamic sensor recordings. Similarly, dynamic signals obtained with two different biosensor-based FIA systems have been used for the binary determinations of glucose/pH or urea/pH pairs [21]. The same methodology was successfully applied later for the quantification of several concentrations of penicillin [22]. In all the described cases, transient signal is directly processed, without any data pre-treatment.

This work describes the use of a potentiometric sensor in a SIA system, which after a chemometric treatment of its transient signal, permits to simultaneously quantify two analytes. The advanced approach suggested takes advantage of the dynamic response and cross-sensitivity contained in a single non-specific sensor to resolve a binary mixture. As case study, quantification of cadmium and lead is performed departing from the signal recorded from one sensor only, after the high reproducible step injection of a sample employing the SIA system.

In the data treatment aspect, it is difficult to build calibration models from dynamic responses, given the increased complexity of the signals after addition of the kinetic dimension. In this work, the difficulty was surpassed by first preprocessing the recordings using DWT to reduce their size and extract significant features [25]. Compressed information was later fed to an Artificial Neural Network (ANN) to finally build the calibration model. The utility of the approach is shown by modelling both analytes in two different study cases: two potentiometric sensors from different nature, PVC or glass membrane, were used to illustrate the concept. The final aim of the work is to enrich the type of information to be used by electronic tongues with multiple sensors, to better resolve the most complex cases.

2. Experimental

2.1. Equipment

Quantification of two heavy metals in solution was the goal of this application. A total of 45 different combinations for cadmium and lead were randomly generated using Excel and then programmed for being automatically prepared (by dilution from stocks) and injected into a cell by a SIA system available at our laboratory [20]. Composition of mixed solutions is available for downloading as Supplementary information. The SIA system shown in Fig. 1 is formed by a fluidic stage and a measurement stage. The former consists of an automatic microburette (Crison 2030 microburette, Crison, Spain) equipped with a 5 ml syringe (Hamilton, Switzerland), a holding coil (5 ml volume, 1 mm Ø PTFE tube, Bioblock, France), an 8 way Hamilton MVP valve (Hamilton, Switzerland) and a 7 ml home-made Perspex mixing cell with a magnetic stirrer. The measurement stage comprises the sensors, a reference electrode (Thermoelectron 900200, MA, USA) and an 8-channel signal conditioning circuit connected to a Data Acquisition System (National Instruments NI 6221 Multifunction DAQ, TX, USA). All active elements involved in the SIA system are controlled using a virtual instrument developed in LabView [20] through the RS-232 port of a PC Pentium III at 600 MHz.

2.2. Reagents and solutions

Standards were prepared by the SIA system using a 0.05 M acetic/acetate buffer at pH 4.5 as carrier and diluting solution. Analytes were in ranges 0–2.44×10^{-4} M for Cd^{2+} and 0–4.97×10^{-5} M for Pb^{2+}. These ranges were determined by the optimal working range of the sensors used. Studied concentrations, although low for conventional potentiometric sensors, are higher than those permitted by the Environmental Protection Agency. It is also worth noticing that for heavy metals these permitted levels are extremely low (75 nM for lead and 45 nM for cadmium). All solutions carrier were prepared using doubly distilled water and analytical grade (or similar) reagents.

2.3. Sensors and procedure

The measuring cell incorporated two ion selective electrodes (ISEs) with cross response to the tested heavy metals, and a Ag–AgCl reference electrode. One ISE was based on a potentiometric Pb^{2+} PVC membrane with trioctylphosphine oxide as ionophore, and the other was based on a chalcogenide glass selective to Cd^{2+}. ISEs were fabricated at the Chemistry Department of St. Petersburg University.

Each ISE was characterized in static and flow conditions. Batch analysis measurements were firstly done in distilled water and later in single ion solutions at different concentrations. Linear working

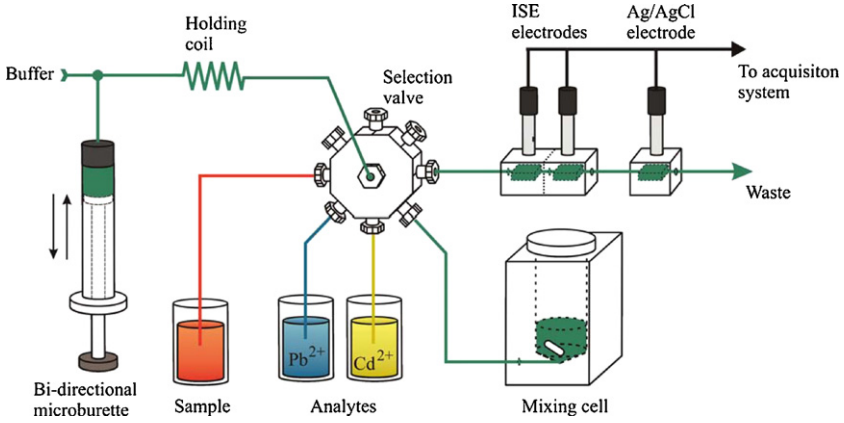

Fig. 1. Scheme of the SIA system employed. The measurement part comprises the ISEs, the reference electrode and the acquisition system (not shown in the figure). The fluidic part is formed by the microburette, the holding coil, the selection valve and the mixing cell with magnetic stirrer.

Table 1
Summary of data calibration results for the Cd-ISE and Pb-ISE in static conditions according to Nernstian model. Slope and intercept values obtained from the linear fit of the linear response zone.

Sensor	Response to distilled water (mV)	Linear fit data	
		Intercept (mV)	Slope (mV/dec)
Cd^{2+}	−365.9	−272.19	16.55
Pb^{2+}	138.7	321.29	26.45

zone was determined from the calibration curves for each sensor. Slope and intercept describing the linear response for each sensor are contained in Table 1. Characterization in flow condition was done by firstly examining the sensors in distilled water, then in acetate buffer and lastly integrating them in the flow cells to determine the responses to single metal solutions automatically prepared by the SIA system. Detection limit was taken at the point of intersection of the two asymptotic behaviours of calibration curves, as recommended by IUPAC. Calibration results are summarized in Table 2. Characterization shows that cadmium electrode response to Cd^{2+} ion presents poor response, having a sensitivity value lower than the theoretical one for double charged ions (29 mV/dec). Despite this bad response, the electrode was not replaced given that was the only one available.

After characterization, the cell containing the set of electrodes was subject to injections of binary mixtures of heavy metals. Samples were injected into the cell with a step profile and the transient response for each ISE was simultaneously recorded during 60 s per sample in time steps of 0.1 s, obtaining two data sets of potentials, one per ISE.

2.4. Information processing and modelling

Both matrices of potentials were preprocessed by DWT to reduce the number of variables before entering the ANN. Preprocessing and modelling were done using MATLAB. DWT was carried out with the Wavelet Toolbox. DWT is implemented in MATLAB using Mallat's pyramidal algorithm (Fig. 2). This signal processing technique operates over a single discrete signal by applying two digital complementary filters performing low-pass and high-pass filtering followed by downsampling. The result of the decomposition is two sets of coefficients named approximation and detail coefficients, each one correlated with the low- and high-frequency content of the signal, respectively. The size of each set after transforming the signal is approximately half the original size. The process can be repeatedly applied on either set of coefficients, taking the decomposition procedure one level down and obtaining two more sets of coefficients (approximation and detail) each time the transformation is carried out. In this work, compression was accomplished by retaining the approximation coefficients resulting from this transformation and discarding the detail coefficients.

The full set of discrete wavelets available in MATLAB's toolbox (the four families Daubechies, Coiflets, Symlets and Biorthogonal Spline) was evaluated with decomposition levels ranging from 1 up to 9. The goal was to find the combination that performed the best in terms of retaining most of the original information with the fewer number of components for correctly modelling the next step. The number of combinations evaluated was 324, considering each Wavelet family was also assayed at different orders.

Calibration model was based on an ANN built with the Neural Network Toolbox. Several ANNs were also attempted in order to find the optimum structure. In all cases, ANNs were feedforward

Table 2
Summary of data calibration results for the Cd^{2+} and Pb^{2+} ISEs in flowing conditions. Sensitivities expressed as slopes obtained from linear fit of the linear working zone.

Sensor	Sensitivity to Cd^{2+} ion (mV/dec)	Sensitivity to Pb^{2+} ion (mV/dec)	Potentiometric selectivity coefficient log $\left(K_{x,y}^{pot}\right)$ [a]	Detection limit (M)[b]
Cd^{2+}	8.51	6.05	1.2 ± 0.1	2.00×10^{-6}
Pb^{2+}	8.97	20.58	-3.2 ± 0.2	4.48×10^{-5}

[b] Determined as the intercept between the linear Nernstian behaviour and the horizontal line in absence of response.

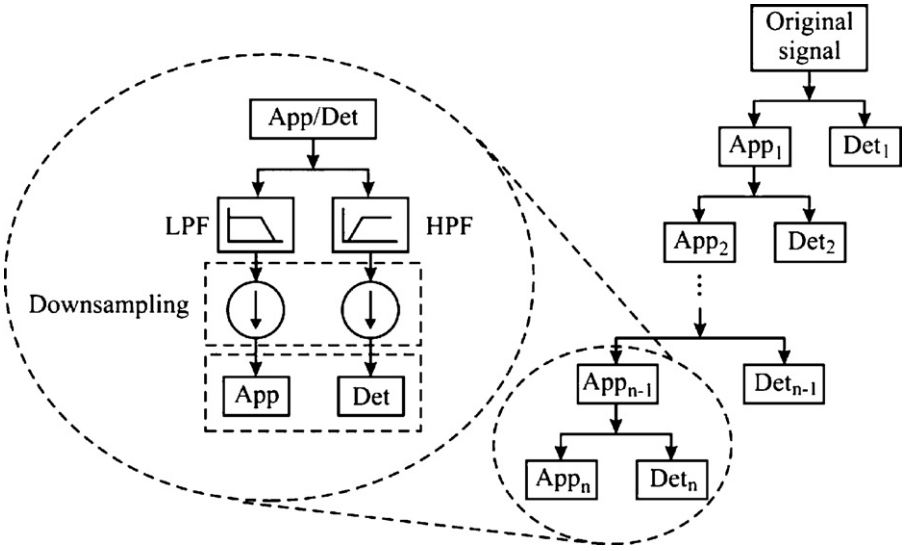

Fig. 2. Mallat's pyramidal algorithm implemented in MATLAB's Wavelet Toolbox. Approximation and detail coefficients are indicated by App and Det, respectively. Subindexes denote decomposition level up to an *n*-th level. LPF and HPF stand for low-pass and high-pass filters, respectively. Downsampling is represented by a circle with a centred arrow pointing downwards.

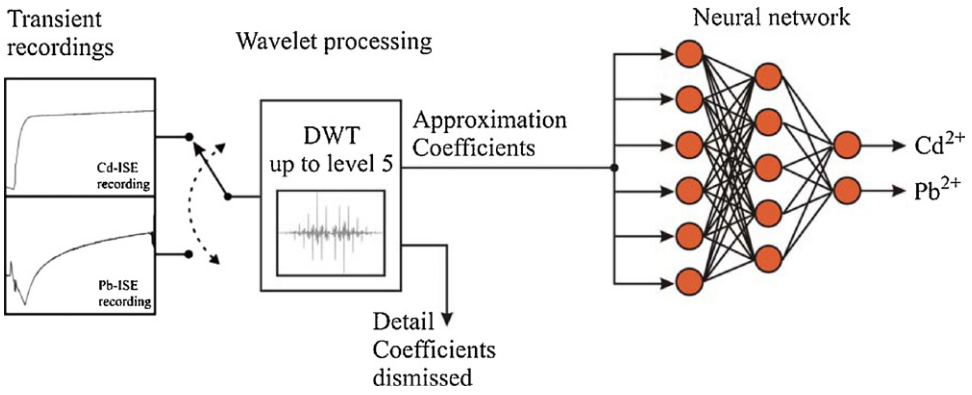

Fig. 3. Scheme depicting both the information processing and modelling stages. Recordings are processed by the DWT and the approximation coefficients obtained from the decomposition are used to feed the ANN for building the calibration model.

type trained with the Bayesian regularization algorithm for better fitting the test set. Approximation coefficients were taken as inputs, and concentrations of cadmium and lead as targets. Sets of inputs and targets were split into two subsets for training and testing purposes. Structures with one and two hidden layers, different number of neurons (from 6 up to 30) and different non-linear transfer functions in their hidden layers were tested. A scheme showing the coupling of preprocessing and modelling stages is depicted in Fig. 3.

3. Results

The departure universe of data consisted of two input matrices (one per ISE) formed by the transient recordings (600 data values) obtained with the 45 samples, plus a target matrix formed by the corresponding concentrations of each binary mixture of heavy metals. The size of each recording made mandatory the compression before building the calibration model with the ANN. As reference, two recordings are shown in Fig. 4, one per each ISE, where one can visualize that the glass membrane ISE (the Cd^{2+} electrode) displays a faster response than the polymeric membrane type (the Pb-ISE).

The combination of wavelet and decomposition level used in our application was chosen based on the compression ratio, percentage of total energy retained by approximation coefficients after each decomposition and degree of similarity between the original recording and the one reconstructed using only the coefficients retained. Compression ratio is the relationship between the original data size to the number of approximation coefficients

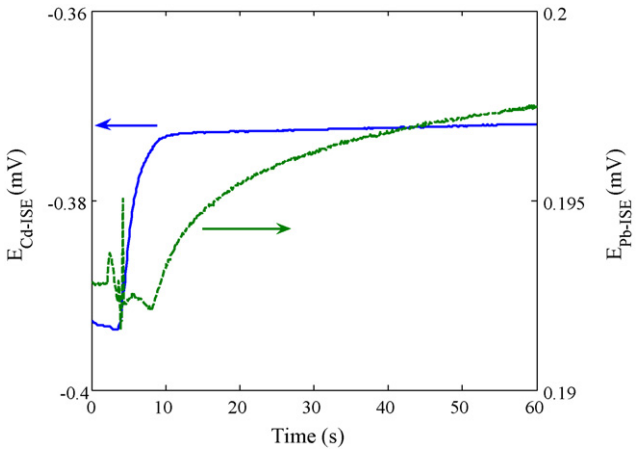

Fig. 4. Example of two transient signals recorded with the ISEs after step insertion of a sample into the cell. Analyte mixture corresponds to concentrations (lead and cadmium) 85.7 and 49.4 μM, respectively.

obtained after decomposition. Total energy is defined as the sum of all squared detail coefficients over all scales plus the square of the remaining approximation coefficients. Finally, comparisons between the original and reconstructed recordings were carried out at all levels of decomposition. This evaluation is proposed since we have loss of information after dismissing the detail coefficients.

Compression ratios reported values as low as 1.9 for Coiflets Wavelet of fifth order and decomposition level 1, to as high as 300 for Daubechies Wavelet of first order and decomposition level 9. Bar graphs in Fig. 5 show the number of approximation coefficients obtained by DWT for the 326 combinations detailed above. Energy retained by approximation coefficients was over 99% of total energy contained in the complete set of coefficients for all decomposition levels, meaning that almost no high-frequency components are contained in raw recordings (most of the high-frequency components are noise).

Degree of similarity between original and reconstructed signals was evaluated by running a test described in [25]. The test compares two discrete signals of the same size and yields a result between 0 and 1 depending on how they match. The result is 0 when the two signals have nothing in common and increases with its matching. Results along the different tests done ranged from 0.746 for signals processed with the Coiflets Wavelet of first order, up to 0.999 for signals processed with the set of second order filters (for decomposition and reconstruction) contained in the Biorthogonal Spline Wavelet, being the latter the family showing best performance.

Approximation coefficients from decomposition levels 1 to 4 and 6 to 9 for all wavelets were not considered for ANN modelling given that (i) the large amount of coefficients from levels 1 to 4 made the network training last too long, (ii) the coefficients from level 6 did not helped the network to converge to the desired error during training and (iii) signals reconstructed with coefficients from levels 6 to 9 yielded similarity values below 0.95. This threshold, imposed to assure a faithful representation in the compression stage, was the reason that only approximation coefficients obtained at decomposition level 5 were used for building the calibration model.

Among the tests, the wavelet function that best performed was the Biorthogonal Spline Wavelet of order 3 for decomposition and order 1 for reconstruction ('bior3.1', according to MATLAB's nomenclature). The number of approximation coefficients retained after decomposition was 23, yielding a final data matrix of size 23×45 for each set of transient signals. Mean degree of similarity was 0.985 for Cd^{2+} ISE and 0.991 for Pb^{2+} ISE. For comparison purposes, Fig. 6 shows two plots for the degree of similarity obtained when original signals from Cd-ISE and Pb-ISE were compared against their corresponding signals reconstructed using the approximation coefficients after wavelet decomposition. Only wavelets of order 3 are

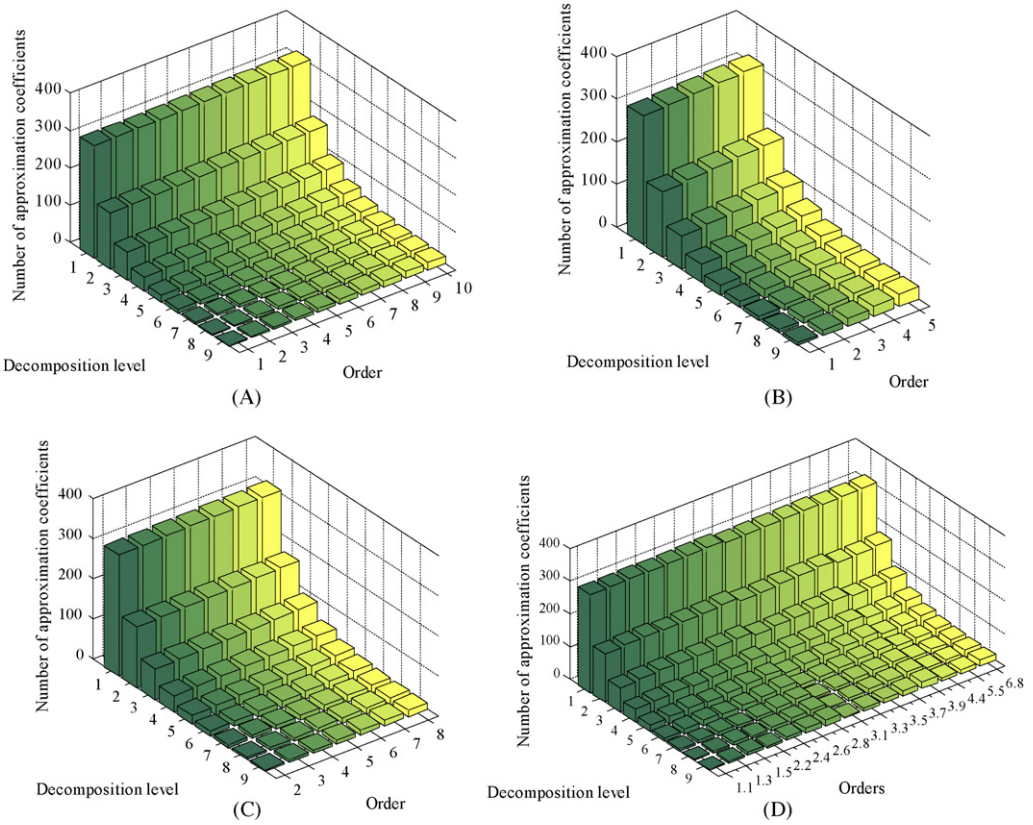

Fig. 5. Bar graphs showing the number of approximation coefficients obtained with nine decomposition levels using discrete wavelet families (A) Daubechies, (B) Coiflets, (C) Symlets and (D) Biorthogonal Spline. All wavelets were tested at all orders available. For the case of the Biorthogonal Spline family, the format used to indicate the orders is as follows, the first number corresponds to the order for decomposition and the second number to the order of reconstruction.

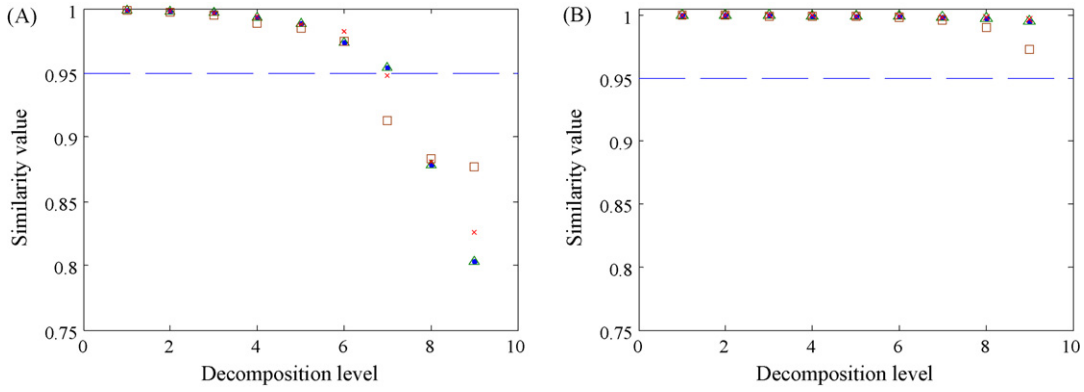

Fig. 6. Plots for similarity values from reconstructed and original recordings obtained with (A) Cd-ISE and (B) Pb-ISE. The dashed line marks the 0.95 value imposed as limit. The markers identify the wavelet family: (●) Daubechies, (△) Symlets, (+) Coiflets, (□) Biorthogonal Spline. Plots were obtained with wavelets of third order for comparison purposes.

indicated since the chosen wavelet is of order 3 for decomposition.

Regarding the calibration model, all trained networks had structures with one or two hidden layers and one output layer. Non-linear activation functions of sigmoidal type were used in hidden layers while linear activation function was used in the output layer. Neurons for the one hidden layer case varied from 6 up to 30. Neurons for the two hidden layers case varied from 6–24 up to 24–6. These combinations were obtained by increasing in one the neurons in the first hidden layer while decreasing in one the neurons in the second hidden layer. Structures with one output for independently modelling each metal ion were proposed, as well as structures with two outputs for simultaneous quantification of cadmium and lead.

Wavelet coefficients and concentrations were randomly split into two subsets for training and testing purposes, 75% of total information was used to determine the parameters of the model while the remaining was used for testing its generalization capability. No third subset was used for internal validation, given the training algorithm used (Bayesian regularization) prevents overfitting by other means. In order to facilitate convergence, input and output data in training subset were firstly normalized in the interval [−1,1]. Data normalization of testing subset was done according to maximum and minimum values obtained from training subset. The sum of squared errors (SSE), from the differences between the expected and calculated values, was used for tracking convergence during training. Error goal was set to 0.09 since this value had proven to avoid overfitting in our work and yielded low dispersion

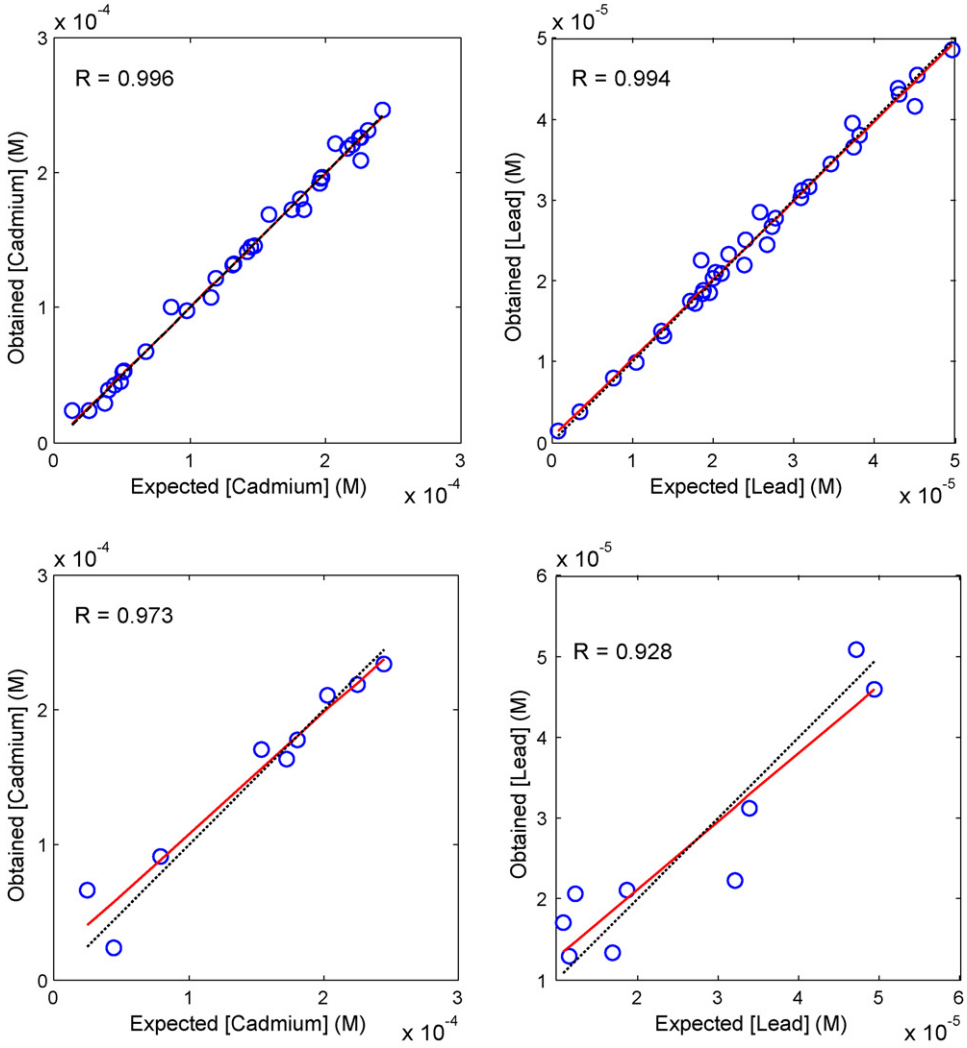

Fig. 7. Comparison of obtained vs. expected concentration for cadmium (left) and lead (right) using the recordings from the Cd-ISE. Dashed line corresponds to ideality and solid line corresponds to the obtained fit. Plots in the upper row are the results for training, plots in the lower row are the results for testing.

when linear regression analysis is performed between the obtained and expected values. SSE and correlation coefficients of the previous comparison were also used as figures of merit when the trained networks were tested.

None of the network structures with two outputs, as well as structures with one hidden layer and two outputs performed well in testing although training was fulfilled. For these cases, error goal was met in almost 50% of training runs but correlation coefficients obtained in testing were below 0.6 and even negative.

Networks with one output for single analyte quantification were those showing better performance. The structure that worked the best had 10 neurons in the first hidden layer, 4 neurons in the second hidden layer, and one neuron in its output layer, both for Cd and for Pb sensor signals. Hyperbolic tangent sigmoid function was used as transfer function in both hidden layers, and linear transfer function in the output layer. Simultaneous analyte determination was accomplished using two parallel networks with the aforementioned structure, one per metal ion and fed with the same DWT reduced transient. Fig. 7 shows the regression plots between the expected and predicted concentration for cadmium and lead obtained with the Cd^{2+} electrode, Fig. 8 are the equivalent plots for the Pb^{2+} electrode, an ISE with a completely different membrane type, and very different intrinsic response rate. Cd^{2+} sensor employed a chalcogenide glass and was fast responding, while Pb^{2+} sensor used a potentiometric PVC membrane and was much slower.

Effectiveness of the data processing methodology was corroborated by doing 25 additional trainings with a 9-fold cross validation over each electrode's recordings. Input and output data were randomly split into five parts, four fifths were taken for training and one fifth for testing. As previously, training data was firstly normalized and then testing data. Error goal was met in all cases. Results obtained yielded mean SSE in testing as low as $0.259 \pm 0.029\,mol^2\,l^2$ for lead prediction using the Pb-ISE, to as high as $0.725 \pm 0.049\,mol^2\,l^2$ for cadmium prediction with the same electrode. Average values for SSEs and correlation coefficients obtained with Cd-ISE are shown in Table 3; Table 4 presents the results obtained with Pb-ISE. Indicated uncertainties correspond to the 95% confidence interval for the 25 replicate training cases.

The proposed methodology was compared against the approach based on PCA preprocessing followed by ANN modelling to provide some reference. PCA was performed on both sets of recordings using the MATLAB's Statistics Toolbox. The analysis of the decomposition showed that for any of the two data sets more than 98% of variance was accounted for by the first two principal components. Two matrices were built with the two principal components from each data set and independently used for modelling. When neural networks with equivalent structures to those above were trained with this PCA preprocessed matrix, none of the networks converged to the desired error goal during training. These results, we believe, highlight the difficulties of the chemometric treatment.

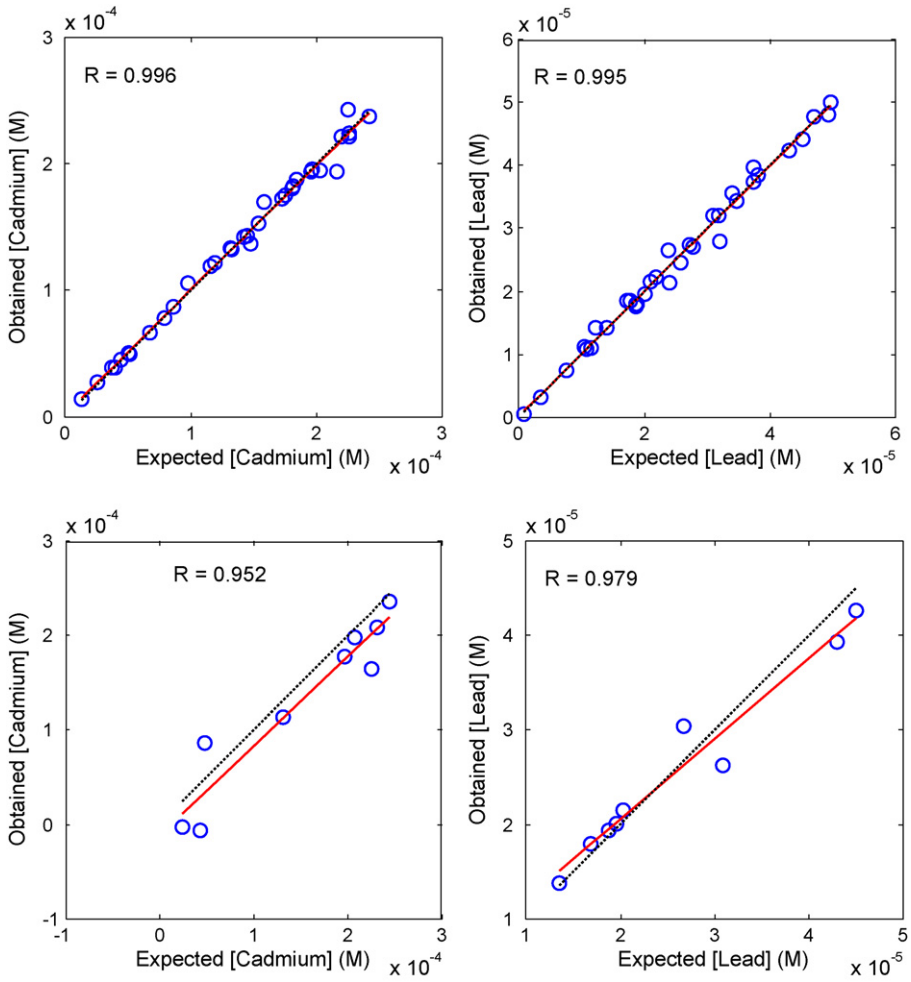

Fig. 8. Comparison of obtained vs. expected concentration for cadmium (left) and lead (right) using the recordings from the Pb-ISE. Dashed line corresponds to ideality and solid line corresponds to the obtained fit. Plots in the upper row are the results for training, plots in the lower row are the results for testing.

Table 3
Mean values for the SSE and correlation coefficient (R) obtained with the cross validation process using the Cd-ISE. Uncertainty intervals calculated at 95% confidence level.

Analyte	Training		Testing	
	SSE ($mol^2\ l^{-2}$)	R	SSE ($mol^2\ l^{-2}$)	R
Cd^{2+}	$0.0980 \pm 3 \times 10^{-4}$	$0.996 \pm 9.9 \times 10^{-4}$	0.544 ± 0.062	0.917 ± 0.019
Pb^{2+}	$0.0977 \pm 5 \times 10^{-4}$	$0.995 \pm 1 \times 10^{-4}$	0.715 ± 0.044	0.844 ± 0.029

Table 4

Analyte	Training		Testing	
	SSE ($mol^2\ l^{-2}$)	R	SSE ($mol^2\ l^{-2}$)	R
Cd^{2+}	$0.0978 \pm 5 \times 10^{-4}$	$0.996 \pm 3 \times 10^{-4}$	0.725 ± 0.049	0.926 ± 0.004
Pb^{2+}	$0.0976 \pm 4 \times 10^{-4}$	$0.995 \pm 1 \times 10^{-4}$	0.259 ± 0.029	0.934 ± 0.031

4. Conclusions

The present work shows a procedure for simultaneous quantitative determination of a binary mixture using the transient recording from a single electrode. The procedure was carried out twice with sensors of different nature to demonstrate its applicability. Our approach takes advantage of the kinetic information of the interference produced on a sensor to develop the calibration models; in the study, any of the Cd^{2+} or Pb^{2+} electrode could be used to resolve a binary mixture of the two heavy metals.

The calibration model is built by first extracting significant features employing the DWT, then evaluating the information obtained after wavelet transformation for getting a good compression/reconstruction relationship, and finally building the calibration model with an ANN. The DWT processing of the recordings has permitted the reduction of the acquired data from each electrode in a factor ca. 26. The aim of the developed application is to improve performance of existing electronic tongue systems, which may be employing signals from fewer sensors but exploiting their dynamic resolution.

3-Hydroxybutyrate dehydrogenase

ABSTRACT

A new kinetic method is proposed for the simultaneous determination of 3-hydroxybutyrate (3HB) and 3-hydroxyvalerate (3HV) based on the different rate of the 3-hydroxybutyrate dehydrogenase-catalysed reactions of these compounds with coenzyme NAD^+. A flow injection system with two reactors of immobilised 3-hydroxybutyrate dehydrogenase and dual detection is used. The concentrations of NADH produced after two different reaction times are measured by fluorometry or spectrophotometry and multivariate linear calibration is applied for quantification. Concentrations of 3HB and 3HV between 1×10^{-6} and 1×10^{-4} M can be determined at an average sampling frequency of 20 h^{-1}. In contrast to usual methods, the proposed here makes possible the discrimination of 3HB and 3HV without previous separation so that usual extraction with chlorinated solvents and/or chromatographic separation is not required. The method is of interest in a wide variety of fields concerning PHAs, as it can provide information on the degradation rate and mechanism, composition and structure of these polymers. Its applicability has been proved through the determination of 3HB and 3HV in the digests of some chemically degraded commercial PHAs.

1. Introduction

Polyhydroxyalkanoates (PHAs) [1,2] are a large group of natural polymers that are synthesized by numerous bacteria under unfavourable growth conditions. Tailor-made PHAs, with controlled composition, structure and properties, are industrially produced with genetically modified bacteria. PHAs have thermoplastics properties but unlike synthetic plastics, they are biodegradable and biocompatible. Most current applications of PHAs are based on these features and are effected in the environmental and medical fields [3,4]. PHAs are ecological plastics that are used in packaging and coating as substitutes for non-biodegradable petrochemical polymers. Their main medical applications are the fabrication of biodegradable body implants and the control of drug delivery, this being used also in pharmacy, agriculture and veterinary. Moreover, the degradation of PHAs is a source of optically active monomers of hydroxyalkanoic acids [5] that can be used to synthesize chiral compounds such as aminoacids, vitamins, antibiotics, pheromones, perfumes or biodegradable solvents. PHAs can be degraded by enzymes (biodegradation) but also by chemical or thermal processes. From an applicative point of view, the degradation kinetics is essential since the degradation rate or the resultant products can determine the potential applications. Chemical hydrolysis is also a crucial stage of methods for indirect analysis of PHAs.

Although more than 150 different monomers of hydroxyalkanoic acids can be combined to give PHAs, only very few of them are actually used. The commonest PHA is poly(3-hydroxybutyrate) (PHB), a homopolymer of (R)-3-hydroxybutyric acid (3HB). The high cost and some disadvantages of PHB have lead to the production of copolymers of 3HB and other hydroxyalkanoic acids. The most widespread commercial products are the copolymers of 3HB and (R)-3-hydroxyvaleric acid (3HV) with variable properties depending on the percentage of poly(3-hydroxyvalerate) (PHV). Experimental products include also blends of PHAs (homopolymers, copolymers or both) and blends of PHAs with other biodegradable polymers. As PHB and PHV are by far the commonest components of PHAs, 3HB and/or 3HV are generally among the ultimate degradation products. The quantification of these monomers can provide information not only on the degradation rate and mechanism but also on the composition and structure of PHAs. Indirect quantification of PHB, PHV and their copolymers is commonly performed after alcoholysis with methanol, ethanol or propanol in sulphuric or hydrochloric acids. The polymers are quantitatively transformed into the esters of 3HB and/or 3HV which can be extracted with chloroform or other solvents and determined by gas chromatography with flame ionization (GC–FID) or mass spectrometry (GC–MS) detection [6,7]. In these methods, the recoveries of PHB and PHV are not complete, due to the partition of the esters between the aqueous and organic phases. Alternatively, the

doi:10.1016/j.talanta.2009.09.049

esters can be hydrolysed to their respective hydroxyacids which are then determined directly in aqueous solution by ion-exchange chromatography with conductivity detection [8]. In concentrated sulphuric acid, PHB is quantitatively converted into crotonic acid that can be analysed by HPLC with ultraviolet detection [9]; this is not applicable to PHV [10]. Alkaline hydrolysis of PHB gives a mixture of crotonic acid and 3HB while PHV is converted into 3HV; these products are then usually determined also by chromatographic methods [9,11]. Whatever the degradation process, the 3HB formed can be determined directly in aqueous solution by enzymatic analysis, this being a rapid alternative to chromatographic methods. Enzymatic determinations are based on the selective action of the enzyme (R)-3-hydroxybutyrate dehydrogenase (3-HBDH) which catalyses the oxidation of 3HB with NAD^+ to give acetoacetic acid and NADH. First described by Williamson et al. [12], this reaction is also the basis of a wide variety of methods for the determination of 3HB in biological samples such as blood, serum, urine or milk for clinical or veterinary purposes [12–16]. In its biopolymer applications, the NADH produced is measured directly by photometry at 340 nm [17] or after coupling with other enzymatic reactions using photometric [8] or amperometric detection [18]. The catalytic action of 3-HBDH is highly selective, but not specific for the R-isomer of 3HB. Although the S-isomer does not react, other (R)-3-hydroxyacids, such as (R)-3-hydroxyvaleric or (R)-3-hydroxyhexanoic acids, can also be transformed at slower rates [19]. The existing enzymatic methods are based on measurements under equilibrium conditions (i.e., when the enzymatic reaction is complete) and the quantification of 3HB is only possible if other interfering hydroxyacids are not present. An enzymatic method has been proposed [8] for the determination of the total sum of 3HB and 3HV although these compounds cannot be individually quantified.

In this article, an enzymatic method is described which makes possible the individual determination of 3HB and 3HV in mixtures of these compounds. It is based on the different rate of the about mentioned 3-HBDH-catalysed reactions:

$$3HB + NAD^+ \overset{3\text{-HBDH}}{\longleftrightarrow} \text{acetoacetate} + NADH^+ + H^+ \quad (1)$$

$$3HV + NAD^+ \overset{3\text{-HBDH}}{\longleftrightarrow} \text{3-ketovalerate} + NADH + H^+ \quad (2)$$

The total NADH produced is measured under two different kinetic conditions and the concentrations of 3HB and 3HV are calculated by mathematical computation using multivariate linear calibration. Highly reproducible measurements are achieved using flow injection analysis with immobilised 3-HBDH. The proposed procedure is applied to the determination of 3HB and 3HV in chemically degraded commercial PHAs.

2. Experimental

2.1. Apparatus and materials

A RF-10AXL fluorescence detector and a SPD 6AV UV–vis spectrophotometric detector were used. Both detectors were simultaneously connected to a SCL-10AVP System Controller and a computer with LC Solution software (all from Shimadzu, Madrid) for data acquisition. Reagents were propelled with a Minipuls 2-HP4 peristaltic pump (Gilson, Madrid) with calibrated vinyl pump tubes (0.60 $cm^3\ m^{-1}$). Samples and standards were injected with a V-1451 injection valve (Upchurch Scientific, Barcelona, Spain) electronically actuated and provided with loops of different volume; the sample loop was fed with another peristaltic pump. Flangeless fittings, unions and tees (Upchurch Scientific) and 0.5 mm i.d. PTFE tubing were used in the flow system. The working temperature was controlled with a Lauda E-103 circulation thermostat (Hucoa-Erlöss, Madrid). Statistica 6 software (StatSoft, Tulsa, USA) was used for statistical computation.

2.2. Reagents

The following chemicals were supplied by Sigma–Aldrich (Madrid): controlled-pore glass PG 240-120, pore size 240, mesh size 80–120; 3-aminopropyltriethoxysilane; glutaraldehyde, 50% (w/v), aqueous solution; (R)-(−)-3-hydroxybutyric acid, sodium salt; (R)-3-hydroxybutyrate dehydrogenase (E.C. 1.1.1.30); (−)-methyl (R)-3-hydroxyvalerate, >98%; crotonic acid (trans-2-butenoic acid), 98%; Trizma® hydrochloride (Tris(hydroxymethyl)aminomethane hydrochloride), reagent grade, >99%. Oxidized β-nicotinamide-adenine dinucleotide, NAD^+, free acid, grade I, 100%, was from Roche Diagnostics (Barcelona). All other chemicals were of analytical-reagent grade. Working solutions of 3-hydroxybutyrate were prepared from a stock solution (5.0×10^{-3} M) that was renewed daily. Stock solutions of 3-hydroxyvalerate (1.8×10^{-3} M) were freshly prepared by the hydrolysis of the methyl-ester in 0.05 M sodium hydroxide (30 min at room temperature).

2.3. Enzyme reactors

The enzyme 3-HBDH (100 U) was immobilised on controlled-pore glass (CPG, 0.1 g) by indirect covalent binding, as described earlier [20]. The immobilised enzyme was stored wet (in deoxygenated 0.1 M phosphate buffer, pH 6.0) and refrigerated (4 °C) in sealed bottles. Under such conditions, 3-HBDH was very stable: after more than 2 years, the stored immobilised enzyme showed about 55% of its initial activity (activities were compared under the proposed working conditions with newly made enzyme reactors). Enzyme reactors were made by packing the CPG-immobilised enzyme into PTFE tubes (1 mm i.d., 5–6 cm long) with 10 μm frits (Upchurch Scientific) at the ends. The reactors showed no measurable loss of activity after at least 150 injections under the proposed working conditions.

2.4. Samples and sample preparation

Three commercial PHAs were used (Goodfellow, Huntingdon, England). One of them (sample BP-1) was described as polyhydroxybutyrate/polyhydroxyvalerate 12%-biopolymer (PHB88/PHV12), granule, 10% plasticised pellets (citric ester). The second product (sample BP-2) was described as polyhydroxybutyrate-biopolymer (PHB) sheet, technical grade. The label of the third product (sample BP-3) described a polyhydroxybutyrate-biopolymer (PHB), non-woven fabric, research grade. Since the information given was ambiguous or incomplete, the samples were analysed by NMR to estimate their composition. The commercial products were dissolved in deuterated chloroform and their ^1H NMR spectra were registered in a Varian 200 VX spectrometer at 200 MHz. In sample BP-1, the molar ratio PHB:PHV was found to be 7.6:1 and the plasticiser was identified as tributyl O-acetylcitrate. The NMR analysis indicated that both BP-2 and BP-3 were in fact copolymers of 3HB and 3HV with an approximate molar ratio PHB:PHV of 4.2:1 and 4.1:1, respectively.

An adequate amount (20–40 mg) of commercial product was dissolved in 1 mL of chloroform in the 100 mL round bottom flask of a reflux setup. After chloroform was evaporated by heating at 40 °C, 4 mL of propanol and 1 mL of concentrated hydrochloric acid were added and reflux was applied for 3 h at 90 °C to perform propanolysis. After diluting and cooling with 80 mL of water, 4 mL of 5 M sodium hydroxide was added to hydrolyse the propyl esters. The mixture was left for 30 min at room temperature and then it was neutralized (pH 7) with hydrochloric acid and made up to 100 mL with water. The resultant sample solutions were analysed for 3HB and 3HV according to the proposed flow injection procedure.

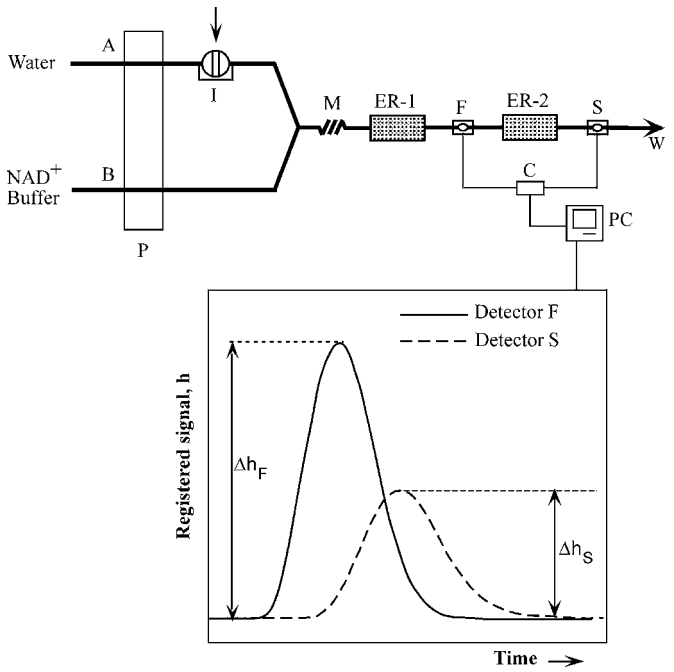

Fig. 1. Diagram of the flow injection system and registered signals. A and B = channels; P = peristaltic pump; I = injection valve; M = mixing coil; ER = enzyme reactors; F = fluorometer; S = spectrophotometer; W = waste; C = control module; PC = computer; Δh_F = fluorescence peak height; Δh_S = absorbance peak height.

2.5. Flow system

The working system is depicted in Fig. 1. It consisted of a flow injection manifold with two enzyme reactors (ER-1, ER-2) containing immobilised 3-HBDH, and two detectors, a fluorometer (F) and a spectrophotometer (S). Both detectors were set for the determination of NADH and were simultaneously connected to a multi-channel data acquisition system where a double real-time signal was registered. Solutions containing 3HB, 3HV or both were injected into a carrier stream (A), merged with the reagent (B, NAD^+ buffered solution) and reacted for two sequential periods as they passed through the enzyme reactors. Every injected solution gave a peak at each detector. The fluorescence peak height (Δh_F) was proportional to the concentration of NADH produced in the first enzyme reactor according to reactions (1) and/or (2). The absorbance peak height (Δh_S) was proportional to the total NADH accumulated after the second enzyme reactor (i.e., after the two reaction periods). With the proposed configuration, the lower sensitivity of the spectrophotometer in comparison with that of the fluorometer was partly compensated by the higher concentrations of NADH to be measured after the second enzyme reactor. The working temperature was controlled by keeping all the solutions (carrier, reagent and injected samples), the mixing coil (M), and the enzyme reactors at constant temperature by means of a circulation thermostat.

2.6. Experimental procedure

The working conditions for the flow system were first established. Some of them (flow rates, sample volume, size of the enzyme reactors and temperature) were fixed after preliminary experiments. The variables of the reagent solution (pH and concentration of NAD^+) were studied and set to get maximum signals. Under the proposed conditions, standard samples containing 3HB, 3HV or both were used to establish the calibration equations for the independent or simultaneous determination of these compounds. Quantifications were based on Δh_F, on Δh_S or on both. The proposed procedure was applied to the determination of 3HB and 3HV in the digests of chemically degraded commercial PHAs.

3. Results and discussion

3.1. Effect of variables

The variables studied and their experimental ranges are summarized in Table 1. The size of the enzyme reactors, the flow rates and the injected sample volume were fixed after preliminary experiments. In the proposed flow system, the registered signals increased on increasing the reaction periods, these being determined by the size of the enzyme reactors and the flow rate through them. Short enzyme reactors were observed to give poor signals unless slow flow rates were used, this giving low sampling frequencies. On the other side, long reactors gave better sensitivity and sampling frequency at moderate flow rates but they produced leaks and became finally obstructed. Predictably, for fixed flow rate and reactors, higher signals but lower sampling frequencies were obtained on increasing the sample volume. The proposed reactors, flow rate and sample volume provided acceptable signals and sampling frequency without flow drawbacks. These conditions can obviously be modified depending on the analytical requirements.

Also predictably, higher fluorescence and absorbance signals were obtained on increasing the working temperature as a result of the increased enzyme activity. However, the rising of temperature produced also less and less reproducible fluorescence peaks. This effect, that was not significant for the absorbance signals, was probably due to the temperature-dependence of the fluorescence of NADH [21] since the flow cell at the fluorometer was not thermostatable. To minimize this effect, a working temperature close to that of the laboratory was proposed.

Once the above mentioned variables were fixed, the influence of pH on the catalytic activity of 3-HBDH for reactions (1) and (2) was first considered. The pH of the reagent solution (1.5×10^{-3} M NAD^+, 0.10 M Trizma®) was varied in the 7.0–9.0 range and 5.0×10^{-5} M solutions of 3HB or 3HV were injected for each pH value. The peak heights obtained at the fluorescence detector are compared in Fig. 2 (a similar graph was obtained from the spectrophotometric detector). The pH profiles indicate that the maximum catalytic activity of 3-HBDH took place at pH close to 8.3 for both 3HB and 3HV. The profiles also indicate that, as expected, 3HV was transformed at lower rate than 3HB.

Table 1
Experimental variables fixed or investigated.

Variable	Experimental range	Fixed/proposed value
Fluorometric detection		
Excitation wavelength		340 nm
Emission wavelength		460 nm
Spectrophotometric detection		340 nm
Flow rates (mL min^{-1})		
A and B	0.10–0.75	0.20
Reactor size (cm)		
M		125
ER-1	1–10	5
ER-2	1–10	6
Sample volume (μL)	35–250	115
Temperature (°C)	20–40	25
pH	7.0–9.0	8.3
NAD^+ (M)	1.5×10^{-4} to 5.0×10^{-3}	1.5×10^{-3}

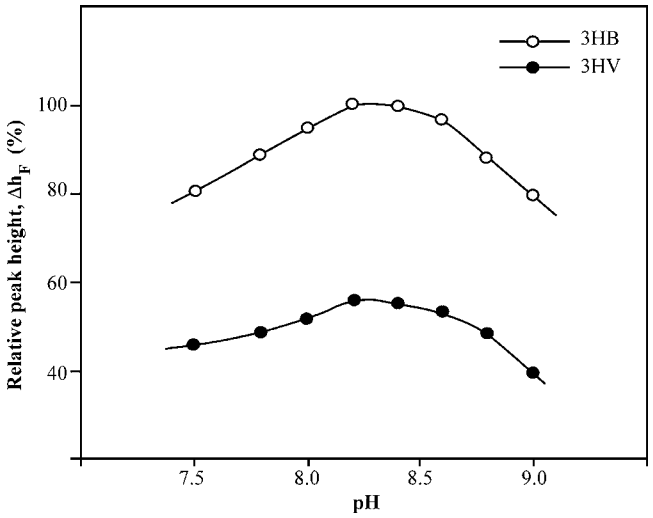

Fig. 2. Effect of pH on the catalytic activity of 3-HBDH. Fluorescence signals for 5.0×10^{-5} M 3HB and 3HV at different pHs.

The concentration of NAD^+ in the reagent solution (0.10 M Trizma®, pH 8.3) varied between 1.5×10^{-4} and 5.0×10^{-3} M. The heights of the peaks registered for both 3HB and 3HV were observed to increase gradually with increasing the concentration of NAD^+, this effect being less pronounced for concentrations higher than 1.5×10^{-3} M. This value was chosen for all subsequent experiments as it provided reduced NAD^+ consumption without a significant loss of sensitivity.

3.2. Quantification of 3HB and 3HV

The calibration equations for these compounds in aqueous solution are summarized in Table 2. For samples containing only 3HB or 3HV, both Δh_F and Δh_S were linearly related with the concentrations of 3HB or 3HV injected. The slope values of equations in Table 2 indicate that the detection of 3HV was less sensitive than that of 3HB, this being an expected result because of the lower reaction rate of 3HV. The calculated limits of detection were in the range from 2×10^{-8} to 5×10^{-8} M (the limits of detection were calculated from the expression LOD = $3\sigma_B/b$, where σ_B was the standard deviation ($n = 10$) of the blank peak height that was obtained when water was injected, and b was the slope of the proposed equation). Relative standard deviations ($n = 10$) between 0.8% and 1.5% were found for the peak heights of samples 1.0×10^{-5} M. The average sampling frequency was 20 h^{-1}.

For samples containing both 3HB and 3HV, the peak heights Δh_F and Δh_S were predicted by multiple linear regression, this being only valid when the total concentration of 3HB + 3HV was below 1×10^{-4} M, approximately. The partial regression coefficients of the multilinear equations (Table 2) were coincident with the individual coefficients found for samples of only 3HB or 3HV. This indicated that the signals of 3HB and 3HV were additive so that the fluorometric or spectrophotometric signals of any mixture of 3HB and 3HV could be calculated by the addition of the signals given by the equivalent individual samples containing only 3HB or 3HV. Apart from not being predictable by multiple linear regression, negative deviations from the additivity were observed for the signals of mixtures with concentrations of 3HB + 3HV higher than 1×10^{-4} M, particularly when the 3HB:3HV molar ratio was close to unity. This suggested some kind of interaction between 3HB and 3HV, probably due to the competition of both substrates for the catalytic site on the immobilised enzyme.

4. Application to PHAs

The above proposed procedure was applied to the determination of 3HB and 3HV in solutions produced by propanolic digestion of commercial PHAs. Propanolysis can convert PHB/PHV stoichiometrically into the propyl esters of 3HB/3HV [6,7] although the degradation kinetics and products may depend on the composition and crystallinity of the polymer or just on the applied degradation conditions (digestion time, temperature, etc.) [8,9].

The possible interferences of citrate and crotonic acid were considered. Citrate was a component of sample BP-1 while crotonic acid is usually produced in chemical degradations of PHB. The injection of solutions up to 1.5×10^{-4} M citrate or crotonic acid gave no measurable peaks, so the interference of these compounds by their contribution to the measured signals was discarded. Their possible interference by reaction with 3HB or 3HV was also investigated. To this end, freshly prepared 2.0×10^{-5} M solutions of 3HB or 3HV with or without 1.5×10^{-4} M citrate or crotonic acid at pH 8.3 were left for 1 h at room temperature and then analysed according to the proposed procedure. As no significant

[b] Mean values of three determinations with 95% confidence limits.

differences were observed between the signals of samples with and without citrate or crotonic acid, the possible interference of these compounds by interaction with 3HB or 3HV was also discarded.

Since the degradation was not certain to yield stoichiometric amounts of 3HB and 3HV, standard addition experiments were performed to validate the procedure. To this end, adequate volumes of sample and standard solutions were mixed, properly diluted with water and finally injected into the flow system. Results are summarized in Table 3. All the concentration values in this table refer to the injected solutions. The estimated concentrations were calculated from the initial NMR analysis supposing full conversion of PHB/PHV into 3HB/3HV. The comparison of the concentrations found with the estimated values indicates that the conversion of PHV into 3HV was seemingly complete in all the samples while that of PHB into 3HB was quantitative only in sample BP-1. The different degradation of samples was undoubtedly due to their different composition and structure; in comparison with BP-1, for example, BP-2 and BP-3 were not-plasticised polymers with higher proportion of PHV.

Whatever the conversion degree or the degradation kinetics, the concentrations of 3HB and 3HV found in all the experiments were in agreement with the effected standard additions. Results therefore indicate that the proposed procedure was adequate to discriminate the concentrations of 3HB and 3HV produced in the degradation of the commercial PHAs.

5. Conclusions

The described enzymatic method makes possible the direct determination and discrimination of 3HB and 3HV. In contrast to the methods commonly used for these compounds, previous separation by extraction with chlorinated solvents and/or chromatography is not required. The method is of interest in a wide variety of fields concerning PHAs, as it can provide information on the degradation rate and mechanism, composition and structure of these polymers. Its applicability has been proved through the determination of 3HB and 3HV in the digests of some chemically degraded commercial PHAs.

ABSTRACT

Arsenic compounds were quantified in the certified reference material MURST-ISS-A2 (Antarctic krill) using HPLC/ICPMS. The data should prove useful for assessing the accuracy of arsenic speciation procedures.

1. Introduction

With an estimated biomass of 120–700 million tons, the planktonic crustacean *Euphausia superba* (Antarctic krill) is probably the most abundant animal species on the planet and the keystone organism in the Antarctic marine ecosystem [1]. Swimming in large groups over long distances, the Antarctic krill feeds on phytoplankton floating in the Southern Ocean and represents the primary food source for whales, seals, cephalopods, penguins and seabirds. Antarctic krill also has economic importance through its use as a human and animal food. In addition, it has been used in ecological studies as a biomonitor of Antarctic ecosystems [2]. For these reasons, a certified reference material (MURST-ISS-A2) based on this matrix was produced [3] and it is currently available on request from the Antarctic Environmental Specimen Bank (www.bcaa.unige.it).

Our ongoing investigation on the occurrence of arsenic compounds in Antarctic marine biota has produced a need for a relevant certified reference material. As a first step to achieving this goal, we present arsenic speciation data for the reference material MURST-ISS-A2 (Antarctic krill).

2. Experimental

2.1. Samples

The certified reference material MURST-ISS-A2 [3] was produced in the frame of the Italian National Programme for Research in Antarctica, under the coordination of the Istituto Superiore di Sanità (ISS), Rome, Italy, and of the Institute for Reference Materials and Measurements of the Joint Research Centre, European Commission (EC-JRCIRMM), Geel, Belgium. This material is certified for a number of trace elements (total concentration only) including arsenic. In this study, three 500-mg batches were considered, each of which was split into four parts (*ca* 100 mg weighed with a precision of ±0.1 mg).

2.2. Reagents and standards

Standard solutions containing 1000 mg As l^{-1} of each of the following compounds were prepared in Milli-Q water (Millipore, El Paso, TX, USA): arsenate as $Na_2HAsO_4{\cdot}7H_2O$ (Merck, Darmstadt, Germany); arsenite as $NaAsO_2$ (Merck), dimethylarsinate as $C_2H_6AsNaO_2{\cdot}3H_2O$ (Sigma–Aldrich, St. Louis, MO, USA) and methylarsonate as $Na_2CH_3AsO_3{\cdot}6H_2O$ (Chem Service, West Chester, PA, USA). Arsenobetaine standard solution (BCR626 certified reference material) was purchased from Sigma–Aldrich. Arsenocholine [4] trimethylarsoniopropionate [5], trimethylarsine oxide [6], oxo-arsenosugar-glycerol [7], oxo-arsenosugar-sulfate

[8] and oxo-arsenosugar-sulfonate [8] were synthesised as previously reported. Oxo-arsenosugar-phosphate was isolated from natural sources [9]. Thio-arsenosugar-glycerol was prepared in house in Graz by blowing H_2S over the surface of a solution of oxo-arsenosugar-glycerol for a few seconds. The vial was closed and shaken, and the surplus H_2S was removed by purging with argon. Formic acid (p.a.) was obtained from Sigma–Aldrich. Methanol (p.a.), ammonium dihydrogen phosphate (p.a.), pyridine (p.a.), aqueous ammonia solution (25%, Suprapur), hydrogen peroxide (30%, Suprapur), hydrochloric acid (37%, Suprapur), and nitric acid (60%, Suprapur) were purchased from Merck. Ammonium formate (p.a.) was purchased from Fluka (Buchs, Switzerland).

The certified reference material DORM-2 was purchased from the National Research Council Canada (Ontario, Canada), and the reference algal sample was from a batch of *Fucus serratus* (brown alga) extracts as described by Madsen et al. [10].

2.3. Determination of total arsenic

The total arsenic concentration in the reference material was determined by microwave-assisted acid dissolution and ICP-AES analysis, according to a procedure previously reported [11]. The found concentration was $5.29 \pm 0.44\ \mu g\ g^{-1}$ (mean ± SD, $n = 3$), in agreement with the certified value $5.02 \pm 0.44\ \mu g\ g^{-1}$ (mean ± SD). The total arsenic concentration in each extract was determined by ICPMS after microwave-assisted acid dissolution with nitric acid.

2.4. Determination of arsenic species

Each sub-sample (*ca* 100 mg weighed with a precision of ±0.1 mg) was weighed directly into a 15-ml polypropylene tube and methanol/water (4.90 g, 1 + 4, w/w) was added. The mixture was shaken top over bottom at ambient temperature overnight, then centrifuged (4500 rpm × 15 min) and filtered through a 0.45 μm hydrophilic PVDF filter (Millipore, El Paso, TX, USA). Arsenic speciation analyses were performed by HPLC/ICPMS on the extracts. Chromatographic conditions are summarized in Table 1. Two instrumental systems were employed: (a) Perkin Elmer-Sciex (Concord, Ontario, Canada) Series 200 HPLC coupled to a Perkin Elmer-Sciex Elan DRC II ICPMS, via a pneumatic nebulizer/cyclonic spray chamber; (b) Agilent (Waldbronn, Germany) 1100 Series HPLC system coupled to an Agilent 7500ce ICPMS via an Ari Mist HP nebulizer (Burgener Research International, Berkshire, England)/Scott double pass spray chamber. The ion intensities at m/z 75 (^{75}As) and m/z 77 ($^{40}Ar^{37}Cl$) were monitored with the time resolved analysis software.

Structures of the investigated arsenic compounds are shown in Fig. 1. Arsenic species in sample solutions were identified by retention time matching and, on occasions, by co-chromatography; they were quantified by external calibration against the standard arsenical prepared in methanol/water (1 + 4, w/w). The anionic arsenic species were quantified by calibration against arsenate, arsenite, methylarsonate and dimethylarsinate standards chromatographed under identical conditions. The responses for the four arsenic species were the same (within 5%) and the mean of the slopes was hence used. The accuracy of HPLC/ICPMS quantification was checked by the analysis of arsenic species in DORM-2 and in the reference algal extract reported by Madsen et al. [10]. For DORM-2 ($n = 3$) we obtained $16.0 \pm 0.5\ \mu g\ As\ g^{-1}$ for arsenobetaine and $0.260 \pm 0.005\ \mu g\ As\ g^{-1}$ for tetramethylarsonium ion (certified values are $16.4 \pm 1.1\ \mu g\ As\ g^{-1}$ and $0.248 \pm 0.054\ \mu g\ As\ g^{-1}$, respectively). Because DORM-2 is certified only for arsenobetaine and tetramethylarsonium ion, we also checked our method for arsenosugars and DMA using the *Fucus* extract that has been fully characterized by HPLC/ICPMS and HPLC/electrospray MS [10]. Measured oxo-arsenosugar-phosphate, oxo-arsenosugar-glycerol and dimethylarsinate amounts were 0.090, 0.095 and 0.004 μg As, respectively, in good agreement with the reported values (0.086 μg As ±2.9%, 0.10 μg As ±3.6% and 0.005 μg As ±20%, respectively).

3. Results and discussion

The total extracted arsenic was $3.6 \pm 0.1\ \mu g\ g^{-1}$ ($n = 4$) corresponding to an extraction efficiency of 71%. Anion-exchange HPLC/ICPMS showed the presence of dimethylarsinate, oxo-arsenosugar-phosphate, arsenate, and oxo-arsenosugar-sulfate; a large quantity of arsenic, presumably present as cationic species, eluted at the void volume (Fig. 2). Cation-exchange chromatography (Fig. 3) demonstrated the presence of significant cationic arsenicals, namely arsenobetaine, oxo-arsenosugar-glycerol and trimethylarsoniopropionate (dimethylarsinate also runs as a cation under these conditions since the arsinoyl group protonates at the low pH employed).

The concentrations of the quantified arsenic species are reported in Table 2. In order to improve the confidence in the analytical results, the samples were analysed in two laboratories using different instrumental systems (see Section 2 for details). An excellent agreement between the results may be observed. The sum of the quantified species corresponded to about 95% of the total extracted arsenic. The variability of the main arsenic species within each batch was also considered. RSD% values ranged from 1–5% for arsenobetaine, trimethylarsoniopropionate and oxo-arsenosugar-phosphate to 10–15% for dimethylarsinate and oxo-arsenosugar-glycerol.

From Table 2, it can be seen that arsenobetaine was the major arsenical in the Antarctic krill sample, with a concentration of $1.9\ \mu g\ g^{-1}$, corresponding to about 45% of the extracted arsenic. Dimethylarsinate and trimethylarsoniopropionate were present as minor but significant constituents (about 5% and 10% of the total extractable arsenic, respectively), as well as oxo-arsenosugars (about 20%). The other investigated species were either below the limit of detection (about $0.02\ \mu g\ As\ g^{-1}$ dry mass) or, when detectable, they contributed less than 1% of the total extracted arsenic.

The presence of arsenobetaine as the dominant species in crustacean is well documented [12–16] as well as the occurrence of

dimethylarsinate [15] and arsenosugars [13,14]. It has been suggested [13] that the arsenic speciation in marine zooplankton could depend on their feeding habits. Higher arsenobetaine concentrations have been reported for carnivorous species compared with herbivorous ones, and the opposite trend has been observed for the arsenosugars [13]. The Antarctic krill is predominantly herbivorous, feeding directly on phytoplankton and ice-algae, although filtering of other particles, such as eggs, larvae, fecal pellets and small zooplankton cannot be excluded. Hence, it is not surprising that this organism contained significant amounts of both arsenobetaine and arsenosugars. The occurrence of trimethylarsoniopropionate as a minor constituent could be linked to the biosynthesis of arsenobetaine, as proposed for aliphatic dimethylarsinoyl compounds [17].

In conclusion, the arsenic speciation data obtained for the certified reference material MURST-ISS-A2 (Antarctic krill) appear to be

ABSTRACT

Multidimensional analysis of instant coffee and barley beverage samples using size exclusion chromatography (SEC) combined with a dynamic surface tension detector (DSTD) and a UV–vis absorbance detector (UV) is reported. A unique finding of this study was the action of the tetrabutylammonium (TBA) cation as a modifying agent (with bromide as the counter anion) that substantially increased the surface pressure signal and sensitivity of many of the proteins in the chromatographically separated samples. The tetrabutylammonium bromide (TBAB) enhancement of the surface pressure signal was further investigated by studying the response of 12 commercial standard proteins (α-lactalbumin, β-lactoglobulin, human serum albumin (HSA), albumin from chicken egg white (OVA), bovine serum albumin (BSA), hemoglobin, α-chymotrypsinogen A, cytochrome *C*, myoglobin, RNase A, carbonic anhydrase, and lysozyme) in buffer performed using flow injection analysis (FIA) coupled with the DSTD with and without various concentrations of TBAB. The FIA-DSTD data show that 1 mM TBAB enhances sensitivity of HSA detection, by lowering the limit of detection (LOD) from 2 mg/mL to 0.1 mg/mL. Similarly, the LOD for BSA was reduced from 1 mg/mL to 0.2 mg/mL. These FIA-DSTD experiments allowed the detection conditions to be optimized for further SEC-UV/DSTD experiments. Thus, the SEC-UV/DSTD system has been optimized and successfully applied to the selective analysis of surface-active protein fractions in a commercial instant coffee sample and in a soluble barley sample. The complementary selectivity of using the DSTD relative to an absorbance detector is also demonstrated.

1. Introduction

The direct measurement of surface tension is of interest in the investigation of molecular interactions at the air–liquid interface, the study of thermodynamic kinetics of protein denaturation at the air–liquid interface, and in determining foaming capabilities of foods and beverages. Proteins play a key role in the stabilization of foams, emulsions, and composite systems in food products and in cosmetics [1–7]. The creation of emulsions and foams in food products represent dynamic processes and the dynamic surface-active properties of protein solutions are considered to play an important role in the formation and stabilization of these systems [6,8,9].

Traditional methods of quantifying surface tension are based on optical observations of drop growth, optical imaging, tensiometry, and manual observations of foam performance [10–12]. Most of these techniques are restricted to static measurements and cannot assess the dynamic nature of foams and emulsions. Additionally there may be other limitations of these methods such as protein adsorption [13] or lack of compatibility with flow injection analysis (FIA) or liquid chromatographic systems [14].

The limitations of previous methods have led to the development of a versatile technique to assess the dynamic surface pressure of flowing liquids. The dynamic surface tension detector (DSTD) is a high-throughput automated chemical analyzer capable of quantifying the surface tension of a complex sample [13–17]. The surface-tension-lowering response observed by the DSTD is converted to a quantity known as the surface pressure. The DSTD provides real-time surface pressure data for surface-active sample

compounds as they migrate to the surface of the drop or as macromolecules such as proteins denature and interact at the air–liquid interface of every drop of sample as it elutes, forms, and is detached. The DSTD is described in more detail and the procedure for calibrating the DSTD with aqueous standard when the sample mobile phase is different is described in Refs. [17–19].

Coffee is a popular beverage worldwide and the surface properties of coffee beverages are of interest to food chemists. The foam present on the top of a cup of coffee (crema) is important for trapping volatilized aromas and improving coffee quality. Researchers have studied the influence of polysaccharide composition on foam stability of espresso coffees by timing how long it takes for the foam layer to disappear during cooling [20]. Another report indicates that this "crema" is important because it is quantitatively related to surface tension phenomena [21]. Instrumental methods have also been used to study how coffee brewing affects foam formation and stabilization [12,21]. Polysaccharides, proteins and melanoidins have been shown to influence foaming capability and foam stability of the beverages [20,21]. Coffee quality and aroma have been shown to be related to foam and viscosity levels, and associated with the presence of oligosaccharides and polysaccharides [21]. In addition to affecting coffee beverage quality, the carbohydrates have also been shown to possess various biological and antibacterial activities [22].

In this report, FIA is coupled to DSTD to provide a means of quickly and accurately investigating the total real-time surface activity of water soluble coffee samples. Additionally, liquid chromatography (LC) is coupled to a UV/Vis absorbance detector and a DSTD to evaluate the surface activity associated with compounds in soluble coffee samples. Since polysaccharides and proteins are important compounds involved in the foaming capability and foam stability of the beverages [20], size exclusion chromatography (SEC) is used to separate these two classes of compounds.

In previous work, we employed denaturing agents in a post-column derivatization SEC-DSTD system in order to increase surface activity of proteins and enhance their DSTD signal [14]. The use of denaturants as post-column modifiers was preferred to the addition of denaturing agents in the mobile phase of SEC because denatured proteins may have a different elution pattern in SEC than the native proteins.

The report herein describes the first use of tetrabutylammonium bromide (TBAB) to increase surface activity of proteins from coffee beverages analyzed by FIA-DSTD and SEC-UV/DSTD. Previous literature reports related to the effect of tetrabutylammonium (TBA) salts on protein conformation [23–25] do not address its effect on protein surface activity. Jain and Ahluwalia reported that tetrabutylammonium (TBA) at a concentration less than or equal to 0.25 M destabilize lysozyme to a greater degree than urea and that polyols are not sufficient to counteract the destabilization effect of TBA [25]. They also found that the destabilization effect increases with increasing concentration and increasing alkyl chain length. This effect was attributed to the hydrophobic interactions between the tail of TBA and the hydrophobic regions of the protein. We also observed that TBA is an enhancer of the surface activity of surfactants like sodium dodecyl sulfate, and of ions like Cr(III), presumably because the tetrabutylammonium cation acts as a counter ion in the formation of ion pairs [26]. In this report, TBAB at concentrations less than or equal to 5 mM were employed both for the solubilization of standard proteins and raw soluble coffee samples and in the mobile phase buffers of SEC separations. The SEC-UV/DSTD configuration provides additional analyte selectivity over traditional detection methods such as absorbance detection, and enables the analyst to obtain analyte-specific information, with potential use in formulation science and quality control applications.

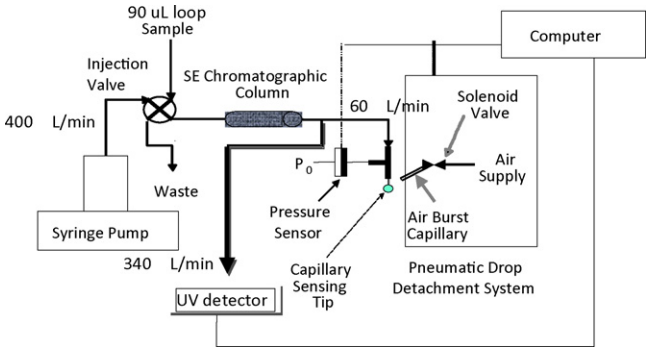

Fig. 1. SEC-DSTD instrument configuration. The flow splitter delivers 60 μL/min to the DSTD and 340 μL/min to the diode array UV–vis absorbance detector (abbreviated as UV in text). The differential pressure, $P(t)$, across the liquid–air interface of each eluting drop, is measured with respect to the atmospheric pressure, P_0 by a pressure transducer on a side arm of the DSTD capillary sensor tip. A small capillary directs a short burst of air regulated to 25 psi at a 45° angle via a computer-controlled solenoid valve and pneumatically detaches the eluent from the sensor tip.

2. Materials and methods

Carbonic anhydrase from bovine erythrocytes (CA, 21803) was purchased from Fluka (Buchs, Switzerland); bovine serum albumin (BSA, A-0281), albumin from chicken egg white (OVA, A-5503), human serum albumin (HSA, A-1887), β-lactoglobulin (β-LG, L-3908) and α-lactalbumin from bovine milk (α-Lac, L-6010), myoglobin from equine skeletal muscle (Myo, M-0630), α-chymotrypsinogen A from bovine pancreas (α-Chy, C-4879), lysozyme from chicken egg white (Lys, L-6876), human hemoglobin (Hb, H-7379), cytochrome *C* from equine heart (CytC, C-7752) and ribonuclease A from bovine pancreas (RNase A, R5125) were purchased from Sigma, Chemical Co. (St. Louis, MO, USA). The buffer solutions were prepared from monobasic monohydrate sodium phosphate, dibasic anhydrous potassium phosphate (BDH Laboratory Supplies, Poole, England), and TBAB (Sigma Chemical Co., P.O. 14508, St. Louis, MO 63178, USA). The phosphate buffer solution (PBS) contained 0.1 M phosphate at a pH of 6.8 or 7.8 as specified. Water deionized with a Milli-Q system (Millipore, 80 Ashby Road, Bedford, MA 01730-2271, USA) was used throughout and degassed prior to use. A Biosep SEC S2000 HPLC column (Phenomenex, Chemtek, Bologna, Italy), with dimensions of 300 mm long by 7.8 mm inside diameter was used for all the SEC experiments with calculated ~5 mL void volume.

Protein solutions were prepared by dissolving lyophilized powder in PBS at the concentration indicated. TBAB-modified protein working solutions were prepared freshly by dissolving protein lyophilized powder in PBS, containing TBAB at the indicated concentration. Samples were injected less than 10 min after preparation, in order to not show significant variation at the DSTD and UV absorbance detector during the working day. The proteins were α-lactalbumin, β-lactoglobulin, HSA, OVA, BSA, hemoglobin, α-chymotrypsinogen A, cytochrome *C*, myoglobin, RNase A, carbonic anhydrase, and lysozyme. Commercial samples of instant coffees (Nescafe and Nescafe Classic from Nestle), soluble barley beverage (Crastan), and milk powder (Kroger) were purchased at the grocery store and were prepared for analysis by dissolving a weighed portion in PBS or PBS/TBAB, and filtering using 0.22 μm Millipore syringe filters, followed by SEC-UV/DSTD analysis.

A detailed schematic of the DSTD configuration with pneumatic detachment is shown in Fig. 1. A narrow bore HPLC gradient pump (P2000, ThermoQuest) equipped with a mechanical degassing system (SC1000, ThermoQuest) was connected to a diode array UV–vis absorbance detector (UV6000, ThermoQuest). A total flow of 0.4 mL/min was split in order to provide 340 μL/min to the UV

detector and 60 μL/min to the DSTD. Samples were introduced via a ten-port injection valve (Rheodyne PR700-102-1, Cotati, CA). A poly(etheretherketone) (PEEK) injection loop of 100 μL of tubing (Upchurch, Oak Harbor, WA) was used for all experiments. The pneumatic detachment apparatus for the DSTD, shown in Fig. 1, consists of a small capillary directing a repeated short burst of in-house air at 45° angle to the capillary sensing tip via a computer-controlled solenoid valve to detach drops from the sensor tip capillary at controlled time intervals. Pneumatic detachment was performed every 2 s, corresponding to 2 μL drops at 60 μL/min, using a solenoid valve (MBD002, Skinner Valve, New Britain, CT, USA). The pressure sensor (Validyne P305D-20-2369, Northridge, CA) was configured with a sensing membrane (Validyne diaphragm 3-36, Northridge, CA) that was optimized for the response time of the DSTD measurements of interfacial kinetics. The sensor capillary tip was made from a short piece of PEEK tubing, 457 μm ID and 635 μm OD. All data were collected at 20 kHz with a personal computer (Intel Centrino® Duo, Intel Corporation, Santa Clara, CA) equipped with a data acquisition card (AT-MIO-16XE-50, National Instruments, Austin, TX). The data were averaged to 50 points/s and collected using LABVIEW (Version 6, National Instruments, Austin, TX) with programs written in-house. Subsequent data analysis was performed using MATLAB 7.0 (MathWorks, Natick, MA). UV–vis absorbance measurements were performed using a Beckman DU-600 spectrophotometer.

Typical raw pressure data from the DSTD have been reported in detail previously [13–15,17]. Four drop profiles are necessary in the dual-mobile phase calibration to obtain the dynamic surface pressure of a protein sample in TBAB: the drop profile of TBAB in 0.1 M phosphate buffer; the drop profile of sample in TBAB with phosphate buffer; the drop profiles of water; the drop profile of the standard 5% acetic acid in water. The four drop profiles and the surface pressure of the 5% acetic acid standard in water (10.3 dyn/cm) were applied yielding the Π value. Additionally, the Π_{mean} value is defined as the surface pressure signal averaged over the last 0.2 s at the end of the 2 s drop.

In all SEC-UV/DSTD experiments, 1 mM TBAB was kept constant in the mobile phase in order to increase the surface pressure signal of protein samples. The elution conditions were the following: 30 min isocratic elution in PBS, 1 mM TBAB at 20 ± 1 °C with a flow rate of 0.4 mL/min in the column. The mobile phase was filtered by a 0.45 μm cellulose acetate filter (Millipore) and degassed (for 10 min) before using.

3. Results and discussion

3.1. FIA-DSTD analysis of standard protein solutions and instant coffee samples: effect of TBAB

It is well known that proteins differ significantly in their surface activity due to differences in structural properties (size, shape, and charge distribution), stability and flexibility [4,27]. It has also been shown that the surface activity of proteins varies with changes in these properties [27–29]. Typically, surface activity increases as the hydrophobic character of the protein is exposed upon denaturation [14,15]. On this basis, we investigated the effect of sub-denaturant concentrations of TBAB on protein surface tension with the aim of employing TBAB as an additive in the mobile phase of SEC to increase DSTD signal of proteins, without inducing protein denaturation. Experiments were initially performed using the FIA-DSTD system to investigate the surface activity of 12 commercial standard proteins at various concentrations of TBAB.

Fig. 2A shows the surface pressure data (Π_{mean}) of a representative protein, β-lactoglobulin (500 mg/L) as a function of the TBAB concentration in 0.1 M PBS (panel A). Concentrations of

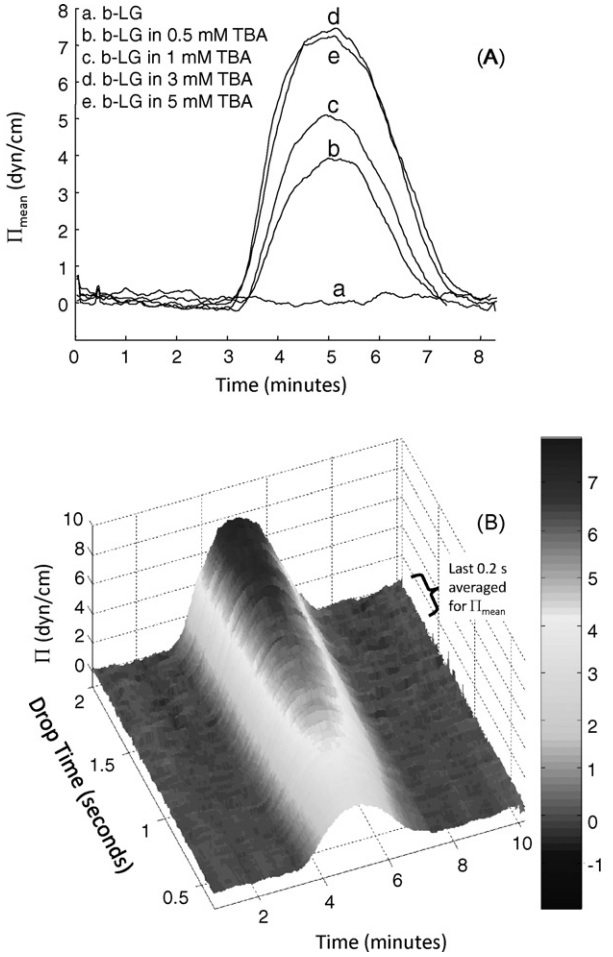

Fig. 2. FIA-DSTD experiments on β-LG (all in pH 6.8 buffer). (A) Dynamic surface pressure plots of β-LG (500 mg/L) in (a) 0.1 M PBS, (b) 0.1 M PBS with 0.5 mM TBAB, (c) 0.1 M PBS with 1 mM TBAB, (d) 0.1 M PBS with 3 mM TBAB, (e) 0.1 M PBS with 5 mM TBAB. Π_{mean} represents the surface pressure signal averaged over the last 10 points at the end of the 2 s drop (i.e., average values from 1.8 to 2.0 s). (B) Surface pressure plot of 500 mg/L β-LG in 0.1 M PBS with 3 mM TBAB; surface pressure values are reported as a function of drop time and elution time, Π_{mean} = 7.4 dyn/cm.

TBAB ≤ 3 mM did not yield a signal, while 5 mM TBAB produced a peak height of ~1.5 dyn/cm, and this background signal contribution was subtracted from the observed sample signal for other samples, as appropriate. As the TBAB concentration was increased, the surface activity of β-LG increased. In Fig. 2B the data show the relatively slow adsorption and diffusion kinetics at the air–liquid interface of TBAB-modified β-LG during the 2 s drop time. The change in the surface pressure signal over the growth of a single drop is attributed to the finite time required for diffusion, adsorption and molecular arrangement of the protein at the air–liquid interface, as has been discussed in another study [29].

Fig. 3A shows the trend of Π_{mean} as a function of TBAB concentration for α-lactalbumin, β-lactoglobulin, HSA, OVA and BSA. At a concentration of 500 mg/L, these proteins showed an increase in surface pressure until a *plateau* value was reached, which was reached between 1 and 3 mM TBA. Hemoglobin (not shown) showed a small increase in its surface activity in this concentration range. The other proteins (α-chymotrypsinogen A, cytochrome *C*, myoglobin, RNase A, carbonic anhydrase, and lysozyme) did not show any increase in surface activity up to 5 mM TBA. The plateau result was pH dependent. By increasing the pH from 6.8 to 7.8 carbonic anhydrase increased its surface activity reaching a plateau value of 2.7 dyn/cm. Hemoglobin and ribonuclease A reached a maximum signal of 8.8 dyn/cm and 4.5 dyn/cm, respectively, for

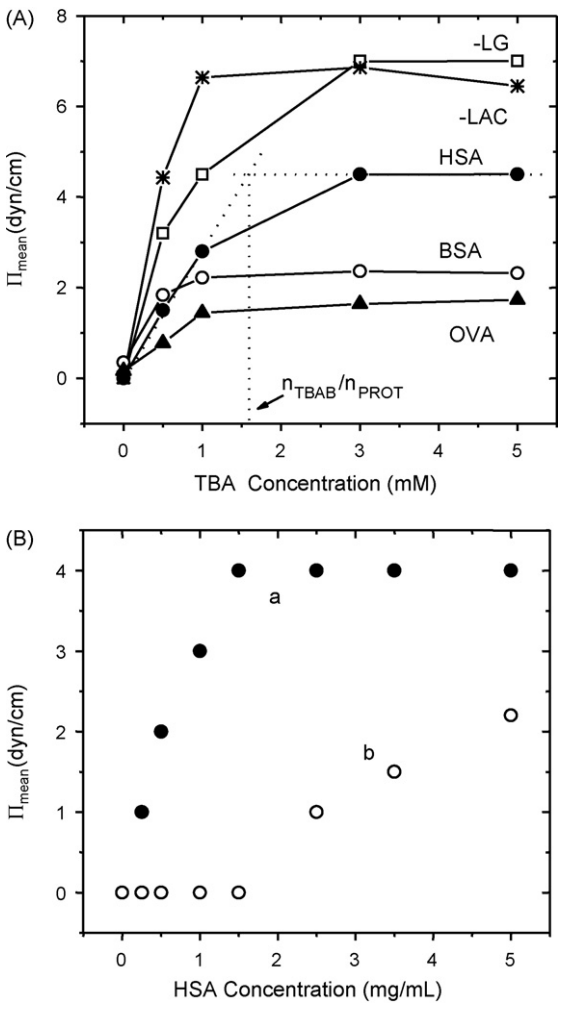

Fig. 3. FIA-DSTD experiments of standard proteins. (A) Surface pressure of 500 mg/L OVA, 500 mg/L BSA, 500 mg/L HSA, 500 mg/L α-Lac and 500 mg/L β-LG as a function of increasing concentration of TBAB. (B) Calibration plot for surface pressure of HSA in 0.1 M PBS, pH 6.8 with (a) or without (b) 1 mM TBAB. A significant enhancement of the surface pressure of these proteins due to TBAB is observed.

3 mM TBA. Table 1 summarizes the maximum value of Π_{mean} for all proteins studied at pH 6.8 and 7.8.

No comparative data are reported in the literature regarding surface activity of TBA-modified proteins. Tetra alkylammonium salts at concentrations ≥0.25 M were found to influence surface activity. This effect was attributed to the hydrophobic interaction between the buffer and the hydrophobic regions of the protein [26], although additional study is warranted. We were using much lower concentrations of TBAB (1–5 mM). It is possible that the increase of protein surface activity is due to ion pair formation with anionic charges located on the protein surface rather than to the interaction of aliphatic chains of TBA with hydrophobic portions of the protein [30], however, additional study is warranted to draw conclusions. Indeed, the five proteins that qualitatively increase surface activity in the presence of 1 mM TBAB in the mobile phase are all characterized by an isoelectric point lower than the pH 6.8 of the mobile phase (Table 1) [31–35]. At pH 6.8, these proteins are all negatively charged. With the exception of myoglobin, all proteins with an isoelectric point greater than pH 6.8 were presumably positively charged, and unlikely to interact as strongly with the tetrabutylammonium cations. Indeed, by increasing the mobile phase to pH 7.8, carbonic anhydrase, hemoglobin and RNase A did yield increased surface tension signals in the presence of TBAB as shown in Table 1.

Referring back to Fig. 3A and an observed trend of Π_{mean} as a function of TBAB concentration for various proteins, correspondingly, Table 1 indicates the molar ratio of TBAB and protein (n_{TBAB}/n_{PROT}) calculated from the intersection of the lines fit to the curves in Fig. 3A. The values of n_{TBAB}/n_{PROT} likely indicate the approximate number of TBA ions associated with each molecule of protein. If so, it may correlate with the number of negative surface charges at the particular pH [30].

Although the effect of TBAB on protein surface activity is not universal, the increase in detection sensitivity for several proteins provided by the TBAB is a very important finding for applying the DSTD as an HPLC detector. Fig. 3B shows the results of calibration experiments performed by the FIA-DSTD system on standard solutions of native HSA in 0.1 M PBS, pH 6.8 (curve b) and TBAB-modified HSA (0.1 M PBS, pH 6.8, 1 mM TBA, curve a). Calibration curves have been obtained by plotting the surface pressure data at the end of the 2 μL drop (Π_{mean}) as a function of the concentration of untreated (native) and TBAB-modified protein. Data show that 1 mM TBAB enhances sensitivity of HSA detection, by lowering the limit of detection (LOD) from 2 mg/mL to 0.1 mg/mL. Taking into account the flow splitting in the apparatus of Fig. 1, with only 15% of the effluent delivered to the detector, the mass LOD for HSA is 3 μg of injected protein and 450 ng of the protein at the DSTD. Likewise, the LOD for BSA was reduced from 1 mg/mL to 0.2 mg/mL. Furthermore, the LOD for RNase A was reduced from 0.3 mg/mL to 0.1 mg/mL, and the LOD for carbonic anhydrase was reduced from 0.4 mg/mL to 0.2 mg/mL. Standard protein solutions were prepared with and without 1 mM TBA in phosphate buffer at various protein concentrations of 5 mg/mL, 2.5 mg/mL, 1.25 mg/mL, 0.625 mg/mL, 0.313 mg/mL, and 0.156 mg/mL. The slope of the linear fit for the HSA calibration with TBA was 0.844 (R^2 = 0.944), while the slope for HSA without TBA was 0.697 (R^2 = 0.931). The HSA signals with TBA were greater than the HSA signals without TBA, and the DSTD

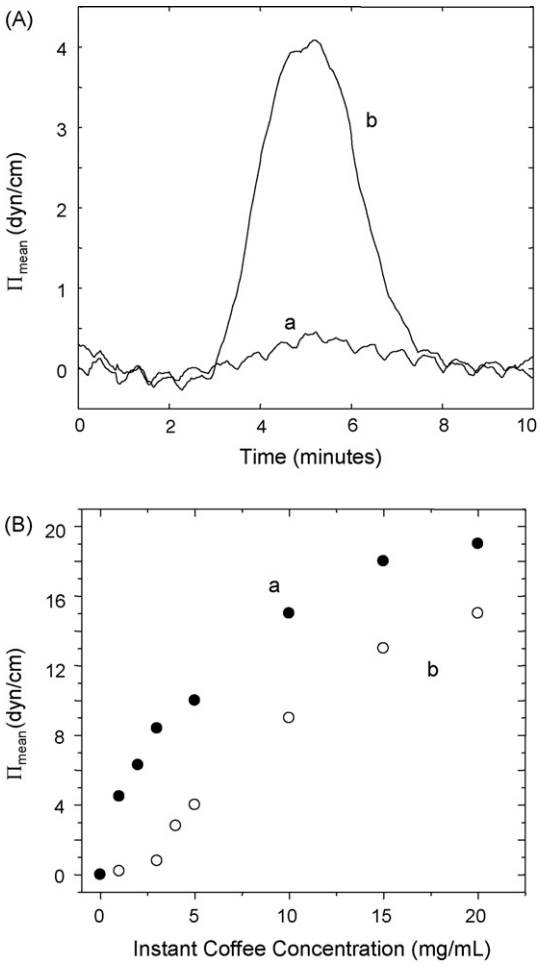

Fig. 4. (A) FIA-DSTD experiments of an instant coffee sample (1 mg/mL) solubilized in 0.1 M PBS, pH 6.8 (curve a) and 1 mM TBAB in 0.1 M PBS, pH 6.8 (curve b). (B) Calibration plot for surface pressure of the coffee sample in 0.1 M PBS, pH 6.8 (curve b) and 1 mM TBAB in 0.1 M PBS, pH 6.8 (curve a).

sensitivity with TBA was greater than the sensitivity without TBA, as shown by the relative slopes. Linear fitting for DSTD calibration is justified in Ref. [17]. The same calibration was performed with other proteins to show that TBA increases the DSTD sensitivity. The slope of the linear fit for BSA calibration with TBA was 1.352 (R^2 = 0.953), while the slope of the linear fit for BSA without TBA was 0.885 (R^2 = 0.914). The slope of the linear fit for OVA calibration with TBA was 1.132 (R^2 = 0.974), while the slope for OVA without TBA was 0.517 (R^2 = 0.959). The slope of the linear fit for α-lactalbumin with TBA was 1.486 (R^2 = 0.982), while the slope for α-lactalbumin without TBA was 1.287 (R^2 = 0.986).

3.2. FIA-DSTD and SEC-UV/DSTD of standard proteins and instant coffee samples

In Fig. 4, FIA-DSTD of an instant coffee sample (1 mg/mL) solubilized in 0.1 M PBS, pH 6.8 (curve a) and 1 mM TBAB in 0.1 M PBS, pH 6.8 (curve b) demonstrates the significant benefit of using the TBAB as a mobile phase additive to enhance sensitivity, ultimately useful for SEC-UV/DSTD. The FIA results indicate that without the TBAB present in the mobile phase, there is likely to be insufficient sensitivity to observe the surface-active compounds in the instant coffee and barley samples while doing SEC. Based on these results, the DSTD was optimized and successfully coupled to SEC for the analysis of protein standards, and several commercially available instant beverage samples. SEC separations of standard

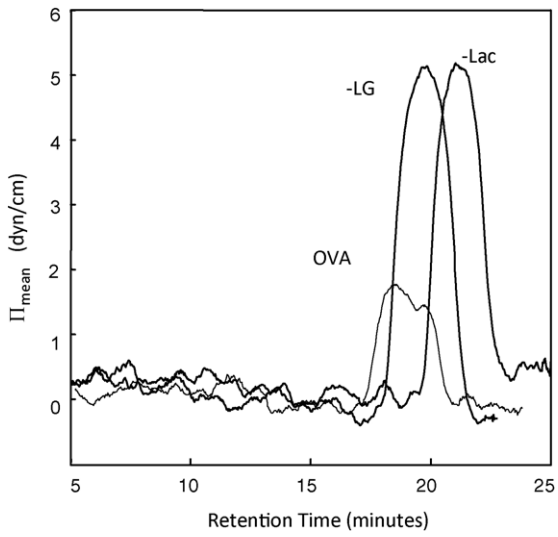

Fig. 5. SEC-DSTD chromatograms of OVA (4 mg/mL and MW = 42.7 kDa), β-LG (2.5 mg/mL and MW = 18.4 kDa), and α-Lac (2.8 mg/mL and MW = 14.2 kDa) in 0.1 M PBS, pH 6.8 with 1 mM TBAB.

proteins in 1.0 mM TBAB were obtained in order to estimate molecular weights for compounds of the beverage samples based on retention times. Three of the standard protein chromatographic responses are shown in Fig. 5, in terms of Π_{mean} as a function of the elution time. OVA (42.7 kDa) eluted at approximately 18 min, β-LG (18.4 kDa) eluted at approximately 20 min, and α-Lac (14.2 kDa) eluted at approximately 21.5 min.

Figs. 6 and 7 show SEC-UV/DSTD chromatograms of a commercial instant coffee sample and a soluble barley beverage, respectively. In these figures, the typical UV absorbance chromatograms at 280 nm are compared with the simultaneously acquired SEC-DSTD chromatograms plotted as Π_{mean} as a function of the elution time. For the Nescafe instant coffee beverage shown in Fig. 6, the UV chromatogram shows one complex band (eluting between 17 min and 24 min) and four peaks (eluting at approximately 25 min, 29 min, 32 min, and 37 min). However, the

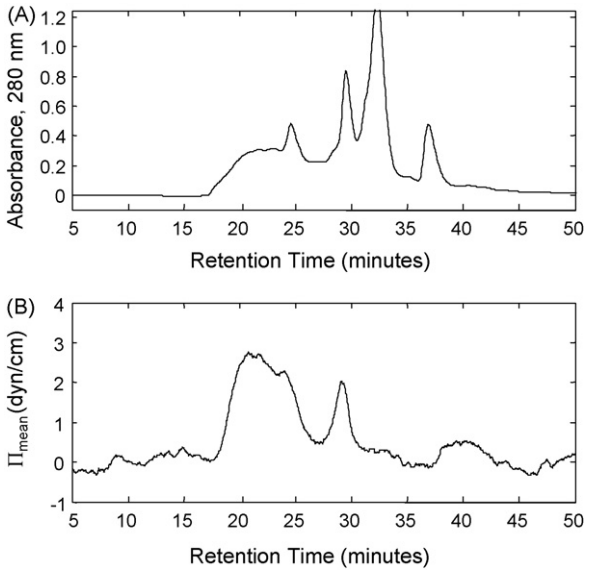

Fig. 6. SEC-UV/DSTD chromatograms of beverage samples. (A) UV absorbance chromatogram at 280 nm for Nescafe instant coffee sample (20 mg/mL in 0.1 M PBS, pH 6.8 with 1 mM TBAB). (B) Simultaneously acquired SEC-DSTD chromatogram with π mean as a function of elution time for the commercial instant coffee sample.

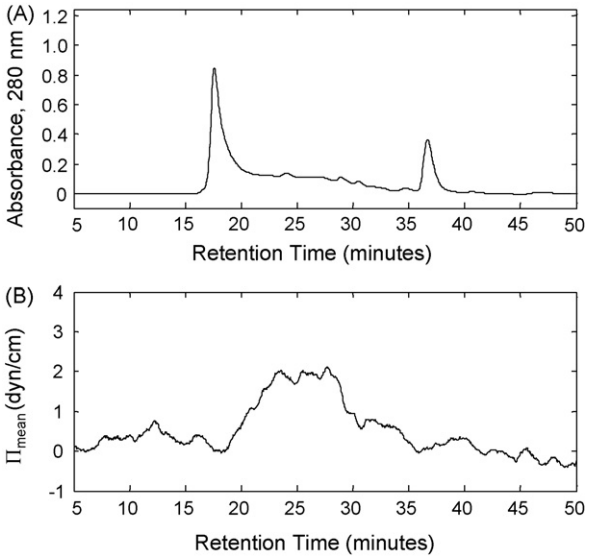

Fig. 7. (A) UV absorbance chromatogram at 280 nm for soluble barley beverage (20 mg/mL in 0.1 M PBS, pH 6.8 with 1 mM TBAB). (B) Simultaneously acquired SEC-DSTD chromatogram with π mean as a function of elution time for the soluble barley beverage.

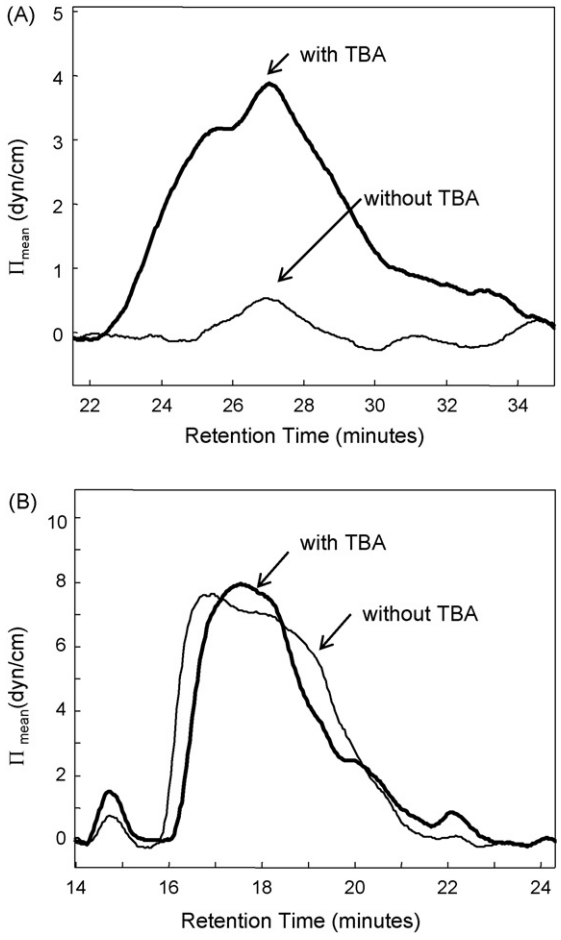

Fig. 8. (A) SEC-DSTD chromatogram for 10 mg/mL Nescafe Classic instant coffee sample with and without 1 mM TBAB. (B) SEC-DSTD chromatogram for 10 mg/mL powdered milk sample with and without 1 mM TBAB.

DSTD chromatogram of the instant coffee indicates that only compounds eluting between 17 min and 29 min were surface active. According to the retention time calibration of the SEC column, the molecular weight of the surface-active compounds in the instant coffee beverage sample corresponded to a range of approximately 1–45 kDa. For the barley beverage sample in Fig. 7, the UV chromatogram shows peaks at 18 min and 37 min with a complex band between these peaks. However, the DSTD chromatogram of this barley sample indicates that only the compounds eluting between 20 min and 30 min were surface active. Thus, the selectivity of the DSTD with respect to UV absorbance detection provided unique surface activity information for these mixtures. SEC-UV/DSTD analyses of these samples eluted in the absence of TBAB yielded the same UV absorbance chromatogram and close to zero signal at the DSTD detector. These results demonstrate that 1 mM TBAB in the mobile phase increased the surface activity of the coffee and barley samples at the DSTD without affecting the SEC separation.

TBAB can increase the signal of sample components to varying degrees, as shown in Fig. 8 where the SEC separations of 10 mg/mL Nescafe Classic instant coffee or powdered milk are shown with and without 1 mM TBAB. In Fig. 8A the DSTD signal for the coffee component was increased from 0.5 dyn/cm without TBAB to 3.8 dyn/cm with TBAB. In Fig. 8B the DSTD signal for the powdered milk component at 14.8 min increased from 0.7 dyn/cm to 1.5 dyn/cm when TBAB was present. The DSTD signal for the powdered milk component at 22 min increased from 0.1 dyn/cm to 0.8 dyn/cm when TBAB was present.

The application of the SEC-DSTD method to commercial food products like instant beverage samples provides a selective view of the surface-active compounds that may differ significantly among the examined samples. For example, it is worth noting that the number and the concentration of surface-active proteins in barley and coffee samples are substantially different. In summary, the DSTD coupled with TBAB as a protein modifier offers a novel tool for improving the sensitive detection of the surface activity of food products such as instant coffee.

4. Conclusions

The SEC-DSTD/UV instrument is chemically selective and provides surface activity information complementary to absorbance data for constituent analysis of commercial coffee and commercial soluble barley samples. Furthermore, the LOD was selectively enhanced (reduced to parts-per-thousand protein concentration) when proteins were combined with mM concentrations of TBAB. This instrument has the potential to be a fundamental tool for quality control during all the steps of food processing (from the raw materials to the processed foodstuff), as well as in the pharmaceutical industry and in environmental chemistry where surface property phenomena of individual compounds in a complex mixture are of interest.

Chitosan-immobilized sodium silicate

ABSTRACT

A natural biosorbent containing amine functional groups, chitosan, and a novel sorbent, chitosan-immobilized sodium silicate, were prepared and utilized for the selective sorption of As(V) from waters prior to its determination by atomic spectrometric techniques, namely, hydride generation atomic absorption spectrometry (HGAAS) and inductively coupled plasma mass spectrometry (ICP-MS). Chitosan was synthesized from chitin and sodium silicate was used as the immobilization matrix due to its straightforward synthesis. Through sequential sorption studies, it was shown that chitosan-immobilized sodium silicate has exhibited a better chemical stability than the chitosan itself which demonstrates the advantage of immobilization method. Both chitosan and chitosan-immobilized sodium silicate were shown to selectively adsorb As(V), arsenate, from waters at pH 3.0 at which neither chitin nor sodium silicate displayed any sorption towards As(V). The sorption of arsenate by chitosan is supposed to have electrostatic nature since pH of 3.0 is both the point at which the amino groups in chitosan are protonated and also the predominant form of As(V) is $H_2AsO_4^-$. A pre-oxidation step is required if both As(III) and As(V) are to be determined. Desorption from the sorbents was realized with 1.0% (w/v) L-cysteine prepared in a pH 3.0 solution adjusted with HCl. Among the possible interfering species tested, only Te(IV) and Sb(III) were shown to cause a decrease in the sorption capacity especially at high interferant concentrations. High concentrations of Sb(III) also resulted in gas phase interference during hydride generation.

The validity of the method was checked both via spike recovery experiments and also through the analysis of a standard reference material. Spike recovery tests were carried out with four different types of water; namely, ultra-pure, bottled drinking, tap, and sea water; and percent recovery values were found to be 114 (±4), 112 (±2), 43 (±4), and 0 (±1), respectively. It was concluded that the proposed methodology can be applied efficiently to low-to-medium ionic strength solutions, such as most drinking waters. The accuracy of the method was additionally investigated through the analysis of a standard reference material and a good correlation was found between the determined ($26.6 \pm 2.4\ \mu g\ L^{-1}$) and the certified ($26.67\ \mu g\ L^{-1}$) value.

1. Introduction

In nature, arsenic can be found in food, water and air in organic and inorganic forms [1] and exists in the −3, 0, +3 and +5 oxidation states [2–4]. Inorganic arsenic species occur as arsenite, As(III), with primary form of H_3AsO_3 and arsenate, As(V), with primary forms of $H_2AsO_4^-$ and $HAsO_4^{2-}$ in natural waters [1]. Arsenates are stable under aerobic (oxidizing) conditions whereas arsenites are predominant under anaerobic (reducing) conditions [3,5].

Both natural and anthropogenic sources contribute to the arsenic levels in the environment, which is distributed throughout earth crust, soil, water, air and living organisms [5]. The presence of arsenic in drinking water is related to the dissolution of minerals and ores [6]. Waste discharges from industrial and mining activities, agricultural use of arsenical pesticides and use of chromated copper arsenate (CCA) wood preservative may enhance the anthropogenic arsenic contamination in air, water and soil [5]. Long term consumption of drinking water contaminated with arsenic is reported to cause cancers of the skin, lungs, kidney and liver. Short term exposure to arsenic may result in vomiting, oesophageal, and abdominal pain, and "rice water" diarrhea [2,6]. Hence, drinking water containing arsenic is a potential threat to the health of humans. The World Health Organization (WHO) revised the guide-

doi:10.1016/j.talanta.2009.09.053

line for arsenic in drinking water from 0.05 to 0.01 mg L^{-1} and has classified arsenic as the most toxic chemical with carcinogenic effects [6].

Because of the undesired health effects mentioned above, finding/devicing economic, easily operable and nontoxic technologies for removal of arsenic are a major goal especially when clean water sources are scarce. Arsenic removal methods from drinking water including precipitation, adsorption, ion exchange, membrane filtration and some other alternative processes have been reviewed [1,2,7]. All processes are limited with lower efficiency for arsenite removal because of the uncharged state of the species under pH 8 which necessitates the oxidation of As(III) before the removal step. In last years, nanozero valent iron has become one of the most attractive materials for arsenic removal which effectively removes both inorganic forms [8,9]. Application of various biomasses in arsenic removal has been reviewed by Mohan and Pittman [2]. Among numerous polysaccarides, cellulose and chitin are the most abundant organic compounds on the earth, with the largest amounts of production per year [10]. The shells of marine crustaceans such as crabs and shrimps are available as waste from the seafood processing industry and are used for commercial production of chitin. Chitosan, the N-deacetylated form of chitin, is an attractive material with unique properties of non-toxicity, film and fiber forming properties, adsorption of metal ions, coagulation of suspensions or solutes, and distinctive biological activities [10,11] and is produced by thermochemical alkaline treatment of chitin. Chitosan has been used as a sorbent for arsenic removal. For example, Kartal and Imamura studied arsenic removal from chromated copper arsenate (CCA)-treated wood via biosorption by chitin and chitosan in 1, 5 and 10 days periods; however, a quantitative removal was not obtained [12]. Chitosan was modified with molybdate and it was shown that the modification increased the sorption capacity by the ability of molybdate ion to complex As(V) [13–16]. Chitosan was also used as a resin for arsenic sorption in column studies with improved resistance to shrinkage which was obtained by cross-linked chitosan functionalized with 3,4-diamino benzoic acid [17]. Boddu et al. used ceramic alumina dip-coated with chitosan for As(III) and As(V) removal in column and an improved sorption capacity was reported for As(III) [18].

As revealed in the literature, effective use of chitosan as a sorbent can be based on the enhancement of its capacity through particular modifications. In the meantime, the resistance of the biomaterial to shrinkage may be improved. Immobilization of chitosan onto a supporting surface increases the surface area of sorbent (compared to chitosan itself) with a corresponding increase in the number of functional groups available for sorption. Using sodium silicate as an immobilization matrix has the advantage of tuning the immobilized amount of functional groups in a narrow synthesis time. Ease of the application and availability of low-cost chemicals are among the other advantages of the silicate-immobilization method. In this study, both chitosan as synthesized and chitosan-immobilized sodium silicate were used in the sorption of As(V) from waters prior to determination by hydride generation atomic absorption spectrometry (HGAAS) and inductively coupled plasma mass spectrometry (ICP-MS).

2. Experimental

2.1. Instrumentation and apparatus

A Thermo Elemental Solaar M6 Series atomic absorption spectrometer (Cambridge, UK) with an air-acetylene burner was used in arsenic determination utilizing the Segmented Flow Injection Hydride Generation (SFI-HGAAS) unit. An arsenic hollow cathode lamp at the wavelength of 193.7 nm and a deuterium lamp were employed as the source line and for background correction, respectively. In HGAAS, the quartz tube atomizer was 10 cm long, 8 mm in internal diameter and 10 mm in external diameter with a 4 mm bore inlet tube fused at the middle for sample introduction. Air-acetylene flame was used for heating the quartz tube externally and nitrogen was used as the carrier gas. Operating parameters for the HGAAS system were as follows: 200 mL min^{-1} carrier gas (N_2) flow rate, 6.1 mL min^{-1} HCl flow rate, 2.0% (v/v) HCl concentration, 3.0 mL min^{-1} $NaBH_4$ flow rate, 1.0% (w/v) $NaBH_4$ concentration (stabilized with 0.1%, w/v, NaOH), 7–8 mL min^{-1} sample flow rate. In addition to HGAAS, ICP-MS (Agilent 7500ce Series, Tokyo, Japan) was also employed in validation and interference studies.

In batch sorption studies, GFL 1083 water bath shaker (Burgwedel, Germany) equipped with a microprocessor thermostat was used for mixing. The elemental composition of chitosan was determined by a LECO-CHNS-932 elemental analyzer (Mönchengladbach, Germany). Determination of the molecular weight was realized using a Petrotest capillary viscosimeter (Dahlewitz, Germany). The crystallographic structure of the sorbent was elucidated by a Philips X'Pert Pro X-Ray Diffractometer (Eindhoven, The Netherlands). The pH adjustments were performed with Ino Lab Level 1 pH meter (Weilheim, Germany). Microimages of sorbents were taken utilizing a Philips XL-30S FEG scanning electron microscope (Eindhoven, The Netherlands). The thermal properties of sorbents were analyzed using a Perkin Elmer Pyris Diamond TG/DTA (Boston, MA, USA). The point of zero charge of chitosan flakes was determined with a Zeta-Meter 3.0+ equipment (Staunton, USA).

2.2. Reagents and solutions

All the chemicals were of analytical reagent grade. Ultra-pure water (18.2 MΩ) was used throughout the study. Glassware and plastic containers were cleaned by soaking in 10% (v/v) nitric acid for 24 h and rinsed with deionized water prior to use.

Stock standard solutions of As(V) and As(III), 2000.0 mg L^{-1}, were prepared by dissolving As_2O_5 (Merck, product code: 1.09939, CAS no.: [1303-28-2]) and As_2O_3 (Fischer, CAS no.: [1327-53-3]), respectively, in ultra-pure water. Stock standard solution of Te(IV), 500.0 mg L^{-1} was prepared by pre-reduction of Te(VI) (Aldrich, product code: 41058-6, CAS no.: [26006-71-3]) by boiling with 6.0 M HCl. Stock solutions of Se(VI), Se(IV), Sb(III) and Sb(V), 1000.0 mg L^{-1}, were prepared by dissolving Na_2SeO_4 (Fluka, product code: 71948, CAS no.: [13410-01-0]), $Na_2SeO_3 \cdot 5H_2O$ (Merck, product code: 1.06607, CAS no.: [26970-82-1]), $C_8H_4K_2O_{12}Sb_2 \cdot 3H_2O$ (Sigma–Aldrich, product code: P-6949, CAS no.: [28300-74-5]) and $KSb(OH)_6$ (Riedel-de Haen, product code: 31149, CAS no.: [12208-13-8]), respectively, in ultra-pure water. Mo(VI) and V(V), 1000.0 mg L^{-1} standard stock solutions were supplied from High-Purity Standards (product code: 100065-1) and Merck (product code: 1.70227), respectively. Lower concentration standard solutions were prepared daily by appropriate dilution from their stock standards before use.

Chitosan flakes were synthesized from practical grade chitin (Sigma, product code: C923, CAS no.: [1398-61-4]).

Sodium borohydride solution was prepared for a daily use from fine granular product (Merck, product code: 8.06373, CAS no.: [16940-66-2]) and stabilized by NaOH (Merck, product code: 1.06498, CAS no.: [1310-73-2]) in water. L-cysteine (Merck, product code: 1.02838, CAS no.: [52-90-4]) was added to all standards and samples to reduce As(V) to As(III) before HGAAS determination.

N,N-Dimethylacetamide (Sigma, product code: D 5511, CAS no.: [127-19-5]) containing 5.0% (w/v) LiCl (Aldrich, product code: 310468, CAS no.: [7447-41-8]) and 0.200 M NaCl (Riedel-de Haen, product code: 13423, CAS no.: [7647-14-5]) containing 0.100 M acetic acid (Riedel-de Haen, product code: 27225, CAS no.: [64-

19-7]) were used in molecular weight determination of chitin and chitosan, respectively.

$BaCl_2 \cdot 2H_2O$ (Riedel-de Haen, product code:11411, CAS no.: [10326-27-9]) was used to prepare 0.1 M solution by dissolving appropriate amount in distilled water. Silicate-immobilization matrix was prepared from sodium silicate solution (Sigma–Aldrich, product code: 338443, CAS no.: [1344-09-8]).

2.3. Synthesis and characterization of chitosan

2.3.1. Synthesis of chitosan

Chitosan flakes were synthesized from chitin under inert atmosphere by the method of Rigby and Wolfrom given in the monograph by Muzzarelli [19]. Briefly, 15.0 g of chitin was treated with 720 mL of 40.0% (w/w) aqueous NaOH solution in a 1-L three-necked round bottomed flask with reflux condenser connected to its middle neck. A thermometer was connected to control the temperature during the reaction and N_2 gas was bubbled through the solution from the side arm to provide inert atmosphere in the reaction medium. Constant reflux was obtained at 115 °C and continued for 6 h. After cooling the alkaline mixture to room temperature, chitosan flakes were washed with distilled water until a neutral filtrate was obtained. The resulting chitosan flakes were dried at 60 °C for 2 h before use.

2.3.2. Characterization of chitosan

A variety of methods were applied for the characterization of synthesized chitosan flakes. Elemental analysis and potentiometric titrimetry were used for the determination of the degree of deacetylation as reported in the literature [20,21]. The molecular weights of chitin and chitosan were determined by viscosimetric method which relates intrinsic viscosity of polymer to its molecular weight according to Mark–Houwink–Sakurada relation as described in the literature [21–26]. Images of chitosan, sodium silicate, and chitosan-immobilized sodium silicate were taken with scanning electron microscopy (SEM). XRD crystallographic properties and thermal gravimetric degradation were also investigated.

2.4. Immobilization of chitosan on sodium silicate

Chitosan was immobilized on polysilicate matrix after slight modification in the method described by Karunasagar et al. [27] in which sodium silicate was used as the immobilization matrix for the plant *Coriandrum sativum*. In the present study, the immobilization procedure was as follows: 6.0% (w/w) sodium silicate was added dropwise into 15.0 mL of 5.0% (v/v) H_2SO_4 until pH rose to 2. The solution pH was checked with pH paper instead of pH meter in order not to cause any damage to the electrode system due to use of silicate solution. Then, 50.0 mL of 2.0% (w/v) chitosan dissolved in 2.0% (v/v) acetic acid was added dropwise to the silicate solution and the mixture was stirred for 15 min. The polymer gel was formed by increasing the pH to 7 by dropwise addition of sodium silicate solution. Formed gel was washed with ultra-pure water until the solution is free of sulphate ion. This was checked by the addition of 0.200 M $BaCl_2$ solution to the filtrate. Usually cloudiness is observed as a result of precipitation reaction between barium and sulphate ions when sulphate is at an appreciable concentration. After the immobilization procedure had been completed, the chitosan-immobilized sodium silicate was dried at 50 °C overnight and ground by mortar and pestle prior to use.

2.5. Sorption studies

Sorption studies were performed for all the sorbents prepared; namely, chitin, chitosan, sodium silicate and chitosan-immobilized sodium silicate through batch process. Effect of the sorbent amount, shaking time, solution pH, reaction temperature and successive loadings was investigated. In all these experiments, batch sorption was followed by the filtration of the mixture through blue-band filter paper and analysis of the filtrate for its arsenic content using HGAAS. Before HGAAS measurements all samples and standard solutions were acidified with the addition of appropriate amount of concentrated HCl to produce 1.0% (v/v) HCl in the final solution. For As(V) determination, L-cysteine was also added to all solutions so as to have 0.5% (w/v) concentration in the final solution which guaranteed the pre-reduction of As(V) to As(III).

2.6. Sorption isotherm models

Sorption isotherm is a constant-temperature curve that describes the retention of a substance on a solid at various concentrations and is used to predict the mobility of the substance in the environment [28]. Sorption isotherm defined by Langmuir assumes that the energy of sorption is constant and sorption occurs at a fixed number of definite localized homogeneous sites with monolayer coverage [28–30]. The nonlinear form of Langmuir isotherm is given in Eq. (1):

$$Q_e = Q_{max} \frac{bC_e}{1 + bC_e} \quad (1)$$

Here, Q_{max} (mmol/g) and b (L/mmol) are Langmuir constants; Q_{max} is the amount of arsenate ion sorption corresponding to monolayer coverage, b is the affinity of arsenate for the sorbent, C_e (mmol/L) is the amount of arsenate in liquid phase at equilibrium and Q_e is the amount of arsenate adsorbed on the surface of sorbent (mmol/g) at equilibrium. The values of constants were evaluated from the linearized form of the equation which is given in Eq. (2):

$$\frac{1}{Q_e} = \frac{1}{Q_{max}} + \frac{1}{Q_{max} bC_e} \quad (2)$$

The intercept and slope of the plot of $1/Q_e$ versus $1/C_e$ were used for determination of Q_{max} and b.

Freundlich isotherm is among the most widely applied isotherms. This isotherm can be applied for heterogeneous surfaces over a wide range of concentrations. The nonlinear form of this isotherm is described by Eq. (3) [31]:

$$Q_e = K_F C_e^{1/n} \quad (3)$$

where K_F and n are constants for a given sorbent–sorbate system. These constants can be evaluated from the linearized form of Eq. (3) given as follows:

$$\log Q_e = \log K_F + \frac{1}{n} \log C_e \quad (4)$$

The intercept and slope of the plot of $\log Q_e$ versus $\log C_e$ in Eq. (4), give K_F and $1/n$, respectively.

Dubinin–Radushkevich (D–R) isotherm model assumes that the ionic species bind preferentially to most energetically favorable sites of sorbent material and allows for multilayer sorption of ions [13]. D–R isotherm is generally described by Eq. (5) [32]:

$$Q_e = q_s \exp(-B\varepsilon^2) \quad (5)$$

where

$$\varepsilon = RT \ln\left(1 + \frac{1}{C_e}\right) \quad (6)$$

The D–R parameter, B, provides information about the mean free energy of sorption defined as the energy required to transfer one mole of ions to the surface of the solid from infinity in the solution. The constant, q_s corresponds to the sorption monolayer capacity

[33]. The mean free energy of sorption can be calculated from D–R parameter B using Eq. (7):

$$E = (2B)^{-1/2} \quad (7)$$

The q_s and B constants are, respectively, obtainable from the intercept and the slope of the experimental plot of $\ln Q_e$ versus ε^2.

2.7. Desorption/dissolution studies

Two different strategies were followed to take the adsorbed arsenate ion back into solution from chitosan or chitosan-immobilized sodium silicate. Firstly, 2% (v/v) acetic acid in which chitosan was completely soluble was used. Secondly, desorption was carried out in L-cysteine which reduces the adsorbed form of arsenic (As(V), arsenate) to the non-adsorbed form (As(III), arsenite). In both strategies, calibration standards were also prepared in the same matrixes using the same method of preparation (matrix-matched standards). Before HGAAS measurements both samples and standards were acidified with concentrated HCl to produce 1.0% (v/v) of HCl in the final solution. For reduction of As(V) to As(III) L-cysteine was added to produce 0.5% (w/v) in the solution (This step was skipped if desorption matrix had already contained L-cysteine.).

2.8. Interference studies

Interference effects of two groups of compounds on arsenic determination were investigated. The first group contained hydride forming ions possessing different oxidation states of several elements; namely, Sb(III), Sb(V), Te(IV), Te(VI), Se(IV), and Se(VI) ions. The second group included Mo(VI) and V(V) for which chitosan is presumed to show sorption affinity [17,34]. Two types of interferences were expected: firstly, during the sorption of arsenate, and secondly, during hydride generation [35].

Initially, the sorption characteristics of chitosan towards each of the possible interfering ions were investigated in the absence of arsenate. For this purpose, 100.0 and 1000.0 $\mu g\,L^{-1}$ concentrations of the ions were mixed with chitosan and shaken under the conditions optimized for arsenate sorption. The percent sorption of each ion was determined by ICP-MS after acidification with concentrated HNO_3 so as to have 1.0% (w/v) acid concentration in the final solution.

In addition, 10.0, 100.0, 1000.0 $\mu g\,L^{-1}$ of each of the interfering species were added in separate experiments into both 10.0 and 100.0 $\mu g\,L^{-1}$ As(V) solutions in order to see the interference effect in presence of arsenate. The sorption experiments were performed under optimized conditions for arsenate described in the previous paragraph. After proper acidification and pre-reduction (L-cysteine) steps, ICP-MS and HGAAS were used for the analyses.

2.9. Method validation

The proposed methodology was validated both through the analysis of a standard reference material (SRM from NIST, Natural Water – Trace Elements, Cat. No. 1640) and via spike recovery experiments. Due to the absence of any information about the oxidation state of arsenic in the SRM, initial experiments were carried out in two ways: shaking with chitosan first directly, and second, after a pre-oxidation step with concentrated HNO_3. The oxidation was carried out by diluting 5.0 mL of SRM with 10.0 mL of ultra-pure water in a teflon beaker. After addition of 3.0 mL concentrated HNO_3, heating was applied on hot plate until evaporation of solution was completed. The remaining residue was dissolved in about 10 mL of ultra-pure water and after pH was adjusted to 3.0, the solution was diluted to exactly 15.0 mL to provide an As(V) concentration of 9.0 $\mu g\,L^{-1}$ in the final solution. The same procedure was also applied to the SRM directly without pre-oxidation step. In line with these experiments, both As(III) and As(V) standard solutions were also subjected to the same procedure; namely, with or without pre-oxidation with HNO_3.

Spike recovery tests were performed with four different types of water; namely, tap, distilled, sea and bottled drinking water. Spiked samples were subjected to the same sorption/elution cycles as previously and recoveries were calculated.

In addition to the validation tests described above, solutions containing both As(III) and As(V) were analyzed with the proposed method to see if there is a mutual interference. In these experiments, both chitosan and chitosan-immobilized sodium silicate were used in a two-stage batch type process. Three different solutions, namely, As(III) only, As(V) only and the mixture of As(III) and As(V) were prepared in a way that the concentrations of the species were 100.0 $\mu g\,L^{-1}$ in each case. After the addition of 50.0 mg of chitosan or chitosan-immobilized sodium silicate, the mixture was shaken for 30 min and then was filtered through blue-band filter paper. The solid and the liquid parts were separated and the filtrate was kept for determination of its arsenic concentration. Solid chitosan (or chitosan-immobilized sodium silicate) remained on the filter paper was taken into 30.0 mL of 1.0% (w/v) L-cysteine solution of which pH was adjusted to 3.0 and shaking was continued for a further 30 min for desorption. This eluate was analyzed by ICP-MS for its arsenic concentration by using matrix-matched standards which were prepared under the same sorption/desorption conditions described above.

3. Results and discussion

3.1. Characterization of chitosan

Surface morphology of chitosan flakes, sodium silicate and chitosan-immobilized sodium silicate was examined from different locations on their surfaces using SEM. The images (not shown) reveal the increasing surface porosity of chitosan-immobilized sodium silicate in comparison to chitosan.

The thermal gravimetric analysis of chitosan shows two notable weight loss stages (Fig. 1). The first stage results in about 9% loss in weight and corresponds to the weight loss of water molecules adsorbed onto surface (25–98 °C) and weight loss of bonded water (98–266 °C). The second stage weight loss occurred between 266 and 328 °C due to rapid thermal degradation of chitosan and resulted in 33% weight loss. The results are in agreement with thermal gravimetric analysis reported for chitosan by different studies in the literature [36,37]. As in the case of chitosan, sodium silicate matrix shows a weight loss of about 9% in the same temperature range due to release of water molecules from the structure. The chitosan-immobilized sodium silicate demonstrates intermediate thermal characteristics between chitosan and immobilization

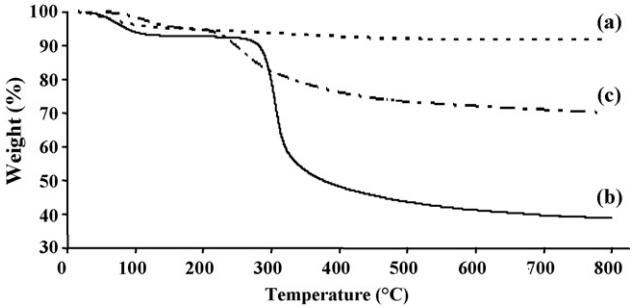

Fig. 1. TGA curves of (a) sodium silicate, (b) chitosan and (c) chitosan-immobilized sodium silicate.

matrix. Careful investigation of the weight loss percentages in thermograms is also indicative of around 30% (w/w) of chitosan in the immobilization matrix of silicate.

The degree of deacetylation of chitosan was determined by two methods: elemental analysis and titrimetry, and the results obtained were in good agreement (84.7% versus 85.4%, respectively). In addition, the percentage of chitosan-immobilized onto sodium silicate was calculated from the carbon ratios of chitosan-immobilized sodium silicate to pure chitosan sample. The amount of chitosan in sodium silicate matrix was calculated as 33.3% in the total mass which is also in accordance with TGA results.

Molecular weights of chitin and chitosan were determined using the Mark–Houwink–Sakurada equation [21–26] and found to be 1215 and 910 kDa, respectively. These results are in accordance with the results in the literature where very scattered molecular weights are reported. The wide range of the reported molecular weight values, especially for chitin, is thought to be arising from the limited solubility of chitin in the given solvent system which prevents accurate determination of the molecular weight. As reported in [26 and the references therein], two factors are effective on incomplete dissolution. Firstly, high molecular weight chitin chains are not soluble, and secondly, the presence of proteins in the unpurified chitin may associate with the N-acetyl groups in the structure and make the product insoluble. To eliminate the possible error in the determination of the molecular weight of the chitin, the insoluble part was filtered, dried, and weighed as suggested in [26]; and the true molecular weight of the chitin was calculated after subtracting the weight of the insoluble part from the total weight taken at the beginning. The calculated molecular weights indicate that the chitin used in this study is of high molecular weight and the deacetylation process not only removes the acetyl groups but also decreases the molecular weight of chitosan by cleavage of glycosidic bonds.

The X-ray diffraction patterns for chitin and chitosan are given in Fig. 2. The most significant difference observed between the two XRD patterns is the decreasing crystallinity of the compound after deacetylation process. Deacetylation procedure involves the disappearance of small peaks; only the peaks at $2\theta = 9–10^\circ$ and $2\theta = 19–20^\circ$ remain. The decrease in the crystallinity when going from chitin to chitosan was also observed by different research groups in the literature who reported that the retained peaks corresponded to hydrated crystals of chitosan [38,39].

(●) chitosan, (○) sodium silicate, (▲) chitin, (□) chitosan-immobilized sodium silicate, $n = 3$. Reaction conditions: 30.0 mL sample volume, 30 min shaking time, 50.0 mg sorbent, 25 °C sorption temperature. The insets obtained with VISUAL MINTEQ software show speciation diagrams of As(V) and As(III).

3.2. Sorption studies

3.2.1. Effect of pH on sorption of As(V) and As(III)

The sorption characteristics of chitin, chitosan, sodium silicate and chitosan-immobilized sodium silicate towards As(V) and As(III) are given in Fig. 3. Chitosan and chitosan-immobilized sodium silicate have maximum sorption at pH 3.0 while sodium silicate and chitin do not show any affinity for As(V) as indicated in the figure. In case of As(III), all sorbents showed the same trend; arsenite ions were not adsorbed significantly (<15% sorption) by any of the sorbents under the working conditions applied. The nature of sorption behavior of chitosan at pH 3.0 can be explained by the electrostatic attraction between the protonated amine groups of chitosan and $H_2AsO_4^-$ ion, which is the main (approximately 85% of the As(V)) species at pH 3.0 (Fig. 3a inset). Chitosan flakes start to dissolve below pH 3 and this property precludes the possibility of them to be used as a biosorption material below this pH. Through zeta potential measurements, the isoelectric point of chitosan was determined to be 4.8–4.9. As the pH of the solution was lowered, positive charge on chitosan flakes increased. This also supported the electrostatic nature of the sorption. As can be seen from the speciation graphs of As(V) and As(III) (Fig. 3 insets), there is no any other pH with the same electrostatic behavior that biosorbent and arsenic species have opposite charges.

3.2.2. Effect of sorbent amount and shaking time on the sorption of As(V)

The percentage sorption of As(V) as a function of different amounts of chitosan and chitosan-immobilized sodium silicate is given in Fig. 4. As seen from the figure, similar sorption percentages were obtained with both sorbents at each amount tested; and 50.0 mg appeared to be the optimum amount for both sorbents under the conditions applied (the concentrations employed were

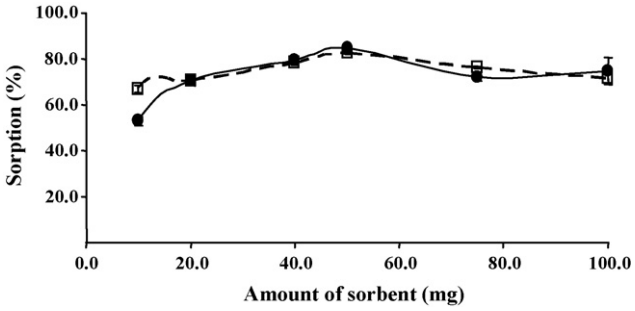

Fig. 4. Effect of sorbent amount on the sorption of 30.0 mL 100.0 μg L^{-1} As(V) solution at pH 3.0, 25 °C sorption temperature. (●) chitosan, (□) chitosan-immobilized sodium silicate, $n = 3$.

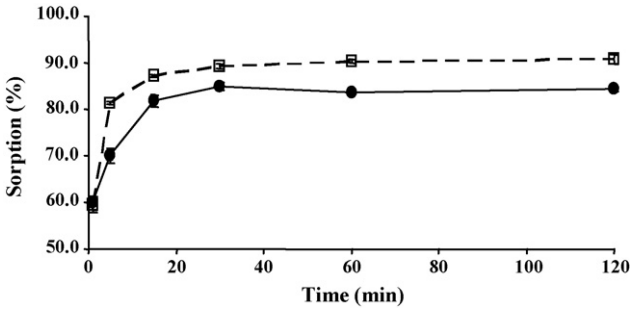

Fig. 5. Effect of shaking time for 50.0 mg sorbent at pH 3.0 in 30.0 mL 100.0 μg L^{-1} As(V) solution at 25 °C sorption temperature. (●) chitosan, (□) chitosan-immobilized sodium silicate, $n = 3$.

lower than the sorption capacity of the sorbents). Otherwise, the amount of chitosan-immobilized sodium silicate would be about three times that of the chitosan itself since the immobilized sorbent contains about 33% chitosan. This behavior can also be explained by the increased surface area of the immobilized sorbent (32.6 m^2/g) compared to that of chitosan (9.1 m^2/g).

Effect of shaking time on the percentage sorption was investigated for 1, 5, 15, 30, 60 and 120 min; the results are given in Fig. 5. As seen in the figure, the results are very similar for both sorbents especially after 15 min which can be taken as the equilibration time. However, the sorption rate before 15 min for the immobilized sorbent was sharper than that of chitosan which can be the indication of less diffusion restricted sorption in chitosan-immobilized sodium silicate.

3.2.3. Effect of solution temperature on the sorption of As(V)

The extent of sorption of As(V) by chitosan and chitosan-immobilized sodium silicate decreases as temperature increases. This behavior is reflected into the negative values of ΔH^o, given in Table 1, which designate the exothermic nature of sorption. The negative ΔS^o values suggest that sorption is associated with a decrease in system entropy probably due to the restriction on the mobility of the sorbate ions that results from binding to the sorbent surface. The process thus appears to be enthalpy-driven. Both parameters contribute to negative ΔG^o values which in turn results when the equilibrium position of a reaction occurs closer to the products.

Table 1
Thermodynamic parameters of chitosan and chitosan-immobilized sodium silicate (50.0 mg sorbent, 30.0 mL of 100.0 μg L^{-1} As(V) at pH 3.0, $n = 3$).

	ΔG^o (kJ/mol)		ΔH^o (kJ/mol)	ΔS^o (J/mol K)	
	298 K	323 K		298 K	323 K
Chitosan	−20.2	−19.8	−24.7	−15.1	−15.1
Chitosan-immobilized sodium silicate	−21.1	−20.9	−23.8	−9.1	−9.1

3.2.4. Successive loading

Sequential sorption of arsenate by chitosan and chitosan-immobilized sodium silicate for two different concentrations was investigated. It can be seen from Fig. 6a that the sorption percentage starts to decrease with the third loading and previously sorbed arsenate even starts to be released from chitosan surface after the sixth loading. This observation cannot be related to the sorption capacity of chitosan since a similar trend was observed for both 100.0 and 1000.0 μg L^{-1} concentrations. In order to clarify this further, the cumulative amount of arsenate on the sorbent was also determined which was approximately 0.015 mmol/g at the sixth load. This amount is still lower than the maximum sorption capacity of chitosan. Several reasons can be suggested to explain the decrease in sorption capacity. Firstly, a gradual dissolution of flakes was observed after each loading which might have caused a decrease in the sorption capacity. More importantly, the dissolution of chitosan flakes must have been associated with the release of previously adsorbed species from the surface which eventually increased the arsenate concentration in the solution. Secondly, although it needs further consideration, it can be speculated that the surface positive charge of chitosan after each loading could have been reduced which might also have resulted in a decrease in the sorption percentage after each step.

In contrast to chitosan, chitosan-immobilized sodium silicate has shown a better chemical stability in a way that no negative sorption (no release from chitosan surface) was observed although the sorption percentage started to decrease after the second load for both concentrations (Fig. 6b). As in the case of chitosan, the decrease in the sorption percentage of chitosan-immobilized sodium silicate cannot be explained by the reduction in the sorption capacity of the immobilized sorbent. Similarly, from the cumulative amount of arsenate on the immobilized sorbent, the amount of arsenate even at the tenth load is approximately 0.016 mmol/g which is about half of the maximum sorption capacity of chitosan-immobilized sodium silicate.

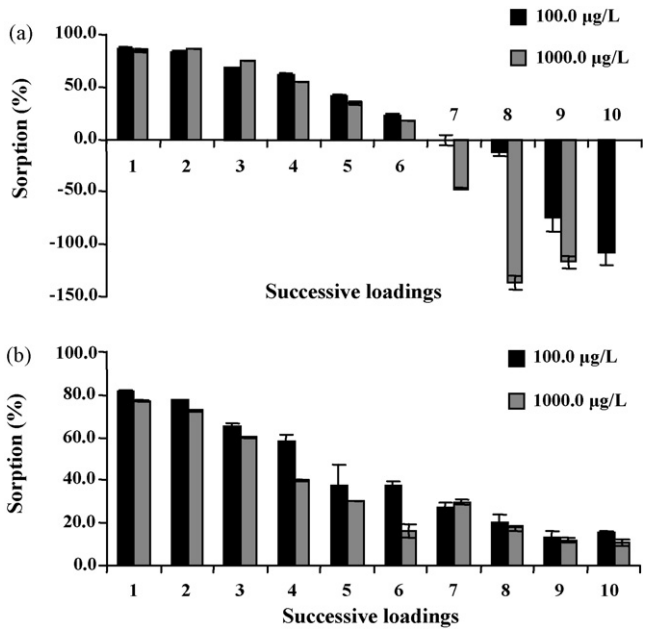

Fig. 6. Percent sorption of (a) chitosan and (b) chitosan-immobilized sodium silicate for 10 successive loadings in pH 3.0, 30.0 mL of 100.0 and 1000.0 μg L^{-1} As(V) concentrations, 50.0 mg sorbent, 30 min at 25 °C batch sorption, $n = 3$.

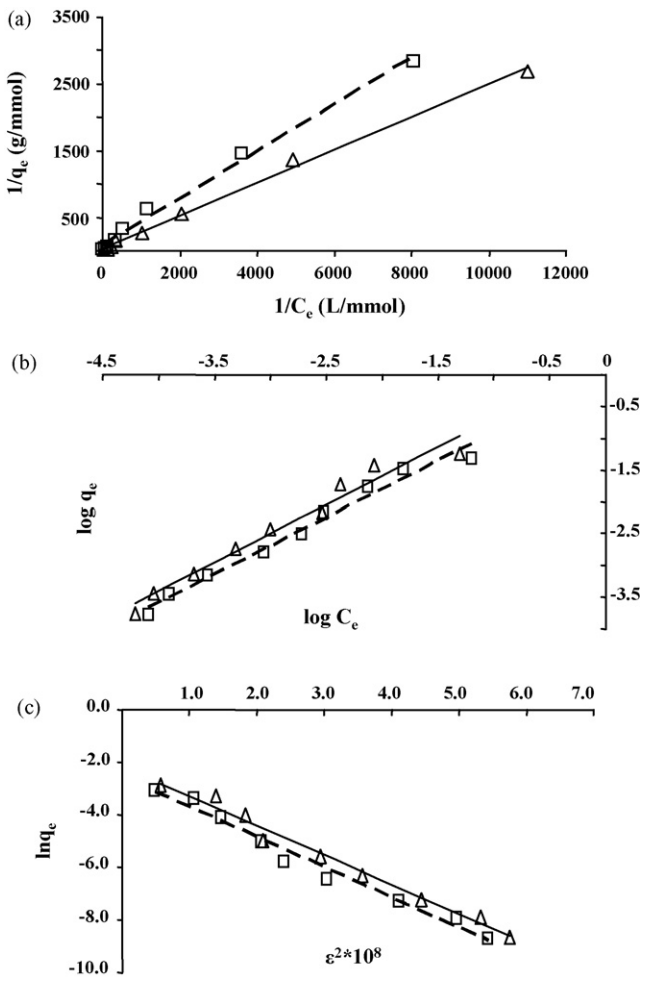

Fig. 7. Linear fits of (a) Langmuir, (b) Freundlich, (c) Dubinin–Radushkevich models for arsenate sorption by (△) chitosan and (□) chitosan-immobilized sodium silicate.

3.3. Sorption isotherm models

Freundlich, Dubinin–Radushkevich and Langmuir isotherm models were tested for sorption of arsenate by chitosan and chitosan-immobilized sodium silicate. The linearized forms of models (Fig. 7) were used for the calculation of coefficients and the results are summarized in Table 2. According to the linear correlation coefficients (R^2), Langmuir model, with R^2 close to unity, appears as the most suitable isotherm for describing the sorption of arsenate on chitosan and chitosan-immobilized sodium silicate. However, D–R isotherm can be considered also to provide adequate description of the sorption data.

3.4. Desorption studies

As described in Section 2.7, two different elution strategies were followed to take the sorbed arsenate ion back into solution from chitosan or chitosan-immobilized sodium silicate. In the first method, 2% (v/v) acetic acid was used and chitosan was completely dissolved together with the previously sorbed arsenate. On the other hand, in the case of chitosan-immobilized sodium silicate, acetic acid was not effective even though acid concentration and volume, and desorption time were doubled. Therefore, as a second method, 1.0% (w/v) L-cysteine prepared in a pH 3.0 solution adjusted with HCl was used as the eluent which was expected to reduce the adsorbed arsenate (As(V)) to arsenite (As(III), non-adsorbed form) through the thiol groups [35 and the references therein]. In the meantime, arsenic in the solution was converted to the hydride forming form. This eluent worked with 100% efficiency and was used in all desorption studies.

3.5. Interference studies

As explained in Section 2.8, two groups of possible interferants were prepared; the first group contained the hydride forming elements; namely, Sb(III), Sb(V), Te(IV), Te(VI), Se(IV), and Se(VI) ions, and the second group included the oxyions of Mo(VI) and V(V) which are expected to be adsorbed by chitosan. It should also be mentioned that the interference effect was classified into two: firstly, whether the ion caused the sorption to increase-or-decrease at least 30% of the original signal obtained with As(V) only, and secondly, the adsorbed ion caused at least 30% increase-or-decrease in the hydride signal of As. For this purpose, all the solutions were analyzed with both HGAAS and ICP-MS.

As a starting point, the sorption of chitosan towards each of the ions mentioned above was investigated under the conditions optimized for arsenate sorption but in the absence of arsenate; and it was found that chitosan shows affinity to all species except Te. The sorption percentage was almost 100% for Mo(VI), V(V) and Se(VI) in both concentrations; namely, 100.0 and 1000.0 $\mu g\,L^{-1}$. These results were in agreement with several studies of Guibal et al. in which they report that the sorption of Mo(VI) by cross-linked chitosan beads was maximum at pH 3 [13]. Similarly Qian et al. found that optimum pH value for maximum sorption of V(V) ions was 3 [40].

No interference was observed from neither Se(IV) nor Se(VI) for an As(V) concentration of 10.0 $\mu g\,L^{-1}$ although chitosan shows high affinity for Se(VI). On the other hand, when As(V) concentration was 100.0 $\mu g\,L^{-1}$, a decrease in sorption percentage was observed in the presence of 1000.0 $\mu g\,L^{-1}$ Se(IV). Sb(V) and Sb(III)

Table 2
Summary of models coefficients (Solution volume, shaking time, solution pH, sorbent amount and reaction temperature were 30.0 mL, 30 min, pH 3.0, 50.0 mg, and 25 °C, respectively, $n = 3$.).

Adsorption model	Parameter	Chitosan	Chitosan-immobilized sodium silicate
Langmuir	R^2	0.9963	0.9918
	Q_{max} (mmol/g)	0.03038	0.01276
	B (L/mmol)	133.43	222.25
Freundlich	R^2	0.9649	0.9781
	K_F	1.655	0.9309
	$1/n$	0.9054	0.8883

	B (mol/kJ)^2	1×10^{-8}	1×10^{-8}
	q_s	0.1166	0.0781
	E (kJ/mol)	7.07	7.07

Table 3
The comparative spike recovery of As(V) and As(III) ions from chitosan and chitosan-immobilized sodium silicate (Sorption conditions: solution volume, shaking time, solution pH, sorbent amount and reaction temperature were 30.0 mL, 30 min, pH 3.0, 50.0 mg, and 25 °C, respectively, $n = 3$; elution conditions: eluent volume, shaking time, solution pH and reaction temperature were 30.0 mL of 1.0% (w/v) L-cysteine solution, 30 min, pH 3.0 and 25 °C, respectively, $n = 3$.).

Solution	Spike recovery (%)			
	Chitosan		Chitosan-immobilized sodium silicate	
	ICP-MS	HGAAS	ICP-MS	HGAAS
100.0 μg L^{-1} As(V)	110.0 (±3.7)	96.3 (±2.5)	104.6 (±3.5)	102.2 (±5.8)
100.0 μg L^{-1} As(III)	10.6 (±0.4)	10.0 (±0.7)	13.1 (±0.2)	13.6 (±2.3)
100.0 μg L^{-1} As(V) + 100.0 μg L^{-1} As(III)	111.2 (±2.4)	95.9 (±3.3)	104.1 (±1.0)	102.4 (±2.7)

behaved differently from the other hydride forming elements in a way that they caused a decrease in hydride signal of arsenic when their concentrations were 1000.0 μg L^{-1}. This finding is in accordance with the results obtained in one of our earlier studies which was about the gas phase interference of Sb(III) during hydride formation in HGAAS system [41]. The interference caused only during hydride formation can be eliminated with the use of ICP-MS if it is available in the laboratory. An unexpected interference (decrease in the arsenate sorption percentage by chitosan) was observed for both As(V) concentrations in the presence of 1000.0 μg L^{-1} Te(IV). As mentioned in the previous paragraph, chitosan demonstrates a very low affinity to Te(IV) (<1%) under the optimized sorption conditions for As(V). It should not be speculated much on this observation; but it can be stated that the presence of Te(IV) may change the reaction conditions during the sorption of As(V) by chitosan which needs further investigation. Although chitosan showed high affinity for V(V), this property did not cause any reduction in the signal due to the high capacity of chitosan. Instead, V(V) caused a small increase in As(V) sorption which necessitates the close control of this oxyion in the sample matrixes. Totally different behavior was obtained in the case of Mo(VI) for two different As(V) concentrations; when As(V) was only 10.0 μg L^{-1}, none of the Mo(VI) concentrations caused interference. However, when As(V) and Mo(VI) concentrations were both 100.0 μg L^{-1}, a decrease in the sorption capacity of chitosan towards As(V) was observed.

3.6. Method validation

The proposed methodology was validated, as explained in Section 2.9, both via spike recovery experiments and also through the analysis of a standard reference material. Initially, arsenate/arsenite speciation was performed using chitosan and chitosan-immobilized sodium silicate. As seen in Table 3, both chitosan and chitosan-immobilized sodium silicate have been found effective in arsenate recovery from spiked solutions whereas they have demonstrated a very low sorption (about 10%) towards arsenite. In addition to the above solutions containing only one arsenic species, either As(V) or As(III), solutions containing both As(III) and As(V) were analyzed with the proposed method to see if the presence of As(III) affected the sorption of As(V). The results indicate that sorption of As(V) is not affected from the presence of As(III) under the conditions employed as expected and this demonstrates the arsenic speciation capability of the chitosan and the chitosan-immobilized sodium silicate.

Subsequently, spike recovery tests were also carried out with four different types of water; namely, ultra-pure, bottled drinking, tap, and sea water. Spiked samples were subjected to the same sorption/elution cycles as previously. The results given in Table 4 show that the proposed methodology works efficiently for ultra-pure and bottled drinking water samples where the recovery values were very close to 100%. The municipality tap water of Urla where the IYTE campus is situated is very hard with high carbonate content. The hard matrix of this tap water had caused a change in Sb(III)/Sb(V) equilibrium in a previous study in which the use of L-cysteine was required to reduce Sb(V) to Sb(III) before the sorption of Sb(III) by Duolite GT-73 chelating resin [42]. Here, the low recovery value given in Table 4 (43.2%) is thought to be due to the high ionic strength of the tap water rather than its effect on the As(III)/As(V) equilibrium. The situation was even worst in the case of spiked sea water in which arsenate could not be recovered because of the very high ionic strength of the solution.

Finally, the accuracy of the proposed methodology was investigated through the analysis of a standard reference material, SRM from NIST (Natural Water – Trace Elements, Cat. No. 1640). Since the oxidation state of arsenic was not stated in the certificate, the SRM was analyzed both with and without a pre-oxidation step and the results compared. The same strategy was also followed with both As(III) and As(V) standard solutions to see the effect of the pre-oxidation step. As expected, SRM and As(III) solutions gave almost the same recovery value of 0% which also showed the importance of pre-oxidation step for unknown samples. When HNO_3 pre-oxidation step was applied, As(V) signal was assumed to be the reference (matrix-matched standard) and As(III) signal was compared to this signal after being oxidized to As(V). A conversion of 95% indicated the success of the oxidation process which also guaranteed the As(III) → As(V) conversion in the SRM. The results demonstrate the good agreement between the result of the proposed method (26.6 ± 2.4 μg L^{-1}) and the certified value (26.67 μg L^{-1}). This strong agreement may also indicate the validity of the method to the natural water samples of low and intermediate ionic strength.

Table 4
Percent recovery for spiked arsenate ion with ultra-pure, bottled, tap and sea water samples after desorption from chitosan (Sorption parameters: solution volume, shaking time, solution pH, sorbent amount and reaction temperature were 15.0 mL, 30 min, pH 3.0, 50.0 mg, and 25 °C, respectively, $n = 3$.).

Water type	Spiked As(V) concentration (μg L^{-1})		
	Initial	Final	Recovery %
Ultra-pure	10.0	11.4 (±0.5)	114.2 (±4.5)
Bottled drinking	10.0	11.2 (±0.2)	112.3 (±1.6)
Tap	10.0	4.3 (±0.4)	43.2 (±4.2)
Sea	10.0	0.0 (±0.1)	0.0 (±0.8)

4. Conclusions

It has been shown that chitosan and chitosan-immobilized sodium silicate can be applied in the sorption of As(V) from several water types. Sodium silicate as an immobilization matrix has the advantage of tuning the immobilized amount of biomass, in this case chitosan, in a narrow synthesis time. The optimum pH for As(V) sorption for both the chitosan and chitosan-immobilized sodium silicate was shown to be 3.0 at which amino groups of chitosan are protonated and the predominant form of As(V) is $H_2AsO_4^-$. Therefore, sorption was assumed to be electrostatic in nature. Speciation of As species was shown to be feasible since no sorption was obtained for As(III) at any pH investigated. If both As(III) and As(V) are to be determined, a pre-oxidation step is necessary. Desorption from the sorbents was realized with 1.0% (w/v) L-cysteine prepared in a pH 3.0 solution adjusted with HCl.

Among the isotherm models tested, Langmuir model appeared to be the most appropriate. Sorption of As(V) by the two sorbents decreased with increase in solution temperature. This exothermic behavior is associated with a decrease in system entropy. Through sequential sorption studies, it was shown that chitosan-immobilized sodium silicate has exhibited a better chemical stability than the chitosan itself which demonstrates the advantage of immobilization strategy.

The results of the interference study have shown that As(V) sorption by chitosan can be decreased especially at high interferant concentration. An exception to this observation was obtained with Sb species which caused gas phase interference during hydride generation rather than decreasing the sorption percentage. In addition, when the concentration of As(V) is 100.0 $\mu g\,L^{-1}$, the presence of V(V) in the samples causes an increase in As(V) sorption.

It can be concluded that the chitosan and chitosan-immobilized sodium silicate sorbents can be used in the sorption/speciation of As(V) from medium-to-low ionic strength solutions prior to its determination with atomic spectrometric techniques like AAS, ICP-AES, or ICP-MS. In addition, the sorbents can be used in the removal of As(V) (or As(III) after a proper oxidation step) from drinking water.

ABSTRACT

Cu nanoparticles have been electrochemically incorporated polypyrrole film that was used for modification of the glassy carbon electrode surface. The performance of the electrode has been characterized by cyclic voltammetry and atomic force microscopy. The electrode has shown high electrocatalytic activity towards the oxidation of dopamine (DA) and uric acid (UA) simultaneously in a phosphate buffer solution (pH 7.00). The electrocatalytic oxidation currents of UA and DA were found linearly related to concentration over the range 1×10^{-9} to 1×10^{-5} M for UA and 1×10^{-9} to 1×10^{-7} M for DA using DPVs method. The detection limits were determined as 8×10^{-10} M (s/n = 3) for UA and 8.5×10^{-10} M (s/n = 3) for DA at a signal-to-noise ratio of 3.

1. Introduction

Dopamine (DA), one of the naturally occurring catecholamines, plays an important role as a neurotransmitter in the renal, hormonal, cardiovascular and central nervous systems. Low levels of DA can lead to brain disorders such as schizophrenia and Parkinson's disease [1–3]. Uric acid (2,6,8-trihydroxypurine) on the other hand, is the main final product of purine metabolism in the human body. Extreme abnormalities of UA levels cause many diseases, such as gout, hyperuricaemia and Lesch–Nyan disease [4–6]. Therefore a simple, sensitive and accurate analytical method for the quantization of DA and UA would be useful for physiological investigations as well as early diagnosis of diseases [7]. Voltammetric techniques offer a powerful tool for the simultaneous determinations of DA and UA in buffered solutions [8–10]. However, the presence of ascorbic acid (AA) in such samples including both DA and UA, the electrochemical oxidation peak of AA takes place at very close potentials and then, homogeneous electron transfer reaction have been observed at bare electrodes [2,11–13]. As well known, modified electrodes may offer higher selectivity, sensitivity, greater time efficiency and higher stability than the bare electrodes. Therefore, several modifier materials such as polymers [14–17], DNA doped polymers [18], dye doped sol–gels [19], metal oxides [20], carbon nanotubes [21–23] and metal nanoparticles (MNPs) [24–26] have been used to overcome this problem.

Among them, MNPs modified electrodes have drawn particular attention due to their high surface area, effective mass transport, catalysis and control over local microenvironment compared to macro-electrodes [27,28]. However, the MNPs at the electrode surface can be fragile in the absence of stabilizing conductive material. To solve this problem, in the first step, the electrode surface can be modified with some conductive stabilizing materials such as ligands, carbon nanotubes and polymers [29,30]. Then, the MNPs are attached to the modified electrode surface. Moreover, the porous structure of conducting polymer allows dispersing of the metal nanoparticles into the polymer matrix and generates additional electrocatalytic sites [31–33]. Polypyrrole (PPy) is one of the most important conducting polymers to support the metal nanoparticles. Some metal nanoparticles–polypyrrole composites have already been reported at PPy/Pt [34,35], PPy/Ag [36], PPy/Ti [37] and PPy/Au [38,39] conducting composites. According to our knowledge, there is no any reported data for the simultaneous determination of DA and UA at nano-Cu/PPy/GCE.

In the present study, a modified electrode was prepared by electrochemical deposition of Cu-metal nanoparticles in over-oxidized polypyrrole film modified GCE and the performance of the electrode developed was characterized by cyclic voltammetry and close surface examination was made by atomic force microscopy (AFM). The Cu nanoparticles incorporated polypyrrole modified GCE was

utilized as the sensing matrix for the simultaneous determination of DA and UA at nanomolar levels.

2. Experimental

2.1. Reagents

Pyrrole, dopamine and uric acid were purchased from Sigma and used without further purification. Pyrrole (Py) was triply distilled until a colorless liquid was obtained and it was then stored under nitrogen before use. Sodium dodecylsulfate (SDS), $CuSO_4$, H_2SO_4, NaOH, ethanol were of analytical-reagent grade and supplied from Sigma. All of the solutions were prepared using ultrapure water provided from an 18 MΩ cm Milli-Q system. All experiments were carried out at ambient temperature and highly pure nitrogen was kept flowing over the solution during electrochemical experiments.

2.2. Apparatus

Voltammetric measurements were carried out using a Bass 100B Electrochemical Analyser and Ivium Stat Electrochemical Interface equipped with a three electrode system consisting of a working electrode (GCE, PPy/GCE and nano-Cu/PPy/GCE), an auxiliary platinum electrode and an Ag/AgCl (sat. KCl) were used as reference electrode. Cyclic, differential pulse (dp) and time base modes were utilized throughout the studies. The pH measurements were made with WTW handheld meter pH 330i ion analyser. Ambios Q-Scope Atomic Force Microscopy was used for the characterization of metal nanoparticles on the electrode surfaces. Bandelin Sonorex model ultrasonic bath was used for cleaning the electrodes.

2.3. Preparation of polypyrrole film modified GCE

A bare GCE was polished successively with different grades of Al_2O_3 slurry (0.05–3 μm) on a synthetic cloth, rinsed with pure water, and sonicated subsequently in a 1:1 ultrapure water and ethanol for 5 min. Electrochemical deposition of polypyrrole (PPy) on GCE was performed using cyclic voltammetry in a solution of 0.1 M Py + 0.01 M SDS in a potential range of −0.35 to 0.85 V versus Ag/AgCl (sat. KCl) at a scan rate of 20 mV s^{-1} in a period of three cycles [40]. Then, the modified electrode was rinsed thoroughly with ultrapure water and transferred into a voltammetric cell containing 0.1 M NaOH solution for electrochemical over-oxidation of the conductive PPy film at +1.0 V for 300 s. The obtained electrode was ready for use after a final wash with ultrapure water and denoted as PPy/GCE.

2.4. Preparation of metal nano-clusters modified polypyrrole film GCE

The Cu-metal nanoparticles (Cu-MNPs) were electrochemically deposited on the PPy/GCE surface by cycling the potential from 0.00 to 1.10 V in 1 mM $CuSO_4 + H_2SO_4$ solution at a scan rate of 50 mV s^{-1} for 10 times. The obtained Cu nanoparticles modified polypyrrole film electrode was washed with ultrapure water and indicated as nano-Cu/PPy/GCE.

3. Results and discussion

3.1. Characterization of surface morphology modified GCE with PPy and nano-Cu/PPy

As well known, the thickness of polymeric film on the electrode surface can be changed by controlling the amount of charge passed [41–43]. Here, 24 mC cm^{-2} integrated charge was used to generate 0.10 μm film thickness in the polymerization procedure. The bare GCE, PPy/GCE and nano-Cu/PPy/GCE surfaces were characterized using AFM measurements. Large pores on the PPy film were obtained by using dodecylsulfate as doping ions as indicated in the literature [40].

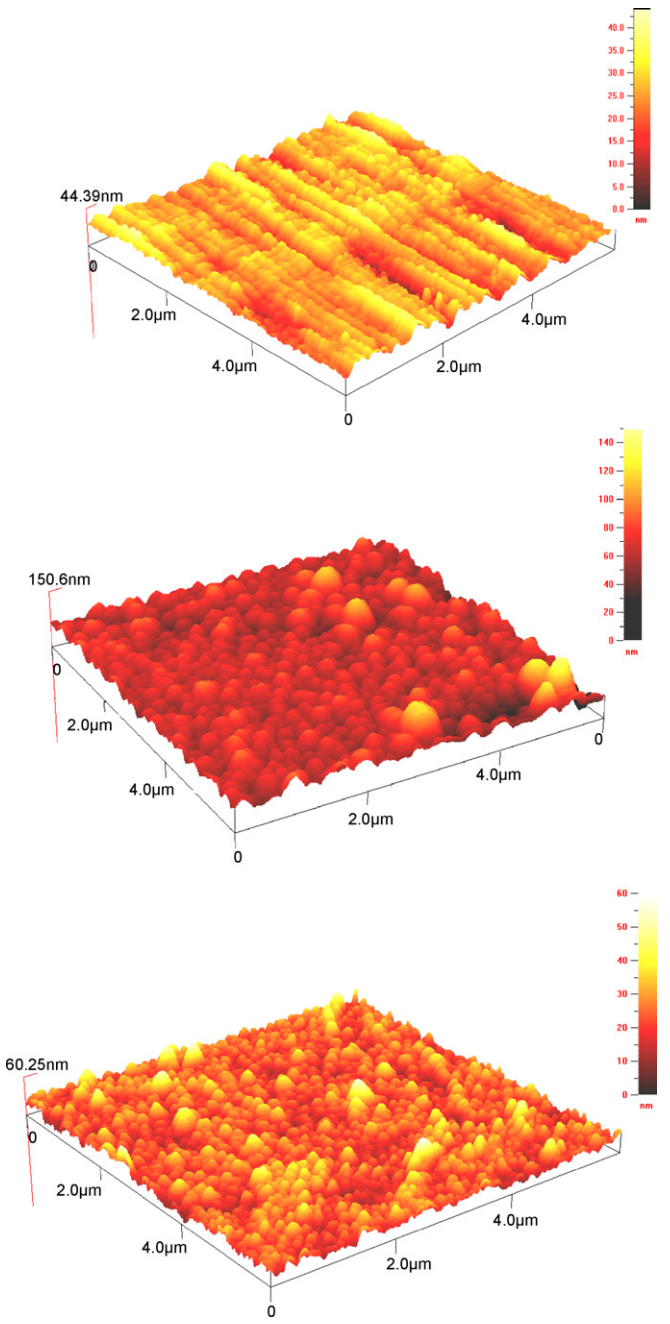

Fig. 1. AFM images of the (A) bare GCE, (B) PPy/GCE, and (C) nano-Cu/PPy/GCE surfaces as three-dimensional views.

The atomic force microscopy (AFM) images have shown the surface morphology and film thickness of the bare and modified electrodes (Fig. 1). Three-dimensional images clearly displayed partially rough surface of the bare GCE (Fig. 1A) and after the modification of the surface with PPy film, even rougher surface image was obtained with irregular islands (Fig. 1B). The average film thickness was measured as ~100 nm with three-dimensional AFM analyses. From Fig. 1C it was evident that the Cu nanoparticles with a 60 nm average diameter were homogeneously distributed throughout the film.

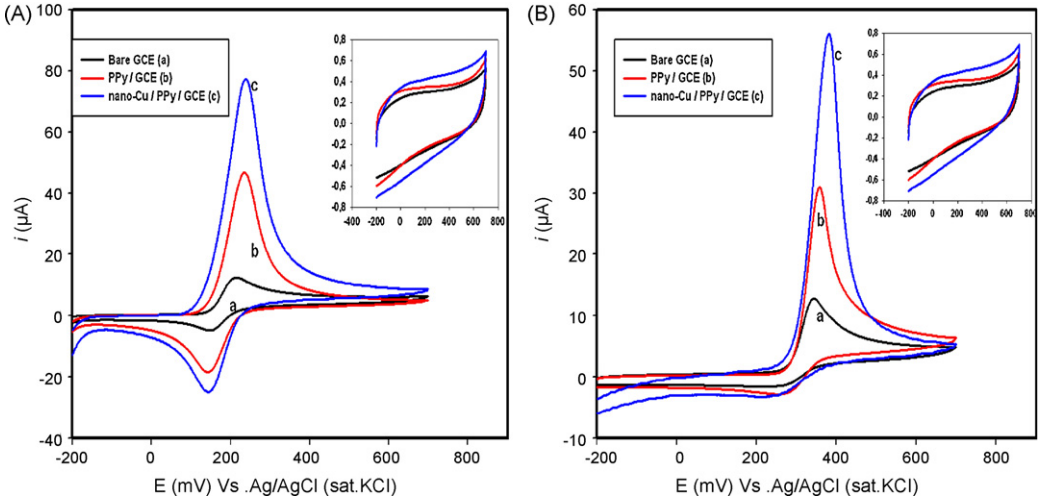

Fig. 2. Cyclic voltammograms obtained at bare GCE (a), PPy/GCE (b), and nano-Cu/PPy/GCE (c) in the absence (inset) and in the presence of (A) 5×10^{-4} M DA and (B) 5×10^{-4} M UA with a scan rate of 50 mV s^{-1} in 0.1 M pH 7.00 PBS.

3.2. Electrocatalytic oxidation of DA and UA on nano-Cu/PPy/GCE

In order to achieve optimal conditions for voltammetric determination of DA and UA, main parameters related to the film formation and solution characteristics were evaluated. These parameters were selected as the pyrrole concentration, electrochemical over-oxidation time of polypyrrole, NaOH concentration, cycle number that effect on electrodeposition of Cu nano-clusters and the pH of supporting electrolyte solution. Optimal conditions were elucidated by means of measuring the peak currents of both compounds with one variable at time method and determined as follows: 0.1 M pyrrole, 300 s, 0.1 M NaOH, 10 cycles for electrodeposition of Cu nanoparticles and pH 7.0 for electrolyte medium, respectively.

Fig. 2 shows the cyclic voltammograms recorded at PPy/GCE and nano-Cu/PPy/GCE in comparison to the bare GCE. Clear background signal was obtained in the absence of DA (Fig. 2A-inset) for the bare and modified electrodes. Upon addition of DA to be 5×10^{-4} M in the cell, oxidation and subsequent reduction peaks have appeared at 0.24 and 0.16 V, respectively indicating a quasireversible electrode process probably due to the diffusion barrier of the polymeric film. Similar peak potentials have been obtained with bare electrode with much smaller peak currents. Electrochemical reaction kinetics were improved as the copper nanoparticles were inserted to the polymeric film matrix by subsequent cycling of the potential in a range of 0–1.1 V. Therefore, nano-Cu/PPy/GCE has exhibited a large peak to peak separation with almost reversible electrochemical behavior ($\Delta E_p = 0.08$ V). The peak currents have also increased 7 times compared with bare GCE and twice as the PPy/GCE. So far the peak characteristics have clearly indicated an electrocatalytic oxidation of DA at PPy modified electrodes by the gain of a more active surface compared to the bare GCE. The increase in the analytical determination sensitivity of DA is a clear indication of the enlargement of active surface area of the electrode modified by PPy and nano-Cu clusters.

The influence of pH solution on the electrochemistry of DA oxidation was studied. The anodic peak potential was shifted linearly with the increase of solution pH with a slope of 0.053 V/pH. The magnitude of the slope for DA oxidation most probably points out that two protons could be involved in the electrode reaction.

Cyclic voltammograms of UA in pH 7.0 phosphate buffer solution at bare GCE, PPy and nano-Cu/PPy/GCE are given in Fig. 2B. UA has shown a quasireversible electrochemical behavior with an anodic peak potential of about 0.35, 0.36 and 0.38 V, respectively. All three voltammograms have displayed a small cathodic peak at 0.28 V indicating a sluggish cathodic electron transfer. Under identical conditions, both PPy/GCE and nano-Cu/PPy/GCE offer significantly increased peak current to UA oxidation. The results suggest a more efficient oxidation reaction of UA at nano-Cu/PPy/GCE probably due to the effective surface area supplied by both polymeric film and Cu nanoparticles on the GCE.

The effect of pH of electrolyte solutions might have a pronounced effect on the response and therefore, oxidation process of 5×10^{-4} M UA was studied in different electrolyte media by cyclic voltammetry. The pH dependencies of E_a clearly illustrate that the electrocatalytic oxidation peak shifts to more negative potentials with increasing the pH. The slope of 0.054 V per pH unit for UA oxidation showed that two protons were involved in the electrode reaction at nano-Cu/PPy/GCE. The highest oxidation current was obtained in neutral pH. The oxidation current was decreased at both lower pH and higher pH than 8 due to the instability of UA under both acidic and alkaline solutions.

3.3. Separation of electrochemical response of DA and UA at modified electrodes

Curves in Fig. 3a–c the cyclic voltammograms of a 5×10^{-4} M DA and UA mixture at bare GCE, PPy/GCE and nano-Cu/PPy/GCE, respectively. Two broad peaks were obtained in ongoing scan and convolution of the oxidation peaks has limited the selectivity and sensitivity of simultaneous determination of DA and UA at a bare GCE. Fig. 3b and c shows that modification of GCE surface with PPy film and incorporation of Cu nanoparticles have resolved the merged voltammetric peaks into two well-defined oxidation peaks at 0.20 and 0.35 V for DA and UA, respectively. The separation of the two oxidation peaks offers the simultaneous determination of DA and UA in a homogeneous solution. Cu nanoparticles deposition also enhanced the catalytic activity of PPy/GCE for oxidation of a DA and UA mixture in both way of oxidation potentials and peak currents. This increase in the catalytic current can be explained by a higher density of carbonyl groups generated on the PPy film after the electrochemical over-oxidation process. The existence of dense carbonyl groups on the PPy film could provide a selective interface for the molecular interaction of DA and UA via hydrogen bonds with the proton donating group of –NH [16].

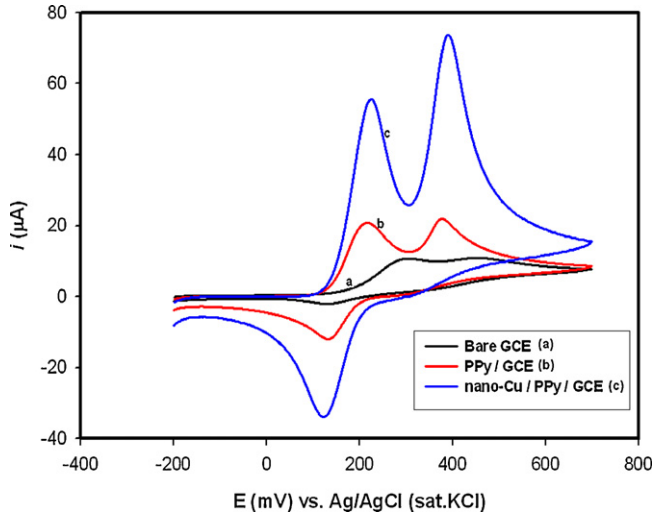

Fig. 3. Cyclic voltammograms of 5×10^{-4} M UA + 5×10^{-4} M DA at bare GCE (a), PPy/GCE (b), and nano-Cu/PPy/GCE (c) with a scan rate of 50 mV s^{-1}.

3.4. Differential pulse voltammetric determination of uric acid and dopamine

Differential pulse voltammetry (DPV) has a discrimination against background noise and offers much higher current sensitivity and better peak separation than cyclic voltammetry. Therefore, DPV was used for the sensitive determination of UA and DA at nano-Cu/PPy/GCE and compared with both PPy/GCE and bare GCE. Under the optimal conditions, the electrocatalytic oxidation currents of UA and DA were linearly related to concentration over the range 1×10^{-9} to 1×10^{-5} M with a coefficient of determination of 0.9973 for UA (figure not shown), and 1×10^{-9} to 1×10^{-7} M with a coefficient of determination of 0.9973 for DA (figure not shown). The regression equations were $i_{pa} = 0.026 + 2.22C$ (i_{pa}: μA, C: μmol/L) and the detection limit 8×10^{-10} M (s/n = 3) for UA and $i_{pa} = 13.761C - 0.024$ and the detection limit was found to be 8.5×10^{-10} M for DA (s/n = 3).

3.5. Selective determination of DA in the presence of a fixed concentration of UA

Fig. 4 displays the DPV obtained for the different concentrations of DA in the presence of 5.0×10^{-6} M concentration of UA at nano-Cu/PPy/GCE. The oxidation peaks with adequate resolution for both compounds were obtained at 0.17 V for DA and 0.36 V for UA using nano-Cu/PPy/GCE. The oxidation peak current of DA has built up linearly ($R^2 = 0.9945$) with increasing concentration in the range of 8.0×10^{-8} to 1.0×10^{-5} M, whereas the voltammetric peak current of UA remained the same.

Similarly, voltammetric determination of UA was carried out in the presence of DA at fixed concentration being 5.0×10^{-6} M. As shown in Fig. 5, no obvious change in the oxidation current of DA was observed while varying concentration of UA and the peak current of UA increased linearly with increasing of UA concentration (8.0×10^{-8} to 1.0×10^{-5} M) with a coefficient of determination of 0.9941.

Detection limits were estimated to be 3.0×10^{-9} mol/L for DA and 4.0×10^{-9} mol/L for UA using 3σ/slope ratio, where σ is the standard deviation of the mean value for 5 independent voltammograms of the blank solution. Stable peak observations at fixed concentration while increasing the other analyte concentration indicated that the oxidation of DA and UA at nano-Cu/PPy/GCE is relatively concentration independent.

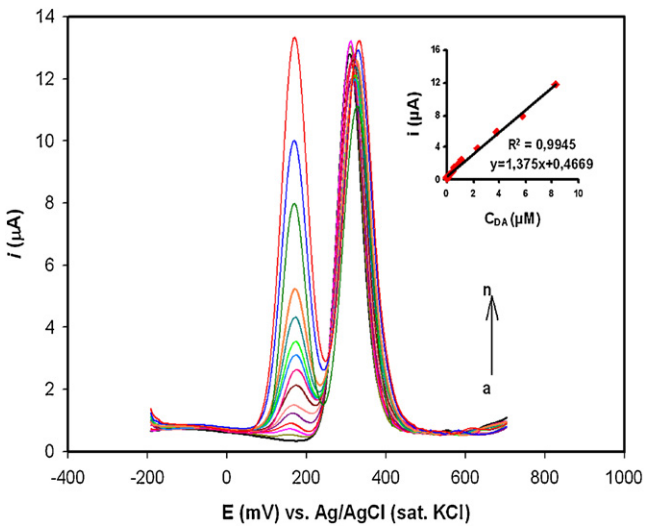

Fig. 4. Differential pulse voltammograms of DA in the presence of UA (5×10^{-6} M) at nano-Cu/PPy/GCE in 0.1 M pH 7.00 PBS with scan rate 20 mV s^{-1} and pulse amplitude 50 mV. DA (a–n): 0.00, 1.0×10^{-8}, 3.0×10^{-8}, 5.0×10^{-8}, 7.0×10^{-8}, 1.0×10^{-7}, 2.0×10^{-7}, 4.0×10^{-7}, 6.0×10^{-7}, 8.0×10^{-7}, 1.0×10^{-6}, 2.0×10^{-6}, 4.0×10^{-6}, 6.0×10^{-6}, and 8.0×10^{-6} M. The inset shows the plot of current versus concentration of DA.

3.6. DPV of DA and UA in the presence of AA

Electrochemical behavior of DA and UA was examined in the presence of AA at PPy/GCE and nano-Cu/PPy/GCE in comparison to the bare glassy carbon electrode. As can be seen from Fig. 6, two peaks at 0.19 V for AA and DA and at 0.38 V for UA (curves a and b) can be detected. Most sensitive results were obtained with nano-Cu/PPy/GCE modified electrode however, these electrodes cannot separate AA and DA oxidation peaks. To avoid the interference of AA on the DA determination at nano-Cu/PPy/GCE, the Cu nanoparticles deposited to the electrode surface was performed in the presence of methionine compound. Therefore, the Cu nanoparticles modified PPy/GCE electrode has accomplished to separate the AA, DA and UA responses into three well-defined peaks with an additional peak at

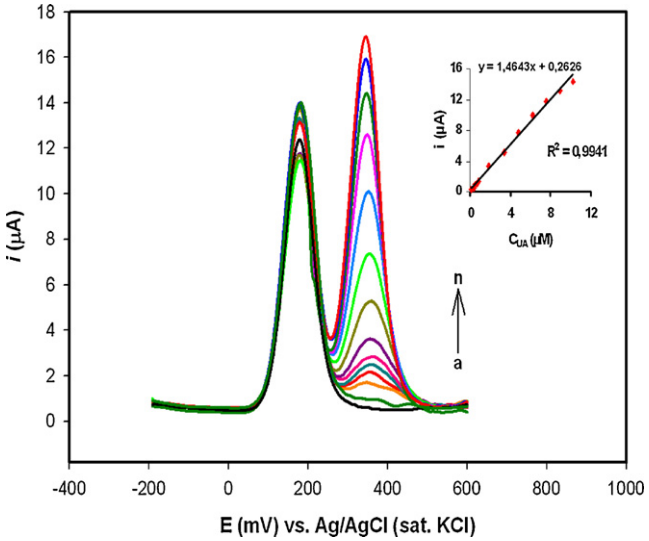

Fig. 5. Differential pulse voltammograms of UA in the presence of DA (5×10^{-6} M) at nano-Cu/PPy/GCE in 0.1 M pH 7.00 PBS with scan rate 20 mV s^{-1} and pulse amplitude 50 mV. UA (a–n): 0.00, 8.0×10^{-8}, 1.0×10^{-7}, 3.0×10^{-7}, 5.0×10^{-7}, 6.0×10^{-7}, 8.0×10^{-7}, 9.6×10^{-7}, 1×10^{-6}, 2×10^{-6}, 4×10^{-6}, 6.0×10^{-6}, 8.0×10^{-6}, and 1.0×10^{-5} M. The inset shows the plot of current versus concentration of UA.

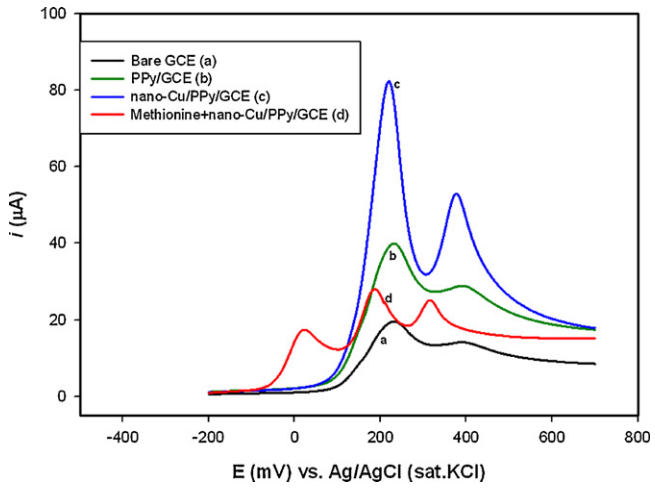

Fig. 6. Differential pulse voltammograms obtained at bare GCE (a), PPy/GCE (b), nano-Cu/PPy/GCE (c) and methionine + nano-Cu/PPy/GCE (d) in the presence of 5×10^{-5} M UA + 5×10^{-5} M DA, 5×10^{-5} M AA with a scan rate of 20 mV s^{-1} in 0.1 M pH 7.00 PBS.

0.0 V for AA with rather less sensitive results. As the main goal was to determine DA and UA, the performance of the method developed was found most satisfactory. In case of any interference of AA, the use of methionine would be the proper answer to the problem.

3.7. Stability of nano-Cu/PPy/GCE

A long-term storage stability of the nano-Cu/PPy/GCE was studied by keeping the electrode in phosphate buffer solution (pH 7.0) at room temperature. The performance of Cu nanoparticles/PPy/GCE for the detection of 5×10^{-7} M UA was tested in PBS of pH 7 for a week. Over the first 2 days, the oxidation of UA signal decreased by 1.3% and the oxidation current response maintained 90.2% of the original peak current value after 1 week. The experiments were repeated for DA and UA mixture and similar stable signals were obtained. These results prove that nano-Cu/PPy/GCE is stable and the voltammetric studies could be replicated for the selective and sensitive determination of DA and UA.

3.8. Real sample analysis

The nano-Cu/PPy/GCE for the determination of DA and UA in practical samples such as DA injection solution and human urine samples was tested. The dopamine hydrochloride injection (DHI) solution (specified content of DA is 40 mg mL^{-1}) was diluted to 10 mL with ultrapure water and 100 μL diluted DHI or some amount of standard DA solutions were injected into each of a series of was piped into each of series of 10 mL measuring flasks and made up to volume phosphate buffer (pH 7.00). An aliquot of 50 μL of those solutions was placed in an electrochemical cell for the determination of DA using differential pulse voltammetry. The results are listed in Table 1. Uric acid analysis was performed as follows: 1.0 mL urine sample was diluted to 10 mL with 0.1 M NaOH solution. An aliquot mL of the diluted solution was injected to electrochemical cell and made up 10 mL with phosphate buffer solution (pH 7.00)

Table 1
Determination of DA in dopamine hydrochloride injection ($n = 3$).

Samples	Added (μM)	Found (μM)	RSD (%)
1	10.50	10.37	1.92
2	15.70	16.00	1.99
3	21.00	21.32	1.97

Table 2
UA analysis in human urine sample ($n = 3$).

	Proposed method (10^{-4} M)	% RSD	Standard method (10^{-4} M)	% RSD
Sample 1	3.10	1.98	3.09	2.01
Sample 2	3.30	1.95	3.40	1.98

for the determination of uric acid in urine sample. The results were compared with standard spectrophotometric method as shown in Table 2. Uric acid in human urine samples was compared. Here the DPV technique was used in the experiments. The real sample analysis data for dopamine injection solution (DOPAMIN, 40 mg/mL) and human urine sample results are listed in Tables 1 and 2. From these results, it shows that the nano-Cu/PPy/GCE shows good catalytic activity for real sample analysis.

4. Conclusion

In the present study reported, a new composite electrode nano Cu/PPy/GCE was prepared by electropolymerization and electrodeposition methods. It was shown that this composite electrode improved the electrocatalytic activities towards the oxidation of DA and UA. The catalytic activity of bare GCE towards DA and UA oxidation was improved by the formation of a uniform PPy film which was incorporated with Cu nanoparticles on the electrode surface due to the increasing electronic conductivity and effective surface area. In the differential pulse voltammetric determination, the detection limits of DA and UA were estimated as 3.0×10^{-9} and 4.0×10^{-9} mol/L, respectively. Thus, Cu nanoparticles modified polypyrrole film electrode showed excellent sensitivity, selectivity and anti-fouling properties for the voltammetric determination of DA and UA individually and simultaneously. The proposed method was demonstrated for DA and UA determination in real samples with satisfactory results.

ABSTRACT

This paper examines specific cases in the literature where analysts using spectroscopic instrumentation report elemental concentrations that agree with information values reported in reference material certificates that are subsequently found to be incorrect.

© 2009 Elsevier B.V. All rights reserved.

1. Introduction

The term "Standard Reference Materials (SRM) Syndrome" was coined by F.P. Byrne [1] in 1974 to characterize the incidents where analysts succeed in accurately measuring the concentration of certified constituents in reference materials for which they know the true constituent concentrations, but fail when such samples are presented as blind unknowns. It is common knowledge that inter-laboratory round-robin analysis results for samples of known concentration are more often in agreement than for samples of unknown concentration. Of course the most logical explanation is that an analyst who obtains an incorrect concentration for a reference material investigates the cause of the error and corrects it. But is there also an element of self-deception or dishonesty involved in this phenomenon?

In order to study this syndrome, two instances were evaluated where information or matrix concentrations for elements listed in SRM certificates were later found to be incorrect and changed in later editions of the certificates. The two elements studied, manganese and magnesium, were chosen for their known certificate discrepancies as well as because the determination of these elements should be simple using most analytical techniques.

While the analytical community accepts certified element concentrations as inherently correct, within the stated uncertainty limits, this aura of validity was often incorrectly carried over to information values because of the status of the certifying body. At the National Institute of Standards and Technology (NIST, formerly the National Bureau of Standards), information values were not certified because they were not determined by a definitive method [2] or by at least two agreeing independent methods [3]. In many cases, the information values were based on either one analytical method or a significant difference existed between two independent analytical method results that implied a systematic bias in one or both of the methods. Since information values were sometimes misinterpreted by the end users as certified values in the validation of new analytical techniques or methodologies in the scientific literature, a unique opportunity is provided to validate the reference material syndrome. This study is based on a compilation of elemental concentration values in the literature [4] as well as the author's extensive involvement in the certification of reference materials.

2. Results

One of the best examples of a change in the information value occurred in the case of SRM 1648, Urban Particulate Matter. The original certificate from 1978 [5] as well as the revised certificate from 1991 [6] reported an information value for manganese of 860 μg/g. This value was based on disagreement between three analytical methods: atomic absorption spectroscopy, neutron activation analysis, and direct current plasma emission spectrometry. (The 1991 certificate incorrectly listed flame emission spectrometry as the certifying method instead of direct current plasma emission spectrometry.) The discrepancy was eventually resolved as reported in the 1998 certificate [7] in which the concentration of manganese was reported as 786 ± 17 mg/kg (μg/g). The

doi:10.1016/j.talanta.2009.09.028

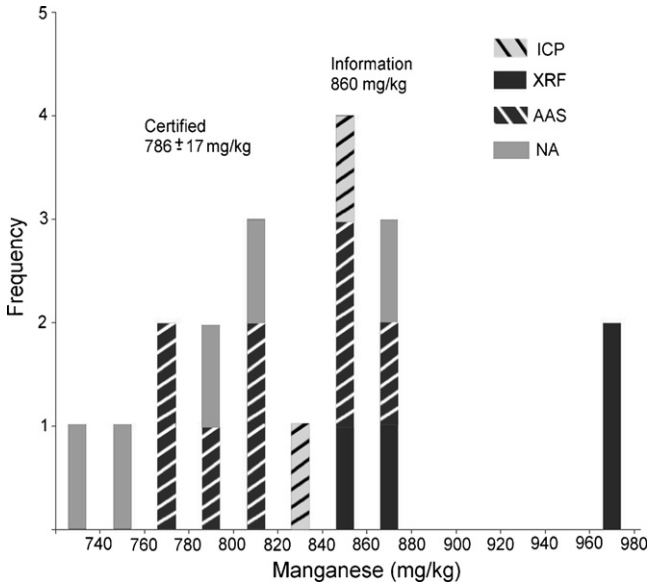

Fig. 1. Histogram of the distribution of literature values for the determination of manganese in SRM 1648 (urban particulates), including analysis techniques (XRF, X-ray fluorescence methods; ICP, inductively-coupled plasma emission spectrometry; AAS, atomic absorption spectrometry; NA, neutron activation methods).

discrepancy was traced to an impure manganese standard used by one of the analytical methods.

Shown in Fig. 1 is a histogram of literature values reported for manganese in SRM 1648 from 1977 to 1984, segmented by analytical technique. The distribution is skewed towards the correct concentration with the maximum at the incorrect information value. There is no question that the reference materials syndrome is a real phenomena. The more important question to ask is why it occurred. Based on the distribution of analytical techniques, there is no obvious technique-based bias. While it is possible that some data may have been fraudulent, it is likely that many errors were made for the same reason that the NIST information value was in error, because of an impure manganese standard. Furthermore, since this time period corresponded to the development of new analytical techniques, such as inductively-coupled plasma emission spectrometry (ICPES), it is also feasible that spectral interferences might have been ignored because the presumably correct answer was obtained. Such interferences would have resulted in concentrations higher than the certified value.

Fig. 2 is a histogram of literature values for magnesium, one of 4 components of SRM 1645, River Sediment, again segmented by analytical techniques. The matrix composition for this SRM was described in the 1978 certificate of analysis [8] as 4% MgO, 4% Al_2O_3, and 4% CaO. These numbers correspond to elemental concentrations of 2.4% Mg, 2.1% Al, and 2.9% Ca and were specifically listed only to "describe the matrix of the material" and not intended as certified or information numbers. A later certificate in 1982 [9] reported a certified value of 2.26 ± 0.04 wt. percent aluminum, 0.74 ± 0.02 wt. percent magnesium, and an information value of 2.9 wt. percent calcium. Thus the initially reported matrix concentration of MgO of 4% was incorrect, and should have been 1.2%. The histogram shows several interesting components. First, there is no specific analytical technique bias. Second, several reported values corresponded to an incorrectly calculated concentration of magnesium (2.4%) based on the matrix composition of 4% MgO. Finally, one analytical method reported a concentration of 4.1% magnesium, corresponding to the incorrect matrix composition of MgO. That same analytical method reported concentrations of 4.2% calcium and 3.9% aluminum. Furthermore, their analysis of SRM 1648 reported a concentration of manganese of 851 μg/g.

3. Conclusion

It is impossible to assign causes to specific cases of the reference materials syndrome, of which there are undoubtedly many. Certainly the primary cause is the tendency of the analyst to implicitly trust the source of the reference material certificate and a misunderstanding of the validity of the numbers reported therein. The period examined corresponded to the development of new analytical techniques, such as ICPES, as well as more mature techniques such as X-ray fluorescence, where the inexperienced analyst could easily be in error. The primary lesson is one that Byrne delineated in

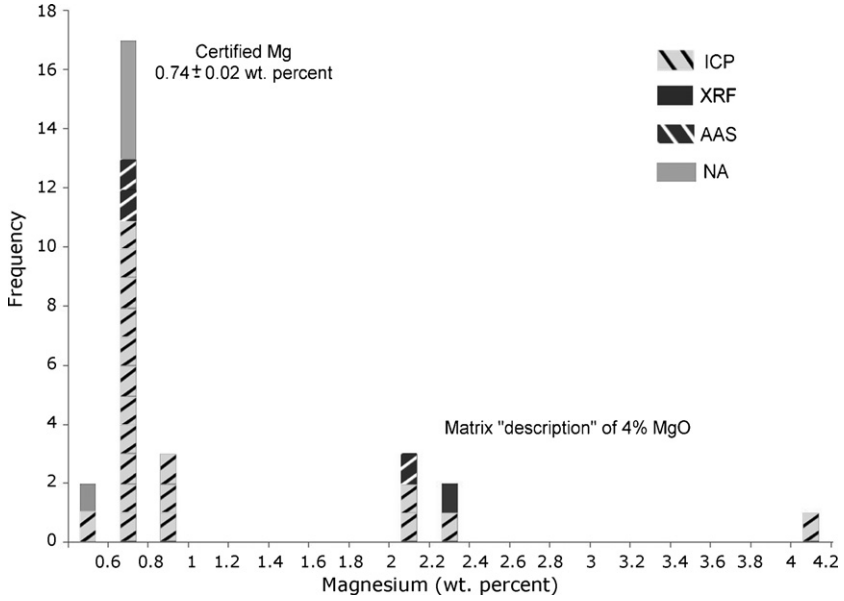

Fig. 2. Histogram of the distribution of literature values for the determination of magnesium in SRM 1645 (River Sediment), including analysis techniques (XRF, X-ray fluorescence methods; ICP, inductively-coupled plasma emission spectrometry; AAS, atomic absorption spectrometry; NA, neutron activation methods including photon activation).

that "the analyst must always be conscious of the human element" and "that he must design his methods testing in such a way that his subconscious will not know the expected result."

ABSTRACT

Pure enantiomers of carboxylic acids are a class of important biomolecules, chiral drugs, chiral reagents, etc. Analysis of the enantiomers usually needs expensive instrument or complex chiral receptors. However, to develop simple and reliable methods for the enantiomer analysis of acids is difficult. In this paper, chiral recognition of 2,3-dibenzoyltartaric acid and mandelic acid was first carried out by aggregation-induced emission molecules bearing optically pure aminol group, which was easily synthesized. The chiral recognition is not only seen by naked eyes but also measured by fluorophotometer. The difference of fluorescence intensity between the two enantiomers of the acids aroused by the aggregation-induced emission molecules was up to 598. The chiral recognition could be applied to quantitative analysis of enantiomer content of chiral acids. More chiral AIE amines need to be developed for enantiomer analysis of more carboxylic acids.

1. Introduction

Pure enantiomers of carboxylic acids are a class of important biomolecules, chiral drugs, catalysts, chiral building blocks, etc. Conventional enantiomer analyses usually need expensive instrument or complex chiral reagents, and are also time-consuming in practice. However, to develop simple and reliable methods for the enantiomer analysis of acids is difficult. Chiral recognition of carboxylic acids in fluorescence can provide time-efficient, accurate, and sensitive enantiomer determination [1]. Especially, fluorescent receptors that are capable of differentiating the two enantiomers of a chiral acid would provide a real time technique in the rapid chiral assays of high throughput drug discovery and catalyst screening. However, to design and synthesize excellent chiral fluorescent receptors for enantiomers of carboxylic acids are still a challenge [1,2].

Recently, a new class of organic compounds with an amazing property of aggregation-induced emission (AIE) or aggregation-induced emission enhancement (AIEE) have been found [3–19]. These compounds have not the quenching problem in the solid state, therefore they not only show a great potential in optoelectronic materials [4,5], but also will act as highly selective and stable fluorescence sensors for protein [6,7], DNA [8,9], organic vapor [10–12], heparin [13], metal ions [14], chlorine [15], immunoassay [16] and even layer-by-layer self-assembling process [17], and so on. Although chiral AIE compounds bearing cholesteryl groups [18,19] were reported as crystal light-emitting materials, research work related to chiral recognition based on AIE or AIEE characters is not reported. During studying chiral recognition [20–22], it occurred to us that novel chiral fluorescent receptors would be obtained if one molecule having AIE character and another molecule having chiral recognition ability were connected. Here we first report that the AIE compound bearing optically pure aminol group can enantioselectively aggregate with one enantiomer of chiral carboxylic acid and results in big fluorescence intensity difference up to more than 200-fold which can be used in quantitative analysis of enantiomer composition.

2. Experimental

2.1. Materials and measurements

All reagents and solvents were chemical pure (CP) grade or analytical reagent (AR) grade and were used as received. ^{1}H NMR and ^{13}C NMR spectra were measured on a 400 MHz spectrometer at 298 K in $CDCl_3$. Absorption spectra were recorded on a UV–vis spectrophotometer. Mass spectrum was measured on a FTMS instrument. Field emission scanning electron microscopy (FE-SEM) images were taken on an electron microscope operating at 10 kV. The suspension or solution of sample was dropped onto a slide and air-dried. Fluorescent emission spectra were collected on a fluorophotometer at 298 K. The fluorescence spec-

trum was measured after the aggregation appeared and stood for 1 h.

2.2. Synthesis of chiral AIE amines

The synthetic route is as Scheme 1.

Synthesis of compound **5**: a solution of **4** (2.2 g, 0.01 mol) and triethylamine (1.5 g, 0.015 mol) in dichloromethane (40 mL) was cooled with iced bath. To the solution chloroacetyl chloride (1.7 g, 0.015 mol) was added during 0.5 h under stirring. The mixture was continued to stir at the iced temperature for about 3 h until **4** disappeared (monitored by silica gel thin layer chromatography; eluent:chloroform). Then the pH of the reaction mixture was adjusted to neutral with 1 M HCl. After organic phase was separated the aqueous phase was extracted with chloroform. The combined organic phase was dried over anhydrous Na_2SO_4, filtered and evaporated to dryness. The residue was recrystallized with THF and methanol to give yellow powder (2.0 g, yield 70%). Mp: 182–184 °C; IR (KBr) ν 3305, 3279, 3184, 3106, 3050, 2954, 2223, 1690, 1601, 1536 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$): δ 8.37 (s, 1H), 7.93 (d, J = 8.4 Hz, 2H), 7.69 (t, J = 7.6 Hz, 4H), 7.50–7.40 (m, 4H), 4.23 (s, 2H).

Synthesis of compound (*1S,2R*)-**6**: to the flask was added **5** (1.19 g, 0.004 mol), (*1S,2R*)-2-amino-1,2-diphenylethanol (0.852 g, 0.004 mol), triethylamine (1.22 g, 0.012 mol) and dried THF (15 mL). The mixture was refluxed for about 48 h until **5** disappeared (monitored by silica gel TLC, chloroform:ethyl acetate 3:1). After concentrated, the residue was subjected to flash column chromatography (silica gel thin layer chromatography; eluent:chloroform:ethyl acetate 5:1) to give light yellow powder (1.23 g, yield 65%). Mp: 195–197 °C; $[\alpha]_D^{20}$ = −29.9 (*c* 1.0, THF); IR (KBr) ν 3447, 3355, 3271, 3055, 3029, 2903, 2216, 1678, 1604, 1571, 1525, 1049; ^1H NMR (400 MHz, $CDCl_3$) δ 9.37 (s, 1H), 7.85 (d, J = 8.8 Hz, 2H), 7.66 (d, J = 8.8 Hz, 2H), 7.52 (d, J = 8.4 Hz, 2H), 7.5–7.17 (m, 14 H), 4.93 (d, J = 6 Hz, 1H), 3.94 (d, J = 6 Hz, 1H), 3.34, 3.22 (2d, J = 17.6 Hz, 2H), 2.20 (br, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 169.6, 141.6, 140.4, 139.6, 134.7, 130.3, 129.4, 129.0, 128.8, 128.5, 128.5, 128.4, 128.1, 127.1, 126.0, 119.4, 118.3, 110.0, 77.2, 69.0, 50.4; ESI^+ MS m/z calcd for $C_{31}H_{27}N_3O_2$ 473 [M], found 474 $[(M+1)]^+$. Scheme 1. Synthesis of chiral AIE compounds (*1R,2S*)-**6** and (*1S,2R*)-**6**.

Synthesis of compound (*1R,2S*)-**6**: the method was the same as (*1S,2R*)-6, yellow powder, yield 67%; Mp: 194–196 °C; $[\alpha]_D^{20}$ = +29.3 (*c* 1.0, THF); IR (KBr) ν 3447, 3357, 3271, 3054, 3030, 2903, 2217, 1678, 1606, 1570, 1526, 1050 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 9.34 (s, 1H), 7.88 (d, J = 8.4 Hz, 2H), 7.68 (d, J = 7.6 Hz, 2H), 7.53 (d, J = 6.4 Hz, 2H), 7.6–7.29 (m, 12H), 7.23 (d, J = 6.4 Hz, 2H), 4.91 (d, J = 6.4 Hz, 1H), 3.94 (d, J = 6.4 Hz, 1H), 3.35, 3.19 (2d, J = 17 Hz, 2H), 2.21 (br, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 169.8, 141.6, 140.4, 139.6, 138.4, 134.7, 130.3, 129.4, 129.1, 129.0, 128.8, 128.5, 128.5, 128.4, 128.0, 127.1, 125.9, 119.4, 118.3, 109.9, 77.2, 68.9, 50.4; ESI^+ MS m/z calcd for $C_{31}H_{27}N_3O_2$ 473 [M], found 474 $[(M+1)]^+$. Anal. Calcd for $C_{31}H_{27}N_3O_2$: C, 78.62; H, 5.75; N, 8.87. Found: C, 78.22; H, 5.27; N, 8.22.

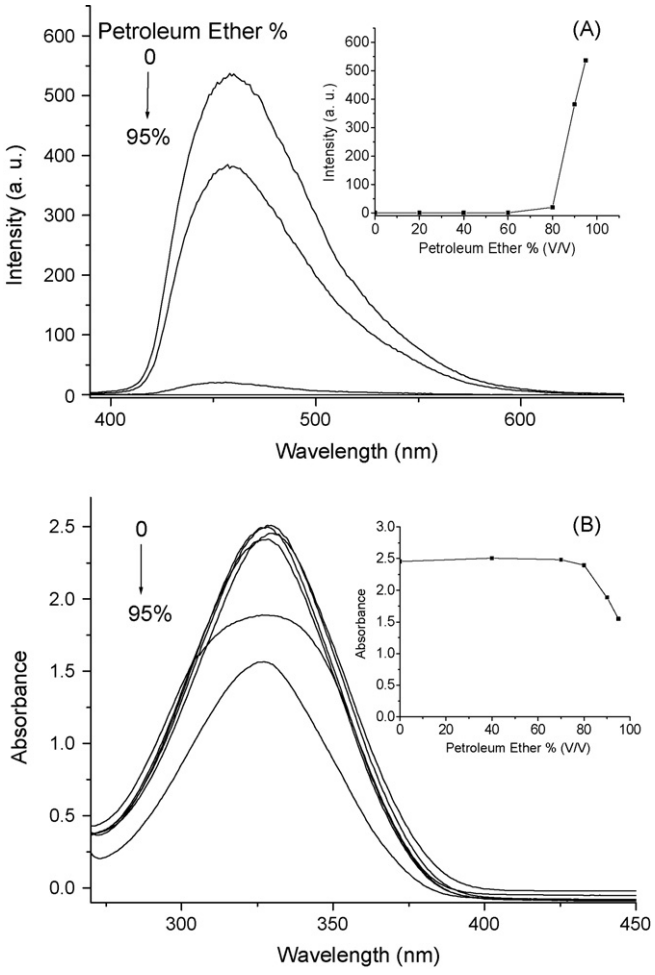
3. Results and discussion

3.1. AIE character of chiral amines **6**

2-Phenyl-3-(*p*-aminophenyl)acrylonitrile **4** is one of cyano-containing AIE molecules, which does not emit fluorescence in solution but emits strong one in solid state [10,23]. It reacted with chloroacetylchloride to give **5** which was easily attached by an optically pure amine to get chiral AIE compound **6** (Scheme 1). The structure of both (*1S,2R*)-**6** and (*1R,2S*)-**6** were fully characterized by ^1H and ^{13}C NMR, MS, elemental analysis and polarimetry.

(*1S,2R*)-**6** and (*1R,2S*)-**6** are soluble in common organic solvents such as ethanol, THF, chloroform and 1,2-dichloroethane, but insoluble in water and in nonpolar solvent such as petroleum ether, *n*-hexane. As expected, just like AIE compound **4**, while dilute solution of (*1S,2R*)-**6** or (*1R,2S*)-**6** in ethanol or 1,2-dichloroethane was almost no fluorescent, the resultant solid after solvents were evaporated exhibited strong blue emission under a UV lamp. When water was added into the solution of (*1S,2R*)-**6** or (*1R,2S*)-**6** in ethanol, or petroleum ether was added into the solution in 1,2-dichloroethane, the resultant suspension also emitted strong fluorescence. As shown in Fig. 1A, the fluorescence intensity of (*1S,2R*)-**6** increased little with increasing the volume ratio of petroleum ether vs 1,2-dichloroethane in the range of less than 80:20. But when the ratio was more than 80:20 the fluorescence intensity increased swiftly. At the ratio of 95:5, the fluorescence intensity of the resultant suspension got up to 536 at λ_{max} = 460 nm which was 2680 times as large as the solution in 1,2-dichloroethane without petroleum ether (intensity 0.2). From macroscopic observation, the solution at the ratio less than 80:20 was homogeneous, but it became suspension at volume ratio larger than 80:20. Therefore, (*1S,2R*)-**6** and (*1R,2S*)-**6** display an AIE character. The absorbance of (*1S,2R*)-**6** almost had not change with increasing content of petroleum ether in 1,2-dichloroethane when the volume ratio of petroleum ether vs 1,2-dichloroethane was less than 70:30 (Fig. 1B). But after the ratio was lager than 80:20, the absorbance of (*1S,2R*)-**6** rapidly decreased. Although the absorbance decreased with increasing petroleum ether the fluorescence intensity greatly increased. This result confirmed that (*1S,2R*)-**6** was truly a AIE compound.

In addition, although the absorption band of the suspension at λ_{max} = 327 nm exhibited a little blue-shift of 3 nm compared with the solution at λ_{max} = 330 nm which probably was ascribed to the solvent effect, the emission band of the suspension at λ_{max} = 460 nm in mixed solvent of petroleum ether and 1,2-dichloroethane (95:5) showed a large red-shift of 18 nm compared with the solution in 1,2-dichloroethane at λ_{max} = 442 nm. Moreover, in a mixed solvent of water and ethanol the maximum emission peak had a red-shift of 35 nm and the maximum absorption peak also displayed a red-shift of 8 nm from solution to suspension (Figs. S9 and S10 in Support Information). This result is in accordance with literature



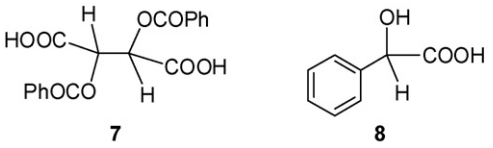


Fig. 1. Change of fluorescence and absorption spectra of (*1S,2R*)-**6** (1.0×10^{-4} M) with increasing content of petroleum ether in 1,2-dichloroethane. (A) Fluorescence spectra. λ_{ex} = 345 nm, ex/em slits = 3/3 nm. Inset, curve of intensity changed with petroleum ether percentage. (B) Absorption spectra. Inset, curve of absorbance changed with petroleum ether percent.

reports, in which addition of water into organic solvent ethanol or THF would arise a red-shift of maximum emission and absorption peak [10,18,24,25]. Therefore, the aggregation in solution by addition of nonsolvent should be one through head to tail stack (J-aggregation) of compound **6** [24,25]. Due to the J-aggregation, the intramolecular vibrational and rotational motions, which behave strongly in a twisted conjugation molecule and will lead to the fast nonradiative relaxation and reduce fluorescence intensity in a solution, are restricted. Meanwhile, the bulky substituents, especially the cyano group[2c,4g], at the carbon-carbon double bond of **6** prevent the molecule from forming excimer which usually results in quenching in solid state, so that the fluorescence increases when this sort of molecule aggregates.

3.2. Chiral recognition

The chiral recognition property of **6** was initially studied with interaction of (*1S,2R*)-**6** and the two enantiomers of a chiral carboxylic acid. As expected, enantioselective aggregates formed when (*1S,2R*)-**6** and chiral carboxylic acid were mixed in 1,2-dichloroethane. When equal volumes of (*1S,2R*)-**6** (0.02 M in 1,2-dichloroethane) and *D*-**7** (Scheme 2, 0.02 M in 1,2-dichloroethane) were mixed and let the solution stand for 0.5 h at room temperature, a suspension appeared. But the mixture of (*1S,2R*)-**6** and *L*-**7** in 1,2-dichloroethane was a clear solution even

Scheme 2. Structure of carboxylic acids used in chiral recognition.

after standing for more than 1 day. Under the same conditions, interaction of (*1S,2R*)-**6** and (*S*)-**8** (Scheme 2) led to a suspension, but the mixture of (*1S,2R*)-**6** and (*R*)-**8** remained a clear solution. Very importantly, the enantioselective aggregation in 1,2-dichloroethane could not only be visualized by naked eyes but also be quantitatively observed by fluorophotometer due to AIE effect of **6** as shown in Fig. 2A and B. The suspension of (*1S,2R*)-**6** and *D*-**7** had a fluorescence intensity of 515, but the solution of (*1S,2R*)-**6** and *L*-**7** showed only 2.6 at λ_{max} = 421 nm, providing this system with a very high enantiomer fluorescence intensity ratio 196 ($I_{D\text{-}7}/I_{L\text{-}7}$). For mandelic acid **8**, the fluorescence intensity ratio of their two enantiomers was as high as $I_{(S)\text{-}8}/I_{(R)\text{-}8}$ = 598.

To confirm that the enantioselective aggregation was the result of chiral recognition by the chiral receptor, the interaction of chiral carboxylic acids with (*1R,2S*)-**6** was also studied. Under the same conditions as that with (*1S,2R*)-**6**, interaction of (*1R,2S*)-**6** with **7** and **8** just led to opposite results, that is, mixture of (*1R,2S*)-**6** with *L*-**7** or (*R*)-**8** gave a suspension but the diastereomeric mixing of (*1R,2S*)-**6** with *D*-**7** or (*S*)-**8** led to a clear solution. And similarly, the suspensions had stronger fluorescence than the solutions (Fig 2C and D). Similarly, the fluorescence intensity ratio for the mixture of (*1R,2S*)-**6** with enantiomers of **7** ($I_{L\text{-}7}/I_{D\text{-}7}$) was as high as 506, and the ratio of $I_{(R)\text{-}8}/I_{(S)\text{-}8}$ got up to160. In addition, FE-SEM revealed that the aggregates in suspension of (*1S,2R*)-**6** and *D*-**7** were composed of nanofibers with a length of 5–20 μm and a width of 50–150 nm, but the solid resulted from evaporation of the solution of (*1S,2R*)-**6** and *L*-**7** was amorphous (Figs. S11 and S12 in Support Information). Therefore the above results demonstrate that the interaction of chiral receptor **6** with chiral acids is indeed highly enantioselective and can lead to strong enantioselectively aggregation-induced emission.

3.3. Quantitative analysis of enantiomer content

In order to ascertain if the fluorescence difference resulted from the enantioselective aggregation could be applied to determination of enantiomer composition, fluorescence intensity of the suspension of (*1S,2R*)-**6** and *D*-**7** in different concentration was measured. As shown in Fig. 3, the fluorescence intensity of suspension increased with increasing the concentration of mixture of (*1S,2R*)-**6** and *D*-**7**. Notably, in the range of concentration less than 2.0×10^{-3} M, the fluorescence intensity linearly increased with the concentration of mixture of (*1S,2R*)-**6** and *D*-**7** as shown in inset of Fig. 3. This is valuable because the concentration of complex of (*1S,2R*)-**6** with *D*-**7** could be conveniently measured by its fluorescence intensity.

Due to direct proportion of fluorescence intensity and concentration in less than 2.0×10^{-3} M, therefore, kept total concentration of both (*1S,2R*)-**6** with *D*-**7** at 2.0×10^{-4} M, the change of fluorescence intensity with content of *D*-**7** in the two enantiomers of **7** was studied. As displayed in Fig. 4, the mixture of (*1S,2R*)-**6** and **7** almost emitted no fluorescence with increasing the molar percentage of *D*-**7** in enantiomer composition of **7** when the percentage of *D*-**7** was less than 50%, but when it was more than 50%, the fluorescence intensity increased with the molar percentage of *D*-**7**. Similarly, when the molar percentage of *L*-**7** was more than 50% the fluorescence intensity of mixture of (*1R,2S*)-**6** and **7** increased with

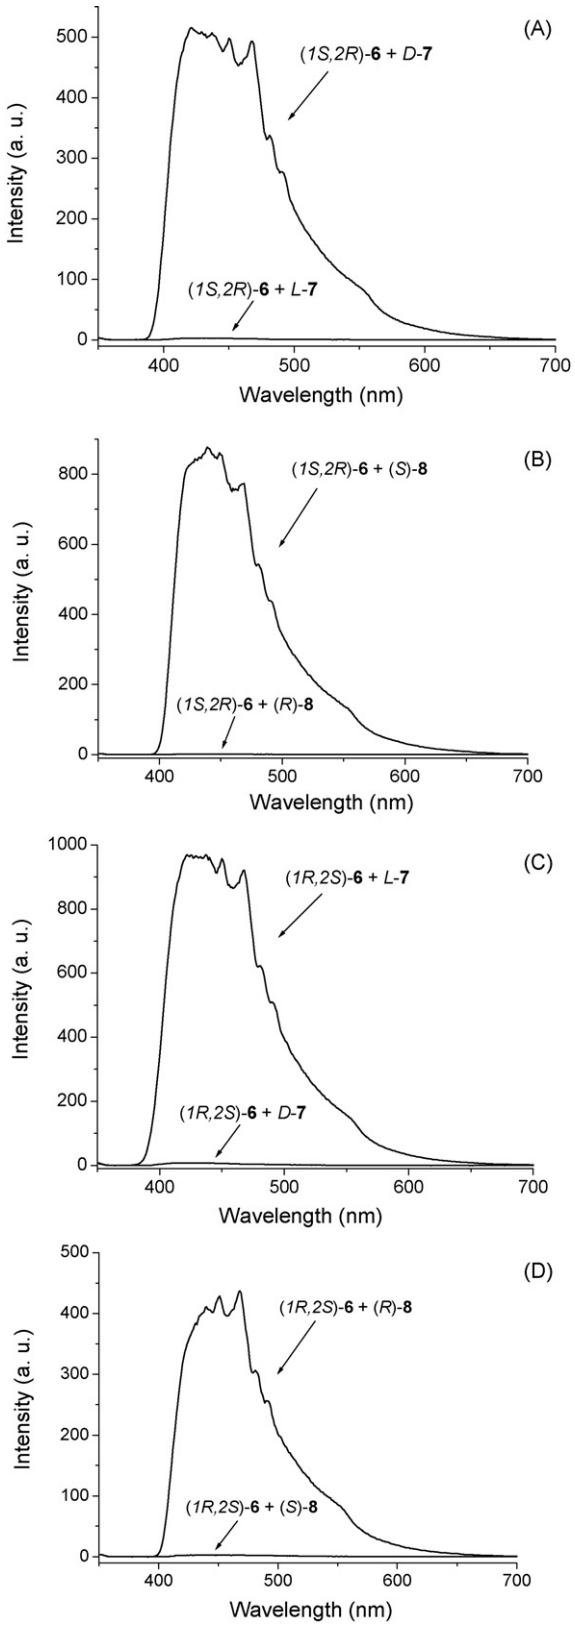

Fig. 2. Fluorescence spectra of mixture of **6** and enantiomers of chiral acids in 1,2-dichloroethane ([**6**] = [**7**] = [**8**] = 0.01 M, λ_{ex} = 345 nm, ex/em slits = 10/5 nm). (A) of (*1S,2R*)-**6** with **7**; (B) of (*1S,2R*)-**6** with **8**; (C) of (*1R,2S*)-**6** with **7**; (D) of (*1R,2S*)-**6** with **8**.

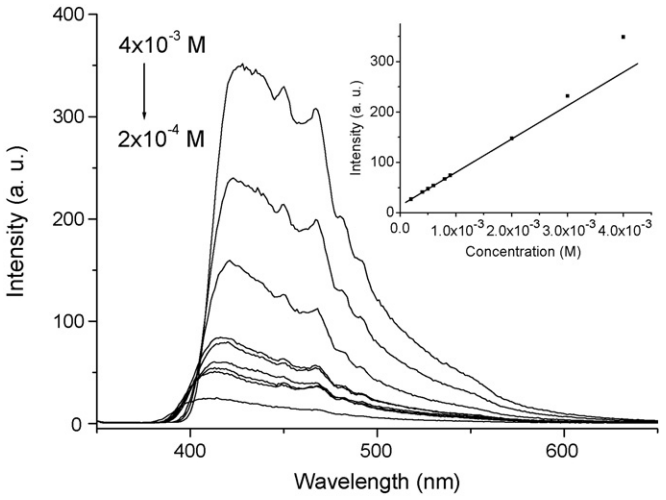

Fig. 3. Change of fluorescence spectra of mixture of (*1S,2R*)-**6** and *D*-**7** with concentration from 2.0×10^{-4} to 4.0×10^{-3} M in 1,2-dichloroethane([(*1S,2R*)-**6**] = [*D*-**7**], λ_{ex} = 345 nm, ex/em slits = 10/5 nm). Inset, curve of intensity changed with concentration.

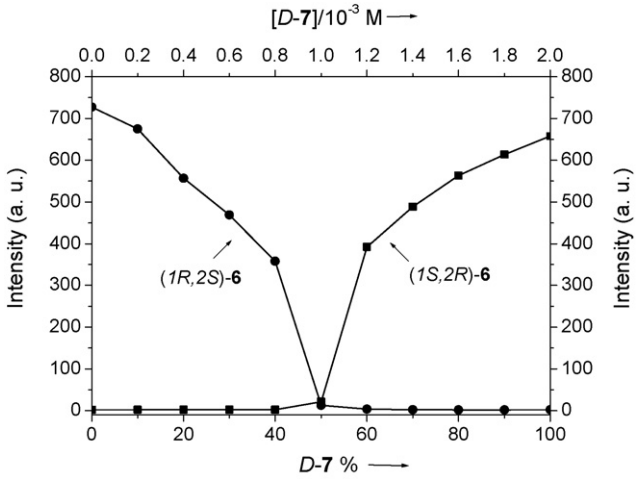

Fig. 4. Change of fluorescence intensity of mixture of amine **6** and acid **7** with enantiomer content of acid **7**. [**6**] = total concentration of two enantiomers of **7** = 2.0×10^{-3} M in 1,2-dichloroethane; λ_{ex} = 345 nm, ex/em slits = 10/5 nm.

the molar percentage of *L*-**7**. As a result, two standard curves were drawn and any enantiomeric composition of **7** could be obtained. This is very important for high throughput analysis of chiral drugs and reagents. By the same method, the enantiomer composition of other chiral acids such as **8** could be also analyzed.

4. Conclusions

In conclusion, combination of AIE component and optically pure amine group could result in excellent chiral receptors for fluorescent chiral recognition of carboxylic acids. This finding provides a totally new and simple methodology for design of fluorescent chiral receptor which can be applied to quantitative determination of enantiomer content, although only two chiral carboxylic acids were tested. Other chiral AIE amines that can analyze enantiomers of more carboxylic acids need to be developed.

Foreword

The role of analytical chemists in the XXI century is becoming critical to help colleagues from other areas of research, such as in medicine, biology, genetics or toxicology, to understand the performances of modern analytical techniques and to outline how to properly apply these methods in their own workflows.

The field of Analytical Proteomics is growing constantly and is becoming a major instrument of support for progress in System Biology or Medical Chemistry. The improvements driven by Analytical Chemistry, through techniques such as mass spectrometry or near magnetic resonance, are quickly implemented in Proteomics. The advances in sample treatment for proteomics allow the handling of more samples in less time and in a non-intensive labour fashion.

It is said in the legend that Atalanta refused to compete with Hippomenes, who finally, helped by the goddess of love, Aphrodite, wins her hand in marriage.

Nowadays Atalanta's role is played by Analytical Chemistry whilst Hippomenes' role is played by the modern Society, which is asking for a skilled use of the tools that are provided to the researchers. Modern methods of analysis can be applied to solve many present problems encountered by our Society, but only if they are married with analytical chemists.

I am grateful to the editors of Talanta who have agreed to publish this special issue on Analytical Proteomics and for allowing Carlos Lodeiro, Hugo Santos and myself to act as Guest Editors.

ABSTRACT

Nowadays isotopic ^{18}O-labeling of peptides has recalled the attention of researchers due to its simplicity of application and high versatility for proteomics studies. Protein quantification, differential peptide mass mapping, studies regarding proteins overexpressed or underexpressed, or the searching of biomarkers can be accomplished by using ^{18}O-labeling. In this critical review we comment on the different ways in which ^{18}O-labeling can be done, highlighting the key parameters of the different sample treatments to obtain a reliable and reproducible labeling. In addition we describe and compare the latest improvement in terms of sample treatment that allows to reduce the handling and to increase the throughput for this sample treatment. Finally, we hypothesize on the future trends of these methods under the light of the new technological advances to speed protein cleavage.

1. Introduction

Mass spectrometry is nowadays a powerful tool for protein quantification, both in a relative or absolute manner, with a continuously growing interest among the research community, as it is showed by the large amount of reviews published regarding this item in the last years, 124 since 2005 (key searching words: protein quantification and mass spectrometry; searching engine: scopus). Those reviews cover a broad area of research activities, including proteomics, genomics and medical care or food chemistry [1–6].

The different strategies that can nowadays be followed for protein quantification are briefly addressed in Table 1, along with their main advantages and drawbacks.

Protein quantification using isotopic labeling of peptides with ^{18}O has recently recalled the attention in research due to its almost perfect characteristics to be used for protein differential expression and for relative protein quantification. Enzymatic labeling with ^{18}O-water is easy to do, all peptides formed during the protein cleavage are labeled, and all that is required is the presence of ^{18}O-water, avoiding extra-reagents or synthetic steps. Indeed some authors, as we will see in the next sections, have claimed absolute protein quantification using this labeling tool for non-gel-based approaches.

Time-consuming and labor-intensive are drawbacks of the ^{18}O-labeling. Therefore, during the last years researchers have focused on how to perform ^{18}O-labeling in a fast and reproducible fashion, using different tools to speed and to simplify the sample handling, such as heating, ultrasonic energy, or centrifugation.

Since most approaches currently used fast ^{18}O-labeling have been developed during the last 5 years, reported conclusions are sometimes inconclusive or even contradictory. Therefore, in this work, we present a critical overview of the last trends in ^{18}O-labeling, focusing on the main drawbacks of the sample treatments and giving advises about how to overcome them. In addition the latest developments to speed the labeling procedure are presented and are critically commented. Finally, future trends based on recent findings for the simplification of protein digestions are addressed for their application in ^{18}O-labeling.

2. The ^{18}O-isotopic labeling

It is generally agreed that the ^{18}O-isotopic labeling of peptides can be considered as consisting in two different chemical reactions. The first one is an amide bond cleavage whilst the second reaction is a carboxyl oxygen exchange. Both chemical reactions can be written as follows:

(i) First reaction: amide bond cleavage

$$RC^{16}ONHR' + H_2{}^{18}O \rightarrow [RC^{16}O^{18}O]^- + [H_3NR']$$

(ii) second reaction: carboxyl oxygen exchange

$$[RC^{16}O^{18}O]^- + H_2{}^{18}O \rightarrow [RC^{18}O^{18}O]^- + H_2{}^{16}O$$

As may be seen peptides incorporate one ^{18}O in the first reaction, during the enzymatic cleavage. If this reaction is done in pure ^{18}O-water (normally 95% reach in $H_2{}^{18}O$) then it can be considered that almost 100% of the peptides will be labeled with one ^{18}O. If the reaction is done in mixed $^{16}O/^{18}O$-water, then the labeling ratio will be proportional to the percentage of $H_2{}^{18}O$ in solution: the higher the amount of $H_2{}^{18}O$ the higher the percentage of peptides labeled. This is the reason why accuracy is solely guaranteed when the labeling is done in pure $H_2{}^{18}O$ (generally 95%). In any case, the labeling cannot be studied without taking into consideration the second reaction, the carboxyl oxygen exchange. This reaction is an equilibrium, that ideally should be displaced towards the double oxygen incorporation, since the introduction of two oxygen in a peptide shifts its mass 4 Da, facilitating the identification of the labeled peptide and its quantification by mass spectrometry-based techniques. Both, the amide bond cleavage and the carboxyl oxygen exchange reactions, can take place at the same time, which is the principle of the direct ^{18}O-labeling procedure; or separately, in two steps, which is the basis for the decoupling method. In the next sections we are going to comment the differences of both procedures along with the variables affecting the performance of each one.

Table 1
Main modern strategies for protein quantification in absolute or relative manner: basics, advantages and pitfalls.

SILAC™	ICAT™	ITRAQ™	^{18}O-labeling
Basic concepts			
Metabolic labeling	Chemical labeling	Chemical labeling	Enzymatic labeling
Labeling at selected amino acids (normally arginine, leucine and lysine)	Labeling at cysteines	Labeling at peptide N-terminus and lysine side chain	Labeling at peptide C-terminus
Labeling occurs during cell growth	Labeling occurs before protein digestion	Labeling occurs after protein digestion	Labeling occurs during protein digestion
Labeling at protein level	Labeling at protein level	Labeling at peptide level	Labeling at peptide level
Advantages and disadvantages			
Uniform labeling of every protein	Only peptides with cysteines are labeled	All peptides are labeled	All peptides are labeled
No reduction of sample complexity	Reduction of sample complexity	No reduction of sample complexity	No reduction of sample complexity
Not applicable to human samples	No sample restriction	No sample restriction	No sample restriction
Mixing of differentially treated samples at intact cell level	Mixing of differentially treated samples at protein level	Mixing of differentially treated samples at peptide level	Mixing of differentially treated samples at peptide level
Interconversion of arginine to proline	Side reactions with methionines	Side reactions with thiols and primary amines	No side reactions
MS quantification	MS quantification	MS/MS quantification	MS quantification

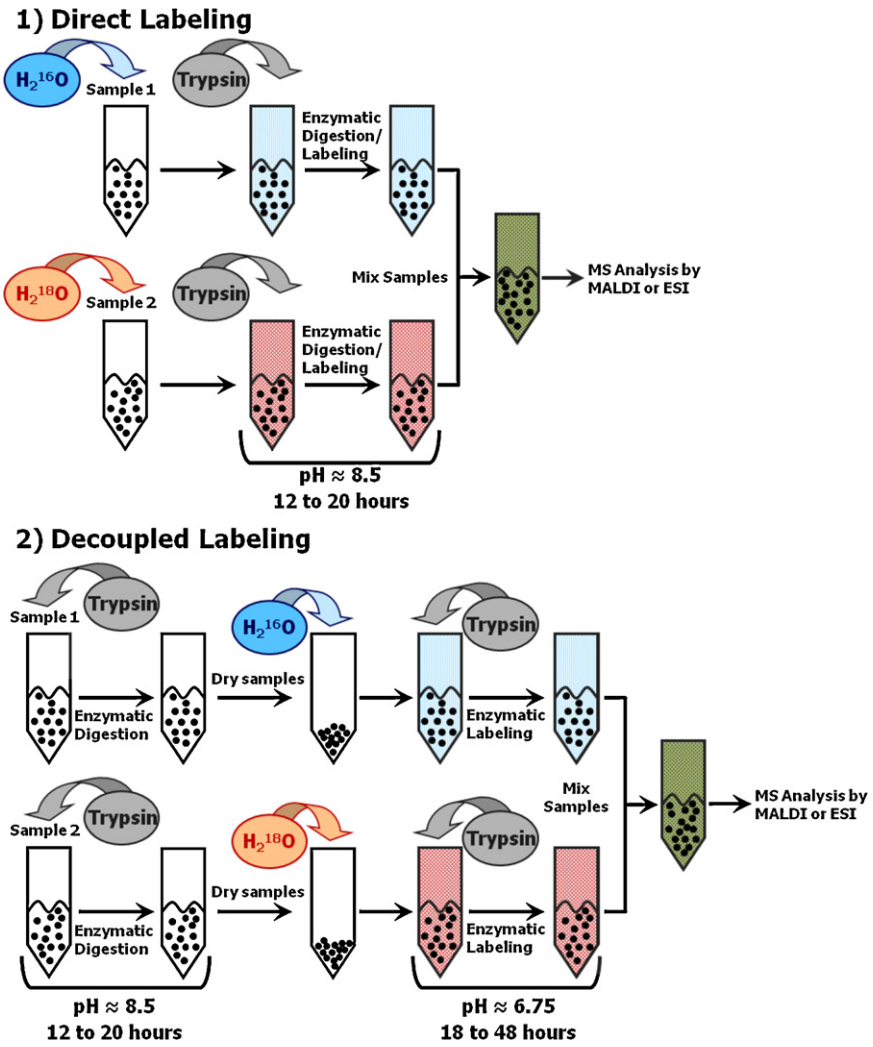

Fig. 1. Comprehensive scheme for the isotopic labeling sample treatment. (1) The direct labeling: samples are dissolved/recomposed in NH_4HCO_3 buffer (25 mM). Then samples are (i) denaturated with acetonitrile, (ii) reduced with DTT, and (iii) alkylated with IAA. Each step is done under the effects of an ultrasonic field provided by a sonoreactor. Then the enzyme is added and the peptides are labeled as the protein is digested. This step is done overnight or with the aid of an ultrasonic bath during 30 min (130 kHz of sonication frequency; 70% sonication amplitude; 60 °C temperature). Finally samples are pooled and are ready to be measured by MS. For more details refer Ref. [7]. (2) The decoupling procedure: the first part of the decoupling procedure is done as in the direct procedure, but samples are digested in ^{16}O-water. Then samples are evaporated to dryness and then they are recomposed in a new solution with a lower pH to speed and facilitate the labeling through oxygen interchange. Samples are evaporated to dryness again and then are recomposed in ^{16}O-water or in ^{18}O-water for the peptide labeling.

3. The different ways of labeling

3.1. The direct labeling

The direct labeling typically done in our laboratory is depicted in Fig. 1. The whole sample treatment entails four main steps [7]: (i) protein dissolution/denaturation; (ii) protein reduction; (iii) protein alkylation and (iv) protein digestion/peptide labeling. The direct labeling can be done accelerating each step with the aid of ultrasonic energy or not [7,8]. As may be seen in Fig. 1, the protein cleavage is done in ^{18}O-water, thus during the protein digestion process, when the peptide bond is broken, one heavy oxygen is incorporated. Further incorporation is done trough the carboxyl oxygen exchange at the same time. The main advantage of this procedure is simplicity and speed. In addition, it can be used in on-line approaches. The main drawback is the lack in labeling efficiency, which makes direct labeling suitable only for relative quantification and for studies regarding proteins overexpressed or underexpressed.

3.2. The decoupling procedure

The decoupling procedure was first proposed by Yao et al. who have demonstrated that the cleavage of the protein can be done separately from the labeling in such a way that almost total double oxygen incorporation can be achieved using the carboxyl oxygen exchange process only [9]. The variant of this procedure usually done in our laboratory is shown in Fig. 1 (manuscript in progress). As may be seen, the decoupling procedure consists in a more elaborated, labor-intensive and time-consuming protocol. In addition to the four main steps of the direct procedure, as described above, it is necessary to dry the sample, once the protein has been digested. Then the sample is recomposed in a solution of acetonitrile/ambic, that facilitates peptide solubilization and that lowered the pH of the solution to speed the subsequent carboxyl oxygen exchange process. Then the sample is dried again and finally recomposed in ^{18}O-water. Finally, the labeling takes place. The advantage of this procedure is that a higher degree of peptides are double labeled in an efficient fashion, which is extremely important for the accuracy

of the quantification, as it will be shown in the next sections. Nevertheless this procedure takes longer than the direct method, usually 12 h, if ultrasonication is used to speed the protein digestion step, otherwise it takes 24–48 h. In addition, it cannot be done on-line, and consequently it is of hard automation.

3.3. The use of immobilized enzymes

Enzymes, such as trypsin, can be immobilized in solid supports that can be used either for protein digestion/labeling in a single step (direct labeling) or in different ones (decoupling procedure). The main advantage of using immobilized enzymes is that once the solution is separated from the solid support, then the protein digestion is stopped and the carboxyl oxygen exchanges is slowed down to almost a negligible effect. This is very important for on-line approaches, where the sample will be mixed with solvents containing ^{16}O-water. This means that some ^{16}O/^{18}O interchange will happen, thus interfering with the quantification process. If the enzyme is not present in the solution the interchange can be consider small to have a significant effect on the quantification process. In addition, the presence of peptides coming from the autolysis of the enzyme is negligible and thus the interferences that they may cause in the subsequent measurements by mass spectrometry are avoided [10].

4. The problem of the ^{18}O-labeling efficiency

The ^{18}O-labeling of peptides following any of the approaches described in Section 3 results in a mixture of non-labeled, single labeled or double labeled peptides. The efficiency in the labeling depends not only on the protocol followed, but also in different variables affecting each protocol, such as pH, type of enzyme used, peptide characteristics, labeling time and conditions of labeling. In addition, the contribution to the peak intensities from the naturally occurring isotopes, others than ^{18}O, such as ^{13}C and ^{15}N, needs also to be considered. The aforementioned variables make ^{18}O-spectra difficult to be interpreted. The influence of sample treatment, as depicted in Fig. 1, on ^{18}O-labeling efficiency of proteins is shown in Fig. 2 through the direct procedure and peptide YLYEIAR ([M+H]$^+$ 927 m/z) from BSA, and Fig. 3, through the decoupling procedure and spectra of peptides LGEYGFQNALIVR ([M+H]$^+$ 1479 m/z) and CEVFR ([M+H]$^+$ 710 m/z) from BSA and α-lactalbumin respectively. As may be seen from Figs. 2 and 3, the decoupling procedure is a robust method that performs the labeling with a better efficiency than the direct procedure. The different conditions used in the labeling step do not affect the double labeling efficiency that was always higher than 90%. On the other hand, the efficiency for protein α-lactalbumin is severely affected when not enough time is given to the labeling reaction, as may be seen in Fig. 3h. This variability in the labeling efficiency makes extremely difficult the interpretation of data from complex protein mixtures, such as proteomes, making hard to distinguish highly up-regulated from highly down-regulated or C-terminal peptides, in studies regarding differential proteomics. This problem is even worst when the direct method is the choice to perform the labeling. As may be seen in Fig. 2, the efficiency in the double labeling is, c.a. 70%. To overcome the labeling efficiency problem, different algorithms have been proposed, as we will see in Section 5 [11]. Other approaches to solve this problem focus on the sample treatment itself, trying to make the labeling as complete as possible, thus minimizing the effects on the efficiency to a residual level.

5. Algorithms for calculating isotopic labeling correction

The basic formula used for ^{18}O-isotopic labeling peak deconvolution is as follows:

$$^{16}\mathrm{O}/^{18}\mathrm{Oratio} = I_0/[I_4 - (M_4 I_0/M_0) - (M_2/M_0(I_2 - (M_2 I_0/M_0))) + (I_2 - (M_2 I_0/M_0))]$$

This formula is explained by looking at Fig. 2 where I_0, I_2 and I_4 represent the experimental (observed) intensities of the monoisotopic peak, named as I_0, and the peaks at 2 and 4 Da, I_2 and I_4, respectively. The theoretical intensities of these peaks corresponding to M_0, M_2 and M_4 are calculated from dedicated software following

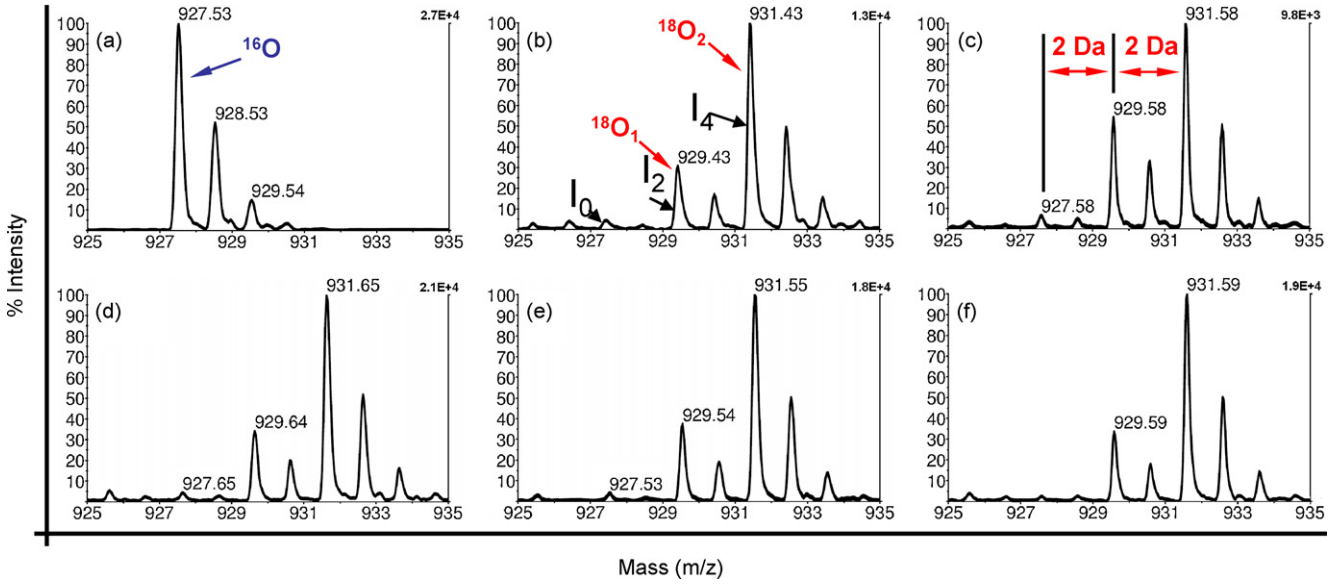

Fig. 2. Reflector positive ion mode MALDI-TOF mass spectra of the peptide fragment (YLYEIAR)H$^+$ obtained in the tryptic digest of BSA. (a) Overnight digestion in 100% $H_2{}^{16}O$ buffer solution at 37 °C (c.a. 12 h); (b) overnight digestion in 95% $H_2{}^{18}O$ buffer solution at 37 °C (c.a. 12 h); (c) ultrasonic bath digestion in 95% $H_2{}^{18}O$ buffer solution at 60 °C (35 kHz frequency; 70% amplitude; 30 min); (d) ultrasonic bath digestion in 95% $H_2{}^{18}O$ buffer solution at 60 °C (130 kHz frequency; 70% amplitude; 15 min); (e) ultrasonic bath digestion in 95% $H_2{}^{18}O$ buffer solution at 60 °C (130 kHz frequency; 70% amplitude; 30 min); (f) water bath digestion in 95% $H_2{}^{18}O$ buffer solution at 60 °C (30 min). Reproduced from Ref. [7].

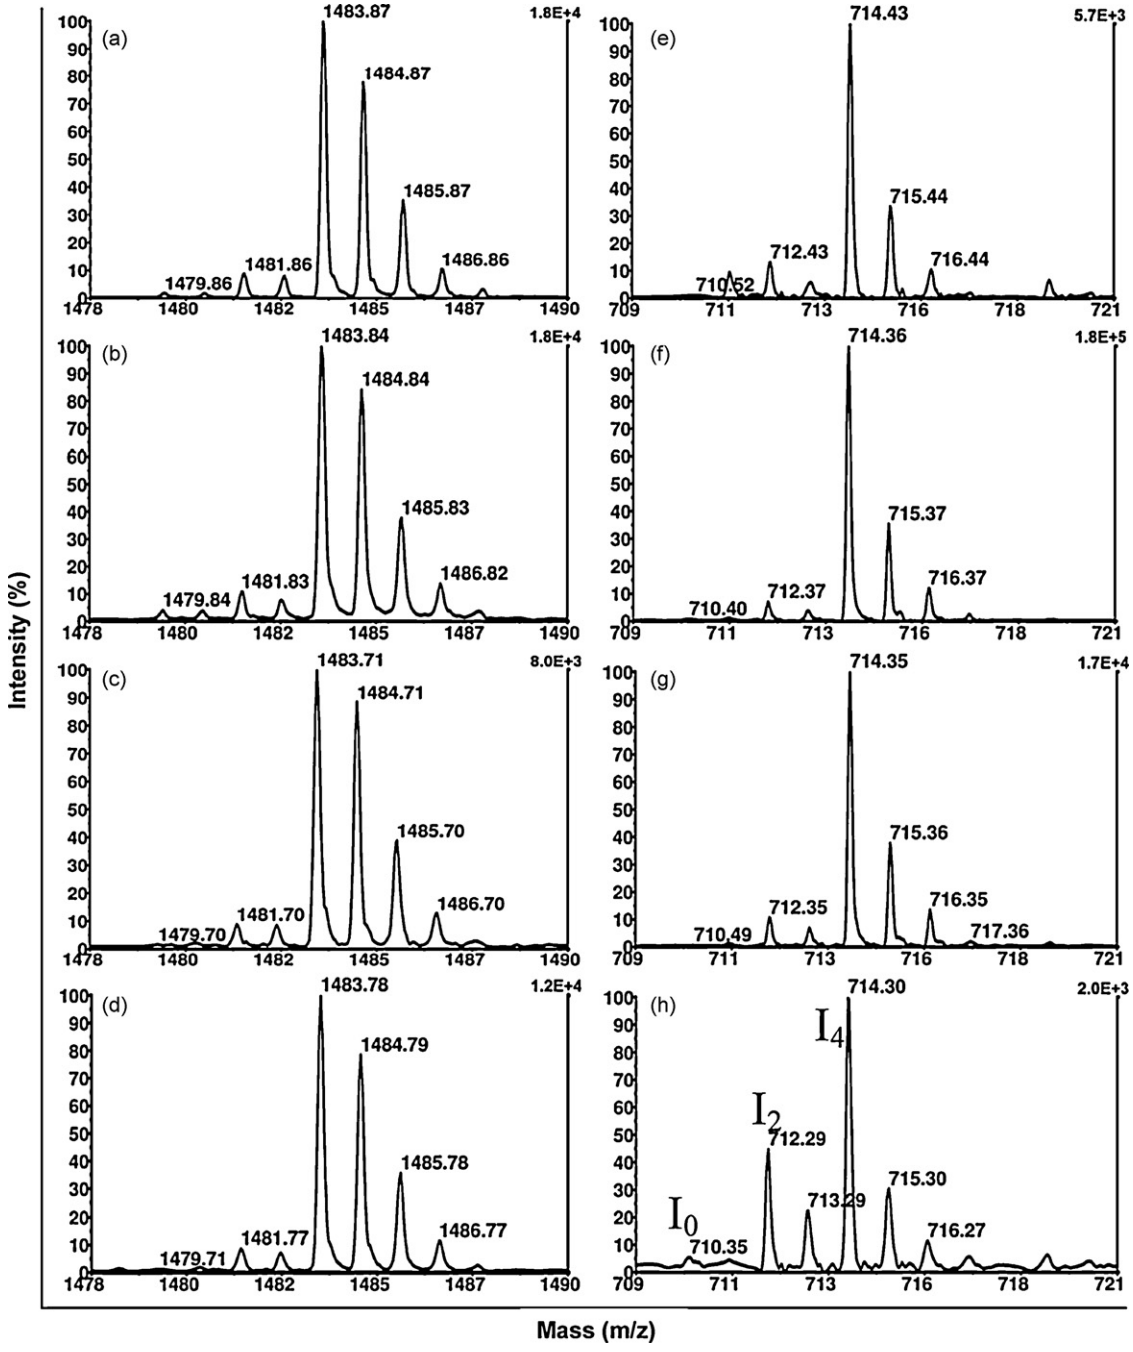

Fig. 3. MALDI-TOF spectra of the peptides LGEYGFQNALIVR ([M+H]$^+$ 1479.80 m/z) and CEVFR ([M+H]$^+$ 710.33 m/z) from BSA and α-lactalbumin, respectively, obtained after ^{18}O-labeling by the decoupling procedure. (a) BSA overnight labeling (6 + 6 h) at 37 °C; (b) sonoreactor labeling of BSA for 15 + 15 min (50% amplitude); (c) sonoreactor labeling of BSA for 5 + 5 min (50% amplitude); (d) sonoreactor labeling of BSA for 2.5 + 2.5 min (50% amplitude); (e) α-lactalbumin overnight labeling (6 + 6 h) at 37 °C; (f) sonoreactor labeling of α-lactalbumin for 15 + 15 min (50% amplitude); (g) sonoreactor labeling of α-lactalbumin for 5 + 5 min (50% amplitude); (h) sonoreactor labeling of α-lactalbumin for 2.5 + 2.5 min (50% amplitude).

peptide identification [12,13]. The isotopic peaks annotated as I_0, I_2, and I_4 are the peaks used for quantification. The non-annotated peaks are primarily composed of $^{13}C_1$ contributions related to the annotated peaks [14].

As may be understood, in most of the modern proteomics approaches the number of peptides to be treated is enormous. Consequently, algorithms have been proposed by different authors, based on the formula described above, accounting for skewed isotopic distributions due to partial single labeling and double labeling, thus variants of the above-mentioned formula are reported from time to time [9,14–16].

QUIL software has been proposed by Wang et al. as an automated quantification tool for high-throughput proteomics using stable isotope labeling and LC–MS^n [17]. QUIL accounts for the dynamic nature of spectral background and subtracts this background accordingly during ion chromatogram reconstruction. For elution profile identification, QUIL minimizes the inclusion of coeluted neighbor peaks, yet tolerated imperfect peak shapes.

Wan et al. have proposed a method for the quantification of proteins with a correction being made for incomplete isotope incorporation due to either ^{16}O-to-$^{18}O_1$ or $^{18}O_1$-to-$^{18}O_2$ exchange effects [18].

As a final example, Eckel-Passow et al. described two multivariate linear regression models for $^{16}O/^{18}O$ stable-isotope labeled data that joint model pairs of resolved isotopic clusters from the same peptide and quantify the abundance present in each of the two biological samples whilst concurrently accounting for peptide–specific incorporation rates of the heavy isotope [19].

6. The enzymes used for ^{18}O-labeling

The enzyme trypsin, a serine protease that predominantly cleaves peptide chains at the carboxyl side of amino acids lysine and arginine, is the enzyme most commonly used for ^{18}O-isotopic labeling. Other two enzymes, the endoproteinase Lys-C that specifically cleaves peptide bonds C-terminally at lysine; and the endoproteinase Glu-C, that cleaves peptide bonds C-terminally at glutamic and aspartic acids are also frequently used.

Trypsin, Lys-C and Glu-C have been reported to incorporate two ^{18}O atoms into the carboxyl termini of all peptides, except the original carboxyl termini [20–24]. However, lysine terminated peptides do not incorporate two oxygen efficiently [25,26]. Chemotrypsin has been claimed as being only capable of label peptides with one oxygen, however, it seems that this process is dependant of the experimental conditions. Thus, it has been demonstrated by Yao et al. that chemotrypsin can double label peptides in a decoupling procedure [9].

Asp-N was used to perform the in-gel digestion of proteins, in 50% of $H_2{}^{18}O$ buffer solution, to characterize and identify five C-terminal peptides out of seven C-terminally processed enolase 2 forms [44].

7. The influence of the pH

The influence of the pH on the labeling process depends on the way in which this is done. In the direct process, the protein is labeled at the same time that is cleaved. To guarantee the efficiency of the process, the pH must be the optimum at which the enzyme cleaves the protein, for instance the optimum pH for the enzyme trypsin is about 8. If the cleavage is done in pure ^{18}O-water, then all peptides will have one ^{18}O at the C-termini at least. Interestingly, the double ^{18}O incorporation will depend on various factors, such as the type of peptide and the pH of the solution. For instance, lysine terminated peptides do not incorporate two oxygen efficiently. In addition, Yao et al. have demonstrated that by lowering the pH of the solution, the double incorporation can be done faster and with higher efficiency [9]. Precisely, the possibility to separate the protein cleavage from the isotopic incorporation doing both separately at different pH is the basis of the decoupling procedure, as proposed by the former mentioned authors. Thus, the first step is the protein cleavage, which is done at the optimum pH of the enzyme used. In addition, this step is generally done in ^{16}O-water, lowering costs, since ^{18}O-water is an expensive reagent. In the second step, after drying, the sample is recomposed in ^{18}O-water at an acidic pH and further enzyme is used to speed the double ^{18}O incorporation. The recommended pH for this step is in between 4.5 and 5.5. In this approach some peptides will be hardly recomposed due to their hydrophobic characteristics, and therefore some peptides will remain unlabeled or will be labeled inefficiently. For this reason, before reconstitution of peptide mixtures in $H_2{}^{18}O$ buffers for the exchange reaction, dissolution of the entire mixture with a strong solvent such as DMSO is critical to get successful homogeneous labeling [9]. Once the labeling protocol has been done using any of the procedures already described, it is mandatory to stop the enzymatic activity. It must be considered that the labeled samples (in ^{18}O) are mixed with their unlabeled counterparts (in ^{16}O) prior to analysis by mass spectrometry to measure their relative ratios. This means that $^{16}O/^{18}O$ chemical back exchange will occur in some degree during the mixing process. The presence of any remaining trypsin at this stage will accelerate the $^{16}O/^{18}O$ carboxyl oxygen exchange. To avoid this problem some authors have suggested lowering the pH of the solutions below 2, since the activity of trypsin and other proteases at that pH is negligible [27]. By this way the problem of oxygen interchange is reduced to a minimum. However, other authors have claimed indeed that lowering pH, even below 2, is not enough to overcome this problem. Thus, Staes et al. [28] have found necessary to destroy the trypsin structure by covalent modification of its thiol group using trypsin inhibitors, to avoid any re-naturation at every step of the subsequent peptide isolation procedure. To complicate things more, Sevinsky et al. reported the failure of covalent trypsin inhibitors in their approach to quantitative proteomics making use of ^{18}O-labeling [29]. In fact the aforementioned authors have proposed the use of immobilized trypsin in the digestion step as the best method to avoid the subsequent chemical exchange, due to residual trypsin.

The carboxyl oxygen exchange is a problem to deal with when a complex mixture of peptides is separated through chromatography. In this case the contact of the labeled peptides with reagents prepared in ^{16}O-water last for long time, as long as the chromatographic separation needs to efficiently separate the mixture of peptides. This contact hinders the double labeling ratios and thus makes the application of this protocol to investigations related to protein expression levels useless. An additional problem is addressed by the method by which the chromatographic separation is done. Some authors have proposed the use of multidimensional chromatography using strong cation exchange (SCX) either as an on-line technology, called MudPIT [30], or as an off-line technique, named 2D-LC [31]. Regarding the aforementioned approaches it has been suggested that the off-line approach is preferable, since the linear gradient that can be used in off-line approaches has higher resolution than the regular step-gradient commonly used in on-line procedures. In addition, off-line methods allow using higher ACN concentrations, and so more fractions can be collected from a single experiment using off-line strategies. Researchers are aware that off-line 2 dimensional chromatographic approaches imply that the samples are dried after the first dimension or that hydrophilic peptides may be lost in the second dimension. Lassman et al. have studied the possibility of ^{18}O-exchange during the course of typical reversed phase chromatography experiments, as well as strong cation exchange separations, and they have found that with appropriate sample handling, the use of ^{18}O-labeling for differential expression analysis can be extended to multi-dimensional chromatography experiments [32]. Thus, they suggest that peptide separation with minimum back exchange is obtained if SCX buffer (5 mM phosphate/25% ACN pH 2.8, column 1.0 mm × 100 mm of polysulfoethyl aspartamide, poly LC) acidified with 5% formic acid pH < 2 is used.

From a critical point of view, the most useful way to perform the labeling is using immobilized trypsin, since once the solution has been separated from the trypsin there is no risk of back exchange or the risk is reduced to a negligible effect.

8. Accelerating and simplifying the sample treatment

As may be seen in Fig. 1, the ^{18}O-labeling handling presents two main drawbacks. On the one hand is labor-intensive and on the other one is time consuming. For those reasons, in the last years, many researchers have focused on how to simplify and to speed the different steps of the ^{18}O-labeling protocols. In the next sections we are going to discuss the advantages and drawbacks of the modern approaches to accelerate and to simplify the isotopic labeling.

8.1. Heating

It is well known that enzymes can perform better at an optimum temperature. Overnight at 37 °C is the handling protocol commonly used to perform protein cleavage. However, Havlis et al. proposed a methodology that enables the digestion of proteins in 30–60 min by warming the sample at 58 °C without compromising the peptide yield and the sensitivity when compared to conventional protocols relying upon overnight enzymatic cleavage [10,33]. The warming was done in a water bath. Variants of this protocol have been proposed from time to time by just changing the heating systems. Thus, Turapov et al. [34] have proposed the use of a PCR thermocycler and a temperature gradient to digest native proteins in less that 5 min. They claimed to be able to perform protein identification using micro-scale amounts of sample (3 μL) without the need of denaturating agents. After treatment, samples were directly spotted on the MALDI target plate, without additional purification. Although these could be a promising approach, the authors did not test the system with a complex sample neither used the method for the digestion of proteins separated through gel electrophoresis.

The above-described methods to speed the protein digestion through warming the solutions are a way to speed the first part of the decoupling procedure as depicted in Fig. 1. However there is a lack on works dealing with the specific purpose of ^{18}O-labeling and warming. Finally, Carreira et al. have stressed the inefficiency to speed the labeling through warming at 60 °C during 30 min in the direct approach [7].

8.2. Micro-spin columns

Mirza et al. [35] have showed the possibility to accelerate the isotopic labeling using immobilized trypsin on micro-spin columns to speed up the enzyme-mediated oxygen substitution. They claimed to be able to complete the labeling for a four protein mixture and whole cell lysate from rat vascular endothelial cells in 15 min. The Sigma company also offers a similar method through its ^{18}O proteome profiler kit® including micro-spin columns (sigma product code P3623. Disclaimer: specific company, product and equipment names are given to provide useful information; their mention does not imply recommendation or endorsement by the authors). However, the procedure described by sigma lasts for 24–48 h.

8.3. Ultrasonic energy

The utilization of ultrasonic energy provided by an ultrasonic probe was first described in 2005 as a method to accelerate the enzymatic cleavage of proteins from overnight to a few minutes [36]. The methodology has been named ultrasonic assisted enzymatic digestion (USAED). The acceleration method using ultrasound can be applied either to proteins dissolved in liquids, to proteins separated by gel electrophoresis [37] and whole proteomes [38]. The physical and chemical properties of enzymatic and chemical reactions are greatly modified with the presence of an ultrasonic field. The mechanisms by which the enzymatic reactions are accelerated by means of ultrasonication are due to the acceleration of the diffusion coefficients because ultrasound (1) increases the temperature of the medium in which it is applied, which increases the velocities of reaction and (2) mix the material present in the solution, making the enzymes becoming in deep contact with the present substances, causing a large increase in the total contact area. It must be remarked that ultrasounds reduce the size of the solids present in solution, incrementing the available contact surface [39,40].

The USAED method can be done using direct in-solution sonication, with an ultrasonic probe, meaning the probe is in contact with the solution, or by using the sonoreactor technology, which allows indirect ultrasonic irradiation of the sample, meaning the solution is treated in sealed cups. Recently, the method has also been applied to accelerate the isotopic labeling with ^{18}O-water in standards of proteins and purified proteins from complex samples using the direct labeling [7] or in standards of proteins and whole proteomes using the decoupling procedure [41]. Regarding the decoupling procedure, it must be stressed, in contrast with the work done by López-Ferrer et al. [41], that on-going work developed in our laboratory suggests that there is no improvement in using ultrasonication to enhance the performance of the labeling step, and that the labeling efficiency obtained is the same with or without sonication as shown in Table 2.

8.4. High pressure

An efficient on-line digestion system that reduces the number of sample manipulation steps for high-throughput proteomics based on high pressure has been reported. By incorporating a pressurized sample loop into a liquid chromatography separation system, both sample and enzyme (e.g. trypsin) can be simultaneously introduced to produce a complete, yet rapid digestion. Both standard proteins and a complex *Shewanella oneidensis* global protein extract were digested and analyzed using the automated on-line pressurized digestion system coupled to an ion mobility time-of-flight mass spectrometer, to an ion trap mass spectrometer, or both. The system denatures, digests, and separates product peptides in a manner of minutes, making it amenable to on-line high-throughput applications. The system was easy to implement and no cross-contamination was observed among samples [42].

9. Applications of the ^{18}O-labeling

9.1. Inverse labeling

The ^{18}O-labeling method has many problems, i.e., tedious data analysis, ambiguity in detection of extreme changes in expression,

Table 2
Comparison between the different methods tested for the ^{18}O-labeling of BSA and α-lactalbumin with the decoupling procedure. The results refer to the average percentage of the double ^{18}O incorporation from the total of peptides labeled in the C-terminal group of selected peptides from BSA and α-lactalbumin (n = 3).

and inability to detect protein modifications due to perturbation. In addition, the method has additional complexities due to ^{13}C effect and its interference on the ^{18}O signals. The ^{13}C effect can make interpretation of a down-regulation very difficult since weak ^{18}O signals can be buried under the normal ^{13}C pattern, and the signals can be easily misinterpreted as non-labeled C-terminal peptides. Since the goal of a protein differential analysis is to extract and to identify the small number of proteins that deviate in expression level upon a perturbation, any method that enables subtractive analysis of protein signals with unaltered levels would be of great value. This is the base of the method called ⟨⟨Inverse ^{18}O-labeling⟩⟩ as first reported by Wang et al. [22]. Inverse ^{18}O-labeling offers a number of merits when applied to a labeling-based proteomic strategy. It offers the rapid identification of the signals from the differentially expressed proteins through quick pattern recognition. It eliminates the ambiguity in detection of proteins with extreme changes in expression caused by the limitation of dynamic range of detection. It also resolves the detection problems associated with protein modifications due to perturbation, where unpaired peaks are detected. Fig. 4 gives a detailed explanation of this approach. Since it was first reported, the inverse ^{18}O-labeling has been applied from time to time in studies regarding proteins overexpressed or underexpressed. Thus, Wang et al. [43] used the direct and inverse labeling in an integrated fashion with solution isoelectric focusing and capillary LC–tandem mass spectrometry to study abundance changes in mitochondrial proteins associated with drug resistance in MCF-7 human cancer cells whilst Ang et al., have used the reverse approach to determine the effect of biofilm culture on the cell envelope proteome of *Porphyromonas gingibalis* W50 [44].

9.2. Applications to gel-separated proteins

The absolute quantification of proteins separated in polyacrylamide gels lacks in efficiency and accuracy, as it was demonstrated by Havlis and Shevchenko [45]. However this method is a powerful tool when applied for relative quantification. The best sample treatment for relative quantification of proteins separated in polyacrylamide gels consists firstly in digest the gel spots containing the control sample, a certain amount of a known protein, and the target sample in ^{16}O-water, afterward the extracted pool of peptides is dried in a speed vacuum. Finally, the control sample is recomposed in ^{18}O-water whilst the target sample is recomposed in ^{16}O-water. The same amount of both samples is then mixed and submitted to mass spectrometry-based techniques. The signal intensities of the same peptides are then compared and the relative $^{16}O/^{18}O$ ratios are used to calculate the concentration of the unknown protein. By carrying out ^{18}O-labeling post proteolysis, the amount of ^{18}O-water required is substantially reduced, since the labeling is performed on the extracted and dried peptides not on the excised gel pieces [22]. The ^{18}O-labeling of N-glycosylation sites during in-gel deglucosylation has been claimed as a way to extend the capabilities of MALDI peptide mass mapping and database searching for the identification of gel-separated proteins [46]. There are also some studies that report in-gel ^{18}O-labeling as a tool for protein quantification and characterization. For instance, Kosaka et al. [47] reported a method for the C-terminal characterization and identification of proteins separated by two-dimensional polyacrylamide gel electrophoresis (2D-PAGE), based on in-gel digestion/labeling of proteins. After 2D-PAGE of a cell lysate of rat liver, 10 different protein spots were

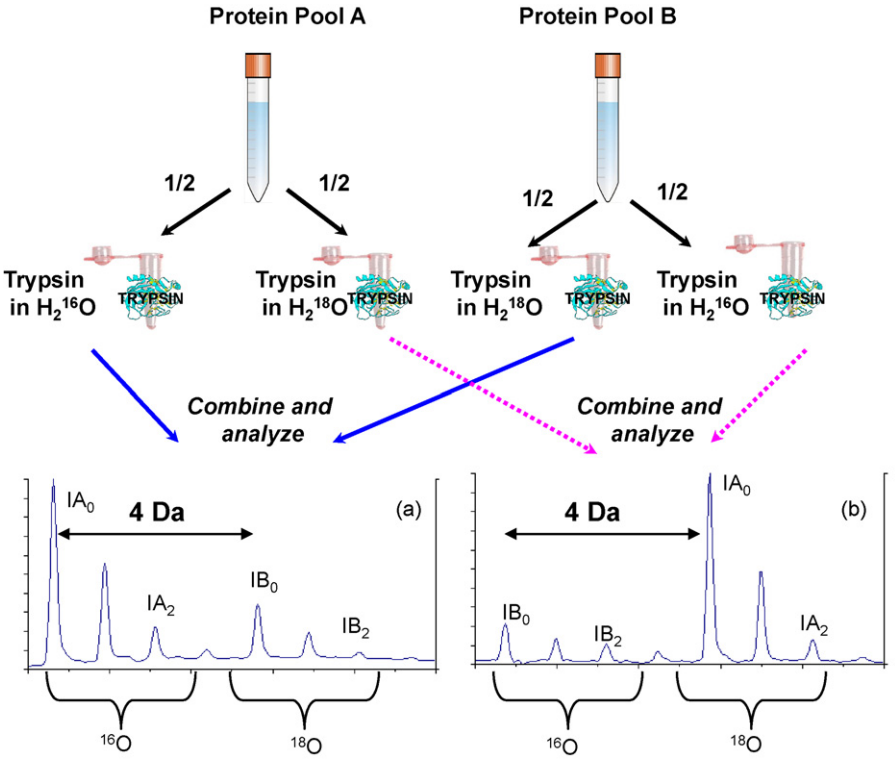

Fig. 4. Inverse labeling. The labeling is swapped between two samples, for instance a target sample (sample A) and a control sample (sample B). In the example provided, sample A correspond to crucian carp (*Ciprinus carpio*) exposed to endocrine disruptors whilst sample B corresponds to non-exposed fish. The example is given through one peptide from the protein vitalogenin, which is overexpressed by crucian carps when they are exposed to endocrine disruptors. As may be seen the overexpression of vitalogenin in the exposed fish is unambiguously verified. Thus in spectrum a the peptide coming from the exposed fish present a intensity (IA_0) three times higher that its counterpart from the non-exposed fish (IB_0), shifted 4 Da thanks to the ^{18}O-labeling. This up-regulation of the protein is verified in the second experiment, spectrum b, where now the vitalogenin's peptide from the exposed fish is shifted 4 Da as now this is the sample isotopically labeled. This time the intensity was also clearly higher in agreement with the information given the inverse experiment. Thus, by comparing the results of the two experiments it is possible quickly to identify those differentially express proteins present in complex mixtures.

in-gel digested during overnight with trypsin in a buffer solution of 50% ^{18}O enriched water, and analyzed by nano-electrospary Fourier transform ion cyclotron resonance mass spectroscopy (nano-ES FT-ICR MS). Due to the high resolution of FT-ICR MS and since the C-terminal peptides were the only unlabeled peptides in the protein digests, the authors were able to identify and characterize the C-termini of 8 proteins, from the initial 10 chosen, with a high level of confidence. On the other side, and following the same strategy, Larsen et al. [48] were unable to characterize and identify by MALDI the C-terminal peptides of different enolase-2-forms form stressed cells of *Saccharomyces cerevisiae*, when using trypsin to digest the separated proteins from 2D-PAGE. However, when the endoproteinase Asp-N was used to perform the in-gel digestion of proteins, in 50% of $H_2{}^{18}O$ buffer solution, they were able to fully characterize and identify five C-terminal peptides out of seven C-terminally processed enolase 2 forms. These results show how important it is the choice of the correct enzyme to perform protein digestion and labeling. In this case the authors were only concerned in distinguishing the unlabeled C-terminal peptide from the labeled internal peptides, so they use an enzyme, endoproteinase Asp-N that only incorporates one ^{18}O atom in the carboxylic group of the peptide whilst trypsin incorporates one or two ^{18}O. This way, they were able to control the oxygen incorporation in the peptides, avoiding the presence of a mixture of single and double labeled peptides which would be responsible for the spreading of the peptide signal over more peaks, thus reducing the intensity in the mass spectra and compromising a correct identification.

The previous examples demonstrate the potential of ^{18}O-isotopic labeling in the detection of modified peptides by mass spectrometry thus enhancing the characterization of protein modifications, many of them implicated in a large number of disease states. On the other hand, there are also a few examples where in-gel ^{18}O-labeling was successfully used for protein quantification and to identify potential biomarkers of disease states. Using a combination between in-gel ^{18}O-labeling and nano-LC/MS/MS, Körbel et al. [49] were able to identify and quantify approximately 180 low-expressed erythropoietin (EPO) receptor-dependent proteins, which are related with signaling pathways and EPO-dependent cellular responses like cell differentiation and proliferation. The developed method relies on immunoaffinity and 1D-PAGE for protein separation; in-gel protein digestion in the presence of in $H_2{}^{16}O$ or $H_2{}^{18}O$ (95% ^{18}O abundance) with non-methylated (non-stabilized) trypsin to avoid post-digestion $^{18}O/^{16}O$ back-exchange; and nano-LC–MS/MS techniques for the detection of low-fentomole proteins. More recently, Chaerkady et al. [50] used lectin affinity enrichment and 1D-PAGE to purify and separate glycosylated proteins from liver tissues of healthy patients and patients with hepatocellular carcinoma. After in-gel digestion with trypsin in the presence of $H_2{}^{16}O$ or $H_2{}^{18}O$ and LC–MS/MS analysis they were able to perform relative quantification and find differential expressed proteins from non-tumor/tumor samples. Finally, the application of in-gel ^{18}O-labeling has been used by Ang et al. [44] in the study of the *Porphyromonas gingivalis* proteome, an oral pathogen related with chronic periodontitis. Based on an inverse labeling strategy, where the control sample was first digested in $H_2{}^{16}O$ and the experimental sample digested in $H_2{}^{18}O$, whilst in the inverse experiment the control sample was digested in $H_2{}^{18}O$ and the experimental in $H_2{}^{16}O$, they found 24 proteins up-regulated and 18 proteins down-regulated in experimental sample. Once more, these examples show the reliability and applicability of the in-gel ^{18}O-labeling technique when applied to comparative proteomic studies.

9.3. Applications to proteins in solution

This is by far the most reported use given to ^{18}O-labeling. A combination of tandem mass spectrometry and ^{18}O-labeled internal standards provide absolute or relative quantification of simple or complex mixtures of proteins in solution. Internal standards could be directly obtained by digesting in ^{18}O-water a stock solution of known concentration of the protein of interest. Since many peptides are quantified in parallel, the resulting estimate of the protein concentration is robust and would also be applicable to complex protein mixtures, when combined with MS/MS spectrometry, if powered by appropriate software [45].

The application of ^{18}O-labeling in assisting sequencing of peptides by helping to distinguish a-type ions from b-type ions in tandem mass spectrometry has been reported by different authors [51,52]. The isomerization of aspartic acid (Asp) to isoaspartic acid (IsoAsp) is a spontaneous reaction that can alter protein structure and function, and for this reason the identification of this phenomenon in proteins is a biochemical challenge. Xiao et al. [53] have proposed a method for the identification and quantification of the above-mentioned reaction based on the utilization of ^{18}O-labeling and tandem mass spectrometry. Wa et al. have proposed a method for the study of the binding sites of proteins when they are immobilized in solid supports. The method is simple: the free protein is cleaved in ^{18}O-water whilst, after its immobilization, the protein is digested in ^{16}O-water. The two digests are mixed and then analyzed by mass spectrometry. Peptides having significantly higher $^{18}O/^{16}O$ ratios than other peptides in the same digest are involved in the immobilization [54]. Another interesting application consists in using the ^{18}O-labeling for the quantification of ribonucleic acids using ^{18}O. RNA labeled and non-labeled samples are mixed and then the intensities of the ^{16}O and $^{18}O_1$ monoisotopic peaks are then correlated through a proposed formula. It must be taken into account that for this biomolecules, the labeling is only single [55]. Havlis et al. have systematically demonstrated that absolute quantification of proteins can be done using ^{18}O-labeling in non-gel-based approaches [45]. In the same work they also compared the performance of the labeling using MALDI or nano-LC-ESI, concluding that both methods produced consistent results; however, the nano-ESI method was more accurate and allowed relatively straightforward quantification in simple protein mixtures. Finally they stressed that for quantifying protein mixtures of higher complexity, LC–MS/MS capabilities are indispensable.

10. Future trends

10.1. Micro-scaling the labeling

One of the main drawbacks related to proteomic approaches deals with the low amount of sample available for handling. In addition ^{18}O-water is an expensive reagent. For this reasons micro-scaling the labeling is an alternative to conventional sample treatments that has the advantages of automation and low sample/reagent consumptions.

Lee et al. have recently described an automated digestion system based on a microfluidic chip for MALDI-TOF-MS [56]. The chip has a bioreactor, 100 μm wide, 100 μm deep and 4 cm effective channel, containing immobilized trypsin. The chip was operated by pressure-driven flow and mounted on a robotic fraction collector system. Advantages of the system are sample consumption at the micro-scale level (flow rate 1 μL/min) and a reaction time of 24 s. The system entails automation for digestion and accomplishment to MALDI droplet deposition system. This approach could also be used for labeling the peptides by just adding some more channels for the introduction of the ^{18}O-water, thus reducing the consumption or reagents and facilitating automation.

10.2. The use of infrared radiation and microwave energy

Bao et al. and Wang et al. have proposed the use of infrared radiation for the digestion of proteins in solution or proteins separated by gel electrophoresis [57,58] respectively. The authors claimed a total time for the digestion of 5 min. The maximum temperature allowed to reach using the infrared radiation was 37 °C. The authors explained that the enhanced activity of the enzyme could be explained considering that vibrations of N–H, C=O and C–N bonds in proteins would led to the vibrations of peptide bonds. These vibrations could increase the frequency of the interaction between the enzyme and the peptide bonds in proteins molecules, resulting in highly efficient proteolysis. In addition, the vibrations could also expose more cleavage sites to the enzyme. Although the aforementioned explanation can be applied to proteins in solution, the sample treatment proposed for proteins separated by gel electrophoresis, as described by Bao et al., included also a step with ultrasonication [58]. Therefore, in the last case it remains unclear if the enhancement in the enzymatic activity was due to the infrared radiation, to the ultrasonication or to the combination of both. Finally, the most recent contribution reported regarding IR deals with its application to on-plate proteolysis for MALDI-TOF-MS peptide mapping. Protein solutions containing trypsin were allowed to digest directly on the spots of matrix-assisted laser desorption/ionization (MALDI) plates under IR radiation. The suitability of IR-assisted on-plate proteolysis to complex proteins was demonstrated by digesting human serum and casein extracted from commercially available milk sample [59]. As it can be seen, the application of IR to speed the direct labeling or to speed the digestion step in a decoupling procedure is a promising methodology that deserves to be investigated.

In the same way as IR, microwave has been used to speed protein digestion of proteins. Fenselau et al. [60,61] pioneered the utilization of microwave energy in proteomics sample treatments and the works of this author dealing with this subject are strongly recommended. It is expected in the near future the linkage between microwave energy and ^{18}O-labeling due to the potential of simplicity, speed and throughput that jointing both it will be obtained.

11. Conclusions

^{18}O-labeling of peptides is an approach that nowadays offers a simply way to perform many different proteomic tasks, including protein quantification in a relative or absolute manner, differential peptide mass mapping or the searching for biomarkers.

The modern technological advances available currently, such as ultrasonic energy, microwave energy, ultracentrifugation, and infrared energy offer many real or potential methods, to speed the labeling, to increase the throughput and to simplify the handling, for this methodology.

From data reported to date and from our own experience the most robust way to perform ^{18}O-labeling seems to be the decoupling procedure jointed to ultrasonication. With this accomplishment peptides are double labeled in more than a 90%.

Finally, the application of the inverse labeling in conjunction with immobilized trypsin to digest the proteins and to label the ones seems to be the most promising approach for unambiguous studies regarding proteins overexpressed or underexpressed,, biomarker discovery and protein quantification.

ABSTRACT

Protein quantification based upon mass spectrometry is gaining ground in diverse applications of biological and clinical relevance. The present article focuses on one of the most complex biological fluids – serum – and provides a novel ICPL based quantification protocol. The results are compared to a label-free (data independent alternate scanning) absolute quantification method. The validation is performed using MRM based protein quantification technique. Regarding the ICPL approach, serum samples used in this study were depleted of high abundant proteins, labeled with ICPL and fractionated according to their respective pI (3–5, 5–7 and 7–12). The samples were further subjected to tryptic digestion followed by treatment with the Glu-C enzyme. The peptides were analyzed on a 2D-nano-LC system using four different concentrations of salt injections (45, 75, 150 and 500 mM ammonium acetate). The LC system was connected *on-line* with the electrospray ion-trap mass spectrometer. For the label-free quantification the serum samples were depleted and digested with trypsin. A proteome-wide comparison was performed using highly reproducible LC and data independent alternate scanning in conjunction with a high mass accuracy orthogonal time-of-flight mass spectrometer. Selected proteins, found by both methods, were validated using the MRM approach. For this purpose non-depleted tryptically digested serum samples were analyzed by LC coupled with a triple-quadrupole MS. The relative protein quantification using ICPL and mass spectrometry allowed for the detection of approximately 200 proteins, whereas about 2/3 of those contained the ICPL label and could therefore be quantified. Label-free approach used no fractionation, less sample and was able to identify and quantify over 110 proteins. The identified proteins covered generally 3–4 orders of magnitude of protein concentration in human serum. Changes in relative abundance of eight proteins were validated using MRM. This study, for the first time, shows the ability of the relative protein quantification based upon ICPL and 2D-LC–MS/MS to quantify serum biomarkers. It provides two additional label-free approaches that could validate and bring additional value to the label-based results, offering a starting point for comprehensive proteomics studies aiming at revealing biomarkers of clinical relevance.

1. Introduction

Serum samples are complex protein mixtures with concentrations spanning up to 10 orders of magnitude leading to difficulties in reliable protein identification and quantification [1–3]. Up until now, several quantification strategies have been described for serum samples. As far as the quantification of specific individual proteins is concerned, methods for spiking isotope-labeled or cloning of concatenated peptides have been developed. After sample digestion, a comparison of the MS signal of the endogenous peptide to the synthetic standard delivers the desired quantification result. Triple-quadrupole instruments and MRM methodologies are particularly suitable tools. For unselective, proteome-wide comparisons, primarily chemical labeling approaches are employed. For example, methanol (substituted with hydrogen or deuterium) esterification reactions [4], tryptic digestion in the presence of $H_2{}^{(16/18)}O$ [5], $^{12/13}$C-acrylamide–cysteine labeling [6], ICAT (isotope coded affinity tags) [7], iTRAQ (isobaric tag for relative and absolute quantitation) [8] and ICPL [9] have been applied. In spite of promising results, several difficulties are associated with some of these quantification methods. It is recognized that chemical labeling bares the drawback of unexpected side reactions and chemical products which complicate the quantification results [10]. Specifically ICAT and other chemical moieties that selectively label cysteine residues cannot be used to quantify proteins that contain none or few cysteines. Isotope coded tags based on N-hydroxysuccinimide (NHS) chemistry like iTRAQ and ICPL have the

doi:10.1016/j.talanta.2009.07.035

potential to bridge these difficulties. These reagents target primary amino groups (e.g. lysine residues that are more abundant that cysteines) enabling the quantification of larger number of proteins. Hergenroeder et al. [11] have shown the application of iTRAQ to identify novel brain injury biomarkers in serum samples. One limitation associated with iTRAQ is the restricted ability to be used in conventional ion-trap instruments because of the reporter masses that are usually in the region of the 1/3 m/z precursor to product ion cut off. The novel stable isotope labeling method, termed ICPL, has emerged as a promising technique to relatively quantify proteins within complex protein mixtures [9,12]. The ICPL reagent is non-cleavable resulting in the permanent mass shift of the labeled peptide. This technique has provided the means to improve the accuracy, sensitivity and dynamic range of existing methods [13]. Up to date there has been no study related to the application of ICPL to quantify serum proteins. To this end, the primary goal of this work is to show the ability of the ICPL and 2D-LC–MS/MS method to relatively quantify serum proteins.

Because of the mentioned drawbacks concerning the label-based methods there is an increasing trend towards label-free quantification techniques. These are predominantly based either on the (i) measurement of MS signal ion intensity of peptide precursors or on the (ii) counting of the fragment ion spectra corresponding to a given protein. The first method consists of the peak area integration of the extracted ion chromatogram for a particular peptide. This value is then compared with the corresponding one in other experiments, in order perform a relative quantification. Although different algorithms and strategies have been employed to analyze the data, a series of inherent sources of error have been identified. The uncertainty arises primarily from the fact that only a limited number of data points across a peak can be acquired per unit of time. This can be associated to limitation of the duty cycle in the MS/MS acquisition mode. Problems resulting from the mass accuracy and resolution of the instrument employed as well as the reproducibility of the chromatographic separation further complicate reliable quantification. The second label-free quantification approach of spectral counting is based on the assumption that the more one protein is present in the mixture the greater is the chance that its peptide would be picked for an MS/MS fragmentation. Here one of the most obvious problems is that this method does not consider any physical properties of the peptide in question. Therefore ionisation differences, changes in the chromatographic peak width are some of the conundrums encountered. Taken together both techniques mentioned have their strengths but offer also significant pitfalls that could cumulate in misleading quantification results. In order to bridge these difficulties novel instrumentation is needed along with a significant improvement in the statistical data evaluation. Recently a novel MS and LC instrument, as well as special software algorithm, was developed with a potential to overcome the problems mentioned [14–16]. The accomplishment is based on highly reproducible LC and data independent, alternate scanning in conjunction with high mass accuracy measurements provided by an orthogonal time-of-flight mass spectrometer. The technique is based on the detection and correlation of all detectable precursor and fragment ions that share the same chromatographic profile. This is achieved by a rapid alteration between low- and elevated-energy states applied to the collision cell [15], which subsequently allows for the simultaneous quantification and identification of proteins in a single experiment. This method has already been applied to complex protein mixtures like the plant secretome [17], exosomes research [18], human serum [19] and the identification of novel MMP-9 substrates in cancer cells [20]. In the present study a functional protocol has been presented for rapid label-free serum proteins quantification, with the goal to compare this novel method with the label-based ICPL protocol. Selected ICPL and label-free data were validated regarding the accuracy of the relative quantification using the MRM as an established targeted quantification technique. For this purpose no synthetic peptides were employed as internal standards but a set of two proteins which served as a pseudo internal standard was used. The technique was put forward by Tabata et al. [21] which demonstrated that the usage of "housekeeping proteins" as normalization standards is a valid quantitative approach. The experimental design is detailed in Fig. 1. The current work offers scientists two independent ways to proceed from the biomarker discovery to their validation in a fast and accurate manner.

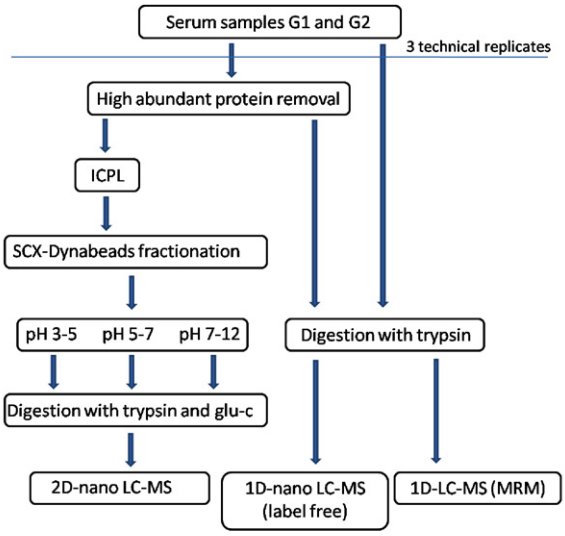

Fig. 1. Schematic representation of the experimental setup. The MRM experiments were conducted without prior removal of the most abundant proteins. In contrast to the label-free method, the label-based ICPL approach involved a pre-fractionation according to different pI of the proteins and subsequent digestion using two different proteolytic enzymes (trypsin and Glu-c).

2. Materials and methods

Unless otherwise indicated all the chemicals were purchased from Sigma–Aldrich (St. Louis, MO, USA) and had at least p.a. and higher quality. Human serum samples used here consisted of two groups of patients (G1 and G2) involving 10 patients each within a clinical trial for analysis of frailty markers (SENEGENE project, Walloon Region, Belgium) at the Catholic University of Louvain, Mont-Godinne University Hospital. The project was approved by the ethics committee and written consent was obtained from all the human individuals involved in the study. Per quantification method at least three technical replicates were performed (see Fig. 1).

2.1. Depletion of the most abundant proteins from the serum samples

A volume of 20 μL of the serum sample was depleted of high abundant proteins using the IgY-12 kit (Beckman Coulter, Fullerton, CA, USA). Unless otherwise indicated all components originate from the above mentioned IgY-12 kit. For long-term storage, the serum samples were kept frozen at −20 °C. Prior to depletion they were thawed at +4 °C for 1–2 h, vortexed briefly and centrifuged for 5 min at 13,000 × *g* (Eppendorf, Hamburg, Germany). Subsequently, 20 μL of each serum sample was mixed with 480 μL of dilution buffer and was added to the freshly reconditioned IgY-12 column. Following this, the samples were incubated for 15 min at RT under constant shaking and subsequently the column was centrifuged for 30 s at 400 × *g*. The filtrate contained the depleted serum proteins (V = 400 μL). The highly abundant proteins bound to the column

were stripped off with 2× 500 μL of stripping buffer and discarded. Subsequently, the column was neutralized with 600 μL of 1:10 diluted neutralization buffer and reconditioned in 500 μL of dilution buffer. After the depletion of 20 μL of serum sample, 96 ± 1% of the initial total protein content was removed. The depleted proteins were precipitated using the 2D Clean-Up kit (GE Healthcare, Piscataway, NJ, USA) and dissolved in 20 μL of sample buffer (Serva, Heidelberg, Germany). The concentration of the samples was set to 5 mg/mL and the pH to 8.5 ± 0.1.

2.2. ICPL labeling, fractionation and digestion of the serum samples

Unless otherwise indicated, all the components used were part of the ICPL kit. An amount of 0.5 μL of the ICPL-reduction solution was added to each of the depleted serum samples followed by 30 min incubation under mild shaking (600 rpm, Thermomixer [Eppendorf]) at 60 °C. Subsequently, 0.5 μL of ICPL-alkylation reagent was added and the samples were incubated for further 30 min at 25 °C protected from the light. After 30 min the reaction was stopped following the addition of 1 μL of ICPL-stop solution and 15 min incubation at 25 °C. The reduced and alkylated protein samples were labeled using 3 μL of ^{12}C-Nic- or ^{13}C-nic-reagent solution for the respective sample. Subsequently, both samples were overlaid with nitrogen gas, vortexed for 10 s and sonicated for 1 min in the ultrasonic bath (Branson, Danbury, CT, USA). The samples were incubated for 2 h at 25 °C. The reaction was stopped by addition of 2 μL of ICPL-stop solution. The samples were incubated for further 20 min at 25 °C and combined together by vortexing. The pH of the mixture was adjusted to 11.9 by adding approximately 1 μL of 2 M NaOH. After 20 min the same amount of 2 M HCl was added to neutralize the samples. This was necessary in order to destroy the surplus label in the sample and prevent any subsequent unspecific reaction. An amount of 100 μg of total protein (considering both samples) was taken for subsequent analysis.

After the ICPL, serum proteins were fractionated according to their respective pI. For this purpose, SCX material immobilized on magnetic beads (Dynabeads [Invitrogen, Carlsbad, CA, USA]) was employed; the beads were separated from the liquid phase by a strong magnet (part no. 105.13D, Invitrogen). Approximately 1 mg of Dynabeads (corresponding to 80 μL beads suspension) was transferred in a reaction tube. The beads were reconditioned twice with 100 μL of pre-loading solution (50 mM HEPES buffer [pH 8.0] and 1 M NaCl). After this step the beads were suspended for 2 times in 100 μL of adsorption solution (20 mM citric acid [pH 3] and 10 mM NaCl). The labeled sample was added to the reconditioned beads and the volume was adjusted with ads. sol. to 200 μL (pH 3). The samples were incubated for 2 min at RT and subsequently the supernatant was removed and saved as fraction 1; the beads were suspended for one more time in 100 μL of ads. sol. and the supernatant was joined with the fraction 1. Following this step further fractions were eluted by mixing 50 μL of corresponding desorption solution (1. 50 mM PBS, pH 7 and 2. 20 mM ammonium acetate, pH 9.5) followed by 2 min incubation at RT. This step yielded fractions no. 2 and 3. Finally the beads were suspended in 50 μL of 100 mM NaOH in order to detach the remaining proteins bound to the Dynabeads. This last fraction was joined with the previous one (no. 3, pH 9.5). As the elution buffers were not compatible with the subsequent enzymatic digestion (outlined below) the proteins found in each fraction were subjected to precipitation using the 2D Clean-Up kit.

The samples were first subjected to tryptic digestion followed by digestion with Glu-C (both recombinant enzymes were supplied by Roche, Basel, Switzerland). To the protein pellets, a volume of 20 μL of 1 M urea and 25 mM NH_4HCO_3 buffer (pH 8) was added. The samples were suspended and sonicated for 1 min in the ultrasonic bath (Branson, Danbury, CT, USA). After sonication 1 μg of trypsin was added and the samples were incubated at 37 °C overnight. Following the 16 h period, 0.5 μg of fresh trypsin was added and the incubation was extended for additional 4 h at 37 °C. Subsequently, 2 μg of Glu-C enzyme was added to each sample. The samples were digested for additional 6 h at 25 °C. To stop the digestion, 20 μL of water containing 0.5% formic acid (pH 2) was added. The samples were desalted using the C18 ZipTips (Millipore, Billerica, MA, USA) and analyzed with the 2D-LC–MS system.

2.2.1. MS analysis and relative quantification of the ICPL labeled peptides

The peptide samples were analyzed on the 2D-nano-LC system Ulimate 3000 (Dionex, Sunnyvale, CA, USA). The LC system was connected *on-line* with the electrospray ion-trap mass spectrometer Esquire HCT ultra (Bruker Daltonics, Bremen, Germany). For the MS analysis, approximately 5 μg of digested protein sample was loaded on the Bio-X-SCX column (500 μm i.d. × 15 mm; Dionex). Subsequently, four different concentrations of salt injections were performed (45, 75, 150 and 500 mM ammonium acetate, 0.1% formic acid). After each salt injection, the eluted peptides from the SCX column were trapped on a C18 pre-column (Acclaim PepMap, 300 μm i.d. × 5 mm; Dionex) and desalted for 5 min at the flow rate of 30 μL/min using solvent A (97.9% water, 2% acetonitrile and 0.1% formic acid). Following this, the separation of the peptides was conducted on the C18 analytical column (Acclaim 75 μm × 150 mm; Dionex) using a 120 min solvent gradient (t = 0 min, 0% B [B: 80% acetonitrile, 19.9% water and 0.1% formic acid]; t = 120 min, 40% B) at the flow rate of 0.3 μL/min. The MS scanned the mass range from 200 to 1600 m/z. The four most intense peptides found in this mass range (bearing +2 and +3 charges) were selected automatically and fragmented in MS/MS mode (m/z range 100–2500). The acquired spectra from all the samples were combined in one raw data file using Analysis Combiner (Bruker) software tool and were deconvoluted with the Data Analysis software (Bruker). The processed data were loaded in the WarpLC software (Bruker) and protein identification and quantitation was conducted with the help of the Mascot search engine (Matrix Sciences, Boston, MA, USA) and the human non-redundant and non-identical protein database Swiss-Prot (Swiss Institute for Bioinformatics, Basel, Switzerland, release 57.0; 20,334 entries). The following parameters were used: MS and MS/MS tolerance 0.6 and 0.3 Da respectively, 1 missed cleavage was allowed and a novel enzyme entry (trypsin + Glu-C) was made in the Mascot engine allowing for lysine, arginine and glutamic acid cleavage sites. The ratios of heavy and light ICPL labeled peptides allowed for the relative quantitation (Table 1).

2.3. Serum sample preparation for label-free quantification

The samples were depleted as described in Section 2.1. A total of 50 μg of proteins per sample were reduced with 25 mM DTT for 30 min at 60 °C and alkylated with 50 mM iodoacetamide for 30 min at RT. After precipitation (as described in Section 2.1), the protein pellet was dissolved in 20 μL of 1 M urea and 25 mM ammonium bicarbonate (pH 8) and sonicated for 1 min in the ultrasonic water bath. To the dissolved proteins, 1 μg of trypsin was added and the samples were incubated overnight at 37 °C. Following the initial period of incubation, 0.5 μg of fresh trypsin was added and the incubation was extended for additional 4 h. The samples were then diluted with 30 μL water containing 0.5% formic acid (pH 2), desalted using C18 ZipTips and analyzed with the 1D-LC–MS system.

Table 1
ICPL based relative protein quantification of serum samples G1 and G2. The value of the ratio displayed refers to G2/G1 comparison. The number of the labeled peptides (H/L) is the mean value of three independent replicates. The standard deviation (SD) of means is based on the respective ratios of the labeled peptides. Score, sequence coverage (SC, %) and the number of peptides are average values ($n = 3$) obtained through Mascot/Swiss-Prot database search.

No.	Protein	MW (kDa)	pI	Score	SC (%)	No. pept.	No. H/L	Ratio	SD

2.3.1. MS analysis and absolute quantification of label-free peptides

The samples were analyzed using a nanoAcquity system (Waters Corporation, Milford, MA, USA) coupled with the SYNAPT mass spectrometer (Waters Corporation, Manchester, UK). An amount of 10 μg of each of the digested serum samples was diluted in 40 μL of 0.1% formic acid in water to a concentration of 0.25 μg/μL. Samples were spiked with yeast alcohol dehydrogenase tryptic digest (final concentration 77 fmol/μL). Finally, 1 μL of the sample was injected, corresponding to an estimated sample load of 250 ng. The LC system configuration was as follows: trap column Symmetry C18 5 μm, 180 μm × 20 mm (Waters Corporation), analytical column BEH C18 1.7 μm, 75 μm × 250 mm (Waters Corporation), solvent A (0.1% formic acid in water), solvent B (0.1% formic acid in acetonitrile) and flow rate 300 nL/min (gradient: 0 min, 97% A; 90 min, 60% A). The following acquisition parameters were set for the SYNAPT mass spectrometer: data independent, alternate scanning (MS^E) mode, 50–1990 *m/z* range, ESI+, V optics, scan time 1 s, cone 24 V and lock mass [Glu1]-Fibrinopeptide B $[M+2H]^{2+}$ 785.8426 *m/z*.

ProteinLynx GlobalSERVER v2.3 was used to process raw data for subsequent protein identification and quantitation. The processing parameters were as follows: MS TOF resolution and the chromatographic peak width were set to automatic, low-/elevated-energy detection threshold to 150/50 counts, identification intensity threshold to 1000 counts and lock mass window to 785.8426/0.25 Da. The Swiss-Prot human database (release 57.0; 20,334 entries) served as the reference. The search tolerances were automatically read from the data and were approximately 9 and 23 ppm for the precursor and product ions, respectively. Peptide modifications carbamidomethylation, deamidation (N/Q) and oxidation (M) were set as variable. One missed cleavage for trypsin digestion was allowed (Table 2).

Table 2
Label-free relative protein quantification of depleted serum samples G1 and G2 (ratio G2/G1). The SD represents the standard deviation of means ($n = 3$). The score was calculated for each individual protein using the identification and quantification software embedded in ProteinLynx GlobalSERVER v2.3.

2.4. Serum sample preparation for quantification based upon MRM

A volume of 100 μL of serum diluted with 100 μL of water was subjected to reduction and alkylation (25 mM DTT for 30 min at 60 °C and 50 mM iodoacetamide for 30 min at RT) followed by addition of 3 μg of trypsin. The samples were incubated at 37 °C overnight. After the initial incubation period, 1.5 μL of trypsin was freshly added and the samples were incubated at 37 °C for additional 4 h. Subsequently, the samples were diluted with 3 volumes of water containing 0.2% formic acid and the MS analysis was conducted as described in Section 2.4.1.

2.4.1. MRM assisted quantification using the triple-quadrupole MS

Waters Alliance 2690 liquid chromatography system coupled with a Quattro Ultima Platinum triple-quadrupole MS instrument (Waters Corporation) was employed for the MRM analysis. Approximately 50 μg of the digested sample was injected on C18 column, Polaris C18, 3 μm beads, 200 Å pore size, 2.1 mm × 150 mm (Varian Inc., Palo Alto, CA, USA). The flow rate was 400 μL/min. Linear separation gradient was used: t = 0 min, 100% water (0.1%, v/v acetic acid) and t = 20 min, 60% water and 40% acetonitrile (0.1%, v/v acetic acid). The eluent flow rate was split to 50% prior to the ESI ionisation. The triple-quadrupole MS instrument was set in the MRM mode, capillary voltage was 2.6 kV, desolvation temperature 250 °C, cone desolvation gas 630 L/h, collision cell pressure 2 μbar, collision energy 15 (for all the peptides selected) and resolution at quadrupole 1 was ±1 Da. The data were accrued and evaluated using the MassLynx (v 4.0) software. Two proteins whose quantities proved to be unchanged between the two groups (both with the label-free and ICPL quantification), namely A2GL and IC1, were used as internal standards to normalize ion intensities between both samples. Proteins selected for quantification as well as their respective peptides and fragments used for MRM are outlined in Table 3.

3. Results and discussion

The application of ICPL combined with the 2D-LC–MS method, including in addition the fractionation of the labeled proteins according to their pI value, enabled the identification of 211 proteins, with a false positive rate (FPR) of 5.3%, in human serum samples. This represents a group of non-redundant proteins in two out of three independent replicates. Of these, 128 (61%) proteins were quantified as they had one or more labeled peptides. The remaining proteins were identified with one or more peptides that did not contain any lysines. Hence, this information was lost and could not contribute to the quantification. Therefore the limiting factor of the ICPL technique is the number of the labeled peptides per protein of interest. Moreover, as ICPL specifically labels all the lysine residues and the positive charge is lost the pI of the respective proteins is shifted towards the acidic end. This results in the fact that the greatest part of the proteome is found in the relatively narrow pH range starting from very acidic to a pH of approximately 6. Nevertheless, very basic proteins (with pI above 10) shifted to lower pI values and were generally found in the fractions between pH 6 and 10. In the acidic environment during the LC–MS analysis, effective fractionation of the labeled proteins on the SCX column proved to be difficult. This was most probably due to the loss of charged lysines and hence the peptides were predominantly eluting in a narrow window of low ionic strength. In order to counteract this, an additional fractionation step was employed at the protein level, according to the respective pI value, which simplified the protein mixture but increased the analysis time. An additional conundrum inherent to the ICPL method was the sequestration of the lysine cleaving sites for the endo-protease trypsin. Hence trypsin cleaves only at arginine sites which results in fragments with large molecular weights. The MS analysis of such large fragments using conventional ion-trap MS is difficult for several reasons. Firstly, the scanning m/z window must be increased which will lead to longer cycle times. Secondly, these large peptides are probably carrying more than 3 charges which cause difficulties related to the resolution power of the mass spectrometer used. In order to try to avoid these problems and to reduce the size of such large fragments an additional enzyme has been employed, namely Glu-C protease, which cleaved the proteins at glutamic acid sites when used in bicarbonate buffer.

In comparison to ICPL, the label-free method did not employ any pre-fractionation and could identify 114 proteins. Considering two out of three independent replicates, 77 (68%) commonly identified proteins (present both in G1 and G2) were quantified. In contrast to the ICPL method, where no quantitative data were available on approximately 1/3 of all proteins identified, label-free approach could provide the quantitative data even for the remaining proteins that were identified in only one out of three replicates. These were of limited significance but could still offer valuable information that can be subject to future validation. One of the possible methods is the MRM approach which was used for selected number of proteins in the present work. Along these lines, the label-free approach offered insights into the actual reproducibility of the technique, due to the absolute quantification of individual samples and replicates. Regarding sample G1, 81 proteins were confidently identified in at least 2 out of 3 replicates. The calculated protein identification false positive rate of the experiment was 1.23% and the peptide FPR of identification 0.34%, including replicating as filter for both the protein and peptide FPR calculations and in addition the number of identified peptides, which had to be at least 2, for the protein FPR calculation. The average column sample loading was calculated to be 116.8 ng using the absolute quantification function afforded

by the search algorithm [22]. The absolute quantity of the individual proteins ranged from 0.007 to 13.7 ng. In the sample G2, 83 proteins were identified. The protein and peptide FPR were both 0%, and the average sample loading 143.1 ng. In this instance, the quantity of the individual proteins ranged from 0.01 to 16.2 ng. It is important to note that these identifications mount from relatively low column loadings and it should therefore be expected that a greater number of proteins can be identified and quantified with either more optimized loadings or a 2D-HPLC approache (the latter was not available at the time of the manuscript preparation). Taken together, for both samples, the mean mass precision of the peptides of the technical replicates was approximately 2.13 ppm and the mean retention time reproducibility approximately 0.1% CV. Injection comparisons between the G2 vs. G1 triplicate analyses using log/log normal intensity plots showed a high inter-injection reproducibility (all results not shown here).

One further important difference between the two quantification approaches was found in the normalization techniques employed. In the case of the ICPL data, there was no need to normalize the signal intensity difference between each of the replicate analysis, since both conditions were introduced at the same time in the MS. The data were solely normalized according to the Gaussian distribution under the assumption that most of the proteins quantified will not change between the two conditions. Regarding the label-free data, an alternative approach was necessary as each of the samples and the replicates was analyzed separately. The observed peptide intensity measurements are normalized to the intensity measurement of the identified peptides of the digested internal standard. Next, the redundant, proteotypic quantitative measurements provided by the multiple tryptic peptide identifications from each protein were used to determine an average, relative protein fold-change. The algorithm performs binary comparisons for each of the conditions to generate an average normalized intensity ratio for all matched proteins. Proteins with a likelihood of quantification smaller than 0.05 were considered to be significantly regulated [14]. The normalization method for the label-free experiment is similar to the one conducted for the ICPL data and is also based on the assumption of a normal distribution.

It is not unreasonable to assume that the standard protocol used for the label-free application, where the tryptic digest is spiked in the peptide mixture of the previously digested sample, may fail to account for differences in the degree of the tryptic digestion as well as for a possible bias introduced in the subsequent fractionation steps. In the attempt to balance these effects out, the method described here does not use any fractionation steps prior or after the digestion. Nevertheless, for future applications we suggest to consider spiking the internal standard prior to sample digestion as this would lead to more robustness in the method workflow and allow for new possibilities in the sample preparation. A combination of several standards as well the consideration of some possible endogenous standard proteins (those that would most probably stay unchanged due to their biology) may further improve the accuracy of the method.

Eight regulated proteins comprising those displaying significant differences or similarities with regard to the relative quantification ratios calculated with ICPL and label-free techniques were selected to be validated employing the MRM approach. The initial ICPL analysis delivered protein identifications along with masses of peptides (MS) and their fragments (MS/MS) that were used in the MRM experiment (see Table 3). These so-called transitions (fragmentation of precursor to product ions) were employed to selectively isolate and quantify proteins using the tandem MS. The choice of the MRM suitable peptides was guided primarily by four important criteria: the peptides should (i) be tryptic and contain no missed cleavage sites, (ii) have a high score (Mascot), (iii) contain no cysteine residues (avoid carbamidomethylation) and (iv) have the sequence specific for the selected protein (all the sequences were checked using the BLAST program (NCBI) and compared with the Swiss-Prot human database). Peptides which fulfilled these requirements were further sorted according to their respective product ion spectra and the ones that contained the most intense "y" series fragments were selected. The respective peptides of two proteins that appeared to have the same concentration in both samples (considering the label-free and ICPL data, Fig. 1) were assigned to serve as a pseudo internal control (A2GL and IC1). Inherent to this approach these pseudo internal standards were used to also account for differences that might result during the tryptic digestion. Peptide ionisation differences were normalized by calculating the average peak area ratio of the internal control peptides between individual injections. This value was employed as the correction factor for the ratio calculations of the remaining eight proteins (A1AG2, A1BG, A2AP, CO8G, FIBB, PEDF, THBG and VTNC). Generally the MRM based quantification correlated well with both methods. In particular for the proteins that have shown opposing quantification results (A2AP, PEDF and THBG) the MRM data were more supportive of the label-free quantification results. One exception was CO8G protein where the MRM quantification was closer to the result obtained by the ICPL method (Table 4). Taken together 66 proteins that were found in common to the two quantification strategies (ICPL and label-free). Of these 7 proteins showed discrepant results. Considering the ICPL data these proteins have been quantified mainly by 2 or more labeled peptides, which shows that successful ICPL quantification is not dependent only on the number of labeled peptides. Apparently other factors like signal to noise ratio (S/N) of the MS spectra appeared to be decisive. Indeed the proteins in question were quantified using predominantly peptides that had an average S/N of 15. Good quantification results were achieved with peptides that had an S/N above 30. The trend was observed throughout the ICPL experiments (data not shown here) and points at the need to assess each of the peptides on individual basis.

In contrast to the sample preparation for the ICPL and the label-free method, the MRM quantification was performed without prior depletion of the major serum proteins. This offered a good basis for an overall evaluation of the sample preparation. The IgY-12 kit was used to selectively remove 12 highly abundant proteins from the serum samples. These proteins are: ALBU, IGHG, IGHM, IGHA, TRFE, HPT, A1AT, FIB(A/B), A1AG(1/2) and A2MG. Of these FIBB and A1AG2 were evaluated in all three quantification methods and yielded similar results. Others (except IGHG1 and IGHG4) have also shown consistent results using the ICPL and the label-free technique. This may indicate that the depletion of the abundant proteins using the IgY-12 kit did not alter the original relationship of these proteins in the serum sample. Moreover the technique proved to be reproducible results are obtained within technical replicates. Along these lines, the MRM together with the label-free results have shown that the additional fractionation with SCX Dynabeads and subsequent double enzymatic digestion (trypsin and Glu-c) employed in the ICPL method did not alter the quantification results.

Table 4
MRM quantification of the eight selected proteins. The SD indicates the standard deviation of means ($n = 3$).

Protein	MRM quantification	
	Ratio	SD
A1AG2	0.54	0.09
A1BG	1.24	0.01
A2AP	1.63	0.29
CO8G	2.77	0.07
FIBB	1.24	0.25
PEDF	1.40	0.38
THBG	0.95	0.13
VTNC	2.37	0.35

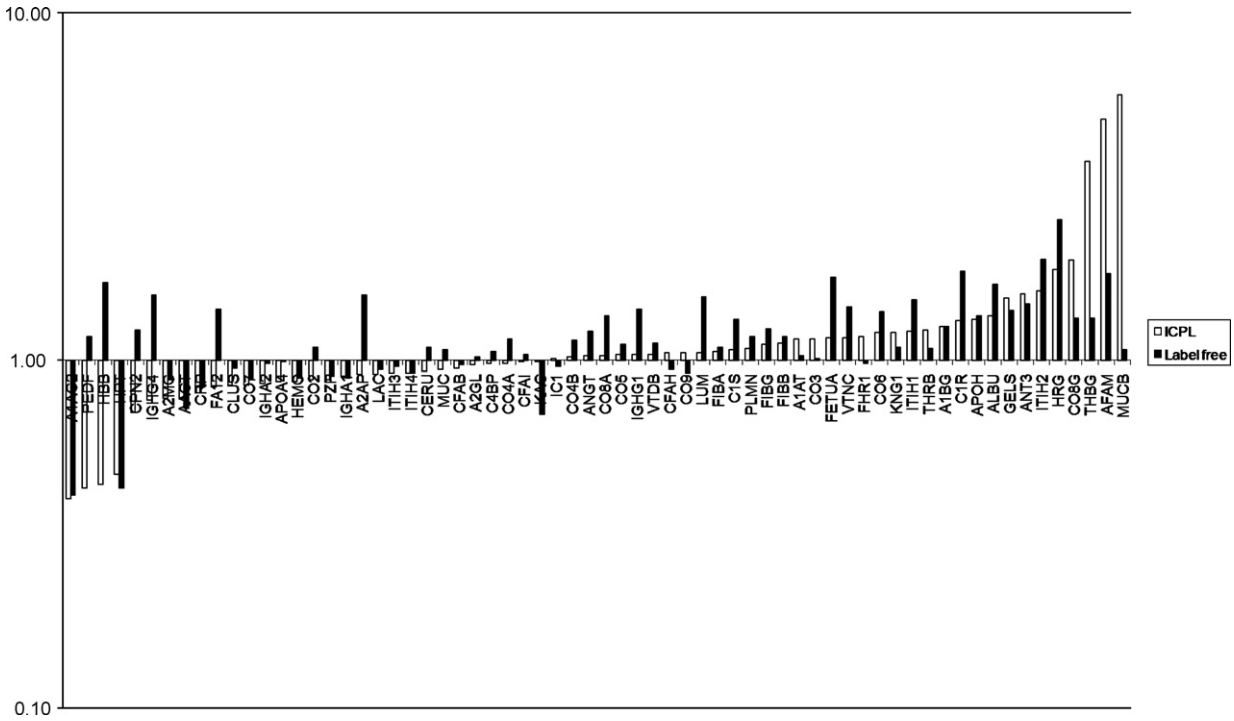

Fig. 2. The comparison of the relative quantification of the G2 vs. G1 sample using the ICPL and the label-free method. In total 66 commonly identified and quantified proteins have been displayed.

4. Summary and perspectives

Considering all the results presented here both ICPL and label-free approach are promising techniques for protein quantification in complex mixtures. In direct comparison label-free approach does seem to a certain extent more advantageous since:

(i) the sample preparation method was simpler (see Fig. 1), the instrumentation required less amount of sample (column load of approximately 0.2 ng was sufficient compared with ICPL where 5 μg were used),
(ii) the quantification appeared to be more accurate (7/8 proteins were validated compared to ICPL where 5/8 proteins showed the similar ratio as the MRM technique; see Fig. 2) and
(iii) quantitative information was provided for all identified proteins in at least one out of three replicates (ICPL could provide the quantification only if the peptides contained the label).

Regarding the serum sample, being characterized with the large dynamic range of protein concentrations, extensive fractionation has clearly shown to improve the number of proteins identified. The MRM strategy, well known as a method of choice for the quantification of small molecules, has proved to be of great value for relative label-free quantification of specific proteins. Future studies should consider the development of suitable pre-fractionation techniques that could be used with the label-free quantification methods. The emphasis in further development of both quantification methods should ideally be laid on functional protein separation (phospho-, glycoproteins, etc.) as this is of significant biological relevance.

Acknowledgments

The authors are grateful to the Walloon Region for the funding of the SENEGENE project, to Dr. Marie de Saint-Hubert and Prof. Christian Swine from the Catholic University of Louvain, Mont-Godinne University Hospital, for providing the serum samples. The authors acknowledge GIGA consortium and the proteomics platform of the University of Liege for providing material help.

ABSTRACT

An evaluation of the ICPL (isotope-coded protein labeling) non-isobaric labeling technique was performed using two different biological models. Two samples containing phage T4 capsids were mixed in a 1:1 ratio after being labeled with the light or heavy versions of the ICPL reagent. The analysis of this proteome demonstrated the feasibility of this approach for differential quantitative proteomics and was employed to optimize the experimental parameters of the ICPL workflow. ICPL-mediated analysis of two more complex proteomes, those of a *Salmonella enterica* serovar Typhimurium virulent strain and an isogenic attenuated mutant, and its comparison with the results obtained in a 2D-PAGE "classical" approach confirmed that ICPL is a valuable alternative to other labeling techniques currently in use. In addition, our results suggest that labeling at the peptide level instead of following the standard ICPL workflow should increase both the number of proteins quantified and the reliability of the quantification.

1. Introduction

The development of new quantitative tools for the analysis and comparison of whole proteomes (differential proteomics) has been continuous during the past years. Traditional approaches, based on previous fractionation of complex proteomes by 2D-gel electrophoresis and comparison of the gel images generated thereby, are being complemented by new techniques that commonly make use of isotopic labeling of the samples to be compared, followed by liquid chromatography coupled to electrospray tandem mass spectrometry [1,2]. Isotopic labeling can be performed *in vivo* (e.g., SILAC [3]), chemically (e.g., ICAT [4], cICAT [5], iTRAQ [6], Lys-tag [7], ICPL [8], TMT [9]) or enzymatically (e.g., $^{16}O/^{18}O$ [10,11]). In addition, label-free techniques show increasing acceptance as ultra-high performance liquid chromatography systems are becoming available and software developments required to compare multiple LC–MS runs are gaining efficiency and reliability [12].

Among differential proteomics methods based on stable isotopic labeling, ICPL is a non-isobaric technique devised to efficiently label primary amines profusely found in proteins. Relative quantification is achieved by comparison of the relative abundance (regarded as either peak intensity or area) of the differentially labeled peptides. The latest version of this reagent allows the comparison of up to four samples at the same time. Theoretically, ICPL overcomes some of the disadvantages found in other chemical labeling techniques, such as iTRAQ (poor detectability of the reporter ions in several types of mass spectrometers) or ICAT (low number of potentially labelable residues). However, the number of articles published to date using ICPL is noticeably low [13–15] when compared with other methods and no clear consensus exists on its feasibility as a quantitative tool. Here we describe a comprehensive evaluation of this technique using two different biological models. First, the proteome of the bacteriophage T4 capsid was labeled with the light or heavy version of ICPL and mixed in a 1:1 ratio. This sample was then used to evaluate the viability and robustness of the ICPL approach as well as to determine the optimal experimental parameters. In the second case, we compared a more complex sample composed of whole proteomes from a *Salmonella enterica* serovar Typhimurium virulent strain and an isogenic strain harboring a mutation in the Intracellular-growth-attenuator-A (*IgaA1*). The Intracellular-growth-attenuator-A (*IgaA*) is a *S. enterica* membrane protein that inhibits the RcsC-YojN-RcsB regulatory system preventing its over activation. Mutations in *IgaA* have been shown to drastically alter the bacterial transcriptome

Abbreviations: CID, collision-induced dissociation; 2D-PAGE, bidimensional polyacrilamide gel electrophoresis; ICAT, isotope-coded affinity tag; ICPL, isotope-coded protein labeling; iTRAQ, isotope tagging for relative and absolute quantification; LC ESI-MS/MS, liquid chromatography coupled to electrospray tandem mass spectrometry; MALDI-TOF, matrix-assisted laser desorption-ionization time-of-flight; ORF, open-reading frame; SILAC, stable isotope labeling with amino acids in cell culture.

[16]. Using this approach, more than 500 different proteins were identified and about 150 could be quantified as well. Our results demonstrate that ICPL may be a very valuable alternative to iTRAQ when the analysis of iTRAQ specific reporter ions is not possible and clearly overcomes the limitations imposed by other non-isobaric labeling approaches, such as ICAT. However, our data also point out that the number of proteins quantified and the reliability of the quantification results would benefit from modifications in the standard experimental workflow.

2. Experimental

2.1. Chemicals and reagents

ICPL-labeling kit including all the reagents needed to differentially label two samples was purchased from Serva Electrophoresis (Heidelberg, Germany). Labeling was performed according to manufacturer's instructions. A more detailed description of the protocol can be found elsewhere [8,14,17]. Recombinant trypsin (proteomics grade) was purchased from Roche Diagnostics GmbH (Mannheim, Germany). Mass spectrometry-grade water, acetonitrile and formic acid used in LC ESI-MS/MS analysis were supplied by Fluka Analytical (Buchs, Switzerland). Except when indicated, all the reagents used in 2D-PAGE analysis were obtained from Amersham Biosciences (Uppsala, Sweden).

2.2. Samples

The T4 bacteriphage capsid proteome was a generous gift of Dr. Peter James (Lund University, Sweden). This sample comprises 37 different proteins with copy numbers ranging between 3 and 960 and molecular weight ranging between 2.5 and 140 kDa. The two different *S. enterica* serovar Typhimurium strains (wild-type and *IgaA1* mutant [16]) were grown in LB medium until stationary phase was reached.

2.3. 2D-PAGE analysis

Sample aliquots (100 μg) were mixed with Rehydration buffer (7 M urea, 2 M thiourea, 4% CHAPS, 0.5% carrier ampholites pH 4–7, 50 mM DTT) in a final volume of 350 μl and applied to a dry IPG strip (18 cm, 4–7 L, General Electric Healthcare, Uppsala, Sweden) for reswelling. Focusing was carried out on an Ettan IPGphor system (General Electric Healthcare) by increasing voltage as follows: 30 V/h for 7 h, 60 V/h for 7 h, 120 V/h for 1 h, 250 V/h for 1 h, 500 V/h for 1 h, 1000 V/h for 1 h, then voltage was increased from 1000 to 8000 V in 0.5 h, and kept constant at 8000 V until a total of 35,000 V was reached. After IEF separation, the strips were equilibrated twice for 10 min in 50 mM Tris–HCl (pH 8.8), 6 M urea, 30% glycerol, 2% SDS, and trace amounts of bromophenol blue. The first equilibration solution contained 1% DTT while the second contained 4% iodoacetamide (IAA). The second dimension (SDS-PAGE) was performed on 12.5% polyacrylamide gels (1 mm, 16 cm × 15 cm). Gels were run at 7 mA per gel overnight maintaining buffer temperature at 4 °C. Staining was carried out with SYPRO Ruby Protein Gel Stain (Sigma–Aldrich, St Louis, MO) as follows: gel was fixed in 10% methanol, 7% acetic acid for 30 min, incubated overnight in SYPRO Ruby staining solution, washed twice with 10% methanol, 7% acetic acid for 30 min, and finally, washed twice with water for 10 min.

Gels were then scanned in a Typhoon™ 9400 Variable Mode Imager (General Electric Healthcare) equipped with a 532 nm excitation laser with the emission filter adjusted to 610 nm and 100 μm resolution. The photomultiplier tube settings were modified to optimize sensitivity to background ratios (600 V for SYPRO-R). 2D-PAGE images were analyzed with Image Master 2D-Platinum 5.0 (General Electric, Healthcare).

2.4. Digestion

ICPL-labeled bacteriophage T4 proteome was dissolved in 2 M Urea, 25 mM ammonium bicarbonate and 10 μg were digested with trypsin (ratio 20:1) for 6 h at 37 °C.

ICPL-labeled *S. enterica* proteome was fractionated in a 12% SDS-PAGE gel. About 25–30 slices were excised manually, deposited in 96-well plates and processed automatically in a Proteineer DP (Bruker Daltonics, Bremen, Germany). The digestion protocol used was described by Shevchenko et al. [18] but the following minor variations were introduced: gel plugs were washed first with 50 mM ammonium bicarbonate and then with acetonitrile prior to reduction with 10 mM DTT in 25 mM ammonium bicarbonate; alkylation was carried out with 55 mM IAA in 50 mM ammonium bicarbonate. Gel pieces were then rinsed with 50 mM ammonium bicarbonate and with 100% acetonitrile, and then dried under a stream of nitrogen. Modified porcine trypsin (sequencing grade; Promega, Madison WI) or endoGluC (Roche, Mannheim, Germany) was added at a final concentration of 16 or 25 ng/μl, respectively, in 25% acetonitrile, 50 mM ammonium bicarbonate and digestion proceeded for 6 h at 37 °C. The reaction was stopped by adding 0.5% TFA for peptide extraction. Tryptic peptides were dried by speed-vacuum centrifugation and resuspended in mobile phase A (0.1% formic acid in water) for LC ESI-MS/MS. In the case of the 2D-PAGE analysis, spots of interest were excised automatically using an Ettan Spot Picker Workstation (GE), deposited into 96-well plates and processed automatically as previously described.

2.5. Peptide mass fingerprint

For the identification of 2D-PAGE spots, MALDI-TOF mass spectra were acquired automatically on a Bruker Reflex IV MALDI-TOF mass spectrometer (Bruker Daltonics, Bremen, Germany) using FlexControl 1.1 and then processed with Xtof 5.1.1. Each spectrum was calibrated internally with two trypsin autolysis reference ions at m/z 842.510 and 2211.105 reaching typically an accuracy of ±30 ppm in the 800–3000 m/z range. All signals corresponding to known contaminants were excluded during the process and signal-to-noise threshold was limited to 20. Tryptic peptide masses were transferred to BioTools 2.0 (Bruker Daltonics) for searching against the Salmonella database using a licensed version of Mascot v.2.2.04 (www.matrixscience.com; Matrix Science, London, UK) as search engine. Search parameters were set as follows: carbamidomethylated cysteins as fixed modification and oxidized methionines as variable one, peptide mass tolerance was set to 80 ppm and one missed cleavage was allowed. In all protein identifications, the probability mowse scores were greater than the minimum score fixed as significant with a p-value below 0.05.

2.6. LC ESI-MS/MS analysis

LC ESI-MS/MS analysis was performed on an Ultimate 3000 nanoHPLC (Dionex, Sunnyvale, California) coupled to an HCT Ultra ion-trap mass spectrometer (Bruker Daltonics, Bremen, Germany). The analytical column used was a silica-based reversed phase column C18 PepMap 75 μm × 15 cm, 3 μm particle size and 100 Å pore size (Dionex, Sunnyvale, California). The trap column was a C18 PepMap (Dionex, Sunnyvale, California), 5 μm particle diameter, 100 Å pore size, switched on-line with the analytical column after a 5 min loading time. The loading pump delivered a solution of 0.1% trifluoroacetic acid in 98% water/2% acetonitrile at 30 μl/min. The nanopump provided a flow-rate of 300 nl/min and was operated under gradient elution conditions, using 0.1% formic acid as mobile phase A, and 0.1% formic acid in 80% acetonitrile, 20% water

as mobile phase B. Gradient elution was performed according the following scheme: isocratic conditions of 4% B for 5 min, a linear increase to 40% B in 60 min, a linear increase to 95% B in 1 min and isocratic conditions of 95% B for 7 min. Injection volume was 5 μl and absorbance was monitored at 214 and 280 nm.

The LC system was coupled via a nanospray source to the ion trap mass spectrometer operating in positive ion mode with the capillary voltage set at 1400 V. Two different automatic data-dependent acquisition methods were used for the T4 bacteriophage sample. In both a full scan (m/z 350–1500) MS analysis was performed and then, either the four most abundant ions were isolated for CID fragmentation (non-SILE method), or the two most abundant ions and their putative ICPL-labeled counterparts according to their measured masses were fragmented (SILE method). In both cases, a dynamic exclusion was applied which prevented the same m/z from being isolated for 1 min after its fragmentation. For the *S. enterica* serovar Typhimurium samples, only the SILE method was used. Raw LC–MS data were processed using DataAnalysis 3.4 (Bruker Daltonics, Bremen, Germany). When samples were first fractionated by monodimensional SDS-PAGE, the data obtained from the LC runs corresponding to different gel slices were merged using the Analysis Combiner tool before processing them as a single experiment. Processed files were analyzed using WARP-LC 1.1 (Bruker Daltonics) for their qualitative and quantitative analysis. For protein identification, LC ESI-MS/MS spectra were searched against the SwissProt database or against a homemade Salmonella SL1344 database containing 5065 ORFs using Mascot. Search parameters were set as follows: carbamidomethylated cysteines as fixed modification, oxidized methionines and ICPL-light (+105.02 Da) and -heavy (+111.04 Da) labeled lysine residues or protein amino termini as variable ones. Peptide mass tolerance was set to 0.5 Da both in MS and MS/MS mode, and one missed cleavage was allowed. Typically, an accuracy of ±0.1–0.2 Da was found both for MS and MS/MS spectra. For quantitative analysis, extracted ion chromatograms of those peptides identified with Mascot scores ≥25 were considered. When only one ICPL-labeled peptide was identified, the extracted ion chromatogram of its putative partner was used for quantification. Putative ICPL pairs were determined allowing a mass tolerance of 0.5 Da and a retention time tolerance of 40 s. Relative ratios between the heavy and light counterparts of ICPL-labeled peptides were calculated using the intensity of their respective monoisotopic peaks.

3. Results and discussion

3.1. Differential proteomics analysis of the T4 bacteriophage capsid proteome

To evaluate the feasibility of the ICPL approach in quantitative proteomics, we first analyzed the T4 bacteriophage capsid proteome. 100 μg of purified T4 bacteriophage capsid were labeled either with the light or the heavy version of the ICPL reagent, mixed in a 1:1 ratio and digested in solution with trypsin (Fig. 1). 2 μg of the mixture were analyzed in each LC ESI-MS/MS run and two different LC ESI-MS/MS acquisition methods were employed (see Section 2): (1) the two most prominent signals in each survey scan as well as their putative ICPL-labeled partners were isolated and fragmented (SILE method) and (2) the four most abundant ions of each MS spectrum were isolated and fragmented (non-SILE method). Two independent LC ESI-MS/MS analysis were performed in each case and raw data were combined using the Analysis Combiner tool included in WARP-LC before their processing for protein identification and quantification. Results obtained in both experiments are summarized in Table 1. A total number of 20 and 23 different proteins, respectively, were identified with Mascot scores ranging from 32 to 1146. In each case, the number of identified

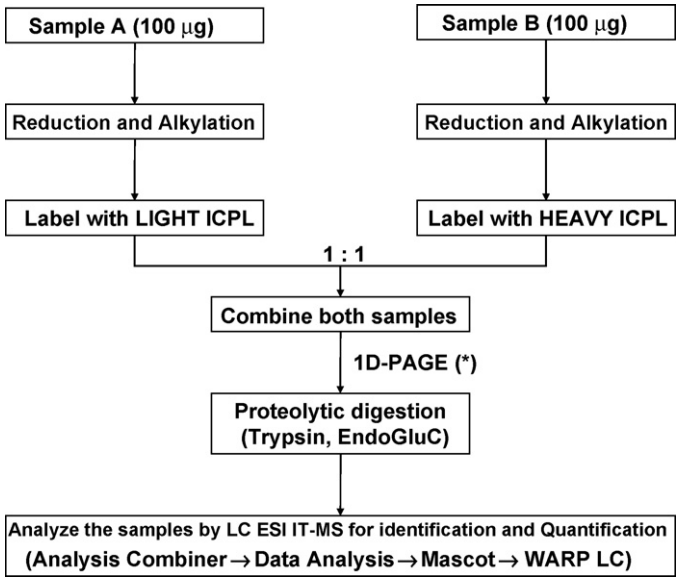

Fig. 1. Diagram of the standard experimental workflow used in the analysis of ICPL-labeled samples. An additional fractionation step (e.g., by 1D-PAGE) is mandatory for the analysis of complex samples.

peptides, either labeled or unlabeled, was very similar as it was the fraction of ICPL-labeled peptides, 37% and 34% for the SILE and non-SILE approach, respectively. This result indicates that none of the approaches offers a truly significant improvement. In terms of protein identification, three additional proteins were identified when the non-SILE method was used. Other minor differences were found: sequence coverage values were higher for 15 out of 23 proteins in the non-SILE dataset while these values were higher for six proteins in the SILE one. ICPL-labeling did not affect significantly the identity score of the peptides, as it was demonstrated by comparing the averaged scores of ICPL-labeled and non-labeled peptides (data not shown). Similarly, the chromatographic behavior of the peptides labeled with the light or heavy versions of the ICPL reagent were near identical, and no differences regarding the retention times of light and heavy ICPL pairs could be detected (data not shown). This feature contrasts with the lack of chromatographic reproducibility introduced by other non-isobaric reagents such as deuterated ICAT [19,20] and increases the reliability of ICPL as a differential proteomics tool.

Regarding protein quantification, no significant differences were found between both datasets. About 2/3 of the identified peptides were not labeled and, thus, did not contribute to the quantification of the protein mixture irrespectively of the acquisition method used (Table 1). When using the SILE acquisition method 19 out of 20 proteins were quantified with ICPL-heavy/ICPL-light (H/L) ratios ranging between 0.73 and 1.24, very close to the expected 1:1 ratio. Similarly, in the non-SILE dataset, 16 out of 20 quantified proteins showed H/L ratios ranging between 0.79 and 1.39. Nonetheless, some significant deviations from the expected values were found. These were caused by different factors, being the most common the coelution of the ICPL-labeled peptides and another molecular species with almost identical m/z value and to the inability of the mass spectrometer and the data processing software to discriminate them. For example, P12726 expression rate is drastically increased by the contribution of a single ICPL-labeled peptide pair, QYKIDACMLR (Table 2). Consistently, the H/L ratio of this protein in the non-SILE analysis (0.98), where the peptide QYKIDACMLR could not be identified, is extremely close to the expected one (Table 2). Fig. 2A shows that this peptide pair elutes very close (elution time 126.9–127.2) to an unidentified charge 3+

Table 1
Differential proteomics analysis of the T4 bacteriophage sample. The protein name, accession number, number of peptides identified (# Pept), number of peptides labeled with ICPL (# Pept (ICPL)), heavy/light ratio (H/L), sequence coverage (Cov (%)) and Mascot score (Score) is given for each protein identified using the SILE and the non-SILE approaches.

peptide pair (Fig. 2B, elution time minute 127.3–127.6). Although elution times do not overlap precisely they are close enough to get mixed up when quantifying with the WARP-LC standard parameters (Fig. 2C). These were set to consider peptide signals with similar m/z value (± 0.5) and retention time ($\pm$ 20 s) as corresponding to the same molecular species. It should be noted that these parameters were not set arbitrarily but according to the technical specifications of the LC ESI-MS/MS equipment employed. An even more drastic situation was found in other cases (e.g., P04533, data not shown).

3.2. Differential proteomics analysis of the S. enterica serovar Typhimurium proteome

To evaluate the performance of ICPL in the relative quantitation of complex proteomes, we compared two different *S. enterica* serovar Typhimurium proteomes (wild-type and *IgaA1* mutant). Protein extracts prepared from wild-type and mutant *IgaA1* strains were labeled with the light and heavy versions of the ICPL reagent, respectively. The experimental workflow used was similar to that described for the analysis of the bacteriophage T4. As the complex-

Table 2
Summary of the results obtained for the T4 bacteriophage protein P12726. The peptide sequence, ICPL labeling (ICPL), calculated m/z value (m/z (calc)), delta mass (Δm (Da)), charge (z), Mascot score (score), signal to noise ratio (S/N), and heavy/light ratio (H/L) is given for each peptide identified using the SILE and non-SILE approaches. ICPL-labeled lysine residues are shown in bold.

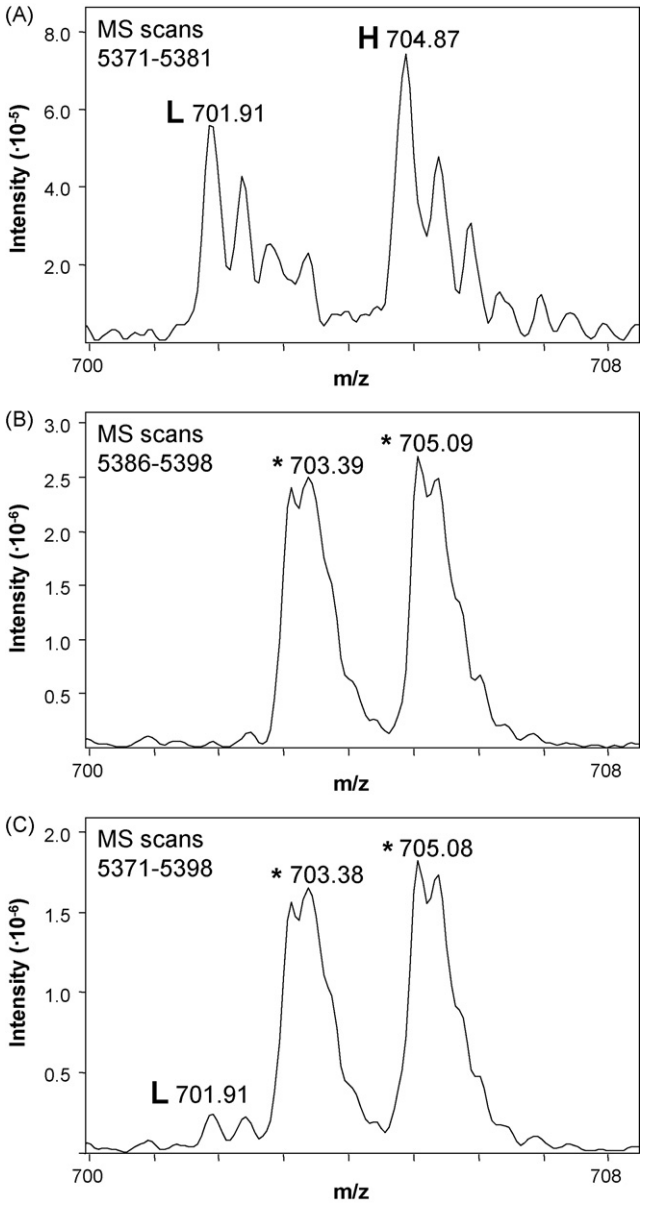

Fig. 2. Averaged survey scans of (A) MS scans 5371–5381 corresponding to the doubly charged peptide QYKIDACMLR labeled with light ICPL (m/z = 701.91) and heavy ICPL (m/z = 704.87); (B) MS scans 5386–5398 corresponding to an unidentified charge 3+ MS signal (m/z = 703.39 and m/z = 705.08) and (C) MS scans 5371–5398. Note that the coelution of m/z signals 703.39 and 705.08 interferes with the calculation of the H/L ratio corresponding to QYKIDACMLR.

ity of the bacterial proteome was much higher, an additional 1D SDS-PAGE fractionation step was carried out after mixing the ICPL-labeled samples (Fig. 1) and, since no significant differences were detected, only the SILE acquisition method was used. In the first experiment, 26 gel-slices were excised and 50% of each slice was digested using trypsin or endoGluC. The resulting peptide mixture was independently analyzed by LC ESI-MS/MS. In a second labeling experiment, 29 slices obtained after 1D SDS-PAGE fractionation of ICPL-labeled samples were digested with trypsin and analyzed by LC ESI-MS/MS. In all cases, the individual MS and MS/MS data obtained from each gel slice were combined using the Analysis Combiner tool available in WARP LC 1.1 and processed as a single file. As shown in Table 3, a total number of 376, 363 and 439 different proteins were identified in each experiment, respectively. However, only between 54% and 64% of the identified proteins were

Table 3
Summary of the results obtained in the *Salmonella enterica* serovar Typhimurium differential proteomics analysis. .

	Experiment #1		Experiment #2
	Trypsin	endoGluC	Trypsin
Proteins identified	376	363	439
Proteins quantified (# pept ≥ 1)	205 (54%)	178 (49%)	281 (64%)
Proteins quantified (# pept ≥ 2)	94 (25%)	79 (22%)	167 (38%)

amenable to quantification, namely those that included at least one ICPL-labeled peptide. Furthermore, the percentage of proteins that could be quantified dropped to values between 22% and 38% when more restrictive criteria were established, such as the use of at least two ICPL-labeled peptides. These results underline the fact that modifying the standard ICPL workflow may be necessary when analyzing complex proteomes (i.e., labeling at the peptide level in order to increase the fraction of labeled peptides and, thus, the number of proteins amenable to quantification). It is also noticeable that the relative number of identified and quantified proteins was very similar for both trypsin and endoGluC digested samples (54% and 49%, respectively). Interestingly, there is a significant set of proteins that were only identified and quantified when a particular protease, endoGluC or trypsin was used, pointing out that the use of several proteases increases the total number of proteins identified. However, this is at expense of a notorious increase in the time and complexity of the analysis.

Table 4 summarizes the results obtained in the three experiments. Only those proteins identified and quantified using at least three peptides in at least two individual experiments are shown (see Supplementary data for additional information). According to their quantitative ratios, proteins were arbitrarily divided in four groups: unaltered (0.5 < ratio < 2); up regulated (ratio >2); down regulated (ratio < 0.5) and a fourth set that includes all those proteins that did not fit any of the previous groups (i.e., quantification values from different experiments were not consistent). Although the specific causes of the inconsistent results in the later group have not been investigated in detail we speculate that, as described for the T4 bacteriophage model, the coelution of ICPL-labeled peptides and other molecular species with almost identical m/z value could explain most of the variability described. In fact, the percentage of proteins showing inconsistent results is very similar in both cases (3 out of 22 (14%) for the T4 model and 12 out of 79 (15%) for the analysis of *Salmonella)*. For each labeling experiment, the number of ICPL-labeled peptide pairs used for quantification and the averaged H/L ratio (*IgaA1*/wild-type) are shown. The results obtained in a 2D-PAGE experiment are also included to compare both strategies and to validate the results obtained in the ICPL approach. In general, both approaches yielded similar results, demonstrating that ICPL quantification values obtained were reproducible and equivalent to that obtained with the "classical" 2D-PAGE workflow. This fact is particularly evident when up regulated or down regulated proteins are considered. Nevertheless, some differences in the absolute values were observed that could be caused by a multiplicity of factors. For example, digestion with endoGluC or trypsin may produce different peptide sets, modulating the effect that outliers may exert in the final averaged value. Additionally, signal to noise ratios may differ among individual experiments, altering the final H/L values. Finally, it should be considered that the ratios calculated for specific proteins in the ICPL experimental approach may correspond actually to the averaged expression ratios of different protein isoforms. These isoforms, that are hardly distinguishable for shotgun proteomics techniques, can be separated and changes in their expression can be individually measured by means of the 2D-PAGE. However, since the presence of protein isoforms is much less frequent in prokaryotes than in higher organisms the multi-

Average H/L ratios (Average) and number of peptides labeled with ICPL (# Pept (ICPL)) are shown for the three independent experiments performed using ICPL. Mutant/wild-type ratios for proteins detected in the 2D-PAGE analysis are also included. Note that several proteins were detected in more than one individual spot in the 2D gel.

plicity of spots found for the same protein may also correspond to artefactual modifications, (e.g., deamidation). Nevertheless, similar differences between approaches based on stable isotopic labeling and 2D-PAGE strategies are not unusual and have been described before [21–23].

4. Conclusions

In summary, our results demonstrate that ICPL is a useful and reliable alternative for the isotopic labeling of complex proteomes and the subsequent estimation of protein expression levels. ICPL overcomes some limitations found in other labeling strategies, such as the low number of peptides amenable for labeling with ICAT or the difficulty to analyze iTRAQ specific reporter ions in many mass spectrometers currently in use. ICPL reaction labeling was found to be very specific and efficient, with no apparent byproducts or undesired side reactions. The chromatographic properties of light and heavy labeled peptides were almost indistinguishable. Similarly, comparable identification scores were determined for both labeled and unlabeled peptides, demonstrating that ICPL labeling does not alter the quality of MS/MS spectra. Nevertheless, our data make evident that further improvements are required to increase the usefulness of ICPL in differential proteomics. Among them, the fraction of labeled peptides should be notably higher (ideally close to 100%) in order to increase the number of quantified proteins and, in parallel, the average number of labeled peptides per protein, since this would result in much more reliable differential expression rates. This may be achieved by labeling at the peptide level, right after protein digestion, instead of employing the standard workflow, in which labeling occurs at the protein level.

Acknowledgements

We wish to thank our colleague Dr. Peter James (Lund University, Sweden) for providing purified T4 bacteriophage capsid used in this study. This works was supported by grants S-GEN-0166-2006 from the Comunidad Autónoma de Madrid (to J.P.A.) and BIO2007-67457-C02-01 from the Spanish Ministry for Science and Innovation (to F.G.-P.). ABSTRACT

Protein tyrosine nitration (PTN) is a post-translational modification of proteins associated with a number of inflammatory diseases. While PTN is rather selective (not all proteins are modified and within a protein, only certain tyrosines are subject to nitration), no consensus sequence has been identified. Since PTN is a low-abundance post-translational modification, it is necessary to enrich modified proteins and/or to detect them with high selectivity and sensitivity. Until now this has been mostly accomplished with anti-nitrotyrosine antibodies in combination with two-dimensional gel electrophoresis and mass spectrometry. We propose a chemical labeling approach designed to allow enrichment of tyrosine-nitrated peptides independent of the sequence context, which is a potential shortcoming of antibody-based approaches. In this procedure, all amines are blocked by acetylation followed by conversion of nitrotyrosine to aminotyrosine and biotinylation of aminotyrosine. The entire reaction sequence is performed in a single buffer with no need for sample cleanup or pH changes thereby reducing sample loss. Free biotin is subsequently removed with a strong cation exchanger, the labeled peptides are enriched on an immobilized avidin column and the enriched peptides analyzed by LC–MS/MS. As a proof of concept, this method was successfully applied to the enrichment of tyrosine-nitrated angiotensin II in a tryptic digest of bovine serum albumin (BSA). The approach presented here is well adapted to peptide analysis, for instance in shotgun proteomics.

1. Introduction

Nitrotyrosine is formed by the reaction of tyrosine with nitrating species, particularly peroxynitrite ($ONOO^-$), which is mostly formed by the combination of a superoxide radical anion ($^{\bullet}O_2^-$) with nitric oxide ($^{\bullet}NO$). Protein tyrosine nitration (PTN) is therefore a post-translational modification of proteins associated with $^{\bullet}NO$-dependent oxidative stress [1]. PTN occurs under physiological conditions and its level (both as protein-bound residue and in its free amino acid form) is increased in at least 50 human diseases [2]. It has been associated with a change in function of several proteins (generally a loss of function), enhanced immunogenicity or an increased protein turn-over [3–5]. PTN is a rather selective process, despite of the reactivity of nitrating agents such as peroxynitrite. Some proteins are preferentially nitrated but the abundance of a given protein or the number of tyrosine residues does not determine susceptibility for nitration [5,6].

Many of the methods developed so far to investigate PTN have focused on the detection and quantification of 3-nitrotyrosine in its circulating free form or after its release by protein hydrolysis (see reviews by Herce-Pagliai et al. [7], Greenacre and Ischiropoulos [2], Duncan [8], Tsikas and Caidahl [9] and Ryberg and Caidahl [10]). While such analyses give an assessment of the overall nitration of tyrosine in proteins, they do not allow to discriminate between individual nitrated proteins nor do they allow determination of their respective levels in a biological sample [11]. The identification of *in vivo* targets for PTN would provide insight into structure–function relationships and advance our understanding how the addition of a nitro group may alter the function or immunogenicity of a given protein. It would also open the possibility to study the association between specific nitrated proteins and a pathological phenotype [5]. Most methods developed to address PTN in individual proteins are based on immunochemical approaches (Western blotting, immunoprecipitation) in combination with gel electrophoresis (in-solution isoelectrofocusing followed by SDS-PAGE [12–14], immunoprecipitation followed by SDS-PAGE [12,15], or 2D-gel electrophoresis [12,15–32]) followed by mass spectrometric (MS) analysis. Despite their relevance, these methods have limitations commonly associated with gel electrophoresis and immunochemistry such as gel-to-gel reproducibility, the detection of low-abundance proteins and the fact that one protein spot may contain several proteins, which complicates interpretation of the MS data [33,34]. The unambiguous immunochemical recognition of nitrotyrosine in proteins generally requires a step of nitrotyro-

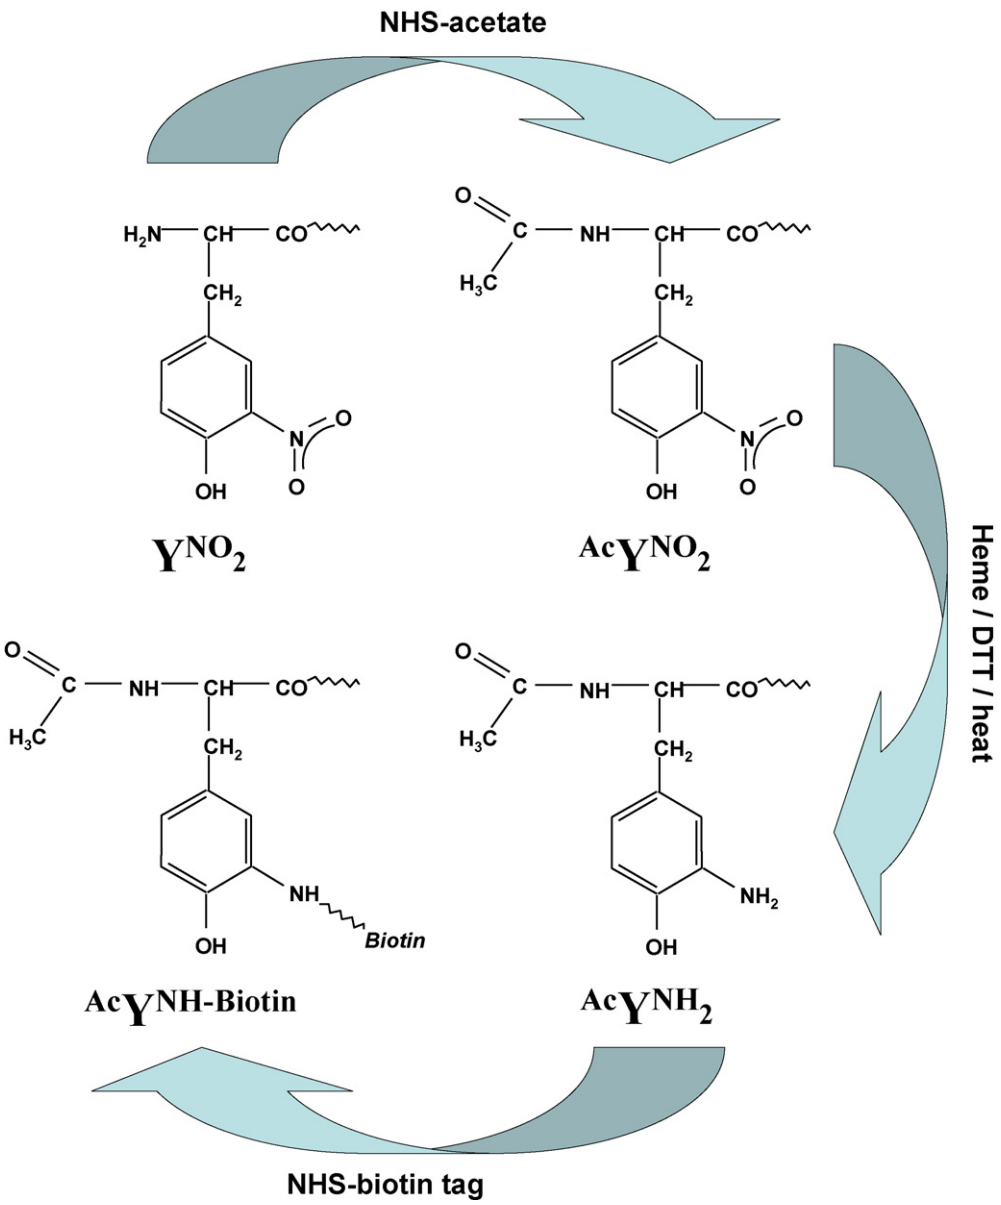

Fig. 1. Reaction scheme of the chemical labeling method as exemplified with an N-terminal nitrotyrosine residue. Blocking all amines by acetylation with NHS-acetate is followed by the reduction of nitrotyrosine to aminotyrosine with heme and DTT in a boiling water bath. The reaction sequence is completed by biotinylation of aminotyrosine with NHS-biotin.

sine reduction in order to ascertain the specificity of the antibody further complicating this approach [16].

In a recent report, Nikov et al. proposed a new approach to enrich nitrotyrosine-containing proteins from a complex mixture [35]. This gel-free, antibody-free method is based on the reduction of nitrotyrosine to aminotyrosine followed by the exploitation of the pK_a difference between the aromatic amine (pK_a = 4.75) [36] and other aliphatic amines that are present in proteins and peptides (pK_a of 8.0 for α-amines and 10.5 for ε-amine) [37] to label aminotyrosine at pH 5.0 with a biotin-containing tag. While an intriguing approach, that may allow enrichment and identification of nitrotyrosine-containing proteins independent of antibodies, it did not prove selective enough, since α- and ε-amines were partially modified by the recommended N-hydroxysuccinimide esters at pH 5.0 (our own results and Refs. [38,39]). Since selectivity of a labeling method is of primary importance when it comes to studying low-abundance post-translational modifications, we designed a multi-step, one-pot chemical labeling approach with the goal of reaching close to 100% conversion at each step (see Fig. 1). The reaction sequence is as follows: (1) blocking of all amines by acetylation, (2) conversion of nitrotyrosine to aminotyrosine, and (3) biotinylation of the amine group of aminotyrosine. Subsequent enrichment of biotinylated peptides using avidin-based affinity chromatography and analysis by LC–MS/MS completes the procedure. This methodology was evaluated in a proof-of-concept study, where nitrated angiotensin II was selectively labeled and enriched from a matrix of trypsin-digested bovine serum albumin (BSA).

2. Materials and methods

2.1. Materials and reagents

Acetic acid N-hydroxysuccinimide ester (NHS-acetate) was from MP Biomedicals (Illkirch, France). Monomeric avidin immobilized on agarose beads was from Pierce (Perbio Science, Etten-Leur, The Netherlands) and dimethyl sulfoxide (DMSO), sodium dihydrogen

phosphate monohydrate, di-sodium hydrogen phosphate dihydrate and formic acid (FA) were from Merck KGaA (Darmstadt, Germany). HPLC-S gradient grade acetonitrile and methanol were from Biosolve (Valkenswaard, The Netherlands). Angiotensin II (human) acetate, bovine serum albumin, dithiothreitol (DTT), biotinyl N-hydroxysuccinimide ester (NHS-biotin) were from Sigma (Zwijndrecht, The Netherlands). Hemin was purchased from Sigma–Fluka (Zwijndrecht, The Netherlands) and peroxynitrite from Calbiochem (Merck Chemicals Ltd., Nottingham, UK). Ultra-pure water (conductivity: 18.2 MΩ) was obtained from a Maxima System (Elga Labwater, Ede, The Netherlands). All incubations at 25 and 37 °C were performed in a Thermomixer (Eppendorf, Hamburg, Germany) at 450 rpm.

2.2. Sample preparation

2.2.1. Nitration of angiotensin II

20 μL of angiotensin II (DRVYIHPF; 500 μM in water) was diluted with 940 μL 500 mM sodium phosphate buffer, pH 7.5. 40 μL of peroxynitrite solution (160–200 mM in 4.7% NaOH) were added and the solution was immediately vortexed for 1 min. The sample was subjected to solid-phase extraction on an Oasis HLB column (Waters, Etten-Leur, The Netherlands) previously conditioned with 1 mL methanol and 1 mL water. After washing the column with 1 mL 5% methanol, the peptides were eluted with 80% methanol in water and dried under nitrogen.

2.2.2. Preparation of trypsin-digested BSA

BSA (1 mg/mL in 100 mM sodium phosphate, pH 8) was digested at 37 °C for 4 h with trypsin at a ratio of 1/20 (trypsin/BSA) by weight. A 1 mL sample was subjected to solid-phase extraction on an Oasis HLB column as described above for angiotensin II.

2.2.3. Addition of nitrated angiotensin II to the digested BSA matrix

The content of a tube of dried nitrated peptide was resuspended in 1 mL 250 mM sodium phosphate, pH 8 (final peptide concentration: 10 μM). After completion, the liquid was transferred to another tube containing the dried BSA digest (final concentration: 1 mg/mL, i.e. 15 μM).

2.3. Chemical labeling

2.3.1. Acetylation of primary amines

10 μL of 500 mM NHS-acetate in DMSO (final concentration: 25 mM) was added to 190 μL of nitrated angiotensin II. The sample was incubated for 2 h at 25 °C and subsequently treated for 15 min in a boiling water bath to hydrolyze remaining reagent and to reverse O-acylations, as previously described [40].

2.3.2. Reduction of nitrotyrosine to aminotyrosine

10 μL of 440 mM DTT (final concentration: 20 mM) and 10 μL of 550 μM hemin (final concentration: 25 μM) were added to the sample prior to incubation for 15 min in a boiling water bath.

2.3.3. Biotinylation of aminotyrosine

10 μL of 115 mM NHS-biotin in DMSO (final concentration: 5 mM) was added to the sample. After 2 h at 25 °C, the sample was incubated for another 15 min in a boiling water bath and supplemented with 170 μL 1% (v/v) FA.

2.4. Removal of excess biotin

The sample was diluted to 1 mL with 11 mM (0.425‰, v/v) FA and applied to a strong cation exchange (SCX) cartridge (3-mL LiChrolut SCX; Merck, Germany), previously conditioned with 3 mL methanol and 3 mL 11 mM FA, to remove the excess of free biotin. After washing the column with 7 mL 11 mM FA, the peptides were eluted in 1.4 mL of 300 mM sodium phosphate, pH 8.0, 150 mM NaCl:methanol (7:3) and collected in a tube of known weight. The samples were concentrated in a vacuum centrifuge (Concentrator 5301; Eppendorf, Hamburg, Germany) at 40 °C until their residual volume was ~600 μL (based on their weight, considering a density of 1 g/mL). Water was subsequently added to 1 mL.

2.5. Enrichment of biotinylated peptides

100 μL of a 50% slurry of monomeric avidin immobilized on agarose beads were washed with 2× 1 mL phosphate buffer saline (PBS) prior to being added to the sample. After 1 h on a rotary shaker at room temperature, an aliquot (40 μL) of the supernatant was removed, diluted with an equal volume of 1% FA, and stored on ice for further analysis ("flow-through fraction"). The beads were packed into a gel loader tip without letting them dry, washed with 5 mL PBS and the retained peptides eluted with 100 μL 8 M guanidinium–HCl, pH 1.4. The eluate was diluted with an equal volume of 1% FA prior to LC–MS/MS analysis ("bound fraction").

2.6. LC–MS/MS

The HPLC part of the LC–MS/MS system consisted of an Agilent series 1100 capillary LC (Waldbronn, Germany) comprising a degasser, a binary pump with stream splitter and flow controller, a temperature-controlled autosampler (4 °C) and a temperature-controlled column compartment (40 °C). A diode array detector set at 214, 280 and 365 nm was used to ascertain nitration of angiotensin II after treatment with peroxynitrite. Chromatographic separation took place in an Atlantis dC18 column (Waters, Etten-Leur, The Netherlands; 1.0 mm i.d. × 150 mm length, particle size 3 μm) operated at 20 μL/min flow rate. Mobile phase A consisted of 0.1% (v/v) FA in ultra-pure water and mobile phase B of 0.1% (v/v) FA in acetonitrile.

All samples obtained after chemical labeling (including the biotinylation step) were diluted to 400 μL with 1% (v/v) FA prior to LC–MS/MS analysis. All other samples were diluted with an equal volume of 1% (v/v) FA. Unless stated otherwise, an injection volume of 4 μL was used, and the separation was performed with an increasing gradient of B (2–47% at 0.5%/min). The analytes were detected by an Agilent SL ion-trap mass spectrometer equipped with an electrospray ionization source operated in positive mode. MS data were acquired over a scan range of 200–1200 m/z. Molecules of interest were selected as precursor ions (preferentially doubly charged states were used, when applicable; isolation width of 2 amu) and analyzed by MS/MS at a fragmentation amplitude of 1 V. Daughter ions were acquired over a scan range of 50–1200 m/z.

All displayed chromatograms underwent one cycle of three-point smoothing based on a Gaussian algorithm and all extracted ion chromatograms (EICs) were retrieved with a tolerance of ±0.2 m/z.

3. Results

3.1. Nitration of angiotensin II

In order to assess the efficiency and selectivity of the labeling method, we applied it to chemically nitrated angiotensin II in a matrix of trypsin-digested BSA. After exposure to peroxynitrite, angiotensin II (native form: "Y"; Fig. 2B, first and second panels) was found to be partially (about 50%) nitrated ("Y^{NO_2}"; Fig. 2B, third and fourth panels). Nitration was accompanied by a shift to a higher retention time upon reversed-phase HPLC and a 45-Da increase

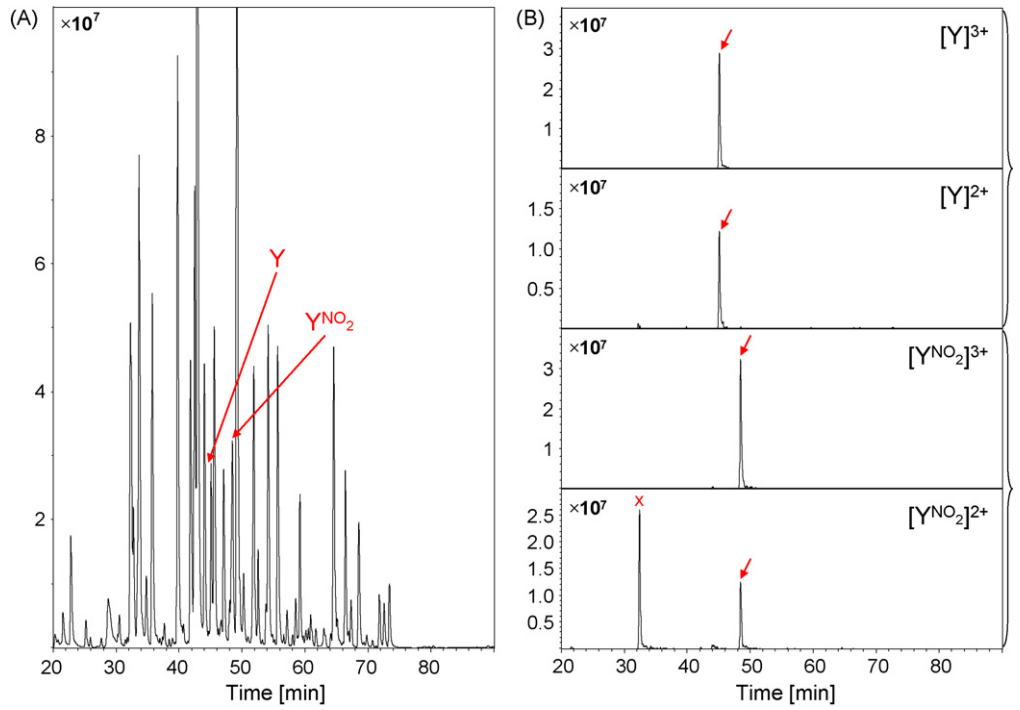

Fig. 2. LC–MS analysis of nitrated angiotensin II in a tryptic digest of BSA: A (left)—base peak chromatogram; B (right)—extracted ion chromatograms (±0.2 amu) of non-modified [Y] and tyrosine-nitrated [Y^{NO_2}] angiotensin II. First and second panels: triply (*m*/*z* 349.8) and doubly (*m*/*z* 523.9) charged molecular ions of [Y] (45.1 min); third and fourth panels: triply (*m*/*z* 364.7) and doubly (*m*/*z* 546.4) charged molecular ions of [Y^{NO_2}] (48.5 min). The peak marked "X" has an *m*/*z* of 546.3. Its isotopic distribution indicates a higher charge state, although resolution of the ion-trap mass analyzer was insufficient to assign the charge state.

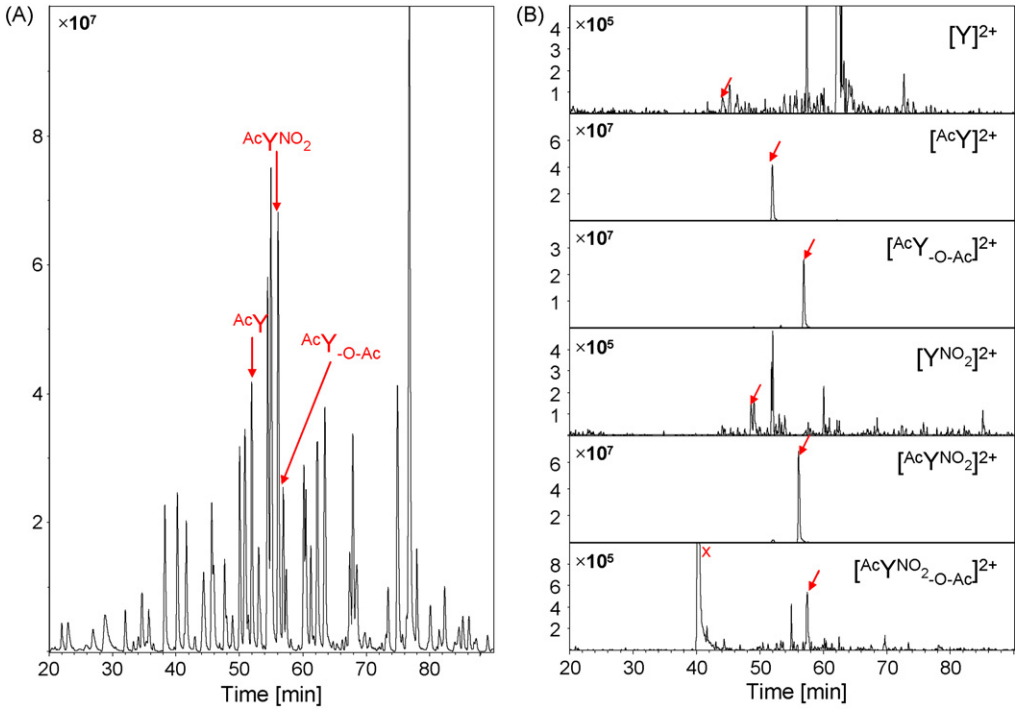

Fig. 3. LC–MS analysis after acetylation of primary amines: A (left)—base peak chromatogram; B (right)—extracted ion chromatograms (±0.2 amu); first panel: doubly charged molecular ion of remaining, non-nitrated angiotensin II ("Y", *m*/*z* 523.9, 45.1 min); second panel: doubly charged molecular ion of non-nitrated, N-acetylated angiotensin II ("^{Ac}Y", *m*/*z* 545.1, 51.9 min); third panel: doubly charged molecular ion of non-nitrated, N-,O-diacetylated angiotensin II ("$^{Ac}Y_{-O-Ac}$", *m*/*z* 566.1, 56.9 min); fourth panel: doubly charged molecular ion of tyrosine-nitrated angiotensin II ("Y^{NO_2}", *m*/*z* 546.4, 45.5 min); fifth panel: doubly charged molecular ion of tyrosine-nitrated, N-acetylated angiotensin II ("$^{Ac}Y^{NO_2}$", *m*/*z* 567.6, 56.1 min); sixth panel: doubly charged molecular ion of tyrosine-nitrated, N-,O-diacetylated angiotensin II ("$^{Ac}Y^{NO_2}$", *m*/*z* 588.4, 57.4 min). The peak marked "X" has an *m*/*z* of 588.5. It is an isotopic peak of a compound of which the molecular ion is of 587.5 *m*/*z*, and which is singly charged, according to its isotopic distribution.

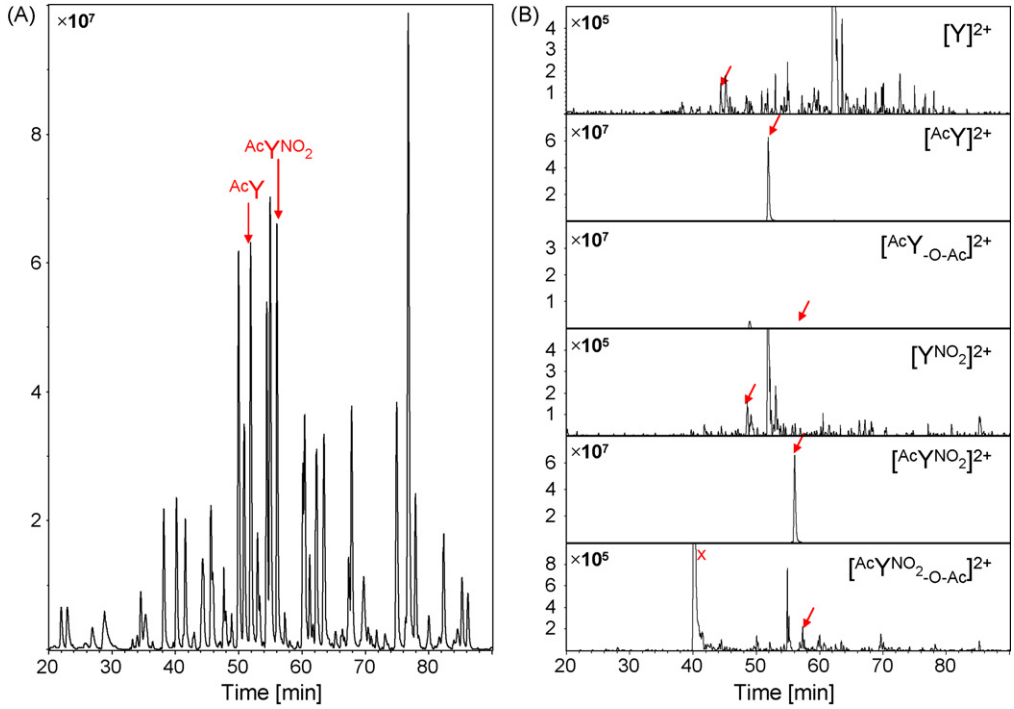

Fig. 4. LC–MS analysis after removal of O-acyl groups: A (left)—base peak chromatogram; B (right)—extracted ion chromatograms (±0.2 amu); first panel: doubly charged molecular ion of non-nitrated angiotensin II ("Y", *m*/*z* 523.9, 45.1 min); second panel: doubly charged molecular ion of non-nitrated, N-acetylated angiotensin II ("^{Ac}Y", *m*/*z* 545.1, 51.9 min); third panel: doubly charged molecular ion of remaining non-nitrated, N-,O-diacetylated angiotensin II ("$^{Ac}Y_{-O-Ac}$", *m*/*z* 566.1, 56.9 min); fourth panel: doubly charged molecular ion of tyrosine-nitrated angiotensin II ("Y^{NO_2}", *m*/*z* 546.4, 45.5 min); fifth panel: doubly charged molecular ion of tyrosine-nitrated, N-acetylated angiotensin II ("$^{Ac}Y^{NO_2}$", *m*/*z* 567.6, 56.1 min); sixth panel: doubly charged molecular ion of remaining tyrosine-nitrated, N-,O-diacetylated angiotensin II ("$^{Ac}Y^{NO_2}$", *m*/*z* 588.4). The peak marked "X" has an *m*/*z* of 588.5 and is singly charged according to its isotopic distribution.

in molecular weight. Using a DAD detector, we also observed an absorbance peak at 365 nm, which is the maximum of absorbance of nitrotyrosine in acidic media (data not shown) [41,42].

3.2. Acetylation of primary amines

The mixture of nitrated and non-nitrated angiotensin II was added to a tryptic digest of BSA to evaluate the selectivity of our labeling and enrichment methodology. In order to avoid side reactions with NHS-biotin, we blocked all primary amines with an excess of NHS-acetate. LC–MS analysis showed that acetylation was complete when investigating the angiotensin II-related peaks (see Fig. 3). Based on previous reports [40,43], angiotensin II (DRVYIHPF) was expected to be mostly doubly acetylated on its N-terminus and the tyrosine hydroxyl group. The non-nitrated peptide was indeed found to be both singly acetylated ("^{Ac}Y"; Fig. 3B, second panel) and doubly acetylated at both the N-terminus and the phenolic hydroxyl group of tyrosine ("$^{Ac}Y_{-O-Ac}$"; Fig. 3B, third panel). In contrast, the nitrated version of the peptide was principally found as singly acetylated derivative ("$^{Ac}Y^{NO_2}$"; Fig. 3B). This difference in reactivity may be explained by a shift of the pK_a of the phenolic hydroxyl group from 10.1 to 7.2 upon nitration [36]. It is thus mostly found in its phenolate form at pH 8, which appears to be less reactive towards NHS-acetate. An alternative explanation for the reduced reactivity might be that steric hindrance of the adjacent nitro group interferes with acetylation.

As shown previously [40], all O-acetyl groups were hydrolyzed after 15 min of incubation in a boiling water bath resulting in singly acetylated angiotensin II ("^{Ac}Y" and "$^{Ac}Y^{NO_2}$"; Fig. 4B, respectively second and fifth panels). The N-acetyl blocking groups withstood this treatment, as shown by the very low-intensity signals (calculated by peak integration to equal respectively 0.7% and 1.1% with respect to the starting material) for non-modified angiotensin II (nitrated "Y^{NO_2}" and non-nitrated "Y", respectively; Fig. 4B, first and fourth panel). By comparing the base peak chromatograms (BPCs) before and after acetylation as well as after the removal of O-acetyl groups (Figs. 2A and 4A) it appears that peak intensities for both native and nitrated angiotensin II doubled upon N-terminal acetylation indicating an increased ionization efficiency.

3.3. Reduction of nitrotyrosine to aminotyrosine

Although the conversion of nitrotyrosine to aminotyrosine is generally performed with sodium dithionite as proposed by Sokolovsky et al. [36], we decided to exploit an alternative reduction reaction previously described by Balabanli et al., due to its better controllability and the lower risk of side-reactions (see Section 4) [44]. Balabanli et al. showed that nitrotyrosine is readily converted into aminotyrosine at physiological pH and high temperature in presence of heme (or hemoproteins) and DTT. This reaction proved to be very efficient, since singly acetylated, aminotyrosine-containing angiotensin II ("$^{Ac}Y^{NH_2}$"; Fig. 5B, second and third panels) was readily detected whereas $^{Ac}Y^{NO_2}$ was barely detectable after reduction (Fig. 5B, first panel). By comparing the BPCs before and after nitrotyrosine reduction (Figs. 4A and 5A) we estimate that the reduction of nitrated angiotensin II decreases peak intensity by roughly a factor three indicating a reduction in ionization efficiency.

3.4. Biotinylation of aminotyrosine

Biotinylation of the aromatic amine in aminotyrosine with an excess of NHS-biotin followed by 15 min incubation in a boiling water bath appeared to be complete as judged by the disap-

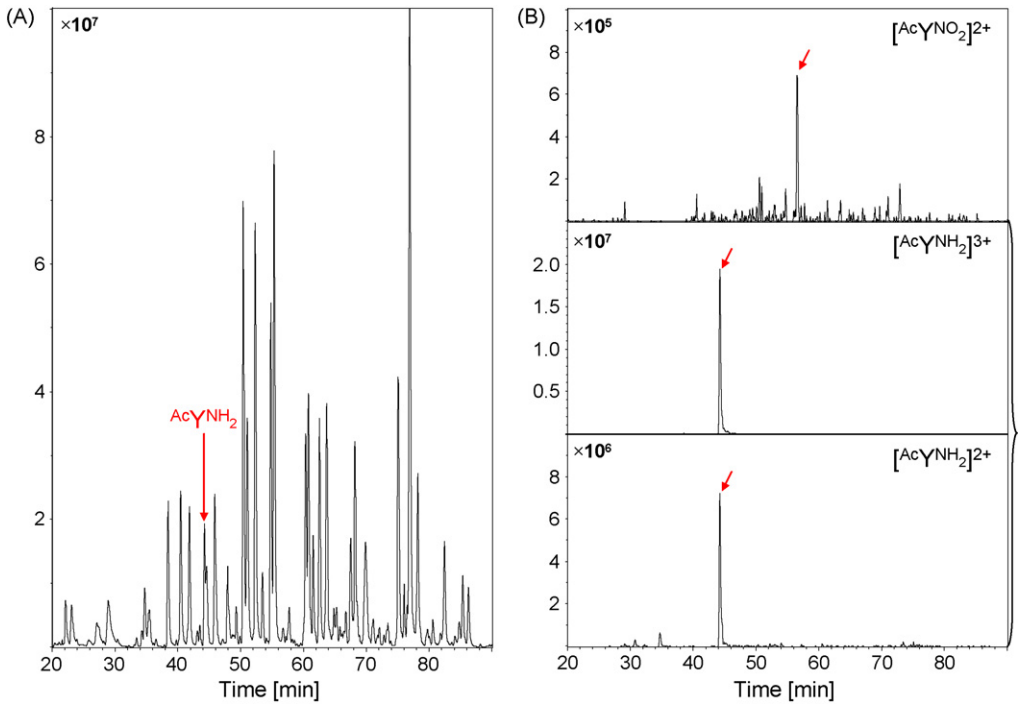

Fig. 5. LC–MS analysis after reduction of nitrotyrosine to aminotyrosine in angiotensin II: A (left)—base peak chromatogram; B (right)—extracted ion chromatograms (±0.2 amu); first panel: doubly charged molecular ion of tyrosine-nitrated, N-acetylated angiotensin II ("$^{Ac}Y^{NO_2}$", *m/z* 567.4, 56.5 min); second and third panels: triply (*m/z* 368.8) and doubly (*m/z* 552.4) charged molecular ions of N-acetylated, aminotyrosine-containing angiotensin II ("$^{Ac}Y^{NH_2}$", 44.2 min).

pearance of the peak corresponding to aminotyrosine-containing angiotensin II ("$^{Ac}Y^{NH_2}$"; Fig. 6B, third and fourth panels). The expected final product of the overall reaction ("$^{Ac}Y^{NH\text{-biotin}}$"; Fig. 6B, fifth and sixth panels) was primarily detected as doubly charged molecular ion. Some O-biotinylated, N-acetylated peptide was still observed ("$^{Ac}Y_{\text{-O-biotin}}$"; Fig. 6B, second panel) indicating that hydrolysis of the O-biotin ester is somewhat slower than for O-acetate. The O-biotin ester was, however, completely removed after

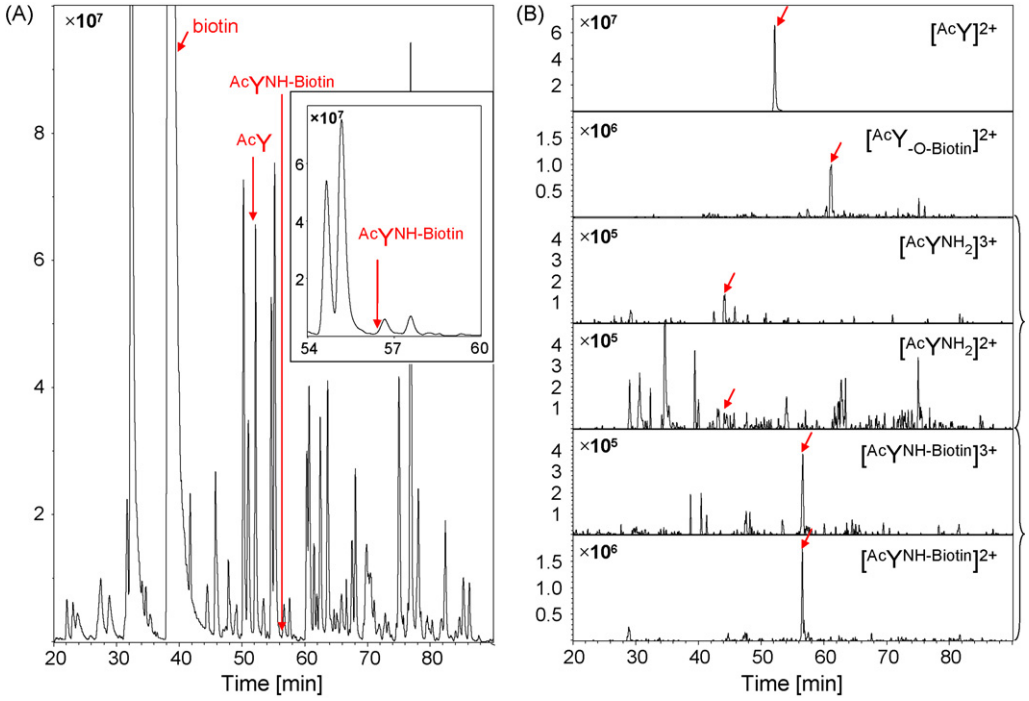

Fig. 6. LC–MS analysis after biotinylation of aminotyrosine-containing angiotensin II: A (left)—base peak chromatogram; B (right)—extracted ion chromatograms (±0.2 amu); first panel: doubly charged molecular ion of N-acetylated angiotensin II ("^{Ac}Y", *m/z* 545.1, 52.1 min); second panel: doubly charged molecular ion of N-acetylated and tyrosine O-biotinylated angiotensin II ("$^{Ac}Y_{\text{-O-biotin}}$", *m/z* 658.3, 61.2 min); third and fourth panels: triply (*m/z* 368.8) and doubly (*m/z* 552.4) charged molecular ions of N-acetylated, aminotyrosine-containing angiotensin II ("$^{Ac}Y^{NH_2}$", 44.2 min); fifth and sixth panels: triply (*m/z* 444.1) and doubly (*m/z* 665.6) charged molecular ions of N-acetylated and aminotyrosine N-biotinylated angiotensin II ("$^{Ac}Y^{NH\text{-biotin}}$", 56.5 min). The peak of free biotin (*m/z* 245.2 $[M+H^+]^{1+}$ and *m/z* 489.2 $[2M+H^+]^{1+}$, 38.3 min) has been truncated in Fig. 6A (actual intensity value: 7.75×10^8).

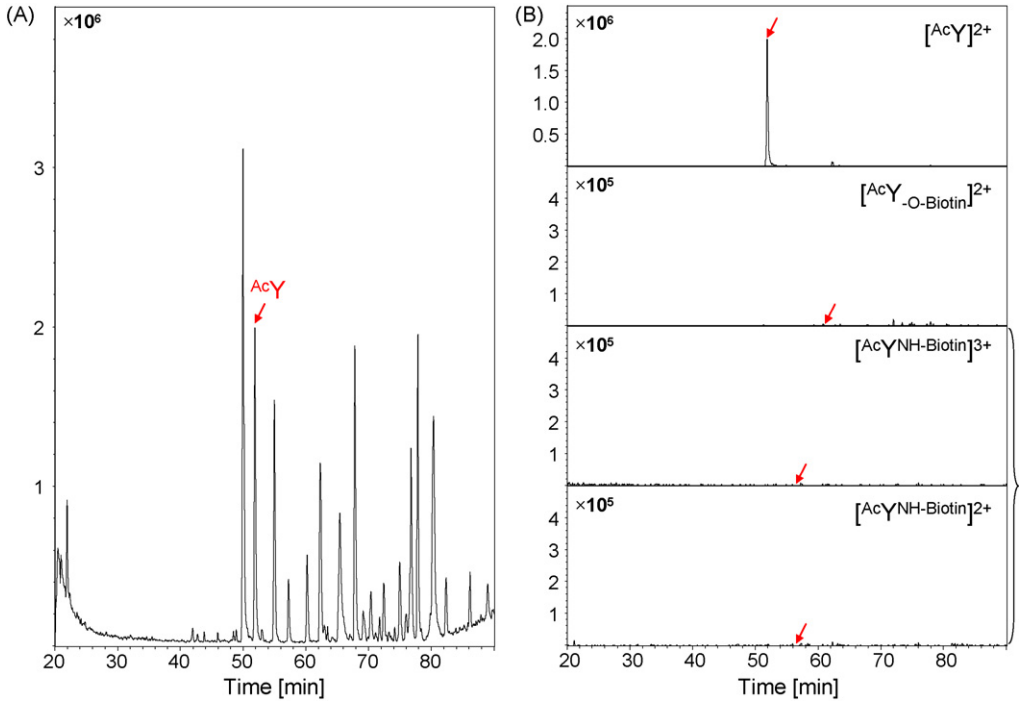

Fig. 7. LC–MS analysis of the flow-through fraction after avidin-based enrichment of biotinylated peptides: A (left)—base peak chromatogram; B (right)—extracted ion chromatograms (±0.2 amu); first panel: doubly charged molecular ion of N-acetylated angiotensin II ("^{Ac}Y", *m*/*z* 545.1, 51.9 min); second panel: doubly charged molecular ion of N-acetylated and tyrosine O-biotinylated angiotensin II ("^{Ac}Y$_{\text{-O-biotin}}$", *m*/*z* 658.3, 61.2 min); third and fourth panels: triply (*m*/*z* 444.1) and doubly (*m*/*z* 665.6) charged molecular ions of N-acetylated and aminotyrosine N-biotinylated angiotensin II ("^{Ac}Y$^{\text{NH-biotin}}$", 56.5 min).

incubation in a boiling water bath for 60 min (Fig. S-1 in Supplementary Material). The excess of free biotin (released after hydrolysis of NHS-biotin) is also retained on the C_{18} reversed-phase column and elutes slightly before the acetylated peptides (Fig. 6A).

3.5. Removal of excess biotin and enrichment of biotinylated, aminotyrosine-containing peptides

Since the large excess of biotin interferes with the subsequent enrichment step on a monomeric avidin column, it was removed

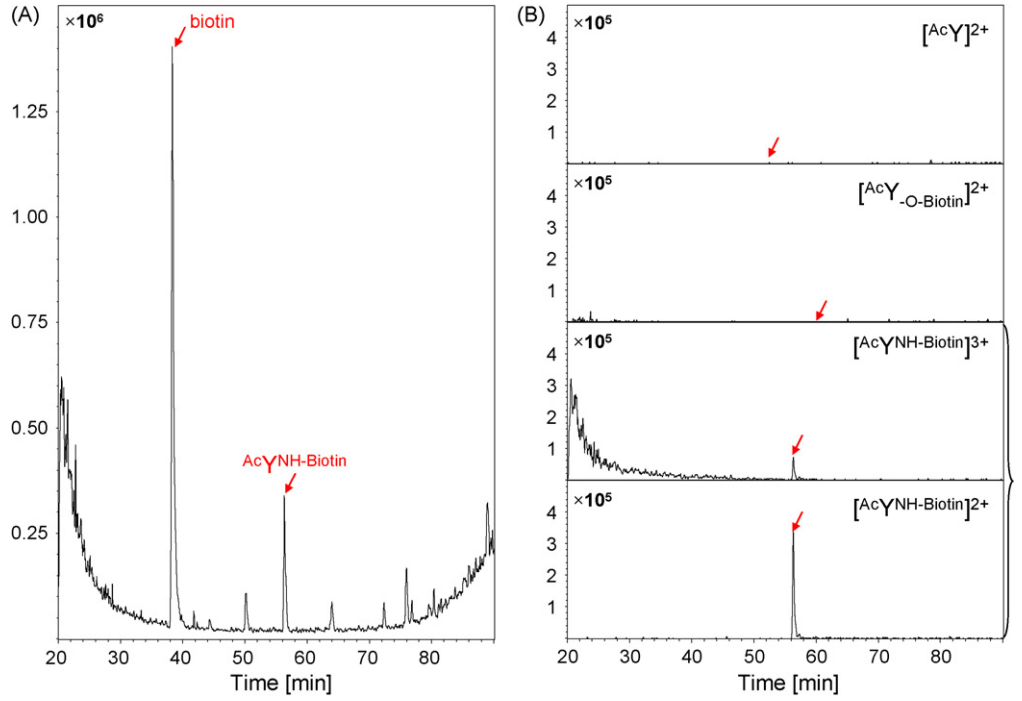

Fig. 8. LC–MS analysis of biotinylated peptides after enrichment on a monomeric avidin column (bound fraction): A (left)—base peak chromatogram; B (right)—extracted ion chromatograms; first panel: doubly charged molecular ion of N-acetylated angiotensin II ("^{Ac}Y", *m*/*z* 545.1, 51.9 min); second panel: doubly charged molecular ion of N-acetylated and tyrosine O-biotinylated angiotensin II ("^{Ac}Y$_{\text{-O-biotin}}$", *m*/*z* 658.3, 61.2 min); third and fourth panels: triply (*m*/*z* 444.1) and doubly (*m*/*z* 665.6) charged molecular ions of N-acetylated and aminotyrosine N-biotinylated angiotensin II ("^{Ac}Y$^{\text{NH-biotin}}$", 56.2 min).

by solid-phase extraction over a strong cation exchange cartridge at acidic pH based on the fact that biotin is expected to be neutral under these conditions while most peptides are positively charged and thus retained. After extensive washing of the SPE cartridge, peptides were eluted with an increased salt concentration at pH 8 in the presence of an organic modifier. The eluate was applied to a monomeric avidin column. Analysis of the flow-through of the avidin column showed that the biotinylated, aminotyrosine-containing angiotensin II was retained while the non-biotinylated, non-nitrated angiotensin II as well as most of the BSA-derived peptides were retrieved in this fraction as expected (Fig. 7). It is noteworthy that the early-eluting BSA-derived peptides were no longer visible in the flow-through fraction indicating that they were lost during the biotin-removal step. This step requires therefore further optimization prior to application of the procedure to endogenously tyrosine-nitrated proteins and peptides.

The relatively small amount of remaining biotin and the biotinylated, aminotyrosine-containing angiotensin II were eluted from the avidin affinity column with 8 M guanidinium hydrochloride at pH 1.4 (Fig. 8). It is noteworthy that none of the "background" peptides derived from trypsin-digested BSA were detected in the eluate indicating strongly that the initial acetylation reaction proceeded to completion. Detection of some biotin showed, however, that biotin removal by SCX was not complete albeit quite efficient when comparing the remaining amount to the large initial excess (Fig. 8A). The identity of $^{Ac}Y^{NH\text{-}biotin}$ was confirmed by MS/MS (Fig. S-2 in Supplementary Material). A few additional small peaks were observed in the base peak chromatogram of the eluate (Fig. 8A). MS/MS analysis revealed that these were mostly low molecular weight contaminants possibly originating from the guanidine solution or the avidin beads. This result shows that nitrated angiotensin II was selectively labeled and enriched from an excess of BSA-derived tryptic peptides.

4. Discussion

Nikov et al. [35] investigated the possibility of selective labeling of nitrotyrosine after reducing it to aminotyrosine followed by reaction with NHS-SS-biotin at pH 5. Selectivity was entirely based on the pK_a difference between the aromatic amine (pK_a = 4.75) [36] and other aliphatic amines present in proteins and peptides (pK_a of 8.0 for α-amines and 10.5 for ε-amines) [37]. The selectivity of a labeling method is of prime importance when it comes to the study of low-abundance post-translational modifications. In agreement with reports by other investigators [38,39], we observed that aliphatic amines reacted with NHS esters to a certain extent at pH 5 (data not shown) indicating that the method of Nikov et al. is not selective enough in the case of a low-abundance post-translational modification such as nitrotyrosine. Amoresano et al. [45] recently described a method for the labeling of *in vitro* nitrated milk proteins and endogenously nitrated *E. coli* proteins with dansyl chloride at pH 5 after reduction of nitrotyrosine to aminotyrosine. Non-selective labeling of primary amines was avoided at the expense of a reduced labeling yield (60%). Although the combination of precursor ion and MS^3 scan modes to detect dansyl-specific fragment ions proved to be a powerful and selective detection technique, this method does not allow enrichment of nitrated peptides. Since tyrosine nitration is a low-abundance protein post-translational modification, similar to protein phosphorylation, it is critical that proteins be enriched prior to LC–MS/MS analysis to overcome limitations in terms of loading capacity of the chromatographic column.

Here we report the further development of a chemical approach for the biotinylation of nitrotyrosine residues in peptides with each step reaching a yield close to 100% as determined by LC–MS. Having a quantitative and selective method is critical to avoid labeling of other functional groups, such as primary amines, thiols or hydroxyl groups, which are much more abundant than nitrotyrosine and would thus lead to the enrichment of many non-nitrotyrosine-containing peptides. All reactions were performed sequentially in the same buffer (250 mM sodium phosphate, pH 8). This amine-free buffer (i) does not interfere with NHS ester-based acylations, (ii) is concentrated enough to prevent pH variation due to the release of acetic acid after hydrolysis of the excess of NHS-acetate and (iii) its pH is compatible with NHS ester-based amine acylations, with the hydrolysis of O-acyl groups upon incubation in a boiling water bath as well as with the non-enzymatic heme-based reduction of nitrotyrosine to aminotyrosine.

Recently Zhang et al. [39] published an approach for the chemical labeling and enrichment of nitrotyrosine-containing peptides independently of our work, based on acetylation of primary amines with acetic acid anhydride followed by reduction of nitrotyrosine with sodium dithionite and the acylation of aminotyrosine with NHS S-acetylthioacetate (SATA). In the following we discuss our results and methodology and compare it to the methodology described by Zhang et al., where appropriate.

4.1. Acetylation of primary amines

The first step of our methodology consists of the quantitative acetylation of all primary amines to avoid subsequent biotinylation of these residues. Using a high molar excess of NHS-acetate allowed to reach a yield of more than 99% (Fig. 3), while Zhang et al. estimated their yield at 91% after reaction with acetic anhydride, which leaves approximately 9% of all reactive amines unprotected [39]. Due to the large excess of primary amines over nitrotyrosine residues in peptides, it is critical to block all sides that will give rise to side reactions (non-selective labeling). Since only one tyrosine (natural occurrence in proteins: 3.2%) [46] in 10,000 is nitrated under inflammatory conditions [1], but 6.0% of amino acids in proteins are lysine [46], there is an 18,750-fold molar excess of ε-amines with respect to aminotyrosines (considering 100% conversion of nitrotyrosine to aminotyrosine). Moreover, if labeling is performed on a trypsin digest, every peptide will bear an additional reactive α-amine (a further 9.1% of all amino acid residues considering an average length of 11 amino acids for a tryptic peptide) [47], resulting in an approximate 28,450-fold molar excess of primary amines over aminotyrosines. Even a moderate percentage of non-acetylated or otherwise reactive aliphatic amines would therefore result in a majority of labeled peptides being devoid of nitrotyrosine. As a result, acetylation of all primary amines must be as close as possible to 100%.

4.2. Reduction of nitrotyrosine to aminotyrosine

The second step of our approach consists of the reduction of nitrotyrosine to aminotyrosine. Although this reaction is generally performed with sodium dithionite [36], we used hemin (i.e. chloroprotoporphyrin IX iron(III)) and DTT as previously described by Balabanli et al. [44]. The advantage of this reaction is that it proceeds to completion within a couple of minutes in a boiling water bath at the same pH as the acetylation reaction. Incidentally, Ghesquière et al. [38] used Fe^{2+}-charged cytochrome *C* as the reducing agent and showed it to be preferable to sodium dithionite, since the latter leads to partial sulfation of tyrosine, as suggested by an 80-Da increase in mass, hence complicating chromatograms and mass spectra.

4.3. Biotinylation of aminotyrosine

NHS-biotin was used to biotinylate aminotyrosine. Due to the blocking of primary amines in step 1 aminotyrosine should be, at this stage, the only amine available for biotinylation. While the

expected biotinylated peptide was observed (Fig. 6B, fifth and sixth panels), signal intensity was rather low, notwithstanding the fact that no starting material was left. We did not observe any side reactions that might explain a major loss of aminotyrosine-containing peptide and assume that the introduction of the biotin moiety at the aminotyrosine residue dramatically decreased ionization efficiency.

The phenolic hydroxyl group of tyrosine reacts as well with NHS-activated esters under the described conditions. By incubating for 60 min in a boiling water bath we assured that all O-biotinylated peptide was removed (Fig. S-1 in Supplementary Material). Although the phenolic hydroxyl group of aminotyrosine has an almost identical pK_a as in tyrosine (10.0 and 10.1, respectively [36]), we did not observe the O-biotinylated side product in this case (Fig. 6B, fifth and sixth panels). This is likely due to the fact that the aromatic amine is more reactive than the hydroxyl group making subsequent biotinylation of the adjacent OH-group sterically unfavorable.

4.4. Removal of excess biotin prior to enrichment on a monomeric avidin column

The binding capacity of the monomeric avidin resin is relatively low (1.2 mg BSA, i.e. 18 nmol/mL of settled resin corresponding to 0.9 nmol for the 100 μL of a 50% slurry of resin that we used). Thus, the resin would be very easily saturated by the 5 mM (1.15 μmol) of NHS-biotin (hydrolyzed to biotin during the boiling step) used during the last step of chemical labeling. We therefore wished to remove the excess of biotin prior to the final enrichment step. Several methods were not deemed optimal. Size-based separation methods (dialysis, gel filtration, ultrafiltration) were not possible because of the small size difference between free biotin (244 Da) and the target peptide (1329 Da). Solid-phase extraction with reverse-phase materials was no option since both molecules have similar retention characteristics (see retention on the C_{18} reversed-phase column; Fig. 6). Anion exchange was also not optimal, since both peptides and biotin contain at least one carboxylic acid moiety. Consequently we exploited SPE on a strong cation exchange resin based on the fact that biotin cannot acquire a positive charge at acidic pH, whereas most peptides can be protonated at histidine or arginine residues, despite the fact that all primary amines have been acetylated. This separation step proved to be efficient, although biotin still resulted in the highest peak upon LC–MS after the SCX step (Fig. 8A), considering that the remaining biotin is only a very small fraction of the initial amount that was present after biotinylation (Fig. 6A). Unfortunately, this cleanup step is also the cause for some peptide loss and requires further study. Comparison of the BPCs before (Fig. 6) and after SCX (flow-through of the avidin-based extraction, Fig. 7) reveals that the peak intensity for $[^{Ac}Y]^{2+}$ is reduced by a factor 30 although the peptide solution was only diluted by about a factor of 2.5. This signal reduction after the SCX column is consistent with the observation that the signal for the labeled peptide decreased by about a factor 5 although it is recovered in a volume that is only two times smaller than that of the biotinylation step (Figs. 6 and 8). Moreover, it appears that certain BSA-derived peptides are no longer observed after SCX, neither in the flow-through nor in the eluate of the avidin-based enrichment.

To circumvent this problem we are presently evaluating ways to perform the chemical labeling at the protein level and to use molecular size-based methods for biotin removal. Initial experiments show that it is possible to perform our sequence of reactions, including the boiling steps, with proteins in a solution containing 6 M guanidinium hydrochloride, so further investigations are warranted.

It is noteworthy that the labeled peptide of interest was recovered as the major peptide in the eluate of the avidin-based resin. No BSA-derived peptides were observed, reflecting the high selectivity of the chemical labeling and enrichment procedure.

5. Conclusion

We describe a methodology for the selective labeling and enrichment of tyrosine-nitrated angiotensin II in a matrix of BSA tryptic peptides. This method constitutes an improvement over previous reports by Nikov et al. [35] and Zhang et al. [39]. First, all chemical reactions proceeded with yields approximating 100%. This reduces the chance of enriching peptides that do not contain nitrotyrosine, which is of prime importance when targeting a low-abundance protein post-translational modification. Second, neither sample cleanup nor change of pH are required until the biotin-removal step. Considering that proteomic samples are often small in volume and contain low amounts of peptides, this is a major advantage.

Our chemical labeling approach is well adapted to the analysis of tyrosine nitration at the peptide level, for instance in shotgun proteomics. We are presently pursuing experiments to perform the labeling reactions at the protein level prior to digestion, notably to facilitate biotin removal.

ABSTRACT

Molecular mass spectrometry (MS) analysis of protein phosphorylation is partially limited by the molecular specie specificity of the analytical responses that might impair both qualitative and quantitative performances. Elemental MS, such as inductively coupled plasma mass spectrometry (ICP-MS) can overcome these drawbacks; in fact, analytical performance is theoretically independent of the molecular structure of a target analyte naturally containing the elements of interest. Nevertheless, isobaric interferences derived from sample matrix and laboratory environment can hinder the quantitative determination of both phosphorus (P) and sulfur (S) as $^{31}P^+$ and $^{32}S^+$ by inductively coupled plasma quadrupole mass spectrometry (ICP-QMS) under standard plasma conditions. These interferences may be overcome by quantifying P and S as oxide ions $^{31}P^{16}O^+$ and $^{32}S^{16}O^+$, respectively.

In this study, we present a systematic investigation on the effect of plasma instrumental conditions on the oxide ion responses by a design of experiment approach for the simultaneous ICP-QMS determination of P and S ($^{31}P^{16}O^+$ and $^{32}S^{16}O^+$, respectively) in protein samples without the use of dynamic reaction, collision reaction cells or pre-addition of oxygen as reactant gas in the torch. The proposed method was evaluated in terms of limit of detection, limit of quantification, linearity, repeatability, and trueness. Moreover, detection and quantification capabilities of the optimized method were compared to the standard plasma mode for determination of $^{31}P^+$ and $^{34}S^+$. Spectral and non-spectral interferences affecting the quantification of $^{31}P^+$, $^{31}P^{16}O^+$ and $^{32}S^{16}O^+$ were also studied. The suitability of inorganic elemental standards for P and S quantification in proteins was assessed. The method was applied to quantify the phosphorylation stoichiometry of commercially available caseins (bovine β-casein, native and dephosphorylated α-casein) and results were confirmed by Matrix Assisted Laser Desorption Ionization Time of Flight MS analysis.

We demonstrate that ICP-QMS, by quantifying P and S as oxide ions, was able to accurately calculate the degree of phosphorylation of β-casein and α-casein and to detect specific partial enzymatic dephosphorylation. The collected results might lead to further development of ICP-QMS interfaces optimized for protein phosphorylation studies and for proteomics investigations.

1. Introduction

Reversible protein phosphorylation is one of the most important post-translational modifications that plays a key role in many cellular metabolic pathways and strictly regulates protein functions [1,2]. The extent of phosphorylation for a specific protein depends on the cell status and can dynamically change over time. A protein can be phosphorylated and dephosphorylated by kinases and phosphatases, respectively, on different sites at different times. It is estimated that about 25–30% of the proteins present in eukaryotic cells are phosphorylated at some point in their life cycle [3]. Such a scenario makes quantitative determination of protein phosphorylation degree of great interest in proteomics investigations. Nevertheless currently this is a challenging task and is far to be routinely surveyed in mass spectrometry (MS) based proteomics. Molecular MS, such as Electrospray Ionization MS (ESI-MS) and Matrix Assisted Laser Desorption Ionization MS (MALDI-MS), are

doi:10.1016/j.talanta.2009.06.082

the most useful tools for protein identification, sequencing, and site specific modification studies. However, some applications in the field of post-translational modification study are difficult. In the case of protein phosphorylation, the main problem affecting molecular MS in phosphoproteomics studies is the species specificity of the analytical responses that limits both qualitative and quantitative performance [4]. This is a general limitation of molecular MS because the signal obtained by MALDI or ESI ion source strongly depends on the molecular features of the ionized species and on the sample matrix. In particular phosphoproteins and phosphopeptides exhibit a lower MALDI-MS and ESI-MS sensitivity with respect to the unmodified peptides and are often not detectable in complex mixtures under standard operating conditions. In addition, the lack of suitable external standards limits quantitative applications and usually only relative quantification is possible. A great effort has been made to overcome these problems and enrichment procedures or selective tagging in the case of phosphorylated proteins and peptides have been proposed [5].

Theoretically, elemental MS, such as inductively coupled plasma MS (ICP-MS) can overcome these drawbacks. In fact, in this case the analytical sensitivity is theoretically independent from the molecular structure of a target analyte containing a natural elemental tag and quantification can be performed by using species-unspecific standards, i.e. inorganics [6–8]. Recently, Pereira-Navaza et al. described the accurate quantification of phosphorylated peptides in complex peptide mixtures by using elemental phosphorus (P) standard [9,10]. Furthermore, ICP-MS was proposed for detection not only of phosphorylation that occurs at the hydroxyl groups of serine (Ser), threonine (Thr), and tyrosine (Tyr) residues but also of acid labile phosphorylation of the side chains of arginine (Arg), aspartic acid (Asp), lysine (Lys), and histidine (Hys) residues often not detectable by MALDI or ESI-MS [11].

Another potential advantage of ICP-MS is the possibility of protein quantification by determination of sulfur (S) [12]. Absolute protein quantification is a challenging task in analytical chemistry and is pivotal for the understanding of proteome variations in living systems [13]. S naturally occurs in cysteine (Cys) and methionine (Met) side chains and constitutes a natural tag that did not require any reaction to be detected in contrast to other quantitative techniques as isotope-coded affinity tagging (ICAT) [14] and metal-coded affinity tagging (MECAT) [15]. Recently, the potentials of this approach were assessed by Schaumlöffel et al. [16] and Wang et al. [17]. They proposed isotope dilution analysis of S as a method for absolute quantification of peptides and proteins, respectively. Furthermore, S was used as an internal standard for quantitative determination of heteroatom/protein stoichiometric ratios. However, quantitative determination of P as $^{31}P^+$ and S as $^{32}S^+$ and/or $^{34}S^+$ by inductively coupled plasma quadrupole mass spectrometry (ICP-QMS) is hindered by severe nitrogen ($^{15}N^{16}O^+$, $^{14}N^{17}O^+$, $^{14}N^{16}O^1H^+$, $^{14}N^{18}O^+$, $^{15}N^{16}O^1H^+$) and oxygen ($^{16}O_2{}^+$) based isobaric interferences derived from sample matrix and laboratory environment. The problem of spectral interferences is less relevant in the case of P. ICP-QMS without collision/reaction cell technology was applied to quantify P as $^{31}P^+$ at trace level in different matrices or tagged molecules under standard plasma conditions [18–20]. This is not the case for S for which interferences hinder accurate quantification as $^{32}S^+$ and $^{34}S^+$ by ICP-QMS, discouraging potential applications for quantification. Spectral interferences of the major isotope ^{32}S can be efficiently resolved by using different instruments. Sector field mass spectrometer was successfully applied to quantify S and other elements in peptides and proteins [21,22]. Since the advent of dynamic reaction and collision reaction cells (DRC/CRC), ICP-QMS instruments can be used to quantitate P and S as oxide ions. In particular, the pioneering work of Bandura et al. [23] describes the quantification of protein phosphorylation by simultaneous ICP-QMS determination of P and S as oxide ions with excellent detection capability. However, only few papers report the quantification of S by ICP-QMS without collision/reaction cell. Menegario et al. [24] used ICP-QMS to determine $^{34}S/^{32}S$ isotope ratio from oxide ions $^{34}S^{16}O^+$ and $^{32}S^{16}O^+$ at m/z 50 and 48, respectively to resolve spectral interferences affecting the corresponding $^{32}S^+$ and $^{34}S^+$ singly charged ions. This approach was proposed by Menegario and Giné for quantification of S in plant digest [25], by Dviak and Goessler [26] for the quantitative determination of inorganic S species by ion chromatography coupled with ICP-QMS, and by Koplík et al. [27] for simultaneous P and S quantification in different matrices. In these works, plasma-operating conditions were optimized to give the maximum oxide ion formation ratio by using one factor at a time (OFAT) approach. Recently, design of experiment (DOE) has been proposed for the multivariate optimization of plasma conditions [28,29]. This approach has several advantages with respect to OFAT optimization process: the evaluation of effects of several factors is less time consuming and significant interactions between factors can be assessed with a lower risk of misinterpreting the results [30,31].

Here we present an optimization of oxide ion detection method that results in a significant improvement of simultaneous quantification of P and S in protein samples allowing to quantification of protein phosphorylation. The factors considered in the optimization procedure (i.e., sample depth, sample uptake flow, extraction lens 1 voltage, and plasma power) were optimized to maximize $^{31}P^{16}O^+$ and $^{32}S^{16}O^+$ yields without using oxygen as reactant gas.

Several assays were performed to compare our optimized conditions with standard plasma conditions. For both analytes the effective advantages of quantification as oxide ion under our conditions were verified by comparing background equivalent concentration (BEC), limit of detection (LOD), and limit of quantification (LOQ) with P and S determined as $^{31}P^+$ and $^{34}S^+$ under standard plasma conditions. In fact, this method has been widely reported for ICP-MS quantification of P [18–20]. While $^{34}S^+$, which is less interfered than $^{32}S^+$, could be potentially used as the analyte ion for S quantification by ICP-QMS under standard experimental conditions. Moreover, spectral and non-spectral interferences affecting the determination of P as $^{31}P^{16}O^+$ and S as $^{32}S^{16}O^+$ under our optimized conditions were studied. In fact, carbon (C), nitrogen (N), silicon (Si), magnesium (Mg), calcium (Ca), and titanium (Ti) are potential sources of spectral interferences at m/z 47 and 48 (Table 1) [32,33]. In particular, C and N polyatomic species were reported as interfering ions at m/z 47 and 48 affecting the analytical

Table 1

performance in terms of sensitivity and trueness in carbon and nitrogen rich matrices [33]. Furthermore, C can also affect the analyte ionization in a species-specific fashion, usually enhancing non metal sensitivity and suppressing metal ionization [9,16,21,34,35]. For P the potential interference sources were also studied when analyzed as $^{31}P^+$ under standard plasma conditions. Performance evaluations for both ionization modes were performed in the same analysis by switching between oxide ion mode and normal plasma conditions, instead of performing the two analyses independently.

Finally, the method was applied to quantify the phosphorylation degree of commercially available caseins (bovine β-casein, native and dephosphorylated α-casein) and results were confirmed by MALDI-MS analysis demonstrating that this method can yield results thus far obtained on more complex instrumental set-up including DRC/CRC system.

2. Experimental

2.1. Chemicals and reagents

Deionized water with a specific resistance of 18.2 MΩ cm (Milli-Q system, Millipore, Watford, Hertfordshire, UK) was used for preparing all solutions and diluting the samples. P (H_3PO_4, 1000 mg L^{-1}, H_2O) and S (Na_2SO_4, 1000 mg L^{-1}, H_2O) stock solutions were purchased by Merck (Darmstadt, Germany) and Romil (Cambridge, UK), respectively. Standard solutions were prepared daily from the stock. Internal standard stock solution (Sc, Ge, Y, In, Tb, Bi, 10 mg L^{-1}, 1% HNO_3) and tuning solution (Li, Y, Ce, Tl, 10 μg L^{-1}, 2% HNO_3) were acquired from Agilent Technology (Palo Alto, California, USA). Tris(hydroxymethyl)-aminomethane (Tris) was obtained from Bio Rad Laboratories (Hercules, CA, USA). Barium hydroxide, acetonitrile, trifluoroacetic acid (TFA), acetic acid, Triton X100, bovine serum albumin (BSA, purity 99%), bovine β-casein (total protein 92%, purity 94%), bovine α-casein (total protein 98.8%, purity 96.9%), enzymatically dephosphorylated α-casein (total protein 87%, purity 87%), and sequence grade modified trypsin were purchased from Sigma–Aldrich (Shnelldorf, Germany). Rhodium stock solution (Rh, 10 mg L^{-1}), sinapinic acid, α-cyano-4-hydroxycinnamic acid (CHCA), L-cysteine (Cys, purity ≥99.5%) and O-phospho-DL-serine (P-Ser, purity ≥99%) were purchased from Fluka BioChemika (Shnelldorf, Germany).

2.2. Sample preparation

Proteins and amino acids were accurately weighed using a Mettler Toledo AX26 DeltaRange™ balance with the readability of 1 μg and then dissolved in 18 MΩ water to give a concentration of at least 1 mg mL^{-1}. Class A volumetric flasks (Assistent, Sondheim, Germany) previously soaked with 10% HNO_3, were used to prepare stock solutions. Stocks were stored at −80 °C until use. Stock solutions were suitably diluted and analyzed by ICP-MS without any further purification. Enzymatic hydrolysis for peptide mass fingerprint (PMF) analysis of caseins was performed by using trypsin. Bovine β-casein, bovine α-casein, and enzymatically dephosphorylated bovine α-casein, 1 μmol L^{-1} in 50 mM ammonium carbonate/2 M urea at pH 8.3, were incubated overnight at 37 °C with trypsin at an enzyme/substrate ratio of 1:100 to produce tryptic digest for MALDI-TOF-MS analysis. Reaction was stopped by addition of 0.1% TFA and 10 μL of solution, corresponding to 10 pmol of peptides, were desalted on Zip-Tip™ C18 micro-columns (Millipore, Watford, Hertfordshire, UK) and eluted with 2 μL saturated CHCA matrix solution (50% CH_3CN, 0.1% TFA) onto the MALDI target. β-Elimination of intact proteins was performed on 50 μmol L^{-1} casein solutions (30 μL) in 2 M urea by adding 15 μL of saturated $Ba(OH)_2$. After 15 min at 37 °C, 5 μL of 10% (v/v) acetic acid was added. Sample desalting was performed by ZipTip™ C4 micro-columns (Millipore, Watford, Hertfordshire, UK). Protein elution with 2 μL of saturated sinapinic acid matrix solution (50% CH_3CN) was performed directly onto the MALDI target.

[a] Optimized by DOE.

2.3. ICP-MS analysis

The analysis equipment employed was an inductively coupled plasma mass spectrometer, model 7500A (Agilent Technologies, Tokyo, Japan) fitted with an ASX-510 autosampler (CETAC, Omaha, NE, USA) and a peristaltic pump. A Babington nebulizer with a Scott spray chamber (Agilent Technologies) was used for sample introduction. A multi-tune method based on the automatic switching between the two operating conditions in the same analysis was used for the simultaneous determination of P and S as $^{31}P^+$, $^{34}S^+$ and $^{31}P^{16}O^+$, $^{32}S^{16}O^+$ under normal and optimized conditions, respectively. The stabilization time after switching was 25 s. Operating conditions are described in Table 2. Normal plasma conditions were optimized for the best sensitivity of 10 μg L^{-1} of ^7Li, ^{89}Y and ^{205}Tl and for the reduction of $^{140}CeO^+/^{140}Ce^+$ and $^{140}Ce^{2+}/^{140}Ce^+$ ratios below 1% and 3%, respectively. While the DOE was used to optimize sample depth, sample uptake flow, extraction lens 1 voltage, and plasma power for $^{31}P^{16}O^+$ and $^{32}S^{16}O^+$ formation. An internal standard solution (Sc, Ge, Y, Rh, In, Tb, Bi, 50 μg L^{-1}) was added on line in a T-piece. Washing of sample introduction system was performed with 18 MΩ cm water. Data analysis was performed using ChemStation software (Agilent Technologies).

2.4. MALDI-TOF-MS analysis

All MALDI-Time of Flight-MS (MALDI-TOF-MS) analyses were performed on a MALDI-TOF-MS Reflex IV (Bruker Daltonics, Bremen, Germany) spectrometer equipped with an MTP multiprobe and a nitrogen laser pulsing operating at 337 nm. Positive ion mass spectra (*m*/*z* range = 700–4000) for PMF analysis were acquired operating in reflectron mode by summing at least 200 single laser shots with a repetition rate of 6 Hz. Source voltages were 20.00, 16.80 and 8.9 kV and reflectron voltage was 23 kV. Angiotensin I (1296.68 Da), ACTH 8–39 (2465.19 Da), Bradichinin (fragments 1–9, 1060.57 Da), and Renin substrate (1758.93 Da) were used as external standard for mass calibration. Acquired spectra were processed with FlexAnalysis 2.3 and BioTools 3.0 software (Bruker Daltonics). Database searches were performed against the nonredundant protein sequence database NCBInr using the peptide search algorithm MASCOT (Matrix Science, http://www.matrixscience.com). A mass tolerance of 100 ppm was allowed during processing of MS data for PMF. Oxidation of Met and phosphorylation of Ser were chosen as optional modifications. One enzyme missed cleavage was chosen for all searches performed without taxonomic restriction.

Table 3

Intact mass determination of native caseins and dephosphorylated β-elimination products were performed operating in linear mode with detection of positive ions (m/z range = 7000–35,000). Source voltages were 20.00, 18.00, and 9.4 kV. External mass calibration was performed using molecular and doubly charged ions of human hemoglobin α (m/z 15,127 and 7564, respectively) and β-chains (m/z 15,868 and 7934, respectively). At least 200 single pulse spectra were summed with a repetition rate of 9 Hz.

$Y = 16,097(\pm442) - 4,245X_1(\pm277) + 2,544X_2(\pm277) + 1,121X_3(\pm277) - 7,521X_4(\pm277) - 1,473X_1X_2(\pm314) - 700X_1X_4(\pm314) + 746X_3^2(\pm384) - 1,396X_4^2(\pm384)$
$R^2 = 0.959$

2.5. Experimental design

A 2^4 two-level full factorial design (FFD) was used to investigate the main and interaction effects of sample depth (X_1, mm), sample uptake flow (X_2, mL min^{-1}), extraction lens 1 voltage (X_3, V) and plasma power (X_4, W) on the $^{31}P^{16}O^+$ and $^{32}S^{16}O^+$ signals (counts s^{-1}) at m/z 47 and 48, respectively. Aqueous standards containing 30 and 300 μg L^{-1} of P and S, respectively, were analysed. Instrumental blank (18 MΩ cm water) signal was measured under each experimental condition and subtracted from the corresponding standard signal. Low (−1) and high (+1) levels were: X_1 = [5–7] mm, X_2 = [0.4–0.8] mL min^{-1}, X_3 = [(−170)–(−140)] V, X_4 = [1000–1300] W. Torch position was automatically adjusted at each sample depth to maximize intensities at m/z 47 and 48. Experimental domains were defined for all the investigated factors on the basis of technical limitation of the system and acceptable signal stability below 5%. Experiments were performed in random order to avoid trends and three replicate measurements were done for all the experimental conditions to check the repeatability. Significant main and interaction effects were evaluated by single factor analysis of variance (ANOVA) of responses and standard least squares regression was used to calculate the best first order fit. Six measurements were also performed at the centre of experimental domain to check the relevant quadratic effect by a lack of fit test. A 95% confidence level was chosen in every case. Star points were added to the full factorial plan when a significant quadratic effect was detected. The axial distance (α) between star points and centre of experimental domain was calculated to obtain an orthogonal central composite design (CCD). The best regression model and coefficients of determination R^2 were then calculated by using all the experiments performed in both phases of experimental design. The desirability function approach was used for multiple response optimization [36]. The overall desirability, D, was calculated as the geometric mean of individual desirabilities:

$$D = [d_1(\hat{Y}_1) \times d_2(\hat{Y}_2) \times \cdots \times d_i(\hat{Y}_i)]^{1/i} \quad (1)$$

where d_i is the desirability associated to the ith fitted response value, $\hat{Y}_i$. Individual desirabilities were defined as follow:

$$d_i(\hat{Y}_i) = 0 \quad \text{if } \hat{Y}_i \le 0 \quad (2)$$

$$d_i(\hat{Y}_i) = \frac{\hat{Y}_i}{1.2 \times \hat{Y}_{i,\max}} \quad \text{if } 0 < \hat{Y}_i < 1.2 \times \hat{Y}_{i,\max} \quad (3)$$

$$d_i(\hat{Y}_i) = 1 \quad \text{if } \hat{Y}_i = 1.2 \times \hat{Y}_{i,\max} \quad (4)$$

The overall desirability D was then maximized by grid search algorithm. All statistical analyses were performed with STATISTICA 6.0 software (StatSoft Inc., Tulsa, OK)

2.6. Method development

Detection limit (LOD) and quantification limit (LOQ) were expressed as signals (y_D and y_Q) on the basis of the mean value ($\bar{y}_b$) and standard deviation (s_b) of the blank responses (n = 20):

$$y_D = \bar{y}_b + 2ts_b \qquad y_Q = \bar{y}_b + 10s_b \quad (5)$$

where t is the constant from the one sided Student's t-test at 95% confidence level for $n-1$ degrees of freedom. The corresponding concentration values were obtained by using an appropriate calibration curve satisfying the relationship: $0.5x_1 < \text{LOD} < x_1$, where x_1 is the concentration of the first calibration level [37]. Linearity was studied according to IUPAC guidelines [38]. Homoscedasticity was verified by applying Bartlett's test. Linearity of calibration functions was verified by the calculation of coefficient of determination (R^2) and Mandel's fitting test. Two-sided t-test was used to confirm the significance of the intercept. Precision was calculated in term of repeatability as relative standard deviation (RSD%) [37]. Trueness was evaluated by recovery tests [37]. A standard of BSA and P-Ser corresponding to the theoretical concentrations of 200 and 50 μg L^{-1} for S and P, respectively, was spiked with known amounts of the same organic standards. Quantification was performed by means of the calculated inorganic standard calibrations. Three spike levels were analysed (n = 3).

Statistical analysis was performed with XLStat and Microsoft Excel.

3. Results and discussion

3.1. Optimization of plasma-operating conditions by design of experiment

Oxide ions are one of the main spectral interferences limiting the multi-element capability of ICP-QMS. Their origin in the argon plasma has been well investigated [39,40]. Usually instrumental parameters were adjusted to minimize their formation maximizing singly charged ion M^+ intensities. However, oxide ions have been proposed as analyte ions to chemically resolve spectral interferences of the corresponding elemental ion [41,42]. In particular, the use of oxygen as reactant gas in DRC systems was successfully proposed for quantification of P and S in native protein sample by low resolution ICP-MS with excellent detection capability [23]. Plasma conditions could also be optimized to enhance oxide ion formation without any DRC system or pre-addition of oxygen as reactant gas

Table 5
Background equivalent concentration (BEC), instrumental limit of detection (LOD) and quantification (LOQ) calculated for P and S under the standard plasma and optimized conditions.

Element (ion, m/z)	BEC (μg L^{-1})[a]	LOD (μg L^{-1})[b]	LOQ (μg L^{-1})[c]
P ($^{31}P^+$, 31)[d]	6.3 (0.2)	1	5
S ($^{34}S^+$, 34)[d]	464 (56)	114	402
P ($^{31}P^{16}O^+$, 47)[e]	4.6 (0.2)	0.4	1.1
S ($^{32}S^{16}O^+$, 48)[e]	84 (5)	13	47

[a] Calculated as $[y_B/(y_{ex} - y_B)] \times x_{ex}$(μg L^{-1}), y_B = blank signal (n = 20), y_{ex} = external standard signal (n = 5), x_{ex} = concentration level (30 and 300 μg L^{-1} for P and S, respectively).
[b] Calculated as concentration corresponding to the signal $y = y_B + 2ts_B$, y_B = average blank signal (n = 20), s_B = standard deviation, t = critical value of t distribution (one tailed, 95% confidence level, 19) = 1.729.
[c] Calculated as concentration corresponding to the signal $y = y_B + 10s_B$, y_B = average blank signal (n = 20), s_B = standard deviation.
[d] Measured under standard plasma conditions.
[e] Measured using the optimized oxide ion mode.

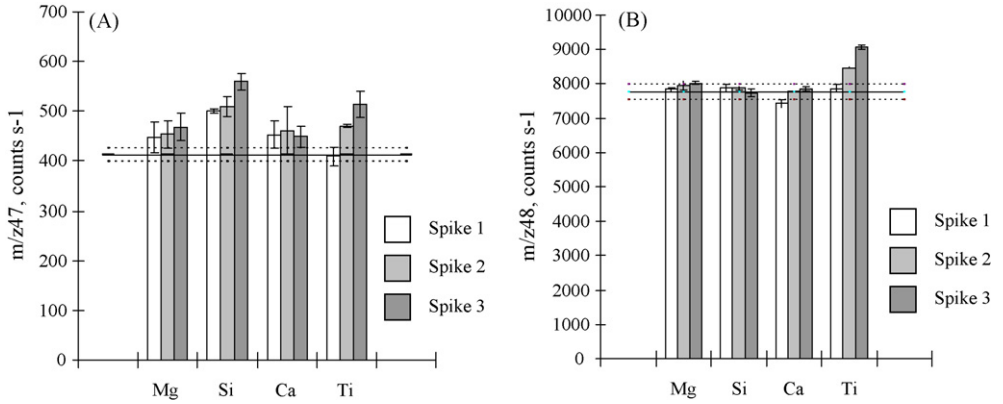

Fig. 2. Evaluation of Mg, Si, Ca, and Ti based spectral interferences at m/z 47 and 48. Data are the mean signal corresponding to increasing concentrations (nmol L^{-1}) of the potential interfering species. Bars are standard deviations ($n = 3$). Solid and dotted lines represent the mean signals and the confidence intervals at 95% confidence level, respectively, of 18 MΩ cm water.

in the torch. This approach has been applied for P and S quantification but optimization has been made by an OFAT approach without taking into account a possible interaction between the studied factors. In this work experimental design was applied to investigate main and interaction effects of sample depth, sample uptake flow, extraction lens 1 voltage and plasma power on $^{31}P^{16}O^+$ and $^{32}S^{16}O^+$ ions formation. It is known that factors affecting residence time of ion in the plasma e.g. carrier gas flow, sample depth, sample uptake flow and the plasma power can have a significant effect on the oxide ion formation. Reducing the residence time and plasma power gives usually increased MO^+/M^+ intensity ratios. In accordance with previous reports, preliminary experiments showed that carrier gas flow was the most important factor affecting oxide ion formation with a high significant positive effect. Small increases of carrier gas flow give significant increase of oxide ion yield and the corresponding experimental domain would be too narrow. Therefore, all measurements were performed by setting carrier gas flow at 1.35 L min^{-1} achieving acceptable short time signal repeatability. The experimental plan and the analytical responses are showed in Table 3. The analytical responses were the net signals for $^{31}P^{16}O^+$ and $^{32}S^{16}O^+$ calculated from the standard signals by subtracting the corresponding blank at each experimental condition. In this way, signals depend only on the analyte ions without any contribution of background that also changes at different experimental conditions. A significant curvature effect was detected by a Lack of Fit test ($p < 0.05$) for analyte ions. Star points were then added to the full factorial experimental design to estimate square terms. Fig. 1 shows the response surface and the corresponding residual plots while the calculated polynomial functions and the correlation coefficients were reported in Table 4. Residual plots (Fig. 1) and the calculated R^2 (Table 4) attest an acceptable descriptive and predictive ability of the calculated model for both analytes. The calculated models were used for the multiple response optimizations by means of the desirability function and the optimal experimental conditions were $X_1 = 4.5$ mm, $X_2 = 0.88$ mL min^{-1}, $X_3 = 135.2$ V and $X_4 = 959$ W corresponding to an overall desirability $D = 0.97$. The excellent global desirability (D) demonstrated that these experimental conditions were optimal for the simultaneous $^{31}P^{16}O^+$ and $^{32}S^{16}O^+$ formation. As expected, a low plasma power and the lowest sample depth within the experimental domain increase oxide ion level. In fact, reducing the distance between the torch and the sample cone the permanence time of ions in cooler plasma is also reduced and the probability of polyatomic ion detection increased. A significant effect of the sample loading flow was also observed. Increasing the sample uptake flow at the highest value within the experimental domain, increased oxide ion intensities were observed. By increasing sample loading flow rate, more aerosol was introduced in the plasma and the mass transport rate simultaneously increased for analyte and solvent [43]. Higher water vapours generate higher oxygen level in plasma enhancing oxide ion formation. Furthermore, water reduced plasma temperature, and ionization efficiency with the same effect [44]. Surprisingly, no significant interaction effect between extraction lens 1 voltage and the other factors was observed. The optimal extraction lens voltage, i.e. the higher value in the investigated experimental domain could be probably explained on the basis of the best compromise between analyte and blank signals. The reliability of the predictive model was evaluated by comparing the predicted responses (7552 ± 904 and $39{,}626 \pm 4006$ counts s^{-1} for $^{31}P^{16}O^+$ and $^{32}S^{16}O^+$, respectively; mean ± CI, 95% confidence level) with the experimental signals at m/z 47 and 48 measured under the optimized operating conditions. The measured signal blank subtracted was 7048 ± 54 and $40{,}533 \pm 372$ counts s^{-1} (mean ± CI, $n = 5$, 95% confidence level) at m/z 47 and 48, respectively. These results agreed with the predicted responses.

Background equivalent concentrations (BEC, μg L^{-1}), instrumental limits of detection (LOD, μg L^{-1}) and quantification (LOQ, μg L^{-1}) were calculated under the optimized conditions and compared with values calculated at mass m/z 31 and 34 corresponding to isotopes ^{31}P and ^{34}S analyzed under standard plasma conditions (Table 5). Analysis of 20 instrumental blanks (18 MΩ cm water) was carried out in multi-tune mode with two sequential steps for every acquisition: first standard operating conditions and then plasma conditions optimized for detection of oxide ions. A significant improvement of BEC, LOD, and LOQ was observed for S by measuring the oxide ion $^{32}S^{16}O^+$ under the optimized conditions with respect to normal plasma conditions even if BEC and LOD were higher than previously published data obtained measuring S as $^{32}S^{16}O^+$ with DRC–ICP-QMS [23]. However, the calculated LOD is of the same order of magnitude obtained measuring $^{32}S^+$ and $^{34}S^+$ with CRC–ICP-QMS with H_2 or Xe as reactant gas and He as collision gas [45]. On the other hand, the calculated LOD for P measured as $^{31}P^{16}O^+$ was of the same order of magnitude of that previously reported [23]. However, higher BEC was calculated in the present case. The effect of higher BEC on LOD was negligible. This is probably related to the higher acquisition time (Table 2) that improved precision of background measurement for oxide ions.

In contrast with S measured as $^{34}S^+$, acceptable LOD and LOQ were calculated for P measured as $^{31}P^+$ under normal plasma conditions. Therefore, both the operating conditions were suitable for quantitative determination of P at trace (μg L^{-1}) levels and could be alternatively used depending on specific sample matrix and related interferences.

Table 6
Calibration functions calculated for P measured as $^{31}P^+$ and $^{31}P^{16}O^+$ and for S measured as $^{32}S^{16}O^+$ using inorganic elemental standards, amino acids P-Ser and Cys (P-Ser/Cys), and BSA spiked with P-Ser (P-Ser/BSA). Blank matrix and five concentration levels ($n = 3$) between 50–300 and 200–1200 ng mL^{-1} for P and S, respectively, were analysed. R^2 values were better than 0.99 for all curves. Significant p values are bold. ND: not determined. CI: 95% confidence interval.

3.2. Study of spectral interferences

Mg, Ca, Si, and Ti based spectral interferences might affect background at m/z 47 and 48 (Table 1). Ca and Ti based interferences can be chemically resolved using DRC–ICP-MS instruments via thermodynamically allowed reactions with oxygen resulting in the corresponding oxide ions. In our experimental conditions we simultaneously maximize the yield of both $^{31}P^{16}O^+$ and $^{32}S^{16}O^+$. However, we cannot exclude that this also resulted in the formation of potential interfering species. Furthermore, Si and Mg can give the corresponding $SiOH^+$ hydroxide ions and $^{24}Mg^{24}Mg^+$ dimers that can interfere at m/z 47 and 48, respectively. Therefore, the potential contribution of these elements on the background has been investigated. Equimolar solutions of Mg, Ca, Ti (5, 10 and 20 nmol L^{-1}, respectively), and Si solutions (200, 400 and 800 nmol L^{-1}) were analyzed. The concentrations of these elements used in our experiments were at least ten fold higher than the typical concentration found in the 18 MΩ cm water [46]. As can be seen in Fig. 2, Mg and Ca do not significantly affect the signal at m/z 48 at these concentration levels. However, the effect of these potential interferences should be checked if analyses have to be performed in buffers containing higher concentration of Mg and Ca instead water. An increase of signal at m/z 47 was observed for Si and Ti spikes. Ti also increases signal at m/z 48. This is probably due to the incomplete oxidation of Ti^+ under these experimental conditions. While Ti was probably not a major problem, since Ti concentration in protein samples can be expected to be low if care is taken to avoid Ti contamination in chemicals used for sample preparation. On the contrary Si might represent an important potential interference. Indeed it is not surprising that Si increased background signal at m/z 47; in fact, the isobaric hydroxide ion $SiOH^+$ is known to be generated in plasma to a level suitable for Si ICP-QMS quantification [47]. Furthermore, Si is very common in nature and constitutes one of the main inorganic components of ultrapure water. For this, Si contribution to the background at m/z 47 could be relevant.

3.3. Study of non-spectral interferences

Organic compounds as proteins are potential sources of non-spectral interferences affecting analyte signals because C naturally occurring in biomolecules might affect the ionization of the heteroatoms bound to proteins. On the other hand, proteins can change physical properties (density, viscosity, and surface tension) of aqueous solutions with respect to aqueous inorganic standard used for quantification, affecting the aerosol transport rate, the vapour mass load, and/or the nebulization processes.

To check possible non-spectral C based interferences and assess the suitability of inorganic element standards for P and S quantification in proteins, we calculated calibration curves for P as $^{31}P^+$ and $^{31}P^{16}O^+$ and S as $^{32}S^{16}O^+$ by analyzing aqueous inorganic standards, amino acids P-Ser/Cys and P-Ser/BSA standards. BSA spiked with known amount of P-Ser was used as a surrogate of phosphoprotein because of high purity of the standards available. This approach was successfully proposed to verify the feasibility of protein quantification via inductively coupled plasma-atomic emission spectroscopy (ICP-AES) analysis of S by using inorganic elemental standard [48]. Table 6 shows the slopes of calculated calibration curves, showing that inorganic phosphate was a suitable external standard for quantification of P as $^{31}P^+$ under normal plasma conditions in aqueous solutions of biomolecules. On the other hand, the slopes of inorganic and P-Ser/Cys calibrations differ at 95% confidence level with slope of P-Ser/BSA calibration when P was determined as $^{31}P^{16}O^+$. This is probably due to the contribution of C based interferences to the signal at m/z 47 that proportionally increases with protein concentration. Therefore, protein levels affect P sensitivity and inorganic standards cannot be used for accurate quantification of P as $^{31}P^{16}O^+$ in aqueous samples of phosphoproteins. In addition data shown in Table 6 demonstrate that a first order calibration function, verified by Mandel's fitting test, correctly describes the relationship between signal and element concentration for P measured under both the ionization modes. In contrast for S a significant curvature was observed when BSA was used as organic standard. The plot of residuals for the BSA calibration (Fig. 3A) in water showed systematic deviations from the linear model indicating that a first order function was inadequate in this case. However, the sensitivities did not significantly differ because the slope of BSA calibration curve overlaps at 95% confidence level with the slope of calibration obtained from inorganic standards (Table 6). Interestingly, deviation from linearity was not observed when using Cys as organic standard (Table 6). This finding suggested that the chemical properties of the protein polymer may clearly affect plasma response of the covalently bound S. Such an effect cannot be corrected by internal standardization or by standard addition method using inorganic or amino acid spikes (data not shown). Possible size-dependent effects on the nebulization, changes of solution properties or unspecific protein losses should be taken into account. Furthermore, we observed an ionic suppression below 4% for inorganic S spikes in BSA (data not shown). This could be an effect of increased C concentrations. In addition plot of residuals showed a significant underestimation of S concentrations at lower BSA levels. If this signal suppression is mainly due to C naturally occurring in proteins, we can expect that this effect will be lower at lower BSA concentrations. However, signal enhancement or suppression also depended on the analyte concentration. Therefore, the effect of the same amount of C might be more important at lower S concentrations. We therefore evaluated the effect of increasing C levels on different concentrations of inorganic P and S. Experiments were performed using Tris as a

carbon source because in contrast with organic solvents it should not increase sample loading resulting in an erroneous evaluation of carbon effects. Tris concentrations were chosen to give C concentrations identical to the analyzed BSA samples, i.e. 0.7–7 mmol L^{-1}. As can be seen in Fig. 4, the effect of increasing C concentrations strictly depended on the analyte levels; indeed lower analyte concentrations showed a more pronounced signal enhancement. However, at 50 mmol L^{-1} or higher Tris comparable signal intensities were measured regardless of the analyte concentrations. Moreover, the slopes of inorganic standards and P-Ser/BSA calibrations for P measured as oxide ion did not significantly differ when 50 mmol L^{-1} of Tris was used (Table 6). Therefore, this concentration of organic modifier can be used to buffer carbon concentration changes in protein samples resolving the observed interferences for P measured as $^{31}P^{16}O^+$. A decrease of sensitivity was observed for P measured as $^{31}P^+$ but the slopes of inorganic standards and P-Ser/BSA calibrations did not significantly differ showing that inorganic standards

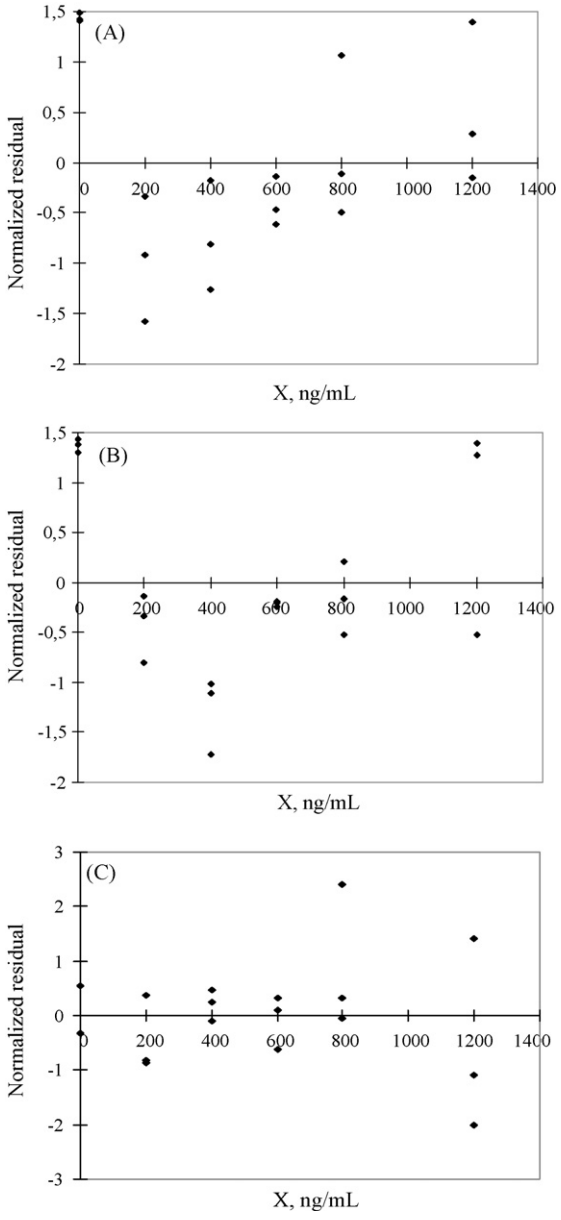

Fig. 3. Plots of normalized residuals (mean zero, standard deviation unity) for S measured as $^{32}S^{16}O^+$ using the optimized ion mode and BSA as organic standard in (A) 18 MΩ cm water, (B) Tris–HNO_3 50 mmol L^{-1}, and (C) 40 mmol L^{-1} Tris–HNO_3–0.1% Triton X100.

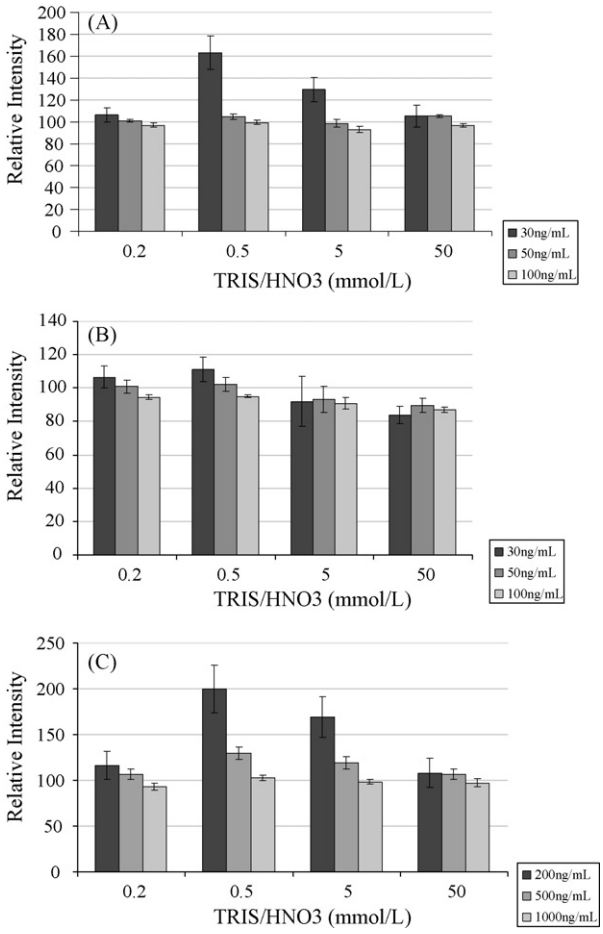

Fig. 4. Effect of increasing C concentration on the analyte signals at different analyte concentration levels. (A) P measured as $^{31}P^+$ under standard plasma conditions. (B) P measured as $^{31}P^{16}O^+$ using the optimized oxide ion mode. (C) S measured as $^{32}S^{16}O^+$ using the optimized oxide ion mode. Data are relative intensity calculated as $[y_{iMj}\ (\text{counts s}^{-1})/y_{iW}\ (\text{counts s}^{-1})] \times 100$, where y_{iMj} and y_{iW} are the net signals for the ith analyte concentration in the jth carbon matrix and 18 MΩ cm water, respectively. Net signals are calculated by subtracting the corresponding blank signal. Data are mean values from triplicate measurement. Bars correspond to standard deviations.

were suitable for P as $^{31}P^+$ quantification under standard plasma conditions (data not shown). In addition, the use of Tris theoretically increases potential applications of this method since normally protein samples are rarely obtainable in water. Furthermore, Tris is widely used as mobile phase for hyphenated chromatography with ICP-MS, thus does not require changes of the sample introduction system and consequent additional optimization works. However, Tris was not able to completely resolve the interference observed for S measured as $^{32}S^{16}O^+$. In fact, residual plot for BSA calibration in 50 mM TRIS (Fig. 3B) revealed systematic deviation from linearity. However, since negative residuals were calculated at low BSA concentrations this cannot be due to a simple C effect on ionization. Therefore, deviations from linearity could be due to changes in solution properties such as viscosity and superficial tension affecting aerosol formation and ion transmission or to unspecific protein loss in the sample introduction phase. We therefore reasoned that detergents, surfactants or organic solvents could be used to reduce these effects, and used a mixture of 40 mmol L^{-1} Tris–0.1% (v/v) Triton X100 in our experiment. Triton X100 was chosen because it has been successfully and extensively used in ICP-MS determination of non-metals in different protein rich matrix [49]. The relative amount of the two organic modifiers was chosen to give a C concentration equivalent to 50 mmol L^{-1} Tris to prevent the effects of carbon on the analyte ionization and at the same time limit Triton

X100 concentration reducing the risk of possible soot deposition. The plot of residuals of BSA calibration in this buffer (Fig. 3C) did not show systematic deviations and a first order calibration function can be used to fit the model (Table 6). This effect of Triton X100 may be, at least partially, explained by a reduction of unspecific protein loss. However, additional effects on density or viscosity of protein solutions and protein transport in the plasma cannot be excluded.

3.4. Analytical figures of merit and determination of casein phosphorylation degree

Table 7 shows LOD and LOQ calculated in 40 mmol L^{-1} Tris/HNO_3–0.1% Triton X100. As expected, higher values with respect to water were calculated. This is particularly evident in the case of P measured as $^{31}P^{16}O^+$. This buffer yields better LOD and LOQ compared to 50 mM Tris (data not shown), probably due to the lower content of N, a more important source of interferences at m/z 47 with respect to C. In all conditions used, an increase of LOD and LOQ was paralleled by a proportional increase of BEC (data not shown). This did not represent a problem for P quantification but it did for S determination thus remaining the limiting factor of ICP-QMS quantification of protein phosphorylation.

For the calculation of a reliable calibration model matrix blanks and seven concentration levels within the specified concentration range (Table 7) were analyzed. Linearity of the calculated calibration functions was demonstrated by assessing homoscedasticity throughout the range tested and by applying the Mandel's fitting test. The homogeneities of variance were verified by Bartlett's test at 95% confidence level ($p > 0.05$) for each analyte ion. The calculated R^2 were higher than 0.99 in all cases. Furthermore, Mandel's fitting test at 95% confidence level provided p values greater than 0.05 confirming the linearity of the calibration curves. As shown, the slopes of established calibration curves were lower than the slopes calculated in 18 MΩ cm water and 50 mM Tris (Table 6). The addition of Triton X100 suppresses sensitivity with respect to 50 mM Tris under both the operating conditions. This effect could not have

been due to changes of C content that was maintained constant and was probably related to the molecular size of the organic modifier that contained an aromatic ring which is more difficult to break [50].

Repeatability and trueness were calculated by analyzing P-Ser/BSA standards (Table 8) quantifying P as $^{31}P^{+}$ and $^{31}P^{16}O^{+}$ under standard plasma and oxide ion conditions, respectively and S as $^{32}S^{16}O^{+}$ using the oxide ion mode by means of the calculated

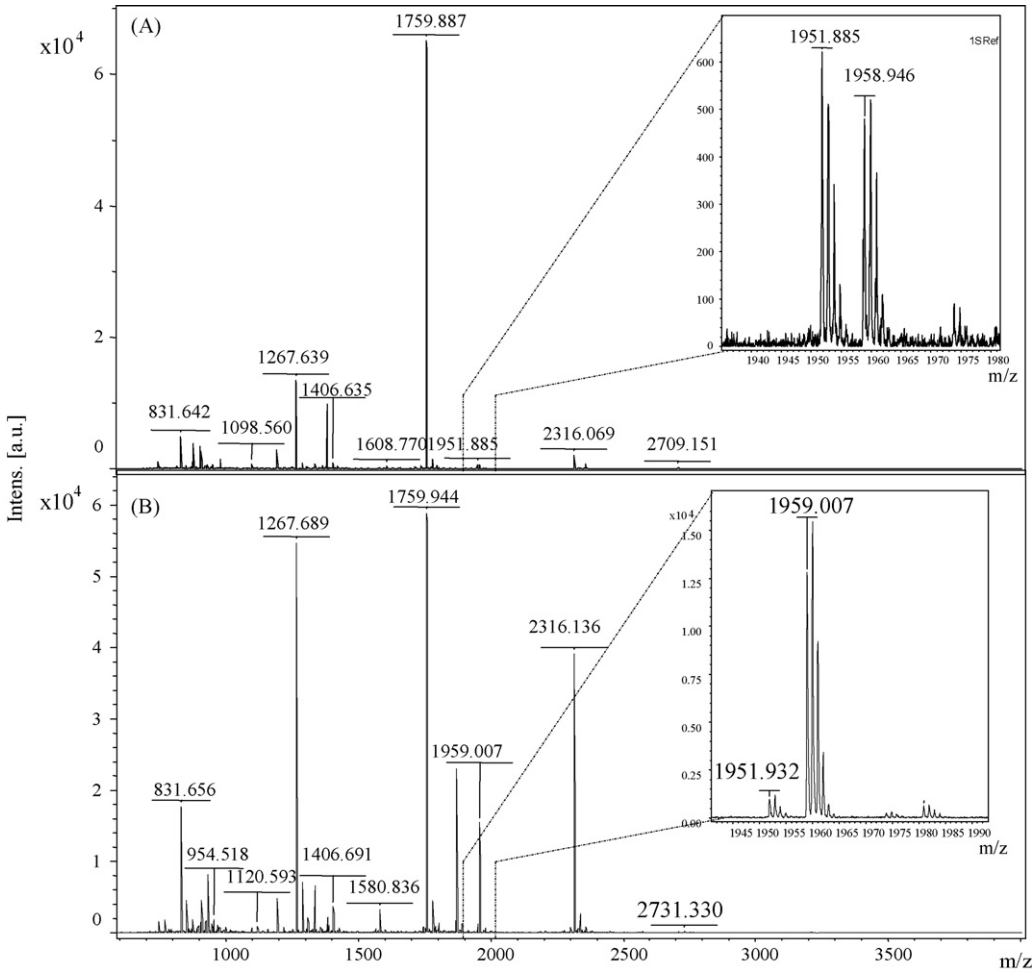

Fig. 6. Positive MALDI-TOF-MS spectra of tryptic peptides (10 pmol) from native bovine α-casein (A) and enzymatically dephosphorylated bovine α-casein (B). The insets show signal of the only phosphopeptide detected in both proteins at *m*/*z* 1951.

calibration function based on inorganic P and S standards. Excellent repeatability was observed for each analyte at the analyzed concentration levels. As expected on the basis of similarity between the slopes of inorganic standard and P-Ser/BSA calibrations, satisfactory recoveries were calculated for S. Better recoveries were calculated for P measured as oxide ion. In this case, the calculated concentrations for the reference standard corresponding to an actual concentration of 50 ng mL^{-1} were in accordance with the theoretical concentrations. Actual carbon concentration did not affect trueness.

For this reason, casein samples were analyzed under the optimized conditions measuring P and S as oxide ions. Increasing protein amounts were analyzed to assess the effect of protein concentrations on the measurement of phosphorylation degree. As can be seen in Table 9, calculated protein concentrations were in good agreement with the predicted concentration especially in the case of bovine β-casein that was available at higher purity. Moreover, results for native and enzymatically dephosphorylated α-caseins were consistent with the specifications provided by the suppliers. Phosphorylation degrees were calculated with an excellent precision for β and α-casein and did not significantly differ from the predicted stoichiometric P/protein ratio of 5 and 8, respectively. Unexpectedly, P was quantified also in enzymatically dephosphorylated α-casein. This could have been due either to partial dephosphorylation or to non-covalent phosphate adducts [51,52]. However, as demonstrated in the following paragraphs, in this case this was due to partial enzymatic dephosphorylation.

3.5. Determination of casein phosphorylation degree by MALDI-TOF-MS

On the basis of the calculated phosphorylation degree, increase of 399.8 and 639.7 Da of the molecular weights (MW) of bovine β-casein and intact α-casein, respectively, can be predicted and can be assessed by molecular MS. Bovine β-casein has been proposed as a model in several studies and was used to check the feasibility of standard PMF procedure. β-Casein gives two phosphopeptides after treatment with trypsin (a tetra-phosphorylated peptide 2-ELEELNVPGEIVE[P-Ser]L[P-Ser][P-Ser][P-Ser]EESITR-25 (2965.2 Da) and a mono-phosphorylated peptide 48-FQ[P-Ser]EEQQQTEDELQDK-63 (2060.8 Da)) that can be detected with different MALDI sensitivities. In particular, the

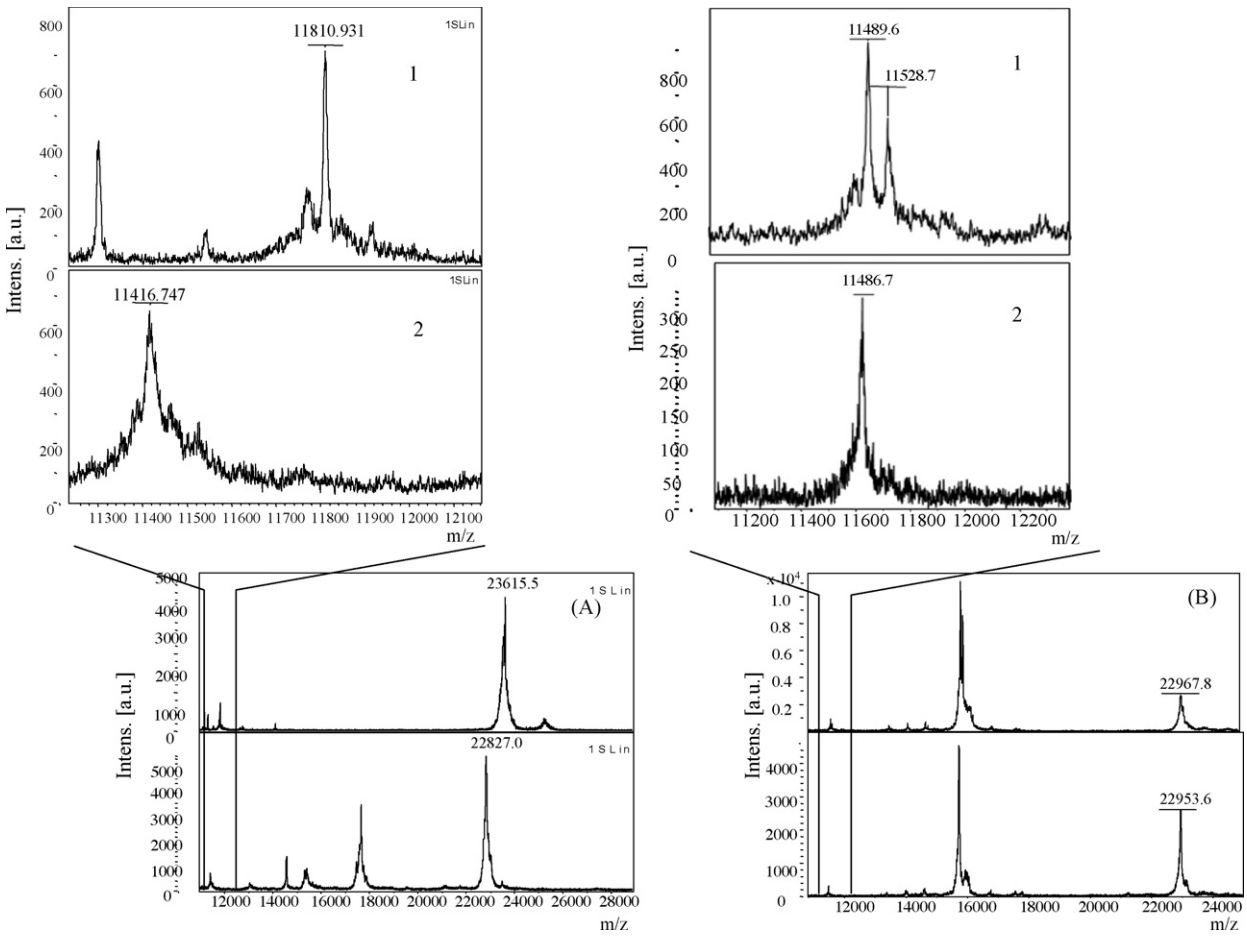

Fig. 8. Linear positive MALDI-TOF-MS spectra of intact (A) and enzymatically dephosphorylated (B) bovine α-casein before (1) and after β-elimination reaction (2). The insets show signals corresponding to the doubly charged ions.

reported MALDI-MS detection limits for the tetra-phosphorylated peptide range between five orders of magnitude depending on the acquisition mode and sample preparation procedure [53–55]. On the basis of these published results, a PMF experiment was performed using 10 pmol tryptic β-casein digest. Fig. 5 shows the mass spectra of tryptic digest of bovine β-casein. Signals at *m*/*z* 2061.83 and 3122.14 correspond to the mono-phosphorylated 48–63 peptide and to the tetraphosphorylated 1-RELEELNVPGEIVE[P-Ser]L[P-Ser][P-Ser][P-Ser]EESITR-25 peptide containing a missed cleavage site. This data confirm the ICP-QMS results. The same amounts of peptides from native and dephosphorylated α-caseins were then analyzed. Digestion of bovine α-casein using trypsin theoretically provides four phosphopeptides: 35-EKVNEL[P-Ser]K-42 (1025.47 Da), 43-DIG[P-Ser]E[P-Ser]TEDQAMEDIK-58 (1926.68 Da), 59-QMEAE[P-Ser]I[P-Ser][P-Ser][P-Ser]EEIVPN[P-Ser]VEQK-79 (2719.90 Da), and 106-VPQLEIVPN[P-Ser]AEER-119 (1659.78 Da). Only the phosphopeptide 104-YKVPQLEIVPN[P-Ser]AEER-119 containing a missed cleavage site was detected (Fig. 6A). Again, the same signal appeared in the mass spectrum of dephosphorylated α-casein (Fig. 6B). Therefore, detection of the mono-phosphorylated peptide was consistent with P measurement by ICP-QMS in this case. It is important to emphasize that in both cases proteins were successfully identified as bovine α-S1-casein isoform by database search (data not shown) but assessment of phosphorylation degree was not directly possible for native α-casein. This was not surprising because all phosphopeptides of native α-casein were often detected by applying different experimental procedures [56,57].

An alternative strategy based on chemical dephosporylation and MALDI-TOF-MS operating in linear mode was proposed. This approach relies on the well-established β-elimination of phosphoserine residues to give dehydroalanine with a loss of 97 Da under basic conditions [58]. The optimum reaction time was estimated by monitoring the reaction products of β-casein. MALDI-TOF-MS was preferred to ESI-MS because of a simpler sample preparation and lower analysis time.

Fig. 7 shows the mass spectra obtained at different reaction times. In the case of caseins, molecular weights were sufficiently low to detect the doubly charged ions with a sufficient resolution (i.e. $m/\Delta m \sim 10{,}000$) and estimate with acceptable accuracy the molecular masses of native proteins and β-elimination products. As can be seen, complete dephosphorylation was obtained after 15 min. This reaction time was chosen to reduce protein degradation due to base hydrolysis of peptide backbone. It is important to note that the experimental MW (23,983 Da) of native β-casein (theoretical MW = 23,583.2 Da), calculated from the doubly charged ion mass, was consistent with the molecular weight calculated on the basis of the phosphorylation degree by ICP-QMS. Fig. 8 shows linear MALDI-TOF-MS mass spectra of β-elimination products of native and dephosphorylated α-caseins. As observed for β-casein, the experimental MW (23,612 Da) of intact α-casein S1 isoform (theoretical MW = 22,974.8 Da) before β-elimination completely agrees with the molecular weights predicted on the basis of ICP-QMS analysis. Molecular weight of α-casein decreased of 788 Da corresponding to the β-elimination of height P-Ser residues, as predicted from ICP-QMS data.

Two signals at m/z 11,489.6 and 11,528.7 were detected in the spectrum of enzymatically dephosphorylated α-casein (Fig. 8B). The signal at m/z 11,528.7 corresponded to the doubly charged ions of mono-phosporylated α-S1-casein isoform. In fact, this signal disappeared under base catalyzed β-elimination demonstrating that this sample contains both dephosphorylated and mono-phosphorylated isoforms of α-casein. Interestingly, the relative intensity of the mono-phosphorylated isoform (∼0.70) in the MALDI-TOF spectrum was consistent with the degree of phosphorylation obtained by ICP-QMS. Moreover, it is important to emphasize that ICP-QMS was able to quantify the degree of phosphorylation of intact caseins and detect partial enzymatic dephosphorylation at protein concentrations significantly lower than those used in MALDI-TOF-MS experiments.

4. Conclusions

In this paper, we showed that without using reaction or collision gas low resolution ICP-QMS was a suitable technology to investigate protein phosphorylation stoichiometries with high confidence and sensitivity and yields better results than standard PMF analysis. Nevertheless, the subtle interferences which might affect the plasma performances must be taken into account in order to actually push forward the analytical capacities in quantifying P and S. We acknowledge that the main limiting factors preventing wider applications in proteomics were the high calculated LOQ for S and the total protein amounts required with the sample introduction device used. However, the results presented in our manuscript demonstrate that quantitative analysis of protein phosphorylation is feasible with the proposed instrumental set-up and data obtained are in accordance with data obtained with molecular MS. While we are aware that better results can be obtained using ICP-HRMS or ICP-DRC/CRC-MS systems, we propose that the presented optimization procedure might be employed to evaluate the performance of highly efficient ICP interfaces in order to further improve protein elemental investigations by less expensive and quadrupole based ICP-MS systems which are more widely available to the scientific community.

ABSTRACT

We developed a new method consisting of the proteomic reactor coupled with step pH fractionation for the analysis of low-abundance proteins from minute amount of sample. These new reactors were implemented using both SAX and SCX materials. The pH fractions from the SAX reactor provided higher peptide and protein identification than SCX reactor and conventional solution digestion. Interestingly, the physical characteristics (pI, molecular weight, missed cleavage site and grand average hydrophobicity (GRAVY) index, and number of acid and basic amino acid) of the peptides obtained from the SAX and SCX proteomic reactors are drastically different. Furthermore, nearly half of the peptides observed from the pH fractionations from the SAX reactor are of low abundance while only 22% low-abundance proteins are observed with conventional in-solution digestion following 2D LC–MS/MS analysis.

1. Introduction

One major challenge in proteomics is the identification of low-abundance proteins in complex mixtures. Currently, up to 50% of the proteins in any tissues or cells proteome have concentration below the detection limits of proteomic methodologies [1–3]. However, low-abundance proteins are often the key molecules in signal transduction pathway. As well, many clinical biomarkers of disease stages or disease progression are of low abundance [4–6]. Fractionation techniques have been used to reduce the sample complexity and dynamic range with the hope of then observing an increase number of low-abundance proteins. Approaches have been developed to fractionate protein and peptides. At the protein level, affinity-depletion [7–10], narrow-range isoelectric focusing (IEF) [11,12], free flow electrophoresis (FFE) [9,13,14], and multiple dimensional liquid chromatography [4,6,15] have been employed to enrich low-abundance proteins. These techniques are also employed for peptide fractionation, for example, the Agilent OFFGEL system, using immobilized pI strips for peptide separation, which is an attractive alternative to in-gel protein digestion in proteome analysis [16]. However, at the peptide level, multidimensional protein identification technology (MudPIT) [17,18] is the most popular method in mass spectrometry-based proteomics. This approach uses strong cation exchange as first dimension and reversed phase as second dimension. SCX chromatography has been routinely employed for peptide fractionation based on salt gradient [19–21]. Furthermore, pH gradients are also suitable for SCX fractionation [22–24]. SAX is another promising type of ion exchange chromatography for peptide fractionation, particularly for phosphopeptide analysis [25–29].

In many applications the amount of proteins available is not a limiting factor with micrograms to milligrams of material readily available. In these instances, the protein fractionation methods can be used to identify low-abundance proteins. Although these preparative methods can cause sample losses, it only becomes a significant issue for minute sample amount. In many instances, such as rare cells and specific regions of tissue slides, only minute amount of samples are available. A pressing issue is the analysis of low-abundance proteins from samples in the low to sub-microgram level.

We have recently introduced a novel proteomic sample processing device for minute protein sample termed the proteomic reactor [30]. The proteomic reactor allows the enrichment, clean-up, and chemical and enzymatic processing of proteomic samples in as little as 50-nL volume. In our recent implementation of the proteomic reactor, we have successfully employed step pH gradient in SCX proteomic reactor for glycopeptides fraction [31]. We also demonstrated that proteomic reactor using polymer-based strong anion exchange (SAX) was a powerful tool for protein identification [in

preparation]. In this study, we will employ pH fractionation on both SAX and SCX proteomic reactors to identify low-abundance proteins contained in minute amount of sample.

2. Materials and methods

2.1. Materials

Water used in the study was prepared from a Milli-Q system. Ammonium bicarbonate and dithiothreitol (DTT) were purchased from EMD Chemicals, Inc. (Darmstadt, Germany). Iodoacetamide (IAA), HEPES, magnesium acetate, EGTA, EDTA and NP-40 were obtained from Sigma–Aldrich (Saint Louis, MO). Glycerol was purchased from MP Biomedicals. YPD medium was home made following common practices [32]. Trypsin was purchased from Promega (Madison, WI). Strong cation exchange and strong anion exchange beads were obtained from Polymer Laboratories, Varian, Inc. The pH buffer kits were obtained from Column Technology, Inc. (Fremont, CA). Acetonitrile with 0.1% formic acid and water with 0.1% formic acid were purchased from J.T. Baker (Phillipsburg, NJ).

2.2. Yeast sample preparation

The yeast extracts were prepared as previously described [32] with minor modifications. Briefly, a 200 mL culture of yeast was grown to an OD_{600} of 0.8 at which point they were harvest by centrifugation and the cells pellet washed with water. Cell pellets were frozen at −80 °C until ready to be used. The cell pellets were resuspended in 1 volume of lysis buffer (100 mM HEPES pH 8.0, 20 mM magnesium acetate, 10% glycerol (V/V), 10 mM EGTA, 0.1 mM EDTA + fresh yeast protease inhibitors cocktail (Sigma–Aldrich, USA) and frozen in liquid nitrogen in small droplets and lysed using a coffee grinder half-filled with dry ice for 1 min. The dry ice was allowed to evaporate and the resulting whole cell extract was sonicated three times for 30 s with at least 1 min on ice between each pulse. Nonidet P-40 (NP-40) was added to a final concentration of 0.4% and the sample was manually mixed for 30 s. The extract was clarified by centrifugation at 14,000 rpm for 15 min (4 °C) and the supernatant transferred to a fresh tube. The final protein concentration was determined using a Bradford protein assay kit (Bio-Rad).

2.3. pH fractionated proteomic reactor

A capillary tubing (200-μm i.d. and 700-μm i.d) was used to create the proteomic reactor. Briefly, a frit was formed at one end of a fused silica tubing using a mixture of potassium silicate (KASIL 1, PQ Corporation, Valley Forge, PA) and formamide (11/2 volume ratio) as previous report protocol [33]. Then, a 5 cm long reactor was constructed in the capillary by pressure packing (400 psi) a slurry of SAX or SCX beads (10 μm, Polymer Laboratories, Varian, Inc.) from the open end of the capillary tubing. As shown in Fig. 1, the SAX and SCX reactor was washed with alkaline buffer (3N ammonium hydroxide, pH 12) and acid buffer (0.5% formic acid, pH 2.5) prior to their utilities, respectively. The reactor digestion was performed according to the published protocol [30] with some modifications. Fifty micrograms of yeast protein sample and 10 μg trypsin were mixed, alkalified (pH 12) or acidified (pH 2.5), and loaded on the 700-μm i.d. SAX or SCX reactor using a pressurized vessel with 150 psi N_2. The SAX and SCX reactors were then washed with alkaline buffer (3N ammonium hydroxide, pH 12, 20 μL) and acid buffer (0.5% formic acid, pH 2.5), respectively. The proteins present on the reactor were subjected to disulfide bond reduction by introducing the reduction buffer (50 mM dithiothreitol, 20 mM ammonium bicarbonate, pH 8.0) in the reactor for 30 min at room temperature. The reactors were again washed with 10 μL of 20 mM ammonium bicarbonate buffer (pH 8.0) to quench the reaction and dried. Proteins were subjected to simultaneous alkylation and trypsin digestions by introducing the digestion buffer (10 mM iodoacetamide, 20 mM ammonium bicarbonate, pH 8.0) in the reactor for 2 h at 37 °C. The resulting peptides were eluted with 35 μL of step pH buffers (pH 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 5.5, 6.0, 8.0, 12; For SAX reactor: pH from 12 to 2.5; For SCX reactor: pH from 2.5 to 12).

2.4. In-solution digestion

A total of 50 μg yeast protein sample was dissolved in 100 μL reducing buffer containing 8 M urea, 1% Triton X-100, 40 mM Tris–HCl, and 10 mM dithiothreitol (pH 8.3). After incubation at 37 °C for 2 h, 2.5 μL of 1 M iodoacetamide was added to the protein solution and incubated in the dark for additional 30 min at room temperature. The sample was then diluted four times using 40 mM Tris–HCl (pH 8.3), reducing the urea concentration to 2 M and digested with trypsin (1/5 amount of the protein) at 37 °C overnight. The tryptic digestion was quenched by adding formic acid to final concentration of 2%. The resulting peptides were desalted using Sep-Pak C18 column (WAT023590, Waters, Milford, MA), then dried by speed vac, redisolved in 40 μL of 5% formic acid solution, and used for 2D-LC–MS/MS analysis.

2.5. LC–MS/MS

The LC–MS/MS was performed as previous described [33]. Each peptide fraction from the SAX or SCX reactor was acidified with formic acid to a final concentration of 5% (v/v) and loaded on a 200 μm × 50 mm fused silica precolumn packed in-house with 5 cm of 5-μm YMC ODS-A C18 beads (Waters Co., Milford, MA) using an 1100 micro-HPLC system (Agilent Technologies, Santa Clara, CA). Following a desalting step, the flow was split, and peptides were eluted through a second 75 μm × 50 mm column packed with the same beads at approximately 200 nL/min. The peptides were eluted using a 2-h gradient (5-80% acetonitrile with 0.1% formic acid) into an ESI LTQ linear ion trap mass spectrometer (Thermo Electron, Waltham, MA). MS/MS spectra were acquired in a data-dependent acquisition mode that automatically selected and fragmented the 10 most intense peaks from each MS spectrum generated.

2.6. 2D LC–MS/MS

All the setting is the same as mentioned above, except for the precolumn. The precolumn was packed in-house first with 5 cm of 5-μm YMC ODS-A C18 beads (Waters Co., Milford, MA) in the front and the n with 8 cm of 10-μm SCX beads (Polymer Laboratories, Varian, Inc.) in the back. The flow-through of the first sample loading was labelled 0 mM salt elution. Then, nine-step salt elutions were performed using 50, 100, 150, 200, 300, 400, 600, 800 and 1000 mM of ammonium acetate solution (pH 2.7), respectively.

2.7. Data analysis

The acquired MS/MS spectra were searched against the decoyed Saccharomyces Genome Database (http://www.yeastgenome.org/, 6716 protein entries, released December 2, 2008) augmented with the reversed sequence of each entry in the forward database. Mascot Distiller was used to generate peak list from raw file, and Mascot 2.2.02 (Matrix Science) was used to search the protein sequence database using the following parameters: carbamidomethyl (C) was set as a fixed modification, while oxidation (M, +15.99492 Da) was set as a variable modification. The precursor and fragment mass tolerances for the LTQ data were set at 2.0 and 0.8 Da, respectively. Trypsin was selected as the enzyme with two potential missed cleavages. Only fully tryptic peptides were accepted in our database

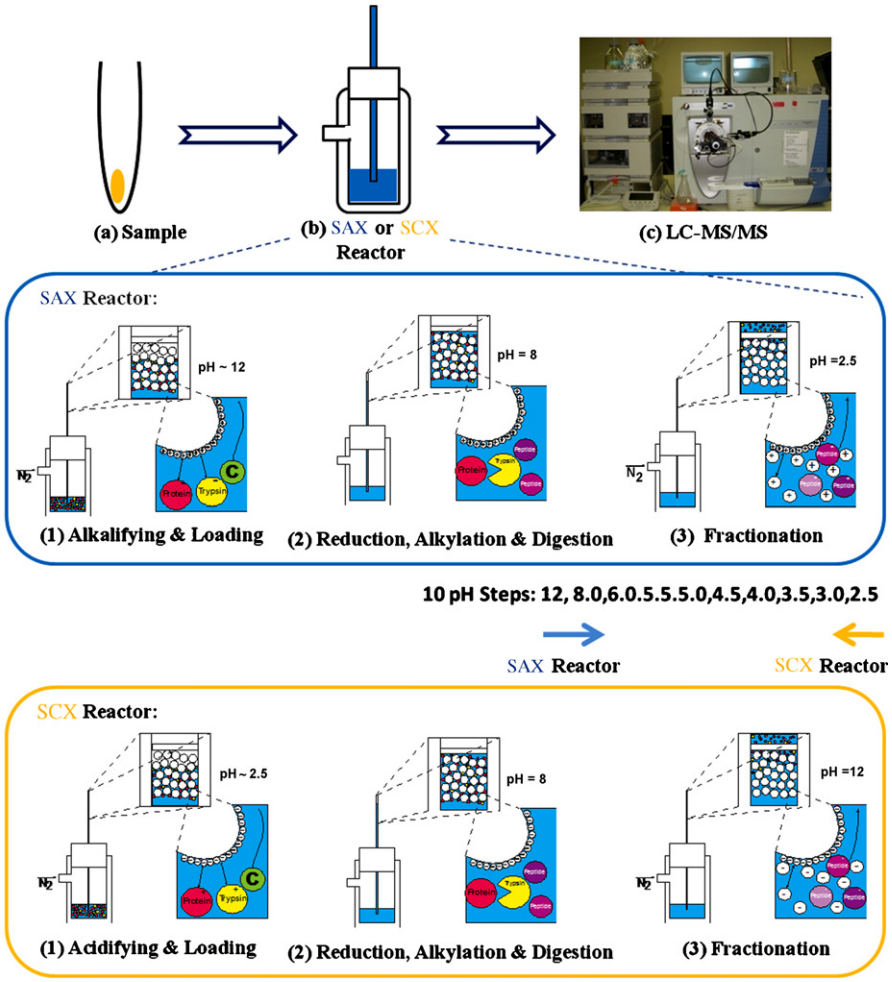

Fig. 1. Flowchart of proteomic reactor based on step pH gradient elution. (A) Yeast protein sample preparation. (B) SAX or SCX reactor: (1) yeast protein sample was mixed with trypsin (5/1, w/w), alkalified or acidified by adding ammonium hydroxide or formic acid, and loaded onto the SAX or SCX reactor; (2) after washing and drying, the reduction buffer (50 mM dithiothreitol, 20 mM ammonium bicarbonate, pH 8.0) was introduced onto the reactor, and the proteins present on the reactor were subjected to disulfide bond reduction; after another washing (10 μL of 20 mM ammonium bicarbonate, pH 8.0) and drying, the digestion buffer (10 mM iodoacetamide, 20 mM ammonium bicarbonate, pH 8.0) was introduced onto the reactor to perform alkylation and tryptic digestion; (3) the resulting peptides were then eluted with 10-step pH gradient buffers (pH 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 5.5, 6.0, 8.0, 12; SAX reactor from pH 12 to 2.5; SCX reactor from pH 2.5 to 12). (C) The resulting peptides from the SAX or SCX reactor were analyzed by LC–MS/MS.

searching results. Mascot cutoff scores were set to 30. Furthermore, only the peptides ranked first with a probability-based Mowse (expect) *P*-value smaller than 0.05 were accepted. The false positive rate was controlled to be less than 0.5%.

3. Results and discussion

We have combined two versions of the proteomics reactor (SCX and SAX) coupled with pH elution followed by LC–MS analysis for proteomic studies (Fig. 1). The expectation was that this would increase the number of proteins identified due to the reducing of the complexity of peptides in each individual fraction. The initial protocol for the proteomic reactor was not compatible with pH fractionation [30,34,35]. In these earlier versions, 100 mM Tris–HCl (pH 8.0) was used as digestion buffer and 200 mM ammonium bicarbonate was used as elution buffer, which are obviously incompatible with step salt or pH gradient elution. We also previously reported that the ammonium bicarbonate buffer is expected to be incompatible for direct and effective separation by SCX chromatography because the cationic ammonium ion and the elevated pH of the buffer (pH 8) will hinder peptide interactions with the SCX matrix [36]. The concentration of ammonium bicarbonate is the key issue for sample loss and band broadening in SCX chromatography. Therefore, we developed a revised protocol for the proteomic reactor that is compatible with pH fractionation. In this study, 20 mM ammonium bicarbonate was selected as digestion buffer in both SCX and SAX reactors, which are suitable for step pH gradient elution. Furthermore, the elution buffers for the SCX and SAX proteomic reactors were modified to provide 10 fractions ranging from pH 2.5 to 12. Here we demonstrate that the proteomic reactors combined with pH fractionation increases the number of protein identified and the likelihood to identify low-abundance proteins in comparison with conventional proteomic approaches.

3.1. Peptide and protein identifications by pH fractionated SAX and SCX reactors

We initially compared the performance of the modified reactors with conventional sample processing approaches. Briefly, identical amount of 50-μg yeast lysate were processed on the proteomic reactors (SAX and SCX) followed by 10 pH elution steps. As well, the same amount of 50-μg yeast lysate was processed by solution digestion followed by 10 step of salt elution in 2D LC–MS/MS analysis. Table 1 compares the peptides, unique peptides and proteins identified in each fraction from the modified proteomic reactors, and the results obtained from the 10 conventional analysis of yeast

Table 1
Identification summary of SAX and SCX reactors using pH fractionation and 2D LC–MS/MS of in-solution digested yeast proteins.

	pH fractions										
	pH 2.5	pH 3.0	pH 3.5	pH 4.0	pH 4.5	pH 5.0	pH 5.5	pH 6.0	pH 8.0	pH 12	Combined

Proteins	261	270	267	213	211	227	186	189	189	198	613

sample. A total of 2919 unique peptides were identified by SAX reactor, resulting in 1106 proteins. As well, 2265 unique peptides were identified by SCX reactor, resulting in 684 proteins. There were three fractions (pH 5.0, 5.5 and 6.0) with more than 1000 peptides identified by SAX reactor, and only two fractions (pH 5.0 and 6.0) by SCX reactor. Theoretically, all peptides should be bound to the SAX reactor at pH 12 and to the SCX reactor at pH 2.5. However, 965 peptide were identified in the fraction of pH 12 in SAX reactor and 640 peptide were identified in the fraction of pH 2.5 in SCX reactor. One possible reason for explaining this phenomenon might be that the trypsin digestion was performed in the buffer of 20 mM ammonium bicarbonate at pH 8.0. As a result, even though the pH of elution buffer for the first fraction is at 2.5 and 12 for SCX and SAX, respectively, the actual pH probably is affected by the residual buffer retained on the SCX and SAX reactors. In contrast, 2146 unique peptides were identified by conventional in-solution digestion and 2D LC–MS/MS analysis, resulting in 613 proteins. The striking feature from this analysis is the improvement that the SAX and SCX proteomic reactors provide over the conventional solution-based approach. First, 30% of the MS/MS generated by the SAX and SCX reactor led to unique peptide identification while only 15% of the MS/MS generated by the conventional approach led to the identification of unique peptides. More importantly, the number of unique protein identified is respectively 80% and 12% higher using the SAX and SCX proteomic reactor over the conventional solution-based approach. This clearly illustrates the improved performance of the proteomic reactor with pH fractionation.

3.2. Efficiency of pH fractionation in SAX and SCX reactors

Proteomic analysis by LC–MS does not identify all the proteins present in the samples in one experiment because of limitation due to dynamic range and duty cycle of the mass spectrometer. However, it has been reported that repetitive analysis of the same sample can increase the number of identified unique peptides and proteins. As reported by Liu et al. [37], 95% saturation in protein identifications can be achieved from 10 replicate runs of yeast soluble cell lysate. We evaluated the saturation effect on unique peptide identification across different pH fractions. To evaluate the efficiency of pH fractionation, overlapping unique peptides across different pH steps was displayed in Fig. 2. The number of unique peptides varied between different pH steps, so the overlapping unique peptides were normalized using the following formula:

$$\text{Overlapping rate} = \frac{\text{overlapping unique peptides between fractions A and B}}{\text{unique peptides of fraction A} + \text{unique peptide of fraction B} - \text{overlapping unique peptides between fractions A and B}}$$

Heatmaps were generated to compare the unique peptide overlaps between the different pH elution. Fig. 2A and B illustrates the heatmaps for the unique peptides from the SAX and SCX proteomic reactor. While there are some overlaps in neighbouring pH fractionation the overlaps between distal fractions is nearly zero. The comparison of the overlap between the 10 salt steps used in conventional analysis is very informative (Fig. 2C). In this case not only are the overlaps between some neighbouring salt steps high (about 45%) but also the overlaps between many distal fractions (for example, 50 and 150, 100 and 800 mM) still remain over 40%. This clearly illustrate that the pH fractionation approach on the proteomic reactor provides a tremendous improvement in peptide separation and hence in dynamic range coverage over conventional solution-based processing of samples.

3.3. Comparison of characteristics of peptides in each fraction obtained through pH fractionated SAX, SCX reactors and conventional 2D LC–MS/MS

We were also interested in the characteristic of the peptides in the pH fractions and if there were any notable differences between the peptides observed from the SAX, SCX proteomic reactors and conventional 2D LC–MS/MS. For every peptide in the pH fractionations we calculated the pI, molecular weight, missed cleavage site GRAVY index, as well as the average number of acid amino acids and basic amino acids. Our analysis of these physical characteristics of the unique peptides surprisingly reveal that the properties of the eluting peptides in the different pH fractions are different between the SAX and SCX proteomic reactors (Fig. 3A–F). Furthermore, the key physical characteristics are different. For example, the unique peptides eluting from pH fractionation of the SAX proteomic reactor shows strong correlation between their pI (correlation coefficient of 0.95), GRAVY index (inverse correlation coefficient of 0.97), number of acidic amino acid (inverse correlation coefficient of 0.95), and molecular weight (inverse correlation coefficient of 0.92) with the pH of the fraction. Interestingly, the unique peptides eluting from pH fractionation of the SCX proteomic reactor show no similar correlation with the pI, the GRAVY index, nor the number of acidic amino acid. Furthermore in contrast to the SAX proteomic reactor, the peptides molecular weight (correlation coefficient of 0.85), the number of basic amino acids (correlation coefficient of 0.77), and the number of miss-cleavage sites (correlation coefficient of

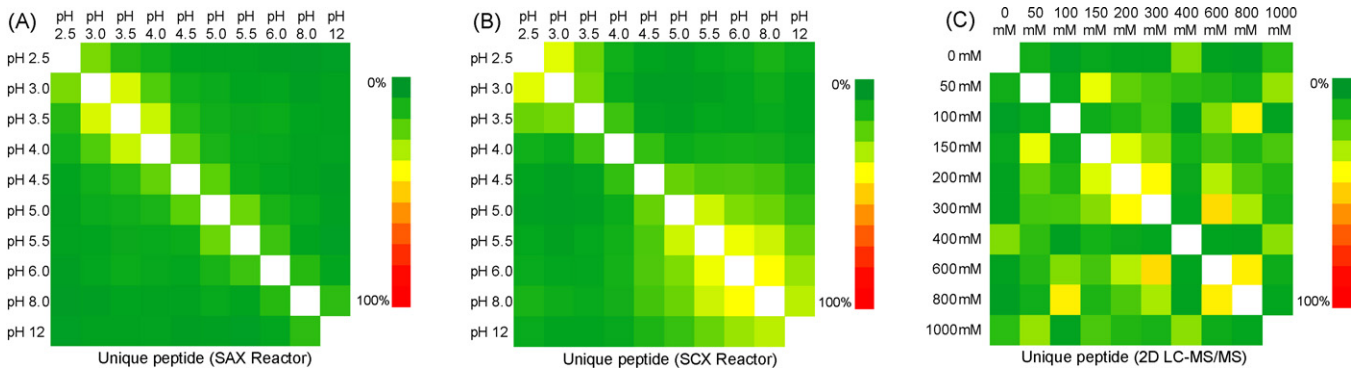

Fig. 2. Heatmap of unique peptide overlap between two fractions in SAX reactor (A), SCX reactor (B) and 2D LC–MS/MS (C).

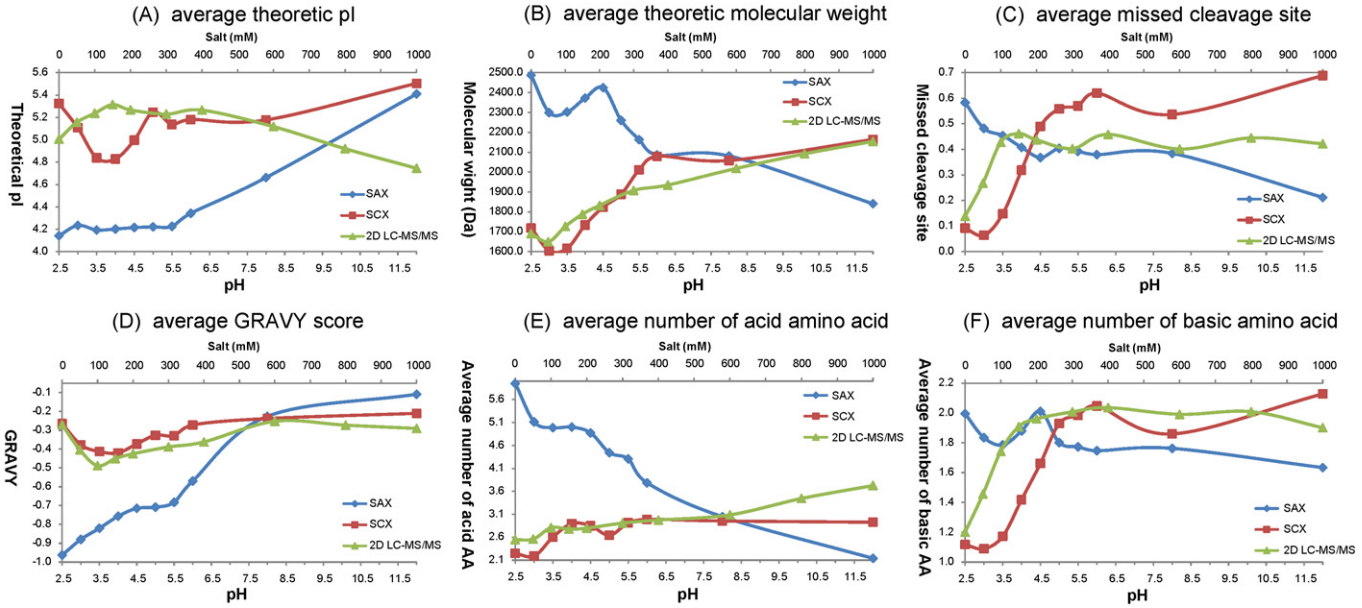

Fig. 3. Distributions of average pI (A), molecular weight (B), missed cleavage site (C), GRAVY (D) and average number of acid (E) and basic (F) amino acid of unique peptides from each fraction in SAX reactor, SCX reactor and 2D LC–MS/MS. F1–F10: pH 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 5.5, 6.0, 8.0 and 12 for SAX and SCX reactors; 0, 50, 100, 150, 200, 300, 400, 600, 800 and 1000 mM ammonium acetate for 2D LC–MS/MS.

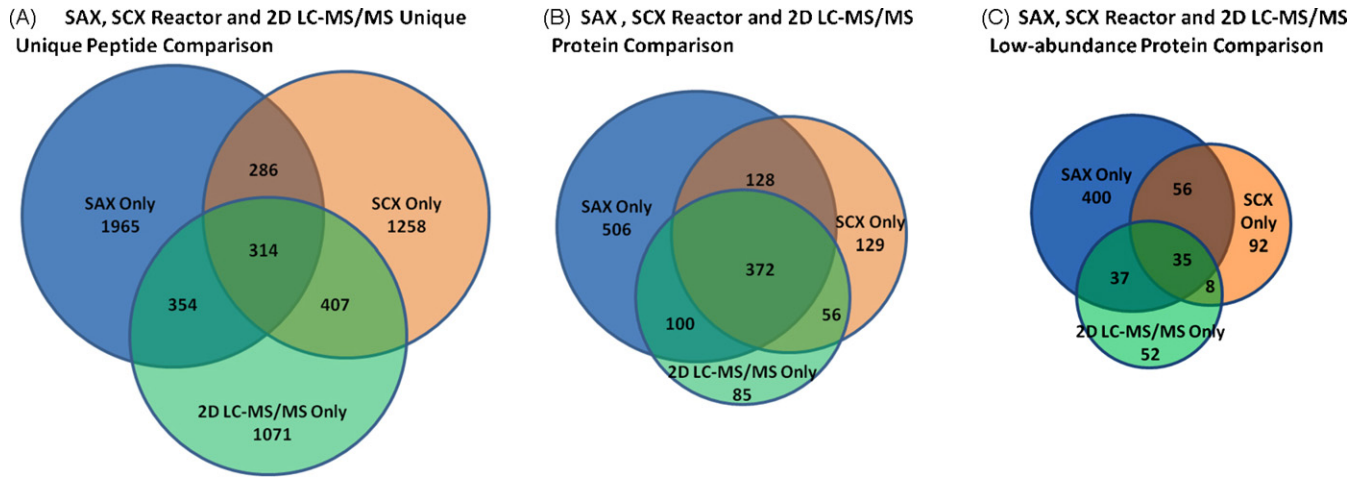

Fig. 4. Overlap between SAX reactor, SCX reactor and 2D LC–MS/MS at the levels of identified unique peptides (A) proteins (B) and low-abundance proteins (C).

0.77) increases with the pH of the fraction. As a control, the unique peptides eluting from step salt gradient elution of the SCX column show no similar correlation with the pI, the GRAVY index, the number of basic amino acid, nor the number of miss-cleavage sites. The peptides molecular weight (correlation coefficient of 0.97) and the number of acidic amino acid (correlation coefficient of 0.98) increases with the salt concentration of the elution. Although, as the name implies, the major separation mechanism of SAX or SCX is electrostatic in nature, ion-exchange packing material is polymer-based, i.e., poly(styrene–divinylbenzene) (PS-DVB), and also exhibit significant hydrophobic characteristics, giving rise to mixed-mode contribution to peptide separation [38,39]. The SCX beads might display stronger hydrophobic interaction than the SAX beads, which could be the reason for the lack of a correlation between the theoretical peptide pIs and the pH of the fractions in the SCX reactor. Clearly, there are cross-correlations between Fig. 3B, C and F. The protein samples were digested by trypsin, i.e., at the residues of K and R. As shown in Fig. 3C, when the missed cleavage sites increase in the fractions of SCX column either by raising the salt concentration or by increasing the pH, the molecular weight and the average number of basic amino acid also increase; and vice versa for the SAX column (Fig. 3B and F). The correlation of pI and the average number of acid amino acid in the fractions of SAX reactor is very strong (inverse correlation coefficient of 0.88, Fig. 3A and E), which indicates that the acid amino acid number of a peptide might be the key issue in pH gradient-based fractionation of SAX column. Clearly the peptides eluted by pH fractionations off the SAX and SCX proteomic reactors have distinct physical properties. This is further illustrated by the limited overlap between the unique peptides (13%) and proteins (39%) observed by the SAX and SCX proteomic reactors (Fig. 4A and B).

4. Identification of low-abundance protein by pH fractionation coupled with the SAX and SCX reactors

The codon adaptation index (CAI), a measurement of codon usage, can be used to predict the expression of a gene, which is positively correlated to protein abundance [40–43]. Usually, yeast proteins with CAI of less than 0.2 are defined as low-abundance protein [13,16,41,44]. Among the 6716 proteins reported in the Saccharomyces Genome Database (http://www.yeastgenome.org/), 6624 proteins (98.6% of the total) are annotated with codon adaptation index (CAI) value. We compared the CAI for protein identified by the modified proteomic reactors and the conventional solution-based proteomics. Interestingly, 48% and 28% of the proteins identified in the pH fractions from the SAX and SCX proteomic reactor have CAI lower than 0.2 (Supplementary Table). In contrast, only 22% of the proteins identified from the conventional solution method (2D LC–MS/MS runs using 10 salt steps) have a CAI lower than 0.2 (Supplementary Table). As shown in Fig. 4C, there are 680 low-abundance proteins (CAI <0.2) identified by the three techniques. Of these, only 5% are common to the three techniques, while 59% of the low-abundance proteins are only identified by the SAX proteomic reactor, 14% by the SCX proteomic reactor and 8% by the conventional approach. These results indicated that the proteomic reactor based on pH elution, particularly the SAX reactor, facilitated the identifications of low-abundance proteins.

5. Conclusion

In this study, we demonstrate for the first time that step pH gradient elution is an efficient fractionation method for routine proteomic reactor. In addition, we have shown that the characteristics of the unique peptides from the pH gradient elution of SAX and SCX reactor are very different which leads to limited overlaps in identified peptides. Finally, our results demonstrate that the proteomic reactor with pH fractionation is a powerful and promising tool for the identification of low-abundance proteins from minute amount of sample.

ABSTRACT

Promising profiling techniques based on new material/solid phase extraction for capturing "molecular signatures" from body fluids are being coupled to MALDI-TOF-MS. Sample preparation significantly influences spectrum quality in this ionization method. Mesoporous silica beads (MSB), by the means of nano-sized porous channels with high surface area, enable harvesting of peptides from plasma and serum excluding large size proteins. We have investigated the morphology of a sample slurry, developed as a new tool for plasma peptides enrichment based on mesoporous materials. Our study highlights a correlation between crystals morphology and enhanced performances in MALDI-TOF-MS analysis. This is the first report which correlates the increase in signal intensity with crystal formation in samples preparations which make use of various kinds of slurries for the analysis of samples clinically relevant like human plasma.

1. Introduction

Discovery of biomarkers for disease diagnosis is the major task for modern predictive medicine. Besides traditional and well-established immunoassays (ELISA, RIA) and other technologies used for the detection of a single over-expressed molecule, proteome profiling of human body fluids based on mass spectrometry (MS) is now becoming an important method for investigating and detecting novel disease-associated markers [1–4]. The ability to screen and discover multiple biomarkers simultaneously has been advanced by the recent success of MS, especially surface-enhanced laser desorption/ionization time-of-flight (SELDI-TOF) MS and matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) MS [5]. The demand for reducing sample complexity in order to increase the detection of low-abundance proteins has generated the development and implementation of proteomic technologies in the field of protein biomarker discovery. Most of these proteomic technology platforms are centered on the implementation of MS in conjunction with several other analytical techniques, such as solid phase extraction, chromatography and electrophoresis [6]. A new emerging field of study is addressed to development, improvement and standardization of pre-MS separations approaches. Among well-established methods for sample preparation such as magnetic beads (MB) [7], or surface-derivatized chips (SELDI) [8], new separation/fractionation platforms are based on innovative application of both traditional and novel materials for selective capture of low molecular weight peptides and polypeptides from biofluid samples [9–12]. Material science is a mine of richness not yet exploited by proteomic community which could contain premises and promises for future generations of "biomarker discovery" pioneers. That is why the design and generation of material-based platforms for capturing "molecular signatures" from body fluids has gained increasing interest in recent years. Sample preparation is crucial step to generate reproducible and good quality mass spectra which are essential prerequisites for successful proteomic pattern analysis. Therefore optimization and more comprehensive investigations of sample preparation methods could be of high impact for MALDI-TOF-MS analysis of biofluids proteome.

We report herein further investigations and optimization of our recently developed procedure based on mesoporous silica particles for selective binding and enrichment of low molecular weight plasma/serum proteins by MALDI-TOF-MS analysis [11]. Mesoporous silica beads (MSB) are incubated with the sample, washed, then suspension in α-cyano-4-hydroxycinnamic acid (CHCA) is loaded on the MALDI target plate. In comparison to the previous standard protocol [11], the results emphasize a significant increase in signal intensity and decrease in background by new modified

procedure. We have additionally investigated by scanning electron microscopy (SEM) on MALDI samples spots obtained from two different preparation procedures based on MSB. A different behavior in matrix crystallization is observed when sample is spotted on MALDI target plate as matrix-particles suspension, which changes dramatically plasma analysis performances.

2. Experimental

2.1. Material preparation and characterization

The synthesis of MSB was performed under hydrothermal condition in presence of cationic surfactant dodecyltrimethylammonium bromide [$C_{12}H_{25}N(CH_3)_3Br$] (CTABr). The molar composition of the starting mixture was: SiO_2:0.2 CTABr, 0.2 NaOH, 0.04 $Al(OH)_3$, 40 H_2O. 10 g of fumed silica were added to a solution of 0.52 g of $Al(OH)_3$, 12.1 g of CTABr, and 1.35 g of NaOH in 120 g of H_2O. The gel was aged for 2 h at room temperature and then heated in oven for 24 h at 140 °C. The product obtained was filtered, washed with deionized water, and dried at 80 °C for 12 h. The activated sample was obtained by solvent extraction in a Soxhlet apparatus. The nitrogen adsorption–desorption volumetric isotherms at 77 K were measured on a Micrometritics Asap 2010 apparatus. Surface area of the samples was obtained by Brunauer–Emmet and Teller (BET) linearization.

2.2. Plasma collection

Blood intended for plasma preparation was collected into the following tubes: BD Plus Plastic K2EDTA, 10 mL, # 367525. The samples were centrifuged at 1300 × *g* for 10 min under refrigerated conditions (2–6 °C), within 15 min of the draw. The resultant plasma was pooled into one secondary conical bottom BD (TM) Falcon tube. The secondary tube was centrifuged at 2400 × *g* for 15 min to remove potentially remaining cellular material and to prepare platelet poor plasma. Samples were then aliquoted and immediately frozen at −80 °C. All experiments were performed on aliquots of first-thawed poor platelet plasma.

2.3. Experimental procedures

Substance P was spiked in human plasma at a concentration of 12.5 ng/ml. Plasma-Substance P was diluted 1:5 (40 μL of plasma in 160 μL of deionized water), MSB (2 mg) were mixed with diluted human plasma-Substance P sample and shaken at room temperature for 1 h. The suspension was centrifuged at 2000 × *g* for 2 min, and then MSB were separated from the supernatant and washed with deionized water (4× 30 μL). After the last wash, bound species were directly extracted in CHCA (30 μL of a 4 mg/mL solution prepared dissolving the matrix in a 1:1 mixture of acetonitrile and 0.1% trifluoroacetic acid). A volume of the above slurry (1 μL) was loaded on MALDI target plate in the "suspension" procedure, otherwise, after centrifugation at 2000 × *g* for 2 min, 1 μL of supernatant solution (30 μL) with extracted peptides, was deposited on MALDI probe ("elution" procedure). Both in suspension and in elution procedure, equal volume of matrix solution (30 μL) was used for extracting bound species from beads, and in both cases 1 μL was deposited on MALDI probe.

Protein concentrations were determined using the Bio-Rad Laboratories (Hercules, CA, USA) protein assay kit (Bradford method) and bovine gamma-globulin as standard following the instructions furnished by the manufacturer.

Standard solution was prepared by mixing 100 μL of a 1 mg/mL stock solution of Substance P, with 100 μL of a 1 mg/mL stock solution of Dynorfine and with 100 μL of a 1 mg/mL stock solution of Insuline (bovine). Stock solutions of standard peptides were all prepared in 0.1% of TFA. 1 μL of standard solution was directly spotted onto a well of MALDI plate and air-dried. Then 1 μL of CHCA matrix solution (prepared as described above) was overlaid on the sample and air-dried. In parallel, 1 mg of MSB was added to100 μL of standard solution, then 1 μL of this suspension was spotted onto a well of MALDI plate and air-dried. Then 1 μL of CHCA matrix solution was overlaid on the sample and air-dried.

2.4. MALDI-TOF-MS analysis

MALDI-TOF-MS analysis was performed on a mass spectrometer (Voyager-DE STR, Applied Biosystems, Foster City, CA, USA) equipped with a 337 nm nitrogen laser. Analyses were performed in linear positive-ion mode, using delayed extraction. The acceleration voltage was 20 kV, guide wire was 0.05% of the accelerating voltage, grid voltage was 91.5%, and the delay time was 220 ns. Same TOF-MS settings and laser shot acquisition of the sample spots were applied to carefully compare spectral read-outs from different MALDI preparations. In particular five 100-laser shots were averaged for each mass spectrum to obtain a good statistical analysis. All spectra were normalized to the base peak and a baseline correction was performed using Data Explorer 4.0 (Applied Biosystems, Framingham, MA, USA). All experiments were carried out at least in triplicate to ensure the reproducibility of the spectra. Same instrument settings were used for both elution and suspension procedures.

2.5. Scanning electron microscopy

The samples were first prepared on MALDI stainless steel target plate following the same procedures of the samples for MALDI-TOF-MS analysis. The samples topography was characterized by scanning electron microscopy, using the electron column of a dual beam system (FEI Nova 600 Nanolab) equipped with a thermal field emitter as electron source. Low beam currents in combination with

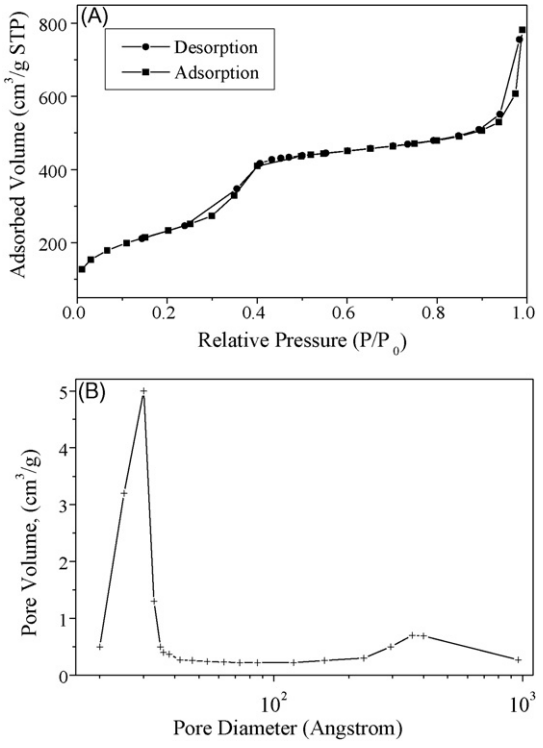

Fig. 1. (A) Nitrogen adsorption–desorption isotherms and (B) Barret–Joyner–Halenda (BJH) pore size distribution of mesoporous silica beads used in proteomic experiments.

a small accelerating voltage of 5 kV were employed in order to prevent the sample from any possible damage. Furthermore, the low beam currents limited the charging effects and consequently no previous metal coating of the sample was required for the analysis.

3. Results and discussion

Mesoporous materials constitute a new generation of materials that show ordered arrangements of channels and cavities of different geometry built up from SiO_2 unities [13]. The pore size is variable ($2\,nm < \Phi_p < 50\,nm$) and can be controlled and modified, in a reasonable range, using in situ [14] and ex situ [15] synthetic strategies. These materials find many uses in catalysis, metal ion extraction, optical applications. Moreover silica particles with highly ordered mesostructures, for example, M41s [16] and SBA-15 [17], have been widely applied in the fields of separation and adsorption [18–20].

MSB used in the experiments hereby described belong to highly ordered mesoporous silica particles synthesized according to reported procedure [21]. Representative nitrogen adsorption–desorption isotherms (Fig. 1, panel A) and the pore size distribution diagram for MSB (Fig. 1, panel B) demonstrate the existence of highly ordered mesopores running along the same direction. In particular nitrogen adsorption–desorption isotherms of sample ($S_{BET} = 848\,m^2/g$, pore volume = $1.21\,cm^3/g$, show two mesopore filling steps at P/P_0 range 0.2–0.4 and 0.9–1.0, indicating a bimodal pore system. The Barret–Joyner–Halenda (BJH) pore size distribution is centered at 25 and 390 Å. The first peak is associated with primary mesopores generated by surfactant micelles, the second one is associated with secondary mesopores resulting from secondary silica condensation.

Here we extended our previous studies in which we developed a strategy based on MSB for plasma peptides profiling [11]. Given the high surface area mesoporous silicates offer the desired adsorptive capacity for binding and enrichment of low molecular weight peptides present in body fluids. Tuning the pore size distribution and surface adsorptive properties, MSB selectively capture peptides and small size molecules excluding large size proteins such as Human Serum Albumin. Plasma samples are exposed to mesopores, then captured molecular species are extracted and profiled by MALDI-TOF-MS. In order to make the analysis more rapid and to circumvents the risk of sample loss, we refined the previous protocol by direct spotting of MSB-loaded suspension on the MALDI target plate. As illustrated in Fig. 2 we called "elution" procedure the previous protocol in order to distinguish from the new modified procedure called "suspension" procedure. A detailed description of procedure is summarized in experimental section. We prepared our samples with CHCA given its optimal chemical–physical properties as a matrix for the MALDI mass spectrometric analysis of peptides.

A comparison of the performance in MALDI-TOF-MS analysis of human plasma, between the "suspension" procedure and the "elution" procedure is shown in Fig. 3 where the MALDI-TOF-MS spectra are evaluated in absolute ion counts units for the same m/z range. A significant enhancement in signal intensity as well as the

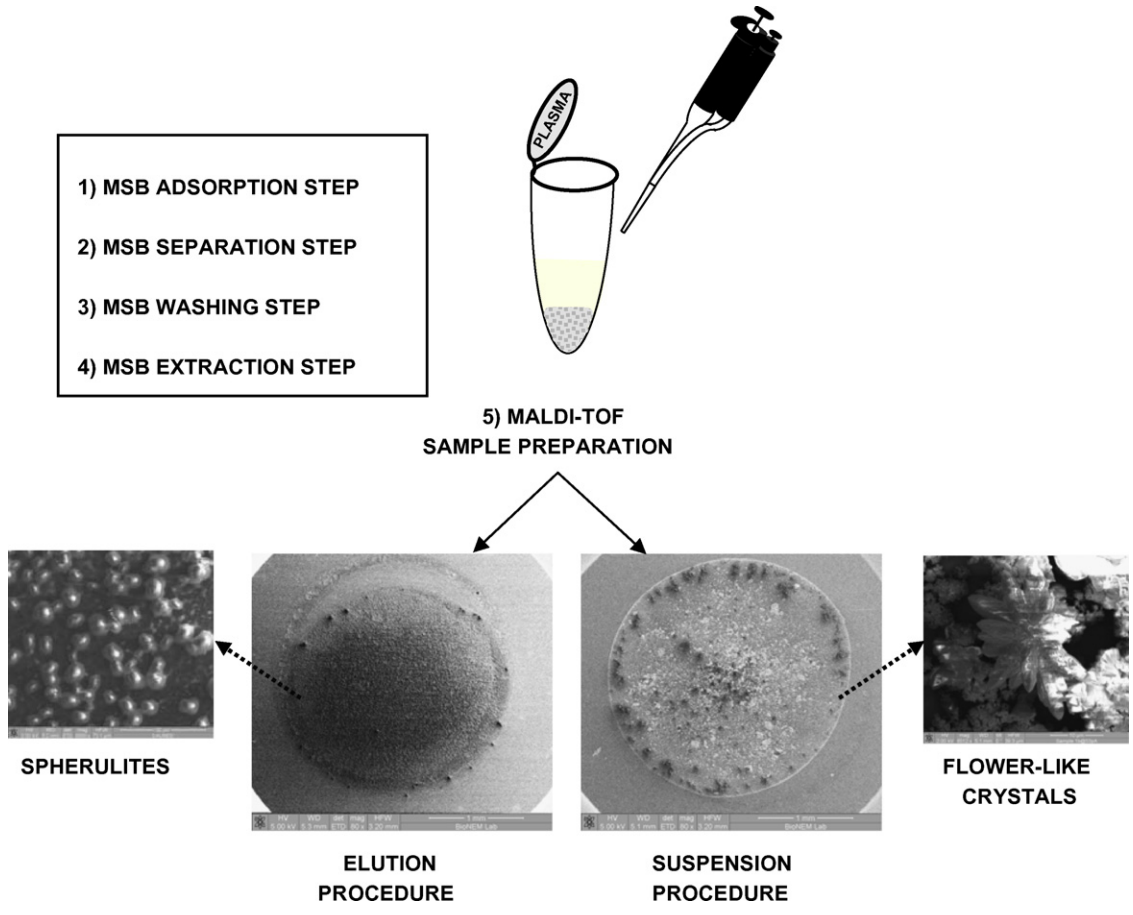

Fig. 2. Extraction of plasma peptides by MSB and MALDI sample preparation on-target plate by "elution" and "suspension" procedure. MSB were mixed with diluted human plasma and shaken at room temperature for 1 h (adsorption step). The suspension was centrifuged, the MSB were separated from the supernatant (separation step) and washed with deionized water (washing step). After the last wash, bound species were directly extracted in CHCA (extraction step). 1 μL of the above slurry was loaded on MALDI target plate in the "suspension" procedure, otherwise, after centrifugation 1 μL of supernatant solution, was deposited on MALDI probe ("elution" procedure). SEM images of two different preparations with magnification inserts are provided.

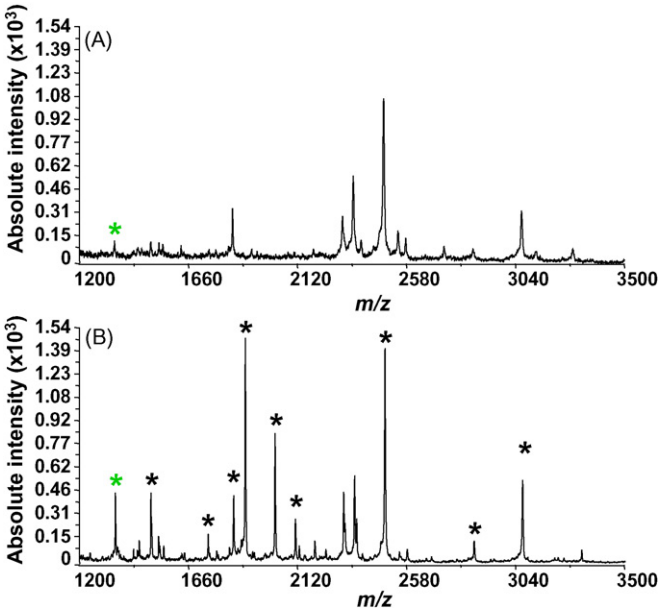

Fig. 3. Performance of the "elution" and "suspension" procedures in MALDI-TOF-MS analysis. (A) MSB were incubated with the sample, washed, captured peptides were eluted and analyzed ("elution" procedure). (B) MSB were incubated with the sample, washed, matrix solution was added and finally 1 μL of slurry was loaded on MALDI target plate. In both cases Substance P was spiked at 12.5 ng/ml (green asterisk). High, medium, and low intensity peaks within the mass range of *m*/*z* 1200–3500 were randomly selected (asterisks) for the variability assessment. Signal intensity is plotted in the same absolute units for both procedures.

number of peaks detected is clearly visible in the new "suspension procedure" (Fig. 3, panel B). A typical effect observed in the MALDI technique is that the spectra do not show good stability of the ion current intensity, therefore to obtain a good statistical analysis we used five hundreds laser pulses to average the mass spectra. Moreover, to carefully compare spectral read-outs from different MALDI preparations, same TOF-MS conditions and laser shot acquisition of the sample spots were applied both in "suspension" and "'elution" procedure.

In order to evaluate the increased detection sensitivity achieved by suspension procedure, Substance P was added to human plasma sample at the concentration of 12.5 ng/ml in both elution and suspension procedures. Substance P was detected with a signal over 10-fold higher when the sample was deposited on MALDI probe as slurry instead of as simple solution (Table 1 and Fig. 3).

In order to better discriminate whether the enhancement in signal intensity we observed was due to different analyte concentration, total protein concentration of the samples spotted on MALDI plate was measured by Bradford assay in three different experiments. Interestingly we found that the supernatant solution by the "elution procedure" contained a total protein concentration of 3.9 ± 0.1 μg/μL, while, in the case of the slurry, the measured protein concentration was 3.68 ± 0.03 μg/μL. Therefore, we consider highly unlikely that the poorer mass spectrum observed in the "elution" procedure may be due to lower analyte concentration.

To better analyze the gain in ion yield, we randomly selected a list of ten peaks (indicated with asterisk in Fig. 3, panel B) of low, medium and high intensity in a set of three replicate experiments. The results are illustrated in Table 1, which shows average absolute areas and area ratios of peaks obtained with suspension and elution procedure. We observed a substantial enhancement in peak areas which for some peaks resulted more than hundred fold, whereas a minority of peaks were detected with roughly the same intensity (Table 1). Although mass accuracy was slightly lower in "suspension procedure", we found a higher reproducibility in peaks area in "suspension procedure" (see percentage coefficient of variance in Table 1).

In the higher *m*/*z* range between 3500 and 7500, the MALDI mass spectrum from suspension procedure (Fig. 4, panel B) shows more spectral features with higher S/N when compared to the MALDI-TOF-MS spectrum from elution preparation (Fig. 4, panel A), even though we notice the presence of some isolated little peaks, more evident in elution preparation, marked with red arrows in Fig. 4, panel A. The superior performance of suspension preparation is evident as the highest signal intensities were gained with almost no background noise (Fig. 4, panel B). Signal-to-noise ratio was increased ninefold for the *m*/*z* 3519 peak (from 4.7 to 43.4), and 16-fold for the *m*/*z* 3830 peak (from 5 to 83) when slurry was used

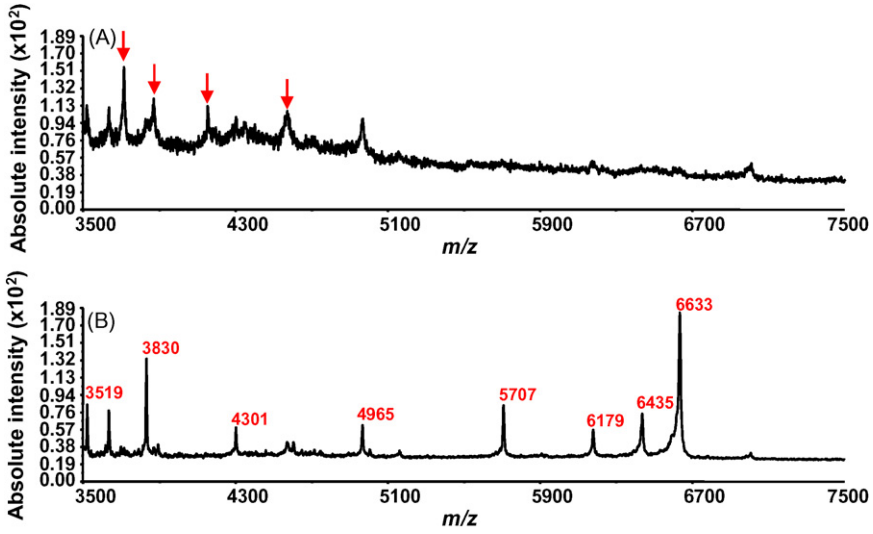

Fig. 4. MALDI-TOF mass spectra of human plasma treated with MSB and spotted on MALDI probe with "elution" (A) and "suspension" (B) procedures in the mass range of *m*/*z* 3500-7500. Same amount of plasma and MSB were used in both procedures as well as the volume of matrix solution used for extraction and for MALDI sample preparation on the probe. Instrument settings were the same in both experiments. Red arrows in panel A show little isolated peaks more evident in "elution" vs. "suspension" procedure. Signal intensity is plotted in the same absolute units for both spectra.

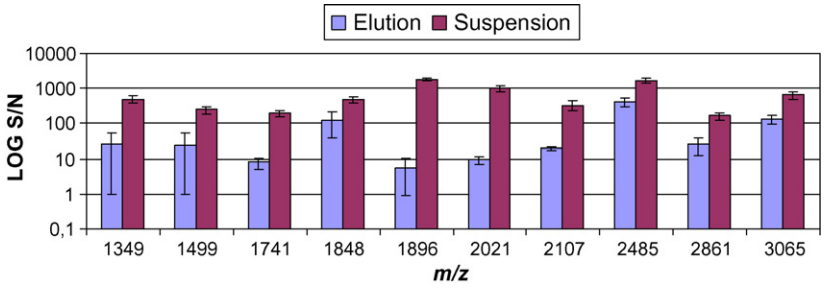

Fig. 5. Comparison of S/N ratio for "elution" (cyan) and "suspension" (magenta) procedures. The values were averaged on three independent experiments and reported, with error bars, on logarithmic scale.

in sample preparation. Enhancement of S/N was also estimated for peaks 4301 (from 8 to 22) and 4965 (from 6 to 25) in suspension preparation as well as the peaks 5707, 6179, 6435 and 6633 were lost in elution preparation (Fig. 4, panel A and B).

To complete MS spectra analysis we also evaluated signal to noise ratios for the same set of peaks of Table 1. Fig. 5 illustrates the stringent increase of performance in suspension procedure with respect to elution procedure with S/N values which increases several fold (over 100-fold for peaks 1896 and 2021).

To gain deeper insight in the mechanisms determining the increased performance of the "suspension procedure", inspection of sample morphology of the two different preparations on MALDI plate was investigated by SEM. This study revealed a higher density of CHCA crystals over the entire well area of sample in the new

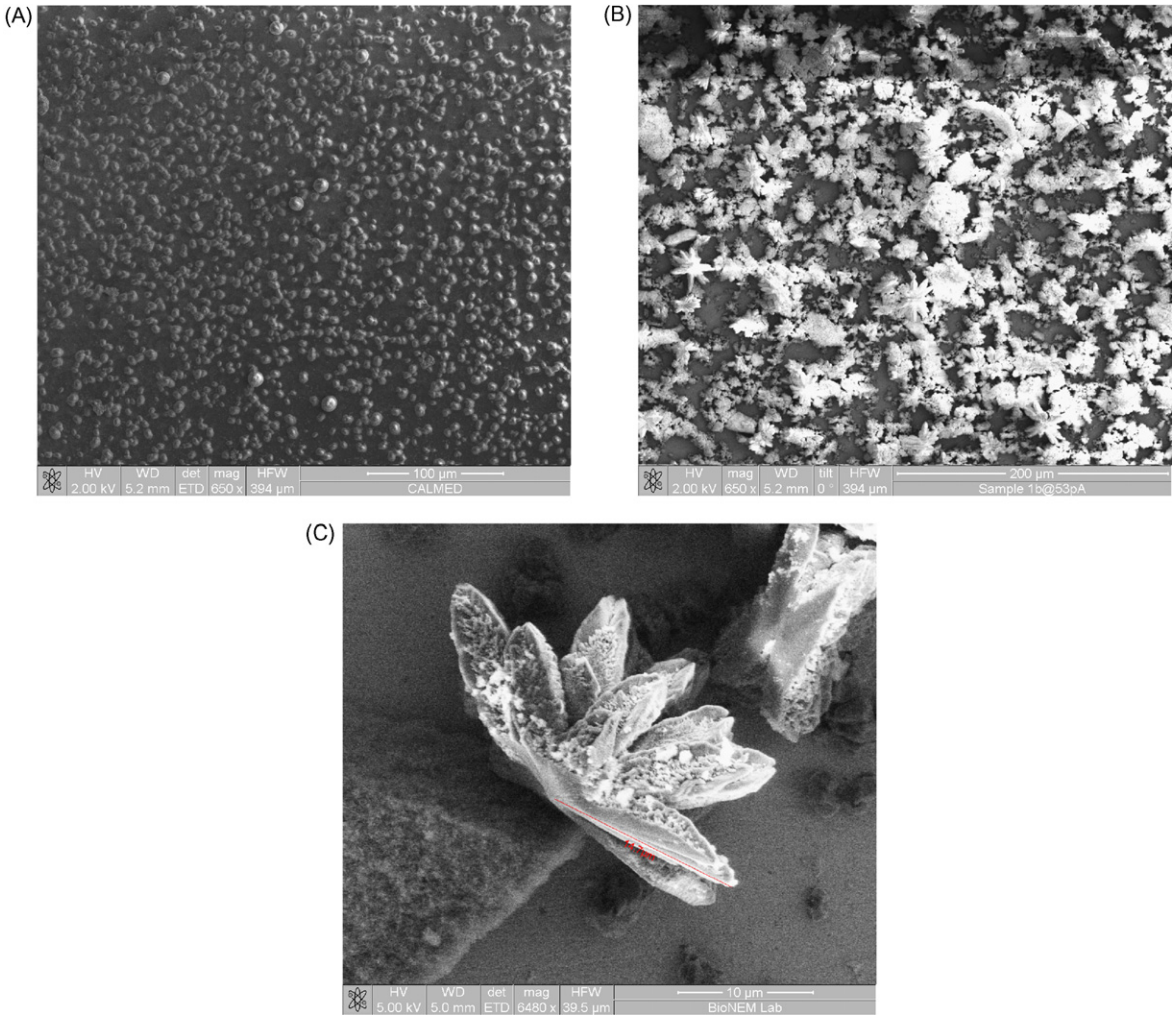

Fig. 6. SEM analysis. (A) SEM image of on-target sample preparation by "elution" procedure; (B) SEM image of on-target sample preparation by "suspension" procedure; (C) A superb flower-shaped crystal obtained from analytes in α-cyano-4-hydroxycinnamic acid matrix, grown among mesoporous silica beads on a typical stainless steel MALDI probe. The crystals radially grow around a bud and a flower-shaped crystal consists of approximately 20 crystalline parts looking like "petals" of the flowers. Promotion of these micron-sized crystals significantly improves MALDI mass spectral read-outs of human plasma peptides extracted by mesoporous silica beads and deposited as slurry on MALDI probe.

"suspension procedure", whereas typically "sweet spots" are observed at the edge of the spot in the standard procedure (see Supplementary material Fig. 1). We speculate that when silica particles are present in sample preparation they represent centers of nucleation for crystals growth after the deposition on MALDI probe. When the particles are absent, as it happens in elution procedure, the crystallization takes place on the smooth surface of the stainless-steel probe thus determining a lower density of crystals per unit area. We observed with SEM that matrix-analytes solution (elution procedure) and matrix-analytes-particles suspension (suspension procedure) crystallize in different shapes and dimensions (Fig. 6). In the case of elution procedure crystallites with roughly spherical shapes are predominant with an average diameter of 7 μm (Supplementary material Fig. 2), whereas larger flower-like crystals are predominant in the suspension procedure (Fig. 6, panel B and C). Careful inspection by SEM revealed that these flowers have different sizes and shapes with petals from 10 to 20 μm (Fig. 6, panel C and Supplementary material Fig. 3).

To further support the hypothesis that the increased performance observed in the case of the "suspension procedure" is due mainly to the crystal shape and not to other reasons (for instance, different analyte concentration) we performed an additional experiment in which MSB were exclusively used for assisting crystallization and not for peptide harvesting. A standard solution containing Substance P, Dynorfine and Insuline was deposited on MALDI probe with and without mesoporous silica, air-dried and then covered with a CHCA solution. As shown in Fig. 7, MALDI and SEM data confirmed the results obtained with human plasma peptides. An enhancement in signal intensity (Fig. 7, panels A and C) was observed in the presence of MSB, which correlated with the appearance of flower-like crystals (Fig. 7, panel B); considering that in this case the peptide concentration is identical in the two samples, the most likely explanation for the observed difference is the different crystal shapes obtained from two sample preparations (Fig. 7, panels B and D and supplementary material Fig. 4). It is important to underline that the crystals obtained in this

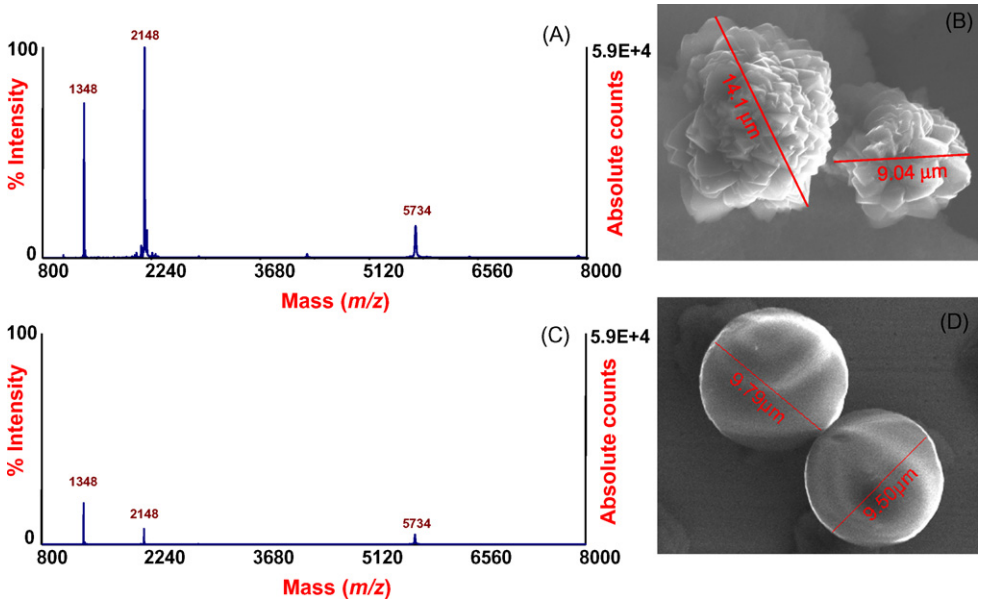

Fig. 7. MALDI-TOF MS spectra and SEM images of a standard solution from two different preparations on MALDI probe. The standard solution was prepared with Substance P (m/z 1348), Dynorfine (m/z 2148) and Insuline (m/z 5734); each peptide at a concentration of 0.33 μg/μL. Panel A illustrates the mass spectrum obtained when 1 μL of standard solution containing mesoporous silica particles was deposited on MALDI plate, air-dried and then the solution of CHCA was added. Panel B shows a high magnification SEM image of floral-shaped crystals obtained from above described preparation. Panel C illustrates the mass spectrum obtained when 1 μL of standard solution without mesoporous silica particles was deposited on MALDI plate, air-dried and then the solution of CHCA was added. MALDI spectra are compared at the same absolute counts. Panel D shows a high magnification SEM image of spherulitic crystals obtained from preparation without silica particles.

experiment, with the standard solution in absence of MSB, retain the spherical shape already observed in the "elution" procedure. Flower-like shapes are still observed when MSB are used, but in comparison to previously described suspension procedure, these flowers are obviously slightly different, due to the different crystallization conditions.

Sample morphology is considered critical in determining the ion yield in MALDI-MS of proteins [22]. It is tempting to speculate that the shape of the crystals obtained with the "suspension procedure", with a more favorable surface to volume ratio, offers a larger surface to the laser beam, allowing a more efficient desorption/ionization process compared to the crystals obtained with the "elution procedure".

Although MALDI is a very popular mass analysis technique, it is still a poorly understood process and one has to be cautious in extrapolating the results. Our experimental observations regarding the possible correlation between the crystals/analyte distribution and resultant MALDI signals have been reported in other systems [23]. Even if other studies investigated on the dependence of matrix crystal morphology on analyte ion yield [24], this is the first report which correlates the increase in signal intensity with crystal formation in samples preparations which make use of various kinds of slurries for the analysis of samples clinically relevant like human plasma.

Materials with micrometer-scale regularity are of great technological applications in microelectronics, information storage, optics, biomedical implants, catalysis and separation technologies [25]. It is hoped that this study would ultimately lead to rational design of improved methods for sample preparation by controlling crystallization conditions in the wide range of biofluid proteomics applications. Detailed studies on influence of particles suspension on matrix-analytes crystallization as well as inspection of the crystallites morphology might help elucidating the mechanisms and facilitating MS-based proteomics research.

ABSTRACT

Despite recent advances in treatment, mantle cell lymphoma (MCL) still represents a disease with dismal prognosis due to its progressive clinical course, high rate of therapy refractory cases and frequent relapses. During recent years, the proteasome inhibitor bortezomib and enzastaurin, an inhibitor of protein kinase c have been explored in MCL. In relapsed disease enzastaurin achieved disease stabilization in a subset of patients. Bortezomib in relapsed and refractory MCL achieves response rates of 30–40%. To identify signal pathways and manifold interactions regulating cellular response to molecular targeted approaches several high throughput screening methods were applied. A combined network analysis of the identified target molecules based on both RNA array expression data and a survey of cellular protein levels resulted in a unified interaction network more comprehensive (bortezomib: 394 and enzastaurin: 174 molecules) than the networks of the individual screening techniques (329/44 and 117/36 molecules respectively). Interestingly, although none of the target molecules were matched in both RNA-expression and protein level analysis they were mapped nonetheless to common pathways. Additionally, the ranking of identified pathways allowed an improved characterization of the observed induction of cell apoptosis.

1. Introduction/background

Mantle cell lymphoma (MCL) is an aggressive lymphoma characterized by a high incidence of refractory cases and constant relapses after initial treatment. Prognosis for MCL patients remains poor [1]. To address the need for new treatment options, several molecularly targeted approaches have reached the clinical testing phase. Among the more promising biologicals rank the proteasome inhibitor bortezomib [2] and the protein kinase c beta inhibitor enzastaurin [3]. Both substances achieve significant treatment responses in subsets of MCL patients and, while their primary targets are well known, comprehensive understanding of their effects are still to be elucidated [4,5].

To characterize the interaction of signalling and physiological function various screening approaches have been developed. In most cases, these screening approaches focus either on RNA-expression analysis (e.g. expression arrays) or directly detect cellular protein levels (e.g. 2D-PAGE or protein arrays). However, each individual screening method lacks important information. Focussing exclusively on RNA-expression analysis misses all post-translational events that directly influence protein expression. Likewise, analysis of the protein level only neglects transcriptional regulation. Thus the optimal approach is a unified interaction network analysis of both, the pooled protein level and RNA-expression data.

2. Material/methods

The well characterized mantle cell lymphoma cell lines Granta 519, HBL-2, Jeko-1 and Rec-1 were treated at a previously defined concentration either with the proteasome inhibitor bortezomib (25 nM) [6] or the protein kinase c beta inhibitor enzastaurin (10 nM). Target molecule identifications by 2D-PAGE and subsequent MALDI-TOF mass spectrometry (4700 Proteomics Discovery System with Mascot™, Applied Biosystems, Foster City, USA) were performed as described previously [7,8]. Briefly, whole cell lysates consisting of 5×10^6 treated or control cells were harvested after 2, 4 and 8 h for 2D-PAGE analysis. The resulting triplicate protein maps were compared for altered protein spot patterns and indicated protein spots selected for mass spectrometry. In parallel, RNA-expression analysis was performed as described previously

[9]. Again, of each individual treated cell line 5×10^6 cells were harvested after 4 and 8 h and processed. The resulting lists of affected gene expression and protein levels were pooled and submitted for network analysis (IPA, Ingenuity Systems; GenomatixSuite, Genomatix).

3. Results

As previously reported, our group analyzed the effect of the proteasome inhibitor bortezomib [8] on a panel of mantle cell lymphoma cell lines, screening for both alterations of the cel-

lular protein levels by 2D-PAGE and RNA-expression changes by Affymetrix array 2–8 h after treatment. In addition, we screened for the impact of the protein kinase c beta inhibitor enzastaurin in the same panel of cell lines. Interestingly, the resulting lists of target molecules of each study exhibited no matches between RNA-expression and protein levels but identified a similar set of affected pathways. To elucidate the comprehensive interaction of RNA-expression and cellular protein levels, we created combined lists of gene expression array data and 2D-PAGE-based analysis of cellular protein levels and applied subsequent interaction network analysis in the resulting master list of regulated molecules. In line with our hypothesis, most molecules identified either on the protein level or by RNA array analysis mapped into a combined functional interaction network.

While combining the lists of 75 identified candidate proteins for bortezomib treated MCL with the corresponding gene lists of the RNA-expression array analysis (393 genes) did not identify additional pathways, it highlighted certain cellular regulations (e.g. apoptosis, DNA repair, gene expression) as the impact ranking of certain pathways shifted due to involvement of additional candidate proteins in the network. Using Genomatix BiblioSphere (Genomatix, Munich) for the literature-based network analysis, the individual analysis of the bortezomib proteomics data resulted in a network containing 44 connected proteins of 59 analyzed (Fig. 1A). Additional 15 proteins (25%) remained unrelated to this network. Analysis of the accompanying RNA-microarray analysis resulted in a network of 329 functionally interacting genes (Fig. 1B) with additional 54 independent genes (16%). Combining both sets of genes,

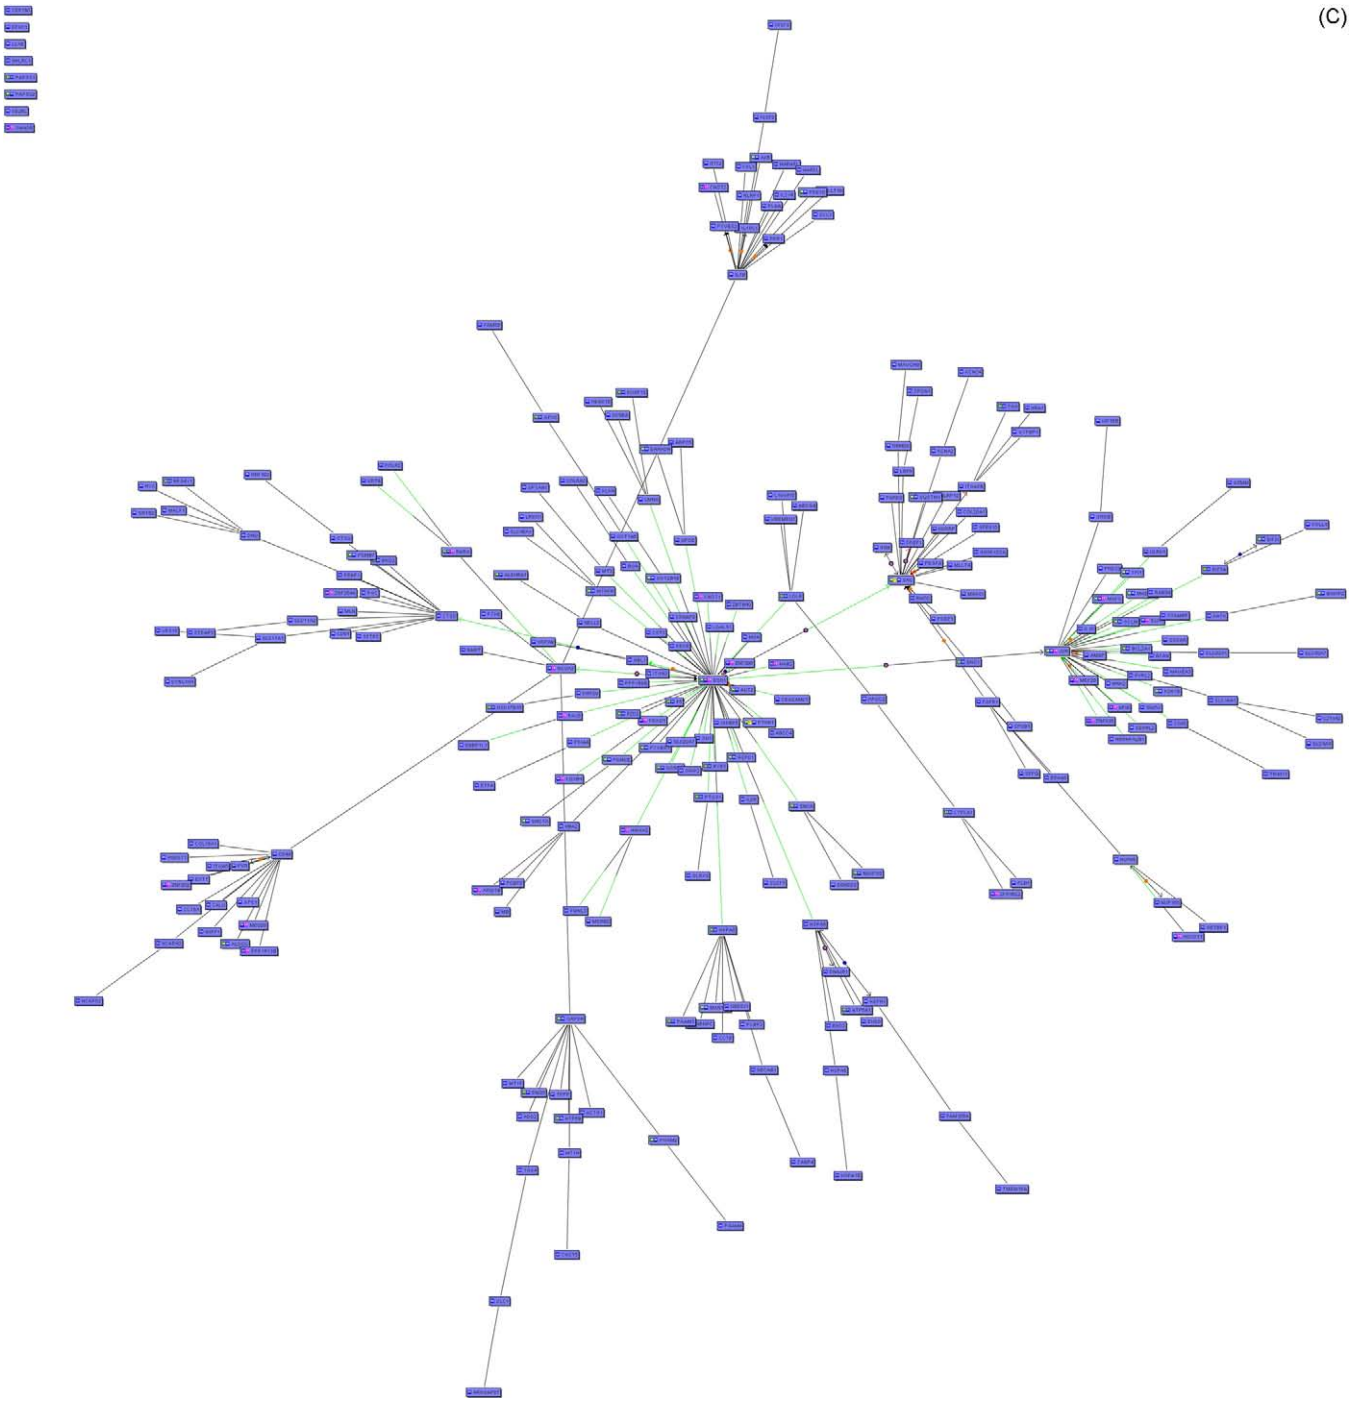

Fig. 1. (*Continued*).

the resulting network encompassed 394 functionally interacting molecules (Fig. 1C), with an additional 51 analyzed genes (13%). Thus, even though the total number of identified molecules did not increase, the number of functionally connected molecules of the interaction network rose to 394. Interestingly, the ranking of involved pathways (based on the number of molecules mapped to a pathway) shifted in the combined analysis to correspond better with the known mode of action of the investigated therapeutics (Fig. 2).

Similar results were also found for enzastaurin treated MCL cells (data not shown).

Combining the lists of 71 candidate proteins for enzastaurin treated MCL identified by 2D-PAGE and mass spectrometry with the corresponding gene lists of the RNA-expression array analysis (180 genes) also highlighted certain cellular regulations (e.g. apoptosis, DNA repair, gene expression) as the impact ranking of certain pathways shifted due to involvement of additional candidate proteins in the network.

In individual analysis, 36 of 56 analyzed proteins identified by 2D-PAGE and mass spectrometry mapped to an interaction network, leaving 20 unrelated proteins. In parallel, RNA-microarray analysis mapped 71 genes to an interaction network with additional 46 independent genes. Combined analysis of proteomics and RNA-expression data again resulted in 14 additional molecules mapped to the interaction network, creating a network of 121 interacting genes. The rate of unrelated molecules in this analysis was also

Fig. 2. Detail on the functional pathway ranking lists (bortezomib treated MCL cell lines) for proteomics data (P), RNA-microarray data (R) and combined network analysis of both. Pathway rankings reflect the number of genes mapped to this pathway. Pathways indicated exclusively by one analysis method are marked dark grey and white lettering, lighter shades (black lettering) indicate increasingly more additional genes mapped to the pathway due to combined analysis of RNA- and protein level alterations.

reduced (53 molecules; 31% for combined versus 20 (36%) and 46 (39%) for individual analysis runs). Again, the shifted ranking of involved pathways corresponds well with the known mode of action of the investigated therapeutics (data not shown).

4. Discussion

MCL is characterized by a rapid clinical progression and incidence of treatment refractory cases. Although the addition of the anti-CD20 antibody Rituximab to standard chemotherapy regimens has been shown to increase initial response rates, therapy options remain limited [1].

The proteasome inhibitor bortezomib is the first biological compound to gain approval of the FDA for treatment of relapsed and refractory MCL [2]. In addition it has been reported to act synergistically with several other biological compounds [10,11] as well as standard therapy regimens [6,12]. Enzastaurin, another promising new compound achieved disease stabilization in relapsed and refractory MCL [3].

Characterization of the drug effect, including primary target molecules as well as the affected signalling pathways will finally allow prediction of susceptibility as well as development of optimal combinations of biologicals targeting interacting pathways thereby acting synergistic. One example may be the combination of cell cycle inhibitors and proapoptotic compounds [13]. Especially in MCL, with the variable degree of cell cycle alteration in different tumours and accordingly varying susceptibility to treatment, another layer of complexity is added. Thus it is essential to concisely elucidate the affected signalling pathways and molecular functions.

Existing screening methods achieve this goal to a certain degree, but represent a view biased by the analyzed molecule. Proteomics commonly suffers from experimental bias as certain proteins possess limited solubility or might remain attached to plasma membranes and are thus not resolved by 2D-PAGE. On the other hand, RNA-expression arrays miss post-transcriptional processes, such as the regulation of cellular damage pathways. Such cellular damage signalling can be divided in two distinct but inter-connected stages: a fast emergency shutdown of cellular progression mediated by a disruption of normal protein homeostasis to prevent further damage and a slightly slower induction of physiological cellular repair mechanisms by activation of damage-signalling dependent gene expression [14]. In these two cell programmes altered protein levels act as inducers of gene expression and vice versa. Especially in most cases of therapeutic cancer treatment normal cellular function is massively disrupted by induction of DNA-damage (alkylating agents), inactivation of essential cellular enzymes (inhibition of the proteasome or cellular phosphatases) or direct activation of external death signals (therapeutic antibodies), resulting in cell death or growth inhibition.

We combined the involved candidate molecules of simultaneous RNA-expression-array- and protein-expression analysis in a comprehensive interaction network analysis. Especially for the proteasome inhibitor bortezomib most expression alterations are

represented on the protein level. Therefore, we selected an early time-point (4 h) to minimize the secondary influence of altered RNA-expression on the protein level, while still detecting early RNA-expression alterations in the microarray analysis. The absence of genes indicated simultaneously by protein and RNA screening confirms that the secondary impact of gene expression on the cellular protein levels is still limited at this early time-point. Thus our study represents two distinct regulation pathways of cellular response targeting either gene transcription identified by RNA array analysis or direct protein interaction as detected by 2D-PAGE analysis. However, the identified candidate molecules map to common interaction pathway networks.

Especially in the case of unspecific therapeutic agents, alternate unrelated triggering events might also converge to signal in a common response pathway and passing parallel checkpoints [4,5,15]. The combined analysis of these two mechanisms of cellular response resulted in a more comprehensive interaction network than the analysis on RNA or protein level. This is reflected by the involvement of additional molecules in the identified interaction network. In our study such a combined approach resulted in 21 additional molecules included into the identified interaction networks in bortezomib treated MCL cell lines. Accordingly, the number of unmapped genes was significantly diminished (25% and 16% respectively to 13%). Whether these observations may be also transferred to DNA-damaging agents or gene therapy approaches (including therapeutic anti-sense oligonucleotides) remains to be confirmed, as those treatment strategies directly interfere with gene expression, thereby avoiding direct protein-mediated regulation.

Role of the funding source

This work was supported by the European Union: 6.FP, Translational research on promising predictive and prognostic markers: “European MCL Network” (contract no. 503351).

E.H. and A.R. are supported by the Interdisciplinary Center for Clinical Research (IZKF) of the University of Wuerzburg, Germany.

ABSTRACT

Six protocols for extraction of proteins from sunflower (*Helianthus annuus* L.) leaves were evaluated for their abilities in both removing interferents and attaining the best resolution in two-dimensional gel electrophoresis. "Classical" phenol extraction followed by precipitation with ammonium acetate in methanol displayed the most efficient protocol, which allowed the detection of 244 protein spots with *ca.* 485 μg of protein in gel electrophoresis. Tandem mass spectrometry was performed to identify proteins in 61 spots, and cross species identification was used for this task. Proteins from twenty two spots were identified, and 12 of these proteins are up to now not included into the ExPASy sunflower protein databank.

1. Introduction

Proteomics is currently one of the most preeminent areas in science [1,2]. To explore and fully understand each aspect involved in proteomic studies is a hard and complex task, but a myriad of case studies have put in evidence a profitably synergism that places proteomics as an important multidisciplinary and interdisciplinary area with many applications [3,4]. Despite all efforts and developments achieved recently in protein separation, purification, characterization and quantification [5–8], sample preparation is the first and perhaps most fundamental step in protein analysis. Proteins are variable in their physicochemical properties and relatively unstable molecules, being located in every one of the many compartments of a cell, and in a variety of forms with different masses and pIs. When dealing with plants tissues, these molecules are commonly purified in the presence of interferents such as polyphenols, pigments, terpenes, and lignins. A general sample preparation protocol for protein extractions and clean-up is therefore nearly unfeasible. Customized sample preparation protocols must therefore be developed to achieve reliable proteomic profiles, particularly when most complex matrices [9,10] are handled as now widely recognized in the proteomic field [11,12].

In plant materials, when the targets are the leaf tissue proteins, sample handling is particularly laborious and therefore crucial owing to both lower protein content (as compared to bacterial or animal tissues), and the presence of large amounts of non-protein components [13]. The presence of these interferents can compromise two-dimensional gel electrophoresis (2-DE) separations, requiring customized experimental strategies for each plant [11,14]. Sample preparation for 2-DE protein separation usually takes several steps and reagents. Protein solubilization requires normally three major steps: (1) extraction of proteins from biological sample, (2) removal of interferents, and (3) preservation of proteins in solution until the separation process is finished [11].

Several sample preparation protocols applied to leaves from different species have been reported [15,16]. However, an evaluation of different protein extraction protocols from sunflower (*Helianthus annuus* L.) leaves, and their 2-DE separations, is apparently not available. Sunflower is of strategic importance owing to its high protein content and wide use in oil production and remediation processes [17–19]. Herein we report on a study aimed to evaluate some protocols for sunflower protein extraction for optimal proteomic analysis.

2. Materials and methods

2.1. Reagents and sample

Reagents employed in electrophoretic separations (acrylamide, bis acrylamide, DTT, iodoacetamide, urea, thiourea, ampholytes, strips for isoelectric focusing, mineral oil) were from Amersham Biosciences (Uppsala, Sweden). Mass spectrometry grade trypsin was from Promega (Madison, USA). All other chemical (including mineral acids, reagents for buffers preparation and gel stain) were obtained from J.T. Baker (Phillipsburg, NJ, USA) and Merck (Darmstadt, Germany). All solutions were prepared with deionized water ($\geq$18.2 MΩ cm) using a Milli-Q water purification system (Millipore, Bedford, USA).

Sunflower leaves (*Helianthus annuus* L.) were cultivated under ambient conditions (during 40 days as described by Garcia et al. [20]) and using plastic pots containing 400 g of soil at average temperatures from 18 to 24 °C (night and day, respectively). In the specific case of this work, the irrigation was carried out using deionized water only. After harvested, the plants were immediately frozen in liquid nitrogen and stored at −80 °C.

2.2. Protein extraction protocols

For each extraction procedure, 1.0 g of fresh wet leaf was grounded in a mortar with liquid nitrogen and an adequate volume of extraction mixture was then added.

Protocols P1 and P2 were based on Bellato et al. [21] excepting the addition of charged ions, as $MgCl_2$, allowing the isoelectric focusing of the proteins. In this way, 3.0 mL of a solution containing 50 mmol L^{-1} Tris–HCl (pH 8.8), 10 mmol L^{-1} DTT, 10 mmol L^{-1} phenylmethanesulphonylfluoride (PMSF) and 0.1% (w/v) SDS was added to the grounded material and mixed with a vortex for 20 min. The remaining insoluble material was then removed by centrifugation at 8500 × *g* (4 °C) for 5 min in a model Bio-Spin-R ultracentrifuge (BioAgency, São Paulo, Brazil) and then a precipitation step was carried out. Acetone/methanol (3:1, v/v) as well as 100 mmol L^{-1} ammonium acetate in methanol, both solutions at −20 °C, were respectively employed as precipitant agents for P1 and P2 protocols. Mixtures were kept at −20 °C overnight until the pellets formation. Then, supernatants were removed and pellets dissolved in an adequate volume (250 μL) of a typical two-dimensional electrophoresis buffer (2-DE buffer) containing 7 mol L^{-1} urea, 2 mol L^{-1} thiourea, 2% (w/v) CHAPS, 0.002% (w/v) bromophenol blue, 0.5% (v/v) ampholytes (pH from 3 to 10) and 1% (w/v) DTT.

Protocols P3 and P4 were based on that reported by Garcia et al. [20] and Carpentier et al. [22] with a modification in the SDS concentration (50% lower). In these protocols 3.0 mL of a solution containing 125 mmol L^{-1} Tris–HCl (pH 6.8), 1.0% (w/v) SDS, 1.0% (v/v) glycerol and 0.5% (v/v) β-mercaptoethanol was used. The procedure for protein extraction and insoluble material removal was the same as described in P1 and P2 protocols. Then, a clean-up step was carried out. Solutions containing 100 mmol L^{-1} ammonium acetate in cold methanol, as well as 20% (w/v) TCA + 0.2% (w/v) DTT in acetone were respectively used for P3 and P4 protocols. Tubes were kept incubated overnight at −20 °C and then centrifuged at 1800 × *g* for 5 min (4 °C). Supernatants were removed and the pellets were washed three times with cold acetone containing 0.2% (w/v) DTT. The mixtures were incubated at −20 °C for 1 h before centrifugation, employing the same conditions described above, and the pellets were dissolved with 2-DE buffer.

Protocols P5 and P6 can be considered as classical protocols for protein extraction from vegetal tissues [11]. P5 protocol, based on Xie et al. [23] comprises the TCA/acetone extraction. 4.0 mL of extraction buffer containing 10% (w/v) TCA and 0.07% (v/v) β-mercaptoethanol in acetone was added to the sample. The mixture was kept overnight at −20 °C and a 5-min centrifugation was carried out at 8700 × *g* (4 °C). The buffer was removed and the resulting material was 8 times washed with cold acetone and then dried with nitrogen. 250 μL of 2-DE buffer was added to the pellet and the mixture was 5-min vortexed. A 5-min centrifugation at 8500 × *g* was carried out and the supernatant was subsequently employed for electrophoretic separations.

Protocol P6 used a phenol based extraction protocol according to Delaplace et al. procedure [24] with a minor modification: 4.0 mL of protein extraction buffer containing 700 mmol L^{-1} sucrose, 50 mmol L^{-1} EDTA, 100 mmol L^{-1} KCl, 10 mmol L^{-1} thiourea, 50 mmol L^{-1} DTT, 2 mmol L^{-1} PMSF dissolved in 500 mmol L^{-1} Tris–HCl at pH 7.5 was added to the grounded material. This mixture was centrifuged at 6000 × *g* (4 °C) for 10 min. Proteins contained in the supernatant were collected and subsequently extracted using the same protein extraction buffer (at pH 7.5) saturated with phenol. This step consisted in the major difference between our protocol and that one proposed by Delaplace [24]. The phenolic mixture was homogenized and centrifuged at 6000 × *g* (4 °C) for 10 min. Phenolic phase (upper phase) was then collected, and those proteins present in this phase were extracted twice after addition of 5.0 mL of protein extraction buffer. The solutions were homogenized using a vortex mixer and centrifuged again at 6000 × *g* (4 °C) for 10 min. The upper phenolic phase was collected and a protein precipitation step using 10 mL of 100 mmol L^{-1} ammonium acetate in methanol was performed. This mixture was kept overnight and subsequently centrifuged at 8700 × *g* (4 °C) for 5 min. The pellet was washed with 4.0 mL of 100 mmol L^{-1} ammonium acetate in methanol, centrifuged at 8700 × *g* and dissolved with 2-DE buffer.

After application of each protocol, total protein concentrations were determined according to the Bradford method [25] using bovine serum albumin fraction V as standard. In this case, the pellets were solubilized into 100 mmol L^{-1} phosphate buffer at pH 7.2 previously to the measurement.

2.3. Two-dimensional gel electrophoresis separation

IPG strips for isoelectric focusing—IEF (13 cm length, pH 3-10, Immobiline™ DryStrip Amersham Biosciences, Uppsala, Sweden) were rehydrated overnight at room temperature with 250 μL of 2-DE buffer containing adequate mass of protein (ranging from 448 to 485 μg). IEF was performed using a Multiphor II system (Amersham Biosciences, Uppsala, Sweden) as follow: (1) step to 500 V (0.5 kVh); (2) gradient to 1000 V (0.8 kVh); (3) gradient to 10,000 V (11.3 kVh); (4) step to 10,000 V (3.0 kVh). After isoelectric focusing, proteins were reduced with 1.0% (w/v) DTT, dissolved into equilibration buffer (50 mmol L^{-1} Tris–HCl pH 8.8, 6 mol L^{-1} urea, 30% (v/v) glycerol and 2.0% (w/v) SDS) for 15 min, and alkylated with 2.5% (w/v) iodoacetamide in the equilibration buffer for 15 min. SDS-PAGE was carried out employing a 12.5% (w/v) polyacrylamide gel on the Ettan™ DALT system with 1 mm lab cast (Amersham Biosciences, Uppsala, Sweden). Constant voltage of 90 V and 25 mA per gel were applied overnight. Protein spots were visualized after staining with colloidal CBB G-250 [26]. The gels were scanned using an ImageScanner II (Amersham Biosciences, Uppsala, Sweden) with the densitometer operating at 300 dpi resolution and the ImageMaster 2D Platinum 6.0 software (GeneBio, Geneva, Switzerland) was employed to gel image analysis.

2.4. Tandem mass spectrometry (MS/MS) analysis

As accurate protein identification is dependent on the gel resolution, 61 spots from the gel obtained with the best protein extraction protocol (P6) were randomly chosen once that little information is achieved in the sunflower protein databank. For this task, the

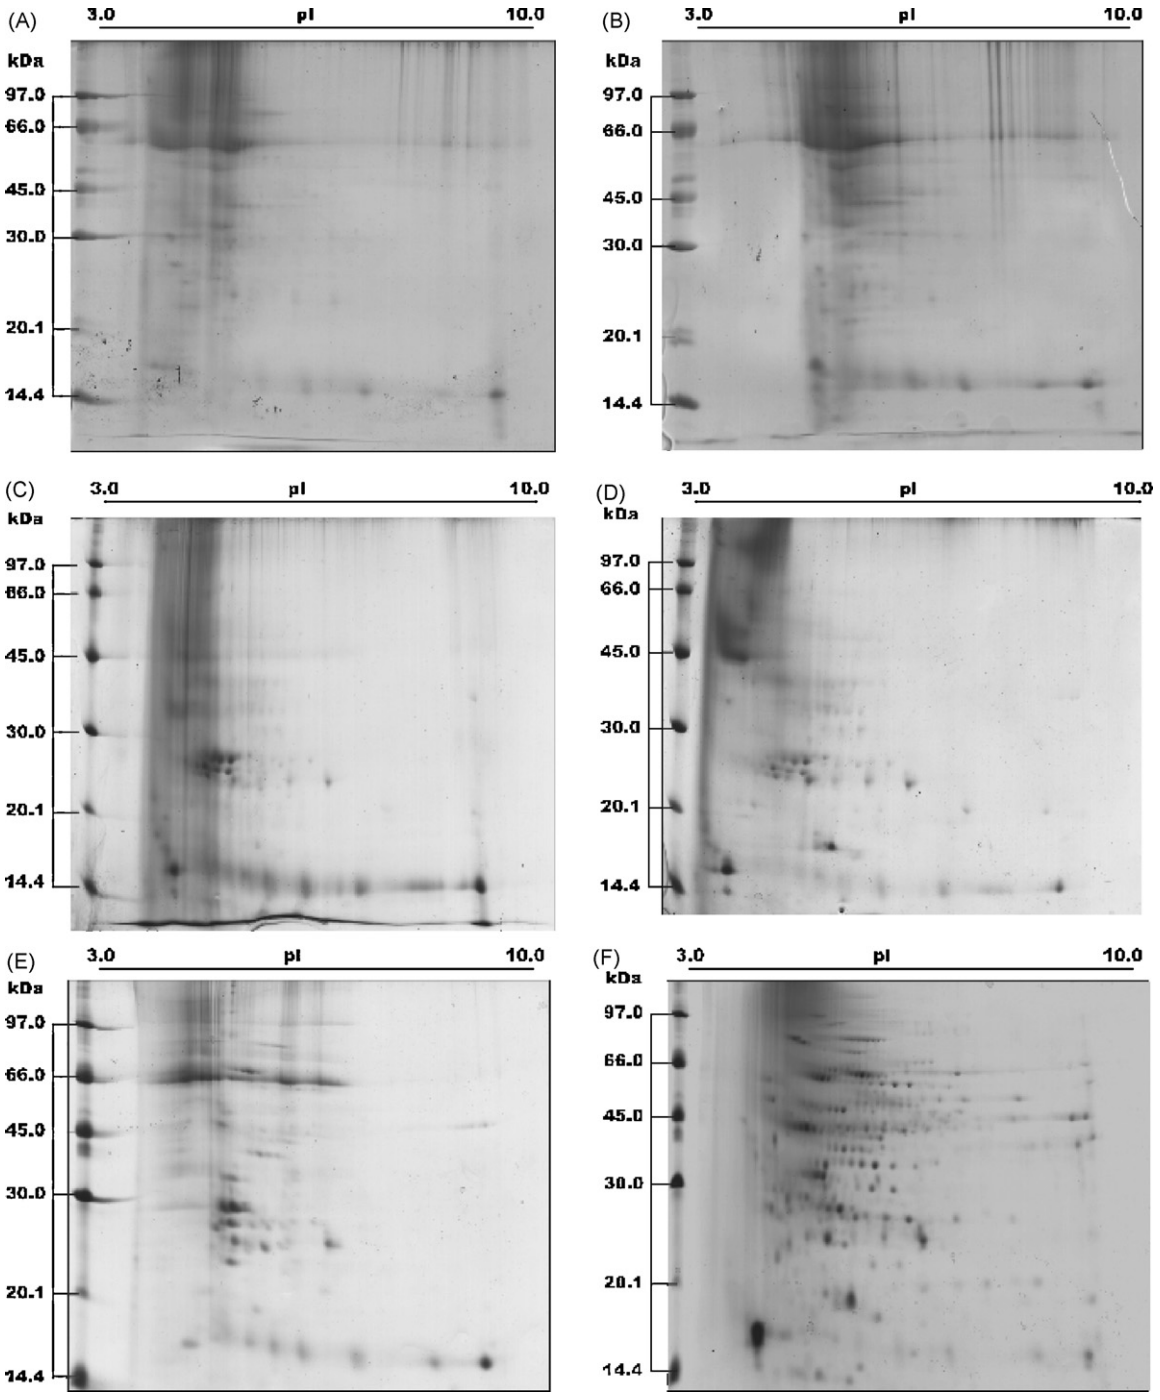

Fig. 1. Gel electrophoresis profiles obtained from P1 (A); P2 (B); P3 (C); P4 (D); P5 (E) and P6 (F) protocols.

spots (*ca*. 2 mm) were manually cut from the gel and placed into a micro-SPE plate containing peptide affinity resin—Montage® In-Gel digest$_{ZP}$ kit (Millipore, MA, USA). The digestion and vacuum elution protocols were performed according to the manufacture's recommendations. Basically, a dye removal step using acetonitrile was firstly employed followed by the tryptic digestion (using *ca*. 166 ng of enzyme for each spot). Then, a clean-up step was carried out using 330 μL of 0.2% TFA solution. Finally, purified peptides were eluted from resin using 20 μL of acetonitrile. For vacuum elution, a Multiscreen® Vacuum Manifold (Millipore, MA, USA) was used.

After tryptic digestion, the resulting peptides were analyzed using the dried droplet method. 1 μL of each sample was mixed with the same volume of MALDI matrix (1% (w/v) α-cyano-4-hydroxycinnamic acid dissolved into 1:1 (v/v) acetonitrile:water solution containing 0.1% (v/v) TFA). The mixture was immediately spotted to the MALDI plate and dried at room temperature until complete solvent evaporation.

Mass spectra were acquired in the positive mode using a MALDI-Q-TOF Premier mass spectrometer (Waters—Micromass, Manchester, UK) and a Nd:YAG laser (337 nm) MALDI source. Lock-Mass correction was performed with PEG 800. The following main parameters were used: laser firing rate of 200 Hz, mass range of 880.0–3000.0 Da, peak detection threshold for MS/MS of 1500.0, mass threshold of 200 Da, scan time of 2 s, Np multiplier set to 0.70, resolution of 10,000 with "V" mode, trigger threshold of 700, signal threshold of 80 and microchannel plate (MCP) set to 2100 V. Spectra

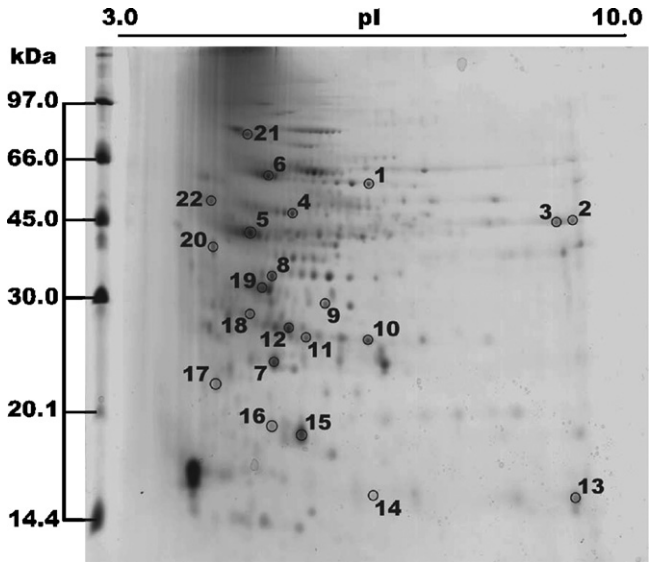

Fig. 2. 2-D gel map of proteins tentatively identified from sunflower leaves by MALDI-Q-TOF MS. Proteins were extracted using the P6 protocol and circled spots were identified.

were collected over 2 s scans, and accumulated over *ca.* 2 min using argon as collision gas. Typical collision energies ranging from 34 to 161 eV were employed. The instrument was controlled by MassLynx 4.1 software and all MS spectra were processed into peak lists files with *.pkl extension using ProteinLynxGlobalServer 2.2.5v (Waters, UK).

Peptides identification was achieved employing MASCOT Distiller software (Matrix Science, London, UK) for improving peak detection by attempting to match an ideal isotopic distribution to the experimental data, followed by MASCOT Server database search engine (Matrix Science, London, UK) [27] using a public sunflower gene databank containing *ca.* 151,000 EST sequences compiled from Plant Genome DataBase [28]. MS/MS search parameters included oxidation of methionine as variable modification, carbamidometylation of cysteine as fixed modification, ±0.1 Da peptide and fragment mass tolerance, and maximum of one missed cleavage. The significance threshold was set at $P < 0.05$, which correspond to a minimum score of 37.

The peptides determined by tandem MS were then used to determine sunflower gene sequences and posterior searching for homologous proteins (cross species identifications) using NCBI's Basic Local Alignment Search Tool (BLAST). Default configurations and no filters were used for BLAST searches.

3. Results and discussion

3.1. Protein extraction methods results

Protocols P1 and P2 were quite inefficient for protein extraction from sunflower leaves. Only 15 protein spots were visualized for P1 protocol, and 24 spots for P2 protocol as showed in the gels (Fig. 1A and B, respectively). In the referred cases, the majority of the extracted proteins presented acidic characteristics.

Protocols P3 and P4 used a lysis buffer comprising β-mercaptoethanol. Although this chemical shows lower efficiency as a reducing agent than DTT, better results (than P1 and P2 protocols) were obtained in terms of variety and quantity of extracted sunflower leaves proteins. This improvement may be attributed to the differences on pH extraction values of P3 and P4 when compared to P1 and P2 protocols. Using P3 protocol, gels with *ca.* 41 detected

Table 2
Identified peptides and confidence levels obtained after MASCOT and Blast searches. Scores are based on each software algorithm. Bold highlighted aminoacids indicate identity with the homologue protein sequence; aminoacids succeeded by (*) indicate similarity with their homologue. The columns % identity/similarity (partial) show the correlation percentage between identified peptides sequences and peptides sequences of the homologue proteins; columns of peptides overall identity/similarity (%) show the number of aligned aminoacids in Blast and their correlation percentage (shown in parenthesis).

spots were obtained (see Fig. 1C), while P4 protocol resulted in gels with *ca*. 64 spots (see Fig. 1D).

Poor separation obtained with P1, P2, P3 and P4 protocols may be attributed to the high concentration of the SDS during protein extraction steps, making difficult the isoelectric focusing, even with previous precipitation step.

The P5 protocol using TCA/acetone based extraction is classical for the clean-up of complex matrixes such as vegetal samples, and for further protein extraction [11,29] using 2-DE buffer. But despite its wide use, P5 protocol applied to sunflower leaves was found to be quite ineffective to remove secondary metabolites such as phenols, lignins, and pigments. Fig. 1E shows the gel obtained for P5 protocol in which 76 spots were detected, including some groups of protein isoforms (*ca*. 66 kDa) not so well resolved.

Application of P6 protocol resulted in a great improvement in the gel resolution, leading to the identification of 244 spots when *ca*. 485 μg of protein was loaded in the gel. Once that it presented the best result, three independently extractions using the P6 protocol were then carried out, and one gel was obtained from each one. Fig. 1F shows the gel profile obtained using this protocol. As one can see SDS is not applied to the extraction buffer in such case since thiourea as well as ionic substances, such as KCl, were added to increase protein solubility [30]. Unlike those from soy or peanuts, sunflower proteins are highly soluble in electrolytes, more than in pure water, owing to the salting-in effect [22,30]. As conclusion, the absence of SDS in extracting buffer may contribute to improve the gel resolution. Moreover, salt addition was found not to compromise isoelectric focusing steps once that its conductivity was within an acceptable level for an IEF experiment. Additionally, phenol contributes to protein solvation and removal of interferents (such as nucleic acids), since it acts as a dissociating agent for proteins reducing protein aggregation and interfering molecules [22,31]. Moreover, sucrose is used in P6 protocol to change phase densities and thus to ensure that the phenolic rich phases will be the upper phase. When the pH of extraction solution was near to seven, PMSF was employed as a protease inhibitor to minimize formation of degradation products. Additionally, phenol/polyphenol absorbents such as polyvinylpirrolidone (PVP) were not used because they are more effective at low pH values.

3.2. Mass spectrometry protein identification

Considering the small number of entries in the *Helianthus annuus* L. protein database, we expected low identification rate for Sunflower proteins. Cross species identifications were therefore used for identification. mRNA sequences were then correlated with peptides previously identified from MALDI-Q-TOF MS. The correlated mRNA sequences were in turn associated with homologue proteins from another organism providing the identity of the sunflower protein by homology.

Gel obtained from P6 protocol was employed for protein identification due to its best separation resolution. Fig. 2 shows circled spots, which were successfully identified (*ca*. 36% from the total spots randomly selected), as well as Table 1 presents their respective identifications by homology and the correlation with the organism (genus and specie) that presented higher homology. Experimental molar mass (estimated from gel electrophoresis spots), expected molar mass (based on protein homologues), and peptide coverage of protein are also shown. As visualized, experimental molar mass of proteins match with theoretical values except for some evident degradation products such as those from spots 17, 18 or 22. For instance, spot 22, in particular, seems to represent a fragment of protein from spot 21. It was observed that experimental molar masses higher than the theoretical values could be attributed to experimental variations, inherent to electrophoresis technique. In this case, acceptable values do not overcome 10%.

Table 1 highlights, in bold, those proteins not included in the ExPASy Proteomics Server [32], which have been therefore first characterized in this study at the proteomic level for *Helianthus annuus*.

Peptides obtained from MS/MS mass spectra data and used for protein identifications as well as the accession code, obtained from the compiled gene databank for each group of peptides can be observed in Table 2. This table includes the percentage of correlation between the identified peptides and peptides of the homologue protein, and the statistical scores given by MASCOT and Blast algorithms.

4. Conclusion

Six different protocols for protein extraction from sunflower leaves, a high complex vegetal sample, were evaluated. The protocol using phenol extraction was found to provide the best extraction efficiency and best protein separation using two-dimensional gel electrophoresis. Although this protocol is quite time consuming, the use of phenol maximizes the elimination of interferents and minimizes most abundant proteins. From 61 sunflower protein spots investigated, 22 spots (36%) were identified by tandem mass spectrometry, and 12 of them (*ca*. 55%) were found to correspond to new Sunflower proteins not listed yet in the current ExPASy databank. This result illustrates the efficiency of the protocol in terms of improved gel resolution and reliable mass spectrometry characterization. The use of the phenol based extraction protocol described herein for extraction and separation of sunflower proteins followed by gel electrophoresis may therefore facilitate sunflower proteomic studies and guide protocols for other complex plant materials.

ABSTRACT

Due to the complex structure of the articular joint, it requires great effort to fully understand joint disease pathogenesis. The proteomic analysis of articular joint tissues could contribute greatly to our insight into the endogenous control mechanisms of matrix turnover and the unravelling of the molecular and cellular mechanisms involved in the progression of the arthritides. To date, most proteome analysis strategies use the two-dimensional gel electrophoresis (2-DE) technique to separate proteins according to their isoelectric point, molecular mass, solubility and relative abundance. In this work, we describe optimization of human joint sample preparation techniques to obtain high quality 2-DE maps of human joint tissues (cartilage and synovium), cells (chondrocytes and synoviocytes) and synovial fluid. These techniques improve the performance of gel-based differential proteomic analysis, and facilitate the application of proteomics to rheumatology studies.

1. Introduction

A comprehensive understanding of the protein pathways involved in normal and disease states is required if we are to effectively treat disease. Proteome analyses not only aim to identify changes in protein expression, but also protein interactions, post-translational modifications and protein distribution. Proteomics, therefore, has become a useful technology for gaining an understanding of the complex and unknown processes that participate in joint disease pathogenesis. More efficient strategies are needed to obtain high throughput proteomics analysis of tissues and cells, in order to gain insight into metabolic dysregulations and structural changes that lead to disease development.

Many proteomic research strategies currently employ two-dimensional gel electrophoresis (2-DE) to separate proteins according to their isoelectric point (p*I*), molecular mass, solubility and relative abundance [1]. The gels are then stained with Coomasie brilliant blue [2], silver nitrate [3] or fluorescent dyes such as SYPRO Ruby or ruthenium II tris(bathophenanthroline disulfonate) [4,5] to visualize the protein spots. Digitized gel images are used for analysis and specific proteins to be identified are removed from the gel and digested using a specific protease, usually trypsin. The proteins are subsequently identified using mass spectrometry [6]. The high resolution of this technology makes it suitable for the analysis and parallel quantitative profiling of complex protein mixtures, such as whole cell lysates or tissues. Unlike other proteomic approaches that work with peptides, such as those methods based on liquid chromatography with tandem mass spectrometry (LC–MS/MS), 2-DE provides information about molecular weight and isoelectric point, and delivers a map of intact proteins that reflects changes in isoforms, post-translational modifications and protein expression levels. Early limitations of 2-DE have been largely overcome, not only with respect to reproducibility and handling, but also with the resolution of proteins that are hydrophobic or that exhibit extreme p*I* values. This has been possible mainly with the development of immobilized pH gradients (IPGs) that enable the analysis of very acid or alkaline proteins (IPGs between 2.5 and 12), and also provide increased resolution and allow detection of low abundance proteins using narrow-overlapping IPG strips. Because of this increased resolution, 2-DE can resolve more than 5000 proteins simultaneously using the proper gel size, sample characteristics and pH gradient. 2-DE technology is now able to detect and quantify less than 1 ng of protein per spot.

Joint diseases are the leading cause of disability in people over 55 years old. These diseases include degenerative pathologies such as osteoarthritis (OA), autoimmune diseases such as rheumatoid arthritis (RA) or psoriatic arthritis (PA), and metabolic disorders such as gout. While all these pathologies progress with joint inflammation and pain, the patterns differ depending on the type and

doi:10.1016/j.talanta.2009.05.022

location of the arthritic disease. Considering the complex structure of the articular joint, intensive effort is required to gain an understanding of joint disease pathogenesis. The proteome analysis of articular joints would be very useful to gain insight into the endogenous control mechanisms of matrix turnover in joint tissues, and to unravel molecular and cellular mechanisms that contribute to disease progression. In this paper we describe the sample preparation techniques we have found useful for the study of human joint proteomics using 2-DE for the analysis of joint tissues, cells and fluids.

2. Materials and methods

2.1. Reagents and chemicals

Culture media and fetal calf serum (FCS) were from Gibco BRL (Paisley, UK). Culture flasks were obtained from CoStar (Cambridge, MA, USA). 2-DE electrophoresis materials, including IPG buffer and strips were from GE Healthcare (Uppsala, Sweden). Anti-human serum albumin (HSA) and immunoglobulin G (IgG) resin were from Vivascience (Sartorius, Germany). Unless otherwise indicated, all other chemicals were obtained from Sigma–Aldrich (St. Louis, MO, USA).

2.2. Collection of cartilage, synovial membrane, joint cells and synovial fluid

Fig. 1 shows protocols followed to obtain joint tissue samples for proteomic analysis. Normal human knee and hip samples were obtained from adult donors, either from joint surgery or autopsy, who had no history of joint disease and macroscopically normal articular tissues. All donors or donor families gave written informed consent for the tissue donation. This study was approved by the Ethics Committee of Galicia (Spain).

Synovial membranes were extracted using biopsy forceps, rinsed in sterile phosphate-buffered saline (PBS), weighed, and either frozen at −80 °C or processed for synoviocyte isolation. Cartilage surfaces of femoral condyles were rinsed thoroughly with sterile saline; parallel sections 5 mm apart were then excised using scalpels to cut vertically from the cartilage surface to the subchondral bone. After resection from the subchondral bone, the cartilage strips were weighed and frozen at −80 °C or processed for chondrocyte isolation.

Synovial fluid from OA patients with joint effusion was aseptically aspirated. Normal synovial fluid was obtained from organ and tissue donors who did not have detectable OA. The synovial fluid was centrifuged at 800 × *g* for 15 min, after which the supernatant was divided into 1 mL aliquots and frozen at −80 °C.

2.2.1. Chondrocyte isolation and culture

The cartilage tissue strips obtained as described above were digested with 2.5 mg/mL trypsin in DMEM at 37 °C for 10 min. After removing the trypsin solution, the cartilage slices were incubated for 12–16 h with type IV clostridial collagenase (2 mg/mL) in Dulbecco's modified Eagle's medium (DMEM) with 5% FCS to release the cartilage cells. The chondrocytes were recovered and plated at high density (4×10^6 per 162-cm^2 flask) in DMEM supplemented with 100 U/mL penicillin, 100 μg/mL streptomycin, 1% glutamine and 10% FCS. The cells were incubated at 37 °C in a humidified gas mixture containing 5% CO_2 balanced with air. Confluency was achieved at 2–3 weeks of primary culture. The cells were serum-starved in fresh DMEM with 0.5% FCS for 48 h prior to trypsinization. Cell viability was assessed by trypan blue dye exclusion. Finally, the chondrocytes ($3–5 \times 10^6$) were recovered from the culture flasks by trypsinization, washed twice in a buffer containing 130 mM NaCl, 5 mM KCl, 2.5 mM Tris–HCl (pH 7.5) and 0.7 mM Na_2HPO_4, and transferred to microcentrifuge tubes for protein extraction.

2.2.2. Synoviocyte isolation and culture

Synovial membranes were minced and exposed to enzymatic digestion with 1.25 mg/mL trypsin in PBS 1 h at 37 °C with agitation. Dissociated cells were plated onto 162-cm^2 flasks and cultured overnight in RPMI 1640 medium supplemented with 100 U/mL penicillin, 100 μg/mL streptomycin, 2 μM glutamine and 10% FCS at 37 °C with 5% CO_2. Non-adherent cells were discarded and the adherent cells were cultured further in fresh medium until confluent, when the cells were trypsinized and subcultured. Synoviocytes from passages 4–8 were recovered from the culture

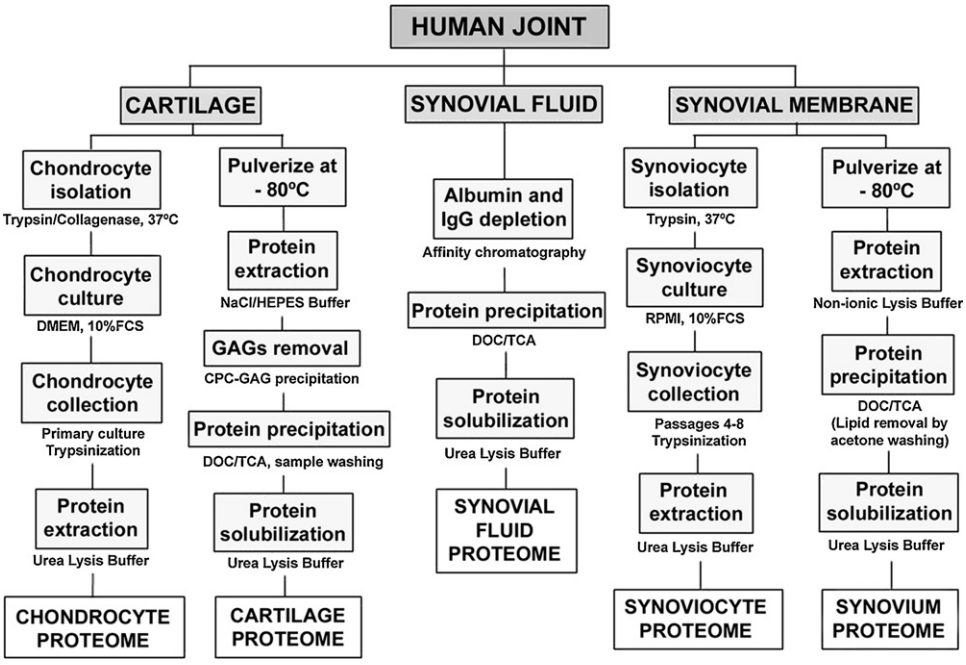

Fig. 1. Schematic workflow for the preparation of different protein samples obtained from human joints for two-dimensional electrophoresis (2-DE) analysis.

flasks, washed twice, and transferred to microfuge tubes for protein extraction.

2.3. Cartilage glycosaminoglycan (GAG) precipitation

We optimized our procedure for 2-DE of cartilage samples by precipitating their GAGs with cetylpyridinium chloride (CPC) with subsequent washing of the sample. Briefly, cartilage samples were pulverized at −80 °C in a tissue grinder, and the resulting powder was transferred to a microfuge tube. The cartilage proteins were extracted using a mild extraction buffer composed of 500 mM NaCl, 50 mM HEPES, pH 7.2, and protease inhibitors. Extraction was carried out for 1 h at room temperature with agitation and occasional vortexing. The samples were cleared by centrifugation at 12,000 × *g* for 10 min; the supernatant was either stored at −80 °C or subjected to proteoglycan (GAG) removal. The removal of GAGs was done using the method of Hermansson et al. [14], with some modifications. Briefly, the GAG content was determined using the dimethylmethylene blue assay [15], and GAGs were precipitated by incubation with 3 mg CPC per mg GAG. After precipitate removal, the proteins in the supernatant were precipitated overnight at 4 °C with 1/10 vol. of 0.2% sodium deoxycholate (NaDOC) and 1/10 vol. of 100% trichloroacetic acid (TCA). The remaining CPC was removed from the precipitate by cationic exchange, washing the pellet with 1 mL 0.4 M sodium acetate in 90% ethanol for 30 min with gentle agitation. The pellets were washed with 1 mL 100% ethanol at −20 °C to remove excess salts, and then with 100% acetone at −20 °C prior to solubilization in ULB as described in the next section.

2.4. General procedures used for two-dimensional electrophoresis (2-DE)

2.4.1. Protein solubilization

Tissue proteins or cell pellets were solubilized by vortexing followed by gentle agitation during a 1 h incubation in 200 μl of an isolectric focusing-compatible lysis buffer (ULB) containing 8.4 M urea, 2.4 M thiourea, 5% cholamidopropyl diethylamoniopropane sulfonate (CHAPS), 1% carrier ampholytes (IPG buffer pH 3–10 nonlinear (NL)), 0.4% Triton X-100 and 2 mM dithiothreitol (DTT).

For protein quantification, 10 μl of the protein extract were diluted 10× with distilled deionized water and precipitated for at least 1 h using 0.02% sodium deoxycholate and 10% trichloroacetic acid. The precipitate was washed once with two volumes of ice-cold acetone, allowed to dry, and solubilized in alkaline sodium dodecyl sulphate (SDS) (5% SDS, 0.1 N NaOH). 5–10 μl of this sample were employed to quantify the proteins in each lysate using the bicinchoninic acid (BCA) technique (Pierce Chemical Company, Rockford, IL, USA).

2.4.2. First dimension: isoelectric focusing

Solubilized protein (100 μg) was incubated for 1 h with gentle agitation in a rehydration buffer (8.4 M urea, 2 M thiourea, 2% CHAPS, 0.5% carrier ampholytes, 1.2% Destreak Reagent (GE healthcare) and 0.002% bromophenol blue). The proteins were then applied to 24 cm, pH 3–10 NL, IPG strips (GE Healthcare) using passive overnight rehydration. Focusing was performed at 20 °C for a total of 64,000 Vhr (IPGphor, GE Healthcare). The strips were stored in tubes at −80 °C.

2.4.3. Second dimension electrophoresis using SDS-PAGE

Second dimension electrophoresis followed equilibration of the strips for 15 min in 6 M urea, 50 mM Tris–HCl (pH 8.8), 30% glycerol, 2% SDS and 1% DTT (reduction step), and 15 min in 6 M urea, 50 mM Tris–HCl (pH 8.8), 30% glycerol, 2% SDS, 0.002% bromophenol blue and 4% iodoacetamide (alkylation step). The strips were first washed with electrophoresis buffer (25 mM Tris–HCl, pH 8.3, 192 mM glycine, 0.1% SDS) then attached to the surface of a 21 cm × 26 cm 10% polyacrylamide gel using 0.5% agarose. Electrophoresis was carried out according to the procedure of Laemmli [7], but using Tris–glycine electrophoresis buffer for the lower (anode) buffer and 2× Tris–glycine for the upper (cathode) buffer. Samples were run at 2.5 W/gel for the first 30 min and then at 17 W/gel until the bromophenol blue dye reached the bottom of the gel.

2.4.4. Gel staining

Gels were stained with either Coomasie Blue or silver nitrate. Coomasie staining used 0.1% Brilliant Blue G-250 (Sigma–Aldrich) in 40% methanol with 10% acetic acid, followed by destaining in 40% methanol with 5% acetic acid.

Silver nitrate staining was performed using standard protocols [8] with modifications. Briefly, gels were fixed overnight at 4 °C in 40% ethanol with 10% acetic acid and washed three times for 10 min with water. Sensitization was carried out for 1 min in 0.02% sodium thiosulphate (Fluka, Buchs, Switzerland). After two consecutive 1-min water washes, the gels were impregnated with 0.2% silver nitrate (Fluka) in 0.075% formalin for 60–90 min. Excess silver nitrate was removed by a few seconds of water rinses, and stain development was carried out in a solution containing 3% potassium carbonate, 12.5 mg/l sodium thiosulphate and 0.025% formalin. Once the bands or spots on the gel reached the desired intensity, the reaction was stopped by transferring gels to 3% Trizma-base (Sigma–Aldrich) in 10% acetic acid. After 30 min in the stop solution, gels were scanned and dried or stored at 4 °C in water.

2.4.5. Image acquisition

Coomasie and silver-stained gels were digitized using a densitometer (ImageScanner, Amersham), and analyzed with PDQuest 7.3.0 computer software (Bio-Rad, Hercules, CA, USA). Utilizing PDQuest tools, protein spots were enumerated, quantified and characterized by their molecular mass and isoelectric point by bilinear interpolation between landmark features of each image previously calibrated with internal 2-DE standards (Bio-Rad).

2.5. Mass spectrometry identification of proteins

2.5.1. Protein in-gel digestion

Selected spots of interest on the gel were excised and transferred to microcentrifuge tubes. Samples selected for analysis were reduced, alkylated and digested with trypsin according to Sechi and Chait [9]. Briefly, spots were washed twice with water, shrunk with 100% acetonitrile and dried in a Savant SpeedVac (Thermo Scientific, Waltham, MA, USA). The samples were then reduced with DTT and subsequently alkylated with iodoacetamide. Finally, samples were digested overnight at 37 °C with 12.5 ng/μl sequencing-grade trypsin (Roche Molecular Biochemicals, Indianapolis, IN, USA).

2.5.2. Mass spectrometry analysis

After digestion, the supernatant was collected and 1 μl was spotted onto a MALDI target plate and allowed to air-dry at room temperature. Subsequently, 0.5 μl of a 3 mg/mL solution of α-cyano-4-hydroxy-trans-cinnamic acid matrix (Sigma–Aldrich) in 0.1% TFA–50% acetonitrile (ACN) was applied to the dried peptide digest spots and again allowed to air-dry. The samples were analyzed using the MALDI-TOF/TOF mass spectrometer 4800 Proteomics Analyzer (Applied Biosystems, Framingham, MA, USA). MALDI-TOF spectra were acquired in reflector positive-ion mode at 1000 laser shots per spectrum. Mass spectra were internally calibrated using autoproteolytic trypsin fragments and externally calibrated using a standard peptide mixture (Sigma–Aldrich). TOF/TOF fragmentation spectra were acquired by selecting the 10

most abundant ions of each MALDI-TOF peptide mass map, excluding trypsin autolytic peptides and other known background ions, at an average of 2000 laser shots per fragmentation spectrum. The parameters used to analyze the data were a signal-to-noise threshold of 20 and resolution higher than 10,000 with a mass accuracy of 20 ppm.

2.5.3. Database search

The monoisotopic peptide mass fingerprinting data obtained from MS and the aminoacidic sequence tag obtained from each peptide fragmentation in MS/MS analyses were used to search for protein candidates using Mascot 1.9 (http://www.matrixscience.com). Tryptic autolytic fragments and other contaminations were removed from the dataset used for the database search. Search parameters for peptide mass fingerprints and tandem MS spectra were set using databases SWISS-PROT/TrEMBL (http://www.expasy.ch/sprot) and NCBI (http://www.ncbi.nlm.nih.gov). Fixed and variable modifications were considered (Cys as the S-carbamidomethyl derivate and Met as oxidized methionine, respectively) allowing one missed cleavage site, a precursor tolerance of 50 ppm and MS/MS fragments tolerance of 0.3 Da. The accepted isoelectric point range was from 3 to 10 and the accepted protein mass range was from 10 to 100 kDa. A positive identification was considered to be the achievement of at least five matching peptides and when at least 20% of the peptide coverage of the theoretical sequences matched, within a mass accuracy of 50 or 25 ppm with internal calibration. In all the positive identifications, the probability scores were greater than the score fixed as significant with a p value <0.05.

3. Results and discussion

3.1. Overview of sample preparation for proteomic analysis

Fig. 1 shows the workflow we designed for the study of joint proteomes using 2-DE. The diverse protein samples were obtained following the procedures described in Section 2.2. Despite the differences between samples described below, the proteins were all extracted using a urea-based lysis buffer and most were cleaned with sodium deoxicholate-trichloroacetic acid precipitation.

For the first dimension of the 2-DE analysis, protein extracts were separated with nonlinear immobilized pH gradient strips covering a wide pH range (3–10) to make possible the study of the complete proteome. In the second dimension, proteins were fractionated on large-format SDS-PAGE gels and visualized with Coomasie blue or mass spectrometry-compatible silver nitrate staining. Selected spots were then excised, destained, in-gel digested with trypsin and analyzed by MALDI-TOF/TOF mass spectrometry. The two-dimensional maps shown in the present work are representative of the results obtained in our laboratory. The proteomic patterns were found to be highly reproducible.

3.2. Pre-treatment and 2-DE of cartilage and synovial membrane samples

3.2.1. Cartilage

Articular cartilage is a tissue with a very low cell density and an extracellular matrix (ECM) composed mainly of water (approximately 75% of tissue weight) and an abundant network of collagen (predominantly type II), proteoglycans and other macromolecules. These features render cartilage proteomic analysis difficult because the relatively few structural proteins are in such abundance that other interesting components may remain masked and undetectable. A number of strategies for enrichment of the less abundant cartilage proteins and removal of contaminants have been developed. These include ultrafiltration [10,11], the use of differential protein solubilization procedures [12,13], and proteoglycan substraction by cetylpyridinium chloride precipitation [12,14] or CsCl gradient ultracentrifugation [13]. Moreover, proteoglycans are strongly anionic, which interferes with isoelectric focusing and makes their removal essential to obtain definitive 2-DE gels. A selective loss or enrichment of some proteins may have occurred due to sample preparation in our studies; this should be considered when interpreting results.

We optimized our procedure for 2-DE of cartilage samples by precipitating their GAGs with cetylpyridinium chloride (CPC) with subsequent washing of the sample (see Section 2.3 and Fig. 1). Fig. 2 shows 2-DE maps of human cartilage proteins obtained prior to (A) and after (B) GAG removal. The differences between the images illustrate the advantage of proteoglycan removal and the efficiency of this approach. The most representative spots from human cartilage maps were excised from the gels to identify the proteins shown in Fig. 3A and listed in Table 1. These included collagen and collagen-associated proteins, such as fibromodulin (FMOD) and cartilage oligomeric matrix protein (COMP). Interestingly, both FMOD and COMP have been proposed as markers for alterations in cartilage metabolism. Degraded fragments of FMOD have been found in RA and OA cartilage [16], increasing with age [17]. Elevated mRNA levels in human OA cartilage and increased total amounts of translated FMOD protein indicate that attempts to repair damaged cartilage

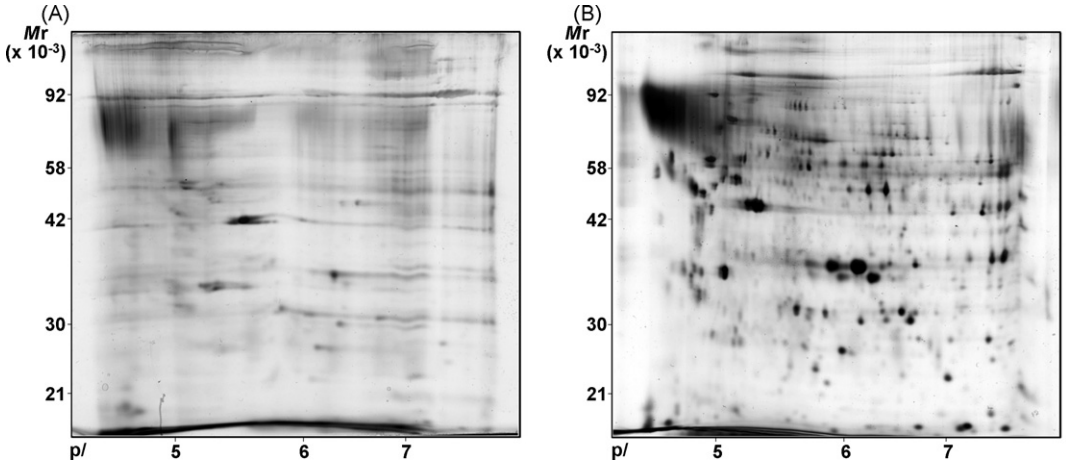

Fig. 2. Effect of glycosaminoglycan (GAG) removal on the proteome of cartilage. Two-dimensional electrophoresis (2-DE) gels of articular cartilage proteins before (A) and after (B) removal of GAGs by cetylpyridinium chloride (CPC) precipitation, showing the improvement in isoelectric focusing obtained after high anionic GAG depletion (IPG strip pH 3–10 NL, 10% T SDS-PAGE, silver staining).

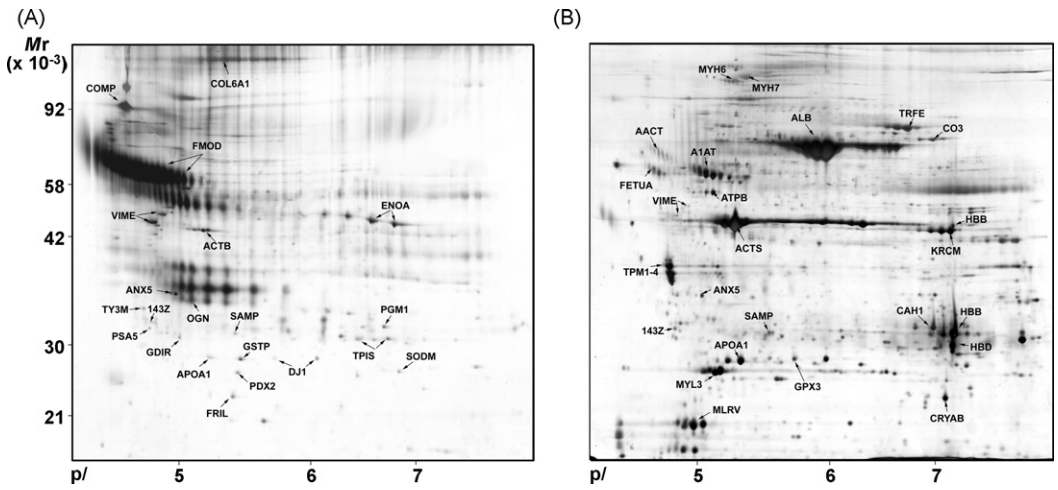

Fig. 3. Two-dimensional electrophoresis (2-DE) map of human articular cartilage (A) and synovial (B) proteins. Proteins are identified by the names used in the SWISS-PROT database (IPG strip pH 3–10 NL, 10% T SDS-PAGE, silver staining). Protein names are listed in Tables 1 and 2.

may be occurring [16,18]. COMP has received great interest in recent years as a biomarker for joint damage, including that resulting from RA [19], OA [20] and other skeletal diseases, as recently reviewed in Ref. [21].

3.2.2. Synovial membrane

The synovial membrane is located within the joint space and maintains normal joint function. Its anatomy can vary, but it often has two layers. The outer layer, or subintima, can be fibrous or fatty, whereas the inner layer, or intima, consists of a sheet of synoviocyte cells of two types, fibroblasts and macrophages. The fibroblast-like synoviocytes manufacture and secrete hyaluronan [22] and lubricin [23] into the synovial fluid, while the macrophages are responsible for the removal of undesirable substances from the synovial fluid.

Following a procedure similar to that used for cartilage samples, synovial membranes from healthy joints were pulverized at −80 °C and synovial proteins were extracted for 1 h using 1 mL of a non-ionic extraction buffer composed of 5 M urea, 1 M thiourea, 2% CHAPS and 2 mM DTT. The samples were then cleared by two successive centrifugations at 12,000 × *g* for 10 min; the supernatants were placed overnight in NaDOC/TCA for protein precipitation, as previously described. Synovial samples are characterized by a high lipid content, requiring that the protein pellet be washed with 500 μl of 100% acetone at −20 °C for 30 min to remove these lipids. The resulting pellet was then dried and solubilized in ULB as described in Section 2. Fig. 3B shows a representative 2-DE map of normal synovial proteins obtained by this technique. Table 2 lists some proteins indentified from this 2D map. In synovial membranes, we found an abundance of proteins related to fibrous structures, such as myosin and tropomyosin, in accordance with the described characteristics of the subintima. Fig. 3 shows the very different proteomic patterns obtained from cartilage and synovium, reflecting the diversity of the structures of the human joint.

Proteomes of degenerative/inflamed synoviums from RA, OA and a chronic arthritic condition, spondyloarthropathy (SpA) were compared using 2-DE followed by tandem mass spectrometry [24]. A similar strategy of separating whole tissue proteins by 2-DE prior to western blotting with sera from RA patients was employed to detect novel citrullinated autoantigens of synovium in RA [25].

Abbreviations as in Table 1.

3.3. Pre-treatment and 2-DE of chondrocyte and synoviocyte samples

A straightforward approach to analyze the human joint is by proteomic analysis of joint cells. Joint cells are responsible for ECM synthesis and turnover; the global study of their proteins may provide valuable information about processes occurring in these tissues in joints. Working directly with cells for proteomic studies is in many ways more straightforward than using samples from other sources because most cellular proteins are easy to extract, their quantitative dynamic range is not extremely high, and they are easily freed from matrix components. Moreover, the culture of joint cells is a widely used method for increasing the quantity of proteins available for extraction. This is particularly useful for cells occurring in low numbers in joint tissue, such as chondrocytes, which represent less than 5% of cartilage weight. Cultures of articular chondrocytes isolated from various animal and human sources currently serve as useful models to study mechanisms controlling responses to growth factors and cytokines. Cultured chondrocytes also shed light on the mechanisms of pathogenesis and degenerative processes of some rheumatic diseases, such as OA. Using cells in primary culture, our group succeeded in partially delineating the proteome of human normal articular chondrocytes [26], generating a chondrocyte 2-DE reference map that at present encompasses almost 200 identified spots that correspond to more than 140 individual proteins. More recently, a similar strategy was used to develop a comparative proteomic analysis of OA chondrocytes employing fluorescent staining of the gels, bioinformatic analysis and identification of proteins varying in abundance [27].

Fibroblast-like synoviocytes, which are the characteristic cell type present in the synovial membrane, have proved to be useful models for the study of joint inflammatory disease, such as RA [28]. Synoviocytes obtained from RA patients have been analyzed by 2-DE, leading to the identification of 192 distinct proteins [29], many of which are known to be involved in cartilage physiology or pathophysiology.

For proteomic analysis, joint cells must be first isolated from their tissues by enzymatic digestion of the ECM with trypsin and, in the case of cartilage, collagenase. Freshly isolated cells can be used for protein extraction and analysis procedures with the caveat that some characteristics of the resulting proteomic profiles may be caused by cellular responses to the enzymatic treatment. Chondrocytes easily de-differentiate into fibroblasts and should be used during the first tissue culture passage while synovial cells are stable during further subculturing and may be trypsin-digested and collected after as many as 12–15 passages. The isolated cells are washed and their proteins extracted in a urea-based lysis buffer. Cellular protein extracts were resolved by 2-DE without need for further cleaning. Chondrocytes (Fig. 4A) and synoviocytes (Fig. 4B) show a marked similarity in their proteomes. The comparison of the synoviocyte map with reference maps allows identification of 82 different proteins involved in a broad range of biological functions. Some of the most abundant proteins appearing in the maps are vimentin, gelsolin or lamin A, filament proteins characteristic of adherent cells. These and 13 other protein forms common to both proteomic maps are depicted in Fig. 4 to illustrate their similarity.

3.4. Pre-treatment for 2-DE of synovial fluid samples

Proteomics shows great promise for discovery of biomarkers to improve the diagnostic capability for a wide range of diseases. Biological markers are needed to better understand and characterize disease types, monitor disease status and progression, and response to current and new therapies. The search for candidates to serve as specific markers of joint damage for early diagnosis of disease is a major aim in rheumatology research. Blood plasma, serum, and other body fluids that come in contact with a variety of tissues are expected to be the best sources of protein biomarkers for proteomic analysis. These circulating fluids have recently been shown to be the most likely carriers of proteins secreted or shed by tissues [30]. The major advantage of serum is its ready availability, but proteins secreted or released from a specific tissue or cell type, i.e. those that hold the highest potential as biomarkers, are so diluted in blood that they are often undetectable by current methods. This has generated great interest in the analysis of "proximal" body fluids, which have been in contact with only one or a few tissues, so less dilution of tissue-derived proteins would be expected. Synovial fluid is one of these "proximal" fluids, being derived directly from the site of joint

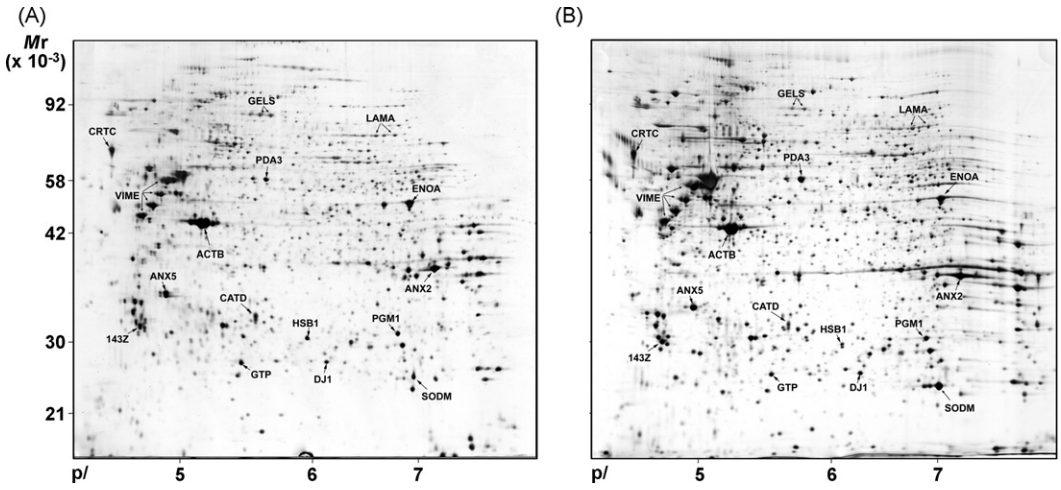

Fig. 4. Two-dimensional electrophoresis (2-DE) maps of human articular chondrocyte (A) and synoviocyte (B) proteins. Representative proteins are identified by the names used in the SWISS-PROT database (IPG strip pH 3–10 NL, 10% T SDS-PAGE, silver staining).

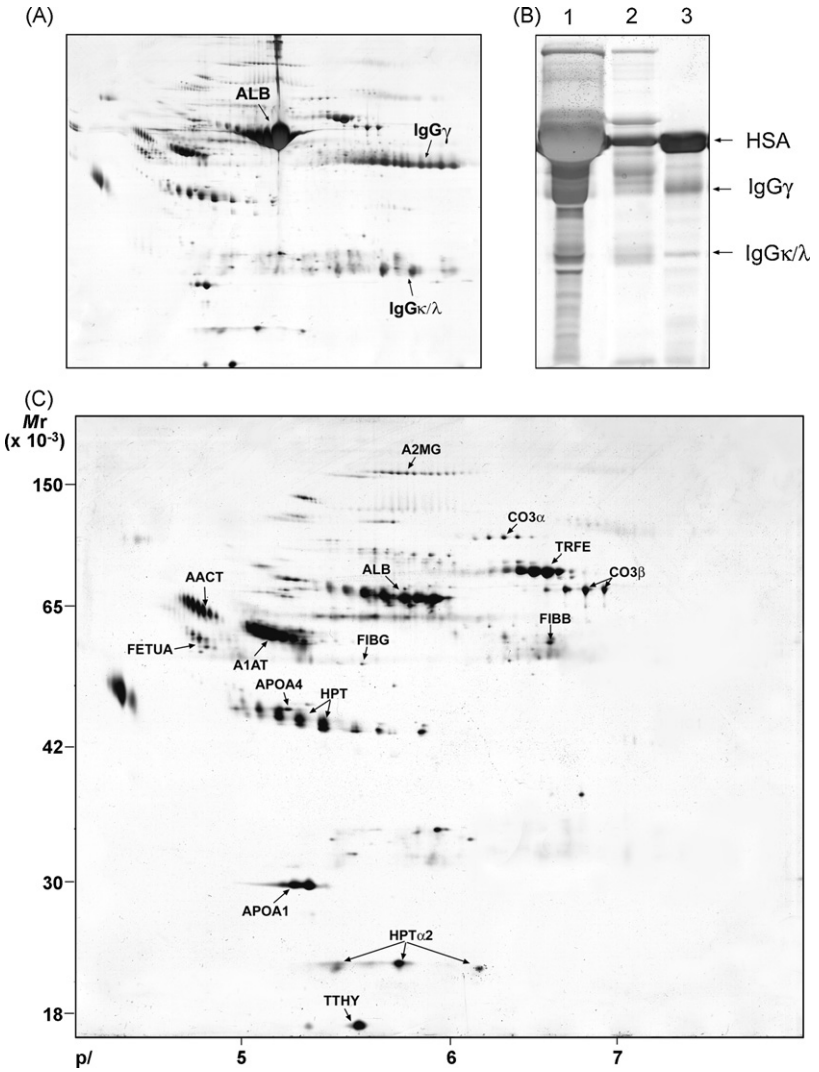

Fig. 5. Effect of albumin and immunoglobulin G (IgG) depletion on the synovial fluid proteome. (A) Whole human synovial fluid two-dimensional electrophoresis (2-DE) map. (B) Silver-stained SDS-PAGE gel showing the effect of depletion on the synovial fluid protein profile. Lane 1: non-depleted synovial fluid; lane 2: depleted synovial fluid; lane 3: protein fraction bound to the affinity resin. (C) 2-DE map of human synovial fluid proteins (IPG strip pH 3–10 NL, 10% T SDS-PAGE, silver staining). The 16 mapped proteins are identified by the names used in the SWISS-PROT database. Protein names are listed in Table 3.

TTHY	Transthyretin precursor	P02766	16.0	5.52	7	69

Abbreviations as in Table 1.

disease. Proteomic studies in rheumatology have been designed to identify prospective biomarkers in SF, and attempt to then validate them in serum.

SF is a hyaluronic acid-rich fluid secreted by the synovium. Under normal conditions it lubricates the joint and provides articular cartilage with the nutrients necessary for chondrocyte metabolism. It also serves as the intermediate carrier of proteins shed by articular cartilage and transferred to the systemic circulation. SF sampling is invasive, thus samples need to be centrifuged to remove contaminating cells, such as mononuclear cells before use for proteomics. It is also useful to digest samples with hyaluronidase to remove the HA, which may complicate proteomics analyses [31]. In both serum and SF, large quantitative variability among samples has been reported for a number of proteins when using 2-DE on samples from OA patients. One study found that 41 of 139 spots sampled showed differences of greater than threefold between any two samples, with nine having greater than 100-fold differences [32]. This study illustrates the need to analyze a large number of samples and a clearly defined reference map for normal SF proteins to differentiate between changes due to OA and normal variation between individuals. Variability among samples was also noted in a proteomic study of recurrent joint inflammation in juvenile idiopathic arthritis, where both plasma and synovial fluid were analyzed using 2-DE and cases with single-event knee joint inflammation were compared to a group with recurrent knee disease [33].

The large dynamic range of individual protein concentrations in plasma, serum, and synovial fluid is one of the most challenging issues in body fluid proteomics aimed at biomarker discovery. Disease biomarkers typically appear in low concentrations, making their detection difficult in the presence of proteins appearing in higher abundance. A practical and effective strategy solution for this problem is the removal of diagnostically uninformative high abundant proteins, thus enhancing the detection of low abundance proteins to penetrate deeper into the plasma proteome. Several systems to deplete plasma of the unwanted high concentration proteins have been developed and are commercially available. They use antibody-based resins with specific affinities for as many as 20 of the most abundant proteins in plasma. We employed resins with affinity for HSA, which represents about 65% of total plasma proteins, and IgG, which represents about 15% of total plasma proteins. Because SF and plasma have a similar composition of high abundance proteins this technique is also suitable for depleting SF of these proteins. Fig. 5A is a 2D map of synovial fluid showing the remarkably high concentrations of albumin and IgG. The affinity chromatography protocol to remove these two proteins is illustrated in Fig. 5B. A conventional SDS-PAGE gel was used to evaluate the protein profiles of SF before (lane 1) and after (lane 2) protein depletion, as well as to define the protein fraction bound to the affinity resin (lane 3). Depletion of these two proteins enabled better visualization of other proteins (Fig. 5C), and improved identification of lower abundance proteins. Table 3 shows those less abundant proteins identified using this technique.

Table 4
Principal protocol recommendations.

Joint sample	Protocol modification before 2-DE
Cartilage	Glycosaminoglycan depletion by CPC precipitation.
Synovium	Lipid removal with acetone.
Cells (synoviocytes and chondrocytes)	Follow protocol for chondrocytes [26].
Synovial fluid	Depletion of albumin and IgG by affinity chromatography.

CPC: cetylpyridinium chloride.

4. Conclusions

The proteomic analysis of the articular joint tissues and cells should prove very helpful for increasing our insight into the endogenous control mechanisms of joint matrix turnover and unravelling the molecular and cellular mechanisms that participate in arthritic disease onset and progression. We have described a set of sample pre-treatment protocols that improve 2-DE proteomic analyses of cartilage, synovium, chondrocytes, synoviocytes, and synovial fluid. The main points of the optimized procedures are summarized in Table 4 and should prove useful to increase knowledge about joint pathogenesis. Hopefully, the proteomic analysis of synovial fluid and other body fluids will result in definition of biomarkers valuable for early diagnosis and monitoring of joint disease.

Monitor protein production
Spectra clustering
Intact insect cell fingerprint

ABSTRACT

A new application of *intact cell MALDI-TOF MS* (*ICM-MS*) methodology is described for monitoring the production of viral proteins and viral like particles using the baculovirus/insect cells expression system. Various MALDI matrices, cell preparation methods, cell/matrix volume ratio and MALDI target application procedures were tested in order to obtain the highest intensity and reproducibility of intact insect cell spectra. The web interface, SPECLUST (http://bioinfo.thep.lu.se/speclust.html), was used to construct dendograms based on MALDI-TOF MS data for evaluation of fingerprint changes.

We demonstrate that insect cell mass spectrum fingerprints are characteristic of each viral protein/particle production. Their changes along the time for each production experiment correlate with the intracellular viral protein content determined by Western blot.

This work shows that this simple, fast and low cost assay, which requires low sample volume, is a powerful analytical tool that complements the most common analytical methods used for monitoring bioprocesses and has potential application in the biotechnological industry namely, in the production of recombinant proteins.

1. Introduction

Since the late 80's [1,2], matrix-assisted laser-desorption/ionization (MALDI) time-of-flight (TOF) mass spectrometry (MS) has been applied in many scientific research areas, mainly in the proteomics field [3]. More recently, the suitability of MALDI MS approaches for identification and characterization of clinically important microorganisms [4], including bacteria [2,5–10], fungi [11–13], viruses [14] and spores [15–18] has been probed. MALDI-TOF MS profiles have also been used to analyze single cells and tissue samples from animals namely, mollusk, insect neurons [19,20] and mammalian cells [21].

Besides detecting various metabolites or characteristic components of the cell envelopes [2,22,23] in the low mass range, intact cell MALDI (ICM-MS[1]) also provides unique insights into cell biology and chemistry based on the detection of chemicals or in the measurement of chemical changes in response to environmental, temporal or other external influences [8,24,25]. MALDI-TOF MS fingerprint comparisons in the mass range 2–20 kDa are currently considered as a rapid approach for bacterial identification, an application termed phyloproteomics [8,17,26–28]. This strategy is based on the computer-assisted comparison of spectral fingerprints obtained directly from intact cells [29–32] with internet-accessible protein sequence databases [17,33–36], for identification of specific biomarkers based on the molecular masses of proteins.

In the intact cell MALDI-TOF MS (ICM-MS) approach, cells are mixed with an energy-absorbing matrix and irradiated with UV-laser. The matrix promotes laser energy transfer to the cells that results in the ionization of cell-surface macromolecules. The quality of the spectra produced is highly dependent on the choice of matrix, composition of the matrix solvent and sample preparation procedure [37]. Matrix solvent influences the release of macromolecules from the cell and co-crystallization with the matrix compound affects the mass range of the molecules being ionized, allowing enhancing the differential ionization of specific compounds, such as proteins, lipopeptides or nucleotides [8,38].

In this study, a novel application for the ICM-MS method is reported. This methodology was used to monitor the production of viral proteins (VP) and virus-like particles (VLPs) by the insect cells *Spodoptera frugiperda* Sf-9/baculovirus expression system. This is a widely used system for recombinant protein and VLP production

doi:10.1016/j.talanta.2009.06.081

as it allows high productivities, it does not contain contaminants from mammalian sources and the baculovirus expression vectors are flexible and easy to handle [39]. In this work, cells involved in real time production of Rotavirus VLP's, were used as a model to follow insect cell fingerprint changes by ICM-MS. These triple layered particles, contain, in the inner shell, 60 dimers of VP2 (102.7 kDa); in the middle shell, 260 trimers of VP6 (44.9 kDa) and in the outer shell, 780 monomers of the glycosylated VP7 (37.2 kDa) [40].

The ICM-MS experimental approach has many advantages, namely: (i) it is compatible with crude samples and sample clean up is minimal; (ii) there is no need for tagging or pre-select proteins or peptides of interest; (iii) uses simple instrumentation; (iv) has high sensitivity; (v) provides complementary information to immunochemical methods; (vi) is compatible with post-translational modifications; (vii) requires low amounts of sample and (viii) is low time consuming due to minimal sample preparation [41]. ICM-MS is therefore, a very interesting alternative to monitor the production of recombinant proteins avoiding high analytical costs, usually associated to immunochemical reagents, large sample volumes and time consuming protocols.

2. Materials and methods

2.1. Cell line and baculovirus

Spodoptera frugiperda Sf-9 and *Sf-21* cell lines were obtained from the American Type Culture Collection (ATCC, USA). Sf-9 cells were used for production of baculovirus and VLPs, Sf-21 cells were used for virus titration. Both cell types were cultured in serum free media SF900II (Gibco, Glasgow, UK) at 27 °C in 250 mL (working volume) Wheaton spinner flasks stirred at 150 rpm or in 500 mL Erlenmeyers with 50 mL (working volume) at 90 rpm.

Autographa californica nucleopolyhedrovirus (AcMNPV) recombinant baculovirus vectors, individually expressing bovine vp2 or vp6 or vp7 gene, under the control of polyhedron promoter, were constructed and kindly provided by Dr. Jean Cohen from Centre National de la Recherche Scientifique-Institut National Recherche Agronomique, Gif-sur-Yvette, France.

The viruses were titrated using the assay described by Mena [42], based on cell viability. Infections were performed at a cell concentration at infection (CCI) of 1×10^6 cell mL^{-1}. The recombinant baculovirus were amplified by infecting Sf-9 cells at a multiplicity of infection (MOI) of 0.1 pfu $cell^{-1}$. Baculovirus were harvested with a cell viability of approximately 70%, corresponding to the 4–5 days post-infection [43], by centrifugation at $200 \times g$ for 10 min. For proteins and VLP production a MOI of 5 pfu $cell^{-1}$ was used. The density of infected cells was determined by haemocytometer cell counts (Brandt, Werthein/Main, Germany) and the viability evaluated by trypan blue exclusion dye (Merck, Darmstadt, Germany) in 0.4% of phosphate-buffered saline (PBS).

2.2. Monitoring kinetics of VPs and VLP production

The following kinetic experiments were carried out in duplicate: (i) *Control* 1, non-infected insect cells; (ii) *Control* 2, insect cells infected with a wild type baculovirus; (iii) *VP production*, insect cells independently infected with monocistronic recombinant baculovirus for VP2, VP6 and VP7 production; and (iv) *VLP production*, insect cells co-infected simultaneously with VP2, VP6 and VP7 monosistronic recombinant baculovirus for VLP2/6/7 production.

Aiming at monitoring VPs production kinetics, samples were collected approximately every 12 h and centrifuged at $200 \times g$ for 10 min. The cell pellet was washed three times with PBS and finally resuspended in 3 μL of 0.9% (w/v) NaCl for insect cell ICM-MS analysis. Total protein content was also assessed using the BCA Protein Assay Kit (Pierce, Rockford, USA).

2.3. VPs quantification

Intracellular viral protein quantification was done by Western blot, according to the protocols previously described [44]. The amount of each protein was normalized using a well characterized VLP standard, produced and purified using a method described elsewhere [45]. Immunochemical staining for recombinant protein detection was carried out with a polyclonal anti-Rotavirus serum (for VP6 and VP7 detection) and a monoclonal antibody produced against VP2, both kindly provided by Dr. Jean Cohen, Gif-sur-Yvette, France. Blots were developed after incubation with an alkaline phosphatase conjugated anti-rabbit IgG antibody (Sigma, St. Louis, USA) and an alkaline phosphatase conjugated anti-mouse IgG antibody (Sigma, St. Louis, USA) using 1-stepTM NBT/BCIP blotting detection reagent (Pierce, Rockford, USA). The product yield was estimated by densitometry analysis of the scanned images (ImageQuant® for Microsoft® WindowsNT®, Molecular Dynamics, Inc., USA, 1998).

2.4. Sample preparation for ICM-MS

The quality of *Spodoptera frugiperda* Sf-9 cell suspension spectra was evaluated using three MALDI matrices. All matrix solutions, 2,5-dihydroxybenzoate (DHB), sinapinic acid (SA) and 2,6-dihydroxyacetophenone (DHAP), were prepared daily in 70% (v/v) acetonitrile 0.1% (v/v) trifluoroacetic acid with the concentration of 20 mg mL^{-1}.

Two sample MALDI target application procedures were tested: direct spotting of the insect cells on the MALDI target plate followed by the matrix solution which were air-dried prior to analysis; or by spotting the previously mixed cell suspension with the matrix solution. Different matrix:cell suspension volume ratios were tested for the direct spotting method 1:1 and 1:0.6. For the mixture spotting a 1:5 volume ratio has been used.

In order to try improving MALDI-TOF spectra intensity [7,46], mechanical disruption of cells was done using glass beads under vigorous agitation for 1 min after the addition of matrix to the cell suspension (1:1). Obtained whole cell lysates were directly spotted on the MALDI plate for further analysis.

2.5. Data acquisition and processing

All mass spectra were obtained using a PerSeptive Biosystems MALDI-time-of-flight (TOF) MS Voyager-DE STR (Framingham, USA) equipped with delayed extraction, and a 337-nm N_2 laser. Mass spectra were acquired in linear delayed extraction mode using an acceleration of 20 kV and a low mass gate of 5000 Da. The laser power was set to just above the threshold of ionization. Spectra for individual samples were accumulated, averaging 150 shots taken across the width of the sample spot for m/z values between 5000 and 25 000.

The individual spectra were initially processed by Data Explorer 4.2 software (Applied Biosystems, Foster City, USA) used for baseline correction, noise removal and peak detection. For each spectra, m/z peaks relative intensities were computed with the most intense peak set to 100%. Peaks with 5% maximum peak area, relative intensity below 5%, and a mass resolution bellow 500 were ignored. From the peak lists obtained as previously described, m/z peaks were deleted if their relative intensity was below 20% for the mass range of 5000–7500 Da; below 10% for the mass range of 7500–10 000 Da; and below 5% for the mass range of 10 000–25 000 Da.

The web interface SPECLUST created by The Computational Biology & Biological Physics Group at Lund University

(http://bioinfo.thep.lu.se/speclust.html) was used to construct dendograms based on MALDI-TOF MS data. To proceed with statistical analysis, the processed mass lists were converted into SPECLUST input format files. This program compares *m*/*z* peak lists by measuring a distance between each pair of lists [50]. A mass tolerance of 10 Da was given to assign peak similarity due to the resolution achieved in the used *m*/*z* range.

3. Results

3.1. Sample preparation and ICM-MS method optimization

Apart from the classical application of MALDI MS in proteomics (e.g. identification of isolated and purified proteins and peptides), it has also been used more recently with intact cells for identification of microbes and monitoring of recombinant protein productions in *E. coli* [25]. It is known that intact cell MALDI spectra profiles can be highly variable [46,47]. Therefore, it is important to investigate the effect of sample preparation procedure on spectra quality and data acquisition reproducibility. Cell treatment (cell suspension or whole cell lysate), appropriate MALDI matrices and several matrix:cell suspension ratios were evaluated. Two MALDI target plate sample application methods were also assessed. In each case, mass spectra were examined for number and relative abundance of *m*/*z* peaks detected. The best condition was direct spotting on the MALDI plate, using 2,6-dihydroxyacetophenone matrix in a matrix:cell suspension volume ratio of 1:1. The number of detectable peaks and their relative intensities were considerably higher when comparing with those detected using sinapinic acid matrix. No peaks were detected when using DHB matrix (Fig. 1).

Different methods for applying samples onto the MALDI target plate and insect cell treatment conditions were also evaluated. The *m*/*z* peaks that passed the acceptance criteria (described under Materials and methods) were listed for each spectrum and both common and new peaks were identified. The number of occurrences was determined for each *m*/*z* peak using *Peaks In Common consensus analysis*, a functionality of SPECLUST. Peaks were considered as *common* when appearing in more than 70% of the spectra and as *new* if fewer occurrences took place. Then, the percentage of *common* and *new* peaks was determined by dividing the number of each occurrence by the total number of peaks per spectra. The mean number of the overall detectable peaks was 23 for the direct application of insect cells onto the MALDI plate, 12 when previously mixing the cell suspension with matrix (1:1 ratio) and 14 for the cell lysate treatment. Fewer peaks were detected when diluting cell suspension in matrix. The higher number of detectable *m*/*z* peaks was obtained by direct spotting the cell suspension onto the MALDI plate (Fig. 2). In this condition, lower inter-spectra variability was also achieved, corresponding to an average of 6 *new* *m*/*z* peaks per spectra (26% of total detectable *m*/*z* peaks). To estimate the reproducibility associated with the selected method, the total number of detectable peaks and the number of peaks assigned as *common* was determined in 6 replicates. The outcome of this analysis revealed an average of 23 detectable peaks in which 15 and 17 of them are common to at least 90% and 70% of the analyzed spectra, respectively.

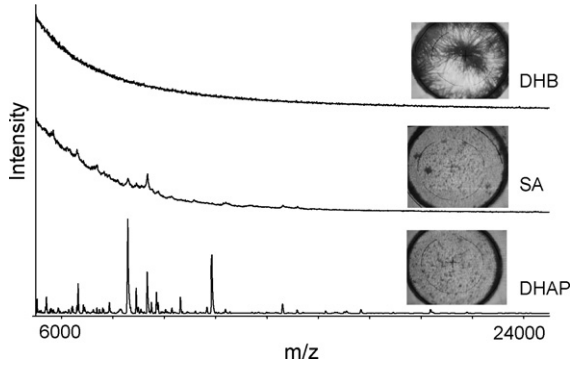

Fig. 1. Effect of matrix on insect cell ICM-MS spectra: Insect cell suspension MALDI-TOF MS spectra using different matrices (DHB, SA and DHAP) and pictures of their co-crystallization are presented. All spectra were collected after direct spotting. A ratio of 1:1 of matrix:insect cell suspension was used. DHAP (20 mg mL^{-1}) in 70% acetonitrile 0.1% trifluoroacetic acid seems to be the optimal matrix since it originates spectra with more detectable peaks.

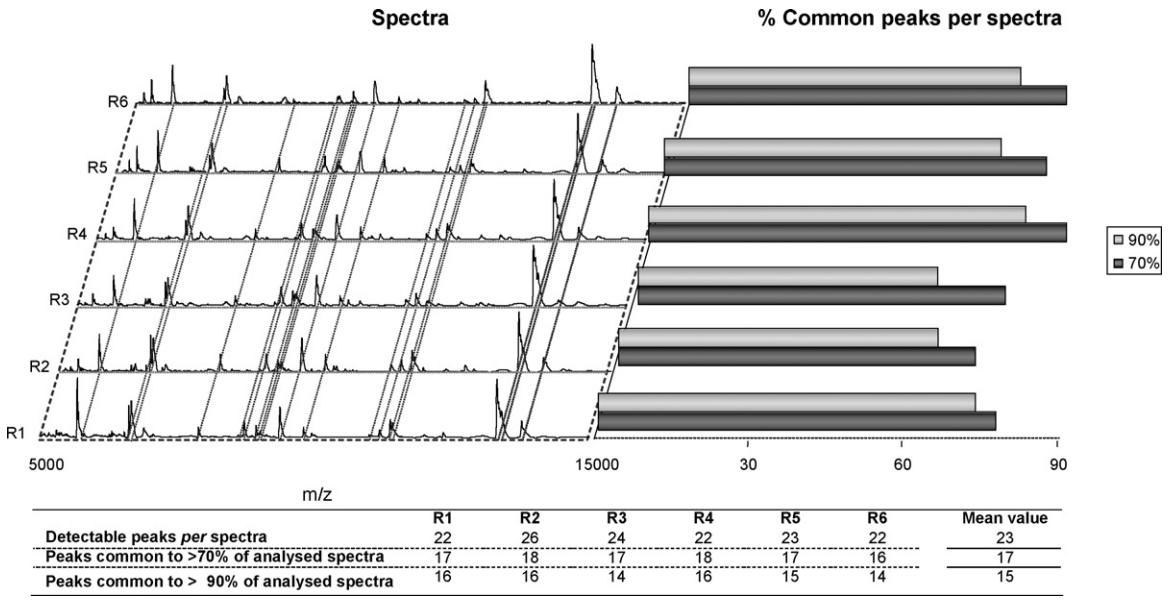
3.2. S. frugiperda cells fingerprint evaluation and the Dissimilarity Score



ICM-MS approach was already been used to study regulation of recombinant protein production *in vivo* by monitoring the *m*/*z* peak that corresponds to the molecular mass of the over expressed protein [25]. Similarly, we examined the presence of *m*/*z* peaks corresponding to the molecular masses of the expressed viral proteins in the MALDI-MS fingerprint of the intact insect cells, but no matching peaks were observed. This could be explained by the fact that the viral proteins VP6 and VP7 are secreted from the insect cells into the culture media, being the VP2 protein the only one that accumulates in the cellular cytoplasm. However, VP2 protein has a molecular mass of 102 kDa, making it more difficult to detect since MALDI ionization efficiency is reduced with protein size. Our strategy was then to evaluate if protein production could be indirectly monitored *in vivo* by studying the real-time changes in the MALDI-MS fingerprints of the intact insect cells during the bioreaction events.

For this purpose, some factors such as cell growth phase on bioreactor or cell stress caused by baculovirus infection had to be evaluated, since they can imply changes on the insect cell's fingerprint, independently of the changes imposed by the production of the viral proteins. In order to evaluate the contribution of these factors to the acquired spectra pattern and reproducibility, we have undertaken assays with *S. frugiperda* Sf-9 cells collected from two different experiments. In *Control* 1, insect cells were simply left under optimal growing conditions in the bioreactor for 5 days. In *Control* 2, insect cells were infected with "empty" wild type baculovirus allowing evaluation of the infection impact on insect cell MALDI spectra fingerprint. For both experiments, ICM-MS spectra were acquired using the optimized conditions previously described for the various insect cell pellets, corresponding in total to 11 time checkpoints (approximately 12 h cycles) of the real bioreactor productions.

After MS data acquisition and processing, 11 *m*/*z* peak lists were generated for each control group assay and submitted for consensus analysis. In SPECLUST, a new list is generated per control group containing the *m*/*z* values for the detectable peaks, where the mean *m*/*z* value is included in the *common* peaks. A simple mathematical expression has been developed to estimate the insect cell fingerprint differences between groups of submitted spectra. The Dissimilarity Score, *dS* (Eq. (1)), is the ratio between the total number of *m*/*z* peaks in the list generated by the *consensus analysis*, P|x|, and the mean number of *m*/*z* peaks per spectrum list in the analyzed group, which represents the mean value of the number of detectable peaks per spectra, |Px|; where *n* represents the number of spectra to be compared.

$$dS = \frac{P|x|}{|Px|}, \quad 1 < dS < n \tag{1}$$

Equal spectra have the same number of *m*/*z* peaks as the number of peaks in the list generated by the *consensus analysis* P|x|, and it will be equal to the mean number of detectable *m*/*z* peaks per spectra |Px|. So when comparing equal spectra, the Dissimilarity Score value is 1 ($dS = 1$).

	R1	R2	R3	R4	R5	R6	Mean value
Detectable peaks *per* spectra	22	26	24	22	23	22	23
Peaks common to >70% of analysed spectra	17	18	17	18	17	16	17
Peaks common to > 90% of analysed spectra	16	16	14	16	15	14	15

Fig. 2. Inter-spectra variability inherent to sample preparation method. Six MS spectra (R1–R6) were acquired after direct spotting of cell suspension: DHAP matrix solution (1:1) onto the MALDI plate. An average of 23 *m*/*z* peaks was detected *per* spectrum, 15 and 17 of them are common to at least 90% and 70% of the analyzed spectra, respectively. Vertical lines match common *m*/*z* peaks.

By opposition, if the compared spectra are completely different with no common peaks in the submitted spectra, the Dissimilarity Score will have the maximum value, equivalent to the number of peak lists that were submitted.

The Dissimilarity Score values are only comparable when submitting the same number of MS spectra per group. In the present work, we have analyzed 11 time checkpoints on cell samples collected from each bioreaction run, which allowed comparing *dS* between different kinetic experiments.

Higher *dS* values correspond to stronger differences among *m*/*z* peak lists of the analyzed time checkpoints. This indicates the occurrence of more extensive modifications on the insect cell fingerprint during the kinetic experiment. This becomes obvious when comparing the insect cells fingerprint variation along time in both experiments (Fig. 3). In *Control* 1 group, there are about 20 *m*/*z* peaks common to 70% of the spectra and 10 common to 90% of the spectra. This is within the estimated spectra variability (15 peaks common to 90% of the spectra in a total of 23 detectable peaks), meaning there are no apparent changes in the fingerprint along the time. In contrast, in *Control* 2, the number of common *m*/*z* peaks decreases to 13 when considering 70% of the spectra and 5 when considering 90% (in a total of 34 detectable peaks). These values are considerably lower, and show that after infection, the insect cells fingerprint changes throughout time. This is also

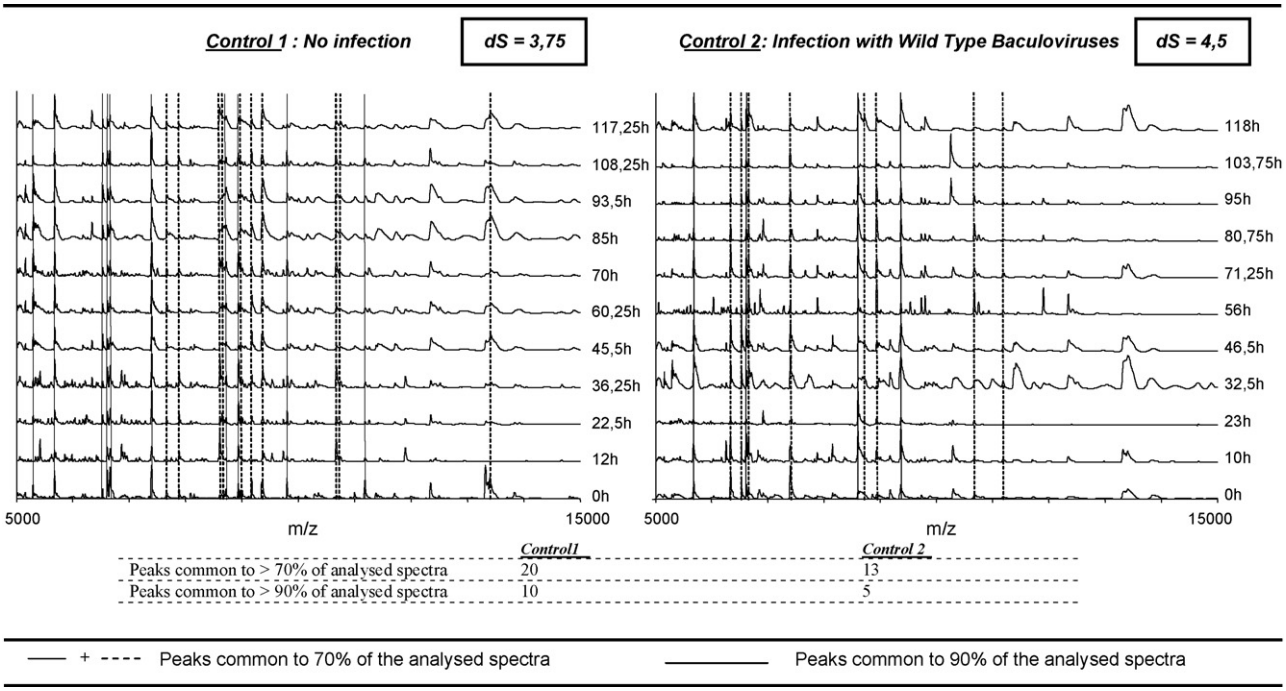


Fig. 3. Sf-9 intact cell fingerprints. Intact cell fingerprints along time for non-infected (*Control* 1) and infected (*Control* 2) are presented in the left and right side, respectively. A strong variation of the fingerprint along the kinetic experiment was observed for the insect cells infected with wild type baculovirus, in accordance with the calculated *dS* values. Vertical lines match common *m*/*z* peaks.

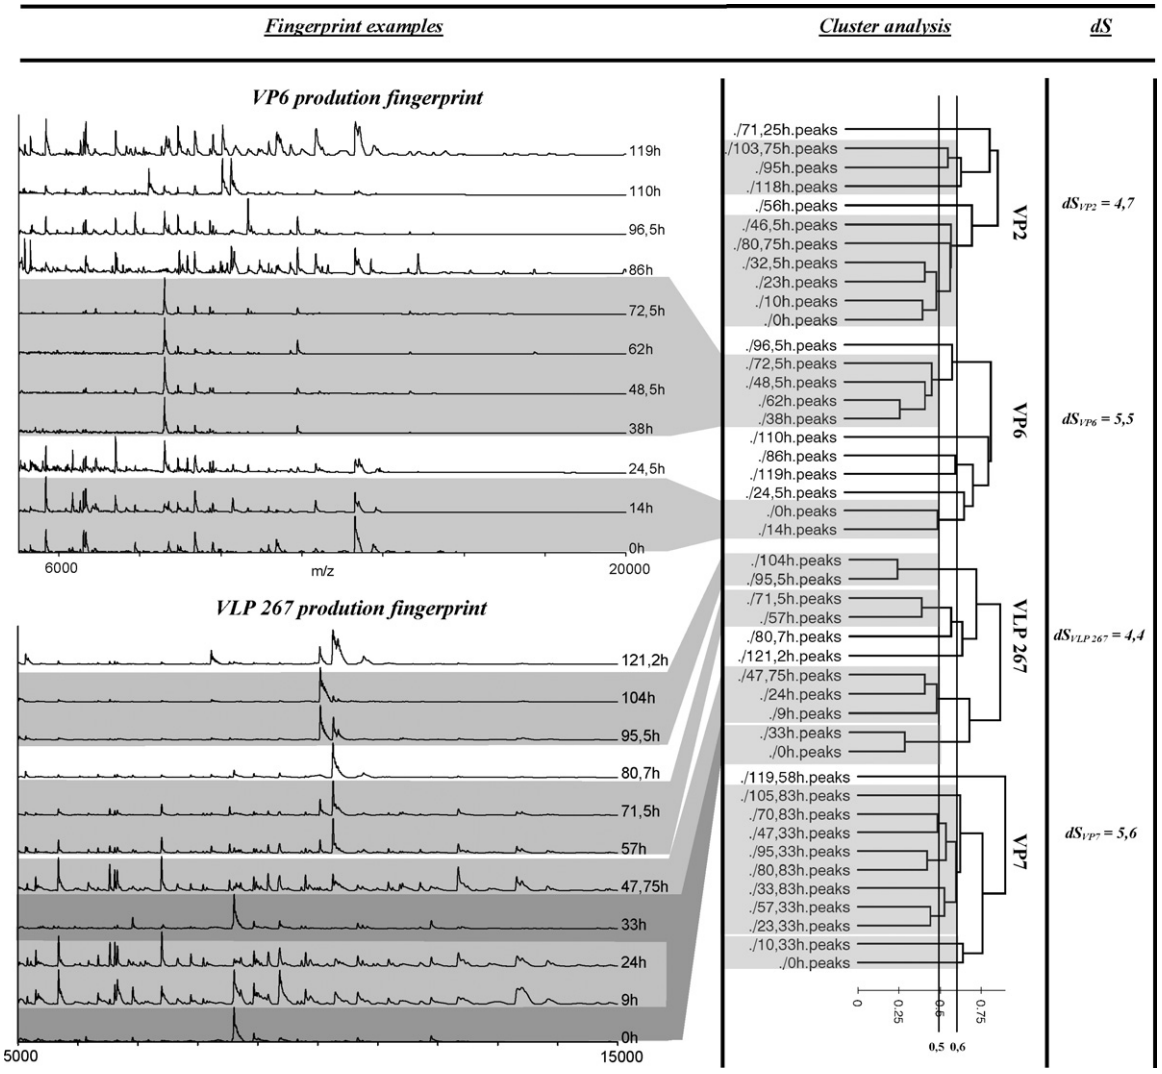

Fig. 4. Fingerprinting the production of VP2, VP6, VP7 and VLP2/6/7 in the Sf-9 cells. Cluster analysis was performed, for each group, using SPECLUST in order to evaluate the changes within time for each production run (middle column) and the Dissimilarity Scores were calculated (right column). Two examples of insect cell fingerprints for individual productions are shown (left column) and the determined similar groups in the correspondent dendograms are highlighted in grey. The grouping of the cluster analysis is consistent with fingerprint changes as judged by visual inspection.

confirmed by the values of the Dissimilarity Score. For both groups the score limits are 1 for ideally equal spectra and 11 for spectra without common peaks. For *Control* 1 $dS = 3.75$ is lower than *Control* 2 $dS = 4.5$, which confirms that insect cells fingerprint in *Control* 2 group suffers more changes along time than in *Control* 1. Apparently, optimal bioreactor working conditions without other external *stimuli* do not cause changes in cells fingerprint. However, significant changes could be detected when infection is induced.

3.3. Fingerprinting the bioproduction of VP2, VP6, VP7 and VLP 267 in insect cells by ICM-MS

So far, it has been proved that the infection process itself induces fingerprint changes on insect cells, but there is still a question left to answer: if fingerprint evolution is affected by the infection mode and assembly of VLP's. Two possibilities were evaluated: infection with baculovirus expressing one recombinant protein and co-infection with three baculovirus for co-expression of three recombinant proteins. To address this question, the groups of fingerprints for each viral protein production were analyzed using two different approaches: (i) the *Dissimilarity Scores* were calculated for each group and (ii) a cluster analysis was performed for each kinetic experiment using SPECLUST.

By comparison of the *Dissimilarity Score* values for the kinetic experiments, it is possible to detect changes in the MS profiles of the insect cells along the production time when the viral proteins are produced separately (VP2 or VP6 or VP7) or when VLP's are produced by co-expression of the three genes (VP2, VP6 and VP7). All the determined values are above the *dS* for *Control* 1 (3.75) where no relevant fingerprint changes occurred. For insect cells producing VP2, VP6, VP7 and VLP 2/6/7, the *dS* are 4.7, 5.5, 5.6 and 4.4, respectively. These values are in accordance with a visual comparison of the spectra, showing fingerprint profile changes for each bioproduction opposed to more stable fingerprints in *Control* 1 (Fig. 4).

In order to analyze these changes in further detail, we performed a *hierarchical clustering* of the mass spectra for each group. The main goal was to compare and correlate results from a Western blot traditional assay with the obtained ICM-MS spectra from insect cells in the various stages of the protein production.

In the SPECLUST cluster analysis, each m/z peak list is initially assigned to its own cluster. Distances are calculated between each pair of m/z peak lists. The closest pair is found and merged to a new cluster. Distances between the new cluster and each of the old

clusters are calculated. This procedure is repeated until there is only one single cluster. Then, a score for matching m/z peaks is created, where the similarity between two m/z peak lists is calculated. This is then translated into a distance measure, which varies between 1 for completely different set of m/z peaks, and zero for a perfect match. This is the starting point in clustering the m/z peak lists and building a dendogram.

To interpret the cluster analysis of the insect cells fingerprints, it was verified that, for distances smaller than 0.6 in the dendograms scale, the grouped spectra were similar [50]. Considering this scale limit, several interesting spectra grouping occurred in each protein/particle production. In detail, for insect cells producing VP2 there are two main spectra groups formed in the dendogram (Fig. 4), one representing times 0–46.5 h and another spectra group that includes the three last time points, collected from 96.5 to 119.0 h.

When comparing with methods routinely used to monitor protein production during bioreaction (e.g. Western blot), in the first group of similar spectra, the turning point in fingerprint change is at 46.5 h, which is consistent with an increase of intracellular protein concentration value related to the initiation of VP2 production (Fig. 5A). The second group of similar spectra (96.5 to 119.0 h) is distinct from the first one, corresponding to the terminus of the bioproduction process. It has been previously reported that VP2 accumulates intracellularly when VP6 is not co-expressed [48]. There are still two time points remaining, 56.0 and 71.2 h, where the spectra are distinct from one and other and from the two formed groups. This is possibly related to a temporary decrease in cell viability (data not shown).

In cells producing VP6, there is also fingerprint grouping which can be related to biological events. Two main groups of similar spectra (Fig. 4) were obtained: the first group includes the time points 0.0 and 14.0 h, which is, in fact, the starting of the protein production (Fig. 5B). In the second group, spectra are similar from the 38.0 to 72.5 h time points, which is consistent with a stable intracellular concentration of VP6 (Fig. 5B). In the last phase of protein production the data do not correlate with each other, which is in accordance with random variation in the intracellular protein concentration, possibly associated with protein excretion events.

VP7 is a glycosylated secreted protein, an interesting correlation with the results obtained in the Western blot analysis is observed. There seems to be two groups of similar spectra: time points 0.0 and 10.3 h, and the rest of the time points. For the first group intracellular VP7 concentration is almost zero, however, after this time period its concentration increases and is maintained constant till the end of the bioreaction (Fig. 5C). This behavior is eventually related to the fact that VP7 is secreted to the extracellular medium early in the bioreaction process, thus, it does not accumulate intracellularly, and it does not trigger major fingerprint changes.

For the VLP 2/6/7 particle production, insect cells undergo even more complex biological processes: infection and replication of three monocistronic baculovirus, the co-expression of three recombinant proteins, and their assembly into VLPs, among other important events. There is a curious phenomenon of spectra grouping, due to similarity between distant time point's fingerprints (Fig. 4). This is observed up to 47.8 h post-infection, where the points 0.0 and 33.0 h group together as so do points 9.0–24.0 h and 47.8 h. These variations in intracellular total protein concentration are eventually related to the several steps involved in the baculovirus replication process, in which baculovirus proteins are expressed (Fig. 5D).

3.4. Infection stress versus viral protein production: distinct specific fingerprints?

Firstly, since it was determined that the infection process itself induces fingerprint changes on the insect cells, it was decided to evaluate if the fingerprint changes of the insect cells producing viral particles and proteins were different and could be correlated with a particular kinetics of viral protein production. Secondly, we tried to understand if the fingerprint changes were specific of each particular recombinant protein being produced with this expression system. To address these questions dendograms were constructed using both the fingerprints of the different protein kinetics and the fingerprints of *Control* 2 (Fig. 6). Taking into account the cluster analysis results, the overall conclusion is that the fingerprint of the first time points of the infection are similar either for infection with wild type baculovirus and for cells producing the different viral proteins. This reveals that in these first time points, fingerprints show only the contribution of the infection processes and infection stress related events. As infection proceeds in time, fingerprints start to differentiate from the initial time point pattern, and no longer are similar with the fingerprint of cells infected with wild type

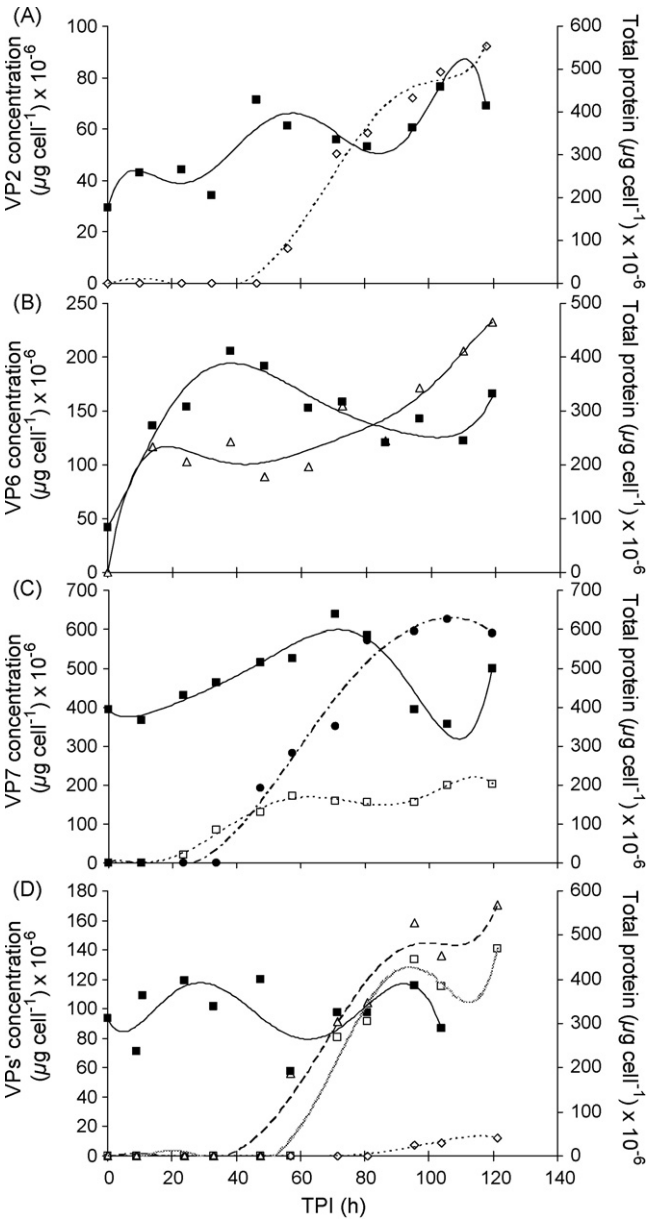

Fig. 5. Kinetics of VP2 (A), VP6 (B), VP7 (C) and VLP 2/6/7 (D) production and total protein concentration. Intracellular VP2 (◊), VP6 (△), VP7 (□) and extracellular VP7 (●) concentration were calculated from densitometry analysis of Western blot bands using a VLP standard for calibration. Intracellular total protein concentration (■) was measured with BCA assay.

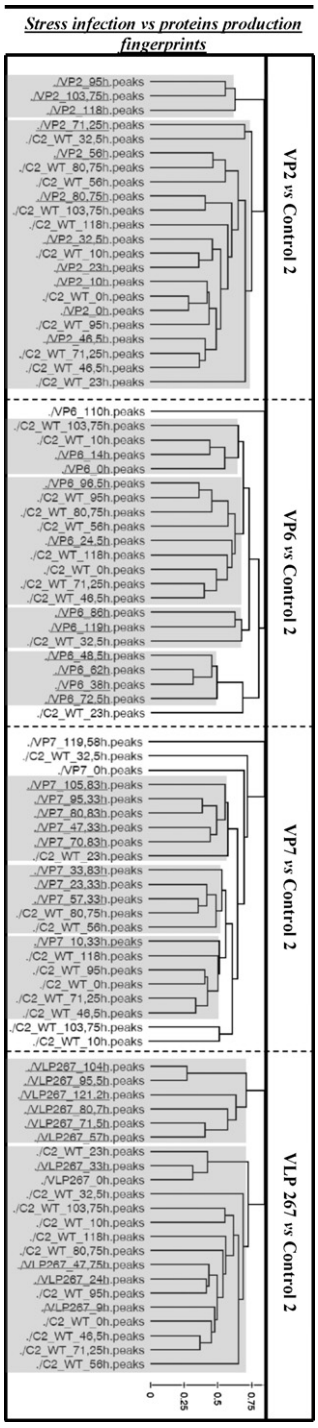

Fig. 6. Comparison of viral protein production with cell stress caused by baculovirus infection. Cluster analysis of insect cells fingerprints of each viral protein production and from infected insect cell (*Control* 2).

baculovirus. This indicates that the production of each viral protein or VLP has an impact on insect cell fingerprint. To determine if each fingerprint change, for the production of a particular viral protein or VLP is specific and unique, cluster analysis was also performed comparing pairs of two of all protein production (data not shown) (VP2 vs. VP6; VP2 vs. VP7; VP2 vs. VLP 2/6/7; VP6 vs. VP7; VP6 vs. VLP 2/6/7; VP7 vs. VLP 2/6/7). This cluster analysis shows that each fingerprint profile depends on the specific protein(s) that is (are) being produced, showing the same cluster behavior as described for the comparison of each protein(s) production(s) with *Control* 2, where only the fingerprints of the first time points are similar.

4. Discussion

The usefulness of mass spectrometry approaches in bioanalysis of recombinant protein from biotechnological production has already been described when using liquid chromatography coupled with a mass spectrometer [49] as being *potentially useful as it may offer rapid development and improved assay specificity*. In this paper we present a new application for the described mass spectrometry method *intact cell MALDI-TOF MS* (*ICM-MS*). This MALDI-MS approach has application in the biotechnological industry allowing monitoring the production of viral proteins and virus-like particles. This technique is presented here as a complementary analytical method to monitor recombinant protein production during bioreaction and using the established pattern for the expression system/recombinant protein produced. Herein this method has been optimized for insect cells/baculovirus expression system and the production of Rotavirus proteins and virus-like particles. The experimental results obtained show that this is a highly reproducible method for each recombinant protein that allows checking if production is in fact occurring, by monitoring fingerprint changes observed when insect cells are producing the viral proteins. Moreover, the proposed method indicates the bioproduction phase allowing monitoring the lag periods. These fingerprint changes are independent of cell stress due to infection and are characteristic of each protein or VLP production.

This very simple, fast (10 min sample preparation) and low cost assay requires low sample volumes and can be used as a complement or even as a substitute of common analytical methods for bioproduction monitoring. However, careful method optimization is still required when applied to other biological samples, since sample preparation procedure can be substantially different.

ABSTRACT

Protein thiols contribute significantly to antioxidant defence and selective oxidation of cysteines is important in signal transduction even in sub-stress scenarios. However, cysteine is the second rarest residue in proteins and it can be difficult to target low-abundance thiol (–SH)-containing proteins in proteomic separations. Activated thiol sepharose (ATS) allows covalent selection of –SH-containing proteins which can then be recovered by reduction with mercaptoethanol or dithiothreitol. This is a robust method for enriching –SH-containing proteins. We have used ATS to estimate the percentage (by weight) of thiol-containing proteins in cell extracts from a range of biological sources: a bacterium, *Escherichia coli*; a fungus, *Trichoderma harzianum*; and a bivalve mollusc *Mytilus edulis*. –SH-containing proteins account for 2.52% (*E. coli*), 1.4% (*T. harzianum*) and 1.4% (*M. edulis*) of total protein. Exposure to pro-oxidants did not materially alter these values. On removal of low M_r thiols such as glutathione, the values for *M. edulis* did not significantly change but those for *T. harzianum* increased threefold. The two-dimensional electrophoresis profiles of ATS-selected proteins for each organism were compared in control and pro-oxidant-exposed preparations. This revealed that some proteins present in controls were absent in pro-oxidant-treated extracts which we attribute to thiol oxidation. ATS has significant potential in enrichment for –SH-containing proteins in redox proteomics.

1. Introduction

Since the adoption of aerobic metabolism as the most efficient means to convert food such as glucose into biologically useful energy, cells have been faced with the "oxygen paradox"; oxygen is essential for aerobic metabolism but inevitably produces highly toxic derivatives such as the superoxide radical, H_2O_2 and the hydroxyl radical [1,2]. These and related species, collectively referred to as reactive oxygen species (ROS), can react with cell components at rate constants approaching, in some cases, diffusion-limited values [1]. Cells have evolved impressive defences against ROS such as the antioxidant glutathione (GSH) and enzymes such as peroxidase, superoxide dismutase and catalase [1] and these maintain a state of redox homeostasis in normal cell functioning. However, if these defences are overwhelmed by an over-supply of ROS, or a decrease in antioxidant defence (e.g. on ageing), a state of oxidative stress results [3] which is often a feature of important human pathologies [3–6].

Proteins absorb ~70% of ROS and this causes covalent changes to amino acid side-chains with the potential to complicate the proteome [1–3]. Redox proteomics often focuses on comparisons of protein profiles of control to those of oxidatively stressed cells [7]. Sulphur-containing residues are especially susceptible to oxidation. Methionine is oxidised sequentially to methionine sulphoxide and sulphone and accumulation of oxidised methionine variants in proteins is a marker for ageing [8]. It has been suggested that methionines may contribute to antioxidant defence by buffering transient ROS increases [8]. Cysteine, the second rarest residue in proteins after tryptophan, is often evolutionarily conserved and possesses functional significance [2]. Oxidation of the cysteine sulphydryl group (–SH) can form sulphenic (–SOH), sulphinic ($-SO_2H$), sulphonic/cysteic ($-SO_3H$) acids, inter-/intra-chain disulphide bridges (–S–S–) or thiolsulphinates [1,2]. Oxidation to –SOH and –S–S– is thought to be

doi:10.1016/j.talanta.2009.10.047

reversible *in vivo* whilst oxidation to $-SO_2H$ or $-SO_3H$ is largely irreversible leading to protein degradation [1,2]. In response to oxidative stress, protein thiols form intra-/intermolecular –S–S– or mixed disulphides with GSH [9,10]. It is increasingly thought that, even under sub-stress conditions, protein thiols can be selectively converted to sulphenic acid with a role in redox signalling [11,12]. Some proteins key to triggering/regulating apoptosis (e.g. NEMO, ASK-1, STRAP, GAPDH, SAG) alter their disulphide bridge structure as part of their activation and a similar redox-sensitivity has been found in some microbial proteins [13–19].

A shortcoming of traditional two-dimensional electrophoresis (2DE) approaches is the fact that it can be difficult to detect or identify low-abundance proteins [20]. This can be overcome by enriching for proteins carrying particular structural features such as glycosylation [21] or phosphorylation [22]. Because of their importance as targets in redox proteomics and yet low-abundance, thiol-containing proteins have been tagged or enriched for studies of oxidative stress and redox signalling [13,23–26]. *N*-Ethyl maleimide (NEM)–biotin conjugates react with available –SH groups and can be selected on avidin columns [25]. Similarly, biotin-conjugated iodoacetamide has been used to trap thiol-containing proteins with low thiol pK_a values in competition with hydrogen peroxide [27]. The difficulties raised by non-specificity of reagents and the need for chemical derivatization to visualise reversible oxidations have been reviewed [28]. Because biotin–avidin binding is a non-covalent binding process, it has limitations including variable binding efficiencies and a need to avoid detergents or chaotropic agents which may be necessary to disrupt protein–protein interactions.

Activated thiol sepharose (ATS) is a commercially available, thiol-specific resin with an activated disulphide structure which reacts efficiently with –SH groups to form a covalent mixed disulphide linkage. The resin has previously been used in a column format for protein purification [29] but has only occasionally been used in a batch format suitable for proteomics work [30,31]. Protein thiols represent some 69% of total cell thiols in cultured human cells with the remainder being contributed by GSH [9]. As has previously been suggested for methionine [8], protein thiols act as an active redox buffer which is actually more quantitatively important than GSH [9]. In eukaryotes, protein thiols seem to account for 2–3% of total protein [9,32]. In this paper, we have used ATS-based covalent selection of –SH-containing proteins from three disparate biological extracts (*Escherichia coli, Trichoderma harzianum and Mytilus edulis*) as a means of enriching for SH-containing proteins in redox proteomics studies. We have quantified the percentage by weight of applied proteins trapped by ATS and find generally comparable values for all extracts to those previously reported for eukaryotes [9]. From this we conclude that ATS provides a robust and generally applicable one-pot route to enriching for the thiol proteome.

2. Materials and methods

2.1. Materials and reagents

Culture components for *E. coli*, dithiothreitol (DTT), urea and all other general reagents suitable for electrophoresis were purchased from Sigma (Poole, Dorset, UK). *T. harzianum* (strain IMI 393899) was maintained on potato dextrose agar (PDA, Oxoid Ltd., Basingstoke, UK). ATS was purchased from GE Healthcare, Little Chalfont, Bucks, UK. *M. edulis* was sampled from a previously used intertidal reference site in Cork Harbour, Ireland [33].

2.2. Culturing and handling procedures

2.2.1. E. coli

E. coli strain DH5α available in our laboratory was grown on LB-agar plates. Single colonies were selected for culture in LB broth. Pre-cultures (10 ml) were grown under constant agitation overnight and then added to 250 ml cultures for growth for an 8-h period at 37 °C with constant agitation until OD_{600} reached 0.4. These cultures were grown in control condition and also in the presence of 1 mM menadione. Cells were collected by centrifugation at 10,000 × *g* for 10 min.

2.2.2. T. harzianum

T. harzianum (strain IMI 393899) available in our laboratory was maintained on PDA. Conidia were collected using 10 ml sterile dH_2O and 15×10^6 spores were used to inoculate 150 ml of Czapek-Dox broth supplemented with 10 ppm of $CdCl_2$ in Roux flasks. Control cultures were grown in the same medium but lacking $CdCl_2$. Fungal mycelia were grown at 24 ± 1 °C for 8 days.

2.2.3. M. edulis

M. edulis was sampled from Cork Harbour, Ireland, at low tide, acclimated for a week in 50-l tanks containing natural aerated seawater collected from Bantry Bay, Ireland. They were kept in a 12-h light/dark cycle, at temperature of 15 °C, fed and with regular water changing (48 h intervals; Phytoplex™ phytoplankton feed, Kent Marine Inc., Acworth, GA, USA). There were three groups of five animals for each treatment and these were exposed (24 h) to 10 ppm of $CdCl_2$. Control groups (3 × 5 animals) were treated identically but not exposed to any treatment. Compounds were poured directly into the tank water and no mortality was observed under any of the conditions used.

2.3. Preparation of protein extracts

2.3.1. E. coli

Cell pellets were collected by centrifugation at 10,000 × *g* for 20 min and suspended in HEPES buffer (10 mM HEPES (N-[2-Hydroxyethyl]piperazine-N′-[2-ethanesulphonic acid]), pH 7) for sonication (Soniprep 150) at 14 μm amplitude 10 times for 15 s with a 1 min interval (on ice). Cell debris was collected by centrifugation at 12,000 × *g* for 5 min. Protein extracts were stored at −20 °C until required.

2.3.2. T. harzianum

Mycelia were collected by filtration on Whatman filter paper, washed with 100 ml of sterile dH_2O and immediately chilled on ice. Approximately 3 g of mycelia (wet weight) was ground in a mortar to a fine powder in liquid nitrogen and was suspended in 12 ml of extraction buffer (10 mM Tris–HCl, pH 7.2; 0.5 M sucrose; 0.15 M KCl; 1 mM EDTA; 1 mM PMSF). The suspension was centrifuged at 40,000 × *g* for 40 min (Sorvall RC 5C plus), the supernatant was ultracentrifuged at 100,000 × *g* for 40 min (Beckman-Coulter Optima L-100XP ultracentrifuge) and finally filtered through 0.2 μm filter. All operations were carried out at 4 °C. Total protein content of the samples was quantified.

2.3.3. M. edulis

Digestive glands were dissected, pooled (five animals), frozen in liquid nitrogen and stored at −70 °C until required. Samples were homogenized (10 mM Tris–HCl, pH 7.2; 0.5 M sucrose; 1 mM EDTA; 1 mM PMSF), centrifuged at 20,000 × *g* for 1 h and supernatants were stored at −70 °C.

Table 1
Thiol-containing proteins retained on activated thiol sepharose.

Species	Expt. 1	Expt. 2	Expt. 3	Mean (±SD)
E. coli				
Total protein loaded (μg)	2000	2000	2000	2000
–SH-containing protein (μg)	58	51.6	41.6	50.4 ± 8.26
% Retained	2.9	2.58	2.08	2.52 ± 0.41
T. harzianum				
Total protein loaded (μg)	2000	2000	2000	2000
–SH-containing protein (μg)	27	29	28	28 ± 1
% Retained	1.45	1.4	1.35	1.4 ± 0.05
M. edulis				
Total protein loaded (μg)	2000	2000	2000	2000
–SH-containing protein (μg)	30	13.4	40.8	28.06 ± 13.8
% Retained	1.5	0.67	2.04	1.4 ± 0.69

2.4. Protein estimation

Protein content was calculated by the method of Bradford using bovine serum albumin (BSA) as a standard [34]. Protein estimations were performed in triplicate and the percent protein retained on ATS was calculated from a known amount of total protein applied. Data from three independent experiments are shown for each organism studied.

2.5. ATS selection of thiol-containing proteins

All buffers used during this procedure were first filtered using 0.2 μm nitrocellulose membranes (ProTran, Schleicher & Schuell, Dasel, Germany) and degassed to reduce air oxidation. A detailed description of the method used is described elsewhere [35]. Briefly, extract samples (2 mg protein) were diluted with urea stock solution to 5 M final urea concentration and incubated in Eppendorf tubes for 10 min at room temperature to unfold protein. ATS (20 mg unswollen resin) and 200 μl binding buffer solution (0.1 M Tris–HCl, pH 7.5; 0.5 M NaCl; 1 mM EDTA) were then added, followed by incubation on ice for 1.5 h with gentle shaking every 15 min. Samples were washed 8 times (500 μl binding buffer), centrifuged (11,000 × *g* for 3 min) after each wash, and supernatants discarded to remove unbound proteins. Elution buffer (200 μl; binding buffer containing 25 mM DTT) was added to sample after the final washing step and beads were incubated for 1 h with gentle shaking every 15 min to release SH-containing proteins. Samples were centrifuged briefly and supernatants collected.

2.6. Two-dimensional electrophoresis

Non-protein contaminants were first removed from protein aliquots (200 μg) by precipitation in 10% (w/v) trichloroacetic acid followed by centrifugation (10,000 × *g* for 10 min) and then washed with acetone. The resulting pellet was re-suspended in rehydration buffer containing 5 M urea, 2 M thiourea, 2% (w/v) CHAPS, 4% (w/v) carrier ampholyte (Pharmalyte 3–10, GE Healthcare), 1% (w/v) DeStreak reagent (GE Healthcare) and a trace amount of bromophenol blue. Proteins (20 μg) were loaded on 7 cm pH 3–10 non-linear immobilised pH gradient (IPG) strips (BioRad, Hercules, CA, USA) and rehydrated overnight for at least 15 h. IPG strips were focused on a Protean IEF Cell (BioRad) with linear voltage increases. Following IEF, strips were equilibrated (20 min) in equilibration buffer (6 M urea; 0.375 M Tris, pH 8.8; 2% (w/v) SDS; 20% (v/v) glycerol) containing 2% (w/v) DTT, and then for 20 min in equilibration buffer containing 2.5% (w/v) iodoacetamide. Equilibrated strips were embedded in molten agarose (0.5%; w/v) containing trace bromophenol blue atop 12% (w/v) SDS–polyacrylamide gels, and electrophoresed at a constant voltage (150 V) at 4 °C using an Atto AE-6450 mini PAGE system (Atto, Tokyo, Japan) until the dye front reached the end of the gel. After separation, gels were silver-stained [36] followed by densitometry scanning.

2.7. Removal of low M_r thiols

In the case of *T. harzianum* and *M. edulis*, the effect of removal of low M_r thiols such as GSH was studied. Extracts were concentrated to a final volume of 1 ml and diluted with 5 volumes of extraction buffer followed by desalting on Ultra-15 Centrifugal Filter Devices (3000 NMWL, Amicon). This process was repeated three times. ATS was then added to 2 mg protein aliquots as described in Section 2.5.

2.8. Statistical analysis

Data are shown for three independent experiments and means and standard deviations were calculated. Significance testing was by paired Student's *t*-test.

3. Results

3.1. Activated thiol sepharose capture of –SH-containing proteins

Accurate protein estimations were made of the quantity of –SH-containing proteins retained on ATS from control extracts (Table 1). For the bacterium *E. coli* the average value was 2.6%, for the fungus *T. harzianum*, it was 1.4% whilst for the bivalve mollusc *M. edulis* the value was 1.39%. Despite the fact that there is some variation in total protein concentrations of the differing extracts, there is remarkably good agreement in the percentage of proteins captured both across each preparation experiment and each species studied suggesting that resting cells contain broadly similar percentages of thiols. In redox proteomics, it is often of interest to study effects of pro-oxidants on populations of –SH-containing proteins and ATS has an important potential role in making such comparisons. We therefore subjected each study species to known pro-oxidants; the redox cycling agent menadione in the case of *E. coli* and the metal $CdCl_2$ in the case of *T. harzianum* and *M. edulis* (Fig. 1). This showed no significant difference in percentage of –SH-containing proteins retained on ATS.

3.2. Contribution of low M_r thiols to retention estimate

It is known that GSH is present in cells in high concentrations both in free form and as mixed disulphides with proteins [9]. It was therefore of interest to assess whether low M_r thiols like GSH might influence our estimate of retained thiols. We removed low M_r thiols by repeatedly passing aliquots of total protein extracts of *T. harzianum* and *M. edulis* through centrifugal concentrators with

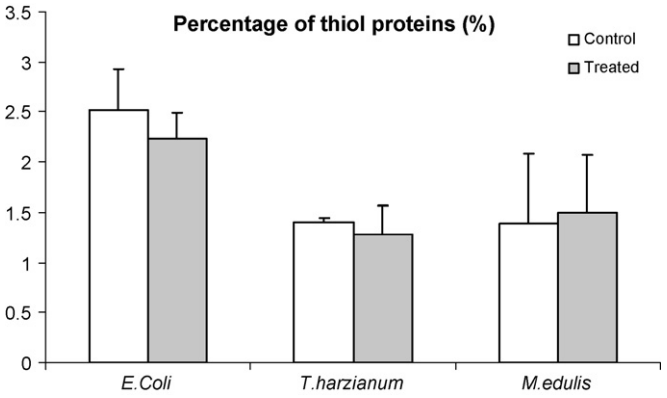

Fig. 1. Percentage of thiol-containing proteins trapped on ATS: mean values of three independent estimates for percentage –SH-containing proteins are shown (±standard deviation) for control (white bars) and pro-oxidant-treated organisms (grey bars).

a size-exclusion of 3 kDa and again capturing –SH-containing proteins on ATS (Fig. 2). This gave a higher estimate of retained thiols in each case with the apparent value for *M. edulis* almost doubling to 2.17% and that for *T. harzianum* almost tripling to 5.08%. The latter increase was statistically significant whilst the former was not. This experiment suggested that it may not always be routinely necessary to remove endogenous GSH from protein preparations as it has a modest effect on the ability of ATS to capture protein thiols. This is generally consistent with recent observations on the proportionately greater contribution of protein thiols than GSH in mammalian cultured cells [9].

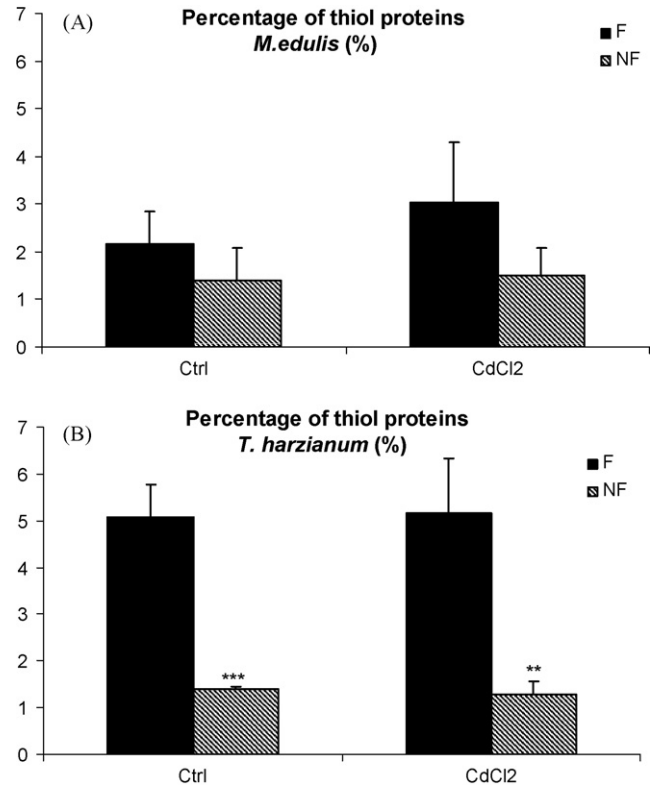

Fig. 2. Effect of removal of low M_r thiols by filtration: (A) *M. edulis* digestive gland. (B) *T. harzianum* mycelia. Samples from control and $CdCl_2$-treated organisms were selected on ATS and filtered through 3 kDa centrifugal concentrators (F, black bars). Percentages of proteins trapped on ATS are compared with non-filtered extracts (NF, hatched bars) (***$p < 0.001$ and **$p < 0.01$).

3.3. Two-dimensional electrophoresis analysis of ATS-retained proteins

One of the principal techniques used in proteomics is 2DE [20]. ATS is a potentially generally useful method for enriching SH-containing proteins to allow their visualisation, quantification or detection in 2DE. A common proteomic comparison often made in redox proteomics is of protein populations exposed to pro-oxidants with non-exposed controls. Pro-oxidants can cause covalent changes to protein structure which are detectable in 2DE [7] and can also cause up- or down-regulated proteomic changes. Comparisons of ATS-selected proteins from test and pro-oxidant-exposed organisms are shown in Fig. 3. These reveal that, whilst most spots are identical in control and pro-oxidant-treated samples, there are subtle differences in which a relatively small number of spots are either weakened or disappear altogether on pro-oxidant treatment. It is known that cysteine is especially susceptible to oxidation, so we interpret this phenomenon as most likely being due to oxidation of –SH groups. It is known that oxidised variants of –SH (like disulphides and sulphenic acids) have very different chemistries and will not bind to thiol-specific reagents or (in the context of the present paper) undergo disulphide exchange to bind to ATS. This resin therefore provides a potentially powerful tool for distinguishing variants in thiol status when comparing proteomes.

4. Discussion

In addition to their potential toxicity at high dose, ROS are now known to be important signalling molecules in biological systems [28,37]. Thus, redox proteomics faces the challenging task of studying large-scale protein oxidation in which gross effects are seen on perhaps very abundant protein targets and more subtle redox effects perhaps involving low-abundance proteins.

4.1. Importance of cysteine as a target in redox proteomics

Cysteines are relatively rare in proteins but they have increased in frequency during evolution and are often conserved in protein families [38]. Some proteins exploit cysteine's redox chemistry in defence against oxidative stress but also in sub-stress redox signalling which makes them especially attractive targets for redox proteomics [9–12,27]. The properties of cysteine's thiol group are crucial in this regard, especially the pK_a for deprotonation. Cysteines normally have a pK_a of approximately 9 but, in some proteins, the surrounding electrostatic field of a thiol can perturb its pK_a to values as low as 4.0 [2]. These are referred to as "active thiols". Although we routinely use a pH value of 7.5 (i.e. similar to that of cytosol), we have observed that ATS binds proteins in a pH-dependent manner with some proteins binding at pH values below 6 whilst maximum binding is observed at pH 9. It is therefore likely that proteins selected at low pH values contain active thiols. These can selectively form oxidised variants such as sulphenic acid, thiolsulphinates and disulphide bridges [2,27,39]. The surrounding structural context of the thiol forms an elegant basis for selectivity whereby only some thiols in only some proteins are oxidised by a given alteration such as a change in redox status. Well-known examples of modifications with relevance to signalling include proteins that trigger apoptosis [13–15], the endogenous inhibition of the Jun N-terminal kinase by disulphide bridged glutathione transferase Pi [40] and reversible coordination to metals in some transcription and replication factors [41].

Cysteines only account for 1–2% of residues in proteins but are predicted in ~27% of tryptic peptides from the human genome allowing coverage of ~96% of proteins by shotgun MS

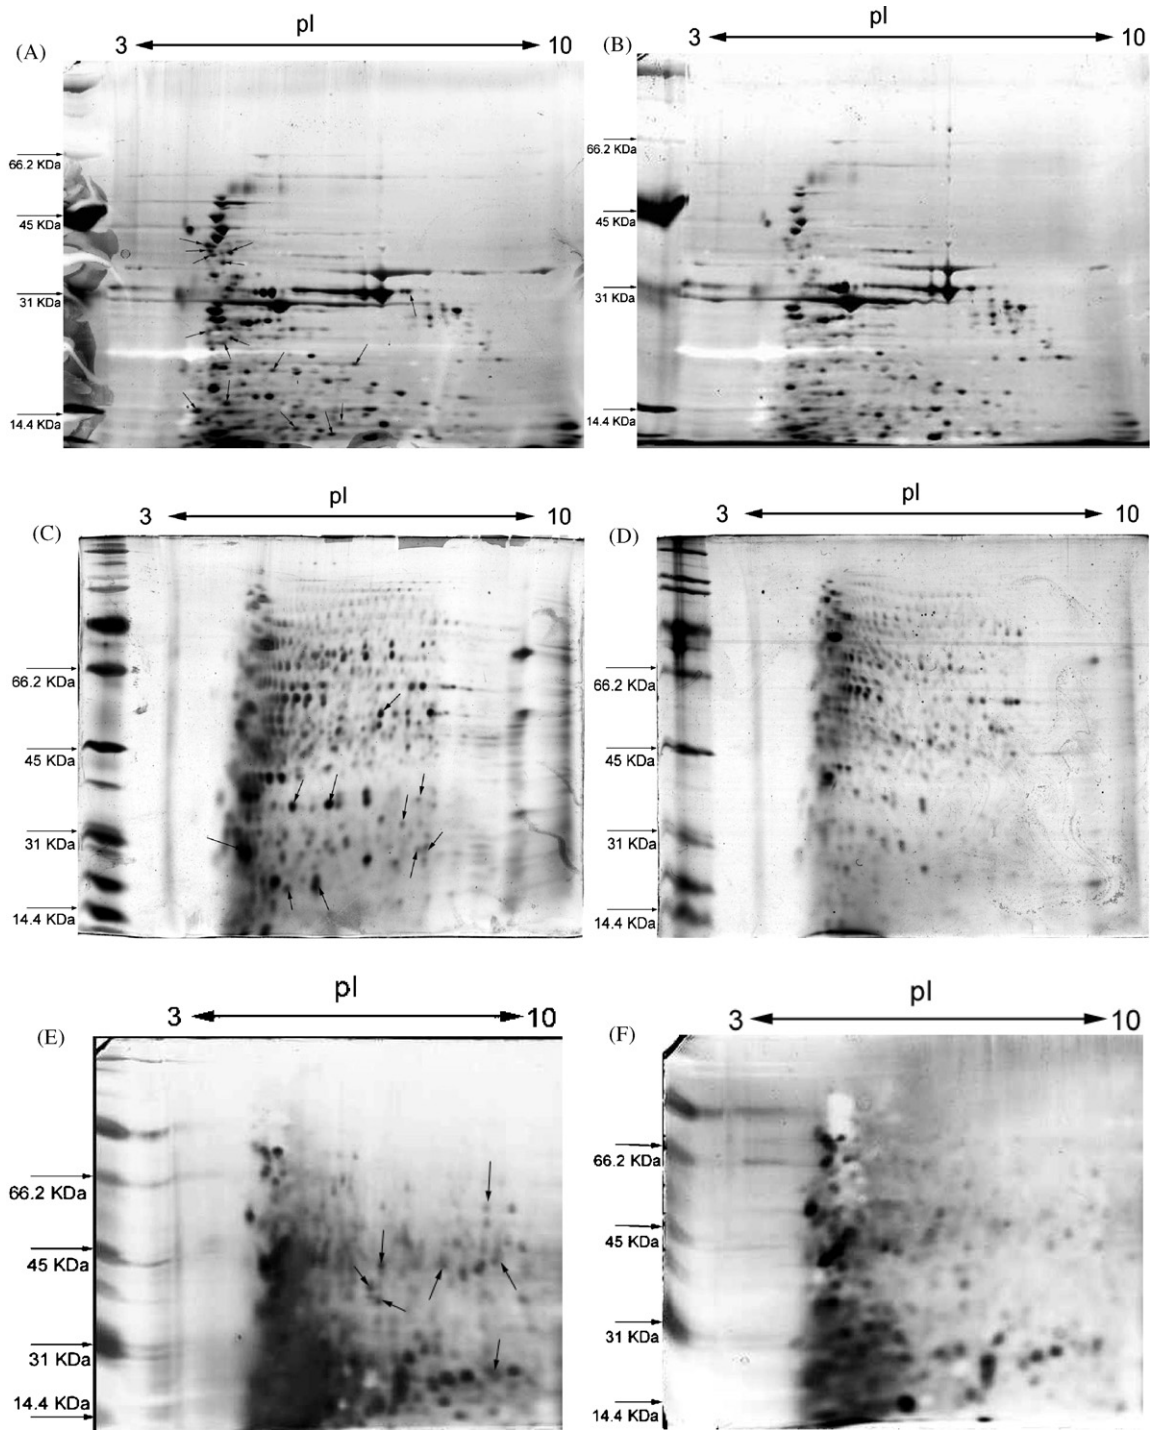

Fig. 3. 2DE profiles of ATS-selected sub-proteomes: thiol-containing proteins were selected on ATS, separated in 2DE and silver-stained. (A) *E. coli* control. (B) *E. coli* grown in menadione. (C) *T. harzianum* control. (D) *T. harzianum* grown in $CdCl_2$. (E) *M. edulis* control. (F) *M. edulis* exposed to $CdCl_2$. Proteins present in control but missing in pro-oxidant-treated profiles are shown with black arrows.

approaches [42]. In 2DE separations, tagging of cysteines has enabled identification of some redox targets [24]. However, these approaches may not detect low-abundance proteins or, even if detectable, there may not be enough material to facilitate detection by MS analysis of excised spots. For this reason, enrichment approaches involving selection of –SH-containing proteins are necessary. Biotin derivatised with –SH-specific groups such as *N*-ethyl maleimide (NEM) or biotin-conjugated iodoacetamide can be trapped on avidin affinity columns [19,27,43] and this general approach has also been applied in shotgun proteomics [44]. Study of protein thiols presents a significant analytical challenge because of the range of redox variants in proteins and difficulties presented by varying reagent specificities [28]. The present paper explores covalent selection of –SH-containing proteins as an alternative to affinity selection. ATS can select proteins under a wide range of experimental circumstances including native and denaturing conditions. Moreover, since beads can be collected by centrifugation and the proteins are covalently attached to the beads, handling losses are kept to a minimum.

4.2. Activated thiol sepharose selection of –SH-containing proteins

Pre-treatment of protein extracts with NEM completely abolishes protein binding to ATS showing high selectivity for –SH-containing proteins [35]. For general applicability, it is important to know that target proteins are being quantitatively captured and are not just a subset of proteins such as those possessing active thiols which might be expected to be more chemically reactive. GSH provides a major category of thiols in cells which both contribute to antioxidant defence and can form mixed disulphides with thiols of certain proteins with functional significance [10]. However, it has recently been shown that protein thiols are even more quantitatively important than GSH and collectively represent an active redox buffer to absorb transient increases in ROS. Thiol-containing proteins represent 2–3% of total protein in cultured human cells [9].

Sequence analyses can provide estimates of the frequency at which residues occur in genomes [38] but are not really predictive of their likely abundance in the proteome since some proteins are present in large amounts whilst others may be expressed at low levels or not at all in some contexts. It is also possible that proteomes may differ from species to species or with growth condition in terms of abundance of –SH-containing proteins. For these reasons, in this study we quantified the percentage of –SH-containing proteins binding to ATS in three widely differing biological sources. Reproducibility was ensured by carrying out a minimum of three independent experiments. Our study revealed percentage values for the three organisms which are closely similar to that reported for cultured human cells (Table 1, Fig. 1) [9]. Using the same experimental protocol, we also found kidney medulla extracts to contain 1.07% –SH-containing proteins (not shown). These observations suggest that ATS can trap essentially all thiol-containing proteins in a single step from a wide range of biological sources. Thus, ATS would have general applicability in redox proteomics studies where there is often a need to trap protein –SH groups quantitatively whilst simultaneously preventing their oxidation during experimental manipulation. This one-step, one-pot approach is complementary to the more traditional multi-step and non-covalent avidin–biotin affinity selection [19,27,43,44].

Since GSH is present in millimolar concentrations in cells, it was possible that it too would bind to ATS, possibly affecting the estimate of percentage –SH-containing proteins. For this reason, in the case of the *M. edulis* and *T. harzianum* extracts, GSH was removed by rapid desalting in centrifugal concentrators and the effect of this on the percentage thiol protein estimate assessed. This gave no effect in the case of *M. edulis* but an increased estimate for *T. harzianum* (Fig. 2). In mammals, GSH levels vary with factors such as disease state, gender and age [45,46]. This ought not to be an important factor in routine use of ATS for 2DE proteomics since most methods remove low M_r contaminants before the IEF step. However, for MS studies, it is possible that co-selection of GSH with protein thiols may lead to unwanted interference and it may be necessary to desalt extracts before ATS capture.

4.3. Use of activated thiol sepharose in redox proteomics

Having established that ATS provided a highly reproducible and quantitative method for the capture of –SH-containing proteins, it was necessary to explore its usefulness in the kinds of studies often performed in redox proteomics. Frequently, this involves comparing preparations from organisms exposed to pro-oxidants with suitable controls and looking for differences. In 2DE [7,20], this might involve analysing spot patterns to look for up- or down-regulated spots. Alternatively, specific redox lesions on proteins such as carbonyl groups might be of interest in 2DE separations [7]. –SH groups are far more readily oxidised than the formally similar –OH group because of a markedly lower bond energy in S–H compared to O–H [47]. This means that protein thiols will readily oxidise if brought into contact with ROS and this is even more likely in the case of active thiols. The reactivity of –SH groups differs markedly from that of their oxidised variants giving a useful means of distinguishing proteins containing –SH from variants containing groups such as –SOH or –S–S–. Binding to ATS involves a disulphide exchange and so is highly selective for thiols and does not bind oxidised variants of thiols. It therefore ought to be possible to compare 2DE profiles from control and oxidised extracts and identify specific spots not present in the oxidised sample due to –SH oxidation. The 2DE profiles obtained here (Fig. 3) confirm that generally similar spot patterns are obtained from matched control and oxidised preparations with hundreds of spots visible. However, close inspection reveals that several spots present in the control pattern are weaker or missing in the oxidised sample. These spots would either be too faint or invisible in 2DE analyses of total proteomes from these sources emphasising the importance of enrichment on ATS.

Further dissection of the thiol proteome is made possible by combining pre-treatment with agents such as NEM to block –SH groups with selective reduction to regenerate –SH groups from oxidised variants. Examples include selective reduction of –S–S– with DTT [24,35], reduction of –SOH with arsenite [26] and reduction of nitrosothiols by ascorbic acid or transition metals as used in the "biotin switch" assay [48]. In such experiments ATS would provide a rapid one-step method with high capacity to enrich for these sub-proteomes in which proteins can be collected by a facile reduction with DTT making them available for analysis by MS or 2DE.

5. Conclusion

ATS selects 1.4–2.52% of the total proteome in diverse microbial and eukaryote extracts. These values agree well with the predicted percentage of thiol-containing proteins observed in mammalian cell culture and are consistent with essentially complete enrichment for the thiol proteome. There is good reproducibility between independent experiments suggesting that this one-step, one-pot approach is sufficiently robust for widespread used in enriching for –SH-containing proteins in redox proteomics. We cannot exclude the possibility that GSH also binds to ATS in some protein sources and this may require inclusion of a desalting step. When combined with selective reduction of oxidised thiol variants, this capture approach could select for sub-proteomes containing disulphides, sulphenic acid and nitrosothiol derivatives of protein thiols.

ABSTRACT

The yeast *Yarrowia lipolytica* uses hydrophobic substrates, such as alkanes, fatty acids and oils, for its growth. It has developed a strategy for the use of such substrates, involving the production of hydrophobic binding structures called protrusions on the cell surface. These protrusions are resemble channels connecting the cell wall to the inside of the cell, and are probably involved in transport mechanisms that we do not yet fully understand. The complete genome of the haploid *Y. lipolytica* strain E150 (CLIB99) was sequenced in 2004 by the Génolevures Consortium. The availability of a complete genome sequence for this species has made it possible to carry out proteomic and other investigations, leading to the characterization of lipid bodies (LB) in terms of (i) their lipid composition, (ii) the major LB proteins, as identified by mass spectrometry, and (iii) differences in protein or lipid composition as a function of the carbon source used. Functional analyses would provide insight into the biological processes associated with these bodies and 2D BN/SDS-PAGE is a highly suitable method for the analysis of protein complexes.

This report provides a first description of the analysis and identification of hydrophobic binding protein complexes in *Y. lipolytica*. For this purpose, we used 2D BN/SDS-PAGE for the separation of protein complexes and HPLC-chip-MS for protein identification. We separated and identified 40 protein complexes (11 heteromultimeric and 29 homomultimeric), providing insight into their function. This study represents a major step forward, as most previous studies identified proteins either on the basis of sequence similarity to proteins from other organisms (44% of the proteins identified in this study) or by prediction (50% of proteins identified in this study) alone.

1. Introduction

Yarrowia lipolytica is a hemiascomycetous yeast that can be isolated from substrates rich in proteins and lipids, such as dairy products (e.g. cheese) and sausages. This species has also been isolated from soil, waste and seawater [1]. This non-conventional yeast is currently used as a model for the study of protein secretion [2,3], peroxisome biogenesis [4], dimorphism transition [1,5], the degradation of hydrophobic substrates (HS) [1] (alkanes, fatty acids, oils) and mitochondrial complex I [6]. Since the recent determination of the complete genomic sequence [7], comparative genomics, proteomics and transcriptomics studies have been initiated. *Y. lipolytica* has a 20.5 Mb genome composed of six chromosomes, for which genome annotation was performed by the Génolevures Consortium [8]. The *Y. lipolytica* genome comprises 6448 genes, 957 of which have at least one intron [9].

Y. lipolytica is well adapted for the utilization of HS as a carbon source, because it can use alkanes, fatty acids and oil. For oil utilization, *Y. lipolytica* produces several lipases, which are secreted either into the medium, as for the extracellular lipase Lip2p [10], or principally into the cell wall, as for Lip7p and Lip8p [11]. Depending on growth conditions, *Y. lipolytica* either breaks down the lipids and uses them for growth through β-oxidation to produce biomass, or stores lipids in lipid bodies (LB) [1]. The water-miscibility of HS is poor. So, when grown on HS, *Y. lipolytica* adapts its physiology and metabolism to facilitate the solubilization of these substrates, together with their transport and degradation. It produces a sur-

Abbreviation: 2D BN/SDS-PAGE, two-dimensional blue native/SDS-PAGE.

factant called liposan [12]. Cell surface modifications occur when this yeast is grown on HS. These changes include the induction of "protrusions" enabling HS droplets to dock on the cell surface [13].

Systematic comparisons have been initiated, to compare *Saccharomyces cerevisiae*, *Y. lipolytica* and other organisms. Swennen and Beckerich performed a comparative genomic analysis of the secretion pathway and showed that 40% of the proteins involved in this process in *Y. lipolytica* were very similar to homologous proteins in animals, whereas only 13% of these proteins were found to be similar to proteins in *S. cerevisiae* [3]. A highly representative two-hybrid library for *Y. lipolytica* has been constructed for the analysis of protein–protein interactions [14]. Sequence of the entire genome of this yeast has facilitated –omics approaches, including proteomics investigations, and has led to the characterization of LB in terms of (i) lipid composition, (ii) the major LB proteins present, as identified by mass spectrometry (MS), and (iii) differences in protein or lipid composition as a function of the carbon source used [15].

Our knowledge of the building blocks used to construct protein complexes in this yeast is limited and cannot be substantially improved by genomic techniques. Various methods have been developed for the identification of protein–protein interactions and to improve our understanding of protein complexes. These methods include yeast two-hybrid systems [16–24], protein microarrays [25,26], affinity purification-mass spectrometry [27–34] and two-dimensional blue native/sodium dodecyl sulfate polyacrylamide gel electrophoresis (2D BN/SDS-PAGE) [35–43]. 2D BN/SDS-PAGE is a highly suitable technique for the analysis of protein complexes. This technique is based on the initial separation of proteins as a function of molecular weight and charge in native conditions (BN-PAGE) as a first dimension. Proteins from the same complex are then separated in a second dimension, in denaturing conditions, as a function of molecular weight (SDS-PAGE). Aligned spots of the same shape on the gel are considered to correspond to proteins from the same protein complex. This applies, in particular, to heteromultimeric protein complexes. Homomultimeric protein complexes give rise to a single spot in the second dimension and are less mobile than expected in the first dimension. The spots are excised and digested with a specific endoprotease, generally trypsin. The products of this digestion are then analyzed by nanoliquid chromatography coupled to tandem mass spectrometry (nanoLC-MS/MS). The MS and MS/MS data are used to identify the proteins forming the complex. By integrating all the results obtained with yeast two-hybrid systems, protein microarrays and 2D BN/SDS-PAGE, complexomic databases can be made more comprehensive and a the protein–protein interaction network can be deciphered, increasing our understanding of protein function [44,45].

We present here, for the first time, a study of hydrophobic binding protein complexes in *Y. lipolytica,* providing new insight, validating the annotation, identifying the partners in the complex that could not be identified by genomic comparisons, due to the low level of homology, and providing information about protein function. The protein complexes were separated by 2D BN/SDS-PAGE. The protein spots were excised, digested with trypsin and identified with the HPLC-chip-IT-MS/MS microfluid chromatography system [46,47]. We identified 40 protein complexes with this experimental procedure: 11 heteromultimeric protein complexes and 29 homomultimeric protein complexes.

2. Materials and methods

2.1. Strain and culture conditions

The wild-type German *Y. lipolytica* strain H222 was grown at 28 °C in glucose complete medium (YPD; yeast peptone dextrose) or YNB-derivative (YNBD) minimal medium [48]. The YNB medium contained 1.7 g/l yeast nitrogen base without amino acids and ammonium sulfate (Yeast Nitrogen Base, Difco, Paris, France), 5 g/l NH_4Cl and 50 mM phosphate buffer (pH 6.8). YNBD contained 20 g/l glucose; YNBYC16 contained 1.5 g/l yeast extract and 10 g/l of hexadecane (C16 alkane). For growth on alkane, cells growing exponentially in glucose minimal medium (YNBD) were centrifuged, washed twice with water and resuspended in minimal medium without a carbon source. The resulting cell suspension was used to inoculate 100 ml of YNBYC16 in 500 ml Erlenmeyer.baffled shaking flasks at an optical density OD600 of 0.05.

2.2. Isolation and characterization of hydrophobic (alkane)-binding complexes

After 24 h of growth in YNBYC16, five 200 ml cultures were filtered through an HA filter with 0.45 μm pores (Millipore, St Quentin en Yvelines, France) and the cells on the filters were washed with 50 ml cold phosphate buffer (50 mM, pH 6.8). Cells were resuspended in 5 ml of extraction buffer (50 mM Tris, 0.75 M 6-aminocaproic acid, 1 mM PMSF, EDTA-free protease inhibitors cocktail (Roche Applied Science, Switzerland)) and centrifuged at 3000 × *g* for 5 min. The resulting pellets were resuspended in 7 ml of extraction buffer at an OD_{600} of 2000 (about 5 g wet weight of cells) and cooled on ice. Cells were disrupted with a CellD cell disruptor (CellD, Roquemaure, France). Disrupted cells were centrifuged at 3000 × *g* for 5 min, at 4 °C. Supernatants were collected and centrifuged for 10 min at 6000 × *g*. The pellet was extracted in 4 ml of alkane (decane, C10) for 30 min (fraction E6) and dried under nitrogen flux. The supernatant S6 was extracted with 4 ml of alkane (decane, C10) for 30 min and frozen at −20 °C. The upper organic fraction (alkane phase) was further centrifuged at 100,000 × *g* for 45 min at 4 °C. Pellet (P100) and supernatant S100 were extracted as described above for P6 and S6, generating the P100E and S100E fractions, respectively, which were then dried.

2.3. Extraction of protein complexes

Fraction P100E was resuspended in 200 μl of extraction buffer to which dodecyl-β-D-maltoside was added to a final concentration of 2% (w/v). Samples solubilized with dodecyl-β-D-maltoside were directly centrifuged at 100,000 × *g* for 30 min at 4 °C. The supernatant was used immediately or stored at −20 °C until further analyses.

2.4. 2D BN/SDS-PAGE

Samples were prepared and BN-PAGE was carried out as described by Schägger et al. [39] but with the following modifications. The gel dimensions were 22 cm × 16.5 cm × 0.1 cm. Linear 3 to 18% (w/v) acrylamide gradient gels were used for the first dimension. Anode and cathode buffers contained 50 mM Tris, 75 mM glycine. The cathode buffer was supplemented with 0.002% (w/v) Coomassie Brillant Blue G-250 (Bio-Rad, Hercules, California). Before loading, 1 μl of sample buffer (500 mM 6-amino-n-caproic acid, 5% (w/v) Coomassie Brillant Blue G-250) was added to 20 μl of sample. The gel was run at 4 °C, 1 W, 100 V and 28 mA. Thyroglobulin (669 kDa) and BSA (66 kDa) (Sigma, Saint-Louis, MO) were used as molecular weight size standards for BN-PAGE analysis.

Individual lanes from the BN-PAGE gel were excised and equilibrated in 1% (w/v) SDS, 6 M urea, 0.125 M Tris/HCl pH 6.8 for 5 min. Each individual lane was immersed in equilibrating buffer supplemented with 100 mM DTT for 20 min and was then soaked for 20 min in equilibrating buffer supplemented with 55 mM iodoacetamide. The gel strip was then washed with equilibrating buffer for 5 min.

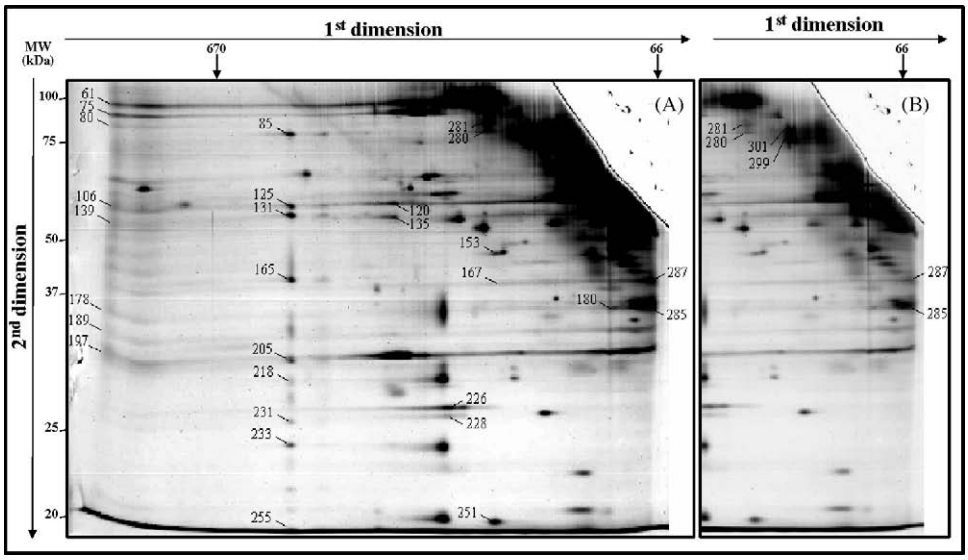

Fig. 1. (A) 2D BN/SDS-PAGE gel showing the heteromultimeric protein complexes of *Y. lipolytica* presenting hydrophobic binding properties. (B) Zoom of the right side of the gel.

The lane was placed on top of the previously poured stacking and separating gels, between the two glass plates. Additional stacking gel mixture was then poured around it.

The gel was then subjected to electrophoresis and, after migration, proteins were visualized by staining the gel with the PROTSIL2 silver staining kit (Sigma–Aldrich, St. Louis, MO), according to the manufacturer's instructions.

2.5. Protein digestion

Silver-stained proteins separated by 2D BN/SDS-PAGE were excised and destained with the PROTSIL2 silver staining kit (Sigma–Aldrich, St. Louis, MO), according to the manufacturer's instructions. Spots were subsequently rinsed twice in ultrapure water for 5 min and dehydrated in 50% ethanol in 50 mM NH_4HCO_3 for 30 min. This step was repeated three times. Spots were also incubated twice with acetonitrile (ACN). After the ACN had been removed, gel pieces were dried at room temperature, covered with the trypsin solution (10 ng/μl in 50 mM NH_4HCO_3) and rehydrated at 4 °C for 45 min. The excess solution was removed and the spots were finally incubated overnight at 37 °C in 50 mM NH_4HCO_3. The supernatant was collected, and an extraction solution (H_2O/ACN/TFA (49.9:50:0.1)) was incubated with the gel slices for 20 min. The supernatant was kept and ACN was incubated with the gel slices for 20 min. Supernatants were pooled and concentrated by drying at 37 °C for 2 h.

2.6. HPLC-Chip-IT-MS/MS

All experiments were carried out with an Agilent 1100 LC/MSD Trap SL series system. Ionization was carried out with the Chip Cube, by HPLC-Chip-MS (Agilent Technologies, Santa Clara, CA, USA). The chip was automatically loaded and placed in the MS nanospray chamber. The chip contained a Zorbax 300SB-C_{18} column (43 mm × 75 μm, 5 μm) and a Zorbax 300SB-C_{18} enrichment column (40 nl, 5 μm). The sample was loaded onto the enrichment column at a flow rate of 4 μl/min, in a 98/2 mixture of H_2O/0.1% FA and ACN/0.1% FA. The liquid chromatography gradient (mobile

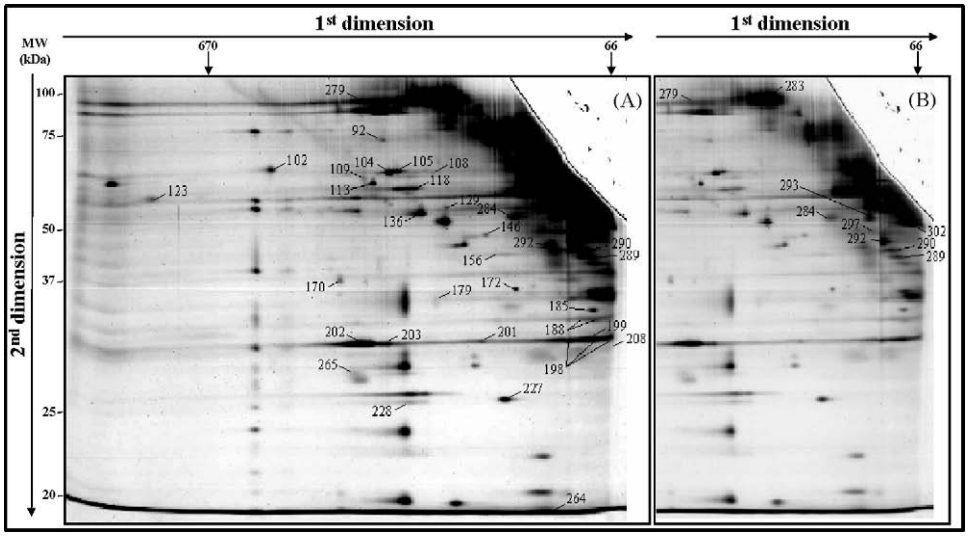

Fig. 2. (A) 2D BN/SDS-PAGE gel showing the homomultimeric protein complexes of *Y. lipolytica* presenting hydrophobic binding properties. (B) Zoom of the right side of the gel.

phase A: H_2O/0.1% FA; mobile phase B: ACN/10% H_2O/0.1% FA) was delivered at a flow rate of 300 nl/min. Tryptic peptides were eluted from the reverse-phase column into the mass spectrometer, using a linear gradient of 15% to 55% B over 30 min. The capillary voltage was set at 1800 V; the flow rate and dry gas temperature were 4 l/min and 280 °C, respectively. The mass range was from m/z 400 to m/z 2200. The MS and MS/MS data were analyzed with Data Analysis software version 3.3. For protein identification, the MS/MS spectra were obtained automatically and Data Analysis software (Agilent Technologies) was used to produce a peak list from raw data: background subtraction with a flatness of 0.8; peak smoothing with the Gauss algorithm, using a smooth width m/z of 0.2 and one cycle; the mass list was generated by the Apex method.

2.7. Protein identification

Database searches were carried out with the Mascot Server software package and the Mascot Daemon client application version 2.0 (Matrix Science, London, UK). Database searches were performed against the *Y. lipolytica* protein sequence database [8]. Many of the 6436 proteins in this database were identified on the basis of similarity to known proteins from other yeasts (particularly *S. cerevisiae*). The parameters used for searches were as follows: one missed trypsin cleavage, mass tolerance of precursor ions and product ions ±0.4 Da, carboxymethylation of cysteine as a fixed modification, oxidation of methionine as a variable modification. Proteins matching at least two peptides were considered to have been identified. Only proteins with a protein score greater than 22 and a p-value less than 0.05 were considered to have been identified.

3. Results and discussion

We used a combination of 2D BN/SDS-PAGE and the HPLC-chip-MS method to analyze protein complexes with alkane-binding properties from the yeast *Y. lipolytica*. We tested different acrylamide gradients with a view to obtaining optimal resolution and repeatable separations during the first dimension for protein complexes. A 3–18% (w/v) acrylamide gradient was chosen for BN/PAGE, as this gave optimal focusing and separation within a given range (Figs. 1 and 2). Proteins from the same complex migrated together in the first dimension, but independently in the second, denaturing dimension. Thus, proteins from the same complex were detected as aligned spots of similar shape on the gel, as previously described [37]. Aligned spots of different shapes were considered to originate from different complexes. Gel analysis led to the identification of 40 different alkane-binding protein complexes in *Y. lipolytica* (Figs. 1 and 2, Tables 1 and 2): 11 heteromultimeric protein complexes (Fig. 1, Table 1) and 29 homomultimeric protein complexes (Fig. 2, Table 2).

3.1. Previously described protein complexes

This technology has been successfully used in the past for protein complex identification [35–43]. Observations of previously described complexes are of interest for the validation of both new technologies and analysis criteria. Heteromultimeric protein complexes # 2, 3 and 11 (Table 1) had already been partially or totally characterized in other studies, and were used here to demonstrate the utility of our approach. For example, protein complex # 3 (Table 1) is an ATPase complex. ATPases catalyze the breakdown of adenosine triphosphate (ATP) into adenosine diphosphate (ADP) and a free phosphate ion. Here, the F-ATPase (Table 1, complex # 3) produces ATP using the proton gradient generated by oxidative phosphorylation. This mitochondrial protein complex has been described as a complex of nine subunits,

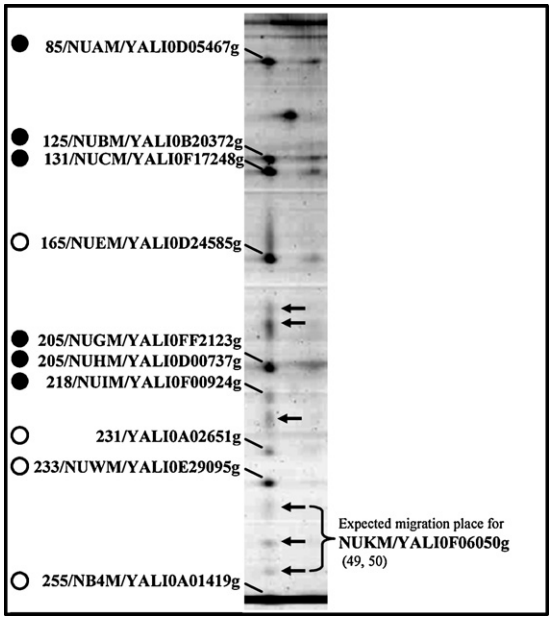

Fig. 3. Zoom on alkane-binding complex # 2 corresponding to respiratory chain complex I. Nuclear-encoded core units (●), and nuclear-encoded accessory subunits (○) of NADH:ubiquinone oxidoreductase identified by MS are indicated. Information is noted as: spot number/gene usual name/accession number. The expected location of the NUKM core subunit is shown on the right. Arrows indicate spots with no identification.

of five different types ($\alpha_3\beta_3\gamma\delta\varepsilon$). However, only two of these subunits α (spot 120, gene ATP1, YALI0F03179g, Table 1) and β (spot 135, gene ATP2, YALI0B03982g, Table 1) were observed on the 2D BN/SDS-PAGE gel. This may be due to the stoichiometry of the different subunits in the complex ($\alpha_3\beta_3\gamma\delta\varepsilon$). However, in this particular case, as previously described in *E. coli* [37], the absence of the γ, δ and ε subunits may also be accounted for by instability of the F-ATPase complex. Furthermore, both the genes identified encode proteins with a potential mitochondrial targeting sequence with a prediction value of 0.99, identified with MITOPROT [48].

3.2. Protein complex # 2: no subunit encoded by the mitochondrial genome

Protein complex # 2 corresponds to the NADH dehydrogenase complex or NADH:quinone oxidoreductase (Table 1). These enzymes are located in the inner mitochondrial membrane and catalyze electron transfer from NADH to coenzyme Q (CoQ). Little is known about these enzymes, despite their importance in biological pathways. For *Y. lipolytica*, Abdrakhmanova et al. [49] described this protein complex as having 14 central subunits: 7 proteins encoded by the nuclear genome and 7 proteins encoded by the mitochondrial genome. Subunit mass fingerprinting analysis of *Y. lipolytica* mitochondrial complex I recently identified 37 subunits [50]. In addition to these the 14 core subunits, this complex contains a large number of accessory subunits in eukaryotes: 32 subunits in bovine heart mitochondrial complex I [51], 21–23 subunits in the fungal enzyme [49,52] and about 16–28 subunits in photosynthetic organisms, such as *Vicia faba L* [53], *Arabidopsis thaliana* and *Chlamydomonas reinhardtii* [54]. We found 10 subunits (Fig. 3). Six of the seven central subunits encoded by the chromosomal genome were identified (NUAM, NUBM, NUCM, NUGM, NUHM, NUIM), while NUKM (YALI0F06050g), was not identified. From the accessory subunits, three proteins were identified (NUEM, NUWM, NB4 M). NUWM was shown to be a specific accessory subunit of *Y. lipolytica* [49] (Table 1, complex

[g] MITO: Mitochondrial (when a mitochondrial targeting sequence was identified by MITOPROT [49], the prediction value is indicated in parentheses); PERO: Peroxisomal (when a peroxisomal targeting sequence of type I (PST1) was observed at the C-terminus of the protein, the three terminal amino acids are indicated in parentheses); CYTO: Cytoplasmic, when mitochondrial prediction was poor and no obvious PTS1 sequence could be observed; ER: endoplasmic reticulum.

2, spot 233). Spot 231 (YALI0A02651g) displayed similarity to the potential *Candida albicans* mitochondrial complex I 21/29 kDa subunit (Q5AEI1|Q5AEI1_CANAL). No homologs were found in hemiascomycetous yeasts other than *Y. lipolytica* and *Debaryomyces hansenii*. Surprisingly, no subunit encoded by the mitochondrial genome was identified in this protein complex. These results suggest that the NADH:ubiquinone oxidoreductase complex with hydrophobic binding properties contains at least of 10 subunits encoded exclusively by the nuclear genome. The comparison of our complex I purified from whole cells on the basis of alkane-binding properties with that obtained by affinity tag purification [49] shows the relevance of our analysis of protein complexes. Indeed, the exclusive presence of proteins encoded by the nuclear genome in complex I suggests that these seven subunits may be assembled before entry into the mitochondria. These results would be consistent with the identification in this study of a premitochondrial complex I. Further investigation is required to determine the mechanisms involved in the entry of this protein complex into the mitochondria.

The NUKM protein (YALI0F06050g) was not identified, but one of the three spots in Fig. 3 may potentially correspond to the size of the NUKM protein. Other spots from this complex, indicated by arrows in Fig. 3, were unfortunately not identified (problems of detection threshold, or absence of identification after MS analysis etc.).

3.3. Protein complexes # 6 and # 12: complexes containing acyl-CoA oxidase isozymes

The association of five isoforms of acyl-CoA oxidase (Aox) (from Aox1p to Aox5p) was described as a 443-kDa heteropentameric complex containing one polypeptide chain of each isoform within the peroxisomal matrix of the yeast *Y. lipolytica* [55]. The Aox complex is assembled in the cytosol and then imported into peroxisomes [55]. The complete *Y. lipolytica* genome sequence [7] revealed

the existence of another gene encoding an acyl-CoA oxidase (*POX6*, YALI0E06567g). In this study, the Aox complex migrated to two different locations (Table 1, protein complexes # 6 and # 12, Fig. 1). At the first, this complex (complex # 6) was consisted of three proteins: gene product O74935 (Pox 2p, spot 299), gene product Q6C6T4 (spot 301) and gene product O74936 (Pox 3p, spot 301, YALI0D24750g). At the second, the complex (complex # 12) seemed to contain only one protein (Pox2p, spot 92, YALI0F10857). These incomplete AcylCoA oxidase complexes may have different affinities for alkanes (membrane), facilitating their migration from the matrix to the membrane of the peroxisomes. This migration may correspond to the complex shown to be involved in peroxisome division [56].

3.4. β-oxidation and glyoxylate cycle complexes

In yeasts and fungi growing on hydrophobic substrates in minimal medium, the tricarboxylic acid cycle is replenished by the reactions catalyzed by isocitrate lyase (ICL) and malate synthase (MLS), forming the glyoxylate bypass, also known as the glyoxylate bypass or glyoxylate shunt. This replenishing function has been described as "anaplerotic" [57] and probably plays an essential role in the growth of microorganisms on fatty acids.

The glyoxylate cycle is a metabolic pathway occurring in plants, some vertebrates and several microorganisms, such as *E. coli* and yeast, and allowing the synthesis of carbohydrates from fats. Fatty acids from lipids are generally broken down into acetate molecules by β-oxidation, for subsequent use as an energy source. The acetate binds to the active thiol group of coenzyme A and enters the glyoxylate cycle, generating carbohydrates in two ways: (i) the acetyl-CoA is fully oxidized to carbon dioxide. In this case, the acetyl-CoA produced by β-oxidation is channeled to the glyoxylate cycle and converted into malate. The malate is released into cytosol, where it is converted into phosphoenolpyruvate; (ii) the succinate is transferred to the mitochondria and converted there into malate by a partial reaction of the citric cycle. The malate is then released from mitochondria into the cytosol, where it is converted into phosphoenolpyruvate. Phosphoenolpyruvate is a precursor for the synthesis of hexoses by gluconeogenesis. The intermediates of the pentose phosphate pathway can be used for the biosynthesis of other compounds, such as RNA and proteins. For example, the cell wall of growing *Y. lipolytica* cells requires very large amounts of carbohydrates for the biosynthesis of complex structural polysaccharides. In the absence of available carbohydrates (for example, in certain microbial environments, such as in the presence of hydrophobic substrates), the glyoxylate cycle enables this yeast to synthesize glucose from lipids via acetate produced through β-oxidation of fatty acids.

Protein complex # 1 is very interesting because it consists of 11 proteins involved in the glyoxylate cycle (Q6C9P6_spot 80, P41555_spot 106 and Q6C8V3_spot 178), the transport of succinate-fumarate (Q6C3I0_spot 189) or β-oxidation (Q9P4D9_spot 75). The Q6CBL6 protein (spot 139) contains a CRAL-TRIO domain. This domain is a structurally conserved element, of about 170 amino acids in length, which forms a large hydrophobic lipid-binding pocket composed of six β-strands α-helices forming the sides of the cavity [58]. This domain is important for the protein–lipid interactions involved in protein targeting, signal transduction, lipid transport, lipid biosynthesis, lipid metabolism and the maintenance of cellular compartments and membranes [59]. In complex # 1, this protein binds to lipids, leading to the entry of the lipid into the β-oxidation cycle. The multifunctional β-oxidation enzyme Q9P4D9 (protein complex # 1, spot 75, Table 1) then catalyzes the transformation of trans-delta-enoylCoA into 3-ketoacylCoA. Furthermore, complex # 1 contains three proteins involved in the glyoxylate cycle. Aconitate hydratase (Q6C9P6_spot 80) transforms citrate in isocitrate. Isocitrate lyase (P41555_spot 106) is the first enzyme unique to the glyoxylate cycle and catalyzes the reversible cleavage of isocitrate to generate glyoxylate and succinate. This enzyme acts at a branch point in carbon metabolism and diverts isocitrate through a carbon-conserving pathway, the glyoxylate cycle, bypassing the two decarboxylation steps of the tricarboxylic acid cycle, which converts isocitrate to succinyl-CoA. The third enzyme of this complex from the glyoxylate cycle is malate dehydrogenase (Q6C8V3_spot 178), which transforms S-malate into oxaloacetate. Moreover, protein complex # 1 contains the Sfcp succinate-fumarate transporter (Q6C3I0_spot 189), which may be involved in transferring succinate to mitochondria. The *SFC1* and *ICL1* genes have been shown to be required for growth on hydrophobic substrates [60]. Alternatively, complex # 1 may correspond to intracellular vesicles, precursors of the extracellular vesicles recently observed in ascomycetes and containing proteins involved in diverse processes [61].

3.5. First observation of proteins

These results will enrich the complexomic and proteomic databases for *Y. lipolytica*. Most of the proteins identified in this report are described as 'Inferred from homology' or 'Predicted' in the database [62]. Thus, these proteins are probably present because orthologs are found in closely related species, or are thought to exist despite a lack of evidence protein-, transcript- or homology-based evidence. In this study, 44% of the 66 distinct proteins identified had been inferred from homology whereas 50% of the proteins identified had been predicted from the genome sequence alone, with no evidence at protein, transcript or homology levels. These protein complexes were localized on the basis of predictions of targeting sequences (mitochondria, peroxisome) or N-terminal signal peptides for secretion, together with published data concerning their distribution. However, proteins lacking an N-terminal secretion signal were recently found to be located at the yeast cell surface [63]. Some of the alkane-binding complexes we have identified may be located in the cell wall, as part of the "protrusion complex" and may be involved in alkane binding and utilization [13,15].

4. Conclusion

In this study, the combination of 2D BN/SDS-PAGE and HPLC-chip-MS methods made it possible to identify 40 different alkane-binding protein complexes: 11 heteromultimeric and 29 homomultimeric complexes. After validation, this approach led to the identification of mitochondrial complex I, which contained only subunits encoded by the nuclear genome, consistent with the possible assembly of this complex before entry into the mitochondria. We detected two different Aox complexes with potentially different affinities for alkane (membrane), facilitating their migration from the matrix to the membrane of the peroxisome. This strategy also highlighted the role of the glyoxylate cycle in the synthesis of carbohydrates from fats. This replenishing function probably plays an essential role in the growth of microorganisms on fatty acids. Finally, this work has contributed new findings to yeast databases. Indeed, these results confirmed the existence of hypothetical proteins previously inferred purely from homology or predicted from the genome sequence in the absence of evidence at the protein or transcript level.

Transformation
Chromatographic determination

ABSTRACT

Recent years have seen an upsurge of interest in developing low cost and reliable methods for the detection and precise determination of ultra-trace concentrations of persistent organic pollutants (POPs), because of their bioaccumulation, transformation and toxicity. Therefore, a comprehensive review with 108 references referring to the distribution, source, accumulation, transformation, types and toxicity of polychlorinated biphenyls (PCBs) and organochlorine pesticides (OCPs) is presented. The review also aims to highlight on the current best practices for the analysis of PCBs and OCPs. Moreover, with the signing of the Stockholm convention on POPs and the development of global monitoring programs, there is an increased need for laboratories in developing countries to determine such class of chemicals. A major focus revealed the need for low cost methods that can be implemented easily in developing countries such as electrochemical techniques.

1. Historical overview

After the Second World War, scientists began to recognize that, certain chemical pollutants were capable of persistent in the environment for long time, migrating in air, water, soil and sediments and accumulating to levels that could harm wildlife and human health. These chemical pollutants called persistent organic pollutants (POPs) [1]. These pollutants are organic compounds of natural

or anthropogenic origin that possess a particular combination of physical and chemical properties such that, once released into the environment, they remain intact for exceptionally long periods of time as they resist photolytic, chemical and biological degradation [2,3]. Compounds of this nature are highly resistant to degradation by biological photolytic and/or chemical means [3].

Recently, POPs are a matter of concern because of their toxicity and tendency to accumulate in food chains [4]. The environmental impact of a particular species becomes more important than a total metal concentration. Thus, metal speciation is of great importance in environmental science. However, due to their low concentrations, pre-concentration (enrichment) step is needed prior to their determination. The pollution by POPs and determination and chemical speciation of toxic trace metal ions will be discussed more in detail below.

The carbon–chlorine bond is very stable toward hydrolysis and the greater the number of chlorine substitution and/or functional group, the greater the resistant to biological and photolytic degradation. Because POPs break down very slowly, they will present in the environment for long time to come, even if all new sources were immediately eliminated [5]. POPs in the environment are transported at low concentrations by movement of fresh and marine waters and, as they are semi-volatile, are transported over long distances in the atmosphere. The result is widespread distribution of POPs across the globe, including regions where they have never been used [2]. The POP's level found in the Arctic of Alaska is surprising to many people. This is because some of these pollutants have been banned from the United State and Canada for many years. POPs travel toward colder area like Alaska and then sink due to the colder temperature. The settled contaminants remain in the area for a long period of time because the temperature does not allow theme to break down very easily. Because of this, they move from the air and water in to soil and plants, then to animals and humans with ease. The persistence of contaminants in the Arctic from distant sources first came to light in the late 1970 when pesticides were found in polar bear fat tissue, then the reality of atmospheric POPs, their effect on wildlife and human health. A well-known story in the Arctic, researches have begun to look for evidence of airborne POPs in other cold ecosystems, our mountain environments [6,7].

2. Distribution of POPs

In 1945, a booming industry launched a new, effective tool for dealing with insect pests: DDT. It held great promise, including the hope of saving crops and eradicating disease-carrying insects. Twenty years later, DDT and other similar chemicals had indeed benefited agriculture and relieved some of the problems associated with insects in many areas of the world. However, these gains came at a price, as DDT is toxic to many more organisms than those it was intended to kill. In particular, birds of prey had trouble to reproduce, and their population declined in many polluted parts of the world. Since, the commercial manufacture of anthropogenically synthesized organic chemicals began in the 1920s. Production, use and trade of these substances rose sharply after World War II, driven by a desire to produce more and better food and cash crops, protect public health, and facilitate industrial development [8,9].

The first public warnings about possible dangers came in relation to local environmental effects in the early 1960s, and grew stronger in the 1970s [7]. During 1960 and 1970 they were extensively utilized in order to protect crops and to prevent health diseases. Some of these compounds such as hexachlorobenzene (HCB), hexachlorocyclohexane (HCH) and Dichlorodiphenyltrichloroethane (DDT) were among the most widely used pesticides in the world during 1970–1980. Nowadays they are banned or restricted in the majority of the industrialized countries, but they still used in Africa, South Asia, Central and South America [7–10].

In the late of 1980s, new scientific discoveries resulted in changing perception, highlighting the transboundary nature of the POPs problem. Many of the discoveries were related to the Arctic region. These discoveries were spurred by both qualitative and quantitative improvements in data samples, measurement and analytical techniques. Also, in August 1989, Canada presented a report on hazardous persistent organic chemicals [8].

In the 1990, research found that the largest lake trout in Bow Lake contain high levels of some of these pollutants such as toxaphene. Since, the lake supports only a small population of large lake trout (2.5 kg) and people do not consume high amounts of fish from the lake, human health is not at risk. However, predators such as osprey feed exclusively on fish [12]. Also in Taiwan, the Danshui consider the largest river in the north, it receives liquid effluents and atmospheric fallout resulting from industrial and municipal emissions which include multiple forms of POP pollutants associated with these emissions, including polychlorinated biphenyls (PCBs), are transported down-river in association with particulates and deposited in river sediments, as well as those in nearby coastal areas. The presence of these pollutants causes a large toxicity on fish and other living organisms in the river [13].

The persistence in the compounds allows them to accumulate in animals and pass on more. When the pollutants progress in to animals, they accumulate in the fat cells, organs and muscles. In Adriatic sea which is an arm of the Mediterranean sea separating Italy from the Balkan peninsula, there are concentrations so low of some of these pollutants such as PCB, HCB, HCH and organochlorine pesticides (OCPs) in the fish liver collected from the Adriatic sea during 1993–2003 such as DDT in order to estimate the long-term changes in residue levels and the present status of contamination of this aquatic zone [14].

In China, many high-yield grain fields have become high-intense by POPs – especially pesticide – application areas in China. It was shown by sampling surveys from 1985 to 1991 that pesticide consumption ranged from 4.65 to 15.75 kg/h m^2 increasing by threefold and 41.8% annually. Pesticide consumption in southeast regions of China including Zhejiang, Shanghai, Fujian, and Guangzhou provinces accounted for 36.7% of the nationwide consumption, while six provinces in the northwest of China, including Qinghai, Ningxia, Gansu, Xinjiang, Heilongjiang, and Inner Mongolia, only accounted for 3.4%. The consumption of pesticides in Zhejiang was about 9.96 kg/h m^2 and 3.7 times that of the national average (2.71 kg/h m^2), and 28 times more than that in Inner Mongolia, which was the lowest user of these chemicals. The distribution pattern of pesticide application in China shown in Fig. 1 was as follows: southeast > central > northwest [15].

In 1999, during the so-called dioxin scandal in Belgium, Polish Veterinary Inspectorate ordered an analysis of food samples of Polish and international origin. The Inspectorate tried not to make the results of those analyses publicly available. This can be seen from the Inspectorate's response to the request of world protection agency (WPA) for allowing access to them. They said that *in the period in question, no such analyses were made in Poland* as seen in Table 1. These data were published in a scientific publication with a limited circulation [16].

3. Sources of POPs

Volcanic activity and vegetation fires are the two possible natural sources of dioxins and dibenzofurans. Some of these volcanoes are located in central Africa. Some attention will be given to sources or uses particular to southern and South Africa. One of these sources is fire, both natural, accidental and managed burning of vegetation [17–20]. POPs, as are apparent from their definition, are very

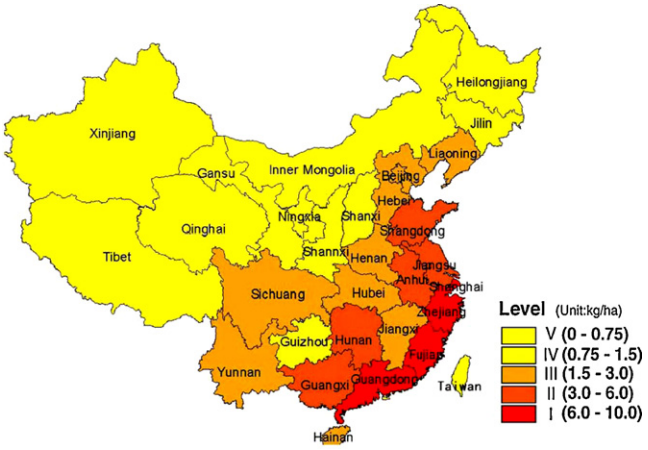

Fig. 1. Distribution of persistent organic pollutants in China in 1996.

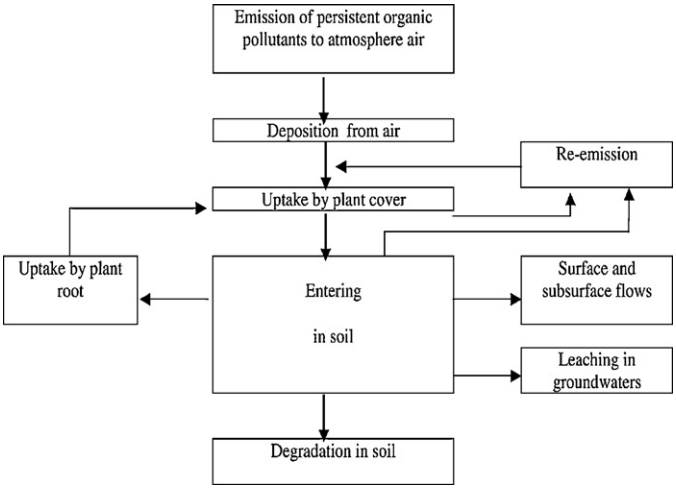

Fig. 2. Conceptual model for the behavior of persistent organic pollutants in the air–plant soil system.

stable in all constituents of the environment. They enter the atmosphere from a number of industrial sources such as power stations, heating stations, incinerating plants as well as from household furnaces, transport, use of agricultural sprays, evaporation from water surfaces, soil, or from the landfills. Other sources for POPs compounds such as the unintentional production can be found by incinerations, chemical facilities, diverse combustions, bushfires and putrefaction and wastes containing PCBs. This class of wastes can be found in many areas and stemming from different activities, e.g. the use of obsolete oil, the repairing and maintenance of equipments, demolition of building, evaporation, cement manufacture, animal carcass incinerator, coal combustion, lixiviation of dumps and recycling operations, incineration-municipal, hazardous, medical waste, sewage sludge, industry-chlor-alkali plants, aluminium secondary plants, organ chlorine pesticide plant and cock plant, landfills-hazardous waste/plastic waste, fly ash storage, and organochlorine pesticide storage [21,22].

The sources of access of the substances, oil, fates, liquid fuels, soil, ash and sediment into the water system are wastewaters from plants producing or using POPs, along with runoffs from fields and roads and from the atmospheric deposition. Their largest reservoirs are oceans and seas, where they gather from river sediments, by the atmospheric deposition, by disposing wastes, and by accidents. They are stored in sediments on the beds of seas, oceans, and large lakes, where they can be released from after a time and then re-enter the atmosphere as shown in Fig. 2 [23,24].

During the last 10 years, a lot of sources of POPs were stopped due to the economical changes in the country. Moreover a lot of new wastewater treatment plants were built during this period. Another reason of the observed decreasing trends in POPs occurrence in waters and sediments is found in the more principal ecological politics of government and local authorities [22]. In Poland, no wide-ranging investigations of dioxin-related environmental contamination, especially the presence of those compounds in human tissues and milk of breastfeeding mothers, have ever been conducted. Any publicly available data is random or based on unreliable estimates. According to the information provided to the Central Statistical Office by the Institute for Environmental Protection, the dioxin and furan emissions in 1998 are estimated at 290.353 g TEQ. According to the Institute, the main sources of dioxin emissions in Poland are given in Fig. 3 [25].

Recently, the Ministry of Environment has undertaken great efforts to provide a basis for estimating the real emission of dioxins and furans. In different regions of Poland, in urbanized areas as well

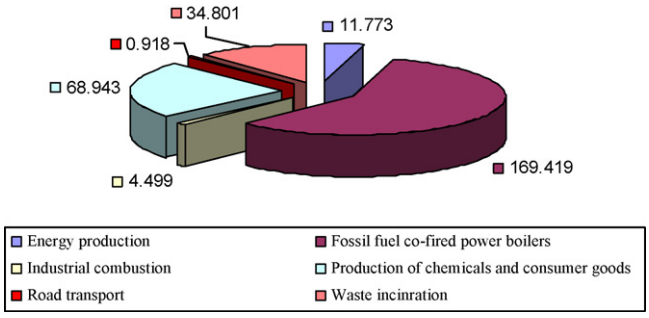

Fig. 3. The main sources of dioxin emissions in Poland.

Table 2
The permissible concentrations (pg-TEQ g^{-1}) of PCBs, DDT and gamma-HCH.

Substance	The permissible dose, pg-TEQ g^{-1} fat
PCBs	2.8
DDT	4.2
Gamma-HCH	13.3

Table 3
Analysis of some selected POPs (mg kg^{-1}) in samples of fatty tissues of patients aged from 10–80 years in one of Warsaw's hospitals.

Substance	mg kg^{-1} of fat		
	Median	Maximum	Mean
PCBs	0.500	36.000	0.856
HCB	0.120	9.020	0.310
Alpha-HCH	0.160		0.016
Beta-HCH	0.120	5.097	0.228
Gamma-HCH	0.030	2.727	0.074
p,p′-DDE	4.382	35.850	5.745
p,p′-DDT	0.478	9.600	0.537

as those potentially free from dioxin contamination, 118 geological samples have been taken. The analysis thereof will allow for determining the so-called background dioxin level. The reference source for monitoring of that compounds in milk of breastfeeding mothers has been reported by Ludwicki et al. [25] to assign the content of other persistent organic pollutants. The investigation covered a group of 462 women from Warsaw and other localities [26]. The permissible concentrations (pg-TEQ g^{-1}) of PCBs, DDT and gamma-HCH are summarized in Table 2. The increased level of persistent organic pollutants was found primarily in older women, aged 30 and more, and those who gave birth to more than four children.

In the years 1989–1992, in one of Warsaw's hospitals, samples of fatty tissues have been undertaken from 277 patients aged from 10 to 80 years and were successfully subjected to analysis for a series of PCBs, HCB, alpha-HCH, beta-HCH, gamma-HCH, *p,p′*-DDE and p,p′-DDT [25]. The results are summarized in Table 3. Higher concentrations of POPs have been found in tissues of older people [25]. In the case of gamma-HCH, only a higher level was noted in the samples that taken from patients aged below 25 years.

4. Type of persistent organic pollutants

In Stockholm 2001, representatives from 92 countries have agreed to sign the Stockholm Convention on POPs to reduce and/or eliminate the release of 12 original POP substances which are namely the dirty dozen. More contaminants have been discovered; the main concern is over the original 12. These contaminants are the 10 intentionally produced chemicals: aldrin, endrin, chlordane, DDT, dieldrin, heptachlor, mirex, toxaphene, hexachlorobenzene (HCB) and polychlorinated biphenyls (PCBs) and the two unintentionally produced substances polychlorinated dibenzo-p-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) [26,27]. Also, polycyclic aromatic hydrocarbons (PAHs) are also classified as persistent organic compounds, and they are formed as unintentionally substances by combustion and burning of organic compounds. Their occurrences are related to anthropogenic processes, and contamination of PAHs in river sediment is especially serious in high-density industrial areas [26]. The chemical structures of the most common persistent pollutants are given in Fig. 4. Moreover, in general POPs can be divided intentionally and unintentionally into two types of POPs as shown in Fig. 5.

4.1. Intentionally POPs

These compounds will be produced as wanted products by different chemical reactions that include chlorine. These types are organic molecules with linked chlorine atoms, high lipophilicity and, usually, high neurotoxicity, and they are called organochlorine compounds (OCs). Examples of OCs are the chlorinated insecticides, such as dichlorodiphenyltrichloroethane (DDT), and polychlorinated biphenyls (PCBs). They have several compounds which can be divided into two types that are industrial chemicals and organochlorine pesticides [28,29].

4.1.1. Organochlorine pesticides (OCPs)

Pesticides are chemicals or biological substances used to kill or control pests. They fall into three major classes: insecticides, fungicides, and herbicides (or weed killers). There are also rodenticides, nematicides, molluscicides, and acaricides. These chemicals are typically man-made synthetic organic compounds, but there are exceptions which occur naturally that are plant derivatives or naturally occurring inorganic minerals. Since, in the seventeenth century the first naturally occurring insecticide, nicotine from extracts of tobacco leaves, was used to control the plum curculio and the lace bug. In the 1940s, many chlorinated hydrocarbon insecticides were developed though they did not come into widespread use until the 1950s. Common examples include aldrin, dieldrin, heptochlor, and endrin. However, in spite of their early promise, these organochlorine insecticides are now much less used because of their environmental pollution impact [30,31].

Pesticides have been widely used throughout the world since middle of the last century. Around 1000 active ingredients have been employed and are currently formulated in thousands of different commercial products. They include a variety of compounds, mainly insecticides, herbicides and fungicides, with very different physico-chemical characteristics, and large differences in polarity, volatility and persistence. Pesticides are employed for many different purposes. About 80% of the pesticides is used in agriculture and moved in the environment by means of volatilization, runoff, infiltration, transport along the food chain, etc. Although the application of OCPs has been forbidden for a considerable period in many countries, the residues continue to induce a significant impact on the environment and its ecosystems [32]. Chemicals used in the control of invertebrates include insecticides, molluscicides for the control of snails and slugs, and nematicides for the control of microscopic roundworms. Vertebrates are controlled by rodenticides which kill rodents, avicides used to repel birds, and pesticides used in fish control. Herbicides are used to kill plants. Plant growth regulators, defoliants, and plant desiccants are used for various purposes in the cultivation of plants. Fungicides are used against fungi, bactericides against bacteria, slimicides against slime-causing organisms in water, and algicides against algae. As of the mid-1990s, U.S. agriculture used about 365 million kg of pesticides per year, whereas about 900 million kg of insecticides were used in non-agricultural applications including forestry, landscaping, gardening, food distribution, and home pest control. Insecticide production has remained about level during

the last three or four decades. However, insecticides and fungicides are the most important pesticides with respect to human exposure in food because they are applied shortly before or even after harvesting. Herbicide production has increased as chemicals have increasingly replaced cultivation of land in the control of weeds and now accounts for the majority of agricultural pesticides. The potential exists for large quantities of pesticides to enter water either directly, in applications such as mosquito control or indirectly, primarily from drainage of agricultural lands [33–35].
